14-Methyl-9,10-epoxy Tricosane (3b). Epoxidation as above of 5 mg of 14-methyl-(Z)-9-tricosene afforded 5 mg of the corresponding epoxide after purification, R_f = 0.71 in 10% EA/H; R_t = 17.24 (T_i = 140°C, 2 min; 7°C/min; 250°C); [^{1}H]NMR ($CDCl_3$): δ 2.98 (m, 2H).

Synthesis of (Z)-*10-Methyl-(Z)-14-tricos-14-en-10-ol (4a).* To a solution of (*Z*)-14-tricosen-10-one (126 mg, 0.375 mmol) in dry THF (5 ml) stirred at 0°C under nitrogen atmosphere was added dropwise methylmagnesium bromide (0.36 ml, 3.0 M solution in ether). The resulting mixture was stirred at 0°C for 1 hr, poured into 0°C satd. aq. NH_4Cl, and the product was isolated with 5%

0.41 in 10% EA/H; R_t = 16.23 (T_i = 140°C, 2 min; 7°C/min; T_f = 250°C). FT-IR (neat): 3374, 3004, 2923, 2852, 145 cm^{-1}; ^1H NMR ($CDCl_3$): δ 5.36 (m, 4H), 2.02 (m, 4H); ^{13}C NMR ($CDCl_3$): δ 130.26, 129.40, 72.66.

cis-*10-Methyl-14,15-epoxytricosan-10-ol (4b).* To a stirred solution of *m*-CPBA (15 mg, 0.07 mmol) in methylene chloride (2 ml) was added the above compound (20 mg, 0.058 mmol) in CH_2Cl_2 (1 ml) at 0°C. The solution was stirred at 0°C for 2 hr, quenched with 0.8 ml of 5% solution of Na_2SO_3, washed with 1 ml 5% solution of NaOH followed by 3 ml of water, filtered through Florisil, concentrated, and purified (SiO_2) to give 20 mg of the colorless oil (95% yield), R_f = 0.11 in 10% EA/H. This product rearranges at room temperature to a product without the double bond and seems to decompose during gas chromatography. ^1H NMR ($CDCl_3$): δ 2.91 (m, 2H), 1.51 (m, 8H), 1.26 (br s, 28H), 1.16 (s, 3H), 0.87 (t, J = 6.7 Hz, 6H); ^{13}C NMR ($CDCl_3$): δ 72.63, 57.18, 57.09.

Synthesis of Dimethyl Analog

1-Cyano-3,3-dimethyl-4-dodecene (24). To a solution of *n*-octyltriphenylphosphonium bromide (1.45 g, 3.2 mmol), prepared from *n*-octyl bromide and triphenylphosphine, in dry THF (10 ml) was added *n*-BuLi (1.5 ml, 1.6 M solution in hexanes) dropwise at −78°C. The orange solution was stirred for 1 hr, then 4-cyano-2,2-dimethylbutanal (0.20 g, 1.6 mmol) (prepared by the procedure described by Poidevin et al., 1979) was added in dry THF (2.0 ml) (Figure 9). The reaction was warmed to rt, poured into water, and the product was isolated with hexane and purified (SiO_2) to give 0.318 g (90% yield) of a colorless oil. FT-IR (neat): 2957, 2925, 2855, 2246, 1466 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.30 (dt, J = 12.1, 7.4 Hz, 1H), 5.09 (d, J = 12.0 Hz, 1H), 2.29 (t, J = 8.2 Hz, 2H), 2.09 (m, 2H), 1.76 (t, J = 8.2 Hz, 2H); [^{13}C]NMR ($CDCl_3$): δ 135.28, 131.87, 120.36.

4,4-Dimethyl-5-tridecenal (25). A solution of the above nitrile (0.30 g, 1.35 mmol) in dry ether (10 ml) was stirred at 0°C under nitrogen atmosphere, then DiBAL-H (2 ml, 1.0 M solution in hexanes) was added dropwise (Zakharkin and Khorlina, 1964). The reaction was stirred for 4 hr at 35°C and then poured into ice cold water (2 ml) and 10% H_2SO_4 solution (1 ml) and stirred for 30 min. The product was isolated with hexane and purified (SiO_2) to give 195 mg (64% yield) of a colorless oil. R_f = 0.53 in 10% EA/H. FT-IR (neat): 2957, 2924, 2855, 1727, 1647, 1466 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 9.76 (t, J = 1.8 Hz, 1H), 5.30 (dt, J = 7.3, 12.0 Hz, 1H), 5.08 (d, J = 12.0 Hz, 1H), 2.42 (t, J = 7.9 Hz, 2H), 2.07 (m, 2H), 1.78 (m, 2H); ^{13}C NMR ($CDCl_3$): δ 202.92, 135.37, 132.00.

4,4-Dimethyl-1-bromotridecane (26). A solution of 4,4-dimethyl-1-tri-

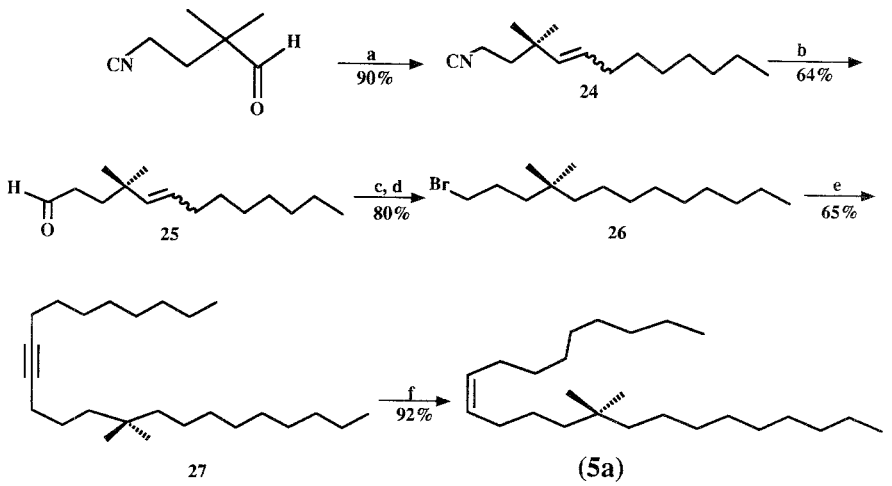

FIG. 9. Synthesis of 14,14-dimethyl (Z)-9-tricosene: (a) n-$C_8H_{17}P(C_6H_5)_3Br$, n-BuLi, THF, −78°C; (b) DIBAL-H, Et_2O, 35°C; (c) $LiAlH_4$, Et_2O, 0°C; (d) H_2, 10% Pd/C, MeOH; (e) Ph_3P, CBr_4, CH_2Cl_2, 0°C; (f) n-$C_8H_{17}CCH$, n-BuLi, HMPA, THF, −78°C (g) H_2, 5% $Pd/BaSO_4$, EtOH.

decanol (obtained into steps from the aldehyde, **14,** by reducing the double bond then the aldehyde to an alcohol) (40 mg, 0.17 mmol) and carbon tetrabromide (64 mg) in dry CH_2Cl_2 (5 ml) was added dropwise to a stirred, 0°C solution of triphenylphosphine in CH_2Cl_2 (60 mg, 1 ml) (Kociénski et al., 1977). The solution was stirred for 2 hr at 0°C and 1 hr at rt. The solvent was removed in vacuo; the white residue was diluted in hexane and filtered, and the product was purified (SiO_2) to give 49 mg of a colorless oil (95%), R_f = 0.8 in 10% EA/H. FT-IR (neat): 2956, 2925, 2853, 1467 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 3.37 (t, J = 7.0 Hz, 2H), 1.80 (m, 2H); [^{13}C]NMR ($CDCl_3$): δ 41.88, 40.42.

14,14-Dimethyl-9-tricosyne (27). A solution of 1-decyne (50 mg, 0.34 mmol) in dry THF (4 ml) was stirred at −78°C under nitrogen atmosphere, and n-Buli (0.3 ml, 1.0 M solution in hexanes) was added dropwise. The solution was stirred for 1 hr, HMPA (1 ml) was added, and the yellowish solution was stirred for 0.5 hr. 14,14-Dimethyl-1-bromotridecane (45 mg, 0.15 mmol) in THF (1 ml) was added, the solution was warmed to rt, poured into water, and the product was isolated with hexane and purified (SiO_2) to give 35 mg of a colorless oil (65%), R_f = 0.85 in 10% EA/H. FT-IR (neat): 3315, 2924, 2854, 1466 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 2.15 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 80.35, 80.24.

14,14-Dimethyl-(Z)-9-tricosene (5a). A mixture of the above tricosyne (30 mg, 0.086 mmol), 5 mg of 5% $Pd/BaSO_4$ and one drop of quinoline in ethanol

(5 ml) was stirred under a slight pressure of hydrogen until no alkyne remained (GC). The mixture was filtered, concentrated, and purified (20% $AgNO_3$–SiO_2) to give 27 mg of >95% *Z* isomer (92% yield), R_f = 0.85 in 10% EA/H; R_t = 13.60 (T_i = 140°C, 2 min; 7°C/min; T_f = 220°C). FT-IR (neat): 3004, 2956, 2923, 2853, 1465, 1403 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.32 (m, 2H), 2.02 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 129.89.

cis-*14,14-Dimethyl-9,10-epoxytricosane (5b).* The above alkene, **5a** (5 mg, 0.014 mmol), was stirred with *m*-CPBA (1 mg) in dry methylene chloride. After SiO_2 purification, 5 mg of the pure epoxide was obtained (95%); R_f = 0.70 in 10% EA/H; R_t = 16.44 (T_i = 140°C, 2 min; 7°C/min; T_f = 220°C). [^{1}H]NMR ($CDCl_3$): δ 2.87 (m, 2H).

Synthesis of Cyclopropyl Analog

Synthesis of 1-nonyl-1-[(Z)*-4-tetradecen-1-yl*]*-cyclopropane (6a).* A solution of 14-methylene-(Z)-9-tricosene **(2a),** (20 mg, 0.06 mmol) and an ethereal solution of diazomethane (1.5 ml, more than 10 equiv.) in dry ether (5 ml) was cooled in an ice-water bath, and palladium(II) acetate (10 mg) was added (Suda, 1981) (Figure 6). Vigorous gas production was observed. After 15 min of stirring, the ether was removed in vacuo, and the residue was purified on SiO_2 using hexane as eluent to give 19 mg (90%) of a colorless oil, R_f = 0.88 in 10% EA/H; R_t = 16.33 (T_i = 140°C, 2 min; 7°C/min; T_f = 250°C). FT-IR (neat): 3067, 2956, 2923, 2854, 1644, 1464, cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.34 (m, 2H), 2.01 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 129.98, 129.85, 104.94, 11.96.

1-Nonyl-1-[cis*-4,5-epoxy tetradec-1-yl*]*-cyclopropane (6b).* The above cyclopropane (5 mg, 0.014 mmol) and *m*-CPBA (1 mg) in dry methylene chloride (1 ml) were stirred at 20°C for 1 hr. After the usual work-up and SiO_2 purification, 5 mg (95%) of the epoxide as a colorless oil was obtained, R_f = 0.65 in 10% EA/H; R_t = 19.02 (T_i = 140°C, 2 min; 7°C/min; T_f = 250°C). [^{1}H]NMR ($CDCl_3$): δ 2.91 (m, 2H).

Synthesis of Fluorinated Analogs

(Z)*-10-Fluorotricos-14-ene (7a).* A solution of (Z)-14-tricosen-10-ol (30 mg, 0.088 mmol) in dry CH_2Cl_2 (2.0 ml) was stirred at −78°C under nitrogen atmosphere; to this solution diethylaminosulfur trifluoride (20 μl) was added (Figure 6). After stirring at −78°C for 1 hr, water was added (0.1 ml), the mixture was warmed to rt, the product was isolated with hexane, and purified (SiO_2) to give 27 mg of a colorless oil (88% yield), R_f = 0.77 in 10% EA/H; R_t = 15.84 (T_i = 140°C, 2 min; 7°C/min; T_f = 250°C). FT-IR (neat): 3004, 2925, 2854, 1655, 1466, cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.32 (m, 2H), 4.54, 4.37 (m, $J_{H\text{-}F}$ = 45.9 Hz, 1H), 2.04 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 130.51, 129.14, 95.52, 93.31; [^{19}F]NMR (C_6D_6): (φ) −184.76 (m, 1F).

cis-*10-Fluoro-14,15-epoxytricosane (7b).* Using *m*-CPBA oxidation, the epoxide was obtained in 95% yield as a colorless oil, R_f = 0.53 in 10% EA/H. GC analysis showed that we obtained two stereoisomers in about 1 : 1 mixture: R_t = 18.05, 18.13 (T_i = 140°C, 2 min; 7°C/min; T_f = 150°C). [^{1}H]NMR ($CDCl_3$): δ 4.56, 4.39 (m, $J_{H\text{-}F}$ = 50.7 Hz, 1H), 2.91 (m, 2H).

(Z)-10,10-Difluoro-14-tricos-14-ene (8a). A solution of (Z)-14-tricosen-10-one (100 mg, 0.30 mmol) in dry CH_2Cl_2 (3 ml) was stirred with DAST (80 μl) in a sealed vial at 35°C for four days (Middleton, 1975). After cooling to −78°C, methanol was added, the mixture was warmed to rt, concentrated, and the product was purified on a short pad of neutral alumina to give 42 mg (40%) of a colorless oil, R_f = 0.80 in 10% EA/H; R_t = 14.89, and about 50 mg of the starting material. FT-IR (neat): 2926, 2855, 1708, 1655, 1463 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.34 (m, 2H), 2.04 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 130.73, 128.46, 125.35 (t, J = 239.9 Hz), 36.20 (t, J = 25.5 Hz); [^{19}F]NMR (C_6D_6) ϕ (ppm): − 102.43 (quintet, J = 16.4 Hz, 2F).

cis-*10,10-Difluoro-14,15-epoxytricosane (8b).* This compound was obtained in more than 90% yield from the above alkene by epoxidation as described above, R_f = 0.57 in 10% EA/H; R_t = 17.69. [^{1}H]NMR ($CDCl_3$): δ 2.87 (m, 2H).

Synthesis of [14,14-^{2}H]- and [14-^{2}H]-(Z)-9-tricosene

(Z)-14-Tricosen-10-ol (28). To a solution of (Z)-14-tricosen-10-one (100 mg, 0.3 mmol) in methanol (5 ml) was added sodium borohydride (10 mg) at 0°C (Figure 10). The resulting solution was stirred for 2 hr, quenched with acetic acid, concentrated, and the product was purified (SiO_2) to give 95 mg

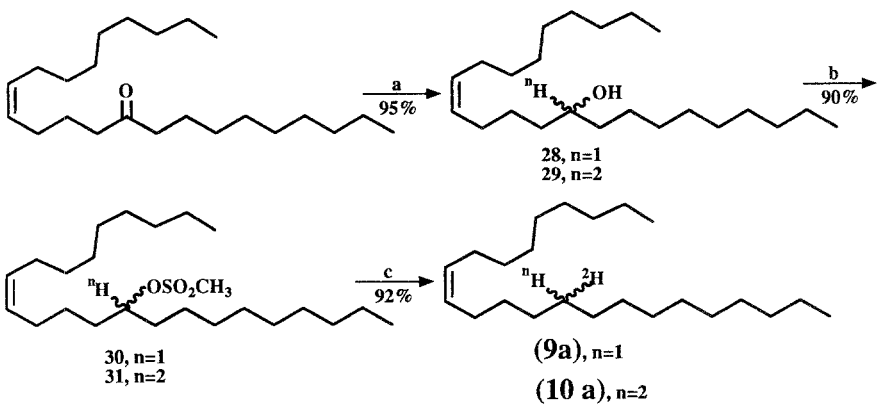

FIG. 10. Synthesis of [14-^{2}H]- and [14,14-^{2}H]-(Z)-9-tricosenes: (a) NaB^{n}H$_4$, CH_3O^nH (n = 1 or 2); (b) CH_3SO_2Cl, Et_3N, Et_2O, 0°C; (c) LiAl^{2}H$_4$, Et_2O, 0°C.

(95%) of a colorless oil, R_f = 0.31 in 10% EA/H; R_t = 15.26. FT-IR (neat): 3375, 3004, 2922, 2854, 1466 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.36 (m, 2H), 3.58 (m, 1H), 2.03 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 130.31, 129.36, 71.85.

[10-^{2}H]-(Z)-14-Tricosen-10-ol (29). To 97 mg (0.29 mmol) of (Z)-14-tricosen-10-one in 2 ml of MeO^2H was added sodium borodeuteride (10 mg, 98 atom % ^{2}H) at 0°C. After purification by flash chromatography, 92 mg (95%) of a colorless oil was obtained. [^{1}H]NMR ($CDCl_3$): δ 5.30 (m, 2H), 2.02 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 130.31, 129.36, 71.39 (t, $J_{C\text{-}H}$ = 20.9 Hz); [^{2}H]NMR (CCl_4 + one drop of $CDCl_3$): δ 3.51 ppm.

10-Mesyloxy-(Z)-14-tricosene (30). To an ice-cold and stirred solution of (Z)-14-tricosen-10-ol (12 mg, 35 μmol) and triethylamine (15 μl, 105 μmol) in CH_2Cl_2 (2 ml) was added methanesulfonyl chloride (3.4 μl, 42 μmol) (Kelkar et al., 1989). The mixture was stirred for 30 min at 0°C and for 4 hr at rt, concentrated, and the product was isolated with ether and purified (SiO_2) to give 13 mg of a colorless oil (90%), R_f = 0.31 in 10% EA/H. FT-IR (neat): 2926, 2855, 1466 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.36 (m, 2H), 4.70 (m, 1H), 2.99 (s, 3H), 2.04 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 130.90, 128.67, 84.20.

[10-^{2}H]-10-Mesyloxy-(Z)-14-tricosene (31). To an ice-cold and stirred solution of [10-^{2}H]-(Z)-14-tricosen-10-ol (50 mg, 0.146 mmol) and triethylamine (61 μl, 0.438 mmol) in CH_2Cl_2 (2 ml) was added methanesulfonyl chloride (14 ml, 0.175 mmol). Deuterium oxide was used (1 ml) for the work-up. Purification (SiO_2) gave 55 mg of a colorless oil (90%). [^{1}H]NMR ($CDCl_3$): δ 5.34 (m, 4H), 2.98 (s, 3H), 2.04 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 130.86, 128.64, 82.97; [^{2}H]NMR (CCl_4 + one drop of $CDCl_3$): 4.64 ppm.

[14-^{2}H]-(Z)-9-Tricosene (9a). To an ice-cold and stirred suspension of lithium aluminum deuteride (2 mg, 98 atom % ^{2}H) in dry ether (1 ml) was added a solution of the mesylate **(30)** (14 mg, 33.36 mmol) in ether (1 ml). The reaction mixture was stirred for 30 min at 0°C then for 1 hr at room temperature. Excess of $LiAl^2H_4$ was destroyed by adding one drop of ethyl acetate, and the mixture was filtered and concentrated in vacuo. The residue was chromatographed (20% $AgNO_3$–SiO_2) to give 10 mg (92%) of a colorless oil (>98% *cis*, detected by capillary GC), R_f = 0.83 in 10% EA/H; R_t = 13.27. [^{1}H]NMR ($CDCl_3$): δ 5.34 (m, 2H), 2.04 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 129.89; [^{2}H]NMR (CCl_4 + one drop of $CDCl_3$): 1.30 ppm.

[14-^{2}H]-(Z)-9,10-Epoxy Tricosane (9b). This compound was prepared from the corresponding alkene **(9a)**, R_f = 0.68 in 10% EA/H; R_t = 15.19. [^{1}H]NMR ($CDCl_3$): δ 2.90 (m, 2H).

[14,14-$^2H_2$]-(Z)-9-Tricosene (10a). To an ice-cold and stirred suspension of lithium aluminum deuteride (8 mg, 98 atom % ^{2}H) in dry ether (1 ml) was added a solution of the mesylate **(31)** (48 mg, 0.115 mmol) in dry ether (1 ml). The crude product was purified by chromatography (20% $AgNO_3$–SiO_2) to give 30 mg of >98% *cis* product as a colorless oil, R_t = 12.59. [^{1}H]NMR ($CDCl_3$):

δ 5.35 (m, 2H), 2.02 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 129.90; [^{2}H]NMR (CCl_4 + one drop of $CDCl_3$): 1.26 ppm.

cis-[*14,14-$^2H_2$*]-*9,10-Epoxytricosane (10b).* Epoxidation of alkene **10a** with *m*-CPBA gave epoxide **10b**. R_f = 0.71 in 10% EA/H; R_t = 14.86. [^{1}H]NMR ($CDCl_3$): δ 2.91 (m, 2H).

Synthesis of Perfluoro Analogs

1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8-Heptadecafluoro-10-iodo-9-tricosene (32). 1-Pentadecyne (418 mg, 2.0 mmol), *n*-perfluorooctyl iodide (1.0 g, 2.0 mmol), and azobis(isobutyronitrile) (AIBN, 100 mg) were placed in a 5-ml round-bottom flask equipped with a short condenser and a magnetic stirrer. The mixture was frozen using a bath of liquid nitrogen, degassed, and thawed under nitrogen atmosphere to eliminate oxygen (Sun and Prestwich, 1990); this process was repeated twice (Figure 11). The mixture was slowly warmed to rt,

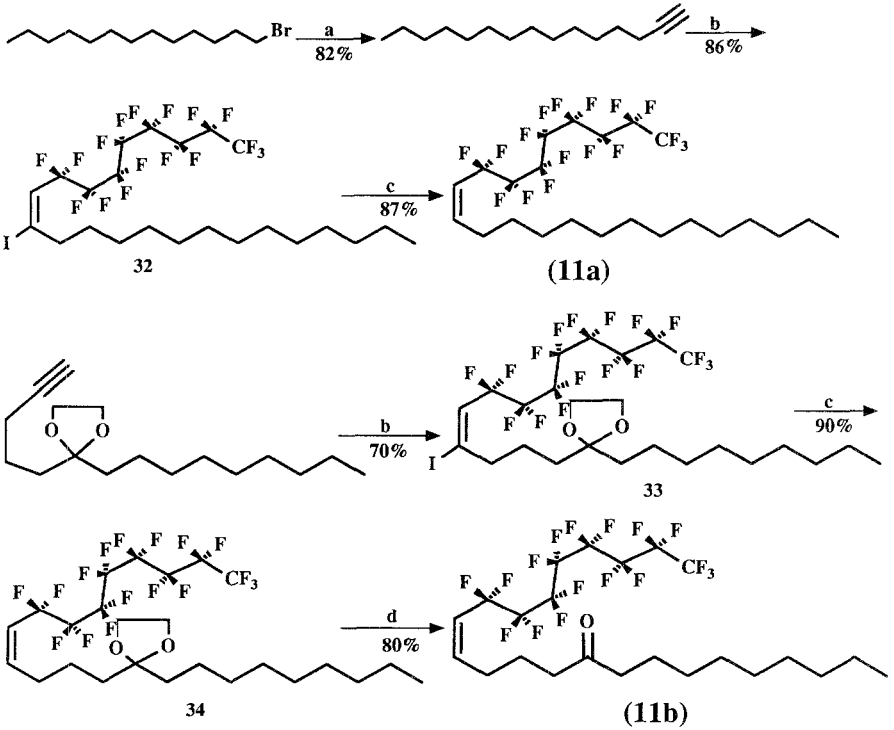

FIG. 11. Synthesis of perfluoroalkyl analog and its expected ketone metabolite: (a) HC≡CLi-EDA, DMSO; (b) *n*-$C_8F_{17}I$, AIBN; (c) *n*-BuLi, THF, MeOH; (d) 3N $HClO_4$, THF, rt.

then heated at 80°C for 20 hr. After cooling to rt the crude brown solution was purified (SiO_2) to give 1.4 g of a colorless oil (93%), R_f = 0.84 in 10% EA/H. GC analysis showed an *E/Z* ratio of 92:8. FT-IR (neat): 2926, 2855, 1634, 1467 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 6.31 (t, J= 14.4 Hz, 1H), 2.62 (dist t, 2H), 1.55 (m, 2H), 1.26 (br s, 20H), 0.88 (t, J = 6.5 Hz, 3H); [^{13}C]NMR ($CDCl_3$): δ 126.56 (t, J = 47.3 Hz), 123.06 t, J = 5.8 Hz); [^{19}F]NMR (C_6D_6): ϕ −85.80, −111.00, −115.60, −126.07, −126.62, −127.50, −128.03, −128.25, −130.96.

(Z)-*1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8-Heptadecafluoro-9-tricosene (11a).* The above iodoperfluorooctyl alkene (180 mg, 0.24 mmol) was stirred in dry ether (5.0 ml) at −78°C, while *n*-BuLi (1.0 ml of 1.6 M solution in hexanes) was added dropwise; the resulting solution was stirred at −78°C for 1 hr. Methanol (1 ml) was precooled at −78°C and added slowly; the mixture was allowed to warm to room temperature. The reaction was poured into saturated ammonium chloride (4 ml) and the product was isolated with ether and purified (SiO_2) to give 130 mg (87%) of a colorless oil, R_f = 0.80 in 10% EA/H; R_t = 5.86. FT-IR (neat): 2926, 2856, 1664, 1467, 1411 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 6.10 (m, 1H), 5.49 (m, 1H), 2.40 (m, 2H); [^{13}C]NMR ($CDCl_3$): δ 145.63 (t, J = 4.7 Hz), 115.86 (d, J = 25.2 Hz); [^{19}F]NMR (C_6D_6): ϕ −85.77, −109.82, −112.74, −126.15, −126.62, −127.50, −127.88, −130.96.

(Z)-*1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8-Heptadecafluoro-10-iodo-14-ethylenedioxy-1-tricosyne (33).* A mixture of 6-ethylenedioxy-1-pentadecyne **(15)** (0.25 g, 0.93 mmol), *n*-perfluorooctyl iodide (0.77 g, 1.4 mmol), and AIBN (30 mg) was heated at 120°C for 24 hr. Purification (SiO_2) gave 534 mg (70% yield) of a colorless oil, which solidified on refrigeration, R_f = 0.50 in 10% EA/H. (*E/Z* 90:10). FT-IR (neat): 2926, 2856, 1718, 1635, 1460, 1413 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 6.34 (t, J = 14.4 Hz, 1H), 3.90 (s, 4H), 2.64 (br t, 2H); [^{13}C]NMR ($CDCl_3$): δ 126.87 (t, J = 2.3 Hz), 122.65, 111.36, 64.94.

(Z)-*1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8-Heptadecafluoro-14-ethylenedioxy-9-pentadecene (34).* The protected iodo ketone **(33)** (120 mg, 0.147 mmol) was stirred at −78°C in dry ether (5 ml), and *n*-BuLi (0.4 ml of 1.6 M solution in hexanes) was added. After quenching with precooled methanol and the usual work-up, the crude product was purified (SiO_2) to give 90 mg (90% yield) of a colorless oil, R_f = 0.48 in 10% EA/H, which solidified upon refrigeration. [^{1}H]NMR ($CDCl_3$): δ 6.32 (m, 1H), 5.46 (m, 1H), 3.92 (s, 4H), 2.2 (m, 2H); [^{13}C]NMR ($CDCl_3$): δ 145.62 (t, J = 4.7 Hz), 115.85, 111.38, 64.95; [^{19}F]NMR (C_6D_6): ϕ: −85.73, −109.90, −126.10, −126.65, −127.50, −127.84, −130.90.

(Z)-*1,1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8-Heptadecafluoro-9-pentadecen-14-one (11b).* A mixture of the perfluoro protected ketone (40 mg, 0.058 mmol) and $HClO_4$ (0.5 ml of 3 N solution) in THF (3.0 ml) was stirred at room tem-

perature for 48 hr, and the product was isolated with ether, concentrated, and purified (SiO_2) to give 37 mg (80% yield) of a white solid, mp = 26–27°C, R_f = 0.54 in 10% EA/H; R_t = 10.80. FT-IR (neat): 2958, 2928, 2857, 1717, 1664, 1461, 1412 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 6.20 (dtt, J = 14.0, 7.8, 2.3 Hz, 1H), 5.50 (m, 1H), 2.42 (t, J = 6.5 Hz, 2H), 2.37 (t, J = 6.5 Hz, 2H), 1.71 (m, 2H), 1.54 (m, 2H); [^{13}C]NMR ($CDCl_3$): δ 211.01, 146.35 (t, J = 4.8 Hz), 116.04 (d, J = 25.3 Hz); [^{19}F]NMR (C_6D_6): ϕ −85.73 (t, J = 9.9 Hz), −109.90 (q, J = 13.3 Hz), (−126.10, −126.65), (−127.50, −127.84), −130.90.

RESULTS AND DISCUSSION

(*Z*)-14-Tricosen-10-one was a suitable starting material in the synthesis of most of the compounds. As shown in Figure 5, the enone **(III)** was most conveniently synthesized in 13.5% overall yield from 1,3-cyclohexanedione by an Eschenmoser fragmentation reaction (Mori et al., 1977; Latli and Prestwich, 1988). Except for compound **1a**, which was synthesized from 5-hexyn-1-ol, the rest of the analogs were obtained or attempted from the enone **(III)**. Transformations of this enone are summarized in Figure 6. First, the diene **(2a)** was obtained from enone **(III)** by Wittig methylenation. Treatment of **2a** with diazomethane using palladium diacetate in catalytic amount gave the cyclopropyl analog **(6a)**. Next, the tertiary alcohol **(4a)** was obtained using the Grignard reagent methylmagnesium bromide. The fluorinated analogs were obtained from the ketone or the alcohol as follows. Reaction of the enone **(III)** with diethylamino sulfur trifluoride to produce the difluoro analog **(8a)** proceeded slowly at 35°C to give the desired difluoro compound. Attempts to obtain this analog from the corresponding 1,3-dithiolane, 1,3-dibromo-5,5-dimethylhydantoin, and HF-pyridine had failed (Sondej and Katzenellenbogen, 1986). In contrast, the reaction of the alcohol was complete in less than an hour at −78°C, to give the monofluorinated analog **(7a)** in quantitative yield.

The 9,14-diene analog (**1a,** Figure 7) was obtained in 51% overall yield, by first protecting 5-hexyn-1-ol followed by alkylation of the lithium acetylide. After reducing the triple bond to a *cis* double bond, deprotecting the alcohol, and then oxidizing it to the aldehyde, the diene was obtained by Wittig reaction.

The 14-methyl compound (**3a,** Figure 8) was prepared in 26% overall yield in five steps from 5-bromo-1-pentene. First, the terminal double bond was oxidized to a methyl ketone using cuprous chloride and palladium dichloride in DMF under an oxygen atmosphere. The resulting 5-bromo-2-pentanone was unstable and decomposed when left at rt. Next, Wittig reaction of this com-

pound with nonyltriphenylphosphine bromide followed by reduction of the double bond gave the methyl-branched alkyl halide, which was coupled with lithium-1-decyne and reduced to the *cis* alkene. Attempts to synthesize 14-methyl-(Z)-9-tricosene from 14-bromo-(Z)-9-tricosene by coupling with dimethylcopper lithium (Corey and Posner, 1967) or by refluxing (Z)-14-tricosen-10-ol with trimethylaluminum in toluene (Harney et al., 1974) had failed. Also tried without success was the reaction of 14-methylene-9-tricosyne with catecholborane (Brown and Gupta, 1975).

The 14,14-dimethyl analog (**5a,** Figure 9) was prepared in 17% overall yield by reacting isobutyraldehyde and acrylonitrile using a solution of 5% NaOH and dioxane as a solvent. The resulting 4-cyano-2,2-dimethyl butanal was used to prepare the dimethyl alkyl halide, which was coupled with acetylenic lithium as described before. An attempted reaction of dimethyl zinc and titanium tetrachloride with the enone **(III)** (Reetz et al., 1985) in order to produce the *gem*-dimethyl analog gave a mixture of nonpolar, unidentified products.

The deuterated analogs (**9a** and **10a,** Figure 10) were synthesized by reduction of the enone **(III)** to the alcohols followed by deuteride displacement on the corresponding mesylates to the desired mono- and dideuterated analogs. The reduction of (Z)-14-tricosen-10-ethylene dithioketal (Fujita et al., 1978) using deuterated Raney nickel (Djerassi and Williams, 1963) gave a mixture of inseparable products.

The perfluoro analog (**11a,** Figure 11) was prepared in 61% in three steps. Bromotridecane was transformed to 1-pentadecyne using lithium acetylide-ethylenediamine complex in DMSO (Novis Smith and Beumel, 1974). Reacting this alkyne with *n*-perfluorooctyliodide and AIBN as a catalyst gave the alkenyl iodides as a 92 : 8 *E*/*Z* mixture. Lithium iodide exchange using butyllithium and quenching at −78°C with methanol (Sun et al., 1990) gave the perfluoro analog, which was very volatile compared to the (Z)-9-tricosene. We were unable to obtain the epoxide of this analog even when using ten equivalents of *m*-CPBA at rt. The other expected metabolite of the perfluoro analog was synthesized from 6-ethylenedioxy-1-pentadecyne **(15)** in 50% yield in three steps. Attempts to prepare the analog **11a** from **11b** using Wolff-Kishner type reduction failed (Kabalka et al., 1979).

The expected epoxide metabolites (Figure 4) were obtained by treatment of each analog with *m*-CPBA acid in methylene chloride. Epoxides were characterized spectroscopically and used to identify metabolic products for in vivo experiments (Guo et al., 1991).

(Received January 15, 1991; accepted May 9, 1991)

Abstract—Analogs of (*Z*)-9-tricosene (*Z*9–23 : Hy) bearing methyl substituents, cyclopropyl groups, fluorine substituents, and additional double bonds were used to probe the substrate requirements for the monooxygenase system that converts *Z*9–23 : Hy to the corresponding epoxide and ketone. Three of the seven analogs tested, 10-fluoro-(*Z*)-14-tricosene, 10,10-difluoro-(*Z*)-14-tricosene, and 14-methyl-(*Z*)-9-tricosene, were metabolized to the corresponding epoxide. Compounds with two methyl groups, a cyclopropane group, a hydroxy group, or an additional double bond at the 14 position were not epoxidized at the 9,10 position. This suggests that only minimal structural change at the 14-position of *Z*9–23 : Hy is allowed with retention of metabolic activity. None of the analogs tested were hydroxylated at the position equivalent to the 14 position of *Z*9–23 : Hy. Of the 13 analogs tested as inhibitors of *Z*9–23 : Hy metabolism, the two compounds that were the most effective inhibitors in both male and female houseflies were (*Z*)-14-tricosen-10-one and 1-nonyl-1-[(*Z*)-4-tetradecen-1-yl]-cyclopropane. These data show that the polysubstrate monooxygenase that metabolizes *Z*9–23 : Hy in the housefly has very strict structural requirements for the substrate.

Key Words—Sex pheromone, sex pheromone analogs, (*Z*)-9-tricosene, housefly, *Musca domestica*, Diptera, Muscidae, polysubstrate monooxygenase.

INTRODUCTION

The sex pheromone components of the housefly, *Musca domestica*, consist of (*Z*)-9-tricosene (Z9–23 : Hy) (Carlson et al., 1971), *cis*-9,10-epoxytricosane (C_{23} epoxide), (*Z*)-14-tricosen-10-one (C_{23} ketone) (Uebel et al., 1978) and C_{28}–C_{30} methylalkanes (Uebel et al., 1976). Z9–23 : Hy is a short-range attractant and elicits the mating strike, the C_{23} epoxide and ketone act as sex recognition factors, and the methylalkanes promote and extend sexual contact as arrestant factors (Adams and Holt, 1987). The effects of structural variations of Z9–23 : Hy (originally named muscalure) on biological activity were examined in olfactometer and pseudofly tests (Carlson et al., 1974). The structural variations included double-bond position, *cis–trans* isomerism, substitution of the double bond with a triple bond, methyl branching at different points in the molecule, carbon chain length, and length of carbon chain linked to the unsaturated bond. The results of those experiments indicated that the structure requirements for activity were less stringent than those for most other sex pheromones.

The C_{23} sex pheromone components on the female housefly first appear on day 2 postemergence during the early vitellogenic stages and accumulate as a function of age and ovarian development (Dillwith et al., 1983; Ahmad et al., 1989). All female body parts contain the sex pheromone components, with the legs and abdomen containing the largest amount (Blomquist et al., 1984b). Male houseflies, which normally do not produce any of the C_{23} sex pheromone components (Adams et al., 1984), can be induced to produce female-specific pheromones after ovary implants or injections of 20-hydroxyecdysone (Blomquist et al., 1984a).

The biosynthesis of the C_{23} sex pheromone components have been studied (Blomquist et al., 1987). Z9–23 : Hy formation in female houseflies occurs by the microsomal elongation of oleoyl-CoA to a 24-carbon fatty acyl moiety that is then converted to an alkene one carbon shorter (Blomquist et al., 1987). The C_{23} epoxide and ketone arise from metabolism of Z9–23 : Hy (Blomquist et al., 1984b). Direct evidence was provided for the role of a cytochrome P-450 polysubstrate monooxygenase (PSMO) in the conversion of the alkene to the epoxide at the 9,10 positions and ketone (Ahmad et al., 1987). The latter is apparently formed by hydroxylation at the methylene carbon 10 carbons from the other end of the molecule with subsequent oxidation to the ketone by another enzyme, which has not been characterized. Males also readily convert exogenous Z9–23 : Hy to the epoxide and ketone and show a relatively higher rate of metabolism than females.

All major body parts of both male and female houseflies metabolized Z9–23 : Hy when it was applied to the surface of the insect (Blomquist et al., 1984b), which suggested that this PSMO is generally distributed. To study the molecular basis of pheromone metabolism requires detailed knowledge of the inter-

action between the pheromone and enzyme, in which the substrate specificity of the enzyme is one of the key points. Radiolabeled pheromones and pheromone analogs have been used to isolate and characterize both the macromolecules and pheromone metabolites in a variety of insect species (Prestwich, 1987; Prestwich et al., 1989), providing new insights into pheromone reception and catabolism.

In this paper, we present data on the metabolism of a variety of Z9-23 : Hy analogs in the male housefly and the effect of the analogs on the metabolism of [^{3}H]Z9-23 : Hy in both male and female houseflies. The chemical synthesis of the Z9-23 : Hy analogs and the justification for choosing the structures synthesized were described in the prior paper in this issue (Latli and Prestwich, 1991).

METHODS AND MATERIALS

Insects. Pupae of the Fales T-II strain houseflies, *Musca domestica*, were provided by the Biology Section, S.C. Johnson & Sons, Racine, Wisconsin. Within 12 hr after emergence, male and female insects were separated, and adult insects were maintained separately according to sex and fed ad libitum on sucrose–low-fat powdered milk (1 : 1, w/w) and water at 25°C.

Chemicals. Analogs of Z9-23 : Hy (Figure 1) were prepared as described in Latli and Prestwich (1991). Z9-23 : Hy was synthesized as described (Carlson et al., 1974).

[9,10-$^3H_2$]-(Z)-9-tricosene. Tritium-labeled pheromone was obtained by hydrogenation of 9-tricosyne using tritium gas and the conditions described above for the unlabeled reaction. The tritium gas reaction was performed by E. Do at Dupont-NEN, and provided a mixture of 40% (Z)-alkene, 37% (E)-alkene, and 23% saturated alkane, as determined by autoradiography of an argentated TLC plate using hexane as eluent. The desired [9,10-$^3H_2$]-Z9-23 : Hy was isolated by chromatography on 20% $AgNO_3$–SiO_2 by gradient elution with ethyl acetate in hexane. [^{3}H]NMR of the purified product was performed and showed that about three fifths of the ^{3}H was present at the 9,10 positions, one fifth at the allylic positions, and one fifth on other methylene carbons. [^{3}H]NMR ($CDCl_3$): δ 5.42 (57.9%), 1.95 (20.9%), 1.25 (21.2%).

(Z)-9,10-Epoxytricosane. To a stirred solution of *m*-chloroperoxybenzoic acid (*m*-CPBA, 13 mg, Aldrich, 80–85% technical grade) in CH_2Cl_2 (1.0 ml) was added (Z)-9-tricosene (20 mg, 0.06 mmol) in CH_2Cl_2 (1.0 ml). After stirring for 2 hr, the solution was stirred with 0.2 ml of 10% Na_2SO_3 for 15 min and then washed with 0.2 ml of 5% NaOH and 0.5 ml of water. The organic solution was concentrated in vacuo and purified by flash chromatography to give 20 mg (95% yield) as a colorless oil of 90 : 10 *cis-trans* by GC. R_f = 0.71 in 10% EtOAc–Hex. R_t = 15.30 (T_i = 140°C, 2 min; 7°C/min; T_f = 250°C).

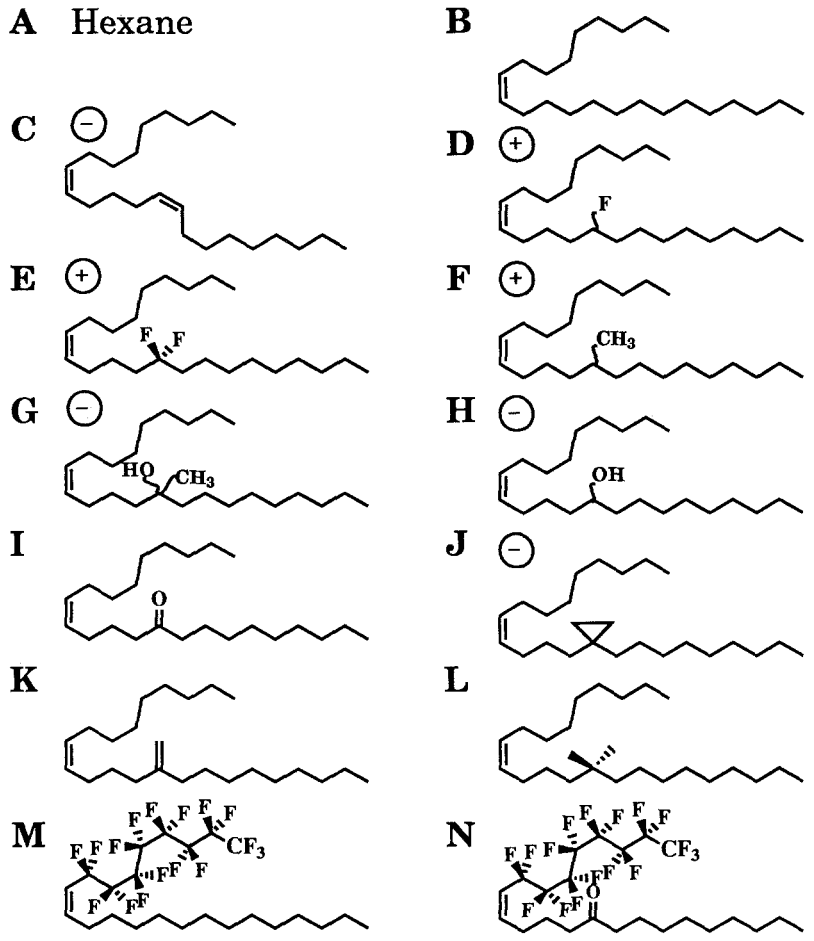

FIG. 1. Z9-23:Hy analogs used in these studies. +, epoxidized by male housefly; −, not epoxidized. Four-day-old unmated male houseflies were treated with (Z)-9-tricosene analogs on the ventral side of the abdomens as described in Methods and Materials. After a 6-hr incubation at 25°C, three groups of 10 flies each were killed, lipids were extracted, and the nonhydrocarbon fraction was analyzed by GC and GC-MS as described in Methods and Materials. + and − are based on GC and GC-MS analysis.

^{1}H NMR ($CDCl_3$): δ 2.86 (m, 2H), 1.44 (m, 4H), 1.26 (br s, 26H), 0.88 (t, J = 6.5 Hz, 6H); ^{13}C NMR ($CDCl_3$): δ 57.28, 31.93, 31.87, 31.60, 29.66, 29.57, 29.37, 29.23, 27.82, 26.62, 22.66, 14.12.

In Vivo Studies. For the studies with Z9–23 : Hy analogs, 4-day-old unmated males were treated on the ventral side of the abdomens with 1 μl of an analog in hexane (5 μg/μl) per insect. The treated flies were held at 25°C in a 200-ml urine bottle covered with a piece of organdy cloth and a rubber band. After 3 and 6 hr, flies were killed by freezing at −20°C and stored at −20°C. Three groups of 10 flies each were used for each data point.

For the studies on the effect of Z9–23 : Hy analogs on [^{3}H]Z9–23 : Hy metabolism, both 4-day-old males and females were used. Insects were treated with 0.5 μl of each analog in hexane (2 μg/μl) on the ventral side of the abdomen. After 10 min, [^{3}H]Z9–23 : Hy (60 Ci/mmol) in 0.5 μl hexane (0.18 μCi) was applied on each housefly on the same location. The amount of the analogs applied (1 μg) was comparable to the amount of Z9–23 : Hy on the cuticular of the female housefly (Ahmad et al., 1989). The amount (mass) of [^{3}H]Z9–23 : Hy applied was small enough that it would have minimal affect on the amount of Z9–23 : Hy on the female housefly (Ahmad et al., 1989). After 2 hr at 25°C, flies were killed by freezing at −20°C and stored at −20°C. Three groups of five flies each were used for each data point for both male and female houseflies.

Extraction and Separation. Houseflies were extracted by rinsing in 5 ml redistilled hexane for 10 min, removing the solvent, and then adding 2 ml of hexane for an additional 1 min. The extracts were combined and reduced in volume under a stream of N_2.

The extracts were separated into hydrocarbon and nonhydrocarbon fractions by chromatography on a minicolumn (6 × 0.5 cm) of Biosil-A (Bio-Rad Labs, Richmond, California). The hydrocarbons were eluted with 7 ml of hexane and the nonhydrocarbons were eluted with 7 ml hexane–diethyl ether 1 : 1.

GC and GC-MS Analysis. The nonhydrocarbon fractions from the Z9–23 : Hy analog metabolism studies were analyzed by gas chromatography (GC) and GC-mass spectrometry (GC-MS) to study the formation of products. Chemically synthesized epoxides (Latli and Prestwich, 1991) were used as standards for GC and GC-MS analyses. All GC analyses were performed on a Hewlett-Packard 5890 controlled by a Hewlett-Packard 3393A integrator fitted with a 30 m × 0.32 mm ID, 0.5 μm stationary phase DB-5 column. The oven was temperature programmed from 200 to 310°C at 5°C/min, then held at 310°C for 15 min. The carrier gas was He, at a flow rate of 2.5 ml/min, and the carrier gas plus makeup gas was at a total flow rate of 30 ml/min. The amount of epoxide formed was determined by comparing the epoxide peak areas with external standards (a known concentration of Z9–23 : Hy solution was used as the external standard).

GC-MS analyses were performed on a Finnigan 4023 mass spectrometer

interfaced with an INCOS data system at 70 eV. A 30-m DB-5 column as above was used. The GC oven was temperature programmed from 30 to 200°C at 20°C/min, 200–280°C at 5°C/min, then held at 280°C for 15 min. The carrier gas was He at 8 psi head pressure, linear flow velocity about 30 cm/sec.

Determination of Radioactivity. Radioactivity was assayed on a Beckman LS 1701 scintillation counter in a 10-ml fluor solution containing 0.4% 2,5-diphenyloxazole (PPO) in toluene at an efficiency of ca. 53% for ^{3}H.

RESULTS AND DISCUSSION

Metabolism of Z9–23 : Hy Analogs. Both female and male houseflies readily metabolize *Z*9–23 : Hy to the corresponding epoxide, with males showing an apparent higher rate of conversion of exogenous substrate than females (Blomquist et al., 1984b; Ahmad et al., 1987). After day 2 postemergence, the female produces large amounts of *Z*9–23 : Hy, whereas the male does not, thus suggesting that the apparent difference in the rates of metabolism of exogenous *Z*9–23 : Hy in part could be due to dilution and thus lowering of the specific activity of the substrate applied to the female. Because of the apparent higher rates of epoxide and ketone formation, male insects were used to examine the metabolism of metabolically blocked analogs of *Z*9–23 : Hy. In addition, the use of males for these studies simplified product analysis as limited endogenous epoxides were present.

Of the seven *Z*9–23 : Hy analogs studied, three were converted to the corresponding epoxides by male houseflies (Figure 1). These include 10-fluoro-(*Z*)-14-tricosene, 10,10-difluoro-(*Z*)-14-tricosene, and 14-methyl-(*Z*)-9-tricosene. Products were characterized by comparison with synthetic epoxide standards using both GC and GC-MS. The mass spectra of the resulting epoxides are shown in Figure 2, and are essentially identical to those of the synthetic standards. All three spectra show a strong ion at *m/z* 155, which arises from cleavage between carbons 10 and 11, with the charge retained on the fragment containing the oxygen, and is diagnostic for the 9,10-epoxide.

Analysis of the metabolic products of 10-fluoro-(*Z*)-14-tricosene showed two GC peaks that were not completely baseline separated (Figure 3). Both peaks gave identical mass spectra as represented in Figure 2A. The most likely explanation for this phenomena is that two racemic pairs of diastereomers are formed, i.e., (9*S**,10*R**,14*R**)-9,10-epoxy-14-fluorotricosane and the 9*S**,10*R**,14*S**) isomer.

Modifying the C-14 position with either one fluorine or two fluorine atoms did not prevent the epoxidation at the C-9, C-10 position. Although introduction of the C–F bond significantly increases the electronegativity of the bond at the C-14 position, only limited steric properties change with the addition of fluorine

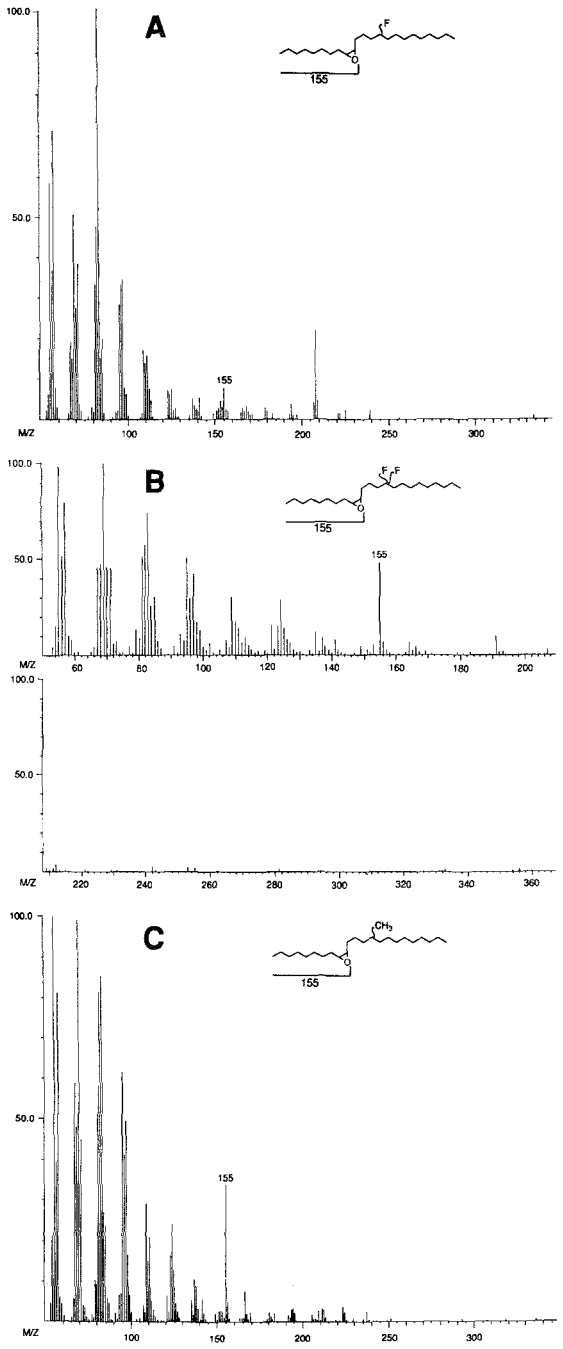

FIG. 2. Mass spectra of the epoxides formed by male houseflies treated with 10-fluoro-(Z)-14-tricosene (A), 10,10-difluoro-(Z)-14-tricosene (B), and 14-methyl-(Z)-9-tricosene (C).

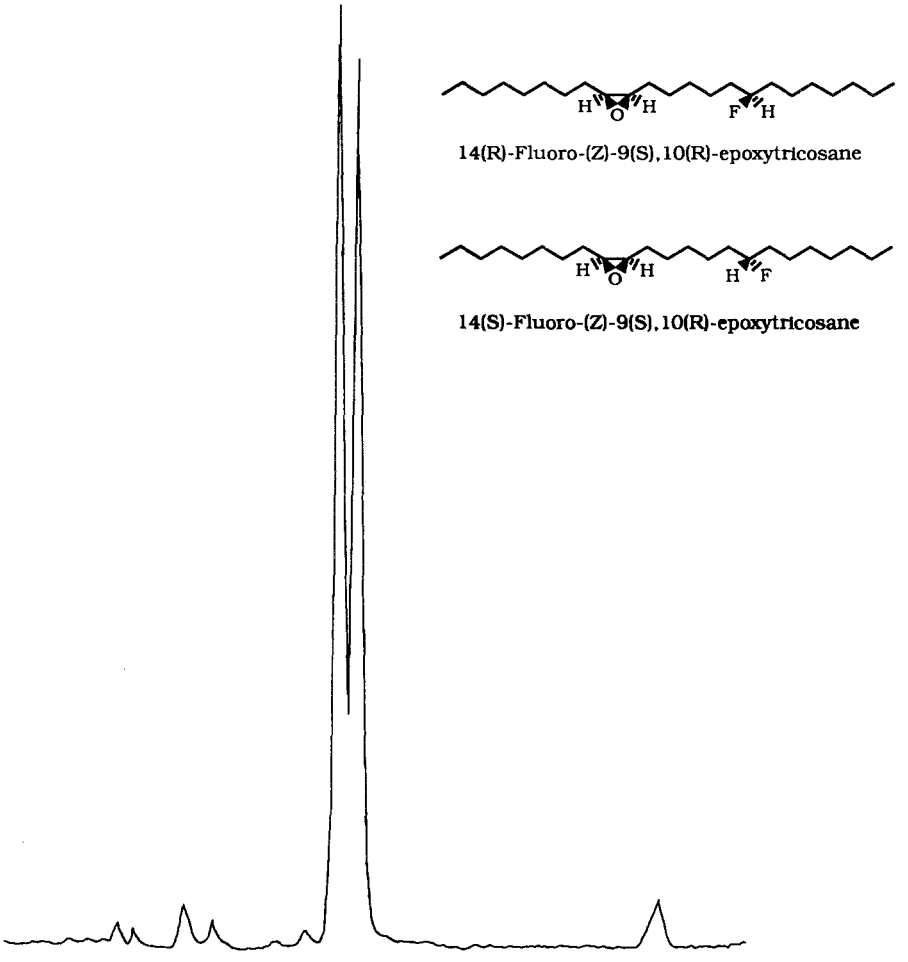

FIG. 3. Portion of the total ion GC-MS trace showing the two GC peaks that yielded identical mass spectra as shown in Figure 1A. The data are interpreted that two epoxide diastereomers were formed.

(Patrick, 1979; Welch, 1987; Sun and Prestwich, 1990). When the C-14 position was modified with the addition of one or two methyl groups, only the monomethyl derivative was converted to the epoxide. This suggests that steric hindrance at the C-14 position markedly effects the PSMO epoxidation at carbons 9 and 10 and that the addition of the second methyl group prevents a productive binding of the analog to the enzyme. Our observation that 1-nonyl-1-[(Z)-9-tetradecenyl]-cyclopropane, an analog with 14,14-dimethyl groups fused into a cyclopropyl ring, is not epoxidized further supports this hypothesis.

No epoxidation was observed for (Z,Z)-9,14-tricosadiene (Figure 1), suggesting that introduction of a double bond at the C-14 position changes the three dimensional structure of the molecule such that it no longer fits the steric requirements for this PSMO. Likewise, introducing a hydroxyl group at the 14 position of Z9–23 : Hy prevents epoxidation, probably by increasing the polarity such that binding in a hydrophobic site is prevented. This is consistent with the absence of a 14-keto 9,10 epoxide on the female housefly. Apparently once the Z9–23 : Hy is modified at either the 9, 10, or the 14 position, it will not serve as a substrate for further oxygenation.

Different rates of epoxidation were observed among the three Z9–23 : Hy analogs that were converted to the corresponding epoxides by male houseflies (Figure 4). Relatively high amounts of each analog were applied (2 μg/housefly); thus, the epoxidation reactions were performed under saturating conditions. The rate of 10-fluoro-*cis*-14,15-epoxytricosane formation was about two times higher than the rate of 10,10-difluoro-*cis*-14,15-epoxytricosane formation, and the rate of 14-methyl-(Z)-9,10-epoxytricosane formation was the lowest (Figure 4). This suggests that the rate of epoxidation is very closely related to the steric barrier size at the C-14 position. Thus, increased steric hindrance or electronic perturbation at C-14 results in a lower rate of epoxidation at the C-9,C-10 position.

None of the metabolically blocked Z9–23 : Hy analogs underwent hydroxylation at the 14-position. Adding any substituent at carbon 14, even a single methyl group, is apparently sufficient to prevent this hydroxylation.

Direct evidence was obtained for the conversion of (Z)-14-tricosen-10-ol to the C_{23} ketone in male houseflies by analysis of the C_{23} ketone produced

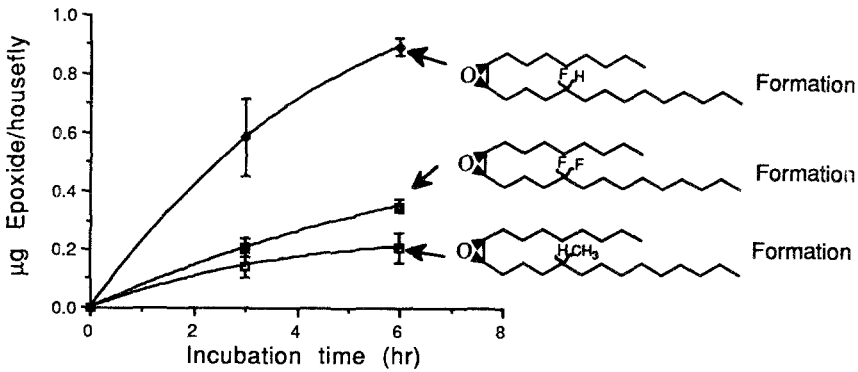

FIG. 4. The formation of epoxides as a function of incubation time. Z9–23 : Hy analogs were applied to the male houseflies (5 μg/housefly) on the ventral side of the abdomens. After the time indicated, houseflies were killed, and the cuticular lipids were extracted and analyzed as described in Methods and Materials.

from the C_{23} secondary alcohol. GC-MS was used and the spectrum compared to the spectrum of the corresponding ketone standard. Previous work (Ahmad et al., 1987) using only TLC R_f values had suggested that the secondary alcohol was an intermediate in the metabolism of the alkene to ketone.

Selective ion monitoring of the GC-MS trace at *m/z* 155 showed that trace amounts of *cis*-9,10-epoxyheptacosane were present in all samples. The mass spectrum of this component showed ions at *m/z* 155 and 267, consistent with cleavage of C–C bonds adjacent to the epoxide with retention of the charge on the oxygen-containing fragment. This is the first identification of *cis*-9,10-epoxyheptacosane in the housefly and suggests that the chain length specificity of the epoxidation enzyme is not absolute for the 23-carbon alkene. It will apparently accept as substrate, although at a much lower rate, the 27-carbon alkene. This is the major alkene in control males and previtellogenic females. Neither males nor females produce appreciable amounts of the 25-carbon alkene (Nelson et al., 1981), and it is not known if shorter chain Z9-alkenes or alkenes with double bonds in different positions are epoxidized.

Effect of Z9–23 : Hy Analogs on [^{3}H]Z9–23 : Hy Metabolism. Twelve synthetic Z9–23 : Hy analogs were applied to both male and female houseflies to study their effect on the metabolism of [^{3}H]Z9–23 : Hy (Table 1). [^{3}H]Z9–23 : Hy (>98% pure as determined by radio-GLC) was used to monitor the effect of the analogs on Z9–23 : Hy metabolism. The percentage of radioactivity recovered from the nonhydrocarbon fraction was used to estimate [^{3}H]Z9–23 : Hy metabolism (Figure 5). Previous work showed that most of the oxygenated material in the nonhydrocarbon fraction was the C_{23} epoxide and C_{23} ketone (Blomquist et al., 1984b). Hexane and nonradioactive Z9–23 : Hy in separate experiments were used as control groups. To study the significance of the inhibition effect *t* tests at the 0.005 level were used (Table 1).

The results show that the analogs studied can be separated into three groups. Group I compounds had no significant inhibition when compared to control groups, suggesting that group I compounds do not interact with the PSMO. Group II compounds were significantly different from the hexane-treated group, but showed no significant inhibition when compared to the nonradioactive Z9–23 : Hy-treated group. Because the percentage of Z9–23 : Hy metabolized is based on the percentage of radioactivity recovered in the nonhydrocarbon fraction, the nonradioactive Z9–23 : Hy-treated group had a lower percentage of substrate metabolized than did the hexane-treated group. The nonradioactive Z9–23 : Hy simply dilutes the specific activity of the [^{3}H]Z9–23 : Hy as substrate and therefore appears as an inhibitor. Therefore, for group II compounds, the results suggest that they do interact in some way with PSMO, but do not significantly inhibit the enzyme activity. Group III compounds significantly inhibit Z9–23 : Hy metabolism when compared with the nonradioactive Z9–23 : Hy-treated group.

Male and female houseflies respond to the analogs somewhat differently.

TABLE 1. STATISTICAL INTERPRETATION OF EFFECTS OF Z9-23 : Hy ANALOGS ON [^{3}H]Z9-23 : Hy METABOLISM IN MALE[a] AND FEMALE HOUSEFLIES

		Significance of the inhibition effect on [^{3}H]Z9-23 : Hy metabolism (α = 0.005)					
		Male			Female

[a] Statistical calculation was based on data presented on Figure 5.
[b] Compound symbols same as Figure 1 and Figure 5.
[c] The classification of the group is described in the text.

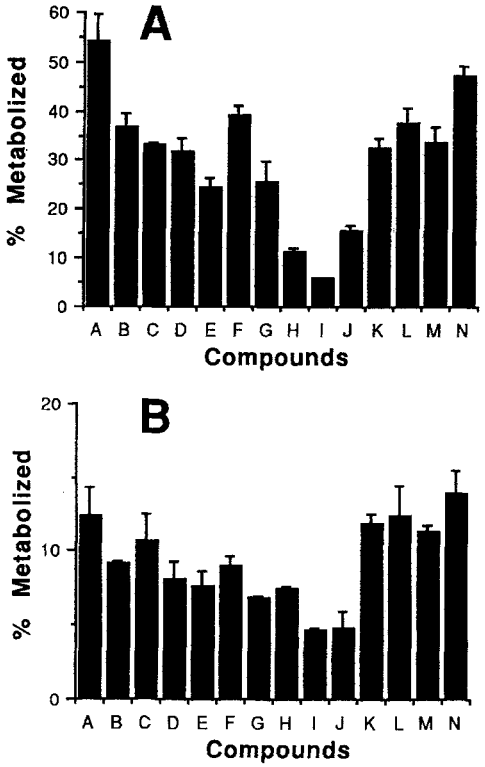

FIG. 5. Effect of Z9-23:Hy analogs on [^{3}H]Z9-23:Hy metabolism. Analogs and [^{3}H]Z9-23:Hy were applied to both male and female houseflies on the abdomens as described in Methods and Materials. After a 2-hr incubation, cuticular lipids were extracted. The percentage of radioactivity recovered from the nonhydrocarbon fraction is presented as the percent [^{3}H]Z9-23:Hy metabolized. Table 1 lists the names of the applied compounds used. See Figure 1 for the structures of these compounds.

Females normally produce C_{23} sex pheromone, and it is therefore not surprising that Z9-23:Hy metabolism in females is less affected by addition of unlabeled Z9-23:Hy than males (Table 1). Nine compounds applied to females are group I compounds (Table 1). For the males on the other hand, only two compounds belong to group I. Some of the group III compounds that inhibit Z9-23:Hy metabolism in females also act as inhibitors in males. These include (Z)-14-tricosene-10-one (I) and 1-nonyl-1-[(Z)-9-tetradecen-1-yl]-cyclopropane (J) (Table 1). Some group III compounds for males, such as 10,10-difluoro-(Z)-14-tricosene (E) and 10-methyl-(Z)-14-tricosene-10-ol (F), do not act as inhibitors in female (Table 1).

The compound that inhibits PSMO activity in both males and females most

significantly is (*Z*)-14-tricosene-10-one (Figure 5, Table 1). This is particularly interesting since it is one of the metabolites of Z9–23 : Hy, suggesting that it may have a role in end-product inhibition.

WHITE ALDER AND DOUGLAS-FIR FOLIAGE QUALITY AND INTEREGG-MASS INFLUENCES ON LARVAL DEVELOPMENT OF GYPSY MOTH, *Lymantria dispar*

G. JOSEPH,[1,*] J.C. MILLER, R.E. BERRY, J. WERNZ, A.F. MOLDENKE, and R.G. KELSEY[2]

(Received February 11, 1991; accepted April 29, 1991)

Abstract—Individual families of gypsy moth collected from a single population exhibited different degrees of fitness when fed diets of white alder, a suitable broadleaf host, and Douglas-fir, an unsuitable conifer host. Members of families on diets of Douglas-fir had significantly lower survival, longer larval periods, lower pupal weights, and shorter pupal periods than members of the same families fed alder. Foliar nutritional quality, including nitrogen level and allelochemical composition (terpenes and phenols), was considered the key factor responsible for these differences. Growth parameters differed significantly for families within diet treatments, indicating that the genetic resources of a family did affect performance somewhat. The influence of a family's genetic resources on larval survival was most notable when larvae were under the greatest nutritional stress.

Key Words—Douglas-fir, *Pseudotsuga menziesii*, gypsy moth, *Lymantria dispar*, Lepidoptera, Lymantriidae, insect-host plant relations, phenolics, terpenes, white alder, *Alnus rhombifolia*.

INTRODUCTION

Developmental rate and survival of the gypsy moth are influenced by many factors, including host species (Hough and Pimentel, 1978; Barbosa et al.,

1986); constitutive and induced chemical variation within the host species (Rhoades, 1983; Rossiter et al., 1988); genetic variation among and within insect populations (Leonard, 1966); and environmental variables, such as temperature and humidity (Elkinton and Liebhold, 1990). Previous studies relating the suitability of hosts to gypsy moth fitness have suggested that certain allelochemicals, such as alkaloids, influence fitness parameters, such as larval development (Doskotch et al., 1981; Barbosa et al., 1983, 1990a,b; Barbosa and Krischik, 1987; Miller and Hanson, 1989a). Plants containing iridoids and alkaloids appear to be poor hosts (Barbosa and Krischik, 1987; Miller and Hanson, 1989a, Barbosa et al., 1990a), but many other plants containing a wide array of allelochemicals permit successful development (Miller and Hanson, 1989a). Lechowicz (1983) suggested that suitable plants are characterized by precipitable (hydrolyzable) tannins and sclerophylly (a combined measure of leaf toughness and water content).

Goldschmidt (1934) and Leonard (1966, 1969) noted significant intra- and interpopulation variance in larval development that was related to the parental source (egg mass) of the larvae. Variation in growth among individuals in a population may be influenced by genetic differences between families that also may influence suitability of hosts, particularly those newly encountered.

The gypsy moth is not an established pest in the forests of the Pacific Northwest of North America. Isolated infestations were detected in Pacific Coast states in the early 1980s, when egg masses were accidentally transported from sites with major infestations in the northeastern United States. Oregon had a serious problem in 1984 (Daterman et al., 1986). Spraying with *Bacillus thuringiensis* in 1985 and 1986 successfully controlled the outbreak. As long as large infestations exist in the United States, new introductions of gypsy moth into western forests remains a possibility.

The objective of this research was to determine the range of certain developmental parameters relative to the parental source of larvae and the allelochemical content of the diet. Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco], a conifer, was selected for study because of its prominent status in forests of the Pacific Northwest, and its limited suitability as a host (Miller and Hanson, 1989b; Miller et al., 1991). White alder (*Alnus rhombifolia* Nutt.) was chosen to represent the highly suitable woody angiosperm hosts that commonly grow intermixed or adjacent to Douglas-fir forests. The differences in host suitability of these two species was believed to be due to significant differences in the allelochemical contents of their foliage.

METHODS AND MATERIALS

Insects. Egg masses were obtained at the end of January from an oak woodland in Seneca Creek State Park, Montgomery County, Maryland, and stored at 4°C until May. Eight large egg masses (each containing ca. 700–1000

eggs) were selected for evaluation of larval performance on Douglas-fir; eggs from four of these masses also were evaluated on alder. Large egg masses were chosen to ensure against selecting two egg masses from the same parents (Doane and McManus, 1981), thus assuring that each egg mass was of a separate family line.

Foliage Collection. Foliage was collected from three alder trees initially selected for their differences in nitrogen content after a preliminary analysis; two trees had higher nitrogen levels (tree-type A) than the third (tree-type B). These differences in nitrogen did not persist, however, resulting in nearly identical nitrogen contents for the two alder types when foliage collection began. Douglas-fir foliage was collected from five trees. Two were 10 years old and had high levels of foliar nitrogen resulting from fertilization (tree-type A); the other three, ranging in age from 10 to 15 years old, were unfertilized and had low foliar nitrogen (tree-type B).

Collections for laboratory feeding trials began in May and were completed by the end of June, coincident with the natural life cycle of gypsy moth larvae in Oregon. Only one tree of each type was harvested on collection days, with the same tree harvested on subsequent days until the foliage became limited; then a new tree of the same type was selected. The freshly gathered foliage was immediately transported to the laboratory, where it was subsampled for chemical analysis and then prepared for feeding by surface sterilizing in 0.25% sodium hypochlorite, rinsing in distilled water, and briefly air-drying.

Larval Feeding Experiment. Upon eclosion, 80 larvae from each of eight families were randomly selected for rearing on Douglas-fir foliage; an additional 42 larvae were selected from each of four of these families and reared on alder foliage. Larvae on Douglas-fir diets were reared in 145-ml cups, 10 per cup until the third instar and three per cup for the remaining instars. Larvae on alder diets were reared in groups of three per cup throughout.

Larvae were reared at 24°C, 45–50% relative humidity, and 16:8 (light–dark) hr photoperiod. Foliage was replaced every two days for early instars and daily for later instars. Larvae were observed every three days to determine percent survival. Pupae were weighed 48 hr after pupation. Days to pupation and pupal period also were determined by daily observations.

Nitrogen Analysis. Subsamples of foliage for nitrogen analysis were washed in dilute soap solution, rinsed three times with distilled H_2O, oven-dried at 60°C for 48 hr, and ground in a Wiley mill to pass a 20-mesh screen. Nitrogen content was determined by a micro-Kjeldahl technique with an automated Technicon Autoanalyzer II (Anonymous, 1975).

Terpene Analysis. Five to twelve branch tips of Douglas-fir, similar to those used to feed larvae, were selected. One-year-old needles were detached, combined into a composite sample, sealed in double air-tight plastic bags, and stored frozen until processed for analysis.

Before analysis, samples were warmed to room temperature inside the bags.

A subsample was withdrawn, frozen with liquid N_2, and ground with a mortar and pestle. Ground tissue was transferred to a capped scintillation vial. Water content was determined on triplicate samples dried at 105°C overnight.

Terpenes were extracted from 0.5 g of the freshly ground subsamples in 1 ml MeOH–H_2O (2 : 1) and 2 ml of pentane containing fenchone (0.1 mg/ml) as an internal standard (Brooks et al., 1987). Samples were shaken mechanically for 60 min and then centrifuged at room temperature in a IEC HN-SII centrifuge at approximately 1000 rpm for 3–4 min. The pentane, containing the terpenes, was removed and stored at −16°C.

Terpenes were analyzed on a Hewlett-Packard 5890 gas chromatograph equipped with a flame ionization detector and a Supelcowax 10 fused silica capillary column (30 m × 0.32 mm ID, 0.25-μm film thickness, 1 : 50 split). Injector and detector were at 250°C. Oven temperature was programmed from 60 to 220°C at 5°/min with a 15-min pause at 220°C. Peak areas were obtained with a Hewlett-Packard 3390A integrator. Compounds were identified by a combination of gas chromatography–mass spectrometry and peak enrichment with standards. Separate response factors for hydrocarbons and monooxygenated and dioxygenated compounds were determined with standards relative to fenchone.

Total Phenol Analysis. A subsample of alder leaves was air-dried after collection and stored in plastic bags at room temperature. A portion of the fresh-frozen Douglas-fir needles analyzed for terpenes was subsampled for phenolic analysis. Before analysis, alder and Douglas-fir foliage were oven-dried for 24 hr at 60°C, ground to pass a 40-mesh screen, and redried overnight. Phenols were extracted from a 100-mg subsample in 8 ml (Douglas-fir) or 10 ml (alder) MeOH–H_2O (7 : 3) on a shaker for 1 hr. The mixture was centrifuged at 1000 rpm in an IEC HN-SII centrifuge at room temperature for 5 min and analyzed with Folin-Ciocalteu phenol reagent as described by Julkunen-Tiitto (1985). Percent transmittance was measured at 700 nm with a Bausch and Lomb Spectronic 21 set to zero with distilled H_2O. A standard curve was prepared with catechin containing a MeOH concentration equivalent to the samples.

Water Content. Water content of foliage samples was measured gravimetrically from freshly cut alder leaves and from frozen Douglas-fir needles stored for terpene analysis.

Statistical Analyses. One-way analysis of variance (ANOVA) was used to determine if the foliage diets contained different concentrations of nitrogen during the feeding experiment. Fisher's least significant difference (LSD) was used to compare the means. Concentrations of total phenols and terpenes were compared only for diets within species by the Student's t test. In order to test the effect of diet on the performance of families, each growth parameter was analyzed separately for males and females with a nested ANOVA; family within treatment was the error term for treatment, and individual larvae within families

was the error term for families. Both the family and larvae were considered random effects. Treatment means were compared by Fisher's LSD. The effect of diet on percent family survival had to be analyzed with a one-way ANOVA because there was a single value for each family; data transformation was not necessary. Significantly different means were identified by Fisher's LSD.

RESULTS

Foliar Quality. The chemical composition of alder foliage differed substantially from that of Douglas-fir throughout the feeding experiment, as illustrated by the seasonal trends (Figure 1) and averages (Table 1). The alder foliage contained higher quantities of both nitrogen and total phenols, but contained no volatile terpenes. The nitrogen contents were within expected ranges for angiosperms and conifers (Mattson, 1980); the two alder types each averaged more than 2% through the sampling period and the two Douglas-fir types averaged 1–2% (Figure 1).

Steam distillation confirmed the absence of terpenes in alder. A bulk fresh leaf sample failed to produce an oil layer above a column water trap; the water was not cloudy, and no characteristic terpene odor was detectable (Farnsworth, 1966). A fresh leaf sample extracted and analyzed like the Douglas-fir needles also exhibited no appreciable quantities of any volatile compounds. Total terpenes in Douglas-fir foliage made up about 1.75% of the dry weight (Table 1), with monoterpenes representing more than 90% of this quantity. α-Pinene, β-pinene, and sabinene were the most abundant monoterpenes.

In addition to the differences in foliar quality between species, foliar quality differed between tree types within a species. When the alder trees were selected for study, they differed substantially in their nitrogen content (3.7% tree-type A, and 2.8% tree-type B), but, as the growing season progressed, their nitrogen contents rapidly converged. By the time the feeding experiment began, their nitrogen contents were the same (Figure 1), and they did not differ when averaged over the season (Table 1). Total phenol concentrations were consistently lower in alder tree-type A (LP), than in tree-type B (HP) throughout the collection period (Figure 1), resulting in a significant difference when averaged for the season (Table 1).

In Douglas-fir, the nitrogen level was consistently higher for tree-type A (Figure 1), and the average content over the collection period differed significantly from that of tree-type B. Total phenols were most similar between the two fir types early in the collection period, May 17–25, (Figure 1); during the rest of May and nearly all of June, they generally were much higher for tree-type B, which had a significantly higher seasonal average (Table 1). Concentrations of total terpenes in the fir varied considerably (Figure 1), and there

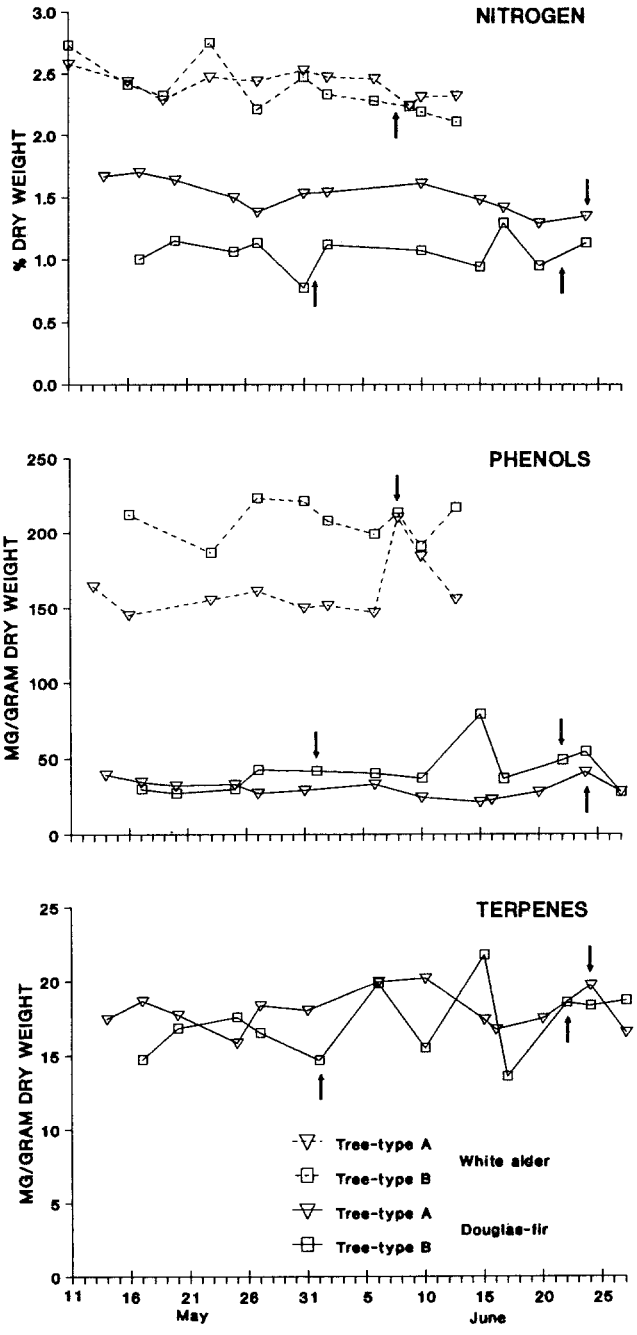

FIG. 1. Seasonal levels (1988) of foliar nitrogen and allelochemicals in white alder and Douglas-fir diets fed to gypsy moth larvae. Vertical arrows indicate when a new tree was selected for harvest within a type.

TABLE 1. SEASONAL MEAN CONCENTRATIONS (±SE) OF NITROGEN AND ALLELOCHEMICALS IN WHITE ALDER AND DOUGLAS-FIR FOLIAGE AND DEVELOPMENTAL PARAMETERS OF GYPSY MOTH FAMILIES FED THESE TISSUES[a]

[a] Nitrogen and survival analyzed with a one-way ANOVA; all other larval parameters were analyzed with a nested ANOVA. Multiple comparisons between means were computed with a standard LSD. Means followed by the same letters are not significantly different at $P \leq 0.05$

[b] LP = low phenols; HP = high phenols.

[c] HNLP = high nitrogen, low phenols; LNHP = low nitrogen, high phenols.

[d] Only intraspecific concentrations were compared statistically by the Student t test; alder significantly different at $P \leq 0.001$, Douglas-fir significantly different at $P \leq 0.05$.

[e] Douglas-fir was compared by the Student t test, not significant at $P \leq 0.05$.

were no significant differences between the two tree types over the course of the experiment (Table 1). Chemically, Douglas-fir tree-type A contained higher nitrogen and lower phenolic concentrations (HNLP) than tree-type B (LNHP).

Water content of the LNHP fir diet was lower than that of the HNLP diet most of the season, averaging 55.3% and 57.1%, respectively (Joseph, 1989). There were no differences in the water content of the alder diets. In May, Doug-

las-fir diets had a lower average water content (56.2%) than alder (63.6%), whereas in June, Douglas-fir contained more water (56.2%) than alder (41.3%).

The morphology and texture of alder leaves differed substantially from that of Douglas-fir needles. Simple puncture tests in our laboratory indicated that 1-year-old needles of Douglas-fir were tougher than white alder leaves.

Larval Survival and Development. Growth and development of families fed alder foliage was much better than that of families fed Douglas-fir foliage (Table 1). Survival was significantly lower on Douglas-fir foliage than on alder; mortality in the first instar accounted for over 90% of the losses. Those families with larvae surviving through pupation on Douglas-fir had significantly longer larval periods, significantly lower pupal weights, and significantly shorter pupal periods than did families reared on alder (Table 1). Longer larval periods and lower pupal weights decrease the fitness of insect herbivores (Rhoades, 1983).

Intraspecific differences in tree nutritional quality affected family performance to some extent. The only difference between families reared on HP and LP alder foliage was the lower pupal weights of families fed the latter (Table 1). Survival, larval periods, and pupal periods did not differ. Survival of families reared on HNLP Douglas-fir was more than twice as high as survival for families reared on LNHP fir. Pupal weights and larval and pupal periods did not differ for larvae in families fed the two types of fir foliage. *F* ratios and *P* values from the nested ANOVA (Table 2) indicated significant differences between families for all parameters, except for female pupal period and male pupal weight. Nevertheless, there were even greater differences caused by the treatment, demonstrating that variation in all growth parameters was most

TABLE 2. *F* RATIOS AND *P* VALUES FOR NESTED ANOVA FOR GYPSY MOTH DEVELOPMENTAL PARAMETERS

[a] *F* = *F* ratio, *P* = level of significance.

strongly influenced by the species of host tree fed to the larvae. Survival, with an F ratio of 151.4, also was greatly influenced by the host species and quality (Table 1).

Although host species strongly influenced development, differences in larval performance were associated with interegg-mass differences (Table 2), especially on diets of Douglas-fir foliage (Table 3). For the four families (I, V, VI, VII) subjected to all diets, survival and growth of each was superior on alder foliage. Only two families (I, V) had sufficient genetic resources to survive and complete development (Tables 3) on the foliage of HNLP Douglas-fir, nutritionally the more suitable of the two Douglas-fir types tested. None of the four families completed their life cycles on the most unsuitable diet, LNHP fir. Six of eight families reared on Douglas-fir survived and completed development on the HNLP foliage, but only two of the eight families were successful on the LNHP foliage, the least nutritious of the two types. Coefficients of variation for family survival on each of the four diets confirmed that survival varied least for families fed the two alder diets (CV 13.6% and 9.4% for LP and HP alder, respectively), and increased inversely as the nutritional quality of the diet declined (CV 54.0% and 168.3% for HNLP and LNHP fir, respectively). Therefore, genetic differences among families are probably most critical to survival when the nutritional quality of the diet is least satisfactory.

The performance of some families relative to the other families varied substantially with the diet (Table 3). For example, survival in family I was the lowest of all four families on both diets of alder; its survival on LNHP fir was low. On fir HNLP diets, however, family I survival was intermediate to high (Table 3) compared to the three other families in this group. Female pupal weights in family I showed similar responses. On LP alder diets, family I females had significantly greater pupal weights than females from the other three families, and family I had one of the two highest pupal weights on HP alder diets (Table 3). Only two of the four families had sufficient larval survival when fed HNLP Douglas-fir to permit measurement of pupal weights, but there were pupae from four additional families reared only on Douglas-fir. Females of family I had the lowest pupal weights of all six families measured. Not enough females survived on LNHP Douglas-fir diet for measurements. Performance of a family on a suitable host diet probably has limited utility for predicting its success and potential adaptability to a new, less suitable host.

DISCUSSION

Both genetic background and host species clearly were critical in determining survival, development, and overall fitness of gypsy moth larvae in this study. Chemical analysis confirmed the nutritional and allelochemical differ-

[a]Because family was used as a random effect in the nested ANOVA, no mean separation was performed.
[b]Fresh weight two days after pupal formation.

ences between alder and Douglas-fir and the poor nutritional quality and limited suitability of Douglas-fir for gypsy moth development (Miller and Hanson, 1989b; Miller et al., 1991).

To what extent did each of the chemical components in the diets contribute to the differences in family performance? Comparing foliar chemistry of alder and Douglas-fir is difficult, because three principal groups of compounds that differ both quantitatively and qualitatively are involved. Relatively modest differences in nitrogen and phenols in the two Douglas-fir diets had significant effects on survival. The alder diets contained much more nitrogen and total phenols than the Douglas-fir diets. The greater nitrogen content of alder undoubtedly made it a better diet nutritionally (Mattson, 1980; Scriber and Slansky, 1981; Mattson and Scriber, 1987) and contributed to the higher survival and better larval growth.

The differences in total phenol concentrations between Douglas-fir and alder must be interpreted with caution, because the types of tannins and phenols may be quite different in the two species. Conifers, including Douglas-fir, produce condensed tannins (Swain, 1979; Stafford and Lester, 1981). Angiosperms can synthesize hydrolyzable as well as condensed tannins (Swain, 1979), and the proportion of each can differ substantially between species (Bate-Smith, 1977). Tannin and phenol composition of white alder apparently has not been reported.

In the Folin-Denis assay for total phenols, a procedure similar to that used in our study, the absorbance of tannic acid (a standard for hydrolyzable tannins) was 2.2 times greater than that of catechin (the same standard for condensed tannins that we used) when normalized (Mole and Waterman, 1987). Consequently, if two plant tissues contained equal quantities of tannins and phenols, one having predominantly hydrolyzable tannins and the other predominantly condensed tannins, the one with hydrolyzable tannins would appear to have twice the total phenol concentration, as calculated from a catechin standard curve. If alder tissues contain a significant proportion of hydrolyzable tannins, a 2.2-fold difference in concentration relative to Douglas-fir could represent no difference at all in total phenols. Total phenol concentrations in alder, however, were 4.4–6.8 times greater than in Douglas-fir. Thus, concentrations of total phenols in the alder diets probably were greater than in Douglas-fir diets, even though the precise structure and composition of the alder tannins are unknown.

The species effect of the greater phenolic concentration in alder and the interactions of phenolics with nitrogen are difficult to evaluate, because the actual tannin structures and toxicities and how toxicities may interact with nitrogen level are unknown. The two alder diets we tested differed only in their concentration of total phenols; this comparison is not complicated by interspecific differences in tannin structures or nitrogen concentrations. The greater pupal weights produced by feeding on HP alder may have resulted from increases in

the relative consumption rate, the efficiencies of conversion of ingested or digested food, or some combination of these (Waldbauer, 1968), since the larval period was unchanged. Plants containing tannins are more acceptable hosts for gypsy moth than are plants containing other allelochemicals—iridoids, sesquiterpenes, and particularly alkaloids (Barbosa and Krischik, 1987; Miller and Hanson 1989a; Barbosa et al., 1990a), and host acceptance in the field is more closely correlated with tannin content than with total phenol content of the leaves (Lechowicz, 1983). Hydrolyzable tannins may act as phagostimulants for adapted species, such as gypsy moth (Bernays, 1981; Lechowicz, 1983; Kleiner et al., 1989). The alder phenolics appear to have acted as phagostimulants in this study.

The combined effect of low nitrogen and high phenol concentrations in Douglas-fir had a greater adverse impact on survival than did either high quantities of phenols alone in alder or the HNLP diet in Douglas-fir. Part of the difference between Douglas-fir and alder, or between the two Douglas-fir diets, may be attributable to the relative amounts of condensed tannins, which are detrimental to several species of herbivorous insects (Bernays, 1981; Klocke and Chan, 1982; Reese et al., 1982; Berenbaum, 1983; Manuwoto et al., 1985; Manuwoto and Scriber, 1986). This detrimental effect has often been ascribed to formation of insoluble complexes between tannins and proteins that diminish metabolizable nitrogen (Feeny, 1976; Rhoades and Cates, 1976). This mechanism, however, does not appear to function in insect herbivores (Bernays, 1981; Manuwoto et al., 1985; J.S. Martin et al., 1985; Manuwoto and Scriber, 1986; M.M. Martin et al. 1987), including gypsy moth (Schultz and Lechowicz, 1986). Survival of gypsy moth larvae was 77% of controls, and larval weights were 40% of controls after 20 days of exposure to tannin- and phenol-rich extract of Douglas-fir (with the terpenes removed) incorporated into artificial diet (Joseph, 1989). When the nitrogen contents of the treatment and control diets were lowered, survival did not change, but weights of larvae fed low-nitrogen, phenol-rich diets were approximately 20% of the controls.

The presence of terpenes in Douglas-fir and their absence in alder is probably the greatest difference in the allelochemistry of the two host species. Two of the three major terpenes in Douglas-fir foliage, α-pinene and β-pinene, were strong phagodeterrents when applied in pure form to food of the gypsy moth (Meisner and Skatulla, 1975). Other monoterpenes, sesquiterpenes, sesquiterpene lactones, and diterpenes also have feeding deterrent activity (Doskotch et al., 1980a,b; El-Naggar et al., 1980).

The impact of terpenes alone on gypsy moth growth and development cannot be evaluated from our data, because their effects are inseparable from the influences of nitrogen and phenols. However, induction of detoxification enzymes in insects ingesting monoterpenes in their diet indicates that these compounds are nutritionally undesirable (Brattsten, 1986; Yu, 1986, 1987; Har-

wood et al., 1990). Douglas-fir terpenes isolated by steam distillation and incorporated into artificial diet at natural concentrations did not affect survival or weights of gypsy moth larvae reared on these diets for 20 days (Joseph, 1989). When the terpenes were combined in artificial diet with an extract containing Douglas-fir phenols, survival and pupal weights were greatly reduced below those on diet containing only the phenol extract, suggesting an interaction or possible synergism between these two groups of compounds.

Most larval mortality occurred during the first instar, when the small larvae were more likely to be repelled by physical barriers such as leaf toughness (Hough and Pimentel, 1978; Ohmart et al., 1985). Barbosa et al. (1986) reported mechanical barriers to biting, and consequent starvation, as a probable cause of mortality for first instars fed conifer foliage. In our experiments leaf toughness probably did affect mortality of first-instar larvae on fir, but not alder. However, the magnitude of the effect relative to foliar chemistry is not determinable from these data. We can conclude that toughness did not contribute to the differences in family performance observed between tree types within a species. Furthermore, incorporation of Douglas-fir foliage extracts into artificial diets, where needle toughness was not a factor, resulted in low survival and decreased larval weight (Joseph, 1989), as observed with our fresh foliage.

Water content is closely associated with leaf toughness; together they provide a measure of sclerophylly (Lechowicz, 1983). Foliar water content in Douglas-fir differed little from that of alder and probably did not contribute much to the differences in family performances between the two host species.

Host adaptability has important implications for potential establishment of gypsy moth in the forests of the Pacific Northwest, where preferred hosts such as Oregon white oak and alder species often are situated in or adjacent to Douglas-fir stands (Daterman et al., 1986). The genetic constitution of some families of gypsy moth clearly permits survival and successful development on an unsuitable host, such as Douglas-fir, even when this host is of low nutritional value. Furthermore, the likelihood of survival increases as the nutritional value of the Douglas-fir increases, as would be the case in fertilized plantations.

In the northeastern United States, gypsy moths effectively utilize conifers such as white pine (*Pinus strobus* L.), pitch pine (*P. rigida* Mill.), and Norway spruce [*Picea abies* (L.) Karst] as secondary hosts during low-density population phases (Rossiter, 1987), and performance and fitness improve on a two-species diet of black oak (*Quercus velutina* Lam.) and either Virginia pine (*Pinus virginiana* Mill.) or loblolly pine (*P. taeda* L.), relative to black oak alone (Barbosa et al., 1986). Utilization of secondary hosts may help to release populations from a low-density stable phase into a higher-density building phase (Campbell, 1981). Therefore, establishment of gypsy moth on Douglas-fir even at low levels might pose a serious threat, especially from larvae in later instars, which survive switching from alder to Douglas-fir (Joseph, 1989). In addition,

establishment on Douglas-fir might give rise to populations with enhanced behavioral or metabolic resistance to pathogens (Rossiter, 1987) or pesticides (Moldenke et al., unpublished data).

In summary, although nutritional quality is a primary determinant of host suitability, the genetic makeup of each family influences the degree of suitability to family members. Genetic differences between families are particularly important when the nutritional quality of the host is limited. If gypsy moth becomes established at low population densities in mixed conifer–broadleaf stands in the Pacific Northwest, some utilization of Douglas-fir can be anticipated.

Acknowledgments—We thank P. Barbosa and P. Gross for supplying gypsy moth egg masses, G.E. Daterman and T.D. Schowalter for reading an earlier draft, T.E. Sabin for help with the statistics, and L. Gerson and A. Berry for laboratory and field assistance. Work leading to this publication was funded by USDA, CRGO, Pest science grant 87-CRCR-1-2478 and by cooperative agreement 87-409 with the USDA, Forest Service, Pacific Northwest Research Station.

PSORALENS IN SENESCING LEAVES OF *Ruta graveolens*

ALICJA M. ZOBEL* and STEWART A. BROWN

Department of Chemistry
Trent University
Peterborough, Ontario, Canada K9J 7B8

(Received March 6, 1991; accepted April 30, 1991)

Abstract—Concentrations of three furanocoumarins, psoralen, xanthotoxin, and bergapten, were measured on the surface and within mature whole leaves of two groups of *Ruta graveolens* L. late autumn plants, 2 and 6 years old, which contained green, yellow, and dry yellow leaves. Upper green leaves contained higher concentrations of these coumarins than lower green leaves, green leaves contained several times as much as yellow leaves, and dry leaves contained even smaller amounts than yellow ones. The dry yellow leaves contained only a very small percentage of furanocoumarins on the surface, suggesting that extrusion to the surface of yellow leaves was slower or had stopped, while loss from the surface continued. The loss of psoralen was the most dramatic in and on the dry leaves. Bergapten's ratio to the other coumarins increased during senescence. Xanthotoxin was always the predominant furanocoumarin in this species.

Key Words—*Ruta graveolens*, Rutaceae, rue, senescence, furanocoumarins, leaf surface, plant defense.

INTRODUCTION

Senescence, a normal process in a plant (Simon, 1967; Mothes, 1980; Janzen and Waterman, 1986) occurs during tissue ontogenesis (Wiermann, 1980), and is characterized by very complex processes differing from those in juvenile tissues (Woolhouse, 1967). Changes occur both in primary metabolism and structure (Malik, 1987; Fobel et al., 1987; Braber, 1980; Patra and Mishra, 1979) and in secondary metabolism (Mann, 1980; Haslam, 1985). Senescence coin-

cides with a change in the action of hormones (Osborne, 1968, Audus 1972), which can be involved in regulation of secondary product metabolism (Ebel, 1979).

At the end of the normal senescence process, leaves dry out and fall to the ground, where leakage both from the leaf surface and its interior occurs, followed by decay. Because some secondary products do not undergo ready turnover (Margna and Vainjaero, 1981) and others do (Barz and Hoesel, 1979; Barz and Koester, 1981), it is important to know what compounds are retained in senescent and dry leaves, because such compounds can potentially enter the environment. Although some secondary metabolites appear to accumulate in plant tissues simply as waste products, others are metabolized and therefore do not accumulate. Some that do accumulate can be allelochemicals (Barz et al., 1985; Jacques et al., 1985) influencing hormone action (Hale and Orcutt, 1987) or serving as natural pest and disease control agents. Certain secondary products that have survived the senescing process may be released by the dead plants into the soil (Barz and Weltring, 1985).

Among products of secondary metabolism, furanocoumarins have long been known to act as growth inhibitors or growth retardants (Rodighiero, 1954; Shina-Roy and Chakraborty, 1976; Friedman et al., 1982). We have found psoralens (linear furanocoumarins) on the surface of rutaceous and umbelliferous plants (Zobel and Brown, 1990a), sometimes in amounts of micrograms per gram fresh weight within the green leaves of *Ruta graveolens* and on the leaf surface (Zobel and Brown, 1989). As with other compounds, these coumarins may pass into the soil both from living leaves on the plant (through the action of rain and other physical weathering processes) and dead ones on the ground. Because furanocoumarins have a broad spectrum of biological activity (Murray et al., 1982; Ivie, 1987a,b), the possibility of effects on the growth of neighboring plants cannot be excluded.

The behavior of coumarins during senescence and their possible role in that process have not yet been explored. In this study we have investigated the extent to which psoralens remain on and within the leaves during the process of senescence.

METHODS AND MATERIALS

Plant Material. R. graveolens L. plants, growing outdoors in the soil during the summer growing season of 1988, were used. Leaf samples of 2- and 6-year-old specimens, each containing about 20 shoots, each with about 30 leaves, were collected for analysis November 1, just before the autumn frosts. We wished to obtain all the necessary stages of leaf development on each plant and to avoid the influence of variations in the vegetative period that we had

observed in *Heracleum lanatum* (Zobel and Brown, 1990b), as well as changing environmental conditions, knowing that frost can cause a 100-fold increase in furanocoumarins. On the plant there were four distinct populations of leaves, all mature: group I, upper green, which were smaller in size; II, lower green, which were larger and older; III, lower yellow, which were still turgid, showing a decline in the amount of chlorophyll; and IV, the lowest, yellow, which had dried on the plant.

Two green leaves from each shoot were removed: the third from the shoot apex (called here "upper green") and the third green leaf from the bottom ("lower green"). The upper leaves were not new growth, but small-sized (2–4 cm) mature, "hard" leaves. Lower green leaves (7–12 cm) showed no signs of damage or yellowing. Below the green leaves on the shoot were yellowish leaves, and the lowest location had dry yellow leaves, collected as "lower yellow" and "lower dry" samples, respectively. Separate samples were collected from the 2- and 6-year-old plants, and each of the four different leaf samples, containing 12–14 leaves, was duplicated.

Analyses. The leaves of each sample were weighed as a group and surface coumarins removed from the surface by a brief dipping in almost-boiling water (Zobel and Brown, 1988). After extraction, the dry weights of these leaves were determined for comparison with those of the senescent leaves. Because there were two groups of leaves, dry and turgid, there were alternative ways of expressing concentrations, on the basis of either dry or fresh weight. For comparison with our previous papers, we chose to calculate on the basis of fresh weight, as the values for only one group of leaves (yellow, dry) then had to be adjusted. Groups III and IV were the most similar, because they developed at the beginning of the vegetative period when all the leaves were growing very actively and were of similar size. Thus calculation of fresh weight of group IV was done according to the equation:

$$\frac{\text{Fresh weight of group III}}{\text{Dry weight of group III}} = \frac{\text{Fresh weight of group IV}}{\text{Dry weight of group IV}}$$

The furanocoumarins in the extracts were purified and determined by previously described procedures (Thompson and Brown, 1984; Zobel and Brown, 1988). The error of the method was $\leq 10\%$.

RESULTS

Table 1 compares the sum of the concentrations (Σ values) of psoralen, xanthotoxin, and bergapten (P + X + B).

Whole Leaves. The whole leaves of the younger group of plants contained higher concentrations than the older: 40% (4200 vs. 2500) in the upper leaves

TABLE 1. CONCENTRATIONS[a] OF TOTAL FURANOCOUMARINS IN AND ON THE SURFACE OF *Ruta graveolens* PLANTS

	Younger plants (2-year-old)			Older plants (6-year-old)		
	$\Sigma P + X + B$[b]			$\Sigma P + X + B$		
Leaves	Whole leaf	On surface	On surface (%)	Whole leaf	On surface	On surface (%)
Upper, green[c]	4200 ± 100	830 ± 30	20	2500 ± 100	760 ± 40	30
Lower, green[c]	1400 ± 100	520 ± 50	37	980 ± 60	190 ± 10	19
Lower, yellow[c]	580 ± 10	130 ± 10	23	1100 ± 100	140 ± 10	13

[d] μg/g dry weight.

and 30% (1400 vs. 980) in the lower green leaves. In both age groups the upper leaves had over twice as much as did the lower leaves, in spite of the fact that all these leaves were mature, differing only in size and location on the shoot.

In the yellowish senescent leaves of the younger plants (becoming senescent but still not dry), the Σ value was about 40% of that of the lower green ones (580 vs. 1400). In the fully dry leaves, this value was still of similar magnitude, indicating that in the course of the drying stage of senescence there was little if any diminution of furanocoumarins. In the yellowish leaves of the older plants, the Σ value was much higher than in the young plants, but in the dry leaves the two values were comparable. In both groups of plants the old, dry leaves, the lowest on the plant, contained a much lower concentration than the younger, upper leaves and the lower, green leaves, although the difference was less pronounced in the older plants. In younger plants the upper green leaves contained over seven times, (and in older plants over three times) the concentration of furanocoumarins as dry ones.

Leaf Surface. In both younger and older plants the total surface concentrations showed similar tendencies, decreasing down the shoot in absolute amounts. Differences between upper green and dry leaves were even more pronounced than in the whole leaf: on the upper green leaves of both age groups, concentrations were >33 times (830/25 and 760/20) as high as on dry ones. In younger plants the percentage of furanocoumarins on the surface decreased toward the base of the shoot from 20% to 4.3%, and on the older plants from 30% to 2.9%. The lower percentage in the case of younger plants reflects the very high

concentration in the whole leaf (4200 μg/g). Except for the upper green leaves, the younger plants had a higher percentage on the surface than the older.

Changes in the individual furanocoumarins during the experiment are shown in Table 2.

Xanthotoxin. Xanthotoxin was the predominant furanocoumarin in each age group, both in the whole leaf and on the surface. Of the three coumarins, xanthotoxin had the highest percentage on the surface only in the case of the lower, yellow leaves of both age groups. In terms of absolute concentrations, the amounts on the surface followed similar trends to those described above for the sum of the three coumarins. In both groups only a small fraction remained on the surface of the lower dry leaves compared to the upper green leaves.

Psoralen. Psoralen concentrations, both in the whole green leaf and on the surface, were always lower than those of xanthotoxin, especially on the surface of the yellow leaves, and throughout the dry leaves. In the whole lower green leaves there were three (200/75) to 10 times (370/35) as much psoralen as in

the yellow, and seven (200/29) to 17 times (370/21) as much as in the dry; on the leaf surface of the younger plants this factor reached 160 (190/1.2).

Bergapten. Bergapten was always found in smaller concentrations than xanthotoxin. Compared to psoralen, it was lower in the upper green leaves, at a similar level in the lower green leaves, but much higher in both yellow and dry leaves. Smaller surface concentrations of bergapten were noted on both upper and lower green leaves, but on yellow and dry leaves the bergapten concentration was several times as high as that of psoralen. Despite lower absolute amounts, the percentage of bergapten on the surface was high—in most cases at least comparable to those of the other two.

The ratios of surface and whole-leaf concentrations of the three coumarins of the upper green leaves and the dry leaves of the same age group are compared in Table 3. This table shows the factors by which concentrations of furanocoumarins are lower in the yellow, dry leaves compared to the upper green, emphasizing the decline in furanocoumarin concentrations from the uppermost leaves to the dry ones at the base. The two groups showed similar tendencies: surface concentrations decreased more than those of the whole leaf, e.g., for younger plants, psoralens decreased on the surface 217 times, but only 60 times in the whole leaf; xanthotoxin 23 times vs 5; bergapten 27 vs 5. Younger plants showed higher ratios of decrease than older ones; the sharpest decrease was observed for psoralen, and the other two were similar. Psoralen appears more susceptible to changes in senescing leaves, showing ratios up to 12 times (60/5) those of xanthotoxin and bergapten.

Ratio of Psoralen to Xanthotoxin and Bergapten. Table 4 shows the proportions of the three furanocoumarins in the leaf and on the leaf surface, with the value for psoralen taken as unity. In both the younger and older plants the concentrations of xanthotoxin were higher than those of psoralen (i.e., >1), most notably in the yellow and dry leaves. Again in both groups, in almost all

cases, the variations on the surface were greater than in the whole leaf. In the green leaves of the younger plants, bergapten was lower than psoralen, but in the yellow and dry leaves it was several times as high. In older plants, although bergapten was less in the upper leaves, there was at least as much in the lower, green leaves, and it was several times as high as psoralen in yellow or dry ones. On the surface, bergapten showed the same tendencies in the green leaves of both groups of plants, being lower than psoralen, but again it was much higher than psoralen in both yellow and dry leaves.

In yellow and dry leaves, both xanthotoxin and bergapten were higher than psoralen, but xanthotoxin was more so, by factors of ca. 8–30, both in the whole leaf and on the surface, in contrast to ca. 4–9 times for bergapten. Bergapten on green leaves, however, was in smaller absolute amounts than psoralen, as shown in Table 2. These findings point to very marked changes in concentrations and proportions of particular furanocoumarins during leaf aging.

DISCUSSION

The process of leaf aging is associated with changes in the physiology of the cells and, therefore, in the concentrations of the products stored in them. Senescence can be either a complex natural process, occurring over the course of the vegetative period, or may be caused by environmental changes. In view of the changes in furanocoumarin concentrations known to occur during the vegetative period in *Heracleum lanatum* (Zobel and Brown, 1990b), autumn leaves, all on the same plant, were chosen so that all the leaves would be mature without new growth, and the naturally senescing leaves would exhibit a range of stages simultaneously. In each of the two groups of plants examined, younger

and older, we distinguished four kinds of leaves, using as a marker their color and location on the shoot.

Younger and older plants tended to exhibit the same changes during senescence. Marked diminutions in furanocoumarin concentrations observed both in and on senescing leaves indicated lower production and extrusion rates during senescence. Changes of surface concentrations in each of these four groups of leaves showed the same tendencies: decreasing concentrations of both total furanocoumarins and each individual furanocoumarin in the whole leaf and, even more strikingly, on the surface. This suggests decreased extrusion as one possible explanation for the decline. Whether it is connected with the presumed need for less protection by leaves located lower on the plant must remain only speculation at this point.

The drop in the total concentration of the three furanocoumarins of aging leaves, in the whole leaf, and on the surface, was followed by a decrease in each individual concentration, but not in the same proportions. That of bergapten on the dry leaves was not so extreme as that of psoralen, whose concentrations decreased drastically by factors of >100. Psoralen was the most susceptible compound to changes due to senescence, both in the whole leaf and on the surface. Xanthotoxin always predominated in absolute amounts, but in the range of changes between the upper green leaves and dry ones it was comparable to that of bergapten. Bergapten might be termed a "senescing compound" because it was found in higher concentrations on and within aging callus cells (Zobel and Brown, 1991). We wish to emphasize the importance of visualizing changes in concentrations of particular coumarins as well as their ratios, in the knowledge that they can react synergistically (Berenbaum and Neal, 1985). Further investigations on the coexistence of other coumarins in the plant and on its surface, both qualitative and quantitative, are indicated.

In yellow, dry leaves there remained only a small fraction of furanocoumarins, which could eventually enter the soil, but the absolute amounts were quite substantial (580–680 μg/g fresh weight, or >70 μg/g dry weight). From the surface of the leaves, during the process of senescence, the loss was from 800 to 25 μg/g. More investigation is needed to measure the extent to which these compounds were washed by rain into the soil, vaporized into the air, or degraded chemically or biologically. Also needed is more study to evaluate the influence of changing environmental conditions on surface furanocoumarin concentrations and to distinguish these from genetically dependent changes such as natural physiological aging.

DIFFERENTIAL EFFECTS OF CONDENSED AND HYDROLYZABLE TANNIN ON POLYPHENOL OXIDASE ACTIVITY OF ATTINE SYMBIOTIC FUNGUS

COLIN NICHOLS-ORIANS[1]

Department of Entomology
Pennsylvania State University
University Park, Pennsylvania 16802

(Received February 19, 1991; accepted May 6, 1991)

Abstract—The leaf-cutting ant *Atta cephalotes* is a generalist herbivore of the neotropics and collects leaf material to cultivate a fungus. It appears that this fungus, a Basidiomycete, is responsible for the ability of the ants to utilize most of the available woody plant species. Tannins and other phenolics are ubiquitous secondary chemicals in woody plants, and Basidiomycete fungi produce enzymes, such as polyphenol oxidase, that are capable of polymerizing and inactivating the phenolics. This study evaluates the effects of a condensed and a hydrolyzable tannin on the activity of polyphenol oxidase and the growth of the fungus. I hypothesized that low concentrations of tannin would not inhibit polyphenol oxidase activity but high concentrations would inhibit the enzyme. Consequently, I predicted that only high concentrations of tannin would inhibit fungal growth. Laboratory assays with the fungus indicated that hydrolyzable tannin (tannic acid) and condensed tannin (quebracho tannin) differ in the mechanism of inhibition. Tannic acid does not inhibit polyphenol oxidase activity but does inhibit fungal growth. Quebracho tannin, however, inhibits both polyphenol oxidase activity and fungal growth. As predicted, both tannic acid and quebracho tannin primarily inhibit the fungus at high concentrations.

Key Words—*Atta cephalotes*, Hymenoptera, Formicidae, attine fungus, fungal performance, condensed tannin, hydrolyzable tannin, polyphenol oxidase.

INTRODUCTION

The leaf-cutting ant, *Atta cephalotes* (L.) (Hymenoptera: Formicidae: Attini), is a dominant herbivore in Central America (Fennah, 1950; Cherrett, 1968;

[1] *Present Address:* Department of Biology, Vassar College, Poughkeepsie, New York 12601.

0098-0331/91/0900-1811$06.50/0

Rockwood, 1976, 1977) and may harvest up to 77% of the plant species in their habitat (Rockwood, 1976). No other insect in the neotropics appears to be so polyphagous (Cherrett et al., 1989). Rather than consuming the leaf material directly, the ants use the harvested leaf material to support the growth of a symbiotic fungus. This fungus is the sole food source of the developing larvae (Quinlan and Cherrett, 1979). The fungus, a white-rotting Basidiomycete, may be responsible for the polyphagous nature of leaf-cutting ants because the fungus produces an array of enzymes that are capable of detoxifying secondary chemicals in leaves (Cherrett et al., 1989). For example, the fungus produces polyphenol oxidase, an enzyme capable of polymerizing and inactivating tannins and other phenolics (Powell, 1984). Yet tannins can inhibit the ants (Kawanashi and Raffauf, 1986; Howard, 1990; but see Littledyke and Cherrett, 1976). Field studies indicate that only high concentrations of tannin inhibit the ants (Nichols-Orians and Schultz, 1990; Nichols-Orians, 1991a–c). Perhaps this is because only high concentrations of tannin inhibit the fungus and its enzymes.

Tannins do inhibit fungal growth and fungal enzyme activity (Seaman, 1984; Cherrett et al., 1989; Nichols-Orians and Schultz, 1990; Nichols-Orians, 1991a). Hydrolyzable tannins have been shown to inhibit the growth of an attine fungus (Seaman, 1984), and condensed tannins appear to be even more inhibitory (Cherrett et al., 1989). This result is consistent with the observation that condensed tannins are very effective inhibitors of fungi and their enzymes (Zucker, 1983). Only high concentrations of tannin appears to inhibit fungal growth (Seaman, 1984). I hypothesized that only high concentrations of tannin inhibit fungal growth because, at high concentrations, the tannin would inactivate the polyphenol oxidases, thereby limiting the degradation of the tannin.

Thus this research investigated how two types of tannins at different concentrations affect the activity of a polyphenol oxidase and the performance of the fungus. Evidence is presented indicating that tannic acid and quebracho tannin differ in their inhibition of polyphenol oxidase activity, yet both inhibit fungal growth.

METHODS AND MATERIALS

Ants–Fungus. Laboratory assays with the fungus were conducted at Penn State in 1989–1990 with fungus obtained from an *Atta cephalotes* colony collected from La Selva, Costa Rica, in January 1987. The colony was maintained at Penn State on a diet of frozen *Forsythia* and fresh cabbage prior to removal of the fungus.

The attine fungus was isolated, maintained on potato dextrose agar plates, transferred to Sabaroud's dextrose broth (SDB), and later grown in a liquid medium designed to test for the effects of tannins on fungal performance (Sea-

man, 1984). This medium (modified FPT) contained the following components per liter of distilled water: (A) major components (g)—KH_2PO_4 (1); $MgSO_4$–$7H_2O$ (0.5); NaCl (0.1); $CaCl_2$–$2H_2O$ (0.1); NH_4 tartrate (5.0); and dextrose (20); (B) minor components (mg)—$ZnSO_4$–$4H_2O$ (4); $MnSO_4$–$4H_2O$ (4); and ferric tartrate (4); (C) organic supplement (mg)—4-Methyl-5-thiazoleethanol (0.180); and 4-amino-5-aminomethyl-2-methylpyrimidine dihydrochloride (0.250). In these experiments, 500 ml of water was replaced with 500 ml of 0.05 M dimethylglutaric acid buffer (pH 5.5) (Powell and Stradling, 1986).

Three basic experiments were conducted. First, I quantified the relationship between the concentration of condensed or hydrolyzable tannin and the polyphenol oxidase (PPO) activity at different points in time (10, 30, 60, or 120 min and 2, 7, or 21 days). There was one replication per concentration at each point in time, except at day 21 where there were three replicates per tannin concentration. Second, I determined whether tannic acid and quebracho tannin inhibit the enzymes directly or whether inhibition is merely a function of reduced fungal growth. Finally, I assessed how the two types of tannin affect fungal growth.

Fungal Preparation. Fungus obtained from the agar plates was placed in 65 ml of SDB and blended for 1 min in a Vertis blender at low speed. Five milliliters of the fungal suspension was pipetted into Erlenmeyer flasks containing 45 ml of SDB. The cultures were then grown for 10 weeks in the dark. After 10 weeks, the fungus was filtered, resuspended in modified FPT (50 ml FPT/flask of fungus), and blended for 1 min at low speed. The fungus was kept evenly suspended using a stir bar and magnetic plate.

One milliliter of fungal suspension was added to 8 ml of modified FPT in sterile test tubes, and placed for four days in the dark at room temperature. After four days, 1 ml of one of four tannin solutions, tannic acid, or quebracho tannin was added to the suspension to give a final concentration of 0, 0.0025, 0.025, and 0.25% tannin. At various time intervals from 10 min to 21 days the activity of polyphenol oxidase (PPO) was determined (using the protocol described below). At day 21, the biomass of fungus was measured.

PPO Activity. Catechol is commonly used as a substrate to measure PPO activity (Flurkey and Jen, 1978). Liquid cultures of fungus were centrifuged at 1000 rpm for 10 min and the supernatants placed on ice. In test tubes, 0.75 ml of the supernatant from the fungal cultures were combined with 2 ml 0.1 M citric acid–sodium citrate buffer (pH 5.5). Following the addition of 0.25 ml of catechol (or distilled water for controls), test tubes were vortexed and incubated at 30°C for 30 min, and then the final absorbance was determined (420 nm) with a spectrophotometer. After subtracting the absorbance of the control, a relative PPO activity was obtained for each treatment. PPO activity is expressed as relative optical density (o.d.).

Statistical Analyses. All statistical analyses were done using SAS (SAS

Institute, 1985). The effect of increasing the concentration of tannic acid or quebracho tannin on the activity of PPO or the biomass of fungus was analyzed with an two-way ANOVA model with tannin type and tannin concentration as the main effects. Bonferroni's test was used to determine whether differences in PPO activity were significant at $P < 0.05$.

RESULTS

Tannic acid and quebracho tannin have different effects on PPO activity. Initially, PPO activity was identical across the different concentrations of tannic acid (Figure 1), but an increase in quebracho tannin concentration resulted in a decrease in PPO activity after only 10 min (Figure 2). These results suggest that tannic acid does not inhibit the enzymes directly but quebracho tannin does.

Because I obtained these results by incubating the tannin with the fungus, the differences in PPO activity could have been due to direct effects on the fungus not on the enzymes directly. Consequently, I used supernatants from

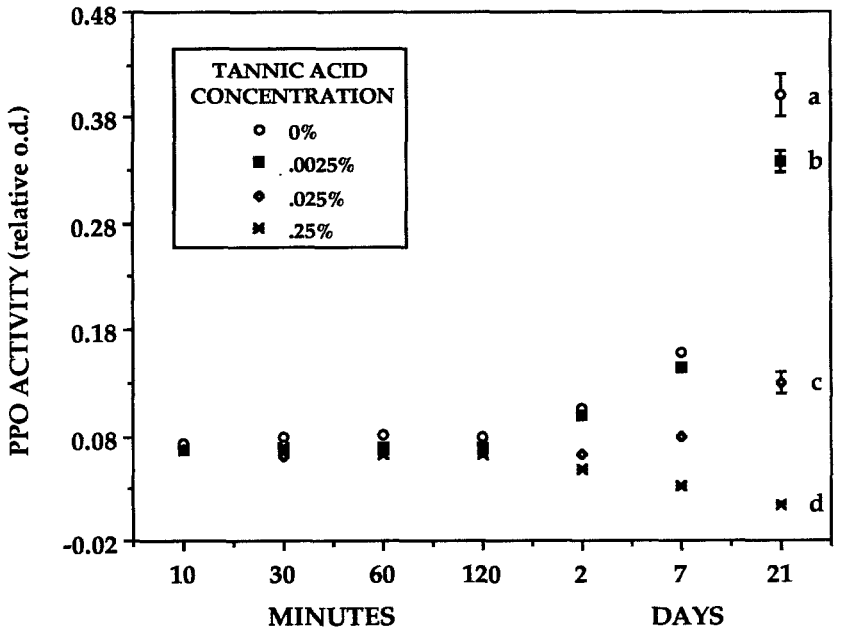

FIG. 1. The effects of tannic acid on the polyphenol oxidase (PPO) activity in liquid cultures at different points in time. $N = 1$ for each concentration of tannin at each point in time except at day 21 where $N = 3$. At day 21, values with different letters are different at $P < 0.05$.

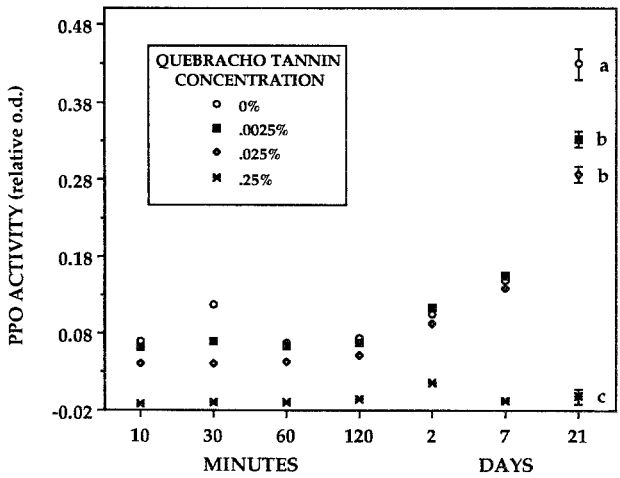

FIG. 2. The effects of quebracho tannin on the polyphenol oxidase (PPO) activity in liquid cultures at different points in time. $N = 1$ for each concentration of tannin at each point in time except at day 21 where $N = 3$. At day 21, values with different letters are different at $P < 0.05$. (Reprinted from Nichols-Orians, 1991a.)

tannin-free cultures to determine whether the addition of either type of tannin inhibited PPO activity directly. As indicated before, tannic acid did not inhibit PPO activity while quebracho tannin did inhibit PPO activity directly (Figure 3).

However, by day 2 it was evident that PPO activity in cultures with tannin was lower for tannic acid as well as quebracho tannin (Figures 1 and 2). By day 21 it was clear that an increase in tannic acid resulted in a decrease in PPO activity ($P < 0.05$) (Figure 1). For quebracho tannin, the highest concentration caused a severe reduction in PPO activity while the lower concentrations caused only a minimal reduction ($P < 0.05$) (Figure 2). Previously, I found that as fungal biomass increases so does PPO activity (Nichols-Orians, 1991a). Therefore, I suggest that the reason tannic acid affected PPO activity beginning around day 2 was due to the direct inhibition of fungal growth, not of enzyme activity.

Indeed, both types of tannin can inhibit fungal growth. At day 21, an increase in tannin concentration appeared to result in a decrease in fungal biomass ($P < 0.001$) (Figure 4). These differences in biomass are conservative estimates because it was not possible to accurately measure fungal biomass in cultures with tannin due to binding between the tannin and the fungus. In fact, at 0.25% tannic acid, I was unable to even approximate fungal biomass because much of the tannic acid had bound to the fungus and precipitated out of solution.

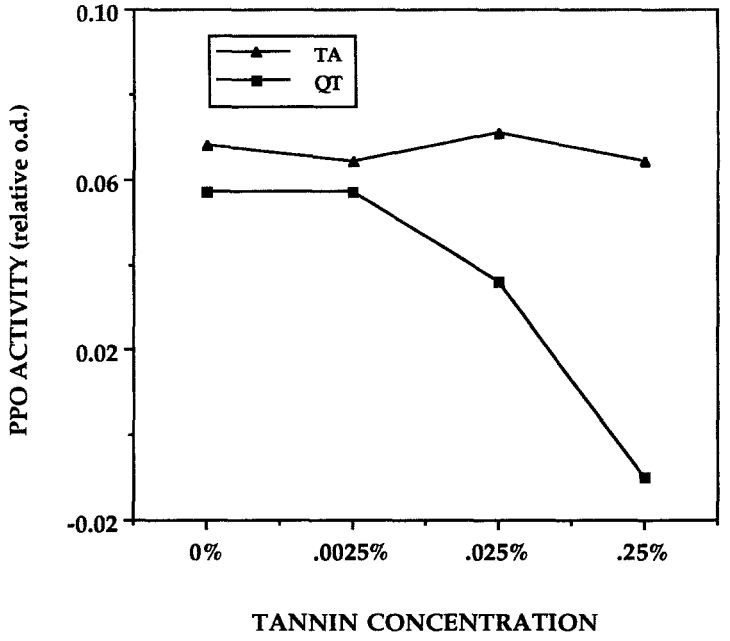

FIG. 3. Direct inhibition of polyphenol oxidase (PPO) activity by tannic acid and quebracho tannin. $N = 1$ at each concentration of tannin.

DISCUSSION

Tannins are ubiquitous secondary chemicals in plants and have a putative effect against many herbivores (see Schultz, 1989, for review). Tannins are most reactive as quinones. The fungus cultivated by the ants produces an enzyme, polyphenol oxidase, that appears capable of oxidizing quinones to a less reactive state (Cherrett et al., 1989). The effectiveness of the PPO may depend on the type and concentration of tannin (Zucker, 1983; Clausen et al., 1990), since tannins can inhibit polyphenol oxidases (Lyr, 1962).

Tannin type is important. According to Cherrett et al. (1989), Powell (1984) found that condensed tannins are more inhibitory of the fungus than hydrolyzable tannins. Here, I found that quebracho tannin (a condensed tannin) inhibits PPO activity directly while tannic acid (a hydrolyzable tannin) does not (Figure 1 and 2). This result is consistent with Zucker's (1983) claim that condensed tannins are more effective inhibitors of fungal enzymes than hydrolyzable tannins. However, these results do not indicate that quebracho tannin is more inhibitory of fungal growth than tannic acid (Figure 4).

Tannin concentration is important as well. Seaman (1984) found that concentrations of tannic acid below 0.03% had little effect on the performance of

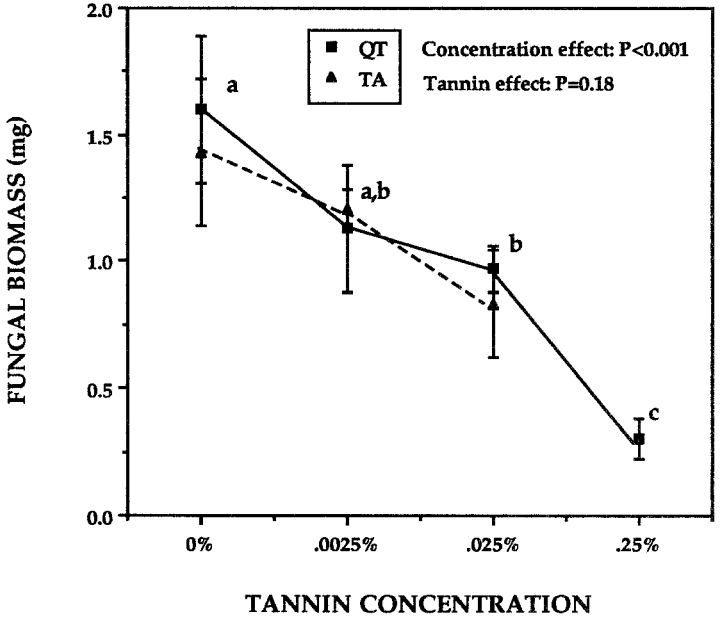

FIG. 4. The relationship between tannin concentration and the biomass of fungus at day 21. $N = 3$ at each concentration of tannin. Values with different letters are different at $P < 0.05$.

a related attine fungus. My results lend support to those of Seaman (1984). I found no difference in fungal biomass for 0% and 0.0025% tannic acid but did measure a reduction in biomass at 0.025% tannic acid (Figure 4). At 0.25% tannic acid the fungus appeared dead. However, a change in the concentration of tannic acid did not affect PPO activity; there was no inhibition at all. Quebracho tannin, on the other hand, inhibits both PPO activity and fungal growth but mostly at the highest concentration (Figures 2 and 4).

In a previous study on the effects of quebracho tannin on the ants and the fungus (Nichols-Orians, 1991a), I had hypothesized that the PPO would be induced by the presence of quebracho tannin (sensu Mayer, 1987), so that in the absence of quebracho tannin there would be no PPO activity. It appeared from that study that PPO was produced constitutively and was not induced by the presence of quebracho tannin, yet the results were not definitive because quebracho tannin inhibited the enzymes directly. This could have made it impossible to detect elevated levels. In this study, it is possible to test for induction because tannic acid does not inhibit PPO (Figure 3). PPO is not induced by tannic acid; PPO activity in control (no tannic acid) cultures is as high or higher than in cultures with tannic acid at all sampling times (Figure 1).

Growing attine fungus in liquid culture is ideal for testing how different types of tannin affect PPO activity. It is not ideal, however, for testing how tannins would affect fungal performance under natural conditions. Fungal hyphae secrete PPOs externally, and presumably the enzymes begin degrading any tannin present in the leaves before the tannin contacts the fungus. Consequently, a particular type of tannin would only come into contact with the fungus if it (1) inactivates the PPO, (2) is unaffected by the PPO, or (3) is present at extremely high concentrations and diffuses rapidly toward the fungal hyphae. Clearly, it is necessary to determine which wins, tannins or PPOs, under natural conditions.

Nevertheless, there are a couple of conclusions that can be drawn from this study. First, different types of tannin will differ in their effects on the ant–fungus system. If quebracho tannin and tannic acid are at all indicative of other condensed and hydrolyzable tannins, respectively, then it appears that only condensed tannins would limit the ability of the fungus to inactivate tannins. Hydrolyzable tannins would only be important if unaffected by the PPOs or if at such high concentration that they satiate the enzymes and subsequently contact the fungus.

Second, tannins are not usually the only phenolics present in woody plants, and nontannin phenolics can have antimicrobial effects also (Harborne, 1988). Thus, the presence of PPO-inhibiting tannins may limit the ability of the fungus to inactivate other phenolics. Many terpenoids are toxic to the fungus (Hubbell et al., 1983; Howard et al., 1988), and perhaps the presence of certain tannins could inhibit enzymes responsible for detoxifying a toxic terpenoid as well. This could enhance the toxicity of that terpenoid. Clearly, comparative studies on the effects of different types of tannin, with and without other secondary chemicals, on the activity of detoxification enzymes and the growth of the fungus are warranted. Future experiments should try to mimic natural conditions as much as possible.

Abstract—Previously it was reported that significant amounts of the tomato phenolic, chlorogenic acid, were oxidized in the digestive system of generalist feeders *Spodoptera exigua* and *Helicoverpa zea*. The covalent binding of the oxidized phenolic (i.e., quinone) to dietary protein exerts a strong antinutritive effect against larvae. In this study, we examined the fate of ingested chlorogenic acid in larval *Manduca sexta*, a leaf-feeding specialist of solanaceous plants. Significant amounts of chlorogenic acid were bound to excreted protein by *M. sexta* when larvae fed on tomato foliage. However, in the case of *M. sexta* we suggest that the strong alkalinity and detergency of the midgut may minimize the antinutritive effects of oxidized phenolics. The solubility of tomato leaf protein is significantly greater at pH 9.7, representative of the midgut of *M. sexta*, than at pH 8.0, representative of the midguts of *H. zea* and *S. exigua*. We suggest that this increase in solubility would compensate for any loss in bioavailability of essential amino acids caused by the covalent binding of chlorogenic acid to amino acids. Furthermore, lysolecithin, a surfactant likely to contribute to the detergent properties of the midgut fluid, was shown to enhance protein solubility as well as inhibit polyphenol oxidase activity. The adaptive significance of gut alkalinity and detergency is discussed.

INTRODUCTION

Investigations continue to be conducted on the impact of plant phenolics and polyphenol oxidases on insect growth using the tomato plant, *Lycopersicon esculentum*, and the generalist noctuids *Helicoverpa* (=*Heliothis*) *zea* and *Spodoptera exigua* as a model system (Felton et al., 1989a,b; Felton and Duffey, 1990; Duffey and Felton, 1989). Upon damage to leaf tissue, liberated polyphenol oxidase oxidizes orthodihydroxyphenolics such as chlorogenic acid to the corresponding reactive, electrophilic quinone (Mayer, 1987). The quinones undergo rapid addition reactions with nucleophiles such as the thiol and amino groups of proteins (Hurrell et al., 1982; Pierpoint, 1983; Kalyanaraman et al., 1987). These reactions occur in the digestive systems of both *H. zea* and *S. exigua*, and, as a consequence, the utilization of dietary protein is impaired (Felton et al., 1989a,b; Duffey and Felton, 1989).

In addition to *H. zea* and *S. exigua*, which consume a variety of plant tissues, the tomato herbivore complex includes other lepidopteran larvae such as the oligophagous *Manduca sexta* and the polyphagous *Trichoplusia ni* (Lange and Bronson, 1981). Of these species, only *M. sexta* and *T. ni* normally restrict their feeding to leaves (Lange and Bronson, 1981). The leaf-specialist *M. sexta* grows relatively more rapidly on tomato foliage than *H. zea* (Hare, 1983; Felton et al., 1989a). Larval *H. zea* is better adapted to feeding on fruit where polyphenol oxidase activity is several orders of magnitude less than foliage (Felton et al., 1989a).

One of the most striking differences in the digestive systems between the leaf specialists and the fruit-feeding lepidopteran species is the alkalinity of the midgut. The leaf-feeders, *M. sexta* and *T. ni*, have a gut pH (ca. 10.0 to 11.0) much greater than the generalist feeders *Spodoptera* and *Helicoverpa* (ca. 8.0) (Dow, 1984; Martin et al., 1987; Felton et al., 1989a). Our contention is that the highly alkaline gut conditions of the leaf-feeding herbivores represent one physiological strategy to enhance the acquisition of dietary protein, thus minimizing the impact of oxidative enzymes and their substrates on dietary protein.

In this paper, we examine the effects of alkalinity and detergency upon the solubility of leaf protein, the activity of foliar oxidative enzymes, and the binding of phenolics to protein. The adaptive significance of gut alkalinity and detergency to leaf-feeding herbivores is discussed.

METHODS AND MATERIALS

Insects. Eggs of *M. sexta* were obtained from Dr. Bruce Hammock, University of California, Davis. Neonate larvae were placed on artificial diet containing 4% fresh weight (fwt) casein (Chippendale, 1970).

Isotope. Tritiated chlorogenic acid prepared by catalytic exchange was

obtained from Amersham Corp. and purified by thin-layer chromatography to remove labile tritium as described (Isman and Duffey, 1983) with a specific activity of 135 mCi/mmol.

Extraction of Leaf Protein. To determine the effect of pH and oxidation on amino acid composition of extracted protein, four leaves were excised at the petiole with a razor blade from each flowering-stage, greenhouse-grown, tomato plant (var. Ace). From each leaf, four leaflets were excised, weighed, and randomly placed in one of four extraction treatments. Each of the four treatments contained eight leaflets weighing approximately 3.0 g (fwt). Leaflets were frozen at −20°C for 1 hr prior to homogenization and separately homogenized for 2 min in a Waring blender containing 100 ml ice-cold buffer from one of four treatments: 0.1 M sodium phosphate buffer at pH 8.0 and at pH 9.7 without diethyldithiocarbamate and at pH 8.0 and pH 9.7 with 2 mg/ml diethyldithiocarbamate. Diethyldithiocarbamate is an effective inhibitor of polyphenol oxidases (Mayer, 1987).

Protein was extracted in the following manner. Following homogenization, the treatments were allowed to sit at 30°C for 2 hr to enhance solubilization of protein and to allow oxidation of phenolics. Each treatment was filtered through a single layer of cheesecloth and centrifuged at 10,000*g* for 30 min at 0–4°C. The supernatant was used for all further enzyme and protein assays. A 50-ml aliquot of the supernatant was removed from each treatment and placed on ice. Ten milliliters of 30% trichloroacetic acid was added to each aliquot followed by centrifugation for 15 min at 10,000*g*. The pellets were washed with 90% methanol and recentrifuged, a process that was repeated several times. The methanol supernatant was discarded in each case. Finally, the pellets were frozen, lyophilized, and weighed to the nearest 0.1 mg.

The extraction and quantification of protein was replicated three times after which the protein was pooled for each of the four treatments. Samples (ca. 50 mg) of the leaf protein were hydrolyzed in 6 N HCl (1 mg protein/ml) for 24 hr at 100°C in vacuo and analyzed for amino acid content by automated amino acid analysis at the Protein Structure Laboratory, University of California, Davis. The total amount of amino acid per gram of foliage was calculated by multiplying the amino acid content of the protein by the average weight of precipitated protein per gram of foliage.

Polyphenol oxidase and peroxidase activities from aliquots of the supernatant from the four treatment regimes were determined with chlorogenic acid and guaiacol–H_2O_2 as substrates, respectively (Ryan et al., 1982). One unit of polyphenol oxidase or peroxidase activity was defined as a change in OD_{470}/min equal to 0.001/min.

To examine the effect of pH on the solubility of leaf protein, leaves were excised from field-grown tomato plants (var. Castlemart) and immediately frozen at −20°C for 1 hr. Leaves were lyophilized and ground to a fine powder.

Forty-milligram aliquots of leaf powder were added to centrifuge tubes containing 1 ml of 0.2 M sodium phosphate buffer at pH 7.0, 8.0, 9.0, or 10.0. The samples were placed on a shaking water bath for 60 min at 30°C and centrifuged for 15 min at 16,000*g*. Ten-microliter aliquots from each sample were assayed for protein with 1.5 ml Coomassie blue protein reagent (BioRad Laboratories, Richmond, California) following the procedure of Jones et al. (1989). Ribulose-1,5-bisphosphate carboxylase/oxygenase (Sigma Chemical Co.) was used as a protein standard. Five replicates per pH concentration were tested.

Effect of Alkalinity and Tomato Polyphenol Oxidase Activity on Binding of Chlorogenic Acid to Leaf Protein. To determine the effect of pH and polyphenol oxidase activity on binding of chlorogenic acid to leaf protein, partially purified tomato polyphenol oxidase was isolated from tomato foliage by precipitation with 35% ammonium sulfate following the method of Gentile et al. (1988). The enzyme preparation contained 9600 units/mg protein of chlorogenic acid oxidase activity. Less than 1% of the total peroxidase activity remained in the polyphenol oxidase enzyme preparation.

Four treatments were performed: pH 8.0 with active polyphenol oxidase, pH 8.0 with heat-denatured polyphenol oxidase, pH 9.7 with polyphenol oxidase, and pH 9.7 with heat-denatured polyphenol oxidase. Each treatment contained 4 ml 0.1 M sodium phosphate buffer containing 14 μmol unlabeled chlorogenic acid, 100,000 dpm [^{3}H]chlorogenic acid, and 5 mg purified ribulose-1,5-bisphosphate carboxylase/oxygenase. At zero time, 0.3 mg of active or inactive polyphenol oxidase was added to the respective treatments. Treatments were placed on a water bath at 30°C and gently shaken for 2 hr. Reactions were stopped with the addition of ammonium sulfate to 95% saturation. After vortexing, samples were centrifuged at 10,000*g* for 30 min. Pelleted protein was washed repeatedly with 80% methanol and centrifuged until radioactivity remaining in the supernatant was equal to background levels. Finally, the protein pellet was solubilized in 0.1% SDS and added to ACS liquid scintillant for direct counting to calculate nanomoles of chlorogenic acid bound per milligram of protein.

Determination of Binding of Chlorogenic Acid to Protein in Insect Gut. To determine if chlorogenic acid binds to protein in the digestive system when *M. sexta* larvae feed on tomato foliage, a 1.0 μCi aliquot of [^{3}H]chlorogenic acid in 50% methanol was applied to each excised tomato leaflet weighing 75–100 mg and the leaflet was allowed to air dry. A leaflet contained on average 2.2 μmol chlorogenic acid/g fwt as determined spectrophotometrically (Broadway et al., 1986). Individual leaflets treated with the isotope were fed to individual day-old fifth instar *M. sexta* larvae that had been starved for 12 hr.

After 3 hr of feeding each larva had ingested an entire leaflet. Feces were

collected as produced, pooled on an individual larval basis, and placed immediately in 5 ml ice-cold double distilled H_2O containing 15 mg diethyldithiocarbamic acid to inhibit residual polyphenol oxidase activity. All larvae ceased defecating within 10 hr.

After larvae ($N = 10$) stopped defecating, the pooled feces of each larva were homogenized for 1 min, centrifuged for 10 min at 20,000*g*, and the supernatant was removed. Each pellet was reextracted in double distilled H_2O containing diethyldithiocarbamic acid and 1% Triton X-100. The supernatants of a given pellet were pooled and placed on ice, and ammonium sulfate to 90% saturation was added to precipitate protein. After 30 min, samples were centrifuged for 30 min at 20,000*g*, and the supernatant was removed for direct counting of [^{3}H]chlorogenic acid by liquid scintillation. Each pellet was washed with 80% methanol and centrifuged to remove residual noncovalently bound chlorogenic acid. After several successive washings, the supernatants were pooled for each sample, and radioactivity was counted by liquid scintillation. Finally, the pelleted protein was solubilized in 0.1% sodium dodecylsulfate, and covalently bound [^{3}H]chlorogenic acid was counted. The unbound chlorogenic acid represented combined radioactivity of the supernatants from the aqueous and methanolic extracts. A small aliquot also was applied to cellulose thin-layer plates and chromatographed as described (Felton et al., 1989a) to verify the formation of a chlorogenic acid–amino acid conjugate.

A 50-μl aliquot of hemolymph was removed from each larva 24 hr after it had ingested the leaflet. Radioactivity of the hemolymph was determined directly by liquid scintillation.

Effect of Surfactant on Foliar Oxidases and Protein Solubility. To determine if lysolecithin, a surfactant that may contribute to midgut detergency, affects foliar polyphenol oxidase activity, tomato leaflets (16 g) were divided into four equal parts and homogenized separately in ice-cold 0.1 M potassium phosphate buffer, pH 6.8, containing one of the following treatments: 0.02%, 0.04%, 0.08% lysolecithin, and a control lacking added surfactant. Following homogenization, the treatments were centrifuged for 20 min at 10,000*g* and assayed in triplicate for polyphenol oxidase activity with chlorogenic acid by measuring increase in absorbance at 470 nm (Ryan et al., 1982). The experiment was replicated five times.

To determine if lysolecithin affects protein solubility, 40 mg lyophilized leaf powder was added to 1 ml 0.1M sodium phosphate buffer, pH 7.0, with and without 0.04% lysolecithin. The treatments were treated similarly to above experiments on effects of pH on protein extractability. The concentration of lysolecithin was selected because it stimulates the surfactant properties of *M. sexta* midgut fluid (Martin and Martin, 1984). Protein was quantified following Jones et al. (1989).

RESULTS

Effect of pH and Oxidase Activity on Amount and Composition of Amino Acids in Extracted Protein. Both pH and polyphenol oxidase activity significantly affected the amount of extractable protein indexed as TCA-precipitable protein (Figure 1). Total amino acids are defined as the total molar content of amino acids in hydrolyzed protein. Essential amino acids are defined as essential amino acids required for larval growth of *Helicoverpa zea* (Rock and Hodgson, 1971). Significantly more total amino acids were extracted at pH 9.7 in both treatments (with or without polyphenol oxidase activity) than at the lower pH of 8.0 (Figure 1). Likewise, the inhibition of polyphenol oxidase resulted in greater amounts of extracted protein amino acids at both pH values. In treatments with polyphenol oxidase activity, nearly 42% more total amino acids and 60% more essential amino acids were obtained at pH 9.7 than at 8.0 (Figure 1). Similar effects were observed in treatments lacking polyphenol oxidase activity, in which approximately 43% more total and essential amino acids were extracted at the higher pH. The method of amino acid analysis does not take into account the essential amino acid, tryptophan, because it is destroyed during hydrolysis.

The effects of pH and polyphenol oxidase treatments on individual amino acids are shown in Table 1. Without exception, greater absolute amounts of all amino acids were obtained at pH 9.7 than at 8.0. In the case of the two most

limiting amino acids (i.e., essential amino acids at the lowest concentrations), 16% more methionine and 37% more histidine were obtained at the more alkaline pH. The presence of polyphenol oxidase activity reduced the total quantity of amino acids at both pH levels. Apparently, the primary cause of this reduction is decreased solubility of phenolic-bound protein (Betschart and Kinsella, 1973).

Oxidized chlorogenic acid is known to bind covalently to amino acids such as lysine, histidine, and methionine (Pierpoint, 1983; Barbeau and Kinsella, 1983). The presence of polyphenol oxidase activity reduced the relative amounts of these amines. When the relative mole percent of amino acids for each protein treatment was taken into account, only methionine, lysine, and histidine were negatively affected by polyphenol oxidase activity (Figure 2). Methionine was reduced by 26%, lysine by nearly 16%, and histidine by 8% at pH 9.7 in the presence of polyphenol oxidase activity. At pH 8.0, lysine was reduced by 11.7%, histidine by 8%, and methionine apparently was unaffected by oxidative activity. However, despite the greater relative loss in methionine, histidine, and lysine at pH 9.7, a greater absolute amount of these amino acids was soluble at the higher pH. Our amino acid analyses do not take into account potential loss of methionine to methionine sulfoxide formation via chlorogenoquinone-mediated oxidation (Igarashi and Yasui, 1985).

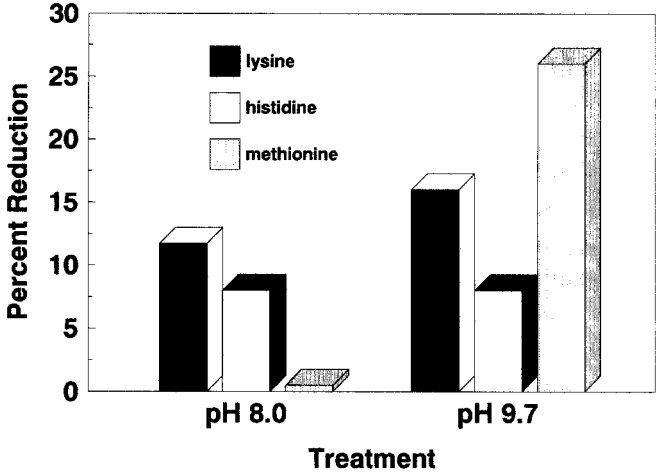

FIG. 2. The effect of polyphenol oxidase activity on the loss of lysine, histidine, and methionine in tomato foliage. Reductions are based upon comparison of molar ratios of amino acids between treatments with and without polyphenol oxidase activity. Values are based upon single analyses of pooled replicates.

The addition of the inhibitor, diethyldithiocarbamate, abolished polyphenol oxidase activity and reduced peroxidase activity by greater than 85% at both pH levels (Table 2). The activity of both enzymes was markedly reduced by the higher pH, with nearly 35% and 65% reductions in polyphenol oxidase and peroxidase, respectively.

When leaf powder was extracted at neutral and at alkaline pH levels, significantly more protein was soluble at alkaline pH (Figure 3; $r = 0.880$, $P < 0.01$). The relationship between pH of extraction buffer and percent protein was significantly correlated, and the slope of the regression line was significantly greater than zero ($P < 0.01$). Nearly 25% more soluble protein on a wet weight basis was observed at pH 10.0 compared to pH 7.0. Furthermore, in the bell pepper plant, *Capsicum annuum*, another solanaceous plant host of *M. sexta*, 45% more soluble foliar protein was obtained at the higher pH (unpublished data).

Effect of Alkalinity and Tomato Polyphenol Oxidase Activity on Binding of Chlorogenic Acid to Leaf Protein. Significantly more chlorogenic acid was bound to protein in the presence of polyphenol oxidase (Figure 4). In treatments containing polyphenol oxidase activity, pH had little effect on the amount of chlorogenic acid bound to protein (58.9 vs. 64.3 nmol/mg protein for pH 8.0 vs. 9.7, respectively). In the absence of polyphenol oxidase activity, pH significantly affected binding with nearly 60% more chlorogenic acid bound per milligram of protein at the higher pH of 9.7.

TABLE 2. EFFECTS OF pH AND DIETHYLDITHIOCARBAMIC ACID ON ACTIVITY OF FOLIAR OXIDASES

Treatment	PPO activity[a]	POD activity[b]
8.0	100	100
8.0 + inhibitor[c]	0	15.0
9.7	65.5	33.8
9.7 + inhibitor	0	4.1

[a] PPO activity = relative polyphenol oxidase activity measured with chlorogenic acid as substrate.
[b] POD activity = relative peroxidase activity measured with guaiacol and hydrogen peroxide.
[c] Inhibitor = diethyldithiocarbamic acid at 2 mg/ml buffer.

Determination of Binding of Chlorogenic Acid to Protein in Insect Gut. Nearly 39% of the excreted [^{3}H]chlorogenic acid was bound to protein when larvae were fed [^{3}H]chlorogenic acid-treated leaflets (Figure 5). Thin-layer chromatographic analyses of aqueous aliquots of the protein precipitate also indicated that chlorogenic acid was bound to protein because greater than 90% of the radioactivity was associated with a single band (Rf = 0.85–0.95) that was both phenolic and amine positive (Felton et al., 1989a).

A relatively large amount (ca. 14%) of the ingested radioactivity was retained in the hemolymph 24 hr following ingestion of the treated leaflet (Figure 5). Two to three times as much radioactivity was found in the hemolymph of *M. sexta* compared to *S. exigua* and *H. zea* larvae (Felton et al., 1989a). Radioactivity recovered in feces and hemolymph accounted for ca. 64% of the ingested radioactivity.

Effect of Surfactant on Foliar Oxidases and Protein Solubility. The addition of the gut surfactant lysolecithin significantly decreased polyphenol oxidase activity (Figure 6).At a concentration of 0.04% lysolecithin, the activity of polyphenol oxidase was reduced by 24%. This concentration of lysolecithin corresponds to a critical micelle concentration equal to that reported in the midgut fluids of *M. sexta* larvae (Martin and Martin, 1984). Peroxidase activity was not affected at the surfactant concentrations tested (data not shown).

The addition of 0.04% lysolecithin to the extraction buffer enhanced the solubility and/or extractability of leaf protein (Table 3). Approximately 9% more soluble protein occurred in the treatment with 0.04% lysolecithin.

DISCUSSION

Alkalinity and detergency have been proposed as adaptations to avoid the antidigestive effects of tannins (Feeny, 1970; Berenbaum, 1980; Martin et al., 1987). Alkalinity reduces hydrogen bonding of tannins with proteins, thus pre-

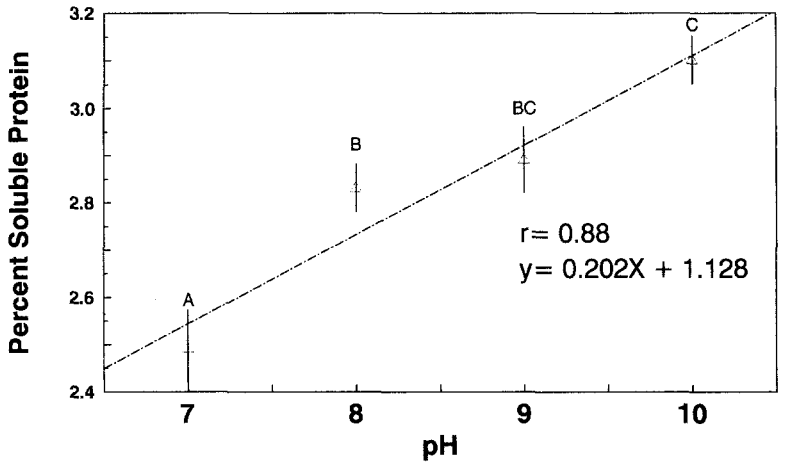

FIG. 3. Effect of pH on the extraction and solubility of tomato leaf protein. Each point represents the mean of three determinations. Error bars represent 95% confidence limits. Points not followed by the same letter are significantly different at $P < 0.05$.

venting protein precipitation (Martin and Martin, 1983; Pierpoint, 1983; Zucker, 1983; Haslam, 1988). Surfactants such as lysolecithin are highly effective at inhibiting the formation of insoluble tannin–protein complexes and appear to be widely present in insect midguts (Martin and Martin, 1984; Martin et al., 1987; Blytt et al., 1988). However, many lepidopteran larvae possess strongly alkaline, detergent gut fluids despite the apparent absence of tannins from their host plants (e.g., *M. sexta*; Martin et al., 1987). In these instances, it cannot be argued that alkalinity or detergency are adaptations for circumventing the antidigestive effects of tannins. We do not question the importance of alkalinity and detergency as adaptive factors mitigating tannin toxicity. These properties may play a significant role in enhancing the solubilization of dietary protein in the digestive tract. This is especially important considering that leaves are considered a protein-limited food source for most insect herbivores (White, 1978; Mattson, 1980; Brodbeck and Strong, 1987).

The plant biochemistry literature is replete with examples that support our findings that alkalinity enhances solubility of leaf nitrogen (e.g., Singer et al., 1952; Betschart and Kinsella, 1973). Leaf protein is generally more soluble and chloroplasts are more effectively disrupted at higher pH than at acidic or neutral pH (Betschart and Kinsella, 1973; Jones et al., 1989). Moreover, alkali extraction is essential for solubilizing cytoplasmic proteins in tobacco leaves, resulting in 25–50% more protein than at neutral or acidic pH (Singer et al., 1952). We have observed that increased levels of dietary protein in *H. zea* or *S. exigua* may substantially or completely alleviate the growth inhibition caused by the

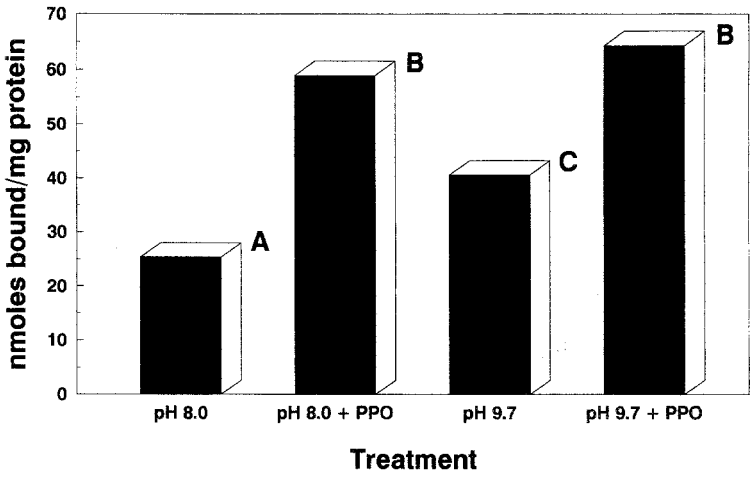

FIG. 4. Effect of pH and polyphenol oxidase activity on the binding of chlorogenic acid to ribulose-1,5-bisphosphate carboxylase/oxygenase. Each bar represents the mean of three determinations. binding of chlorogenoquinone to protein (Duffey and Felton, 1989; Felton et al., 1989b, unpublished data). Moreover, the nutritional quality of protein extracted at alkaline pH (8.0–12.0) is often superior to protein extracted at neutral pH (Woodham, 1983).

Polyphenol oxidase activity is markedly reduced at alkaline pH from many solanaceous host plants of *M. sexta*, e.g., tomato, bell pepper, eggplant, and potato (see Table 1) (Felton et al., 1989a; Fujita and Tono, 1988; Sharma and Ali, 1980; Kang et al., 1983). Although the enzyme is active across a broad pH spectrum in many plant species, the pH optimum for most species is in the acidic to neutral range (i.e., 5.0–7.0; Mayer and Harel, 1979). It is noteworthy that none of the major lepidopteran herbivores of the tomato plant have a gut pH near the optimum of ca. 7.0 for enzyme activity (Felton et al., 1989a). Thus, alkalinity may improve herbivore performance on marginal food sources by reducing the activities of polyphenol oxidase and enhancing the acquisition of greater amounts of dietary protein.

Although alkaline pH reduces polyphenol oxidase activity, the formation of chlorogenoquinone can occur nonenzymatically in basic conditions (Hurrell et al., 1982; Barbeau and Kinsella, 1983, 1985; Cilliers and Singleton, 1989). However, Hurrell et al. (1982) found that significant nutritional damage to protein by nonenzymatically produced chlorogenoquinone was only observable under conditions of continuous oxygenation and stirring. Recently, Appel and Martin (1990) reported that the midgut of *M. sexta* larvae possessed strong

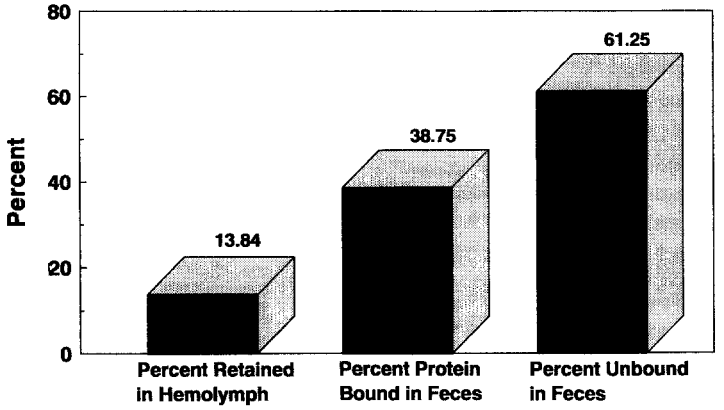

FIG. 5. The uptake and excretion of [^{3}H]chlorogenic acid by fifth-instar *Manduca sexta* larvae.

reducing properties (redox potential = −136 mV) and a slightly anaerobic environment, which may further minimize the antinutritive effects induced by the oxidation of phenolics such as chlorogenic acid. However, whether a specific quinone species will be reduced depends upon the difference in redox potentials of the midgut and the quinone. Also, it must be reiterated that once the quinones are formed and bound to nucleophilic portions of amino acids, changes in redox potentials will not disrupt the irreversible covalent bonds that form. The fore- and hindguts of *M. sexta* were reported to be oxidizing, and it is possible that much of the binding that we observed took place in these regions of the gut. Binding occurring in the foregut will still impair the utilization of amino acids. Furthermore, the activity of tomato polyphenol oxidase is so great that it is likely much of the phenolic binding to protein occurs in the initial stages of ingestion. The midgut reducing conditions may still serve to minimize nonenzymatic oxidations of other phenols.

The amount of chlorogenic acid bound to excreted protein by *M. sexta* (i.e., 38.8%; Figure 4) was similar to that observed in *S. exigua* and *H. zea* (38% and 49%, respectively, Felton et al., 1989a). In the case of *M. sexta*, the antinutritive effect of quinone binding may be mitigated by the increased levels of soluble amino acids occurring at the higher midgut pH (Figure 1, Table 1). Our estimates on protein solubility in the digestive system of *M. sexta* may be quite conservative because the midgut pH has been reported as high as 11.3 (Dow, 1984).

The upper limit in gut pH is restricted by the energetic costs required for maintaining a high pH and the negative consequences of high pH on protein quality and enzyme function. At pH levels of 12 or more, protein nutritional

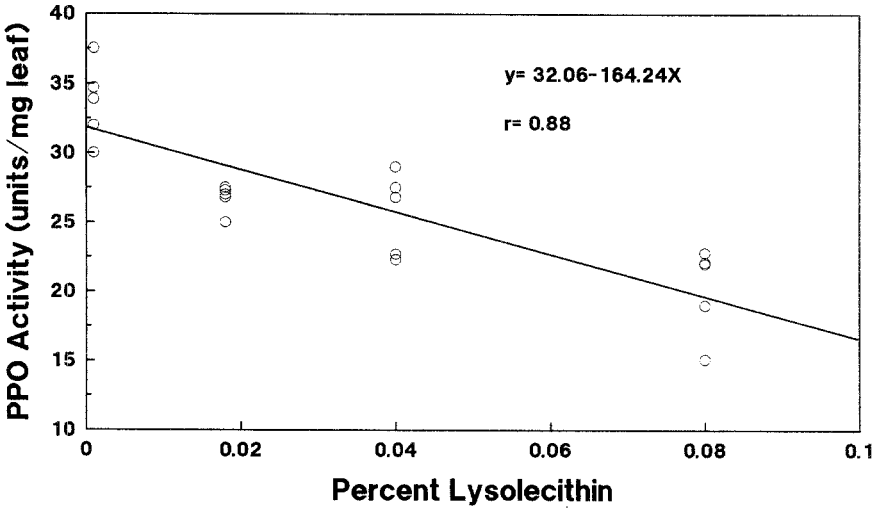

FIG. 6. Effect of the surfactant, lysolecithin, on tomato foliar polyphenol oxidase activity. Each point represents the mean of one replicate performed in triplicate. PPO = polyphenol oxidase activity.

quality is degraded as a consequence of amino acid racemization, thiol oxidation, and formation of toxic cross-linked amines such as lysinoalanine (Friedman, 1982; Pierpoint, 1983; Whitaker and Feeney, 1983; Finot, 1983; Hurrell and Finot, 1985). At such a high pH, digestive enzymes would likely denature and be unable to function. These restrictions, therefore, would partially determine the upper limit for the evolution of gut pH.

The surfactant lysolecithin also has the ability to enhance protein solubility (Table 3) and diminish polyphenol oxidase activity (Figure 6). The reduction in polyphenol oxidase activity may be due to protein denaturation or conformational changes. Certain detergents are known to inactivate polyphenol oxidase activity (Meyer and Biehl, 1981). The ability of surfactants to enhance extraction of leaf protein is due to the disruption of chloroplasts and other protein bodies (Betschart and Kinsella, 1973). Lysolecithin also has been shown to solubilize membrane-bound protein and phytosterols in plant cells (Sandstrom and Cleland, 1989). In addition, surfactants may play an important role in protein digestion by denaturing substrate protein and exposing more binding sites for proteolytic enzymes (Mole and Waterman, 1985).

In conclusion, we concur with the theory that the alkalinity and detergency of midgut fluids of lepidopteran larvae represent adaptations to leaf-feeding. Whereas previous investigations have advocated these properties as adaptations to avoid toxicity from tannin–protein complexes (Feeny, 1970; Martin and Mar-

tin, 1984; Martin et al., 1987), we contend that they may have other significant functions for folivores. Both detergency and alkalinity were shown to reduce foliar polyphenol oxidase activity and enhance the extraction and/or solubility of leaf proteins. Moreover, surfactants may aid in the digestion of protein and in the acquisition of other key nutrients such as sterols (Sandstrom and Cleland, 1989). Gut alkalinity also may be important for extracting hemicelluloses of cell walls (Terra, 1988). Thus, gut alkalinity and detergency may represent important nutritional adaptations for facilitating the uptake of essential or limiting nutrients from host plants.

(Received February 8, 1991; accepted May 15, 1991)

Abstract—Experiments were performed to assess the effect of four foliar essential oil phenotypes from a coastal redwood (*Sequoia sempervirens*) population on isolates of *Pleuroplaconema* sp., its ubiquitous endophytic fungus. Isolates were exposed to essential oils extracted from their trees of origin and from other trees. The hypotheses tested were: (1) redwood leaf essential oils extracted from distinct trees would have a differential effect on *Pleuroplaconema* sp. growth, and (2) growth of isolates from a particular tree would be differentially affected when exposed to essential oil phenotypes different from that of their tree of origin. The essential oil phenotypes were differentially inhibitory, but the pattern of inhibition did not support the second hypothesis. *Pleuroplaconema* sp. showed low average tolerance to all of the essential oils; two phenotypes reduced growth 70–80% and the other two 50–60% at the dose tested. The overall growth response of individual isolates to all treatments suggests that more than one fungus genotype per tree was represented in the experiment. The variability in tolerance of individual isolates to the essential oils was low for three phenotypes. The low tolerance of *Pleuroplaconema* sp. to redwood essential oils, in spite of its predominance and specialization in this conifer, is discussed considering: (1) the possible pathogenic ancestry of this fungus, and (2) that essential oil phenotypes may be important in controlling the activity of *Pleuroplaconema* sp. after it colonizes the leaf.

Key Words—*Sequoia sempervirens, Pleuroplaconema* sp., essential oil

phenotypes, leaf fungus endophytic control, tolerance variability, terpenoids, latent infections, symbiosis.

INTRODUCTION

Volatile terpenoids occurring in complex mixtures, also known as essential oils, are ubiquitous in conifers. Studies on the effect of essential oils, or their components, on food-spoiling fungi or human pathogenic fungi frequently show the antifungus nature of these chemicals (e.g., Benjalili et al., 1982; Pauli and Knobloch, 1987). These compounds have been associated with differential susceptibility of some conifers to fungus pathogens (Rockwood, 1973, 1974; Thibault-Balesdent and Delatour, 1985) or to protective reactions after pathogen attack (Gibbs, 1968; Raffa and Berryman, 1982; Gambliel et al., 1985; Miller et al., 1986). Furthermore, many pathogenic or wood-inhabiting fungi may be inhibited by saturated atmospheres of conifer monoterpenes of their hosts (Cobb et al., 1968; Hintikka, 1970; De Groot, 1972; Väisälä, 1974; Flodin and Fries, 1978; Bridges, 1987; Ennos and Swales, 1988). On the other hand, some of these volatile terpenoids alone or in combination have neutral or even stimulatory effects on certain pathogenic fungi (Fries, 1973; Flodin and Fries, 1978; Franich et al., 1982; Bridges, 1987).

Terpenoid variability within and among populations of some plants tends to be multimodal, i.e., few or several terpenoid mixture phenotypes are distributed among many individuals (Langenheim and Stubblebine, 1983; Squillance et al., 1985; Leather et al., 1987). However, few studies have considered terpenoid phenotypes and fungi. Furthermore, most of these have: (1) included only one phenotype or a pooled sample of phenotypes and apparently one isolate per fungus species, or (2) various terpenoid phenotypes and only one fungus isolate (Cobb et al., 1968; Shrimpton and Whitney, 1968; Flodin and Fries, 1978; Franich et al., 1982; Arrhenius and Langenheim, 1983; Tripathi et al., 1985).

Fungi with endophytic stages colonizing aerial tissues are ubiquitous in conifers (Carroll, 1986; Petrini, 1986). They even have been proposed to be "as common among plants as are mycorrhizae" (Carroll, 1988). However, little is known about their relationships with terpenoid mixtures. Although some of these fungus symbionts can be latent pathogens, many fungi do not cause apparent harm to the plant in their endophytic stages and can be isolated from symptomless leaves. In this paper, the term "endophyte" is used to refer to these kinds of fungi.

Some endophytes antagonize herbivores and possibly pathogens of the plant that they inhabit (Clay et al., 1985; Carroll, 1986, 1988). For this reason mutualism has been proposed in some endophyte–plant systems (Carroll, 1988; Clay, 1988). These mutualisms have been postulated to have evolved from

plant–pathogen relationships, since most proven endophytic mutualists are close relatives of virulent pathogens and some otherwise harmless endophytes can cause disease when the plant is under stress (Carroll, 1988; Clay, 1988). Most leaf endophytes in conifers apparently remain inactive after colonizing the leaf, and active fungus growth and reproduction occur when the leaf senesces or is damaged (Carroll, 1986). The mechanisms by which this apparent inactivity is maintained and by which growth is resumed are not known, although the mechanisms discussed by Verhoeff (1974) for latent fungus pathogenic infections (i.e., control by secondary chemicals of the host, changes in the nutritional quality of the tissues or a combination of both factors) may be similar for all endophytes.

The purpose of this research was to explore the relationships between foliar essential oil phenotypes in a coastal redwood [*Sequoia sempervirens* (D. Don. ex Lamb.) Endl.] population and *Pleuroplaconema* sp., the most frequent and ubiquitous endophyte in redwood leaves (Rollinger and Langenheim, 1989; Espinosa-García and Langenheim, 1990). We tested specifically the hypotheses that (1) some of the frequent essential oil phenotypes in a redwood population would differentially affect *Pleuroplaconema* sp. growth; and (2) growth of isolates would be differentially affected when exposed to essential oil phenotypes different from that of their tree of origin.

Pleuroplaconema sp. [possible asexual state of *Chloroscypha chloromela* (Phil. and Hk.) Seaver, that is known only from coastal redwood (Petrini, 1982)], has never been associated with disease in this host. According to Carroll's criteria (1986), this is a fungus anticipated to form a mutualistic association with redwood. *Pleuroplaconema* sp. spores are apparently dispersed by water-splashing, which results in colonization of a great proportion of the redwood foliage (Rollinger and Langenheim, 1989; Espinosa-García and Langenheim, 1990). The fungus then appears to cease growth until the leaf senesces or dies.

Coastal redwood leaves have a relatively high amount of essential oils. Monoterpenes constitute 60–88% of the mixture, accounting for 0.1–6.6% of the leaf dry weight (Hall, 1985). The other components are sesquiterpenes, oxygenated terpenoids and, in trace amounts, allyl phenylethers (Gregonis et al., 1968; Hilal et al., 1977; Okamoto et al., 1981). Redwood leaf essential oil is variable within the population and developmentally variable within the individual, both in yield (i.e., total amount) as well as in compositional pattern (i.e., percentage of individual compounds relative to the total amount). The essential oil compositional pattern has been characterized by the predominant monoterpene fraction throughout its geographic distribution (Hall and Langenheim, 1987). Both this compositional pattern and yield change during the first six months of leaf development but then stabilize until the beginning of senescence (Hall and Langenheim, 1986b); The compositional pattern is constant

throughout the mature leaves from a tree, but the yield of the leaves on the uppermost part of the tree is higher than that of the other leaves (Hall and Langenheim, 1986a).

Five essential oil compositional patterns were recognized from a sample of 36 adult trees from a Santa Cruz population (Espinosa-García, 1991). Four trees, each representing a compositional pattern, which in this paper are called "essential oil phenotypes," were used in the experiment (Figure 1). Fourteen monoterpenes and one sesquiterpene are represented, although each of the four phenotypes was characterized by its own spectrum of five predominant monoterpenes (sabinene, limonene, β-phellandrene, γ-terpinene, and α-pinene) and the sesquiterpene caryophyllene. In three of the phenotypes (I, II, and IV), sabinene is the most abundant compound, followed by relatively similar but characteristically different amounts of limonene, γ-terpinene, β-phellandrene, and α-pinene. In phenotype III, however, β-phellandrene occurs in the highest amount with α-pinene, sabinene, and limonene being relatively similar in con-

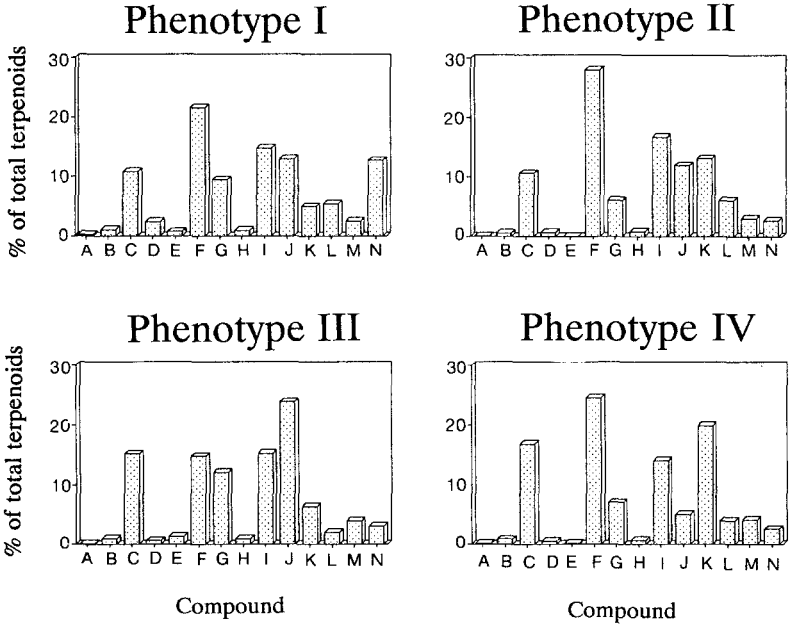

FIG. 1. Essential oil phenotypes used in the experiment. Bars represent percent of individual compounds relative to the total amount of monoterpenes plus caryophyllene. Each terpenoid profile was obtained from an individual representing an essential oil compositional pattern group. A, tricyclene; B, thujene; C, α-pinene; D, camphene; E, β-pinene; F, sabinene; G, myrcene; H, α-phellandrene; I, limonene; J, β-phellandrene; K, γ-terpinene; L, p-cymene; M, terpinolene; N, caryophyllene.

centration. The relatively high amount of caryophyllene also distinguishes phenotype I.

METHODS AND MATERIALS

Four trees with distinctive essential oil phenotypes were the source of both foliage for essential oil extraction and *Pleuroplaconema* sp. isolates. An additional tree from a compositional pattern not represented in the experiment was used as a source of isolates to have a better representation of the fungus population. The trees were part of a ca. 85-year-old second-growth forest dominated by redwood. The stand was apparently even-aged with no old-growth forest in the vicinity.

Essential Oil Extraction. Foliage from each tree was collected the second week of November 1989. Leaves 1–3 years old were detached from twigs and extracted by two methods. The first was a small-scale extraction where 2 g of leaves per tree were ground in pentane with tetradecane added as internal standard. This pentane extract was dried with sodium sulfate, concentrated to 0.1 ml under a mild nitrogen stream, and analyzed by gas chromatography (GC). The terpenoid profiles were compared with those obtained in a larger-scale extraction procedure. In this second extraction, 300–400 g of leaves per tree were soaked in pentane for five days at room temperature in the dark. Each extract from soaked leaves was fractionate-distilled, the residue saved, and the distillate returned to the jars where the soaked leaves remained. This procedure was repeated three times. Each time the residue was stored in amber bottles in the freezer. After the fourth distillation, distillate and liquid from cold traps were combined (ca. 1 liter), dried and concentrated to 50 ml under nitrogen. The concentrate was added to the previously collected residues, and this was dried and distilled to remove the solvent. Pentane at concentrations higher than 0.17 mg pentane/ml air are known to be inhibitory to the growth of some *Pleuroplaconema* sp. isolates (Espinosa-García, unpublished results). Complete removal of pentane was not possible without loss of some monoterpenes; therefore, lost monoterpenes were replaced with commercially prepared compounds (Aldrich, Co. and ICN Chemicals). The more than 95% purity of these chemicals was confirmed by GC. Because β-phellandrene was not available commercially, the remaining amount of this compound in the extracts was used as a base to adjust the relative proportions of the other monoterpenes determined from the small scale extraction. These reconstituted concentrates were analyzed with GC and their patterns were compared with those obtained with the small-scale method. No significant differences existed in the monoterpene fraction, and the pentane concentrations were below levels known to inhibit *Pleuroplaconema* sp. growth. Pentane and volatile terpenoids in the extracts were quan-

tified by adding 5 μl of 99% tetradecane to 60 μl of extract in a tightly closed minivial. After mixing thoroughly, an aliquot was injected and analyzed by GC.

Gas Chromatographic Analysis. A Perkin-Elmer Sigma 300 gas chromatograph with glass capillary column 0.9 mm ID and 86 m long coated with 12% Carbowax 20 on Chromosorb and flame ionization detector was used. Injections were split to a 40:1 ratio with He as carrier gas at a 2 ml/sec flux, with the following temperature program: 65°C held 5 min, 6°C/min increase up to 180°C and held for 10 min. Injector temperature was 210°C, and the detector temperature was 250°C. Monoterpenes and caryophyllene were identified by retention time and the peak enrichment method.

Fungus Isolates. Leaves 1–3 years old were collected from a lower canopy branch from each tree and placed separately on water–agar tubes following surface sterilization with serial immersion in 95% EtOH for 1 min, 65% household bleach for 10 min, and 35% EtOH for 30 sec twice. One *Pleuroplaconema* sp. isolate was taken from each leaf age class per tree to increase the probability of isolating different fungus genotypes. Because the isolates were not of single spore origin, they may have been multiclonal. A total of 15 isolates, three per tree, was used. The isolates were transferred and incubated at room temperature (ca. 20–25°C) in redwood broth agar [macerated redwood foliage extract (equivalent to 50 g foliage/liter), filtered through Whatman No. 1 paper, and autoclaved; filter-sterilized glucose (5 g/liter), ampicillin (100 mg/liter), and streptomycin (25 mg/liter), and autoclaved water agar (15 g/liter) were added]. These cultures were used as inoculum source for colonies that provided plugs from colony edges for tests.

Experimental Design and Statistical Analysis. The experiment had a nested factorial design of extract type by isolates (5 × 15) nested by isolation origin. All *Pleuroplaconema* sp. isolates were exposed to the essential oil from all extract types. In the control treatment isolates grew with no volatiles. Isolate exposure to the treatments was replicated four times. Results were analyzed using analysis of variance (ANOVA) and means were compared with Duncan's multiple-range test. ANOVA was performed for the entire group of isolates as well as for isolates grouped by tree. Pearson correlation coefficients were calculated among isolate tolerance values to phenotypes:

$$\text{Tolerance} = \frac{\text{average growth exposed to volatiles}}{\text{average growth with no volatiles}}$$

Stepwise multiple regression was performed with: (1) growth in absence of essential oil and tolerance to all phenotypes, and (2) tolerance and concentration of terpenoids in the phenotypes (Table 1). Tolerance and the sum of the concentrations of sabinene and γ-terpinene were regressed because these monoterpenes inhibit the growth of *Pleuroplaconema* sp. in an additive fashion (Espinosa-García, 1991).

TABLE 1. CONCENTRATION (mg/vial) OF MOST MONOTERPENES, CARYOPHYLLENE, AND OTHER VOLATILE COMPOUNDS DELIVERED IN EXTRACTS FROM REDWOOD FOLIAGE USED IN EXPERIMENT

	Tree 1	Tree 2	Tree 3	Tree 4
Tricyclene	0.004	0.000	0.003	0.002
Thujene	0.029	0.014	0.026	0.025
α-Pinene	0.383	0.313	0.439	0.521
Camphene	0.079	0.019	0.016	0.017

γ-Terpinene	0.192	0.386	0.181	0.615
p-Cymene	0.183	0.177	0.056	0.121
Terpinolene	0.096	0.088	0.114	0.125
Caryophyllene	0.462	0.076	0.086	0.079
Monoterpene total	3.137	2.865	2.801	3.013
Other compounds[a]	1.937	2.138	2.193	1.984

[a] Total of sesquiterpenes, oxygenated terpenoids and other minor components.

Statistical analyses were carried out using the SAS statistical package, version 5 (SAS Institute Inc., Cary, North Carolina).

Procedure. Plugs (4 mm diameter) of actively growing colonies were inoculated into 7-ml glass vials with ca. 1 ml of medium that solidified when the vial was horizontal. A filter paper disk (7 mm diameter) then was put on the inside of the vial's screw cap, 10–20 μl of extract were dispensed on the paper, and the vial was immediately closed very tightly. When applicable, the vials received ca. 5.0 mg of volatile terpenoids (Table 1), enough to saturate the vial's atmosphere. Once the vials were closed, they were grouped according to essential oil phenotype and put in tightly closed 1-liter jars sealed with parafilm. Cultures were incubated at 25°C in the dark for 15 days. At the end of the incubation period, linear growth approximated to the nearest 0.5 mm was measured under a dissecting microscope.

RESULTS

All the essential oil phenotypes showed statistically significant inhibitory effects on growth (Table 2). Phenotype IV was the most inhibitory, followed closely by phenotypes II and III. The least inhibitory was phenotype I (Table 2).

TABLE 2. RESULTS FOR NESTED ANOVA WITH TREATMENTS (ESSENTIAL OIL PHENOTYPES AND CONTROL), ISOLATE GROUPS, AND ISOLATES NESTED BY TREE OF ORIGIN[a]

Variation source	*DF*	MS	*F*	*P*
Treatments (T)	4	0.2676	35.4	≤0.005
Isolate groups (G)	4	0.0075	0.6	NS
T × G	16	0.0031	1.3	NS

	Overall growth average (mm) for the treatments (standard error in parentheses)
Control	9.55a (±0.50)
Phenotype I	4.70b (±0.36)
Phenotype II	2.74c,d (±0.22)
Phenotype III	3.86b,c (±0.33)
Phenotype IV	2.02d (±0.18)

[a] ANOVA was performed with arcsin of the square root of percent growth of the control divided by 1000. Means followed by the same letter are not significantly different according to Duncan's multiple-range test with $\alpha = 0.05$.

Stepwise multiple regression between isolate tolerance and the concentration of compounds in the essential oils showed that γ-terpinene was the only compound sufficiently significant to be included in the regression model. This monoterpene had a negative correlation with tolerance ($R^2 = 0.33$ $F = 24.19$, $P < 0.0001$). According to the model, γ-terpinene alone explains one third of the variance in tolerance. However, the sum of the concentrations of sabinene and γ-terpinene was correlated with 56% of the growth reduction of *Pleuroplaconema* sp. (Figure 2). On the other hand, phenotype III produced a growth reduction higher than expected according to the sum of these monoterpenes; phenotype I, with more sabinene and γ-terpinene than phenotype III, was less inhibitory (Figure 2).

Isolates from different trees did not grow uniformly as a group when exposed to volatiles of the phenotypes (Table 3). Isolate groups 2 and 4 reacted similarly to phenotypes I and III. Isolates from trees 1, 3, and 5 were similarly inhibited by phenotypes II, III, and IV. Groups from trees 2 and 4 were most inhibited by phenotypes IV and II. The standardized average response (as per-

cent of growth of control) shows that *Pleuroplaconema* sp. isolates grouped by origin vary relatively little in their strong inhibition response (Figure 3). Performance of the isolate groups exposed to volatiles of their original tree was not uniformly higher or lower compared to their performance with other phenotypes (Figure 3, Table 2). Contrary to our second hypothesis, all isolate groups were strongly inhibited when exposed to their original tree volatiles.

To determine the possibility that the isolates from each tree differed in growth rate both with and without essential oils, two-way ANOVAs were performed with the isolates grouped by origin in relation to their response to the essential oil phenotypes (Table 4). In all cases the phenotypes had a highly significant effect on the growth of *Pleuroplaconema* sp. Within each tree, all isolates (except the ones from tree 3) had a statistically significant different growth rate in the control and essential oil phenotype treatments combined (Table 5). Furthermore, the variance explained by isolates and the interaction term isolate by treatment in the ANOVAs were significant (Table 4). The interaction term indicates that at least one isolate within each tree was reacting differently to the essential oils. Although the amount of variance of these interaction terms is not large, the possibility that various genotypes of *Pleuroplaconema* sp. are producing this effect is high.

The relative tolerance of each *Pleuroplaconema* sp. isolate to the volatiles varied according to phenotype (Figure 4). This parameter was calculated by

dividing growth in the presence of the volatiles from a phenotype by growth with no volatiles. The variabilities in response to volatiles from phenotypes IV and II were the most restricted, with tolerance values mostly below 0.5. Tolerances to volatiles from phenotypes III and I were more evenly spread, with some isolates scoring responses in the 0.71–0.8 category, i.e., a mild growth inhibition. Pearson correlation coefficients among isolate performances with each essential oil phenotype showed that tolerances to phenotypes I, II, and III are highly correlated (Table 6). However, tolerance to phenotype IV showed no statistically significant correlation with that of other phenotypes. Stepwise multiple regression between growth in absence of volatiles and tolerance to the essential oil phenotypes showed that tolerance to phenotypes alone or in combination was never significant in explaining growth without volatiles.

DISCUSSION

Results from this experiment agree with previous work, finding that volatile terpenoids, alone and in mixtures, generally inhibit fungus growth (Cobb et al., 1968; Shrimpton and Whitney, 1968; De Groot, 1972; Väisälä, 1974; Benjalili et al., 1984; Thibault-Balesdent and Delatour, 1985; Tripathi et al., 1985; Bridges, 1987; Ennos and Swales, 1988). The essential oil phenotypes

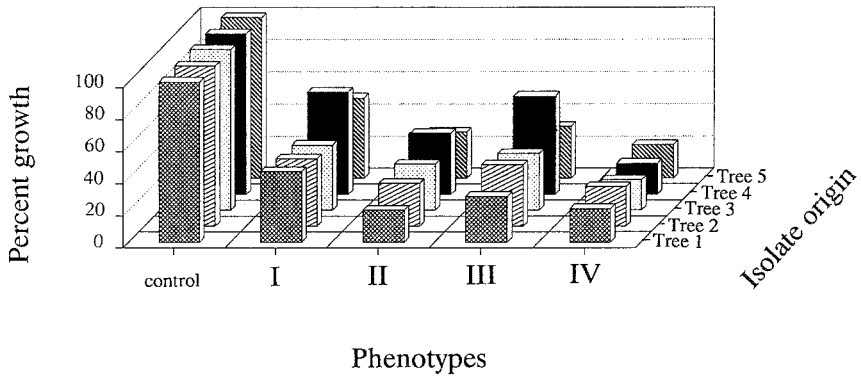

FIG. 3. Average growth response of groups of *Pleuroplaconema* sp. isolates to essential oil phenotypes from redwood. Isolates were grouped according to their tree of origin.

in this experiment have the same terpenoids, but some of them occurred in different concentrations. For example, the γ-terpinene concentration range in the phenotypes was sufficient to explain one third of the growth inhibition of *Pleuroplaconema* sp. in the multiple-regression analysis. Thus, this agrees with other results showing that growth inhibition intensity can be dose dependent (Väisälä, 1974; Flodin and Fries, 1978; Benjalili et al., 1984; Hall, 1985; Tripathi et al., 1985).

Two thirds of the variance in growth of *Pleuroplaconema* sp. were not explained by single components of the essential oils in the multiple regression analysis. This indicates that more than one terpenoid is important in affecting the endophyte or that other important components did not show sufficient variation to be detected by this analysis. In fact, the sum of the concentrations of sabinene and γ-terpinene correlated with the growth reduction of *Pleuroplaconema* sp.; the variance explained by the summed concentrations was almost twice as large as that explained by γ-terpinene alone. Fungi and other plant consumers generally encounter terpenoids in mixtures as in redwood. Single terpenoids assayed alone can be inhibitory, and some have been linked to resistance or susceptibility to fungus pathogens in conifers (Rockwood, 1974; Thibault-Balesdent and Delatour, 1985). In some cases, a single component of a terpenoid mixture may explain the growth inhibition of a fungus (Arrhenius and Langenheim, 1983). However, each of several terpenoids constituting such a mixture may frequently be able to inhibit the same fungus species (Cobb et al., 1968; De Groot, 1972; Flodin and Fries, 1978; Tripathi et al., 1985; Bridges, 1987). Thus, several compounds may be important when a fungus or other plant consumer encounters a terpenoid mixture, and synergistic, antagonistic, or additive effects of these compounds on consumers are possible (e.g., Chararas et al., 1982; Espinosa-García, 1991).

[d] Average from 19 measurements.

The redwood essential oil phenotypes were characterized by combinations of four or five compounds with relatively similar concentrations. However, the greater inhibition by phenotypes IV and II may partially result from greater concentrations of sabinene and γ-terpinene here than in the other types. Both compounds were equally inhibitory to *Pleuroplaconema* sp. in single-compound trials, and mixtures of these compounds inhibited the fungus in an additive way (Espinosa-García, 1991). Although these two monoterpenes combined may explain 56% of the inhibition by the phenotypes, discordant results with phenotypes I and III and the 44% unexplained growth reduction indicate that more compounds are important in the *Pleuroplaconema* sp. inhibition. Phenotype III, with the lowest concentration of sabinene and γ-terpinene, produced stronger inhibition than did phenotype I, which had a higher concentration of these monoterpenes. Perhaps the high proportion of β-phellandrene or its combination with other monoterpenes in phenotype III is producing this effect. Thus, additive effects or synergism of the redwood essential oils components acting on the endophyte would seem to provide a reasonable explanation for our results.

Water dispersal makes host reinfection by the same *Pleuroplaconema* sp. strains highly probable, and its endophytic habit greatly increases the likelihood of contact with the host's leaf volatiles. For these reasons, we hypothesized that strains of the endophyte would be adapted to specific phenotypes. Adaptation to single hosts has been proposed for a pine canker fungus (Ennos and Swales, 1988) and pine leaf-scale insects (Edmunds and Alstad, 1978). Our results, however, do not support this hypothesis, because the isolates were strongly

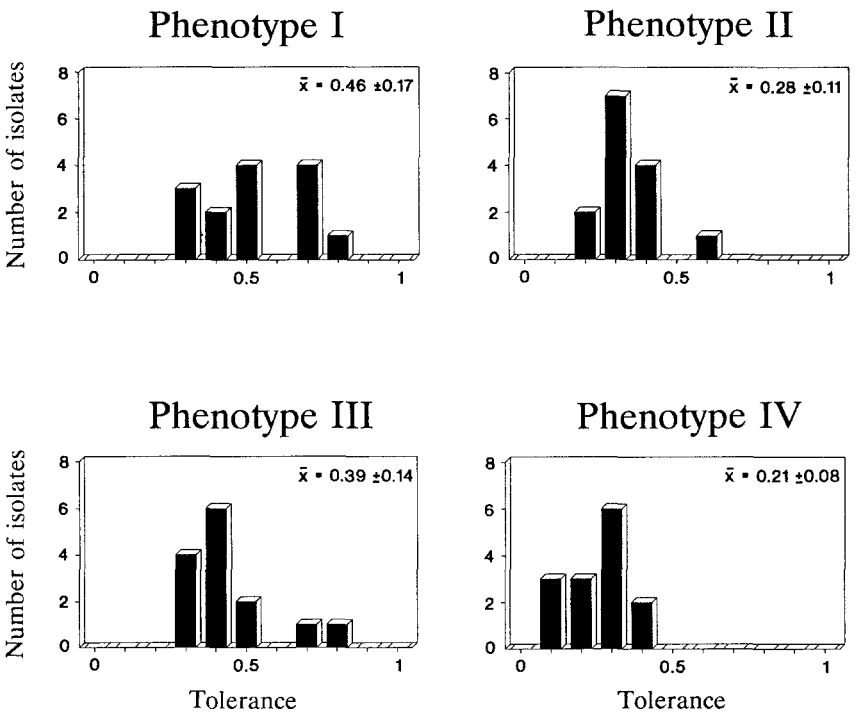

FIG. 4. Tolerance of individual isolates of *Pleuroplaconema* sp. to essential oil phenotypes from redwood foliage. Tolerance = growth with essential oil/growth without essential oil.

inhibited when exposed to the essential oil phenotypes from their original trees. In fact, the ubiquitous and abundant redwood symbiont showed a rather uniformly high susceptibility to its host's volatile terpenoids. This result is puzzling considering the possible pathogenic ancestry of *Pleuroplaconema* sp. and the fact that growth of some fungus pathogens is differentially affected (inhibited or stimulated) by the terpenoids of their hosts (Bridges, 1987). This variable response occurs in single strains of the pine canker pathogen *Crumenulopsis sororia*, which react differently to single monoterpenes of their host (Ennos and Swales, 1988). This further suggests that a host population that has individuals with different essential oil phenotypes will be "perceived" differently by fungi; some trees would be suitable for some fungus individuals whereas some others would be unsuitable. Moreover, variability in resistance traits (e.g., monoterpenes) and virulence traits (e.g., monoterpene tolerance) has been suggested to be common in plant–fungi pathosystems (Ennos and Swales, 1988). Therefore,

TABLE 6. PEARSON CORRELATION COEFFICIENTS (r) AMONG ISOLATE PERFORMANCES WITH EACH ESSENTIAL OIL PHENOTYPE (P)

[c] $P < 0.005$.
[d] NS = nonsignificant.

Pleuroplaconema sp. may be "perceiving" redwood individuals as similar, thus reacting to essential oils as a nonpathogenic fungus.

The different overall reaction of the isolates from a tree to all treatments and the variance explained by the isolates alone and in combination with the treatments suggest that different genotypes of *Pleuroplaconema* were colonizing single branches of redwood. Carroll (1990) anticipated this kind of multiple simultaneous infection of the same host by different strains of the same endophyte that has been demonstrated for fungus pathogens (Day, 1980; Ennos and Swales, 1988).

Only a few examples have documented variability in susceptibility to terpenoids within populations of fungi. Ennos and Swales (1988) showed that *Crumenulopsis sororia* displays either a wide or narrow variability in tolerance to single monoterpenes of its host. This differential tolerance was heritable, and for some compounds heritability was very high. They thus suggested that these traits have adaptive values. Mean tolerance values to five monoterpenes in *C. sororia* were never below 0.55 and frequently above 0.65. The mean tolerance values of *Pleuroplaconema* sp. to the volatiles of the redwood phenotypes were always below 0.5 (Figure 4). The distribution of tolerance values to the phenotypes was skewed toward the high susceptibility side for three phenotypes. Tolerance to phenotype I was the only one with a wider range. If tolerance to terpenoids is heritable, with adaptive value in conifer pathogens, and *Pleuroplaconema* sp. has a pathogenic ancestry, we might speculate that tolerance to terpenoid mixtures would have been selected against in this redwood symbiont in its evolutionary history.

Pleuroplaconema sp. tolerance to three essential oil phenotypes was correlated, but growth performance with phenotype IV was not correlated with other phenotypes. Tolerance to monoterpenes in some pathogenic fungi has been suggested to be controlled by one or a few related mechanisms (Thibault-

Balesdent and Delatour, 1985; DraczynskaLusiak, 1987; Ennos and Swales, 1988). Analogously, *Pleuroplaconema* sp. might have a common tolerance mechanism in dealing with essential oils phenotypes, although some components or a particular combination in phenotype IV would require a different tolerance mechanism.

The absence of correlation between growth with no terpenoids and tolerance to the essential oil phenotypes probably indicates that this trait is not costly in terms of linear growth to *Pleuroplaconema* sp. This lack of association also has been shown for *Crumenulopsis sororia* and its host's monoterpenes (Ennos and Swales, 1988), but its significance is not clear to us.

Pleuroplaconema sp. shows a relatively high susceptibility to redwood volatile terpenoids when compared with other endophytic fungi. Fungus species that can have endophytic stages, but that are known to be pathogenic to redwood, are less inhibited by redwood essential oil phenotypes than *Pleuroplaconema* sp. (Espinosa-García, 1991). Low virulence in some pathogenic fungi has been associated with inability to break down host secondary compounds formed after fungus infection, i.e., phytoalexins (VanEtten et al., 1989). Although the phytoalexins in those pathosystems were phenolic compounds, a similar process might occur with either preformed terpenoids or those that are induced. The higher sensitivity of *Pleuroplaconema* sp. to redwood terpenoids may be associated with a process of increased susceptibility to the host secondary chemicals with concurrent pathogenicity attenuation. In this scenario, terpenoids must be defensive against pathogens, and selection against this tolerance in the fungus symbiont would be viable. Otherwise, the balance would be tilted toward the pathogenic side of the symbiosis. A possible relationship between increased specialization in endophytic lifestyle, with low or null pathogenic potential, and high susceptibility to the host secondary chemicals may be worth exploring in plant–endophyte systems where mutualism is known or suspected.

The sensitivity of *Pleuroplaconema* sp. to its host terpenoids also may be explained if these compounds are important in maintaining the apparent inactivity of the fungus after colonization. Krupa and Fries (1971) demonstrated that *Boletus variegatus*, an ectomycorrhizal fungus, induces high amounts of volatile terpenoids when it colonizes roots of *Pinus sylvestris*. This induction, as well as the antifungus properties of terpenoids, led these authors to propose a model in which host terpenoids, and other nonvolatile secondary compounds, would restrict the growth of the fungus symbiont and maintain the mutualistic state. The redwood–*Pleuroplaconema* sp. relationship might fit a similar model, but with preformed terpenoids as controlling agents.

To consider that *Pleuroplaconema* sp. activity is controlled by terpenoid volatiles would require that their concentrations in mature leaves would suppress fungus growth. This could be accomplished by the activity of the volatiles regardless of the leaf nutritional quality for the fungus or because a low nutri-

tional quality induces a higher susceptibility in the endophyte. Although the 5 mg of volatiles per vial used in the experiment were enough to initially saturate the vial's atmosphere (1.4–1.5 mg of a monoterpene are enough to saturate 6 ml of air), they did not completely halt the growth of any isolate. Experiments performed with the same incubation vials and a constantly maintained saturated atmosphere of sabinene or γ-terpinene completely stopped *Pleuroplaconema* sp. growth (Espinosa-García, 1991). Concentrations of these compounds, which were sufficient to saturate initially the vial atmosphere, did not halt the growth of this fungus. Hence, essential oil loss or inactivation probably prevented a stronger inhibition of *Pleuroplaconema* sp. in this experiment, and a saturated atmosphere that was maintained longer would completely halt the growth of this endophyte. The considerable emission of volatile terpenoids to the atmosphere by conifer foliage (e.g., Yokouchi and Ambe, 1984; Schindler and Kotzias, 1989) indicates that internal atmospheres of conifer leaves, such as redwood, are likely to be saturated with terpenoids. In spite of monoterpene loss from the redwood leaf, the total amount of monoterpenes and their profile apparently vary little after the leaf reaches maturity (Hall and Langenheim, 1986a). Thus, the internal atmospheres of redwood leaves are probably supplied constantly with volatile terpenoids escaping from the resin ducts, and these compounds are affecting *Pleuroplaconema* sp. The total amount of leaf redwood monoterpenes decreases by half in senescent leaves (Hall and Langenheim, 1986b). This drop could be attributed to the failure of the leaf to replace compounds lost to the atmosphere or possibly to some catabolism (Croteau, 1988; Njar et al., 1989). In this context, *Pleuroplaconema* sp. may be kept inactive by redwood's terpenoids at certain levels, but the fungus may be released when these decrease to lower amounts. This possibility would require a relatively uniform effectivity of the essential oil phenotypes against all genotypes of the fungus, which appears to be the case. This experiment simulated internal atmospheres of redwood leaves, but other conditions of living leaves are more difficult or impossible to manipulate. Although these factors within living leaves could influence the response of endophytes to essential oils, this experiment is the first approach that will lead to further investigations on the relationships between *Pleuroplaconema* sp. and redwood leaves.

The apparent inactivity of other endophytes within leaves may be maintained or influenced by secondary chemicals. *Colletotrichum gloesporioides*, the anthracnose fungus of citrus, infects a leaf and after a long period can colonize one cell or remain apparently inactive as a small intercellular hypha. The infections are asymptomatic unless leaves are detached or the plant is put under stress (Tokunaga and Ohira, 1973). *Pestalotia subcuticularis* also can form asymptomatic infections in attached leaves of *Hymenaea courbaril* seedlings and can be isolated from apparently healthy leaves. However, it readily produces necrotic spots in detached or senescent leaves and also can be found in a

pathogenic state attacking mature leaves (Nascimento, 1980; Fail and Langenheim, 1990). Furthermore, *P. subcuticularis* produced asymptomatic infections in greenhouse experiments with seedlings of *H. courbaril* and *Copaifera pubiflora*, but 12-year-old saplings developed visible symptoms (Arrhenius and Langenheim, 1986). Seedlings of these tropical tree genera typically show higher yields of sesquiterpenoid resin than their parent trees, and generally fungus attack is much heavier on leaves of parent trees than on the seedlings (Nascimento, 1980; Langenheim, unpublished results). These cases, as well as those documenting pathogenicity of endophytes when plants are under stress (Millar, 1980; Andrews et al., 1985) and where endophytes are activated after herbivore attack (Carroll, 1986) may indicate that plant endogenous factors, actively kept at certain levels by the plant, are controlling the activity of endophytic fungi. Although changes in nutritional quality of plant tissues to the fungi probably are important, secondary chemicals, such as essential oils tested in this experiment, are possibly one of the proximate and/or ultimate causes of the apparent inactivity in some endophytes.

Acknowledgments—We wish to thank Dr. G.C. Carroll, Dr. F. Cobb, Jr., Dr. G.R. Lazo, J. Rollinger, R. Goralka, Dr. S. Schwab, and two anonymous reviewers for their comments on the manuscript. We also appreciate E. García-Márquez's help during the setup of the experiment. We are also grateful to G. Hall and S. Wood for the help with statistical analysis and the extraction process of some essential oils, respectively. This work was partially funded by U.C.S.C. Faculty Research funds grant to J.H.L., and graduate student grants to F.J.E. from the U.C.S.C. Biology Department. F.J.E. wishes to thank the Universidad Nacional Autónoma de México and México's Consejo Nacional de Ciencia y Tecnología for supporting him with a fellowship during the period of this study.

(Received January 17, 1991; accepted May 16, 1991)

Abstract—Surface extracts of the leaves of five species in the Umbelliferae, *Citrus limon* (Rutaceae), and *Psoralea bituminosa* (Leguminosae) were examined for the presence of coumarins, after a previous study had shown the presence of three psoralens. In the current investigation eight more coumarins were identified by mass spectrometric techniques: the simple coumarins scopoletin, scoparone, and osthol, the linear furanocoumarins imperatorin and phellopterin, the angular furanocoumarins angelicin and pimpinellin, and the pyranocoumarin seselin. Five of these occur in *Apium graveolens*, and scopoletin, scoparone, and imperatorin were each found in three of the species examined. The co-occurrence of all these coumarins on the surface may be significant in communication between the plant and its environment.

Key Words—Furanocoumarins, coumarins, mass spectrometry, leaf surface.

INTRODUCTION

Psoralen, xanthotoxin, and bergapten are the most common linear furanocoumarins (psoralens) of plants in the families Umbelliferae, Rutaceae, and Leguminosae, and recent studies in our laboratory have demonstrated their presence, to some extent, on the surface of leaves (Zobel and Brown, 1988b, 1989, 1990a) and fruits and seeds (Zobel and Brown, 1991). Their existence within the seeds and fruits of these families has long been known (Murray et

*To whom correspondence should be addressed.

0098-0331/91/0900-1859$06.50/0

al., 1982), with new compounds continually being found (Ceska et al., 1987, 1988). The concentrations and proportions of the three main psoralens on plant surfaces vary during the vegetative periods (Zobel and Brown, 1990b) and are influenced by air pollution (Zobel et al., 1991), as is the concentration in the whole leaf (Dercks et al., 1990; Zobel et al., 1991). Concentrations of furanocoumarins are also increased by other environmental stress (Beier and Oertli, 1983; Zangerl and Berenbaum, 1987), as well as by fungal infections (Ashwood-Smith et al., 1985; Surico et al., 1987), or treatment with elicitors (Matern et al., 1988).

Many toxins formed within a plant can be extruded outside the cells where they are synthesized and are thus prevented from being toxic to these cells. Both quality and quantity of these extruded compounds must be important for a defensive role in the plant (Beier and Oertli, 1983; Nitao and Zangerl, 1987; Städler and Buser, 1984; Towers, 1987; Zobel and Brown, 1989).

An extraction method has been developed recently in this laboratory for removing compounds from the plant surface without damaging epidermal cells (Zobel and Brown, 1988a). Research utilizing this approach has laid new stress on the plant surface as a compartment for keeping phenolic compounds isolated from sites of potential damage and as the first barrier in the contact between the environment and the plant body (Zobel and Brown, 1989). During analysis of surface extracts of plants causing dermatitis (Zobel and Brown, 1990a), a number of unidentified compounds were found in addition to psoralen, xanthotoxin, and bergapten. The aim of the present work has been to identify those compounds for which quantities and chromatographic separation were adequate.

METHODS AND MATERIALS

Plant Material. Leaves of *Psoralea bituminosa, Ferula communis* var. Glauca, *Pastinaca sativa, Apium graveolens, Pimpinella anisum*, and *Citrus limon* were obtained from the Royal Botanical Gardens, Hamilton, Ontario; *Heracleum lanatum* was collected from the campus of Trent University, in July 1989.

Analytical Techniques. Relatively clean extracts of surface deposits were obtained by briefly dipping leaves in almost boiling water as previously described (Zobel and Brown, 1988a, 1989). HPLC analysis was performed as described by Thompson and Brown (1984), on a 7.5-cm Nova-Pak C_{18} column eluted with 15% aqueous acetonitrile. Up to 2 ml of eluate was concentrated to 30 μl by evaporation at 70°C, and the residue was transferred to a capillary tube and dried at room temperature. Each capillary tube was inserted directly into the solids probe of a ZAB-2FQ mass spectrometer. The probe temperature was 100°C and the source temperature was 250°C. Chemical ionization (CI)

mass spectra were obtained with isobutane as the CI agent, at an indicated pressure in the source housing of 3×10^{-5} mbar (3×10^{-3} Pa), which corresponds to a source pressure of ca. 1 mbar (100 Pa). Helium was used as the collision gas for collision-induced dissociation (CID) with a beam attenuation of ca. 20%.

RESULTS AND DISCUSSION

Seven plant species previously investigated by us for localization of psoralen, xanthotoxin, and bergapten on the surface (Zobel and Brown, 1988b, 1990a) contained other coumarins, unidentified at the time, which also had been extruded to the surface of the cuticle covering their leaves (unpublished). Eight additional coumarins have now been identified by means of CI mass spectrometry (Munson and Field, 1966) with isobutane as the CI agent (Harrison, 1983).

Mass Spectrometric Analyses. Pure samples of eight coumarins from our collection were examined mass spectrometrically, and the electron impact (EI), CI, CID and mass-analyzed ion kinetic energy (MIKE) mass spectra (Cooks et al., 1973) of each were examined. The relative ion intensities of these mass spectra are shown in Tables 1–4.

The relative ion signal intensities for four types of mass spectra are given in Table 1 for each of scopoletin (Scheme 1, **1a**), and osthol **(1b).** For each species, the base peak in the EI mass spectrum is the molecular ion. The principal fragment ions observed for **1b** and the corresponding neutral losses were *m/z* 213 ($CH_3\cdot$), *m/z* 201 (CO + $CH_3\cdot$), *m/z* 189 (55 amu, possibly $C_4H_7\cdot$), and *m/z* 175 ($C_5H_9\cdot$). For **1a** the principal fragment ions were *m/z* 177 ($CH_3\cdot$), *m/z* 164 (CO), and *m/z* 149 ($CH_3\cdot$ + CO).

[b] Chemical ionization mass spectrum with isobutane as a CI agent.
[c] Collision-induced dissociation mass spectrum of $(M + 1)^+$ using He as collision gas.
[d] Mass-analyzed ion kinetic energy spectrum of $(M + 1)^+$.
[e] Overlapping.

Isobutane CI produced ion signals due to $(M + 1)^+$ for each of **1a** and **1b;** the signal intensities of $(M + 1)^+$ accounted for ca. 50% of the total ion intensity, with the remaining ion signals corresponding to the principal components of the EI mass spectrum. The CID mass spectrum of $(M + 1)^+$ for **1a** was dominated by losses of $H\cdot$, H_2, and $CH_3\cdot$, with the ion of *m/z* 178 forming the base peak both in the CID and MIKE mass spectra. In each mass spectrum, neutral losses of ca. 30 amu, that is, CO, HCO, and possibly H_2CO, were accompanied by relatively large releases of kinetic energy, which produced overlapping fragment ion peaks. The CID and MIKE mass spectra were dominated by the loss of a moiety of 56 amu leading to formation of *m/z* 189.

The mass spectra of imperatorin (Scheme 2, **2a**) and phellopterin **(2b)** as shown in Table 2 exhibit the effect of 5-methoxylation on the stability of the prenylated coumarins. The molecular ion is weak in the EI mass spectrum of each compound, and the base peak corresponds in each case to loss of the prenyl ($C_5H_9\cdot$) moiety. Further loss of CO to form *m/z* 173 is a dominant process for **2a,** whereas further loss of CH_3 to form *m/z* 216 is favored for **2b.** As the $(M + 1)^+$ is twice as intense relative to the base peak of the CI mass spectrum as is the $(M + 1)^+$ ion for **2a,** it appears that methoxylation may stabilize the protonated coumarin with respect to prenyl loss. The CID and MIKE mass spectra of the $(M + 1)^+$ ions of **2a** and **2b** are dominated by the loss of C_5H_8.

The mass spectra of seselin (Scheme 3, **3**), shown in Table 3, are dominated by the formation of *m/z* 213 due to $CH_3\cdot$ loss from the molecular ion and CH_4 loss from $(M + 1)^+$. Rearrangement of the dimethylpyran structure to lose methyl and formation of a seven-membered ring is known. Further loss of CO to form *m/z* 185 is prevalent.

The mass spectra of angelicin (Scheme 4, **4a**) and pimpinellin **(4b)** shown in Table 4 once more indicate enhanced stabilization due to methoxy substitution: the molecular ion of **4b,** dimethoxy substituted **4a,** is the base peak in the

indicates the somewhat unusual unimolecular losses of 13, 44, and 56 amu to yield fragment ions of *m/z* 174, 143, and 131, respectively. Loss of $CH_3\cdot$ to form *m/z* 232 is the dominant feature of both the CID and MIKE mass spectra of **4b.** Additional decomposition channels involved losses of HCO to form *m/z* 218 and (HCO + CH_3) to yield *m/z* 203.

Distribution. The distribution of the eight coumarins is as follows: (1) *Apium graveolens:* scopoletin **(1a),** osthol **(1b),** scoparone **(1c),** imperatorin **(2a),** phellopterin **(2b);** (2) *Pimpinella anisum:* scopoletin, imperatorin, seselin **(3),** scoparone **(1c);** (3) *Psoralea bituminosa:* angelicin **(4a);** (4) *Citrus limon:* scopoletin, scoparone, seselin; (5) *Heracleum lanatum:* phellopterin, pimpi-

SCHEME 4

nellin **(4b)**; (6) *Ferula communis* var. Glauca: imperatorin; (7) *Pastinaca sativa:* imperatorin.

As shown, we identified only one additional coumarin in the last three species, and the highest number was five in *A. graveolens*. Imperatorin, scopoletin, and scoparone were the most often identified, although some additional peaks remain to be characterized. Scopoletin, an acidic coumarin, should have been removed completely by extraction with dilute alkali during the purification (Zobel and Brown, 1988a), and its presence in this fraction suggests carryover from a high concentration on the surface.

Tissues of some of these species are known to contain the above-mentioned coumarins (Murray et al., 1982): angelicin in *P. bituminosa* (Samylina, quoted by Murray et al., 1982), imperatorin in *Pastinaca sativa* (Soine et al., 1956; Beyrich, 1966), pimpinellin and phellopterin in *H. lanatum* (Steck, 1970), and scopoletin in *Pimpinella anisum* and *Citrus limon* (Kartnig et al., 1975; Feldman and Hanks, 1965). Some other compounds were found for the first time in the seven species examined here but had been known to occur in other species of these genera (Murray et al., 1982). Thus we foresee the identification of more coumarins on plant surfaces, not only on leaves and fruits, but perhaps even on root surfaces.

While there are still some unidentified peaks in the plant surface extracts, the complexity of the mixtures extruded to the surface is clearly revealed even by the number of coumarins already shown to be present. Quantitative and possibly qualitative changes, such as those already demonstrated on the surface of *H. lanatum* for psoralen, xanthotoxin, and bergapten, may also occur during the vegetative period. Some compounds may be in such small concentrations on the surface that only very sophisticated methods could show their presence, e.g., bioassay for the identification of psoralens on *Daucus carota* leaves, as performed by Ashwood-Smith's group (Ashwood-Smith et al., 1983; Ceska et

al., 1986), but they could still play an important role because of possible synergistic reactions, as has been shown for xanthotoxin and myristicin (Berenbaum and Neal, 1985).

Ecological Implications. Furanocoumarins develop in a plant qualitatively and quantitatively in coevolution with certain insects (Berenbaum, 1978; Berenbaum et al., 1986; Feeny, 1987) and can act not only as insect repellents, but also as attractants for some insects, stimulating oviposition, as by the carrot fly on *Daucus carota* (Ashwood-Smith et al., 1983; Städler and Buser, 1984; Ceska et al., 1986). Besides furanocoumarins, which were in very low concentrations, these authors found other compounds on carrot leaves in higher concentrations than xanthotoxin and psoralen.

The present study shows that this newly recognized compartment, the plant surface, is a repository for numerous compounds. Flavonoids (Wollenweber and Dietz, 1981; Wollenweber, 1986) are the only other large group of phenolic compounds proved to be in substantial concentrations on the surface of many plant species. The concentrations, proportions, and degree of volatility of substances on the plant surface may prove to be a key to explaining communication among plants, and between plants and insects, as well as other herbivores. They could well be concerned, too, in self-protection against changing environmental conditions, as their concentrations change with varying environmental conditions (Zobel, 1991). Our investigations to date represent only the first steps in probing the complexity of the protective epicuticular wax layer and the atmosphere surrounding the plant.

Acknowledgments—This study was financially supported by the Natural Sciences and Engineering Research Council of Canada operating grants A2502 to R.E.M. and A2487 to S.A.B. We are grateful to Dr. James Pringle of the Royal Botanical Gardens for his assistance in collecting plant material.

(Received February 4, 1991; accepted May 16, 1991)

Abstract—The content and distribution of amathamide alkaloids within single colonies of the bryozoan *Amathia wilsoni* (Ctenostomata) varied depending on the location in the colony. Three colonies in all, collected from the same site at the same time, were analyzed and gave very similar results. The outermost, more exposed, tips of the colony had an alkaloid content of nearly 9% of dry weight, while basal parts were apparently devoid of alkaloids. Samples taken midway between tips and base yielded intermediate concentrations of about 1%. Very little variation in the proportions of individual amathamides A, B, C, E occurred between exposed tips of the colonies. However, some differences in ratios were found between tips from exposed and more protected regions.

Key Words—*Amathia wilsoni*, bryozoans, amathamides A, B, C, D, E, alkaloid distribution.

INTRODUCTION

Much of the interest in marine chemical ecology has developed from the study of marine natural products. These organic compounds, which are also known

*To whom correspondence should be addressed.

0098-0331/91/0900-1871$06.50/0

as secondary metabolites, are often postulated to be mediators in marine ecological interactions. The roles played by secondary metabolites in the terrestrial environment have been relatively well studied, particularly in the case of compounds from higher plants. This is not so for marine natural products. During the last three decades a considerable number of compounds, having a wide variety of novel functional groups and structures, have been discovered from marine organisms (Faulkner, 1990). Although some of these compounds have biological activity that is of potential pharmacological value, only a few of them have been investigated for their ecological functions (Bakus et al., 1986). Most studied have been the secondary metabolites from marine algae and their involvement in predator–prey relationships (Norris and Fenical, 1982; Van Alstyne, 1988). The ecological significance of compounds originating from marine invertebrates has been reviewed recently (Coll and Sammarco, 1988). Several functions have been ascribed to metabolites from soft corals, while antifouling agents from sponges (Sears et al., 1990), gorgonians (Gerhart, 1986; Rittschoff et al., 1985), and ascidians (Davis and Wright, 1990) have been reported also (Bakus et al., 1986).

The secondary metabolites of bryozoans have been relatively poorly investigated; one reason for this is collection constraints (Faulkner, 1990). Most bryozoan natural products are alkaloids. A wide range of structural types has been described, and some compounds have pronounced biological activity such as the antitumor action of the bryostatins (Suffness et al., 1989). In one of the very few investigations of the ecological significance of bryozoan metabolites, the roles played by tambjamine alkaloids have been described. These compounds are produced by the bryozoan *Sessibugula translucens* and have a range of activities including fish feeding inhibition and antimicrobial action. The tambjamines were also shown to be sequestered and utilized by two species of nudibranchs that grazed on a bryozoan and by a third nudibranch, which in turn preyed upon the two other bryozoan-eating nudibranchs (Carté and Faulkner, 1983).

Amathia wilsoni (Ctenostomata) is the largest and most common bryozoan occurring in Tasmanian coastal waters. Previously we have shown that this bryozoan gives rise to a series of amathamide alkaloids (A–F) and a possible biosynthetic precursor 2-(2,4-dibromo-5-methoxyphenyl)ethanamine (Blackman and Matthews, 1985; Blackman and Green, 1987; Blackman and Fu, 1991). The proportion of total alkaloid and relative amounts of alkaloids A–F from different colonies at the same locality was essentially identical and did not show any significant seasonal variation. Collections from different locations did, however, exhibit considerable variation in these characteristics. In this paper we report on the alkaloid distribution within single colonies collected at the same site and time.

METHODS AND MATERIALS

During September 1990, colonies of *Amathia wilsoni* were collected from waters 5–10 m deep, surrounding Arch Island, SE Tasmania (43°17′S, 147°10′E). After collection, colonies were cleaned of any visible fouling organisms, individually packed, and kept at 0°C until transported to the laboratory, where they were stored at −20°C.

Eight samples of colonial material (3–4 cm) were selected from varying parts of two colonies. Dry weight was recorded after freeze drying for 48 hr. Before extraction, an internal standard (eicosane) was added to each sample. Each sample was extracted with 1 ml of freshly distilled dichloromethane three times. The resultant combined crude extracts were stored at 0°C until analysis using GC-MS. Five amathamides (A–E) were identified from these samples, F was below the detection level.

A third colony was used to develop a more detailed map of the amathamide distribution. The colony was placed on graph paper, and the size and arrangement of the main and side branches traced. Sequential samples comprising approximately 2 cm of colony material then were removed from one third of the colony. Their orientation and position were recorded. Each sample then was freeze-dried before extraction using the method described above. The smaller portions for individual analyses were removed from this colony in order to obtain higher spatial resolution of amathamide distribution within the colony. As a consequence, only four amathamides were identified from these samples; amathamides D and F were below the detection level.

The various crude extracts were analyzed by GC-MS. The amathamides do not give strong molecular ions. Mass spectra of these compounds are therefore dominated by the *N*-methylpyrolidine fragment (*m/z* 84 base peak). The lack of fragmentation makes identification using mass spectra difficult, and so to identify the bases in the crude extract GC retention times of the amathamides were compared with those of isolated pure amathamides. For greater resolution and for targeting of specific ions, the selected ion monitoring facility of the Hewlett Packard 5970 mass selective detector (Sweeley et al., 1966) was used.

Gas chromatography was performed on a Hewlett Packard 5890A gas chromatograph using a 18-m methylsilicone column with a head pressure of 10 psi. An initial temperature of 50°C was used in the oven program. This was followed by a ramp of 30°C every minute up to 150°C with a subsequent reduction to 10°C/minute up to a final temperature of 300°C. The ions chosen for the selective monitoring were the characteristic amathamide base peak and internal standard fragment ions. The peak areas were calculated using the integration software on the HP5970.

We have assumed that the behavior of the various amathamides is con-

sistent during GC. A calibration curve of the internal standard peak area to the peak area of a chosen amathamide at varying concentrations was calculated to allow for the nonlinear relationship between internal standard peak area and amathamide peak area. In this way absolute concentrations of alkaloids were calculated on a percentage dry weight basis.

RESULTS

Amathamide concentrations of different sections of two colonies of *A. wilsoni* are shown in Table 1. From the table it can be seen that total concentrations and proportions of the five amathamides are very constant in samples from the tips of the two colonies. Samples from the bases of the colonies differed markedly from the tips in yielding no detectable amathamides. In general the middle portion of a colony yielded a concentration approximately 0.1 times that in the tip. Colony tips yielded an average of 0.087 g/g, middle portions 0.0087 g/g, and base regions 0 g/g dry weight total amathamide. Figure 1 traces 1–3 show typical GC-MS traces for samples from a colony tip, mid-portion, and base.

Figure 2 shows in greater detail the distribution of total alkaloid content and proportions of the four major amathamides in portions of two branches of a single colony. Again, the increase in alkaloid concentration towards the exposed tips is evident. Proportions of the major amathamides vary in ways that bear no clear relation to location in the colony. Amathamide C, although varying from 37.7% to 68% of the total, is always the major component. The greatest variability is in the proportion of B, which ranges from 3% to 26.4% of the total, with the lowest values occurring in exposed tip samples. Amathamide A

"Below detection level.

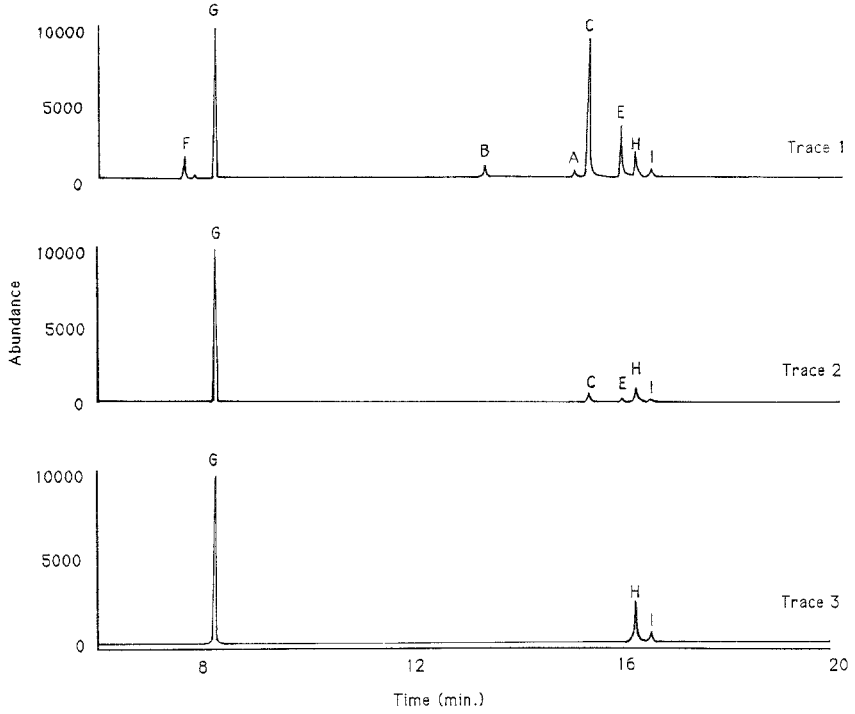

FIG. 1. Typical full-scan GC traces of sections of an *A. wilsoni* colony. Trace 1, tip sample; trace 2, intermediate, and trace 3, basal. A: amathamide A, B: amathamide B, C: amathamide C, E: amathamide E, F unidentified peak, G: internal standard, H: cholesterol, and I: unidentified sterol.

proportions in general vary in the same way as those of B, and concentrations of these two are inversely related to that of C. Proportions of amathamide E vary only from 17.1% to 27.7%. These data with additional measurements from other parts of the colony are given in Table 2 and their locations shown in Fig. 3.

Primary metabolites were found consistently in all GC traces from tip, intermediate, and base samples in similar amounts. This suggests that the proportion of living to inert material was comparable in each of the regions sampled with the exception of the basal attachment structure. These metabolites are detailed in Figure 1.

DISCUSSION

We have demonstrated a gradient in concentration of alkaloid secondary metabolites from high levels in exposed tips to undetectable at the base within three colonies of *A. wilsoni* collected at the same time and at the same location.

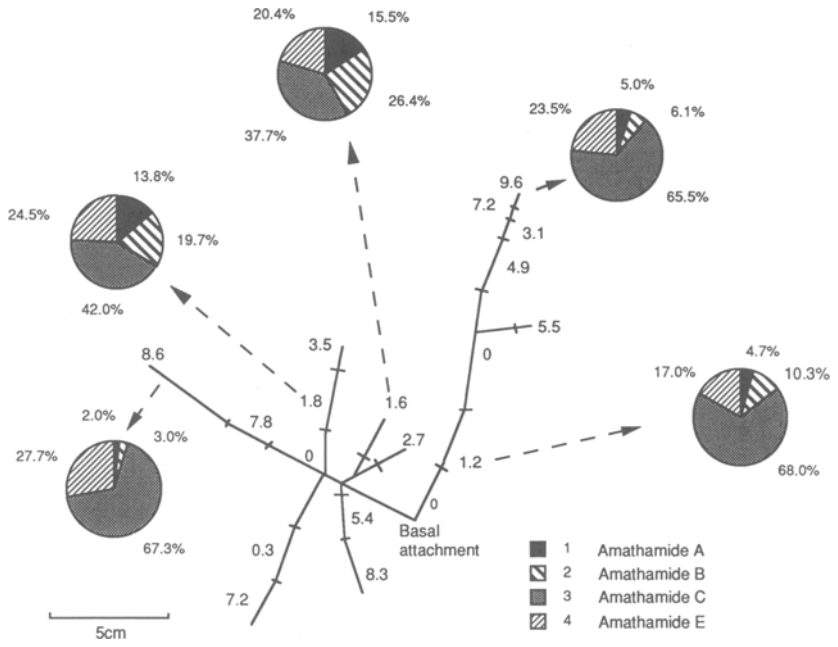

FIG. 2. Schematic of a section of a colony of *A. wilsoni* showing two major branches with associated subbranching. Numbers represent total amathamide as a percentage dry weight at each location. Pie charts represent the proportion of the major amathamides at the position indicated by the arrows. (Branch angles are schematic only.)

Samples taken midway between tips and base of a colony yielded concentrations approximately 0.1 times that of the tips. Exposed tips (those found at the periphery of the colony) exhibited a higher overall alkaloid content and different alkaloid proportions when compared to tips sampled from the interior of the colony. The concentrations reported here are the highest recorded for amathamides and the highest found for any alkaloid compounds in bryozoans. We calculate that total alkaloid concentration for a whole *A. wilsoni* colony would have been about 0.9% of dry weight. Macroalgae commonly yield secondary metabolites in comparable concentrations to those described in the present paper (e.g., phlorotannins in brown algae up to 12% dry weight; Steinberg, 1986).

Blackman and Green (1987) recovered 0.25% (of dry weight) crude alkaloid material from *A. wilsoni* and a range of 1×10^{-3} to 8×10^{-2}% for isolated individual amathamides. They used whole colonies in their procedure, and this may explain why their yields were substantially lower than in the present paper. Other secondary metabolites recovered from bryozoans have been generally in the range of 8×10^{-5} to 0.45% (flustramines); 0.45% (tambjamines); and 7.5

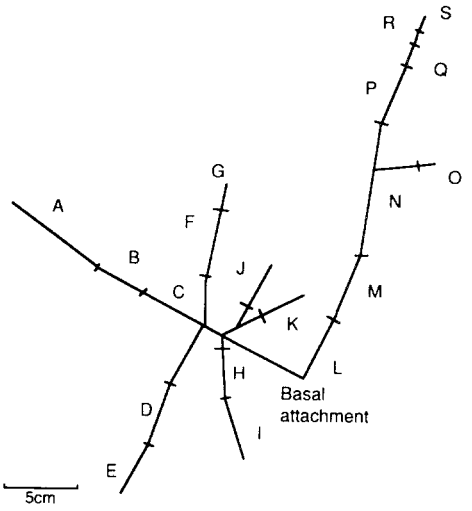

FIG. 3. Schematic of a section of a colony of *A. wilsoni* showing two major branches with associated subbranching. Numbers refer to location within the colony. Amathamide proportions at each location are detailed in Table 2. (Branch angles are schematic only.)

$\times 10^{-3}$ to 1.14×10^{-2}% (bromogramine-derived alkaloids) (Christophersen, 1985). The figures quoted are for isolated compounds, and considerable losses are experienced during the purification process. Thus many of these compounds may be similarly differentially distributed within colonies, and much higher yields from selected regions can be anticipated.

The ecological significance of this nonuniform distribution in alkaloid concentration is not yet clear. Several secondary metabolites of bryozoans have been implicated in protection from grazers, and in antifouling. For example, extracts of *Flustra foliacea* were shown to be effective antifoulants (Christophersen, 1985) and to be acutely toxic to larvae of another bryozoan (Dyrinda, 1983). *Sessibugula translucens* produces tambjamines that are believed to be defense secretions acting to deter grazers, although some nudibranch predators are able to exploit these metabolites for their own defense (Carté and Faulkner, 1983).

Spatial differences in distribution of secondary metabolites have been inferred in marine algae and in a bryozoan by reference to antibiotic properties (Al-Ogily and Knight-Jones, 1977). They showed that older parts of a colony of *Flustra foliacea* were more effective in producing inhibition zones in bacterial cultures than younger growing surfaces. Noting an inverse correlation between antibiotic activity and larval settlement, they suggested that settling

larvae of spirorbids and another bryozoan were avoiding the areas of antibacterial activity. By settling preferentially on the youngest sections, larvae would gain the advantage of less intense spatial competition, although other explanations of the observed distribution are possible (Davis et al., 1989). In contrast, other workers have shown that actively growing tips of some algal species display maximal antibacterial activity (Sieburth and Conover, 1965).

Concentration of secondary metabolites in one area of the colony does not necessarily imply that these chemicals are synthesized in this area. Best and Thorpe (1985) demonstrated transport of metabolites between polypides within a colony of *Membranipora membranacea*. Moreover, most of the tracer ^{14}C, taken in with the food, accumulated in the rapidly growing edges of the colony. On the other hand, specialization of function within colonies is common in the Bryozoa (Silen, 1977). We could detect no gross morphological differences between zooids situated in the exposed tips compared to those more remote from the periphery of colonies of *A. wilsoni* that might have signalled such specialization. However, basal regions clearly had considerably fewer feeding zooids than any other region sampled.

Hay et al. (1988) found that tropical seaweeds in the genus *Halimeda* could gain protection from diurnal fish grazers by producing more herbivore-susceptible new growth at night and also providing it with enhanced chemical defense. New growth contained high concentrations of predator-deterrent terpenoids (2–4.5% of ash-free dry weight) compared to plant portions older than about 24 hr. This form of rapidly mobilizable defense allied with other morphological defenses is very effective where cycles of grazing pressure are very predictable, e.g., with diurnal herbivorous fish on many coral reefs. We are not aware of any comparable data on growth of bryozoans but suggest that such a cycle would not provide protection from the range of grazers on colonial animals in temperate waters (both invertebrate and vertebrate). However, a comparison of the amathamide concentration in colony tips collected at night and during the day would be interesting if the amathamides proved to have predator deterrent properties.

Anthoni et al. (1990) hypothesized that some of the secondary metabolites isolated from bryozoans, perhaps including the amathamides, are manufactured by associated microorganisms. Failure to detect amathamides in two species of bryozoans growing in close proximity to amathamide-containing colonies of *Amathia wilsoni* was taken by Blackman and Green (1987) as evidence arguing against a dietary origin for these chemicals. They proposed that *A. wilsoni* synthesized the amathamides, although the possibility remains that they are synthesized by symbionts. We are planning further work to compare the surface microflora of these colonies and also the microflora associated with different regions of the same colony. We also plan to search for endosymbiotic zoox-

anthellae, although, to our knowledge, none has ever been described from bryozoans. It remains to be established whether the amathamides have antimicrobial properties or provide protection against grazers.

Acknowledgments—We thank Mr. N. Davies for assistance with the GC-MS analysis, Mr. P. Bock for positive identification of the bryozoans, and an anonymous referee for constructive comments. Financial support from ARC grant 889/010 is gratefully acknowledged.

(Received February 19, 1991; accepted May 20, 1991)

Abstract—When specimens of the lucerne leafroller, *Merophyas divulsana*, were sampled from an area with a history of crop damage, they were found to have (*E*)-11-tetradecenyl acetate, hexadecyl acetate, and tetradecyl acetate as principal components of the pheromone gland. A synthetic mixture of these compounds proved to be a successful lure in delta traps. On the other hand, apparently identical moths collected in areas with no history of crop damage were found to have (*Z*)-11-tetradecenyl acetate as the major component of the sex pheromone gland. The distribution of the two moths provides the basis for a plausible explanation of the regional pest activity reported for *M. divulsana*.

Key Words—Sex pheromones, pheromone blends, moth populations, lucerne, pest, *Merophyas divulsana*, Lepidoptera, Tortricidae.

INTRODUCTION

The lucerne leafroller, *Merophyas divulsana* (Walker) is a tortricid moth, native to Australia, and widely distributed (Common, 1963). It is a significant pest of cultivated lucerne (*Medicago sativa* L.) in parts of Queensland and New South

Wales, especially the Lockyer (Qld) and Hunter (NSW) Valleys (Allsopp et al., 1983; Bishop, 1984; Turner, 1969). In the Hunter Valley, field populations of the moth can reach high numbers in late summer and autumn when successive discrete generations occur approximately five weeks apart. In instances of high infestation (95% of stems infested), crop losses up to 40% can occur (Bishop and O'Connell, 1988). Control methods have included applications of insecticides but not without problems associated with damage to beneficial predators and parasites or high mammalian toxicity. In recent years integrated control methods have been investigated (Franzmann and Rossiter, 1981; Allsopp et al., 1983; Bishop and McKenzie, 1986) in efforts to minimize interference with ecologically based pest management systems developed for control of the introduced aphid pests, spotted alfalfa, and bluegreen aphids. One promising approach suggests that careful selection of harvesting cycles can control *Merophyas divulsana* without the need for application of insecticide. In field trials in the Hunter Valley, harvesting of lucerne three weeks before expected peaks in the late-instar larval population was successful in keeping damage levels below an economic threshold of 10% yield loss (Bishop and McKenzie, 1986).

The present investigation into the sex pheromone of *M. divulsana* was initiated in the belief that traps baited with synthetic pheromone would be useful in monitoring population cycles and thus permit harvesting to be timed for best effect as a control method. It was also hoped that it might be possible to explain the apparent regional pest activity of the species.

METHODS AND MATERIALS

Late-instar larvae of *M. divulsana*, collected in eastern Australia, were reared on fresh lucerne in the laboratory. Male and female pupae were separated, and the adult moths were allowed to emerge in a 14:10 hr light–dark regime.

Extracts of pheromone glands for gas–liquid chromatographic (GLC) analysis were prepared from ovipositors excised from female moths taken at the beginning of scotophase and not less than 24 hr after eclosion. Usually a single ovipositor was allowed to stand in 10 μl of hexane (Waters Associates, HPLC grade) for at least 15 min. GLC analyses of extracts from individual moths were carried out on a Varian 3700 gas chromatograph (splitless injection) fitted with one of four columns: BP5, 5% phenyl methyl silicone, bonded phase, 12 m $\times$ 0.32 mm, 170°C; BP10, cyanopropyl silicone, bonded phase, 12 m $\times$ 0.32 mm, 170°C; BP20, polyethylene glycol, bonded phase, 25 m $\times$ 0.32 mm, 170°C; SCOT, SP1000, 43 m $\times$ 0.5 mm, 165°C; all obtained from SGE Scientific Pty. Ltd. Injections were made at 40°C and isothermal conditions main-

tained for 4 min (inlet purged after 2 min). The column oven was then rapidly heated (50°C/min) to the operating temperature (165° or 175°C) and the remainder of the run completed isothermally at that temperature.

Extracts to be used for chemical derivatizations were purified by evaporation and recondensation of the volatiles. The hexane extract, together with washings (2 × 5 μl), was injected in 3-μl aliquots, into a small glass tube (54 mm × 3 mm ID) packed with glass beads (250 mg, 60–80 mesh) and the hexane evaporated under a flow of nitrogen (25 ml/min, 40 sec/aliquot). Volatiles were removed from the glass beads in a flow of helium (2.5 ml/min) at 135°C during 10 min and trapped in a glass capillary cooled with dry ice. $LiAlH_4$ reductions of purified extracts were carried out in small tubes with 50 μl of dried ether and excess $LiAlH_4$. Wet ether was added to destroy the complex and excess reagent. Hexane (20 μl) was added and the organic phase removed with a syringe for GLC analysis. Ozonolyses were carried out using an oxygen–ozone mixture generated with a microozonizer similar to that described by Beroza and Bierl (1976). The ozone mixture was passed (2 ml/min) for 6 sec through 20 μl of hexane cooled in Dry Ice; 1–2 μl of this solution added to a purified gland extract was sufficient for complete ozonolysis. Splitless injection of the reaction mixture into a GLC inlet at >200°C was sufficient to decompose the ozonide to the respective aldehyde ester.

GLC data were recorded with a Hewlett Packard HP3392A integrator. Kovats indices (KI) for all sample peaks were calculated using the retention times for a set of normal hydrocarbon standards (C_{18}, C_{19}, C_{20}, C_{22}, and sometimes C_{24}) coinjected with the sample. Peaks were identified by comparison of KI values with those from a library of known compounds. Identifications were confirmed by the GLC analysis of the products from nanoscale ozonolysis and reduction ($LiAlH_4$) reactions.

Field-trapping experiments were carried out near Singleton in the Hunter Valley, NSW. Comparisons were made between live virgin females and candidate synthetic pheromone mixtures formulated on the basis of the chromatographic analyses. Lures, prepared by impregnating of small sections of medical-grade rubber tubing with blends of synthetic pheromone components or by using live female moths in small cages, were placed in modified Biotrap (delta type) traps. The treatments (including controls) were arranged in a 5 × 5 Latin square (trial A) or in four 3 × 3 balanced lattice squares (controls separate, trial B) with the traps fixed to pegs 30 cm above the ground at 20-m intervals.

Counts of male moths were made after three or four days. Analysis of variance was carried out on $\log_e$ transformed counts. Means were separated using Fisher's (protected) least-significant difference procedure. Smaller trials were also carried out at Wilton, NSW.

Voucher specimens of insect material have been placed with the Australian National Insect Collection (ANIC).

RESULTS

Initially *M. divulsana* larvae were collected from a site of moderate infestation (>25% of stems infested) at Singleton, NSW, and also from a site of low infestation (<1 infested stem/m^2) at Wilton, NSW, in 1987 during the January to April season when the pest is most active.

For the Singleton material, GLC analysis of individual gland extracts showed peaks consistent with tetradecyl acetate (*n*14:OAc, 19%), (*E*)-11-tetradecenyl acetate (*E*11-14:OAc, 42%), and hexadecyl acetate (*n*16:OAc, 38%) with small to trace amounts of (*Z*)-11-tetradecenyl acetate (*Z*11-14:OAc, 1%), (*E*)-11-tetradecenyl alcohol (*E*11-14:OH), heneicosane (C_{21}), and tricosane (C_{23}). The GLC peaks were identified by coincidence of KI values with those from a library of known compounds measured on at least two different columns (Table 1). Confirmation was obtained from the GLC analyses of reduction and ozonolysis products. $LiAlH_4$ reduction of a purified gland extract resulted in the disappearance of peaks assigned to acetates and the increase in or appearance of corresponding alcohol peaks (*n*14:OH, *E*11-14:OH, *Z*11-14:OH, and *n* 16:OH with KI on SP1000 of 2137.2, 2179.3, 2191.1, and 2338.1, respectively). Ozonolysis removed peaks for *E*11-14:OAc and *Z*11-14:OAc, and a new peak coincident with the ozonolysis product from a known sample of *Z*11-14:OAc (the acetate of 11-hydroxy-undecanal) was formed (KI on SP1000, 2305.2). In these reactions the C_{21} and C_{23} hydrocarbon peaks were unaffected.

Similar analyses were carried out on extracts from the low-density population found at Wilton where there was no evidence of crop damage. A distinctly different result was obtained. The major component of the pheromone

gland was found to be Z11–14:OAc (80%) followed by *E*11–14:OAc (16.5%), *n*14:OAc (2%) and *n*16:OAc (1.5%) with trace amounts of Z11–14:OH and *E*11–14:OH. For convenience, the insects having *E*11–14:OAc as the major component are henceforth referred to as E-type and those with Z11–14:OAc as Z-type. Figure 1 shows GLC traces for typical specimens of each type.

M. divulsana larvae were subsequently collected between December 1987 and April 1988 from various locations (Figure 2) having either a high level of infestation with obvious crop damage or a very low density with no apparent crop damage. The sex pheromone gland extracts obtained from moths reared from this material were analyzed as above. The results are shown in Table 2. Without exception all moths obtained from low-level infestations were found to be Z-type. Similarly the moths obtained from locations with significant pest activity proved to be E-type. Only at Windsor were the E- and Z-type moths found to be coincident, and at this location, where pest activity was apparent, one of the 13 specimens (collected at the same time) was found to be Z-type.

Analyses of specimens taken monthly from Singleton during the course of a year (1987) were entirely consistent with the E-type moth and showed no seasonal variation. Similarly specimens taken from Wilton over the same time were all of the Z-type.

A morphological comparison of specimens from populations of the two

pheromone types of *M. divulsana*, including a study of genitalia, failed to reveal any consistent differences (M. Horak, personal communication).

In field trials at Singleton, candidate synthetic pheromone blends were compared with live female E-type and Z-type moths as lures in delta traps (Table 3). The synthetic mixtures, labeled E1, E2, Z1, and Z2 for convenience, were based on the analytical results for the E- and Z-type moths from Singleton (E1)

and Wilton (Z1) and on overall averages for each type (E2 and Z2). The Z-type female moth attracted about one third as many males as the live E-type female. At a dose level of 1 mg/bait (trial A) the synthetic E1 mixture was also only one third as effective as the E-type female. When the dose of the synthetic baits was reduced (trial B), the baits based on GLC analysis of E-type moths (E1 and E2) proved to be equally effective as the live female moth. The synthetic Z-type baits (Z1 and Z2) were, by comparison, poor attractants.

A small trial was carried out at Wilton where Z-type moths had been found exclusively. The low incidence of moths at this location did not allow a comprehensive test; however, when E1 and Z1 lures (ten of each, 0.1 mg dose) were compared, after seven days 25 male *M. divulsana* were caught in the Z1 baited traps and no moths were found in the E1 baited traps.

DISCUSSION

Lucerne is an exotic species widely cultivated in Australia for animal fodder. The lucerne leafroller, *M. divulsana*, is a native tortricid largely known for its pest activity in lucerne crops, but it is a polyphagous species and has been found on a wide variety of exotic plants. Its native host range is unknown and Australian National Insect Collection host records list only four native plants, all herbaceous species, each from a different family. The present investigation was prompted by the significant pest activity of *M. divulsana* on lucerne in eastern Australia and the potential for the use of synthetic pheromones in its control. In this regard our initial results were promising.

[b] Doses in milligrams of major unsaturated component per bait.

Female *M. divulsana*, reared from material collected in a lucerne crop at Singleton, NSW, during a period of high infestation, were found to have *E*11-14:OAc, *n*16:OAc, and *n*14:OAc as principal components in the sex pheromone gland. In a field trial carried out at Singleton, baits containing mixtures of these compounds were found to be as attractive to male moths as a single live virgin female moth taken from the same population.

However, the investigation of the sex pheromone of *M. divulsana* was complicated by the discovery of a second population at Wilton, NSW, also found on lucerne but at low density and having a distinctly different ratio of components in the sex pheromone gland. In this case *Z*11-14:OAc was found to be the major component with smaller amounts of *E*11-14:OAc and *n*14:OAc. The proportions of *E*11-14:OAc and *Z*11-14:OAc measured for individual moths were such that each moth could be unequivocally assigned to one or the other population. Individual GLC analyses showed ratios of *E*11-14:OAc to *Z*11-14:OAc clustered about values of 1000:16 (*Z*11-14:OAc range 0–99) for E-type moths and 236:1000 (*E*11-14:OAc range 169–408) for Z-type moths, for all of the moths examined.

Specimens taken from both locations at intervals during the course of a year were found to be consistently E-type at Singleton and Z-type at Wilton. When E-type and Z-type females and synthetic mimics were tested in comparative field trials at Singleton, and Z-type female and synthetic lure were both found to attract some male moths, although not as well as the corresponding E-type baits. At Wilton, in a test of the E-type and Z-type synthetic lures, the Z-type bait was successful whereas the E-type bait failed to attract moths.

When the study was extended to include the GLC analysis of specimens from a variety of locations, both within and outside the range of the observed pest activity of the moth, it became apparent that the E-type moth only occurs in locations where pest control measures for *M. divulsana* are always or sometimes necessary. In other locations, where the moth can be found in low numbers and crop damage does not occur, the Z-type moth is found. The locations of the sampling sites for the E-type and Z-type moths along the eastern seaboard of Australia are shown in Figure 2; the 200-m contour line is drawn to indicate the coastal topography. Significantly, the E-type moth appears to be restricted to the river valleys and coastal areas of the central eastern Australian coast, an area that includes the known range of pest activity. Thus the distribution data (Figure 2) provide the basis for an explanation of the apparent regional pest activity of the lucerne leafroller. The description of *M. divulsana* as a sporadic (Fitzgerald et al., 1980) or occasional (Holtkamp and Goodyer, 1982) pest of lucerne is probably inappropriate when considered in the context of the pest histories for specific localities. Although *M. divulsana* has a wide distribution in Australia (Figure 3), for most localities the insect occurs in low numbers on cultivated lucerne and control measures are seldom, if ever, necessary. This is not true for areas on the eastern coast of Australia, particularly southeast Queensland and the Hunter Valley, NSW, where *M. divulsana* is an annual problem and an important pest (Turner, 1969; Bishop, 1984). If the apparent correlation between the range of pest activity and the distribution of the E-type moth is sustained, the occasional pest behavior could be explained in terms of differing host preferences of the two types, and chemical analysis of the pheromone gland extracts will provide a means for assessing the likelihood of pest activity in any given area.

The two pheromone types of *M. divulsana* have been found to occur at the same time at one site (Windsor), and at another site, both moths have been detected but at different times during the January to April season. At Scone, NSW, a single specimen taken during a period of low population density and no crop damage proved to be Z-type. When this site was revisited at a later time (1989) when crop damage was occurring (and subsequent to the compilation of the data in Table 2), the E-type moth was found. Because of this and also the difficulty in detecting the presence of a low population of Z-type moths

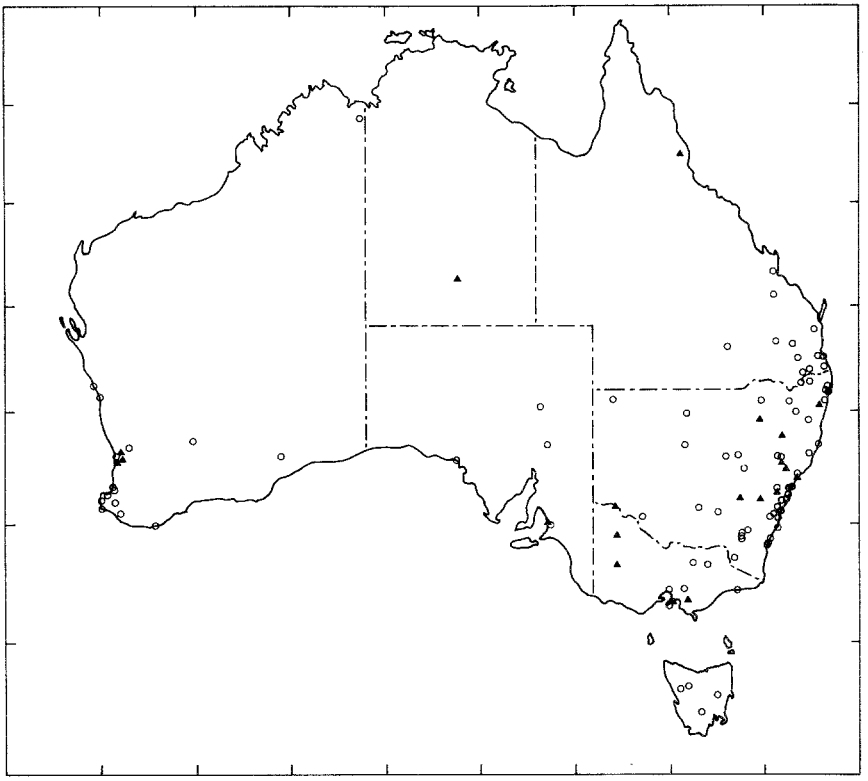

FIG. 3. Distribution of *Merophyas divulsana* in Australia taken from field notes (▲) and specimens (○) held by the Australian National Insect Collection.

in the presence of pest proportions of the E-type moth, it has not been possible to determine the extent of population overlap, if any.

Within species, considerable variation in the ratio of one or more of the saturated (Horak et al., 1988) or unsaturated (Guerin et al., 1986) components of the pheromone gland is a common occurrence. However, there have been relatively few reports of discretely different blends within populations of otherwise morphologically indistinguishable moths. Sex pheromone polymorphism has been described for the European corn borer in the United States and Europe (Roelofs et al., 1985; Klun and cooperators, 1975), the western avocado leafroller in California (Bailey et al., 1986), and the larch budworm in Europe (Guerin et al., 1984). In these species the different pheromone types are not reproductively isolated and have been described as races, types, or strains. On the other hand, sibling species have been proposed for some morphologically

indistinguishable New Zealand tortricids on the basis of discrete pheromone gland blends, the specificity of synthetic lures, and differences in host-plant preference (Foster et al., 1987; Foster and Roelofs, 1987). The differing pest status of the two *M. divulsana* types suggests that they might best be regarded as sibling species also; however, further studies are being carried out to determine other possible behavioral differences and the extent to which the two populations may be reproductively isolated.

(Received March 13, 1991; accepted May 20, 1991)

Abstract—Chemical analyses of three species in the Neotropical ant genus *Megalomyrmex* have identified this taxon as the third myrmicine genus to produce alkaloids as major venom products. Workers of *M. leoninus* and workers and ergatoids of *M. goeldii* produce one or more of four *trans*-2,5-dialkylpyrrolidines previously identified in other myrmicine genera. *M. modestus*, on the other hand, is distinctive in producing the novel alkaloid (5*E*,8*E*)-3-butyl-5-hexylpyrrolizidine **(5d)**, whose structure was established using a micro-Hofmann degradation sequence. The relationship of *Megalomyrmex* to other alkaloid-producing ant genera is discussed along with the possible chemotaxonomic significance of the analyzed species when viewed in terms of the recognized species groups in this genus.

Key Words—*Megalomyrmex*, Hymenoptera, Formicidae, venom, alkaloids, ants, *trans*-2,5-dialkylpyrrolidine, 3,5-dialkylpyrrolizidine, Hofmann degradation.

INTRODUCTION

The ant genera *Monomorium* and *Solenopsis* are distinctive in producing poison gland products dominated by alkaloids (Jones et al., 1982). Ants in no other taxa in the large subfamily Myrmicinae have been demonstrated to produce venoms in which nitrogen heterocycles are major constituents rather than proteins and peptides (Blum, 1985).

Monomorium and *Solenopsis* are far and away the largest of the 13 genera in the *Solenopsis* genus-group, an assemblage whose members are mostly found in the Old and New World tropics (Bolton, 1987). Ants in these genera are considered to form a taxonomic grouping that is isolated from all other ants in the Myrmicinae (Bolton, 1987). In view of the natural relationship of the alkaloid-producing genera *Monomorium* and *Solenopsis* with the other members of the *Solenopsis* genus-group, we consider all these genera as appropriate candidates for producers of alkaloidal venoms.

In the present report we describe the results of the analysis of three species in the genus *Megalomyrmex* and demonstrate that alkaloids are produced by each species. One of these, *M. modestus*, produces the novel (5*E*,8*E*)-3-butyl-5-hexylpyrrolizidine (**5d,** see Figure 2), whose structure and stereochemistry were assigned by microdegradative methods.

METHODS AND MATERIALS

Chemical Analyses

Gas chromatographic analyses were carried out using a Shimadzu GC-9A equipped with a 30-m × 0.5-mm-ID open DB-17 column (1-μm film thickness). The temperature for the analyses was programed from 60 to 215°C at 10°/min, and the carrier gas flow rate was 15 ml/min. On a given day, retention temperatures were reproducible to 1°C. Preparative gas chromatography was conducted with a Varian model 1400 gas chromatograph equipped with a 2-m × 5-mm-ID column packed with 10% OV-17 on 100–120 mesh Supelcoport. Gas-phase IR spectra were obtained using a Hewlett-Packard model 5965A FTIR. ^{1}H- and ^{13}C NMR spectra were obtained from $CDCl_3$ solutions using a Varian XL-200 spectrometer. Electron impact mass spectra were obtained using an LKB-9000 GC-MS equipped with a 30-m × 0.52-mm-ID open DB-17 column (1-μm film thickness), a LKB-2091 equipped with a 25-m × 0.31-mm-ID HP-5 column, or a Finnigan ion trap model 800 equipped with a 25-m × 0.31-mm-ID HP-5 column. Unless otherwise specified, all gas chromatographic retention times and elution patterns refer to use of the DB-17 column. High-resolution mass spectra were obtained using a VG 7070F instrument in the EI mode at an ionizing voltage of 70 eV. Melting points are uncorrected.

Ants

Megalomyrmex modestus workers were collected on the summit (1800 m) of Ayan Tepui, Estado Bolivar, Venezuela. *M. leoninus* workers were collected east of Caracas, Estado Miranda, Venezuela. Workers and ergatoids (reproductives) of *M. goeldii* were obtained in the south of Bahia, Brazil. Ants or venom (*M. leoninus*) were placed in methylene chloride, and these extracts were used directly for chemical analyses. Specimens of all ants were deposited in the collection of the Los Angeles County Museum of Natural History, Los Angeles, California, and have been accessed by Roy R. Snelling. The alkaloids found in the ants are listed in Table 1. The structures of **1–4** (Figure 1) were assigned by comparison of their mass spectra and gas chromatographic retention times with those of authentic samples. Analysis of the extracts of *M. modestus* revealed the presence of a single volatile component whose mass spectrum had important ions at *m/z* 251(M+), 194(80), and 166(100) and was unchanged after attempted hydrogenation (H_2, PtO_2 in ethanol). The gas chromatographic retention time, mass spectrum, and infrared spectrum of this compound were identical to those of **5c/5d** (Scheme 1) prepared below.

Hofmann Degradation of the M. modestus *Extract*

The solvent was removed from a small portion of the extract from *M. modestus*, and the residue was heated to 100°C in a sand bath in a closed vial with a few drops of methyl iodide for 1 hr. After removal of the methyl iodide in vacuo, the residue was treated with 0.2 ml of 1.6 M *n*-butyllithium in hexane and stirred for 24 hr. After the addition of three drops of saturated $NaHCO_3$, the mixture was stirred for 0.5 hr, and the hexane solution was added to 0.3 ml of hexane containing 25 mg of PtO_2, which had been freshly hydrogenated. Hydrogen was bubbled slowly through the mixture for 0.5 hr. GC-MS analysis of the resulting mixture using selected ion monitoring for **5**, **8**, and **10** revealed only an equivalent amount of **5** (*m/z* 194, 166) and the second eluting isomer

Synthesis of 3-Butyl-5-hexylpyrrolizidine

5,8,11-Heptadecatrione (6). A solution containing 0.5 g of 4-oxooctanal (3.6 mmol), 0.5 g of 1-nonen-3-one (3.6 mmol), 0.1 g of 5-(2-hydroxymethyl)-4-methyl-3-benzylthiazolium chloride, and 2 ml of triethylamine was heated to reflux under a nitrogen atmosphere overnight. After cooling, the mixture was taken up in ether and filtered through a short Florisil column. The solvent was

removed, and Kugelrohr distillation at 250°C (0.05 mm Hg) gave 0.6 g (60% yield of **6**; [^{1}H]NMR δ = 2.7(8H, br s), 2.1(4H, t, J = 6 Hz), 1.55(4H, m), 1.25(8H, br m), 0.85(6H, m); [^{13}C]NMR δ = 209.73(2C), 208.16, 42.82, 42.51, 36.12(4C), 31.59, 28.89, 25.97, 23.83, 22.49, 22.33, 14.02, 13.83; MS *m/z* (relative intensity) 282(1, M+), 240(3), 225(3), 222(2), 212(6), 197(12), 194(5), 169(41), 141(42), 127(26), 113(30), 85(53), 57(64), 55(44), 43(100); HRMS *m/z* 282.2186 ($C_{17}H_{30}O_3$, M+, calcd. 282.2195).

3-Butyl-5-hexylpyrrolizidine ***(5).*** (A) A solution containing 0.35 g of triketone **6** (1.25 mmol) in 10 ml of methanol was subjected to the usual reductive amination conditions (0.1 g NH_4OAc, 0.1 g $NaCNBH_3$, 0.02 g KOH, 12 hr) and worked up to provide 0.2 g of a mixture of three components in a 1:6:1.5 ratio with identical mass spectra: MS *m/z* (relative intensity) 251(2, M+), 250(2), 222(2), 195(12), 194(80), 167(12), 166(100), 138(2), 126(2), 124(2), 122(2), 109(4), 108(4), 82(5), 81(6), 70(5), 69(5), 68(8), 67(8), 55(10), 43(5), and 41(8). A variety of gas chromatographic columns (DB-17, DB-1, DB-FFAP, and DB-wax) and conditions were employed in unsuccessful attempts to separate all four possible stereoisomers produced in this reaction. The FTIR spectrum of the first eluting components **5a** had distinctive bands at 2798 and 2707 cm^{-1}, and the following spectral data were also obtained: **(5a)** [^{1}H]NMR δ = 2.5(1H, m), 2.2(2H, m), 1.8–1.2(24H, complex m), 0.86(6H, br t); [^{13}C]NMR δ = 72.16, 60.02(2C), 35.78(4C), 31.89, 29.65, 29.00, 26.75, 25.59(2C), 23.02, 22.06, 14.05(2C); second eluting (major) component **(5b)**; [^{1}H]NMR δ = 3.55 (1H, m), 2.6(2H, m) 1.9(4H, m), 1.5–1.1(20H, m), 0.85(6H, br t); [^{13}C]NMR δ = 66.80(2C), 64.63, 37.06, 36.75, 31.95, 31.75(4C), 29.61, 29.37, 27.14, 22.99, 22.67, 14.13(2C), third eluting component **(5c** and **5d):** [^{1}H]NMR δ = 3.6(1H, m), 3.0(1H, m), 2.88(1H, m), 1.7–2.0(4H, m), 1.6–1.1(20H, m), 0.85(6H, br t); [^{13}C]NMR δ = 66.05(br), 64.01, 58.06(br), 38.2(br), 32–29(complex m), 28.23, 27.05, 22.96, 22.88, 22.61, and 14.06; HRMS *m/z* 251.2622 ($C_{17}H_{33}N$, M+, calcd. 251.2613). (B). A mixture containing 0.1 g of **6,** 0.5 g of ammonium acetate, 0.09 g of 5% rhodium on carbon catalyst, and 2 ml of conc. ammonium hydroxide in 50 ml of ethanol was hydrogenated at 3 atm of pressure for 12 hr. The mixture was filtered through celite, and the solvent removed in vacuo. The residue was taken up in ether and dried over anhydrous potassium carbonate. Analysis revealed the presence of ca. 60% of three isomeric components in a 14:5:1 ratio with gas chromatographic retention times, IR, and mass spectra identical to those prepared above.

Synthesis of Pyrrolidine Standards

*2-Butyl-*N*-methyl-5-nonylpyrrolidine* ***(8).*** A mixture containing 1.0 g of 16-heptadecen-5,8-dione (Jones et al., 1988) and 200 mg of 10% Pd/C in 50 ml of EtOH was hydrogenated at 3 atm of pressure for 24 hr. After filtration,

the solvent was removed to provide 0.74 g of 5,8-heptadecadione **(7)**, mp 53–55°C: [^{1}H]NMR δ = 2.68(4H, s), 2.44(4H, t, J = 7 Hz), 1.58(4H, m), 1.3 (14H, m), 0.84(6H, br t); [^{13}C]NMR δ = 209.76, 209.72, 42.91, 42.59, 36.02(2C), 31.86, 29.40(2C), 29.25(2C), 25.97, 23.88, 22.65, 22.33, 14.07, 13.81; MS *m/z* 268(1, M+), 239(2), 226(7), 211(8), 183(16), 169(9), 157(5), 156(40), 155(20), 141(59), 127(35), 114(51), 113(39), 95(27), 85(100), 71(77), 57(99), 55(6); HRMS *m/z* 268.2408 ($C_{17}H_{32}O_2$ M+, calcd. 268.2402). A solution containing 0.27 g (1 mmol) of **7**, 0.13 g of methylamine hydrochloride, and 0.15 g of $NaCNBH_3$ in 10 ml of MeOH was stirred for 48 hr. After the addition of 0.1 g of $NaBH_4$, the mixture was stirred for 0.5 hr and worked up in the usual manner. GC-MS analysis showed the presence of two components in a 5 : 1 ratio with identical mass spectra: MS *m/z* 267(1, M+), 266(2), 211(9), 210(54), 141(10), 140(100), 98(9), 83(8), 82(12), 69(3), 55(15); HRMS *m/z* 267.2932 ($C_{19}H_{37}N$ M+, calcd, 267.2926). Upon isolation by preparative gas chromatography, magnetic resonance spectra were obtained for each component. First eluting component: [^{1}H]NMR δ = 2.25(3H, s), 2.04(2H, m), 1.84(2H, m), 1.7(2H, m), 1.3(22H, m), 0.9 (6H, br t); [^{13}C]NMR δ = 67.80(2C), 39.02, 34.53, 34.20, 31.90, 30.04, 29.64, 29.59, 29.33, 29.04(2C), 28.94, 26.75, 23.08, 22.67, 14.08(2C); second eluting component: [^{1}H]NMR δ = 2.80(2H, m), 2.38(3H, s), 1.95(2H, m), 1.6–1.1(24H, m), 0.9(6H, br t); [^{13}C]NMR δ = 63.38(2C), 36.15, 31.90, 30.58, 30.27, 30.02, 29.68, 29.58, 29.33, 29.10, 28.73(2C), 26.89, 23.05, 22.67, 14.10(2C).

2-Heptyl-5-hexyl-N-*methylpyrrolidine* ***(10)***. A mixture containing 2.2 g (16 mmol) of 1-nonen-3-one (Jones et al., 1989), 2.04 g of octanal, 0.25 g of 5-(2-hydroxymethyl)-4-methyl-3-benzylthiazolium chloride and 3 ml of triethylamine was heated to reflux under a nitrogen atmosphere overnight. The cooled mixture was taken up in ether, filtered through a short Florisil column, and after removal of the solvent, the residue was recrystallized from cold MeOH to give 2.5 g (58% yield) of 7,10-heptadecadione **(9)**, mp 63°C: [^{1}H]NMR δ = 2.68(4H, s), 2.45(4H, t, J = 7.0 Hz), 1.6(4H, m), 1.3(14 H, m), 0.9(6H, br t); [^{13}C]NMR δ = 209.65(2C), 42.90(2C), 36.03(2C), 31.66, 31.58, 29.19, 29.03, 28.89, 23.90, 23.85, 22.58, 22.46, 14.0, 13.96; MS *m/z* 268(1, M+), 198(10), 184(15), 183(11), 155(17), 141(22), 137(50), 114(41), 113(38), 109(14), 85(25), 81(15), 71(40), 69(17), 57(100), 56(11), 55(43); HRMS *m/z* 268.2403 ($C_{17}H_{32}O_2$ M+, calcd. 268.2402). Reductive amination of 1 mmol of **9** with methylamine hydrochloride in the same manner as for **7** provided a similar mixture of two components with identical mass spectra; MS *m/z* 267(1,M+), 266(2), 183(13), 182(88), 169(13), 168(100), 96(13), 82(15), 70(9), 69(10), 55(15); HRMS *m/z* 267.2939 ($C_{18}H_{37}N$ M+, calcd. 267.2926). First eluting component: [^{1}H]NMR δ = 2.25(3H, s), 2.02(2H, m), 1.85(2H, m), 1.68(2H, m), 1.3(22H), 0.85(6H, br t); [^{13}C]NMR δ = 67.86(2C), 39.03, 34.51(2C), 31.90(2C), 30.03, 29.73, 29.33, 29.06(2C), 26.79, 26.75, 22.69,

22.65, 14.11(2C); second eluting component: [^{1}H]NMR δ = 2.8(2H, m), 2.40(3H, s), 1.95(2H, m), 1.6–1.2(24H, m), 0.9(6H, br t); [^{13}C]NMR δ = 63.43(2C), 35.12, 31.88, 31.84, 30.55(2C), 29.96, 29.65, 29.32, 28.71(2C), 26.88, 26.84, 22.62(2C), 14.06(2C).

RESULTS

Examination of methylene chloride extracts of *Megalomyrmex leoninus* and *M. goeldii* revealed the presence of known *trans*-2,5-dialkylpyrrolidines **1–4** (Table 1, Figure 1) (Jones et al., 1989), whose structures and stereochemistry were confirmed by comparison with available authentic samples. In the case of *M. goeldii*, collections of workers and ergatoids were available; the compositions of the mixtures of alkaloids from the castes were somewhat different. The workers of this species produce mostly *trans*-2-butyl-5-heptylpyrrolidine **(2)** and *trans*-2-heptyl-5-hexylpyrrolidine **(4),** with smaller amounts of **1** and **3,** while the ergatoids produce mostly *trans*-2-butyl-5-pentylpyrrolidine **(1)** and *trans*-2-hexyl-5-pentylpyrrolidine **(3)**, with smaller amounts of **2** and **4.**

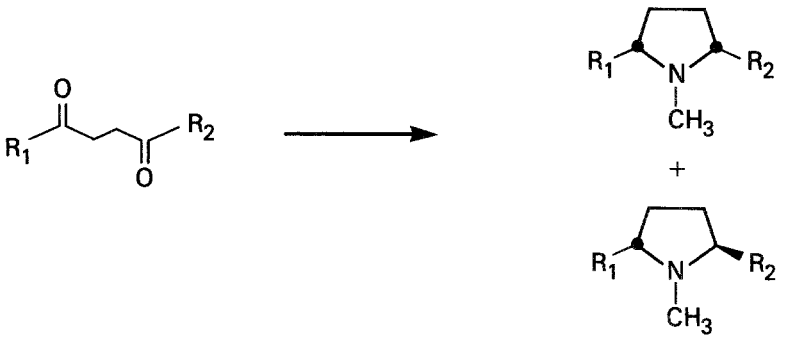
In contrast to the previously described alkaloids found in *M. leoninus* and *M. goeldii*, GC-MS analysis of the methylene chloride extract of *M. modestus* revealed the presence of one major volatile component whose mass spectrum had important ions at *m/z* 251 (M+), 194(80), and 166(100). These intense fragment ions show the loss of C_4H_9 and C_6H_{13} from a nucleus of $C_7H_{11}N$. This spectrum was unchanged after catalytic hydrogenation, indicating that the two units of unsaturation implicit in the nucleus are due to the presence of a bicyclic system. The 3,5-disubstituted pyrrolizidine ring system is typical of such compounds that occurs in other myrmicine species (Jones et al., 1980).

The overall carbon–nitrogen skeleton of the likely candidate, 3-butyl-5-hexylpyrrolizidine **(5)** was confirmed by synthesis (Scheme 1). The condensation of 4-oxooctanal (Kulinkovich et al., 1985) and 1-nonen-3-one (Jones et al., 1989) in the presence of a thiazolium salt catalyst provided 5,8,11-heptadecatrione **(6).** Reductive amination of **6** with sodium cyanoborohydride and ammonium acetate formed pyrrolizidine **5** in good yield. In the case of unsymmetrical triketones, this methodology produces all four possible pyrrolizidine stereoisomers (Jones et al., 1980, 1988) (Scheme 1); however, in the case of **5,** only three gas chromatographic peaks in a 1 : 6 : 1.5 ratio with identical mass spectra could be observed. The first and second eluting components of the synthetic mixture could be assigned as (5*Z*,8*Z*)-3-butyl-5-hexylpyrrolizidine **(5a)** and (5*Z*,8*E*)-3-butyl-5-hexylpyrrolizidine **(5b)** on the basis of their spectral data and relative retention times (Jones et al., 1980, 1988). The mass spectrum and gas chromatographic retention time of the alkaloid from *M. modestus* were identical to those of the third eluting component.

The [^{1}H]- and [^{13}C]NMR spectra of the third eluting component confirmed the presence of either or both of two diastereomers, (5*E*,8*Z*)-3-butyl-5-hexylpyrrolizidine **(5c)** and (5*E*,8*E*)-3-butyl-5-hexylpyrrolizidine **(5d).** Along with the usual signal at δ = 3.6 for the C-8 proton, the [^{1}H]NMR spectrum of this component had distinct signals at δ = 3.0 and 2.88 for the methine protons on C-3 and C-5 carbons attached, respectively, to alkyl groups *endo* and *exo* to the *cis*-fused pyrrolizidine ring system. In contrast with the two [^{13}C]NMR signals observed for **5b** at δ = 66.78 (C-3 and C-5) and 64.62 (C-8), in this component the three methine signals appeared at δ = 66.05, 64.01, and 58.06 ppm. While these data indicated that one of the alkyl groups was *endo* and the other *exo*, the lack of splitting of these signals due to the similarity of the butyl and hexyl groups at C-3 or C-5 made it impossible to distinguish **5c** and **5d** in this component.

In an unsuccessful attempt to prepare a higher proportion of **5c/5d,** the reductive amination of **6** was conducted under hydrogenation conditions using 5% Rh/C as a catalyst. It is noteworthy that this procedure formed the three pyrrolizidine components **5a, 5b,** and **5c/5d** in a 14:5:1 ratio and is the most efficient preparation of the *trans*-fused (5*Z*,8*Z*)-3,5-dialkylpyrrolizidines reported to date.

Since the gas chromatographic retention time of the alkaloid from *M. modestus* was identical to that of **5c** or **5d,** a selective Hofmann degradation was carried out on a small portion of the *M. modestus* extract in order to determine the stereochemistry of the natural pyrrolizidine. After quaternization with methyl iodide, cleavage of the one of either of two of the C—N bonds (Figure 2) would be expected to provide 2,5-dialkyl-*N*-methylpyrrolidines with side chain unsaturation, which could subsequently be removed by hydrogenation without altering their stereochemistry. With this in mind, the two possible final products, 2-butyl-*N*-methyl-5-nonylpyrrolidine **(8)** and 2-heptyl-5-hexyl-*N*-methylpyrrolidine **(10)** were prepared by reductive amination of the corresponding 1,4-diketones with methylamine in the presence of sodium cyanoborohydride (Borch, et al., 1971) (Scheme 2). The *cis* and *trans* isomers of **8** and **10** were isolated and their stereochemistry assigned from their magnetic resonance spectra. The ^{13}C spectra of the first eluting *cis* isomers of **8** and **10** show a resonance at δ = 67.8 for the methine carbons, while the later-eluting *trans* isomers show a resonance at δ = 63.4 for these carbons (Gessner et al., 1987). With the stereoisomers of **8** and **10** characterized, a small portion of the extract from *M. modestus* was quaternized and the residue was then stirred with an excess of *n*-butyllithium (Bach et al., 1974). After hydrogenation, GC-MS analysis using selected ion chromatography for the α-cleavage ions of **5, 8,** and **10,** revealed the presence of the original natural pyrrolizidine, possibly from the elimination of the quaternary methyl group, together with *trans*-**8.** Ions at *m/z* 168 and 182, indicating the presence of **10,** were not detected. These results



7: $R_1 = n-C_4H_9$, $R_2 = n-C_9H_{19}$ **8:** $R_1 = n-C_4H_9$, $R_2 = n-C_9H_{19}$

9: $R_1 = n-C_6H_{13}$, $R_2 = n-C_7H_{15}$ **10:** $R_1 = n-C_6H_{13}$, $R_2 = n-C_7H_{15}$

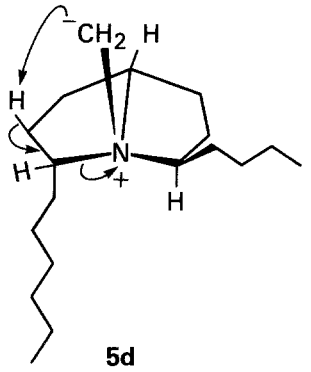
SCHEME 2.

show that the natural pyrrolizidine from *M. modestus* is (8*E*,5*E*)-3-butyl-5-hexylpyrrolizidine **(5d).**

On closer inspection, the regiospecificity as well as the stereoselectivity of the Hofmann degradation is evidence for the stereochemistry of **5d.** Thus, the stereoselectivity of the elimination reaction of quarternary ammonium salts with alkyllithium bases has been attributed to the formation of an ylid intermediate followed by intramolecular *syn* proton abstraction (Bach et al., 1974). In these elimination reactions, pyrrolidine ring protons would be expected to be more readily abstracted by the base than acyclic side chain protons (Jewers and McKenna, 1958), so that in 3,5-dialkylpyrrolizidines the base would attack the 2 or 6 positions. In **5d** the 2-*exo* proton is blocked by the *exo* 3-butyl group while the 6-*exo* proton is accessible to the ylid anion (Figure 2), resulting in exclusive formation of *trans*-**8** after hydrogenation.

DISCUSSION

Megalomyrmex joins the genera *Monomorium* and *Solenopsis* as the third myrmicine genus whose members are known to produce alkaloidal venoms. All three genera are members of the *Solenopsis* genus-group, and they constitute about 95% of the recognized species (Bolton, 1987). Significantly, alkaloids of the *Megalomyrmex* species are similar to that of species of both *Monomorium*



5d

FIG. 2. Regiospecific ring opening of the **5d** methiodide.

and *Solenopsis* (Jones et al., 1982). Some species in the *Solenopsis* subgenus *Diplorhoptrum* produce some of the 2,5-dialkylpyrrolidines identified from *Megalomyrmex goeldii* (Pedder et al., 1976), while other *Diplorhoptrum* species produce venoms containing single alkaloids **2** or **3** comparable to *Megalomyrmex leoninus* (Jones et al., 1979; Blum et al., 1980). On the other hand, the 2,5-dialkylpyrrolidines **1–4** identified in *M. goeldii* and *M. leoninus* recently have been identified in a *Monomorium* species (Jones et al., 1989). Indeed, *Monomorium* species characteristically produce 2,5-dialkylpyrrolidines in their venoms, and the occurrence of these compounds in *Megalomyrmex* species may be taxonomically significant.

Analyses of the alkaloids produced by workers and ergatoids of *M. goeldii* clearly demonstrate that each caste has a distinctive quantitative alkaloidal fingerprint (Table 1). The major compounds produced by workers of *M. goeldii*, **2** and **4**, are minor or trace constituents of the ergatoids. On the other hand, the venom of the ergatoid queens is dominated by **1** and **3** and contains **2** and **4** as minor components. Similar differences in the composition of worker and queen venoms have been observed previously in *Solenopsis* species.

Solenopsis (Solenopsis) species produce venoms containing *cis*- and *trans*-2,6-dialkylpiperidines in characteristic proportions (Brand et al., 1973a,b). In these ants, the venoms of queens typically contain the isomers of a single alkaloid in a relatively fixed ratio. On the other hand, the ratios of the isomers of this compound are very different in the venoms of the workers. Furthermore, in the case of some *Solenopsis* species, qualitative differences in alkaloids also distinguish the venoms of workers and queens from each other (Brand et al., 1973a,b).

In *Megalomyrmex* and *Solenopsis* species producing venoms that differ between workers and queens, the distinctive venoms produced by the two castes must reflect the emphasis that each places on selected alkaloids in the colonial milieu. For example, the alkaloids produced by the ergatoids of *M. goeldii* are

structurally similar to *trans*-2,5-dialkylpyrrolidines that have been demonstrated to have substantial insecticidal, antibiotic, and repellent activities (Escoubas and Blum, 1990; Cutler and Blum, unpublished data; Blum et al., 1991). The marked biological activities of these alkaloids could be highly adaptive in the nest environment and could provide ergatoid queens with a means of inoculating eggs with fungicides that offer protection against invasive spores for example. It will not prove surprising if the venom compositions of workers and queens are identified with the adaptiveness of these secretions vis-à-vis specific competitors.

The genus *Megalomyrmex* has been revised into four species groups (Brandão, 1990), and it seems worthwhile to compare the alkaloids produced by these species. For example, although *M. goeldii* and *M. modestus*, two species in the Modestus group, produce venoms that are qualitatively distinct, the pyrrolidine **4** may be regarded as a monocyclic analog of the pyrrolizidine **5d.** While **5d** occurs alone in *M. modestus*, its formation may be envisioned by the closure of its N—C-3 bond from a "*cis*-**4**"-like precursor; it may be significant that this species has been included in the same species group as *M. goeldii*, which produces *trans*-**4** (Brandão, 1990). In *Monomorium* species that produce 3,5-dialkylpyrrolizidines in their venom, concomitant *trans*-2,5-dialkylpyrrolidines, isomeric with the *cis*-2,5-dialkylpyrrolidines that would result from cleavage of one ring of the bicyclic system, have been detected (Jones et al., 1988). These observations suggest that the bicyclic alkaloids may be produced in ants when the initially formed ring is *cis* disubstituted (Jones et al., 1990). Significantly, the genera *Megalomyrmex* and *Monomorium* are considered to be closely related (Bolton, 1987), so that similarities in their venom biochemistry may not be unexpected. Obviously, in the absence of data on the alkaloids produced by other *Megalomyrmex* species, it is impossible to generalize about the chemistry of the species groups.

The production of alkaloids by *Megalomyrmex* species offers optimistic grounds for regarding other genera in the *Solenopsis* genus-group as sources of nitrogen heterocycles. Analyses of species in additional genera may provide valuable data on the biochemical evolution of alkaloidal venoms in the largest of the ant subfamilies, the Myrmicinae.

Acknowledgments—We thank Dr. R.J. Highet of the Laboratory of Biophysical Chemistry, NHLBI, for the NMR spectra, and Noel Whittaker of the Laboratory of Bioorganic Chemistry, NIDDK, for the high-resolution mass spectra.

CHEMICAL CONTENTS OF STINGING TRICHOMES OF *Cnidoscolus texanus*

S.E. LOOKADOO and A.J. POLLARD*

Department of Biology
Furman University
Greenville, South Carolina 29613

(Received January 14, 1991; accepted May 28, 1991)

Abstract—Plants known as nettles bear trichomes that deliver a painful sting when touched. Studies of members of the Urticaceae have suggested that their trichomes may contain histamine, acetylcholine, and serotonin. We report investigations using TLC, HPLC, and UV-VIS spectrophotometry to analyze the hair fluids of *Cnidoscolus texanus*, a member of the Euphorbiaceae, along with standards of known histamine, acetylcholine, and serotonin. Of these, only serotonin was detected in hair extracts. Up to four other compounds were detected and partially characterized, but they have not been identified.

Key Words—Serotonin, nettles, trichomes, stinging hairs, plant defense mechanisms, *Urtica dioica*, *Cnidoscolus texanus*.

INTRODUCTION

This study presents a partial analysis of the fluids contained within the stinging trichomes of *Cnidoscolus texanus* (Muell. Arg.) Small (Euphorbiaceae), a nettle native to the southwestern United States and adjacent Mexico. Nettles are plants that bear stinging trichomes (stinging hairs) and are found in four plant families: Urticaceae, Euphorbiaceae, Loasaceae, and Hydrophyllaceae. The basic structure of stinging trichomes consists of a multicellular pedestal upon which is a single elongate, tapering cell with a slightly swollen tip (Thurston and Lersten, 1969). These hairs are known to contain chemicals that serve as defenses against herbivores (Pollard and Briggs, 1984). When an animal brushes against the plant, the tip of the hair fractures, the broken end of the hair (often beveled like

*To whom correspondence should be addressed.

0098-0331/91/0900-1909$06.50/0

a hypodermic needle) penetrates the skin, and the contents are expelled. The results of the sting vary, depending on the species, from mild discomfort and swelling about the area of penetration, to much more serious effects (Lutz, 1914; Francis, quoted in MacFarlane, 1963) including reported human fatalities (Winkler, 1922).

Most studies of the chemical contents of nettle trichomes have focused on members of the Urticaceae. Early work using in vitro bioassay techniques (Emmelin and Feldberg, 1947, 1949; Collier and Chesher, 1956), concluded that hairs of *Urtica* and related genera contained histamine, acetylcholine, and serotonin (5-hydroxytryptamine). Although they are frequently cited, these conclusions have been questioned by studies using more modern instrumentation (Robertson and MacFarlane, 1957; MacFarlane, 1963; Willis, 1969; Oelrichs and Robertson, 1970; Thurston, 1974). Very little research has considered the stinging chemicals of plants outside the Urticaceae. A study of *Cnidoscolus oligandrus* in the Euphorbiaceae (Cordeiro et al., 1983) reports the presence of histamine. On the other hand, Willis (1969) concluded that neither *Cnidoscolus stimulosus* nor several species in the Urticaceae contained any of the above-mentioned compounds and suggested that all shared an unidentified high-molecular-weight compound that might be responsible for the sting.

This study considers another member of the Euphorbiaceae, *Cnidoscolus texanus*, commonly known as bull nettle or spurge nettle. The species was chosen for several reasons. Previous research has suggested that its stinging hairs represent a defensive adaptation against mammalian herbivores (Pollard, 1986). As stated above, the few existing studies of *Cnidoscolus* spp. have generated contradictory results. The plant has a high number of very large trichomes (3–8 mm in length) covering its entire aboveground surface area, making it possible to obtain extracts that consist only of chemicals from the trichomes, free of contamination from other plant structures. Characterization of extracts was attempted using thin-layer chromatography, high-performance liquid chromatrography, and UV–visible spectrophotometry, in comparison with known standards of histamine, acetylcholine, and serotonin.

METHODS AND MATERIALS

Chemicals. Standards of acetylcholine HCl, histamine, and 5-hydroxytryptamine HCl were all obtained from Sigma Chemical Company, as were TLC indicator solutions. All other chemicals and solvents were either HPLC- or reagent-grade materials. Stock solutions at 0.01 M were made using methanol for acetylcholine and serotonin, and 1 : 1 methanol–acetone for histamine. In UV-VIS spectrophotometry, 0.01 M aqueous solutions also were used.

Plant Extracts. *Cnidoscolus texanus* specimens originated in populations near the Cimarron and Red rivers in Oklahoma. Hairs were obtained from live specimens (three genotypes) maintained in the Furman University greenhouses or from dried field-collected specimens (massed collections from many individuals). Hairs were carefully scraped from the stems and petioles using a razor blade and sieved to remove any extraneous plant material. In order to provide sufficient material, hair samples from several genotypes were combined and ground using a mortar and pestle. Ground hairs were placed in 30 ml of extraction solvent, vortexed for 20 min, centrifuged for 5 min at 2400 rpm, and the supernatant pipetted off for concentration and analysis.

Three extraction protocols were used: (1) extraction in 1 : 1 methanol–acetone solvent and concentration by drying to 1.5 ml under nitrogen; (2) extraction in deionized water, lyophilization to dryness, and reconstitution in 1.5 ml of 1 : 1 methanol–acetone solvent; and (3) extraction in deionized water, lyophilization to dryness, and reconstitution in 1.5 ml of deionized water. Aqueous samples (protocol 3) were used in UV-VIS spectrophotometry. Organic samples (protocols 1 and 2) were used in chromatographic techniques, with the difference being that protocol 2 extracted only water-soluble compounds from the plants, while protocol 1 could extract organic-soluble materials not in solution in intact stinging trichomes (e.g., epicuticular waxes).

Thin-Layer Chromatography. TLC was performed using both silica gel and Avicel microcrystalline cellulose plates, both with a 250-μm coating and containing 254 nm fluorescent indicator, in a mobile phase of 12 : 3 : 5 *n*-butanol–acetic acid–water. Extracts were spotted in parallel with standards (diluted to 0.001 M) of histamine, acetylcholine, and serotonin. Specific indicator solutions used in development of plates were ninhydrin for histamine, Dragendorff's reagent for acetylcholine, and Ehrlich's reagent for serotonin. For more general visualization of spots, plates were examined under ultraviolet light and developed with iodine vapor. Tracings were made of all plates, and R_f values measured.

UV-VIS Spectrophotometry. Spectra were determined using a Beckman DU-50 spectrophotometer, for both organic and water extracts, along with standards also dissolved in organic solvents or water. Solvent background runs were also performed. All spectra were measured from 200 to 700 nm at a scan speed of 750 nm/min.

High-Performance Liquid Chromatography. HPLC was performed using a system of Beckman pumps and controller, with Hewlett-Packard UV diode array detector and data processing programs. In all cases the column used was a Beckman 5-μm C_{18} Ultrasphere all-purpose column. Two HPLC protocols were employed: (1) a 4.6-mm × 25-cm column with 1-μl injection loop, using a 60-min program, which gave a gradient of 100% water to 100% methanol, at a rate of 1 ml/min; and (2) a 10-mm × 25-cm column with 1-ml injection loop,

a rate of 1 ml/min; and (2) a 10-mm × 25-cm column with 1-ml injection loop, run for 60 min at 0.7 ml/min in a set eluent of 90% reagent alcohol (9:5:5 ethanol–methanol–2-propanol) plus 10% hexane.

RESULTS

Based on comparisons of fresh and dry weights, each *C. texanus* hair contained an average of 0.97 mg of fluid. The pH of a slurry of crushed hairs and deionized water was 5.0. In no case was any difference noted between the results for hairs from fresh specimens and those from dried specimens; removal of hairs from dried specimens was considerably easier.

Table 1 lists R_f values from TLC of standard solutions. Silica gel plates provided good identification of serotonin but poor separation of histamine and acetylcholine, while cellulose plates provided good identification of histamine but poor separation of acetylcholine and serotonin. Staining reactions using indicator solutions were as expected, with particularly clear visualization of acetylcholine. TLC of *Cnidoscolus* extracts gave three to four spots, with no consistent differences between aqueous and organic extraction protocols. Separations were generally clearer on silica gel than on cellulose. Table 2 shows R_f values and responses to indicator solutions.

UV-VIS spectrophotometry revealed, for both organically dissolved and aqueous histamine and acetylcholine, absorption maxima at approximately 220 nm. Organic solutions of serotonin revealed a more complex absorption pattern, with maxima at approximately 220 nm, 320 nm, and 360 nm. Aqueous serotonin, however, did not absorb above 320 nm. Spectra for *Cnidoscolus* extracts behaved much like those for serotonin, with similar peaks in organic solution and loss of the high-wavelength peaks in aqueous solution. Because UV-VIS spectra had no peaks in the visible range, and otherwise resembled very closely the spectra from the HPLC UV-diode array detector, only the latter have been reproduced here.

The two HPLC protocols produced similar results (elution times given here

[b] A plus sign indicates correspondence (within 95% confidence intervals) with R_f of standard; H = histamine, A = acetylcholine, S = serotonin.
[c] A plus sign indicates positive staining response; H = histamine (ninhydrin), A = acetylcholine (Dragendorff's reagent), S = serotonin (Ehrlich's reagent).

are from protocol 1 and were longer under the slower flow rate of protocol 2). In all cases, chromatograms of standards displayed a single clear peak. Histamine and acetylcholine were poorly differentiated, with elution times of approximately 3 min and a spectrum showing a single absorption maximum at approximately 220 nm (Figure 1). Serotonin was retained much longer, with elution times of 25–30 min, and gave multiple absorptions at 230 nm, 280 nm, and 310 nm (Figure 1). Chromatograms of *Cnidoscolus* extracts showed several peaks early in the run; however, none of these had spectra similar to those of histamine and acetylcholine. At approximately 25–30 min, *Cnidoscolus* extracts gave a large, broad peak with a spectrum matching that of the serotonin standard (Figure 2).

DISCUSSION

Results indicate the presence of serotonin in the trichomes of *Cnidoscolus texanus*, a conclusion supported by all three techniques used in this study. No evidence was found to support the presence of histamine or acetylcholine in the stinging hairs of this species. Although TLC revealed some spots with R_f values similar to acetylcholine and histamine, none showed a corresponding reaction to indicator reagents. Histamine and acetylcholine were somewhat poorly resolved by the other techniques used in this study, with similar retention times in HPLC and UV absorption peaks that were suspiciously close to the instruments' limits of detection. However, to the extent that standards could be detected, no corresponding results were found for hair extracts.

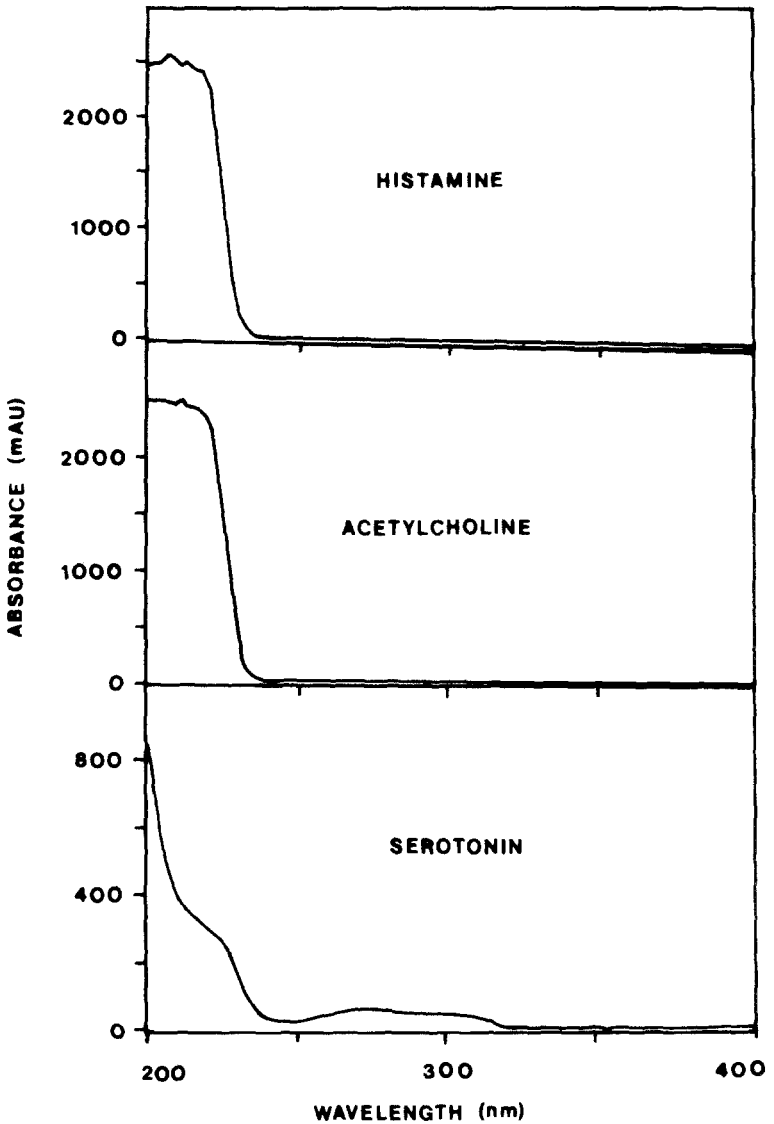

FIG. 1. Spectra of authentic standards (run separately) from HPLC UV diode array detector. Top: histamine (time = 2.95 min); middle: acetylcholine (time = 3.01 min); bottom: serotonin (time = 33.87 min).

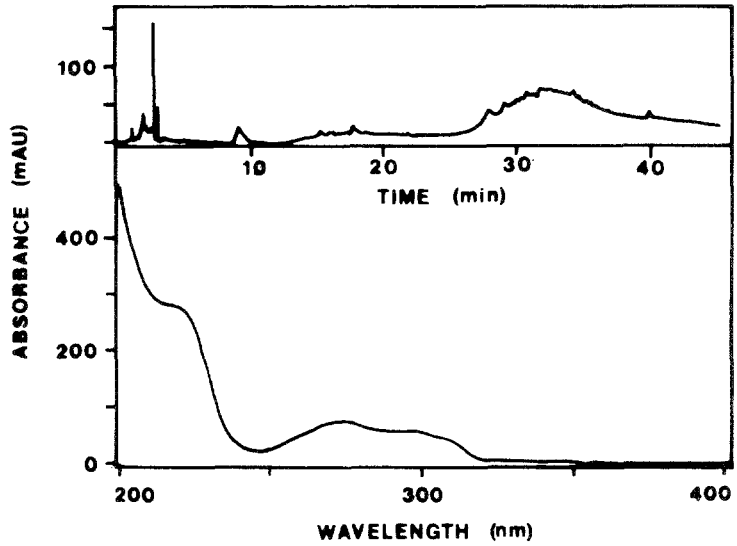

FIG. 2. Results of HPLC analysis of *Cnidoscolus texanus* hair extracts. Top: chromatogram scanned at 260 nm; bottom: Spectrum at 31.70 min.

There were several indications of unknown compounds in the trichomes, including a substance that repeatedly gave a strong spot at very high R_f values (0.99–1.00) in silica-gel TLC, and one or more substances rapidly eluted (2–5 min) in HPLC (Figure 2). It is quite possible that these may be the same substance detected with the two different chromatographic techniques. It is hoped that future studies may allow further characterization of the substance(s) and purification of sufficient quantities to examine biological activity. Earlier studies (e.g., Collier and Chesher, 1956; Robertson and MacFarlane, 1957; Willis, 1969; Thurston, 1974) have suggested that unknown substances, instead of or in addition to histamine, acetylcholine, and serotonin, may be responsible for the sting of various nettle species. Thus, identification of novel compounds in stinging hairs is an important subject for further research.

The results of this study on *C. texanus* are not in agreement with the findings of Cordeiro et al. (1983) on *C. oligandrus*, which was reported to contain histamine and not serotonin, nor with those of Willis (1969) on *C. stimulosus*, which was reported to contain neither. This sort of disagreement, which may represent real chemical differences between species or may be due to differences in methodology and difficult experimental material, is common in the literature of nettle stinging hair chemistry. Such questions will only be resolved by extensive further studies.

This is the first report of the presence of serotonin in nettles outside the

Urticaceae. Along with other literature mentioned above, this provides further support for the idea that nettles in two quite distantly related families show remarkable convergent evolution in both structural and chemical aspects of their defensive systems.

Acknowledgments—We thank R.J. Tyrl and M.J. Stone for supplying some of the plant material used in this study, and L.P. Stratton for comments on the manuscript. This material is based upon work supported by the National Science foundation under grant CSI-8650497. S.E.L. received support during the course of the study from the Furman Advantage Program.

(Received January 28, 1991; accepted May 28, 1991)

Abstract—Female smaller tea tortrix moths *Adoxophyes* sp. (Lepidoptera: Tortricidae), which initiated calling at 1, 2, or 3 days old, respectively, were analyzed individually for (*Z*)-11-tetradecenyl acetate (Z11-14:OAc) and (*Z*)-9-tetradecenyl acetate (Z9-14:OAc) in the pheromone gland via GLC. Among different age groups, broad and similar distributions were found for pheromone quantity ($\bar{X}$ = 58.6 ± 52.9 ng/female; range 1.3–219.8 ng/female). The ratio of the two pheromone components averaged 65:35 but ranged from 84:16 to 40:60. The significance of the pheromone blend variation to the attraction of males was tested in a field experiment. The ratio of males trapped by the most attractive blend versus the least attractive one was 2.2.

Key Words—Sex pheromone, smaller tea tortrix moth, *Adoxophyes* sp., Lepidoptera, Tortricidae, (*Z*)-11-tetradecenyl acetate, (*Z*)-9-tetradecenyl acetate.

INTRODUCTION

In moths, intraspecific variation in relative quantities of the sex pheromone components have been reported in some species such as *Argyrotaenia velutinana* (Miller and Roelofs, 1980), *Heliothis virescens* (Pope et al., 1982), *Pectinophora gossypiella* (Haynes et al., 1984), *Agrotis segetum* (Löfstedt et al., 1985), and *Ephestia cautella* (Barrer et al., 1987). These variations are likely to be important at a number of evolutionary levels: sexual selection, allopatric speciation, and reproductive isolation between species (Cardé and Baker, 1984;

*To whom correspondence should be addressed.

0098-0331/91/0900-1917$06.50/0

Löfstedt, 1990). In our previous study of the *Adoxophyes* sp. (Kou et al., 1991), variation in the proportion of the sex pheromone components, (Z)-11-tetradecenyl acetate (Z11–14:OAc) and (Z)-9-tetradecenyl acetate (Z9–14:OAc), was found among different times of the photoperiod. In that study, pooled samples were used to quantify the sex pheromone blend variation, so the unusual proportion of sex pheromone components in the individual females might be overlooked. In the present study, individual variation of pheromone components in the gland was quantified by gas chromatography to determine the intraspecific variation in pheromone production in *Adoxophyes* sp. Field-trapping experiments also were conducted to obtain an estimate of the biological significance of the variation to mating success, as measured by trapping activity.

METHODS AND MATERIALS

Insects. Female pupae of the smaller tea tortrix moth used in this study were obtained from the Taiwan Tea Experiment Station (TTES), Hsinchu, Taiwan. The laboratory culture of *Adoxophyes* sp. in TTES had been reared for 10 generations, and each generation had been combined with the wild insects in a 1:1 ratio. Female pupae were maintained in environmental chambers at 23–26°C under 14:10 hr light–dark photoperiod. Emerged moths were fed with 10% aqueous sucrose solution.

Preparation of Pheromone Gland Extracts. Emerged females were put into 30 × 30 × 30-cm transparent plastic boxes and fed with 10% sucrose solution. Ovipositor extracts were prepared from individual females, which initiated calling at 1, 2, or 3 days old. The extraction was performed at the time of maximum calling activity (ca. 8 hr into the scotophase) (Kou et al., 1990, 1991; Tamaki et al., 1969) by soaking the tip in 5 μl hexane containing 50.0 ng (Z)-11-tetradecenyl acetate (Z11–16:OAc) as internal standard.

Quantification of Sex Pheromone Components. The ovipositor was soaked in the solvent for 10 min; then the extract was subsequently analyzed for Z11–14:OAc and Z9–14:OAc using the internal standard method of quantitative analysis. Two microliters of the extract was injected onto a 35-m × 0.25-mm-ID fused silica capillary column coated with a 0.25-μm film of Carbowax 20 M phase; the column was installed in a Shimadzu 14-A gas chromatograph (GC) equipped with a flame ionization detector. Chromatographic conditions: nitrogen carrier at a linear flow velocity of 20 cm/sec, column temperature was isothermal at 190°C. The proportion of the two pheromone components was calculated.

Field Trapping. The males' response specificity to alterations of the pheromone blend proportion observed in female gland extract was carried out in a tea plantation, during August 2 to November 2, 1990. Synthetic chemicals

(99.5% purity) of 12 different blend proportions of Z11–14:OAc and Z9–14:OAc (84:16, 80:20, 75:25, 72:28, 68:32, 66:34, 64:36, 62:38, 60:40, 56:44, 53:47, and 40:60) were prepared so as to cover most of the observed blend proportions from individual females. One milligram of synthetic chemicals was dissolved in hexane and loaded in plastic capsules (capsule for electron microscope, type C050, 8 mm ID × 17.8 mm, TAAB Ltd., Berkshire, England). The plastic capsule was hung on the inside top of a wing-shaped sticky trap. Traps were placed randomly, 10 m apart and 1.2 m above the ground. All field data were analyzed with one-way analysis of variance (ANOVA), then by Student-Newman-Keuls' test when a significant F value was found in the ANOVA (Steel and Torrie, 1980).

RESULTS

Relative Quantities of Sex Pheromone Components in Gland Extracts. A sample of 19, 21, and 9 females which initiated calling at 1, 2, and 3 days old, respectively, produced the distribution of pheromone proportions summarized in Figure 1. Within each age group, there was considerable variation between individual moths in the proportion of pheromone components (Figure 1A–C). Broad and similar distributions of relative quantities were found for each of these age groups. The ranges of the proportion of Z11–14:OAc for these three age group were 51–80%, 40–80%, and 54–84%, respectively. The mean proportions of Z11–14:OAc for the 1-, 2-, and 3-day-old groups were 65.3 ± 7.4%, 64.0 ± 8.3%, and 67.7 ± 8.6%, respectively. When the amount of variation in the relative proportion of Z11–14:OAc was measured with the coefficient of variation (CV), calculated as the standard deviation in percent of the mean [$CV = (SD/\overline{X}) \times 100$], a very constant coefficient of variation was found among the different age groups. The arcsin transformed CV was 8.1%, 9.3%, and 9.7% for the three age groups, respectively (Table 1).

The range for sex pheromone titer (Z11–14:OAc + Z9–14:OAc) also varied widely (4.0–219.8 ng/female, 1.3–200.8 ng/female, and 6.5–64.5 ng/female for the 1-day-old, 2-day-old, and 3-day-old age groups, respectively; with $\overline{X}$ = 58.6 ± 52.9 ng/female for all three age groups). The average titer of Z11–14:OAc was 42.0, 46.3, and 17.3 ng/female. Although the mean proportion of Z11–14:OAc increased a little bit with age (Table 1), both the mean value and total range of the proportion of Z11–14:OAc in the individual gland extracts were quite constant among the different age groups, so that results from all three age groups could be pooled (Figure 1D). The mean of the pooled age group was 65.2 ± 8.1% Z11–14:OAc and the range, 40–80% Z11–14:OAc.

Field Trapping. Male response to different pheromone blends of individual females in the field is shown in Table 2. No significant difference was found in

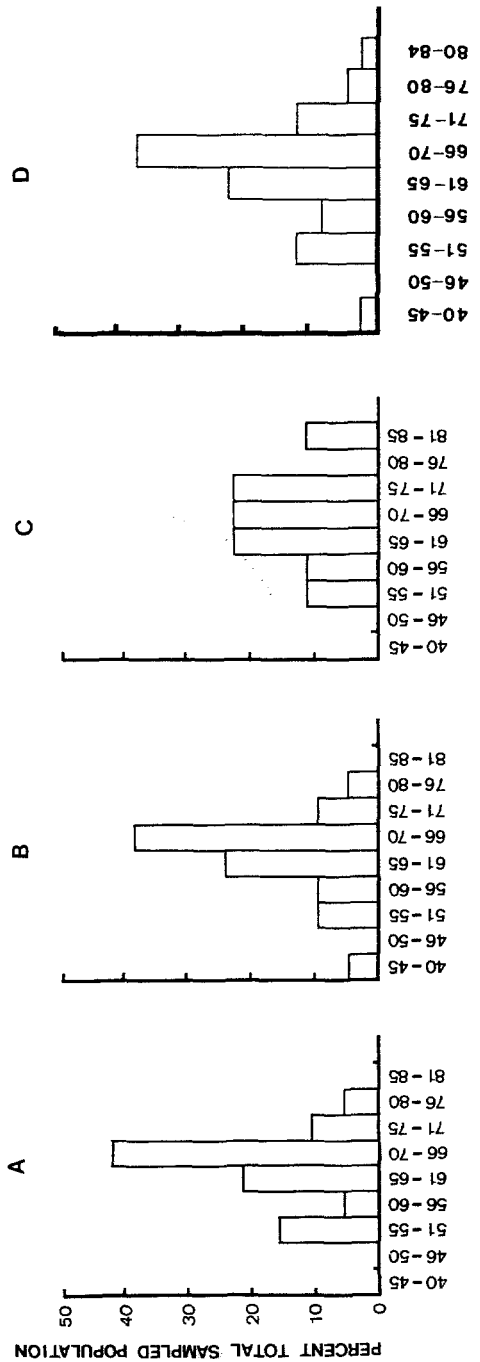

FIG. 1. Distribution of pheromone blend proportions in *Adoxophyes* sp. females that initiated calling (A) at 1 day old ($N = 19$), (B), 2 days old ($N = 21$), (C) 3 days old ($N = 9$), and (D) 1–3 days old ($N = 49$).

TABLE 1. AVERAGE AMOUNT OF Z11–14:OAc IN PHERMONE GLANDS OF FEMALE *Adoxophyes* sp. INITIATING CALLING AT (N = 19), 2 (N = 21), AND 3 Days Old (N = 9); AND COEFFICIENT OF VARIATION (CV)

Age group	Mean Percentage (%/female) $\bar{X} \pm$ SD	CV	CV (arcsin transformed)	Mean pheromone titer (ng/female), $\bar{X} \pm$ SD)
1 day old	65.3 ± 7.4	11	8.1	42.0 ± 43.8
2 day old	64.0 ± 8.3	13	9.3	46.3 ± 31.0
3 day old	67.7 ± 8.6	13	9.7	17.3 ± 13.8

the field attractivity among the 12 different blends (Table 2) (ANOVA, $P > 0.05$). Among the 12 different blends, the blends of 72:28, 56:44, and 53:47 (Z11–14:OAc/Z9–14:OAc) tended to be more attractive (although not statistically significantly so) than the other blends. The ratio of males trapped by the most attractive blend versus the least attractive one was 2.2.

DISCUSSION

The present result showed that there is a wide range of blend proportions within the population of *Adoxophyes* sp. The range of blend proportions of the main pheromone component (Figure 1, 40–84% Z11–14:OAc) in this species was three times broader than that reported for the *A. velutinana* (4–15%) (Miller and Roelofs, 1980), but was similar to that reported for *E. cautella* (60–99%) (Barrer et al., 1987). The coefficient of variation in this species (8.1%, 9.3%, and 9.7% for the 1-, 2-, and 3-day-old age groups, respectively) was close to that reported for *A. velutinana* (9.7%) (Miller and Roelofs, 1980). In *Adoxophyes* sp., in spite of the slight difference in the range of blend proportion among different age groups, the mean pheromone blend proportion tended to remain constant among different age groups (Figure 1, Table 1).

Attygalle et al. (1986) pointed out that the precise regulation of pheromone ratios might be a consequence of a great demand of selection pressure and isolation control for certain moths, brought about by the presence of closely related and sympatrically occurring species. In the tea plantation in Taiwan, no other sympatric species share the same two blend components with *Adoxophyes* sp. until now, so there would be little selective pressure for *Adoxophyes* sp. to maintain precise control over the relative quantities of Z11–14:OAc to Z9–14:OAc in each individual female. The mean and variation of blend proportion would be limited only by other, possibly intraspecific, factors as suggested by

TABLE 2. MEAN TRAP CATCHES (MALES/TRAP/WEEK) OF MALE *Adoxophyes*. SP. WITH 12 DIFFERENT BLENDS OF SEX PHEROMONE IN A TEA PLANTATION, AUGUST 2–NOVEMBER 2, 1990

Blend proportion of Z11-14:OAc/Z9-14:OAc	Mean catch[a]
84/16	2.5 ± 2.4a

40/60	3.0 ± 2.1a
Control	0.4 ± 0.6b

[a]Means followed by the same letter are not significantly different (ANOVA, $P > 0.05$).

Barrer et al. (1987) in *E. cautella*. If *Adoxophyes* sp. was sometimes sympatric with other species that shared the same two blend components, then such populations could be expected to regulate blend proportions much more precisely and possibly centered on a different mean, as in *Archips argyrospilus* (Roelofs et al., 1974; Cardé et al., 1977).

In the field test, the ratio of males trapped by the most attractive blend versus the least attractive one was only 2.2; a similar ratio also had been obtained from *A. segetum* in a field test (Löfstedt et al., 1985). The result of males' field response to the broad range of pheromone blend proportions may suggest that either the majority of males were broadly tuned, responding almost equally to the different blend proportions (Barrer et al., 1987) or the broad response was due to the existence of different behavioral morphs in the population, responding to different isomer ratios (Hansson et al., 1990; Löfstedt, 1990). Actually, in *A. segetum*, the broad response profile of the male might be due to the sympatric occurrence of different male pheromone morphs (Hansson et al., 1990). Whether the *Adoxophyes* sp. was the same as *A. segetum* still need further study.

In this study, a wide range of pheromone quantities was obtained from strongly calling *Adoxophyes* sp. females; similar results also had been reported in other moths such as the false codling moth, *Cryptophlebia leucotreta* (Attygalle et. al., 1986); the turnip moth, *A. segetum* (Löfstedt et al., 1985); and *E. cautella* (Barrer et al., 1987). Whether this variation was a reflection of a dif-

ferent synthesizing rate in the gland or a different release rate still needs further study.

Acknowledgments—We thank the Taiwan Tea Experiment Station, Hsinchu, for supplying the smaller tea tortrix moth, and Miss S.L. Hsao and Miss R.S. Tsai for help during the field test.

ANALYSIS, SYNTHESIS, FORMULATION, AND FIELD TESTING OF THREE MAJOR COMPONENTS OF MALE MEDITERRANEAN FRUIT FLY PHEROMONE[1]

R.R. HEATH,* P.J. LANDOLT, J.H. TUMLINSON, D.L. CHAMBERS,[2] R.E. MURPHY, R.E. DOOLITTLE, B.D. DUEBEN, J. SIVINSKI, and C.O. CALKINS

Insect Attractants, Behavior, and Basic Biology Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Gainesville, Florida 32604

(Received September 18, 1989; accepted May 30, 1991)

Abstract—Three major components, ethyl-(*E*)-3-octenoate, geranyl acetate, and (*E,E*)-α-farnesene, emitted as volatiles by laboratory-reared and wild male medflies were collected and analyzed qualitatively and quantitatively. Peak emission of these compounds occurred during the third to fifth hours of the photophase and differences were observed in the ratios of the three components emitted by male laboratory-reared and wild flies. These three compounds were synthesized, and a method was developed to formulate a synthetic blend that released the compounds in a ratio similar to that emitted by wild male medflies. Attractiveness of the blend to female medflies was demonstrated under field conditions by comparing trap catches. Black spherical traps, baited with the synthetic blend to release 1.6 male equivalents, caught significantly more females than blank traps and traps from which the blend released was 0.3, 3.2 or 6.4 male equivalents.

Key Words—Insecta, Diptera, Tephritidae, Mediterranean fruit fly, pheromone, attractant, *Ceratitis capitata*, ethyl-(*E*)-3-octenoate, geranyl acetate, (*E,E*)-α-farnesene.

INTRODUCTION

The Mediterranean fruit fly, *Ceratitis capitata* (Wied.) (medfly), is a worldwide pest of many deciduous and tropical fruits. Although not established in the continental United States, small infestations in Florida and California have necessitated multimillion dollar eradication programs. It is estimated that in California an infestation of the medfly could result in a $206,000,000 loss in crops and would require a $156,000,000 control program, which would include the use of 1,818,000 kg of pesticide (Dowell and Wange, 1986). The most effective monitoring tool available for the medfly is trimedlure (Beroza et al., 1961), and it is routinely used in California, Texas, and Florida. Trimedlure predominantly attracts males, although a small percentage of females do respond to this chemical (Nakagawa et al., 1970). The lack of a useful attractant for female medflies prompted us to analyze the male-produced pheromone (Féron, 1962) and evaluate it as a lure for females.

Baker et al. (1985) reported the identification of nine compounds emitted by male medflies. However, they gave no behavioral data to substantiate pheromonal activity. Subsequently, Jang et al. (1989) determined electroantennogram responses of male and female medflies to those nine compounds and to an additional 56 compounds collected from air passed over male medflies. The latter were identified by gas chromatography–mass spectroscopy (GC-MS) by matching the spectra obtained with a mass spectral library. We report in this paper the qualitative and quantitative analyses of three principle components of the volatiles emitted by laboratory-reared and wild male medflies during the photophase. Additionally, we synthesized these compounds, developed a method to formulate each of the compounds individually so as to release these three compounds as a synthetic blend in a ratio similar to that emitted by wild male medflies, and investigated the attractiveness of the pheromone blend at four release rates by trapping wild female medflies in the field.

METHODS AND MATERIALS

Insects. Laboratory-reared *C. capitata* pupae were obtained from the USDA-APHIS mass-rearing facility located in Petapa, Guatemala. Sexually immature 2- to 3-day-old adults were sexed and maintained in 30 cm^3 screen cages containing a mixture of brown sugar and yeast hydrolysate. Flies were held indoors under natural light conditions and ambient temperature and humidity. Wild flies were obtained from infested coffee beans (*Coffee arabica*) collected near Antigua, Guatemala. Beans were held on a screen over soil until maggots left the fruit to pupate in the soil. Emerged flies were maintained in cardboard 1-liter cups with a cotton wick descending from the floor of the containers into a second, water-bearing, cup. When adults were 1–2 days old, they

were sexed and maintained as described above. The yeast hydrolysate food source was replaced with sugar water 24 hr prior to the collection of volatiles from the insects. Volatiles were collected on Porapak-Q (see later) from wild and laboratory-reared male medflies 5–10 days old in groups of 8–12 flies/chamber for 2-hr periods throughout the photophase. Similar collections of volatiles from female medflies were made.

Collection of Emitted Pheromone. The push–pull system used to collect volatiles emitted by the insects has been described previously (Landolt and Heath, 1987). Briefly, compressed air, purified by passing through two charcoal filters, entered two glass chambers 5 cm OD × 30 cm long, each containing 8–12 flies. A frit near the upwind end of the chamber produced a laminar airflow over the insects, and this flow was then pulled through a collector trap by vacuum. Each chamber contained three collector traps, any one of which could be selected for volatile collection without disturbing the flies. The airflow was 0.9 liters/min with a slight positive pressure (+0.2 cm H_2O) established in the insect holding chamber (incoming air to vacuum). Vent flow was monitored with a flowmeter from a vent in the chamber, and the vent flow was maintained at 2% of the airflow through the filter. Pressure drop in the insect chamber due to the collector trap was reduced to near zero by the use of vacuum downwind of the collector filter.

In preliminary experiments, volatiles emitted by male and female medflies were collected on traps using charcoal or Porapak-Q (Alltech Assoc., Deerfield, Illinois) as the adsorbent. Most collector traps initially were extracted in Guatemala as described below, and the extracts were sealed in glass ampoules and shipped to Gainesville, Florida. Some traps were sealed with Teflon tape and transported in glass vials to be extracted in Gainesville, Florida. Analyses of extracts obtained by both methods determined that the filters could be sealed with Teflon tape without loss of the collected volatiles. Based on results of this initial work, subsequent analyses were done on Porapak-Q collector traps that were sealed with Teflon tape and extracted after arrival in Gainesville, Florida.

Charcoal traps (2 mm × 4 mm ID) were prepared as described by Tumlinson et al. (1981). After collection of volatiles, each collector trap was extracted with three 20-μl portions of CH_2Cl_2 followed by three 20-μl extractions with hexane. A 200-ng internal standard of hexadecane was added, and each sample was concentrated to ca. 50 μl under argon for analysis as described below. Porapak-Q traps were prepared by packing ca. 60 mg of the adsorbent in 4-cm-long × 4.0-mm-ID glass tubes, resulting in a bed length of 15 mm. Silanized glass wool was used to contain the adsorbent. The Porapak-Q traps were cleaned by Soxhlet extraction with CH_2Cl_2 for 24 hr prior to use. Volatiles collected on the Porapak-Q traps were eluted with 500 μl of hexane–ether (90:10) and then 200 ng of hexadecane was added as internal standard for subsequent analyses. The average amount of each volatile component collected

per male medfly per hour, as determined by GC analyses (see later), was designated as one male-hour-equivalent (MHe).

Chemical Analyses. Gas chromatographic (GC) analyses were conducted using a Hewlett-Packard model 5890 gas chromatograph, equipped with splitless capillary and cool-on column injectors and flame ionization detectors. Helium was used as the carrier gas at a linear flow velocity of 18 cm/sec. Columns used in this investigation were: 50 m × 0.25 mm ID BP-1, 50 m × 0.25 mm ID Supelcowax-10, and 50 m × 0.25 mm ID CPS-1, a high-polarity cyano-silicone column. Each was operated at 60°C for 2 min, then temperature programmed at 30°C/min to 160°C. The chromatographic data were stored and analyzed in a Nelson 4000 data system.

The identities of the compounds were confirmed by GC-MS analyses using the BP-1 capillary column, operated as described above, coupled to a Nermag model R1010 mass spectrometer in the chemical ionization mode. The reagent gas in the mass spectrometer was either methane or isobutane. Spectra of the natural products were compared with those of candidate synthetic compounds. Additionally, 300-MHz proton magnetic resonance (PMR) spectra were obtained on both natural and synthetic compounds. Carbon-13 spectra (75.4 MHz) were obtained on all synthetic compounds.

Chemicals. Geranyl acetate was purchased from ICN Biomedicals Inc. (Plainview, New York). Prior to use, the material was purified by $AgNO_3$ high-performance liquid chromatography (HPLC) using previously described methods (Heath et al., 1977). Analysis by capillary GC on the columns described above indicated a purity of >99%.

The ester ethyl-(*E*)-3-octenoate was prepared from (*E*)-3-octenoic acid (ICN Biomedicals) by the following method. The acid (1.42 g, 10 mmol) was placed in a 50-ml flask together with 2.00 ml (30 mmol) of absolute ethanol, 0.120 g of *p*-toluenesulfonic acid, and 25 ml of benzene. This mixture was heated under reflux overnight, with the water produced collected in a Dean-Stark trap. When 10 mmol of water had been collected, the mixture was diluted with ether and washed (separating funnel) with water-saturated sodium bicarbonate and dried over anhydrous sodium sulfate. Removal of the drying agent and solvent left a yellow oil that was vacuum distilled, bp 80°C/8 mm Hg, to give a clear liquid (1.53 g, 90% yield). The ester was purified by $AgNO_3$ HPLC. Mass spectra and NMR spectra were consistent with the structure of ethyl-(*E*)-3-octenoate. Capillary GC analysis on columns described above indicated a purity of >98%.

(*E,E*)-α-Farnesene was prepared by the method described by Negishi and Matsushita (1984) with modification. The 1-buten-3-yne used in this procedure was either purchased from Wiley Organics (Columbus, Ohio) or prepared by the method of Brandsma (1971). The toluene solution of trimethylaluminum

used in this procedure was purchased from Aldrich Chemical Company (Milwaukee, Wisconsin). The geranyl chloride used in the preparation was prepared from geraniol (Aldrich Chemical Company) by the method of Calzada and Hooz (1974). Briefly, 1-buten-3-yne is carboaluminated with trimethylaluminum using a catalytic amount of dichlorobis-(N^5-cyclopentadienyl) zirconium. Without isolation, the resulting alkenylalane is coupled with geranyl chloride in the presence of a catalytic amount of tetrakis(triphenylphosphine) palladium. The ratio of 1-buten-3-yne to geranyl chloride should be at least 2 : 1. The use of a smaller ratio resulted in excessive amounts of geranyl chloride remaining after work-up. While it is possible to add the geranyl chloride as a solution in THF, it was more convenient to add the catalyst as a solid via a piece of Gooch tubing. It was necessary to chill the contents of the reaction flask in a dry ice–isopropanol bath during the trimethylaluminum addition as this step is exothermic. Because of difficulty in maintaining a temperature of 0°C with an ordinary ice bath during the hydrolysis with 3 N hydrochloric acid, the hydrolysis was begun with the flask contents at −25°C (CO_2/CCl_4). Due to the large amount of gas evolved during the hydrochloric acid addition, it was necessary to add the acid slowly while at the same time maintaining the low temperature.

The removal of unreacted geranyl chloride from the crude product was very important, since its presence during distillation causes extensive decomposition of the product. Geranyl chloride and catalyst residues were removed as follows: after concentration on a rotary evaporator at aspirator vacuum, the residue (about 125 ml for the scale described in the reference) was diluted 2 : 1 with hexane and allowed to stand in the refrigerator (6–7°C) overnight, which resulted in a yellow precipitate. This was removed by filtration and the filtrate passed first through a short (15–20 cm) silica-gel column (60–200 mesh, EM Science, New York, New York) to remove the catalyst residue, and then through a short (15–20 cm) basic alumina column (Woelm, 60–200 mesh, activity grade I) for removal of the unreacted geranyl chloride. The solvents then were removed and the residue vacuum distilled as a colorless or slightly yellow liquid (bp ≈60° at 0.05 mm). The yields were in the range of 60–70%, which is lower than that reported by Negishi and Matsushita (1984). It is suspected that the catalyst that we used may have deteriorated and thus resulted in reduced yields. The (*E,E*)-α-farnesene was found to be 96% geometrically pure with an overall purity of 86% based on analysis by capillary GC. This material was purified by $AgNO_3$ HPLC to provide a compound that was of >98% purity. Infrared and NMR spectra were in complete agreement with those reported by Negishi and Matsushita (1984). Infrared reported (Negishi and Matsushita, 1984) (neat) cm^{-1} 3080 (m), 2960(s), 2900(s), 1664(m), 1635(m), 1601(m), 981(m), 883(s); [^{1}H]NMR reported (Negishi and Matsushita, 1984) [$CDCl_3$, $(CH_3)_4Si$] δ = 1.59 (S, 3H), 1.63 (S, 3H), 1.66 (S, 3H), 1.74 (S, 3H), 2.03 (m, 4H), 2.82 (t, J =

6, 2H); [^{13}C]NMR [$CDCl_3$, $(CH_3)_4Si$] δ = 11.62, 16.07, 17.63, 25.69, 26.89, 27.35 , 39.88, 110.37, 122.36, 124.50, 131.10, 131.74, 133.79, 135.55, 141.69.

Formulations. In the first field test, all three synthetic components were formulated in glass capillaries of different inside diameters and with different lengths of the vapor–air column above the liquid in the capillary in a manner similar to that reported by Weatherston et al. (1984, 1985a,b). Capillaries (A.H. Thomas Company, Philadelphia, Pennsylvania #7707-B20 series) were sealed at the bottom and release rates were measured by the methods previously described using Porapak-Q as the adsorbent (Landolt and Heath, 1987). Regression analysis of the release rate versus the cross-sectional area of the capillary divided by vapor column height then was obtained. Using the resulting equation from this curve, we obtained the capillary inside diameter and vapor column height required for the desired release rate. Capillary formulations used in this study are reported in Table 1. Further validation of this method was obtained by the collection of volatiles emitted from capillaries formulated in the same manner as those loaded for field bioassays. Similarly, random samples of capillaries used in field bioassays were returned to the laboratory and release rates were measured and compared to the predicted release rate for the given exposure time. Release rates reported are based on measurement at an ambient room temperature of 22.5°C. No attempt was made to adjust for temperature effects on the release rate of the pheromone in the field.

(*E,E*)-α-Farnesene was formulated on rubber septa (Heath et al., 1986) for the second field test, while geranyl acetate and ethyl octenoate were formulated as described for the first field test. Septa were loaded with 10, 50, 100, 500, and 1000 μg of (*E,E*)-α-farnesene in 200 μl hexane and aired in the hood for two days. The load amount required for the desired release rate was determined from the linear equation obtained from release rate versus septum load.

Field Tests. Tests were conducted during March 1987 and March 1988. Traps used were 7.5-cm-diam. polypropylene hollow spheres painted black and coated with Stickum Special. Such a design was found to be very attractive visually to both sexes of medfly and was recommended by Nakagawa et al. (1978) for the testing of attractants. Pheromone dispensers were mounted on a 1-cm-long piece of 0.95-cm-ID Tygon tubing glued to the sphere ca. 2 cm down from the sphere top (trap hanger point). An "umbrella" also was mounted over pheromone dispensers on each trap to prevent rain from contaminating the capillary tubing. Each umbrella was a white plastic vial snap-cap (2 cm diam.) mounted above the lures with an insect pin stuck into the tubing. Traps were set up in north-to-south rows of coffee shrubs in a coffee farm near Antigua, Guatemala (Finca Portrero, at Ciudad Viejo). Dosages were initially randomized within each block and traps were rotated one position daily through the duration of the experiment. Each replicate block was placed in one row or hedge

TABLE 1. RELEASE RATE OF MEDFLY PHEROMONE FROM CAPILLARIES

	Capillary		Capillary formulations			
			Day 5 release rate		Day 30 release rate	
Release (MHe)	ID (mm)	Vapor height (mm)	Predicted[a] (ng/hr)	Measured laboratory[b] (ng/hr ± SD)	Predicted (ng/hr)	Measured field[c] (ng/hr ± SD)

3.2[d]	1.68	5	640	642 ± 42	620	630 ± 68
6.4	3.49	6	1151	1130 ± 67	1090	

[a] Predicted based on regression analysis as follows: Ethyl octenoate release rate (ng/hr) = 14.3 × area of capillary ÷ length of vapor height (r^2 = 0.98, N = 10); geranyl acetate release rate (ng/hr) = 1.22 × area of capillary ÷ length of vapor height (r^2 = 0.97, N = 10); (*E*,*E*)-α-Farnesene release rate (ng/hr) = 0.72 × area of capillary ÷ length of vapor height (r^2 = 0.99, N = 10).

[b] Mean of three analyses.

[c] Mean of three analyses. Samples of 6.4 MHe used in field were lost.

[d] Release rate of 3.2 MHe was obtained by using two of the 1.6 MHe capillaries.

of coffee shrubs. Traps within blocks were 7.6 m apart. Blocks were roughly 8 m apart and traps were hung from coffee branches at heights of 1–1.5 m. Each day, flies were removed, sexed, and counted, and each days' catch was considered a replicate. In the first series of tests (1987), the attractiveness of the three major chemicals identified from wild medfly male volatiles was evaluated using a release rate equivalent to 0.3, 1.6, 3.2, and 6.4 MHe in the same ratio emitted by the wild male medflies. Spheres without chemicals were used as blanks. All chemicals were formulated in glass capillaries as described. Jackson traps (Harris et al., 1971) with a cotton wick containing 2 ml of standard trimedlure, used in USDA APHIS monitoring programs, were placed within test plots to provide an indication of fly populations. Traps and trimedlure were obtained from USDA, APHIS, PPQ, Guatemala City, Guatemala. Trimedlure baits are the

standard means of monitoring medfly populations. Three blocks of the six treatments were randomized daily for a six-day period. The second series of tests (1988) were set up in a similar manner with the following changes. The (*E,E*)-α-farnesene was dispensed from rubber septa, and no trimedlure-baited traps were placed in test plots. The duration of this test was eight days. Trap catch data were subjected to ANOVA and daily means separated using Duncan's (1955) multiple-range test.

RESULTS

Analysis of Volatile Constituents. Analysis of volatiles collected from 5- to 10-day-old virgin males and females indicated that three major compounds were present and were produced only by male medflies (Figure 1). These compounds were identified as geranyl acetate, ethyl-(*E*)-3-octenoate, and (*E,E*)-α-farnesene, based on retention times on the BP-1 and Supelcowax columns and the comparison of NMR and EI and CI mass spectra with synthetic compounds. These compounds accounted for 90% of total peak areas seen in the chromatograms and were previously reported by Baker et al. (1985) and Jang et al. (1989) to be present in the volatiles emitted by male medflies. Additionally, in

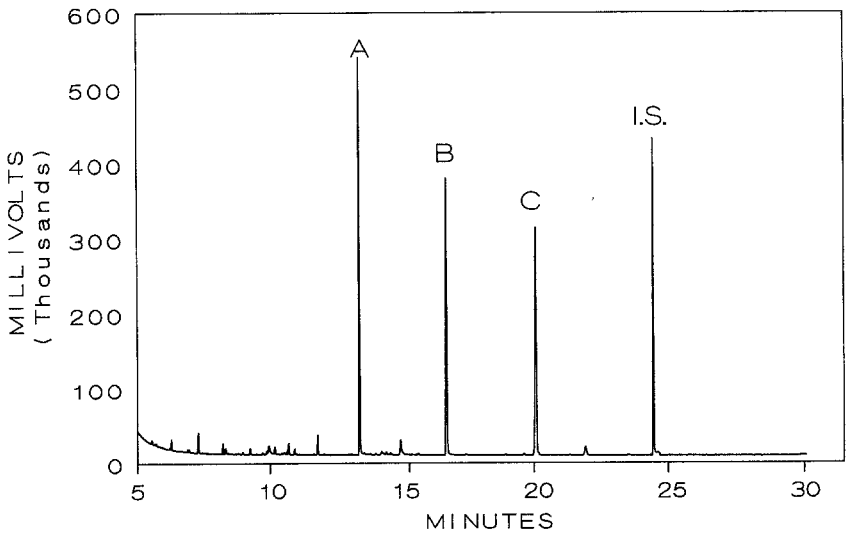

FIG. 1. Volatiles collected from eight wild male medflies during the third to fifth hour of the photophase, analyzed on a 50 m × 0.25 mm ID BP-1 (SGE) fused silica capillary GC column. Peak A = ethyl-(*E*)-3-octenoate, B = geranyl acetate, C = (*E,E*)-α-farnesene, and I.S. = internal standard, 8 μg of hexadecane.

the preliminary experiments, volatiles extracted from Porapak-Q traps immediately after collection from male medflies in Guatemala and sealed in ampoules and analyzed later in Gainesville were identical to those from collector traps sealed with Teflon tape, returned to Gainesville, and then extracted and analyzed. We confirmed that these compounds do not degrade when adsorbed on Porapak-Q for 20 days by analysis of synthetic material that was collected and extracted, and analyzed immediately compared with material that was collected, stored under ambient conditions in the laboratory for 20 days, and then extracted. It was noted during the preliminary experiment ($N = 10$) that less (E,E)-α-farnesene was recovered from volatiles collected on charcoal traps than from volatiles collected on Porapak-Q collector traps. This also was confirmed by the collection of volatilized synthetic compound, which indicated that a 40 $\pm$ 5.2% ($\bar{X} \pm$ SD) loss of (E,E)-α-farnesene occurred when charcoal was used in the collector trap compared with Porapak-Q ($N = 6$).

Periodicity of Pheromone Production. The results of the analyses of volatiles collected on Porapak-Q for 2-hr periods throughout the photophase from wild male medflies 5–10 days old is shown in Figure 2. Peak collection of volatiles occurred 3–5 hr into the photophase, with less material collected in the earlier and later 2-hr periods. No differences were observed in the patterns

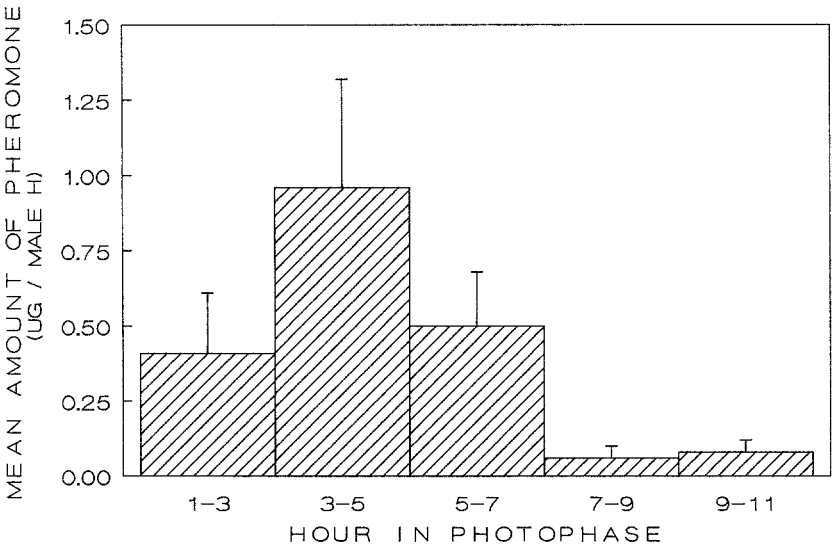

FIG. 2. Mean amount of 18 pheromone collections using Porapak-Q from wild male medflies 5–10 days old in groups of 8–12 flies/chamber for 2-hr periods throughout the photophase. Small bars indicate standard deviation.

of pheromone released by wild (N = 16) versus laboratory-reared (N = 11) flies.

Comparison of Volatiles. Significant differences in the ratios of ethyl-(E)-3-octenoate, geranyl acetate, and (E,E)-α-farnesene were found when the volatiles collected on Porapak-Q traps from wild medflies were compared with volatiles obtained from laboratory-reared flies (Figure 3) during the third to fifth hour of the photophase. Average percentages of ethyl-(E)-3-octenoate, geranyl acetate, and (E,E)-α-farnesene from wild males were 50.3 $\pm$ 5.6 SD, 24.7 $\pm$ 2.7 SD, and 25.0 $\pm$ 4.0 SD, respectively (N = 18), while average percentage releases from the laboratory-reared males were 29.6 $\pm$ 5.9 SD, 38.3 $\pm$ 2.7 SD, and 32.1 $\pm$ 3.8 SD, respectively (N = 10). The mean percent of ethyl-(E)-3-octenoate in wild fly volatiles was significantly greater than that in lab fly volatiles (t = 9.04, P = <0.00001), while the mean percent of geranyl acetate was significantly less in wild fly volatiles (t = 26.0, P < 0.001). The total amount of the three components released by the 5- to 10-day-old laboratory-reared flies during the 2-hr period of peak production was 360 $\pm$ 180 SD ng/male/hr (N = 6) while the 5- to 10-day-old wild flies released 960 $\pm$ 240 SD

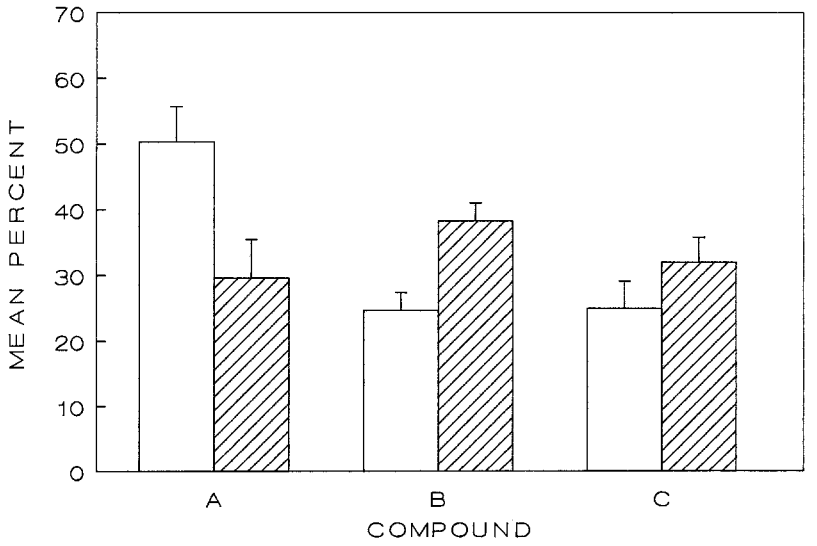

FIG. 3. Comparison of volatiles collected on Porapak-Q traps from wild medflies (N = 18) with volatiles obtained from laboratory reared flies (N = 10) during the 3- to 5-hr period of the photophase. Open bars indicate the percent of compound emitted by wild flies and slash bars the percent from laboratory reared flies. Percents are normalized to 100. Small bars indicate standard deviation. Letter designation as follows: A = ethyl-(E)-3-octenoate, B = geranyl acetate, and C = (E,E)-α-farnesene.

ng/male/hr ($N = 6$). The release rate used for subsequent formulation of synthetic material was based on the amount released by the wild flies (960 ng/hr).

Formulations. Regression analyses of release rate versus the area of the capillary–vapor column height was obtained for each of the three components used in the field bioassay. Results from the linear regression analyses are shown in Table 1. Capillaries then were formulated from these data to provide the desired release rate of each compound at approximate released percentages of 55.2 ± 0.6 SD, 23.9 ± 0.8 SD, and 21.0 ± 1.3 SD for ethyl-(*E*)-3-octenoate, geranyl acetate, and (*E,E*)-α-farnesene, respectively. Prior to use in the field, release rates and ratios of the formulations were determined in the laboratory by GC analysis of collected volatiles and compared to the desired predicted values (Table 1). Release rate and ratio data obtained from laboratory studies indicated that the longevity of the formulation was in excess of two weeks with less than a 5% decrease in emission rate of any of the three compounds investigated. After field use, capillaries were returned to the laboratory, and the change in vapor column height was measured. Additionally random samples of the capillaries used in the field were taken, and the release rates from these capillaries were measured and were found to be in close agreement with the predicted rate for the time they were used (Table 1). These measurements were in agreement with measurements obtained under laboratory conditions. It was noted that use of large (3.49 mm ID) capillaries for the formulation of (*E,E*)-α-farnesene resulted in what appeared to be movement of the compound towards the top of the capillary. Although the release rates from the capillaries were consistent with the predicted release rates, this observation prompted us to formulate (*E,E*)-α-farnesene in rubber septa for the second series of field tests. Based on regression analysis of release rate of (*E,E*)-α-farnesene versus increased load on rubber septa, a release rate approximately the same as that from the capillaries used the previous year was obtained. Release rates were measured in the laboratory from septa after two to nine days of exposure in the fume hood. The results of these analyses are shown in Table 2. Delays in shipment of the septa used in the field precluded the analysis of release rates from these septa.

Field Tests of Three Component Pheromone Blends. In the 1987 field tests, we compared a control unbaited sphere to spheres baited with the three component blend formulated to release at 0.3, 1.6, 3.2, and 6.4 MHe (Figure 4). A total of 259 female medflies were caught in this test. Females were trapped with all treatments and the control trap; however, the sphere baited with 1.6 MHe of pheromone was significantly more attractive. It should be noted in this test that traps with pheromone released at 0.3 and 3.2 MHe caught significantly fewer females than the spheres baited with pheromone that released 1.6 and 6.4 MHe. In field tests conducted during 1988, the same general trend in female trap captures on spheres loaded with different amounts of the three-component

TABLE 2. RELEASE RATE OF (*E*,*E*)-α-FARNESENE FROM RUBBER SEPTA

	Rubber septa formulations (*E*,*E*)-α-Farnesene			
			Measured[b] release rate (ng/hr ± SD)	
MHe	Desired release rate (ng/hr)	Septa[a] load (μg)	Day 2	Day 9
0.3	80	20	70 ± 7	65 ± 8
1.6	320	100	345 ± 40	326 ± 43
3.2	640	200	690 ± 50	652 ± 58
6.4	1151	400	1208 ± 72	1142 ± 67

[a]Septa load based on release rate (ng/hr) = 34.54 × load amount (μg), $r^2 = 0.991$ (septa were loaded with four increasing amounts of compound and release rates from each septum were determined three times).
[b]Mean of three analyses.

male pheromone was observed (Figure 4); traps baited with pheromone released at 1.6 and 6.4 MHe caught more females than the blank and the 0.3 and 3.2 MHe pheromone traps. In this test, a total of 368 females were trapped. Statistically, only the spheres baited with pheromone released at 1.6 MHe were significantly better than the other treatments. This may be due in part to the use of rubber septa formulation for (*E*,*E*)-α-farnesene in this test. Release rates from rubber septa are wind dependent, and this may account for the high variance in capture of flies in traps baited with pheromone as was found in the statistical analysis of data.

DISCUSSION

The first report of a putative medfly pheromone was published by Jacobson et al. (1973). Recent findings do not support their findings, and it is suggested that due to limited analytical methodology available at the time the report is incorrect. Baker et al. (1985) identified nine volatile compounds emitted and/or extracted from sexually mature male Mediterranean fruit flies. The identified components in addition to those reported here included 3,4-dihydro-2H-pyrrole, (*E*)-2-hexenoic acid, dihydro-3-methylfuran-2(3,H)-one, 2-ethyl-3,5-dimethylpyrazine, linalool, and ethyl acetate. It was claimed that the 3,4-dihydro-2H-pyrrole is active, but no data were reported to support pheromonal activity of this or other identified compounds. The amounts and ratios of the nine identified components released by male flies were not reported. Jang et al. (1989) detected 69 compounds using GC analysis of collections of headspace from sexually mature male laboratory reared medflies and identified 56 of these compounds.

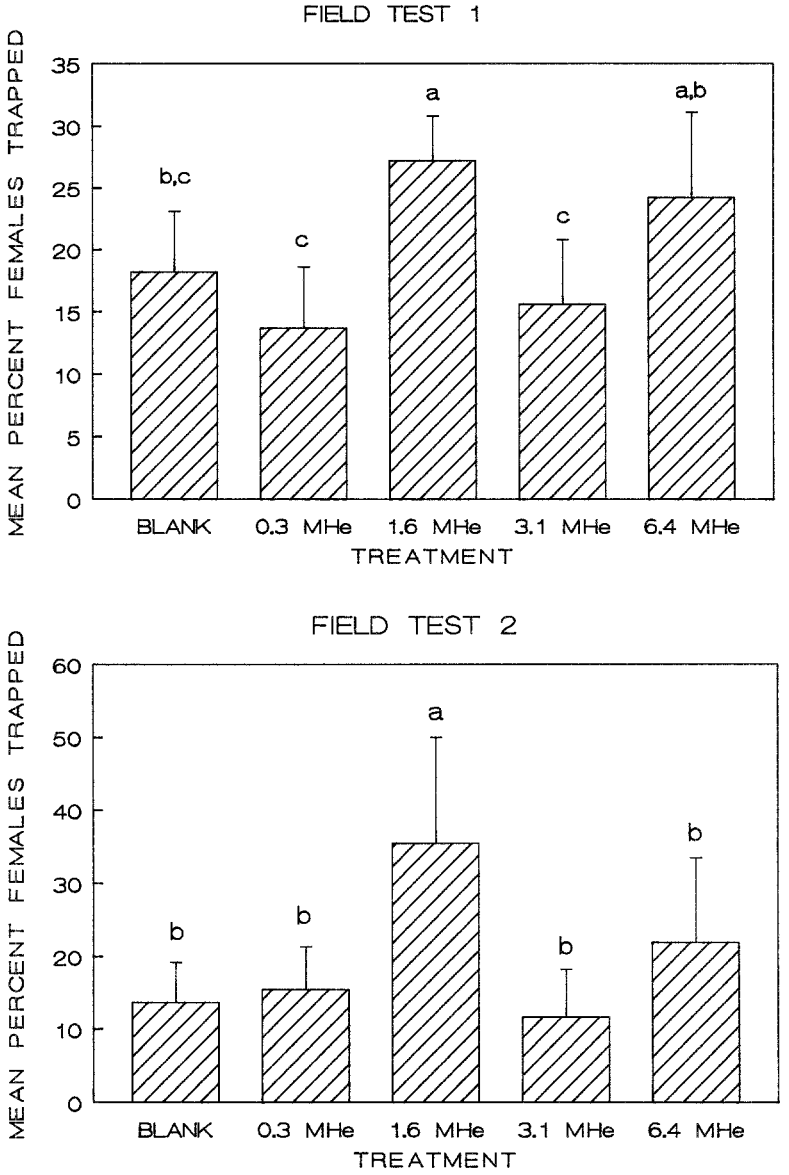

FIG. 4. Results of the field test 1 conducted in 1987 and field test 2 in 1988. Comparison of a blank sphere with spheres that had the three-component blend formulated to release pheromone in increased amounts. Release rate is in male hour equivalents (MHe) based on amount produced by wild male medflies. Bars with the same letter are not significantly different, Duncan's (1955) multiple range test ($P < 0.05$, $N = 6$ for test 1 and $N = 8$ for test 2).

Evaluation of six compounds [ethyl-(*E*)-3-octenoate, geranyl acetate, (*E,E*)-α-farnesene, 3,4-dihydro-2H-pyrrole, linalool, and ethyl acetate individually and as a blend] showed significant activity for all compounds and the blend compared to blanks. Baker et al. (1990), using sterile medflies, tested racemic linalool, 2,3-dimethylpyrazine, 2,5-dimethyl pyrazine, and geranyl acetate individually and in combination. Based on the results of female capture data using baited yellow delta traps and yellow squares, it was determined that the traps containing large amounts of the compound(s) singularly and in combination were more attractive to released female medflies than the control trap.

It is apparent from the studies reviewed that there are a considerable number of putative pheromonal compounds produced by male Mediterranean fruit flies. Our research effort was to provide some focus regarding the release, synthesis, formulation, and testing of three major compounds released by male medflies. A principal problem in interpreting the results of previous published studies on medfly pheromone is the lack of quantitative data and control over chemical release ratios and rates, both in analysis of male volatiles and in testing of compounds for pheromonal activity.

In this paper we demonstrated that ethyl-(*E*)-3-octenoate, geranyl acetate, and (*E,E*)-α-farnesene are three major compounds emitted by virgin male medflies and are released in a precise ratio within a population or group from one source, although this ratio differs significantly between laboratory-reared and wild flies. We have developed a formulation method that releases the three synthetic pheromone compounds in the same ratio released by wild males. Field tests demonstrated the attractiveness of the formulated blend to medfly females at 1.6 MHe but indicate a need for precise control of release rate. Thus we demonstrated that female medflies can be captured in the field with a three-component synthetic pheromone blend. In the first field evaluation of the pheromone, it was found that the black sphere baited with pheromone at a release equivalent to 1.6 MHe captured 25 times more female medflies than the trimedlure in the Jackson trap (11 females/pheromone trap/day versus 0.44 females/trimedlure trap/day). Conversely, the trimedlure-baited Jackson trap caught 14 times more male medflies than the pheromone-baited trap that released at 1.6 MHe (29 males/trimedlure trap/day versus 2.1 males/pheromone trap/day). Differences in lure type and trap design, however, preclude statistical comparison of this data.

The apparent bimodal response distribution observed on traps baited with pheromone at different release ratios is similar to that observed for the papaya fruit fly attraction to 2-methyl-6-vinylpyrazine (Landolt et al., 1988; Landolt and Heath, 1990). The apparent bimodal nature of the numbers of papaya fruit fly females captured at different pheromone release rates was likely due to different responses by mated versus virgin females to the pheromone (Landolt and Heath, 1990). Female medflies captured in these tests were not preserved and

dissected to determine their mating status. More field tests and behavioral studies are planned to investigate the nature of the dose–response relationship, the efficacy of the three-component pheromone system, and whether other compounds reported and yet to be identified as released by males will enhance attraction and capture of female medflies.

(Received April 22, 1991; accepted June 3, 1991)

Abstract—The antioxidant vitamin E, α-tocopherol, was tested as a candidate elicitor of alterable antiherbivory in soybean plants against cabbage looper larvae. Although a nonspecific antioxidant, vitamin E proved elicitory to the involved sulfhydryl-dependent receptor-energy transducer protein in soybean plasma membrane. Effects of α-tocopherol were dependent on dosage, time, and space in the plant. The observed elicited effects were all decreases in herbivory. The best negative phytochemical correlate of looper feeding was the percentage of increased total HPLC peak area of extractables from elicited as compared to nonelicited leaves. Some specific compounds, e.g., glyceollins, were quantitatively major components of the total profile of secondary metabolites.

Key Words—α-Tocopherol, elicitor, alterable resistance, soybean, *Trichoplusia ni*, Lepidoptera, Noctuidae, antiherbivory.

INTRODUCTION

Alterable (inducible) resistance in plants against herbivores and other environmental stresses is a major investigate topic in chemical ecology. Such alterable resistance apparently involves a plant receptor system that receives and processes, from the extracellular environment of the plant, a signal indicating the presence of a stressful entity (e.g., insect defoliator or plant pathogen) (Sequeira,

*To whom correspondence should be addressed.

0098-0331/91/1000-1941$06.50/0

1983; Low and Heinstein, 1986; Norris, 1992). Such receptors may be plasma membrane-bound, may possess a transmembrane signal-transduction capability, and may interact with one or more intracellular effector molecules (e.g., second messengers) (Yoshikawa et al., 1983; Stössel, 1984; Schmidt and Ebel, 1987; Low and Heinstein, 1986; Norris, 1988). Various heavy metals, including mercuric compounds, and several sulfhydryl reagents are known to interact as messenger ligands with the plant receptor to elicit altered plant resistance similar to that induced by various stressful biotic factors (Stössel, 1984; Gustine, 1987; Norris, 1992). The classical sulfhydryl reagents, iodoacetic acid (IAA) and *N*-ethylmaleimide (NEM), were recently shown to elicit such changed resistance in soybean plants against cabbage looper defoliation (Neupane and Norris, 1990, 1991). Such results further support an interpretation that sulfhydryls are involved in signal transduction for alterable plant resistance to insect herbivory. Sulfhydryl involvement was shown previously in quite analogous signal transduction in insect chemoreception (Norris et al., 1970; Rozental and Norris, 1973, 1975; Norris, 1979, 1981, 1986, 1988). Thus, common sulfhydryl-dependent parameters of signal transduction apparently exist between environmental factors and both plant and animal cells. Such sulfhydryls in peptides and proteins may be susceptible to environmental oxidation to disulfides, and such disulfides may be reduced by other environmental conditions to sulfhydryls. Based on these facts, we hypothesized that application of an antioxidant to the soybean plant could alter its resistance to cabbage looper defoliation. The results from experimental testing of this hypothesis are presented in this paper.

METHODS AND MATERIALS

Insects. The cabbage looper (CL), *Trichoplusia ni* (Hübner), was reared in the laboratory on a pinto bean-based artificial diet (Shorey and Hale, 1965) at 27 ± 2°C and 50 ± 10% relative humidity with a 14-hr photophase (14 : 10 light–dark).

Plants. Seeds of an unnumbered soybean plant introduction obtained from Jacob Hartz Seed Co., Stuttgart, Arkansas, were germinated in moisture-sterilized vermiculite in plastic flats in a controlled climate in the University of Wisconsin Biotron. Young seedlings were transplanted at the first-leaf stage, one per pot, into 10.5-cm-diam. plastic pots containing a support medium (Griffy-mix). The plants then were provided with 30–40 ml of half-strength Hoagland's solution (Hammer et al., 1978) four times a day (i.e., every 6 hr). A 14-hr photophase involving 12 hr of full light intensity, i.e., 300–500 μE/m^2/sec; a day temperature of 27 ± 1°C; a night temperature of 20 ± 1°C; and a relative humidity of 65 ± 5% were maintained.

Soybean plants in the V3 stage of development (Fehr and Caviness, 1977) were used for experiments.

Chemical (α-Tocopherol) Elicitor Treatments. Soybean plants having a fully expanded second-trifoliolate (T2) leaf were treated with α-tocopherol (3,4-dihydro-2,5,7,8-tetramethyl-2-(4,8,12-timethyltridecyl)-2H-1-benzopyran-6-ol, vitamin E) [Sigma Chemical Co., St. Louis, Missouri; 670 mg (about 1000 IU) *d*-α-tocopherol per gram] as follows. Sealed plastic ampules containing 200 IU of active ingredient, α-tocopherol, were ruptured with a sterile razor blade, and the contents were squeezed into a measured volume of white oil (American White Oil-Heavy, No. 30 U.S.P., American Oil Co., Chicago, Illinois, to yield a final α-tocopherol concentration of 12.5 or 25 IU/ml of white oil. One-half milliliter of one of the two α-tocopherol formulations or the white oil (solvent) control was applied over the upper surface of the three leaflets of the first-trifoliolate (T1) leaf of each soybean plant with a clean camel's hair brush.

Harvest of Soybean Leaves. Leaves were removed from the plants at 48, 72, and 96 hr after treatment for immediate use in CL feeding bioassays or for immediate storage in 100% methanol at −20°C until further experimental use. The following specific procedures were used: (1) Of the two unifoliate leaves per plant, one was used for CL bioassay and the other for chemical analyses. (2) With the T1 leaf, the central leaflet was used for chemical analyses, and the two outside leaflets were used for CL bioassays. (3) With the T2 leaf, the use was the same as with the T1 leaf.

Bioassay of Leaves. The appropriate leaves, or leaflets, were placed between moistened paper towels in a plastic crisper immediately after removal from a plant and then brought within 15 min to the laboratory for CL bioassay. Leaf disks (12 cm diam.) were cut from each leaf using a No. 6 cork borer. Two leaf disks, one from a given leaf on a treated plant and the other from the same leaf on an untreated plant, were secured, with their abaxial surface up, in an opposed position, 2 mm apart in the center of a petri dish, using cut-off insect pins inserted through a filter paper covering an underlying layer of paraffin. Another piece of filter paper was attached to the inner surface of the Petri-dish lid and was moistened with water to maintain the turgidity of leaf disks. One third-instar CL larva, which has been previously starved for 2 hr, was placed in each prepared Petri-dish arena and allowed to make a choice in feeding between the two presented leaf disks at 27 ± 2°C and 65 ± 5% relative humidity. Each assay was run until at least 50% of one leaf disk was eaten or until 8 hr had passed. The number of replicate plants per treatment or control ranged from 15–25. The area eaten per leaf disk by the CL larva was measured in square centimeters, using an automated area meter (model LI-3100, LI-COR, Lincoln, Nebraska). Ten leaf disks were held in petri-dish arenas as if in assays,

but without the CL larva, and after 8 hr their mean square centimeter area was determined as the standard area per CL-unfed (control) leaf disk. The uneaten area of each assayed leaf disk was substracted from the determined standard control leaf-disk area to yield the experimental area eaten.

The statistical significance of the resultant difference in the two leaf areas (cm^2) consumed by CL in each choice bioassay was evaluated by the Student's *t* test.

Extraction and HPLC Separation of Leaf Chemicals. Individual soybean leaves that had been stored in 100% methanol at −20°C in darkness were removed from that solvent and homogenized in a new 50 ml of 100% methanol for 3 min using an Omni-mixer (Ivan Sorvall, Inc., Norwalk, Connecticut). The resultant homogenate and the storage methanol per leaf were filtered through Whatman No. 1 filter paper. The total filtrate per leaf was rotoevaporated to dryness using a 50°C water bath. Each dried sample of extractables was prepared for high performance liquid chromatography (HPLC) as follows: (1) Extractables per leaf were redissolved in 50 ml of a mixture of double-distilled (dd) water, ethyl acetate, and ethanol (6:5:1), and then partitioned four times in a separatory funnel between ethyl acetate and ethanol (25:5). (2) The combined ethyl acetate fractions per sample were rotoevaporated to dryness and redissolved in 10 ml ethyl acetate. (3) Each sample was then stored in a dried, preweighted, screw-cap septum vial and dried under a nitrogen stream. (4) The dried weight per sample was determined. (5) The dried sample in the closed vial was stored at −20°C in darkness inside a desiccator.

Before HPLC, each dried sample of leaf extractables was first dissolved in the containing vial in HPLC-grade ethyl alcohol at 1 ml/10 mg extractables. The resultant contents of each vial were vortexed on a Vortex-Genie for 5 min and then were filtered through a 5-μm Metrical membrane. In HPLC 20 μl of a filtrate were injected per run into a gradient system consisting of mixtures of hexane–2-propanol through a 5-μm, 4.6-μm × 25-cm Ultrasphere SI column (Beckman No. 235341) controlled by an Altex model 422 programming microprocessor and two Altex model 100A pumps. Data were recorded, reduced, and illustrated through a Spectra Physics 4100 computing integrator. Three replicate injections and analyses were conducted per sample of leaf extractables.

RESULTS

Insect Bioassays. α-Tocopherol at 12.5 IU caused CL larvae to feed significantly ($P < 0.05$) less on disks from all leaves of soybean plants, as compared to control soybeans, at 48 hr after treatment (Figure 1). The only other significant effect of the 12.5 IU α-tocopherol treatment on CL feeding was an induced preference for disks from control third-trifoliolate (T3) leaves at 96 hr after treatment.

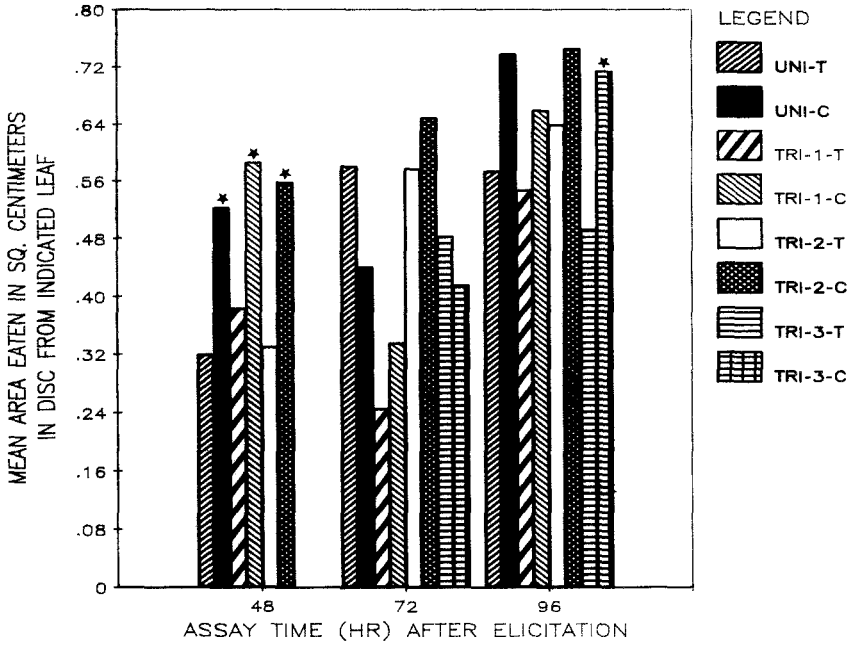

FIG. 1. α-Tocopherol (12.5 IU) elicited differences in cabbage looper feeding (cm^2) on disks cut from the indicated leaf of elicited versus nonelicited (control) soybean plants and presented to the insect in a two-choice assay (*significantly different, $p < 0.05$). UNI-T, unifoliate leaf on an elicited plant; UNI-C, such a leaf on a control plant; TRI-1-T, the first trifoliolate leaf on a treated (elicited) plant; TRI-1-C, the first trifoliolate leaf on a control plant; TRI-2 and TRI-3, ditto above.

α-Tocopherol at 25 IU did not significantly ($P < 0.05$ or greater) alter CL larval feeding preference for soybean leaves until 72 hr after treatment in first- (T1) and second- (T2) trifoliolate leaves (Fig. 2). There subsequently was also a highly significant ($P < 0.01$) induced preference for disks from control T2 and T3 leaves at 96 hr after treatment.

HPLC Resolution of Leaf Extractables. The HPLC-resolved profiles of compounds in the extractables from leaves of elicited (treated) and nonelicited (control) soybean plants were qualitatively similar (Figure 3A and 3B). Major chemicals in the mixture include glyceollins (peak 5, Figure 3A, 3B), coumestrol (peak 9), and daidzein (peak 12) (Neupane and Norris, 1991; Sharma and Norris, 1991). The percentage of total HPLC peak area attributable to individual resolved peaks did not differ ($P < 0.05$) between comparable samples from elicited versus nonelicited (control) soybeans either when highly significant

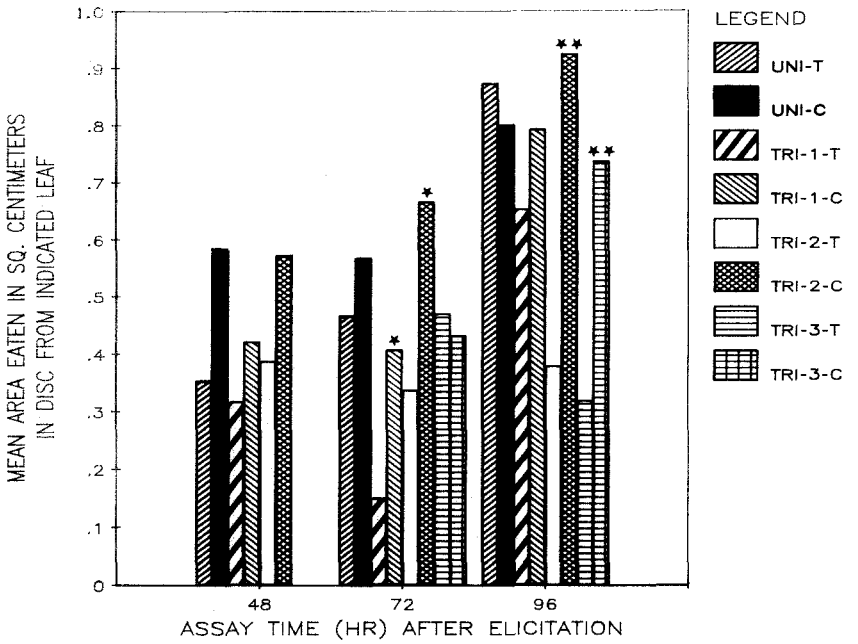

FIG. 2. α-Tocopherol (25 IU) elicited differences in cabbage looper feeding (cm^2) on disks cut from the indicated leaf of elicited versus nonelicited (control) soybean plants, and presented to the insect in a two-choice assay (*significantly different, $P < 0.05$; **$P < 0.01$).

antiherbivory was induced (Figure 4) or no significant ($P < 0.05$) change was elicited (Figure 5).

The mean difference in the area eaten (cm^2) per disk from the same leaf of paired elicited versus nonelicited (control) plants showed a strong positive correlation with the percentage of increased total area under the HPLC peaks of the involved samples from elicited as compared to control soybeans (Figure 6). A linear regression, $Y = -0.13 + 0.042X$, of the mean difference in leaf disk area eaten upon the percentage of increased total area under the HPLC peaks for elicited plants had $r = 0.937$.

DISCUSSION

An Antioxidant as Elicitor. The antioxidant vitamin E (α-tocopherol) proved to be an effective elicitor of alterable soybean resistance to CL herbivory. These results thus support our hypothesis that the application of an antiox-

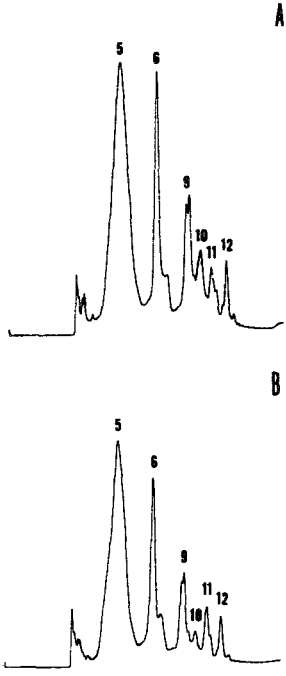

FIG. 3. The similar HPLC-resolved profiles of compounds in the described extractables from leaves of (A) vitamin E-elicited versus (B) nonelicited (control) soybean plants (peak 5, glyceollins; peak 9, coumestrol; and peak 12, daidzein).

idant to a soybean plant can alter its resistance to CL defoliation. We may therefore conclude that even though energy transduction between environmental stress factors and plant cells involves receptor sulfhydryl chemistry, nonspecific antioxidants such as α-tocopherol may alter the redox state of such receptor sulfhydryl chemistry sufficiently to act as elicitory entities regarding alterable soybean resistance to CL herbivory. The sulfhydryl-dependent receptor involved is located in the soybean plasma membrane (Liu and Norris, 1992). This is significant because such a cell membrane appears to be the major site of plant plastic strain, injury, and damage caused by environmental stresses (Levitt, 1980). The plant plasma membrane thus may be the common site where the elicitory effects of various environmental factors (e.g., insect herbivory and certain sulfhydryl reagents) may be mechanically interactive. If this proves to be true, it would support the earlier interpretation that successful (i.e., survivor) plants have evolved to cope with a variety of environmental stresses but rarely, if ever, to deal with a specific stress (e.g., insect herbivory) (Norris, 1988).

Some Parameters of α-Tocopherol Elicitation. The effectiveness of

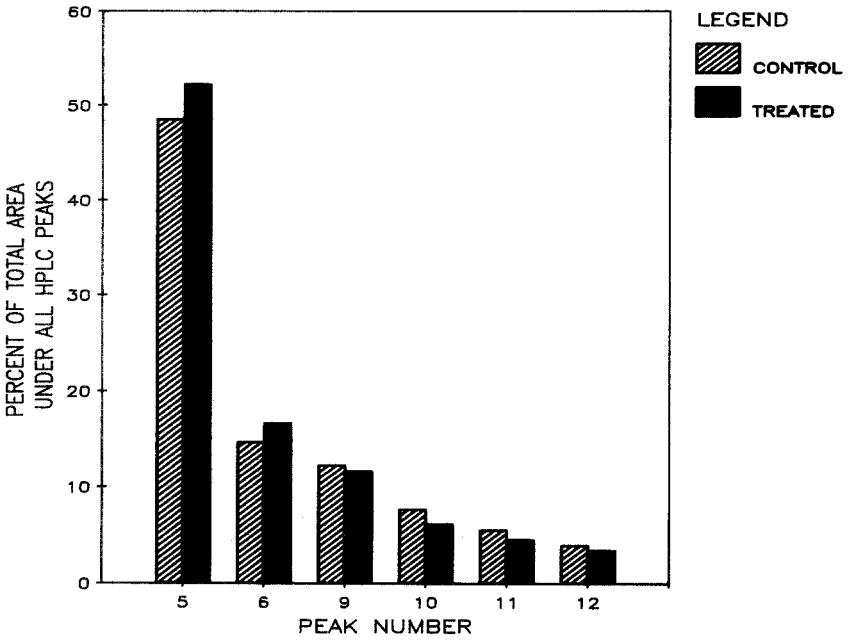

FIG. 4. The percentage of the total area (cm^2) under all HPLC peaks for a given extractable sample (i.e., T3 leaf, 96 hr) attributable to the indicated (numbered, Figure 3) peak did not differ ($P < 0.05$) between elicited (treated) versus control (nonelicited) soybean plants. CL showed a highly significant ($P < 0.01$) feeding preference for the leaf from the control plant in the choice bioassay.

α-tocopherol was clearly dependent on dosage, time, and space parameters. The observed treatment alterations of soybean leaves were all decreases regarding CL preference for herbivory. Significant effects were observed at 48, 72, and 96 hr after treatment. Such effects at 96 hr were limited to the younger T2 and T3 leaves. These leaves might be expected to be the more metabolically active ones on the plant. It is now clear from several previous studies (Chiang et al., 1987; Khan et al., 1987; Norris, 1988) and the present findings that alterable (inducible) soybean resistance to insect herbivory is very dynamic in response to elicitor dose, time since treatment, and space within a plant. At a given elicitor dosage and time after treatment, opposite induced effects on herbivory may even be expected in spatially separated leaves on a plant (Neupane and Norris, 1990; Haanstad and Norris, 1991).

Antifeedant Effects Correlate with Total Extractables. The best negative phytochemical correlate of the bioassayed CL feeding on treated foliage was the percentage of increased total HPLC peak area of the extractables from such

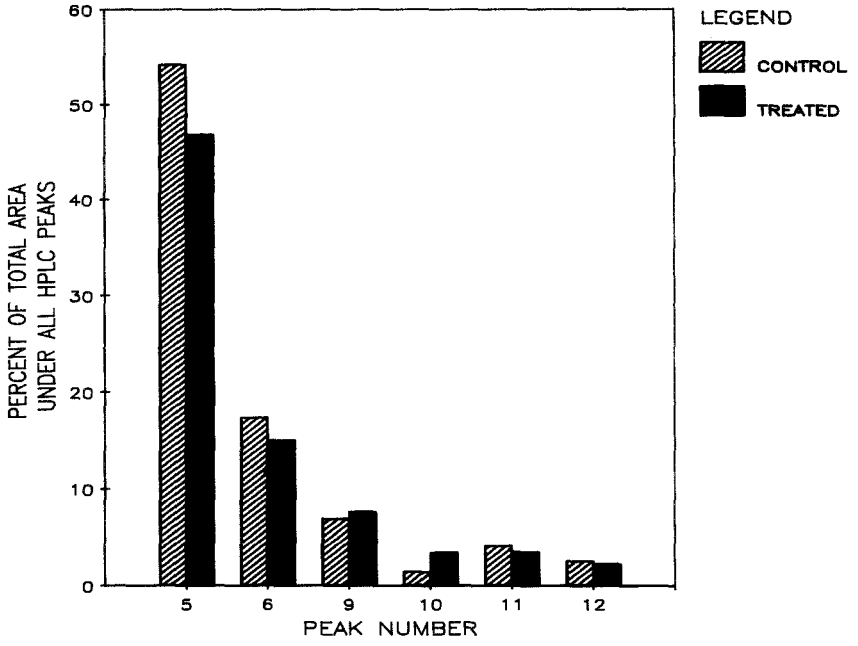

FIG. 5. The percentage of the total area (cm^2) under all HPLC peaks for a given extractable sample (i.e., T3 leaf, 72 h) attributable to the indicated (numbered, Figure 3) peak did not differ ($P < 0.05$) between elicited (treated) versus control (nonelicited) soybean plants. CL showed no significant ($P < 0.05$) feeding preference for the leaf from the control or elicited plant in the choice bioassay.

leaves as compared to that for the nonelicited control plants. Thus, in spite of the proven antifeedant and/or antibiotic effects (Sharma and Norris, 1991) of many of the specific chemicals resolved in the extractables, the findings in the current study support the quantity of the overall mix (i.e., profile) of compounds in the pertinent leaf extractables as especially responsible for the observed effects on CL feeding behavior. Concentrations of specific compounds (e.g., glyceollins) (Neupane and Norris, 1991) also have been highly positively correlated with induced antiherbivory in soybean leaves. Such specific chemicals are major contributors to the overall composition of the pertinent leaf extractables.

Other Effects of Phytoalexins. The results of this study and several others (Kogan and Paxton, 1983; Khan et al., 1987; Norris et al., 1988; Sharma and Norris, 1991) clearly show that phytoalexins, known primarily as antibiotics against microbial plant pathogens, actually are also major antifeedants and antibiotics to insect herbivores. Such findings support the interpretation that inducible defensive phytochemistry is not really specific for pathogens or pests.

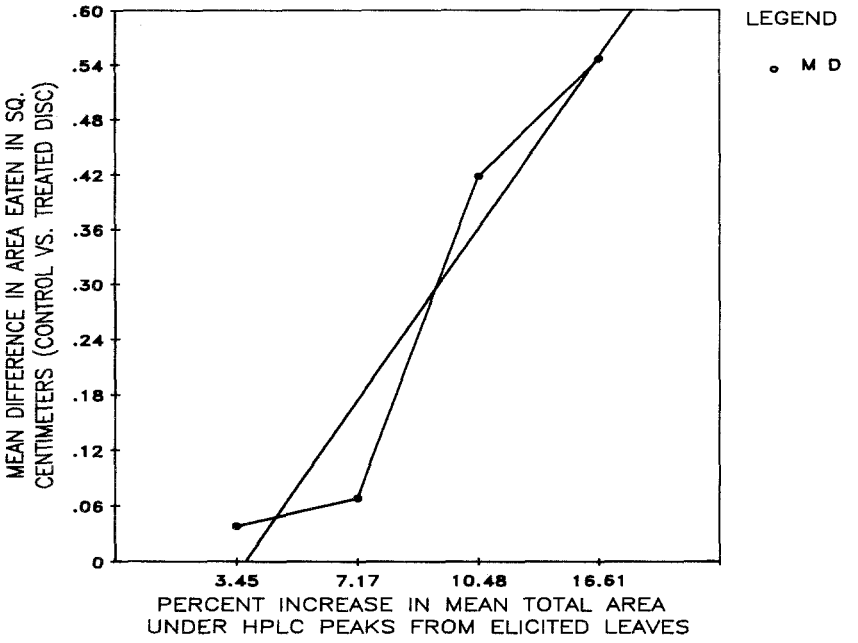

FIG. 6. Linear regression, $Y = -0.13 + 0.042X$ ($r = 0.937$), of the mean difference in the area eaten (cm^2) per disk from the same leaf on paired elicited versus nonelicited (control) soybean plants upon the percentage of the increased total area under the HPLC peaks of the extractables from the elicited as compared to the control leaf.

(Received April 15, 1991; accepted June 11, 1991)

Abstract—HPLC analysis of crude dichloromethane extracts of shaken liquid cultures of the hyphomycetous fungus *Tolypocladium geodes* Gams revealed the presence of efrapeptins. These peptides, which have mitochondrial ATPase inhibitory activity as well as antifungal and insecticidal properties, are previously known only from the congeneric species, *T. niveum* Rostrup. The identity of efrapeptins was confirmed by fast atom bombardment mass spectrometry and by amino acid analysis. HPLC analyses of efrapeptins extracted from single isolates of both *T. geodes* and *T. niveum* indicated that both species produced the same efrapeptins but the profile of relative abundance of the compounds produced was diagnostic for the isolates examined. Efrapeptin F was the major component of the mixture from *T. geodes* with the order of abundance of the six efrapeptins detected being F > G > D ~ E > H > C. Efrapeptin D was the major component from *T. niveum* with the order of abundance of the six efrapeptins detected being D > E > F > C ~ G > H. Efrapeptin F differs from efrapeptin D by a single amino acid residue, efrapeptin F having an alanine where efrapeptin D has a glycine. Addition of alanine to the culture medium increased the relative abundance of efrapeptin F in the profile of both species. Conversely, addition of glycine increased the relative abundance of efrapeptin D in the profile of both species.

INTRODUCTION

The hyphomycetous fungal genus *Tolypocladium* contains a number of soil-inhabiting species, some of which are pathogenic to insects (Bisset, 1983). One species in the genus, *T. niveum* (Rostrup) is especially notable for its secondary metabolites. It produces the cyclosporins, a group of cyclic peptides with well-known immunosuppressive and antifungal activity (Dreyfuss et al., 1976, and references cited), and the efrapeptins (Figure 1), a comparatively lesser known group of antibiotics that have been shown to be potent inhibitors of ATPases from mitochondria, chloroplasts, and bacteria (Gupta et al., 1991a,b, and references cited).

Insecticidal activity has been reported for crude extracts of several species of *Tolypocladium*, including *T. geodes*, and has been attributed to an unidentified material referred to as "tolypin" (Matha et al., 1988). However, at present, the only chemically characterized compounds from *Tolypocladium* species with documented insecticidal activity are the cyclosporins (Weiser and Matha, 1988) and the efrapeptins (Krasnoff et al., 1991), and these two classes of compounds are known so far only from *T. niveum*.

As part of an ongoing investigation of the role that efrapeptins play in the biology of *Tolypocladium* species, we have been screening extracts of isolates of various species for insecticidal activity as a probe for the presence of efrapeptins. We recently detected insecticidal and feeding deterrent activity against adult tephritid fruit flies of several species (*Anastrepha suspensa*, *Ceratitis capitata*, and *Rhagoletis pomonella*) with crude dichloromethane extracts of culture broth from an isolate of *T. geodes* (Krasnoff and Gupta, unpublished data). FIG. 1. Structure of efrapeptins C, D, E, F, and G (compounds C–G, respectively). Amino acid residues are abbreviated as follows: alanine (ALA), glycine (GLY), leucine (LEU), α-amino-isobutyric acid (AIB), β-alanine (β-ALA), isovaline (IVA), and pipecolic acid (PIP). Ac = acetyl, FW = formula weight.

this paper we present evidence that *T. geodes* produces efrapeptins and that the relative abundance of the efrapeptins produced by the strain studied is distinct from that produced by an isolate of *T. niveum*. We also present evidence that the amino-acid composition of the culture medium affects the profile of efrapeptins produced by both species.

METHODS AND MATERIALS

Growth of Fungi. Fungal inoculum was obtained from cultures maintained under liquid nitrogen in the USDA-ARS entomopathogenic fungi collection (ARSEF). To compare production of efrapeptins by *T. geodes* (ARSEF #2684) and *T. niveum* (ARSEF #616) under identical conditions, conidia were harvested in sterile 0.1% Tween-80 from 7- to 9-day-old cultures grown on slants of Sabouraud dextrose agar + 1% yeast extract (SDAY) at 22 ± 1°C. Concentrations of initial conidial suspensions were determined using an improved Neubauer hemacytometer. Suspensions of ca. 1×10^6 conidia/ml were made by dilution of initial suspensions in sterile 0.1% Tween-80. These were used to inoculate 100-ml batches of Czapek-Dox (Difco) liquid medium + 0.5% bactopeptone (Difco) in 250 Erlenmeyer flasks with 1×10^6 conidia. Liquid cultures were grown at 22 ± 1°C on a rotary shaker (160 rpm) for 11 days. Six replicates were produced for each species.

To investigate the effect of glycine and alanine on efrapeptin production, the fungi were grown in the above medium as well as media supplemented with either 1.0% L-alanine or 1.0% glycine (Sigma). Agar plugs from 13-to 14-day-old cultures grown on SDAY at 22 ± 1°C were used as inoculum for this experiment. Liquid cultures were grown at 22 ± 1°C on a rotary shaker (160 rpm) for 11 days. Each of the three treatments (control medium, alanine-supplemented medium, and glycine-supplemented medium) was duplicated.

Production of Extracts. Fungal mycelium, harvested after 11 days of growth, was separated from the broth by filtration through eight layers of cheese cloth. The broth was then centrifuged at 860 *g* for 10 mins. The pellet, containing conidia and mycelial fragments, was discarded and the supernatant was extracted three times with 100-ml portions of dichloromethane. The organic layer was concentrated *in vacuo*, then taken up in 60 ml of dichloromethane, washed twice with 10-ml portions of deionized water, dried over anhydrous sodium sulfate, filtered, and concentrated *in vacuo* once again. The extract was then transferred through a cotton filter to a vial in 3 × 2-ml portions of dichloromethane and concentrated to dryness with gentle heating under a stream of dry nitrogen. Extracts were stored at −20°C. Prior to HPLC analysis, samples were dissolved in methanol and filtered through a 0.45-μm membrane filter cartridge.

Isolation and Characterization of Efrapeptins. A sample of the crude dichloromethane extract of culture broth of the *T. geodes* isolate was analyzed on a reverse-phase C8 analytical column (0.4 × 15 cm, particle size 5 μm) eluted with MeCN–12.5 mM $(NH_4)_2SO_4$ (63:37) at a flow rate of 1.2 ml/min. Detection was by monitoring UV absorption at 225 nm (0.2 aufs). Material for fast atom bombardment mass spectrometry (FABMS) and amino acid analysis was obtained from repetitive semipreparative HPLC on a reverse-phase C8 column (0.9 × 50 cm) eluted with MeCN–12.5 mM $(NH_4)_2SO_4$ (75:25) at a flow rate of 5.5 ml/min. Detection was by monitoring UV absorption at 225 nm (0.5 aufs). Amino acid analysis was performed on an analyzer in which amino acid composition of the hydrolyzate was determined as the phenylthiohydantoin derivatives by comparing HPLC retention times with those of standards. Efrapeptin profiles were evaluated by HPLC analyses using an integrating chart recorder (Hewlett-Packard 3390 A) for quantitative comparison of peak areas. Semiquantitative comparisons among samples of relative amounts of efrapeptins produced per unit of crude extract were made by comparing total efrapeptin peak area and correcting for amount of crude extract injected (product of injection volume and concentration of extract solution). A standard curve was generated to verify that the response of the UV detector to efrapeptins was linear with respect to the amount of extract injected onto the HPLC.

RESULTS

Isolation and Characterization of Efrapeptins. HPLC analysis of crude dichloromethane extracts of *T. geodes* indicated the presence of a mixture of efrapeptins (Figure 2). Peaks from the *T. geodes* extracts cochromatographed with efrapeptins C, D, E, F, and G from a partially purified mixture from *T. niveum* (ARSEF #616) (Gupta et al., 1991b). A peak eluting after efrapeptin G possibly corresponds to efrapeptin H as shown by Jackson et al. (1979). Peak H made up ca. 6% of the total area of the efrapeptin fraction from *T. geodes*. The amino acid sequence of this peak remains to be determined.

Identification of efrapeptins from *T. geodes* extracts was confirmed by data from FABMS analysis and amino acid analysis of an HPLC-purified mixture of efrapeptins C, D, E, F, G, and H. FAB mass spectra showed molecular ions (M^+) at *m/z* 1606, 1620, 1634, 1648, and 1662. The quaternary nitrogen in the C-terminal blocking group of the efrapeptins (Figure 1) is responsible for producing unusually intense molecular ion peaks (M^+) instead of the usual $M+H^+$ under FABMS conditions (Gupta et al., 1991b). This spectrum is consistent with the presence of efrapeptins C (1606), D (1620), E (1634), F (1634), G (1648), and a sixth compound of molecular weight 1662, probably efrapeptin H.

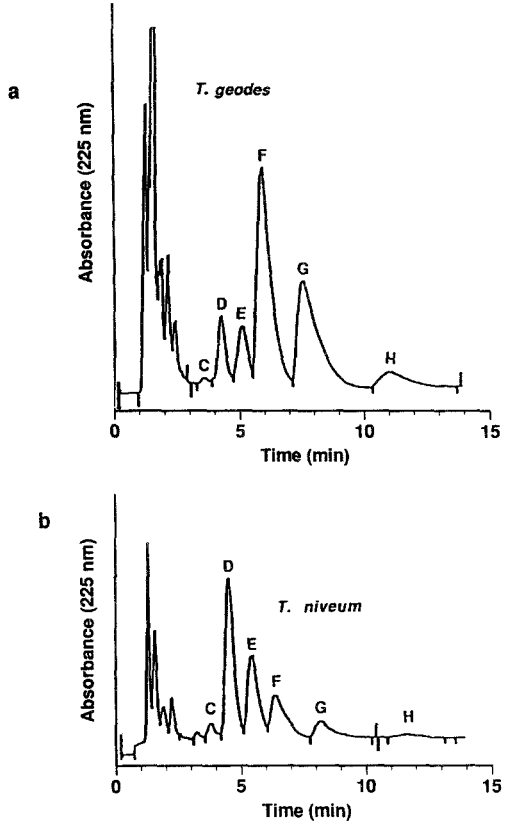

FIG. 2. HPLC chromatograms of crude extracts from *Tolypocladium geodes* (5 μl of 5 μg/μl solution in methanol) and *T. niveum*. (4 μl of 5 μg/μl solution in methanol). Samples were injected on a reverse-phase C8 analytical column (0.4 × 15 cm, particle size, 5 μm; solvent MeCN–12.5 mM $(NH_4)_2SO_4$ (63:37); flow 1.2 ml/min; detection UV 225 nm, 0.2 aufs. Fungi were grown on Czapek-Dox liquid medium + 0.5% bactopeptone.

Amino acid analysis of the HPLC-purified mixture confirmed the presence of α-aminoisobutyric acid (aib), leucine (leu), isovaline (iva), glycine (gly), β-alanine (β-ala), and alanine (ala) in a molar ratio of 672.2 (aib):257.3 (leu):203.2 (iva):185.1 (gly):148.8 (β-ala):123.8 (ala). This corresponds well with the molar ratio calculated for a mixture of efrapeptins C, D, E, F, and G, by taking into account their amino acid content (Figure 1), their relative abundance in *T. geodes* crude extracts as determined by HPLC analyses (see below), and standardizing to the molar estimate for leucine from the analysis: 717.0 (aib):257.3 (leu):183.6 (iva):153.2 (gly):128.7 (β-ala):104.1 (ala).

Comparison of Efrapeptin Profiles. Efrapeptin F was the major component of the efrapeptin profile of *T. geodes* with the order of abundance of the six detectable efrapeptins being F > G > D ~ E > H > C (Table 1, Figure 2a). Efrapeptins F and G accounted for >75% of the efrapeptin fraction of *T. geodes*. The major component in the efrapeptin profile of *T. niveum* was efrapeptin D with the order of abundance of the six efrapeptins being D > E > F > C ~ G > H (Table 1, Figure 2b). Efrapeptins D, E, and F accounted for >85% of the efrapeptin fraction of *T. niveum*. Efrapeptin G, a major component in the *T. geodes* profile, was a minor component in the *T. niveum* profile. Conversely, efrapeptin E, a major component in the *T. niveum* profile, was a minor component in the *T. geodes* profile.

Although *T. geodes* produced almost twice as much extract per unit of broth, 18.7 ± 1.2 mg/100 ml (±standard error for $N = 6$) compared with *T. niveum*, 8.9 ± 0.2 mg/100 ml (±standard error, $N = 6$), it produced only 0.63 times as much of the efrapeptins per unit mass of extract as *T. niveum*. Thus *T. geodes* produced 1.3 times more efrapeptins per unit volume of broth than *T. niveum*.

Effect of Supplemental Alanine and Glycine on Efrapeptin Profiles. Efrapeptins F and D differ only by an amino acid substitution at position 13 (Figure 1), D having a glycine and F having an alanine. With the standard medium (Czapek-Dox + 0.5% bactopeptone), *T. geodes* produced a ratio of efrapeptin F to D of 5.3:1 (ratios presented are based on the average of two replicates; Figure 3a). Cultured with 1% alanine this ratio increased to 11.3:1 (Figure

TABLE 1. RELATIVE ABUNDANCE OF EFRAPEPTINS C, D, E, F, G, H IN DICHLOROMETHANE EXTRACTS OF CULTURE BROTH FROM *T. geodes* AND *T. niveum* EXPRESSED AS AVERAGE PERCENTAGE OF TOTAL EFRAPEPTIN FRACTION BASED ON HPLC PEAK AREA $n = 6$ SAMPLES; (RANGE OF PERCENTAGES SHOWN IN PARENTHESES)[a]

Efrapeptin	Species	
	T. geodes	*T. niveum*
C	0.6(0.4–0.7)	6.0(4.8–7.7)
D	8.3(6.6–9.5)	39.9(37.1–41.8)
E	9.1(8.4–10.0)	24.5(22.3–26.1)
F	44.5(42.9–46.1)	21.9(20.3–23.1)
G	31.7(30.3–33.6)	6.8(4.4–9.4)
H	6.0(5.1–7.4)	1.0(0.0–0.4)

[a] Means for all six compounds were significantly different between species at $\alpha = .01$ (T-tests with α-levels adjusted by Bonferoni's inequality).

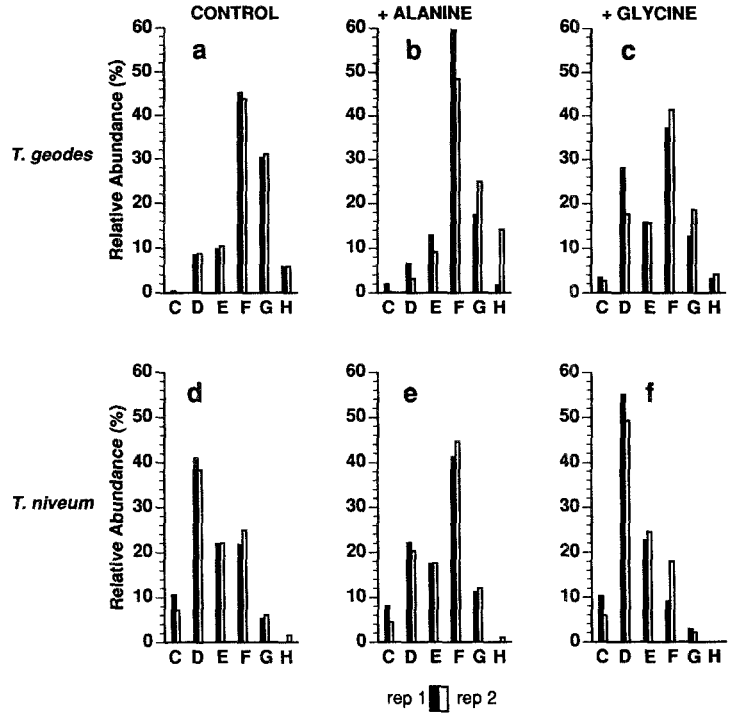

FIG. 3. Effect of supplementing standard growth medium (Czapek-Dox + 0.5% bactopeptone) with 1% alanine or 1% glycine on the efrapeptin profiles of *Tolypocladium geodes* and *T. niveum*. Relative abundance of efrapeptins C, D, E, F, G, and H (labeled on the *x* axes) in dichloromethane extracts of culture broth expressed as percentage of efrapeptin fraction based on HPLC peak area. Shown are results from two replicates.

3b). Cultured with 1% glycine, this ratio decreased to 1.7:1 (Figure 3c). With the standard medium, *T. niveum* produced a D to F ratio of 1.7:1 (Figure 3d). Grown with 1% alanine, this ratio decreased to 0.5:1 (Figure 3e). Grown with 1% glycine this ratio increased to 3.9:1 (Figure 3f). Thus in both species supplemental glycine had the effect of increasing the production of D relative to F while supplemental alanine had the effect of increasing the production of F relative to D.

Some analogous effects, although not as dramatic and consistent, were noted with the secondary components of the two species, efrapeptins E and G, which also differ from each other only by the replacement of glycine with alanine at position 13 (Figure 1). With additional alanine, the ratio of G to E in *T. geodes* extracts actually decreased from 3.1:1 to 1.9:1 counter to the expected pattern (Figure 3a,b). With additional glycine, however, the ratio decreased

predictably from 3.1:1 to 1:1 (Figure 3c). In *T. niveum* extracts the E to G ratio, which was 3.9:1 in the controls (Figure 3d), decreased predictably to 1.5:1 with additional alanine (Figure 3e) and increased predictably to 9.2:1 with additional glycine (Figure 3f).

DISCUSSION

We have documented the production of efrapeptins by *T. geodes* and have described a distinct difference between the efrapeptin profile of the isolate studied and that of an isolate of *T. niveum*. Two independent HPLC analyses of an efrapeptin fraction from another *T. niveum* isolate (Jackson et al., 1979; Krishna et al., 1990) show that efrapeptin D is the primary component with the order of abundance of efrapeptins essentially the same as reported here for *T. niveum*. This points to the possibility that the strain-specific differences we have documented here are representative of species-level characteristics. However, we recognize the need to evaluate a broader range of isolates of each species to support such a claim and are currently expanding our survey of isolates to provide a better overall picture of the intra- and interspecific patterns of variation in efrapeptin production in *T. geodes* and *T. niveum*.

The literature on antibiotics and mycotoxins is replete with reports of species-specific or strain-specific profiles based on the presence or absence of various compounds (e.g., Frisvad, 1986; Katz and Demain, 1977; Moss, 1982). However, documentation of strain- or species-specific differences of the type we have described here, i.e., where there is a diagnostic pattern of relative abundance in a microheterogeneous group of secondary metabolites, is relatively rare. Examples are the actinomycin profiles of *Streptomyces chrysomallus* and *S. antibioticus* (Katz, 1974) and the xanthomegnin/viomellein profiles of *Aspergillus ochraceus*, *Penicillium cyclopium*, and *P. viridicatum* (Stack and Mislivec, 1978).

There are precedents in the antibiotic literature for what has been called "directed" or "controlled" biosynthesis, i.e., the favoring of particular components of a microheterogeneous mixture by providing exogenous precursors (Katz, 1974). It is intriguing that this phenomenon has been previously reported to occur with cyclosporins, the other class of antibiotics known to be produced by *T. niveum* (Kobel and Traber, 1982).

As mentioned above, efrapeptin D, the primary product of *T. niveum*, differs from efrapeptin F, the primary product of *T. geodes*, by one amino acid substitution, efrapeptin D having a glycyl residue in position 13 where F possesses an alanyl residue. In analogous fashion, the second most abundant efrapeptins for each species, E in *T. niveum* and G in *T. geodes*, differ in precisely the same way, E having glycine in position 13 where G has an alanine. Although

nothing has been published regarding the biosynthesis of the efrapeptins, the difference observed here between the two species points to the existence of a mechanism whereby *T. niveum* favors the inclusion of glycine vs. alanine at position 13 and vice versa for *T. geodes*. This could involve differences in the levels of biosynthesis of the constituent amino acids, differences in the preference for one amino acid over another at a particular step in biosynthesis, or a combination of both scenarios. The only firm conclusion that can be made based on our findings regarding the biosynthesis of efrapeptins is that both fungi studied can incorporate exogenous amino acids into the peptide chains. This suggests the possibility that similar effects might be observed with α-aminoisobutyric acid and isovaline supplements in that several differences among the known efrapeptins are due to substitutions of these two amino acids at positions 4 and 15 (Figure 1). The effects of glycine and alanine supplements on the production of the major components in the efrapeptin profiles of the two species also have a practical implication; they point to the feasibility of directing biosynthesis toward either efrapeptin D or F, thus making purification more efficient in any large-scale effort to produce efrapeptins.

T. geodes is the second species in the genus *Tolypocladium* for which efrapeptin production has been documented. The presence of efrapeptins in *T. geodes* may account for the antifungal activity observed by Lundgren et al. (1978) in isolates of *T. geodes* and the insecticidal activity observed in extracts of *T. geodes* reported by Matha et al. (1988). Our results suggest the possibility that efrapeptins may occur elsewhere in the genus and their presence (and quantitative profiles) may be of taxonomic relevance. A more complete view of the pattern of efrapeptin distribution among species of *Tolypocladium* should offer insights into the evolution and function of these secondary metabolites.

Abstract—Chemoorientation behavior of the larval eastern tent caterpillar, *Malacosoma americanum*, was studied using the synthetic trail pheromone 5β-cholestane-3,24-dione. Divergent arms of Y mazes were treated with various concentration ratios of the pheromone. At application rates of 10^{-10}–10^{-9} g/mm of trail, larvae showed a significant preference for stronger trails when concentration ratios differed by as little as 4 : 1. At application rates of 10^{-8} and greater there was no significant difference in trail choice even when trails differed in strength by a full order of magnitude. Other studies showed that the caterpillars abandon the pattern of choosing stronger over weaker trails when they repeatedly fail to find food at the end of a stronger trail. Experiments in which larvae were required to choose trails separated by a gap demonstrated orientation by chemoklinotaxis. Caterpillars that had one of the maxillary palps ablated looped in the direction of their intact chemoreceptor when placed on filter paper treated uniformly with pheromone, indicating that they may also orient by tropotaxis. The relevance of these findings to the tent caterpillar communication system is discussed.

Key Words—Chemoorientation, pheromone, eastern tent caterpillar, *Malacosoma americanum*, trail following, klinotaxis, tropotaxis, 5β-cholestane-3,24-dione, Lepidoptera, Lasiocamsidae.

INTRODUCTION

Previous behavioral experiments with eastern tent caterpillars, *Malacosoma americanum* (Fitzgerald, 1976), and caterpillars of the lackey moth, *Malacosoma neustria* (Peterson, 1988), demonstrated that larvae deposit chemical markers to facilitate orientation to and from feeding sites. A major component of the pheromone system of the eastern tent caterpillar, 5β-cholestane-3,24-dione, was identified recently and shown to elicit trail following at threshold levels of 10^{-11} g/mm of trail (Crump et al., 1987). Caterpillars mark exploratory trails as they move to food by dragging a ventral secretory site against the substrate (Fitzgerald and Edgerly, 1982). Successful foragers overmark these trails as they return to the tent (Fitzgerald and Peterson, 1983). Overmarked trails are analogous to the recruitment trails used by ants and serve to lead siblings to food finds.

Observations made in earlier studies indicated that the trail system of the eastern tent caterpillar consists of chemical trails of variable age and strength. For example, both the availability and the quality of foliage affect the marking intensity of caterpillars (Fitzgerald and Peterson, 1983). Moreover, although the chemical marker is long-lived and may persist for weeks under field conditions, it declines in effectiveness as it ages (Fitzgerald and Gallagher, 1976; Peterson, 1988). As caterpillars move over this trail system, they must choose between the divergent trails that occur at forks in the branches. Previous studies showed that caterpillars choose newer over older trails at these choice points (Fitzgerald and Gallagher, 1976), but the effect of pheromone concentration on trail selection behavior has not been assessed previously. We therefore undertook studies to determine how caterpillars respond to trails containing different quantities of the synthetic marker.

A second study was undertaken to investigate the orientation mechanisms of trail-following tent caterpillars. 5β-Cholestane-3,24-dione is perceived by contact chemoreception mediated by the maxillary palps (Roessingh et al., 1988), which are bilateral mouthpart chemoreceptors (Schoonhoven, 1987). Generally, organisms that perceive stimuli via bilateral receptors may use tropotactic or klinotactic orientation mechanisms (Bell, 1984; Bell and Tobin, 1982; Kennedy, 1986). In tropotaxis, animals orient to spatial gradients of stimuli by sampling simultaneously left and right from the paired sensory receptors (instantaneous comparisons) (Bell and Tobin, 1982). In klinotaxis, sampling is done successively (temporal comparisons) (Bell and Tobin, 1982), either along a path (longitudinal klinotaxis) or from side to side (transverse klinotaxis). In both klinotaxis and tropotaxis, locomotory output may take the form of turning to the more stimulated side (Kennedy, 1986). Thus, manipulations of the sensory system, the stimulus field, or both, are necessary to determine if tropotactic or klinotactic mechanisms are being used.

METHODS AND MATERIALS

Malacosoma americanum larvae were collected as early instars from field colonies or reared from field-collected egg masses hatched in the laboratory. Laboratory colonies were kept as described previously (Fitzgerald and Peterson, 1983).

Tent caterpillar larvae readily orient to artificial trails made of synthetic 5β-cholestane-3,24-dione (Crump et al., 1987; Peterson, 1988). To determine if larvae distinguish a higher dosage pheromone trail from a lower dosage one (i.e., a stronger trail from a weaker one), we applied the synthetic pheromone to filter-paper Y mazes (Figure 1). The design of the maze enabled larvae to encounter discretely weaker and stronger pheromone stimuli at the fork. 5β-Cholestane-3,24-dione dissolved in hexane was applied to the paper strips using 5-μl capillary pipets. The runway of the maze was treated with the higher dosage of pheromone. Concentrations ranged from 2.5×10^{-10} g/mm to 2.5×10^{-6} g/mm. Twenty second- or third-instar caterpillars were used in each test. Each caterpillar was tested on a separate Y maze.

Large numbers of caterpillars frequently collect at newly discovered feeding sites and may exhaust them before all of the caterpillars in the colony have

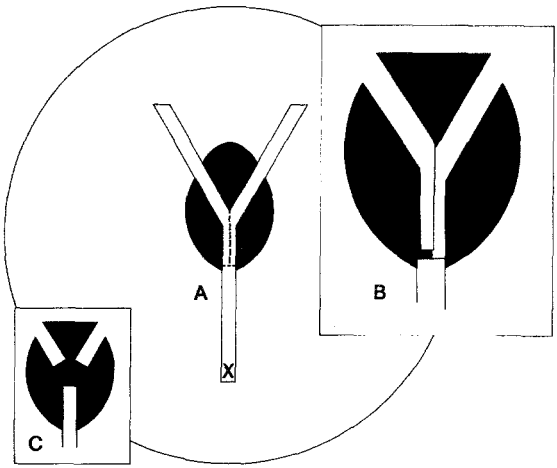

FIG. 1. (A) The Y mazes used in this study were drawn in pencil on filter paper. Black areas were cut out and removed and the stem of each maze was cut along the dotted line. As shown in (B), this allowed each arm to be bent slightly upward when applying the pheromone to prevent bleed-over. As the caterpillar moved down the stem of the maze from point (X), it contacted both treated arms before they diverged. (C) In some trials, sections were removed from the juncture of the stem and arms to prevent instantaneous comparison of trail strength as described in the text.

fed. Hungry caterpillars are likely to choose the heavily marked trails that lead to such sites initially, but they must be prepared to abandon them for weaker trails or unmarked branches when they discover that they no longer lead to food (Fitzgerald and Peterson, 1988). Studies were conducted to determine how long an individual persists in choosing the more heavily marked of two trails when the trail does not lead to food. The response of 20 third-instar larvae to the alternate arms of paper Y mazes was observed. Trails of the synthetic pheromone were established on the arms of the maze using a concentration of 2.5×10^{-9} g/mm for the stronger trail and a 1/10 dilution for the weaker trail. Each animal was allowed to move ad libitum back and forth over the maze for 5 min, and its choice was recorded each time it encountered the juncture of the strong and weak trail. The maze was oriented vertically and suspended from cardboard with insect pins to discourage the caterpillars from leaving it. A new maze was constructed for each animal.

To determine if larvae can orient chemoklinotactically, the Y maze was modified to force larvae to make temporal comparisons of two trails. A small gap was created in the maze by cutting away the junction of the runway and arms (Figure 1). The gap did not impede the forward progress of the caterpillars but was sufficiently large to ensure that the second-instar caterpillars were unable to sense both trails simultaneously, requiring them to swing their heads from trail to trail. The arms of the maze were treated with synthetic pheromone using a concentration of 2.5×10^{-9} g/mm for the stronger trail and a 1/10 dilution for the weaker. The responses of 20 second-instar caterpillars were observed.

To determine if tent caterpillars make instantaneous comparisons with their palps, we unilaterally ablated the palps by pinching with a fine forceps while gently holding the animal under a dissecting microscope. Insects were allowed to recover overnight and were examined prior to testing to ensure that the palp was completely removed. Control animals were handled in the same way but were not operated on.

Both surgically altered and control animals were tested on a uniform field of pheromone, which was prepared by placing a sheet of 11-cm Whatman No. 2 filter paper into a Petri dish and adding 2 ml of 10^{-9} g/ml of the synthetic pheromone dissolved in hexane. This technique produced a uniform wetting of the paper with pheromone solution. The filter paper was air-dried for 30 min. A caterpillar was placed in the center of the field and its activity was recorded on video tape. The test was terminated when the larva encountered the edge of the field. The caterpillar pathways were traced onto transparencies directly from the video. The pathways were digitized using SigmaScan (Jandel Scientific, Corte Madera, California), and the path length was measured. From these data we calculated an index of "search intensiveness" (Schal et al., 1983), by counting the number of times the animal crossed its own path (loops) clockwi. and counterclockwise, then dividing the number of loops by the distance traveled.

Thus, the index increases in magnitude with the number and compactness of the loops.

RESULTS

Tent caterpillars exhibited rhythmic side-to-side head movements (wig-wagging) (Bell and Tobin, 1982) as they walked on artificial trails. Encounters with discontinuities or Y-maze branches were often accompanied by a locomotory pause and head waving over a larger radius. Caterpillars typically checked both arms of the Y maze before proceeding.

In dosage-discrimination tests, tent caterpillar larvae preferred stronger to weaker trails (Figure 2). When the trail pheromone was applied at a dosage of 2.5×10^{-10} g/mm, all larvae tested at the 10:1 concentration ratio chose the stronger trail. The preference was less pronounced at a 4:1 concentration ratio, and there was no significant preference for the stronger trail at a 2:1 concentration ratio. At higher pheromone concentrations, preference for the stronger trail was diminished in tests of 10:1 concentration ratios. For example, there was no significant preference for stronger trails when the weak trail dosage was 10^{-8} or 10^{-7} g/mm (Figure 2). The results demonstrate that tent caterpillars

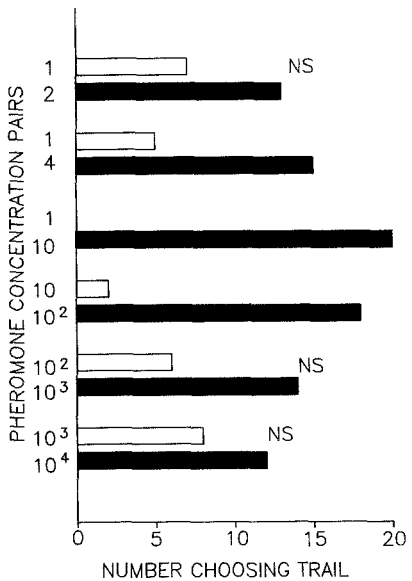

FIG. 2. Dosage dependency of eastern tent caterpillar trail following. The y axis values are multiples of the base concentration of 2.5×10^{-10} g of pheromone per millimeter of trail. NS = not significant, all others significant at $P < 0.05$ (G test).

can distinguish differences in trails of less than an order of magnitude when the marker is applied at near threshold strength, but orientation to stronger trails is less pronounced at higher absolute pheromone dosages. Pheromone concentrations in these tests were several orders of magnitude above threshold, levels unlikely to occur in nature. Such concentrations may lead to saturation of the maxillary chemoreceptors and prevent discrimination.

Observations of caterpillars allowed to make repeated choices between the weak and strong arms of a Y maze show that caterpillars initially prefer the stronger of the two but eventually move onto the weaker one (Figure 3). By the fourth encounter, greater than 50% of the larvae had chosen the weaker trail. The maximum number of encounters required for any individual caterpillar to choose the weaker trail was 16 ($N = 1$), and the minimum number was two ($N = 3$).

The ability of caterpillars to make temporal comparisons of stimulus intensity was demonstrated in tests involving Y mazes altered by removing a section of the trail at the choice point (Figure 1). Nineteen of the 20 larvae tested chose the stronger trail after crossing the gap ($P < 0.005$, G test).

The results of the ablation experiments are summarized in Figure 4. Caterpillars with the left palp removed looped clockwise, in the direction of their intact chemoreceptor. Caterpillars with the right palp removed looped counterclockwise, also in the direction of their intact chemoreceptor. Unoperated caterpillars traveled in loops, but there was no consistent directionality to their movements. Examples of looping behavior are given in Figure 5.

DISCUSSION

Our study shows that tent caterpillars can discriminate trails on the basis of relative pheromone concentration. Under field conditions, trails branch frequently and at each juncture caterpillars must chose between alternate pathways. At normal hunger levels and when trail recency is not a factor, caterpillars initially choose more heavily marked trails over weaker ones (Figure 2). Since the trail system of the caterpillar becomes weaker with distance from the tent due to progressive branching of its structure, caterpillars can return directly to the tent after feeding by selecting stronger over weaker trails at each juncture point. By applying the same rule, outbound foragers can move directly to the feeding sites marked by the largest numbers of successful foragers, even though the overall trail gradient declines with distance from the tent.

Discrimination of trails by strength may be only one form of discrimination used by the caterpillars. Previous studies showed that caterpillars can also discriminate trails by age (Fitzgerald and Gallagher, 1976). Although the ultimate basis for the discrimination of aged trails might also be relative trail strength,

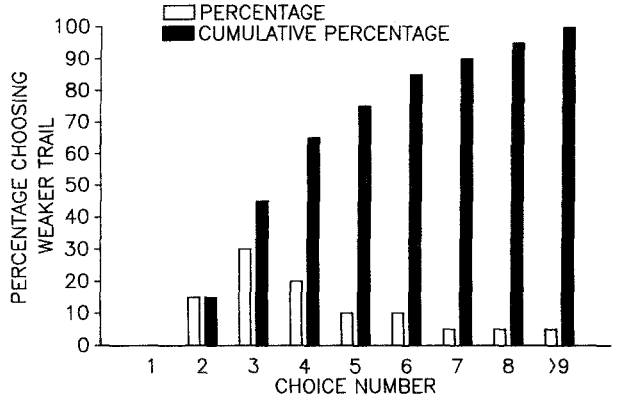

FIG. 3. Percentage of caterpillars choosing weaker trail (2.5×10^{-10} g/mm) over stronger trail (2.5×10^{-9} g/mm) during first through ninth (or greater) encounter with choice point of maze. See text for details.

the accumulation of a degradation product could be involved. In addition, the ability of caterpillars to discriminate between trails marked by hungry and sated caterpillars may be due to qualitative differences between the trail types (Crump et al., 1987).

The tendency of tent caterpillars to aggregate at feeding sites commonly leads to the local exhaustion of foliage and to the cessation of trail marking. In a similar circumstance, the volatile recruitment trails of many ants disappear quickly, facilitating the rapid abandonment of the site. In contrast, the nonvolatile trail marker of the tent caterpillar persists long after a feeding site has been

exhausted. We show here that tent caterpillars deal with this problem by abandoning the pattern of following the most heavily marked trails when such behavior fails to reward the forager. Indeed hungry caterpillars eventually break into an exploratory mode in which they leave established trails altogether, moving over unmarked branches in search of food (Fitzgerald and Peterson, 1988).

Our results show that tent caterpillars may orient by using either temporal or instantaneous comparisons of stimulus intensity. The ability of caterpillars to make temporal comparisons, clearly shown in the gap test, suggests that chemoklinotaxis is responsible for discrimination of trail differences at branch points. Moving caterpillars also wave their heads from side to side (wig-wagging) (Bell and Tobin, 1982; Kennedy, 1986), suggesting they employ klinotaxis (transverse klinotaxis) (Kennedy, 1986) as they move along unbranched trails. The pronounced circling response of caterpillars with unilaterally ablated palps shows that input biases also have the potential to influence orientation behavior as larvae move along trails. Studies of the ant *Lasius* (Hangartner, 1967), a species that exhibits marked zigzagging behavior as it moves along odor trails, have been similarly interpreted to demonstrate that the insect makes

simultaneous, bilateral comparisons of trail strength with its antennal chemoreceptors (Schöne, 1984).

Some species of ants regulate the number of individuals on trails by using a system of mass communication in which group transfer of information plays a prominent role (Wilson, 1971). Such systems are based on: (1) modulation of trail laying in response to variation in the quantity or quality of resources, and (2) the ability of trail followers to orient on the basis of the amount of trail pheromone produced by recruiters. Our present study and a previous study showing that tent caterpillars modulate their recruitment trail-laying in response to factors such as leaf quality or crowding at feeding sites (Fitzgerald and Peterson, 1983) indicate that eastern tent caterpillars employ a similar process.

Acknowledgments—P. Roessingh participated in preliminary experiments and discussions of tent caterpillar orientation mechanisms at Wageningen University, The Netherlands. Trail chemicals were provided by R. Silverstein and D. Crump. Supported by NSF grant BNS-8908610.

Abstract—Three sex pheromone components of the carob moth were isolated and identified from the extract of female pheromone glands, using a variety of techniques including coupled gas chromatographic–electroantennographic recordings, coupled gas chromatographic–mass spectrometric analysis, microozonolysis, electroantennographic assays of monounsaturated standards, wind-tunnel bioassays, and field trials. The major component was identified as (*Z,E*)-9,11,13-tetradecatrienal, a novel lepidopterous pheromone component structure. Two minor components, either one of which improves the upwind flight response of males when blended with the major component, were identified as (*Z,E*)-9,11-tetradecadienal, and (*Z*)-9-tetradecenal.

Key Words—Flight tunnel, gas chromatography–electrophysiology, mass

INTRODUCTION

The carob moth, *Ectomyelois ceratoniae*, is a worldwide pest of nuts and fruits, including carobs, almonds, and dates (Gothilf, 1984). It has been expanding its range into new parts of the world. For instance, in the United States this species is a primary pest of dates in the desert valleys of southern California, and it now threatens to move north into the vast almond and pistachio groves of the San Joaquin Valley (Warner, 1988). There is thus an urgent need for a sensitive means of monitoring endemic populations and for detecting new ones, such as is offered by traps with synthetic sex pheromone lures. Opportunities exist also for direct control using mating disruption, because the labor-intensive nature of the crop would allow for application of disruptants at minimal additional labor cost. To provide this needed tool, we undertook to identify the female sex pheromone of this species, and although we provided a brief report on the identification (Baker et al., 1989), the present paper presents more extensive data on the identification and new information about the laboratory and field activity of these compounds.

METHODS AND MATERIALS

Chemical Analysis of Female Pheromone Gland Extract. Moths were obtained from infested dates near Indio in the Coachella Valley of Riverside County, California, in 1985. Larvae were reared on a honey and wheat-bran diet in one-gallon jars in the laboratory (Warner, 1988), the pupae were segregated by sex, and the moths allowed to emerge on a 14:10 light–dark photoperiod regime. The sex pheromone glands of 2- to -5-day-old females were excised into ca. 50 μl of CS_2 in a micro-test-tube during the normal period of female pheromone emission in the fourth through sixth hours of scotophase. The glands from up to 100 females were extracted for 15–45 min, the solvent was recovered with a syringe, and the extract was pooled with other similarly collected samples and stored at −20°C.

Aliquots of the extract, usually 10–20 female equivalents (FE) were injected onto 30-m × 0.25-mm-ID capillary gas chromatographic (GC) columns, coated either with nonpolar DB-1 or polar DB-WAX or DB-225 (J & W Scientific, Folsom, California) for analyses by GC–mass spectrometry (GC-MS) and GC–electroantennography (GC-EAG). Column conditions for the DB-

1 and DB-WAX columns were as follows: H_2 carrier gas flow of 1.5 ml/min, injector temperature 250°C, oven temperature program, 2 min at 80°C, then 10°/min to 230°C, and flame ionization detector at 250°C. Conditions for the DB-225 column was: H_2 carrier gas flow of 1.5 ml/min, injector temperature 250°C, oven temperature program 2 min at 80°C, then 15°/min to 180°C, and flame ionization detector at 250°C. GC-MS analyses were performed using a Hewlett-Packard 5890 gas chromatograph with a direct interface to a Hewlett-Packard 5970 mass selective detector (electron impact, 70 eV). All NMR spectra of synthetic samples were obtained with a Bruker WM 400 spectrometer at 400 MHz.

Microozonolysis was performed using an adaptation of the previously published technique (Beroza, 1975). The unknown compound was first collected from the DB-1 column by turning off the flame ionization detector and placing a melting-point tube over the end of the detector jet. A small piece of Dry Ice was touched to the side of the tube so that the effluent would more readily condense onto the glass walls. Ozone was then generated in a 500-ml Ehrlenmeyer flask by introducing oxygen into the flask at ca. 50 ml/min and creating a continuous spark inside the flask with a Tesla coil (high-voltage source) applied to an electrode. The melting point tube then was placed at the outlet of the ozone-flask for no more than 2 sec to expose the adsorbed compound to the ozone, and within ca. 10 sec the tube was rinsed with 5 μl of CS_2 solution. The CS_2 was then removed and injected onto the GC to examine the sample for ozonolysis reaction products, which were identified by comparisons with ozonolysis products from synthetic standards.

Electroantennogram Analysis. To examine antennal sensitivity to geometric and positional isomers, as well as to functional groups, electroantennograms (EAGs) were recorded (Roelofs, 1984) using a series of synthetic standards of acetates and alcohols purchased from Dr. S. Voerman at the Institute for Pesticide Research, Wageningen, The Netherlands. Several 14- and 16-carbon aldehydes were available (Albany International) including tetradecanal, (*Z*)-9-tetradecenal, (*Z*)-9-hexadecenal, (*E*)-9-hexadecenal, (*Z*)-7-hexadecenal, and (*Z*)-11-hexadecenal. Serial dilutions of each compound were made in hexane such that 10 μg were applied to filter paper in 10 μl of solvent, and then the filter paper was placed inside a Pasteur pipet. A male carob moth antenna was placed between two saline-filled glass electrodes, and the signal amplified with a Hansson model 103 amplifier and displayed on a storage oscilloscope. Each sample pipet was inserted into the airstream in a glass tube upwind of the antenna, and 1 ml of air was puffed through the tube from a glass syringe whose plunger was depressed by hand in less than 30 msec; the resulting antennal depolarization was measured on the oscilloscope screen. After every three to four puffs of test compounds, a standard control compound, (*E*)-6-tetradecenyl acetate, was puffed in order to monitor possible deterioration of the preparation.

EAG amplitudes were standardized according to the responses to this internal standard by dividing the amplitude of the EAG generated from the test compound by that from the standard. Within a particular series of isomers having the same chain length and functional group, presentation of the test compounds was randomized.

Simultaneous GC-EAG analysis (Arn et al., 1975) was performed on the DB-1, DB-WAX, and DB-225 30-m × 0.25-mm-ID GC columns (J & W Scientific). Briefly, the effluent was split 1 : 1 so that it entered two 1-m-long deactivated fused silica columns just before they left the GC oven, and make-up gas was added just before the split point to improve splitting and to drive the effluent rapidly through the deactivated columns and to the flame and EAG detectors, respectively. Simultaneous GC and single-cell (GC-SC) analysis (Wadhams, 1984; Van der Pers and Löfstedt, 1983) was performed using the same splitting technique, except that instead of a whole antenna, an electrode was placed over a single sensillum trichodeum (see next section) to record the single neurons' responses to the GC effluent simultaneously with the FID.

Single Cell Antennal Recordings. Recordings from single antennal neurons were made using the cut-sensillum technique of Kaissling (1974; Van der Pers and Den Otter, 1978). An antenna was removed from a male carob moth and its base placed in a saline electrode serving as the ground. A single sensillum trichodeum was then positioned over the edge of a glass knife, and the sensillar tip excised with a second glass knife edge brought down over the first knife edge by means of a micromanipulator. A saline recording electrode was then maneuvered to contact the sensillum and to record from the neurons within after amplifying the signal using a Hansson model 103 amplifier. Recordings of both the AC and DC components of the signal were stored on VCR tape using a Vetter model 420 F four-channel FM recorder and displayed and printed on a Gould model 1604 (DSO) digital oscilloscope/printer.

Wind-Tunnel and Field-Trapping Tests. Behavioral assays were conducted in a 3.5 × 1.0 × 1.0-m wind tunnel previously described in detail by Kuenen and Baker (1982). Two- to five-day-old males were placed in the wind tunnel at least 2 hr before testing in order to acclimate them to the conditions (24–26°C, 0.3 lux, 30–70% relative humidity, 0.5 m/sec wind velocity). Bioassays were conducted 4–6 hr into the scotophase, the optimal sexual activity period for this species. Treatments were loaded onto filter-paper disks (Whatman No. 1) affixed to metal clips 6 cm high complete with metal base. The cork–wire holder for each filter paper was placed on a 15 × 15-cm sheet metal platform 15 cm above the floor of the tunnel, 30 cm from the tunnel's upwind end. Males were released one at a time from screen cages, 4 cm long × 3 cm diameter, 1 m from the odor source and 15 cm above the tunnel floor. The cages were placed on the metal platform in the plume until the male took flight or until 30

sec elapsed. Males were scored for taking flight, locking-on to the plume and progressing upwind, flying to within 50 cm or 10 cm of the source, and contacting the source. Tests were conducted using a randomized, complete-block design so that all treatments were presented on a given day.

In order to see whether or not the reduced attraction with synthetics was due to antagonistic contaminants, we tested the attraction of males to calling females in the wind tunnel compared to calling females plus the 8:1:1 (333 μg) synthetic blend in polyethylene Beem embedding capsules, size 3 (Ted Pella Inc., Redding, California) (see next section). Six females were placed in a cage in a Pherocon 1C trap just as they were in the field except the trap was placed in the wind tunnel. A second trap was also used, but was loaded with a cage containing six females, to which was also affixed the Beem capsule containing the synthetic blend. Under the same wind-tunnel conditions used in the other tests, 10 males were released downwind and allowed 2 min to approach and enter each trap, presented singly to the males. Males were scored for close approach to the trap (<10 cm), the duration of hovering in front of the trap, and whether or not they were captured on the sticky surface.

Field-trapping tests were conducted in date gardens in the Coachella Valley near Indio, California, beginning in 1989. Polyethylene Beem capsules, which were left unsealed, were loaded with 333 μg of the 8:1:1 mixture of synthetic (*Z,E*)-9,11,13-tetradecatrienal, (*Z,E*)-9,11-tetradecadienal, and (*Z*)-9-tetradecenal, and individual capsules were affixed to the bottoms of Pherocon 1C traps. Five virgin female carob moths were placed in screen cages in Pherocon 1C traps as a positive control. They were given continuous access to distilled water on a dental wick. Traps were counted and rebaited twice per week over several weeks. Males were removed and the traps rerandomized whenever counts were taken. Trap bottoms were replaced each week when the Stickem surfaces became coated with dust.

Synthesis. (*Z*)-9-Tetradecenal and (*Z,E*)-9,11-tetradecadienal were prepared from the corresponding alcohols by oxidation with pyridinium dichromate–molecular sieve (Herscovici et al., 1982) and by Swern oxidation (Mancuso et al., 1978). The crude products were purified by HPLC (RP-18; low-pressure gradient; methanol–water) or by flash chromatography on silica gel (5% ether in hexane) followed by Kugelrohr distillation (0.1 mm Hg, oven temperature 100°C). Syntheses of (*Z,E*)-9,11,13-tetradecatrienal have been published elsewhere (Baker et al., 1989; Millar, 1989, 1990).

The trienal was very unstable and usually trimerized or polymerized in the space of a few weeks even at -20°C under Ar, either neat or in dilute solution (hexane, benzene, ether). When freshly prepared, the trienal was >98% stereoisomerically pure by capillary GC (DB-5). However, the trienal was contaminated with 2–5% of a rearrangement product that coeluted with the trienal on

silica gel flash chromatography or HPLC. This rearrangement product has not yet been isolated or fully characterized. The trienal was also thermally unstable and decomposed when subjected to GC injector temperatures above 250°C.

RESULTS

EAGs of Monounsaturated Standards. Standardized EAG responses revealed that male antennae were far more responsive to 14-carbon aldehydes than to other molecules to which they were exposed. Although we had a limited array of aldehydes to test, by far the most active compound was (*Z*)-9-tetradecenal, generating a response 3.8 times (±0.91 SD; $N = 8$) as great as that to the standard compound, (*E*)-6-tetradecenyl acetate. In comparison, the next most active compound, either monounsaturated or saturated, was tetradecanal with a response of 2.3 (±0.45 SD; $N = 8$), followed by (*Z*)-9-tetradecenyl acetate with a response of 2.1 (±0.19 SD; $N = 5$) (Figure 1). Responses to an array of 16-carbon aldehydes, including (*Z*)-11-hexadecenal, hexadecanal, (*E*)-9-hexadecenal, (*Z*)-9-hexadecenal, and (*Z*)-7-hexadecenal all were below a standardized response of 1.3. Thus, the high responses to 14-carbon aldehydes suggested that at least one of the sex pheromone components contained an alde-

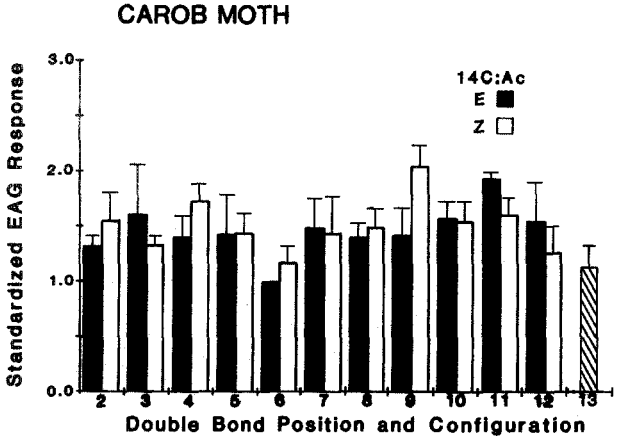

FIG. 1. Standardized EAG amplitudes in response to a series of tetradecenyl acetates ($N = 5$ antennae). Compounds were dispensed at a loading of 10 μg on a filter paper strip and placed in Pasteur pipets. One milliliter of air was puffed through each pipet into an airstream and over the male antenna, the series of compounds being tested in a randomized, complete-block design. The standard response was the millivolt response to a test compound divided by the millivolt response to the most recent puff of (*E*)-6-tetradecenyl acetate, such puffs being interspersed with the test puffs every three to four compounds.

hyde moiety and was 14 carbons in length. Although lower than those of the 14-carbon aldehydes, the EAG responses to the series of 14-carbon acetates (Figure 1) and alcohols, for which complete sets of standards from Δ4 to Δ12 were available, were illuminating, because they highlighted potential involvement of molecules having a (*Z*)-9 configuration and also an (*E*)-11 configuration.

Analysis of Pheromone-Gland Extract. Combined GC-EAG analysis of the extract from ca. 10 FE of pheromone-gland extract consistently revealed three peaks from the FID corresponding to EAG activity on either the DB-1 or DB-WAX columns in GC-EAG trials (Figures 2 and 3, respectively). These three peaks were labeled compounds I, II, and III; the order of elution, based on the amplitude of the EAG's, was the same on the two columns, with a compound corresponding to a small EAG peak eluting first, a compound evoking a larger EAG response eluting second, and the compound with the largest EAG response eluting last (Figures 2 and 3). The compounds were present in a ratio of 8 : 1 : 1

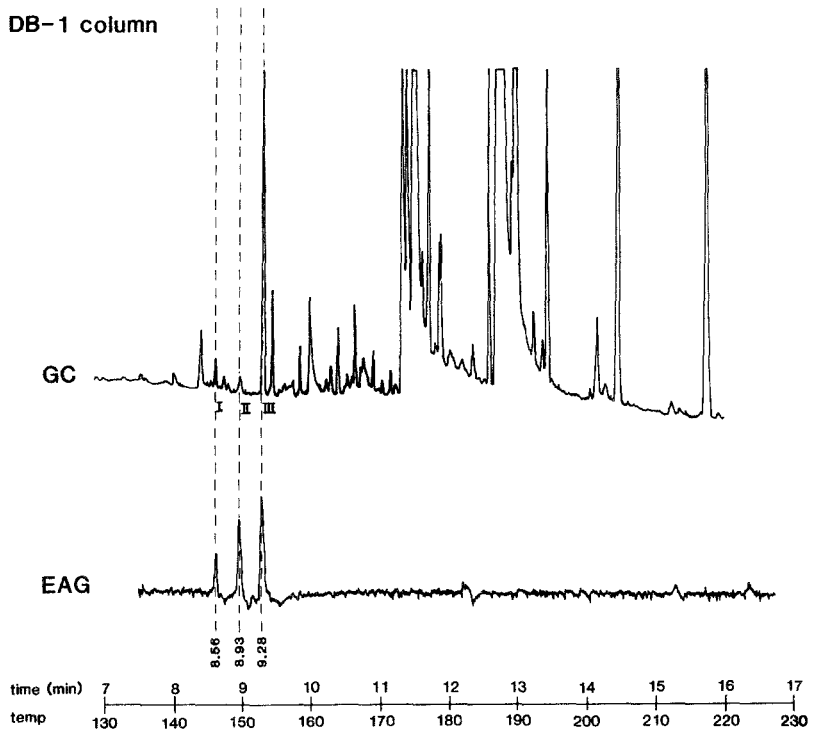

FIG. 2. GC-EAG response to 10 FE of female carob moth sex pheromone gland extract injected onto a 30-m DB-1 capillary GC column. The EAG-active peaks at 8.56, 8.93, and 9.28 min were labeled compounds, I, II, and III, respectively.

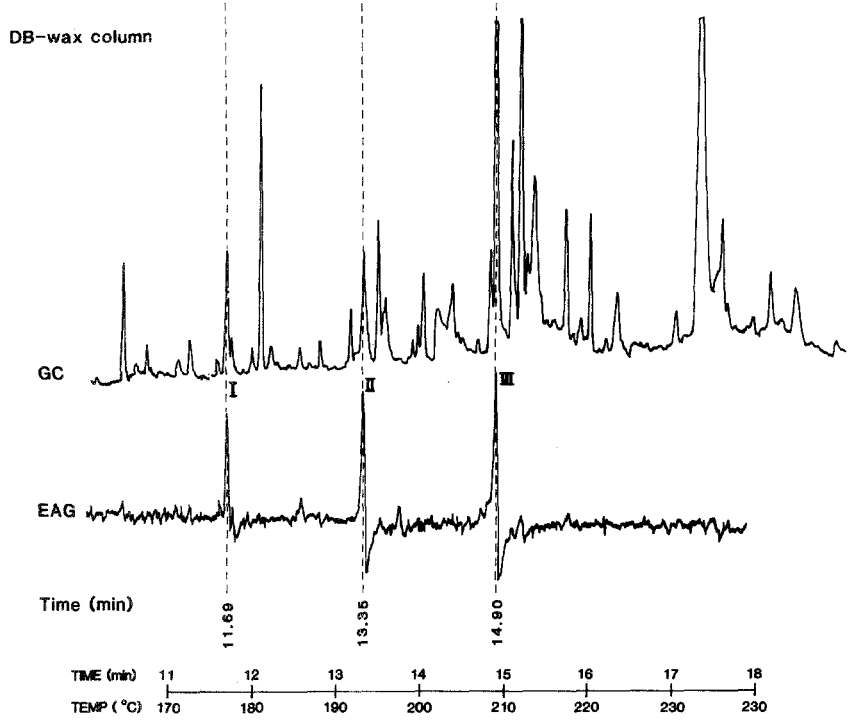

FIG. 3. GC-EAG response to 10 FE of female carob moth sex pheromone gland extract injected onto a 30-m DB-WAX capillary GC column. The EAG-active peaks at 11.69, 13.35, and 14.90 min were labeled compounds I, II, and III, respectively.

(III : II : I). The retention time of compound I corresponded precisely to that of (*Z*)-9-tetradecenal on both columns. The retention indices of compounds II and III relative to I were 1.043 and 1.048 on DB-1 and 1.142 and 1.274 on DB-WAX, respectively. The retention indices of II and III on the two columns relative to (*Z*)-9-tetradecenal and to the other compounds in our library indicated that compounds II and III possibly involved conjugated double bonds since nonconjugated systems elute very close to monounsaturated compounds (c.f., Heath and Tumlinson, 1984). Since the pattern of EAG responses to monounsaturated standards indicated that two configurations evoked high activity [(*Z*)-9 and (*E*)-11] and only one GC-EAG active peak was present in the monounsaturated region on GC in the extract, we reasoned that in at least one of the compounds, (either II or III), a (*Z*,*E*)-9,11 dienal would be involved.

GC-MS analysis of compound I revealed a mass spectrum identical to that of a synthetic standard of (*Z*)-9-tetradecenal. The mass spectrum of compound II showed a base peak at *m/z* 67 plus a significant signal at *m/z* 208, consistent

with the molecular ion of a tetradecadienal (Figure 4A). Conjugated double bonds stabilize the molecular ion in long-chain aliphatic compounds, whereas M+ is virtually missing in monounsaturated analogs or analogs with isolated double bonds (Löfstedt and Odham, 1984; Ando et al., 1988). Compound III had a mass spectrum characterized by a base peak at *m/z* 79 and an intense signal at *m/z* 206 (Figure 4B), suggesting a tetradecatrienal or a tetradecenynal with at least some conjugation.

Ozonolysis of the fraction of female-gland extract containing compound III, collected from the DB-1 column at 9.1–9.4 min, yielded a new peak at 6.70 min, which upon comparison with the bifunctional ozonolysis product of synthetic (Z)-9-tetradecenal proved to be 1,9-octanedial. This showed that the first double bond in compound III was at the C9 position and that any other double bonds must occur farther out on the alkyl chain. Excluding allenes and enynes, this meant that the other two double bonds could only be in the 11 and 13 positions. We thus suspected that compound III was (*Z,E*)-9,11,13-tetradecatrienal and that compound II was (*Z,E*)-9,11-tetradecadienal.

Synthetic II and III. The mass spectrum of synthetic (*Z,E*)-9,11-tetradecadienal was identical to that of the natural compound II from the extract (Figure 4A). Moreover, combined GC-EAG recordings on both the 30-m DB-WAX and DB-225 columns demonstrated that (*Z,E*)-9,11-tetradecadienal had a retention time identical to compound II from the extract and that was EAG active, while the *E,E* isomer eluted later and was relatively inactive. Likewise, the retention time of (*Z,E*)-9,11,13-tetradecatrienal was identical to that of nat-

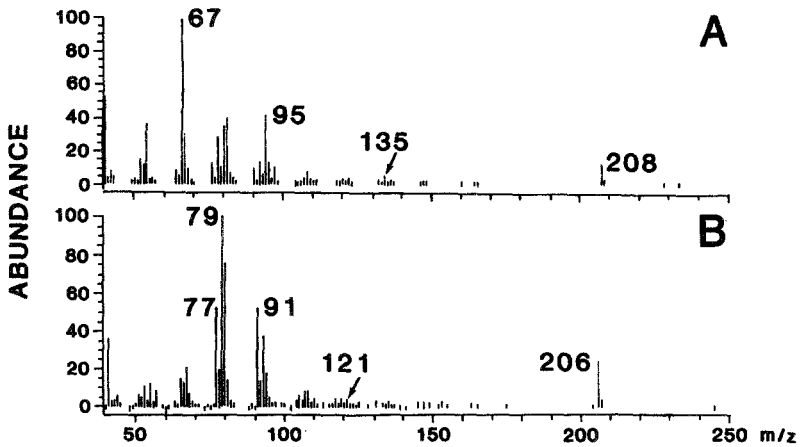

FIG. 4. (A) Mass spectrum (EI 70 eV) of compound II, identical to that of (*Z,E*)-9,11-tetradecatrienal. (B) Mass spectrum (EI 70 eV) of compound III, identical to that of (*Z,E*)-9,11,13-tetradecatrienal.

ural compound III, and it was EAG-active, whereas the *E,E* isomer eluted later and was relatively inactive on EAG. The mass spectrum of compound III was identical to that of synthetic (*Z,E*)-9,11,13-tetradecatrienal (Figure 4B), confirming the structure of III to be (*Z,E*)-9,11,13-tetradecatrienal.

Although the evidence strongly indicated that compound I was (*Z*)-9-tetradecenal, current knowledge of pheromonal biosynthetic pathways in the Lepidoptera allowed for the alternative possibility that compound I could be unsaturated in the 11 position. This possibility is enhanced when considering that the retention time of (*E*)-11-tetradecenal would likely be very similar to (*Z*)-9-tetradecenal on most columns, and it would exhibit a virtually identical mass spectrum. A small amount of (*E*)-11-tetradecenal was therefore synthesized from (*E*)-11-tetradecenol, and it consistently had a retention time of 9.77 min on the DB-225 column compared to 9.86 min for (*Z*)-9-tetradecenal. The natural extract exhibited no FID peak at 9.77 min and no EAG activity at that elution time in two different GC-EAG analyses on DB-225, whereas there was a small FID peak at 9.87 min plus strong EAG activity at 9.86 min during the same GC-EAG analyses of this extract. These results, coupled with the earlier GC-MS and GC-EAG analyses on the two other columns again strongly support (*Z*)-9-tetradecenal as the structure of compound I.

As was the case for compound I, for which no ozonolysis results could be obtained, possible double bond positions and geometries different from the indicated (*Z,E*)-9,11-tetradecadienal existed also for compound II. However, the same GC-EAG analyses of the natural extract on the DB-225 column revealed a small peak at 11.20 min with correspondingly strong EAG activity at 11.20 min and no other EAG activity except for the usual single peaks corresponding to compounds I and III. Synthetic (*Z,E*)-9,11-tetradecadienal exhibited a retention time of 11.19 min on this same column. These results, coupled with the earlier GC-MS and GC-EAG analyses on the two other columns again strongly support our assignment of (*Z,E*)-9,11-tetradecadienal as the structure of compound II.

GC–single-cell recordings using synthetic I, II, and III confirmed that the retention times and single-cell activity corresponded to (*Z*)-9-tetradecenal, (*Z,E*)-9,11-tetradecadienal, and (*Z,E*)-9,11,13-tetradecatrienal, respectively (Figure 5). Moreover, the monoenal and dienal both caused a large-spike-amplitude cell to fire in some of the sensilla, whereas the trienal caused a smaller-spike-amplitude cell in the same hair to fire. The fact that the trienal excites one kind of receptor cell and the monoenal and dienal excite a second type of cell is consistent with the behavioral data (below) that indicates that the trienal alone is not as active behaviorally as a blend of the trienal plus either I or II.

Wind-Tunnel and Field-Trapping Studies. The activity of synthetic compound III in evoking upwind flight by carob moth males was confirmed in wind-

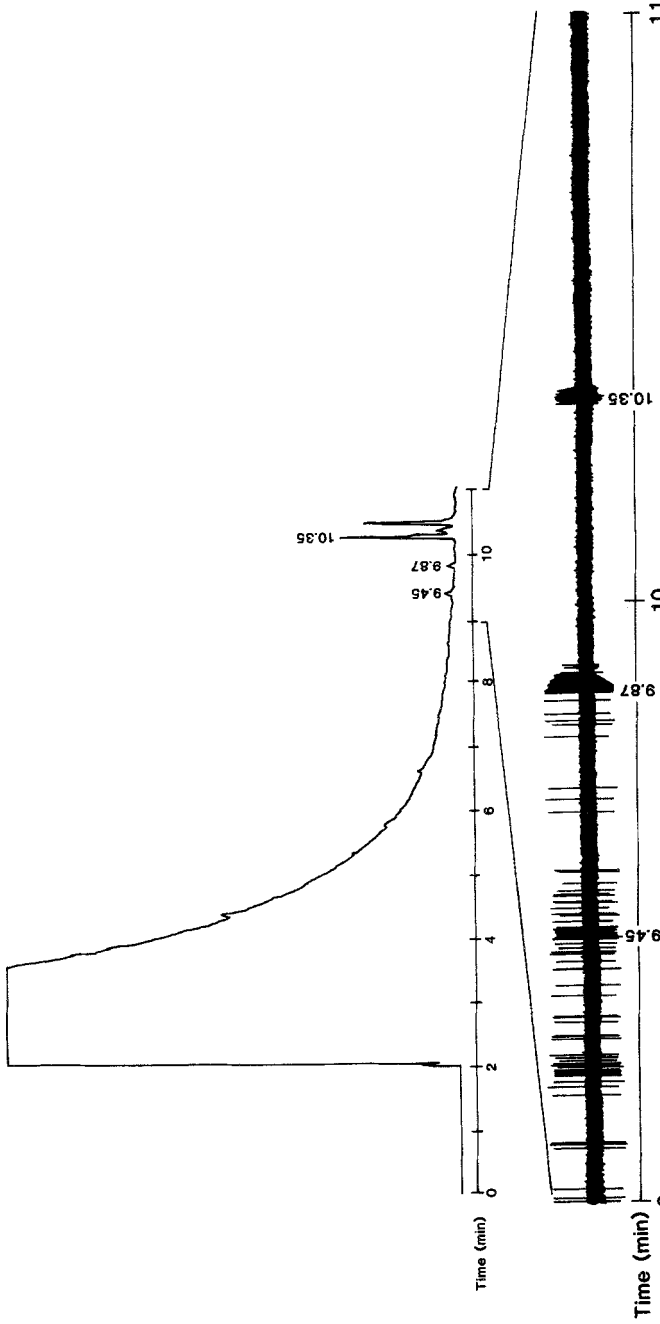

FIG. 5. GC–single-cell analysis of a 1:1:8 blend of synthetic (Z)-9-tetradecenal, (Z,E)-9,11-tetradecatrienal, and (Z,E)-9,11,13-tetradecatrienal, respectively, injected onto a 30-m DB-1 column in a Varian 3740 GC (column conditions 80°C, 2 min hold, 15°/min to 180°C; He carrier flow of 1.5 ml/min; injector temperature 200°C; FID detector temperature 250°C). The first two compounds, (monoenal and dienal), evoked action potentials from a large-spiking cell in the sensillum, whereas the trienal caused action potentials to be discharged from a smaller-spiking cell in the same sensillum.

tunnel studies. In an initial test, compounds I and II (0.5 ng each) were inactive by themselves in evoking upwind flight from 3 m downwind (0/18 and 0/19 males flew upwind, respectively), but 0.5 ng of the triene alone did cause upwind flight and source location (9/23 flew upwind, 4/23 touched the source). In further experiments, a blend of the three compounds (40 ng, 5 ng, 5 ng, respectively) approximating the 8 : 1 : 1 ratio found in gland extract was nearly as good as 5 FE of gland extract in eliciting upwind flight and source contact (Figure 6). The trienal by itself was poorer in causing source contact than blends that included either the monoenal, the dienal, or both (χ^2 2 × 2 test of independence, $P < 0.05$). Thus it appeared that either the monoenal or dienal or both were behaviorally important components of the sex pheromone blend, in which the trienal plays the primary role in attracting males.

Further wind-tunnel experiments with a wider variety of ratios (source loading, 40 ng of trienal) confirmed that the 8 : 1 : 1 ratio approximating that found in the female gland extract was significantly better at causing complete upwind flight and source contact than the 1 : 1 : 1 or 1 : 0 : 0 ratios (Figure 7; χ^2 2 × 2 test of independence, $P < 0.05$). Although there was a trend for the other ratios to be slightly poorer than 8 : 1 : 1, it appears that the trienal needs to exceed the amounts of the other two components by 2 : 1 : 1 or greater to be optimal. As in the first experiment, none of the synthetic blends was quite as

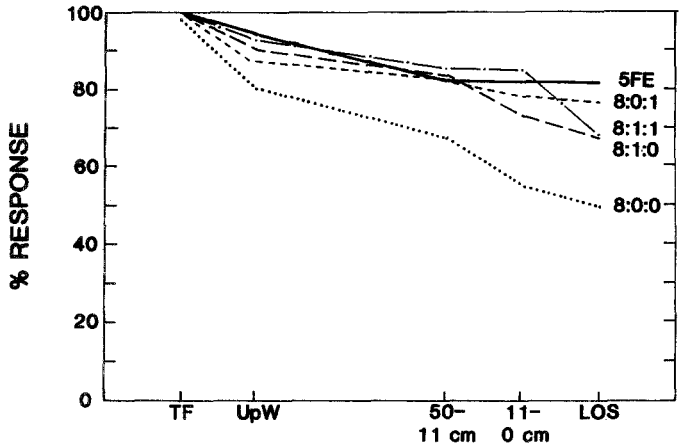

FIG. 6. Percentages of male carob moths flying in the wind tunnel in response to various blends of (*Z,E*)-9,11,13-tetradecadienal, (*Z,E*)-9,11-tetradecadienal, and (*Z*)-9-tetradecenal, or 5 FE of gland extract. Source loading on filter paper was 40 ng of the trienal applied in 10 μl of hexane. $N = 28$ males tested to each treatment. TF = take flight in plume, UpW = lock on and fly upwind in plume, 50–11 cm = flight to within between 11 and 50 cm of the source, 11–0 cm = flight to within between 0 and 11 cm of the source, and LOS = male lands on the source.

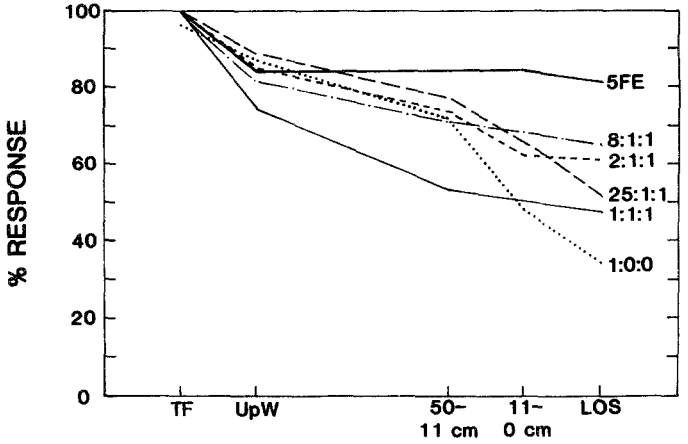

FIG. 7. Percentages of male carob moths flying in the wind tunnel in response to various blends of (*Z,E*)-9,11,13-tetradecatrienal, (*Z,E*)-9,11-tetradecadienal, and (*Z*)-9-tetradecenal, compared to 5 FE of gland extract. Source loading on filter paper was 40 ng of the trienal applied in 10 μl of hexane. Abbreviations are the same as in Figure 6. N = 35 males tested to each treatment.

effective as the natural extract in evoking source contact. Again the trienal alone evoked lower levels of source contact than blends containing the monoenal or dienal (Figure 7). A series of dosages of the 1 : 1 : 8 blend of I, II, and III was tested to determine if higher amounts of synthetic compounds could better mimic the natural extract. Although there was no dosage that was excessively high among the ones we tested, none of these source loadings caused levels of source contact as high as the natural extract (Figure 8) (χ^2 2 × 2 test of independence, $P < 0.05$).

In the field, the 8 : 1 : 1 mixture of the three components, dispensed at a loading of 333 μg of the major component in polyethylene Beem capsules, captured significant numbers of carob moth males. Traps containing five live females consistently captured greater numbers of males [18.6 ± 17.32 (SD) and 30.2 ± 34.1 (SD) N = 10 and 9, respectively] than the synthetics, which captured a mean of 9.9 ± 12.1 SD and 6.5 ± 9.9 SD males (N = 30 and 27, respectively). Blank traps captured 0 males in all tests.

The reduced attraction of males to the synthetic blend was not apparently due to contaminants in the synthetic compounds. In the wind tunnel six live calling females attracted and captured an average of 5.13 (±1.89 SD, N = 8) out of every 10 males that were released, whereas the addition of the synthetic blend on Beem capsules did not reduce the capture; rather this latter treatment increased the capture slightly, causing 5.85 (±2.17, N = 8) out of every 10 males released to become ensnared. In response to the females plus synthetics,

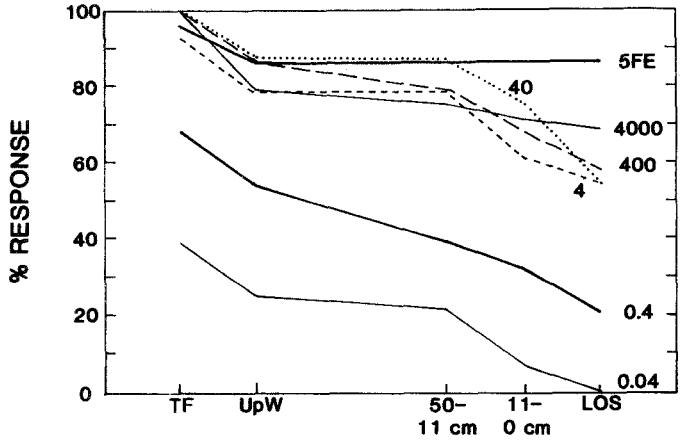

FIG. 8. Percentages of male carob moths flying in the wind tunnel in response to various source loadings of the 8 : 1 : 1 blend of (*Z*,*E*)-9,11,13-tetradecatrienal, (*Z*,*E*)-9,11-tetradecadienal, and (*Z*)-9-tetradecenal, compared to 5 FE of gland extract. Source loadings were 0.04, 0.4, 4, 40, 400, and 4000 ng of the trienal, applied in 10 μl of hexane. N = 60 males tested to each treatment. Abbreviations are the same as in Figure 6.

males only spent 7.96 sec (±6.90 SD) hovering in front of the trap, whereas they spent 11.47 sec (±13.71 SD) hovering in front of traps in response to live calling females. A mean of 6.25 (±1.83 SD, N = 8) males out of every 10 released was observed hovering in front of the trap containing synthetics plus females, whereas 4.75 (±2.12 SD, N = 8) out of 10 were seen hovering in front of traps containing females only.

DISCUSSION

The (*Z*,*E*)-9,11,13-tetradecatrienal identified as the major component of the carob moth sex pheromone in this study represents a novel structure with regard to previously identified lepidopteran sex pheromone components. Indeed, among the known acetate, alcohol, and aldehyde sex pheromone components of moths, only a few compounds possess more than two double bonds, and only recently were conjugated trienes reported. Tellier and Descoins (1990) confirmed our earlier findings (Baker et al., 1989) on *E. ceratoniae* and identified (*Z*,*E*)-9,11,13-tetradecatrienal and the corresponding acetate in the saturniid moth, *Stenoma cecropia*. (*E*,*E*,*E*)-10,12,14-Hexadecatrienyl acetate is a sex pheromone component of the mulberry pyralid, *Glyphodes pyloalis* (Ando et al., 1988; Honda et al., 1990) and (*E*,*E*,*Z*)-10,12,14-hexadecatrienal was iden-

tified as a component of the sex pheromone of *Manduca sexta* (Tumlinson, 1989; Tumlinson et al., 1990).

Although the activity of the 8 : 1 : 1 blend under field conditions appears to be low relative to calling females, we believe that this reduced activity can be explained in part by the lability of the trienal, which loses its integrity rapidly even in solution when stored in a freezer. The trienal appears to be the major component of the pheromone, without which attraction does not occur. The activity of freshly prepared lures in wind tunnel tests is nearly equal to that of female extract, and so it appears that in order for reliable field lures to be prepared for monitoring, the problem of decomposition of the trienal must be overcome. However, even with this limitation and the relatively low trap capture levels relative to females, the synthetic lures emitting the 8 : 1 : 1 blend of trienal, dienal, and monoenal have already produced useful seasonal data for use by date growers attempting to accurately time their single application of malathion dust to protect the date crop during ripening. Because of the labor-intensive nature of date-growing, development of a stable formulation holds promise for disruption of mating, because dispensers could easily be hand-placed and replaced during the season by workers who tend the crop, all with minimal extra labor costs.

Acknowledgments—We thank Wendy Villano for assisting in the rearing of the carob moth. This project was supported in part by the California Date Packers Council and by grants from the California Department of Food and Agriculture and the Swedish Natural Science Research Council (NFR).

(Received November 29, 1990; accepted June 24, 1991)

Abstract—Porapak Q-captured volatiles of male *Polygraphus rufipennis* (Kirby) boring in black spruce and white spruce from Newfoundland and British Columbia, respectively, contained 3-methyl-3-buten-1-ol. Volatiles from logs in which the males had been joined by females contained the compound in reduced quantities. Hindgut extracts from male and female *P. rufipennis* disclosed no male-specific volatiles, but 3-methyl-3-buten-1-ol was detected in extracts of male-produced frass. The compound was not present in extracts from fresh phloem tissue. *P. rufipennis* of both sexes responded strongly in the field to traps baited with 3-methyl-3-buten-1-ol released at 4390 μg/day. There was little response to unbaited traps, fresh uninfested black spruce logs, or to 3-methyl-3-buten-1-ol released at lower rates. Combination of 3-methyl-3-buten-1-ol with either one of five terpenes prevalent in black spruce did not enhance beetle catch. Approximately half of 20 black spruce trees baited with 3-methyl-3-buten-1-ol were attacked, compared to 20.0% of 10 unbaited control trees. This new aggregation pheromone could be used to monitor or manage *P. rufipennis* populations.

INTRODUCTION

The four-eyed spruce bark beetle, *Polygraphus rufipennis* (Kirby), is a phloeophagous bark beetle restricted to Abietineae hosts in northern and mountainous areas of North America. It breeds principally in weakened and dying trees, but may be a major cause of tree death when it reaches outbreak levels in mature forests, especially in stands of black spruce, *Picea mariana* (Mill.) B.S.P. (Swaine, 1918). In Newfoundland, black spruce trees defoliated by eastern spruce budworm, *Choristoneura fumiferana* (Clem.), have been predisposed to attack by *P. rufipennis*, resulting in considerable mortality of these trees (Raske and Sutton, 1986).

As for other polygynous members of the tribe Polygraphini, *P. rufipennis* appears to have a Eurasian–African origin. It is closely allied to *Polygraphus poligraphus* (L.) of Europe and northern Asia, and reached North America in recent geologic time (Wood, 1982). *P. poligraphus* is reported to utilize three male-produced compounds, terpinene-4-ol and *cis*- and *trans*-4-thujanol, as aggregation pheromones (Leuze, 1977; Brümmer, 1981; Francke and Vité, 1983). Semiochemical-based communication in *P. rufipennis* has been demonstrated (Bowers and Borden, 1990) but its chemical basis is unknown. Semiochemicals could lead to the development of a valuable detection and monitoring tool for this pest. A potent aggregation pheromone was evident in the response of *P. rufipennis* to male-produced frass and male-infested logs (Bowers and Borden, 1990). We report the identification and field testing of 3-methyl-3-buten-1-ol, an aggregation pheromone of this species.

METHODS AND MATERIALS

Experimental Insects. P. rufipennis adults and brood for laboratory and field experiments in Newfoundland were collected and reared on black spruce from Powderhorn Lake and Miguels Lake in central Newfoundland and from Thorburn Lake and Conception Bay South in eastern Newfoundland. Adults and brood for laboratory experiments in British Columbia were collected from and reared on black spruce from Nazko and Cottonwood creek near Quesnel and from white spruce, *Picea glauca* (Moench) Voss, from Penticton and Bowron Lake. The cut ends of 40-cm-long infested logs were sealed with hot paraffin wax to delay desiccation, and the logs were placed in emergence cages

held at 23–28°C with a photoperiod of 16:8 (light–dark). Emergent beetles were collected every 24–48 hr, sexed (Bright, 1976), and used immediately in experiments. Logs not immediately used were maintained in cold chambers at 4°C for up to eight months.

Collection of Beetle and Host Volatiles. Volatiles from living adults boring in fresh host logs were collected by aeration and adsorption on Porapak Q (50–80 mesh, Applied Sciences Division, Milton Roy Laboratory Group, State College, Pennsylvania) (Byrne et al., 1975). The Porapak Q was thermally conditioned and packed into metal (15.5 cm × 6.4 mm OD) or glass traps (12.0 cm × 6.0 mm OD).

Aerations were carried out in Newfoundland in the laboratory at 21°C under full background lighting. Fresh logs were infested with newly emerged beetles and placed in a 120-liter container made from food-grade high-density polyethylene modified after that used by Peacock et al. (1975). Air was drawn with a vacuum pump at 1.8 liters/min through a charcoal filter, over a log, and through a Porapak Q-filled metal trap. Beetles were allowed to feed before aerations for 24–48 hr on logs to ensure gallery establishment and were checked for evidence of frass production; uninfested control logs received 50 holes made with a No. 5 cork borer to simulate beetle feeding. Eleven aerations of fresh spruce logs yielded a total of 792 lhr (1 lhr = amount of volatiles collected from one log for 1 hr); 10 aerations of male-infested logs yielded a total of 41,142 bhr (1 bhr = amount of volatiles collected from one beetle boring in a log for 1 hr); one aeration of a female-infested log yielded a total of 3750 bhr; six aerations of logs infested with one male and two female beetles per gallery yielded a total of 18,732 bhr from mated males.

Logs from the same tree were used for each aeration experiment to minimize possible effects of host variation. Within each experiment, uninfested control logs were aerated first, followed by male-infested logs and logs infested by males and females. The odor-laden Porapak Q was extracted after 72 hr in 5.0 ml of redistilled hexane or pentane and ethyl ether (95:5) and stored in a Teflon-lined vial at −40°C. Between treatments, the aeration container was wiped clean with acetone and the glass wool and the activated charcoal filter was replaced. Filters were flushed with double-distilled pentane and ethyl ether followed by a 2-hr nitrogen purge.

Aerations in British Columbia utilized a water aspirator with an airflow rate of 1–2 liters/min. Single beetle collections were made using an on-tree collection device (Gries et al., 1988), consisting of a Porapak Q trap connected to an expanded glass tube placed over the entrance hole of the beetle's gallery. Aerations were carried out in the laboratory at 21°C on a photoperiod of 16:8 (light–dark). Treatments included aeration of single males, one male and three females, a control vial filled with finely ground phloem tissue, and an empty control vial. Six males boring in white spruce were individually aerated for 60

hr in each of three experiments. Three females were added to each male gallery in experiments 1 and 2, and the 60-hr aeration was repeated. The third female refused to enter four male galleries in experiment 1. Beetle establishment and frass production were recorded for each experiment. Logs from experiment 1 were dissected three weeks following aeration to verify that females had established broods. Trapped volatiles were extracted in 0.5 ml pentane and ethyl ether (95:5), and stored at −40°C in a vial with a Teflon-lined cap.

Collection and Preparation of Frass and Abdominal Extracts. Phloem tissue was obtained by removing samples of bark from fresh black spruce with a No. 5 cork borer. Frass was collected after allowing newly emerged beetles to bore freely into fresh spruce logs or by confining them with gelatin capsules in preformed entrance holes. To prepare extracts, phloem and frass were pulverized in redistilled pentane or hexane and ethyl ether (95:5) (1.0 ml/0.1 g material) over Dry Ice. Abdominal extracts from 500 male and 250 female beetles were prepared by excising beetles from logs and crushing the abdomens in either chilled pentane or hexane and ethyl ether (95:5) (10 μl/abdomen) in a vial held on Dry Ice. The vials were sealed with a Teflon-lined cap and stored at −40°C.

Analysis of Trapped Volatiles. Volatiles were analyzed in a Hewlett-Packard 5830A gas chromatograph (GC) equipped with a 18835B capillary inlet system and a flame ionization detector (FID). Helium was the carrier gas, and the injection port and detector temperatures were 260 and 270°C, respectively. Mass spectroscopy (MS) was done with a Hewlett-Packard 5985 coupled GC-MS. Captured volatiles were concentrated to 5 μl by evaporation over gentle heat or with a stream of nitrogen at −10°C and analyzed on a 60-m × 0.32-mm-ID DB-1 fused silica column with temperature programming from 30 to 130°C at 1°C/min. Abdominal and frass extracts were analyzed on a 30-m × 0.25-mm-ID fused silica column coated with SP-1000 (Supelco, Inc., Bellafonte, Pennsylvania), with temperature programming from 70 to 180°C at 2°C/min. To identify beetle-produced compounds, chromatograms of volatiles produced by the attacking virgin males were compared with chromatograms of host volatiles and with those following the addition of the females.

Field Bioassays. The candidate pheromone was tested in 1987 and 1988 in black spruce stands near Powderhorn Lake and Crooked Bog 5.0 and 8.0 km, respectively, north of Badger, Newfoundland. Volatiles (Table 1) were released from 400 μl polypropylene Eppendorf tubes (Brinkman Instruments, Rexdale, Ontario) suspended in eight-unit multiple-funnel traps (Lindgren, 1983) or affixed at 1.3 m height to the north side of a black spruce bole. Open and capped tubes released 3-methyl-3-buten-1-ol at rates of 4390 and 200 μg/day, respectively. For an ultra-low rate of 6 μg/day, the candidate pheromone was released from 3-cm-long × 0.2-mm-ID, polyester Conrel fibers (Albany International Co., Needham, Massachusetts) placed inside a closed Eppendorf tube. Terpene hydrocarbons were released from an open Eppendorf tube.

TABLE 1. SOURCE, PURITY, AND RELEASE RATES OF VOLATILE MATERIALS USED IN *P. rufipennis* FIELD-TRAPPING AND TREE-BAITING EXPERIMENTS

Compound	Abbreviation	Source	Purity (%)	Approximate release rate (μg/day)[a]

[a] Eppendorf tubes loaded with 200 μl of 3-methyl-3-buten-1-ol or terpene. For 3-methyl-3-buten-1-ol at lowest release rate, Conrel fibers were 3-cm long, sealed at one end, and placed inside a capped Eppendorf tube. Release rates determined in the laboratory at 20°C; values represent means for two measurements.

Vapona No-Pest Strip (Boyle-Midway Can. Ltd., Toronto, Ontario) was used to kill captured beetles in multiple-funnel traps. Trap baits were replaced at weekly intervals. Traps were monitored twice weekly and captured beetles were removed, placed in 75% ethanol, and separated by species and sex.

Six trapping experiments were conducted (Tables 2–5). Experiments 1 and 2 tested the candidate pheromone at two release rates, with treatments randomly assigned to 30 traps spaced at least 20 m apart. Experiment 1 was run during the beetle's spring flight and experiment 2 during the summer flight. Experiments 3 and 4 tested the candidate pheromone alone and in binary combination with each of the major terpenes identified in twigs of black spruce (von Rudloff, 1975) in a randomized complete block design. Because the Powderhorn stand was located on a gentle slope, blocks were laid on contours to minimize within-block variability. Blocks were 20 m apart and traps 15 m apart. Experiment 5 compared the candidate pheromone at two different release rates to a fresh spruce log infested with 50 newly emerged male beetles. The logs were wrapped with Saran screening to prevent further attack and tied to the side of multiple-funnel traps spaced 20 m apart in a linear sequence. Treatments were randomly assigned to traps at the beginning of each replicate. Experiment 6 was similar to exper-

ized design with at least 20 m between trees. Treatments included an empty (control) Eppendorf tube, and the candidate pheromone released at a rate of 6 μg/day from a 0.2-mm-ID Conrel fiber inside a tube, or released at 200 μg/day from a closed tube.

Treatments for experiment 8 included: an empty (control) tube, and the candidate pheromone at 200 μg/day alone or with either α-pinene, bornyl acetate, β-pinene, 3-carene, myrcene, or a mixture of the above five terpenes released from separate tubes at rates given in Table 1. Treatments were assigned at random to five blocks spaced 20 m apart and with baited trees spaced 15 m apart.

All baited trees were codominants ≥ 10 cm diameter at breast height (dbh) and had light damage (≤30% cumulative defoliation) from *C. fumiferana* in the previous 10 years. Baits were placed on trees at breast height on June 3 at the beginning of the spring flight; they were replaced on July 1 at the beginning of the summer flight. The incidence of attack on baited trees and the nearest four trees ≥ 10 cm dbh surrounding each baited tree was assessed on September 2 by counting attacks, represented by frass piles and resin flow, on areas of bark surface within two 16.7 × 30-cm open frames 1.3 m high on the north and south aspects of the tree. Attacks with fresh frass were considered successful and attacks with copious resin flow in the entrance holes were considered unsuccessful. The number of successful and unsuccessful attacks on the north and south aspects of attacked trees were combined and expressed as attack density per square meter of bark surface.

Data were analyzed using the SAS statistical package version 6.0 (SAS Institute Inc., Cary, North Carolina). Data were transformed with a $\log_{10}(X + 1)$ transformation to meet the assumptions of homoscedasticity and normality prior to analysis of variance and Duncan's multiple-range test. The chi-square statistic was used to examine differences in the attack frequencies of unbaited and baited trees. Differences in the mean attack density on unbaited and baited trees was tested using a two-sample *t* test. In all tests the maximum probability of a type-I error was set at 0.05.

RESULTS

Analyses of volatiles from *P. rufipennis* males, females, and hosts disclosed an unknown compound produced by males; this compound was produced in a lesser amount after males were joined by females (Figure 1). The unknown volatile was produced by males in both black and white spruce. Comparison of host volatiles with volatiles from female-infested logs did not disclose any female-specific compounds. There was no chromatographic evidence for more than one male-produced compound.

The mass spectrum of the unknown compound indicated major fragments of mass *m/z* 41(100), 56(88), 68(69), 31(65), and 86(20). This fragmentation pattern matched the mass spectrum of the primary alcohol, 3-methyl-3-buten-1-ol (Heller and Milne, 1978). GC-MS comparison of the beetle-produced compound with an authentic sample of 3-methyl-3-buten-1-ol indicated identical retention and mass spectral characteristics.

Chromatograms of hindgut extracts from male and female *P. rufipennis* disclosed no sex-specific volatiles. However, 3-methyl-3-buten-1-ol was detected by GC-MS in extracts of frass from males but not females, boring in

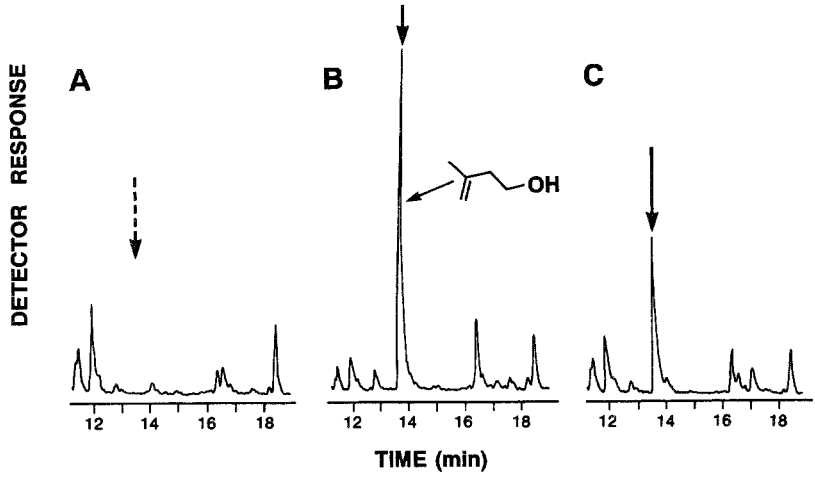

FIG. 1. Representative chromatograms of airborne volatiles collected from (A) a black spruce log, (B) from an individual *P. rufipennis* male boring in black spruce, and (C) the same male following addition of three females. Arrow denotes retention time of 3-methyl-3-buten-1-ol. Temperature programming: 30–130°C at 1°C/min.

black spruce (Figure 2). The compound was not present in extracts from phloem tissue.

Bioactivity of 3-methyl-3-buten-1-ol was demonstrated in field-trapping and tree-baiting experiments. Traps baited with 3-methyl-3-buten-1-ol released at 200 μg/day in the spring caught significantly higher numbers of both male and female beetles than unbaited traps or those baited with 3-methyl-3-buten-1-ol released at 6 μg/day (Table 2, experiment 1). Attraction of males and females to 3-methyl-3-buten-1-ol released at 6 μg/day did not differ significantly from unbaited traps. Catches during the summer were low, and there was no significant difference between treatments (Table 2, experiment 2). Release of 3-methyl-3-buten-1-ol at 200 μg/day in combination with terpenes of black spruce did not improve beetle catch (Table 3 , experiments 3 and 4). A significant increase in male and female response occurred when the release rate of 3-methyl-3-buten-1-ol was increased to 4390 μg/day (Tables 4 and 5). Responses by beetles of both sexes in the summer to the male-infested logs were significantly lower than to 3-methyl-3-buten-1-ol at high release rates but significantly higher than to 3-methyl-3-buten-1-ol at low release rates (Table 4, experiment 5). Similarly, in spring, responses by male and female beetles to male-infested logs were significantly higher than to unbaited traps and uninfested logs, but lower than to 3-methyl-3-buten-1-ol released at 4390 μg/day (Table 5, experiment 6).

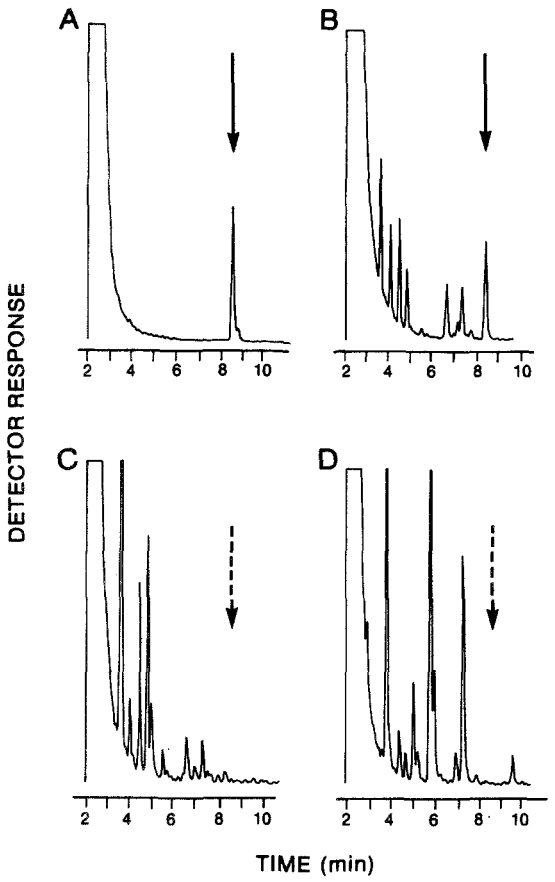

FIG. 2. Gas chromatograms of (A) synthetic 3-methyl-3-buten-1-ol, compared with (B) male frass extract, (C) female frass extract, and (D) extract of fresh phloem tissue. Arrow denotes retention time of 3-methyl-3-buten-1-ol. Temperature programming: 70–180°C at 2°C/min.

Forty-five percent of the black spruce trees baited with 3-methyl-3-buten-1-ol were attacked by *P. rufipennis* compared to 20% of the unbaited trees, but the difference was not significant. In contrast, significantly more trees surrounding baited trees were attacked than those surrounding unbaited trees. The rate of attack success was low for both control trees (10%) and baited trees (20%). No trees surrounding control trees were successfully attacked, but 52.8% of the trees surrounding baited trees were successfully attacked. Analysis of mean attack density on unbaited and baited trees, or those surrounding them, disclosed no evident trend. Similarly, there was no indication that the major ter-

penes of black spruce significantly enhanced beetle response to baited trees or to trees surrounding them. Very few trees in this experiment were attacked, precluding detection of differences in attack density.

DISCUSSION

Our results demonstrate that the isoprene alcohol, 3-methyl-3-buten-1-ol, is produced by male *P. rufipennis* and is an aggregation pheromone for this species. These findings are consistent with previously reported pheromones for polygynous bark beetles where pioneer males produce and release aggregation pheromones (Wood et al., 1966; Bakke, 1975, 1976; Harring and Mori, 1977; Francke et al., 1977; Stoakley et al., 1978; Baader, 1989). Although we have no direct evidence for more than one pheromone, the high release rate of 3-methyl-3-buten-1-ol required to elicit attraction in the field suggests other pheromones may be necessary to effect a maximum response. Knowledge that insects generally use multicomponent pheromones (Silverstein and Young, 1976) and recent advances on the pheromone system of the six-spined spruce bark beetle, *Pityogenes chalcographus* (L.), (Byers et al., 1989, 1990) provide impetus to hypothesize the existence of additional pheromones. The presence of 3-methyl-3-buten-1-ol as a pheromone in *P. rufipennis* is of ecological interest. Isoprene alcohols have been reported in only two bark beetle species of the Scolytinae: 2-methyl-3-buten-2-ol in males of the spruce bark beetle, *Ips typographus* L. (Bakke et al., 1977), and 3-methyl-3-buten-1-ol in males of the larch engraver, *Ips cembrae* Heer (Stoakley et al., 1978). Like *P. rufipennis*, both European species feed mainly on weakened trees but will attack healthy standing trees during epidemics (Postner, 1974). Although phylogenetically different, *P. rufipennis* exploits the same highly volatile methylbutenol as *I. cembrae* to further its individual reproductive success. Use of such a compound may be of selective advantage to individuals in northern habitats where midsummer temperatures are often low. Dickens (1981) and Birgersson et al. (1984) suggested that methylbutenol compounds may be short-range orientation or arrestment substances that act to concentrate pioneer beetles on a resistant host tree. Similarly, Schlyter et al. (1987) inferred from field trials that 2-methyl-3-buten-2-ol functions primarily as a landing stimulus for *I. typographus*. We have no definite knowledge as to the effective range of 3-methyl-3-buten-1-ol.

The pheromone system of *P. rufipennis* shows no apparent relationship to that of the closely related European species, *Polygraphus poligraphus* (L.), that also attacks spruce. Male *P. poligraphus* produce three sex-specific compounds, *trans*-4-thujanol, *cis*-4-thujanol, and terpinen-4-ol (Francke and Vité, 1983). *P. rufipennis* previously was treated as a synonym of *P. poligraphus* (Schedl, 1957); however, our findings support Wood (1982), who separated the

two species on the basis of statistical differences in pronotal punctures and tubercles at the bases of the elytra.

The presence of 3-methyl-3-buten-1-ol in male frass is consistent with earlier studies that demonstrated that both males and females respond positively to male-produced frass in laboratory bioassays (Bowers and Borden, 1990). The absence of pheromone in the hindgut is surprising. It is possible that another biosynthetic site may be responsible for its production. For example, (*E*,*Z*)-MD, a major component of the pheromone of *Pityogenes chalcographus*, is found predominantly in the head and thorax of the male beetle. Furthermore, contents of hindguts and the composition of the released pheromone are known to differ (Peacock et al., 1975; Silk et al., 1980). For these reasons it cannot be assumed that a released pheromone will always be detected in the hindgut.

The magnitude of the response to traps releasing 3-methyl-3-buten-1-ol at 4390 μg/day suggests that the 200 μg/day release rate used in tree-baiting experiments may not have been optimal and that a stronger response to baited trees would occur with higher release rates. It is also possible, as hypothesized above, that an additional pheromone may be required to effect an optimal response.

Although host terpenes often enhance response to beetle-produced pheromones (Hughes et al., 1976; Lanier et al., 1977), no such enhancement was evident for *P. rufipennis*, and 3-carene even appeared to inhibit aggregation (Table 3, experiment 3). The low response to fresh uninfested logs suggests that *P. rufipennis* does not rely exclusively on major host terpenes in searching for and exploiting quality resources. However, it is possible that minor host constituents may be involved in *P. rufipennis* host selection. Tømmerås and Mustaparta (1987) reported that minor host constituents stimulated single olfactory receptor cells of *I. typographus* and probably reveal qualitative differences between individual host trees. Moreover, computer-simulated searching strategies (Gries et al., 1989) suggested that random search alone is unlikely to maintain an *I. typographus* population.

Virtually nothing is known about the biogenesis of 3-methyl-3-buten-1-ol in *P. rufipennis*. Production probably occurs from acetate via the mevalonic acid pathway. Hackstein and Vité (1978) and Renwick and Dickens (1979) suggested that in *I. typographus* and *I. cembrae* the compound occurs de novo and is under hormonal control.

The results of this study have implications for management of *P. rufipennis*. Identification of the *P. rufipennis* aggregation pheromone could lead to the development of a monitoring or management tool for use in future pest management operations.

(Received April 17, 1991; accepted June 19, 1991)

Abstract—During a laboratory study evaluating *Rhizophagus grandis* (a specific native predator of the Eurasian bark beetle, *Dendroctonus micans*), as a potential biocontrol agent against the North American bark beetle, *Dendroctonus valens*, it was found that feeding larvae and laboratory-produced frass of the potential prey elicited very high oviposition responses in the predator. Comparative chemical analysis of this laboratory-produced larval frass revealed that one major volatile compound, (−)-fenchone, is associated with the larvae of both *Dendroctonus* species. *D. micans* also generated pinocamphone while oxygenated monoterpenes in the frass of *D. valens* were camphor, *cis*-4-thujanol, fenchol, terpinen-4-ol, myrtenal, pinocarvone, borneol,

*To whom correspondence should be addressed.

0098-0331/91/1000-2003$06.50/0

verbenone, piperitone, campholenaldehyde, *trans*-myrtanol, *cis*-myrtanol, *p*-cymen-8-ol and 5-oxo-camphor. This range of prey-produced compounds with a possible biological effect on *R. grandis* was narrowed down subsequent to comparative analysis of field-collected larval frass. (−)-Fenchone, pinocamphone, camphor, terpinen-4-ol, borneol, fenchol, and verbenone were found to be common to both prey species. A mixture of these seven components was tested in a bioassay, where it elicited as much oviposition as did larval frass of *D. micans*. The oviposition stimulants for *R. grandis* are thus clearly among the mixture's constituents.

Key Words—Dendroctonus micans, Dendroctonus valens, Rhizophagus grandis, Coleoptera, Rhizophagidae, Scolytidae, oviposition stimuli, biological control, monoterpenes.

INTRODUCTION

The highly specific predator *Rhizophagus grandis* Gyllenhal is very often found in the brood chambers of the greater European spruce beetle, *Dendroctonus micans* (Kugelann) (Bergmiller, 1903; Francke-Grosmann, 1954; Grégoire, 1988). Since the mid-1960s, *R. grandis* has been used for the biological control of *D. micans* in Soviet Georgia (Kobakhidze, 1965), France (Grégoire et al., 1984), United Kingdom (King and Evans, 1984), and Turkey (Serez, personal communication).

The red turpentine beetle *Dendroctonus valens* LeConte, which attacks several species of pine in North America (Smith, 1971), is considered phylogenetically very close to *D. micans* (Stock et al., 1987). It also has a very similar life history: both species are solitary colonizers of healthy trees, have a relatively long life cycle as compared to other *Dendroctonus* species, and spend their whole larval stage gregariously feeding on the living phloem of the host.

It has been found that the oviposition of *Rhizophagus grandis* is dependent on the presence of prey larvae and that the stimuli responsible for oviposition in *R. grandis* are volatile compounds present in the larval frass of *D. micans* (Baisier and Grégoire, 1988; Baisier et al., 1988). *R. grandis* does not occur in North America, but its introduction could be useful for the biological control of bark beetle species close to *D. micans*, such as *D. terebrans* (Miller et al., 1987; Moser, 1989) and *D. valens*. This latter species is locally considered as a pest and is not known to be associated with effective natural enemies (Smith, 1971). In laboratory experiments aimed at testing the potential of *Rhizophagus grandis* against *D. valens*, larval frass of *D. valens* elicited very high oviposition responses among the predators.

The objective of the present study was to carry out a comparative analysis of the larval frass of *D. micans* and *D. valens* in order to identify common compounds involved in eliciting predator oviposition. Using laboratory-produced larval frass, comprehensive chemical analyses were carried out by com-

bined gas chromatography–mass spectrometry. The volatiles produced by bark beetle larvae were assigned by differential analyses of frass extracts and extracts of bark and bark powder prepared under similar conditions. The volatiles common to both *Dendroctonus* species were then found by comparing the frass extracts from the two species. These results were completed by comparative analysis of field-collected larval frass of both species. Finally, the biological activity of the selected compounds selected was confirmed in oviposition bioassays.

METHODS AND MATERIALS

Extracts of Laboratory-Produced Frass

Laboratory-produced larval frass of both species was obtained from "oviposition boxes" (Baisier et al., 1988), which are 43-ml clear polystyrene containers filled with either fresh phloem of spruce (*D. micans*) or pine (*D. valens*), phloem powder, live larvae of either *D. micans* or *D. valens*, and are suitable for *R. grandis* oviposition. The control boxes contained fresh phloem and phloem powder, but no larvae. The extracts from *D. micans* were prepared in Brussels, Belgium, and those from *D. valens* were made in Berkeley, California. For each bark beetle species, three series of boxes were prepared:

Series 1 (control boxes) contained fresh host phloem and phloem powder (*Picea abies* for *D. micans*, *Pinus lambertiana* for *D. valens*). Care was taken to match the weights of the fresh phloem pieces in each box [average fresh weight $\pm$ SD = 19.0 g $\pm$ 0.93 of *P. abies* for *D. micans* ($N = 2$), 19.6 g $\pm$ 1.21 of *P. lambertiana* for *D. valens* ($N = 4$)].

Series 2 (oviposition boxes) was prepared like the first series, but also contained 25 live bark beetle larvae. Phloem fresh weight was 18.0 g $\pm$ 0.16 of *P. abies* for *D. micans* ($N = 2$) and 19.0 g $\pm$ 2.27 of *P. lambertiana* for *D. valens* ($N = 4$). Total mean larval biomass was 944.0 mg $\pm$ 22.6 mg for *D. micans* and 709.5 mg $\pm$ 65.9 mg for *D. valens*.

Series 3 was the same as series 2, except that two pairs of *R. grandis* were also included as an oviposition control test, to check that oviposition by the predators occurred in the experimental material ($N = 5$ boxes for both species).

When the first young *R. grandis* larvae started to appear in series 3 (after 19 days for *D. valens* and 10 days for *D. micans*), the boxes of series 1 and 2 were opened. The *Dendroctonus* larvae in series 2 were removed, and the content of the boxes (phloem, phloem powder, and, in addition, frass in series 2) was immersed in pentane (Merck, 95% pure for *D. micans*; Aldrich, 99% pure for *D. valens*).

Extracts of Field-Collected Larval Frass

The samples were collected on standing trees from brood chambers containing live larvae and immediately put into pentane. For *D. valens*, samples were collected in California on either *P. lambertiana* or *P. ponderosa*. For *D. micans*, samples were collected on *P. abies* in Belgium and in Great Britain.

Chemical Analysis

Gas chromatographic analysis of the extracts was carried out on a Carlo Erba Fractovap Series 2150 gas chromatograph with split injector and flame ionization detector. For separation, a fused silica column with FFAP as the stationary phase (50 m, 0.25 mm ID) was used under a temperature program of 60°C to 220°C at a rate of 3°/min. Helium served as the carrier gas with a flow rate of 1.8 ml/min. Mass spectra (EI^+, 70 eV) were recorded on a Varian MAT 311A and a VG 70-250 S instrument in a GC-MS coupling mode under the above gas chromatographic conditions.

Identifications were based on comparison of gas chromatographic retention times and mass spectra of natural compounds and authentic reference samples.

The absolute configurations of natural fenchone and isopinocamphone were determined by gas chromatographic enantiomer separation on a chiral stationary phase: octakis(3-*O*-butyryl-2,6-di-*O*-pentyl)-γ-cyclodextrin (König et al., 1989).

Synthetic Compounds

Compounds used in bioassays were either purchased or synthesized in our labs. The racemate of camphor (Aldrich) and terpinen-4-ol (Merck) showed purities of 99% and 90%, respectively; (+)/(−)-borneol (Fluka) was 85% chemically pure and had a rotation value of $[\alpha]_D^{20} = -18°$ (c = 2.43-EtOH). The chemical purity of the ketones (−)-fenchone (Fluka) and (−)-verbenone (Bedoukian) was 97%; fenchone showed an enantiomeric excess of 98% and verbenone 80% (by gas chromatography). (−)-Fenchol was synthesized from (+)-fenchone according to Beckmann and Metzger (1956); chemical purity of the product proved to be 99%, rotation value $[\alpha]_D^{20} = 12.9°$ (c = 1.3 pentane). (−)-α-Pinene (Aldrich) served as starting material for the synthesis of (−)-pinocamphone (Zweifel and Brown, 1964). Our product was 99% chemically pure and showed a rotation value of $[\alpha]_D^{20} = (-23.8°$ (c = 0.47, EtOH).

Bioassay

Three series of 20 oviposition boxes were prepared: stimuli, frass, and control blank. Each box contained a pair of *R. grandis*, which were fed daily half a larva of *Calliphora erythrocephala*. *R. grandis* larvae produced in the

boxes and gathered on these prey were collected and counted daily. Adult predators were regularly checked; dead males were replaced, and when dead females were observed (one occurrence only) the corresponding box was removed from the test.

For the control blank series, the boxes were filled each with two disks of fresh spruce bark (4.1 cm in diameter) and bark powder.

For the frass series, the boxes each were filled with two disks of fresh spruce bark and with bark powder mixed with 8 g of *D. micans* larval frass collected in France (Gard) in September 1991.

For the stimuli series, the boxes each were filled with two disks of fresh spruce bark and bark powder. Each box also received 220 mg of a mixture of: pinocamphone, camphor (racemic), (−)-fenchone, terpinen-4-ol (racemic), (−)-α-fenchol, borneol, (*S*.vt)-(−)-verbenone, and pentane, in the ratios 4:14:14:14:14:14:15. For (−)-fenchone, this quantity corresponds approximately to the amount found in 56 g of frass (Francke and Meyer, unpublished). The quantity of pinocamphone used was determined by its availability. Pentane was added to the mixture in order to dissolve the camphor, borneol, and fenchol and 37 mg of this mixture (i.e., 50 μl) was deposited on the surface of the bark powder in each box on the first day of the experiment. Later, a new dose was incorporated into each box every fourth day during 20 days (corresponding thus to a total of six incorporations, amounting to a total of 220 mg/box). After each new incorporation, the boxes were left open for 1 min to allow evaporation of the pentane.

Statistical Analysis

Chemical Analysis. For each compound and for each bark beetle species, the percentages of total amount of volatiles in the control boxes and the oviposition boxes were compared using one-way analyses of variances after arcsine transformation of the data (Dagnelie, 1970).

Bioassay. The numbers of larvae collected in each series at the end of the bioassay were compared using one-way analysis of variance after square root transformation of the data, and a Newman-Keuls multiple comparison of means (Dagnelie, 1970). Only the boxes where oviposition had occurred were used in this analysis. The proportions of "sterile" boxes in each series were analyzed using binomial tests (Dagnelie, 1970) based upon a 0.033 individual probability for a box to be accidentally "sterile;" this 0.033 probability was calculated from previous rearings in normal oviposition boxes (i.e., containing one pair of predators and *D. micans* larvae) and where four boxes out of 120 were found to produce no larvae (Baisier, unpublished).

RESULTS

Oviposition control tests (series 3) showed perfect suitability of the oviposition boxes for oviposition:(1) *D. micans*: an average (±SD) of 138.8 ± 30.52 *R. grandis* larvae were produced; (2) *D. valens*: 219.2 ± 87.02 *R. grandis* larvae were produced. There were significantly more larvae in the *D. valens* oviposition boxes than in those with *D. micans* (*t* test: $t = 1.95$; $P > 0.05$), which is consistant with earlier results (unpublished).

Oviposition was not tested in control boxes, since these latter had never shown biological activity in previous studies.

Extracts of Laboratory-Produced Frass. The concentrations of monoterpene hydrocarbons and oxidized monoterpenes found in the material of the oviposition boxes containing *Dendroctonus* larvae (i.e., series 2) and control boxes containing no larvae (i.e., series 1) are given in Tables 1 and 2 (expressed as percentages of the total amount of volatiles) and in Figure 1A and 1B for *D. valens*. One-way analysis of variance for each oxidized monoterpene indicated

[(−)-fenchone, pinocamphone, camphor, fenchol, terpinen-4-ol, borneol, and verbenone] are present in the field-collected frass of both species (although verbenone is lacking from the *D. valens* frass from *P. lambertiana* and fenchol and borneol are lacking in the *D. valens* extract from *P. ponderosa*).

Bioassay. The candidate oviposition stimuli proved as effective as *D. micans* larval frass in eliciting oviposition (Figure 2). At the end of the experiment, the stimuli series produced an average (±SE) 26.3 ± 2.58 larvae while the frass series produced 35.1 ± 3.82 larvae, and the control blank series produced 9.6 ± 1.55 larvae. According to a Newman-Keuls multiple range test, oviposition in the stimuli and frass series were not significantly different from each other, but differed from the control blank series ($\alpha = 0.05$). These features appeared early in the process of egg production: daily range tests on the larvae collected in the three series showed a consistantly significant difference between the frass and stimuli series on the one hand, and the control blank series on the other hand, from day 12 onwards ($\alpha = 0.05$).

A binomial test showed an abnormal proportion of sterile boxes in the control blank series ($P = 0.0008$), while there was no significant sterility among the boxes in the two other series (frass: $P = 1.000$; stimuli: $P = 0.9429$).

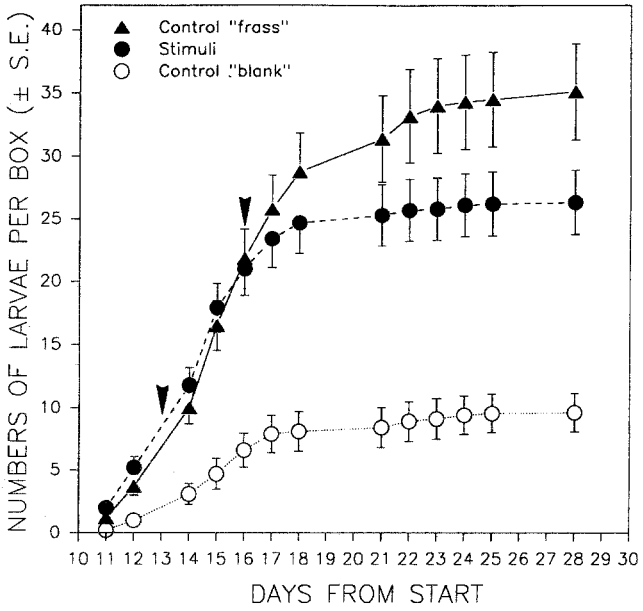

FIG. 2. Oviposition in the bioassay, as reflected by the daily collection of young larvae appearing in three series. Black arrows indicate when the last two fresh 37-mg doses of stimuli have been incorporated into each box of the stimuli series.

DISCUSSION

The different levels of comparisons made during this study allowed us to focus on a small number of candidates likely to act as oviposition stimuli for *R. grandis*.

1. As a first step, the compounds produced by the larvae of both bark beetle species were identified from biologically active material, i.e., laboratory-produced larval frass. Since earlier analyses of volatiles contained in the bark of *Picea abies* had demonstrated that a number of oxidized monoterpenes are already present in the bark of unattacked *Picea abies*, e.g., pinocamphone, isopinocamphone, *trans*- and *cis*-verbenol, verbenone, myrtenol (Heemann and Francke, 1977), it was necessary to distinguish between host components and compounds generated from bark beetle activity. This was achieved by comparing volatiles from oviposition boxes (containing either *D. micans* or *D. valens* larvae) with those from control boxes (containing only vegetal material).

2. By comparing the volatiles from oviposition boxes of both species, some compounds produced by the larvae of both species were shown to be possible oviposition stimuli for *R. grandis*. These compounds were (−)-fenchone, camphor, terpinen-4-ol, and piperitone.

3. By comparing the natural larval frass of both bark beetles, borneol, verbenone, fenchol, and pinocamphone also were taken into account, while the absence of piperitone in the field-collected frass suggested that this component could be excluded.

The results of the bioassays confirm the conclusions drawn from the differential method developed in this work. The synthetic stimuli elicited as much oviposition as the frass, and significantly more than the blank boxes. During a large part of the experiment, the oviposition rates as reflected by the numbers of larvae collected daily in the stimuli and the frass series were also similar (around 3 eggs/female/day, see Figure 2). However, there are important differences in the numbers of eggs laid in these series as compared to more normal situations, i.e., boxes containing also live *D. micans* larvae. Unfortunately no such control could be added to the present experiment, but in earlier experiments involving oviposition boxes with a pair of predators and live larvae of *D. micans* (Baisier, unpublished), we found an average 107.0 larvae collected per box (min. = 70.4; max. = 130.1; $N = 73$), which suggests that frass or synthetic stimuli elicit only about one third of the oviposition expected from more natural situations. One aspect of these differences lies in higher oviposition rates in boxes containing prey larvae: up to 7 or 8 eggs/female/day (Baisier, unpublished), instead of about three with frass or stimuli. It has been argued (Baisier et al., 1988) that the differences between frass and live larvae as sources of stimuli might be attributed to faster depletion of the stimuli from the frass. This argument does not seem to hold in the case of the synthetic chemicals,

which were introduced gradually into the boxes, even at periods when the numbers of larvae collected had started to decline (see Figure 2). There is a possibility that some active components are still missing from the mixture or that the stimuli were too concentrated in the experiment, inhibiting further oviposition. Finally, it is possible that the mixture tested includes too many candidate stimuli, among which are some antagonist or indifferent compounds. Focusing on sorting out the respective activities of these seven components will be the subject of further experiments.

Abstract—A variety of plant pests are suppressed by the incorporation of cruciferous plant material into soil. Although this effect is attributed to decomposition of glucosinolates into toxic products, little is known concerning glucosinolate degradation in the soil environment. Arenas (30 × 18 × 8 cm) that contained soil amended with 30 g defatted winter rapeseed meal (*Brassica napus* L.)/kg soil on one half and unamended soil on the other were constructed. Isothiocyanate concentrations in the soil were measured using infrared analysis of CCl_4 extracts, and ionic thiocyanate (SCN^-) using ion chromatography on aqueous extracts. Quantities were monitored during a 100-hr time period in conjunction with a wireworm bioassay. Isothiocyanate production reached a maximum of 301 nmol/g soil at 2 hr, but decreased by 90% within 24 hr. Production of SCN^- reached a maximum of 180 nmol/g soil at 8 hr but persisted longer than isothiocyanate. Separate late instar wireworms (*Limonius infuscatus* Mots.) were repelled by the presence of rapeseed meal in less than 24 hr even though the meal was shown in separate experiments not to be toxic. We propose that rapidly produced isothiocyanates are responsible for this repellency, but other products such as SCN^- may play a role.

Key Words—Rapeseed, *Brassica* spp., isothiocyanate, thiocyanate, defatted

INTRODUCTION

Glucosinolates are organic anions possessing a β-D-thioglucose moiety, a sulfonated oxime, and any one of a variety of aliphatic or aromatic R groups (Figure 1). Nearly 100 different glucosinolates have been isolated or identified from degradative products (Chew, 1988). They are produced exclusively in dicotyledonous plants and are most common in members of the order Capparales. Those plants with the highest concentrations are in the families Resedaceae, Capparidaceae, and Brassicaceae (Fenwick et al., 1983).

Glucosinolates themselves possess limited biological activity. However, enzymatic degradation by thioglucoside glucohydrolase (EC 3.2.3.1) results in the formation of a number of allelochemicals (Figure 1). Glucosinolate chemistry and degradation pathways in plant tissues have been reviewed (Chew, 1988; Röbbelen and Thies, 1980; Larsen, 1981; Björkman, 1976; Kjaer, 1976).

Interest in glucosinolates and the associated degradation products has been generated because of the possibility of using plant residues as a substitute for synthetic organic pesticides. Cruciferous plant tissues or tissue extracts have

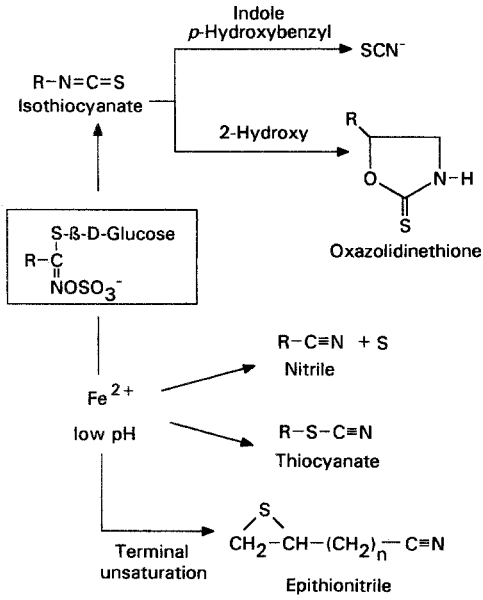

FIG. 1. Glucosinolate degradation products.

been reported to be phytotoxic (Jiménez-Osornio and Gliessman, 1987; Fenwick et al., 1983) and insecticidal (Lichtenstein et al., 1964). The most thoroughly described control of a plant pathogen is for *Aphanomyces* root rot of peas, in which a variety of cruciferous plant amendments applied to infested soil reduced either the level of *Aphanomyces euteiches* or the severity of the disease symptoms (Papavizas, 1966; Papavizas and Lewis, 1971; Lewis and Papavizas, 1971; Chan and Close, 1987). These effects are generally thought to result from glucosinolate degradation products. However, conflicting or inconsistent results with respect to pest inhibition have been obtained as a result of what we believe is an incomplete understanding of glucosinolate degradation pathways in soil (Parke and Rand, 1989; Davis, 1988; Waddington, 1978; Papavizas and Lewis, 1971).

No studies identifying products specific to glucosinolate degradation in soils have been reported. The role of glucosinolate degradation products and allelochemic suppression of pathogens or other soil-borne plant pests has, therefore, not been established. Our objective was to quantify glucosinolate degradation products occurring in soil amended with defatted rapeseed meal (RSM) in combination with a wireworm bioassay.

METHODS AND MATERIALS

Defatted Rapeseed Meal. Mature seed was harvested from the Dwarf Essex cultivar of winter rapeseed (*Brassica napus* L.) and the oil extracted using a CeCoCo experimental press, the design of which has been reported (Peterson et al., 1983). Glucosinolate concentrations in the RSM (Table 1) were determined using a modified procedure of Daun and McGregor (1983). Samples of

TABLE 1. GLUCOSINOLATE CONCENTRATIONS IN DEFATTED *B. napus* MEAL USED IN SOIL AMENDMENT EXPERIMENTS

Glucosinolate		Amount
Semisystematic name	Trivial name	(μmol/g meal)
2-Hydroxy-3-butenyl	Progoitrin	87.8
3-Butenyl	Gluconapin	41.8
4-Pentenyl	Glucobrassicanapin	11.7
Indole[a]	Glucobrassicin Neoglucobrassicin	7.6
2-Hydroxy-4-pentenyl	Napoleiferin	6.5

[a] Concentration determined from SCN^- formed by enzymatic degradation. Several different indole glucosinolates have been identified in rapeseed meal (Daun, 1986; Sang et al., 1984).

RSM (100 mg) were placed in 15 × 100-mm test tubes and heated to 100°C. After temperature equilibration, 6 ml of boiling water was added to denature endogenous thioglucoside hydrolase and extract glucosinolates. One micromole of benzyl glucosinolate was added to each sample as an internal standard. The samples were vortexed, 200 μl of a 1:1 (v/v) mixture of 0.6 M lead acetate and 0.6 M barium acetate was added, and the samples were vortexed again. The samples were centrifuged at 2000 *g* for 10 min, and the supernatant was poured onto diethylaminoethyl (DEAE) Sephadex A-25 anion exchange columns. The columns were washed with 3 ml of 4 M acetic acid and twice with 3 ml of distilled water and 3 ml of 0.02 M pyridine–acetate (1:3.2, v/v pyridine to glacial acetic acid) to remove neutral compounds. Purified sulfatase (1 ml) was added, and the columns were allowed to stand overnight. The resulting desulfoglucosinolates were eluted into 1.8-ml autosampler vials with 1.5 ml of distilled water, dried at 60°C under a stream of air, and derivatized with trimethylsilane. Samples of 1.5 μl were injected with a Varian model 8000 autosampler into a Varian 3700 gas chromatograph equipped with a FID detector and a 2.4-m × 6.4-mm-OD × 2-mm-ID glass column packed with OV-7 on Chromosorb W (AW-DMCS). Helium was used as a carrier gas at a flow rate of 30 cm/min. Injection port temperature was maintained at 280°C and detector temperature at 310°C. An initial oven temperature of 235°C was held for 5 min, and the temperature was increased at a rate of 3°C/min until a final oven temperature of 265°C was reached. This final temperature was held for 3 min. The glucosinolate peaks were quantified with a Hewlett-Packard 3390A integrator using the peak area of benzyl glucosinolate as the internal standard.

Indole glucosinolates were estimated by measuring SCN^- production in a water–RSM slurry. Indole and *p*-hydroxybenzyl glucosinolates yield inherently unstable isothiocyanates that spontaneously degrade to form SCN^-, thus providing the basis for the assay (McGregor, 1991). Our assay included only indole glucosinolates, because *p*-hydroxybenzyl glucosinolates require a basic pH for SCN^- formation and are not known to be present in RSM (Fenwick et al., 1983). A RSM sample (0.150 g) was placed in a 50-ml flask to which was added 20 ml of 0.0035 M $CaCl_2$ solution. The sample was incubated at 27°C for 20 min (with enzyme) or 1 hr (without enzyme), filtered through Whatman No. 42 filter paper, a 0.45-μm Supor-450 membrane (Gelman Sciences, Ann Arbor, Michigan), and a Maxi-Clean IC-RP cartridge (Alltech Associates, Deerfield, Illinois), and measured for SCN^- by ion chromatography. Omission of the Maxi-Clean filtration step, incubation for longer time periods, elevated pH values, and treatment with and without enzyme resulted in similar amounts of SCN^- production.

Glucosinolate Degradation Products in Soil. Isothiocyanates and ionic thiocyanate (SCN^-) were quantified in RSM-amended soil. We have adapted the method of Ashley and Leigh (1963) for measuring methyl isothiocyanate in

soils to the determination of isothiocyanates produced as a result of glucosinolate degradation. This method was used in combination with the ion chromatographic determination of SCN^- in the following manner. To a polypropylene centrifuge tube containing 6–8 g of soil, 10 ml of 0.005 M $CaCl_2$ and 20 ml of CCl_4 were added. The tube was capped, shaken for 1–2 min, and centrifuged for 10–12 min at 630*g*. The aqueous layer was removed with a syringe and analyzed for SCN^- using ion chromatography (Brown and Morra, 1991). A Dionex 4000i ion chromatograph equipped with an AS5 column, anion micromembrane suppressor, and conductivity detector was used in combination with an eluent containing 4.3 mM $NaHCO_3$, 3.4 mM Na_2CO_3, and 0.8 mM 4-cyanophenol. A second glass syringe was used to remove the bottom layer of CCl_4, and the extract was placed in a 25-ml flask along with 0.5–1.0 g of Na_2SO_4 to dry the sample. The sample was dried for 2–24 hr, filtered through a 0.45-μm syringe filter, and stored at 4°C until analysis by FT-IR. Sample extracts could be stored at least four days before analysis without a loss of isothiocyanates. Infrared analysis was conducted using a Digilab FTS-80 FT-IR spectrometer (Bio-Rad, Cambridge, Massachusetts) equipped with a TGS detector and a 3-mm NaCl cell (Spectra Tech, Stamford, Connecticut). Spectra were recorded in the absorbance mode and signal-averaged for 80 scans. Peak height for isothiocyanate in the soil extracts was compared to a standard curve produced using CCl_4 solutions of allyl isothiocyanate (AITC) (Aldrich, Milwaukee, Wisconsin).

Wireworm Bioassays. Wireworms were field collected in the spring of 1989 from sites in Walla Walla County, southeast Washington, and Umatilla County, northeast Oregon, under nonirrigated spring pea (*Pisum sativum* L.) and fall wheat (*Triticum aestivum* L.) rotations. Holes 6 cm diam. × 15 cm deep were dug at each collection site into which 50 ml of a 1:1 (v/v) mixture of wheat and corn seed was placed to act as a bait. The seed had been soaked in water for 36 hr prior to placement. The hole was then filled with soil to a height approximately 2 cm above the surface of the surrounding soil and covered with a "solar heater" (Toba and Turner, 1983) consisting of a 40-cm^2 black polyethylene sheet stapled to the center of a 1-m^2 transparent polyethylene sheet. A quantity of soil 15 cm diam. × 35 cm deep surrounding the bait was dug after three to five weeks. Soil was sieved through 6.5- and 3.5-mm wire mesh screens to collect the wireworms. The wireworms were late-instar *Limonius infuscatus* Mots. (Coleoptera: Elateridae). Voucher specimens are deposited in the W.F. Barr Entomological Museum, University of Idaho, Moscow, Idaho.

The effects of soil-incorporated RSM on wireworm mortality and behavior were tested in a Latahco silt loam soil (Argiaquic Xeric Argialbolls). The top 25 cm of soil was field-collected, air-dried, and crushed to pass a 2.0-mm sieve. The collected soil contained 17 g total C, 1.5 g total N, 185 g clay, and 745 g silt/kg soil, and had a pH of 6.0. Total C and N were determined by Dumas

combustion (CHN-600 Determinator, Leco Corp., St. Joseph, Michigan), particle-size distribution by the hydrometer method (Gee and Bauder, 1986), and pH by glass electrode (1 : 1 soil to water).

The effects of soil-incorporated RSM on wireworm larval mortality were studied in the laboratory using the following bioassay procedures. Air-dried Latahco soil was mixed with the RSM at a rate of 30 g meal/kg soil. Sufficient water was added to the soil–RSM mixture to bring it to an average moisture content of 16% (w/w), an amount of moisture equivalent to 56% of that contained by the soil at −0.033 MPa. The mixture was placed into 473-ml glass jars, and one wireworm was placed on the soil surface in each of 20 replicates. Twenty wireworms were also tested in the control, which contained unamended soil. The jars were incubated uncovered at 27°C under a 12-hr photoperiod. Each jar was weighed daily and sufficient water to replace evaporative losses was added. Larvae were checked after 17 days and were recorded as alive or dead.

Wireworm behavior in response to the RSM was tested individually in plastic arenas (30 × 18 × 8 cm). One side of the arena was filled with the soil–RSM mixture (30 g meal/kg soil) and the other side with Latahco soil only. The soil in the arenas was adjusted to an average moisture content (w/w) of 18%. A potato section of uniform size was placed at each end of the container at a depth of 2.5 cm. An individual wireworm was placed head downward in the soil at the center of each of 30 replicates, and the containers were covered with Clysar EHC 60 (DuPont) medium-gauge film (moderate O_2 and CO_2 permeability) for moisture retention. The arenas were maintained in the dark at 23°C for 24 or 100 hr at which time the x–y coordinates of each wireworm with respect to the interface of the unamended to the amended soil were determined by destructive sampling.

Soil was sampled from trays prepared identical to those above, but lacking wireworms. After a specific incubation time, one soil sample was removed from the amended and one from the unamended side of each of four replicates. Samples were obtained from the entire vertical profile of the soil using a hollow tube having a 1.6-cm ID. They were immediately placed in a centrifuge tube containing CCl_4 and analyzed for isothiocyanate and SCN^- as previously described. Duplicate soil samples were also removed and soil moisture content was determined by weight loss on drying at 105°C for 24 hr. Soil moisture content values were used to convert isothiocyanate and SCN^- concentrations in wet soil to concentration per unit weight of dry soil.

RESULTS AND DISCUSSION

Isothiocyanate Analysis. Although a method for the indirect determination of allyl isothiocyanate (AITC) in soil has been suggested (Chae and Tabatabai, 1983), it has not been tested with actual soil extracts or plant tissues. We have

instead chosen to use an infrared method originally proposed by Ashley and Leigh (1963) for the measurement of methyl isothiocyanate produced in dithiocarbamate-amended soils. In our experiments a similar infrared analysis technique proved to be a convenient method to identify and quantify total isothiocyanate content. Infrared spectroscopy can be used to measure asymmetrical stretching of the $-N=C=S$ functional group in the 2174–2041 cm^{-1} region (Silverstein and Bassler, 1967) and has the advantage of being both qualitative as well as quantitative. The $-C\equiv N$ functional group of nitriles, epithionitriles, and thiocyanates also absorbs at this frequency; however, confusion between group identification is unlikely because the sharp nitrile peak shape is easily distinguished from that of the strong, broader isothiocyanate peak. Characteristic isothiocyanate peaks were indeed observed for RSM-amended soils, while evidence for nitrile production was not observed under the present conditions (Figures 2 and 3). Preliminary experiments indicate that nitrile production may occur if the soil is waterlogged (unpublished data). Carbon tetrachloride soil extracts from unamended soil exhibited virtually no background absorbance in the desired range (Figures 2 and 3).

Quantification of isothiocyanate concentrations was performed using AITC as a standard to represent the anticipated 3-butenyl and 4-pentenyl isothiocyanates. Additional glucosinolates present in the meal are expected to produce unstable isothiocyanates leading to products other than isothiocyanate (Figure 1).

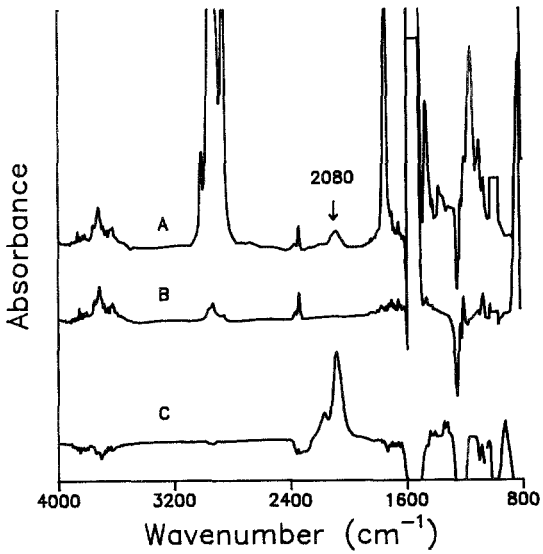

FIG. 2. Infrared spectra of (A) a soil extract from soil amended with defatted seed meal of *B. napus*, (B) a soil extract from unamended soil, and (C) an allyl isothiocyanate solution.

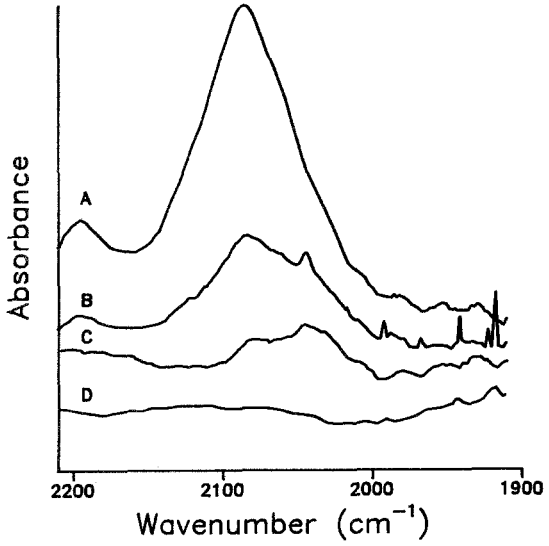

FIG. 3. Infrared spectra of soil extracts from soil amended with *B. napus* defatted seed meal at (A) 2, (B) 6, and (C) 12 hr after amendment. Spectrum D is a soil extract from an unamended soil.

AITC is similar to both 3-butenyl and 4-pentenyl isothiocyanates in that all are aliphatic with terminal unsaturation. Calibration curves were linear ($R^2 > 0.99$) over the concentration range of 1.4–18.0 μg/ml with an estimated limit of detection of 1.0 μg/ml (peak height for 1.4 μg/ml was 3.5X background noise). Various standard isothiocyanate solutions were examined for peak position and absorbance intensity. Intensity varied somewhat with the molecular character of the specific compound (Table 2); however, these effects are insignificant in the present case since aliphatic isothiocyanate intensities were all very similar.

Wireworm Bioassays. Defatted rapeseed meal amended to soil at the rate of 30 g/kg had little effect on wireworm survival as determined 17 days after wireworm introduction. Larval survival in the amended soil was 95% and in the unamended soil treatments 100%. Larval burrows were apparent in all containers except for one amended replicate in which the larva died, suggesting that death occurred soon after introduction into the jar.

In the behavioral test, wireworms responded negatively (G test, $df = 1$, $P < 0.01$) (Sokal and Rohlf, 1969) to defatted rapeseed meal when amended to soil at the same rate used in mortality studies (Figure 4). The response was rapid, with no difference in wireworm behavior between the 24- and 100-hr incubations. This is consistent with the time course for the production of isothiocyanates and SCN^- in which both compounds were produced immediately

TABLE 2. PEAK POSITION AND RELATIVE HEIGHT OF REPRESENTATIVE ISOTHIOCYANATES

Isothiocyanate	Peak position (wavenumber, cm^{-1})	Relative height[a]
Methyl	2105	0.99
Allyl	2088	1.00
Benzyl	2082	1.20
Propyl	2076, 2095[b]	0.98
Phenyl	2055	1.24
RSM	2080, 2046[c]	

[a] Peak heights relative to allyl isothiocyanate equal 1.00.
[b] Peak at 2076 cm^{-1} is dominant and was used for peak height comparison.
[c] Peak at 2080 cm^{-1} is dominant.

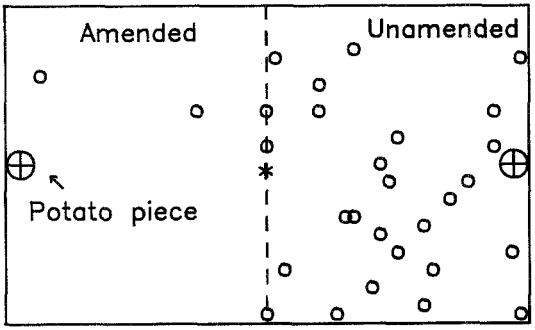

FIG. 4. Composited top view of wireworm locations in arenas 24 hr after amendment of soil with defatted seed meal of *B. napus*. Asterisk represents wireworm placement at bioassay initiation, open circles *x*–*y* coordinates of wireworms at bioassay termination, and dotted line the interface of amended and unamended soil.

upon introduction of water to the system (Figure 5). Carbon tetrachloride extracts of RSM showed no absorbance peaks corresponding to those produced in the presence of moisture. These data indicate that thioglucoside glucohydrolase was not inactivated by the pressing procedure used for oil removal. Isothiocyanates were not present in the RSM, and glucosinolates remained intact because water was absent and thus unavailable for glucosinolate hydrolysis. This is confirmed by the fact that addition of enzyme was unnecessary for maximum SCN^- production during the measurement of indole glucosinolates.

Maximum isothiocyanate concentrations of 301 nmol/g soil were measured at 2 hr (Figures 3 and 5). In RSM, substrates for isothiocyanate production

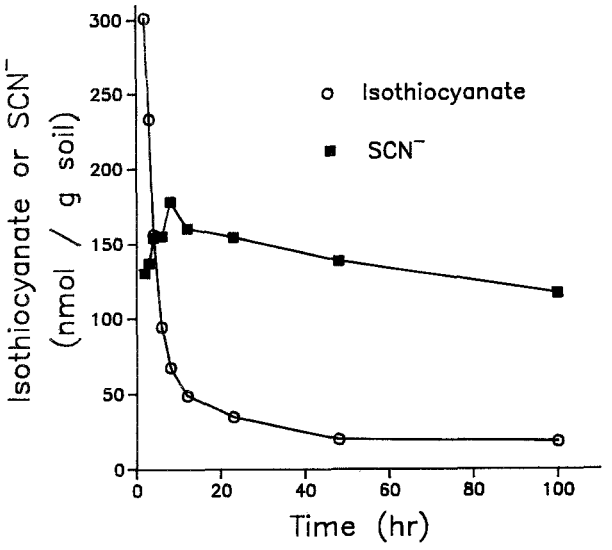

FIG. 5. Isothiocyanate and SCN^- in extracts from soil amended with defatted seed meal of *B. napus*.

include only aliphatic glucosinolates lacking a hydroxyl group at the β position (Figure 1). The amount of potentially available substrate for isothiocyanate production was equivalent to the total concentration of 3-butenyl and 4-pentenyl glucosinolate present in the RSM-amended soil or 1600 nmol/g soil (Table 1). The amount of isothiocyanate actually recovered in soil extracts was 19% of this total, assuming that all production took place in the first 2 hr of incubation.

Our method for isothiocyanate analysis does not measure total production, only the net extractable amount. Losses of isothiocyanate through volatilization and sorption processes are likely. Volatile losses for methyl isothiocyanate have been reported, and an increase in clay, organic matter, pH, or soil water content has been shown to reduce such losses (Ashley et al., 1963; Munnecke and Martin, 1964). Although the exact fate of isothiocyanates in soil is unknown, Lewis and Papavizas (1970) suggested that failure to detect isothiocyanates in headspace samples of soil amended with *Brassica* tissues may have resulted from an interaction with soil constituents. The likelihood of such reactions is increased by the fact that RSM contains high concentrations of protein. Isothiocyanates will react irreversibly with amine and sulfhydryl groups in this protein (Wood, 1975), thus reducing the amount available for extraction from the amended soils. More recently, it has also been shown that allyl isothiocyanate will react irreversibly with and oxidatively cleave disulfide bonds under

relatively mild conditions as occurred in our RSM–soil system (Kawakishi and Kaneko, 1985; Kawakishi et al., 1983).

It has been assumed that isothiocyanates play a key role in the inhibition of plant pests by cruciferous tissues. Pest inhibition by organic isothiocyanates, exclusive of glucosinolates, has been demonstrated in soil. For example, methyl isothiocyanate (MITC) is used directly as a soil fumigant or generated in situ from sodium *N*-methyldithiocarbamate (Miller, 1988). The amount of MITC recommended for soil sterilization can be calculated by assuming a 15.2-cm depth of incorporation, soil bulk density of 1.4 g/cm^3, and 100% conversion of dithiocarbamate to MITC. The calculated values range from 517 to 1294 nmol MITC/g soil depending upon the specific crop and type of control required. Although recommended rates exceed the amount of isothiocyanate measured from RSM degradation (301 nmol/g soil), it is likely that wireworms responded negatively to the concentrations produced in our RSM-amended soils.

Formation of SCN^- was rapid, but production lagged somewhat behind that of isothiocyanate with the maximum of 180 nmol/g soil measured at 8 hr (Figure 5). This amount of SCN^- is equivalent to 73% of the total potentially produced from indole glucosinolate present in the RSM. SCN^- was more persistent than isothiocyanate and 108 nmol/g soil remained after 100 hr. Longer residence times than isothiocyanate are expected, even though the biological decomposition of SCN^- has been documented (Beekhuis, 1975).

Although lower in toxicity than isothiocyanate, SCN^- destabilizes the tertiary structure of proteins through an electrostatic interaction (Voet and Voet, 1990; Wood, 1975). Thiocyanate has insecticidal properties when used in combination with other chemicals, exhibits herbicidal properties such as germination/growth inhibition (Stiehl and Bible, 1985; Ju et al., 1983), defoliant activity, and at higher rates acts as a soil sterilant (Beekhuis, 1975). The impact of SCN^- on wireworm behavior is unknown, but its production in RSM may contribute to repellency.

Other products potentially produced from the degradation of glucosinolates in RSM may also have allelochemic effects. It is possible that volatile products such as carbonyl sulfide (COS), carbon disulfide (CS_2), and hydrogen sulfide (H_2S) may be produced from glucosinolate degradation by way of an organic isothiocyanate intermediate (Bailey et al., 1961; Challenger, 1959). However, these volatiles were not detected in headspace samples above soils amended with *Brassica* tissues (Lewis and Papavizas, 1970). An additional product that would be expected from the degradation of glucosinolates containing a β-OH group is oxazolidinethione (Figure 1). Biological activity appears to be relatively low or unknown, other than well-known goitrogenic effects, but may be a factor in that glucosinolates producing these compounds comprise a major portion of the total glucosinolate content in RSM (Table 1).

These experiments showed that rapeseed meal was not toxic to wireworms

at the rate tested. However, wireworms were repelled by the presence of rapeseed meal in less than 24 hr. Rapidly produced isothiocyanates are probably responsible for this repellency, but other products such as SCN^- may also play a role. In order to fully understand the allelochemic behavior of glucosinolates in soil, it will be necessary to evaluate the biological activity of specific degradation products.

Acknowledgments—Funding for this research was provided by the Institute for Molecular and Agricultural Genetic Engineering and the Idaho Agricultural Experiment Station. Our identification of the wireworms was verified by P.J. Johnson, Department of Entomology, University of Wisconsin.

(Received April 1, 1991; accepted June 26, 1991)

Abstract—The existence of a female sex pheromone of the noctuid moth *Brithys crini* Fabricius was confirmed in both laboratory bioassay and field tests. Crude extracts and airborne volatiles from females were analyzed by gas chromatography and mass spectrometry and the data compared with authentic compounds. The primary sex pheromonal compound was Z11-16:Ald. Scanning electron microscopy showed that the external surface of the sex pheromone gland was covered with folds that might increase the sex pheromone evaporation area.

Key Words—Sex pheromone; (Z)-11-hexadecenal; *Brithys crini*, Lepidoptera, Noctuidae.

INTRODUCTION

The noctuid moth, *Brithys crini* Fabricius, is a serious pest of the white amaryllis (*Zephyranthes candida* Herb.) during winter in the northern part of Taiwan. In nature, there are three to four generations during the year. This insect can have 10–11 generations a year in the laboratory at 27–28°C and a light-

*To whom correspondence should be addressed.

0098-0331/91/1000-2035$06.50/0

dark ratio of 16 : 8 hr. The current method of controlling this pest with pesticides is not always effective. The use of sex pheromones has had some success in combating insect pests (Mitchell, 1981) and may be an attractive supplement to existing control practices. Because the sex pheromone had not been identified, we conducted chemical identification using gland volatiles and extracts. Efficacy of the pheromone was tested both by laboratory bioassays and field tests. External morphology of the gland-bearing ovipositor was studied by scanning electron microscopy.

METHODS AND MATERIALS

Insects. The insects were reared on white amaryllis plants, and females were separated from males at the pupal stage. Adults were kept in separate rooms under a light–dark cycle of 16 : 8 hr.

Scanning Electron Microscopy. The abdominal tips of 3-day-old virgin females were cut off during the calling period. The scanning electron technique (fixation and dehydration) employed was as described by Chow et al. (1976). The dried abdominal tips were coated with gold in a vacuum evaporator (Eiko Engineering IB-2 Ion-coater). Micrographs were taken with a JEOL JSE-15 scanning electron microscope at an acceleration voltage of 15 kV.

Pheromone Extract. Pheromone glands were dissected from the ovipositors of 40 2- to 3-day-old females and immersed in hexane. After 15 min, the supernatant solution was transferred to a small vial and concentrated to 120 μl by letting the samples stand in a fume hood. Gland volatiles were obtained from calling females by putting one end of an open glass tube, 7 mm OD $\times$ 60 mm long and filled with 3 mg conditioned Porapak Q, near the female's sex pheromone gland and aspirating air for approximately 1 hr with a suction machine. The trapped volatiles were rinsed from the Porapak with 300 μl hexane and then concentrated to the desired volume.

Bioassay of Crude Extract. For aggregating effect, 10 3-day-old males, which had been conditioned under continuous light since emergence, were put into a glass jar 2 hr before the light was turned off. The crude extract was serially diluted with hexane to make the amount of the extract in 10 μl of solution 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, and 10^{0} female equivalents (FE). Each solution was applied to the inside wall of a pipet tip, and air was blown out through the pipet with a rubber bulb toward each test individual. Vibration of wings, exposure of the genital claspers, and hovering flight were the criteria of the male's positive sexual response. This experiment had five replicates.

Preliminary Field Trapping of Released Males. Preliminary field trapping with female crude extract was carried out during October 14–16, 1988, in two white amaryllis fields near the Institute of Zoology, Academia Sinica, Taipei.

For comparing the attractive efficacy of different amounts of FE, extracts of 2 FE, 6 FE, 10 FE, and 15 FE were applied on 1-cm × 1-cm filter paper. The filter paper then was hung on the inside and at the top of a wing-shaped sticky trap (sticky surface on inside trap bottom). Blank traps and traps baited with one virgin female per trap were used for comparison. Traps were randomly placed and rotated 5 m apart and 1.5 m above ground. A total of 85 laboratory-reared 3- to 4-day-old unmated males were released at dusk of the first test day.

Duncan's new multiple-range test (Steel and Torrie, 1980) was used to analyze the bioassay and field test results.

Chemical Analysis. Gas chromatography (GC) of extract was performed on three capillary columns: a Varian 3700 GC equipped with flame ionization detector, with a 30-m fused-silica capillary column coated with a 0.25-μm layer of DB-1 phase, a 35-m vitreous silica capillary column coated with a 0.25-μm film of Carbowax 20 M phase, and a 30-m fused-silica capillary column coated with a 0.25-μm film of SP-2340 phase. Helium at a flow rate of 30 ml/min was the carrier gas. Gas chromatographic–mass spectrometric (GC-MS) analysis was conducted as described previously (Kou et al., 1990).

The sex pheromone components were identified by comparison of their mass spectra with that of authentic standards. Subsequently, the identifications were verified by comparison of the GC retention time of the natural product to that of authentic standards on the three capillary columns under the same GC conditions as described above. Standards of (*Z*)-11-hexadecenal (Z11-16:Ald) were purchased from Sigma Chemical Co. (*Z*,*Z*)-7,11-hexadecadien-1-ol (*Z*7,Z11-16:OH) and (*Z*,*E*)-7,11-hexadecadien-1-ol (*Z*7,*E*11-16:OH) were produced by hydrolysis of hexalure (*Z*,*Z*)-7,11- and (*Z*,*E*)-7,11-hexadecadienyl acetate at the Pesticide Research Institute, Faculty of Agriculture, Kyoto University, Kyoto, Japan.

RESULTS AND DISCUSSION

Scanning Electron Microscopy. Scanning electron micrographs of the *B. crini* sex pheromone gland are shown in Figure 1; the whole abdominal tip is puffed like a round ball (Figure 1A). Further investigation showed that the external surface of the sex pheromone gland was covered with folds (Figure 1B), which might function to increase the evaporation area.

Laboratory Bioassay. The results of bioassay with female crude extract are shown in Table 1. Male sexual responses were significantly ($P < 0.05$) increased with the increasing amount of FE. The percentage of sexual response was 0% for the control and 10^{-5} FE, with an average of 4.0%, 34.0%, 62.0%, 82.0%, and 94.0% at 10^{-4} FE, 10^{-3} FE, 10^{-2} FE, 10^{-1} FE, and 1 FE, respectively.

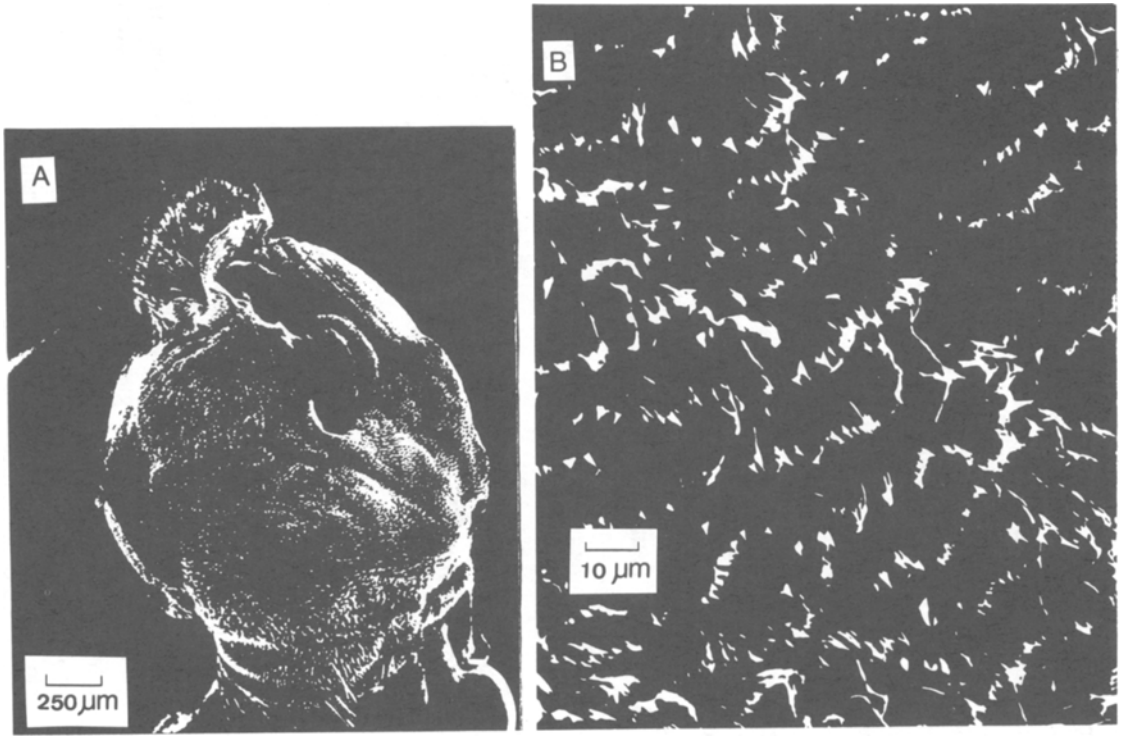

FIG. 1. (A) Scanning electron microscope view of the female *Brithys crini* sex pheromone gland (37X, 15 kV). (B) Scanning electron microscope view of the surface folding of female *Brithys crini* sex pheromone gland (720X, 15 kV).

Preliminary Field Trapping. The results of the field test are shown in Table 2. Totals of 11, 8, 21, and 17 males were trapped at dosages of 2 FE, 6 FE, 10 FE, and 15 FE, respectively. However, no significant difference was found between treatment and control; this might be attributed to the short experimental period and only two replicates being made.

Chemical Analysis. The gas chromatograms of the female crude extract (0.3 FE) and airborne collection are shown in Figure 2. A peak with an R_t value of 17.02 min was produced by both crude extract (Figure 2A) and airborne material (Figure 2B) from calling females (indicated by arrows), so this peak was regarded as the main sex pheromone component. The compound causing this peak was further isolated as shown in Figure 3. Comparison of the R_t values of the female extract, *Z*7,*Z*11-16:OH, *Z*7,*E*11-16:OH, and *Z*11-16:Ald are

TABLE 1. SEXUAL RESPONSE OF MALE *Brithys crini* TO CRUDE FEMALE EXTRACT

Pheromone source	Male response (%)
Control (CH_2Cl_2)	0a[a]
10^{-5} FE	0a
10^{-4} FE	4.0 ± 8.0a
10^{-3} FE	34.0 ± 19.5b
10^{-2} FE	62.0 ± 7.4c
10^{-1} FE	82.0 ± 14.6d
10^{0} FE	94.0 ± 12.0d

[a] Means followed by different letters are significantly different ($P < 0.05$, Duncan's new multiple-range test).

TABLE 2. NUMBER OF MALE *Brithys crini* TRAPPED IN WHITE AMARYLLIS FIELDS DURING OCTOBER 14-16, 1988

	Males trapped	
Pheromone source	Total	Mean (males/trap)
2 FE	11	5.5 ± 2.5a[a]
6 FE	8	4.0 ± 2.0a
10 FE	21	10.5 ± 4.5a
15 FE	17	8.5 ± 2.5a
1 Female	1	0.5 ± 0.5a
Control	0	0.0 ± 0.0a

[a] Means followed by same letters are not significantly different ($P = 0.05$, Duncan's new multiple-age test).

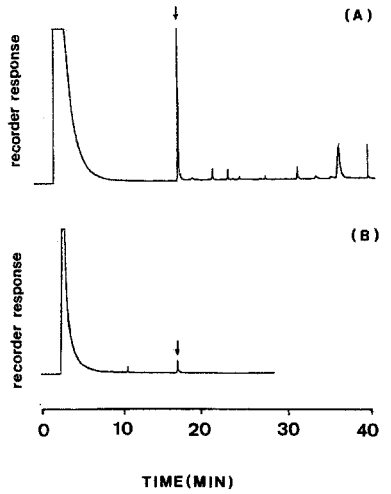

FIG. 2. Gas chromatograms of 0.3 FE gland extract (A) and an airborne collection (B) from calling *Brithys crini* females. The gas chromatography was performed on a 30-m × 0.25-mm DB-1 column that was temperature programmed from 100 to 250°C at 5°C/min.

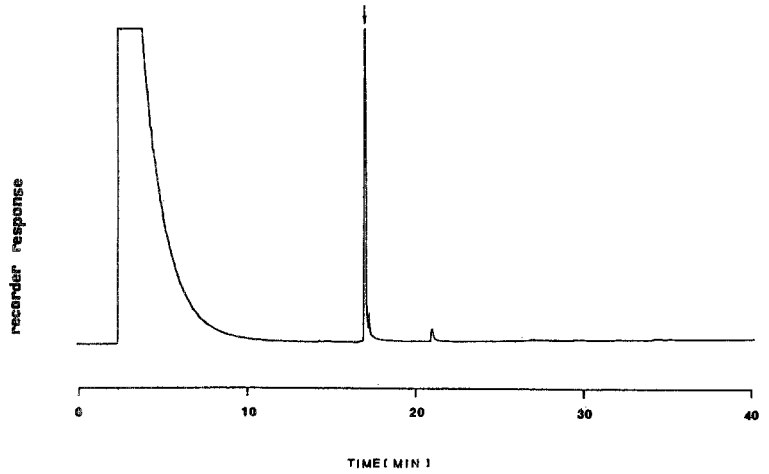

FIG. 3. Gas chromatograms of the supposed female sex pheromone fraction, which had a major peak as indicated by arrow, after elution from the silicic acid column. The gas chromatography was conducted as described for Figure 2.

shown in Table 3. The R_t value of Z11-16:Ald is quite close to that of the isolated peak in the female crude extract in all three columns used. The mass spectrum of the compound corresponding to the above isolated peak was also essentially identical to that of known Z11-16:Ald, as shown in Figures 4 and 5. Z11-16:Ald had been reported to be a sex pheromone in many noctuid moths and some other lepidopterous moths (Takahashi et al., 1979; Tamaki, 1988), so it is not surprising to find it in *B. crini*. With the external standard method

Announcement

The Natural Products Network for Eastern and Central Africa (NAPRECA) announces

The Fourth NAPRECA Symposium
on Natural Products, December 16–21, 1991
in Addis Ababa, Ethiopia

It is hoped that this symposium will have a strong representation from Africa and also draw renowned scientists from all over the world. A number of leading scientists from many parts of the world have already expressed interest to participate in this symposium. The scientific program is intended to cover all aspects of natural products chemistry, pharmacology, and botany.

The following distinguished scientists have been invited and agreed to deliver lectures. We do hope and expect that this list will grow:

Prof. E. Wenkert (University of California, San Diego, USA), Prof. Bert Fraser-Reid (Duke University, USA), Prof. Atta-Ur-Rahman (HEJ Research Institute of Chemistry, Pakistan), Prof. L. Skattebøl (University of Oslo, Norway), Prof. P.G. Waterman (Strathclyde University, UK), Prof. B. Sener (Turkey), Dr. D.M. Vyas (Squib Co., USA), Prof. Y. Kashman (Tel Aviv University, Israel), Prof. J. Connolly (Glasgow University, UK), Prof. J.R. Cannon (University of Western Australia), Prof. N. Saleh (National Research Center, Egypt).

Oral and poster presentations are invited. The official language will be English.

For registration information please contact: Dr. Ermias Dagne, NAPRECA, Department of Chemistry, Addis Ababa University, P.O. Box 1176, Addis Ababa, Ethiopia.

(Received March 4, 1991; accepted July 1, 1991)

Abstract—*Coenosia tigrina* larvae feed on earthworms. We hypothesized that earthworm mucus contains a kairomone that stimulates oviposition behavior in adult *C. tigrina* females, thus minimizing the search area in the soil required for newly eclosed larvae to find earthworms. In bioassays, adult females responded with extension of the ovipositor 25–43% of the time to earthworm-mucus-soaked filter paper disks compared to 6–7% in response to water-soaked disks. Ovipositor extension on mucus-soaked disks was followed by egg-laying 29% of the time and 0% of the time on water-soaked disks. Egg-laying by *C. tigrina* followed a diurnal periodicity, with most eggs laid in the latter half of the photophase even in the absence of earthworm mucus. More eggs were deposited from 1600 to 1800 hr by females given access to earthworm mucus during that period than were deposited by females not given access. There was no difference in the number of eggs deposited from 0600 to 0800 hr, by females given access to earthworm mucus or not. This is a time of day when few eggs are normally laid. This paper is the first report of an earthworm-produced kairomone in an insect-earthworm interaction. The kairomone may have potential for enhancing biological control of the onion maggot, *Delia antiqua*, which is a prey of adult *C. tigrina*.

Key Words—*Coenosia tigrina*, *Eisenia foetida*, *Eisenia rosea*, Lumbricidae, kairomone, oviposition stimulant, diurnal periodicity, oviposition bioassay, onion maggot, *Delia antiqua*, Anthomyiidae, Diptera.

INTRODUCTION

Coenosia tigrina (F.) (Diptera: Anthomyiidae) adults are predators of other flies (Hobby, 1931), including the onion maggot fly, *Delia antiqua* (Meig.) (Anthomyiidae), of which it may have potential as a biological control agent (Perron and LaFrance, 1952; LeRoux and Perron, 1960). The soil-dwelling *C. tigrina* larvae preferentially feed on lumbricid earthworms and require several worms to complete development (Morris and Cloutier, 1987). To date their only recorded natural prey is *Eisenia rosea* (Sav.) (Yahnke and George, 1972). However, they will develop normally in the laboratory while feeding on five different lumbricid species including *E. rosea* and the congeneric, *E. foetida* (Yahnke and George, 1972; Morris and Cloutier, 1987). Larvae hatch several days after eggs are deposited on the soil surface, and although they may survive for up to 12 days in the soil without food (Yahnke and George, 1972), they have limited mobility. Earthworms are also rather sedentary, generally migrating distances on the order of only a few meters each year (Bouché, 1983; Hoogerkamp et al., 1983). Thus, a dense earthworm population is normally a reliable food source for *C. tigrina* larvae.

Typically, female Diptera oviposit near the food of their larvae, thus increasing the probability that the larvae will survive. However, earthworms are negatively phototactic (Edwards and Lofty, 1977), and our observations have indicated that *C. tigrina* oviposits primarily during the day. Therefore, we hypothesized that *C. tigrina* females would oviposit in response to a cue indicating the presence of earthworms. Host-produced chemicals that stimulate increased search and oviposition have been documented in the host-selection process with respect to hymenopteran and dipteran parasitoids (Arthur et al., 1972; Nettles and Burke, 1975; Vinson, 1976; Bouchard and Cloutier, 1984; Nordlund and Lewis, 1985; Vinson, 1986). These chemical stimuli are referred to as kairomones because they mediate an interspecific interaction that benefits the receiver (Nordlund, 1981). An oviposition-enhancing kairomone for *C. tigrina* could improve the biological control potential of this insect.

The hypothesis that a kairomone(s) in earthworm mucus stimulates oviposition in *C. tigrina* was tested in the laboratory. We also documented the daily rhythm of oviposition and determined to what extent the rhythm was influenced by the putative kairomone.

METHODS AND MATERIALS

Effect of Earthworm Mucus on Oviposition Behavior. A laboratory culture of *C. tigrina* was established using eggs from field-collected females. Eggs were placed on wet strips of filter paper and placed in loosely capped glass vials at 25°C. After eclosion, larvae were kept at 20°C and were fed sections of the

earthworm, *E. foetida* once every two to five days. When flies emerged, they were placed individually (to prevent cannibalism) in clear plastic 250-ml vials screened with muslin at one end and placed over a plastic cup containing wet tissue paper, which acted both as a water source and an oviposition substrate. Flies were fed daily with 5–10 pomace flies, *Drosophila melanogaster* L., introduced into each cage and a sucrose solution dabbed on the muslin. Cages were kept in an environmental chamber at 25 ± 1°C with a relative humidity of 65 ± 5% and a 16:8 light–dark photoperiod. To ensure mating, each female was given access to a recently emerged male for three to four days during the preoviposition period (Morris and Cloutier, 1987). To ensure that emerging adults did not come into contact with earthworm products, pupae were placed on moist sterile soil. Outside of the tests, flies were not given access to earthworms and earthworm products.

To obtain earthworm mucus for the bioassay, we placed dry, 6-mm-diam. filter paper disks in clean plastic Petri dishes each containing five *E. foetida* earthworms. Copious amounts of mucus were produced under these conditions. Each *C. tigrina* female was introduced individually into an 8.8-cm-diam. plastic Petri-dish arena at room temperature (20–25°C) containing a mucus-saturated disk. Control females were given a distilled-water-moistened paper disk. Test flies were run simultaneously with control flies, one pair at a time. A total of 18 flies were used in this experiment, and all were used in either the experimental or control trials, never both. A fly was recorded as responding if there was at least one extension of the ovipositor within a 10-min test period. This was often followed by egg deposition, which was also recorded. Defecation by females, which also involves ovipositor extension, was recorded but not counted as a positive response. The bioassay was carried out during the last 3 hr of the photophase as preliminary observations indicated that most egg-laying occurred during this period. The 10-min bioassay period allowed time for seven to nine replicates every day for five consecutive days. Flies were used once every 24 hr, and fresh kairomone sources were used for each fly tested. This experiment was repeated two years later, with a fresh laboratory culture of flies and earthworms; 24 flies were tested.

Influence of Time of Day on Oviposition Response to Earthworm Mucus. Once it was determined that oviposition was affected by a kairomone from earthworms, the influence of the kairomone on the daily rhythm of egg-laying was tested by making earthworm mucus available during either the late afternoon when oviposition normally occurs or early in the morning when oviposition is rare. This experiment was designed to determine the degree to which oviposition is dependent on the earthworm kairomone. Field-collected *C. tigrina* females were kept at 20 ± 1°C, 65 ± 5% relative humidity, at a photoperiod of 16:8 light–dark (0400–2000 hr). For the first five days, July 19–23, 1985, females were maintained in cages as above in the absence of earthworm prod-

ucts [females lived 48 days on average at 20°C (Morris and Cloutier, 1987)]. Following this, two groups were exposed to earthworm mucus within their cages at different times of day by placing mucus-soaked filter paper disks in the oviposition cups during specific periods: one group from 0600 to 0800 hr when there was a minimum of egg-laying (Mucus-AM), and the other from 1600 to 1800 hr when a high frequency of oviposition was expected (Mucus-PM). The control group received no earthworm mucus in their oviposition cups. Oviposition cups were replaced every 2 hr, and the eggs, which were laid between the folds of the wet tissue paper, were counted.

RESULTS

Effect of Earthworm Mucus on Oviposition Behavior. In 18 of 42 trials (43%), flies extended the ovipositor in response to the mucus-saturated disks versus only 3 of 43 (7%) doing so in response to the water-saturated disks. These data indicate that earthworm mucus stimulates ovipositor extension [$\chi^2 = 12.8$, $P < 0.001$, all χ^2 values were calculated using Yates' correction (Wardlaw, 1985)]. Of the 18 trials in which flies extended the ovipositor, oviposition took place in six (33%) within the 10-min test period compared to none among the control flies. The incidence of defecation during the bioassays was not significantly different between the test and control flies ($\chi^2 = 0.36$, $P > 0.05$). When this experiment was repeated, flies extended their ovipositor in 17 of 67 trials (25%) in response to mucus but only in 4 of 67 trials (6%) in response to distilled water ($\chi^2 = 9.54$, $P < 0.005$). Eggs were laid in four of the trials with ovipositor extension in the test group and none in the control. In the two bioassay experiments together, egg deposition was significantly greater in the presence of mucus than in the controls ($\chi^2 = 8.29$, $P < 0.01$). In a concurrent test, we found that mucus from sexually mature, starved *E. foetida*, filtered through a 0.20-μm-pore diameter cellulose membrane filter and diluted to 1.7% by weight in water, also elicited an ovipositor extension response significantly more frequently (25%, $N = 69$) than the control (6%, $N = 67$; $\chi^2 = 8.29$, $P < 0.01$). In four of the trials that elicited ovipositor extension, eggs were also laid.

Influence of Time of Day on Oviposition Response to Earthworm Mucus. This experiment was started with 44 insects, but due to mortality, only 33 insects were used in the data analysis. The majority of eggs were laid in the last 8 hr of the photophase regardless of whether earthworm mucus was present or not: 91, 83, and 66% were laid during this period in the Mucus-PM, control, and Mucus-AM groups, respectively (Figure 1). The increased number of eggs laid during the last 8 hr of the photophase (bar graphs in Figure 1) was due to an increased percentage of females laying eggs (line graphs in Figure 1) and to

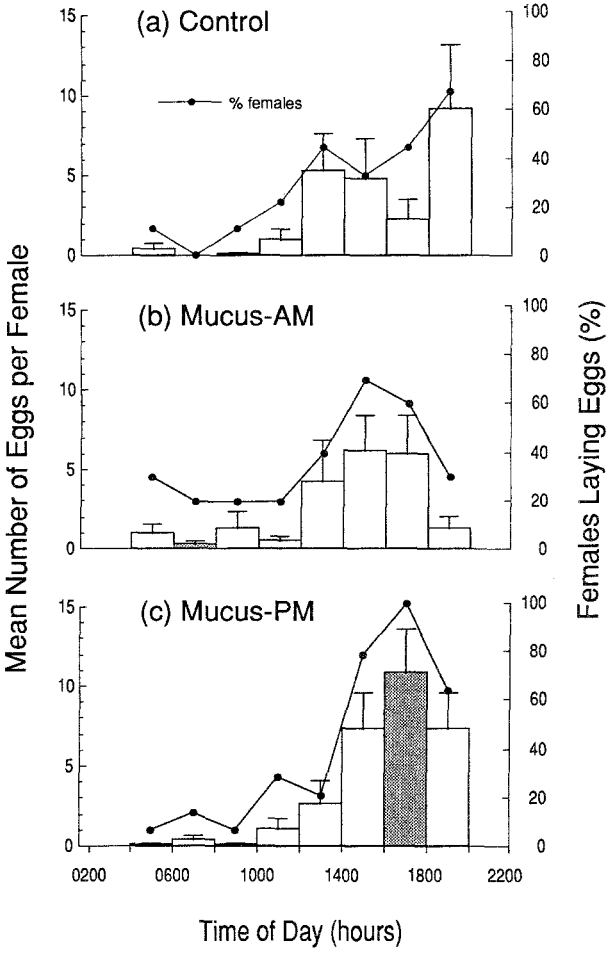

FIG. 1. The mean number of eggs (±SE; bar graphs) laid per female over five days during each 2-hr period of the photophase (0400–2000 hr) and the percentage of females that laid eggs at least once during each 2-hr period over the five days. Earthworm mucus was: (a) not present (control, $N = 9$); (b) present from 0600 to 0800 hr (Mucus-AM, $N = 10$), or (c) present from 1600 to 1800 hr (Mucus-PM, $N = 14$). Shaded bars indicate the period when earthworm mucus was present in (b) and (c). Eggs laid during the scotophase are indicated in the text.

females laying more eggs per bout of oviposition and laying on more days during this period.

The presence of earthworm mucus resulted in a significant increase in the mean number of eggs laid per female over the five days between 1600 and 1800

hr [for Mucus-PM, 10.9 ± 2.7 (±SE), $N = 14$, compared to 4.3 ± 1.4, $N = 19$ for the other groups; $t = 2.33$, $P < 0.05$]. This also was the only 2-hr period when 100% of females in a treatment laid eggs (Figure 1). No such increase was seen when earthworm mucus was presented in the morning (0.3 ± .2, $N = 10$ for Mucus-AM, compared to 0.2 ± .2, $N = 23$ for the others; $t = 0.30$, $P > 0.05$).

There were no significant differences in the mean number of eggs laid per female over five days in the different groups (30.5 ± 4.3, $N = 14$ for Mucus-PM; 26.8 ± 7.0, $N = 10$ for the Mucus-AM; and 27.3 ± 4.6, $N = 9$ for the control), indicating that the presence of earthworm mucus had little effect on the long-term rate of oviposition. Some eggs were laid during the scotophase: 1.1 ± .6, 6.0 ± 2.6 and 3.0 ± 1.9 for Mucus-PM, Mucus-AM, and control groups, respectively.

DISCUSSION

This is the first demonstration of an earthworm-produced kairomone in an insect–earthworm interaction. *C. tigrina* will oviposit without the kairomone. However, its presence increases the likelihood of oviposition and the number of eggs laid at the site and time of contact. Thus, the kairomone should act to concentrate oviposition in proximity to high earthworm populations. Presumably in nature, earthworm mucus is deposited by earthworm species that are periodically active at the soil surface, including the one recorded natural prey, *E. rosea*, and the species we used in our tests, *E. foetida* (Reynolds, 1977).

Egg-laying by both laboratory-reared and field-caught *C. tigrina* occurs primarily in the latter half of the photophase, and it is only during this period that *C. tigrina* is responsive to the earthworm kairomone. Oviposition periodicity is at least partly under endogenous control as it continues unchanged for at least 24 hr under continuous light (Morris, unpublished). Some insect rhythms have been shown to be synchronized with periods of high probability of exposure to a biologically active stimulant (Danislevsky et al., 1970). Oviposition by *C. tigrina* in the late afternoon and evening may be related to favorable environmental conditions, to the periodicity of activity of certain earthworm species, or to other factors.

Many arthropods are predators and parasites of earthworms (Reynolds, 1977). Some of these can be expected to use a similar kairomone. Kairomones from earthworms that mediate prey-finding or recognition by their predators have been demonstrated previously for garter snakes. Nonvolatile components of warm water washes of the earthworm *Lumbricus terrestris* elicit prey attack in newborn garter snakes after contact with the snakes' tongues (Sheffield et al., 1968). Garter snakes are also attracted to volatile components of water

washes of earthworms (Kirschenbaum et al., 1985), and some progress has been made toward the identification of both volatile and nonvolatile biologically active materials (Burghardt et al., 1988).

C. tigrina larvae develop normally when feeding on any of five lumbricid species tested in the laboratory, although at least one of these species was only used as prey if bisected (Yahnke and George, 1972; Morris and Cloutier, 1987). Thus, it is likely that a number of lumbricid species are prey whose mucus contains an oviposition kairomone. If true, this would be advantageous, as different earthworm species occur sympatrically (Satchell, 1980). Therefore, the presence of the mucus of one species at the soil surface could also signal the presence of other earthworm species that are prey for *C. tigrina*.

Management to encourage high earthworm populations in and around onion fields should increase *C. tigrina* densities and hence predation on the onion maggot fly. The kairomone itself, if identified and produced cheaply, could be used to manipulate *C. tigrina* behavior and possibly to achieve similar ends.

(Received March 25, 1991; accepted July 1, 1991)

Abstract—The effect on mule deer (*Odocoileus hemionus hemionus* Rafinesque) preference of compounds in mountain big sagebrush [*Artemisia tridentata* Nutt. ssp. *vaseyana* (Rydb.) Beetle], Wyoming big sagebrush (*A. t.* ssp. *wyomingensis* Beetle and Young), basin big sagebrush (*A. t.* ssp. *tridentata*), and black sagebrush (*A. nova* Nels.) was compared using a two-choice preference test. Compounds tested included: *p*-cymene, 1,8-cineole, methacrolein (two concentrations), and the nonvolatile crude terpenoid fraction (NVCTF) from each taxon. The compounds were tested by applying them to chopped alfalfa hay at concentrations similar to those found in nature. The intake of the treated hay was compared with that of an untreated control. Eight deer were used as test animals in an 8 × 8 Latin-square design. All compounds tested significantly deterred ingestion ($P < 0.05$). Compound influence on preference, in order of increasing deterrence, was as follows: 50% methacrolein, mountain big sagebrush NVCTF, methacrolein, basin big sagebrush NVCTF, *p*-cymene, Wyoming big sagebrush NVCTF, black sagebrush NVCTF, and 1,8-cineole. Methacrolein appears to be an important preference determinant among big sagebrush subspecies, and *p*-cymene between black sagebrush and big sagebrush. The NVCTFs containing sesquiterpene lactones as one of their constituents were closely related to the preference of all four taxa. Future studies of animal preference for sagebrush should consider all of the potential defensive chemicals in the foliage.

Key Words—*Artemisia tridentata*, *Artemisia nova*, *Odocoileus hemionus*, allelochemicals, terpenoids, diet selection, preference test.

INTRODUCTION

The relative palatabilities of various sagebrush (*Artemisia* L.) taxa have been measured in numerous studies (Scholl et al., 1977; Sheehy and Winward, 1981; Welch et al., 1981, 1983; Behan and Welch, 1985; Welch and McArthur, 1986; Personius et al., 1987; Wambolt et al., 1991). Although these studies agreed that a taxon was a desired indicator of preference, they offered no clear explanation of causes for differences in taxon preference. It is desirable for management purposes to know which sagebrush taxa will be preferred by herbivores such as mule deer (*Odocoileus hemionus hemionus* Rafinesque). Therefore, accurate predictions require a better understanding of which plant characteristics influence preference.

Presumably, plant chemistry plays a major role in determining sagebrush palatability and thus preference by herbivores (Rosenthal and Janzen, 1979). Identification of compounds or groups of compounds that influence mule deer preference for sagebrush has not been accomplished. Many studies (Sheehy, 1975; Scholl et al., 1977; Narjisse, 1981; Welch et al., 1983; Behan and Welch, 1985; Personius et al., 1987) have attempted to correlate allelochemicals in sagebrush to palatability, but results have been inconsistent. Most studies have focused on monoterpenes (Welch et al., 1982), which are just one of several groups of compounds occurring in sagebrush foliage. We believe other allelochemicals in sagebrush, alone or in combination with monoterpenes, may determine herbivore preference.

Personius et al. (1987) isolated 31 chemical constituents from forage samples of four sagebrush taxa, mountain big sagebrush [*Artemisia tridentata* ssp. *vaseyana* (Rydb.) Beetle], Wyoming big sagebrush (*A. t.* ssp. *wyomingensis* Beetle and Young), basin big sagebrush (*A. t.* Nutt. ssp. *tridentata*), and black sagebrush (*A. nova* Nels.). Plants were growing together under natural conditions in southwestern Montana and preferentially browsed during winter by mule deer. Personius et al. (1987) related compound concentrations to mule deer preference for the four taxa using a stepwise discriminate analysis. Although they identified probable preference determinants, the deterring effects of the compounds remained conjecture as their individual effects on deer were not tested.

The objective of this study was to determine the individual effect of sagebrush allelochemicals on mule deer forage preference during controlled feeding

trials. The compounds tested were those previously found to be preference determinants (Personius et al., 1987).

MATERIALS AND METHODS

Sample Collection. Sagebrush foliage used to extract nonvolatile crude terpenoid fractions (NVCTFs) was collected between August 13 and September 19, 1986 at the site near Gardiner, Montana, described in detail by McNeal (1984), Personius et al. (1987), Striby et al. (1987), and Wambolt and McNeal (1987). The current year's vegetative leaders were clipped in the manner used by Personius et al. (1987) and Striby et al. (1987), to closely approximate the foliage used by browsing mule deer. Due to the extremely short annual leader growth of black sagebrush, some older growth and reproductive structures were unavoidably collected with the current year's material. Clippings were placed on ice in airtight plastic bags, transported daily to the laboratory, and stored at −23°C until extraction.

Extraction Procedure. Chloroform extractions of NVCTFs were conducted using a procedure similar to Kelsey et al. (1982) and Personius et al. (1987). Modifications were necessary to accommodate larger quantities of material required for a feeding trial. Batches of sagebrush foliage (250 g) were extracted with chloroform (3000 ml) by gently stirring for 5 min. After filtering through a screen and Whatman No. 4 paper, the chloroform was evaporated with vacuum and a 50–55°C water bath.

Volatile compounds were removed from the extract by steam distillation. Approximately 250 ml of extract was redissolved in 250–300 ml of chloroform. Steam was passed through the solution until 1000 ml of water had evaporated from the flask, generating the steam. This left a suspension of nonvolatile compounds in water that settled out upon cooling. The water was poured off and the extract spread in a glass dish (5–7 mm layer) to dry at 60°C for 72 hr. The water layer was washed with chloroform (3 × 100 ml) and discarded. The chloroform was used to redissolve the next batch of extract, from the same taxon, to be distilled.

The mountain big sagebrush nonvolatile extract was solid, whereas the extracts from the other taxa were tarlike. The solid extract was ground to a powder with a mortar and pestle to facilitate weighing and handling. All batches within a taxon were placed in a single container and mixed to ensure uniformity. Volatile compounds tested (1,8-cineole, methacrolein, and *p*-cymene) were purchased commercially, making their extraction unnecessary.

Compound Application. Compounds selected for testing among those identified by Personius et al. (1987) included: 1,8-cineole, methacrolein, *p*-cymene, and the NVCTF (containing sesquiterpene lactones) of each taxon. Volatile

terpenoids were tested at the same concentrations Personius et al. (1987) found in the taxon having the greatest quantity (percent extracted-tissue dry weight) of each compound. The highest concentration of 1,8-cineole (1.10%) was found in mountain big sagebrush. The greatest concentrations of methacrolein (0.24%) and *p*-cymene (0.24%) were found in basin big sagebrush and black sagebrush, respectively.

To understand the effect of compound concentration on preference, we also tested methacrolein at one half its greatest observed concentration. This lower concentration (0.12%) of methacrolein (50% of greatest methacrolein concentration) equaled levels Personius et al. (1987) found in Wyoming big sagebrush.

Nonvolatile extracts were applied to the feed to achieve a 7% concentration. Seventy-five grams of extract was dissolved in 1000 ml of chloroform and poured over 1000 g of chopped alfalfa hay. After thoroughly mixing by hand, the treated hay was spread under a fume hood to dry for 90 min at 22°C and stirred at 30-min intervals. The hay was then spread out, air-dried 12 hr at 22°C, and stored in plastic bags until needed.

Volatile compounds were applied to the feed with a water carrier immediately prior to the start of the preference tests to minimize concentration changes due to evaporation. Twenty milliliters of a water-compound suspension, calculated to deliver the desired concentration, was sprayed onto 250 g of feed. Similarly, 20 ml of untreated water was applied to the control feed so preference would not be biased by water content.

Test Facilities and Animals. The preference tests were conducted between November 1986 and January 1987 at the E.H. Steffen Center, Department of Forestry and Range Management, Washington State University, Pullman, Washington. During the preference tests and the pretest adjustment period, the deer were kept in individual wire mesh pens void of any other forage. One end of each pen opened into the rear of an adjacent wire mesh metabolism cage.

At the front of each cage, a feed and water bunk was divided into thirds with plywood sheets. During a trial, an 8-liter rubber water bucket was placed in one end section, and the treated and control feeds placed in the remaining two sections.

Eight captive deer, five females and three castrated males, were used in the preference tests. Animals included six Rocky Mountain mule deer, one Columbian black-tailed deer (*Odocoileus hemionus columbianus* Richardson), and one hybrid of the two subspecies. Deer were captured as young fawns, bottle-raised at Washington State University, and essentially treated the same since shortly after birth. They were maintained on free-choice diets of alfalfa hay, alfalfa–grain concentrate pellets, and grass growing in the pastures. Free access to water and trace-mineralized salt was provided. The three oldest deer (6.5 years and two at 2.5 years) had been exposed to a variety of diets during previous feeding trials. Some of these trials included terpenoid-containing con-

ifers, but no sagebrush. The remaining deer were 1.5 years old and had no such previous experience. All deer were accustomed to feeding trial protocols.

Experimental Design and Statistical Analysis. An 8 × 8 Latin square design was employed. Seven compounds (methacrolein at two concentrations) were rotated among eight deer during eight time periods. A two-choice preference test (Bell, 1959; Goatcher and Church, 1970) was conducted during each five-day test period. This was followed by a two-day rest when deer were fed only untreated feed to reduce any possible carryover effect of a compound during the next test period.

Due to the volatile nature of 1,8-cineole, *p*-cymene, and especially the highly volatile methacrolein, the daily preference tests were kept to 20 min to minimize any concentration changes. One group of four deer began the test at 1:00 PM, the second group started at 1:30 PM, each following a 5-hr fast. The fast was used because a pretrial test with domestic sheep showed it was necessary to stimulate animal intake immediately upon presentation of the feed. The fast was kept short to ensure selectivity would be expressed by unstarved animals. Preference was expressed as:

$$\text{Preference} = \frac{\text{intake treated feed (g)}}{\text{intake treated feed (g)} + \text{intake control feed (g)}} \times 100$$

A 12-day adaption period preceded the preference tests. The deer were placed in their individual pens and cared for as they were throughout the preference tests. This included a fast period, free access to water and trace-mineralized salt, and high-quality chopped alfalfa hay.

Each deer was given the simultaneous choice between 270 g treated and untreated feed on each day of the preference test. Positions of treated and control feeds in the bunk were switched daily to minimize the effect of habit or position preference. Immediately following each preference test, the deer were given their normal daily ration, at 15% higher than the previous day's intake. The deer had access to their ration until 8:00 or 8:30 AM the following day, i.e., 5 hr prior to the next test.

The black-tailed male was brought into the experiment prior to preference test three to replace a mule deer that became sick and had to be removed. The replacement animal had an 11-day adaption period, but was not tested with two compounds. Therefore, two of 64 cells in the Latin square were lost, and the NVCTF of mountain big sagebrush and the 50% methacrolein were tested with seven of the eight deer.

We analyzed differences in preference among compounds, animals, and test periods using the General Linear Model of SAS (Statistical Analysis Systems, 1985). Significant differences were found when least-squares mean separation was at ($P < 0.05$). We totaled the intakes of treated and control feed for the entire five-day test period to analyze for preference ratios. We used the

preference ratio derived from the square of the sums, rather than the sum of the squares to avoid giving too much weight to days with abnormal intake. This method also accommodated days when neither treated nor control feed was eaten, as happened on two of 310 possible deer test days. On days when neither feed was eaten, the sum of squares method gave a 0:0 preference ratio, which could not be defined. Preference ratios were determined to be different from the theoretical "no-preference" index of 50 with a Student's t test.

RESULTS AND DISCUSSION

Deer preference was significantly different ($P < 0.05$) among the compounds tested. Preference did not differ ($P < 0.05$) among test periods nor among test animals.

All of the preference ratio means were significantly different ($P < 0.05$) from the no-preference index of 50 (Table 1). The larger the mean, or the closer to the no-preference index of 50, the less the compound was discriminated against. All compounds except methacrolein, 50% methacrolein, and the NVCTF of mountain big sagebrush were below Bell's (1959) "rejection threshold" of 20% of intake, and fell within Goatcher and Church's (1970) "strong rejection zone." These three compounds fell within Goatcher and Church's (1970) "moderate rejection zone." Apparently all compounds tested acted as preference deterrents.

TABLE 1. MEAN MULE DEER PREFERENCE[a] FOR CHOPPED ALFALFA HAY TREATED WITH EIGHT COMPOUNDS FOUND IN FOUR SAGEBRUSH TAXA[b]

Compound[c]	Preference
1,8-Cineole	1.60A[d]
Arno NVCTF	11.06B
Artrwy NVCTF	13.21B
p-Cymene	15.09B
Artrtr NVCTF	15.83B
Methacrolein	23.00C
Artrva NVCTF	24.85CD
50% Methacrolein	29.87D

[a] Preference = [intake treated feed (g)/intake treated feed (g) + intake control feed (g)] × 100. An index of 50 would indicate an equal quantity of treated and untreated feed was consumed, or no preference was shown.

[b] Arno: *A. nova*, Artrwy: *A. t.* ssp. *wyomingensis*, Artrtr: *A. t.* ssp. *tridentata*, Artrva: *A. t.* ssp. *vaseyana*.

[c] 1,8-Cineole, *p*-cymene, and methacrolein are volatiles.

[d] Means followed by the same letter were not significantly different ($P < 0.05$).

Volatility of compounds had little influence on preference rankings at the concentrations tested (Table 1). Note that volatile and nonvolatile compounds were interspersed throughout the list.

1,8-Cineole ($P < 0.05$) was the strongest preference deterrent. Of the four volatile compounds tested, 1,8-cineole was the most abundant in sagebrush tissue and was applied to the test feed at the highest concentration. It is less volatile than methacrolein, so its concentration on the treated feed should have remained higher during the trial period. However, its vapor concentration immediately above the feed was likely lower than the more volatile compounds. Stepwise discriminate analysis (Personius et al., 1987) had shown it to be a possible preference "attractant," as its concentration among taxa increased with increasing preference by mule deer. Sheehy (1975) also indicated 1,8-cineole may be an attractant. Our study challenges those observations, although we cannot say conclusively it is a deciding preference determinant. Any effects it may have on preference may be masked by one or more of the other compounds in sagebrush.

p-Cymene was applied at the same concentration as methacrolein, yet it had a greater deterrent effect. Methacrolein was a better predictor of preference than *p*-cymene. These statements are not necessarily contradictory. A stronger deterrent may not be a better predictor of preference. Data from Personius (1985) indicated that *p*-cymene was most important as a preference indicator between black sagebrush and the big sagebrush complex. Our results concur that *p*-cymene may be an important preference determinate between the two species.

Methacrolein may be more important as a preference indicator among the three big sagebrush subspecies (Personius et al., 1987). These differences make a direct comparison of methacrolein and *p*-cymene, as preference determinants, difficult. Methacrolein is more volatile than *p*-cymene and 1,8-cineole. This would reduce its effectiveness as a preference deterrent and would reduce its concentration significantly more than the others by the end of each preference test.

Methacrolein is also a severe mucosal tissue irritant (Tatken and Lewis, 1983). When deer stuck their heads into a feed bunk containing feed freshly treated with methacrolein, they typically coughed. Yet, methacrolein and 50% methacrolein were the least deterring of all volatile compounds tested. One deer preferred methacrolein to the control feed on some days and would eat it while coughing.

Methacrolein was significantly ($P < 0.05$) more of a deterrent than was 50% methacrolein, indicating that compound concentration had an effect on preference. Inexperienced red deer calves (*Cervus elaphus*) rejected monoterpene odors by concentration rather than by quality (Elliott and Loudon, 1987). The highest methacrolein concentration tested was similar to the concentration found in basin big sagebrush, the least preferred taxon. The 50% methacrolein

was a concentration similar to that found in Wyoming big sagebrush, which is intermediately preferred. Mountain big sagebrush, the most preferred taxon, contains only a trace of methacrolein (Personius et al., 1987).

The NVCTF is a mixture of many compounds including: bitter tasting sesquiterpene lactones, cuticular waxes, coumarins, and flavonoids (Kelsey et al., 1982; Personius et al., 1987). This mixture varies in concentration and compound composition among the sagebrush taxa, making it necessary to test the extracts from all four taxa. To avoid confounding the effects of compound composition with concentration on preference, the NVCTFs from all taxa were tested at the same concentration.

Only the NVCTF from mountain big sagebrush was significantly different ($P < 0.05$) from the same fraction in the other taxa. As expected, it was the least deterrent NVCTF tested. Mountain big sagebrush naturally has the lowest NVCTF concentration (13.87% extracted tissue dry weight ETDW). If the other taxa had been tested at higher concentrations as they occur in nature, the difference probably would have been even greater.

Preference for the NVCTF of basin big sagebrush was not significantly different ($P < 0.05$) from the NVCTF of Wyoming big sagebrush. This was not surprising because the two taxa are preferred to nearly the same degree and have about the same quantity of NVCTF (16.98 and 15.55% ETDW, respectively) in nature (Personius et al., 1987). Although the NVCTFs from basin and Wyoming big sagebrush appear to be preferred to the NVCTF from black sagebrush, the difference was not significant ($P < 0.05$). Here again concentration could have an effect. The NVCTF of black sagebrush naturally occurs at higher concentrations (20.12% ETDW) than do those of basin big sagebrush or Wyoming big sagebrush (Personius et al., 1987). If the black sagebrush NVCTF had been tested at the higher concentration found in nature, the difference may have been significant. In addition, the extracted black sagebrush tissue had more stems and woody material than did the other taxa.

The epidermal extract of sagebrush stems and branches contains fewer terpenes than extracts of leaves (Kelsey, 1986). Consequently, the more woody tissue extracted, the lower the sesquiterpene lactone concentration in the final NVCTF. If sesquiterpene lactones are preference determinants, then this woody tissue could reduce the deterrent properties of the extract. This could partly explain why the preference for feed treated with the NVCTF of black sagebrush was not significantly lower ($P < 0.05$) than the preference for feed treated with the NVCTF of basin or Wyoming big sagebrush. Possibly the contents of NVCTF, *p*-cymene, or the combination of the two in black sagebrush may separate it from big sagebrush in terms of palatability.

The NVCTFs are likely important preference determinants. The results of this study concur with the findings of Personius et al. (1987), who found sesquiterpene lactones in the NVCTF were good indicators of preference. Burnett

et al. (1977) also found sesquiterpene lactones to deter herbivory by eastern cottontail rabbits (*Sylvilagus floridanus* Allen) and white-tailed deer (*Odocoileus virginianus* Zimmermann).

In preference tests it is often difficult to design experiments that accurately represent natural conditions. Although care was taken to approximate the concentrations found naturally in the taxa studied, the compounds were applied artificially. All sesquiterpene lactones and probably most of the monoterpenes in sagebrush occur in glandular trichomes on the epidermal surface (Kelsey and Shafizadeh, 1980; Kelsey et al., 1984). Under field conditions, volatile components, such as methacrolein and the monterpenes, may be released slowly through the trichome membrane and surrounding cuticular waxes of undisturbed or undamaged leaves, but released rapidly when trichomes are burst. Undoubtedly, volatile compounds sprayed onto the surface of chopped alfalfa were released more rapidly and in higher concentrations than occurred in nature. Volatility was of minor consequence to the application of the NVCTFs, which probably were more accurately simulated than were the volatile compounds.

Of all the studies attempting to correlate mule deer preference with sagebrush chemistry, the experiments of Personius et al. (1987) used the most natural conditions and the most comprehensive chemical analyses. Discriminate analysis determined that in addition to some monoterpenes, nonterpene volatiles and nonvolatile compounds such as sesquiterpene lactones could also be influencing preference. Our choice tests provide further evidence that a variety of allelochemicals, located in trichomes on the epidermal surface of sagebrush foliage, could be affecting deer selection. Consequently, future studies of animal preference for sagebrush should take into consideration all of the potential defensive chemicals associated with these shrubs.

CHEMICAL BASIS OF EGG CANNIBALISM IN A CATERPILLAR (*Utetheisa ornatrix*)[1]

FRANZ BOGNER and THOMAS EISNER*

Cornell University, Section of Neurobiology and Behavior
W347 Mudd Hall, Ithaca, New York 14853-2702

(Received March 27, 1991; accepted July 1, 1991)

Abstract—Larvae of the moth *Utetheisa ornatrix* are shown to cannibalize eggs in the laboratory. They proved most cannibalistic if they were systemically deficient in pyrrolizidine alkaloid (PA), the defensive agent that protects *Utetheisa* at all stages of development against predation, and which *Utetheisa* acquire as larvae from their food plant. In exercising cannibalistic choice, *Utetheisa* larvae feed preferentially on eggs that are PA-laden rather than PA-free. Egg cannibalism can therefore provide *Utetheisa* with a supplemental means of PA procurement. Moreover, presence of PA in the egg, while providing the egg with defense against predation, can increase its vulnerability to cannibalism. Although evidence is presented that *Utetheisa* larvae cannibalize eggs in nature, it is argued that such feeding may occur only opportunistically in the wild, rather than as a matter of course.

Key Words—*Utetheisa ornatrix*, Lepidoptera, Arctiidae, pyrrolizidine alkaloid, egg cannibalism, acquired defense, phagostimulant, specific hunger.

INTRODUCTION

The larvae of the moth *Utetheisa ornatrix* feed on plants of the genus *Crotalaria* (Leguminosae), containing toxic pyrrolizidine alkaloids (PAs). The larvae tolerate the PAs and store them systemically, retaining them through development into the adult stage. Adults transmit PAs to the eggs (Eisner and Meinwald, 1987; Dussourd et al., 1988). The sequestered PAs protect eggs against coccinellid beetles (Dussourd et al., 1988), larvae against wolf spiders (Eisner and

Eisner, 1991), and adults against orb-weaving spiders (Eisner and Meinwald, 1987).

Utetheisa in nature contain variable quantities of PA. Existing evidence suggests that this can be a consequence of feeding on *Crotalaria* species of different PA content or of having varying access to the seeds of *Crotalaria*, where the PAs are concentrated (Conner et al., 1990). PAs, therefore, may be a limited resource, which *Utetheisa* may not always acquire at optimal levels, sufficient for defense.

PAs are strongly phagostimulatory to *Utetheisa* larvae. In concentrations as low as 10^{-4}% they can render an inert substrate such as agar edible to larvae (Blankespoor, Firlik, Pressman, Conner, and Eisner, unpublished). Moreover, PAs are phagostimulatory in the two chemical forms (free base, *N*-oxide) in which they occur in nature (Bogner and Eisner, 1991). Monocrotaline, for instance, one of the principal PAs available to *Utetheisa* from its food plants, when added as free base or *N*-oxide to filter paper, will induce larvae to chew holes into the paper (Bogner and Eisner, 1991).

Given this proven larval avidity for PAs, we postulated that the compounds might provide a basis for cannibalistic drive, and specifically for directing cannibalistic choice in *Utetheisa* larvae. Larvae deficient in PAs, able to recognize PA-laden conspecifics, might turn cannibalistically upon these as a way to make up for their chemical deficiency. Laboratory data that we obtained with PA-free larvae that were given access to pupae, showed that such larvae are in fact cannibalistic, and that they direct their attacks preferentially on pupae that are PA-laden (Bogner and Eisner, 1991). However, we discovered that pupal cannibalism is not likely to be a major factor in *Utetheisa*, since the larvae pupate at sites away from their food plants. The larvae themselves appeared not to be at high risk, since under most conditions they seemed able to take quick evasive action when contacted by other larvae. The truly vulnerable stage appeared to be the egg.

We here present evidence that under certain test conditions *Utetheisa* eggs are cannibalized by larvae. We demonstrate that larvae are particularly prone to be cannibalistic when they are PA-deficient, and that if given a choice, they show high preference for PA-containing eggs. We also present field data indicating that *Utetheisa* eggs may be cannibalized in nature.

METHODS AND MATERIALS

Experimental Animals. Except where otherwise specified, the *Utetheisa* were from a laboratory culture that we have maintained for over a decade, established with stock collected in the environs of Lake Placid, Florida (voucher specimens in Cornell insect collection, lot 1154).

We reared the moths on two diets: PB diet, a semisynthetic mixture (Miller et al., 1976) based on pinto beans and free of PAs, and CS diet, identical to the PB mixture, but with 10% (by weight) of its pinto bean fraction replaced by mature *Crotalaria spectabilis* seeds. *C. spectabilis* is one of the two major food plants of *Utetheisa* in the southeastern United States. Its principal PA is monocrotaline, present as both free base and *N*-oxide (Johnson et al., 1985).

Utetheisa raised on CS diet contain substantial levels of monocrotaline. Analyses of two samples taken years apart from our colony showed a microgram per moth content of 628 ± 48 (SEM) ($N = 31$) (B. Roach, unpublished) and 782 ± 141 (SEM) ($N = 4$) (J. Kopecky, unpublished). Moths raised in the field on seed-bearing *C. spectabilis* contain comparable levels of monocrotaline [701 ± 59 (SEM) μg/moth ($N = 22$); Conner et al., 1990]. *Utetheisa* raised on PB diet are PA-free.

Eggs from *Utetheisa* raised on CS diet contain monocrotaline [1.8 ± 0.1 (SEM) μg/egg, based on analyses of 10 egg clusters; J. Kopecky, unpublished], while those from PB-raised moths are PA-free. Chemical data for eggs in the wild are available only for *Utetheisa* associated with *Crotalaria mucronata*, another major food plant, which contains usaramine as its principal PA, rather than monocrotaline. Eggs from such moths contain on the order of half the PA present in eggs from CS-raised parents [0.8 ± 0.1 (SEM) μg usaramine/egg, based on analyses of seven egg clusters; B. Roach, cited in Dussourd et al., 1988]. The PAs in *Utetheisa* eggs, as in all developmental stages, are stored primarily as *N*-oxide rather than free base.

In what follows, we use the prefix (+) or (−) to denote *Utetheisa* eggs, larvae, or adults from our colony that are either monocrotaline-laden (CS-diet culture) or monocrotaline-free (PB-diet culture).

Collection of *Utetheisa* eggs was effected by providing cages housing (+) or (−) adults with linings of wax paper, upon which the females readily oviposited, clustering their eggs in batches as they do in nature [cluster size on *C. mucronata* leaves in the field = 20.2 ± 2.3 (SEM) eggs/cluster ($N = 45$) (range 6–100)]. Egg batches for testing were prepared by trimming the wax paper (1–2 cm^2) around the clusters, and adjusting egg number to 8–12/batch by removing excess eggs.

The larvae of the cabbage butterfly, *Pieris rapae*, used for comparative purposes in some of the tests, were from a laboratory colony raised on artificial diet (Bell et al., 1981). *Pieris* eggs were obtained by placing cups lined with Parafilm in cages housing *Pieris* adults. *Pieris* ordinarily lay their eggs singly, but they laid them in quantity in the cups, so that experimental batches comparable (8–12 eggs) to those of *Utetheisa* could be readily prepared by trimming of the Parafilm (due to the greater spacing of the *Pieris* eggs, the Parafilm pieces were somewhat larger than the wax paper pieces used with *Utetheisa* eggs).

In the laboratory experiments, egg age at time of testing (for both *Utetheisa* and *Pieris* eggs) was usually 24 hr (maximum 60 hr).

Chemical Samples. Monocrotaline-free base was obtained from a commercial source; the *N*-oxide was prepared in Professor Jerrold Meinwald's Cornell laboratories by oxidation of the free base with hydrogen peroxide (Mattocks, 1969).

Experimental Protocol. This was similar to the one we used in tests for pupal cannibalism (Bogner and Eisner, 1991). Mid-size *Utetheisa* or *Pieris* larvae were used. These were tested individually in cylindrical plastic chambers (85 mm diameter; 35 mm height), in which they were offered a choice of two egg batches, positioned on opposite quadrants of a circular piece of filter paper that fit the bottom of the chamber. The batches were anchored in place with small squares of double-sided sticky tape affixed to the underside of the wax paper or Parafilm backing of the eggs. The larvae were placed directly into the chamber without prestarving.

Fate of eggs was checked at 24 hr, and scored as consumption of one batch or the other, of both batches, or of neither. The criterion for consumption was injury or disappearance of a fixed minimum of eggs (three in batches of 8–9; four in batches of 10–12). This minimum applied to each of the two batches, when the result was scored as "both consumed." As a rule, consumptions were in excess of the minimum; (+) eggs, for instance, particularly in tests with (−) larvae, were usually eaten in their entirety.

All tests were repeated 25 times, using previously untested larvae for all trials.

Test Series 1. The intent here was to test for differences in acceptability of (+) and (−) eggs, in other words, of eggs naturally endowed with PA and of those free of PA. The test larvae were of three kinds: (+) larvae, (−) larvae, and field-collected larvae [(F) larvae]. The latter (also in the mid-size range) were taken on a *Crotalaria mucronata* stand outdoors (same stand as in field test C, below), in the vicinity of Lake Placid, Florida, and were tested immediately after capture (no prestarving).

Test Series 2. The aim was to see whether PA in the form of a topical additive to (−) eggs could render these as acceptable as (+) eggs. *Utetheisa* larvae were offered a choice of two (−) batches, of which one was topically treated with PA and the other was presented as control. The PA was monocrotaline, and it was tested separately as free base and *N*-oxide. The chemical was added to the egg batches in methanol solution (10 μl, providing about 1 μg PA/egg). Control batches were treated by addition of 10 μl methanol only. The tests were undertaken in parallel with (+) and (−) larvae.

Test Series 3. In tests 3A and 3B, *Utetheisa* larvae were offered a choice between *Utetheisa* eggs [either (+) or (−)] and *Pieris* eggs. In test 3C, they

were offered a choice of only *Pieris* eggs, with one batch treated by addition of about 1 μg/egg monocrotaline free base (administered in methanol solution as in test series 2), and the other (control) treated by addition of methanol only. The tests were done in parallel with (+) and (−) larvae.

Test Series 4. The test larvae here were of *Pieris* only, and they were given choices of *Pieris* egg batches as controls, and experimental batches consisting of either (+) or (−) *Utetheisa* eggs (tests 4A, 4B) or of *Pieris* eggs treated by topical addition of about 1 μg/egg monocrotaline free base (test 4C). Topical addition of the PA (and of the methanol solvent to the control batches) was effected as in test series 2.

Field Tests. In order to test for egg cannibalism under field conditions, *Utetheisa* egg clusters were staked out on *Crotalaria mucronata* plants outdoors and visually checked for fate at intervals after exposure. Batches of both (+) and (−) eggs, prepared as they were for the laboratory tests (8–12 eggs/batch, on wax paper backing), were affixed to the upper surfaces of *C. mucronata* leaves with small pieces of two-sided sticky tape. Batches of the two types were exposed in approximately equal numbers, in three separate tests. An effort was made not to group the batches by type, and to space them at minimal distances of about 0.5–1.5 m. Fate was recorded descriptively for each batch.

Tests A and B. The site for both these tests was an area (≈ 20 m^2) on the MacArthur Agro-ecology Research Center, Lake Placid, Florida, where both *C. mucronata* and *Utetheisa* occur in the wild. The *C. mucronata* on the site, estimated at some 50 plants, were mature and bore seed pods at all developmental stages. They carried a moderate infestation of *Utetheisa*, judged to be at a level of no more than several larvae per plant. The two tests were carried out a few days apart, and were each of 66 hr duration: (A) 27 (+) batches/26 (−) batches (December 25–28, 1990); (B) 18 (+) batches/14 (−) batches (January 3–6, 1991)

The egg batches in these tests were less than 24 hr old when exposed, so there were no hatchings during the experimental period (*Utetheisa* egg incubation time is four to five days).

Test C. The site for this test was on the grounds of the Archbold Biological Station, several miles West from the site used in the previous two tests. It consisted of an area (≈ 100 m^2) with approximately 500 *C. mucronata* grown from planted seeds. The plants were as mature as those in tests A and B and were also beset (visual estimate) with only moderate numbers of *Utetheisa* larvae.

The single test at this site involved staggered exposure, during the period of September 1–8, 1990, of 26 (+) batches and 26 (−) batches, for 40 hr/batch. Since the batches were of unknown mixed ages, there were some hatchings during the test. Visual checks were at intervals of 2 to several hours, between 8 AM and 7 PM.

RESULTS

Test Series 1 (Figure 1). Of the two categories of laboratory-reared larvae, only the (−) larvae proved strongly cannibalistic. Moreover, these larvae showed a clear preference for (+) eggs (see Figure 5). The field-collected larvae were also cannibalistic and shared the predilection for (+) eggs. What little feeding the (+) larvae did was also mostly on (+) eggs.

Test Series 2 (Figure 2). The (−) larvae, again, did most of the feeding, and they fed preferentially on the eggs bearing the monocrotaline additive, irrespective of whether this additive was in form of free base (Figure 2A) or *N*-oxide (Figure 2B).

Test Series 3 (Figure 3). The feeding was once again primarily by (−) larvae, and it was restricted largely to the two situations (3A, 3C) in which monocrotaline-bearing samples were available as choices. These samples were either (+) eggs or *Pieris* eggs topically laden with monocrotaline, and they were both strongly favored in their respective tests. Untreated *Pieris* eggs were largely shunned.

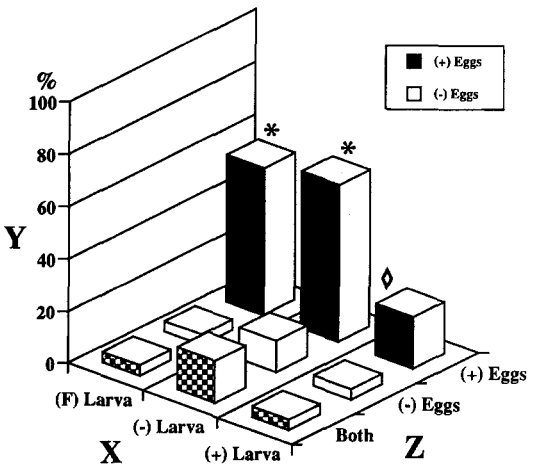

FIG. 1. Test series 1. Choice preference of *Utetheisa* larvae for (+) or (−) *Utetheisa* egg batches (choices are given in rectangles). The X axis gives the type of larva [(F) Larva = field-collected], Z axis the breakdown of choices made (nonfeeders are omitted), and Y axis the percent distribution of choices. $N = 25$ replications/test. Statistical conventions (applicable to Figure 1–4): asterisk(s) indicate level of significance of difference from alternative choice (and in most cases also from the "both" choice) in same test (* $P < 0.01$; ** $P < 0.001$); diamond(s) indicate level of difference from same choice in neighboring test ($^{\diamond}P < 0.025$; $^{\blacklozenge}P < 0.01$, $^{\blacklozenge\blacklozenge}P < 0.001$) [$G$ test, with P-value conversions (Sokal and Rohlf, 1981)].

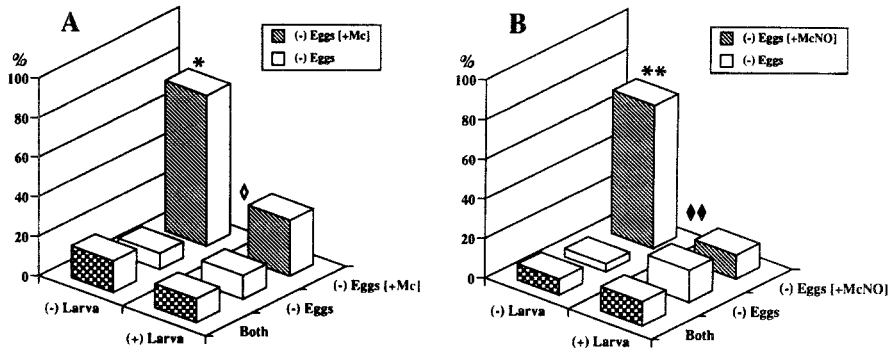

FIG. 2. Test series 2. Choice preference of (+) and (−) *Utetheisa* larvae for (−) *Utetheisa* eggs treated or untreated by addition of either monocrotaline free base [+Mc] or monocrotaline *N*-oxide [+McNO]. Conventions as in Figure 1.

Test Series 4 (Figure 4). *Pieris* larvae proved readily prone to feed on conspecific eggs. They essentially shunned *Utetheisa* eggs of either type, sampling these only in trials where they fed on the *Pieris* choice as well (Figure 4A, 4B). They also discriminated against *Pieris* eggs if these were treated with monocrotaline (Figure 4C).

Field Test A. This was the only test in which the majority of surviving batches were (−) rather than (+) eggs. Actual tallies at the end of the 66-hr exposure period were: 19 of the 27 (+) batches intact; 24 of the 26 (−) batches intact. Two cases of cannibalism were witnessed, both by nearly full-grown larvae (fourth instar, by estimate), which were discovered while still positioned over the site of the batch they had consumed (such lingering behavior was also noted in the laboratory tests). Nothing definitive can be said about the agents responsible for the fate of the other eight batches that we scored as "nonintact" in this test. Some of these batches had entirely disappeared, while others had disappeared in part or showed injury to some of the eggs.

Field Test B. The results here were similar, except that batch survival was skewed in favor of the (+) eggs. The tallies were: 13 of 18 (+) batches intact; 2 of 14 (−) batches intact. We again remained ignorant in most cases of the cause of injury or disappearance of batches, but we did witness two cases of cannibalism, and these again involved nearly grown larvae and (+) eggs. While in one of these cases the caterpillar was again found lingering over the batch site (the eggs had been consumed), in the other it was discovered in the act of eating.

Field Test C. No instances of cannibalism were witnessed in this test, which differed from the preceding two in that we were able to identify the primary predator responsible for batch mortality. The results were: 23 of 26 (+) batches

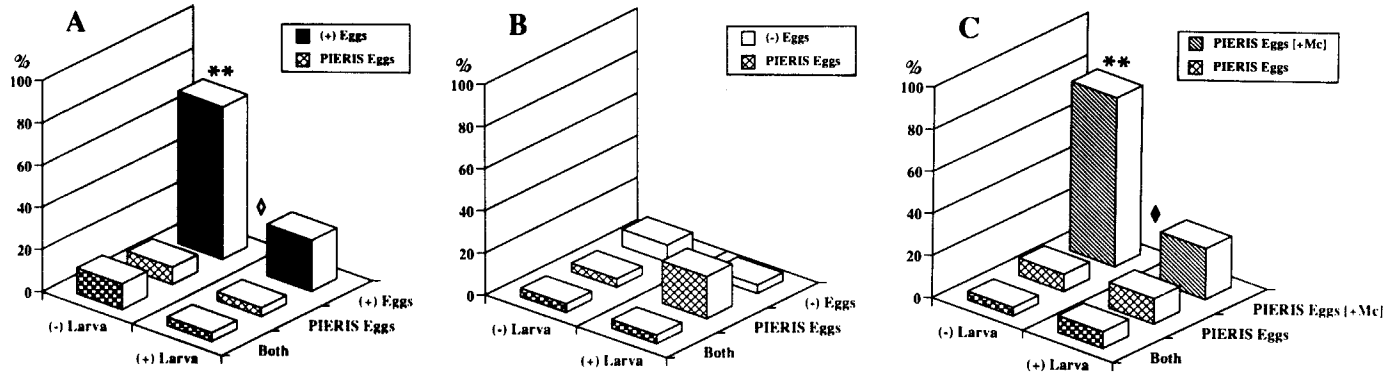

FIG. 3. Test series 3. Choice preferences of (+) and (−) *Utetheisa* larvae for *Utetheisa* eggs and *Pieris* eggs offered in various paired combinations. Mc = monocrotaline free base. Conventions as in Figure 1.

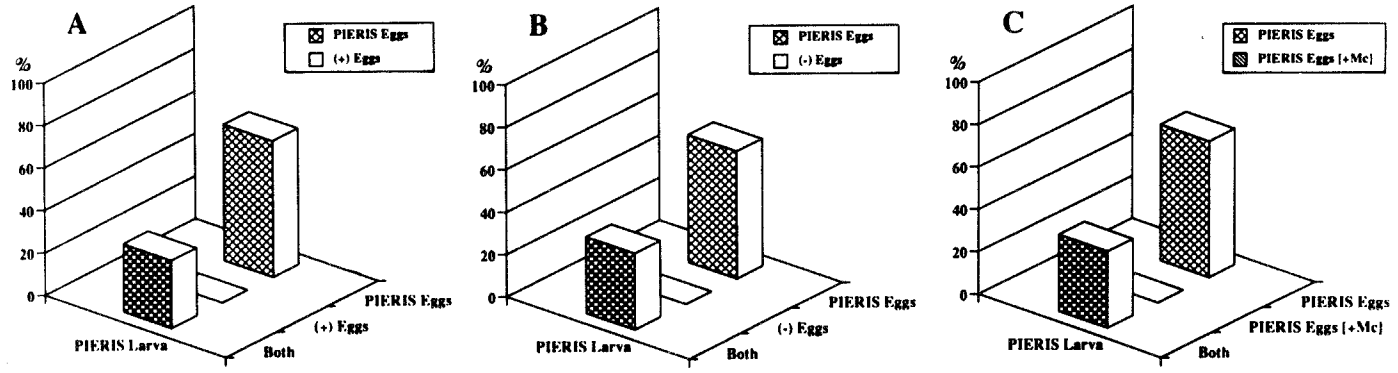

FIG. 4. Test series 4. Choice preference of *Pieris* larvae for *Utetheisa* eggs and *Pieris* eggs offered in various paired combinations. Mc = monocrotaline free base. Rectangles flush with base plane are 0 values. Conventions as in Figure 1.

intact; 14 of 26 (−) batches intact [about an equal fraction (13% and 14%) of intact batches of each category hatched during the experiment]. The predator responsible for consumption of batches that we scored as "nonintact" was a green lacewing larva (*Ceraeochrysa cubana*), which characteristically hollowed out the eggs by sucking up their contents. This predator [which was witnessed in the act of attacking (−) batches on two occasions] accounted for the death of 10 (−) batches and only one (+) batch. No causative agent was discovered to account for the fate of the other two (+) batches and two (−) batches that were scored as "nonintact" and that had actually disappeared or partly disappeared.

DISCUSSION

Utetheisa larvae are evidently prone to cannibalize eggs, certainly in the laboratory. Moreover, they are particularly inclined to consume eggs if they themselves are PA-deficient and the eggs PA-endowed. In other words, they appear to be driven to cannibalism by systemic PA-deficiency and are selective in their cannibalistic choice of items that contain the missing chemical. As we demonstrated in a previous study (Bogner and Eisner, 1991), the same caveats apply to pupal cannibalism in *Utetheisa*. Hunger alone cannot be the motivating force. The larvae used in both this and the pupal study were not starved prior to testing.

The specificity with which exogenous PA can trigger larval feeding in *Utetheisa* is noteworthy. The larvae showed no predisposition to cannibalize (−) eggs or to ingest *Pieris* eggs, unless these items were topically "labeled" by addition of monocrotaline. Moreover, as was clear from the tests with the (−) eggs, the free base and *N*-oxide forms of monocrotaline were equally effective as labels. In *Utetheisa* eggs, PA occurs primarily (>95%) as *N*-oxide (Dussourd et al., 1988).

The results with *Pieris*, although not bearing directly on the issue of *Utetheisa* cannibalism, raise points of interest. First, *Pieris* larvae themselves proved prone to cannibalize eggs. Moreover, they essentially ignored *Utetheisa* eggs, whether these contained PA or not. However, they were not unresponsive to PA. If monocrotaline was added topically to *Pieris* eggs, *Pieris* larvae decidedly avoided these. Vis à vis a caterpillar other than *Utetheisa*, therefore, monocrotaline can act as a deterrent rather than attractant. Conceivably, this could play a role in the natural protection of *Utetheisa* eggs against such caterpillars of other species as might show facultative tendencies to ingest insect eggs.

The field tests, while not as extensive or revealing as one might wish, did demonstrate that *Utetheisa* egg cannibalism can occur in nature. While the conditions under which we witnessed the event—and we did see four manifestations

of it—were not strictly natural, they did involve exposure of egg batches on food-plant leaves, where eggs are normally laid. The point worth noting is that all four instances involved larval consumption of (+) rather than (−) eggs, which is in line with what was to be predicted from the laboratory findings. The laboratory data had also told us that field-collected larvae can behave as if systemically deficient in PA and hungry for the compounds: the field larvae in our choice tests (Figure 5), which stemmed from the same *C. mucronata* stand on which we had exposed the egg batches (test C), were distinctly cannibalistic toward (+) eggs. Previous chemical work (Conner et al., 1990) had shown that *Utetheisa* field-reared on *C. mucronata* have lower systemic PA levels than those raised on *C. spectabilis*, the source of the seeds in the laboratory diet of our (+) larvae. It could be, therefore, that larvae raised on *C. mucronata*, unlike our (+) larvae, are somewhat underendowed with PA, and for that reason cannibalistically inclined.

The field data point further to the likelihood that cannibalism is only a lesser threat to *Utetheisa* eggs in nature. Predation, in our judgment, must be the greater hazard by far, and it is of course primarily as defensive agents against predators that PAs are acknowledged to function. Indeed, (+) egg batches in our field tests fared better on the whole than did (−) batches, and in one test, heavy predation by one predator (a chrysopid larva) accounted for most of the mortality of (−) eggs. In an earlier field test, in which 100 (+) and 100 (−)

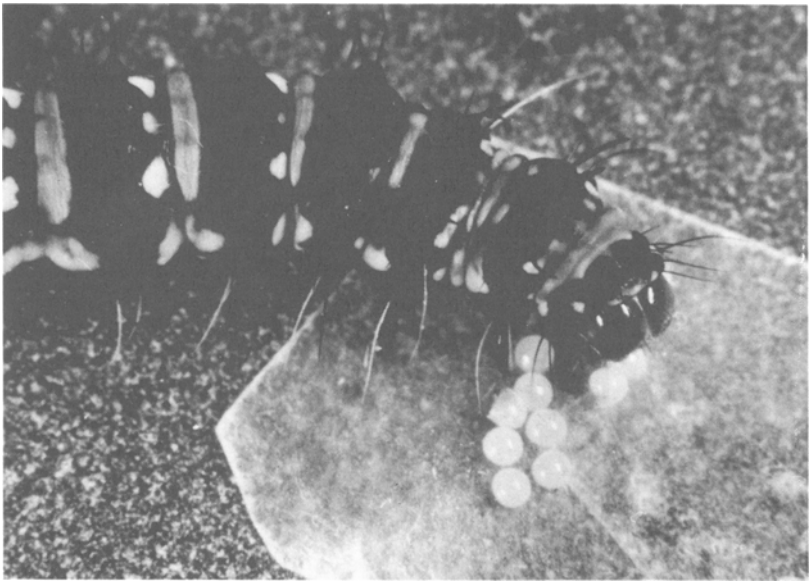

FIG. 5. Medium-sized (−) *Utetheisa* larvae in process of cannibalizing (+) eggs.

batches were staked out, the (−) eggs also endured higher mortality than the (+) eggs (Dussourd et al., 1988).

The fact that PAs can play conflicting roles in the eggs of *Utetheisa* raises questions. Are there times when the threat from cannibalism outweighs that from predation? In our earlier paper (Bogner and Eisner, 1991), we postulated that there might be such times and that they might be coincident with *Crotalaria* seeds being in short supply and *Utetheisa* larvae, consequently, PA-deficient. Such times could prevail when *Crotalaria* are immature or when their seeds are overgrazed by *Utetheisa* and other seed-eaters (for instance, caterpillars of the pyralid moth, *Etiella zinckenella*). *Utetheisa* feeding on immature *Crotalaria* are known to accrue sharply lessened systemic loads of PA (Conner et al., 1990). One could thus imagine dietary PA availability playing an important role in setting cannibalistic drive levels in *Utetheisa* populations in nature.

Egg cannibalism can provide *Utetheisa* larvae with only relatively modest quantities of PA. Eggs on average contain 1–2 μg PA, so an average-sized cluster of 20 eggs could supply no more than a small fraction of the several hundred micrograms of PA accrued by the adult moth. Egg cannibalism in *Utetheisa* might therefore occur only opportunistically, rather than as a matter of course, and serve only as a subsidiary means of PA procurement. One wonders, however, whether egg cannibalism might not be of greater significance in younger, perhaps first or second instar larvae, such as one does not generally find feeding on the PA-rich seeds of *Crotalaria*. We have no data on such young larvae and are also ignorant of whether these might early in life, as perhaps shortly after emergence, turn upon conspecific eggs that they encounter. It would be intriguing if, in the selection of cannibalistic targets by such young larvae, kin recognition were to enter into play.

Other cases have been documented (probably far fewer than actually exist) of insects bestowing defensive metabolites upon their eggs (McCormick and Carrel, 1987; Eisner, 1988; Dussourd et al., 1989). It would be interesting if the phenomenon here demonstrated, of usurpation of such chemicals by cannibalization of eggs, were to occur in other insects as well. We suggest that it does.

Acknowledgments—Study supported by NIH grant AI02908, Hatch funds (191-7402), and the Deutsche Forschungsgemeinschaft (Bo 944/1-2). We thank Patricia Bogner, Glen Scoles, and Maria Eisner for much help; B. Roach and J. Kopecky for unpublished analytical data; and B. Roach for preparing monocrotaline *N*-oxide. The field tests were carried out at the Archbold Biological Station and the MacArthur Agro-ecology Research Center, Lake Placid, Florida; Mark Deyrup kindly planted the *Crotalaria* stand.

(Received April 9, 1991; accepted July 1, 1991)

Abstract—The sex pheromones of two populations of *Graphania mutans* (Walker) were analyzed. Females from an Auckland population produced (*Z*)-9-tetradecenol (*Z*9–14 : OH), (*Z*)-9-tetradecenyl acetate (*Z*9–14 : OAc), (*Z*)-7-tetradecenol (*Z*7–14 : OH) and (*Z*)-7-tetradecenyl acetate (*Z*7–14 : OAc), while females from a Lincoln population produced these four compounds and a large amount of (*Z*)-9-tetradecenal (*Z*9–14 : Ald). Significant differences, paralleling the difference between females, were observed when the responses of males of both populations to the above and other related compounds were tested by electroantennogram, field-trapping, and wind-tunnel bioassays. The most distinct difference was observed in the wind tunnel. Males from both taxa flew upwind and touched pheromone sources containing sex pheromone extract of females of their own taxon, but either did not initiate upwind flight or arrested upwind flight shortly after taking flight in response to extract from females of the other taxon. The difference between the pheromone systems of the two populations is probably due to the presence and importance of *Z*9–14 : Ald in the pheromone blend of the Lincoln population. Thus the addition of a relatively large amount of *Z*9–14 : Ald to a four-component pheromone blend (i.e., *Z*9–14 : OH, *Z*9–14 : OAc, *Z*7–14 : OH, and *Z*7–14 : OAc) attractive to Auckland males completely suppressed trap catches of male *G. mutans* in Auckland but large numbers of males were caught at both Lincoln and Nelson in traps baited with this five-component blend. In wind-tunnel studies, the addition of even small (1% of amount of *Z*9–14 : OH) amounts of *Z*9–14 : Ald to the four-component blend resulted in a significantly greater proportion of Auckland males arresting upwind flight than to the four-com-

ponent blend. It is suggested that these two populations of *G. mutans* represent distinct sibling species within the described concept.

Key Words—*Graphania mutans*, Lepidoptera, Noctuidae, sex pheromones, (Z)-9-tetradecenyl acetate, (Z)-9-tetradecenol, (Z)-9-tetradecenal, sibling species, identification, wind tunnel.

INTRODUCTION

Graphania mutans (Walker), (Noctuidae: Hadeninae), an endemic species distributed throughout New Zealand, is a pest of some horticultural crops such as apples. The larvae of this species feed on and scar the surface of the fruit, thereby making it unsuitable for export (Suckling et al., 1990). This damage often occurs early in the season and is additive to the damage caused by other lepidopterous pests such as leafroller moths and codling moth (Wearing et al., 1991).

In New Zealand, the identification of sex pheromones of all the other major lepidopterous pests found on apples, and the more accurate monitoring of populations of these pests that this has allowed, has facilitated the development of reduced insecticidal spray programs (Suckling, 1989). In particular, a number of insecticidal sprays can be omitted in many apple-growing areas during the early part of the season. During this period, damage to fruit by other pests such as *Graphania mutans* can occur, and hence the ability to specifically monitor populations of this pest, using sex pheromones, would be of great value in reduced spray programs.

The genus *Graphania* contains a number of species morphologically very similar to, and sympatric with, *G. mutans*. The adults of *G. mutans* are highly variable in color pattern; seven names have been synonymized with *mutans* (Dugdale, 1988). With this variability in mind, we used the approach previously used in the analysis of the sex pheromones of sibling species complexes of various tortricid species in the genera *Planotortrix* and *Ctenopseustis*, i.e., analysis of the sex pheromones of distinct geographic populations and determination of whether differences exist between the sex pheromones of these populations (Foster et al., 1991). We report here the results of this study on *G. mutans*.

METHODS AND MATERIALS

Insects. Two laboratory cultures of *G. mutans* were established by collecting gravid females in light traps situated in Auckland and Lincoln (near Christchurch) and allowing these females to oviposit inside small glass vials (2.5 cm diam. × 10 cm).

Neonate larvae were allowed to feed on a semisynthetic corn diet (Poitout

and Bues, 1970) until they had reached the second instar, whereupon they were transferred into a small waxed cardboard ice cream cup (Lily Inc., No. 134, Auckland) (three larvae per container), containing more of the corn diet. The larvae were maintained inside the cup at 18–20°C, 16:8 hr light–dark photoperiod until they had pupated. The sexes were separated as pupae and placed in moist vermiculite. Adults were used either in the various experiments (see below) or to perpetuate the culture. For the latter, groups of males and females (one to three each) were placed inside a plastic bag, supported by an inner wire frame (35 × 25 × 13 cm), and allowed to mate. The resultant eggs were removed and placed inside a small, humid container until they hatched.

Determination of Sexual Activity. The beginning of sexual activity by female *G. mutans* was defined as when the female extruded the terminal segments of her abdomen, thereby exposing her pheromone gland (i.e., "calling"). In order to observe the periodicity of calling behavior, females from the Auckland colony were placed in small transparent containers (4 cm high × 40 cm diam.) that allowed observation of, but did not interfere with, this behavior. Females 1–5 days old were observed every 15 min, commencing from 2 hr preceding the scotophase through to 1 hr into the photophase.

Mating of single pairs of 3-day-old Auckland males and females was observed under the above conditions.

Pheromone Extraction and Chemical Analysis. The tip of the abdomen of a 3- to 4-day-old female was everted and dissected just prior to the commencement of the calling period, placed in 10–50 μl of distilled pentane, and extracted for 0.5–12 hr prior to analysis by gas chromatography (GC) or gas chromatography–mass spectrometry (GC-MS). One to 10 glands were extracted and analyzed at a time.

Extracts were analyzed by GC using two columns: a 50-m × 0.32-mm-ID Carbowax 20 M (Quadrex Corp., New Haven, Connecticut), temperature-programmed from 100 to 210°C at 4°C/min (initial delay of 1 min), and a 60-m × 0.25-mm-ID SP2340 (Supelco Inc., Bellefonte, Pennsylvania), temperature-programmed from 60 to 140°C at 8°C/min (initial delay of 1 min), then to 180°C at 2°C/min. The gas chromatographs used were, respectively, a Philips 4500 and a Varian 3500. Splitless injection, and nitrogen at a linear flow velocity of 10 cm/sec as carrier gas, were used for both columns. This combination of columns and GC conditions allowed the separation of all monounsaturated tetradecenyl acetate isomers and virtually all tetradecenal isomers from each other (Heath et al., 1980). Alcohols could not be analyzed adequately using the SP2340 column as they were degraded on this column. Therefore they were converted to acetates by reaction with acetyl chloride for further confirmation of their structure. Tridecanyl acetate was used as an internal standard.

The mass spectra of compounds in extracts of pheromone glands were

recorded using a Nermag 10-10C equipped with either a 25-m × 0.22-mm-ID CPSIL 5CB or a 25-m × 0.22-mm-ID CPSIL 88CB (Chrompack, Middelburg, Netherlands). The mass spectra of the various compounds were compared with the mass spectra of synthetic samples.

Electroantennograms. The electroantennogram (EAG) responses of isolated male antennae were recorded according to the method of Roelofs (1984). The various chemicals (monounsaturated, 12-, 14-, and 16-carbon acetates, alcohols, and aldehydes; 1-μg dose on filter paper) were presented into the airstream using a 5-ml syringe. Data were corrected according to Renou (1979). The responses of at least five different antennae were tested to each of the series of chemicals.

Field-Trapping. Field trapping was carried out at Mt Albert Research Centre (Auckland, north North Island), Appleby Research Orchard (Nelson, northern South Island), and at Lincoln (near Christchurch, mid-coastal South Island). The appropriate amount of chemical was loaded onto a rubber septum (Thomas Scientific) and placed inside a Pherocon 1C sticky trap (Zoecon Corp., Palo Alto, California). The traps were hung approximately 1.5 m above the ground on various fruit trees (apple, nectarine, peach) or on monkey apple (*Acmena smithii*) hedges surrounding the orchards. Traps were placed at least 10 m apart. Unless stated otherwise, traps were checked and rerandomized every one to two days.

For analysis of the field-trapping experiments, data were transformed by $\sqrt{(X + 0.5)}$, an ANOVA conducted, and the means of the treatments compared using Duncan's multiple range test. Comparisons between treatment means were made at the $P = 0.05$ level.

Wind Tunnel. Male moths were flown inside a 1.3-m-long wind tunnel based on the design of Miller and Roelofs (1978). The tunnel was illuminated using six 15-W incandescent red light bulbs (Osram Co., Auckland) situated above the tunnel. The temperature throughout the various experiments was controlled at 20 ± 1°C. The chemicals or pheromone gland extract were placed on a piece of filter paper (1.5 × 1.5 cm) seated on a thin metal rod stand approximately 15 cm above the floor of the tunnel. Just prior to the start of the scotophase, individual males were placed inside capped wire mesh cylinders (2.5 cm diam. × 5 cm) and transferred into the wind tunnel room. In a preliminary experiment, males were found to respond best between 5.5 hr and 6.5 hr after the onset of the scotophase; all subsequent tests were carried out during this period. Individual 3-day-old male moths were introduced into the mouth of the tunnel (approximately 1.2 m downwind of the chemical source), and their behavioral responses to the source recorded. The following behaviors were recorded: raising of the antennae and wing movement (activation), initiation of upwind flight (take flight), flight to beyond the midpoint of the tunnel (midpoint), flight to within 15 cm of the source (approach), touching of the source

(touch), and landing on the source (land). Males from the Auckland colony were used in all the wind-tunnel experiments testing the responses of males to synthetic chemicals. Each wind-tunnel experiment was run as a complete randomized block design. The distributions of the separate behavioral responses to the various blends tested within an experiment were compared using Kruskall and Wallis tests. Differences are reported at $P = 0.05$.

RESULTS

Sexual Activity. Virtually all of the insects used in these observations emerged towards the end of the scotophase. In the first night following emergence, only 4/18 of the females called. However, on the second night following emergence, 80% of the females called. In subsequent nights (up to the fifth night following emergence), the percentage of females that called declined gradually. Females of all ages began calling during the fourth hour of the scotophase through to the onset of the photophase; the greatest percentage of females called during the fifth and sixth hours of the scotophase. Following the commencement of calling by females, males became highly activated and copulation quickly followed.

Chemical Analysis. Extracts of the pheromone glands of females from the Auckland *G. mutans* colony were initially analyzed by GC using the Carbowax 20 M column. From these extracts, the following compounds were tentatively identified on the basis of retention times (relative amounts): tetradecyl acetate (14:OAc) (0.9), (Z)-7-tetradecenyl acetate (Z7–14:OAc) (2.7), (Z)-9-tetradecenyl acetate (Z9–14:OAc) (23.1), tetradecanol (14:OH) (8.6), (Z)-7-tetradecenol (Z7–14:OH) (14.5), and (Z)-9-tetradecenol (Z9–14:OH) (100). Analysis of the crude extract using the SP2340 column was consistent with the assignments of the above acetates. When the extract was acetylated and the reaction product mixture analyzed by GC (using the Carbowax 20 M column), the chromatogram showed the almost complete disappearance of the peaks tentatively identified as alcohols and much greater amounts (relative to the internal standard) of the three acetates. Mass spectral analysis of gland extract from the Auckland females, and comparison with spectra of authentic samples, confirmed the assignments of these compounds. Females contained on average, 3.3 ng of Z9–14:OH.

G. mutans from Lincoln were analyzed similarly. GC analysis using the Carbowax 20 M column yielded chromatograms that were very different from those obtained from the analysis of Auckland *G. mutans* females. The following tentatively identified compounds (relative amounts) were observed: (Z)-9-tetradecenal (Z9–14:Ald) (100), Z7–14:OAc (0.5), Z9–14:OAc (34.9), 14:OH (3.0), Z7–14:OH (15.4), and Z9–14:OH (40.9). The tentative identification of

these acetates and aldehyde was supported by GC analysis using the SP2340 column. Acetylation of the gland extract and subsequent analysis using the Carbowax 20 M column, as above, was also consistent with the assignment of the three alcohols. GC-MS analysis of gland extract confirmed the assignments of the above compounds. Females contained on average 3.5 ng of Z9–14 : Ald.

Electroantennograms. For both the Auckland and Lincoln *G. mutans* males, the greatest EAG response in each of the series (i.e., 12-, 14-, and 16-carbon monounsaturated acetates, alcohols, or aldehydes) tested, was always to the isomer with a (*Z*)-9 double bond. Between the series, the largest amplitude response for both types of males was to the 14-carbon compounds; for the Auckland males the largest response amplitudes were to the acetates, whereas for the Lincoln males they were to the aldehydes. Between the 14-carbon series the converse was true for the lowest amplitude responses, i.e., the aldehydes and the acetates elicited the lowest amplitude response from the Auckland and Lincoln males, respectively. Except for the relative amplitudes of response, the EAG profiles to each of the series tested were very similar for both populations of males.

Field-Trapping. Field trials 1–5 (Table 1) tested the effects of the various chemicals identified in females of the Auckland and Lincoln populations on trap catches of males of the Auckland population.

In the first field trial (Table 1), *G. mutans* males were caught in significant numbers in traps baited with the four monounsaturated chemicals found in the Auckland females (Table 1); traps baited with the higher dosage (1000 μg of Z9–14 : OH) of the four-component blend caught significantly greater numbers of males than traps baited with the lower dosage (100 μg). At the higher dosage (1000 μg of Z9–14 : OH), the addition of 1% of Z9–14 : Ald to the four-component blend resulted in a significant decrease in the number of males caught.

In trial 2 (Table 1), blends that lacked Z7–14 : OAc did not elicit trap catches of male *G. mutans* significantly greater than the number caught in the blank traps. Similarly, in trial 3 (Table 1), traps baited with the blend that lacked Z9–14 : OAc did not catch any males. Increasing the amount of Z9–14 : OAc in the blend from 0 to 500 μg increased trap capture. However, increasing the amount of Z9–14 : OAc in the blend still further to 1000 μg significantly decreased (relative to the blend containing 500 μg) the catch (trial 3).

Changing the amount of Z7–14 : OH in the blend over the range 0–1000 μg resulted in slight, but not significant changes in the numbers of males caught, relative to the standard blend containing 130 μg of Z7–14 : OH (trial 4, Table 1). In contrast, the removal of Z7–14 : OAc from the three-component blend tested in this trial (trial 4) significantly reduced the numbers of males caught to a level not significantly different from the blank, thereby confirming the result from trial 2.

In trial 5, traps baited with blends containing less than 1000 μg of Z9–

[a] Means accompanied by the same letter are not significantly different at $P < 0.05$ (Duncan's multiple range test).

[b] Conducted at Mt Albert Research Centre (MARC), Auckland, between January 28 and February 15, 1988; four replicates of each treatment were tested.

[c] Conducted at MARC and Kumeu Research Orchard, between February 2 and 19, 1988; four replicates per treatment.

[d] Conducted at MARC between February 16 and March 6, 1988; three replicates per treatment.

[e] Conducted at MARC between April 18 and June 1, 1988; three replicates per treatment.

[f] Conducted at MARC between September 7 and November 14 , 1988; four replicates per treatment. Traps were examined and rerandomized every week.

14 : OH caught fewer males than traps baited with the blend containing 1000 μg of Z9–14 : OH; with the exception of the blend that contained 100 μg of Z9–14 : OH, these catches were significantly different from the number of males caught in the 1000 μg (of Z9–14 : OH) blend. Also in this trial, the amount of Z7–14 : OAc in the four-component blend was increased from 30 μg to 100 μg. There was no significant difference between the number of *G. mutans* caught in traps baited with either of these two blends.

The field trials conducted at Lincoln and Nelson tested various blends containing chemicals identified in the females from the Lincoln population against the four-component blend that was attractive to male *G. mutans* in Auckland (Table 2). In both Lincoln and Nelson, traps baited with the Auckland-type blend caught *G. mutans* males. However, the greatest catch (not significantly different from the number caught in traps baited with the Auckland-type blend) of males was in traps baited with the five-component blend containing 1000 μg of Z9–14 : Ald. Traps baited with the four-component blend lacking Z7–14 : OAc but containing Z9–14 : Ald caught significantly less males than traps baited with the five-component blend, but significantly more males than the blank traps.

A trial comparing the four-component blend developed for the Auckland population of *G. mutans* with the five-component blend used in the Lincoln and Nelson trial was conducted in Auckland. Another five-component blend, consisting of the Auckland-type blend plus 1000 μg of Z9–14 : Ald, was also included (Table 3). Over two months, male *G. mutans* were caught only in traps containing the Auckland-type blend; the blank traps and traps baited with either the Lincoln-type blend or the other five-component blend did not catch any males.

[a]Trial conducted from March 30 to June 1, 1988 at MARC, using five replicates. Traps were checked and rerandomized weekly. Means accompanied by the same letter are not significantly different at $P < 0.05$ (Duncan's multiple range test).

Wind Tunnel. Male *G. mutans* from the Auckland colony were flown initially to extract of sex pheromone glands of their own females. Males responded to as little as 0.1 female equivalents (FE) of extract, with 33% (6/18) of the males tested touching the source. The percentage of males touching the source containing 1 FE of extract was greater (53%; 15/28), but not significantly ($P > 0.05$) so. After being placed in the plume of the 1 FE source, males initially remained stationary, with a mean latency to activation of 54 sec (range 6–217.8 sec). Activation consisted of males raising their antennae and fanning their wings, with a mean duration from activation to initiation of flight of 88.8 sec (range 6.6–93.6 sec). Once males took flight, the time of flight (to landing on the source) was relatively short, with a mean of 58.8 sec (range, 42–108 sec).

Three wind-tunnel experiments investigating the effects on male flight responses of varying the amount or ratios of Z9–14:Ald, Z9–14:OH:Z7–14:OH, and Z9–14:OAc:Z7–14:OAc, respectively, were conducted. In each of these experiments, males were flown to a standard reference blend consisting of 10 ng Z9–14:OH, 3 ng Z9–14:OAc, 1.5 ng Z7–14:OH, and 0.5 ng Z7–14:OAc, in addition to the various other blends tested.

An increase in the amount of Z9–14:Ald in the blend had a significant effect on male responses (Figure 1). The addition of 1% (of amount of Z9–14:OH) of Z9–14:Ald to the four-component blend resulted in a significant ($P < 0.05$) decrease in the percentage of males touching the source (74% of males for the four-component blend as opposed to 33% of males for the blend with 1% Z9–14:Ald). Rather than being due solely to a decrease in the percentage of males activating to the respective sources, this difference was the result of arrestment of flight occurring throughout each stage of upwind flight. However, greater amounts of Z9–14:Ald added to the blend reduced the number of males activating and significantly ($P < 0.05$) increased the percentage of arrestment of flight before males had reached the midpoint of the tunnel. Only 5% (1/20)

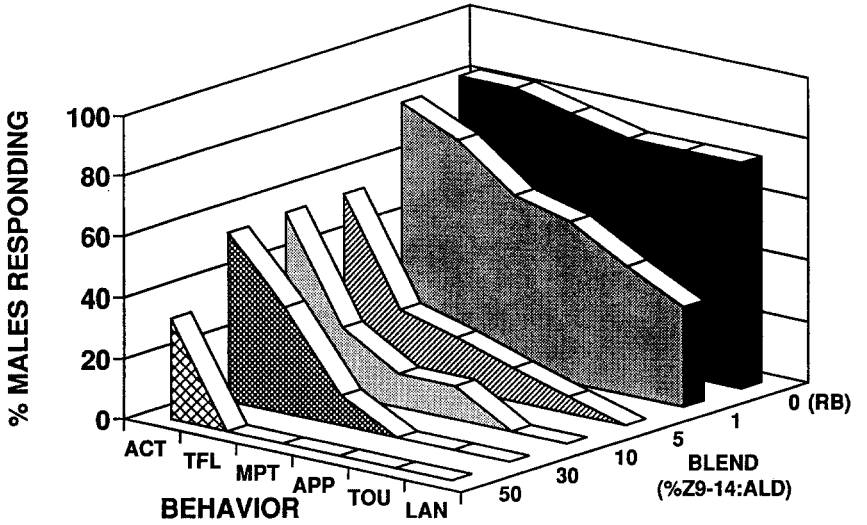

FIG. 1. Percentage of male *Graphania mutans* (Auckland population) responding to a four-component reference blend (RB) plus varying amounts of (*Z*)-9-tetradecenal (Z9–14:Ald), in a wind tunnel. The RB consisted of 10 ng (*Z*)-9-tetradecenol, 3 ng (*Z*)-9-tetradecenyl acetate, 1.5 ng (*Z*)-7-tetradecenol, and 0.5 ng (*Z*)-7-tetradecenyl acetate on filter paper. The responses measured were: activation (ACT), taking flight (TFL), midpoint (MPT), approach (APP), touch (TOU), and landing (LAN); for a detailed description of these responses refer to text.

of the males touched the source containing 5% Z9–14:Ald, and no males touched the sources with blends containing greater amounts of Z9–14:Ald.

Of all the ratios of Z9–14:OH:Z7–14:OH tested (Figure 2) the greatest percentage of males that touched the source did so to the reference blend; this percentage was significantly greater ($P < 0.05$) than the percentages of males that touched the sources containing any of the other blends tested (i.e., with higher or lower ratios of Z9–14:OH:Z7–14:OH). Blends with lower ratios of Z9–14:OH:Z7–14:OH (i.e., with lower amounts of Z9–14:OH) were characterized by greater numbers of males having arrested flight by each of the successive positions in the tunnel. However, to the blend lacking Z7–14:OH, once males had reached the midpoint of the tunnel they continued on to the source without any arrestment of flight.

To the different ratios of Z9–14:OAc:Z7–14:OAc, the greatest percentage of males that landed on the source was to the reference blend ratio (i.e., 3:0.5) (Figure 3). The percentage of males touching the source (64%) containing this blend was significantly greater ($P < 0.05$) than the percentages of males touching the source for all other blends except the 3:1.5 blend (41% of

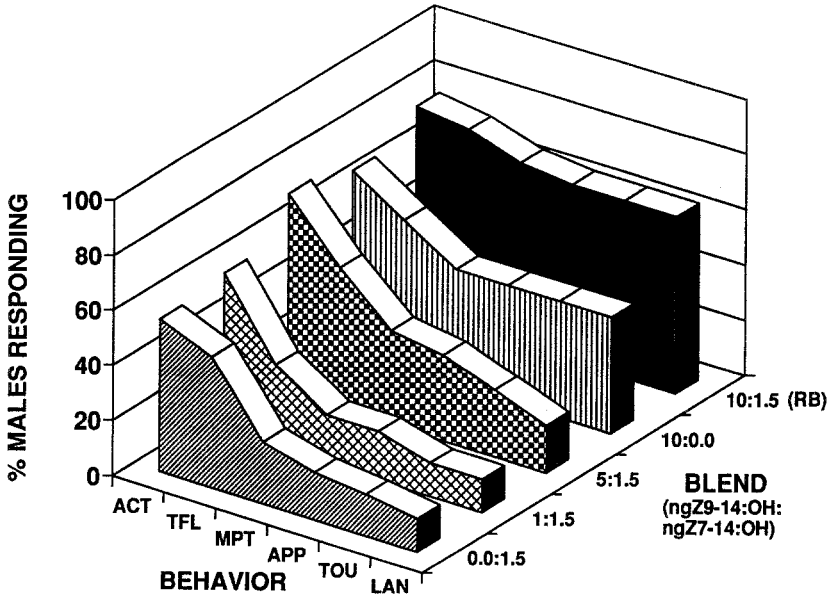

FIG. 2. Percentage of male *Graphania mutans* (Auckland population) responding to a four-component reference blend (RB) and four component blends with varying amounts of (Z)-9-tetradecenol (Z9–14 : OH) and (Z)-7-tetradecenol (Z7–14 : OH), in a wind tunnel. The RB and acronyms are as in Figure 1.

males). Consistent with the lack of catches in the field-trapping trials, blends lacking either Z9–14 : OAc or Z7–14 : OAc failed to elicit any males to touch the source. However, there was a significant ($P < 0.05$) difference between the responses of males to these two blends; the blend lacking Z9–14 : OAc did not activate males, but 50% of the males were activated by the blend lacking Z7–14 : OAc. Arrestment of flight to all blends (except the one lacking Z9–14 : OAc) tended to occur after males had activated and before they had reached the midpoint of the tunnel.

Males of the Auckland and Lincoln cultures were flown to pheromone extract from their own or the other females (Figure 4). Approximately 80% of both Auckland males and Lincoln males flew upwind and landed on the sources containing 1 FE of pheromone extract from their respective females. However, none of the Auckland or Lincoln males flew upwind and touched the source containing pheromone extract of the Lincoln or Auckland females, respectively. This failure to fly upwind and touch the source was generally characterized by low percentages of males activating (25–40%; c.f., 76% and 100% of males of both cultures were activated by extract from their own females). None of the nine (of 21) Lincoln males that were activated by Auckland female pheromone

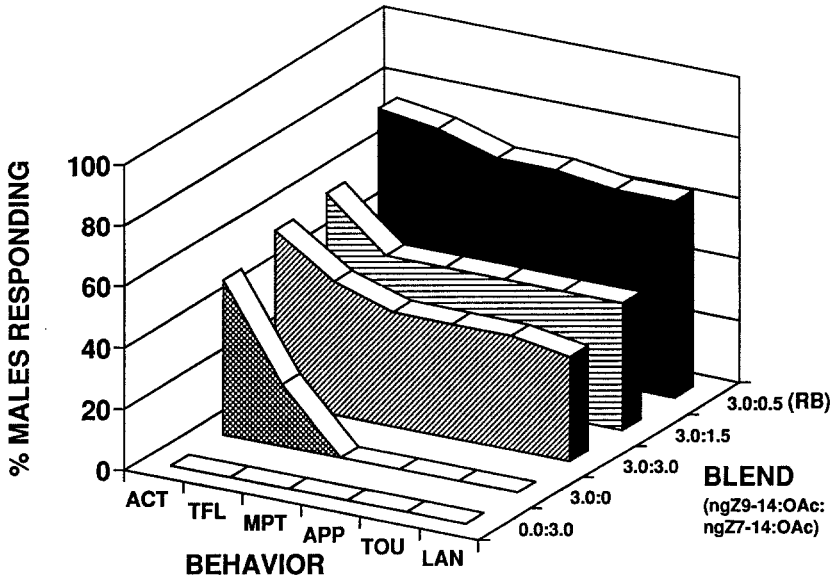

FIG. 3. Percentage of male *Graphania mutans* (Auckland population) responding to a four-component reference blend (RB) and four-component blends with varying amounts of (Z)-9-tetradecenyl acetate (Z9–14 : OAc) and (Z)-7-tetradecenyl acetate (Z7–14 : OAc), in a wind tunnel. The RB and acronyms are as in Figure 1.

extract flew upwind for greater than 20–30 cm, but all five (of 19) of the Auckland males that were activated by Lincoln pheromone extract flew upwind for approximately 30 cm; all of these males arrested upwind flight before the midpoint of the tunnel.

DISCUSSION

By analyzing the sex pheromones of two distinct populations of *G. mutans*, we have shown that this morphologically described species consists of (at least) two taxa that differ in their sex pheromones. In their respective pheromone blends, females of both taxa produce four components in common: Z9–14 : OH,Z7–14 : OH,Z9–14 : OAc, and Z7–14 : OAc, although in somewhat different ratios. However, females of the taxon from Lincoln also produce relatively large amounts of Z9–14 : Ald while females of the taxon from Auckland do not produce this compound. Paralleling pheromone production by the females, males of both taxa also show similarities and differences in responses to the chemicals found in females. Profiles of EAG responses to series of monounsaturated chemicals are quite similar for males of both taxa, suggesting

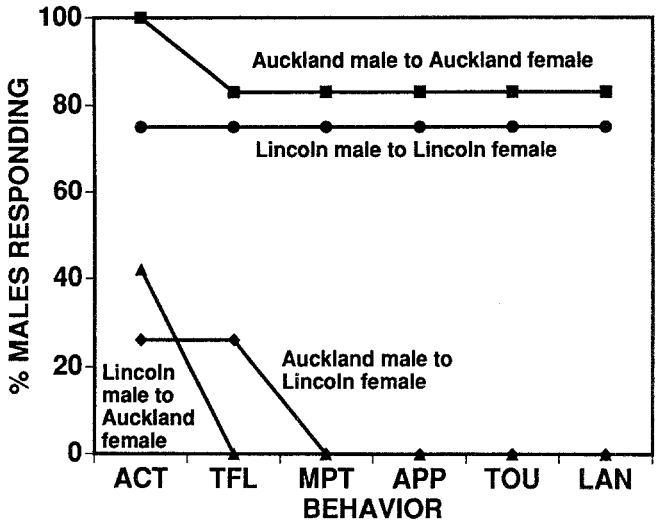

FIG. 4. The flight responses of male *Graphania mutans* from Auckland and Lincoln populations to pheromone extract from females of their own and the other population. The response acronyms are as in Figure 1.

that they share a similar olfactory receptor complement. However, the relative amplitudes of EAG responses to the different series by males of the two taxa suggest that the relative abundances of the different olfactory cells differ between the two types of males. These differences are further matched by the behavioral responses of males in a wind tunnel to pheromone extract from the respective females. Males of either taxon only respond by touching the filter paper source containing pheromone extract of their own females. In response to pheromone extract of the other females, males either did not activate or they arrested flight shortly after take off.

While there are probably other differences, such as the importance of ratios of the various compounds, we believe that a key difference between the sex pheromone systems of the two taxa is the presence and importance of Z9–14 : Ald in the blend of the Lincoln taxon. Although, due to a shortage of insects, we have not fully defined the sex pheromone blend of the Lincoln taxon and, in particular, unequivocally established the role of Z9–14 : Ald, we nevertheless find the evidence for Z9–14 : Ald being a critical element in the sexual communication system of this taxon to be compelling. This compound is the most abundant of the compounds identified in the gland of females of this taxon. Males of this taxon show a high-amplitude EAG response to this compound. In the field trials at Lincoln and Nelson, males were caught in high numbers in traps baited with the four common components plus 1000 μg of Z9–14 : Ald, as

well as in traps containing Z9–14 : Ald and lacking Z7–14 : OAc (in contrast, males of the Auckland taxon were not caught in significant numbers in traps baited with blends lacking Z7–14 : OAc). Finally, in the wind-tunnel experiment using extracts, the difference in response between males of the two taxa to their respective females' extract correlated with the major observed difference in extract from these females being Z9–14 : Ald content (i.e., either none or a relatively large amount). Therefore, the circumstantial evidence suggests that Z9–14 : Ald is a critical component in the sex pheromone of this taxon. If this is accepted, then it follows that the field-trapping results at Nelson and Lincoln, where males were caught in high numbers in traps baited with either the Lincoln-type blend or the Auckland-type blend is the result of both taxa being present in sympatry in these two locations. Further evidence in support of this comes from the field trial in Lincoln where traps baited with the Lincoln-type blend caught more than twice the number of males than traps baited with the Auckland type blend; unfortunately, only two replicates were used at Lincoln and so this difference was not statistically significant.

In contrast to the proposed effect of Z9–14 : Ald in the blend to Lincoln males, the presence of even small amounts of Z9–14 : Ald in the common four-component mix appears to inhibit the flight responses or field catches of *G. mutans* males from Auckland. Likewise, in field-trapping trials, the five-component blend that gave good catches of males in both Lincoln and Nelson did not catch any males in Auckland. Clearly, the very high relative proportion of Z9–14 : Ald produced by Lincoln females would result in the complete inhibition of upwind flight responses of the males of the Auckland taxon, as was observed in the wind tunnel using female extracts.

The effect of Z9–14 : Ald in blends on males of the two *G. mutans* taxa is contrasting; in one taxon (the Lincoln) it serves as a component (''major'') of the pheromone, in the other taxon (Auckland) it results in the arrestment of upwind flight responses when added to the pheromone blend. Compounds that are observed to have the latter function are usually viewed as ''reproductive isolating mechanisms'' between closely related species (in the sense outlined by Cardé 1986) and more recently as ''behavioral antagonists'' (Linn et al., 1988; Glover et al., 1989; Linn and Roelofs, 1989), i.e., their use in pheromone systems has evolved as a direct adaptation to ensure that so-called ''mating mistakes'' are reduced or eliminated. An alternative, more parsimonious explanation for the evolution of such compounds, based on the ''specific mate recognition'' theory of Paterson (1985), would be that Z9–14 : Ald has evolved in mate recognition in the Lincoln taxon. Therefore, the second function of this compound, as an intertaxon isolating mechanism or behavioral antagonist, would arise as an incident of recognition in the Lincoln taxon. Appealing as these possibilities are, neither parsimony nor the coincidence of the compound apparently eliciting different and exclusive behavioral responses from males of the

two taxa are evolutionary proof. Nevertheless, the two *G. mutans* taxa may offer an excellent example to study, and therefore test, specific mate recognition, reproductive isolation, or behavioral antagonism.

Given these differences between the pheromone systems of these two taxa, it appears that the two *G. mutans* taxa may in fact be distinct sibling species. This phenomenon in *G. mutans* is similar to that observed during similar studies on endemic New Zealand tortricid pests. These studies, led by sex pheromone analyses of different populations, showed that the previously described *Planotortrix excessana* and *Ctenopseustis obliquana* actually consist of two and three sibling species, respectively (Dugdale, 1990; Foster et al., 1991). These sibling species differ somewhat in their allozyme patterns and are morphologically very similar. However, there are major differences between their pheromone systems. The difference in the pheromonal communication systems of the two taxa of *G. mutans* is similarly striking, although, so far, no morphological difference between these two taxa has been detected (Dugdale, personal communication). More complete characterization of the sex pheromone of the Lincoln taxon, and further examination of the morphology, ecology, and allozyme patterns of these two taxa of *G. mutans* is planned and, it is hoped, will establish whether they should be considered as distinct sibling species.

In addition to elucidating the distinct pheromone taxa within *G. mutans*, we have identified and chemically and behaviorally characterized the sex pheromone of a *G. mutans* population from Auckland. The sex pheromone of this taxon consists of (at least) a four-component blend of two alcohols and two acetates. The most abundant compound identified in the gland was *Z*9–14 : OH; however, somewhat surprisingly, in our bioassays we found that this component could be removed from the blend without the complete suppression of either field catches or the upwind flight responses of males. In contrast, two of the less abundant components in the gland (*Z*9–14 : OAc and *Z*7–14 : OAc) could not be removed from the blend without complete suppression of field catches or arrestment of flight before the midpoint of the wind tunnel. At this time we do not have any information regarding the relative ratios of the compounds released in the effluvia of female *G. mutans*. However, it is interesting that the relative abundance of *Z*9–14 : OH in the gland does not correlate with a "major" behavioral function in the sense usually assigned to the most abundant component in a blend in pheromone studies. Rather this function is apparently served by *Z*7–14 : OAc and *Z*9–14 : OAc.

The fourth component in the blend of this taxon, *Z*7–14 : OH, when added in large amounts to the three-component blend significantly reduced trap catches. However, when *Z*7–14 : OH was completely removed from the blend, trap catches decreased slightly but not significantly. The effect of this component in the blend at relative ratios close to that found in the female was established in the wind tunnel. A comparative study using field-trapping techniques generally

observes differences in the end results of behavioral responses rather than differences in the actual behavioral responses themselves (Kennedy, 1977). Consequently, subtle effects in behavior elicited by chemicals are less likely to be detected by field-trapping techniques than by more direct, discriminating bioassays such as wind tunnels (Baker and Linn, 1984). By use of the wind tunnel we were able to establish the importance of *Z*7–14 : OH in the pheromone blend of *G. mutans*; the absence of this compound from the reference blend (i.e., four components) increased the percentage of males arresting flight before the midpoint of the tunnel and therefore resulted in a decrease in the percentage of males touching the source. The wind tunnel study also confirmed that the other three components elicited behavioral activity. Thus the absence of either *Z*9–14 : OAc or *Z*7–14 : OAc from the blend significantly decreased the percentages of males activating and taking flight relative to the four component blend, while significantly fewer males reached the midpoint of the tunnel when presented with the blend lacking *Z*9–14 : OH.

In many species of moths the ratios of pheromone components produced by females are regulated within fairly tight ranges that usually correspond with the ratios of these components to which males respond optimally (see for example Miller and Roelofs, 1980; Roelofs et al., 1975). Our data suggest that this is the case with *G. mutans*. Our initial formulation of a synthetic blend was based on the ratios observed in females. When various ratios in this blend were changed, generally the responses of males, as measured by trap catches and flight-tunnel behavior, decreased. In the flight tunnel, changes in the relative amounts of any of the four components were characterized by males arresting flight after activation and before reaching the midpoint of the tunnel rather than by arrestment at later stages (near the source) of upwind flight. A further study looking at more subtle changes in the various ratios along with examining the variability in production of the four components between individual females is planned.

The pheromone blends for both taxa of *G. mutans* can now be used for monitoring this pest in orchards. This should allow a better understanding of the pest status of both taxa and hence control programs can be modified for more effective control of these pests as necessary. The use of these two pheromone blends should also facilitate work examining the distribution of these two taxa around New Zealand.

Acknowledgments—We are very grateful to Mr. J.S. Dugdale for insects, advice, and assistance throughout the course of this work. Thanks are due to Dr. D.M. Suckling, Messrs W.P. Thomas, G. Burnip, D. Rogers, and Ms. A. Barrington, and Ms. D.C. Whiting for collecting or supplying insects used in this work; and also to Mr. P.W. Shaw and Dr. D.M. Suckling for running the field trails at Nelson and Lincoln. Thanks also to Mr. C. Malosse for recording the mass spectra. The visit of B.F. was supported by a grant from I.N.R.A.

Abstract—Pheromone components and sex attractant blends consisting of 3*Z*,6*Z*,9*Z*-triene hydrocarbons and racemic and chiral forms of 3*Z*,6*Z-cis*-9,10-epoxydienes have been elucidated for two noctuid and one geometrid moth species. Male *Euclidea cuspidea* moths were attracted to blends of 3*Z*,6*Z*,9*Z*-heneicosatriene (3*Z*,6*Z*,9*Z*-21 : H) with 3*Z*,6*Z-cis*-9,10-epoxyheneicosadiene (3*Z*,6*Z-cis*-9,10-epoxy-21 : H). In addition to these compounds, 3*Z*,6*Z*,9*Z*-20 : H, and two regioisomeric C_{21} epoxides were tentatively identified in pheromone gland extracts. *Caenurgina distincta* moths were attracted by an 8 : 1 blend of 3*Z*,6*Z*,9*Z*-20 : H with 3*Z*,6*Z-cis*-9,10-epoxy-20 : H. *Eupithecia annulata* moths were attracted by either 3*Z*,6*Z-cis*-9,10-epoxy-20 : H or 3*Z*,6*Z-cis*-9,10-epoxy-21 : H, and by the 9*S*,10*R* enantiomer of each epoxide. 3*Z*,6*Z*,9*Z*-21 : H and 3*Z*,6*Z-cis*-9,10-epoxy-21 : H were tentatively identified from pheromone glands. Pheromone components were identified by a combination of coupled gas chromatography–electroantennography, gas chromatography–mass spectrometry, and field bioassays.

Key Words—Pheromone, sex attractant, Noctuidae, Geometridae, epoxide,

triene hydrocarbon, 3*Z*,6*Z*,9*Z*-eicosatriene, 3*Z*,6*Z*,9*Z*-heneicosatriene, 3*Z*,6*Z*-*cis*-9,10-epoxyeicosadiene, 3*Z*,6*Z*-*cis*-9,10-epoxyheneicosadiene.

INTRODUCTION

The first diene monoepoxide pheromone component, 3*Z*,6*Z*-*cis*-9,10-epoxyheneicosadiene (3*Z*,6*Z*-*cis*-9,10-epoxy-21:H; subsequent abbreviations follow this model), in combination with 9*Z*,12*Z*-octadecadienal (9*Z*,12*Z*-18:Al) and 9*Z*,12*Z*,15*Z*-18:Al, was identified in pheromone gland extracts and effluvia of the saltmarsh caterpillar moth, *Estigmene acrea* Drury (Lepidoptera: Arctiidae) (Hill and Roelofs, 1981). The biologically active epoxide enantiomer was subsequently determined to have the 9*S*,10*R* configuration (Mori and Ebata, 1981). Since that time, this compound, or homologs of it, have been identified as sex attractants or pheromone components for a number of lepidopteran species. For example, 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H has been reported as a sex pheromone component of the arctiid species *Creatonotos transiens* L., *C. gangis* Walker (Bell and Meinwald, 1984), *Antichloris viridis* (Meyer, 1984), *Hyphantrea cunea* Drury (Hill et al., 1982; Einhorn et al., 1982), and *Phragmatobia fuliginosa* L. (Descoins and Frérot, 1984). This compound also has been identified in female pheromone gland extracts from the arctiids *Tyria jacobaeae* and *Cymbalophora pudica* Esper, and it was shown to elicit strong electroantennogram responses from male moth antenna, although no data on its attractiveness to male moths was reported (Frérot et al., 1988a,b). This C_{21} epoxide, or the C_{18-20} homologs, also have been reported as sex attractants for several geometrid and noctuid moth species (Wong et al., 1985; Kovalev and Nikolaeva, 1986).

Racemic and chiral regioisomers of the *cis*-9,10-epoxydienes, 3*Z*,9*Z*-*cis*-6,7- and 6*Z*,9*Z*-*cis*-3,4-epoxydienes, also have been reported as sex attractants and sex pheromone components for a number of geometrid and noctuid species (Becker et al., 1990; Millar et al., 1987, 1990 a–d; Hansson et al., 1990). The behavioral response to the compounds is often synergized or antagonized by the corresponding 3*Z*,6*Z*,9*Z*-trienes.

Preliminary data on the attraction of male moths of a number of noctuid and geometrid species to lures containing blends of 3*Z*,6*Z*,9*Z*-trienes, alone or in combination with mixtures of racemic *cis*-monoepoxydienes (combined monoepoxides, CME-3*Z*,6*Z*,9*Z*-X:H, X = 19–21), or racemic and enantiomeric forms of 19- to 21-carbon 3*Z*,6*Z*-*cis*-9,10-epoxydienes were published several years ago (Wong et al., 1985). Since that time, we have investigated the pheromone chemistry of several of these species in more detail. We report here: (1) the identification of sex pheromone components for the geometrid species *Eupithecia annulata* Hulst and the noctuid species *Euclidea cuspidea* Hübner, by a combination of coupled gas chromatography–electroantennogram detection (GC-EAD), gas chromatography–mass spectrometry (GC-MS), and

comparisons with synthetic standards; (2) the elucidation and field testing of sex pheromone and sex attractant blends for the above two species, and for *Caenurgina distincta* Cram; and (3) the determination of the chirality of the epoxydienes that are attractive to the above species.

METHODS AND MATERIALS

Insects, Electroantennography, and Pheromone Identification. Female moths of unknown mating status were collected from the field by sweep-netting or black-light trapping and used as a source of pheromone. Males were captured as described above or in sticky wing-traps (Phero Tech, Vancouver, British Columbia; traps are similar to Pherocon 1C traps from Scentry, Inc., Buckeye, Arizona). Preparation and analysis of pheromone gland extracts by coupled GC-EAD and coupled GC-MS was carried out as previously described (Millar et al., 1987, 1990d). GC-MS analyses were carried out with a Finnigan 4000E instrument interfaced to an INCOS 2300 data system, in electron impact (70 eV) or chemical ionization (isobutane) modes. DB-5 (50 m × 0.32 mm; J&W Scientific, Folsom, California) and Ultra-2 (Hewlett-Packard, Avondale, Pennsylvania) capillary columns were used with He carrier gas, programmed from 40 to 250°C. GC-EAD studies were carried out with a Hewlett-Packard 5910 GC equipped with either a DB-1701 or a DB-5 capillary column (30 m × 0.32 mm, J&W Scientific). The column effluent was split 7:3 in favor of the FID detector, and signals from the EAD and FID signals were recorded simultaneously with a matched pair of Hewlett-Packard 3392A integrators. Injections were made in splitless mode, programmed from 40 to 225°C.

Insect Trapping. Field experiments were carried out in a mixed forest area (black spruce, jack pine, willow, aspen) approx. 100 km northeast of Saskatoon, Saskatchewan. Phero Tech wing-traps were used. Details of lure preparation (red rubber septa), and the setup of field survey traps and field experiments were as previously described (Millar et al., 1990d). Trap captures were transformed $[(x + 1)^{1/2}]$ and subjected to analysis of variance. The homogeneity of the variances of the transformed means was confirmed with Bartlett's test (Sokal and Rohlf, 1981). Treatments with zero captures overall were not included in the ANOVA, as replicates within a treatment must have some variance to satisfy the assumptions of the ANOVA test. Significantly different means were separated by Duncan's (1955) multiple-range test.

Synthetic Chemicals. The syntheses of the 3*Z*,6*Z*,9*Z*-trienes (Underhill et al., 1983) and the enantiomerically enriched forms of the 3*Z*,6*Z*-*cis*-9,10-epoxydienes (Wong et al., 1985) have been reported previously. The chemical purity of all compounds used was >98% by capillary GC. The enantiomerically enriched 3*Z*,6*Z*-*cis*-9,10-epoxydienes had chiral purities of 93% ee (9*R*,10*S* series) and 92% ee (9*S*,10*R* series) respectively (Wong et al., 1985).

RESULTS

Euclidea cuspidea *Hübner*. The preliminary report by Wong et al. (1985) suggested that males of this species were attracted by blends of 3Z,6Z,9Z-21 : H in combination with one or more C_{21} monoepoxydienes. Analysis of a female pheromone gland extract by GC-EAD elicited three strong responses from a male moth antenna at retention times corresponding to 3Z,6Z,9Z-20 : H, 3Z,6Z,9Z-21 : H, and 3Z,6Z-*cis*-9,10-epoxy-21 : H (Figure 1). The concurrent flame ionization detection (FID) trace showed peaks at these retention times, and two further peaks at retention times corresponding to 3Z,9Z-*cis*-6,7-epoxy-21 : H and 3Z,9Z-*cis*-3,4-epoxy-21 : H. The five compounds were present in the ratio of 3Z,6Z,9Z-20 : H (1.6), 3Z,6Z,9Z-21 : H (100), 3Z,6Z-*cis*-9,10-epoxy-

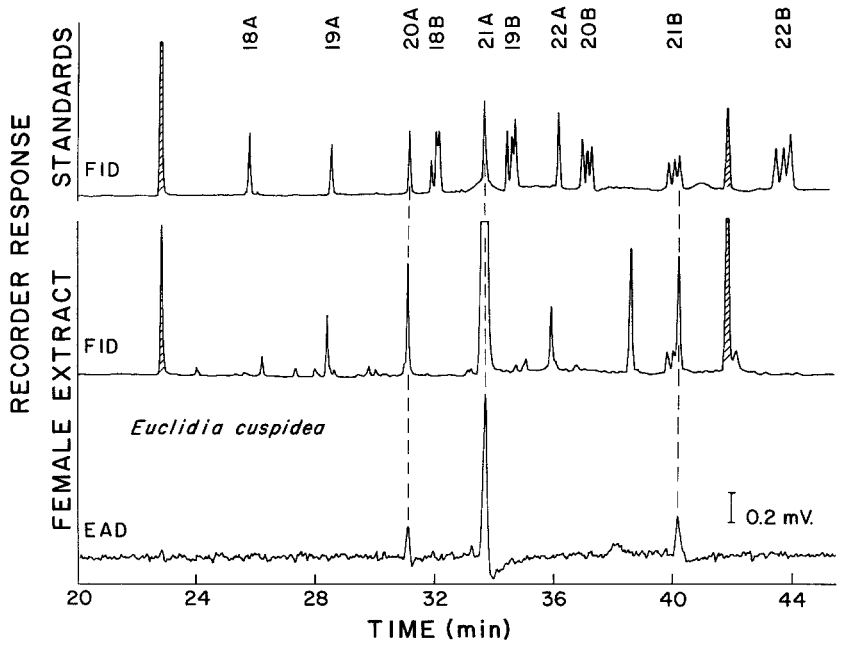

FIG. 1. Simultaneously recorded flame ionization detector (FID) and electroantennographic detector (EAD) responses of *Euclidea cuspidea* male antennae in GC-EAD experiments. Upper trace is an FID trace of a mixture of C_{18-22} 3Z,6Z,9Z-trienes (designated by the letter A and preceded by the carbon chain length) and their monoepoxydiene analogs (designated with the letter B); the latter eluted from the 30-m DB-1701 column in the order 6,7, 3,4, and 9,10 monoepoxydiene. Internal standards (heptadecane and tetracosane) are shaded. Lower pair of traces are in response to a pheromone gland extract from conspecific females.

21:H (2), 3*Z*,9*Z*-*cis*-6,7-epoxy-21:H (0.4), and 6*Z*,9*Z*-*cis*-3,4-epoxy-21:H (0.4).

The presence of all five components in pheromone gland extracts was confirmed with both selected ion monitoring (SIM) and full-scan chemical ionization (isobutane) mass spectrometry. Exact retention time matches were obtained for all five compounds versus synthetic standards, and full-scan Cl mass spectral matches were obtained for 3*Z*,6*Z*,9*Z*-21:H and 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H versus standards (Figures 2 and 3). The isobutane Cl mass spectrum of 3*Z*,6*Z*,9*Z*-21:H (Figure 2) was characterized by a base peak at *m/z* 289 $(M + H)^+$, and adducts at *m/z* 347 $(M + C_4H_9)^+$, and 291 $(M + H)^+$. Fragments at *m/z* 277, 263, 249, and 235 may be attributed to sequential losses of C_nH_{2n} (n = 5–8) from the *m/z* 347 adduct ion. Ions at *m/z* 123, 137, 151, 165, and 179 may be attributed to a series of homologous fragments ($C_nH_{2n-4} + H^+$, n = 10–14) containing the three unsaturations. Fragments at *m/z* 211 and 223 were not readily assignable.

The isobutane Cl spectrum of 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H (Figure 3) was much simpler, with a base peak at *m/z* 307 $(M + H)^+$ and a large fragment at *m/z* 289 $(M + H - H_2O)^+$. Diagnostic ions arising from rearrangement and cleavage of the epoxide functionality were present at *m/z* 123 $(C_9H_{15})^+$ and 183 $(C_{12}H_{23}O)^+$, locating the epoxide at the 9,10 position. The potential M + 57 adduct at *m/z* 363 was beyond the scan range used (120–350 amu).

The full-scan isobutane Cl spectra of the other three components were not as good due to the low levels at which they were present, but the spectra clearly matched those of the synthetic standards. In particular, the peak corresponding to 3*Z*,6*Z*,9*Z*-20:H gave strong fragment ions at *m/z* 333 (M + 57), 277 (M+1), and 275 (M−1), and the peaks corresponding to 3*Z*,9*Z*-*cis*-6,7-epoxy-21:H and 6*Z*,9*Z*-*cis*-3,4-epoxy-21:H gave strong ions at *m/z* 307 (M+1) and *m/z* 289 (M+1−18).

Wong et al. (1985) had demonstrated that 3*Z*,6*Z*,9*Z*-21:H and CME-3*Z*,6*Z*,9*Z*-21:H were not active as single components, so our field tests began with blends of 3*Z*,6*Z*,9*Z*-21:H with epoxides. In the first experiment (replicated three times), lures containing 3*Z*,6*Z*,9*Z*-21:H + 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H (450:20 μg) attracted 21 moths, while the corresponding blends with the *cis*-6,7- and *cis*-3,4-epoxide regioisomers caught none, demonstrating that the 9,10 epoxide was the attractive regioisomer. Furthermore, lures containing 3*Z*,6*Z*,9*Z*-21:H in combination with 3*Z*,6*Z*,9*S*,10*R*-epoxy-21:H (450:10 μg) attracted 42 moths, while the corresponding lure containing the 9*R*,10*S* enantiomer attracted no moths, indicating that the attraction was enantiospecific.

Experiments conducted in 1985 confirmed these data (Table 1). Mixtures of 3*Z*,6*Z*,9*Z*-21:H with the enantiomers of 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H, in a series of ratios bracketing the blend ratio found in pheromone gland extracts were tested, and the blends with the 9*S*,10*R* enantiomer were significantly more

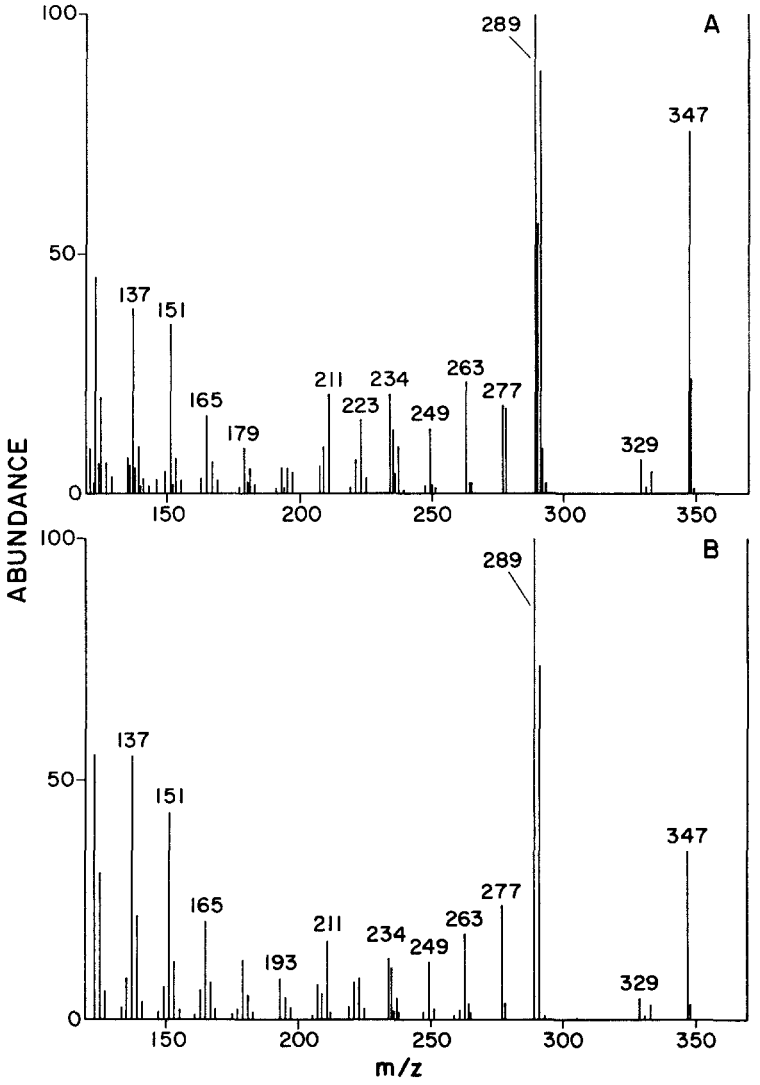

FIG. 2. Chemical ionization mass spectra (isobutane) of 3*Z*,6*Z*,9*Z*-heneicosatriene: (A) synthetic standard; (B) compound from *E. cuspidea* female pheromone gland extract.

attractive than those with the 9*R*,10*S* enantiomer. A blend of 3*Z*,6*Z*,9*Z*-21 : H with CME-21 : H (500 : 50 μg) was as attractive as the blend of 3*Z*,6*Z*,9*Z*-21 : H with 3*Z*,6*Z*-9*S*,10*R*-epoxy-21 : H, indicating that the other epoxide regioisomers were not antagonistic.

Further tests were conducted with a basic lure composed of 3*Z*,6*Z*,9*Z*-

TABLE 1. ATTRACTION OF *E. cuspidea* TO BLENDS OF 3Z,6Z,9Z-21 : H AND ENANTIOMERS OF 3Z,6Z-cis-9,10-EPOXY-21 : H[a]

Lure (μg)	Males captured
3Z,6Z,9Z-21 : H (500) + 3Z,6Z-9*R*,10*S*-epoxy-21 : H (1)	1a
3Z,6Z,9Z-21 : H (500) + 3Z,6Z-9*R*,10*S*-epoxy-21 : H (10)	1a
3Z,6Z,9Z-21 : H (500) + 3Z,6Z-9*R*,10*S*-epoxy-21 : H (50)	17b
3Z,6Z,9Z-21 : H (500) + 3Z,6Z-9*S*,10*R*-epoxy-21 : H (1)	2a
3Z,6Z,9Z-21 : H (500) + 3Z,6Z-9*S*,10*R*-epoxy-21 : H (10)	39c
3Z,6Z,9Z-21 : H (500) + 3Z,6Z-9*S*,10*R*-epoxy-21 : H (50)	49c
3Z,6Z,9Z-21 : H (500) + CME-3Z,6Z,9Z-21 : H (50)	45c

[a] Traps relicated three times and set out from June 1 to July 10, 1985. Values followed by the same letter are not significantly different ($P > 0.05$).

21 : H and 3Z,6Z,9*S*,10*R*-epoxy-21 : H (450 : 10 μg) spiked with varying amounts of 3Z,6Z,9Z-20 : H (1, 10, 50, or 100 μg), and the enantiomers of 3Z,9Z-*cis*-6,7-epoxy-21 : H (5 or 50 μg). There were no significant differences in trap captures between the basic lure and the adulterated lures; that is, the C_{20} triene and the 3Z,9Z-*cis*-6,7-epoxy-21 : H enantiomers have no apparent biological activity as attractants for this species despite being present in the pheromone gland.

Caenurgina distincta *Cram.* Blends of 3Z,6Z,9Z-20 : H with 3Z,6Z-*cis*-9,10-epoxy-20 : H have been implicated as potential sex pheromone components for this species (Wong et al., 1985). GC-EAD analysis of a pheromone gland extract from a field-collected female moth showed strong antennal responses from a male antenna at retention times corresponding to 3Z,6Z,9Z-19 : H, 3Z,6Z,9Z-20 : H, 3Z,6Z,9Z-21 : H, 3Z,6Z-*cis*-9,10-epoxy-20 : H, and 3Z,6Z-*cis*-9,10-epoxy-21 : H (Figure 4). The concurrent FID trace showed discernible peaks only at the retention times of the C_{20} and C_{21} trienes, indicating that the quantities of the other components in the extract eliciting antennal responses were very small. When challenged with synthetic standards, a male antenna demonstrated strong responses to C_{19}–C_{21} trienes, 3Z,6Z-*cis*-9,10-epoxydienes, and 3Z,9Z-*cis*-6,7-epoxydienes (Figure 4, upper traces).

A number of two-component blends of 3Z,6Z,9Z-20 : H with 3Z,6Z,9Z-21 : H were found to be minimally attractive and not significantly different from 3Z,6Z,9Z-20 : H alone. In like fashion, blends of 3Z,6Z,9Z-20 : H with the shorter-chain EAG-active homolog 3Z,6Z,9Z-19 : H had been demonstrated to have no synergistic effects (Wong et al., 1985).

A field test in 1985 (replicated four times) demonstrated that 3Z,6Z-9*S*,10*R*-epoxy-20 : H was the more attractive of the two enantiomers, as a 1 : 8 blend of epoxide–3Z,6Z,9Z-20 : H attracted 59 male moths, while the corresponding

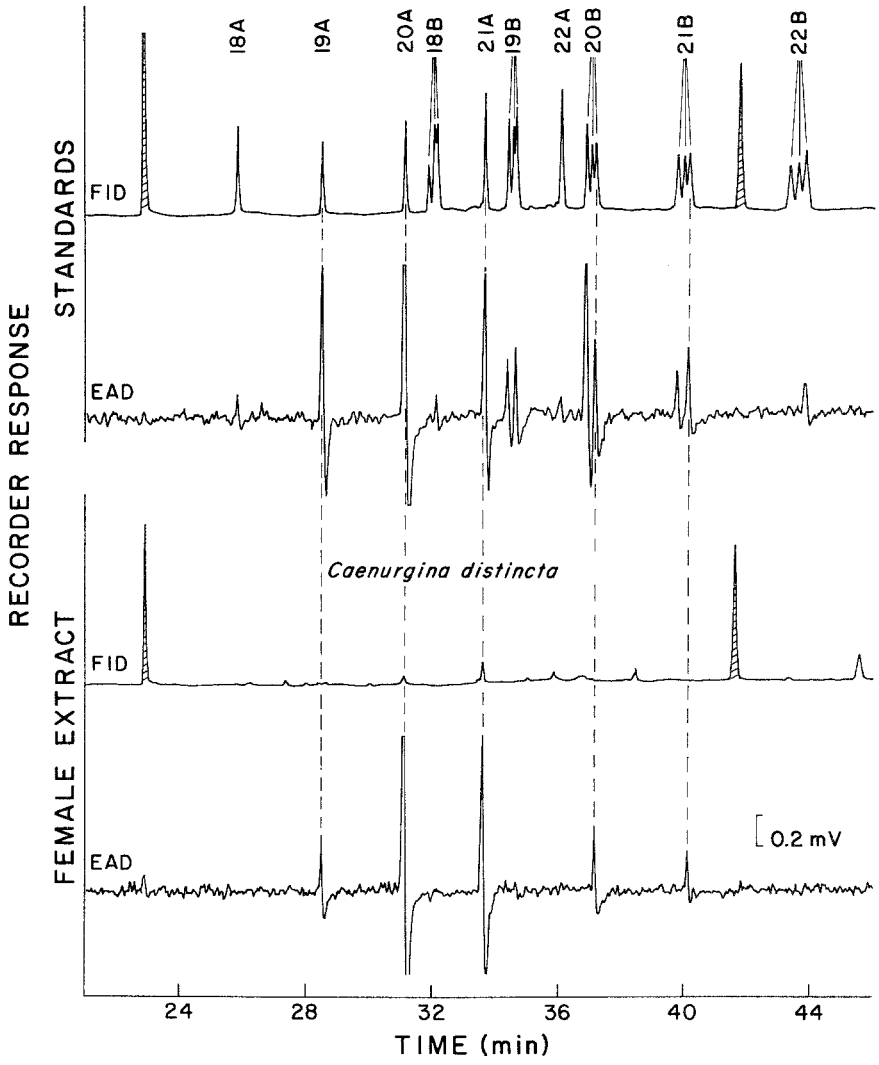

FIG. 4. Response of *Caenurgina distincta* male antennae in GC-EAD experiments using a DB-1701 column. Upper pair of traces are in response to a mixture of C_{18-22} synthetic standards; lower pair are in response to a pheromone gland extract from a conspecific female. Number and letter designations are identical to those of Figure 1. Internal standards (heptadecane and tetracosane) are shaded.

blend with the 9*R*,10*S* enantiomer attracted only five moths. Concurrently, lures containing racemic 3*Z*,6*Z*-*cis*-9,10-epoxy-20:H in combination with 3*Z*,6*Z*,9*Z*-20:H (1:4 blend) attracted 55 moths, suggesting that the 9*R*,10*S* enantiomer was not antagonistic.

Because a strong antennal response had been elicited by 3*Z*,9*Z*-*cis*-6,7-epoxy-20:H, the effect of adding the enantiomers of this compound to an attractive lure blend (3*Z*,6*Z*,9*Z*-20:H + 3*Z*,6*Z*-*cis*-9,10-epoxy-20:H, 400:100 μg) was tested. Additions of 5 or 50 μg of either 6,7-epoxide enantiomer had no discernible effect on the attractiveness of the basic blend.

Eupithecia annulata *Hulst (Geometridae).* The preliminary report of sex attractants for males of this species had implicated monoepoxydienes of chain lengths C_{19-21}, but moths were attracted by a variety of lures, and there was no clear indication of a specific attractant or attractants (Wong et al., 1985).

Further evidence for the role of C_{19-21} monoepoxydienes was obtained from electroantennogram studies with the enantiomers of the *cis*-3,4-, -6,7-, and -9,10-monoepoxydienes of chain length C_{18-22}. Only the *cis*-9,10 epoxides elicited responses greater than 1 mV. The C_{19-22} 3*Z*,6*Z*-9*R*,10*S*-monoepoxydienes elicited male antennal responses of 0.9 $\pm$ 0.1 mV (N = 2), 3.9 $\pm$ 1.7 mV (N = 8), 1.7 $\pm$ 0.6 mV (N = 8), and 0.6 $\pm$ 0.2 mV (N = 2) respectively. The corresponding 9*S*,10*R* series elicited responses of 2.1 $\pm$ 1.1 mV (N = 3), 3.0 $\pm$ 0.8 mV (N = 8), 3.6 $\pm$ 1.1 mV (N = 8), and 1.4 $\pm$ 0.6 mV (N = 3).

GC-EAD studies were conducted with pheromone gland extracts from three field-collected female moths of unknown mating status. The extract from the first female elicited a male antennal response at the retention time of 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H. This was corroborated by analysis of the extracts from the second (Figure 5) and third females, and additional antennal responses were seen at the retention times of 3*Z*,6*Z*,9*Z*-21:H (both extracts) and 3*Z*,6*Z*-*cis*-9,10-epoxy-20:H (second extract only). An FID peak was detected concurrently for the triene in the second extract (Figure 5), but the region of the FID chromatogram where the epoxides eluted was obscured by late-eluting compounds from the previous extract. 3*Z*,6*Z*,9*Z*-20:H was not detected in the extracts either by the FID detector or the antennae; the small peak seen on the FID trace (Figure 5) in the vicinity of the 3*Z*,6*Z*,9*Z*-20:H had a retention time sufficiently different from that of 3*Z*,6*Z*,9*Z*-20:H to be discernible (0.13 min; run-to-run variability of retention times of standards was determined to be $\leq$0.02 min).

When a male antenna was challenged with synthetic standards, strong responses were elicited by the C_{19}–C_{21} *cis*-9,10 epoxides, with weaker responses to the C_{20} and C_{21} trienes and also to the 19–21 carbon 3*Z*,9*Z*-*cis*-6,7-monoepoxydienes (Figure 5, top traces).

Corroborating evidence for the presence of 3*Z*,6*Z*,9*Z*-21:H and 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H in the pheromone gland extract from another field-collected

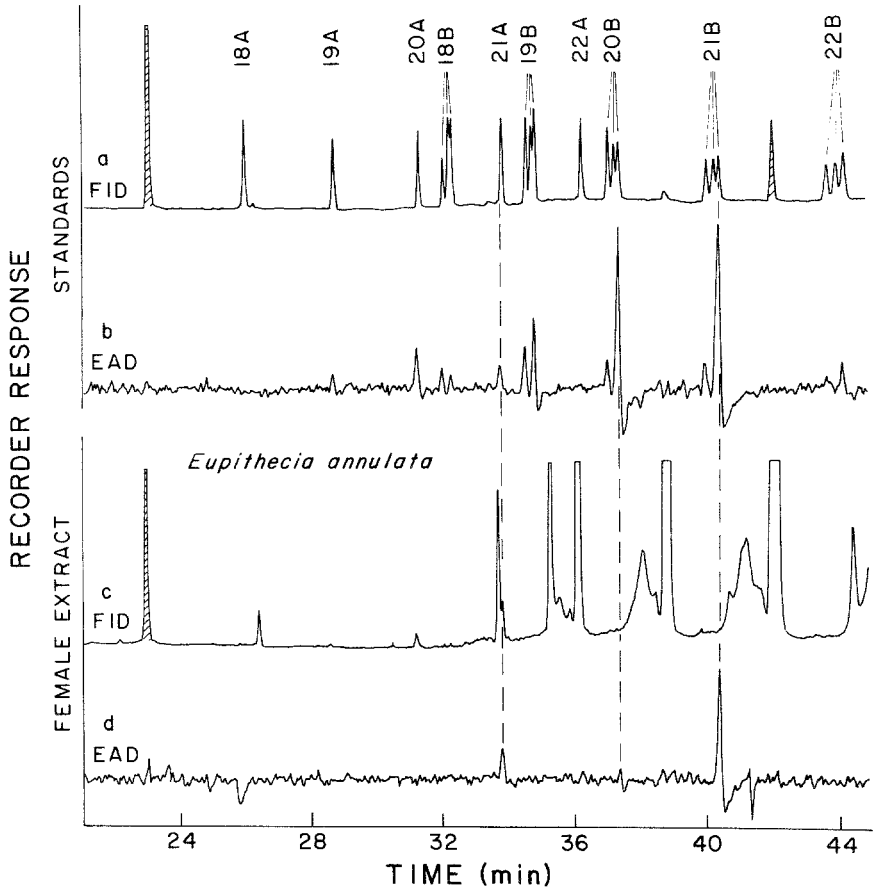

FIG. 5. Response of *Eupithecia annulata* male antennae in GC-EAD experiments using a DB-1701 column. Upper pair of traces are in response to a mixture of C_{18-22} synthetic standards; lower pair are in response to a pheromone gland extract from a conspecific female. Number and letter designations are identical to those of Figure 1. Internal standards (heptadecane and tetracosane) are shaded.

female moth was obtained from chemical ionization (isobutane) GC-MS analysis of the extract, with selected ion monitoring. Retention time matches (DB-5 column) and ion ratios matches versus synthetic standards were obtained for both compounds [3*Z*,6*Z*,9*Z*-21:H, 100 pg standard: *m/z* 291 (100, M+1), 289 (96, M−1); insect extract, *m/z* 291 (100), 289 (92); 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H, 100 pg standard: *m/z* 307 (76, M+1), 289 (100, M+1−18), 275 (23); insect extract: *m/z* 307 (81), 289 (100), 275 (26)]. The homologous 3*Z*,6*Z*-*cis*-9,10-epoxy-20:H was not detected.

In preliminary field tests in 1984, 316 male moths were captured in total. Of these, only one moth was captured in a trap that did not contain either 3*Z*,6*Z*-*cis*-9,10-epoxy-20:H or 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H as a major or single component. In addition, traps containing the regioisomeric 3*Z*,9*Z*-*cis*-6,7- or 6*Z*,9*Z*-*cis*-3,4-epoxydienes caught no moths, confirming that the 9,10 isomers were the attractive regioisomers in the CME-3*Z*,6*Z*,9*Z*-20 or -21:H mixtures.

When tested as single components, 3*Z*,6*Z*-*cis*-9,10-epoxy-21:H and the C_{20} and C_{19} homologs all attracted some moths, while the C_{22} homolog was not attractive at all (Table 2).

A further test demonstrated that 3*Z*,6*Z*-9*S*,10*R*-epoxy-21:H was the attractive C_{21} enantiomer, as three traps baited with this compound (100 μg) caught 60 moths, while traps with the 9*R*,10*S* enantiomer caught one moth. A consecutive experiment (replicated four times) with the C_{20} homologs demonstrated that the 9*S*,10*R* enantiomer of the C_{20} homolog was attractive, catching 119 moths, while the traps baited with the C_{20} 9*R*,10*S* enantiomer caught no moths.

Field tests with blends of the C_{20} and C_{21} 9*S*,10*R* epoxides were inconclusive, as captures in traps containing lures with a variety of blends (1:19 to 19:1) of the two homologs were the same or lower than to 3*Z*,6*Z*-9*S*,10*R*-epoxy-21:H alone, and there was no evident trend in the data as the ratio was changed (data not shown).

During the course of field tests with *E. annulata*, it was noticed that there was considerable variability in the trapping data. For example, in two instances in the field survey, one replicate of a lure caught >70 moths, while the other caught none, suggesting that moth populations may be localized or that the responses might depend on what type of tree a trap was hung on. An experiment was set out to try and explain the variability. One replicate of each lure in the experiment was placed at random in the lower canopy of each of four large black spruce trees (in previous experiments, traps in black spruce had caught moths). The trap captures in this experiment were still variable (Table 3). For

example, in tree 1, the trap catches with the 3Z,6Z-*cis*-9,10-epoxy-20:H and 3Z,6Z,9*S*,10*R*-epoxy-20:H lures were virtually identical (236 and 227 moths, respectively). However, the same lures in tree 4 produced quite different captures (20 and 240 moths, respectively). Similar amounts of variability can also be seen in comparisons of other lures.

DISCUSSION

3Z,6Z,9Z-21:H and 3Z,6Z-*cis*-9,10-epoxy-21:H have been identified as sex pheromone components of *E. cuspidea* by a combination of retention time matches with synthetic standards on two different capillary GC columns (DB-5 and DB-1701), by the EAD response elicited by these compounds in the pheromone gland extracts, and by full-scan Cl mass spectral matches with synthetic standards.

As further proof of the geometry of the double bonds in the triene, a mixture of all possible geometric isomers of 3Z,6Z,9Z-21:H was generated by scrambling the double bonds with nitrous acid (Sonnet, 1974), and GC retention times of all the isomers were compared. Only one isomer (an isomer with two *E* and one *Z* double bonds) of the seven other possible stereoisomers of 3Z,6Z,9Z-21:H had a retention time indistinguishable from 3Z,6Z,9Z-21:H with the GC conditions used.

The evidence for the identification of the other three components from the gland extracts is also strong, consisting of retention time matches on two GC columns, SIM mass spectral matches, and partial matches with full-scan Cl mass spectra of standards. The role of the components is unclear, as only one

compound (3Z,6Z,9Z-20:H) elicited an appreciable EAD response, and in field tests no biological activity could be attributed to either enantiomer of the 3Z,9Z-*cis*-6,7-epoxide component. These compounds may have a function as antagonists in interspecific communication.

In similar fashion, 3Z,6Z,9Z-21:H and 3Z,6Z-*cis*-9,10-epoxy-21:H were tentatively identified in *E. annulata* pheromone gland extracts by retention time and SIM mass spectral matches. The homologous 3Z,6Z-*cis*-9,10-epoxy-20:H was not detected by GC-MS, although an antennal stimulatory compound at this retention time had been detected in GC-EAD studies.

Pheromone gland extracts from *C. distincta* were also complex, with five antennal stimulatory compounds being detected in GC-EAD studies. Tentative evidence for the identifications of these compounds was provided by capillary GC (DB-1701) retention time matches with synthetic standards. We were unable to obtain sufficient numbers of female moths to analyze pheromone gland contents by GC-MS. It is also of interest to note that 3Z,6Z,9Z-20:H and 3Z,6Z,9Z-21:H, blends of which were minimally attractive to *C. distincta*, have been reported to be sex pheromone components of the sympatric congener, *C. erechtea* (Underhill et al., 1983).

It must be emphasized that the chiral compounds used in this study were highly enantiomerically enriched but not enantiomerically pure (approx. 96:4 ratio of enantiomers). The possibility that some of the results described were actually due to the blend of the major enantiomer admixed with the small amount of enantiomeric impurity, rather than to the major enantiomer alone, cannot be discounted.

Our objective in conducting the research described here and previously was to delineate the general types and patterns of pheromone components in the Geometridae, Noctuidae, and Arctiidae. We have not definitively elucidated the intricate details of the pheromone chemistry of one particular species, but rather have tried to define in general terms the types of compounds that may be active as pheromone components for a number of species, as demonstrated for the three species described here. In particular, the pheromone chemistry of the species reported here is complex, with extracts from pheromone glands containing as many as five components producing stimulation of male moth antennae in GC-EAD studies. In addition, the chirality of each of the epoxide compounds, which can exist in either of two enantiomeric forms, further complicates the elucidation of the correct pheromone blend. In several cases, it has been shown that moths produce and/or respond to blends of enantiomers (Hansen, 1984; Millar et al., 1990d, 1991a) and so the single peak seen for an epoxide in GC traces should realistically be considered as a possible blend of the two enantiomers until proven otherwise.

At this point, the significance of the components in the pheromone gland that elicit strong EAD responses but that have no apparent effect on the attrac-

tiveness of a blend to which they have been added is not clear. They may have some subtle function in courtship or close-range interactions, which may not be apparent from our relatively crude bioassay criterion of the number of insects caught in a trap. Alternatively, the presence of the compounds in the glands does not necessarily mean that they are actually released by calling females. For example, 3*Z*,6*Z*,9*Z*-19:H was identified several years ago from pheromone gland extracts of the giant looper *Boarmia selenaria* Schiffermüller and was reported as a pheromone component of this insect (Becker et al., 1983) based on EAG data. However, field tests later showed that this compound was not attractive in field or wind-tunnel tests and that the attractive pheromone component produced by calling female moths was actually 6*Z*,9*Z*-3*S*,4*R*-epoxy-19:H (Becker et al., 1990).

The strong antennal responses generated by challenging *C. distincta* antennae with 3*Z*,9*Z*-*cis*-6,7-epoxy-21:H are inexplicable at this point, because this compound was not found in pheromone gland extracts nor did it have any discernible effect on trap captures in field tests. A strong antennal response would suggest that there is a reason for the persistence of this detection capability in the insect. That is, one would not expect the capability to detect the 6,7-epoxides to persist unless these compounds were either conspecific pheromone compounds or behavioral antagonists produced by congenerics to prevent cross-attraction. It is also inexplicable that *E. annulata* antennae responded maximally to 3*Z*,6*Z*-9*R*,10*S*-epoxy-20:H of all the compounds tested in EAG studies, especially as this compound was not attractive in field trials nor did it appear to be strongly antagonistic, as numerous moths were caught over several field seasons in traps with lures containing 3*Z*,6*Z*-*cis*-9,10-epoxy-20:H, alone or in combination with other components (Table 2, for example).

In all cases reported here, the principal bioactive epoxides have the 9*S*,10*R* configuration. This configuration has been reported in the majority of *cis*-9,10 epoxide pheromone components and sex attractants for which the chirality of the attractive enantiomer has been investigated. For example, in EAG studies, the arctiid male moths *Estigmene acrea* Drury and *Hyphantria cunea* Drury (Mori and Ebata, 1981), *Cymbalophora pudica* Esper, and *Tyria jacobaeae* L. (Frérot et al., 1988a,b) all give stronger antennal responses to the 9*S*,10*R* enantiomer of their epoxide pheromone components than to the opposite enantiomer, and the configuration of the pheromone component in the first species has been proven by comparison of the circular dichroism and optical rotatory dispersion spectra with those of synthetic standards (Mori and Ebata, 1981). On the other hand, Wong et al. (1985) reported 9*S*,10*R* epoxide sex attractants for one geometrid and two noctuid species, and 9*R*,10*S* epoxide attractants for another two geometrid and one noctuid species. In addition, Wong et al. (1985) reported that the geometrid species *Cabera erythemaria* Guenée was attracted to a racemic blend of the enantiomers of 3*Z*,6*Z*-*cis*-9,10-epoxy-19:H, rather than

to either enantiomer alone. Thus, at this point it would appear that there is no clear biosynthetic bias for one epoxide enantiomer over the other.

The variability seen in the trap captures in the final experiment conducted with *E. annulata*, in which a set of one replicate of each treatment in the experiment was placed in each of four different trees, is inexplicable. Our hypothesis that the variability seen in previous field tests with this species would be decreased by standardizing trap placement, that is, by removing the effects of localized populations or host tree effects, was not supported. It is also unlikely that wind direction affected the trap captures, as the traps were set out for several days in an area of variable wind direction. In addition, the traps were rerandomized during the course of the experiment, to minimize effects due to wind direction and to nearest-neighbor traps. It is clear that populations were localized and nonrandomly distributed, as the overall trap captures per tree varied over an order of magnitude.

Acknowledgments—We gratefully acknowledge the assistance of Lawrence Hogge with mass spectral runs, and the assistance of Ian Warkentin, David Charest, and Leah Richardson with field testing.

SELECTIVE ODOR PERCEPTION IN THE SOIL COLLEMBOLA *Onychiurus armatus*

GÖRAN BENGTSSON, KATARINA HEDLUND,* and STEN RUNDGREN

Department of Ecology
University of Lund,
S-223 62 Lund, Sweden

(Received February 27, 1991; accepted July 3, 1991)

Abstract—The olfactorial response of the fungivorous soil collembolan *Onychiurus armatus* was examined in a bioassay covering volatile compounds identified in the odor blends of two of its preferred fungal species *Mortierella isabellina* and *Verticillium bulbillosum*. The odor of the fungi was trapped using activated carbon filters, extracted with diethyl ether, and subjected to GC-MS analysis. About 50% of the compounds resolved by GC were identified by a combination of electron impact and chemical ionization mass spectrometry. In a Y-shaped olfactometer the collembolans were attracted to a variety of common odors, such as CO_2 and 2-methyl-1-propanol, and a species-specific odor, such as 1-heptene, and arrested by, for example, decanal and 2-octene. The response was not improved by pairwise combinations of common and specific odors. An amount of 0.5 ng of ethyl acetate or 3 pg of 1-pentanol was sufficient to attract the collembolans. The specific compounds of *V. bulbillosum*, 1-heptene and 1-octen-3-ol, may be key stimuli explaining why *O. armatus* prefers *V. bulbillosum*.

Key Words—Fungal volatiles, GC-MS, *Mortierella*, *Verticillium*, olfactorial, attractants, fungivor, Collembola, *Onychiurus armatus*.

INTRODUCTION

The process of optimal foraging through habitat selection is catalyzed in insects by different perception mechanisms, enabling them to recognize an array of stimuli associated with specific food sources. Soil-living Collembola, are known to feed selectively on fungi (Leonard, 1984; Newell, 1984; Bengtsson et al.,

*To whom correspondence should be addressed.

0098-0331/91/1100-2113$06.50/0

1985), rank fungal species hierarchically in order of decreasing palatability (Shaw, 1988), and use odors to discriminate between species (Bengtsson et al., 1988). Mycelia produce volatile compounds formed via normal metabolic activities (Karahadian et al., 1985; Watson et al., 1986; Talou et al., 1987), but the odor blend differs with growth substrate (Bengtsson et al., 1988) and age of the colony (Karahadian et al., 1985).

The resolution power of the perception system of collembolans is not known. It is possible that the odor blend in general is used to distinguish between patches with relatively high and low microbial activity. In addition, animals may be attracted (sensu Barton Browne, 1977) to compounds that are species specific. A specificity may be achieved by single compounds that are only found in related species or by a specific ratio between compounds that are generally distributed among many species (Visser, 1986).

The collembolan *Onychiurus armatus* (Tullb. sensu Gisin, 1960) is a euedaphic species that is common in temperate soils. It is fungivorous and when given a choice among five species of soil fungi, it ranked *Verticillium bulbillosum* as the most palatable one followed by *Paeciliomyces farinosus* and *Mortierella isabellina* (Bengtsson et al., 1985). In an olfactometer test *O. armatus* preferred the odor of *V. bulbillosum* when the fungi grew on agar, but preferred that of *M. isabellina* when the growth substrate was soil (Bengtsson et al., 1988). The purpose of this work was to extend the examination of the odor blend of *M. isabellina* and *V. bulbillosum* by identifying individual odor components and evaluating their potential as olfactorial stimuli for *O. armatus*. The hypothesis was that the attraction to an odor source is triggered by a mixture of compounds associated with fungal metabolism in general and reinforced by some species specific substances that can be used for finer ranking.

METHODS AND MATERIAL

Collembolans and Fungal Cultures. Onychiurus armatus was extracted from a mor horizon of a spruce forest soil in southeastern Sweden. Cultures of the collembolans were kept in Petri dishes with a layer of plaster of Paris/charcoal (9:1, v/v) at 12°C and in darkness and fed hyphae of *Mortierella isabellina* (Oudem).

The fungi *M. isabellina* and *Verticillium bulbillosum* (W. Gams and Malla) were grown on a 5-mm layer of either soil or agar (2% agar, 2% malt extract, 30 μg/ml chlortetracycline) in 100-ml glass vials with a bottom area of 18 cm^2. The soil, a spruce forest mor, was sterilized in a 10 MeV electron accelerator with a dose of 45 kGy. Agar and soil were inoculated with a spore suspension, and the vials were sealed with a silicon septum and incubated at 15°C for one

week to ensure that the mycelium extended to the edge of the vials without apparent loss of activity in old parts.

Trapping of Volatiles. Two sterile syringes were pierced through the silicon septum and one of them (air outlet) was connected to a suction pump by Teflon tubing. Air was drawn into the vial through the other syringe (air inlet), that was connected by Teflon tubing to an activated carbon filter (4 cm OD, 12 cm long), to remove traces of volatiles in the incoming air. Fungal odor substances were trapped by sucking 100 ml of air from the culture vial through a 2-mm-thick layer of activated carbon that was sandwiched between disks of 300 mesh stainless steel mesh and fused into a 7-mm ID Pyrex tube. The activated carbon filter was placed between the air outlet and the suction pump, and the volatiles of 10 replicate vials were extracted with 3 × 20 μl diethyl ether (Merck). The extracts were kept in 3-mm OD glass capillaries at −20°C until analysis. Odors from sterile vials with agar and soil substrates, respectively, were trapped, extracted, and used as blanks. Aliquots of 10 μl were saved for GC-MS analysis without further purification.

Derivatization. Aliphatic alcohols in the extracts were derivatized with heptafluorobutyric anhydride (HFBA), as the resulting derivative is stable for molecular weight determination by GC-MS (Hogge and Olsson, 1982). HFBA (1 μl) was added to 10 μl of the extract and mixed in glass capillaries for 30 sec by repetitive refilling of a 10-μl Hamilton syringe. The reaction was completed after 5 min at room temperature. Excess reagent was removed by washing the derivative twice with 10 μl 0.1 M NaOH. The two phases were separated by centrifugation (500 *g*). The samples were kept in sealed glass capillaries at −20°C.

Gas Chromatography and Mass Spectrometry. A Varian 3700 GC with a flame ionization detector (FID) and a 25-m fused silica capillary column coated with SE-54 was used for analysis. The carrier gas, hydrogen, had a flow rate of 1.5 ml/min. The injector temperature was 250°C and the detector 300°C. The first 5 cm of the column was cooled 1 min before and after injection by sliding a solid aluminum cylinder (4 cm diam., 5 cm long) halfway onto the column by a vertical slit in the cylinder. The cylinder was kept at −20°C before the injection, which was made in splitless mode. Conditions for the oven were 45°C for 5 min and then programming at 2°C/min to 180°C.

The mass spectrometer was a Ribermag R10-10C quadropole instrument equipped with a Carlo Erba model 4160 GC. Helium was used as carrier gas at 40 ml/sec. Gas chromatographic conditions were as described for FID. The mass spectrometer was operated in the positive ion electron impact ionization mode (EI) at 75 eV. EI was used to get total ion spectra of underivatized odor extracts. Positive ion chemical ionization (pos. CI) was used to determine molecular weights of compounds from underivatized odor extracts that would

not produce stable molecular peaks by EI. The reagent gas, ammonia, was ionized with electrons at 45 eV. HFBA derivatives were analyzed by negative ion chemical ionization (neg. CI) with isobuthane as a reagent gas ionized with electrons at 90 eV.

Bioassay. Synthetic odor substances (pro analysis) of volatiles identified from *M. isabellina* and *V. bulbillosum* and some general microbial metabolites were assayed in a Y-shaped olfactometer made of a glass tube (10 mm ID) with 4-cm-long arms (angle of 45°) and a base of 2 cm. The glass surface was roughened on the inside to facilitate movements of collembolans and to hold water to prevent desiccation. A 2-cm-long glass tube, the release chamber, was connected at one end with clamps to the base of the Y and at the other end fitted to a 30-cm-long Teflon tubing connected to a flowmeter and a suction pump. The end of each arm was connected with clamps to two glass tubes in a series. The first one (2 cm long) held a 1-cm^2 piece of filter paper (Munktell, 1F) with the odor substance or a pure solvent, diethyl ether, as blank and the second one (3 cm long) was filled with activated carbon to provide clean air. An odor substance diluted in diethyl ether was deposited on a filter paper and the solvent was allowed to evaporate at room temperature for 1 min before the filter paper was placed in one side arm of the olfactometer and the blank, a filter paper with only solvent applied, in the other. Seven adult *O. armatus* were placed in a release chamber that was sealed with parafilm and were kept there for 15 min. Air was drawn through the Y-tube at a rate of 3 ml/min for 2 min using an empty release chamber, which was then replaced by the one with collembolans. Each group of *Onychiurus* was exposed to the odor for 10 min in darkness at 15°C in the horizontally positioned Y-tube. The numbers of collembolans present in the side arms or remaining in the release chamber were counted and compared with an expected distribution by a chi-square test, using the null hypothesis that animals were equally distributed in side arms and release chamber. All comparisons were made from six replicate observations. A substance was considered attractive if more than half the collembolans had left the release chamber and significantly more of them were present in the arm facing the odor than in the one with the solvent. When more than half of the collembolans left the release chamber and were found in the blank, the odor was regarded as a repellent. A substance was arresting to the collembolans when significantly more than half of them remained in the release chamber.

The amount of odor released from a filter paper during the olfactometry test was estimated by determining the evaporation rate of 50 μl of ethanol, ethyl acetate, and 1-pentanol, respectively, in 100-ml glass vials at room temperature. The vials were weighed repeatedly during 125 min, and the amount that evaporated during 10 min was calculated by linear regressions of logarithmic amounts of the odor versus time.

RESULTS

V. bulbillosum produced approximately equal numbers of odor substances regardless of the substrate, whereas *M. isabellina* emitted twice as many when grown in soil (Figure 1). Identified volatiles had a relatively low molecular weight ranging from 74 up to 152. Substances with molecular weights lower than 74 were not considered since they were obscured by the solvent peak. Aliphatic alcohols and alkenes were the most common volatiles, followed by ketones and aromatic substances (Table 1). The structure of the alcohols was suggested from the abundance of $C_nH_{2n-1}^+$ and C_n H_{2n}^+ ion series, although the EI spectra were inconclusive due to the decomposition of the molecular ion. As an example, the EI spectra of peak 11 in Figure 1 showed $C_nH_{2n}^+$ ion series at larger masses (Figure 2A), indicating a possible molecular ion at m/z 130. Analysis by neg. CI of HFBA derivative revealed the molecular weight of the alcohols based on the abundance of the fragment representing a loss of HF from the molecular ion (Figure 2B). More than 50% of the peaks remained unknown due to low ion abundance and poor spectral purity. Among the substances identified, 2-methyl-1-propanol, α-pinene, 1-phenylethanone, 2-octene, and decanal were present as volatiles from both species and independent of growth substrate (Table 1). Species-specific odors of *M. isabellina* were identified as pentanone, 3-methyl-1-butanol, γ-octalone, 1-methylphenylethanone and camphor, while *V. bulbillosum* emitted 1-heptene and 1-octen-3-ol.

Two thirds of the tested substances attracted *O. armatus* at one or more of the applied doses (Table 2). The collembolans were attracted to 2-methyl-1-propanol that was produced by both fungi as well as to other common fungal metabolites, e.g., CO_2 and 2-propanol (Table 2). Only one substance specific to *V. bulbillosum*, 1-heptene, attracted the collembolans. 2-Methyl-1-propanol and camphor attracted the collembolans at the highest dose applied and were the only tested substances with a negative correlation between dose and response. Half of the identified odors were neutral or arrested the collembolans in the olfactometer. All amounts of decanal and 2-octene tested arrested collembolans while 2-pentanone and α-pinene did not elicit any behavioral response at all.

Pairwise combinations of the general odors methanol and ethanol and the specific odors 1-octen-3-ol and camphor did not increase the numbers of attracted collembolans compared with the numbers attracted to a single odor (Table 3). A combination of 10 ng camphor and 10 ng methanol arrested the majority of the collembolans in the release chamber, and those leaving were repelled from the odor into the side arm with a blank. At the highest dose applied, 25 ng camphor and 25 ng methanol, the collembolans were repelled from the release chamber to the side arm with the blank.

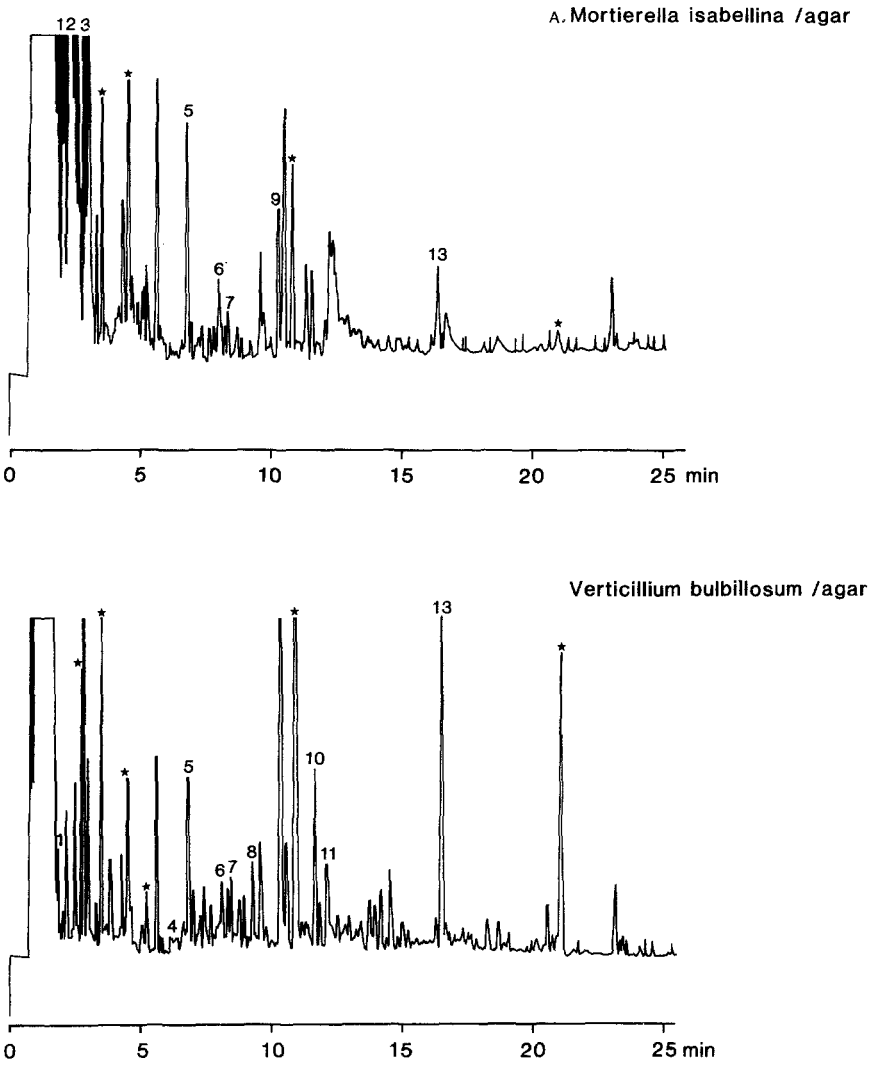

FIG. 1. Gas chromatograms of volatiles trapped from cultures of *Mortierella isabellina* and *Verticillium bulbillosum* (A) grown on 2% malt extract agar and (B) grown in soil. Identified compounds are numbered and listed in Table 1.* Volatiles present in vials with sterile agar or soil.

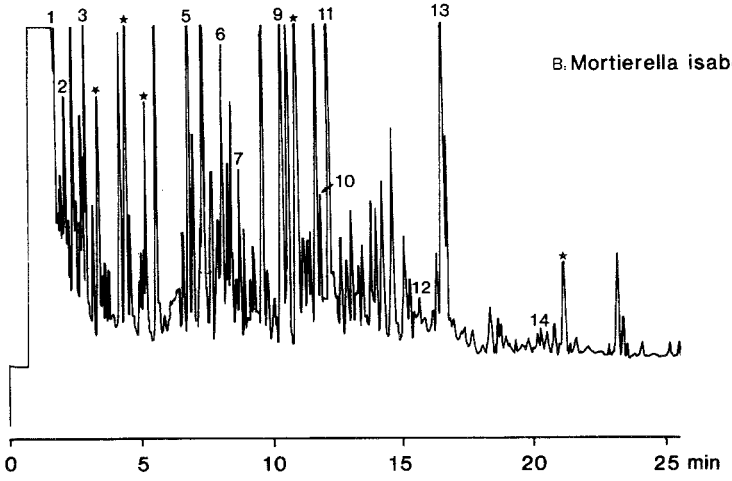
The actual amount of an odor reaching the collembolans was lower than the dose applied. About 0.5 ng evaporated from 1 ng of ethanol or ethyl acetate during 10 min, while only 3 pg evaporated from 1 ng of the less volatile substance pentanol.



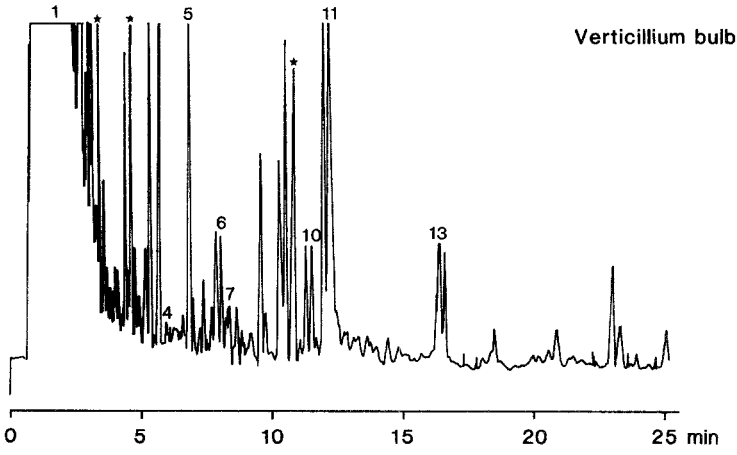


FIG. 1. *Continued*

DISCUSSION

The ability to perceive general compounds of microbial activity that are produced along common biosynthetic pathways, such as CO_2, ethanol, and 2-methyl-1-propanol (Williams et al., 1981; Zechmann et al., 1986; Talou et al., 1987), should help *O. armatus* in locating patches with high microbial activity. Collembolans are known to move towards sources of CO_2 (Moursi, 1962), which they locate in a similar way as plant parasitic nematodes find CO_2-

[a]The numbers refer to Figure 1.

emitting roots in soil (Klinger, 1965) or insect parasitoids locate the yeast in which their drosophilid hosts live (Vet et al., 1984). It is possible that a release of general fungal odors is perceived by collembolans and enables them to navigate among fungal patches in the habitat just as general plant odors, e.g. certain alcohols and aldehydes, are used in habitat selection by herbivorous insects (Visser, 1986). On the other hand, substances that characterize a specific fungus may be found among higher alcohols and less volatile substances, which can be synthesized by decomposition of the substrate (Kana et al., 1988) and be both species- and habitat-specific. These volatiles can aid the collembolans in their search for a palatable fungus within a patch of enhanced microbial activity. *O. armatus* preference for *V. bulbillosum* in comparison with *M. isabellina* (see Bengtsson et al., 1988), may be explained by the perception of 1-heptene and 1-octen-3-ol. The attraction to *M. isabellina* growing in soil may be associated with its production of camphor and 1-methylphenylethanone.

However, substances that in the present study appear to be species-specific also occur in odors of other microorganisms. 3-Methyl-1-butanol is produced by fungi (Kaminski et al., 1974, Sinha et al., 1988) but also by bacteria (Williams et al., 1981) and yeasts (Kana et al., 1988). 1-Octen-3-ol is produced by basidiocarps (Vanhaelen et al., 1980) and hyphae of other species (Kaminski

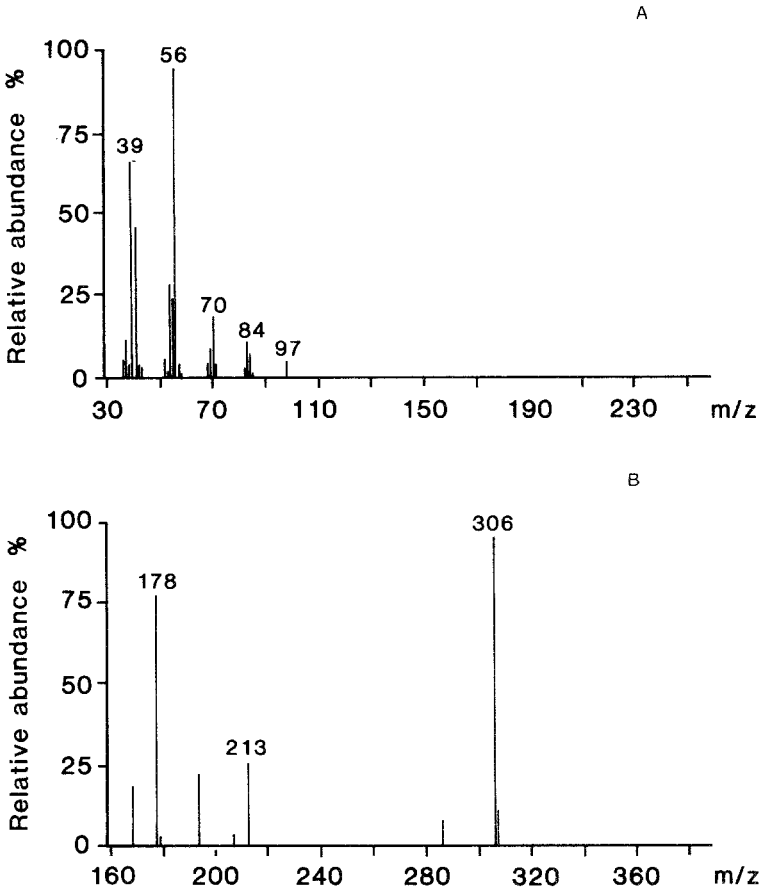

FIG. 2. (A) Electron impact mass spectra of 1-octanol (peak 11 in Figure 1) emitted by *Mortierella isabellina* grown in soil. (B) Negative ion (isobuthane) chemical ionization mass spectra of HFB *o*-acyl derivatives of 1-octanol from *M. isabellina*. The fragment 306 (*m/z*) is M-HF.

et al., 1974; Sinha et al., 1988). Camphor and γ-octalone are not reported from other fungi, but γ-octalone is produced by the yeast *Pityrosporum* (Labows et al., 1979). The specificity of the food choice of the collembolans may be further explained by some of the unknown odors, as 50% of the substances in the odor plumes are unidentified. However, a living fungus attracted about 50% of the collembolans (Bengtsson et al., 1988), which corresponds to their response to a single odor substance. Unless the specificity of the perception system increases, the response to the identified odors is sufficient to explain the response to the mycelium.

TABLE 2. PROPORTION OF *Onychiurus armatus* IN SIDE ARM OF Y-SHAPED OLFACTOMETER WITH ODOR SUBSTANCE AT 1, 10, OR 25 ng[a]

Substance	Proportions of collembolans in the side arm (%)		
	1 ng	10 ng	25 ng
Methanol	42.2[1b]	41.5[1]	39.5
Ethanol	18.6[3]	41.3[2]	4.9[3]
2-Propanol	34.1[1]	53.5[1,2]	21.4
2-Methyl-1-propanol	19.0[4c]	28.6	47.6[1,2]
2-Methyl-1-butanol	31.7	43.9[2]	17.1
1-Pentanol	55.9[1,2]	33.3	11.4[c]
1-Octen-3-ol	37.5[1]	2.9[c]	33.3
1-Octanol	38.1	7.1[c]	44.2[2]
Phenylethanol	7.0[c]	n.d.[d]	15.5[c]
Camphor	4.8[c]	10.0	39.0[2]
2-Pentanone	28.6	14.3	9.7
n-Decanal	26.2	21.4	16.7[c]
α-Pinene	33.3	35.7	26.2
1-Heptene	21.4	51.2[1,2]	9.8[c]
2-Octene	4.9[c]	2.4[3]	0.0[c]
Dipentene	7.1	14.3[3]	23.8
Ethyl acetate	43.6[1]	33.3	14.3
Carbon dioxide[e]	45.5[1,2]		

[a] The substances are given in order of chemical classes and molecular weights. The proportions were determined from the sum of six replicates with seven collembolans in each replicate.

[b] [1)]Significantly more ($P < 0.05$) than 50% of the collembolans moved out of the release chamber and [2)]were attracted to the arm with a substance or [3)]repelled to the side arm without odor substance.

[c] Significantly more ($P < 0.05$) than 50% of the collembolans were arrested in the release chamber.

[d] n.d. = not determined.

[e] Tested as 1% CO_2 in air.

Compounds that arrest the collembolans in the olfactometer, such as decanal and 2-octene, and those that attract at low and arrest at high concentrations, such as 1-pentanol and 1-heptene, can elicit a stop for searching and trigger feeding on a palatable fungus. Such mixed functions of odorous compounds are known from the host searching behavior of parasitoids (Waage, 1979), feeding of herbivorous insects (Miller and Strickler, 1984), and prey encounters by predatory mites (Sabelis et al., 1984).

The minimum amount of odor needed to elicit a response of collembolans in the olfactometer test was 1 ng. Other fungivores, for instance, nematodes were attracted to 0.1 ppm ethyl acetate in water agar (Balan, 1985) and *Drosophila* to 100 ppm of acetaldehyde in water (Hoffmann and Parsons, 1984). However, in a comparison with the total amounts of highly volatile odor sub-

TABLE 3. PROPORTION OF *Onychiurus armatus* IN SIDE ARM OF Y-SHAPED OLFACTOMETER WITH COMBINATION OF TWO ODOR SUBSTANCES AT 1 + 1, 10 + 10, AND 25 + 25 ng[a]

Substance	Proporation of collembolans in side arm (%)			
	1 + 1 ng	10 + 10 ng	25 + 25 ng	Other amounts
Camphor + methanol	26.2	2.4[b,c]	19.0[1,3b]	7.1[3] (25 + 1 ng)
Camphor + ethanol	19.0	33.0	14.3	14.3[3] (25 + 10 ng)
1-Octen-3-ol + methanol	11.9[3]	40.5	16.7[c]	
1-Octen-3-ol + ethanol	14.3[3]	19.0	19.0	40.5 (1 + 10 ng)

[a] The proportions were determined from the sum of six replicates with seven collembolans in each replicate.
[b] See footnote [b] of Table 2.
[c] See footnote [c] of Table 2.

stances applied in the tests, the collembolans have the lowest threshold for a response, as the dose was 1 ng, while that presented to the nematodes was about 20 ng (data estimated from Balan, 1985). The actual amount of odor reaching the collembolans was lower than the dose applied on the filter paper, as only 3 pg evaporated from 1 ng pentanol during 10 min. The minimum amount of odor needed to attract collembolans can be used to estimate the scale and distance on which collembolans find patches of food in natural soil.

Amounts as well as qualitative differences of volatiles can be used as keys of recognition by collembolans, as the proportions of the volatiles emitted from *V. bulbillosum* and *M. isabellina* differ between the species as well as between their growth substrates. Interspecific variation in amounts of fungal volatiles has been shown by Vanhaelen et al. (1980), who found that the proportion of 1-octen-3-ol from fruit bodies of 15 basidiomycete species varied from 0.4% to 22%. The amounts of volatiles emitted by a fungus also decrease with its age (Karahadian, et al. 1985), which may explain why collembolans discriminate old hyphae in favor of young ones (Leonard, 1984).

The number of volatiles that can be distinguished by a collembolan and the number of sensilla that are needed for food recognition are still unknown. Wright (1964) suggested that a bee could survive if it was able to recognize a minimum of six odors, but a rather immobile larva of the polyphagous caterpillar *Manduca sexta* can distinguish between 3^{23} combinations of odors (Schoonhoven, 1968). Whether a single key substance, a blend of substances, or the concentrations of fungal volatiles make *Onychiurus* able to choose a palatable fungus is unknown. The decisions are assumed to be based on the integration of inputs from a number of receptors with different sensitivity

(Chapman, 1988). It is unlikely, as remarked by Dethier (1947), that a single attractant guides insects to their food, but the location of food is achieved by a complex array of stimuli, involving soil humidity and temperature.

(Received April 6, 1991; accepted July 3, 1991)

Abstract—Male American palm weevils (APWs), *Rhynchophorus palmarum* (L.) produced two sex-specific compounds, which were disclosed by volatile collections on Supelpak-2 and gas chromatography. One was a minor compound, not always detected. The major male-produced volatile was identified as (2*E*)-6-methyl-2-hepten-4-ol through coupled gas chromatography–mass spectrometry and gas chromatography–Fourier transform infrared spectrometry, proton nuclear magnetic resonance spectrometry, and rational synthesis. We propose the trivial name rhynchophorol for this new molecule, which proved to be the essential component of the APW aggregation pheromone by electroantennography, coupled gas chromatography–electroantennography and behavioral bioassays.

Key Words—Aggregation pheromone, Coleoptera, Curculionidae, *Rhynchophorus palmarum*, American palm weevil, (2*E*)-6-methyl-2-hepten-4-ol, synthesis.

INTRODUCTION

The American palm weevil (APW), *Rhynchophorus palmarum* (L.), is a major pest of coconut and oil palm crops in tropical America and the West Indies (Lepesme et al., 1947; Genty et al., 1978). It is occasionally a pest on sugarcane (Restrepo et al., 1982). APW adults cause indirect damage to palm trees by vectoring the nematode responsible for red ring disease (Griffith, 1987). Direct damage is also caused by the larvae that develop in the stems, buds, and rachis of leaves and inflorescences of cultivated, ornamental, or wild palm trees (Lepesme et al., 1947; Wattanapongsiri, 1966). The only way to prevent red ring disease is to eliminate the adults and larvae of the APW since the difficulty and cost of nematicide treatments are extreme.

Despite its economic importance, few studies have been devoted to the chemical ecology of this weevil (Hagley, 1965). The APW is very large (35–50 mm long), hard to observe in the field, and difficult to manipulate in the laboratory. The endophytic development of the larvae (three to six months) in palm or sugarcane stems makes this species particularly difficult to rear in the laboratory, especially in temperate countries where natural food plants are not available.

Rochat et al. (1991) reported field and laboratory evidence documenting the existence of a male-produced aggregation pheromone in the APW. This species belongs to the second genus in the Rhynchophorinae for which pheromone-based communication has been reported. Pheromones in the Rhynchophorinae have been studied previously in the sole genus *Sitophilus* (Faustini et al., 1982; Phillips and Burkholder, 1981; Phillips et al., 1985, 1987, 1989; Walgenbach et al., 1983, 1987; Walgenbach and Burkholder, 1986).

This paper describes the collection, electrophysiological activity, and behavioral bioassays of the male-produced volatiles; and the identification, synthesis, and biological activity of the essential component of the APW aggregation pheromone.

METHODS AND MATERIALS

Insects and Volatile Collections. APWs were obtained from a laboratory colony reared on sugarcane. The colony originated from mixed strains from Colombia and Guadeloupe. Eclosed adults were separated by sex, kept individually (27 $\pm$ 2°C and 85 $\pm$ 10% relative humidity, in a 12:12 hr light–dark regime) in cylindrical plastic boxes (105 $\times$ 75 mm) with a wire mesh cover, and fed with sugarcane.

Five virgin APW males or females were placed in a cylindrical glass jar (6 $\times$ 22 cm) with three sugarcane pieces. Three pieces of the same size and from the same stem were placed in a similar jar as a control. The volatiles

emitted by APWs and/or sugarcane were simultaneously trapped in two glass cartridges connected downstream to the jars for two days (procedure 1) or one day (procedure 2). Each cartridge was filled with 0.5 g (procedure 1) or 0.2 g (procedure 2) of Supelpak-2 adsorbent (16/50 mesh; Supelco). The volatile collections were performed at 27 ± 2°C with a 12:12 hr light–dark regime. Air was passed at 500 ml/min through the glass systems. In procedure 1, the cartridges were eluted with 2.5 ml of methylene chloride (HPLC grade, Waters). The eluates were concentrated at 100 μl under nitrogen (150 ml/min) and used in pitfall bioassays. In procedure 2, the cartridges were eluted with 1 ml of methylene chloride and the extracts were used in electroantennography and for analytical investigations. Ten and 50 volatile collections were made using procedures 1 and 2, respectively. All extracts were stored at −30°C until use.

Analysis of Volatiles. Natural and synthetic volatiles were analyzed on a Carlo Erba Fractovap 2900 chromatograph equipped with 25-m × 0.32-mm-ID fused silica capillary columns coated with a polar phase (WCOT FFAP CB, Chrompack; temperature program: 35 to 55°C at 20°C/min, 8 min at 55°C and 55 to 220°C at 5°C/min) or a nonpolar phase (WCOT CPSil 8CB, Chrompack; temperature program: 35 to 60°C at 25°C/min, 5 min at 60°C, and 60 to 250°C at 5°C/min) with helium as carrier gas.

Gas chromatography–mass spectrometry (GC-MS) analyses were performed with a Girdel 32 chromatograph coupled to a R10-10C Nermag quadrupole mass spectrometer. The chromatograph was equipped with a fused silica capillary column (25 m × 0.32 mm ID; WCOT CPSil 5CB, Chrompack) and operated isothermally at 60°C. The electron impact (EI) was realized at 70 eV. The chemical ionization (CI) was obtained using ammonia as reactant gas at 92.5 eV.

Gas chromatography–Fourier transform infrared spectrometry (GC-FTIR) was carried out with a IFS-85 spectrometer coupled to a HRCG 5160 Carlo Erba chromatograph equipped with a fused silica capillary column (30 m × 0.32 mm ID; WCOT DB-5, J&W Scientific) heated from 30 to 170°C at 10°C/min. The light pipe was heated at 220°C.

Proton nuclear magnetic resonance spectrometry ([^{1}H]NMR) spectra of the natural major pheromone compound of APW males (R1) and synthetic compounds I–III (below) were recorded with a Brucker AC 400 spectrometer in C_6D_6 (99.93%, CEA, France). R1 (ca. 50 μg) was obtained by micropreparative capillary GC performed on a Girdel 300 chromatograph equipped with a 15-m × 0.53-mm-ID fused silica column (WCOT DB-5; J&W Scientific) and operated isothermally at 70°C. The splitting of crude extracts and the collections of R1 were performed with a Malosse (1990) fraction collector.

Chemical Synthesis. Racemic (2*E*)-6-methyl-2-hepten-4-ol (I), (2*E*)-5-methyl-2-hepten-4-ol (II), and (2*E*)-2-octen-4-ol (III) were synthesized by reacting crotonaldehyde at −10°C in THF with Grignard reagents of isobutyl

bromide, 2-bromobutane, and 1-bromobutane to give the corresponding alcohols I–III as confirmed by GC-MS and [^{1}H]NMR spectrometry (For proton number, see Figure 4).

Compound I showed EI ions at *m/z* (% relative abundance) 113 (2), 110 (3), 95 (8), 86 (8), 85 (6), 71 (100), 69 (8), 67 (11), 57 (10), 53 (8), 43 (20), 41 (21). I had [^{1}H]NMR δ (ppm) at 0.88 (d, 3H; H-8), 0.91 (d, 3H; H-7), 1.22 (ddd, 1H; H-5′) 1.44 (ddd, 1H; H-5), 1.5 (dd, 3H; H-1), 1.77 (m, 1H; H-6), 3.97 (m, 1H; H-4), 5.41 (m, 2H; H-2, H-3) with the following coupling constants (Hz): $J_{1-2} = 5$, $J_{1-3} = 0.8$, $J_{4-5} = J_{4-5'} = 8$, $J_{5-5'} = 13.5$, $J_{5-6} = J_{5'-6} = 6$, $J_{6-7} = J_{6-8} = 4.2$.

Compound II showed EI ions at *m/z* 110 (2), 100 (3), 95 (3), 81 (3), 71 (100), 69 (8), 57 (6), 53 (7), 43 (12), 41 (13). II had [^{1}H]NMR δ (ppm) at 0.89 (t, 3H; H-7), 0.95 (d, 3H; H-8), 1.25 (m, 2H; H-6), 1.55 (de, 3H; H-1), 3.75 (td, 1H; H-4), 5.45 (dd, 2H; H-2, H-3) with the following coupling constants (Hz): $J_{1-2} = 5.6$, $J_{1-3} = 2$, $J_{2-3} = 15$, $J_{3-4} = 5.4$, $J_{4-5} = 14.5$, $J_{4-OH} = 5.5$, $J_{5-8} = J_{6-7} = 6.8$.

Compound III showed EI ions at *m/z* 113 (2), 110 (3), 95 (2), 86 (12), 81 (8), 71 (100), 69 (9), 58 (8), 57 (7), 53 (9), 43 (14), 41 (17). III had [^{1}H]NMR δ (ppm) at 0.9 (t, 3H; H-8), 1.19–1.52 (m, 6H; H-5, H-6, H-7), 1.55 (de, 3H; H-1), 3.89 (m, 1H; H-4), 5.44 (dd, 2H; H-2, H-3) with the following coupling constants (Hz): $J_{1-2} = 5.9$, $J_{3-4} = 6.3$, $J_{4-5} = 6.4$, $J_{7-8} = 6.8$.

Compounds I–III were purified to >90% by distillation at 70°C and 10 mm Hg, as checked by GC-MS. I was further purified by HPLC using a Waters Associates model 510 chromatograph equipped with a 0.3 × 10-cm column (Silica normal phase, 8-μm particles; Chrompack). Compounds were detected with a differential refractometer R 401 (Waters Associates). The final purity of I was >99%. Racemic 6-methyl-4-heptanol (IV) was obtained by catalytic (PtO_2, methanol) hydrogenation of purified I.

Electroantennography. Electroantennograms (EAGs) were recorded from insects immobilized in a Plexiglas apparatus, using glass capillary electrodes filled with saline solution and connected to chloridized silver wires. The reference electrode was positioned at the base of the rostrum in a 0.5-mm-wide hole punched into the cuticle with an iron pin. The recording electrode was inserted into the antennal club (distal part and external area) on which the olfactory sensilla are located (Rochat, 1987). The electrical signal was fed into a 725-microprobe amplifier (WP Instruments inc.) and displayed on a Tektronix 5510 oscilloscope. Antennae of eight APWs of both sexes were subjected in randomized order to stimulation by air, solvent, six extracts containing APW and/or sugarcane volatiles, and eight synthetic chemicals (100 ng), including I tested also at 10 ng doses (Figure 2). All compounds except I–IV were commercial products of 99% purity. R1 was purified in an identical manner as I. One microliter of methylene chloride containing the natural or synthetic vola-

tiles was applied to a filter paper (17 × 17 mm) placed into a glass cartridge. Successive stimulations were separated by 2 min. EAG amplitudes were submitted to a two-way analysis of variance by stimulus (F1) and sex (F2). Interaction F1 vs. F2 would reveal sexual dimorphism in antennal responses to chemicals. Mean EAG amplitudes were compared using Newman-Keuls test ($\alpha = 0.01$).

Coupled gas chromatography–electroantennography (GC-EAD) was performed with a GIRA chromatograph modified according to Wadhams (1982). The chromatograph was equipped with a 25-m × 0.20-mm-ID fused silica column (WCOT HP-5, Hewlett Packard) heated from 60 to 220°C at 4°C/min. Helium was the carrier gas. The column effluents were split (50:50) between the FID and the antenna. A makeup flow of helium (20 ml/min) was added in the splitting device to accelerate the exit of the GC effluents towards the antenna. The effluents were driven from the chromatograph through a heated transfer line into a moistened airstream (1.4 l/min, 85% relative humidity, 26°C) focused onto the antennal preparation. The EAG signal was filtered (0.01–100 Hz bandpass) with an ERE amplifier (Ruy, France). GC and EAG signals were monitored on a two-channel chart recorder. Two APWs of both sexes were submitted, each one, to two extracts containing male (0.1 male-day-equivalent) + sugarcane volatiles.

Behavioral Bioassays. Insects were bioassayed using a two-choice pitfall olfactometer (Rochat et al., 1991) adapted from Pierce et al. (1981). The olfactometer consisted of a circular arena of 40 cm (diameter) × 14 cm (height) connected to two glass jars 9 cm (height) × 6.5 cm (diameter). According to preliminary investigations on the daily activity of the APW (Rochat, 1987), bioassays were run during the first half of the scotophase at 27 ± 2°C under red light at 40 lux. A single weevil was released at the center of the olfactometer arena and its position was recorded after 30 min. Weevils were classified as responding only if they fell into either the stimulus or the control jar or clung to the underside of the arena inside the jar.

Twenty to 32 weevils of both sexes were bioassayed in each of the following situations: (1) control treatment with two empty jars; (2) virgin male effluvia (0.1 male-day-equivalent) + sugarcane volatiles vs. sugarcane volatiles alone; and (3) 10 ng of (±)-I vs. solvent. One microliter of methylene chloride extract containing a natural or synthetic stimulus was applied to a filter paper (17 × 17 mm) placed into a glass jar just prior to the test. APW responses were quantified by the proportion of test weevils that responded after 30 min and the number of APWs choosing a stimulus jar. The first measure reflected the activity level of the population of test weevils (Walgenbach and Burkholder, 1986). The proportions of weevils that responded in situations 2 and 3 were compared with that obtained in absence of stimulus (situation 1) using the χ^2 test for two independent samples (Siegel, 1956). The numbers of weevils choosing a stim-

ulus were compared to the numbers of choices for the associated control jars using the nonparametric binomial test with the null hypothesis of an equal probability of choosing the control or the stimulus (Siegel, 1956).

RESULTS

Collection and Isolation of Male-Produced Pheromone. Comparisons of trapped volatiles from sugarcane, APW males + sugarcane, and APW females + sugarcane revealed the presence of two male-specific compounds: R1 and R2 (Figure 1). Females produced no detectible sex-specific volatiles. R1 was detected in 58 of 60 volatile collections analyzed by GC and was always the major of the two male-specific compounds. The mean release rate of R1 by APW males in 40 volatile collections was estimated by GC, using synthetic I as a standard, to be ca. 40 ng/male/hr. This rate varied between collections from ca. 0.5 to 140 ng/male/hr. R2 was detected in 48 of 60 extracts. The R1 : R2 ratio (based on GC peak areas) ranged most frequently between 100 : 15 and 100 : 5.

EAG Activity of Male-Produced Pheromone. Extracts containing male-produced + sugarcane volatiles gave very strong EAGs in both APW males and females (Figure 2). Extracts containing volatiles from sugarcane alone or from APW females + sugarcane induced EAGs as weak as those to air and solvent. Isolated R1 (40 ng) and a total extract containing R1 (15 ng) and R2 (R1 : R2 ratio of 100 : 18) induced EAGs of almost equal amplitudes.

All GC-EAD recordings from both male and female APWs showed high EAG responses to R1 (Figure 3). No EAGs were recorded in response to the sugarcane volatiles or to R2.

Pheromone Identification. The highest fragment ions observed in the EI mass spectrum of R1 were *m/z* 113 and *m/z* 110 (Figure 4). We assumed this compound to be an oxygenated aliphatic compound of mol wt 128. This assumption was confirmed by the CI $-$ NH_3 mass spectrum, which showed ions at *m/z* (% relative abundance): 146 ($M + NH_4^+$, 2), 129 ($M + H^+$, 9), 28 ($M^{+\cdot}$, 100), 111 ($M + H - H_2O^+$, 7), and 71 (1). Thus the *m/z* 110 ion was due to the loss of water and the *m/z* 113 ion to the loss of a methyl group from the molecule ion of a compound with $C_8H_{16}O$ formula. Absorption at 3649 cm^{-1} in the FTIR spectrum of R1 assigned the oxygen function to an hydroxyl group, and absorption at 966 cm^{-1} indicated a *trans* C—C double bond. Catalytic (PtO_2, methanol) microhydrogenation of R1 saturated the C–C double bond according to the CI mass spectrum, which showed ions at *m/z*: 148 ($M + NH_4^+$, 100), 130 ($M^{+\cdot}$, 5), 112 ($M - H_2O^+$, 11) and 87 (81). The couples of 18 amu-distant ions at *m/z* 73/55 and *m/z* 87/69 in the EI mass spectrum of the hydrogenated R1 (i) located the hydroxyl group in a C-4 position. (i), a couple

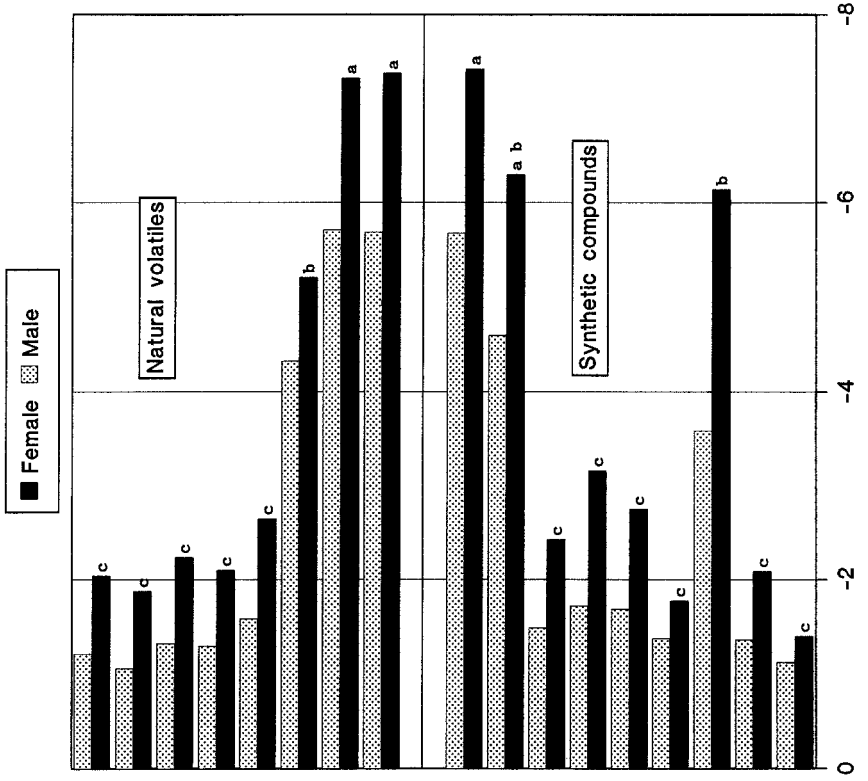

FIG. 2. Mean EAG responses from APW males and females ($N = 8$) to natural volatiles from APW and/or sugarcane and to synthetic pheromone-related compounds. Stimuli associated with the same letter do not differ significantly (Newman-Keuls test, $P < 0.01$) in terms of mean EAG amplitudes calculated on combined male and female responses.

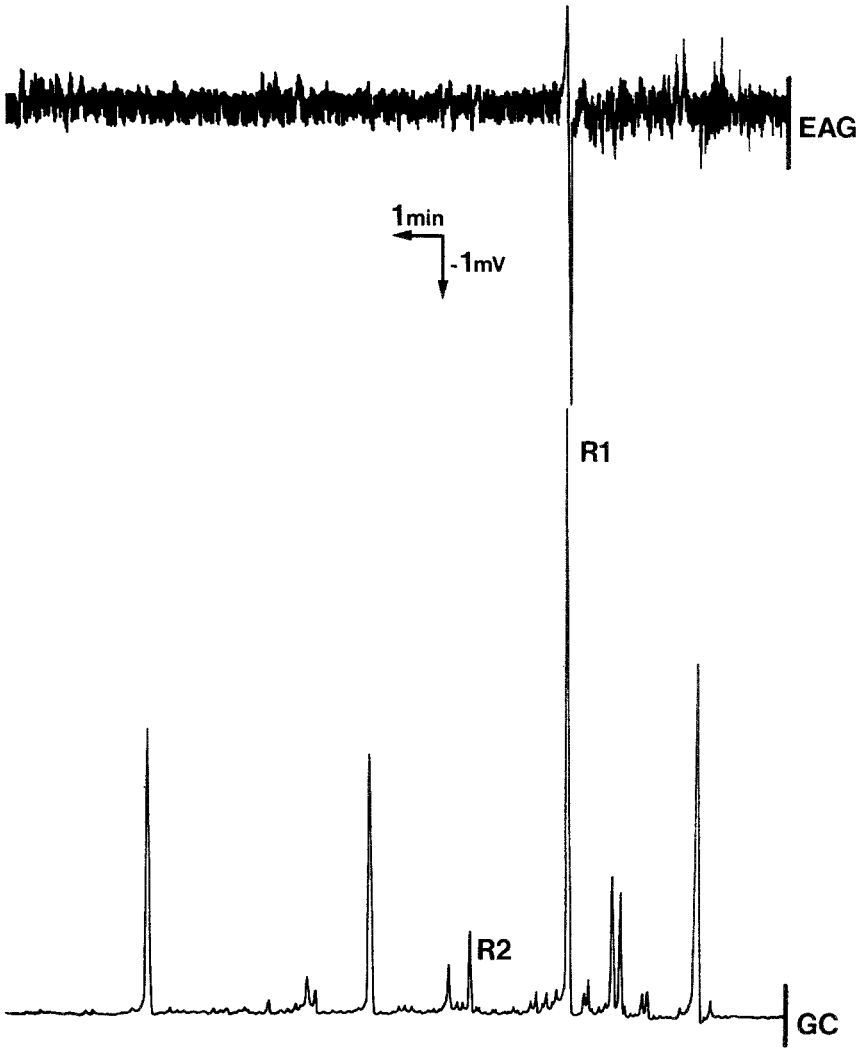

FIG. 3. GC-EAD recording from a female APW submitted to Supelpak-2-trapped volatiles from five APW males and sugarcane.

of 18 amu-distant ions at *m/z* 71/53 in the EI mass spectrum of R1 (ii) and GC-FTIR informations (iii) assigned the *trans* C–C double bond to be in C-2 position. The C-4 position of the hydroxyl group is in accordance with the presence of an even ion at *m/z* 86 resulting from a McLafferty rearrangement. Organization of the terminal four carbons of the chain to achieve complete structural identification of R1 could lead to three molecules: (2*E*)-6-methyl-2-hepten-4-

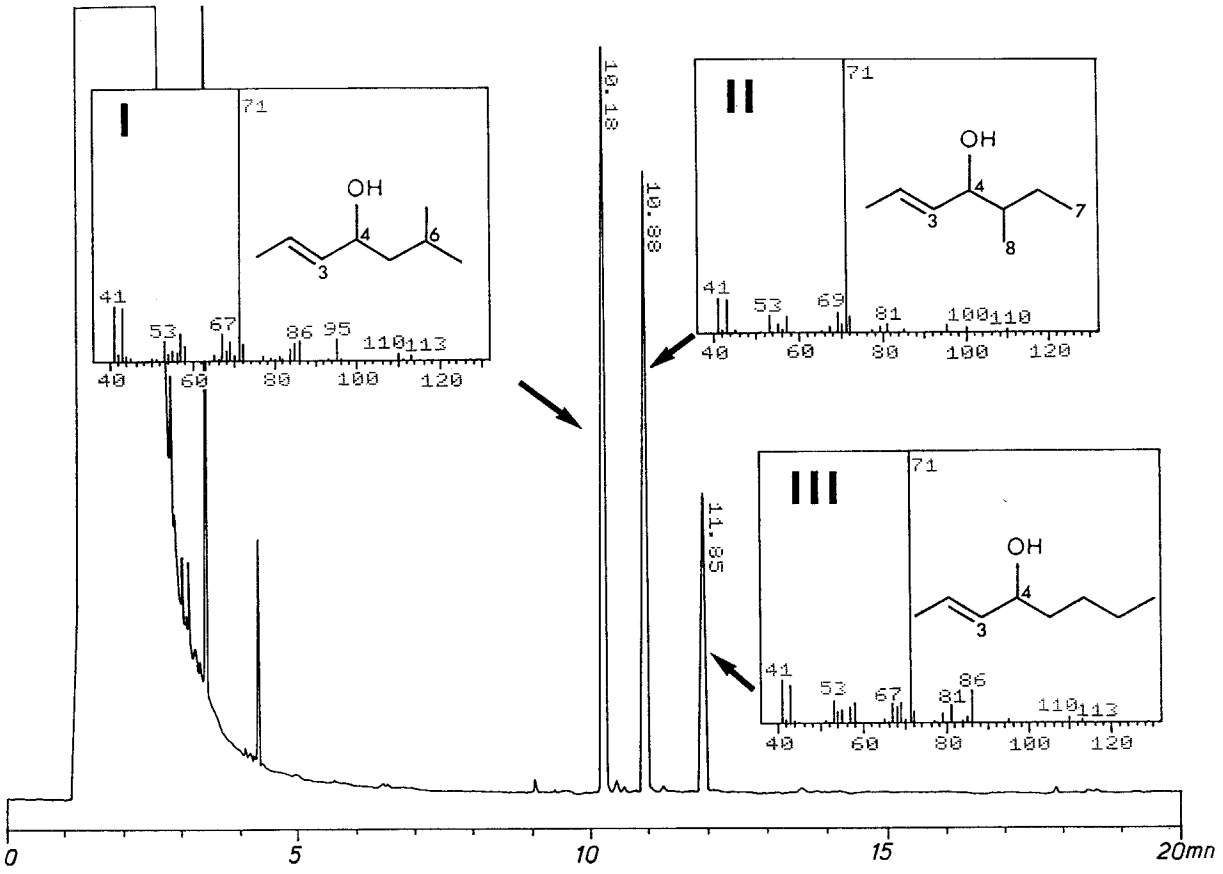

FIG. 4. Gas chromatogram (apolar column) and EI mass spectra of synthetic (2*E*)-5-methyl-2-hepten-4-ol (I), (2*E*)-5-methyl-2-hepten-4-ol (II), and (2*E*)-octen-4-ol (III).

ol (I), (2*E*)-5-methyl-2-hepten-4-ol (II), and (2*E*)-octen-4-ol (III). McLafferty rearrangement with II gave an even fragment ion at *m/z* 100 but not at *m/z* 86 as did R1, I and III. Comparisons of mass spectra; GC retention times of I, II, and III (Figure 4); and coinjection with R1, both on polar and apolar columns, led us to assign R1 to be (2*E*)-6-methyl-2-hepten-4-ol. The [^{1}H]NMR spectrum of R1 confirmed the identification of (2*E*)-6-methyl-2-hepten-4-ol. R1 shifts (ppm) were: 0.88 (d, 3H; H-8), 0.91 (d, 3H; H-7), 1.22 (ddd, 1H; H-5′), 1.44 (ddd, 1H; H-5), 1.5 (dd, 3H; H-1), 1.77 (m, 1H; H-6), 3.97 (m, 1H; H-4), 5.41 (m, 2H; H-2, H-3) with the following coupling constants (Hz): $J_{1\text{-}2} = 5$, $J_{1\text{-}3} = 0.8$, $J_{4\text{-}5} = J_{4\text{-}5'} = 8$, $J_{5\text{-}5'} = 13.5$, $J_{5\text{-}6} = J_{5'\text{-}6} = 6$, $J_{6\text{-}7} = J_{6\text{-}8} = 4.2$.

EAG Activity of Synthetic Pheromone and Analogs. Although the EAGs recorded from females were significantly greater in amplitude than those recorded from males ($F = 85.8$, $P < 0.001$), the EAG profiles disclosed no interaction stimulus by sex ($F = 1.27$, $P > 0.20$). Thus, there was no sexual dimorphism in the antennal responsness to the eight synthetic compounds tested. EAGs in response to I (10 and 100 ng) were significantly higher than to any octenol, including II and III (Figure 2) which in turn were not different from those to air and solvent. The mean EAG amplitudes obtained with 40 ng of isolated R1 and 100 ng of (±)-I were not statistically different. The mean EAG response to IV, a saturated analog of I, was significantly greater than to air and solvent and to any of the tested chemicals but I. However, IV had to be used at 10-fold higher doses than I to give EAGs of the same amplitude.

Behavioral Bioassay. In the two-choice pitfall olfactometer, (±)-I and volatiles from APW males induced similarly high numbers of weevils of both sexes to respond. Both males and females preferred significantly (±)-I to the solvent control (Table 1). Equivalent responses to (±)-I were obtained with wild APWs from Colombia and Guadeloupe (unreported data).

DISCUSSION

Rochat et al. (1991) showed that APW males produce a volatile aggregation pheromone. The strong EAGs in response to the male volatiles by APWs of both sexes corroborated the behavioral effect of the pheromone and showed that the response was due to a single major compound. The collection of variable amounts of this compound from male weevils may be due partly to the heterogeneity in age of the experimental weevils. Indeed, the age is a major factor influencing the production of aggregation pheromones in two *Oryzaephilus* species (Pierce et al., 1989).

Identification of (2*E*)-6-methyl-2-hepten-4-ol (I) as the essential pheromone compound was confirmed by both electrophysiological and behavioral data. We propose the trivial name rhynchophorol for this new pheromone.

TABLE 1. APW RESPONSES TO NATURAL AND SYNTHETIC MALE AGGREGATION PHEROMONE (RHYNCHOPHOROL) IN TWO-CHOICE PITFALL OLFACTOMETER AFTER 30 MIN

Treatment	Sex tested	Number tested	Number of responses[a]	Percent response		Binomial probability stimulus vs control[b]
				Stimulus	Control	
2 empty jars (control)	Male	30	8	50	50	0.637
	Female	20	2	50	50	—
Virgin male + food volatiles vs. food volatiles	Male	31	21**	71	29	0.021
	Female	21	14***	93	7	0.001
10 ng of (±)-I[c] vs solvent	Male	32	20**	85	15	0.001
	Female	31	20***	80	20	0.006

[a] Difference from the control (χ^2 test) indicated by:
n.s.: not significant, ** $P < 0.01$ and *** $P < 0.001$.
[b] Under the null hypothesis to respond to the stimulus and to the control with an equal probability of 0.5.
[c] (±)-I: racemic (2*E*)-6-methyl-2-hepten-4-ol (rhynchophorol).

(±)-Rhynchophorol was a potent lure for the APW in laboratory conditions without food volatiles or the minor male-specific compound. (±)-Rhynchophorol at 10-ng doses did not exhibit any inhibitory effect, and there was no evidence for a differential peripheral reception of (±)-rhynchophorol and natural rhynchophorol. Nevertheless, further investigations are underway to determine the enantiomeric composition of natural rhynchophorol since chirality in beetle communication is of major consequence (Mori, 1984; Borden, 1985; Walgenbach et al., 1987; Phillips et al., 1989).

Rhynchophorol is a new eight-carbon aliphatic and oxygenated pheromone. Such pheromones have been found in three coleopteran families: Cerambycidae (2,3-octanediol and 2-hydroxy-3-octanone; Sakai et al., 1984), Curculionidae (sitophilure, 5-hydroxy-4-methyl-3-heptanone; Phillips et al., 1985; 5-methyl-4,6-heptanedione; Blight et al., 1984) and Scolytidae (ipsenol, 2-methyl-6-methylene-7-octen-4-ol, and ipsdienol, 2-methyl-6-methylene-2,7-octadien-4-ol; Silverstein et al., 1966; sulcatol, 6-methyl-5-hepten-2-ol; Byrne et al., 1974; 4-methyl-3-heptanol; Pearce et al., 1975).

Although the genera *Rhynchophorus* and *Sitophilus* are very close, there is no obvious structural relationship between rhynchophorol and sitophilure. Because of its terpenoidic skeleton, rhynchophorol appears to be closely related to the scolytid pheromones ipsenol, ipsdienol, and sulcatol. This similarity suggests biogenesis of rhynchophorol from host-plant terpenes, as has been dem-

onstrated or assumed for many scolytid pheromones (Vanderwel and Oehlschager, 1987).

Field-trapping data (Rochat et al., 1991) and recent laboratory results (Rochat et al., unpublished data) support the hypothesis that APW males produce rhynchophorol only when they feed on the host plant. The biological significance of the male APW pheromone would thus be a signal to aggregate on a suitable food resource, as occurs in many other beetles (Walgenbach and Burkholder, 1986; Borden, 1985; Renwick, 1988).

The identification of the APW aggregation pheromone is a considerable step towards improving traditional methods used to control this major pest. APW adults have been caught in poisoned traps baited with palm stem pieces for many decades (Morin et al., 1988) without any attention paid to the role that the APWs themselves could play in attracting conspecifics. The use of synthetic rhynchophorol may lead, either alone or with host-plant kairomones, to a great improvement in the efficiency of APW trapping for survey and control of this major pest.

Acknowledgments—We thank IRHO and especially D. Mariau for financial and technical support, and Fedepalma and P. Genty (Colombia) for providing us with wild weevils. We are indebted to M. Leverve, F. Radnai, and G. Pype for insect rearing; I. de Cruz and J.L. LeQuéré for their assistance, respectively, in micropreparative HPLC and coupled GC-FTIR spectrometry; J. Einhorn for helpful discussions in mass spectrometry; and two anonymous reviewers for helpful comments on the manuscript.

SEX PHEROMONE COMMUNICATION IN THE SCREWWORM, *Cochliomyia hominivorax*: ONTOGENETIC AND STRAIN EFFECTS

L. HAMMACK[1]

Biosciences Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Fargo, North Dakota 58105

(Received May 6, 1991; accepted July 3, 1991)

Abstract—A laboratory behavioral assay was used to examine ontogenetic and strain effects on sex pheromone production and reception in the screwworm, which employs a female-produced contact pheromone to stimulate male copulatory attempts. Pheromone levels peaked between three and six days after adult emergence in females of two strains that had been colonized fewer than 50 generations. Pheromone was detectable at low levels in newly emerged flies of both sexes but disappeared from males by two days of age, when males first became responsive to females. A similar decline in pheromone with ontogenetic age was previously described for females of a strain colonized over 100 generations. Interstrain tests between the two newer strains, which differed by 35 generations in duration of colonization, demonstrated lower female pheromone activity but higher male responsiveness to pheromone in the older strain, despite the similar shape within these strains of curves relating female age and pheromone activity. The data suggest that conditions of screwworm colonization result in gradual loss of the pheromone peak that develops three to six days after emergence in newly colonized females. Higher male responsiveness associated with longer colonization involved change in both thresholds and dose dependency and may be relevant to control of the screwworm via the sterile insect technique.

Key Words—Screwworm, *Cochliomyia hominivorax*, Calliphoridae, Diptera, blow fly, mating stimulant pheromone, contact sex pheromone, laboratory adaptation.

INTRODUCTION

The screwworm, *Cochliomyia hominivorax* (Coquerel) has been eradicated from the United States and Mexico, where it has the potential to inflict losses exceeding $600,000,000 annually, primarily to livestock producers (Snow et al., 1985). It remains the most destructive agent of myiasis throughout tropical and subtropical areas of Central and South America (Guimarães et al., 1983; Dear, 1985; Snow et al., 1985; Krafsur et al., 1987) and threatens Old World livestock and wildlife after its recent discovery in Libya (El-Azazy, 1989; Gabaj and Beesley, 1989). The screwworm is well established in Libya and capable of spreading into sub-Saharan Africa and the Middle East, with seasonal incursions into southern Europe (Gabaj et al., 1989; Palca, 1990).

Eradication of the screwworm from North America was accomplished with the sterile insect technique (SIT), which is also planned for *C. hominivorax* populations in Central America and northern Africa (Snow et al., 1985, McGourty, 1989). SIT success is subject to factors influencing mating behaviors because sexually sterilized released males must mate with native females in order to render their eggs sterile and thereby drive the population toward extinction (Knipling, 1955).

Sex pheromones are important for mating in many species of insects (Tamaki, 1985). The screwworm is no exception. A contact pheromone in cuticular lipids of females stimulates copulatory attempts from males when applied to objects mimicking flies (Mackley and Broce, 1981; Hammack, 1986).

A distinctive asymmetry in mating behavior characterizes crosses between screwworm strains that differ in duration of colonization, i.e., mating attempts occur more frequently between old-strain males and new-strain females than in the reciprocal direction (Alley and Hightower, 1966; Spates and Hightower, 1967; Hammack, 1987; Mangan, 1988). Cuticular lipid profiles also change during colonization, but only in females (Pomonis and Mackley, 1985), suggesting colonization effects on sex pheromone communication. Reduced female pheromone activity and enhanced male responsiveness to pheromone associated with longer colonization account for at least one case of asymmetric mating isolation between old and new screwworm strains (Hammack, 1987). The dependence of mating on pheromonal cues indicates that the sex pheromone system can be used to assess the reproductive compatibility of screwworm populations.

The present study examines ontogenetic and strain effects on sex pheromone activity and male responsiveness in screwworm strains reared fewer than 50 generations in the laboratory and differing by 35 generations in duration of colonization. Such ontogenetic data are needed to ensure validity of interstrain comparisons, but detailed information is available only for a strain (009) colonized over 100 generations (Hammack, 1987). Age and strain data are also

needed to optimize pheromone recovery and detection for isolation and characterization of the screwworm sex pheromone(s).

METHODS AND MATERIALS

Insects. Two strains of screwworm were tested. The FC96 strain originated from a single egg mass collected in Chiapas, Mexico, in October 1983 and was used in generations 36–43, unless stated otherwise. FC96 had served as the newer strain in a previous study; it was maintained by single-pair matings from generation six to minimize sexual harassment of caged females by males and possibly reduce selection for pheromone changes (Hammack, 1987). A newer strain derived from multiple egg masses collected in Belize in October 1986 was tested after 11–19 generations in the laboratory. Belize colonies were maintained in mixed-sex groups. Belize is the strain currently being reared in Mexico for SIT, although its name was changed to OW87 upon introduction into mass production.

Larvae were reared on a beef-based diet; adults were maintained on corn syrup and water at 25 ± 1°C under a 12 : 12 hr light–dark photoperiod (Hammack, 1984). All test insects were virgin and, unless stated otherwise, were obtained by separating the sexes within 24 hr of emergence, using CO_2 anesthesia.

Pheromone Preparation and Bioassay. Pheromone was obtained from 4-day-old females, except as otherwise indicated. Insects supplying pheromone were killed by freezing, thawed, and either mounted on corks for testing or extracted for 15 sec at the rate of 20/ml of *n*-hexane (Hammack, 1987). Extracts were prepared from 200 females, unless stated otherwise, and were stored at −70°C.

The pheromone activity of killed and extracted insects was measured in bioassays that determined whether or not test males attempted copulation when paired with decoy insects for 1 min (Hammack, 1987). Each decoy was mounted on a cork that was fitted into a glass test tube (15 × 150 mm) containing one test male. Inversion of the tube forced the male to contact the decoy. Each decoy was exposed to a series of 10 test males and then discarded. Test males were used only once. Decoys were either whole dead screwworm adults (both sexes) or males washed three times in hexane (≥0.2 ml/wash) and then treated with female extract applied in 5 μl of hexane. Washed decoys treated only with hexane elicit no copulatory responses (Hammack, 1987).

Experiments. The first series of tests investigated the relationship within strains between age in days after adult emergence (±4 hr) and pheromone activity of females and males. Whole dead females of the FC96 strain were examined between 0 and 8 days old in one test and between 6 and 16 days in another.

Pheromone activity was also measured in extracts of FC96 females ranging from 2 to 16 days old and Belize females from 1 to 12 days old. Whole dead FC96 males 0–8 days old were examined in a fifth test. Within each test, flies supplying pheromone had emerged on the same day from a single larval rearing group. Pheromone activity was estimated from the responses of 100 5- to 8-day-old FC96 males or 50 10- to 12-day-old Belize males.

A second series of tests examined the effect of male age on responsiveness to dead female decoys in the FC96 strain. Different groups of males were tested daily 0–8 days after adult emergence in the first test of the series ($N = 100$) and at 7, 8, 10, 12, 14, and 16 days in the second one ($N = 50$). Males tested before 3 days of age had been separated from females without anesthesia.

An extract of each strain of females was prepared in six of eight successive generations beginning when Belize and FC96 strains were in generations 11 and 46, respectively. Each extract was applied at the rate of 0.5 female equivalent (FE) to separate hexane-washed decoys of each strain. Each extract and decoy combination was tested with 50 8- to 11-day-old test males of each strain. Percentages of males attempting copulation were transformed ($\arcsin\sqrt{Y}$) and examined by analysis of variance (ANOVA procedure, SAS Institute, 1988). The model was a factorial one having three classes (extract, test male, and decoy) each at two levels (FC96 and Belize strains).

The relationship between pheromone dose (X) plotted on a logarithmic scale and percent males attempting copulation (Y) was obtained within FC96 and Belize strains with 100 males per test dose. FC96 males were 6–8 days old; Belize males were 10–12 days old. The FC96 extract was prepared from 40 females. Linear regression was used to analyze each set of data (REG procedure, SAS Institute, 1988). Dose–response data were also acquired with extract of Belize females, but FC96 test males in generations 86–91. One hundred 6- to 8-day-old males were assayed at each of five doses between 0.064 and 0.25 FE. The procedure was repeated with 10- to 12-day-old males. Regression analysis was again used for data analysis, with the addition to the model of age (Z) as an independent variable (REG procedure, SAS Institute, 1988).

Within tests, responding males were matched with respect to larval rearing group of origin and time of day of testing. In addition, treatments within tests were bioassayed simultaneously with similarly aged males, except when age effects on male responsiveness to pheromone were examined.

RESULTS

The pheromone activity of FC96 female decoys increased from adult emergence until 2 days of age and then remained high enough through 16 days of age to stimulate copulatory attempts in more than 80% of test males (Figure

1). When the response frequency was reduced by diluting extracts to 0.5 FE, a peak in pheromone activity emerged between 4 and 6 days of age (Figure 1). Belize females were also maximally stimulatory when extracted between 3 and 6 days of age (Figure 2), although 1.0 FE was required to approach response levels obtained with 0.5 FE in the FC96 series.

Mature male decoys of the FC96 strain showed no pheromone activity, but newly emerged ones elicited copulatory attempts from nearly 30% of test males

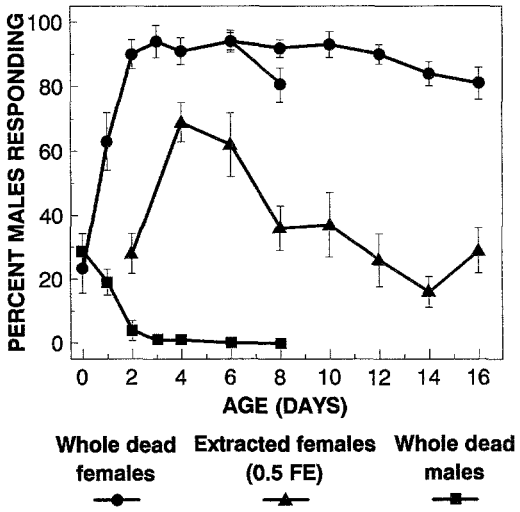

FIG. 1. Effect of age on sex pheromone activity in screwworm flies of the FC96 strain (mean ; pmSEM) pm SEM). Extract concentration is expressed in female equivalents (FE).

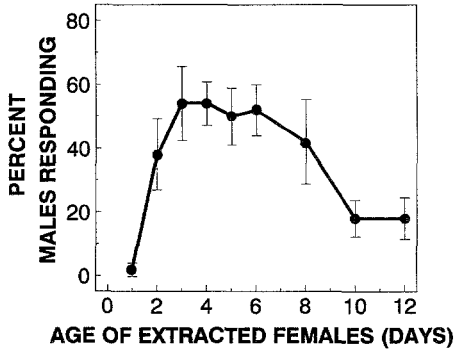

FIG. 2. Effect of age on sex pheromone activity in screwworm flies of the Belize strain. Each point is the mean response (±SEM) to 1.0 female equivalent of extract.

(Figure 1). The sharpest decline in pheromone activity of males occurred by 2 days of age (Figure 1).

Newly emerged and 1-day-old males failed to react to female decoys killed at 4 days of age (Figure 3), when female pheromone activity was highest. However, male responsiveness increased from 2 to 5 days of age and then remained high through 16 days (Figure 3).

Screwworm strain significantly affected the activity of female extracts and the responsiveness of males to those extracts; however, the strain used for decoys did not affect behavior when decoys were washed in hexane before treatment with extract (Table 1). None of the interaction terms was significant (Table 1). Belize females were more stimulatory than FC96 females to males of both strains, but Belize males were less responsive than FC96 males to females of both strains (Table 2).

Figure 4 shows that slope (b) of the regression line relating pheromone concentration plotted on a logarithmic scale and the percentage of males responding appeared steeper in the FC96 [b = 97.2, 95% confidence interval (CI) = 61.1–133.3] than in the Belize strain (b = 53.1, 95% CI = 41.1–65.2). Responses of FC96 males to extract of Belize females confirmed a strain difference in the slope of dose–response lines and indicated that the difference resulted from variation in male behavior rather than composition of female extracts. The regression model explained a significant amount of variation in the response of FC96 males to Belize extract ($F_{2,7} = 41.70$, $P < 0.0001$, $r^2 = 0.92$, $Y = 132.30 \log_{10} 100X - 0.50Z - 91.72$); however, only dose contributed significantly to the model ($t_1 = 9.13$, $P < 0.0001$), age of test males did not ($t_1 = -0.33$, $P = 0.75$). Deletion of the age variable from the model

TABLE 2. MEAN PERCENTAGE OF MALES (± SEM) OF TWO SCREWWORM STRAINS ATTEMPTING COPULATION IN RESPONSE TO 0.5 FEMALE EQUIVALENT OF EXTRACT FROM EACH STRAIN[a]

Strain and sex	Belize females	FC96 females
Belize males	42.2 ± 2.5	12.0 ± 4.1
FC96 males	91.2 ± 2.9	70.8 ± 5.9

[a] Based on six replicates of 100 males per comparison.

simplified the equation to $Y = 132.30 \log_{10} 100X - 96.22$, with 95% CI about b ranging from 100.8 to 163.8. Thus, FC96 males generated a steep dose–response line whether tested with extract of FC96 or Belize females.

DISCUSSION

Sex pheromone activity peaked between 3 and 6 days of age in FC96 and Belize females that had been colonized fewer than 50 generations. In contrast, pheromone activity was greatest at emergence in 009 strain females that had

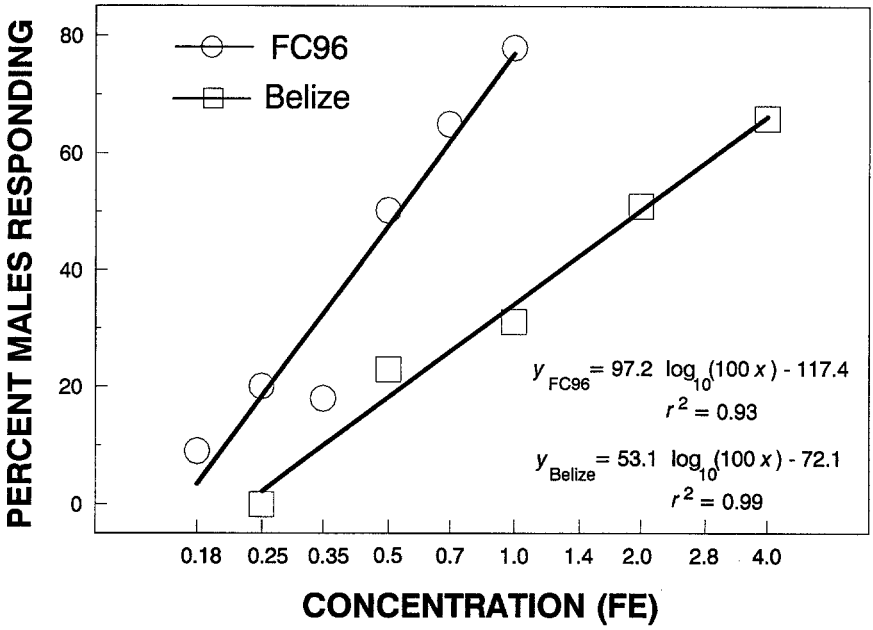

FIG. 4. Relationship between sex pheromone concentration expressed in female equivalents (FE) and male responses within FC96 and Belize screwworm strains.

been colonized more than 100 generations, presumably as a result of greater laboratory adaptation (Hammack, 1986, 1987; Mangan, 1988). Although the curves relating age and pheromone activity were similarly shaped within FC96 and Belize strains, the interstrain comparisons clearly demonstrated higher activity peaks in the Belize strain, but lower male responsiveness to pheromone. These differences followed expectation, i.e., lower pheromone activity in older strain females combined with greater willingness of older strain males to respond to pheromone and mate (Alley and Hightower, 1966; Spates and Hightower, 1967; Hammack, 1987; Mangan, 1988).

The data suggest that colonization leads not to a shift in the age when particular pheromone components are produced, but to gradual loss of the activity peak occurring three to six days after emergence in newer strain females. Screwworm females 3–6 days old are therefore best for determination of interstrain pheromone compatibilities and for recovery of maximum quantities of pheromone for chemical analysis.

It is conceivable that the strain differences in patterns relating ontogenetic age and female pheromone activity develop because different active chemicals occur at emergence and at sexual maturity, and only those present at maturity are affected by colonization. This scenario is consistent with the observations

that pheromone activity varies neither with strain nor sex of newly emerged fly (Pomonis and Mackley, 1985; Hammack, 1987) and is highest at emergence in 009 females colonized more than 100 generations (Hammack, 1987) and in males of a newer strain (FC96). Different active compounds are known to occur at emergence and sexual maturity in *Drosophila melanogaster*. Newly emerged flies of both sexes stimulate male courtship, albeit for reasons that are not entirely clear, but their activity derives from compounds other than the (*Z*,*Z*)-7,11-heptacosadiene that acts as the courtship-stimulating pheromone of mature *D. melanogaster* females (Pechine et al., 1988; Schaner et al., 1989).

Colonized females synthesizing little, if any, sex pheromone would be invaluable for screwworm behavioral studies and for deciphering hormonal, biochemical, and genetic mechanisms controlling pheromone production. A quantitative decrease in pheromone production with colonization is consistent with available data (Hammack, 1987), although qualitative changes such as altered pheromone blend or inhibitor cannot yet be ruled out. Male cuticular lipids potentially transferred at mating, as well as nonspecific paraffins absent from the cuticle, inhibit pheromonal responses of the tsetse fly, *Glossina morsitans* (Coates and Langley, 1982). In *D. melanogaster*, a courtship-inhibiting pheromone of males and mated females varies qualitatively with strain (Scott and Jackson, 1988). These examples illustrate that pheromone inhibitors occur in Diptera; however, any inhibitor in the screwworm likely functions in a different context because screwworm mating does not affect female pheromone activity (Hammack, 1987).

Whereas female screwworm flies colonized fewer than 50 generations attained peak activity by 3–4 days of age, male responsiveness to sex pheromone peaked only after four days. In nature, delayed maturation of males might deter mating among siblings that tend to emerge in spatial proximity to one another, especially when combined with the tendency for males of a cohort to emerge a day after females. Tests at reduced dosage would be necessary to establish that male responsiveness to pheromone is stable between five and 16 days; however, responses of FC96 males to dilutions of Belize extract provided no indication of response variation between six to eight and 10–12 days.

A stable response to pheromone between five and 16 days would correlate with a plateau in male mating frequency that lasts from 3–4 to 16 days of age (Crystal, 1967; Adams, 1979). Females become receptive to mating at 3 days of age (Crystal, 1967; Adams, 1979), when sex pheromone activity approached a peak in the FC96 and Belize strains. The decline in pheromone activity observed here after six days is not reflected in mating rates, but these rates are available only for a strain colonized more than 150 generations. Such colonized females maintain a stable mating level from 3 to 14 days of age (Crystal, 1967), which correlates with the absence of age-dependent changes in pheromone activity from three to eight days in the long-colonized 009 strain (Hammack,

1987). Discrepancies between pheromone and mating patterns may also result if females limit mating rates, which appears to be the case within screwworm strains (Adams, 1979; Hammack, 1987). Females are expected to mate less readily than males in a species with monogamous females and polygamous males displaying only the most cursory courtship before attempting copulation (Bushland and Hopkins, 1951; Thornhill and Alcock, 1983).

Differences were evident in sex pheromone dose–response patterns of FC96 and Belize males: thresholds were lower but dose dependency greater in the longer colonized FC96 strain. Greater dose dependency indicates less variation in response thresholds among individuals, which might be attributed in part to the single egg mass derivation of the FC96 strain. Inbreeding attending laboratory culture can also reduce genetic heterogeneity (see Delves and Barton Browne, 1989). Lower thresholds may simply reflect a greater willingness of colonized males to respond under suboptimal conditions. For example, screwworm mating in nature likely involves flight activity (Guillot et al., 1978), which is severely restricted in laboratory cages. The subsequent appearance in two FC96 sublines of further declines in female pheromone activity without immediate change in male responsiveness (unpublished data) suggests that pheromone loss by females drives male threshold changes. However, the apparent drop with colonization in the pheromone activity of FC96 females does not support the hypothesis that sexual harassment of caged females by males selects for pheromone loss (Hammack, 1987; Mangan, 1988) because breeding FC96 females had been isolated from males except for the few minutes needed for mating.

Changes in male mating behaviors with colonization are relevant to SIT because of its dependence on the mating success of sterilized mass-reared males with native females. Success rate may suffer because of detrimental effects on either sex or species discrimination. However, the cost to males of freely evaluating receptivity of potential mates is generally slight if it requires little time and energy (Thornhill and Alcock, 1983). Detrimental effects on discriminatory abilities may therefore only minimally affect mating success in an insect like the screwworm that lacks elaborate courtship. Mangan (1985) has even suggested that heightened mating aggressiveness may be beneficial because it could augment the transitory interference with host seeking by native females that follows sterile male releases. We clearly need a better understanding of colonization effects on mating behavior of screwworms reared for SIT. Knowledge that colonization modifies sex pheromone communication will assist in this endeavor.

Acknowledgments—I thank Patsy L. Evenson, Donna K. Galitz and Philip T. Meyer for insect rearing and technical assistance. Robert L. Mangan (USDA-ARS Subtropical Agriculture Research, Weslaco, Texas), Franklin D. Parker (USDA-ARS Screwworm Research, San Jose, Costa Rica), J. George Pomonis, and David B. Taylor kindly provided useful criticism of an earlier draft of the manuscript.

CORTICOSTERONE AND PROLACTIN DO NOT MEDIATE ALARM PHEROMONE EFFECT IN THE RAT

ERNEST L. ABEL* and MARAPPA G. SUBRAMANIAN

Abstract—Corticosterone and prolactin do not reflect the alarm pheromone effect in the rat. Male rats were immersed in water previously swum in by 0, 1, or 2 other rats. Immobility decreased considerably after immersion in water previously swum in by one animal and did not decline further because of a "floor effect." Plasma corticosterone levels were increased by immersion in both fresh and soiled water. Prolactin levels were not increased significantly. Water condition did not significantly affect plasma corticosterone or prolactin levels when rats were sacrificed immediately after testing or 20 min after testing. These results indicate that neither corticosterone nor prolactin mediate the alarm pheromone phenomenon.

Key Words—Forced swim test, corticosterone, prolactin, rats, *Ratus ratus*.

INTRODUCTION

We have reported previously that when rats, *Ratus ratus*, are tested in fresh water in the forced swim test they exhibit considerable immobility, but if the water in this test has been soiled by another rat, they exhibit almost no immobility (Abel, 1991a,b; Abel and Bilitzke, 1990). We have interpreted this result as evidence that rats secrete an alarm pheromone in this test that affects the behavior of other rats subsequently exposed to it (Abel, 1991c).

There are several hypotheses concerning interpretation of the immobility response in the forced swim test. One of these hypotheses is that the test is stressful, and the immobility response during the test period represents an adaptive response to this stress (Hawkins et al., 1978). The argument that the test

*To whom correspondence should be addressed.

0098-0331/91/1100-2155$06.50/0

is stressful is supported by Satoh et al. (1985) and a recent study from our laboratory (Abel, 1991b) showing that animals that undergo the forced swim test exhibit significantly increased plasma corticosterone levels. Since both corticosterone and prolactin are secreted in response to a wide variety of stressors (Axelrod and Reisine, 1984; Gala, 1990), the first part of this hypothesis is supported. In a previous study, we have shown that foot shock prior to testing causes rats to exhibit less immobility in the forced swim test (Abel and Bilitzke, 1990), suggestive of an increased stress response. Other studies have shown that foot shock and other stressors increase plasma corticosterone and prolactin in rats (e.g., Kant et al., 1983; Amario et al., 1986; Brown and Martin, 1974). By extension, one might expect that plasma levels of corticosterone and/or prolactin ought to be higher in animals tested in soiled water since they exhibit much less immobility than rats tested in fresh water (Abel, 1991a,b; Abel and Bilitzke, 1990) since these hormones are both elevated in response to stressors. The purpose of this study was to determine if indeed testing rats in soiled water causes them to have higher corticosterone and prolactin levels than testing animals in fresh water. Since corticosterone levels may not attain their maximal levels until 15–30 min after arousal (Seggie and Brown, 1975), animals were sacrificed either immediately or 20 min after removal from the test.

METHODS AND MATERIALS

Male Sprague-Dawley rats (Charles River, Portage, Michigan) 90–100 days of age were housed in polycarbonate cages in a vivarium at a constant room temperature of 21 ± 1°C and humidity (40 ± 5%) and a 12-hr light–dark cycle. Food and water were available ad libitum. Animals were tested for floating immobility in a Plexiglas cylinder (Corning Glass, Corning, New York) (45.7 cm height, 22.2 cm inside diameter) filled to a height of 38 cm with tap water maintained at 28 ± 1°C. The criterion for immobility was floating vertically in the water making only those movements needed to keep the head above water (Borsini and Meli, 1988). Animals were immersed for a 11-min period.

Animals were tested in three squads (N = 8/squad). Animals in the first squad were tested in fresh tap water. Each animal in the second squad was tested immediately after an animal in the first squad had been removed. Animals in the third squad were tested in water previously swum in by an animal in the first and second squad. Thus, animals were immersed in water that had been previously swum in by either one or two animals.

Immediately after removal from the water, each animal was blotted dry and either sacrificed by decapitation within 15 sec of removal from the water or at 20 min after removal. However, immobility was scored only for the former group. An untreated group served as controls for the test procedure itself. Trunk

blood was collected for subsequent corticosterone and prolactin analysis. The data were analyzed by analysis of variance (ANOVA). Post-hoc testing was done by the Duncan multiple-range test.

Corticosterone and Prolactin Assay. Serum corticosterone levels were determined using a commercially available radioimmunoassay (RIA) kit (ICN Biomedicals Kit #07-120102). Serum prolactin was assayed by a double antibody RIA method as described previously (Subramanian and Abel, 1988) using the reagents provided by National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases.

RESULTS

The immobility data are shown in Figure 1. Animals immersed in soiled water were less immobile than those immersed in fresh water ($F = 92$, $df = 2,21$, $P < 0.001$). Post-hoc testing indicated that the two soiled conditions did not differ significantly.

Group differences in corticosterone levels were significant ($F = 41.5$, $df = 6,65$, $P < 0.001$) (Figure 2). Post-hoc testing indicated that all groups in the forced swim test had higher corticosterone levels than untreated controls ($P < 0.05$) and animals sacrificed 20 min after removal from the test had significantly higher levels than those sacrificed immediately after testing ($P < 0.05$).

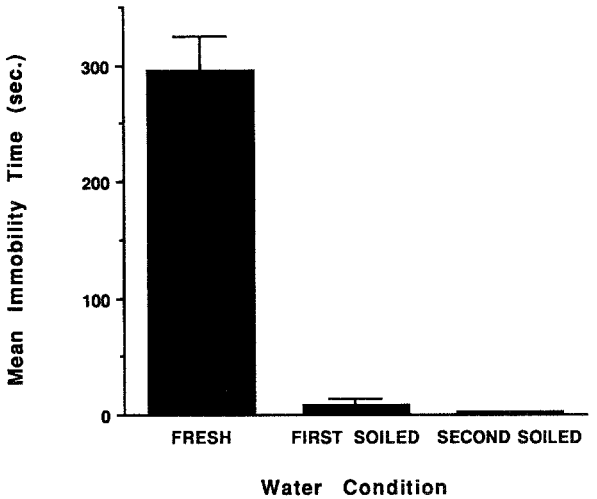

FIG. 1. Mean immobility times for rats in the forced swim test. Animals are tested in fresh water or water soiled by one or two other rats ($N = 8$/condition). Vertical lines indicate SEM.

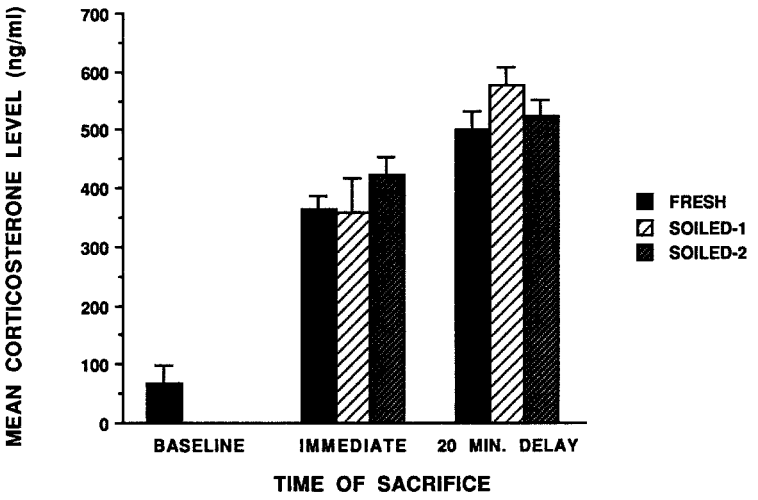

FIG. 2. Mean serum corticosterone levels in nontested rats (baseline), and rats tested in fresh water or water soiled by one or two rats. Animals were sacrificed immediately after an 11-min test or 20 min after the 11-min test (N = 8/condition). Vertical lines indicate SEM.

However, animals tested in water soiled by one or two animals did not differ from animals tested in fresh water.

Group differences in prolactin levels were not statistically significant (Figure 3).

DISCUSSION

As reported by Satoh et al. (1985), the forced swim test resulted in a relatively large increase in serum corticosterone levels relative to untreated control animals. The study also corroborated previous studies (e.g., Seggie and Brown, 1975) indicating that corticosterone levels in response to stress are likely to be higher if sampling occurs 15–30 min after testing than if immediately after testing. In contrast to these results, serum prolactin levels were not increased by the forced swim test. The study also indicated that while swimming in soiled water was more stressful than swimming in fresh water, as reflected in virtually no immobility (cf., Abel and Bilitzke, 1990; Abel, 1991a,b), swimming in soiled water did not result in significantly higher corticosterone levels than swimming in fresh water. Although plasma corticosterone levels rise in response to stress (Axelrod and Reisine, 1984; Hennessey et al., 1979; Amario et al., 1986), some studies have found that the increases do not reflect the intensity of

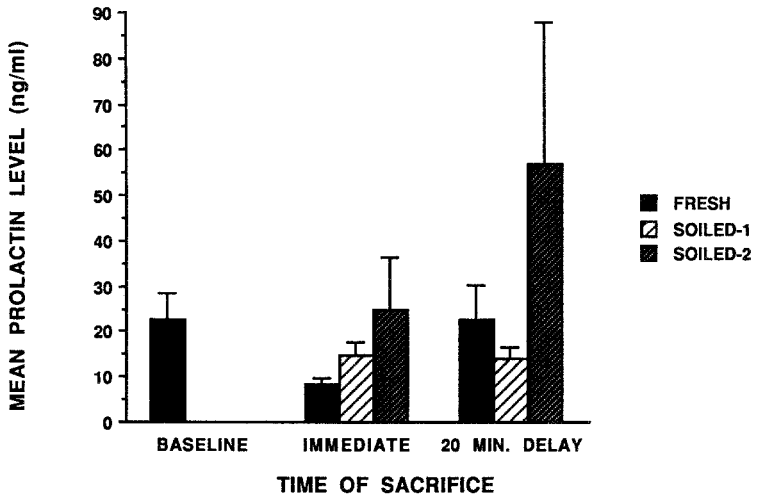

FIG. 3. Mean serum prolactin levels in nontested rats (baseline), and rats tested in fresh water or water soiled by one or two rats. Animals were sacrificed immediately after an 11-min test or 20 min after the 11-min test (N = 8/condition). Vertical lines indicate SEM.

the stressors experienced by animals (e.g., Ader, 1970). This insensitivity may be due to a "ceiling effect." In other words, some stressors may elicit a maximal response so that further increases cannot be seen. With less intense stressors, corresponding increases in corticosterone responses have been observed (Hennessey et al., 1979; Amario et al., 1986). A previous study from our laboratory supported this hypothesis by showing that the forced swimming test elicits a greater serum corticosterone response than being placed in an unfamiliar environment, which in turn produces a greater corticosterone response than baseline (Abel, 1991b). However, the higher corticosterone levels of animals sacrificed at 20 min after testing compared to immediately after testing showed that levels in the latter were not at their maximum, indicating that levels could still have increased if stress levels were different. Using a different paradigm, Mackay-Sim and Laing (1980) also reported that corticosterone levels were not increased in animals exposed to alarm pheromones (from shocked rats). Our results and Mackay-Sim and Laing's (1980) suggest that neither corticosterone nor prolactin mediate the behavioral response to alarm pheromone in rats.

The inescapable swim test used in this study is a variation of the original test described by Porsolt et al. (1977). In that test, an animal is given a 15 min preexposure to the test and 24 hr later, is tested again for 5 min. Duration of immobility is typically longer than during the first 5 min of the first immersion.

Increased immobility in this version of the test may reflect decreased stress due to habituation to the test condition (Borsini et al., 1989) or some other learning/memory function (West, 1990).

In the present version of the test, animals are tested on day one only, in either fresh water or water soiled by another animal. The diameter of the tank and the depth of the water are such that the animal is unable to float or touch the bottom of the tank. Since rats exposed to foot shock or loud noise prior to testing exhibit much less immobility in fresh water than controls, we have interpreted decreased immobility as reflecting a stress response (Abel and Bilitzke, 1990).

Although the condition of the water is not stated in studies using the Porsolt et al. (1977) procedure, we assume that in some cases, the water is not changed and is therefore soiled for some animals. However, immobility still occurs. On the surface, this would seem contrary to our findings. However, we have found that an animal must be immersed a minimum of 3.5 min for it to produce a detectable effect on subsequent animals in the Long-Evans strain. (Abel and Bilitzke, 1990). Other strains may require a longer period of soiling.

RESPONSE OF *Dendroctonus brevicomis* AND *Ips paraconfusus* (COLEOPTERA: SCOLYTIDAE) TO COMBINATIONS OF SYNTHETIC PHEROMONE ATTRACTANTS AND INHIBITORS VERBENONE AND IPSDIENOL

T.D. PAINE* and C.C. HANLON

Department of Entomology
University of California
Riverside, California 92521

(Received February 8, 1991; accepted July 8, 1991)

Abstract—*Dendroctonus brevicomis* and *Ips paraconfusus* are sympatric bark beetle species colonizing *Pinus ponderosa* in western North America. Interspecific and intraspecific competition for resources is, in part, mediated through semiochemicals. The response of *D. brevicomis* to its attractant pheromone was significantly reduced by simultaneous release of either verbenone or racemic ipsdienol. Trap catch was significantly further reduced by including both inhibitors with the attractant pheromones. However, although the response of *Ips paraconfusus* was significantly inhibited with the addition of either verbenone or racemic ipsdienol, both compounds together did not result in a significant further reduction in trap catch. There was a trend for greater reduction in response of *D. brevicomis* to attractant pheromones with increased release rates of either 69% (+)-/31% (−)-verbenone or 84% (−)-/16% (+)-verbenone. Response of associates to attractants and inhibitor combinations was also determined.

Key Words—*Dendroctonus brevicomis*, *Ips paraconfusus*, bark beetle, verbenone, ipsdienol, pheromones, inhibitors, Coleoptera, Scolytidae.

INTRODUCTION

The western pine beetle, *Dendroctonus brevicomis* LeConte, uses a combination of beetle-produced pheromones [(+)-*exo*-brevicomin {(+)-*exo*-7-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1]octane} and (−)-frontalin{(−)-1,5-dimethyl-6,8-dioxabiocyclo[3.2.1]octane}] (Silverstein et al., 1968; Kinzer et al., 1969;

*To whom correspondence should be addressed.

0098-0331/91/1100-2163$06.50/0

Wood et al., 1976) and host odors, primarily myrcene (Bedard et al., 1969), during the aggregation phase of tree colonization (Wood, 1972). The engraver beetles, *Ips paraconfusus* Lanier and *I. pini* (Say), are sympatric with *D. brevicomis* in California and may colonize the same host material. *Ips paraconfusus* pheromone consists of three components: (−)-ipsenol[(−)-2-methyl-6-methylene-7-octen-4-ol], (+)-*cis*-verbenol, and (+)-ipsdienol[(+)-2-methyl-6-methylene-2,7-octadien-4-ol] (Silverstein et al., 1966). The pheromone of *I. pini* in California was initially described as a single component pheromone, (−)-ipsdienol (Birch et al., 1980a, b); however, there is some suggestion that a second component may be important to complete the pheromone blend (S.A. Teale, personal communication).

The pheromones produced have interspecific effects in addition to the intraspecific effect. Attraction of *I. pini* to its pheromone is inhibited by racemic ipsenol (Birch and Light, 1977) and to (+)-ipsdienol (Birch et al., 1980a, b). These compounds are components of *I. paraconfusus* aggregation pheromone. Similarly, attraction of *I. paraconfusus* to its pheromone is inhibited by (−)-ipsdienol (Light and Birch, 1979), a component of the aggregation pheromone of *I. pini*. *Dendroctonus brevicomis* was inhibited by actively boring *I. paraconfusus* (Byers and Wood, 1980). Subsequent studies by Byers and Wood (1981a) demonstrated that at least two of the constituents of *I. paraconfusus* pheromone must be present for the inhibitory effect.

Although the constituents of *D. brevicomis* pheromone function to attract individuals, high release rates of *exo*-brevicomin or myrcene may also function to interrupt the response (Tilden et al., 1981). Oxidation of tree-produced α-pinene by either beetles or by microorganisms results in production of verbenone. This compound found in male *D. brevicomis* (Byers and Wood, 1980) interrupts the response of *D. brevicomis* (Bedard et al., 1980) to its attractant pheromone. In addition, verbenone similarly inhibits the attraction response of *I. paraconfusus* (Byers and Wood, 1980, 1981a).

Colonization of conifers usually occurs as a community process. Although there may be a temporal separation, it would be expected that each species in the community would produce the components of its pheromone with the resulting potential for interspecific and intraspecific interactions. The objective of the study presented here was to determine how the compounds associated with inhibition would effect aggregation of *D. brevicomis* and *I. paraconfusus* if presented singly or in combination.

METHODS AND MATERIALS

The behavioral responses of *D. brevicomis* and *I. paraconfusus* to interspecific and intraspecific chemical signals were examined at two locations during July and August 1990. Each site had obvious tree mortality, and examination

of the recently killed trees indicated that populations of both *D. brevicomis* and *I. paraconfusus* were high. While both sites were located within Yellow Pine Forest ecosystems (Munz and Keck, 1973), one site (Julian, San Diego County) was at 1300 m elevation, dominated by *Pinus coulteri* D. Don. and *Q. agrifolia* Nee near the interface with the Chaparral ecosystem, while the other site (Palomar Mountain, San Diego County) was at 1500 m elevation and dominated by mixed conifers.

One of 12 combinations of *D. brevicomis* attractant [Db = (+)-*exo*-brevicomin (released at 2.6 mg/24 hr at 25°C), (−)-frontalin (2.0 mg/24 hr), and myrcene (300 mg/24 hr)], *I. paraconfusus* pheromone [Ip = 50% (+)-/50% (−)-ipsenol (0.2 mg/24 hr), *cis*-verbenol (2 mg/24 hr), and 95% (+)-/5% (−)-ipsdienol (0.2 mg/24 hr)], 16% (+)-/84% (−)-verbenone (10 mg/24 hr), and/or 50% (+)-/50% (−)-ipsdienol (10 mg/24 hr) was placed on a Lindgren funnel trap (trap and all synthetic compounds from Phero Tech Inc., Delta, British Columbia, Canada). Inhibitors were always tested in combination with one or more of the attractant pheromones. An unbaited trap was also tested as a control. A 3-cm^2 piece of DDVP-impregnated plastic was placed in the collection cup of each trap to kill any captured beetles. A line of traps spaced at 20-m intervals containing one of each of the 13 treatments constituted a block. Three lines of traps were located in the Julian site and two lines of traps were located at Mount Palomar in two separate tests. Beetles were collected from the traps daily for 12 days, each day constituting a replicate. After each collection, the chemical baits were shifted in a predetermined sequence to a new position within each line. The trapped insects were brought into the laboratory and the numbers of *I. paraconfusus* and *D. brevicomis* were counted. We also counted *Dendroctonus valens* LeConte and the predators *Enocleris lecontii* (Wolcott) (Coleoptera: Cleridae) and *Temnochila chlorodia* (Mannerheim) (Coleoptera: Trogositidae).

Verbenone has been reported as an inhibitor of both *I. paraconfusus* and *D. brevicomis*. However it is not clear whether either or both enantiomers of verbenone are effective at inhibiting the response to the attractant pheromones. We tested a mixture of 16% (+)-/84% (−)-verbenone released at five elution rates at the Mount Palomar site during August 1990. Funnel traps were baited with one of six treatments: *D. brevicomis* pheromone [*exo*-brevicomin (released at 2.6 mg/24 hr at 24°C), frontalin (2.0 mg/24 hr), and myrcene (300 mg/24 hr)] alone and *D. brevicomis* pheromone plus the verbenone enantiomers eluted at 0.01 mg/24 hr (at 25°C), 0.18 mg/24 hr, 1.8 mg/24 hr, 5 mg/24 hr, and 20 mg/24 hr. As in the previous test, an unbaited trap served as a control. Each of the seven treatments was replicated 10 times. Beetles were collected from the traps three times at 72-hr intervals. An identical test was subsequently conducted using 69% (+)-/31% (−)-verbenone in the same location.

Differences in trap catches among the 13 treatments at each location for

each beetle species, as well as the differences in the response of *D. brevicomis* among release rate treatments for an enantiomeric blend were determined using General Linear Modeling procedures (PROC GLM) and Duncan's new multiple-range test on SAS for microcomputers (SAS Institute, 1988).

RESULTS

At both study sites, the traps baited with *D. brevicomis* pheromone (Db) alone caught significantly more of that species than any of the other treatments [Julian: $F = 18.41$, $df = 12$, $P = 0.0001$ (Table 1); Palomar: $F = 13.99$, $df = 12$, $P = 0.0001$ (Table 2)]. Four treatments [Db and verbenone, Db and ipsdienol, Db and *Ips paraconfusus* pheromone (Ip) and Db and Ip and ipsdienol] at both sites inhibited the response of *D. brevicomis* to the attractant pheromone, but still caught more beetles than the blank control traps. The three remaining treatments (Db and Ip and verbenone, Db and verbenone and ipsdienol, and Db and Ip and verbenone and ipsdienol) further reduced catches of *D. brevicomis* to levels not significantly different from either the unbaited control or to those treatments lacking the aggregation pheromone (Db) of this species.

The arrival of *I. paraconfusus* at traps at the Mount Palomar location was significantly inhibited ($F = 8.34$, $df = 12$, $P = 0.0001$) by the addition of verbenone and ipsdienol to treatments that included the aggregation pheromones (Table 2). The aggregation pheromones of this species alone and in combination with the aggregation pheromones from *D. brevicomis* were the only two treatments that were significantly different from the responses to the unbaited control. Although the response of *I. paraconfusus* was significantly greater ($F = 6.87$, $dd = 12$, $P = 0.0001$) to the aggregation pheromones of both *I. paraconfusus* and *D. brevicomis* together, the response to the aggregation pheromone of *I. paraconfusus* alone was not different from the unbaited control or any of the inhibitor treatments at the Julian location (Table 1).

While there were some beetles caught in the traps, there were no significant differences in the arrival of *E. lecontii* ($F = 0.76$, $df = 12$, $P = 0.2799$) to any of the 13 treatments tested in the first study at Julian, but the response of both *D. valens* ($F = 4.27$, $df = 12$, $P = 0.0001$) and *T. chlorodia* ($F = 3.25$, $df = 12$, $P = 0.0002$) was significantly greater to the E-M-F and [50% (+)-/50% (−)-ipsenol, *cis*-verbenol, and 95% (+)-/5% (−)-ipsdienol] and ipsdienol treatment (Table 1). The response of *D. valens* at the Mount Palomar location was not significantly different to any treatment ($F = 0.90$, $df = 12$, $P = 0.5519$). However, there were significant differences observed for the response of the other two associates to the same treatments at the Mount Palomar site [*E. lecontii* ($F = 2.06$, $df = 12$, $P = 0.0197$), *T. chlorodia* ($F = 2.12$, $df =$

12, $P = 0.0159$), Table 2]. Individuals of these three species were also caught in traps baited with *D. brevicomis* aggregation pheromone and different release rates of verbenone. The response of *D. valens* was significantly less ($F = 3.60$, $df = 6$, $P = 0.0021$) when any 69% (+)-/31% (−)-verbenone treatment was included, but there were no significant differences among treatments for *E. lecontii* ($F = 0.96$, $df = 6$, $P = 0.4519$) or *T. chlorodia* ($F = 1.71$, $df = 6$, $P = 0.1199$) (Table 3). In contrast, when 16% (+)-/84% (−)-verbenone was tested, catch of *D. valens* was significantly greater than the unbaited control ($F = 2.37$, $df = 6$, $P = 0.0311$) for only the lowest release rate (Table 4). Response of *E. lecontii* was significantly different from the control ($F = 2.72$, $df = 6$, $P = 0.0147$) at the highest release rate, and response of *T. chlorodia* was not different to any verbenone treatment ($F = 1.37$, $df = 6$, $P = 0.2287$).

The response of *D. brevicomis* to the aggregation pheromone alone was significantly greater ($F = 15.06$, $df = 6$, $P = 0.0001$) than to any of the treatments containing the 69% (+)-/31% (−)-verbenone (Table 3). There was no clear dose–response relationship, but all treatments attracted more beetles than did the unbaited control. In contrast, the responses of *D. brevicomis* to the two lowest release rates of 16% (+)-/84% (−)-verbenone were not significantly different ($F = 17.57$, $df = 6$, $P = 0.0001$) than the response to the aggregation pheromone alone (Table 4). However, traps baited with the lowest release rate of this enantiomeric blend of verbenone plus aggregation pheromone caught significantly more beetles than did the treatment with the next lowest release rate. As in the previous test of enantiomers, all treatments attracted more beetles than did the unbaited control traps.

DISCUSSION

Our results confirm that the response of *D. brevicomis* to its aggregation pheromone is reduced by the presence of *I. paraconfusus* pheromone, racemic ipsdienol, or verbenone, but also demonstrate that the presence of multiple inhibitor compounds further reduces the response. While it is not clear why the response of *I. paraconfusus* to its aggregation pheromone was not different ($P = 0.05$) from the control treatment at the Julian site, the reduction in the response at the Mt. Palomar location was not significantly enhanced by the addition of more than one inhibitory compound. However, at the Julian location, there was a tendency for the treatments with either *D. brevicomis* or *I. paraconfusus* pheromones alone or both pheromones together plus only a single inhibitor to have higher trap catches. The response of the associates was generally very low to any of the treatments. However, Wood et al. (1968) demonstrated that *E. lecontii* responds to pheromone constituents of *I. paraconfusus*, while Vité and Pitman (1969) found that *T. chlorodia* responded to *D. brevicomis* pheromone.

[a] Insects removed every three days from 10 locations per treatment. Numbers within columns followed by the same letters are not significantly different (P 0.05, analysis of variance and Duncan's multiple-range test).

The process of tree colonization by *D. brevicomis* takes place within a very short time and is mediated by attractant semiochemicals (Wood, 1972). However, there is the potential for competition among the arriving beetles for the limited amount of available resource (Alcock, 1982; Berryman et al., 1985). One of the mechanisms used by the beetles appears to be a complex coordination of timing in release of attractants and production of inhibitory compounds (Byers et al., 1984). Consequently, the arriving beetles are spaced to maximize individual fitness (Schlyter et al., 1987; DeJong and Sabelis, 1988).

The recognition of verbenone as an inhibitor occurs in several species within the *Dendroctonus* and *Ips* genera. Pitman et al. (1969) identified verbenone from *D. brevicomis*, *D. frontalis* Zimmermann, and *D. ponderosae* Hopkins. Subsequent investigations demonstrated that the compound inhibits arrival of beetles to attractive sources (Bedard et al., 1980; Ryker and Yandell, 1983; Payne and Billings, 1988). *Ips paraconfusus* and *I. typographus* (L.) were also shown to be inhibited by verbenone (Byers and Wood, 1980, 1981a; Bakke, 1981).

It is not common to observe individuals of a single bark beetle species colonizing a tree. Rather it is usually a community of species (Paine et al., 1980). The interactions among the members of the community may be mediated by the pheromone communication system (Birch et al., 1980a, b; Smith et al., 1990). However, several beetle species may produce the same chemical compounds and exploit the inhibitor message to reduce competition. Male *D. brevicomis* and male *D. ponderosae* produce (+)-ipsdienol from myrcene (Renwick et al., 1976; Byers, 1982; Hunt et al., 1986). This enantiomer inhibits conspecifics (Byers, 1982; Hunt and Borden, 1988) as well as *I. pini* (Birch et al., 1980a, b), a potential competitor of either species. Thus, *D. brevicomis* and *D. ponderosae* release two compounds (verbenone and ipsdienol) that have interspecific and intraspecific inhibitory effects. The effect of releasing the inhibitors simultaneously has not been observed previously for a *Dendroctonus* species. There was a suggestion from the studies of Bakke (1981) that the release of two inhibitory compounds was more effective for inhibiting the response of *I. typographus* than the release of either compound alone, but subsequent work could not confirm those results (Schlyter et al., 1988).

The chemical components of the pheromone blends have multifunctional effects; they may function as attractant pheromones, inhibitory pheromones, or as synomones. The insects may produce the compounds, or production may be the result of microbial action on either ingested substrate or exposure to volatile substrates. Brand et al. (1975) isolated a bacterium from *I. paraconfusus* that utilized α-pinene to synthesize *cis*- and *trans*-verbenol. Byers and Wood (1981b) reported that streptomycin treatments of *I. paraconfusus* prevented the conversion of myrcene to ipsenol and ipsdienol. In contrast, *I. typographus* produces *cis*- and *trans*-verbenol but requires associated yeasts to convert these compounds to verbenone (Leufven et al., 1984; Leufven and Birgersson, 1987).

The yeasts were unable to produce either the verbenols or verbenone directly from α-pinene (Leufven et al., 1988). Similarly, *D. ponderosae* requires a gut microorganism to produce verbenone (Hunt and Borden, 1989).

There is an obvious ecological advantage to both arriving and colonizing beetles to avoid either marginal resources or intense competition. Verbenone, derived from α-pinene through the intermediate verbenols by microbial action in several systems, appears to be a common signal that the resource may be attacked and potentially unsuitable for further colonization (Schlyter et al., 1988). The terpene alcohols, ipsenol and ipsdienol, may also be interspecific and intraspecific inhibitors that serve to reduce detrimental competition. Light et al. (1983) demonstrated that interspecific competition between *I. paraconfusus* and *I. pini* produced greater negative effects than intraspecific competition and speculated that these competitive interactions may be the selective force that resulted in mutual pheromone inhibition between the species. The geographic range of *D. brevicomis* is within the range of *Pinus ponderosa* Lawson. *Ips pini* and *D. brevicomis* are sympatric in much of that range, and the enantiomer of ipsdienol produced by *D. brevicomis* is an effective inhibitor of *I. pini* where sympatry occurs (Birch et al., 1980a, b). It is, however, a constituent of the attractant pheromone of *I. paraconfusus* that overlaps with *D. brevicomis* in only a portion of the geographic range.

While parallel studies have not been completed for *I. paraconfusus* and *D. brevicomis*, the competitive interactions may be similarly detrimental. However, it is not clear why the presence of multiple inhibitors produced a greater effect on *D. brevicomis* than *I. paraconfusus*. It is possible that this *Ips* species is more sensitive to the presence of the inhibitors or the described pheromone blend for this species is incomplete, and as a result, the maximum reduction was observed to any single compound. There is a difference between *I. paraconfusus* and *I. typographus*. The results of Bakke (1981) suggest that attraction of *I. typographus* is inhibited more by a combination of ipsenol plus verbenone than by either compound alone. However, in the European spruce system, this species may be more of an ecological homologue to *D. brevicomis* than to *I. paraconfusus* in western North America.

Acknowledgments—We thank J. Trumble, R. Redak, P. Luft, T. Grasswitz, P. Leddy, S. Bertram, and M. Moratorio for helpful reviews of the manuscript; Phero Tech Inc. (Delta, British Columbia, Canada) for the release devices used in the enantiomeric dose test; and D. Messore, S. Gilbert, M. Goeden, and S. Bertram for data collection. This study was supported in part by a grant from the California Department of Forestry and Fire Protection.

(Received March 25, 1991; accepted July 8, 1991)

Abstract—The female sex pheromone of the fungus-growing termite *Pseudacanthotermes spiniger* (Termitidae, Macrotermitinae) was isolated from sternal glands of alates. The compound inducing attraction and excitation in males was identified as the (3*Z*,6*Z*,8*E*)-3,6,8-dodecatrien-1-ol by GC-MS, microhydrogenation, GC-FTIR, and NMR. This unsaturated alcohol is present in both sexes but in much higher quantities in females than in males (about 10 times). The hypothesis is suggested that this alcohol, which is detected at extremely low concentrations by the workers of *P. spiniger*, may be used either as a trail-following pheromone or a sex pheromone according to concentrations and to target castes. The presence of this alcohol in Macrotermitinae reinforces the idea of a phylogenetic proximity between this subfamily of higher termites and the lower termites Rhinotermitidae, where the unsaturated alcohol was previously found. The sternal glands of alates of *P. spiniger* also contain a geometric isomer of (3*Z*,6*Z*,8*E*)-3,6,8-dodecatrien-1-ol.

Key Words—Termites, Isoptera, Macrotermitinae, *Pseudacanthotermes spiniger*, insect sex pheromone, (3*Z*,6*Z*,8*E*)-3,6,8-dodecatrien-1-ol.

INTRODUCTION

Termite colonies generally reproduce by seasonal dispersal flights of winged males and females (alates). The meeting and the pairing of these alates is mediated through various factors, among which chemical stimuli from abdominal glands are of prime importance. However, sex pheromones have been demonstrated only in a few cases: *Kalotermes* (Wall, 1971), *Zootermopsis* (Pasteels, 1972; Stuart, 1975), *Hodotermes* (Leuthold, 1977), *Reticulitermes* (Buchli, 1960; Stuart, 1969, 1975; Clément, 1982), *Trinervitermes* (Leuthold and Lüscher, 1974; Leuthold, 1977), and only one publication has dealt with the chemical nature of termite sex pheromone (Clément et al., 1989).

In this paper, we report on the isolation and the identification of the female sex pheromone of a fungus-growing termite, *Pseudacanthotermes spiniger*. This species is one of the rare species of termites in which pairing occurs in the air during the swarming flight (Grassé and Noirot, 1951; Grassé, 1984). The nests of *P. spiniger* are entirely subterranean, but epigeous turrets (up to 1.5 m high) are built by the workers just before the swarming season. The alates are gathered in these "swarming turrets" some weeks before the flight. For some years, *P. spiniger* has been becoming more abundant in the sugarcane plantations of equatorial Africa and is becoming economically important.

METHODS AND MATERIALS

Alates of *P. spiniger* were collected in the savannah near Franceville in Gabon, where the colonies of *P. spiniger* swarm at the end of the rainy season (May 1988, 1989, 1990). One hundred fifty thousand alates were collected either directly from swarming turrets or during the flight by covering these turrets with mosquito nets.

In *P. spiniger* sex attraction is intense and can be observed in the laboratory for several days and even several weeks. In Petri dishes, the females take up a "calling" posture with their highly raised abdomen exposing the sternal gland. There is no differentiated tergal gland in the alates of *P. spiniger*. The males are attracted by these calling females. As soon as they touch the females, a tandem run is released. The female is the leader, the male follows, palpating with antennae and mouthparts the female abdominal extremity. As already mentioned (Stuart, 1969), this suggests that in the sexual behavior both olfactory and tactile stimuli are involved. Therefore, two males were used for each sex attraction bioassay since a single male is deprived of tactile communication and shows rather unstable behavior.

Laboratory Bioassays. Sex attraction bioassays were carried out by introducing two males into 15-cm-ID Petri dishes. These dishes contained small bent

pieces of Whatman No. 1 filter paper (1 cm^2) on which 20 μl pentanic extracts were applied with a microsyringe. The solvent was evaporated immediately before the bioassay. A similar piece of paper treated with 20 μl pentane and evaporated to dryness was used as control. The two males were introduced at the same time and at the same distance from the pieces of paper. During 300 sec, the time spent by one or two males licking or palpating the different pieces of paper was measured. A bioassay was noted as positive for an extract when the time was longer than 150 sec. After each bioassay, the Petri dish was cleaned with ethanol and pentane; males and pieces of paper were replaced.

Extracts. Two kinds of extracts were prepared: (1) Extracts from whole individuals were prepared by washing dealate males or females in doubly distilled pentane for 1 hr at 4°C, 250 ml solvent was used for 4000 individuals. Samples were stored at −20°C. (2) Extracts from sternal glands were prepared by removing the glands under a stereomicroscope with microscissors and forceps from cold anesthesized males or females. The glands [dimensions of the gland (μm)—females: 1800/550/150; males: 600/250/80] were removed from adjacent tissues (hemolymph, fat body) with a paper towel and transferred to a vial of doubly distilled pentane (200 glands/2 ml solvent) and allowed to soak for 1 hr at 4°C; then the glands were removed and the extracts were used immediately for bioassays or stored at −20°C for chemical analyses.

For all bioassays, the extracts were tested at a concentration of one individual equivalent.

Chemical Analyses. Gas chromatographic analyses (GC) were carried out with a Packard 429 gas chromatograph fitted with a split–splitless injector and a flame-ionization detector. The capillary column used was either a DB-5 fused silica column (30 m × 0.32 mm ID, J&W Scientific) or a CP-WAX 58 CB column (25 m × 0.25 ID, Chrompack) with temperature programming from 50°C to 220°C, at 2°C/min. Injector and detector temperatures were, respectively, 230°C and 250°C. Helium was used as the carrier gas at a flow rate of 5 ml/min. The GC traces were recorded and integrated by a CR3A Shimadzu integrator.

For preparative GC, a Girdel 30 chromatograph fitted with a Pyrex column (3 m × 3.2 mm) packed with 5% SE 30 on 100–120 mesh Chromosorb AW-DMCS, and a flame-ionization detector was used with helium as the carrier gas (flow rate 15 ml/min). Oven temperatures were programmed from 100°C to 200°C, at 2°C/min. An effluent splitter was used that allowed 50% of the effluent to flow to the detector. Fractions were collected in U-shaped glass tubes (1 mm ID) cooled to 0°C.

Gas chromatographic–mass spectrometric (GC-MS) analyses were carried out with a Nermag R 10-10-C quadrupole mass spectrometer coupled to a Girdel 31 gas chromatograph fitted with a split–splitless injector and a DB-5 fused

silica capillary column (60 m × 0.32 ID). The GC conditions described above were used. The column was connected directly to the ion source of the spectrometer through a heated transfer line maintained at 260°C.

Electron impact (EI) mass spectra were obtained at 70 eV on an 0.8-sec cycle, the instrument scanning from 25 to 300 amu with the ion source maintained at 150°C. Positive chemical ionization (CI) mass spectra were generated at 90 eV using methane or ammonia (and deuterated ammonia) at a source pressure of 0.2 and 0.3 torr, respectively, with a source temperature of 90°C, and the instrument scanning from 60 to 300 amu in 0.7 sec. Negative CI was obtained with the hydroxyl anion OH^- by ionizing a 5:1 mixture of methane and nitrous oxide (CH_4–N_2O) at a source pressure of 0.3 torr.

Microhydrogenation was performed on line in the GC-MS system by means of a fused silica capillary reactor. The reactor, consisting of a 60-cm piece of deactivated fused silica capillary column (6 m × 0.32 mm ID), statically coated with a 0.5% CH_2Cl_2 solution of palladium acetyl-acetonate (Fluka) was connected to the outlet of the analytical column with a zero-dead volume capillary butt-connector (Supelco) (Le Quéré et al., 1989). Palladium metal was precipitated at 220°C under hydrogen flow. Hydrogen was then used as the carrier gas at a flow rate of 1.5 ml/min, and the GC conditions were those previously described.

Fourier transform infrared (FTIR) spectra were taken in the gas phase on a Bruker IFS 85 FTIR spectrometer coupled, via a Bruker gold-coated lightpipe (20 cm × 1.0 mm ID) maintained at 200°C, to a Carlo-Erba 5160 gas chromatograph equipped with a DB-5 fused silica capillary column (30 m × 0.32 mm ID), an on-column injector, and a flame ionization detector. The carrier gas was helium at a flow rate of 3 ml/min and temperature programming from 30 to 60°C at 10°C/min and then to 200°C at 3°C/min.

For NMR analysis, the trapped component was rinsed from the tube into a Teflon-lined capped vial with distilled pentane, evaporated to dryness, and redissolved in deuterochloroform ($CDCl_3$, 99.96% D, CEN-CEA, Gif sur Yvette). The purity of collected fractions was monitored by capillary GC.

[^{1}H]NMR spectra were recorded on a Bruker WM400 instrument in 5-mm-ID NMR tubes. The signal due to the residual protons of the deuterated solvent was used as internal reference (δ = 7.24).

RESULTS

Origin Sex Pheromone. In *P. spiniger*, the males are attracted by the females; the females are never attracted by the males. In bioassays, the females are neither attracted by the male extracts nor by the female extracts (0 positive out of 30 bioassays performed).

The results obtained with the males (Table 1, A) show that the bioassays are not biased when using two males, since these two individuals never joined together for a long time on control papers in the Petri dish.

The males were strongly attracted by female extracts (Table 1, B). In most of the cases, the males started running rapidly toward the female extracts and met each other on the female extract in few seconds. Then, they could stay on the extract during the entire bioassay, while licking and palpating the piece of paper and each other alternately. In a few cases (3/20), males were attracted by the male extracts. This is not completely surprising since male–male homosexual tandems have been observed sometimes.

If given a choice between extracts from female sternal glands and extracts from whole females without sternal gland, the males always choose the sternal gland extract (Table 1, C). It could be concluded that the females of *P. spiniger* attract males by means of a sex pheromone that is secreted by their sternal gland.

Isolation of Sex Pheromone. The GC patterns of male and female washes were similar. However, a compound with a retention time of 57 min was about 10 times more abundant in females than in males. The same peak was observed in the sternal gland extracts of both sexes, and it was also about 10 times higher in female glands than in male glands (Figure 1, compound A). Compound B, with a retention time of 62 min, is also more abundant in females than in males.

The extracts from whole individual washes were fractionated by gas chro-

	Control 2	0	0.5 ± 0.4

[a] Choice tests for male dealates between filter paper impregnated with various extracts. All extracts were tested to one individual or one gland equivalent. A bioassay was considered as positive when males licked and palpated extracts for at least 150 sec. (Duration of the bioassay = 300 sec.) T: mean time ($\pm$SD) spent by males on extracts. Control 1: piece of filter paper. Control 2: filter paper previously impregnated with pentane. Number of replicates: 20.

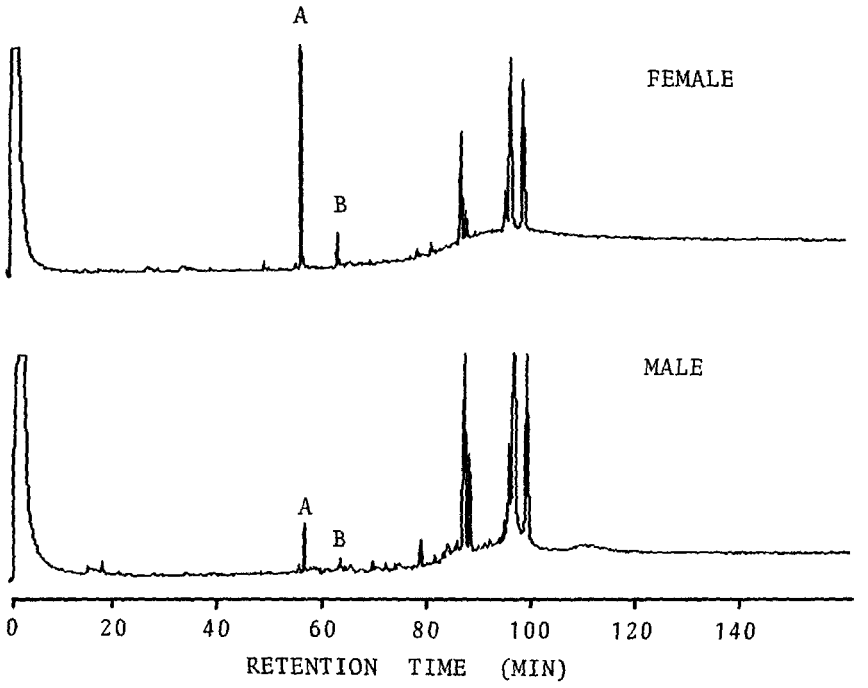

FIG. 1. Gas chromatograms of sternal gland extracts from female (upper) and male (lower) alates *Pseudacanthotermes spiniger*. Compounds A and B are much more abundant in females than in males. A is the female sex pheromone of *P. spiniger*.

matography, and the fractions were tested in bioassays at the concentration of one individual equivalent (Figure 2 and Table 2). Only fractions 2 and 4 were attractive for males and able to induce sexual behavior in these individuals (quick moving, licking, antennal palpating). Fraction 2, which only contained compounds A and B, was as active as the whole female wash. When only fractions 1 and 3 were tested, there was no positive response. Fractions 4 and 5 enabled us to separate compounds A and B: only fraction 4 with compound A was active. Compound A is the female sex pheromone of *P. spiniger*.

Identification of Sex Pheromone. The mass spectrum of compound A is presented in Figure 3. A spectral search in various MS data bases gave no plausible candidate. However, a fragment ion at *m/z* 31 suggested a primary aliphatic alcohol (Budzikiewicz et al., 1964), and the fragmentation pattern was found typical of a polyunsaturated compound. The molecular weight, suggested by an important ion at *m/z* 180, was confirmed by chemical ionization GC-MS, with methane and ammonia as reagent gases. The methane-CI mass spectrum displayed pseudomolecular ions at *m/z* 179 $(M - 1)^+$, 180 $(M)^+$ and 181 (M

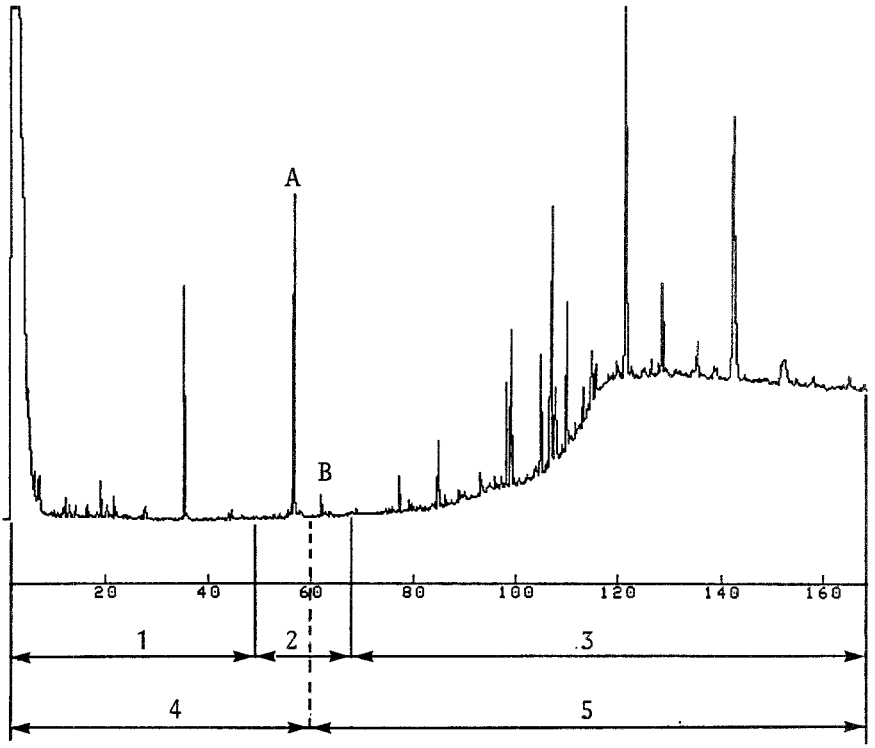

FIG. 2. Chromatographic fractions of washes of female alates *Pseudacanthotermes spiniger*. Fraction 2 contains compounds A and B, which are especially abundant in females. Fraction 4 contains A , fraction 5 contains B. Only fractions 2 and 4 induced attraction and excitation in male dealates.

$+ 1)^+$ and a prominent ion at m/z 163 $(M - 17)^+$, characteristic of an unsaturated alcohol of molecular weight 180 (Sarris et al., 1985). This was confirmed by the ammonia-CI mass spectrum, which showed intense pseudomolecular ions at m/z 181 $(M + 1)^+$ and 198 $(M + NH_4)^+$, and a weak ion at m/z 163 $(M - 17)^+$. These molecular ions and their isotopic contributions suggested a molecular formula $C_{12}H_{20}O$ and three sites of unsaturation.

The functionality was confirmed with a CI-MS experiment with deuterated ammonia (ND_3) as reagent gas. The pseudomolecular ions at m/z 183, $(M - H + D + D)^+$ and 203, $(M - H + D + ND_4)^+$ revealed one exchangeable proton (Lin and Smith, 1979).

Online microhydrogenation (Le Quéré et al., 1989) gave a mass spectrum typical of a straight-chain primary alkanol, with no molecular ion. However, an ion at m/z 168, tentatively attributed to $(M - H_2O)^+$, suggested a molecular

weight of 186, and thus, the structure 1-dodecanol. This was confirmed by spectral search in MS data bases and by OH^- CIMS [m/z 185 $(M - 1)^-$], revealing three carbon–carbon double bonds in the original compound, accounting for the three sites of unsaturation, and consequently, the structure dodecatrien-1-ol.

The GC-FTIR spectrum of A (Figure 4) confirmed the hydroxyl group (ν OH: 3657 cm^{-1}; ν C–O: 1049 cm^{-1}). The C–O stretching frequency was characteristic of a primary alcohol (Nyquist, 1984). The OH stretching frequency was rather low for a primary alcohol, suggesting an intramolecular hydrogen bonding, probably with one of the carbon–carbon double bonds, in a $(5 + \pi)$ system (Nyquist, 1984), revealing a 3-alken-1-ol subunit. Other important features of the vapor-phase infrared spectrum were the C=C stretching frequency at 1659 cm^{-1} and the CH out-of-plane deformation frequency (δ CH) at 719, 949, and 980 cm^{-1}. The former (719 cm^{-1}) was attributed to a *Z*-disubstituted ethylenic bond and the pair 949 and 980 cm^{-1} to *Z,E*-conjugated double bonds.

Finally, the structure of compound A, isolated by preparative GC, was established by [^{1}H]NMR, including two-dimensional chemical shifts correlation (COSY) and selective decoupling experiments. The 400-MHz [^{1}H]NMR spec-

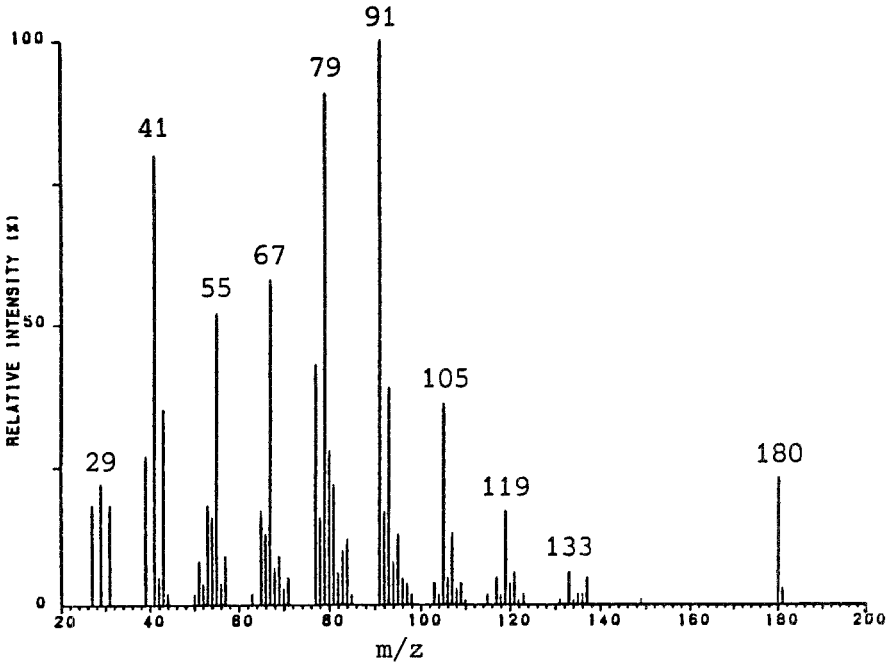

FIG. 3. Mass spectrum (70 eV) of compound A.

trum (Table 3) revealed well-resolved multiplets due to six olefinic hydrogens at δ 6.32, 5.98, 5.70, 5.58, 5.42, and 5.25 ppm.

The proton at δ 6.32 (dd) was coupled (J = 15 Hz) to a vinyl hydrogen (δ 5.70), confirming one *E*-double bond, and coupled (J = 10.9 Hz) to another olefinic proton (δ 5.98), confirming the conjugated double bonds. The *Z* geometry of this second double bond was confirmed by the coupling constant (J = 10.7 Hz) measured in the olefinic resonance at δ 5.98 (dd) which, itself, revealed a coupling with the vinyl hydrogen at δ 5.25.

The olefinic proton at δ 5.70 (dt) was also coupled (J = 6.9 Hz) to a methylene resonance at 2.09 (dt) which was connected (J = 7.0 Hz) to another methylene signal at δ 1.42 (tq), itself coupled to a methyl triplet (J = 7.4 Hz) at δ 0.92. Therefore, the partial structure $CH_3-CH_2-CH_2-CH=CH-CH=CH-$ could be deduced.

The olefinic multiplet at δ 5.25 (dt) was also coupled to a methylene group at δ 2.95 (dd, J = 7.4 Hz), itself coupled (J = 7.4 Hz) to another vinyl hydrogen at δ 5.58. The latter was coupled to the olefinic resonance at δ 5.42 with a coupling constant (J = 10.7 Hz) characteristic of a *Z*-ethylenic bond. This olefinic signal (dt) revealed a coupling (J = 7.3 Hz) with a methylene resonance

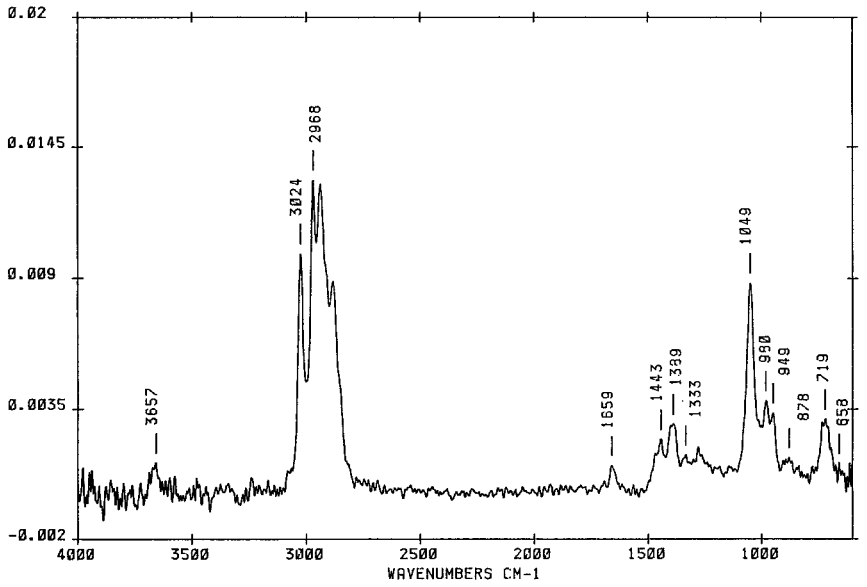

FIG. 4. Gas-phase infrared spectrum of compound A.

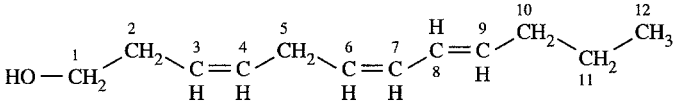
TABLE 3. [^{1}H]NMR SPECTRUM OF COMPOUND A IDENTIFIED AS (*Z,Z,E*)-3,6,8-DODECATRIEN-1-OL[a]



Compound A: (*Z,Z,E*)-3,6,8-Dodecatrien-1-ol

6.32 (1H, dd, J = 15 and 10.9 Hz, H_8)
5.98 (1H, dd, J = 10.9 and 10.7 Hz, H_7)
5.70 (1H, dt, J = 15 and 6.9 Hz, H_9)
5.58 (1H, dt, J = 10.7 and 7.4 Hz, H_4)
5.42 (1H, dt, J = 10.7 and 7.3 Hz, H_3)
5.25 (1H, dt, J = 10.7 and 7.4 Hz, H_6)
3.67 (2H, t, J = 6.4 Hz, H_1)
2.95 (2H, dd, J = 7.4 and 7.4 Hz, H_5)
2.37 (2H, dt, J = 7.3 and 6.4 Hz, H_2)
2.09 (2H, dt, J = 7 and 6.9 Hz, H_{10})
1.42 (2H, tq, J = 7 and 7.4 Hz, H_{11})
1.20 (1H, br s, —OH)
0.92 (3H, t, J = 7.4 Hz, H_{12})

[a] 400.13 MHz, δ ppm/TMS, $CDCl_3$. Chemical shift (integration, multiplicity, coupling constants, assignment).

at δ 2.37 (dt), which was connected (J = 6.4 Hz) to another methylene group at δ 3.67 (t). The chemical shift of the latter was characteristic of an oxygen-bearing methylene. Finally, a broad singlet at δ 1.20 was tentatively attributed to the hydroxyl proton resonance.

Thus, the structure of compound A was demonstrated to be (*Z*,*Z*,*E*)-3,6,8-dodecatrien-1-ol as depicted in Table 3.

Compound A was identical to the product identified as the trail-following pheromone of various subterranean termites (Matsumura et al., 1968; Tai et al., 1969; Tokoro et al., 1989, 1990). The spectroscopic data are in good agreement with those published for the trail-following pheromone. Particularly, the mass spectrum and the [^{1}H]NMR spectrum were identical (Yamaoka et al., 1987; Eya et al., 1990).

There is about 15–20 ng (3*Z*,6*Z*,8*E*)-3,6,8-dodecatrien per female and 1–3 ng per male. Until now, it was not possible to test the activity of the synthetic alcohol on male alates of *P. spiniger*.

The other product of fraction 2 (compound B), with a longer GC retention time, gave exactly the same EI and CI mass spectra; it was therefore identified as a geometric isomer of the major product. The complete assignment of its structure is in progress.

Attempts to Detect Dodecatrienol in Food. P. spiniger is a fungus-growing termite that eats dead plants. The debris of wood or leaves are first packed together in the nest in small sawdust heaps and then incorporated into fungus gardens before ingestion by the workers. Several samples of sawdust (10 g/25 ml pentane) and fungus combs (100 g/250 ml pentane) were extracted during 2 hr with distilled pentane and analyzed by gas chromatography. No trace of the dodecatrienol was found in either sawdust or fungus combs.

DISCUSSION

(3*Z*,6*Z*,8*E*)-3,6,8-dodecatrien-1-ol (dodecatrienol) was first isolated and identified by Matsumura et al. (1968, 1969) from total extracts of workers of *Reticulitermes virginicus* and from food of this termite, which was wood infected by the fungus *Gloephyllum trabeum*. As this alcohol was detected by the workers at extremely low concentrations, it was considered to be the trail pheromone. However, it was never identified in the sternal gland itself, which produces the trail pheromone in termite workers. Some authors considered that dodecatrienol could be either an exogenous diet-related pheromone or just an attractant (Stuart, 1970; Ritter and Coenen-Saraber, 1969; Tschinkel and Close, 1973). Nevertheless, dodecatrienol has been found recently in workers of *Reticulitermes speratus* (Tokoro et al., 1990) and *Coptotermes formosanus* (Tokoro et al., 1989) fed with filter paper and it actually seems to be a trail-following pheromone of termites.

Our results in *P. spiniger* show for the first time that dodecatrienol occurs in the sternal gland of termites. As there is no dodecatrienol in the food, this substance must be synthesized by the termites themselves. In *P. spiniger* dodecatrienol is found in the swarming imagoes and is about 10 times more abundant in the female sternal glands than in male glands. Dodecatrienol has an unquestionable power of attraction and excitation over the male alates. It therefore can be considered as the sex pheromone of *P. spiniger*. It is interesting to note that tetradecyl propionate, the ester identified as a sex pheromone in *Reticulitermes flavipes*, is also present in both sexes but in much larger quantities in female alates than in males (Clément et al., 1989).

In *P. spiniger* the role of dodecatrienol might be not restricted to the only pairing of the alates. Some observations (Bordereau et al., 1991) show that the dealate imagoes are able to follow artificial trails prepared with pentanic solutions of dodecatrienol at very low concentrations. This would reunite partners after an accidental separation during the nuptial promenade. Moreover, dodecatrienol is also detected at extremely low levels by the workers of *P. spiniger* (Bordereau et al., 1990). In *P. spiniger*, dodecatrienol could be so used either as a sex or as a trail-following pheromone. This double function would depend on a variation of the capacity of detection according to target caste. At high concentrations, it acts as a female sex pheromone, eliciting attraction and excitation of the males, whereas at low concentrations it would act as a trail-following pheromone for workers and swarming imagoes.

The observations of Quennedey and Leuthold (1978) in *Trinervitermes bettonianus* are in good agreement with this hypothesis of a functional duality, as the sternal gland extracts of the workers, when applied in adequate concentrations, have the same capacity for male attraction as the female sternal gland extracts. In this species, the cembrene A identified as a trail-following pheromone is present in workers and in very much larger quantities in alates; however, its biological activity in sex attraction is not known (McDowell and Oloo, 1984).

It may seem surprising that a compound can be used as both a trail-following pheromone, which is detected at a very short distance, and a sex pheromone, which is considered to act at a long distance. Dodecatrienol is not an highly volatile component and cannot be detected beyond some tens of centimeters. However, in termites, sexual attraction never occurs at great distance, the only exception being *Hodotermes mossambicus* (Leuthold, 1977). In most species and in *P. spiniger* in particular the conditions of the dispersal flight favor the meeting of sexes. Flights are usually synchronous, and the alates do not disperse very much. In *P. spiniger*, where pairing occurs in the air, the alates have a zigzag and whirling flight, which greatly favors meetings between individuals.

Therefore, it is suggested that *P. spiniger* represents a very parsimonious

pheromonal system in which a single compound can assume at least two functions. This agrees with the economy principle often observed in social insects (Blum and Brand, 1972; Pasteels, 1976), and this interpretation would explain the presence of dodecatrienol in male alates. In these individuals, it would function only as a trail pheromone. However, the presence of dodecatrienol in both sexes could be also a vestigial character. In some primitive species such as *Kalotermes flavicollis* (Wall, 1971) or *Zootermopsis* (Castle, 1934; Pasteels, 1972), males and females may attract reciprocally.

Finally, the presence of dodecatrienol both in Rhinotermitidae, which are lower termites, and in Macrotermitinae, which are higher termites, must be underlined. This reinforces the phylogenetic proximity of Rhinotermitidae and Macrotermitidae, which was previously suggested on the basis of morphological and anatomical characters (Emerson, 1955; Deligne, 1985). Moreover, a great number of species of lower and higher termites are very sensitive to dodecatrienol (Ritter and Coenen-Saraber, 1969; Matsumura et al., 1972; Howard et al., 1976; Kaib et al., 1982). This suggests that dodecatrienol could be a basic pheromonal component common to many termite species while additional components would provide the specificity. This could explain the anatomical diversity and the complexity of the termite sternal gland (Quennedey, 1977).

Acknowledgments—We thank Professor Ch. Noirot and R. Brossut for review of this manuscript; H. Nkombe, C. Moussavou, and P. Okouma for helpful technical assistance and collecting termite alates; and the University of Masuku, Gabon, for use of their facilities and financial support.

RELATIONSHIPS BETWEEN CHEMICAL STRUCTURE AND INHIBITORY ACTIVITY OF C_6 THROUGH C_9 VOLATILES EMITTED BY PLANT RESIDUES[1]

JUDITH M. BRADOW

USDA, ARS, Southern Regional Research Center
P.O. Box 19687
New Orleans, Louisiana 70179

(Received April 26, 1991; accepted July 8, 1991)

Abstract—Leaf, stem, flower, fruit, and root residues of a wide variety of plants have been reported to emit bioactive *n*-alkanes, 2-alkanols, *n*-alkanals, 2-alkenals, 2-alkanones, and *n*-alkanoic acids containing from six to nine carbon atoms. During a 72-hr exposure to the vapor phase of these compounds (6.9, 20.8 or 34.4 μM/liter), germination of onion, carrot, and tomato seeds was inhibited to varying degrees. The extent of inhibition caused by these plant residue volatiles depended upon the compound type and concentration, carbon-chain length, and the seed species tested. Tomato seeds recovered more fully from exposure to these volatile inhibitors than did those of carrot and onion. Degree of recovery in all three species depended on the type and concentration of volatile present. The C_7 and C_8 compounds were the most inhibitory among these 24 volatiles. Of the six classes of chemicals examined, the 2-alkenals were the most inhibitory, followed by the 2-alkanols, *n*-alkanals, and 2-alkanones, which were equally effective as seed germination inhibitors. The straight-chain alkanes and alkanoic acids were relatively noninhibitory. Tests of a C_7 and C_9 alkadienal indicated that the C_7 compound was the more inhibitory.

Key Words—Allelopathy, allelochemicals, *Allium cepa*, *Daucus carota*, *Lycopersicon esculentum*, cover crops, insect attractants, conservation tillage, hydrocarbons, alcohols, ketones, aldehydes, carboxylic acids.

INTRODUCTION

Residues of both aerial and root tissues of many plant species emit mixtures of structurally simple volatile organic compounds containing six to nine carbon

[1] Mention of a commercial or proprietary product does not constitute an endorsement by the U.S. Department of Agriculture.

0098-0331/91/1100-2193$06.50/0

atoms in unbranched chains (Johnson et al., 1971a,b; Connick et al., 1987, 1989; Bradow and Connick, 1990). Many of the alcohols, aldehydes, and ketones from these volatile mixtures are well-known flavor components (Johnson et al., 1971a,b; French, 1985), have insect semiochemical activity (Visser, 1979, 1983; Light et al., 1988; Ramachandran et al., 1990), and also affect fungal growth and seed germination (French et al., 1977; French and Leather, 1979; French, 1985). Furthermore, these compounds are highly inhibitory of seed germination (Bradow and Connick, 1988a,b) and seedling growth (Bradow and Connick, 1988c) in several crop species. These volatiles also have been implicated in reductions in seedling survival and growth (Buntley, 1986; Dabney et al., 1986; Menges, 1987) and cotton yield (Rickerl et al., 1988) related to the presence in the soil of cover crop residues and other plant debris (Bradow and Connick, 1990).

Recent investigations of the activities of these compounds as seed germination inhibitors (Bradow and Connick, 1988a,b) and insect semiochemicals (Light et al., 1988; Ramachandran et al., 1990) have suggested that there are strong relationships between chemical structure, particularly carbon-chain length, and biological activity. Therefore, a comparative study was undertaken in which vapor-phase *n*-alkanes, 2-alkanols, 2-alkanals, *n*-alkanals, 2-alkenals, 2-alkanones, and *n*-alkanoic acids containing six, seven, eight, or nine carbon atoms were assayed for inhibitory effect on seed germination of onion, carrot, and tomato. The three seed species were exposed separately for 72 hr to three concentrations, either 6.9, 20.8, or 34.4 μM/liter, of the 24 individual compounds. The effects of a continuous seven-day exposure and a three-day exposure followed by removal of the test volatile and a 96-hr recovery period were also determined.

A C_7 and C_9 alkadienal were included in the assays on the basis of appropriate chain length and reported occurrence in volatile emissions from plant residues (Buttery et al., 1980, 1982a; Flath et al., 1984; Hernandez et al., 1989).

METHODS AND MATERIALS

Chemicals and assay seeds used in the bioassays were purchased from commercial sources. The assay technique, using desiccators as seed germination containers, was the protocol previously described (Bradow and Connick, 1987, 1988a,b; Connick et al., 1987). Briefly, seeds of onion (*Allium cepa* L., cv. Texas Early Grano 502), carrot (*Daucus carota* L., cv. Danvers Half-Long) or tomato (*Lycopersicon esculentum* Mill. cv. Homestead) were spread on double sheets of deionized water-saturated Whatman No. 1 filter paper placed on the porcelain plate of a 2.5-liter glass desiccator. Central circles (22 mm diam.)

had been removed from the filter paper to facilitate diffusion of the volatiles, and the filter-paper circles were divided into eight equal segments (replicates) containing 20 seeds each. Each desiccator well contained a 10-ml glass beaker (volatile source) resting on 50 g of pure sand in a glass crystallizing dish (100 × 50 mm). The sand was moistened with 10 ml of deionized water. The source beaker was left empty in the controls.

In the time-dependent studies, a volume equivalent to 34.4 μM/liter (full volatilization assumed) of the test compound was placed undiluted in the source beaker, and the separate seed species were incubated under a 10-hr/31°C day/21°C night temperature cycle for 72 hr before germination evaluation (three-day data). Radicle protrusion was the germination criterion for all seed species. The source beaker was then removed (three- + four-day data) or the test volatile was renewed by the addition of a second 34.4 μM equivalent (seven-day data). Each assay was performed twice (16 replicates, total), and controls were repeated at three-month intervals during the study. Germination of the control assays did not change significantly during the course of the experiment, and the germination rates of the seed lots used were not statistically different.

Concentration-dependent seed germination bioassays were performed using the same desiccator apparatus with the source beaker containing the appropriate volume of a single test compound to give a nominal volatile concentration of either 6.9, 20.8, or 34.4 μM/liter, assuming total volatilization and negligible adsorption (Bradow and Connick, 1988a). These concentrations were chosen on the basis of active concentration ranges determined earlier (Bradow and Connick, 1988a–c, 1990). With the control, the treatment concentration ratio was 0:1:3:5. Seed germination was evaluated after a three-day exposure to a test volatile. The volatile source was then removed, and the seeds were incubated for an additional four days. In both types of assays, the humidity within the desiccators was maintained by the addition of 10 ml deionized water to the sand after the three-day germination evaluation.

After normalization by the transformation $(x + 0.5)^{0.5}$, germination count data from the three-day and three- + four-day concentration-dependent assays were compared separately for each seed species, using three-way analyses of variance (six compound types × three concentrations × four carbon-chain lengths). For each seed species, two-way analyses of variance were used to examine the effects of chain length and concentration within compound type. Within the three-day (all three concentrations), seven-day, and three- + four-day data (34.4 μM/liter data only), one-way analyses of variance were used to determine significant differences between the mean effects of the test compounds and the appropriate deionized water controls, using Tukey's Honestly Significant Difference procedure (significance level, $P = 0.01$). The concentration-dependent data were also examined by regression analysis (Sokal and Rohlf, 1981).

RESULTS

Compound Type, Concentration, and Carbon-Chain-Length Effects on Seed Germination. When the seed germination rates of onion, carrot, or tomato seeds exposed for 72 hr to the C_6–C_9 plant residue volatiles (omitting the two alkadienals) were compared using separate three-way analyses of variance, compound type (*n*-alkane, 2-alkanol, etc.), volatile concentration (6.9, 20.8, or 34.4 μM), and carbon-chain length (six, seven, eight, or nine carbon atoms) had significant effects on all three seed species (Table 1). Significant interactions between compound type and concentration and between compound type and chain length were also observed. There were no significant interactions between chain length and concentration or between all three factors. The absence of an interaction between chain length and concentration may arise from the choice of only volatiles in the C_6–C_9 chain-length range, the range that had been found to be most active at low concentrations in earlier investigations (Bradow and Connick, 1988a,b; 1990).

When the volatile source was removed after the 72-hr exposure and the seeds were incubated an additional 96 hr before germination evaluation, three-way analyses of variance of the three-day + four-day data showed that the effects of compound type and concentration upon the "recovering" seeds remained highly significant (Table 2). Carbon-chain length continued to be a significant factor only in onion seed response. The interactions between compound type and concentration and chain length observed after the initial 72-hr

exposure persisted in the responses of onion and carrot, but the interaction between compound type and chain length was not significant in "recovering" tomato seeds.

Seed Germination Effects of Chain Length and Concentration within Compound Type. When the effects upon each seed species of a 72-hr exposure to 6.9, 20.8, or 34.4 μM of a specific type of compound were examined, no significant interactions were observed between concentration and chain length (Table 3). The seed species responded to different degrees to some compound types, e.g., there was no significant concentration effect when carrot seeds were exposed to 2-alkenals because all three concentrations of (*E*)-2-hexenal, (*E*)-2-heptenal, and (*E*)-2-octenal prevented germination (see Table 6 below). The chain length of the *n*-alkanes and 2-alkanols had no significant effect on carrot seeds, nor did chain length of 2-alkanols and alkanals alter the effect of those compound types on tomato germination (Table 3). In assays using onion seeds, chain length of the 2-alkanones was not important. In the case of the *n*-alkanoic acids in the volatile phase, neither increased concentration nor higher molecular weight affected onion or carrot response.

When the assay seeds were allowed to recover for 96 hr after a 72-hr exposure to one of the three concentrations of the test volatiles, no significant interactions were observed between carbon-chain length and concentration (Table 4). These two experimental factors had no significant effect on onion seeds exposed to *n*-alkanes, 2-alkanols, or *n*-alkanoic acids. Tomato seeds allowed to recover from volatile exposure showed no effects of concentration or chain

[a] *, **, *** = significant at the 0.05, 0.01, and 0.001 probability levels, respectively.

length when the test volatile type had been *n*-alkane or *n*-alkanoic acid. Volatile concentration effects persisted in carrot seeds exposed to 2-alkanols, alkanals, 2-alkenals, and 2-alkanones. Residual chain-length effects were observed in carrot responses after treatment with *n*-alkanes, 2-alkanols, and 2-alkenals.

Effects of Volatile Exposure Duration and Concentration on Onion Seeds. After an exposure of 72 hr, all concentrations of all the test compounds inhibited onion germination, compared to the deionized water control (Table 5). The two unsaturated C_7 aldehydes were the most inhibitory, followed by (*E*)-2-octenal. Regression analyses of these three-day data showed that, when the data for the water control were included, the concentration dependence of the effects of each of the test volatiles had a significant linear component. However, flat responses to many of the compounds over the assay concentration range used contributed to significant regression curve deviations from the linear. Simple linear concentration responses were observed only in onion seeds exposed to *n*-hexane, *n*-heptane, 2-hexanone, 2-heptanone, 2-octanone, and *n*-heptanoic acid. The steepest linear regression slopes were observed when the C_6, C_7, and C_8 2-alkenals, (*E*,*E*)-2,4-heptadienal, and *n*-heptanal were the test compounds. Significant concentration effects were observed in the three- + four-day data only when (*E*)-2-hexenal, (*E*)-2-heptenal, (*E*,*E*)-2,4-heptadienal, 2-heptanone, 2-octanone, and 2-nonanone were the test volatiles. Compared to the three-day concentration-dependent data, there were no significant changes in slope in the regression curves obtained with these compounds and this "recovery" treatment protocol (data not shown).

When the volatile source was removed after the three-day exposure and seed germination evaluated under an exhausting safety hood, an additional four-day incubation allowed onion seeds exposed to 2-nonanol and 2-heptanone to germinate as fully as the water controls. Seeds exposed to (*E*)-2-hexenal, (*E*)-2-heptenal, and (*E*,*E*)-2,4-heptadienal did not germinate further after the volatile source was removed. Germination of onion seeds initially treated with 34.4 μM 2-hexanone was significantly higher than that of the controls. Furthermore, onion seeds exposed continuously to 34.4 μM *n*-hexane, *n*-nonane, 2-nonanol, and the *n*-alkanoic acids, with the exception of *n*-nonanoic, germinated as well as the controls. Over all time and concentration treatments of onion seeds, (*E*)-2-heptenal and (*E*,*E*)-2,4-heptadienal were the most inhibitory, *n*-hexane the least.

Effects of Volatile Exposure Duration and Concentration on Carrot Seed Germination. Carrot seeds were less sensitive than those of onion to low concentrations of the test volatiles (Table 6). At 6.9 μM, the four *n*-alkanes, the C_6–C_8 2-alkanals, (*E*)-2-nonenal, (*E*,*E*)-2,4-nonadienal, 2-hexanone, 2-octanone, and all *n*-alkanoic acids, except *n*-hexanoic, had no significant effect on carrot seed germination after a 72-hr incubation. When the concentrations of the individual test compounds were increased to 34.4 μM, only *n*-octane,

[a] Percentages are the means of 16 replications. Values in columns followed by the same letter and associated with a given exposure time are not significantly different ($P = 0.01$). Standard errors of means were $< 1.5\%$.

n-nonane, *n*-hexanoic acid, and *n*-nonanoic acid had no significant inhibitory effect. An increase in germination, compared to that of the water control, was observed in carrot seeds exposed to 20.8 μM *n*-hexane. At 34.4 μM, 2-heptanol, 2-octanol, *n*-heptanal, *n*-octanal, *n*-nonanal, (*E*)-2-hexenal, (*E*)-2-heptenal, (*E*)-2-octenal, (*E*,*E*)-2,4-heptadienal, 2-heptanone, 2-octanone, and 2-nonanone prevented carrot seed germination. After 72 hr, (*E*,*E*)-2,4-heptadienal, (*E*)-2-heptenal, (*E*)-2-octenal, and (*E*)-2-hexenal were the most inhibitory of carrot seed germination, based on data from all three test concentrations. The three-day concentration-dependent responses of carrot seeds to all test compounds, except *n*-hexane, *n*-octane, *n*-nonane, *n*-hexanoic acid, *n*-heptanoic acid, and *n*-nonanoic acid, had significant linear components. As in the case of onion, flat concentration responses caused significant deviations from linear in the regression analyses. This deviation was nonsignificant in carrot seed assays of *n*-nonane, nonanal, 2-nonenal, 2-nonanol, *n*-nonanoic acid, and *n*-heptanoic acid.

After the volatile source was removed and the carrot seeds were incubated an additional four days, the initial three-day exposure to 34.4 μM (*E*)-2-hexenal, (*E*)-2-heptenal, and (*E*,*E*)-2,4-heptadienal proved sufficient to prevent germination. Residual, but lesser, inhibition was also observed in seeds exposed to 2-octanol, *n*-heptanal, *n*-octanal, *n*-nonanal, (*E*)-2-octenal, and 2-octanone. Initial exposure to 34.4 μM *n*-hexane, *n*-nonane, 2-hexanol, 2-hexanone, and all four *n*-alkanoic acids increased carrot seed germination over that observed in the water controls. Significant concentration-dependent effects persisted in carrot seeds exposed to (*E*)-2-hexenal, (*E*)-2-heptenal, (*E*)-2-octenal, (*E*,*E*)-2,4-heptadienal, and 2-octanone (data not shown). A seven-day continuous exposure to 34.4 μM 2-hepatanol, 2-octanol, *n*-heptanal, *n*-octanal, *n*-nonanal, the C_6–C_8 2-alkenals, (*E*,*E*)-2,4-heptadienal, 2-heptanone, 2-octanone, and 2-nonanone suppressed germination to less than 10% of that of the water controls. The same treatment with the four *n*-alkanes, *n*-hexanal, 2-nonenal, and the four *n*-alkanoic acids increased carrot seed germination significantly in comparison to the controls. Overall, (*E*,*E*)-2,4-heptadienal, (*E*)-2-heptenal, and (*E*)-2-hexenal were the most inhibitory of carrot seed germination.

Effects of Volatile Exposure Duration and Concentration on Tomato Seed Germination. Tomato seed germination was very sensitive to a 72-hr exposure to low concentrations (6.9 μM) of 2-alkanols and 2-alkanones (Table 7). At higher concentration, *n*-octanal, *n*-nonanal, (*E*)-2-hexenal, (*E*)-2-heptenal, and (*E*,*E*)-2,4-heptadienal were also inhibitory. When the volatile concentration was 34.4 μM, the four 2-alkanols, alkanals, 2-alkanones, the C_6–C_8 2-alkenals, and (*E*,*E*)-2,4-heptadienal all prevented tomato seed germination. With exception of *n*-nonane, all the volatiles tested inhibited tomato seed germination at the end of the three-day exposure. The three-day concentration-dependent responses of tomato seed had significant linear components in all cases, except when

[a] Percentages are the means of 16 replications. Values in columns followed by the same letter and associated with a given exposure time are not significantly different ($P = 0.01$). Standard errors of means were $< 1.5\%$.

n-nonane was the test substance. Significant deviations from linear were observed in the data obtained in assays of all four 2-alkanols, *n*-alkanals, 2-alkanones, (*E*)-2-hexenal, (*E*)-2-heptenal, and (*E*)-2-nonenal, both dienals, and *n*-hexanoic, *n*-heptanoic, and *n*-nonanoic acids. Unlike the germination of onion and carrot, tomato seeds were inhibited by the highest concentration of the *n*-alkanoic acids. Over all treatment concentrations, 2-nonanol, 2-nonanone, 2-heptanol, 2-octanol, 2-heptanone, 2-octanone, 2-hexanol, and 2-hexanone were the most inhibitory of tomato seed germination (in decreasing order of inhibitory activity).

Tomato seeds exposed for three days to the four *n*-alkanes, 2-hexanol, 2-nonanol, *n*-hexanal, (*E*)-2-nonenal, (*E*,*E*)-2,4-nonadienal, and the *n*-alkanoic acids, with the exception of *n*-octanoic, all germinated to the same degree as the controls when the volatile source was removed and the seeds incubated an additional four days. After the four-day recovery period, the only residual concentration-dependent effects were observed in tomato seeds initially exposed to (*E*)-2-heptenal, (*E*,*E*)-2,4-heptadienal, and 2-octanone (data not shown). Tomato seeds differed from the other assay seeds in "recovery" capacity, e.g., seeds completely inhibited after a three-day exposure to the *n*-alkanals germinated almost as fully as the water controls following the four-day "recovery" period. Continuous exposure for seven days to 2-heptanol, 2-octanol, *n*-nonanal, (*E*)-2-heptenal, (*E*)-2-octenal, (*E*,*E*)-2,4-heptadienal, 2-heptanone, 2-octanone, and 2-nonanone prevented tomato seed germination. Over all concentration and time treatments, the greatest inhibition responses were observed in tomato seeds exposed to 2-octanone, (*E*)-2-heptenal, 2-nonanone, (*E*,*E*)-2,4-heptadienal, 2-heptanone, 2-heptanol, 2-octanol, 2-hexanone, and 2-hexanol.

DISCUSSION

The C_6–C_9 volatiles examined in this study are released by the residues of roots, leaves, stems, flowers, and fruits of a large variety of plant species (Table 8). All 26 compounds have been reported to occur in several plants, with the exception of *n*-octanoic acid (caprylic acid). Both monocots (e.g., rice, maize, and oat) and dicots (e.g., *Amaranthus* spp., leguminous cover crops, and tomato) release these compounds when subjected to extraction and isolation procedures ranging from passive adsorption of headspace components to steam and vacuum distillation (references cited in Table 8).

The most commonly reported classes of compounds were the alkanals, followed by the alkenals and 2-alkanones. The *n*-alkanes and 2-alkanols were less commonly reported, and the *n*-alkanoic acids were the least widely distributed. Compounds containing six and seven carbon atoms were the most frequently observed and those containing eight carbons, the least. Two alkanals,

n-hexanal and *n*-nonanal, and (*E*)-2-hexenal were the most common volatile components listed in the literature cited in Table 8. The next most common compounds were 2-heptanone and (*E*)-2-nonenal. Distributions of the C_7 and C_9 alkadienals were similar to those of the corresponding 2-alkenals and considerably smaller than those of the analogous *n*-alkanals.

Techniques used for sampling, identification, and assay of bioactive volatiles associated with various plant tissues and residues differ according to the purpose of the study and the interests of the researchers. Therefore, the compounds listed in Table 8 cannot be categorized simply as plant residue emissions, food flavor components, or insect semiochemicals. Many of the compounds in the compilation were identified in steam and vacuum distillates (e.g., Bestmann et al., 1988; Buttery et al., 1971, 1978; Buttery and Kamm, 1980; Flath et al., 1984) or in extracts of headspace gases trapped in liquid nitrogen (Bullard and Holguin, 1977; Morrison et al., 1986). Vacuum steam distillation and Tenax solid adsorbent trapping methods have been compared in studies of plant volatile profiles (Buttery et al., 1982b, 1983). More recently, adsorption on Tenax has become the method of choice for trapping volatile emissions in studies of insect attractants (Buttery et al., 1983, 1984, 1985, 1986; Buttery and Ling, 1985; Lundgren et al., 1985; Lwande and Bentley, 1987; Hernandez et al., 1989; Connick and French, 1990) and allelochemicals and aroma components emitted by plant tissue (Connick et al., 1987, 1989; Lundgren et al., 1985; Bradow and Connick, 1990; Connick and French, 1990).

If the list of C_6–C_9 compounds in Table 8 were limited to only those volatiles identified after desorption from Tenax traps, it would include the four *n*-alkanes, 2-heptanol, *n*-hexanal, *n*-heptanal, *n*-nonanal, the four (*E*)-2-alkenals, (*E*,*E*)-2,4-heptadienal, and the four 2-alkanones (Buttery et al., 1982a,b, 1984, 1985, 1986; Buttery and Ling, 1984, 1985; Lundgren et al., 1985; Connick et al., 1987, 1989; Lwande and Bentley, 1987; Hernandez et al., 1989; Bradow and Connick, 1990). (*Z*,*Z*)-2,4-Nonadienal (but not the *E* geometric isomer tested here) was identified by headspace sampling and Tenax trapping (Hernandez et al., 1989). The relative gentleness of the Tenax trap procedure suggests that volatile profiles determined using this method most closely approximate the natural emissions of the source plant material. Just as the bioassay species responded differently to natural plant residue emissions (Bradow and Connick, 1987), onion, carrot, and tomato seeds differed in sensitivity to those C_6–C_9 volatile compounds. The observed species differences depended on incubation duration and recovery capacity following removal of the volatile. The degree of germination inhibition, compared to the deionized water controls, summed across concentrations for each assay seed, allows comparisons of both species sensitivity and volatile activity. After a 72-hr incubation, (*E*)-2-heptenal and (*E*,*E*)-2,4-heptadienal were the most inhibitory of onion and carrot

seed germination. In contrast, after the same exposure period, tomato seeds were more strongly inhibited by 2-hexanol, 2-heptanol, 2-heptanone, 2-octanol, 2-octanone, 2-nonanol, and 2-nonanone, these compounds having approximately the same inhibitory activities.

Similar examinations of the cumulative inhibition of germination in the three assay species subjected to the three- + four-day "recovery" exposure protocol indicated that (*E*)-2-hexenal, (*E*)-2-heptenal, and (*E*,*E*)-2,4-heptadienal had the greatest residual effect on onion and carrot seed germination after the 96-hr recovery period. Much less residual inhibition was observed in tomato seeds, and these three compounds, plus 2-octanone, most effectively prevented further germination. These three aldehydes were also most effective in preventing onion seed germination during the seven-day incubation. After the seven-day exposure, (*E*)-2-hexenal, 2-heptanol, and three C_7 aldehydes, 2-octanol, *n*-octanal, (*E*)-2-octenal, 2-octanone, 2-nonanone, and *n*-nonanal caused the most inhibition of carrot seed germination. A seven-day exposure to 2-hexanol, 2-heptanol, (*E*)-heptenal, (*E*,*E*)-2,4-heptadienal, 2-heptanone, 2-octanol, (*E*)-octenal, 2-octanone, *n*-nonanal, and 2-nonanone essentially prevented tomato seed germination.

Over all three seed species and exposure periods, (*E*)-2-heptenal and (*E*,*E*)-2,4-heptadienal were the most inhibitory compounds tested. Based on germination inhibition in onion, carrot, and tomato, the activity series of the six compound classes was: (*E*)-2-alkenals > 2-alkanones ≥ *n*-alkanals ≥ 2-alkanols >> *n*-alkanoic acids ≥ *n*-alkanes. The overall inhibitory activity of C_7 and C_8 compounds was approximately equal. The C_6 compounds were less inhibitory than compounds with seven and eight carbons, but more inhibitory than those with nine, despite the marked sensitivity of tomato seeds to several C_9 compounds.

Similar decreases in bioactivity with increasing or decreasing chain length have been observed in electroantennogram (EAG) responses of insects to plant volatiles (Light et al., 1988; Ramachandran et al., 1990). The greatest response amplitude of Mediterranean fruit fly was observed when the plant volatile (e.g., 1-alkanol, *n*-alkanal, *n*-alkanoic acid) contained six carbons atoms (Light et al., 1988). Rice leaf folder EAG responses were greatest to C_7 *n*-alkanals, and C_8 alkenals (Ramachandran et al., 1990).

The C_6–C_9 compounds examined here have wide ecological significance, retarding seed germination, attracting insects (Visser, 1979, 1983; Light et al., 1988; Ramachandran et al., 1990), and retarding seedling root elongation (Bradow and Connick, 1988c). These biologically active compounds can have very significant effects on crop yield and quality whenever tillage practices that incorporate large amounts of green cover crop or other plant residues into the root zone are employed.

Acknowledgments—The author wishes to thank Mary P. Lovisa for her invaluable technical assistance and Mr. William J. Connick, Jr., and Dr. Richard C. French for their excellent suggestions.

ROLE OF AVIAN TRIGEMINAL SENSORY SYSTEM IN DETECTING CONIFERYL BENZOATE, A PLANT ALLELOCHEMICAL

WALTER J. JAKUBAS[1,2,*] and J. RUSSELL MASON[3]

(Received May 6, 1991; accepted July 8, 1991)

Abstract—Coniferyl benzoate, a secondary metabolite found in quaking aspen (*Populus tremuloides*) and other plants, is an avian feeding deterrent of ecological and potential commercial importance. This study was conducted to determine if coniferyl benzoate is a trigeminal stimulant for birds and to ascertain if trigeminal chemoreception of coniferyl benzoate can mediate avian feeding behavior. Five European starlings (*Sturnus vulgaris*) with bilateral nerve cuts (ophthalmic branch of the trigeminal nerve) and four starlings that had sham surgeries were fed a commercial diet treated with coniferyl benzoate. Birds receiving bilateral nerve cuts ate significantly more feed than intact birds, indicating trigeminal detection of coniferyl benzoate and trigeminal mediation of feeding behavior. In the past, trigeminal chemoreception has not been recognized as important in the detection of plant secondary metabolites despite the irritant or astringent properties of a number of them.

Key Words—European starlings, *Sturnus vulgaris*, ruffed grouse, *Bonasa umbellus*, phenylpropanoid, feeding deterrent, chemical senses.

INTRODUCTION

Anatomical and behavioral evidence that the chemical senses (i.e., taste, smell, and trigeminal) are sufficiently evolved in birds to permit discrimination among

*To whom correspondence should be addressed.

0098-0331/91/1100-2213$06.50/0

chemical cues has existed for some time (Wenzel, 1973). However, research on the diverse ways birds make use of their chemical senses (e.g., Baltharzart and Schoffeniels, 1979; Clark and Mason, 1985, 1988; Wenzel, 1986; Waldvogel, 1987) and the importance of avian chemoreception in the management of pest species (e.g., Mason and Silver, 1983; Mason et al., 1989; Mason, 1989) are just coming to the forefront.

Understanding how birds detect plant secondary metabolites could provide additional insights into avian ecology and the development of avian repellents. Plant secondary metabolites can influence avian food selection (Cook et al., 1971; Remington and Braun, 1985; Greig-Smith and Wilson, 1985; Jakubas et al., 1989), nestling parasite loads (Clark and Mason, 1988), and possibly, population densities (Jakubas and Gullion, 1991). In an applied context, the chemical structures of aversive plant secondary metabolites can serve as chemical models for developing avian repellents (Crocker and Perry, 1990; Jakubas et al., 1991). In this regard, phenylpropanoids related to cinnamic acid and coniferyl alcohol may be both ecologically and commercially important (Jakubas et al., 1989; Crocker and Perry, 1990; Jakubas et al., 1991). For example, coniferyl benzoate, an ester of coniferyl alcohol, is a feeding deterrent for ruffed grouse (*Bonasa umbellus*) (Jakubas and Gullion, 1990), European starlings (*Sturnus vulgaris*) (Jakubas et al., 1991), and possibly other passerines (Jakubas et al., 1989). Coniferyl benzoate naturally occurs in quaking aspen (*Populus tremuloides*); in gum benzoin Siam, from *Styrax tonkinensis*; and in jasmine oil (Freudenberg and Bittern, 1950; Adamson, 1972; Kato, 1984; Jakubas et al., 1989). Ecologically, it appears to be important in mediating the feeding behavior of ruffed grouse when they select quaking aspen flower buds (Jakubas et al., 1989; Jakubas and Gullion, 1990, 1991). It has been proposed that the irritant property of coniferyl benzoate may be one of the primary sensory cues used by ruffed grouse when selecting aspen buds (Jakubas, 1989).

Chemical irritation, such as from spicy foods or noxious fumes (e.g., ammonia) are sensations commonly attributed to trigeminal chemoreception (Silver, 1987). Trigeminal sensations (the common chemical sense) occur from stimulation of free nerve endings in the epithelium or mucosa and include the sensations of touch, pain, temperature, and proprioception (movement) (Silver, 1987). In most terrestrial vertebrates, the trigeminal (Vth) nerve innervates the epithelia of the head region, including intranasal, intraoral, and corneal surfaces (Silver, 1987). In the birds, the trigeminal nerve is principally divided into three branches, the ophthalmic (upper mandible and eye), maxillary (above eye and between mandibles), and mandibular (lower jaw and muscles) (Breazile and Yasuda, 1979).

Coniferyl benzoate was proposed to be a trigeminal stimulant because of the burning sensation it produces when ingested or rubbed on the eyelids (Jakubas, 1989, and unpublished data). In addition, coniferyl benzoate often will

cause an eczematous reaction when applied to the skin (Hjorth, 1961; Kato, 1984). Although coniferyl benzoate is a human irritant, this may not mean that birds perceive it similarly. For example, capsaicin, the pungent chemical found in peppers of the Capsicum family, is a strong trigeminal irritant to mammals but not to birds (Mason and Maruniak, 1983; Szolcsanyi et al., 1986). Confirmation that birds use trigeminal chemoreception to sense coniferyl benzoate, may help explain the repellency of analogous compounds (see Jakubas et al., 1991).

The objectives of this study were to (1) determine if coniferyl benzoate is a trigeminal stimulant for birds and (2) ascertain if trigeminal chemoreception of coniferyl benzoate can mediate avian feeding behavior. European starlings were chosen for this study because they have good chemosensory abilities (Clark and Mason, 1987; Espaillat and Mason, 1990) and are similar to ruffed grouse in their sensitivity to dietary coniferyl benzoate (see Jakubas et al., 1991; Jakubas and Gullion, 1990). In addition, anesthesia and surgical techniques for denervation of chemosensory systems in starlings are well documented (Mason and Silver, 1983; Clark and Mason, 1987; Mason et al., 1989).

METHODS AND MATERIALS

Diet Preparation. Coniferyl benzoate was obtained by continuous liquid–liquid extraction of benzoin Siam tears #3 (Alfred L. Wolff, Paris, France) and purified by crystallization following the procedures in Jakubas et al. (1991). Coniferyl benzoate was added to the test feed (5:1 mixture of Chick Starter and AVN Canary/Finch diet; Purina Mills Inc., St. Louis, Missouri) by dissolving a known quantity of crystalline material in diethyl ether, thoroughly mixing the solution with the feed, and evaporating the ether under a hood. The level of coniferyl benzoate applied to the feed (3.2% w/w) corresponds to levels in aspen flower buds that are generally not fed on by ruffed grouse (Jakubas and Gullion, 1990, 1991). Treated feed was stored under nitrogen, at −17°C, to prevent decomposition of coniferyl benzoate. The control feed was prepared by mixing the test feed with diethyl ether and evaporating the ether as described above.

Feeding Trials. Twelve European starlings were captured using a funnel trap in Philadelphia, Pennsylvania, during early April and transferred to indoor facilities three weeks prior to testing. The birds were individually caged (61 × 36 × 41-cm cages) and housed under constant temperature conditions (approx. 22°C), with a 11:13 hr light–dark cycle. Water and feed were provided ad libitum. The maintenance diet was a 5:1 mixture of Chick Starter and AVN Canary/Finch diet, to which oyster shell grit (United Volunteer Aviaries, Nashville, Tennessee) was added.

Seven days before surgery, birds were conditioned for five days to a food-deprivation routine. During this time, birds were deprived of their normal diet overnight. The following morning they were given 10 g of control feed approximately 2 hr after light onset. After 2 hr, consumption was measured and the maintenance diet returned to the cages for the remaining hours of light. Tap water was available ad libitum throughout the conditioning period and subsequent feeding trials.

On day 6 (one day prior to surgery), starlings were randomly assigned to receive either bilateral trigeminal nerve cuts (TNC) or sham surgeries and were food-deprived overnight. For TNC, birds were anesthetized by intraperitoneal injection of chloropent (4 ml/kg body wt) and placed in a head holder. To avoid disturbing the olfactory nerve, the ophthalmic branches of the trigeminal nerve were exposed and cut at the junction of the nervus ophthalmicus: ramus medialis and ramus nasales (see Breazile and Yasuda, 1979). Cut nerve ends were reflected to impede regeneration. The resulting cavity was packed with gelfoam and the skin closed with cyanoacrylate glue. Identical procedures were followed for sham surgeries except the trigeminal nerve was not cut. Five of six birds survived the TNC surgery, and four of six the sham surgery.

Starlings were allowed to recover from surgery for two days, after which they were given 2-hr feeding trials on each of seven days. Starlings were presented control feed on days 3–5 to evaluate their postsurgery condition. On days 6–9, birds were given the treatment diet containing 3.2% coniferyl benzoate.

Consumption of the control diet during the three days preceding and following surgery was analyzed in a three-factor analysis of variance (ANOVA) with repeated measures over days. Similarly, consumption of the treated diet was assessed in a two-factor ANOVA with repeated measures over days. Tukey's Honestly Significant Difference tests (Winer, 1962, p. 198) were used to isolate significant ($P < 0.05$) differences among means. Birds were euthanized by an overdose, via intraperitoneal injection, of sodium pentobarbitol. Nerve cuts were confirmed by necropsy.

RESULTS

Two-hour consumption of the control diet did not differ before or after surgery ($P > 0.25$). Prior to surgery, birds that were subsequently given TNC consumed 5.31 $\pm$ 0.25 g of control feed, while sham-operated birds ate 5.21 $\pm$ 0.31 g of feed. Following surgery, TNC birds consumed 5.59 $\pm$ 0.29 g of control feed and sham-operated birds ate 5.27 $\pm$ 0.34 g. However, TNC birds consumed significantly more of the 3.2% coniferyl benzoate diet than sham birds ($F = 22.8$; 1,7 *df*; $P < 0.01$) (Figure 1). Mean consumption of the 3.2% coniferyl benzoate diet over the four days of the trial was 0.99 $\pm$ 0.14 g for

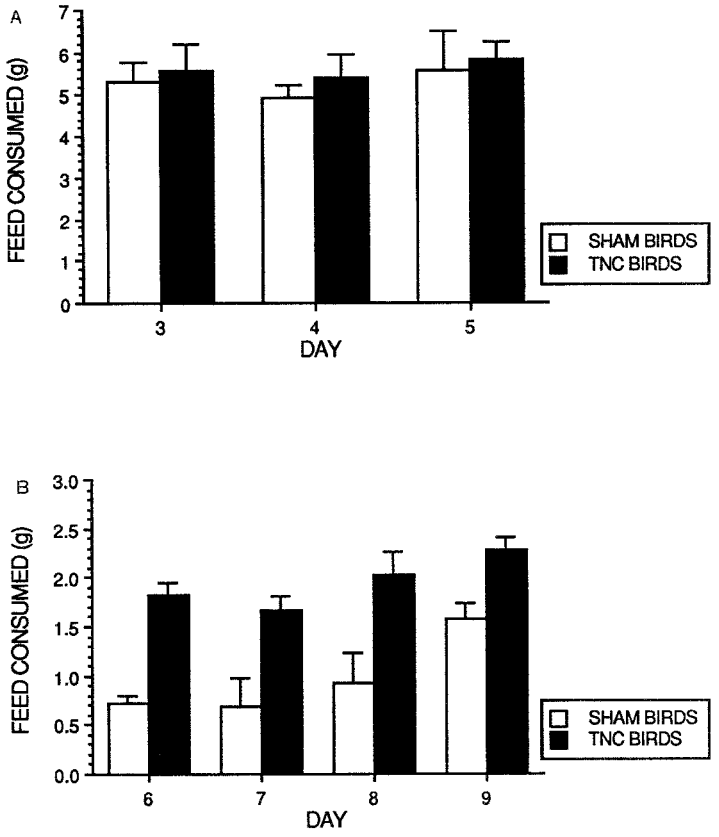

FIG. 1. Daily mean consumption (with standard error bars) during 2-hr feeding trials of (A) control feed and (B) feed treated with coniferyl benzoate (3.2% w/w) for starlings that received bilateral trigeminal nerve cuts (TNC) or sham surgeries.

sham-operated birds and 1.95 ± 0.09 g for the TNC birds. Over days, consumption differed ($F = 10.3$; 3,21 *df*; $P < 0.01$), and post-hoc tests revealed that for both TNC and sham birds, consumption on day 9 was significantly higher than consumption on day 6 (Figure 1). Necropsies on the TNC starlings did not reveal any regrowth of the sectioned trigeminal nerves.

DISCUSSION

Birds with bilateral sections of the ophthalmic branch of the trigeminal nerve (TNC) ate more feed treated with coniferyl benzoate than did sham birds. However, the groups did not differ in consumption of the control feed, sug-

gesting that birds receiving TNC were less sensitive to coniferyl benzoate than intact birds and that trigeminal chemoreception was involved in detection of this compound. These findings agree with other studies indicating that nasal–trigeminal chemoreception can mediate avian feeding behavior and that chemical repellency in birds, in some cases, may be associated with compounds that elicit a trigeminal response (Mason and Silver, 1983; Mason et al., 1989; but see Mason and Maruniak, 1983).

Trigeminal chemoreception has not been recognized in the past as being important to the perception of plant secondary metabolites by animals. For example, Chapman and Blaney (1979) recognized that the chemical senses are commonly used to perceive plant secondary metabolites; however, they incorrectly assumed that chemical irritation was not mediated by the chemical senses and virtually disregarded the importance of trigeminal chemoreception in this early review article.

An example of how trigeminal chemoreception may affect the feeding behavior of animals in the field can be illustrated with ruffed grouse and their selection of aspen buds. Typical avian trigeminal innervation (see Breazile and Yasuda, 1979) should enable ruffed grouse to sense coniferyl benzoate as it manipulates aspen buds with its beak when feeding. Consequently, the level of coniferyl benzoate in the copious external resin of the bud might serve as the initial cue to the bud's suitability. Trigeminal chemoreception (and other chemical senses) may be especially important to ruffed grouse when selecting aspen buds, due to a lack of visible patterns (e.g., color, size, outer resin, and UV absorbance) that could be used to distinguish buds having high levels of coniferyl benzoate or nutrients (Jakubas, 1989, and unpublished data). Indeed, preliminary data indicate that grouse do not feed in trees having buds that produced an oral burning sensation (human perception) (Jakubas, 1989). Given the unspecialized nature of trigeminal receptors (i.e., free nerve endings), the use of trigeminal chemoreception by starlings to detect coniferyl benzoate, by inference, supports the concept that ruffed grouse may use trigeminal chemoreception to detect differential levels of coniferyl benzoate. Differences in trigeminal chemoreception do exist among species; however, many irritants are perceived similarly (Szolcsanyi et al., 1986; Harti et al., 1989). Since trigeminal chemoreception is apparently involved in detecting coniferyl benzoate in species (i.e., humans and starlings) from two animal classes, it seems unlikely that this compound would not elicit a similar response in grouse.

Although ophthalmic nerve sections in starlings appear to have decreased their aversion to coniferyl benzoate-treated feed, it is obvious that TNC birds still found it less suitable than control feed (Figure 1). One explanation for the difference in consumption of control (5.59 ± 0.29 g) and treated feed (1.95 ± 0.09 g) among TNC birds may be the incomplete denervation of the trigeminal (Vth) nerve. Both the mandibular and maxillary branches of the nerve were left

intact. Complete denervation was not attempted because it would likely have resulted in prolonged aphagia and lack of responsiveness to food (see Zeigler and Karten, 1973a,b). Alternatively, the data suggest that taste and/or olfaction may have been involved in detection of coniferyl benzoate. Passerine species possess functional olfactory (Clark and Mason, 1989) and taste (Espaillat and Mason, 1990) capabilities, and either or both may have influenced the starling's response.

The increase in consumption of feed treated with coniferyl benzoate over time (Figure 1) may indicate that the birds habituated to the effects (sensory or postingestional) of coniferyl benzoate. Whether habituation to this compound occurs in field situations remains open to question. Factors such as increased toxicity, due to higher consumption of coniferyl benzoate or synergistic reactions with other phenolic compounds, may reinforce avoidance of coniferyl benzoate in field situations. We speculate that toxicity was not a significant factor in the laboratory, since the quantity of coniferyl benzoate consumed during the 2-hr feeding trials was relatively small and may have not been sufficient to invoke a toxic response.

Taste and olfaction are frequently cited as important in animal food selection (e.g., Arnold and Hill, 1972) and in the detection of plant secondary metabolites (Chapman and Blaney, 1979). However, based on our study and earlier work indicating that nasal–trigeminal chemoreception can mediate feeding behavior (e.g., Mason and Silver, 1983; Mason et al., 1989), we propose that trigeminal chemoreception may be important in the detection of many of the common secondary metabolites that have irritant or astringent properties. Compounds with these properties include: tannins (astringent), diphenols (irritants), phenylpropanoids (irritants), and diterpenoid esters (irritants) among others (Robinson, 1983). Trigeminal sensations elicited by these compounds may simply serve as a cue for avoidance or may significantly contribute to the compound's repellency.

Acknowledgments—We would like to thank Larry Clark and Florence Caputo for their advice on surgical procedures, Don Norman for his technical assistance, Pankaj Shah for his assistance in the laboratory, and the two anonymous reviewers for their comments on the manuscript. Funding for this project was provided by NIDCD postdoctoral training grant DC0014-12 and by U.S. Department of Agriculture, Animal and Plant Health Inspection Service Cooperative Agreement No. 12-34-41-0040-CA between the Monell Chemical Senses Center and the Denver Wildlife Research Center.

(Received April 9, 1991; accepted July 12, 1991)

Abstract—Among the substances isolated from ethyl ether extract of *Pistia stratiotes* L., linoleic acid, γ-linolenic acid, (12*R*,9*Z*,13*E*,15*Z*)-12-hydroxy-9,13,15-octadecatrienoic acid, (9*S*,10*E*,12*Z*,15*Z*)-9-hydroxy-10,12,15-octadecatrienoic acid, α-asarone, and 24*S*-ethyl-4,22-cholestadiene-3,6-dione were found to inhibit the growth of some microalgae in solid medium. Toxicity of α-asarone on the growth of sensitive algal strains in liquid medium is discussed.

Key Words—*Pistia stratiotes*, allelochemicals, microalgae, unsaturated C_{18} fatty acids, α-asarone, sterols, growth inhibition.

INTRODUCTION

Pistia stratiotes L. (Araceae), commonly known as water lettuce, is a floating-leaved macrophyte occurring in tropical waters (Holm et al., 1977). In slow-flowing rivers and in the littoral regions of lakes, *P. stratiotes* can form a dense aggregation of floating rosettes, which create compact, thick mats, disturbing navigation and fisheries. Moreover, water lattuce can invade the rice fields, seriously limiting the growth of this crop (Sculthorpe, 1985).

Apart from the mechanical effects, floating mats of *P. stratiotes* can have a strong impact on its habitat. In fact, the large and extensive cover of the plant reduces gaseous exchanges between the water and the atmosphere and curtails

*To whom correspondence should be addressed.

0098-0331/91/1100-2223$06.50/0

the penetration of light (Attionu, 1976), limiting the growth of submerged hydrophytes and phytoplankton (Chokder, 1968).

At the present time, it has not been ascertained if the interference of *P. stratiotes* on other organisms living in its habitat involves exclusively competition, through removal or reduction of resources from the environment, or if it can also be caused by allelopathic effects. In a series of studies concerning in vitro interactions between aquatic plants and microalgae, we have now considered the isolation and the characterization of potential allelochemicals from *P. stratiotes*.

METHODS AND MATERIALS

Plant Collection and Extraction. Plants of *P. stratiotes* were cultured outdoors in Naples Botanical Garden during spring and summer of 1989 in 1000-liter cement tanks. Fresh, whole plants were collected in September and dried at room temperature. Dried plants (5 kg) were sequentially extracted with ethyl ether, chloroform, and methanol in a Soxhlet apparatus. All the extracts were frozen and stored at −20°C until used.

General Experimental Procedures. The gas–liquid chromatoghraphic apparatus consisted of a capillary-column chromatograph (FRACTOVAP 4160, Carlo Erba) equipped with a Varian 4270 integrator. An OV-1 column (25 m × 0.32 mm ID, film thickness 0.1–0.15 μm) with a column temperature of 180°C was used for analysis of fatty acid methyl esters with authentic samples purchased from Alltech Associates. The HPLC apparatus consisted of a pump module (Varian Vista 5500) and a refractive index detector (Varian RI 3). A Hibar-LiChrosorb RP8 column (Merck, 7 μm, 250 mm × 10 mm ID, MeOH–H_2O 4:1) was used for fatty acids separation. A LiChrosorb SI 60 (Merck, 7 μm, 250 mm × 7 mm ID, hexane–isopropyl ether 4:1) was used for sterols separations. A LiChrosorb-NH_2 column (Merck, 7 μm, 250 mm × 10 mm ID, $CHCl_3$–MeOH 41:4) was used for sitosterol acylglycosides separation. [^{1}H]NMR spectra were recorded at 400 MHz on a Bruker AM 400 spectrometer in $CDCl_3$ solution. Chemical shifts (δ values) are relative to residual $CHCl_3$ (δ 7.270). [^{13}C]NMR spectra were recorded at 100 MHz in $CDCl_3$ solution and the chemical shifts (δ values) are relative to the central signal of the $CDCl_3$ triplet (δ 77.00). MS spectra were recorded at 70 eV on a Kratos MS 80 spectrometer.

Ethyl Ether Extract Fractionation. The extract (10 g) was redissolved in ethyl ether (500 ml) and shaken with 2 N aq. NaOH (2 × 250 ml). The organic layer was washed with water until neutral to give a mixture of neutral compounds (8 g). The aqueous layers were acidified with 2 N aq. H_2SO_4 and then extracted with ethyl ether to give a mixture (1.2 g) of acidic compounds.

The acid mixture was chromatographed on HCl-washed silica gel, eluting with mixtures hexane–ethyl ether. The fractions eluted with a 19:1 mixture (370 mg) were separated through reverse-phase HPLC to give linoleic (**1,** 72 mg), γ-linolenic (**2,** 105 mg), oleic (47 mg), elaidic (7 mg), and stearic (125 mg) acids, identified as methyl ester derivatives by comparison with authentic samples (MS, GLC). The fractions eluted with a 4:1 mixture (150 mg) were rechromatographed on acid alumina (grade III) to give (12*R*,9*Z*,13*E*,15*Z*)-12-hydroxy-9,13,15-octadecatrienoic acid (**3,** 35 mg) (Figure 1), (9*S*,10*E*,12*Z*,15*Z*)-9-hydroxy-10,12,15-octadecatrienoic acid (**4,** 44 mg), and ricinoleic acid (60 mg). Aliquots of **3** and **4** were converted with ethereal CH_2N_2 into the corresponding methyl esters, which showed physical properties (MS, [^{1}H]NMR, [^{13}C]NMR) identical to those of authentic samples (Pollio et al., 1988).

The mixture of neutral compounds was column chromatographed on silica gel (82 g) eluting with hexane–ethyl ether mixtures to give fractions A–E. Fraction A (hexane, 900 mg) consisted of a complex mixture of triacylglycerols [^{1}H]NMR: 4.15 (dd), 4.30 (dd), 5.28 (m), which was not further investigated, and acetylphytol, identical to an authentic sample. Fraction B (hexane–ethyl ether 9:1, 2.5 g) was rechromatographed on silica gel. Hexane–ethyl ether (44:1) gave a mixture of polyprenols that was resolved through reverse-phase preparative TLC (acetone–water 9:1) into 9-prenol, 10-prenol, 11-prenol, and 12-prenol, which were identified on the basis of their spectroscopic features (Monaco et al., 1983). Elution with hexane–ethyl ether (43:2) gave α-asarone (**5,** 30 mg), which was compared with a commercially available sample. An aliquot of fraction C (hexane–ethyl ether 4:1, 1.6 g) was column rechromatographed on silica gel to give the fractions that were resolved through preparative TLC to give 24*S*-ethyl-4,22-cholestadiene-3,6-dione (**6**), 24*S*-ethyl-5,22-cholestadien-3β-ol (**7**), 24*S*-ethyl-8(14),22-cholestadien-3β-ol (**8**), and 24*S*-ethyl-22-cholestene-3,6-dione (**9**), identified on the basis of their IR, UV, [^{1}H]NMR (Table 1) and [^{13}C]NMR spectra (Table 2). Fraction D (hexane–ethyl ether 1:1, 170 mg) consisted of four sterols that were purified through preparative TLC ($CHCl_3$–acetone 21:1) and HPLC and identified as 5α,8α-epidioxy-24*S*-ethyl-6,22-cholestadien-3β-ol (**10**), 24*S*-ethyl-5,22-cholestadien-7-on-3β-ol (**11**), 24*S*-ethyl-4,22-cholestadien-6β-ol-3-one (**12**), and 24*S*-ethyl-22-cholesten-11β-ol-3,6-dione (**13**). Fraction E (hexane–ethyl ether 3:7, 120 mg) was column rechromatographed on silica gel (12 g) eluting with hexane–ethyl ether 3:7 to give four sterols that were separated through argentation preparative TLC ($CHCl_3$–acetone 9:1) and identified as 24*S*-ethyl-5,22-cholestadiene-3β,7α-diol (**14**), 24*R*-methyl-5-cholestene-3β,7α-diol (**15**), 24*S*-ethyl-5,22-cholestadiene-3β,7β-diol (**16**) and 24*R*-methyl-5-cholestene-3β,7β-diol (**17**).

Chloroform Extract Fractionation. The extract (85 mg) was column rechromatographed on silica gel. Hexane–ethyl ether 3:2 gave sitosterol-3-*O*-

[2′,4′-diacetyl-6′-stearyl]-β-D-glucopyranoside, whereas ethyl ether gave a mixture of sitosterol-3-*O*-[2′-stearyl]-β-D-xylopyranoside and sitosterol-3-*O*-[4′-stearyl]-β-D-xylopyranoside, which were separated by HPLC LiChrosorb-NH_2. These glycosides were identified (Della Greca et al., 1991) on the basis of their spectroscopic properties and by chemical degradation.

Methanolic Extract Fractionation. The extract (70 g) was distributed between H_2O and AcOEt. The organic layer gave a residue (3.2 g) that was chromatographed on silica gel. $CHCl_3$–acetone (7:3) gave a mixture of acylglycosylsterols that was acetylated with acetic anhydride in dry pyridine. The mixture of acetyl derivatives was resolved through argentation preparative TLC (hexane–AcOEt 4:1) to give peracetyl derivatives of sitosterol-3-*O*-[6′-*O*-stearyl]-β-D-glucopyranoside, sitosterol-3-*O*-[6′-*O*-linaloyl]-β-D-glucopyranoside, and sitosterol-3-*O*-[6′-*O*-linalonyl]-β-D-glucopyranoside.

Bioassay. All the algal strains were cultivated on Bold basal medium (BBM) (Nichols, 1973). The growth of each alga was followed at 550 nm with a colorimeter (Bausch and Lomb Spectronic 20). Fractionated material and the purified compounds were assayed on algal strains as previously reported (Aliotta et al., 1990). For liquid tests, α-asarone was dissolved in EtOH. These solutions (20 μl each) were added to test tubes containing 6 ml of inoculated medium, giving final concentrations of 5×10^{-4} M, 10^{-4} M, 5×10^{-5} M, and 10^{-5} M, ranges generally used to evaluate a biological activity. A blank containing only EtOH (20 μl) in BBM was also tested.

The test tubes were incubated on a shaking apparatus which held them at a 71° angle and rocked them with an amplitude of 11 cm at the rate of 62 cycles per minute (Shihira and Krauss, 1965). The shaker was illuminated by fluorescent lamps Philips (TLD 30 w/55) (150 μE sec/m^2) under a photoperiod of 16 hr light–8 hr dark.

Growth of cultures was followed daily either by measuring the absorbance increase at 550 nm with a Bausch and Lomb Spectronic 20 Colorimeter or by counting the cell numbers with a Coulter counter Industrial Model D. The initial inocula corresponded to 0.05 units of absorbance. Cell numbers ranged from 5×10^4 (*Ankistrodesmus braunii* C202-7a) to 6×10^5 ml (*Synechococcus leopoliensis* T625), depending on the algal size.

Growth experiments were carried out in triplicate, and results were evaluated on the basis of the average of three tests. The different types of inhibition caused by α-asarone on the sensitive algae (reduced growth rate or lag-phase) were calculated, respectively, according to Blankley (1973) and to Pinto and Taddei (1986).

α-Asarone was assayed in the medium previously filtered on Whatman glass microfiber filters (diameter 1.6 μm) in order to remove the algae and subsequently lyophilized. The residue was redissolved in EtOH and α-asarone was

detected with a Perkin-Elmer LAMBDA 7 Spectrophotometer at λ 313 and 354 nm.

RESULTS AND DISCUSSION

The crude extracts of *P. stratiotes* were assayed for their biological activity on microalgae. The ethyl ether extract was effective in inhibiting the growth of 17 algal strains (Table 3), whereas both the chloroform and the methanol extracts as well as the pure compounds isolated from these sources were inactive (not shown). Sequential chromatographic processes (CC, TLC, and HPLC) afforded the pure compounds, which were identified on the basis of their spectroscopic properties as fatty acids, hydroxy fatty acids, α-asarone, polyprenols, sterols and glycosyl sterols.

Concerning the active compounds isolated from *P. stratiotes*, it must be emphasized that linoleic **(1)** and γ-linolenic **(2)** acids are widely distributed in the plant kingdom, and their activity may be attributed to the hydroperoxide derivatives formed in the bioassay conditions (Aliotta et al., 1990). By contrast, hydroxy fatty acids (**3** and **4**) are uncommon and have been isolated recently from *Dunaliella acidophila* (Pollio et al., 1988). These compounds, which showed an increased toxicity with respect to **1** and **2** on the same algal strains, are produced by lypoxygenase oxidation of α-linolenic acid (Funk et al., 1976).

The phenylpropanoid α-asarone **(5)** has been found in a few plants belonging to Aristolochiaceae and Araceae and seems to be a potential chemotaxonomic marker of these families.

Finally, among sterols isolated, 24*S*-ethyl-4,22-cholestadiene-3,6-dione **(6)** showed a slight growth-inhibitory activity on two algal strains (C249-1 *Muriella aurantiaca* and T1075 *Closterium acerosum*). The widely distributed 24*S*-ethyl-5-cholesten-3β-ol **(7)** had algistatic effects on some strains (not shown).

The toxicity of α-asarone, the most active compound isolated from *P. stratiotes*, was also tested in liquid cultures of the most sensitive strains. The growth of all the algae was severely inhibited by this compound at concentrations ranging between 5×10^{-5} M and 10^{-4} M (not shown). It is noteworthy that α-asarone caused two different types of inhibition. In fact, in the experiments carried out on the strains C202-7a (*Ankistrodesmus braunii*), T76 (*Scenedesmus quadricauda*), and T755 (*Porphyridium aerugineum*) we observed a lag phase, whose lengthening was dependent on the initial concentration of the phenylpropanoid. After the lag time, the algae resumed the same growth rates as the controls. By contrast, the growth rates of strains T625, T1444, T1816, and T1648 decreased with increasing α-asarone concentrations.

In Figure 2 are reported the growth curves of strains T76 *Scenedesmus quadricauda* (lag phase) and T1648 *Selenastrum capricornutum* (decreased

3	50	47	84	48
4	50	47	85	48

[a] No variation was observed in the blanks.

growth rate) at different concentrations of α-asarone. The concentration of α-asarone in the medium of the two cultures was also measured (Table 4). In the medium of strain T1648 with 5×10^{-5} M and 10^{-4} M solutions, the concentration remained fairly constant during the first four days of the growth, whereas a progressive reduction was found in the medium of strain T76. In the experimental conditions reported, the value 5×10^{-5} M of α-asarone represented the lowest toxic dose to this latter strain. These preliminary results seem to indicate that the algae in which α-asarone caused a lag phase are able to partially detoxify the medium, as already reported for other toxic substances (Blankley, 1973; Albertano et al., 1981).

The marked antialgal activity of α-asarone confirms that the phenylpropanoids may interfere with growth processes in plants. In this respect, we are investigating a possible relationship between structure and biological activity of these compounds.

Abstract—Volatiles released from corn seedlings on which beet armyworm larvae were feeding were attractive to females of the parasitoid, *Cotesia marginiventris* (Cresson), in flight tunnel bioassays. Analyses of the collected volatiles revealed the consistent presence of 11 compounds in significant amounts. They were: (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, indole, α-*trans*-bergamotene, (*E*)-β-farnesene, (*E*)-nerolidol, and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. A synthetic blend of all 11 compounds was slightly less attractive to parasitoid females than an equivalent natural blend. However, preflight experience with the synthetic blend instead of experience with a regular plant–host complex significantly improved the response to the synthetic blend. Our results suggest that *C. marginiventris* females, in their search for hosts, use a blend of airborne semiochemicals emitted by plants on which their hosts feed. The response to a particular odor blend dramatically increases after a parasitoid experiences it in association with contacting host by-products.

Key Words—Hymenoptera, Braconidae, *Cotesia marginiventris*, corn, parasitoid, host searching, semiochemicals, synomones.

INTRODUCTION

Although many studies have demonstrated the attraction of parasitoids to volatile semiochemicals, only a few of these chemicals have been isolated and identified (Weseloh, 1981; Vinson, 1981; Eller, 1990). Recent findings that show that responses to semiochemicals by parasitoids are often flexible and can be modified by experience (e.g., Alphen and Vet, 1986; Lewis and Tumlinson, 1988; Vet and Groenewold, 1990) have led to increased interest in the subject from the biological control perspective. It appears possible to condition parasitoid females with specific chemicals so that their subsequent responses to these chemicals are intensified significantly (Lewis and Tumlinson, 1988). This may have positive consequences for mass release programs that so far have suffered from low searching efficiency and high departure frequencies from target areas by released parasitoids (Lewis and Nordlund, 1985). Prerelease experience with volatiles that will guide the wasps to larval pests in a target area is likely to increase the rate of parasitization and, thereby, the effectiveness of the wasps as control agents. To make this possible, identification and formulation of the essential semiochemicals will be necessary.

Cotesia marginiventris (Cresson) (Hymenoptera: Braconidae), a larval endoparasitoid, attacks many economically important Lepidopterous species such as *Spodoptera frugiperda*, *S. exigua*, *Pseudoplusia includens*, and *Heliothis* spp. (Lepidoptera: Noctuidae). The parasitoid frequently causes high mortality among these pests (e.g., Tingle et al., 1978; Pair et al., 1982; McCutcheon and Turnipseed, 1981), but might be much more effective after well-timed augmentative releases. Like other parasitoids, *C. marginiventris* increases its responses to volatile semiochemicals emitted by a plant–host complex after experiencing certain contact kairomones in association with these volatiles (Dmoch et al., 1985; Turlings et al., 1989, 1990a). Several host-derived cues stimulate close-range searching behavior in *C. marginiventris* (Loke et al., 1983; Loke and Ashley, 1984a–c). However, plants damaged by the host larvae are the main source of the volatiles (synomones) that attract the wasp in the vicinity of hosts (Turlings et al., 1991). Here we present the results of a study in which these synomones were collected, tested for their attractiveness to the parasitoid, and eventually identified. The activity of the identified compounds was confirmed by testing synthetic versions in flight-tunnel bioassays.

METHODS AND MATERIALS

The Insects. Cotesia marginiventris were reared and held as described by Turlings et al. (1989). All flight-tunnel tests were conducted with 3- to 5-day-old mated females 4–8 hr into the photophase. In all cases, late second- or early

third-instar beet armyworm (BAW), *Spodoptera exigua* (Hübner), larvae were used as hosts in the experiments. They were reared according to the procedure described by King and Leppla (1984).

Mass Collections of Volatiles for Bioassays and Identification. Volatiles released by BAW larvae feeding on corn seedlings were collected using an all glass push–pull odor collection system. Before entering the system, air was humidified in a gas dispersion tube and purified with in-line activated charcoal filters. The air then entered the first of three Pyrex glass tubes connected in series. The first tube contained a glass frit, which ensured that a laminar air flow would enter the second tube, which contained the odor source. The first tube ended in a 110- to 115-mm male ground-glass joint that was connected to a female counterpart of the second joint. The second tube was ~36 cm long (including joints) with an outside diameter of 11 cm. Its outlet was a 50- to 55-mm male ground-glass joint that fitted the inlet of the third tube, which ended in three collector ports. To optimize the collection, two ports were used simultaneously by attaching stainless-steel tubes (0.64 cm OD × 0.5 cm ID) to each port. The third port was not used and was sealed with a glass stopper. A collection trap was connected to the upwind end of each steel tube, while the downwind end was connected with Tygon tubing to Alborg flowmeters, which were connected to house vacuum.

Collection traps consisted of 3.7-mm-ID × 4-cm-long glass tubes with a 325-mesh stainless-steel frit sealed across the diameter of each tube about 4 mm from the upwind end. Approximately 50 mg of Super Q adsorbent (80–100 mesh) (Alltech, Deerfield, Illinois) was placed on top of the frit and held in place with a small plug of glass wool. Before each collection, the traps were rinsed with methylene chloride.

In the collection chamber, we placed 100 early third-instar BAW larvae on 40 10-day-old greenhouse-grown corn seedlings that were cut just before collection, and their stems were wrapped in wetted cotton. With the odor source and traps in place, a collection was started by balancing house air and house vacuum so that approximately 300 ml/min passed through each trap and the pressure was only slightly higher inside the system than outside. The pressure could be read with a user-designed glass pressure gauge that was connected to a side arm at the downwind part of the collection chamber.

Each collection was run for 24 hr. After 10–12 hr, traps were removed and extracted with 300 μl of pure methylene chloride, then connected back on to the system and extracted once more after another 12–14 hr. The amount of volatiles collected is expressed in collection minute equivalents (CME). Each collection contains 1440 CME (= 24 hr).

Collections for Quantifications. For more exact quantification of the volatiles released by a complete plant–host complex, a smaller system was used. The glass collection chambers consisted of two parts. Purified air entered the

first part through a 2-cm-long $\frac{1}{4}$-in.-OD inlet, which widened into a section (6 cm long; 3 cm ID) containing a glass frit. The second part, also 3 cm in diam, was 15 cm long with a 2-cm-long $\frac{1}{4}$-in. outlet. The second part contained the odor source. Both parts had fitting glass ball joints that were clamped together. One collection trap with 25 mg Super Q adsorbent was connected to the $\frac{1}{4}$-in. outlet with a brass Swagelock fitting containing Teflon ferules. Three corn seedlings that had been fed upon overnight were placed with 15 BAW in the chambers. Volatiles were collected for 1 hr (300 ml/min). Each trap was rinsed with 200 μl methylene chloride, and internal standards were added (1 μg each of octane and nonyl-acetate in 50 μl methylene chloride). Of each collection sample (total volume 250 μl), 1–2 μl was analyzed using capillary gas chromatography (GC) (see below). The collection was repeated on six different days with new plant and herbivore material. The same procedure was followed to collect volatiles from undamaged seedlings. Collections with only wetted cotton wool inside the chamber were performed to determine system impurities.

Collections of Different Components of Complete Plant–Host Complex. The above procedure also was used to collect volatiles of the three main components of a complete plant–host complex. A complex of three overnight damaged corn seedlings was divided into larvae, frass, and damaged leaves as described by Turlings et al. (1991). The larvae were starved for 2 hr and then washed with water. The frass was wiped off the leaves with two pieces of cotton wool (one wet and one dry), and the damaged leaves were washed with water to remove any remaining larval by-products. Volatiles of the three components and of a complete plant–host complex were collected simultaneously for 3 hr. Collections were repeated five times, and GC analyses were used to determine the volatiles present in each of the samples.

Chemical Analyses. Analyses were conducted on a Varian model 3700 GC and a Hewlett-Packard model 5890 GC, both equipped with split–splitless capillary injector systems and flame ionization detectors. Data collection, storage, and subsequent analysis was performed on a Perkin Elmer chromatographic data system. Helium at a linear flow velocity of 19 cm/sec was used as a carrier gas. Most of the initial analyses of the volatile collections were performed on two fused silica capillary columns. They were 50 m $\times$ 0.25 mm ID with a 0.25-μm-thick film of bonded methyl silicone (007) and 50 m $\times$ 0.25 mm ID with a 0.25-μm-thick film of bonded cyanopropyl methyl silicone (CPS-1). Both columns were obtained from Quadrex Corporation (New Haven, Connecticut) and were run at an initial temperature 50°C for 3 min, then temperature programmed at 5°C/min to 180°C. All injections of 1–3 μl were made in the splitless mode.

Samples were also analyzed by GC-mass spectroscopy (GC-MS) with a Nermag model R1010 mass spectrometer in both the electron impact and the

chemical ionization modes. The methyl silicone and CPS-1 columns used in the previous analyses were used in the GC-MS analyses with helium as carrier gas. Methane and isobutane were used as reagent gases for chemical ionization.

Vapor-phase infrared spectra were obtained from a Nicolet 20SXC GC-FTIR spectrometer interfaced to a Hewlett-Packard model 5890 GC. Samples were introduced to the FTIR via the methyl silicone column described above.

Several compounds that required [^{1}H]NMR analysis for full identification were analyzed with a Nicolet 300 MHz Fourier transform NMR spectrometer interfaced to a Nicolet model 1280 data system. The natural compounds as well as synthetic standards were purified by micropreparative GLC on a 30-m × 0.53-mm-ID SPB-1 (1.5-μm film thickness) column (Supelco) in a Hewlett-Packard model 5890 gas chromatograph. To allow injection of large volumes (up to 100 μl), a deactivated column (30 m × 0.53 mm, Quadrex Corporation) preceded the SPB-1 column [see Grob (1982) for details on this technique]. Just before entering the detector, the effluent from the column was split, one part going to the FID detector, the other exiting into a collector as originally designed by Brownlee and Silverstein (1968). The split ratio was manipulated so that >95% of the sample entered a glass capillary collection tube (35 cm long, 1.2 mm ID) in the collector. Dry Ice in acetone was used to cool the part of the capillary tube furthest away from the GC. Tubes were inserted into the collector just prior to elution of the compound to be collected and removed immediately after elution. For collection of the most volatile compounds, approximately 8 mg of Super Q adsorbent was packed between two glass wool plugs at the cold end of a collection tube. Temperature programs varied for the collection of different compounds. The collected material was transferred into an NMR tube by rinsing the glass capillary with approximately 25 μl of benzene-D6. The NMR tubes were 5 mm (OD) at the top, with a 50 × 2-mm (OD) coaxial extension at the bottom (Wilmad Glass Company, Buena, New Jersey). Data points were collected with a 6-μsec pulse (90° tip angle). Where necessary, proton decoupling was accomplished by standard decoupling techniques (decoupler power ca. 0.5 W).

All spectra of the natural products were compared with those of candidate synthetic compounds. (3*E*)-4,8-Dimethyl-1,3,7-nonatriene and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene were synthesized by the Wittig reaction of geranial and farnesal, respectively, with methylenetriphenyl phosphorane (analogous to Maurer et al., 1986). *α-trans*-Bergamotene was provided by Douglas B. McIlwaine at Brown University, Providence, Rhode Island. All other synthetic standards used in this study were obtained from commercial sources.

Flight-Tunnel Bioassays. The Plexiglas flight tunnel described by Turlings et al. (1991) was used to test the attractiveness of specific samples to females

of *C. marginiventris*. During each test, the following conditions were maintained inside the tunnel: 15 cm/sec airflow; 55–70% relative humidity; 27.5–29°C; and approximately 500 lux lumination. For each experiment, a sample dissolved in 200 μl methylene chloride was applied on a strip (1 × 5 cm) of green construction paper. The paper was pinned at the upwind end of the tunnel with an insect pin at a 45° angle from horizontal (highest point upwind), on top of a $\frac{1}{4}$-in. stainless-steel tube, centered 30 cm above the flight-tunnel floor. Four minutes were allowed for the solvent to evaporate before the first wasps were tested. The wasps were released from a glass funnel (Turlings et al., 1991) in groups of three (a number that easily allows the observer to recognize each individual throughout each trial), 80 cm downwind from the odor source. Unless stated otherwise, females were given a 20-sec contact experience with a complex of corn seedlings fed upon by BAW larvae, just before their introduction into the flight tunnel. This experience significantly increases their response to host-related odors (Turlings et al., 1989, 1990a). Here we report only on the percentage of females that exhibited a complete flight toward each odor source.

Dose–Response Tests. The volatiles collected using the above-described mass collection procedure were tested at five different doses. Equivalents of 10, 30, 100, 300, and 1000 collection minute equivalents (CME) were diluted with methylene chloride to a total volume of 200 μl/sample. Samples were labeled such that the experimenter did not know the concentration of each sample until after a complete trial. Six females (two groups of three) were tested to each concentration on a given day. This was repeated six times.

Flights to Synthetic Odor Blends. After all major compounds in the complete natural odor blend emitted by BAW larvae feeding on corn were identified, a synthetic blend of these compounds was made. First, all compounds were purified by preparative GLC as described above. After purification, the compounds were combined in a blend that closely mimicked a collected natural blend (Table 2 below). Both the synthetic and natural blends were tested for attractiveness to *C. marginiventris* in the flight tunnel at a concentration close to the optimal (approximately 250 CME) found in the dose–response tests. Five treatments were tested individually on a given day. Females that were experienced on a regular plant–host complex were tested to either a natural blend, a synthetic blend, or to solvent (methylene chloride) only. In addition, females that had a preflight experience with the synthetic blend were tested to either the natural or the synthetic blend. For the synthetic experience, a filter paper disk (diam. 5.5 cm) was treated with a synthetic sample (same as used for odor sources) and with five to seven fecal pellets of BAW fed on corn. Several minutes after the solvent had evaporated, wasps were introduced to the paper, which they would traverse and antennate vigorously. After 30 sec, the females were transferred to the flight tunnel to observe their long-range responses to one of the odor blends.

RESULTS

Dose–Response Tests. Female *C. marginiventris* exhibited complete flights to all doses of the collected volatiles. Responses, however, were clearly dose related, with an optimal response of 60–75% complete flights to dosages between 200 and 300 CME (Figure 1).

Surprisingly, the overall response dropped significantly at the highest dose (1000 CME) tested. The percentages of females flying to the optimal dose were similar to those that have been observed for females responding to volatiles of complete plant–host complexes (Turlings et al., 1991). This is strong evidence that the naturally active compounds were present in the tested extracts.

Analyses and Identifications of Collected Volatiles. The GC profiles of the collected volatiles revealed the consistent occurrence of 11 compounds in large amounts (Figure 2; Table 1). None of the compounds were found in the profiles from system blanks (= collections made with only wetted cotton present in the collection chamber), and only trace amounts of some volatiles were detected in collections from undamaged leaves (Figure 2).

Compounds 1–5 and compound 7 were identified by comparing their GC-MS spectra with those obtained from synthetic standards and reported spectra

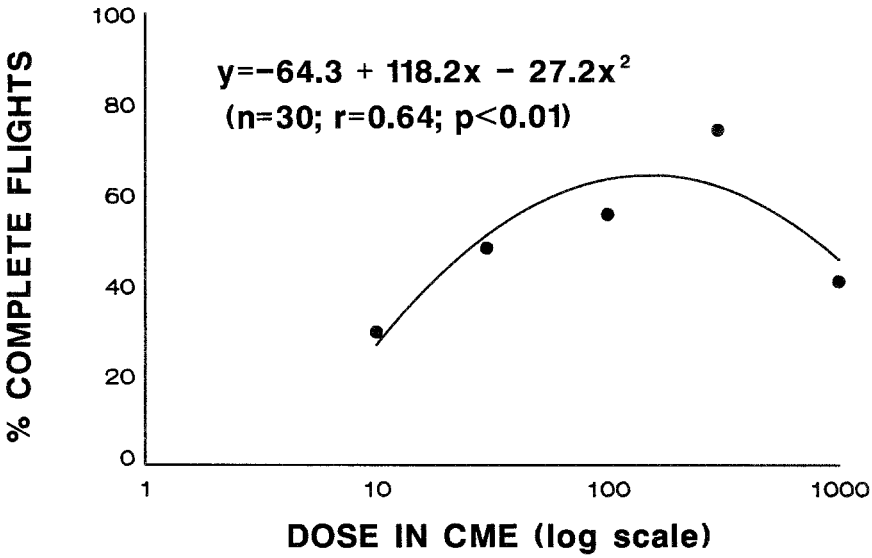

FIG. 1. Responses by (N = 36) *C. marginiventris* females to different doses of extracts of volatiles collected from BAW larvae feeding on corn seedlings. Units are collection minute equivalents (CME), representing the time during which the volatiles were collected from 100 second-instar BAW larvae feeding on 40 seedlings.

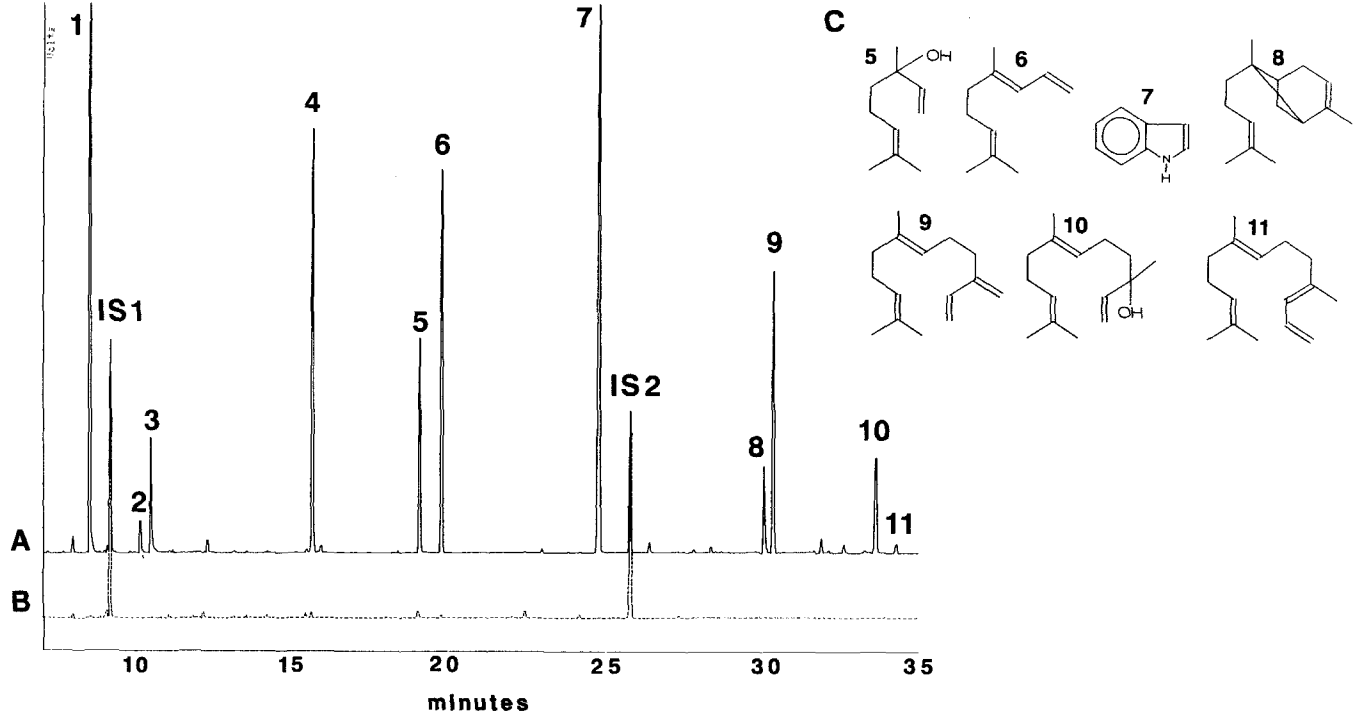

FIG. 2. (A) Chromatogram of volatiles released by a complex of corn seedlings damaged by BAW larvae. The 11 major compounds were identified as 1, (*Z*)-3-hexenal; 2, (*E*)-2-hexenal; 3, (*Z*)-3-hexen-1-ol; 4, (*Z*)-3-hexen-1-yl acetate; 5, linalool; 6, (3*E*)-4,8-dimethyl-1,3,7-nonatriene; 7, indole; 8, α-*trans*-bergamotene; 9, (*E*)-β-farnesene; 10, (*E*)-nerolidol; 11, (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tri-decatetraene. (B) Chromatogram of volatiles released by undamaged corn seedlings. (C) Structures of the last seven compounds with corresponding peak numbers. Chromatograms were obtained by analysis of the volatiles on a 50-m 007 methyl silicone column (0.25 mm ID, 0.25 μm film thickness), after a 2-hr collection. IS1 and IS2 are the internal standards *n*-octane and *n*-nonyl-acetate.

TABLE 1. COMPOUNDS IDENTIFIED IN VOLATILES COLLECTED FROM CORN SEEDINGS FED UPON BY BAW LARVAE

Peak[a]	Compound	Kovats[b]	Amount (ng/hr[c])	Relative %
1	(*Z*)-3-hexenal	775	2015 (785)	5–21
2	(*E*)-2-hexenal	834	310 (108)	1–4
3	(*Z*)-3-hexen-1-ol	845	502 (118)	2–5
4	(*Z*)-3-hexen-1-yl acetate	991	2058 (286)	12–20
5	Linalool	1089	427 (40)	2–4
6	(3*E*)-4,8-dimethyl-1,3,7-nonatriene	1110	676 (140)	3–7

10	(*E*)-nerolidol	1551	947 (329)	6–10
11	(3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tri-decatetraene	1569	61 (16)	0–1

[a] Correspond with peak numbers in Figure 2.
[b] Kovats GLC index (Kovats, 1965) for the 48–m methyl silicone capillary column.
[c] Average amounts released by three corn seedlings that had been fed upon overnight. During the 1-hr collections, 15 BAW larvae fed on the seedlings ($n = 6$). Standard deviations are shown in parentheses.

(Visser et al., 1979; Stenhagen et al., 1974). They were (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, linalool, and indole. All are commonly found in plants (e.g., Visser et al., 1979; Tollsten and Bergström, 1988). Compounds 6 and 8–11 are less common but have all been reported several times as plant-produced chemicals (see Discussion). Synthetic candidates for these compounds, when analyzed by GC, had the same retention times on the two different columns as their natural versions. Moreover, MS, IR and [^{1}H]NMR spectra were identical to the natural products. The [^{1}H]NMR spectra matched with the spectra reported by others: (3*E*)-4,8-dimethyl-1,3,7-nonatriene and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Maurer et al., 1986; Dicke et al., 1990a), α-*trans*-bergamotene (Corey et al., 1971), (*E*)-β-farnesene (Bowers et al., 1972), and (*E*)-nerolidol (Doskotch et al., 1980).

Sources of Collected Volatiles. The damaged plants released, by far, most of the volatiles (Figure 3). All compounds were collected from the damaged leaves in significant amounts, except for compounds 1–3. Preliminary data, however, indicated that when starved larvae are allowed to feed on the leaves, the three most volatile compounds are released in large amounts. Clearly, the highly volatile compounds are only released in the observed amounts as a result of active plant damage. No detectable amounts of the 11 volatiles were released

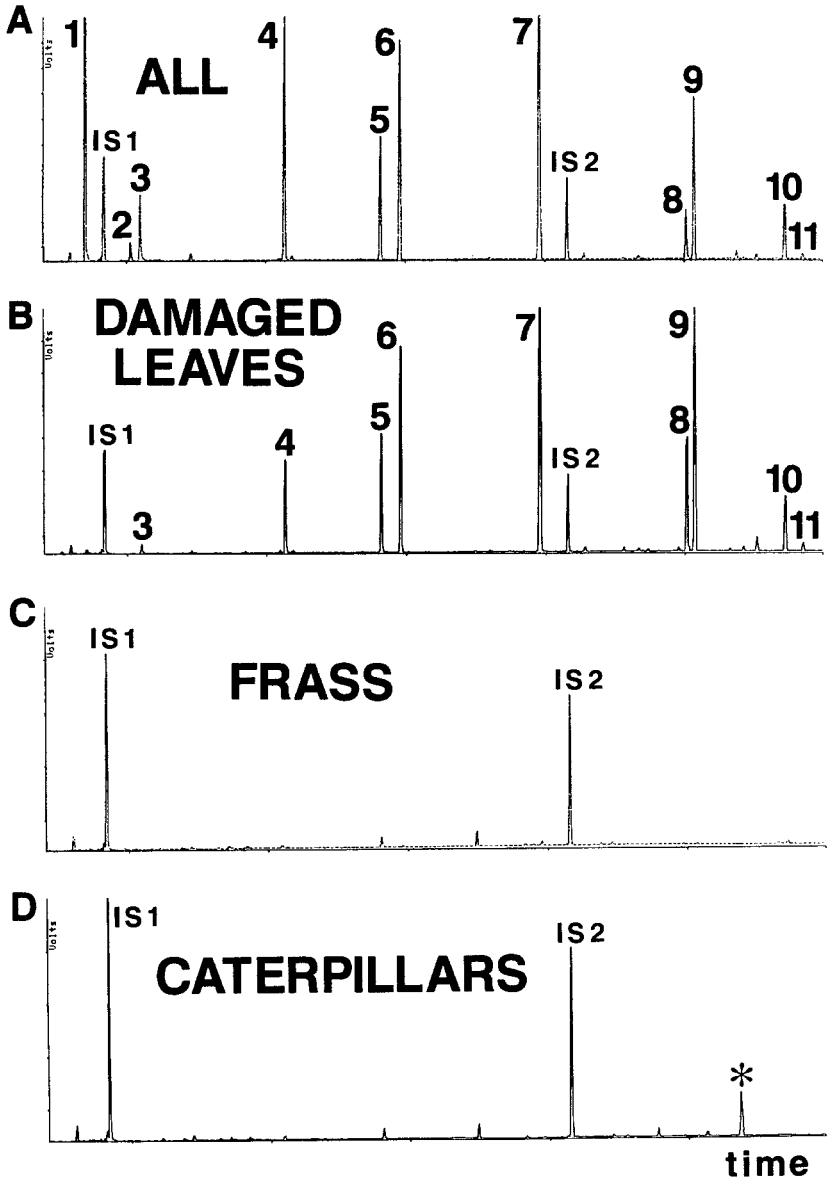

FIG. 3. Volatiles released by different components of a complete plant–host complex: (A) complete complex of BAW larvae feeding on corn seedlings; (B) water-washed corn seedlings that were damaged by BAW larvae; (C) BAW frass wiped from the damaged corn seedlings; and (D) starved water-washed BAW larvae. Peak numbers correspond with those in Figure 1. The asterisk marks pentadecane, a volatile emitted by the oral secretions from BAW larvae. Details on chromatography and internal standards are given with Figure 1.

by frass or larvae (Figure 3). In the collections of the starved larvae, however, an additional peak showed up. This compound was emitted by oral secretions that the larvae regurgitated while fighting among themselves. This was confirmed when collections from hexane extracted filter paper saturated with the oral secretion resulted in the same peak. The compound was identified as pentadecane by GC-MS.

Responses to Synthetic Odor Blend. A collected natural blend and a synthetic mimic (Table 2) were used in further bioassays. Collection procedures were different for Table 1 and Table 2. Volatiles in Table 1 were collected for only 2 hr the day after the larvae had started feeding on the corn seedlings. In contrast, the collections for Table 2 started with larvae on fresh leaves and were continued over a 24-hr period. Several compounds are not released when the larvae just start feeding (Turlings et al., 1990b). Hence, the large differences obtained for some of the major compounds.

A majority of the insects would fly to the extracts of volatiles collected from BAW feeding on corn seedlings (Table 3). Females that were experienced on the synthetic blend and those that had a natural experience responded equally well to the naturally derived volatiles. However, experience did make a difference for the females that were tested to a synthetic blend of the identified compounds. Significantly fewer wasps that had received a natural experience flew

	SYNTHETIC	36	19	52.8 (15.0) A
Solvent	NATURAL	36	0	0.0 C

[a] Blends from Table 2 were used in amounts equivalent to 200–300 CME (1% = 25 ng).
[b] On six different days six females were tested for each treatment. Standard deviations in parenthesis. Analysis of variance was performed on the daily percentages after arcsin transformation, followed by Duncan's multiple-range test. Different letters indicate significant differences between treatments ($P < 0.05$)

to the synthetic blend than did females that had received a synthetic experience. The responsiveness exhibited by females with a synthetic experience to a synthetic odor blend did not differ from that of females that were tested to the natural extract. None of the tested females flew to the solvent alone.

DISCUSSION

C. marginiventris females responded in a dose-related manner to the collected volatiles (Figure 1). The reduced response at the highest dose tested indicated that for optimal bioassay results release rates should be balanced carefully. By applying the extracts to filter paper, the obtained release rates were obviously far from natural. Before the importance of each individual compound in the attraction of *C. marginiventris* can be determined, exact formulations resulting in release rates similar to a natural situation (Table 1) must be obtained.

The technique of collecting plant volatiles directly from an airstream passed over the odor source has some major advantages over the often applied harsh methods of extraction or steam distillation. The latter two techniques give no indication of how much of each identified compound is actually released into the environment and may result in destruction or isomerization of essential chemicals. This may account for our finding that (*Z*)-3-hexenal was one of the major components, whereas elsewhere it is seldom reported as a plant volatile. Due to its high volatility, (*Z*)-3-hexenal is much harder to collect than the other

green leaf volatiles, including (*E*)-2-hexenal. This is illustrated by our preliminary attempts to re-collect the compounds from the GC as described earlier. Initially, a (U-) tube immersed in liquid nitrogen was used; collection efficiency was extremely poor for (*Z*)-3-hexenal, while it was high for all other volatiles. Only when the collection tubes were used that contained a small amount of Super Q adsorbent was it possible to collect (*Z*)-3-hexenal effectively. High amounts of (*Z*)-3-hexenal are not only characteristic for BAW damage or corn. Preliminary results showed that artificial damage of corn and damage of other plants (i.e., cotton, tomato, and cowpea) resulted in the release of similar relative amounts of (*Z*)-3-hexenal (unpublished data). Buttery et al. (1987) reported on the fast isomerization of (*Z*)-3-hexenal [probably into (*E*)-2-hexenal] in crushed tomato leaves. Our respective results suggest that damaged green leaves release much more (*Z*)-3-hexenal than previously reported.

When Buttery and Ling (1984) collected the volatiles of corn plants that were cut at the stem, they also found (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, linalool, and (*E*)-β-farnesene. Thompson et al. (1974) extracted the essential oil from corn and identified 59 compounds, including indole and nerolidol. No previous reports on corn volatiles mention α-*trans*-bergamotene, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, or (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. The latter two apparently related methylene terpenoids were recently reported by Maurer et al. (1986), who found them in the oil of *Elettaria cardamomum* (cardamom oil). Kaiser (1987) (as referenced by Dicke et al., 1990a) reported these compounds from night-scented flowers of different plant species that are pollinated by moths. These compounds are released by Lima bean leaves (Dicke et al., 1990a) and cucumber leaves (Dicke et al., 1990b) that have been subjected to spider mite infestation (see below).

The terpenoid α-*trans*-bergamotene appears to be rare. It has been reported from cotton (Minyard et al., 1966) and from buck's horn (staghorn sumac) (*Rhus typhina*) (Bestmann et al., 1988). (*E*)-β-Farnesene was the most predominant terpenoid in the collections. It has been identified previously from corn leaves by Buttery and Ling (1984), but they found it in much smaller amounts relative to the other compounds. (*E*)-β-Farnesene attracts a chalcid wasp (Kamm and Buttery, 1983) and serves as an alarm pheromone for aphids (Bowers et al., 1972; Edwards et al., 1973; Wohlers, 1981). The *E* isomer of nerolidol is present in the essential oil of several *Melaleuca* tree species (Jones and Harvey, 1936; Naves, 1960; Doskotch et al., 1980). Picker et al. (1976) found it also in the bark of the Australian tree *Flindersia laevicarpa*. Doskotch et al., (1980), who isolated (*E*,*S*)-nerolidol from *Melaleuca leucadendron* leaves, showed that it functions as a feeding deterrent for gypsy moth larvae.

We still need to establish which optical isomers of linalool, α-*trans*-bergamotene, and (*E*)-nerolidol are released by corn seedlings. We used racemic mixtures of the latter three in our synthetic blend, and this may explain why

females with a natural experience did not respond well to the synthetic blend (Table 3). An experience with the blend that contained the racemic mixtures, however, increased the responses to a level comparable to the responses to a natural blend. These results again illustrate the significant effects of experience on the responses to airborne semiochemicals in parasitoids. If, in the future, synthetic blends are used to condition parasitoids to perform more effectively when released in host-infested areas, the best results are likely to be obtained with the closest mimics of naturally released odors.

The damaged plants are clearly the main source of the identified compounds (Figure 3). This agrees with the responses of the parasitoids to the different components of a complete plant–host complex (Turlings et al., 1991). The wasps are significantly more attracted to the damaged plants than to frass or to larvae. Undamaged plants are far less attractive (Turlings et al., 1991), and here it is shown that undamaged plants release only minute amounts of some of the compounds (Figure 2). That undamaged plants are relatively odorless may be a trait that makes them inconspicuous to herbivores. When under attack by herbivores, however, a dramatic change occurs in the number and amounts of volatiles plants release. Results similar to ours were obtained by Dicke and coworkers, who found that spider mite-infested plants initiate the release of terpenoids (Dicke and Sabelis, 1988; Dicke et al., 1990a,b). The compounds were not released by undamaged plants, nor were they detected from artificially damaged leaves. Of the compounds that we identified as being released by BAW-damaged corn, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, linalool, and the two methylene terpenoids also were released by spider mite-infested Lima bean (Dicke et al., 1990a). At least one of the methylene terpenoids, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, is involved in the attraction of predatory mites that feed on spider mites (Dicke and Sabelis, 1988; Dicke et al., 1990a,b). Preliminary results suggest that these methylene terpenoids are released by several green plants that have been under attack by herbivores (unpublished data), and they may elicit behavioral responses in a variety of insects. These plant responses may be direct defenses against their attackers, as high terpenoid contents inhibit insect feeding in several cases (e.g., Doskotch et al., 1980; Mihaliak et al., 1987; Gunasena et al., 1988; Turlings and Tumlinson, 1991). In addition, however, the volatiles released by the injured plants may serve as signals to attract natural enemies of herbivores (Dicke and Sabelis, 1988; Dicke et al., 1990a,b; Turlings et al., 1990b; Turlings and Tumlinson, 1991).

Acknowledgments—We are particularly grateful to B.D. Dueben and R.E. Murphy for valuable advice and assistance. We thank Drs. R.J. Bartelt, L.B. Bjostad, M. Dicke, F.J. Eller, P. Greany, and R.L. Jones for their helpful comments on the initial manuscript. D.B. McIlwaine at Brown University provided us with α-*trans*-bergamotene. Dr. V. Chew provided us with valuable statistical advice.

CROSS-REACTION TO SKIN EXTRACT BETWEEN TWO GOBIES, *Asterropteryx semipunctatus* AND *Brachygobius sabanus*

R.J.F. SMITH,* B.J. LAWRENCE, and M.J. SMITH

Biology Department

(Received May 6, 1991; accepted July 15, 1991)

Abstract—Two gobies that possess alarm pheromones were tested for cross-reactions to water extracts of injured members of the other species in the first such cross-reaction test conducted in the Family Gobiidae. *A. semipunctatus* reacted to extract from injured *Brachygobius sabanus* with the same bobbing and reduction in activity as it shows in response to conspecific extract. However, *B. sabanus* showed a feeding response, including increased activity, to extract from injured *A. semipunctatus*. Even a one-way cross-reaction suggests some degree of homology between the alarm pheromone systems of the two species.

Key Words—Alarm pheromone, Schreckstoff, alarm substance, goby, *Asterropteryx semipunctatus*, *Brachygobius sabanus*, Gobiidae, fish behavior.

INTRODUCTION

In the alarm pheromone systems of ostariophysan fishes (Schutz, 1956; Pfeiffer, 1977; Smith, 1986) and percid darters (Smith, 1979, 1982), the members of the taxonomic group that share the chemical alarm system show some degree of cross-reaction between species or even between genera or families. Although there is often some reduction in response with increasing taxonomic distance, the presence of any cross-reaction probably indicates homology between the alarm systems of the members of a taxonomic group. Such homology of response to a common active compound occurs in the ostariophysan fishes (Schutz, 1956; Pfeiffer, 1982).

Two species of gobiid fishes, *Asterropteryx semipunctatus* (Smith, 1989) and *Brachygobius sabanus* (Smith and Lawrence, 1992) have now been reported to show a defensive response (fright reaction) to chemicals from injured conspecifics. Six other gobiid species, *Gobius niger*, *G. paganellus*, *Pomatoschistus microps*, *P. minutus* (Pfeiffer, 1977), *Gnatholepis anjerensis* (Smith, 1989), and *Coryphopterus nicholsii* (Hugie, personal communication) have been tested and apparently do not show a fright reaction to chemicals from injured conspecifics. The question thus arises, do *A. semipunctatus* and *B. sabanus* react to each other's skin extract? If they do cross-react, it may indicate that there is a homologous component to goby alarm pheromones. If they do not cross react, it would support, but not confirm, the hypothesis that chemical alarm signaling has arisen independently in two gobiid species. We compared cross-reactions between the two species using the same observers and criteria as had been used in the original studies of each species.

METHODS AND MATERIALS

Asterropteryx semipunctatus were collected from patch reefs in Kaneohe Bay, Oahu, Hawaii, by scuba divers and snorkelers using plastic bags or hand nets. Those *A. semipunctatus* that were used as receivers for skin extract from *Brachygobius sabanus* were kept in running seawater in holding tanks at the Hawaii Institute of Marine Biology, then transferred to 38-liter observation aquaria in groups of three. They were allowed at least seven days of acclimation before observation. The holding and observation aquaria were maintained between 24° and 27°C under a 12:12 hr light–dark photoperiod. During this time, the fish were fed with live plankton collected in Kaneohe Bay. *A. semipunctatus* that were used as extract donors were transported by air to the Department of Biology, University of Saskatchewan, where they were maintained in artificial seawater at 24°C under a 12:12 hr light–dark photoperiod and fed live and frozen brine shrimp and commercial flake food. Extract receivers included 12 males (mean total length 34 mm), 13 females (mean total length 37 mm), and two small fish that could not be sexed (mean 22 mm). Extract donors were four males (mean 28 mm) and six females (mean 25 mm).

Brachygobius were purchased from commercial pet suppliers in Calgary, Alberta, and Kaneohe and Aiea, Hawaii. Our specimens (ROM 56628) were tentatively identified by R. Winterbottom of the Royal Ontario Museum as *Brachygobius sabanus* Inger, 1958. There are some inconsistencies involving the degree of scalation of the operculum and pelvic-fin length of our specimens and the description of the type specimens (collected in North Borneo). The original source of the fish is unknown. A sample of the receivers, eight males (mean total length 25 mm) and two females (mean 27 mm), was measured. The nine donors included four females (mean 27 mm) and five males (mean 24 mm).

B. sabanus were kept in brackish water prepared by mixing 37 liters of freshwater with 1 liter of seawater. At the Hawaii Institute of Marine Biology they were fed live brine shrimp and marine plankton and kept under a 12 : 12 hr light–dark photoperiod between 24° and 27°C. At the University of Saskatchewan they were kept at 27–29°C under a 12 : 12 hr light–dark photoperiod and fed live whiteworms and live brine shrimp. They were observed in groups of four and were allowed at least seven days of acclimation before being observed.

All observations were conducted using 38-liter tanks. The observer sat quietly in full view of the fish and recorded their behavior using a mechanical counter. The behavior of *B. sabanus* receivers was also recorded on videotape for later analysis of swimming time. The observation tanks in Hawaii, housing *A. semipunctatus* receivers, were equipped with seawater inlet tubes and the chemical stimuli were injected into the inlet. The observation tanks in Saskatoon, housing *B. sabanus* receivers, were equipped with power filters and the chemical stimuli were injected into the inlet tube running from the filter to the tank. The arrangement of sand and shelters was the same as in the original studies of alarm pheromone responses in the two species (Smith, 1989; Smith and Lawrence, 1992).

In the standard test procedure, the fish were observed for 15 min; then the chemical stimuli were injected into the inlet tube, and the fish were observed for an additional 15 min. The totals for the two 15-min observation periods were compared for each tank of fish. This procedure was repeated nine times for *A. semipunctatus* receivers and 10 times for *B. sabanus* receivers, each time with a different group of fish. Each group was used only once. Since the fish in a tank cannot be considered independent, comparisons were made on the basis of group totals. Following each test, food dye was injected into the system and the time from injection to dispersal through the tanks was recorded as an estimate of the time from stimulus injection to the reception of the stimulus by all fish in the tank. The mean time for the dye to enter the tank was 22 sec, with 181 sec for full dispersal in the *A. semipunctatus* tanks and 10 sec for entry and 32 sec for dispersal in the *B. sabanus* tanks.

A. semipunctatus are negatively buoyant, benthic fish. They move episodically rather than continuously, with movements separated by intervals when they remain stationary. Each time a fish changed position, it was counted as making one move. Bobbing behavior was also counted, in which the anterior part of the goby rose slowly off the bottom, apparently by extension of the pelvic fins, then settled to the bottom again. A fish could move without bobbing and bob without moving. In *A. semipunctatus*, bobbing occurs in response to visual and olfactory stimuli from predators (Smith, 1989; Smith and Smith, 1989). *B. sabanus* are often negatively buoyant and can move about episodically in much the same manner as described above, but they can also swim in

midwater, maintaining neutral buoyancy with their swim bladder. As well as counting moves, we recorded the total swimming time, the time in a 15-min observation period when one or more fish was swimming, for *B. sabanus*. Agonistic encounters were also counted, as in Smith and Lawrence (1992). *B. sabanus* was never observed to bob.

Chemical extracts of injured fish were prepared by killing the donor with a blow to the head, placing it in a clean disposable Petri dish, cutting it several times on each side with a scalpel, rinsing the fish in tank water and drawing up the extract into a clean syringe. *A. semipunctatus* donors were cut 25 times and rinsed with 7 ml of water, and the extract was drawn into a 5-ml syringe. *B. sabanus* donors were cut 50 times, rinsed in 10 ml, and the extract was drawn into a 10-ml syringe. These procedures mimic the original studies for each type of receiver. Extracts were used within 20 min of preparation. Control stimuli, water, and extracts of nongobiid fishes were tested in the original studies of each species and were not repeated here.

The results of each test were analyzed with a Wilcoxon matched-pairs, signed-rank test (Siegel, 1956) comparing the total number of acts, or minutes of swimming, before stimulus introduction with the total after introduction, for each group of fishes.

RESULTS

A. semipunctatus responded to skin extract from *B. sabanus* with decreased activity in eight of the nine trials; the mean change was −15% (Figure 1). There were no bobs during the prestimulus interval but one group performed 63 bobs and another 20 bobs in the poststimulus interval. These two groups showed substantially greater activity reduction than the other groups, −40% and −42%, respectively. Qualitatively, the response of the *A. semipunctatus* resembled the response shown to conspecific extract (Smith, 1989).

B. sabanus responded to skin extract from *A. semipunctatus* with increased moves in all 10 trials; the mean change was +86% (Figure 1). Swimming time did not change significantly, but the number of agonistic encounters increased in eight of 10 groups, by an average of 123%. This response was opposite to the response of *B. sabanus* to conspecific extract and more closely resembled a feeding response (Smith and Lawrence, 1992). Other, qualitative resemblances to a feeding response included increased biting at the substrate, moving out of shelters, and attacking snail shells.

DISCUSSION

A. semipunctatus responds to extract from injured *B. sabanus* with the same sort of antipredator response that it shows in response to extract from injured conspecifics or stimuli from predators (Smith, 1989). The response

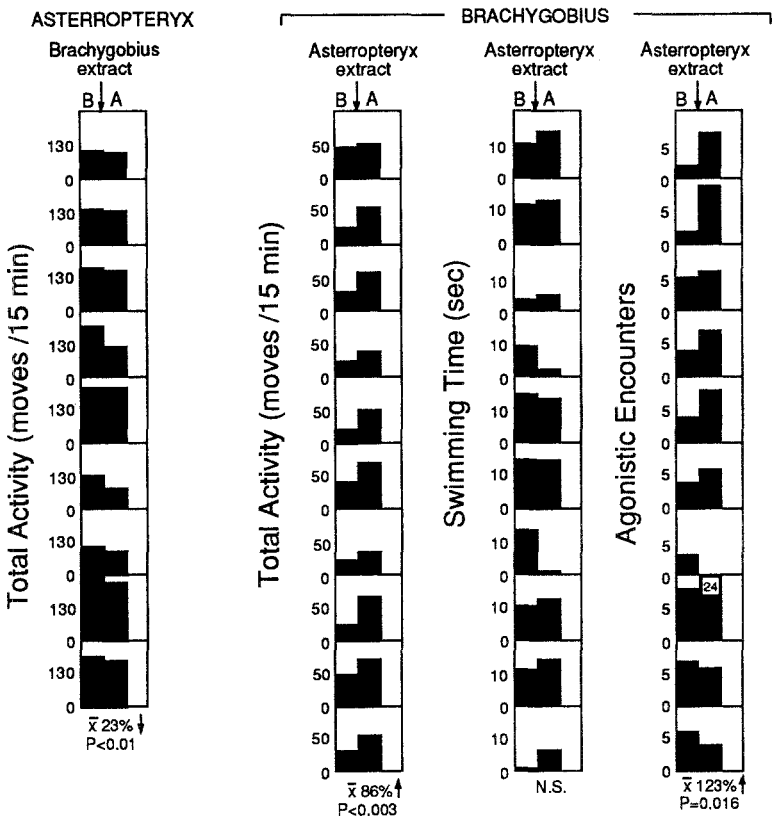

FIG. 1. Behavioral responses of gobies to skin extracts from heterospecific fishes. Values plotted are the number of moves by *Asterropteryx semipunctatus* in 15-min intervals before (B) and after (A) exposure to extract from injured *Brachygobius sabanus* and the number of moves, total swimming time, and number of agonistic encounters by *B. sabanus* in 15-min intervals before and after exposure to extract from injured *A. semipunctatus*. P = probability based on Wilcoxon matched-pairs, signed-rank test, N.S. = not significant.

seems slightly weaker than the response to conspecific extract—a mean decrease in moves of 23% with bobbing in six tanks of 10 (Smith, 1989)—but this is reasonable considering that the two species are in different genera. Schutz (1956) catalogued several examples of declining cross-reaction with phylogenetic separation in the alarm system of ostariophysan fishes. The presence of two very strong reactions to *B. sabanus* extract with approximately 40% activity reduction and frequent bobbing reinforces the conclusion that *A. semipunctatus* responds to *B. sabanus* extract with an antipredator response. In contrast to these results, control tests by Smith (1989) had demonstrated that *A. semipunc-*

tatus showed small, about 5%, nonsignificant increases in activity and no increase in bobbing when given control water or water that had contained uninjured conspecifics as a stimulus. Extract from a nongobiid fish, the Mexican molly *Poecilia mexicana*, induced an 18% increase in activity but no bobbing, and extract from *Gnatholepis anjerensis*, a goby that lacks alarm pheromone, led to a similar 18% increase in activity (Smith, 1989).

B. sabanus responds to extract from injured *A. semipunctatus* as if it were a feeding stimulus. In control tests conducted by Smith and Lawrence (1992), *B. sabanus* responded to extract of an injured nongobiid, the guppy *Poecilia reticulata*, with significant increases in moves, swimming, and agonistic encounters. This response was characterized as a feeding response because it resembled the response to brine shrimp extract. The response to conspecific extract was a reduction in moves, swimming, and agonistic activity, associated with moving to shelters. The response of *B. sabanus* to *A. semipunctatus* extract differed from the feeding responses described by Smith and Lawrence (1992); responses were directed more to the bottom of the tank, whereas the response to guppy extract and brine shrimp extract was directed more to the surface or midwater. The significance of this observation in not clear, although cyprinodonts are usually surface fish while gobies are often benthic.

A possible explanation for this one-way cross-reaction between two gobiid species that have been shown to possess alarm pheromones is that the two species share active components in their chemical alarm signal but that *B. sabanus* is more selective in avoiding "false alarms" from injured heterospecific fishes. This selectivity might be favored if *B. sabanus* shared its environment with other pheromone-bearing gobies that were subject to attack by predators that do not prey on *B. sabanus* or if *B. sabanus* preyed on other gobies, perhaps by fin nipping. *A. semipunctatus* does not respond indiscriminately to all goby skin extracts since it responds with feeding behavior to skin extract from injured *Gnatholepis anjerensis*, a sympatric goby (Smith, 1989). Our results suggest that there are homologies between the two gobiid alarm pheromone systems. The phylogeny of gobies is not clear, and it is therefore difficult to fit our results into any phylogenetic pattern.

Acknowledgments—This study was supported by facilities provided by the Hawaii Institute of Marine Biology and the University of Saskatchewan, and by funding from the Natural Science and Engineering Research Council of Canada and the Edwin W. Pauley Foundation grant to the Hawaii Institute of Marine Biology Summer Program. We thank Frank Stanton, Lisa Privitera, Jeff Mahon, and Steve Woytowich for collecting fish; Elizabeth Hinks for feeding and maintaining fish; and Alicia Mathis for reading the manuscript and offering helpful comments.

EFFECT OF APIFOROL AND APIGENINIDIN ON GROWTH OF SELECTED FUNGI

CINDY SCHUTT[1] and DAVID NETZLY*

Biology Department
Hope College
Holland, Michigan 49423-3698

(Received December 10, 1990; accepted July 16, 1991)

Abstract—Selected fungi were grown on agar plates in the presence of naringenin, apiforol, apiforol 7-*O*-rhamnoglucoside, or apigeninidin. Of the four compounds tested, only apigeninidin inhibited the growth of *Fusarium oxysporum*, *Gibberella zeae*, *Gliocladium roseum*, *Alternaria solani*, and *Phytophthora infestans*. In contrast, the growth of *Rhizoctonia solani*, *Sclerotium rolfsii*, and *Rhizopus stolonifer* (− and +) was not effected by any compound. Since apigeninidin is present in seeds of *Sorghum* sp., we hypothesize that apigeninidin may play a role in mold resistance and that apiforol accumulates as a biosynthetic precursor of apigeninidin, not as a fungal defense compound.

Key Words—Fungi, mold resistance, apiforol, 3-deoxyanthocyanidin, apigeninidin, flavan-4-ol, allelopathy, *Sorghum bicolor*.

INTRODUCTION

In many arid regions of the world, sorghum is grown as the major food crop. However, much of the potential yield is lost due to preharvest fungal growth (molding) on seeds of certain *Sorghum bicolor* lines (Frederiksen, 1986). A positive correlation has been reported between seed extracts of sorghum that contain high amounts of flavan-4-ols and increased mold resistance from both greenhouse-grown (Jambunathan et al., 1986) and field-grown sorghum lines (Jambunathan et al., 1990). Recently, apigeninidin, a 3-deoxyanthocyanidin,

was reported to accumulate in response to *Helminthosporium maydis* and *Colletotrichum graminicola* infection in sorghum mesocotyls (Nicholson et al., 1989; Snyder and Nicholson, 1990). Both apiforol (flavan-4-ol) and apigeninidin are present in seeds of certain sorghum cultivars (Nip and Burns, 1969; Watterson and Butler, 1983). Apiforol is the presumed precursor of apigeninidin (see Stich and Forkman, 1988) (Figure 1). The purpose of this work was to determine (1) if apigeninidin is inhibitory to fungi other than members of the Deuteromycetes and (2) if apiforol (flavan-4-ol) or apiforol 7-*O*-rhamnoglucoside inhibit the growth of any fungal species.

METHODS AND MATERIALS

Flavan-4-ol and 3-Deoxyanthocyanidin Chemical Synthesis. Naringenin (100 mg, Sigma) or naringin (100 mg, Sigma) was dissolved in 2 ml of 100% methanol and reduced with sodium borohydride (50 mg). After 45 min, the reduction product was acidified with 10% (v/v) acetic acid in methanol to quench the borohydride and to lower the pH of the solution to between 6 and 7. This solution was evaporated to dryness at 35°C. Residue containing apiforol or apiforol 7-*O*-rhamnoglucoside was scraped off the flask and stored dry at room temperature in the dark. Presence of flavan-4-ol was confirmed by the formation of a red pigment in the presence of 30% (v/v) conc. HCl in isopropanol.

Apigeninidin was synthesized from the residue containing apiforol. Residue was reconstituted in a small amount of methanol and the solution was added to 7 ml of 2 N HCl and heated (100°C) for 1 hr. Apigeninidin was extracted from the acidic solution with ethyl acetate and taken to dryness at 35°C.

Fungal Bioassay. Residue containing apiforol, apigeninidin, and apiforol 7-*O* -rhamnoglucoside was dissolved in absolute methanol and applied to filter

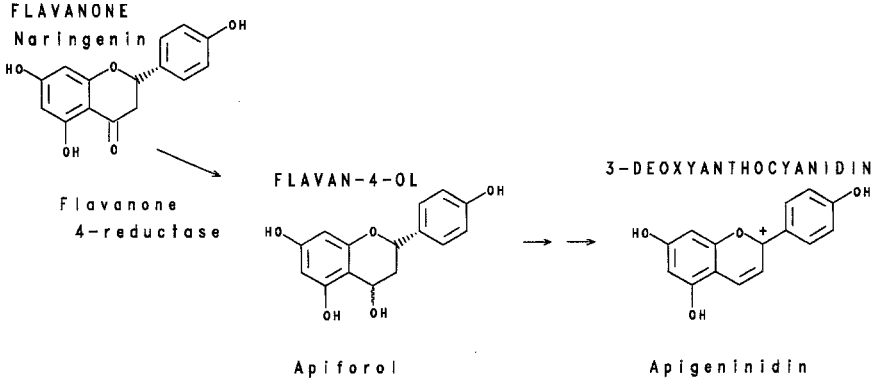

FIG. 1. Proposed biosynthetic pathway for apigeninidin (3-deoxyanthocyanidin).

paper disks (1.2 cm diameter). Control disks had only methanol applied. Petri plates containing potato dextrose agar (Difco) were inoculated with propagules of the following fungi obtained from Carolina Biological Supply Co.: *Fusarium oxysporum*, *Gibberella zeae*, *Gliocladium roseum*, *Rhizopus stolonifer* (+ and − strains), *Alternaria solani*, *Phytophthora infestans*, *Rhizoctonia solani*, or *Sclerotium rolfsii*. Filter disks containing the individual compounds were placed in the center of the agar plates after the methanol had evaporated. Petri plates were incubated in the dark at room temperature. The ring of growth inhibition around the filter disks was measured (average of three measurements) each day for three days, or, in the case of apigeninidin, for up to 10 days.

RESULTS

The growth of *Fusarium oxysporum*, *Gibberella zeae*, and *Gliocladium roseum* was inhibited by apigeninidin (3.6 μmol) in the three-day experiment (Table 1). In contrast, apiforol and apiforol 7-*O*-rhamnoglucoside were not effective in inhibiting the growth of any of the fungal species tested (Table 1). Naringenin, the biosynthetic precursor of apiforol, was also ineffective as a fungal growth inhibitor.

Based on these results, the effect of apigeninidin on the growth of five additional fungal species was tested (Figure 2). The length of this experiment was extended to 10 days.

The growth of *Alternaria solani* and *Phytophthora infestans* was inhibited by apigeninidin. The growth of *Rhizoctonia solani*, *Sclerotium rolfsii*, and *Rhizopus stolonifer* (−) was not appreciably inhibited. Of the fungi tested, *R. stolonifer* (− and +) was the least sensitive to apigeninidin.

DISCUSSION

Apigeninidin inhibited the growth of members of the Deuteromycetes, Oomycetes, and Ascomycetes. Since apigeninidin is accumulated in sorghum seeds and it inhibits the growth of *Alternaria solani*, which is a common pathogen on sorghum grain (Frederiksen, 1986), apigeninidin may have a direct role in the resistance of *A. solani* on sorghum grain. However, there is evidence that mold resistance is more complex than can be explained by one chemical such as apigeninidin (see Jambunathan et al., 1990).

Apiforol has been detected in sorghum seeds (Bate-Smith and Rasper, 1969; Watterson and Butler, 1983; Jambunathan et al., 1990). Apiforol 7-*O*-rhamnoglucoside has not been found as a natural constituent of sorghum but was tested in order to determine what affect glycosylation might have an apiforol

activity. Our results with these flavan-4-ols do not rule out the possibility that other flavan-4-ols and/or their glycosides may be biologically active.

In our method of apiforol synthesis, some naringenin was detected and presumably some self-polymerization products were present in the final apiforol preparation. Flavan-4-ols readily undergo acid-induced self-polymerization reactions (Stich and Forkmann, 1988). Therefore, we tested naringenin by itself and found it to be inactive. However, we do not know if a polymer of apiforol would have different biological activity than its monomer. Similarly, apigeninidin undergoes apparent self-polymerization reactions under acidic conditions after its synthesis, as determined by the difference in mobility between freshly prepared and "aged" apigeninidin on paper chromatography in 2 N HCl (Netzly, unpublished).

In summary, apigeninidin was found to inhibit the growth of various fungi. It is not known if this compound has other biological activities as well. Preliminary data indicate that its mode of action is not as a mutagen (Netzly, unpub-

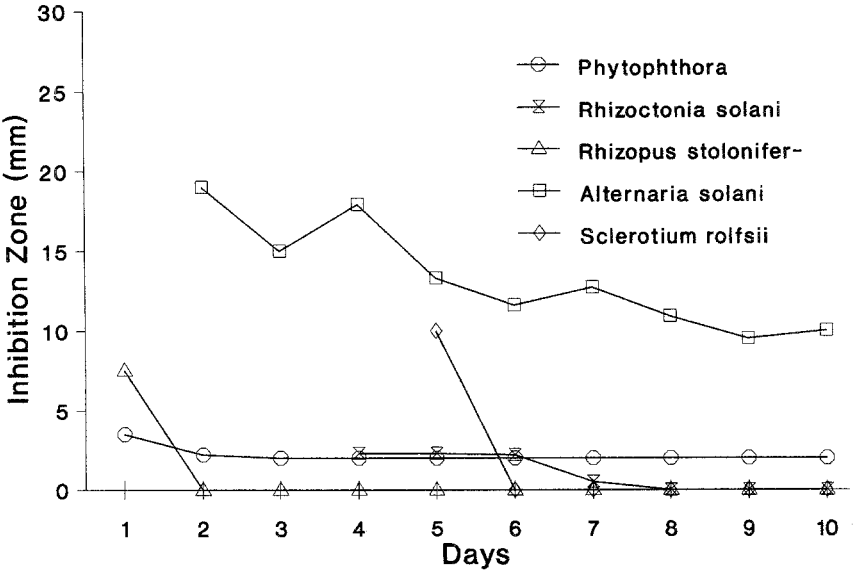

FIG. 2. Effect of apigeninidin (3.6 μmol) on the growth of additional fungal species. Values are an average of four to five experiments.

lished). Secondly, while there is a direct correlation between mold resistance and the presence of flavan-4-ols in sorghum seeds (Jambunathan et al., 1986), our data suggest that apiforol does not directly affect the growth of any fungal species tested. We hypothesize that the correlation between mold resistance and flavan-4-ol accumulation in seeds is because apiforol (flavan-4-ol) is the presumed precursor of apigeninidin, a fungal growth inhibitor.

ALLELOPATHIC DOMINANCE OF *Miscanthus transmorrisonensis* IN AN ALPINE GRASSLAND COMMUNITY IN TAIWAN[1]

CHANG-HUNG CHOU* and YI-FENG LEE

Institute of Botany
Academia Sinica
Taipei, Taiwan 11529
Republic of China

(Received March 6, 1991; accepted July 22, 1991)

Abstract—A study site located at 2600 m elevation in Tartarchia Anpu, Nantou county, Taiwan, exhibits a unique grassland community composed of two principal species, *Miscanthus transmorrisonensis* and *Yushinia niitakayamensis*, and 35 other species. The relative frequencies of the two species are 12% and 11%, while their relative coverages are 25% and 19.5%, respectively. The values for the remaining 35 species are lower than 4% each, while species diversity of the community is −3.04839, indicating great diversity. To elucidate the mechanism of dominance of *M. transmorrisonensis*, allelopathic evaluation of the plant was conducted. Aqueous extracts of *M. transmorrisonensis* plant parts with two ecotypes were bioassayed. The extracts showed significant phytotoxic effects on seed germination and radicle growth of four tested plants: rye grass, lettuce, and two varieties of Chinese cabbage. In addition, rhizosphere soils under *Miscanthus* also exhibited significant phytotoxicity, indicating that allelopathic interaction was involved. Some responsible phytotoxic phenolics, namely, *p*-coumaric, ferulic, vanillic, protocatechuic, *o*-hydroxyphenylacetic, and *m*-hydroxyphenylacetic acids, and 4-hydroxycoumarin and phloridzin were identified. Allelopathy thus can play an important role in regulating plant diversity in the field.

Key Words—*Miscanthus transmorrisonensis*, allelopathy, phytotoxin, population, phenolics, plant diversity, grassland community.

INTRODUCTION

Miscanthus floridulus (Labill.) Warb., a dominant endemic grass, is ubiquitously distributed in areas below 2000 m elevation in Taiwan. On the other hand, *M. transmorrisonensis* is distributed in mountainous areas above 2200 m. Chou et al. (1987) reported that four major clusters of ecotypic populations were found among 27 populations of *M. floridulus*. The unique ecotypes of the species were present in various habitats and adapted to different environmental regimes, such as those of high salinity, polluted soil, and moisture deficiency (Chou and Chang, 1988; Chou and Chen, 1990). On the other hand, the adaptive mechanism of *M. transmorrisonensis* to areas of high elevations in Taiwan depends primarily on temperature (Chou et al., 1991). A reciprocal transplanting experiment conducted on the two plants revealed that *M. transmorrisonensis* could survive in the high temperature of lower elevations but that *M. floridulus* did not survive two severe winters at the higher elevation. Both species displayed relatively pure vegetation, and the allelopathic potential of *M. floridulus* was demonstrated (Chou and Chung, 1974). The mechanism of dominance of *M. transmorrisonensis* has yet to be studied. The growth performance and ecological adaptation of the grass has resulted in excellent survival at low temperatures in Yushan National Park (Chou et al., 1991).

Allelopathy has been regarded as one of the important survival strategies and plays a significant role in the dominance of grassland communities (Rice, 1977, 1984; Muller, 1966; Tinnin and Muller, 1971; Newman and Miller, 1977; Gliessman, 1978). The allelopathic dominance of *M. transmorrisonensis* was evaluated by conducting a series of experiments in fields at Yushan National Park, in a Phytotron of the National Taiwan University, and in a greenhouse and laboratory of the Academia Sinica at Taipei.

METHODS AND MATERIALS

Study Site. The study site chosen for most field experiments in the present study is located at 2600 m elevation at Tartarchia Anpu of the Yushan National Park, Nantou County, Taiwan. The weather pattern of the study site during the period 1988–1990 was described by Chou et al. (1991). The temperature ranged from 4.5°C to 8°C in winter and from 16°C to 18°C in summer. The amount of annual precipitation was high, about 2000–2600 mm. The site at Tartarchia Anpu contains a unique grassland community, comprised of two dominant stands of *Miscanthus transmorrisonensis* and *Yushinia niitakayamensis* (Figure 1).

Field Experiments. The botanical composition of the study site was determined by the quadrat method, 1 × 1 m each, and the coverage and frequency of each species present in the community was measured. Sixty quadrats were randomly used in a 10-hectare section of grassland. Most of the species appear-

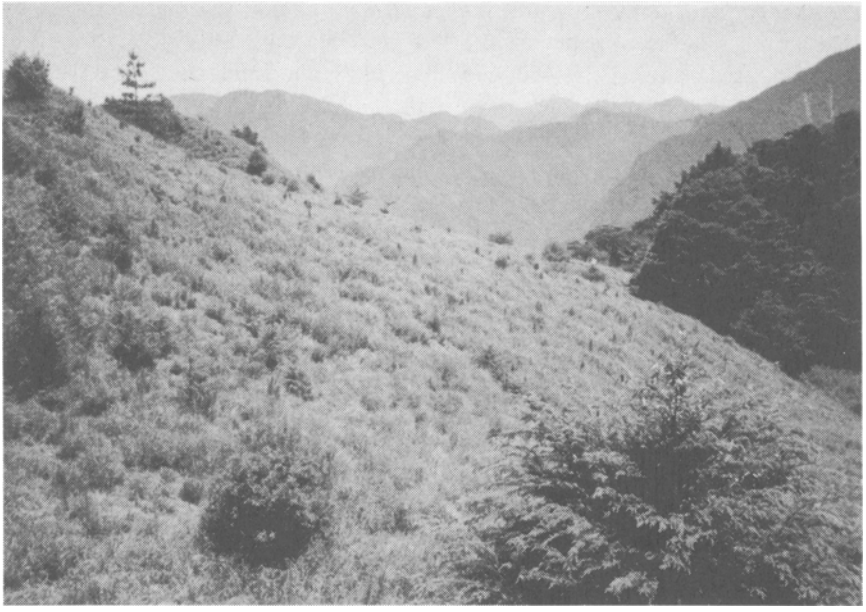

FIG. 1. A unique vegetation of alpine grass, *Miscanthus transmorrisonensis*, exhibits a relatively pure stand at Tartarchia Anpu, Nantou, Taiwan, at 2600 m elevation.

ing in the quadrats were identified, but some were identified only as to genus and need further study. In addition, species diversity of the grassland community was also computed by using the Shannon-Wienner index (Brewer, 1979), defined as follows:

$$H' = \sum P_i \times \ln P_i \quad (1)$$

where P_i is the number of individuals of each species over total number of individuals in the community, and $\ln P_i$ is the natural log of P_i.

Clearing Experiment. Four quadrats, 2 × 2 m each, in the Tartarchia Anpu grassland were selected for a ground-clearing experiment in order to learn the succession of vegetation in the area.

Materials. Plant materials were collected from the study site. Some of the samples were air-dried at room temperature, and the remainder were stored in a cold room prior to use. Samples collected from rhizosphere soil of *M. transmorrisonensis* at depths 0–10 cm and 10–20 cm from the soil surface were used for bioassays and for chemical extraction and identification of some components.

Seed Germination and Growth Performance between M. transmorrisonensis *and* Lolium multiflorum. According to Harper (1977), seeds of rye grass

(*Lolium multiflorum*) and *M. transmorrisonensis* were sown alone and sown by mixing seeds of the two species in a 1 : 1 ratio in a tray, 34 × 43 cm for each. Six planting densities, 225, 450, 675, 900, 1350, and 1800 seeds per tray, were employed. Each treatment was done in three replicates. The trays were placed in a greenhouse of the Academia Sinica, Taipei. The number of seeds germinated, number of leaves per seedling, and seedling height were recorded two, three, five, and six months after sowing.

Preparation of Aqueous Extracts of Plant Parts. A series concentration, 1%, 2%, 3%, 4%, and 5%, of aqueous extracts of *M. transmorrisonensis* plant parts and their rhizosphere soil was obtained by methods described by Chou (1989) and Chou and Young (1975). The extracts of leaves and soils were employed for bioassay of phytotoxicity and for further chemical identification of phytotoxins, by using techniques described by Chou and Muller (1972) and Chou and Kuo (1986).

Laboratory Assays. The grass leachates and extracts were bioassayed to determine phytotoxicity (Chou and Young, 1975). Seeds of lettuce (*Lactuca sativa* var. Great Lakes), Chinese cabbage (*Brassica oleracea*), tall fescue (*Festuca arundinacea*), and rye grass (*Lolium perenne* and *L. multiflorum*) were used for bioassay. The seed germination percentage and length of radicle growth of the test plants were measured 72 hr after incubation.

Quantitative Determination of Phytotoxic Phenolics. The phytotoxic phenolics present in the aqueous extract and leachate of the grass were obtained by using extraction and purification techniques as described by Chou and Muller (1972) and Chou (1989). The phytotoxins from the *Miscanthus* rhizosphere soil were obtained by using extraction techniques (Wang et al., 1967; Tang, 1986), and the compounds were identified by means of paper chromatography (Wang et al., 1967) and HPLC (Chou and Kuo, 1986).

RESULTS

Botanical Composition of Study Site. Relative frequency and relative coverage for each species in the 60 quadrats used are given in Table 1; 37 species appeared in the area. The relative frequencies of *Miscanthus transmorrisonensis* and *Yushinia niitakayamensis* were significantly higher than those of the other 35 species, being 11.76% and 10.95%, respectively. Besides these two species, *Baeothryon subcapitatum*, *Carex satsumensis*, *Curculigo orchioides*, *Gaultheriza itoata*, *Gentiana atkinsonii*, *Haloragis misrantha*, *Hypericum nagasawai*, *Rhododendron* spp., and *Swertia arisanensis* had relative frequencies above 4%, while those of the other 26 species were much below 4% (Table 1).

The relative coverages of *M. transmorrisonensis* and *Yushinia niitakayamensis* were 24.83% and 19.45%, respectively; these values are significantly

higher than those of the other 35 species. The values are well correlated to the relative frequencies mentioned above. Overall, *M. transmorrisonensis* and *Yushinia niitakayamensis* were dominant in the area (Table 1). To express the species diversity of this grassland community at Tartarchia Anpu, the Shannon-Wienner Index (H′) was used. The index of the community was −3.04839, indicating that the species diversity in the community is great.

Vegetation Succession of Grassland Community in Tartarchia Anpu. To understand the botanical succession in the Tartarchia grassland area, the response of plants after experimental clearing is given in Table 2. Fourteen species were found 18 months after clearing. The percent coverages of *M. transmorrisonensis* and *Yushinia niitakayamensis* were 17.4% (relative coverage is 29.06%) and 9.33% (relative coverage is 15.57%), respectively, indicating that these two species are dominant. Compared to the findings given in Table 1, the total number of species appearing in the cleared plots had not reached its maximum diversity, indicating that the succession was still proceeding.

Seed Germination and Seedling Growth of M. transmorrisonensis. Because the dominant species in the area is *M. transmorrisonensis*, 1000 seeds of the plant were sown in a 43 × 34-cm tray filled with soil collected from the study site of Tartarchia Anpu. The seeds germinated were counted two, three, five, and six months after sowing. The rate of seed germination per 1000 seeds was

extremely low, ranging from 8.00 to 8.50 (Figure 2). The findings are indicative of the growth performance of *M. transmorrisonensis*, reflecting the low survival rate and poor growth of the plant in a greenhouse of the Academia Sinica, Taipei.

Competitive Exclusion between Lolium multiflorum *and* M. transmorrisonensis. To compare the competitive exclusion between grasses of *L. multiflorum* and *M. transmorrisonensis*, experiments were performed by sowing seeds of each species alone as control and 1 : 1 mixtures of seeds in different densities. Results showed that, in both control and mixed experiments, the seed germination rate varied with densities. In general, in both separate and mixture experiments, seed germination rates of *L. multiflorum* were significantly higher than those of *M. transmorrisonensis*, regardless of planting density. Some recent field experiments also confirmed that the germination rate of *L. multiflorum* was significantly higher than that of *M. transmorrisonensis* (Chou et al., 1991, unpublished data). The germination rate in general was drastically decreased with time elapsed after sowing (Figure 3). There was no significant difference between treatments of seeds sowed alone and mixed, suggesting that no competition occurred between the grasses during the germination stage. Comparing the growth of these two plants based on seedling height, the growth of *M. transmorrisonensis* was better than that of *L. multiflorum* (Figure 4); this was particularly pronounced at the higher density of 900 seeds/0.15 m^2 (Figure 4). The growth of *Lolium multiflorum* was significantly poorer than that of *M.*

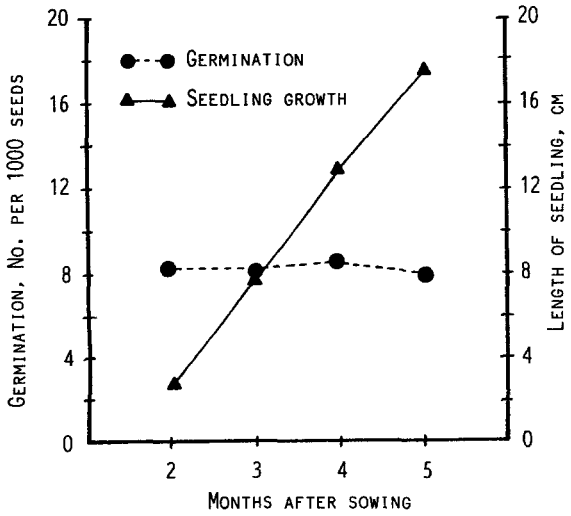

FIG. 2. The survival and growth performance of *M. transmorrisonensis* expressed by seed germination and growth in a greenhouse of the Academia Sinica, Taipei.

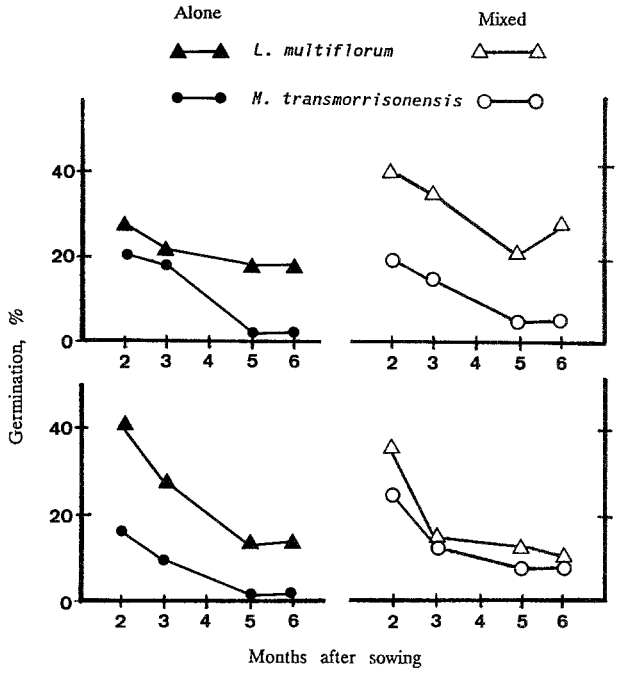

FIG. 3. A comparison of seed germination between *Lolium multiflorum* and *M. transmorrisonensis* by sowing seeds of each species alone or mixed seeds at a density of 450 seeds/0.15 m^2 (upper figures) and 1800 seeds/0.15 m^2 (bottom figures).

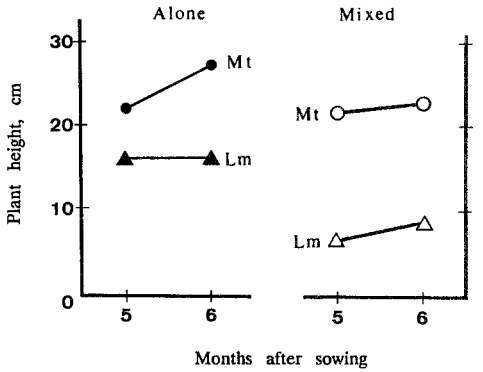

FIG. 4. A comparison of seedling growth between *M. transmorrisonensis* (Mt) and *Lolium multiflorum* (Lm) by sowing seeds of each species alone or mixed at a density of 1800 seeds/0.15 m^2.

transmorrisonensis after the *Miscanthus* seedlings were established in the field (the experiment is still continuing and data will be reported later). It could be suggested that *L. multiflorum* is not able to compete with *M. transmorrisonensis* in the field, so that the latter species becomes dominant.

Phytotoxic Effect of Aqueous Extracts on Radicle Growth of Tested Plants. The results of aqueous extracts of leaves of *M. transmorrisonensis* bioassays showed that the extracts significantly suppressed the radicle growth of plants, lettuce, rye grasses (both annual and perennial species), festuca, and cabbage, at the 1% concentration, in which the osmotic concentration was below 10 mosm. Among the test plants, lettuce (*Lactuca sativa*) was the most sensitive to the extract, and *Lolium perenne* was the least (Figure 5). The inhibition of radicle growth ranged from 13% to 35% for the 1% extract and from 42% to 90% for the 5% extract.

Leaf extracts of two major ecotypes, narrow leaf type (<1 cm in width) and wide-leaf type (>2 cm), of *M. transmorrisonensis* were bioassayed against lettuce and two varieties of Chinese cabbage. Bioassay results represented by

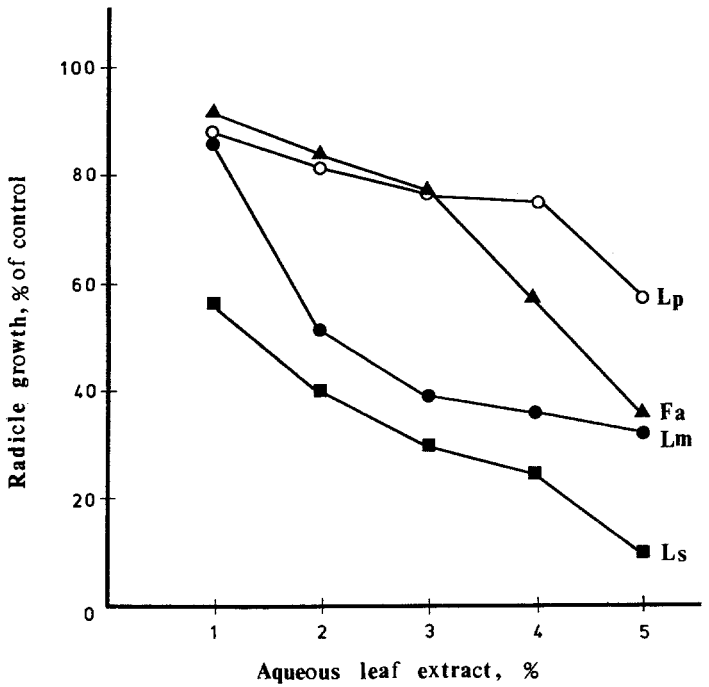

FIG. 5. The aqueous extracts of *M. transmorrisonensis* leaves in a series of concentrations on the radicle growth of four tested plants: Lp = *Lolium perenne*, Lm = *L. multiflorum*, Fa = *Festuca arundinacea*, and Ls = *Lactuca sativa*.

3% extracts exhibited remarkable phytotoxicity on the test plants; the phytotoxicities were significantly higher in the extract of narrow leaves than in that of wide leaves, reflecting that the allelopathic activity varied with different ecotypes of *Miscanthus* (Figure 6). Evidently, most leaves of *M. transmorrisonensis* found in the study site of Tartarchia Anpu were narrow ones, but those found in Hoshe were wide ones.

Bioassay of aqueous extracts of *Miscanthus* rhizosphere soils collected from two soil depths, 0–10 and 10–20 cm, was also conducted on the radicle growth of four test plants: rye grass, two varieties of Chinese cabbage, and lettuce. Results showed that the soil collected from the 10- to 20-cm layer exhibited significantly higher phytotoxicity than did that from the 0- to 10-cm layer. The inhibition of lettuce and Chinese cabbage ranged from 60% to 70%, while that of rye grass was insignificant, indicating that soil phytotoxicity varied with the plant tested (Figure 7). We conclude that both leaves and soils of *M. transmorrisonensis* contain phytotoxic substances, which suppress the growth of weeds in the field.

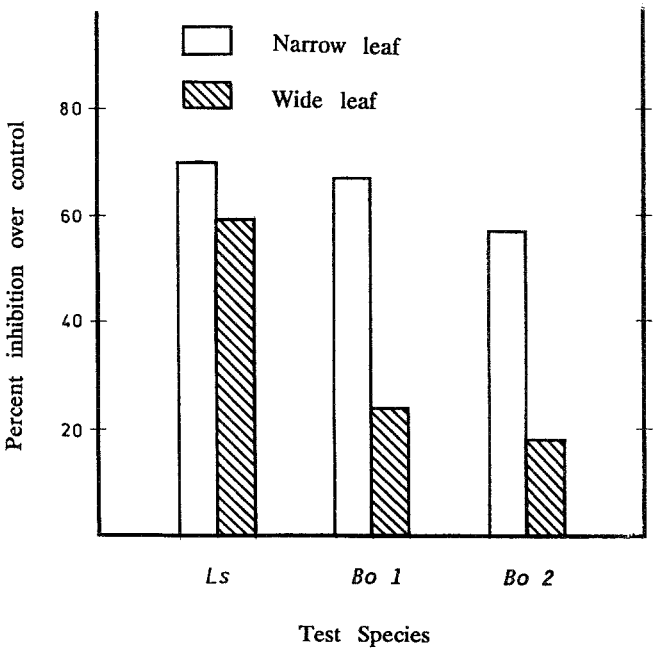

FIG. 6. The inhibitory effect of aqueous extracts of *M. transmorrisonensis* with two different ecotypes on the radicle growth of two species, *Ls* = *Lactuca sativa*, *Bo*1 = *Brassica oleracea* variety 1, and *Bo*2 = *B. oleracea* variety 2.

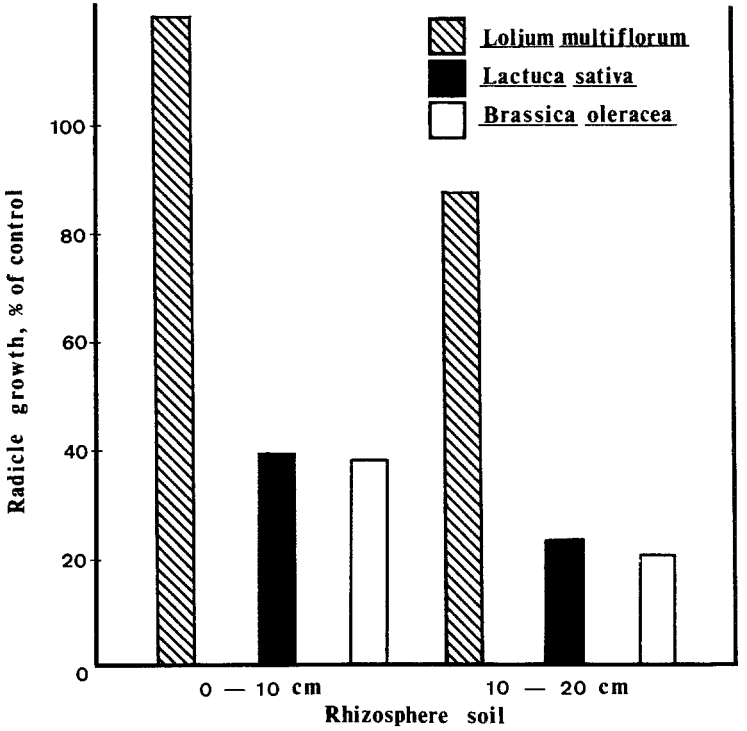

FIG. 7. The phytotoxic effects of the rhizosphere soils collected from the soil surface at two depths under a *M. transmorrisonensis* stand.

nensis. Some phytotoxic substances present in aqueous leachate and extracts of leaves of *M. transmorrisonensis* were identified by paper chromatography and HPLC. The compounds identified are caffeic, gallic, *p*-hydroxybenzoic, ferulic, *m*-hydroxybenzoic, and *o*-hydroxyphenylacetic acids, and 4-hydroxycoumarin and phloridzin (Table 3). The first five compounds were present in the leaf, and the first four compounds in the root of *Miscanthus*. Caffeic, gallic, ferulic, and *p*-hydroxybenzoic acids were found in the soil of *Miscanthus*. Relative amounts of phytotoxins in plants versus soil are shown in Table 3.

By using chromatography followed by bioassay as described by Chou and Chung (1974), spots appearing on paper chromatograms developed in 2% acetic acid were cut off and eluates bioassayed with lettuce seeds as test material. The same chromatographic paper without spotting with extract was also developed in 2% acetic acid and served as a control. The bioassay results for chromatographic segments according to R_f values showed significant inhibition. The inhibiting substances were isolated, and the structures were identified by PC

[a] Quantitative comparison among compounds was determined by HPLC, where the amounts of content were as follows: + + +: 10^{-3} mol/g sample; + +: 10^{-3}–10^{-4} mol/g sample; +: 10^{-4} mol/g sample.

and HPLC; the responsible phytotoxins were those given in Table 3. These compounds have been found to be allelopathic by many scientists (Chou and Lin, 1976; Chou and Muller, 1972; Chou and Waller, 1989; Rice, 1977, 1984; Tang, 1986; Waller, 1987).

DISCUSSION

Regarding the mechanism of dominance of *M. transmorrisonensis*, competition and allelopathy should both be considered and evaluated by experiments. So far as competition for light and soil moisture is concerned, the area is wide open, receiving sufficient solar radiation and substantial precipitation throughout the year (Chou et al., 1991). Soil nutrients are sufficient for the growth of *Miscanthus* and weeds (Chou and Chiu, unpublished data). Physical competition for light, soil moisture, and soil nutrients would not likely be limiting factors for permitting the dominance of *M. transmorrisonensis*.

On the other hand, the allelopathic potential of *M. transmorrisonensis* has been clearly demonstrated by bioassay results mentioned in Figure 5. The plants exhibited phytotoxic activity on the growth of many tested plants, and the rhizosphere soil of the plants also showed significant phytotoxicity (Figure 7). The same phytotoxins were found in both the plant parts and soil (Table 3). The data suggest that the dominance of *M. transmorrisonensis* may be due to allelopathic effect. Because the amounts of several phytotoxic substances in the plants and soil were so small, the identification of these compounds was difficult, and some remain unidentified.

Because *Miscanthus transmorrisonensis* and *Yushinia niitakayamensis* are

dominant in the grassland community, the competitive exclusion between the two species has to be taken into consideration. More than 15 years of observation by the senior author has shown that both species are aggressive and also resistant to the invasion of other species. One important cause of the aggressive nature of *Y. niitakayamensis* is its rhizome system, which leads to suppression of the growth of other weeds except *M. transmorrisonensis*. The growth performance of *M. transmorrisonensis* is unique, and its rhizome system is the same as that of *Yushinia*. Consequently, the potential of competitive exclusion between these two species is apparently the same, and it is difficult to draw conclusions as to which is superior.

Although it was impossible to collect seeds of associated weeds mentioned in Table 1 for competition study, we took a temperate grass species, *Lolium multiflorum*, for the bioassay study. Naqui and Muller (1975) reported that *L. multiflorum* exhibited a strong allelopathic potential and aggressiveness in fields. The present findings obtained from experiments of mixing seeds of *M. transmorrisonensis* and *L. multiflorum* indicated that the seed germination rate of the latter was significantly higher than that of the former but that the growth performance of the former was noticeably better; this results in better survival of the former species as far as adaptation is concerned. On the basis of previous studies, the authors have found that both *M. floridulus* and *M. transmorrisonensis* can adapt well to different habitat and, thus, form different ecotypes (Chou and Chang, 1988; Chou and Chen, 1990; Chou et al., 1991). As described in Figure 6, the narrow-leaf ecotype of *M. transmorrisonensis* found mostly in the area of Tartarchia Anpu showed significantly higher phytotoxicity than did the wide leaf ecotype found in the Hoshe area. This finding suggests that the allelopathic potential was more pronounced in the severe winter than that in the moderate environment.

Acknowledgments—The authors express their gratitude to Drs. C.Y. Chiu, F.S. Hsu, Y.C. Wang, and colleagues of the Forestry Experiment Station at Hoshe, National Taiwan University, for their field assistance. Acknowledgments are also due to Professors Otis Dermer and G.R. Waller for their critical review of the manuscript.

(Received May 7, 1991; accepted July 22, 1991)

Abstract—Three taxa of the lantana plant (*Lantana camara* var. *aculeata*)—I (white-pink), II (yellow-pink), and III (yellow-red)—differed in the content of lantadenes and compounds X, Y, and Z. Lantadene A, lantadene B, and lantadene C were the major lantadenes of taxon III. It contained small amounts of lantadene D. Taxa I and II contained very small amounts of lantadene A and lantadene B. Compounds X, Y, and Z were the major constituents of taxa I and II, and they constituted 59% and 92% of the total constituents in these taxa, respectively. Ingestion of lantana leaf powder of taxon III by male guinea pigs caused severe hepatotoxicity. Taxon I elicited mild hepatotoxicity in one out of six animals while taxon II was nontoxic. The biological and ecological significance of the presence of high amounts of compounds X, Y, and Z in taxa I and II is not known.

Key Words—Lantana, *Lantana camara* var. *aculeata*, lantadenes, hepatotoxicity, ecological aspects.

INTRODUCTION

Lantana (*Lantana camara* L.) is one of the ten most noxious weeds in the world (Holm et al., 1979). The plant causes animal toxicosis, resulting in hepatotoxicity and photosensitization, allelopathy, and has a number of other interactions with the biosphere (Sharma et al., 1988b). The generic epicenter of *L.*

*To whom correspondence should be addressed.

0098-0331/91/1100-2283$06.50/0

camara is regarded as Mexico and Central America (Spies, 1984) from where it has been introduced to the rest of the world via Europe (Stirton, 1977). At present, the lantana plant has wide distribution in nearly 50 countries spread over Oceania, Asia, Africa, South America, and North America (Sharma et al., 1988b). Furthermore, this plant is rapidly spreading to areas hitherto free of it and is turning into a great ecological threat in lantana-infested regions of the world (Sharma et al., 1988b). Varietal differences have been found in the chemical composition and toxicity of lantana plant in Australia (Hart et al., 1976a). However, no information is available on the comparative aspects of the chemistry and toxicosis of lantana in other parts of the world (Sharma and Sharma, 1989). There are some reports on the chemistry of lantana in India (Sharma and Sharma, 1989). These reports do not mention details of the variety and geographic location. The corresponding information on animal toxicosis is also lacking except for *L. camara* var. *aculeata* (Red) (Sharma, 1984). *L. camara* var. *aculeata* (Red) is the most wide spread and is very rich in lantadene A followed by lantadene B and C (Sharma and Sharma, 1989). One of the active principles in the lantana plant responsible for eliciting hepatotoxicity is lantadene A (Sharma et al., 1988a). Hybridization in the lantana plant has resulted in continuous variation in morphological characters (Spies, 1984). Numerous taxa of lantana plant differ in the characteristic of leaves, prickles, and flower color, and their nomenclature is not established so far (Yates, 1966, Mathur and Mohan Ram, 1978, 1986). *L. camara* plants bearing prickles have been placed in the variety *aculeata*. However, there are further flower color variations in the same variety. Thus, the different taxa in the variety examined in our study (*Lantana camara* var. *aculeata*) have been organized according to flower color, as done by the previous workers (Spies, 1984, Mathur and Mohan Ram, 1978). Our field observations on the three taxa used in our study over most of the last decade reveal that they are quite constant in their morphological characters, which precludes the possibility of free natural hybridization. Information on the chemistry of these toxic plants would be helpful in understanding the ecological aspects of their spread, in exploring the possibility of utilizing their biomass, and in developing a molecular rationale for control strategies through biological or chemical approaches (Hart et al., 1976a; Harborne, 1989; Sharma, 1988). Recently, we have emphasized the possibility of utilization of lantana as a resource for drug research and investigations into development of biocides (Sharma and Sharma, 1989; Sharma et al., 1988b). We report here the comparative lantadenes content and toxicity of three taxa of the lantana plant.

METHODS AND MATERIALS

Lantana Samples. The flower color in lantana changes after anthesis. So, for description of the taxa investigated, flower color just after anthesis and on

maturity has been given. Table 1 lists the taxa of the lantana plants (*Lantana camara* var. *aculeata*) studied.

Lantana leaf samples of taxa I and II were collected from the vicinity of Panjab University Chandigarh Campus [550 m above mean sea level (msl); latitude, 30°42′N; longitude, 76°48′E], India. Leaf samples of taxon III were collected from the vicinity of IVRI Regional Station, Palampur, Kangra Valley Laboratories (1290.8 m above msl; latitude, 32°60′N; longitude, 76°32′E), India. The samples were air-dried and finely ground in an electric grinder using a 1-mm sieve. The powdered samples were used for analysis of lantadenes and toxicity testing using a guinea pig as the laboratory animal model.

Analysis of Lantadenes. Lantana leaf powder (100 g) was extracted with methanol, decolorized, and purified further by solvent partition, acetone extraction, and column chromatography on silica gel (60–120 mesh) and neutral alumina as described previously (Sharma et al., 1987). The residue from the above step was subjected to isocratic column chromatography on silica gel (60–120 mesh). The elution was done with benzene–diethyl ether (80:20) as described previously (Sharma et al., 1990), and the volume of the partially purified extract was made to 50 ml. Aliquots (10 μl) of the above preparation were used for ascertaining the profile of lantadenes and related compounds by thin-layer chromatography using standard lantadene A, B, C, and D prepared in our laboratories (Sharma and Sharma, 1989; Sharma et al., 1990). Thin-layer chromatography was done on silica gel G plates (Stahl, 1969) using the solvent systems hexane–methanol–ethyl acetate (85:10:5) and benzene–methanol–ethyl acetate (85:10:5). Determination of the relative contents of the lantadenes was done by thin-layer chromatography in combination with dichromate oxidation (Skipski and Barclay, 1969). The relative amounts of different lantadenes and other constituents are expressed as percent of total content in each taxon.

Toxicity Studies. Twenty-four male guinea pigs (body weight 400–450 g) drawn from the stock colony of the Indian Veterinary Research Institute were fasted overnight with water ad libitum. They were divided at random into four groups (A, B, C, and D) of six animals each. Animals in groups A, B, and C were offered lantana leaf powder (10 g/kg body weight) of taxa I, II, and III, respectively, mixed in feed. Animals in group D served as controls. Animals

TABLE 1. LANTANA TAXA STUDIED

	Flower color on anthesis	Flower color on maturity
Taxon I	White	Pink
Taxon II	Yellow	Pink
Taxon III	Yellow	Red

in the experimental and control groups were monitored daily for appearance of ictericity by the microictericity test (Sharma et al., 1988a). Nearly 10 μl blood was drawn from the ear vein into heparinized capillaries. The capillaries were sealed at one end with modeling clay, centrifuged at 2000 rpm for 10 min, and the color of plasma layer was observed. The plasma layer in control animals was off-white in color and was graded negative. Appearance of any yellowness in the plasma layer indicated development of ictericity, jaundice, and toxicity and was graded positive qualitatively (Sharma et al., 1988a). Animals in group C became severely icteric in two to four days and were sacrificed along with animals in groups A, B, and D. Liver was collected for determination of hepatomegaly (Sharma et al., 1980) and histopathological examination (Culling, 1957). Blood was collected in EDTA-Na_2 and plasma prepared for bilirubin estimation (Malloy and Evelyn, 1937) and assay of acid phosphatase activity (EC 3.1.3.2) (Barret and Heath, 1977).

RESULTS AND DISCUSSION

The comparative thin-layer chromatographic profile of the extracts of three taxa of lantana is shown in Figure 1. Taxa I and II are similar with respect to their relative lack of lantadene A, C, and D. The special feature of both these taxa is the presence of compounds X, Y, and Z. Interestingly, compounds X, Y, and Z are absent from taxon III (Table 2). As reported earlier, lantadene A and B are the predominant lantadenes, followed by lantadene C and D in taxon III (Sharma and Sharma, 1989). Taxon I contained another unidentified compound (lantadene D'), which moved closer to lantadene D (Figure 1). Lanta-

[a]The values are mean ±SD, $N = 3$. The data for individual constituents have been expressed as percent of the total lanatdenes content. N.D., not detectable.

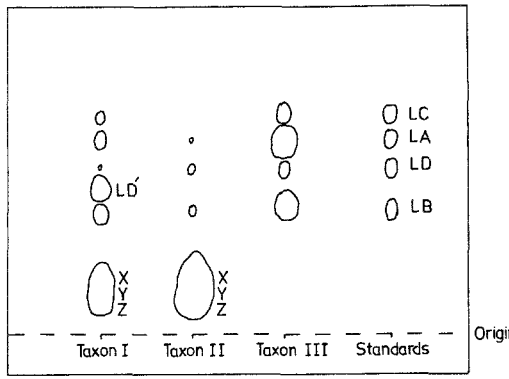

FIG. 1. Diagrammatic sketch of the thin-layer chromatographic profile of partially purified lantadenes from taxa I, II, and III of lantana. Solvent system: hexane–methanol–ethyl acetate (85:10:5). Amount of sample applied for extracts of taxa I, II, and III, 10 μl; amount of sample applied for standard lantadene A, B, C, and D, 40 μg. LA, lantadene A; LB, lantadene B; LC, lantadene C; LD, lantadene D; LD', lantadene D'.

dene A, B, C, and D are distinctly resolved in TLC using hexane–methanol–ethyl acetate (85:10:5) as the solvent system (Figure 1). Under these conditions, lantadene A, B, C, and D were detectable even in samples of taxon II, but the amount of sample was high enough to mask the resolution of compounds X, Y, and Z, which appeared as a single unresolved spot (Figure 1). Compounds X, Y, and Z could be better resolved in TLC using the solvent system benzene–methanol–ethyl acetate (85:10:5) and had R_f values of 0.34, 0.30, and 0.27, respectively. They differed in their color reaction as well, using acetic anhydride–sulfuric acid (9:1) as spray reagent. Lantadenes A, B, C, and D gave reddish brown spots, while compounds X and Y gave purple spots that had golden fluorescence at 366 nm. On the other hand, compound Z gave pinkish purple spots that had pinkish golden fluorescence at 366 nm. The separation profile on TLC indicated that compounds X, Y, and Z are much more polar than lantadene A, B, C, and D. Color reaction using Libermann-Burchard reagent indicated that compounds X, Y, and Z could be 3-β-hydroxy triterpenoids or sterols (Brieskorn and Herring, 1959). Hart et al. (1976a,b) observed that *L. camara* Common Pink did not contain lantadene A or B but contained lantic acid and lantanolic acid as the major constituents. Both lantic acid and lantanolic acid have a 3-β-hydroxyl group in their structure (Sharma and Sharma, 1989). The identity of compounds X, Y, and Z with the known triterpenoids of *L. camara* Common Pink has not been established so far. The molecular aspects of the impact of the relative differences in the content of lantadenes and other components in three taxa of lantana on interaction between insects used for biological control of lantana (Sharma, 1988) or herbivores are not known so

far. Taxon III is the most widespread (Sharma et al., 1988b); perhaps its high toxicity contributes to its better survival. Hart et al. (1976a) observed that lantadene A and B are the major triterpenoids in *L. camara* Common Pinkedged Red, Townsville Red-centered Pink, and Mackay Red-centered Pink. On the other hand, *L. camara* Common Pink was not found to contain either lantadene A or B (Hart et al., 1976a). The data of Hart et al. (1976a) are comparable to our observations (Figure 1) in that red flower color invariably appeared to be associated with a high content of lantadene A and B, and absence of red color in lantana flowers implied absence or relative lack of lantadene A and B. Investigations on the chemistry of plants are useful in resolving taxonomic problems (Tanowitz et al., 1987; Hegnauer, 1988). The phytochemical data on the lantana plant from the present studies and those reported earlier (Hart et al., 1976a; Sharma and Sharma, 1989) would also be helpful in ascertaining the interrelationship between different taxa and delineation of their exact taxonomic position.

The effect of ingestion of three taxa of lantana plant in guinea pigs is shown in Table 3. Five of six animals offered taxon III became severely icteric within two to three days. One animal in this group exhibited only transitory ictericity. Accidental ingestion of lantana foliage by the grazing animals or oral administration of partially purified lantana toxins is known to cause anorexia, constipation, hepatomegaly, obstructive jaundice, and photosensitization (Yadava and Verma, 1978; Sharma et al., 1981). There was a marked increase in the conjugated form of bilirubin in blood plasma in group C (Table 3), which is characteristic of obstructive jaundice (Cornelius, 1980). Similarly, there was a marked increase in liver weight in animals in group C (Table 3). Lantana poisoning is known to cause lysosomal injury and release of lysosomal acid phosphatase (Sharma et al., 1983). Animals in group C had significant increases in acid phosphatase activity (Table 3). Histopathological studies showed that all the animals in group C had liver lesions typical of lantana poisoning (Sharma et al., 1981). Only one animal in group A exhibited hyperbilirubinemia (plasma bilirubin content was 6.61 mg/100 ml). This animal had hepatomegaly as well, the liver weight being 1.3 times the normal value. The remaining five animals in group A had no symptoms of toxicity and were biochemically comparable to the controls (Table 3). Only one animal in group A that had exhibited clinical signs of toxicity, an increase in bilirubin level, and hepatomegaly exhibited hepatic lesions of lantana toxicity. The animals in group B had no cellular or subcellalar lesions representative of liver injury in lantana poisoning and were comparable to the control animals (Table 3). None of the animals in group B had ictericity, hepatomegaly, or a rise in acid phosphatase activity (Table 3). Seawright (1965) investigated the hepatotoxicity of a number of taxa of *Lantana* spp. in Queensland. It was observed that, except for flower color, no other morphological characteristics of the plant samples examined were related to

TABLE 3. EFFECT OF THREE TAXA OF LANTANA PLANT IN GUINEA PIGS[a]

Group	Lantana sample	Liver weight (g/100 g)	Bilirubin (mg/100 ml)			Acid phosphatase (μmol pNP/min/liter)
			Conjugated	Unconjugated	Total	
A	Taxon I	3.24 ± 0.13 (5), N.S.	0.13 ± 0.04 (5), N.S.	0.14 ± 0.09 (5), N.S.	0.28 ± 0.09 (5), N.S.	56.27 ± 13.00 (5), N.S.

[a]Values are mean ±S.D. a, $P < 0.005$; N.S., nonsignificant. pNP, *p*-nitrophenyl phosphate. The intake of lantana leaf powder from the amount offered was: group A, 10 g/kg body wt; group B, 10 g/kg body wt; Group C, 7.8 g/kg body wt. The data for the sixth animal in group A, which got intoxicated are given in the text.

toxicity. The survey further indicated that pink lantana was either nontoxic or mildly toxic, while red-flowered lantana was consistently toxic (Seawright, 1965). The phytochemical basis of these observations was reported later (Hart et al., 1976a,b). These studies did not mention the flower color at anthesis. Perhaps the nontoxic pink taxon investigated by Seawright (1965) was comparable to taxon II in our study and the mildly toxic one could be taxon I of our study (Tables 2 and 3). In New Zealand, the lantana taxon most wide spread is the pink flower type, and it has been safely grazed by sheep and goats (Hill and Seawright, 1983). After the report of Hill and Seawright (1983), red-flowered lantana was spotted in New Zealand and resulted in the first incidence of lantana poisoning in that country (Black and Carter, 1985). Thus, data on morphological, toxicological, and phytochemical observations on different taxa of lantana in different parts of the world suggest that there could be a genetic linkage between flower color and triterpenoid profile, resulting in the evolution of taxa with varying degrees of hepatotoxicity (Seawright, 1965; Hill and Seawright, 1983; Black and Carter, 1985; Hart et al., 1976a,b; Sharma and Sharma, 1989). The full implications of the differences in chemical composition of different taxa of lantana plant on biological control measures, predator preferences, allelopathic aspects, spread potential, and overall interactions with the biosphere are not known at this stage. It would be important to further explore the possibility of utilization of nontoxic taxa of lantana, viz., taxon II in animal feeding systems, particularly in the ruminants. It is also germane to develop strategies to exploit abundant natural products such as lantadene A and B in taxon III and compounds X, Y, and Z in taxa I and II for drug research and development of value-added products.

Acknowledgments—We thank Prof. O.P. Sharma Sr., Department of Basic Sciences, Himachal Pradesh Krishi Vishvavidyalaya, Palampur, for help in identification of lantana specimens.

(Received March 13, 1991; accepted July 23, 1991)

Abstract—Biological and chemical evaluations of a plastic laminate sex pheromone dispenser for *Helicoverpa zea* (Boddie) were made in central Texas. Based on these evaluations, the following performance criteria and specifications are suggested for a dispenser to be effective for two weeks: (1) 1.27 × 2.54-cm size; (2) 400-μm thick orange PVC outer layers; (3) 1.25 mg of a blend of (*Z*)-11-hexadecenal, (*Z*)-9-hexadecenal, (*Z*)-7-hexadecenal, and hexadecanal in a ratio of 87:3:2:8 formulated in the adhesive reservoir layer; (4) release rate in the range of 0.12–0.33 μg/hr/dispenser, as measured in the laboratory at 35°C; and (5) residual pheromone content in the range of 0.55–1.25 mg/dispenser during the period of use.

Key Words—Bollworm, sex pheromone, trapping, corn earworm, *Helicoverpa zea*, Lepidoptera, Noctuidae.

INTRODUCTION

Sex pheromone dispensers for monitoring populations of numerous pest species are currently being used. However, established criteria or specifications for the field performance of these dispensers are limited (Leonhardt et al., 1990). These performance criteria or specifications are important in ensuring the availability of consistently effective sex pheromone dispensers. The parameters that are

*To whom correspondence should be addressed.

[1] This paper reports the results of research only. Mention of a proprietary product does not constitute an endorsement by the USDA.

important are: (1) content of active ingredient, (2) rate of emission, (3) ratio of components in pheromone blend, and (4) duration of effectiveness. For trapping the bollworm (BW), *Helicoverpa zea* (Boddie), a highly effective laminated plastic pheromone dispenser has been developed (Hartstack et al., 1980; Lopez et al., 1981, 1987; Zvirgzdins and Henneberry, 1983; Lopez and Shaver, 1990; Drapek et al., 1990); however, performance criteria or specifications are not available. Research reported here was aimed at the development of these. The variables evaluated were: (1) active ingredient—amount and ratio of components, (2) biological assay—effect of aging, and (3) release of active ingredient—rate, composition, and residual quantities with aging time.

METHODS AND MATERIALS

Source of Dispensers. The pheromone dispensers for BW were obtained from Hercon Environmental Co., Emigsville, Pennsylvania 17318. The initial dispensers came from lot V0283 and the subsequent supply from lot V0436. These dispensers, which were 1.27 × 2.54 cm in size, consisted of an adhesive reservoir layer containing the pheromone sandwiched between two layers of orange polyvinyl chloride (PVC) film (400 μm thick). This laminated dispenser system has been described by Quisumbing and Kydonieus (1982). According to information provided by the supplier, each dispenser contained 1.25 mg of the four-component pheromone blend in the ratios identified by Klun et al. (1980). These components were (*Z*)-7-hexadecenal (*Z*7–16:Al) (2%), (*Z*)-9-hexadecenal (*Z*9–16:Al) (3%), (*Z*)-11-hexadecenal (*Z*11–16:Al) (87%), and hexadecanal (16:Al) (8%). A small piece of copper wire, inserted through a small hole punched at one end of the dispenser, was used to attach the dispenser to the trap.

Field Bioassays. All field tests were conducted in the Brazos River Valley near College Station, Texas, in Burleson County. The primary agricultural products in the area include corn, sorghum, cotton, small grains, and cattle. Large populations of BW develop each year in this cropping system.

The pheromone trap used was the 75–50 wire cone trap (Hartstack et al., 1979). The traps were installed along fence lines or turn rows either adjacent to or just within the borders of corn and cotton fields.

The traps were generally installed so that the base of the traps was about 1 m above ground level, but the height was adjusted so that the bottom of the trap was at canopy level as the crops grew taller than 1 m. In tasseling corn, the height of the traps was maintained at tassel level. At each trap location, a 1.8-m length of 1.9-cm-diam. electrical conduit was driven into the ground so that the top of the conduit was about 1 m above ground level. The pipe base of the wire traps was inserted into the conduit. To adjust trap height, reinforcement

bars (1.3 cm diam.) of the proper height were inserted inside the conduit and the top of the reinforcement bar was inserted into the base pipe of the wire cone traps.

Conventional agricultural practices were conducted in the areas where traps were operated, including the application of insecticides as needed. In cotton fields, numerous insecticide applications were made during the period of evaluations. Traps were operated when the different crops were actively fruiting to have greater BW activity.

Unless otherwise specified, all evaluations were made using trap lines with traps spaced 50 m apart. Whenever possible, additional traps that were not included as part of the evaluations were operated at each end of a trap line to minimize edge effects. In all tests involving three or more treatments, a Latin-square in time design was used. Treatments were randomized initially so that each treatment occurred only once at each location in each replicate. They were rotated within each replicate after each daily service so that for each period of days equal to the number of treatments, each treatment was exposed for one night at each location. When only two treatments were evaluated, the two treatments were alternated in the trap line and were rotated nightly. The treatments were rotated by moving the dispensers and leaving the traps in place. This allowed each dispenser to be evaluated in each trap in each replicate during a period equivalent to the number of treatments. Dispensers were attached to the traps via pieces of thin wire and a paper clip to reduce contact of the dispensers with the trap and possible residual effects.

Evaluation of Pheromone Dispensers. Evaluations were conducted to determine whether dispensers from both lots V0283 and V0436 were equally effective as baits in the wire cone traps. Initial comparisons were made from April 24 to May 7 with five replicates in one trap line with traps spaced 38 m apart. In subsequent evaluations, dispensers of both lots aged under field conditions for 14 days were compared to unaged dispensers to determine the effect of aging.

To determine the effect of aging, dispensers (V0436) were exposed for 8, 16, and 24 days to ambient conditions from June 10 to July 8, 1986, by attaching them to a wire stretched between two poles in an outdoor grassy area. This exposure was similar to the exposure that the dispensers would receive in a trap. After exposure, the dispensers were wrapped in foil and stored in a freezer for about two to three weeks until evaluated. In an initial test, unaged and 8- and 16-day-old dispensers and five virgin females per trap were compared. The virgin females (1–2 days old) were reared in the laboratory and were replaced every two days. The females were confined in a small screen container and were fed a 5% sucrose solution in a small plastic cup with a cotton dental wick. The screen container was secured to the angle iron forming the base of the cone trap as close as possible to the same location as the pheromone dispensers. This

test was conducted for eight days (July 23–30). A second test was conducted by replacing the unaged dispensers in the first test, which were now eight days old, with unaged dispensers and comparing these with the 16- and 24-day-old dispensers. The 16- and 24-day-old dispensers were the ones that had been used in the initial test for eight days. Test III was a repeat of test II with the addition of unaged dispensers and use of the 16- and 24-day-old dispensers from the other tests.

Another evaluation of aged dispensers was conducted using six dispensers (lot V0436) for each age group exposed as previously described for 8, 16, and 24 days starting on August 14, 22, and 30 until September 6. After exposure, all the dispensers were removed from the field, wrapped in aluminum foil, sealed with transparent tape, and stored in a freezer. Starting on September 13, four of the dispensers from each age group were evaluated for eight days using the procedure previously described. The remaining two dispensers of each group also were aged in the field in the same area where all the dispensers were originally exposed to provide a total of six similarly aged dispensers.

To compare the effect of pheromone dosage on the attractiveness of the laminated plastic dispensers (lot V0436), the basic 1.27 × 2.54-cm dispenser containing 1.25 mg of the pheromone blend was either subdivided or used in multiples to obtain dosages of 0.625, 2.5, and 5.0 mg. The 0.625-mg treatment consisted of half of the standard dispenser (1.27 × 1.27 cm). The 2.5- and 5.0-mg treatments consisted of two and four of the basic dispensers, respectively, stacked broadside and exposed simultaneously. The same baits were evaluated for 16 days.

Chemical Analyses. Initial and residual amounts of pheromone components in unaged and aged dispensers were determined. Pheromone components were extracted from the dispensers for about 14 hr with a solvent mixture of 10–20 ml of 1 : 1 hexane–acetone.

Rates of emission from unaged and aged dispensers were measured using procedures reported by Leonhardt et al. (1988). Two dispensers at a time were placed in a glass tube housed in an oven at 35°C; a constant nitrogen flow (100 ml/min) was passed over the dispensers and through traps that were packed with glass beads and Tenax (ST-023; Envirochem., Kemblesville, Pennsylvania). After 6 hr, trapped volatiles were eluted with a 1 : 1 hexane–ether mixture for analyses. The emission rate per dispenser was calculated by dividing the amount of volatiles collected by six and two.

The combined amounts of *Z*7–16 : Al + *Z*9–16 : Al + *Z*11–16 : Al and 16 : Al were determined by automatic injection of 3 μl onto a 30-m × 0.75-mm wide-bore, capillary column, coated with nonpolar SPB-1 (160°C for 2 min; 2°C/min to 190°C final temperature). The amounts of the positional isomers, *Z*7–16 : Al, *Z*9–16 : Al, and *Z*11–16 : Al, were determined on a 60-m × 0.25-

mm capillary column coated with bonded polar Supelcowax 10 stationary phase (100°C for 2 min, 5°C/min to 175°C where it was held).

Chemical analyses were made of the initial and residual pheromone content of one unaged dispenser and one aged for 48 days and of the emission rate from two dispensers at one time for each age category for unaged and aged pheromone dispensers of lot V0283. The dispensers were aged for 7, 21, and 48 days in the laboratory at room temperature. This evaluation was conducted to determine the relative release rates of all four components in the dispensers.

Total combined amounts of unsaturated aldehydes for each of five dispensers from lots V0283 and V0436 were evaluated to determine differences among dispensers of the same lot and between lots. In these analyses, only the total of the unsaturated aldehydes was determined, as a combined value, without identification of the amounts of each positional isomer.

Chemical analyses were made of the unaged and 8-, 16-, 24-, and 32-day-old V0436 dispensers aged and evaluated in the field from the 1990 test. Six dispensers from each age group were analyzed; four dispensers evaluated two at a time were analyzed for emission rate, and all six (including the four dispensers evaluated for emission rate) were analyzed for residual content. The emission rate and residual content of dispensers from each age group were calculated based on mean amount per dispenser.

Statistical Analyses. Statistical analyses were made using the General Linear Models Procedure and means were separated using Duncan's (1955) multiple-range test (SAS, Institute 1985) with $\alpha = 0.05$ when three or more treatments were involved. Student's t tests ($\alpha = 0.05$) were used when the tests involved only two treatments. Regression analyses were made using Statgraphics (STSC Inc., 1987).

RESULTS AND DISCUSSION

Field Bioassays. No significant difference ($t = 0.5$; $df = 138$, $P > 0.05$) was observed between dispensers of lots V0283 and V0436. The mean numbers ($\pm$SD) of BW males captured per trap per night during a two-week period with each dispenser were 25.0 ($\pm$19.4) and 24.6 ($\pm$16.6), respectively.

Comparison of lots V0283 and V0436 over a period of 20 days indicated no significant differences between the unaged dispensers of each lot until the last four days of the evaluation period ($F = 39.3$, $df = 29$, $P < 0.05$) (Table 1). Comparison of dispensers from each lot aged for 14 days with unaged dispensers indicated a decline in capture due to aging. Significant differences for lot V0283 between the unaged and aged dispensers were observed on the ninth to sixteenth day but not the last four days of the evaluation. For lot V0436,

[a] Means in the same row followed by different letters are significantly different according to Duncan's (1955) multiple-range test with $\alpha = 0.05$. Values (F; df) associated with the statistical analyses for the different periods are: 8–11 (5.13; 12, 51), 12–15 (3.30; 12, 51), 16–21 (3.40; 12, 50), 22–25 (13.47; 12, 51), 26–29 (6.71; 12, 51) and overall (39.28; 28, 290), all with $P < 0.05$.

significant differences were observed between the unaged and aged dispensers on the fifth and eighth days and again on the thirteenth to the twentieth days of the evaluation.

Field aging for eight days of laminated plastic dispensers from lot V0436 in test I indicated no significant difference between the unaged and 8-day-old dispensers (Table 2). However, there was a significant reduction in captures with dispensers aged for 16 days as compared with either unaged or dispensers aged 8 days. Additional evaluations conducted in tests II and III further verified that the effectiveness of the 16- and 24-day-old dispensers had declined significantly compared to the unaged dispensers. The results of the 1990 test verified the significant reduction in efficacy of the dispensers after 16 days of aging (Table 3). The duplication of this test was necessary to show that storage of the dispensers for a long period of time did not reduce their efficacy. It also provided field-evaluated dispensers for use in the emission rate and residual chemical content analyses.

These findings indicate that the laminated plastic dispenser can be used for at least 12 days under central Texas conditions without a significant decline in efficacy. Although there were no unaged dispensers in these tests for comparison with the dispensers that were 5–8 and 13–16 days old, the fact that no significant differences were observed between the 1- to 4- and 9- to 12-day-old dispensers supported the conclusion of no significant decrease in efficacy over at least a 16-day period. One significant aspect of these evaluations is the com-

TABLE 2. MEAN NUMBER OF *H. zea* MALES CAUGHT IN WIRE CONE TRAPS BAITED WITH LOT V0436 PLASTIC LAMINATED DISPENSERS FIELD AGED FOR 0, 8, 16, AND 24 DAYS AND WITH FIVE VIRGIN FEMALES, 1986

Test and days[b]	Mean no. (±SD) males captured/trap/night with indicated bait[a]

5–8	68.4 ± 38.4 b	125.4 ± 36.2 a		76.4 ± 29.5 b	37.2 ± 13.6 c

[a] Means in the same row followed by different letters are significantly different according to Duncan's (1955) multiple-range test ($\alpha = 0.05$). Values (F) for the statistical analyses are: I(1–4) = 5.88, I(5–8) = 6.44, II(1–4) = 11.54, II(5–8) = 7.57, III(1–4) = 7.69, III(5–8) = 9.54, all with $df = 12, 51$ and $P \leq 0.05$.

[b] Test I was run July 23–30; test II was run July 31 to August 9; test III was run August 4–11.

[c] Traps were not operated on August 1–3, 1986, because of unavailability of virgin females of the right age. During this two-day period, the dispensers were placed in a freezer in the laboratory.

[d] Most of the virgin females died during the two-day period between July 30 and August 1, 1986, so the traps were operated an extra two days to make up for this effect.

[e] The dispensers evaluated were actually two days older than indicated because of the extra two days of exposure between July 30 and August 1, 1986.

parison of the captures in the unaged and 8-day-old dispensers to virgin females; the dispensers were consistently more effective than the virgin females. Zvirgzdins and Henneberry (1983) and Carpenter et al. (1984) reported similar results.

A definite dosage response for pheromone amounts above 2.5 mg was observed for BW males (Table 4). Equal or higher numbers of males were captured in traps baited with the standard 1.25-mg dispenser than the 0.625-mg dose in the plastic laminate; however, the differences were not significant. The 2.5-mg dosage consistently captured lower numbers of BW males; however, the differences were significant for only two of the four evaluation periods. Overall, for the 16-day evaluation period, captures with the 2.5-mg dose were significantly lower than for the 1.25- or 0.625-mg dosages. The 5.0-mg dosage captured significantly lower numbers of BW males when compared with the 0.625- and 1.25-mg dosage throughout the test period. These results indicate that a 1.25-mg dosage is optimum for field efficacy with some flexibility allowed for a lower or higher dosage. Similar trends were observed by Hartstack et al.

TABLE 3. MEAN NUMBER OF *H. zea* MALES CAUGHT IN WIRE CONE TRAPS BAITED WITH LOT V0436 PLASTIC LAMINATE DISPENSERS FIELD AGED FOR 0, 8, 16, AND 24 DAYS, 1990

Age (days)[b]	Mean no. (±SD) males captured/trap/night during indicated periods[a]

Overall	42.1 ± 30.0 a	44.1 ± 29.5 a	33.7 ± 21.6 b	25.9 ± 19.8 c

[a]The standard 1.25-mg (2.54 × 1.27 cm) dispenser was used. For the 0.625-mg treatment, the standard dispenser was cut in half and for the 2.5- and 5.0-mg treatments, two and four standard dispensers were used, respectively.

[b]Means in the same row followed by different letters are significantly different according to Duncan's (1955) multiple-range test ($\alpha = 0.05$). Values (F; df) associated with the statistical analyses for the different periods are: 8–11 (5.13; 12, 51), 12–15 (3.30; 12, 51), 16–21 (3.40; 12, 50), 22–25 (13.47; 12, 51), 26–29 (6.71; 12, 51) and overall (39.28; 28, 290), all with $P < 0.05$.

(1980); however, the differences they observed when comparing 5.0-, 2.5-, 1.25-, 0.63-, and 0.32-mg dosages cut from a 10-mg, 6.7 cm^2 dispenser were not statistically significant.

Chemical Analyses. Chemical analysis of one unaged plastic laminate dispenser from lot V0283 indicated a pheromone content of 1.46 mg, higher than

the nominal 1.25 mg (Table 5). The percentages of Z7–16:Al (2.7%) and Z9–16:Al (5.5%) were higher than the nominal 2.0 and 3.0%, respectively, while the measured amount of Z11–16:Al was somewhat lower (83.6% vs. 87%) and 16:Al was about the same (8.2 vs. 8.0%). Laboratory aging for 48 days reduced total pheromone content of one dispenser to 0.85 mg. The percentages of each component remained similar to those in the unaged dispenser, indicating that each component was released in proportion to its content. This was verified by collection and analysis of volatiles. Emission rates of total pheromone blend ranged from 0.31 μg/hr/dispenser for the unaged dispensers to 0.15 μg/hr/dispenser for the dispensers aged 48 days.

Chemical analyses of five dispensers each from lots V0436 and V0283 showed considerable variation in the pheromone content of the dispensers. Dispensers from lot V0436 contained a mean (±SD) of 1.29 (±0.21) mg of the pheromone blend with a range of 1.15–1.66 mg/dispenser. The pheromone content of dispensers from lot V0283 was 1.43 (±0.12) mg/dispenser; variation between dispensers ranged from 1.27 to 1.53 mg. Because no differences were observed in the performance of dispensers from these two lots in field bioassays, differences observed in the pheromone content of the dispensers from both lots were not sufficient to cause differences in efficacy. Also, the highest amounts of pheromone in these dispensers were not high enough to cause a decrease in efficacy.

Chemical composition of unaged and field-aged dispensers of lot V0436 evaluated in the 1990 tests indicated that the mean (±SD) total pheromone content of 1.23 (±0.08) mg in the unaged dispensers was essentially identical

TABLE 5. COMPOSITION (mg/DISPENSER) AND EMISSION RATES (μg/hr/DISPENSER) OF PHEROMONE CHEMICALS FROM UNAGED OR AGED LAMINATED PLASTIC DISPENSERS (LOT V0283) EXPOSED UNDER LABORATORY CONDITIONS

Days aged	Indicated component, mg (% of total)[a]				
	Z7–16:Al	Z9–16:Al	Z11–16:Al	16:Al	Total
Chemical composition					
0	0.04 (2.7)	0.08 (5.5)	1.22 (83.6)	0.12 (8.2)	1.46
48	0.02 (2.3)	0.03 (3.5)	0.73 (85.9)	0.07 (8.2)	0.85
Release rate					
0	0.006 (1.9)	0.008 (2.6)	0.28 (90.3)	0.02 (6.5)	0.31
7	0.006 (2.1)	0.008 (2.8)	0.26 (87.7)	0.02 (6.9)	0.29
21	0.005 (1.9)	0.008 (3.0)	0.24 (88.9)	0.02 (7.4)	0.27

[a] (Z)-7-Hexadecenal = Z7–16:Al, (Z)-9-Hexadecenal = Z9–16:Al, (Z)-11-Hexadecenal = Z11–16:Al, and Hexadecanal = 16:Al.

to the total pheromone dosage of 1.29 (±0.21) mg found for dispensers of lot V0436, which were compared with dispensers from lot V0283 (Table 6). There was a gradual decrease in the amount of pheromone in the dispensers to 0.89 (±0.09), 0.53 (±0.03), 0.26 (±0.02), and 0.17 (±0.02) mg after 8, 16, 24, and 32 days of field aging, respectively. A similar pattern was observed in emission with mean (±SD) rates of 0.33 (±0.03), 0.21 (±0.03), 0.10 (±0.02), 0.063 (±0.033), and 0.034 (±0.014) μg/hr/dispenser for dispensers aged 0, 8, 16, 24, and 32 days, respectively. The low emission rates at 16 and 24 days were probably the cause of the poor trap captures. Regression analyses of mean residual pheromone content and mean emission rate produced the equations: $y = 1.35664 \exp(-0.064856x)$ ($R^2 = 0.983$) and $y = 0.338363 \exp(-0.0721527)$ ($R^2 = 0.997$) for residual pheromone content in milligrams per dispenser and emission rate in micrograms per hour per dispenser both designated as y, respectively, as a function of aging time in days (x).

The relative percents of the 16:Al emitted and in the residual were very similar for the 0- and 8-day-old dispensers; however, the residual pheromone in the 16- and 24-day-old dispensers showed increasing percents of the somewhat less volatile 16:Al.

Calculation of the ratio(s) of the mean number of males captured with the

TABLE 6. COMPOSITION (mg/DISPENSER) AND EMISSION RATES (μg/hr/DISPENSER) OF PHEROMONE COMPONENTS FROM UNAGED OR AGED (8, 16, 24 OR 32 DAYS) LAMINATED PLASTIC DISPENSERS (LOT V0436) EXPOSED UNDER FIELD CONDITIONS, 1990

[a] Mean based on six dispensers.
[b] Mean based on the release rate from four dispensers evaluated two at a time in each emission tube.

aged dispensers as compared to the unaged dispensers for the two years (1987 and 1990) indicated a dramatic decrease in efficacy after approximately 14 days of use (Figure 1). These ratios were calculated by considering the period of evaluation in four-day intervals. The ratios were calculated by dividing the mean number of males captured by the aged dispensers (first or second four-day period) by the mean number of males captured with the unaged dispensers during each corresponding four-day period (0–4 and 5–8 days old) from Tables 2 and 3. Each value was plotted as the midpoint of each interval for age.

Criteria for satisfactory performance of a pheromone dispenser in terms of the ratio described above have not been established; however, the closer the ratio values are to 1 over the period of aging, the better the dispenser. With the laminated plastic dispenser, a 0.5 ratio was observed at approximately 24 days of aging. At 10, 14, 18, and 22 days of aging, the mean ratios were 0.93, 0.91, 0.68, and 0.65, respectively. Using a best-fit regression model ($R^2 = 0.970$) for the ratios indicated that the efficacy of the dispensers decreased by 10% in 12.0 days, by 20% in 15.5 days, and by 30% in 18.5 days. As such, a 14-day

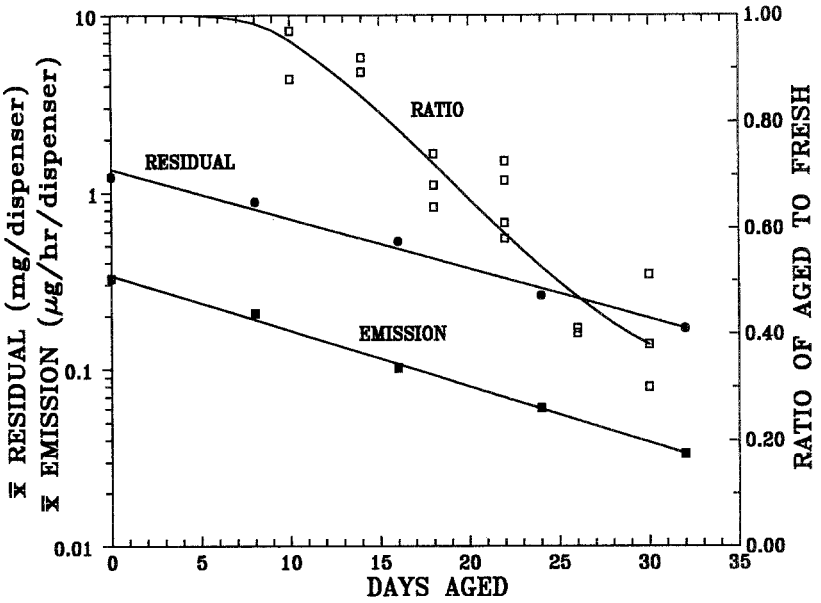

FIG. 1. Residual content, emission rate, and ratio of mean trap captures of aged to new plastic laminate dispensers for *H. zea* relative to the number of days of aging. Ratios were calculated from the values in Table 2 by dividing the mean number of males captured by the aged dispensers (first or second four-day period) by the mean number of males captured with the new dispensers during each corresponding four-day period (0–4 and 5–8 days old).

period of use would be satisfactory with less than a 20% reduction in efficacy. Corresponding criteria for the dispenser to have satisfactory performance (a ratio of 0.85 or more) over a 14-day period calculated from the regression equations would be a residual pheromone content equal to or greater than 0.55 mg/dispenser but not much greater than 1.25 mg/dispenser and an emission rate equal to or greater than 0.12 μg/hr/dispenser but not much greater than 0.33 μg/hr/dispenser.

In summary, performance criteria and specifications recommended for a plastic laminate pheromone dispenser expected to be effective for two weeks are: (1) 1.27 × 2.54 cm in size; (2) 400-μm thick orange PVC outer layers; (3) 1.25 mg of a blend of *Z*11–16:Al, *Z*9–16:Al, *Z*7–16:Al, and 16:Al in a ratio of 87:3:2:8 formulated in the adhesive reservoir layer; (4) release rate in the range of about 0.12–0.33 μg/hr/dispenser as measured in the laboratory at 35°C; and (5) residual pheromone content in the range of 0.55–1.25 mg/dispenser during the period of use. Although these criteria and specifications were evaluated for performance under central Texas conditions, it is likely that they will be broadly applicable because they are based on evaluations conducted under typical summer conditions.

(Received March 20, 1991; accepted July 23, 1991)

Abstract—The hawthorn lace bug, *Corythucha cydoniae*, and the eggplant lace bug, *Gargaphia solani*, possess alarm pheromones that are produced in dorsal abdominal glands (DAGs). When *G. solani* nymphs are grasped, they emit secretion from both DAGs; the posterior DAG secretion alone elicits alarm, but the anterior DAG secretion may hasten the response. In *C. cydoniae*, the response is due to a synergism between the anterior and posterior DAG secretions, and nymphs are apparently unable to voluntarily release their DAG secretions; both DAGs must be ruptured for the pheromone to escape. The alarm pheromones are interspecifically active in patterns matching the intraspecific activities. Compounds identified from tingid DAG secretions that are involved in the alarm messages are: (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, acetaldehyde, geraniol, and linalool. A new natural product of unknown function (designated nerolidol aldehyde) was identified from the anterior DAG secretions of both species.

Key Words—Hemiptera, Tingidae, *Corythucha*, *Gargaphia*, altruism, semiochemical, defensive behavior, maternalism, allomone, abdominal glands, (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, acetaldehyde, geraniol, linalool.

INTRODUCTION

Of the 1800 species of tingids worldwide, relatively few are gall-makers or myrmecophiles; the vast majority feed gregariously on mesophyll underneath

*To whom correspondence should be addressed.

0098-0331/91/1100-2307$06.50/0

leaves (Drake and Ruhoff, 1965). Exposed, sedentary lace bugs seem likely to have specialized defenses against predators and parasitoids. Indeed, two adaptations by which tingids blunt their potential attackers have now been extensively studied. Females of the eggplant lace bug, *Gargaphia solani*, and other *Gargaphia* species, assiduously guard their eggs and nymphs (Fink, 1915). Maternalism does effectively deter most predators, although a "cheating" counterstrategy has evolved in *G. solani* whereby some females furtively "dump" their eggs among those of a guarding female (Tallamy and Horton, 1990, and references therein). However, maternal care is not widespread among tingids, at least not to the extent observed for *Gargaphia* spp. (Faeth, 1989), but nymphs of species from many genera have secretory setae bearing fluid droplets scattered over their bodies (Livingston, 1978). In *Stephanitis* and *Corythucha* the droplets contain compounds (probably in aqueous solution) having an oxygenated six-member ring with a long side chain (acetogenins) (Oliver et al., 1990, and references therein). A biological role for these acetogenins has not been firmly established, yet it seems likely that the droplets fulfill a defensive role. Perhaps the acetogenins simply act as soaps to allow the droplets to wet small aggressors (Aldrich, 1988a).

Kearns and Yamamoto (1981) reported that aggregated nymphs of *G. solani* quickly become alarmed when a conspecific nymph is crushed nearby. Furthermore, they described similar alarm behavior toward crushed nymphs for the hawthorn lacebug, *Corythucha cydoniae*, as well as two other *Corythucha* spp., and found cross-activity between *G. solani* and all three *Corythucha* spp. To our knowledge, alarm pheromones in the Tingidae have not been explored further. Therefore, the present study of the alarm pheromone systems of *G. solani* and *C. cydoniae* was undertaken.

METHODS AND MATERIALS

Insects. The hawthorn lace bugs, *C. cydoniae*, used in the study were from a colony reared on cuttings of Washington hawthorn, *Crataegus phaenopyrum*, at 26 ± 1°C with a 16:8 hr light–dark photoperiod. The initial behavioral and chemical work with *G. solani* used nymphs collected in the field from horsenettle, *Solanum carolinense*, near the Beltsville laboratory during late summer, 1989. Later experiments with *G. solani* were performed using individuals from a laboratory colony maintained on greenhouse-grown eggplant, *Solanum melongena*, under insectary conditions as above.

Scanning Electron Microscopy. Lace bug exuviae were sputter coated with gold–palladium in a Technics Hummer 5 instrument and examined with a Hitachi S-530 scanning electron microscope.

Extractions. Immature tingids possess two dorsal abdominal glands (DAGs) attached to the 3–4 and 4–5 intersegmental membranes (Cobben, 1978), and the contents of the glands are shed at each molt with the exuviae (Aldrich, 1988b). For *G. solani*, the combined contents of the DAGs could be satisfactorily extracted by cutting out a small piece of cuticle containing the gland reservoirs under a dissecting microscope from fresh exuviae and extracting several such reservoir pairs with 25–100 μl CH_2Cl_2 or CS_2. 1-Nonanol was used as an internal standard in one extract of 20 *G. solani* fifth-instar exuviae (< 1-day-old) for quantitation of DAG volatiles. DAG samples from *G. solani* were also prepared by pressing small pieces of filter paper down on the abdominal tergum of live nymphs and then extracting the papers in ca. 100 μl of CH_2Cl_2. For *C. cydoniae*, these methods were unsatisfactory because the acetogenins from the setal droplets (Lusby et al., 1989) overwhelmingly contaminated the samples. The following sampling technique was devised to avoid this problem. Fresh exuviae were removed from leaves and placed ventral-side down on double-stick tape on a slide under the dissecting microscope. Using microscissors, a cut was made laterally along each side of the tergum; this flap of cuticle was peeled backwards with forceps and stuck to the tape, thus exposing the inner surface of the two DAG reservoirs. A capillary tube drawn to a very fine point was inserted in a Drummond Microcap (Broomall, Pennsylvania) holder and fastened in a micromanipulator next to the microscope stage. When the reservoir of a DAG was pierced with the micropipet, the secretion was captured by capillary action, and could then be expelled into solvent or used directly for bioassay. This method was subsequently used to separately sample the DAGs of *G. solani*.

Chemical Analysis. Samples were analyzed by gas chromatography (GC) on a bonded methyl silicone column (0.25 mm film, 14 m × 0.25 mm ID; DB-1, J&W Scientific, Folsom, California) using a Varian 3700 GC with helium as carrier (40 cm/sec), and a temperature program from 45°C for 2 min to 230°C at 15°/min. Electron impact mass spectra (EI-MS) were obtained at 70 eV using a Finnigan 4510 GC-MS, equipped with a 30-m DB-1 column. Volatiles from exuviae of *C. cydoniae* were derivatized with *o*-benzylhydroxylamine after the method of Ollett et al. (1986). Approximately 50 exuviae were crushed in a 250-μl gastight syringe equipped with a GTS Valve (Hamilton Company, Reno, Nevada) in the off position, and then the volatiles were bubbled through the derivatizing solution by opening the valve and slowly depressing the syringe plunger. The *o*-benzyloximes were also analyzed by chemical ionization mass spectrometry (CI-MS) using NH_3 and CH_4 as reagent gases. One underivatized sample of *C. cydoniae* exuviae crushed in a gastight syringe as described above was analyzed by GC-MS. The sample was injected under pressure using the GTS valve with the GC oven turned off and cooled to ca.

0°C with Dry Ice in order to obtain EI-MS of very volatile compounds normally inseparable from organic solvents. A head-space sample of acetaldehyde was analyzed in the same fashion.

The unknown compound eluting at a retention time (*RT*) of 11.0 min (Figures 2 and 3) was isolated from an exuvial extract of *G. solani* by applying the concentrated CH_2Cl_2 extract to a Baker 3-ml silica gel extraction cartridge, and eluting successively with hexane (5 ml), 10% ethyl acetate in hexane (5 ml), and 25% ethyl acetate in hexane (3 ml). The unknown reproducibly eluted in the last fraction. A small sample thus prepared was hydrogenated for 20 min (PtO_2, EtOH, 1 atm). For NMR, ca. 165 mg of *Gargaphia* exuviae were processed as described, and the unknown was further purified by preparative GC (15 m × 0.53 mm ID, DB-1). A [^{1}H]NMR spectrum for this compound was recorded in D_6-benzene at 300 MHz on a General Electric QE-300 instrument with TMS as an internal standard.

Standards. The following compounds were obtained commercially: acetaldehyde and 1-nonanol (Aldrich Chemical, Milwaukee, Wisconsin); geraniol and nerol (Bedoukian Research, Danbury, Connecticut); and linalool (Givaudan, Clifton, New Jersey). (*E*)-4-Oxo-2-hexenal was synthesized according to Ward and VanDorp (1969). Nerolidol aldehyde [(*E*,*E*)-2,6,10-trimethyl-10-hydroxy-2,6,11-dodecatrienal] was synthesized after the method of Demole and Enggist (1973).

Bioassays. Bioassays were begun with *C. cydoniae* using a procedure similar to that of Kearns and Yamamoto (1981). A feeding aggregation of >10 fifth-instar nymphs was chosen for observation, and a conspecific nymph from another aggregation (normally on a different cutting) was sacrificed for the test. A leg was grasped with forceps and the nymph was held 5–10 mm above the test aggregation for ca. 1 min; then the entire body of the test nymph was positioned between the prongs of the forceps, crushed, and immediately held over the test aggregation. A response was considered positive if most of the nymphs walked away within 1 min. Fifth-instar nymphs in the process of ecdysis (evident in aggregations by their unmelanized cuticle) were also bioassayed as above, after which the fresh exuviae were tested for alarm induction as follows: First the exuviae were lifted by an appendage and offered to the test aggregation for 1 min; then the DAG reservoirs of the exuviae were ruptured with forceps under a microscope and the macerated exuviae were again held over the same test aggregation.

Alarm pheromone tests were performed with the hawthorn lace bug by positioning a leaf aggregation of *C. cydoniae* fifth-instar nymphs about 1 cm in front of the exit port from the thermal conductivity detector of the GC equipped with a DB-1 megabore column. For GC-effluent testing, several aggregations (>200 individuals) of *C. cydoniae* would be quick-frozen by placing the leaves

on which they were aggregated onto Dry Ice. The frozen nymphs were brushed off the leaves into a 10-ml gastight syringe barrel, having a Teflon membrane (0.5-mm pore size; Millipore Corp., Bedford, Massachusetts) in the bottom, and equipped with a GTS valve. The barrel of the syringe was flushed with a stream of N_2, and the plunger was inserted as far as possible without crushing the nymphs. Then, with the GTS valve in the off position, the nymphs were crushed and the volatiles injected into the GC under pressure. Control experiments were performed in an analogous manner with an empty syringe. Responses were judged positive if most of the aggregated nymphs were dispersed by the effluent.

For bioassay of the DAG secretions (test I), the contents of the anterior and/or posterior gland exuvial reservoirs were extracted in a micropipet as previously described. A leaf with a nymphal aggregation to be tested (>10 third- to fifth-instar nymphs) was placed on the microscope stage with the illumination lowered so as not to warm the insects. A second micromanipulator was arranged on the opposite side of the microscope stage with a pair of forceps holding a small triangular piece of filter paper. The DAG secretion(s) to be tested were transferred to the point by bringing the pipet in contact with the paper and then the impregnated paper was quickly lowered to within about 0.5 cm of the aggregation. As part of this series, solutions (3 μg/μl CH_2Cl_2) of geraniol, linalool, (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, and combinations thereof, were tested by wetting the point tip with test solution and proceeding as for the gland extracts. Absence of a response was scored a (−), a moderate response was (±), and complete dispersal was a (+).

In an effort to fully mimic the natural response of the hawthorn lace bug with synthetic standards, a second bioassay series (test II) was performed using only *C. cydoniae* nymphs. The day before the testing session, five fifth-instar nymphs (or fourth instars if necessary) were placed on single hawthorn leaves with petioles in water vials; 25–50 such preparations were set up for each session. Test solutions of acetaldehyde, geraniol, linalool, nerol, (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, and combinations thereof, were prepared in CH_2Cl_2 at a range of concentrations, plus CH_2Cl_2 controls (see Table 2 below). Responses were scored by a "blind" observer with no prior knowledge of the material being tested. An aggregation to be tested was positioned by one person (J.W.N.) on a microscope stage with reduced illumination, while a second person (J.R.A.) applied 1 μl (Drummond Microcap) of test solution to a paper point on the end of an insect pin. The loaded filter paper was held about 0.5 cm above the aggregation and the response of the majority of nymphs was scored as follows: 0 = no response, 1 = agitation and jiggling in place, 2 = wandering, 3 = slowly moving away (after a delay of >20 sec), and 4 = quickly moving away (within 20 sec).

RESULTS

Gargaphia solani nymphs do not have setal droplets (Figure 1A). In *C. cydoniae* nymphs, setal droplets are abundant (Figure 1B), and after ecdysis or when droplets are brushed off due to overcrowding, they are regenerated. In *G. solani* the openings of the anterior and posterior DAGs are evident in SEMs, but in *C. cydoniae* the external openings of the DAGs are not apparent.

Preliminary experiments (J.W.N.) with the hawthorn lace bug confirmed that a potent alarm pheromone is released from crushed nymphs. Feeding aggregations of nymphs usually respond within 10–15 sec by removing their stylets from the leaf, jiggling and bobbing, and rapidly dispersing. If a *C. cydoniae* nymph is grasped without being crushed, aggregated nymphs are not alarmed. Occasionally, aggregated *C. cydoniae* nymphs failed to respond to crushed nymphs. Microscopic examination (J.R.A.) indicated that the alarm pheromone was released only if the abdomen was crushed, suggesting that the pheromone

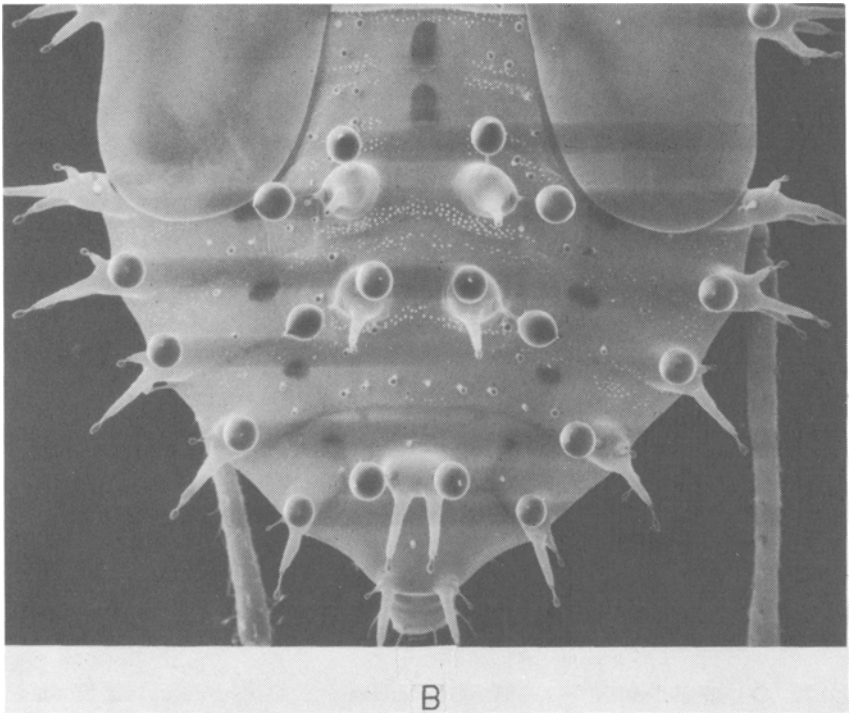

FIG. 1. Continued

is contained in the DAGs. Exuviae with intact DAGs did not elicit alarm, but when the exuvial DAG reservoirs were ruptured the full range of alarm behavior was elicited. When the abdomen of the newly ecdysed fifth instar (ca. 10 min after ecdysis) was crushed and the nymph was held near an aggregation, no alarm was induced. This experiment was repeated many times with the same result.

In contrast to *C. cydoniae*, it is not necessary to crush a nymph of *G. solani* in order to elicit alarm in aggregated conspecific nymphs. Merely grasping a nymph firmly by a leg is usually sufficient to elicit clear-cut alarm among clustered *G. solani* nymphs. Pinched *G. solani* nymphs that induced alarm had a distinctly terpenoid odor (J.R.A., personal observation).

Techniques for directly sampling DAG secretions were first perfected using *G. solani* fifth-instar nymphs. Extracts of exuviae with intact reservoirs exhibit four prominent peaks by GC, but late-eluting compounds (characteristic of tingids having setal droplets) are absent (Figure 2; bottom trace, compounds **1**–**4**). A fifth-instar *G. solani* nymph produces about 8 ng of **1**, 19 ng of **2**, 34 ng

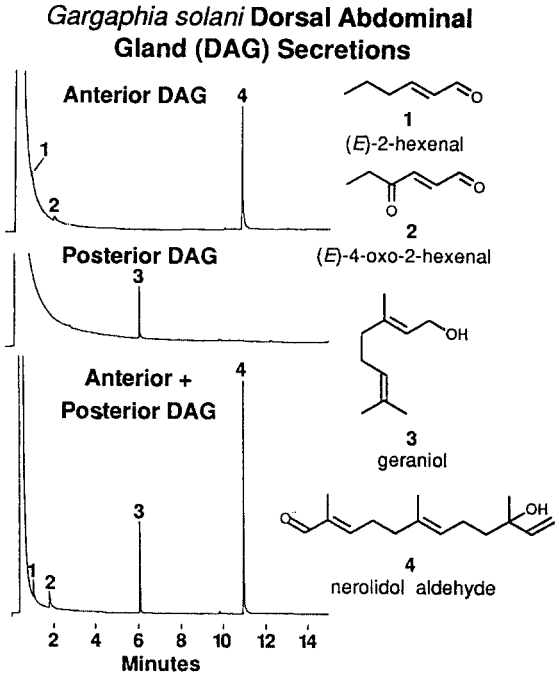

FIG. 2. Dorsal abdominal gland (DAG) secretions of *Gargaphia solani* fifth-instar nymphs: anterior DAG (one exuvial reservoir; splitless GC), posterior DAG (one exuvial reservoir; splitless GC), and anterior plus posterior DAGs (60 exuviae; 1:50 GC split).

of **3**, and 100 ng of **4**, based on quantitation of an extract of 20 exuviae. Extracts of filter paper pressed onto the tergum of *G. solani* nymphs produced GC traces (not shown) matching those of exuvial DAG reservoirs, verifying that these nymphs are able to voluntarily release secretion from both DAGs. GC analysis of secretion isolated from the anterior DAG reservoir of exuviae showed that this secretion contains compounds **1**, **2**, and **4** (Figure 2, top), whereas secretion isolated from the posterior DAG exuvial reservoir contains compound **3** (Figure 2, middle).

For *C. cydoniae*, separate extraction and GC analysis of the anterior and posterior DAG reservoirs also showed that the two glands produce qualitatively different secretions (Figure 3). Compound **4** is the predominant component in the anterior DAG secretion of the hawthorn lace bug, but compound **2** was not detected and compound **1** was barely detectable. In the posterior DAG secretion of *C. cydoniae*, compound **3** occurs with another component **(5)** not found in *G. solani* nymphs.

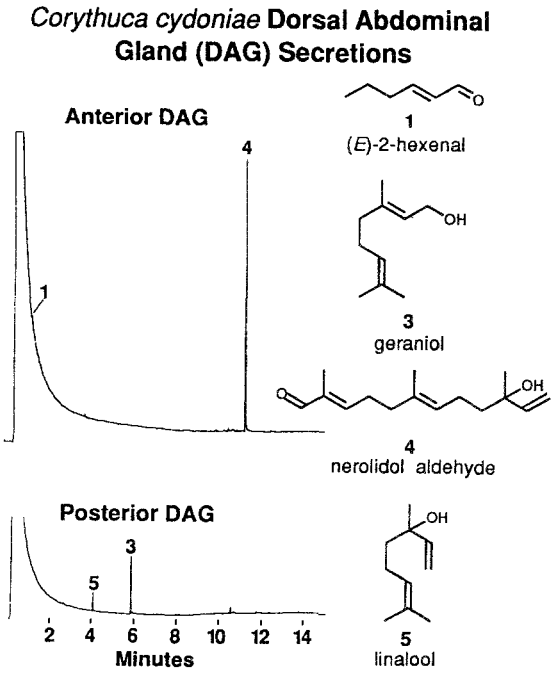

FIG. 3. Dorsal abdominal gland (DAG) secretions of *Corythucha cydoniae* fifth-instar nymphs: anterior DAG (10 exuvial reservoirs; splitless GC) and posterior DAG (two exuvial reservoirs; splitless GC).

The EI-MS of compounds **1, 2,** and **5** matched those for the following compounds commonly encountered in heteropteran exocrine secretions (Aldrich, 1988a,b): (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, and linalool, respectively. The EI-MS of compound **3** gave a near-perfect computer-matched fit to the MS of geraniol. The identities of these four compounds were verified by coinjection with authentic compounds.

A match for the EI-MS of compound **4** was not found in the computerized mass spectral library, but the pattern of lower mass (m/z < 140 amu) ions resembled that of nerolidol. The CI-MS with NH_3 indicated a molecular weight of 236, and ND_3 CI-MS showed that the molecule contains one exchangeable hydrogen. Hydrogenation produced a compound with a molecular weight of 244 and two exchangeable hydrogens, suggesting the initial presence of three C=C bonds and one C=O bond, the latter possibly as an aldehyde. The [^{1}H]NMR (C_6D_6) spectrum was as follows: δ 1.10 (s), 1.46 (s), 1.64 (s), 1.84 (t, J = 7.2), 2.03 (m), 4.96 (d, J = 11.7), 5.11 (t, J = 7), 5.19 (d, J = 16.8), 5.74 (dd, J = 18 and 11), 5.89 (t, J = 7), and 9.31 (s). The singlet at δ = 9.31 clearly indicates an aldehyde, and both the mass spectral and NMR data are

consistent with an oxygenated nerolidol, most likely with one of the distal methyls oxidized to —CHO. A search of the literature revealed that Demole and Enggist (1973) had synthesized (*E,E*)- and (*E,Z*)-2,6,10-trimethyl-10-hydroxy-2,6,11-dodecatrienal. Although different solvents precluded a direct comparison of our NMR data with those reported, the *E,E* isomer seemed most consistent with our data. Spectral comparisons and GC coinjection experiments of the synthetic standard of (*E,E*)-2,6,10-trimethyl-10-hydroxy-2,6,11-dodecatrienal with component **4** (designated nerolidol aldehyde) confirmed this identification for the natural product.

Bioassays testing the response of *C. cydoniae* nymphs to volatiles from crushed conspecifics eluting from the GC were performed before determining that the DAGs produce the alarm pheromone. Nymphs at the effluent were alarmed within 30–40 sec after injection, indicating that one or more extremely volatile compounds were involved. Once it was established that exuvial DAG reservoirs contain the alarm pheromone, the low temperature GC-MS experiment to identify the very volatile compound(s) was undertaken using *C. cydoniae* exuviae. A small peak occurred just after a scan time of 150 sec at ca. 0°C, and the EI-MS of this peak gave a high computer fit for the MS of acetaldehyde (Figure 4A). GC-MS of a head-space sample (ca. 90 ng) of authentic acetaldehyde under similar GC conditions (temperature was difficult to exactly duplicate) produced a peak having nearly the same retention time and an EI-MS virtually identical to that for the exuvial compound (Figure 4B). CI-MS of *C. cydoniae* exuvial volatiles derivatized with *o*-benzylhydroxylamine confirmed the presence of the benzyloxime of acetaldehyde ($CH_3CH{=}NOCH_2C_6H_5$; mol wt 149); NH_3 CI-MS *m/z* (%): 167 ($[M+NH_4]^+$, 100) and 184 ($[M+(NH_3)_2+H]^+$, 55); CH_4 CI-MS *m/z* (%): 91 (100) and 150 ($[M+H]^+$, 75).

The first intraspecific bioassays using DAG secretions showed that alarm behavior in *C. cydoniae* occurs only if nymphs are simultaneously exposed to anterior and posterior DAG secretions, whereas *G. solani* nymphs are alarmed by exposure to posterior DAG secretion alone (Table 1). Inclusion of the anterior DAG secretion with the posterior secretion caused *G. solani* nymphs to respond sooner. When *C. cydoniae* nymphs were tested using secretions from *G. solani* exuviae, the results were the same; neither secretion alone had significant activity, while the combined secretions were highly alarming. The result of the one reciprocal interspecific test performed was also consistent with the intraspecific tests; posterior DAG secretion from *C. cydoniae* elicited alarm in *G. solani* nymphs. Bioassays with synthetic compounds **1, 2, 3,** and **5** showed that for *G. solani* nymphs geraniol **(3)** by itself released typical alarm behavior (Table 1). Geraniol with (*E*)-2-hexenal **(1)** and/or (*E*)-4-oxo-2-hexenal **(2)** may have slightly hastened the response of *Gargaphia* nymphs, but this effect was not precisely assessed. Linalool **(5)** by itself or with **1** or **2** was inactive for *G.*

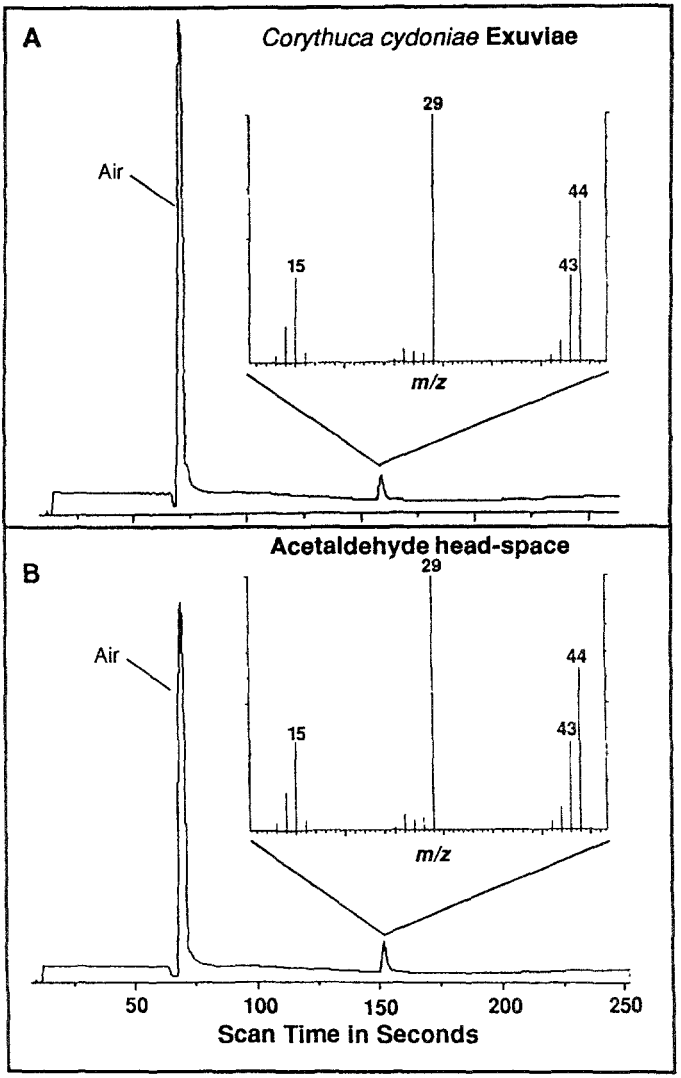

FIG. 4. Low-temperature gas chromatography-mass spectrometry (GC-MS) of (A) *Corythucha cydoniae* exuviae and (B) acetaldehyde head-space (reconstructed ion chromatograms and EI-MS).

solani. For *C. cydoniae* nymphs, the bioassay results using synthetics were less clear than for *G. solani*. Although (*E*)-4-oxo-2-hexenal (**2**) was not detected in the DAGs of *C. cydoniae* nymphs, this compound alone showed moderate alarm-inducing activity, and combinations **2** + **3**, **2** + **5**, and **1** + **2** + **3** yielded

TABLE 1. ALARM PHEROMONE TEST I USING DORSAL ABDOMINAL GLAND (DAG) SECRETION AND SYNTHETIC COMPOUNDS[a]

[c]Not found in *C. cydoniae* DAGs.
[d]Not tested.

the highest activities. Despite the positive response rating for the latter three combinations, it must be pointed out that this chemically elicited alarm behavior did not fully mimic the natural response of *C. cydoniae* nymphs.

The second bioassay series with *C. cydoniae* nymphs used a more precise scoring system and included two additional compounds (acetaldehyde and nerol) (Table 2). The results are consistent in that (*E*)-4-oxo-2-hexenal **(2)** was more active than (*E*)-2-hexenal **(1)** and the monoterpenes. The combination of **2** + **3** was quite active (score = 3.33 ± 0.49), whereas combining nerol, which is a geometrical isomer of geraniol **(3),** with **2** greatly reduced activity. The role of acetaldehyde in the alarm pheromone remains questionable; the two highest concentrations tested induced responses interpreted as alarm, but the observer sometimes noted the responses "seemed different." An attempt to demonstrate a synergism between acetaldehyde and compounds **1–3** (concentration = 0.0065

[a] Responses were scored from 0 (no response) through 4 (full response) as described in the text. Scores listed are $X \pm \text{SEM}(N)$.
[b] Responses to CH_2Cl_2 alone = 0.60 ± 0.13 (40).
[c] Units are $\mu g/\mu l$ CH_2Cl_2 except for one solution tested on a molar basis (0.0065 M).
[d] Not found in *C. cydoniae* or *G. solani* DAGs.
[e] Occurs in *G. solani* DAGs, but not detected in *C. cydoniae* DAGs.

M) failed to show any appreciable synergism. None of the responses recorded in this bioassay series consistently equaled a natural response.

Nerolidol aldehyde **(4)** was synthesized after both bioassay series were completed, but when **4** was tested (2.5 $\mu g/\mu l$) against *C. cydoniae* nymphs it failed to elicit alarm behavior either alone or with **3** and/or **5.**

DISCUSSION

In *G. solani*, maternalism appears to substitute for the droplet chemical defense. A potent alarm pheromone is a second line of defense for *Gargaphia*, as well as for other tingids, and our discovery that tingid alarm pheromones emanate from the DAGs adds to the list of heteropterans having alarm pheromone activity associated with the secretions from these glands (Blum, 1985).

Gargaphia solani nymphs clearly are able to release DAG secretion. Notwithstanding the discussion of Kearns and Yamamoto (1981), the alarm pheromone system of the eggplant lace bug does not resemble that of various treehoppers (Homoptera: Membracidae), where the body wall of a nymph must be ruptured for the alarm pheromone to be released (Nault et al., 1974; Wood, 1976). The *Gargaphia* alarm-aggregation system seems much more like that of cotton stainer bugs (Pyrrhocoridae: *Dysdercus* spp.), where the posterior DAG secretion of nymphs triggers alarm and the two anterior DAGs produce an aggregation pheromone (Farine, 1987; Calam and Youdeowei, 1968). A diol corresponding to the tingid sesquiterpenoid is known from plants (Bohlman and Zdero, 1980), but nerolidol aldehyde is a new natural product. Whether this compound is part of an aggregation pheromone in *Gargaphia* remains to be determined.

While the alarm pheromone system of *Gargaphia* is not exceptional for Heteroptera, the system as it appears to function in *Corythucha* is extraordinary. Evidence that the alarm message in *Corythucha* is due to synergism between the two DAG secretions is, we believe, compelling. Yet all indications are that the nymphs are unable to voluntarily emit their DAG secretions; the glands must be physically ruptured for the pheromone to escape, a system truly analogous to that of treehoppers. Furthermore, many other tingid lineages having setal droplets might possess alarm pheromone systems as in *Corythucha*. This is apparently true for nymphs of the azalea lace bug *Stephanitis pyrioides* and the rhododendron lace bug *S. rhododendri* (J.W.N., personal observation).

The occurrence of sealed DAGs is not unprecedented in the Heteroptera; adults and nymphs of some mirids in the Bryocorinae specializing on toxic plants reportedly have one DAG with no external opening (Aryeetey and Kumar, 1973). When immatures of these mirids are disturbed, the DAG is vibrated, and drops of fluid simultaneously exude from setae over their bodies. It is pos-

sible that host-plant alkaloids are sequestered in the DAG and delivered when needed via the blood or an epidermal syncitium, as in milkweed bugs (Lygaeidae: *Oncopeltus* spp.) (Scudder et al., 1986), to setae or cuticular weak points (Aldrich, 1988a). However, none of the compounds identified in *Corythucha* DAG secretions have been detected in their setal droplets (Lusby et al., 1989).

Many questions remain unanswered in the present study, not the least of which is: what role, if any, does acetaldehyde play in the alarm behavior of *Corythucha*? For that matter, is acetaldehyde present in *Gargaphia*, and why do crushed adults cause delayed alarm among their nymphs (Kearns and Yamamoto, 1981)? (A single effort to directly observe acetaldehyde from exuviae of *G. solani* by low-temperature GC was inconclusive, and the metathoracic scent gland secretion has not been analyzed for any tingid adults.) Perhaps the most interesting question to emerge from this study is: has the alarm pheromone system of some nonmaternalistic tingids become totally altruistic?[4]

Acknowledgments—We wish to thank Rose Haldenmann for tireless efforts maintaining tingid colonies and preparing for bioassays, and Rolland Waters for the NMR spectrum. We are also grateful to Kim Kal for helping to collect *Gargaphia* and prepare extracts. Ken Wilzer helped collect tingids and provided invaluable computer assistance in the preparation of the manuscript, and Dawn Harrison performed many of the mass spectral analyses.

(Received May 23, 1991; accepted July 23, 1991)

Abstract—The overwintering eggs and the larvae of the leaf beetle *Galeruca tanaceti* (L.) contain hydroxylated anthraquinones. In both developmental stages, 1,8-dihydroxy-3-methylanthraquinone (= chrysophanol) and 1,8-dihydroxyanthraquinone (= chrysazin) were detected by GC-MS and GC-FTIR analyses. In the eggs, chrysazin was found only in traces. Anthraquinones were also present in ovaries and hemolymph of gravid females, which were investigated in order to examine the incorporation of these substances into the eggs. Neither in acidified nor in nonacidified extracts of the host plants *Tanacetum vulgare* L. and *Achillea millefolium* L. were anthraquinones found. The activity of these anthraquinones as chemical defense substances was proved in bioassays with the ant *Myrmica ruginodis* NYL. Further possible biological significances of anthraquinones are discussed.

Key Words—*Galeruca tanaceti*, Coleoptera, Chrysomelidae, anthraquinones, eggs, larvae, hemolymph, ovaries, *Tanacetum vulgare*, *Achillea millefolium*, feeding deterrence.

INTRODUCTION

Chrysomelids protect and defend their eggs against enemies by different strategies (Hinton, 1981; Lengerken, 1954). Females of *Phaedon cochleariae*, for

*To whom correspondence should be addressed.

0098-0331/91/1100-2323$06.50/0

example, hide their eggs in small cavities gnawed into the undersurface of the host-plant leaf. This oviposition behavior possibly serves not only as egg camouflage, but also as protection against desiccation of the eggs. Other chrysomelid species make their eggs almost inaccessible for predators and parasites by covering the eggs with feces and/or secretion. Eggs of *Timarcha* species, for example, are so firmly embedded in a "nest" consisting of plant material and feces that a single egg can hardly be loosened from the site. Eggs of Clytrinae are coated by a hardened scatoshell consisting of fecal material and gland secretions. Several chrysomelid species provide their eggs with chemicals that act as feeding deterrents against predators. Other chemicals are even toxic for the predators (overview: Pasteels et al., 1988a,b). The eggs of several *Chrysomela* species contain salicin in amounts that are toxic for ants (Pasteels et al., 1986). Other defensive egg compounds that cause feeding deterrence or rejection in predators are cardenolides in *Chrysolina* species (Pasteels and Daloze, 1977; Daloze and Pasteels, 1979), isoxazolinone derivatives in several *Chrysomela* and *Phratora* species, as well as in *Plagiodera versicolora* and *Gastrophysa viridula* (Pasteels et al., 1986), high amounts of oleic acid in *Gastrophysa cyanea* (Howard et al., 1982a), and cucurbitacins in the eggs of several Galerucinae that feed upon Cucurbitaceae (Ferguson and Metcalf, 1985).

Galeruca tanaceti L. (subfamily Galerucinae) is usually found on the Compositae *Tanacetum vulgare* L. and *Achillea millefolium* L. (Prevett, 1953). Eggs are deposited in September/October preferably at the tip of grass stalks; they overwinter until next April or May when the larvae hatch. The eggs are laid in batches that vary in size: usually about 20–30 eggs are deposited per batch. Each egg batch is cemented together and covered by a bright yellow secretion, which is produced by glandular cells of the oviduct (Scherf, 1956, 1966). Within half an hour after egg deposition, the liquid secretion is tanned by a dopa-oxidase and colored black peripherally (Messner, 1983). The hardened secretion, which is unsoluble in organic solvents, may serve as a mechanically protective device. The aims of this study were to examine whether the eggs of *G. tanaceti* are chemically defended and protected during the long period of overwintering, and to determine the origin of protective compounds. Furthermore, we investigated whether biologically active substances of the eggs are also present in the larvae of *G. tanaceti*.

METHODS AND MATERIALS

Larvae, eggs, and adults of *Galeruca tanaceti* (L.) were collected in 1989 and 1990 in the environs of Bayreuth and stored at $-40°C$ until preparation of extracts.

Chemical Analysis. The hardened secretion from 15 egg batches was

removed and the eggs were crushed in acetone, treated by ultrasound, centrifuged, and the clear supernatant fractionated by thin-layer chromatography (TLC) on silical gel 60 F_{254} (0.2 mm) with hexane–isopropyl acetate–1-butanol (6:2:1; v/v/v) as eluent. A parallel TLC run of an acetone extract, which was prepared from a single egg batch, showed, after spraying with 6% methanolic KOH, a bathochromic shift from yellow to purple in the fraction of the R_f value 0.86. The remaining nonsprayed fraction was scraped off the plate, dissolved in acetone, and repeatedly centrifuged for complete removal of the silicagel. The purified TLC fraction was analyzed by GC-MS and GC-FTIR. EI mass spectra (70 eV) were obtained using a Carlo Erba Vega Series 2 gas chromatograph with split injection (split 1:5; injector temperature: 220°C) coupled to a Finnigan Iontrap ITD 800. A 12 m × 0.32 mm FS-OV-1701 column was used, which was programmed from 100°C to 220°C at 20°C/min, from 220°C to 260°C at 5°C/min, and from 260°C to 280°C at 20°C/min (carrier: 50 kPa helium). Infrared spectra were obtained by GC-FTIR on a HP 5890 Series II gas chromatograph coupled to a HP 5965 infrared detector (temperature: 250°C) with splitless injection at 220°C. Samples were separated on a HP1 column (25 m × 0.31 mm) with an oven temperature program from 100°C to 240°C at 50°C/min (carrier: 65 kPa helium). Transmission spectra were recorded from 750 cm^{-1} to 4000 cm^{-1}.

A TLC fractionation of an acetone extract of 20 *G. tanaceti* larvae (third instar), conducted with the same method as used for the egg extract, showed, after spraying with 6% methanolic KOH, a bathochromic shift from yellow to purple in the fraction of the R_f value 0.83. The remaining nonsprayed TLC fraction of an acetone extract prepared from 20 *G. tanaceti* larvae (L3) was purified and analyzed as described before.

Hemolymph was obtained from 20 gravid *G. tanaceti* females by cutting the forelegs at the articulation between coxa and femur and soaking up the emerging hemolymph with small pieces of filter paper, which were extracted in acetone. Then, ovaries were dissected from these females (oviducts were cut off) and also dissolved in acetone. Detailed descriptions and drawings of galerucine genitalia have been presented by Silfverberg (1976) and Suzuki and Yamada (1976). Both hemolymph and ovary extracts were treated by ultrasound, repeatedly centrifuged, and the clear supernatants analyzed by GC-MS.

Extracts of host-plant leaves also were investigated. Three leaves each of *Tanacetum vulgare* L. and *Achillea millefolium* L. were ground, extracted in acetone, and examined for hydroxylated anthraquinones using the TLC method described above. These are hereafter called nonacidified extracts. The method of Wouters (1985) was modified for preparation of acidified extracts. Fragments of three leaves from each investigated host plant were hydrolyzed in unstoppered reaction tubes with 2 N HCl for 3 hr in a boiling water bath. The hydrolyzed solutions were cleared in a centrifuge and repeatedly extracted with

diethylether. The combined ether phases were evaporated under N_2 to a few milliliters and analyzed by GC-MS. The conditions for the GC-MS analyses of hemolymph, ovary, and acidified host-plant extracts were the same as for the investigation of the egg extracts.

Bioassay. A feeding bioassay was conducted with the ant *Myrmica ruginodis* NYL., in order to examine whether eggs of *G. tanaceti* were avoided by predators. Twenty ants were placed in a Petri dish (14 cm diam.) and starved for two days. After this starvation period, an aqueous test suspension was prepared by crushing two egg masses in 500 μl H_2O. A mealworm (last instar) was ground in 500 μl H_2O for the control suspension. Five microliters of each suspension was offered simultaneously to the ants. Every minute the number of feeding ants at the test and control suspension was recorded for a period of 10 min. After 20 replications, the bioassay was statistically evaluated by the Wilcoxon signed-rank test for paired differences (Sachs, 1984). The same method was used for testing an aqueous mealworm suspension plus synthetic chrysophanol (test) against a "pure" aqueous mealworm suspension without chrysophanol (control) to examine the effect of chrysophanol on the feeding behavior of *M. ruginodis*. The chrysophanol concentration of the test suspension was 1.4×10^{-2} M and 0.6% of the mealworm weight (0.3 g/500 μl H_2O).

RESULTS

The TLC of an acetone extract of *G. tanaceti* eggs revealed a fraction at R_f 0.86 with a bathochromic shift from yellow to purple when sprayed with 6% methanolic KOH. A bathochromic shift in alkaline solution is reported for a great many hydroxyquinones (Thomson, 1976). The total ion current chromatogram of this (nonsprayed) fraction revealed two peaks with mass spectra that show the typical fragmentation patterns of anthraquinones (Figure 1A). The EI mass spectrum of compound **1** had characteristic ions at *m/z* 240 (100%, M^+), 212 (36%, M − CO), 184 (47%, M − 2CO), 155 (9%), 138 (21%), 128 (30%), 92 (24%), indicating 1,8-dihydroxyanthraquinone (= chrysazin) (Howard et al., 1982b; McLafferty and Stauffer, 1989). A synthetic reference sample (Roth AG, Basel, Switzerland) showed an identical mass spectrum and the same retention time as compound **1**. The EI mass spectrum of compound **2** revealed fragments at *m/z* 254 (100%, M^+), 226 (26%, M − CO), 198 (18%, M − 2CO), 169 (7%), 152 (20%), 141 (10%), 115 (19%), suggesting 1,8-dihydroxy-3-methylanthraquinone (= chrysophanol), which was confirmed upon comparison with a synthetic reference sample (Aldrich Chemical Co., Steinheim, Germany) (Howard et al., 1982b; McLafferty and Stauffer, 1989). In addition, the FTIR spectrum of compound **2** conformed with that of synthetic chrysophanol (Figure 2).

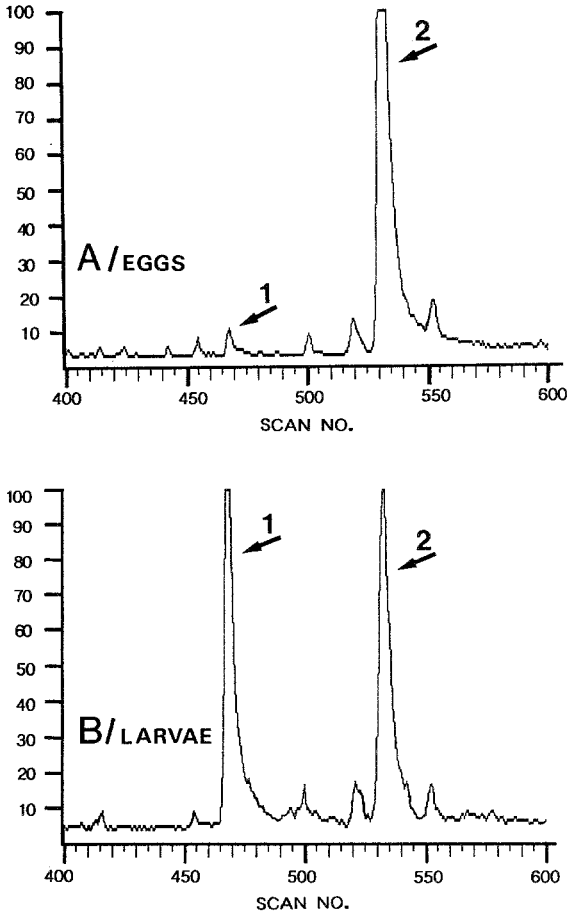

FIG. 1. Total ion current chromatogram of TLC fraction of 15 *Galeruca tanaceti* egg masses (A) and 20 larvae (B) from scan number 400 to 600. Characteristic fragments of the mass spectra of peak 1 and 2 are given in the text.

The site of production of the anthraquinones may be microorganisms living on deposited eggs, the embryo itself, or the female, which incorporates anthraquinones into the eggs. The GC-MS analysis of the hemolymph of *G. tanaceti* females revealed the presence of chrysophanol and traces of chrysazin. Chrysophanol was also detected in the ovaries; chrysazin, however, was not found. In the TLC of the nonacidified acetone extracts of *T. vulgare* and *A. millefolium*, no bathochromic shift occurred. GC-MS analyses of acidified extracts, which were examined in order to check for possible glycosidated chrysophanol and chrysazin derivatives, also showed no anthraquinones in the plant material.

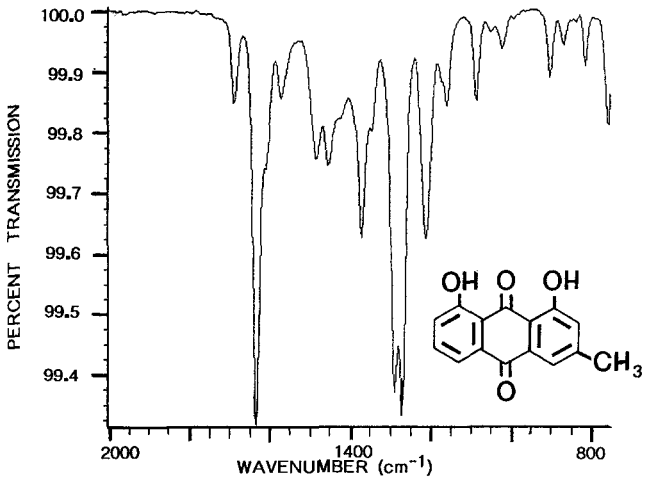

FIG. 2. FTIR spectrum of compound 2 from Figure 1A, in all respects identical with the spectrum of chrysophanol.

Therefore, the females do not acquire these substances from their host plants, since no hydroxylated anthraquinones were detected in the leaf extracts.

The TLC of an acetone extract of *G. tanaceti* larvae showed, after spraying, a bathochromic shift from bright yellow to purple in the fraction of R_f 0.83. A GC-MS analysis of the respective nonsprayed fraction revealed the presence of the same anthraquinones as in the eggs. The total ion current chromatogram of this TLC fraction is shown in Figure 1B. The mass spectra of these peaks were the same as those described above for the egg extract. A comparison of the FTIR spectrum of synthetic chrysazin (Roth AG) and of compound **1** from the total ion current chromatogram of the larval extract showed no differences (Figure 3).

The feeding bioassays with *M. ruginodis* revealed that the ants significantly preferred feeding upon mealworms compared to feeding upon the eggs of *G. tanaceti* (Figure 4). The highest difference between the number of feeding ants upon eggs and mealworms was reached after a test period of 10 min: only 27.5% of the feeding ants were recorded at the eggs of *G. tanaceti*. In order to examine whether this deterring activity of *G. tanaceti* eggs is due to the detected anthraquinones, a second feeding bioassay was conducted which tested feeding of *M. ruginodis* upon mealworms plus chrysophanol (test) compared to feeding upon "pure" mealworms (control). Figure 5 shows that after a test period of 8, 9, and 10 min, significantly fewer ants fed upon the test than upon the control suspension. The highest significant difference between the number of feeding

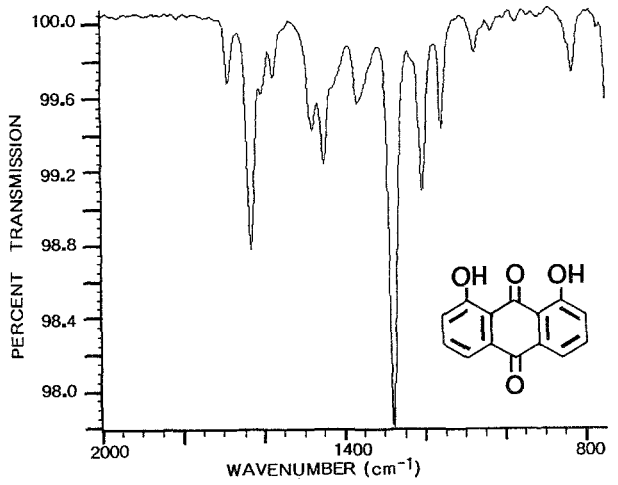

FIG. 3. FTIR spectrum of compound 1 from Figure 1B, in all respects identical with the spectrum of chrysazin.

ants upon test and control suspension was attained after 8 min: 35.8% of the feeding ants were recorded at the mealworm suspension plus chrysophanol.

DISCUSSION

Up to now, anthraquinones were unknown in eggs of Coleoptera; however, they have been detected in chrysomelid larvae. Howard et al. (1982b) found chrysophanol, chrysazin, and two anthrones in larvae of the elm leaf beetle, *Pyrrhalta luteola*, which, like *G. tanaceti*, belongs to the subfamily Galerucinae. Both chrysomelid species obviously do not acquire the anthraquinones from their host plants. As suggested for the production of anthraquinones in scale insects (Kayser, 1985), symbiontic microorganisms may also produce these compounds in both chrysomelid species. In *G. tanaceti*, the presence of anthraquinones in the hemolymph of females and in the ovaries indicates that females incorporate these compounds into the eggs, thus providing the eggs with protective compounds.

Eisner et al. (1980) reported on the feeding deterrence of the anthraquinone glucoside carminic acid against the ant *Monomorium destructor*, whereas the carnivorous caterpillar of a pyralid moth, *Laetilia coccidivora*, is not deterred by carminic acid; rather, it utilizes the ingested carminic acid from prey cochineals for defensive purposes of its own. As demonstrated by the bioassay described above, feeding of ants upon *G. tanaceti* eggs is significantly reduced compared to feeding upon normally accepted mealworms. An additional bioas-

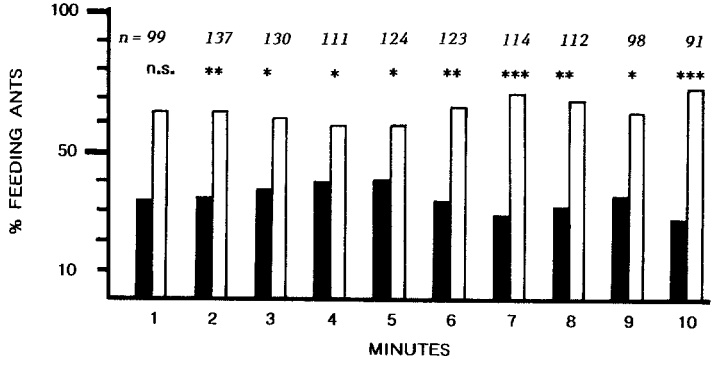

FIG. 4. Feeding bioassay with the ant *Myrmica ruginodis*. Black bars: feeding activity on an aqueous test suspension of *Galeruca tanaceti* eggs (2 egg masses/500 μl H_2O). White bars: feeding activity on simultaneously offered aqueous control suspension of mealworms (1 last-instar mealworm/500 μl H_2O). Registration of feeding ants during a test period of 10 min. Asterisks indicate level of significance: *, $P \leq 0.05$; **, $P \leq 0.01$; ***, $P \leq 0.001$; n.s. = not significant; Wilcoxon signed-rank test for paired differences.

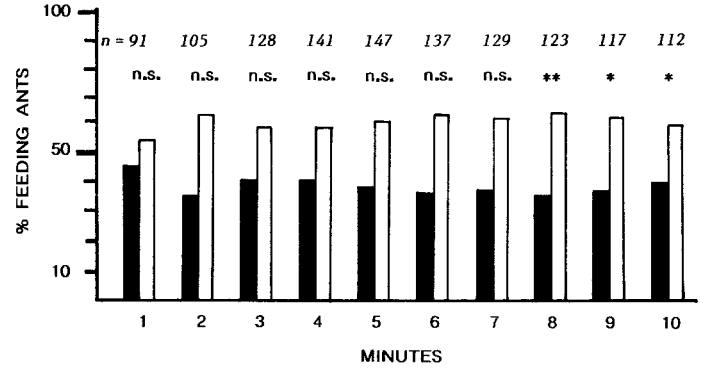

FIG. 5. Feeding bioassay with the ant *Myrmica ruginodis*. Black bars: feeding activity on an aqueous test suspension of mealworms plus added synthetic chrysophanol (1.4×10^{-2} M). White bars: feeding activity on a simultaneously offered aqueous control suspension of mealworms without chrysophanol. Registration of feeding ants during a test period of 10 min. Asterisks indicate level of significance: *, $P \leq 0.05$; **, $P \leq 0.01$; n.s. = not significant; Wilcoxon signed-rank test for paired differences.

say revealed that synthetic chrysophanol also causes a diminished feeding activity of the ants; however, the feeding reduction in the bioassay with eggs was stronger (see Figures 4 and 5). These results indicate that the main anthraquinone in the eggs of *G. tanaceti* contributes to the feeding deterrence of the eggs

against ants. Detailed knowledge on the anthraquinone concentrations in the eggs is essential to assess exactly the role of anthraquinones in the feeding-deterring activity of the eggs. In addition to the dosage, the mixture of the detected anthraquinones may also be relevant when bioassaying for feeding deterrence. Further quantitative investigations of the anthraquinones in *G. tanaceti* will be necessary to elucidate their biological significance. In this qualitative study, only a rough estimation of the chrysophanol concentrations was possible: the chrysophanol content is lowest in the hemolymph and ovaries of a single female, increases in the larva, and is highest in one egg mass.

When tasting an insect egg, a predator destroys the tiny prey. Therefore, the deposition of distasteful eggs in batches seems to be advantageous, since this oviposition behavior enhances the chance that only a single egg of an egg mass is damaged while the others remain untouched (Stamp, 1980). Anthraquinones from the above-mentioned chrysomelid larvae can only be released and display their activity against enemies by the emerging hemolymph from wounds. It remains to be proved whether the chrysomelid larvae are able to survive slight wounding. Wiklund and Järvi (1982, p. 1001) demonstrated that naive bird predators "often release distasteful prey insects unharmed after tasting them."

In addition to the feeding-deterring activity against ants, anthraquinones are also known as repellents against birds. For the protection of seeds, 9,10-anthraquinone is sold commercially as an avian repellent. Furthermore, hydroxylated anthraquinones have been demonstrated to act as antimicrobial agents (Cudlin et al., 1976) and might protect the eggs against microbial diseases. Adewunmi and Adesogan (1984) report on the molluscicidal activity of anthraquinones against snails. The ingestion of trematod eggs by herbivorous snails is a well-known phenomenon, whereas the coincident uptake of insect eggs and plant material, to our knowledge, has not been examined.

Acknowledgments—Many thanks are due to Konrad Dettner, Uwe Noldt and Regina Fettköther for valuable contributions and critical review of the manuscript.

ANNOUNCEMENT

The 9th annual meeting of the International Society of Chemical Ecology will take place in Kyoto, Japan, July 6–9, 1992.

Sessions will consist of 30 min. presentations by invited speakers and 12 min. presentations by contributing speakers, with 5 min. and 3 min. discussion periods, respectively. Thus far, organizers have planned sesssions on the chemical ecology of medicinal plants (K. Fuji), allelopathy (C.H. Chou), aqueous biosphere (D. Daloze), natural products (K. Mori, K. Nakanishi, and A.B. Smith, III), and fruit flies (J.L. Nation). Poster presentations on session themes, as well as general chemical ecology, are invited.

An abstract is required for oral and poster presentations, to include author's name, title, organization, and address, paper title, and subject matter. A form for this purpose should be requested. Program details, abstract forms, registration forms, and accommodation applications are also available from:

ANNOUNCEMENT

SYMPOSIUM ON PHYTOCHEMISTRY AND AGRICULTURE

The Phytochemical Society of Europe and the Department of Organic Chemistry of the Wageningen Agricultural University are sponsoring an international symposium to be held at the International Agricultural Centre in Wageningen, The Netherlands on April 22–24, 1992.

Speakers will include W. Barz (Münster), A. Bruggink (Venlo), B.V. Charlwood (London), W.M.J. van Gelder (Wageningen), F.J. Gommers (Wageningen), E. Haslam (Sheffield), B.P.S. Khambay (Harpenden), W. Kraus (Stuttgart), E. Krebbers (Gent), G. Massiot (Reims), J.N.M. Mol (Amsterdam), R.J. Molyneux (Albany), A. Nahrstedt (Münster), J.A. Pickett (Harpenden), P.W. Price (Flagstaff), J. O'Reilly (Little Island), L.M. Schoonhoven (Wageningen), A. Sheak (Kathmandu), S. Stymne (Uppsala), D. Tepfer (Versailles), and M. Wink (Heidelberg).

Topics will include crop protection with natural products, antifeedants, pyrethroids, screening for new insecticides, interactions between plants and microorganisms, phytoalexins, tritrophic interactions, cyanogenesis and food plants, alfalfa saponins, alkaloids in potatoes, plants toxic for cattle, natural colors, production of aroma chemicals, plant cell cultures, biosynthesis of fatty acids, polyphenols, cultivation and use of *Ginkgo biloba*, setting up an essential oil producing firm in a developing country, and comparing production of chemicals by plants and synthesis.

Poster presentations are invited. Any enquiries regarding the conference should be addressed to:

CONTROL OF CHEMICALLY STIMULATED FEEDING BEHAVIOR IN SAND FIDDLER CRABS *Uca pugilator*: EVIDENCE FOR HEMOLYMPH FEEDING INHIBITORY FACTOR

MARGARET A. SEARS and DAN RITTSCHOF*

Department of Zoology and Marine Laboratory
Duke University
Beaufort, North Carolina 28516

(Received April 18, 1991; accepted July 24, 1991)

Abstract—*Uca pugilator*, the sand fiddler crab, is a deposit-feeder. It feeds on exposed sand flats as the tide recedes. Feeding movements are evoked by stimulation of chemoreceptors on the dactyls. Previous studies have demonstrated that a proteinaceous factor associated with the sinus gland region inhibits chemically-stimulated feeding behavior. Here, that work is extended to show the existence of a similar inhibitory factor present in the hemolymph of fed crabs in the laboratory and in the hemolymph of crabs returning from feeding in the field. The factor is not detected in fasted laboratory crabs or in field crabs walking from burrow areas to feeding sites. Injection of glucose results in inhibition of feeding activity in intact crabs. Injection of glucose, but not galactose, stimulates feeding in eyestalk-ablated crabs. We suggest that neural responsiveness is stimulated by glucose, and that elevated glucose in intact crabs results in release of feeding inhibitory factor from the sinus gland. Release of feeding inhibitory factor into the blood enables crabs to return to burrow areas without stopping when they encounter food-laden sediments.

Key Words—*Uca pugilator*, crustacean feeding, endocrine factors, feeding behavior, daily movements, feeding ecology.

INTRODUCTION

The needs of organisms, and consequently their behavior, can be ordered into a hierarchy (c.f., Maslow, 1970), a prioritization of activities that has, through

*To whom correspondence should be addressed.

0098-0331/91/1200-2337$06.50/0

evolutionary time, proven successful. For example, organisms meet energetic needs and then perform activities that use energy to ensure survival and reproduction. We hypothesize that in crabs, behavioral prioritization can be hormonally controlled. That is, hormones play a direct role in determining the behavioral hierarchy and time budgeting of daily activities. This concept is supported for crustaceans by two reports in the literature (Gleeson et al., 1987; Sears et al., 1991). For the sand fiddler crab (*Uca pugilator* Bosc), daily activities include feeding (Robertson et al., 1980, 1981), burrow building and maintenance, sexual displays, and (at appropriate lunar phases) mating (Crane, 1975; Salmon and Hyatt, 1983). Here we provide evidence that hormones modulate chemosensory behavior in sand fiddlers.

Crab and shrimp eyestalks contain a proteinaceous factor that modulates chemically-stimulated feeding behavior in *U. pugilator* (Sears et al., 1991). This feeding inhibitory factor (FIF) is associated with the eyestalk (X-organ, sinus gland complex), a secretory neuroendocrine organ that has a major role in the regulation of moulting, ovulation, ion balance, and hemolymph glucose levels (for review see Beltz, 1988). FIF-like activity can be found in fed intact crabs and in intact crabs injected with glucose. Crabs captured while walking from burrow areas to feeding sites and fasted intact crabs do not contain detectable amounts of FIF activity in their hemolymph. Crabs returning from feeding, and fed intact crabs, contain high levels of FIF in their hemolymph. Eyestalk-ablated crabs are also devoid of FIF activity and do not produce FIF-like activity when fed or injected with glucose. The molecular size of circulating FIF is similar to that of FIF isolated from eyestalks.

Here, we show that the circulating levels of FIF are related to the behavioral and satiation state of the crabs.

METHODS AND EXPERIMENTS

Eyestalk-Ablated Crabs

Eyestalks were ablated with forceps. At least 12 hr elapsed after ablation and before testing (Rittschof and Buswell, 1989). This interval was sufficient for depletion of eyestalk hormones as indicated by chromatophore state (Brown, 1940). Eyestalk-ablated crabs were held overnight in finger bowls containing several mm of seawater at 23°C. Bowls were rinsed and seawater was replaced 15 min prior to feeding assays.

Assays of Feeding Inhibition

For assays, intact and eyestalk-ablated crabs were transferred to 20-cm finger bowls containing 20 ml of 0.0625 M glucose (the threshold concentration for a detectable response) in 100 kd filtered seawater. Feeding responses were

observed directly. Feeding assays tested glucose-stimulated feeding responses (Sears et al., 1991). Seawater (34–37 ppt), filtered to remove particles >100 kd, was used to make solutions for feeding assays in which 10–30 crabs were tested in groups of five and were observed for 30 sec. A positive feeding response was recorded for each crab that moved the minor chela at least twice in a feeding motion.

Hemolymph Glucose Assays

Hemolymph glucose concentrations were assayed enzymatically using the deproteinated blood protocol from a commercially available glucose oxidase reagent kit (Sigma Chemical, St. Louis, MO #510-DA). Hemolymph glucose levels were determined on intact, eyestalk-ablated, and ablated crabs injected with glucose 1 hr beforehand in isosmotic (900 mOsM/1) 100 kd filtered seawater.

Effects of Increased Hemolymph Glucose on Feeding Responses of Intact and Ablated Crabs

The effect of elevated glucose levels on feeding responses was determined using 30 intact and 30 eyestalk-ablated crabs. Each crab was injected with 25 μl of 4 g/l (100 μg) glucose in saline solution. Based on previous glucose assays, this amount of glucose was sufficient to bring the hemolymph glucose concentration of a 2.1 g ablated crab to levels (10 mg/dl) found in intact crabs. Feeding assays were conducted 1 hr after injection.

Effects of Increased Hemolymph Glucose or Galactose on Feeding in Ablated Crabs

Glucose can be metabolized directly by neural tissue, but galactose cannot (Lehninger, 1978). The effects of elevated glucose and galactose in eyestalk-ablated crabs were compared. Thirty ablated crabs were injected with saline, 25 μl of 4 g/l or 40 g/l glucose or galactose solution. Based on previous glucose assays, these concentrations were sufficient to bring hemolymph hexose concentrations to 10 mg/dl and 100 mg/dl, respectively. Sixty minutes after injection, feeding responses were measured and stimulation of feeding was calculated:

$$\frac{\text{Final \% response} - \text{Initial \% response}}{\text{Initial \% response}}$$

FIF Titres of Hemolymph from Unfed and Fed Crabs

FIF titres in fiddler crab hemolymph were estimated by injecting hemolymph into eyestalk-ablated crabs 1 hr prior to bioassay. A 25 μl volume of hemolymph was drawn from the sinus within the large cheliped of a male crab, using a Hamilton syringe. This sample of hemolymph was immediately injected into an eyestalk-ablated crab (technique described in Sears et al., 1991). Eyestalkless crabs were assayed immediately before injecting samples and then 1 hr after injection. Materials tested for inhibition of feeding activity were diluted with isosmotic (900 mOsM/l) 100 kd filtered seawater and 25 μl volumes injected into crab blood sinuses. Injection was either into the blood sinus within the large cheliped of eyestalkless males, or into the sinus at the proximal joint of the fifth walking leg (both sexes). Preliminary tests indicated equivalent response times for the two injection methods.

Hemolymph titres of FIF with respect to feeding were determined in both laboratory and field situations. In the laboratory, intact crabs were maintained for 3 days with either an unlimited supply of fish flake food (Tetramin) and cat food (Friskies Ocean Fish Flavor), or fasted in finger bowls containing 100 kd filtered seawater. Hemolymph was drawn from 30 crabs in each condition, injected into eyestalk-ablated crabs, and the injected crabs bioassayed for feeding inhibition.

In the field, 25 μl samples of hemolymph were taken from crabs on the way down the beach to feed as the tide ebbed, or 2 hr after low tide as crabs traveled back to their burrows after feeding. Samples were from crabs located at Bird Shoal, Beaufort, North Carolina, USA. Hemolymph from each sample of crabs was immediately injected into eyestalk-ablated crabs which had been brought into the field. Crabs were tested in the field in the feeding bioassay immediately before injection and in the field 1 hr after injection. When not in use, ablated crabs were stored in buckets containing 1 cm of seawater, covered with towels. Ambient temperature was 37°C.

Size Estimation of FIF from Hemolymph

Hemolymph containing FIF activity was subjected to size fractionation to estimate the molecular size of circulating FIF. Cascade pressure dialysis was used to estimate the molecular size of hemolymph FIF. A total of 2 ml of hemolymph was drawn in the field from 100 intact male crabs as they were returning to their burrows after feeding (approximately 2 hr after low tide). The pooled hemolymph was diluted as it was collected into 20 ml of isosmotic 100 kd filtered seawater stored on ice until it was returned to the laboratory.

In the laboratory, the diluted hemolymph was centrifuged at 10,000 rpm for 10 min to remove particulates. The supernatant was then separated into $<5{,}000$ d and $>5{,}000$ d size fractions by ultrafiltration through a 5000 d mem-

brane (Amicon YM series). The >5000 d fraction residue was washed twice with isosmotic saline and brought back to the original 20 ml volume. Both the filtrate and the residue were lyophilized and returned to 2 ml volumes. FIF titres in the two size fractions of hemolymph from fed crabs was determined. For assays, 25 μl of <5000 d and >5000 d size fractions of hemolymph were injected into 30 eyestalk-ablated crabs. Feeding responses were measured and percent inhibition of feeding was calculated.

Statistical Analysis

Levels of feeding responsiveness under different conditions were compared by determining a Z statistic for the difference between two proportions (Walpole, 1974). Significance was set at the $p < 0.05$ level.

RESULTS

Effects on Feeding of Elevated Hemolymph Glucose Concentrations in Intact and Ablated Crabs

Injection of glucose inhibited feeding in intact crabs but stimulated feeding in eyestalk-ablated crabs (Figure 1). A 10 mg/dl increase in hemolymph glucose concentration resulted in 45% inhibition of feeding by intact crabs ($Z = 3.15$, $P < 0.001$) compared to 112% stimulation in ablated crabs ($Z = 10.6$, $P < 0.001$).

Effects of Increased Glucose or Galactose on Feeding of Eyestalk-ablated Crabs

Glucose stimulated feeding to a much greater extent than galactose in ablated crabs (Figure 2). Hemolymph concentrations of glucose $\geq$ 10 mg/dl resulted in 100% stimulation of feeding ($Z = 10.6$, $P < 0.001$). In contrast, injection of 10 and 100 mg/dl galactose resulted in 17% and 22% stimulation, respectively, which failed to differ significantly from control (saline injected) crabs.

Effects of Hemolymph Taken from Unfed and Fed Crabs

Injection of 25 μl of hemolymph drawn from intact fed crabs in both the laboratory and the field significantly inhibited feeding ($Z = 7.46$, $P < 0.001$) in eyestalk-ablated crabs (Figure 3). Injection of hemolymph from fasted (unfed) laboratory crabs stimulated feeding ($Z = 1.79$, $P < 0.05$), while hemolymph from crabs moving toward feeding areas (field) had no effect.

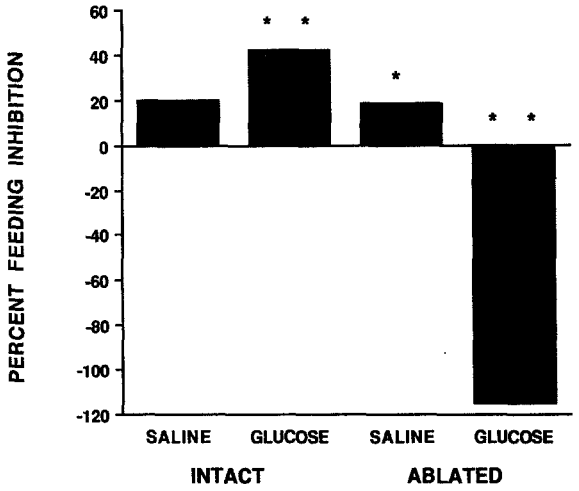

Fig. 1. Change in feeding activity of intact and eyestalk-ablated crabs following injection of saline or glucose. Feeding activity for each group of crabs was determined prior to injection. One hour after injection feeding activity was again assayed. Injection of glucose significantly inhibited feeding in intact crabs while injection of saline did not. Eyestalk-ablated crabs injected with saline were inhibited from feeding, but when injected with glucose, feeding activity increased (negative inhibition is stimulation of feeding). * = $p < 0.05$; ** = $p < 0.01$.

Comparison of Hemolymph Size Fractions

Feeding inhibition activity was found in the >5000 d fraction of hemolymph drawn from satiated intact crabs. Injection of the >5000 d fraction resulted in 80% inhibition of feeding responses by eyestalk-ablated crabs ($Z = 5.58$, $P < 0.001$), whereas the <5000 d fraction resulted in 0% inhibition.

Summary of Injection Experiments

Inhibition of feeding responses and corresponding eyestalk equivalents for injection experiments are summarized in Table 1. Levels of FIF were undetectable in ablated crabs injected with saline or with hemolymph from fasted or crabs in the field that were on their way to feeding areas.

DISCUSSION

Feeding inhibition might be the result of depressed glucose levels due to the absence of crustacean hyperglycemic hormone (CHH) (Kleinholz et al., 1967). Injection of glucose into eyestalk-ablated crabs stimulates feeding

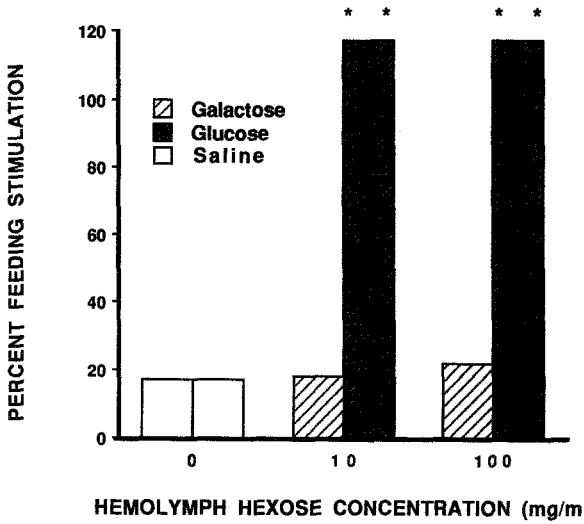

Fig. 2. Feeding activity after injection of hexose sugars into eyestalk ablated crabs. After determination of feeding activity, galactose or glucose was injected into eyestalk-ablated crabs. One hour later, crabs were assayed a second time. Glucose dramatically stimulated feeding. Galactose had no effect. ** = $p < 0.01$.

responsiveness to glucose. This result eliminates the possibility that feeding inhibition is mediated indirectly by CHH through elevation of glucose levels.

Since injection of glucose stimulates feeding in ablated crabs, we suggest it acts directly on the nervous system. The nervous system is an obligate glucose user (Lehninger, 1978). Ablated crabs which lack CHH have depressed glucose levels (Kleinholz et al., 1967). After injection of glucose, the nervous system may work more efficiently, thereby increasing feeding responsiveness. Thus, for ablated crabs, the more they eat, the more they are stimulated to feed. A common dietary sugar, galactose, cannot be used directly by nervous tissue. Injection of galactose resulted in only slight stimulation. This supports the hypothesis that glucose is acting directly on the nervous system.

Glucose injections result in inhibition of feeding in intact animals, but not in ablated animals. This suggests that the sinus gland secretes FIF in response to elevated hemolymph glucose levels. Injection of hemolymph from satiated, but not from hungry crabs, inhibits feeding in ablated crabs. The biological activity found in the hemolymph is similar in molecular size to FIF isolated from the eyestalk (Sears et al., 1991). These results suggest that after the crabs have fed for some time, increased glucose levels stimulate the release of FIF. FIF modulates and finally halts chemically-stimulated feeding responses.

We have constructed an algorithm of fiddler crab responsiveness. As fid-

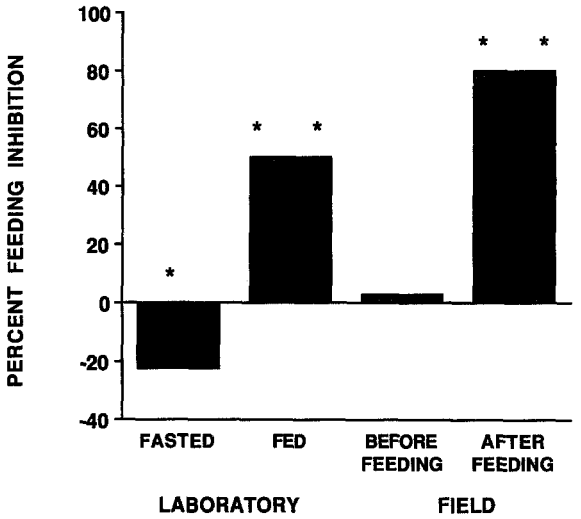

Fig. 3. Feeding activity of crabs following injection of hemolymph from crabs sampled in the laboratory and in the field (on their way to and returning from feeding areas). Hemolymph from unfed (fasted) crabs in the laboratory stimulated feeding in eyestalk-ablated crabs. Hemolymph from fed crabs from either the laboratory of the field dramatically inhibited feeding in ablated crabs. * = $p < 0.05$; ** = $p < 0.01$.

dler crabs feed, hemolymph glucose levels rise. Elevated glucose triggers the release of FIF from the sinus gland into the hemolymph. Circulating FIF acts on the central or peripheral nervous system to decrease responsiveness to external chemical stimuli, first restricting feeding to rich patches of food and finally halting feeding entirely. Once feeding has stopped, crabs return to burrow areas and continue with other activities. There are times when crabs are food-limited and forced to stop feeding by the tides (Salmon and Hyatt, 1983). It would be informative to titer FIF levels at these times. If normal FIF titres decline with fasting at a rate comparable to injections of FIF (Sears et al., 1991), then inhibitory effects of FIF could be expected to diminish prior to the time of the next declining tide.

Male fiddler crabs spend considerable time performing elaborate mating displays (Salmon and Hyatt, 1983). In addition, fiddler crabs are at risk of predation when they are away from their burrows on the sand flat feeding (see Salmon and Hyatt, 1983, p. 41). They must build burrows for predator avoidance and for use as incubation chambers for gravid females. By halting feeding once nutritional and energetic needs are met, FIF plays an important role in budgeting time crabs spend on non-feeding activities.

TABLE 1. SUMMARY OF INHIBITION OF FEEDING RESPONSES AND APPROXIMATE CORRESPONDING EYESTALK EQUIVALENTS OF FIF IN EYESTALK-ABLATED CRABS OF 0.1 ml HEMOLYMPH VOLUME AFTER INJECTION WITH SALINE, HEXOSES, OR HEMOLYMPH. NEGATIVE INHIBITION VALUES INDICATE STIMULATION

Material injected	Percent inhibition	FIF eyestalk equivalents per crab
Lab		
Saline	17	0
Glucose	112	0
Galactose	−22	0
Unfed hemolymph	−22	0
Fed hemolymph	43	0.32
< 5000 d fed hemolymph	0	0
> 5000 d	80	1.2
Field		
Unfed hemolymph	0	0
Fed	80	1.2

There are a variety of criteria for determining whether a specific factor is a hormone (Beltz, 1988): (1) presence in a neurosecretory organ: FIF has been localized to the region of the X-organ sinus gland complex in shrimp eyestalks. Immunocytochemistry would be required to demonstrate the existence of FIF in this neurosecretory organ. (2) Release into the circulation: FIF-like biological activity has been demonstrated in both the laboratory and the field in the hemolymph of fed, but not of unfed crabs. This circulating biological activity has the same approximate molecular size as FIF from the sinus gland region. Purification and characterization of FIF should establish whether or not eyestalk and hemolymph factors are actually the same molecules. (3) Effectors that respond to the factor at its circulating concentration: crabs show dramatic alteration in chemically-stimulated behavior when injected with FIF from eyestalk extracts or from hemolymph of fed crabs. Donor crabs with different FIF titres exhibit different behaviors. Eyestalk-ablated crabs do not respond by producing FIF activity as do intact crabs. (4) Sufficient stability in the hemolymph: although FIF is less solvent-, heat-, and trypsin-stable than many other sinus gland hormones (Sears et al., 1991), FIF is sufficiently stable in the hemolymph to be detected for changes in its titre before and after feeding. These results support the hypothesis that FIF is a hormone from the sinus gland. Its function appears to be to regulate behavior by modulating chemically-stimulated feeding.

PEPTIDE ATTRACTION OF HERMIT CRABS *Clibanarius vittatus* BOSC: ROLES OF ENZYMES AND SUBSTRATES

C.M. KRATT and D. RITTSCHOF*

Marine Laboratory and Department of Zoology
Duke University
Beaufort, North Carolina 28516

(Received April 18, 1991; accepted July 29, 1991)

Abstract—Hermit crabs are obligate users of gastropod shells. Shell availability is often the limiting factor for crab population size. Crabs have an extensive behavioral repertoire for obtaining shells. Here we extend our studies of the chemical ability of crabs to locate the shells of dead and dying gastropods from a distance. We show that peptide cues generated by the action of specific proteases on specific substrates attract crabs. The specificity of the crab response is dependent upon the type of substrate as well as the suit of enzymes attacking the substrate. Single specific enzymes are not as effective as mixtures of enzymes in generating cues from pure (and totally foreign) substrates such as ovalbumin. However, the activation of trypsinogen by enterokinase yields only a single hexapeptide and results in potent crab attraction. We conclude that the specific sequence of the peptide determines attraction. Thus, the key to crab attraction is the presence of a particular sequence in a substrate and the ability of enzymes or mixtures of enzymes to release that sequence.

Key Words—Hermit crabs, *Busycon carica*, *Clibanarius vittatus*, peptide attractants, salivary glands, proteases, shell cues.

INTRODUCTION

Marine hermit crabs are obligate users of gastropod shells. The availability and kinds of snail shells control hermit crab population density (Vance, 1972). Proper shell fit is important because it can influence growth (Fotheringham, 1976; Spight, 1985), fecundity (Childress, 1972; Bach et al., 1976; Bertness, 1981),

*To whom correspondence should be addressed.

0098-0331/91/1200-2347$06.50/0

and even copulatory success (Hazlett, 1989; Hazlett and Baron, 1989). Hermit crabs display complex behaviors associated with assessing and trading shells with other hermit crabs (Hazlett, 1966, 1981; Kuris and Brody, 1976; Jackson and Elwood, 1989). New shells enter aquatic crab populations upon death of the gastropods that grew the shells (McLean, 1974; Spight, 1977; Herrnkind et al., 1981; Wilber and Herrnkind, 1982, 1984). Snail mortality may be due to physical occurrences such as large storms or temperature changes (Spight, 1977; Rittschof, 1980a; Wilber and Herrnkind, 1982, 1984) or due to biological occurrences such as snail predation events (McLean, 1974; Wilber and Herrnkind, 1984).

Chemicals released from the flesh of dead and dying gastropods signal the availability of new shells (McLean, 1975; Rittschof, 1980a; Hazlett and Herrnkind, 1980; Gilchrist and Abele, 1984; Wilber and Herrnkind, 1984; Lepore and Gilchrist, 1988). Chemical signals are highly specific (Rittschof, 1980a,b). That is, hermit crab species A is attracted to odors of dead snail species B while hermit crab species C is attracted to the odors of dead snail species D. Most aquatic hermit crabs studied are chemically attracted to obtain shells rather than to feed (McLean, 1975; Rittschof, 1980a). The hermit crabs which are chemically attracted are generally those with small shells (Gilchrist and Abele, 1984), poor fitting shells (Rittschof, 1980a), or heavily fouled shells (Hazlett and Herrnkind, 1980).

Rittschof (1980b) postulated that predatory gastropods had a role in generating chemical crab attractants. That role was the release of proteases upon feeding. The putative proteases were postulated to act upon prey snail muscle proteins to generate peptide crab attractants. Recently, Rittschof et al. (1990b) showed that enzymes from the salivary glands of predatory gastropods (Graham, 1941) could act upon the muscle proteins purified from two gastropod species to attract the striped-legged hermit crab *Clibinarius vittatus*. Attraction was to cues from the flesh of gastropods whose shells were often occupied by *C. vittatus*.

Here we extend the study of Rittschof et al., (1990b) to more clearly understand the substrate–enzyme interactions that generate peptides attractive to hermit crabs. We demonstrate that both the proper substrate(s) and proper enzyme(s) are necessary components for producing cues eliciting hermit crab responses. However, less dramatic responses can be elicited upon changing either substrate or enzyme mixtures. Using a single protease to digest three substrates, we find that whelk flesh produces peptides attractive to *C. vittatus* while digestion of clam flesh or ovalbumin does not. Poor substrates do produce effective attractants when digested with mixtures of proteases. The greater number of cleavage sites results in smaller and more compositionally diverse digestion products. Finally, we show that hermit crab attraction appears to be due to specific peptides. This conclusion is supported by the results of three experi-

ments: (1) mixtures of peptides are not necessarily more attractive than single peptides, (2) putative enzymes of the salivary gland conservatively and specifically cleave 50 kD mollusc muscle proteins to generate highly potent cues, and (3) a specific hexapeptide is a highly potent attractant.

MATERIALS AND METHODS

Study Site and Field Assay

Hermit crab attraction to test substances was determined by field assays (Rittschof et al., 1990b). Assays were performed in the immediate vicinity of the Duke University Marine Laboratory, Beaufort, North Carolina, in low intertidal areas inhabited by the striped-legged hermit crab, *Clibanarius vittatus*. Protein substrates and/or enzymes (see specific experiments below) were mixed in 2 ml of deionized water and 4 ml of sea water. Test substances were prepared and incubated (from 20–60 min depending on the requirements of the reaction) in 2.1-cm diameter 14-kD cutoff dialysis bags (Spectrum Medical Industries, Los Angeles, California). The bags were used directly in field assays.

Each field assay consisted of two or three test substances, one of which was always trypsinized *Busycon carica* flesh. Trypsinized *B. carica* flesh has been documented to be highly attractive to *C. vittatus* (Rittschof et al., 1990b) and was used as a standard attractant to which the attractiveness of other substances was compared. For each type of test substance, eight to ten replicate dialysis bags were prepared. The dialysis bags were placed in individual 100-ml polypropylene cups covered with fiberglass windowscreen, secured with rubber bands.

Cups were buried with the windowscreen flush with the sand along a transect line in the intertidal region during daytime low tides. Water levels varied with the tide between 15 and 45 cm. The cups were placed 2–3 meters apart in a series that alternated treatments.

Cups were monitored for crab attraction for 60 to 90 min by walking up and down the beach parallel to the transect line. A positive response was recorded when a hermit crab touched the windowscreen of a cup. Each responding crab was captured and held until the end of the assay to minimize social interactions (McLean, 1975; Rittschof, 1990b) and to ensure that each crab was counted only once. Response frequencies were analyzed by the G-test, a goodness-of-fit test with expected frequencies based on an extrinsic hypothesis (Sokal and Rohlf, 1981).

Crab responses to treatments could be due to a positive stimulus or to chance. Therefore, the degree of a treatment's potency was determined by comparing the attractiveness of the treatment both to the attractiveness of a known positive stimulus and to a measure of chance encounter. Attractiveness of a

positive stimulus was obtained from trypsinized *Busycon carica* flesh. A measure of chance encounter obtained from crab responses to the test apparatus alone indicated no attractiveness of the latter, i.e., 0 crabs came to the apparatus and 41 crabs came to trypsinized *B. carica* flesh.

Two types of treatments were tested in field assays. Protein digestion assays tested the attraction of crabs to mollusc and commercial protein preparations digested by proteolytic enzymes. Proenzyme activation assays tested the attraction of crabs to proenzymes specifically clipped by activating enzymes.

Whelk Blood and Muscle Proteins

A series of protein digestion experiments utilized specific groups of blood and muscle proteins, extracted from *B. carica*, relaxed overnight in 0.2-M $MgCl_2$ at 4°C. The snails were bled by cutting the foot several times with a scalpel. The blood was collected in a solution of 1 mM phenylmethylsulfonyl fluoride (PMSF) and ethyl alcohol. Tris (0.05 M), ethylenediamine-tetraacetic acid (EDTA, 1 mM), and PMSF (1 mM) pH 7.0 buffer was added to double volume and the solution was centrifuged at 4000 × g for 10 min to remove debris. Half of the solution, hereafter referred to as hemolymph, was stored refrigerated. The remaining hemolymph was ultra-centrifuged at 370,000 × g for 2 hr at 4°C to precipitate hemocyanin from the other blood proteins. The blue hemocyanin pellets were redissolved in fresh buffer solution and stored refrigerated.

Muscle proteins were extracted from whelk flesh by the procedure of Rittschof et al. (1990a,b). In brief, cleaned muscle tissue was coarsely minced and extracted in the cold with 0.3 M KCl buffered with 0.15 M Na_2HPO_4 (pH 7.0). The solution was then clarified by filtration and diluted to 0.05 M KCl to precipitate proteins. Upon centrifugation, pelleted precipitate was redissolved in 2.0 M KCl buffered with 50 mM phosphate to pH 7.0 and clarified supernatant was collected and diluted to ionic strength of 0.25 M KCl. The flocculent white (intermediate ionic strength) precipitate was separated from the supernatant through centrifugation. The ionic strength of the supernatant was then lowered to 0.05 M KCl and a second flocculent white (low ionic strength) precipitate was collected through centrifugation. These procedures generated fractions containing those proteins extracted from muscle in high salt conditions which become insoluble when the ionic strength is lowered.

Whelk Salivary Gland Homogenate

Busycon carica salivary glands have been hypothesized to secrete enzymes which function in the digestion of food (Rittschof et al., 1990a,b); therefore, they were used as a source of predatory snail proteolytic enzymes in some protein digestion assays. Salivary gland homogenate was prepared by the procedure of

Rittschof et al. (1990b). In brief, salivary glands were coarsely dissected from the head region of freshly killed *B. carica*, pooled, homogenized in Tris buffer (0.05 M Tris, 1 mM EDTA, pH 7.5) at 25°C, and stored in aliquots at −20°C.

Commercially Purified Proteins

All commercially purified proteins, including structural proteins, enzymes, and proenzymes, were obtained from Sigma Chemical Company, St. Louis, Missouri. Ovalbumin (chicken egg, grade V, #A5503) was the source of purified protein substrate in several protein digestion assays. Ovalbumin was dissolved in filtered seawater to a concentration of 25 $mgml^{-1}$ immediately prior to experimentation.

Enzymes, used in the protein digestion assays, were trypsin (10,200 BAEE units mg^{-1}, from bovine pancreas, Type III, #T8253), alpha-chymotrypsin (50 BTEE units mg^{-1}, from bovine pancreas, Type VII, #C3142), and trypsin-chymotrypsin (1120 BAEE units mg^{-1} of trypsin activity, 1110 BTEE units mg^{-1} of chymotrypsin activity, from porcine pancreas, Type II, #8128). Enzyme solutions were prepared at a concentration of 1 $mgml^{-1}$ in deionized water and were used immediately. Enzyme and proteins were incubated at RT for 20 min prior to field assays.

Proenzymes used were trypsinogen (from bovine pancreas, #T1143) and α-chymotrypsinogen a (from bovine pancreas, Type II, #C4879). The activating enzymes were enterokinase (from bovine intestine, #E5510), and trypsin (from bovine pancreas, Type III, #T8253), respectively. Incubation procedures were provided by the Sigma Chemical Company, St. Louis, Missouri. Trypsinogen (10 $mgml^{-1}$) and enterokinase (77 $mgml^{-1}$) were incubated in a Tris-HCl buffer (ph 5.8) at RT for 1 hr prior to the field assay. Chymotrypsinogen (50 $mgml^{-1}$) and trypsin (0.5 $mgml^{-1}$) were incubated in 0.05 M phosphate buffer (pH 8.0) at RT for 1 hr prior to the field assay.

Protein Characterization

Proteins of mollusc flesh treatments were characterized by sodium dodecyl-sulfate polyacrylamide gel electrophoresis (SDS PAGE, a 7.5% resolving gel with a 5% stacking gel; Laemmli, 1970). Photographs of gels were subjected to static image analysis (using JAVA software from Jandel Scientific, Corte Madera, California), a densitometry tracing technique. Proteins were characterized both before and after enzymatic digestion.

Experiments

The first series of experiments was designed to test responses of *C. vittatus* to whelk and clam flesh when presented frozen and thawed or when treated with trypsin or chymotrypsin. This series tested the effectiveness of the flesh types

as a source of protein substrate as well as tested the effectiveness of endogenous enzymes, trypsin, and chymotrypsin in generating attractive signals. Five field assays were performed, each comparing hermit crab response to the standard attractant (trypsinized *B. carica* flesh) and a test substance. The test substances were frozen and thawed *B. carica* flesh (1 g per replicate, see *Field assays* above), fresh *B. carica* flesh digested with chymotrypsin, frozen and thawed *Mercenaria mercenaria* flesh (1 g), and fresh *M. mercenaria* flesh (1 g) digested with trypsin (0.5 mg = 5100 BAEE units) or chymotrypsin (2.0 mg = 100 BTEE units).

The second series of experiments tested the effectiveness of an enzyme combination in yielding attractive signals from the potent protein substrate, *B. carica* flesh, and from the less potent protein substrate, *M. mercenaria* (see previous series of experiments). We tested the hypothesis that a less potent protein substrate, if digested with an appropriate enzyme combination, would result in attractant molecules. Four field assays were performed, each comparing trypsinized *B. carica* flesh to a test substance. Test substances were fresh whelk flesh (1 g) or fresh clam flesh (1 g), digested by trypsin-chymotrypsin (0.09 mg #T8128 and 0.5 mg #T8253 = 5,200 BAEE units of trypsin activity and 100 BTEE units of chymotrypsin activity) or *B. carica* salivary gland homogenate (2 mg of protein).

The third series of experiments attempted to pinpoint the source of the attractant protein in *B. carica* flesh. Proteins were extracted from *B. carica* muscle and blood (see above). Muscle proteins included an intermediate ionic strength precipitate and a low ionic strength precipitate. Blood fractions included hemolymph, consisting of all blood proteins, and hemocyanin, the major blood protein. Four field assays were performed to compare the attractiveness of each of the four trypsinized protein fractions with that of trypsinized *B. carica* flesh. Protein amount was 30 mg and trypsin amount was 0.5 mg (5100 BAEE units).

The next series of experiments tested the effectiveness of a single commercially purified protein, rather than a crude protein mixture, as a source of peptide attractants. These experiments tested the hypothesis that if any protein of sufficient complexity, in sufficient quantity is cut with the proper enzymes, its cleavage products can elicit a response. Five field assays were performed to test crab response to 150 mg untreated ovalbumin or ovalbumin digested by trypsin, chymotrypsin, trypsin-chymotrypsin mix, or salivary gland homogenate.

The next two series of experiments tested the responses of hermit crabs to specific peptides rather than to a mixture of many peptides. The experiments tested the hypothesis that hermit crabs are attracted to specific peptides released during activation of predatory snail digestive proenzymes, trypsinogen and chymotrypsinogen, were activated with enterokinase and trypsin, respectively, to yield peptide products. The solution of the proenzymes with their activating

enzymes, as well as different reactant and product combinations, were tested for attractiveness. Mixture amounts per replicate cup were based upon activity units. The incubated mixture of purified bovine trypsinogen (10 mg) and purified bovine enterokinase (77 mg) was tested in a field assay with the following controls: trypsinogen (10 mg), trypsin (10 mg), enterokinase (77 mg), and trypsin (10 mg)-enterokinase (77 mg). The incubated mixture of purified bovine chymotrypsinogen (50 mg) and purified bovine trypsin (0.5 mg) was tested in a field assay with the following controls: chymotrypsinogen (50 mg), trypsin (0.5 mg), and chymotrypsin (50 mg).

RESULTS

Hermit Crab Attraction

C. vittatus has been reported to be readily and specifically attracted to chemicals released from trypsin-treated *B. carica* flesh (Rittschof et al., 1990b). Hermit crabs respond to chemical cues indicating shell availability and not to those indicating food (Rittschof et al., 1990b). Here we compare crab responses to trypsinized *B. carica* flesh to crab responses to *B. carica* and *M. mercenaria* flesh treated with enzyme sources that might release crab attractants. Responses of crabs were used in conjunction with SDS PAGE analysis to test alternative hypotheses about crab attractant molecules. One hypothesis was that potency of attraction was inversely proportional to the amount of protein remaining visible on the gel. The other hypothesis was that potency was due to specific interactions of enzymes and substrates and not necessarily proportional to the amount of protein remaining on the gel.

Attraction to Enzyme Digests of Gastropod Flesh

Overall, whelk flesh is more potent than clam flesh in attracting *C. vittatus* (Figure 1). All whelk flesh treatments attracted crabs as effectively as whelk flesh treated with trypsin ($G < 3.84$, $p > 0.05$, 1 *df*, for all treatments). In contrast, crabs were not attracted to frozen and thawed *M. mercenaria* flesh ($G = 70.30$, $p \ll 0.01$, 1 *df*) or to *M. mercenaria* flesh treated with trypsin ($G = 13.5$, $p < 0.01$, 1 *df*). Clam flesh treated with chymotrypsin attracted 16 crabs, significantly fewer than those attracted to trypsinized whelk flesh ($G = 7.8$, $p < 0.01$, 1 *df*).

Enzymes alone, in amounts equivalent to enzymes in treatments, were compared to responses to whelk flesh and trypsin in field assays. Neither trypsin (four crabs) nor chymotrypsin (no crabs) attracted crabs ($G > 30$, $p < 0.01$, 1 *df* for both enzymes).

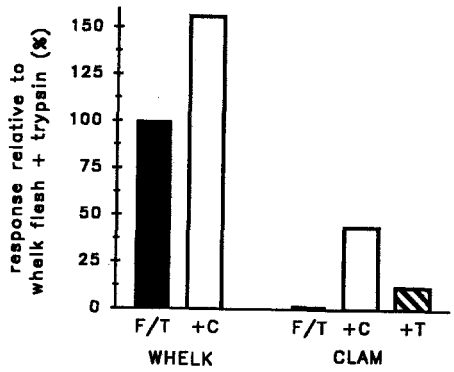

FIG. 1. Responses of *C. vittatus* to *B. carica* or *M. mercenaria* flesh. Frozen and thawed = (F/T); Hydrolyzed by trypsin = +T or chymotrypsin = +C. Assays compared the attractiveness of each treatment with the attractiveness of *B. carica* flesh + trypsin. Actual number of crabs responding (treatment: *B. carica* + trypsin) were: whelk F/T, 15:15 ($G = 0.00$, $p > 0.05$, 1 *df*), whelk + C, 28:18 ($G = 2.19$, $p > 0.05$, 1 *df*), clam F/T, 1:57 ($G = 70.3$, $p \ll 0.01$, 1 *df*), clam +C, 16:36 ($G = 7.89$, $p < 0.01$, 1 *df*), clam + T, 2:17 ($G = 13.55$, $p < 0.01$, 1 *df*).

Attraction to Complex Digests of Mollusc Flesh

Whelk and clam flesh, when treated with a trypsin-chymotrypsin mixture, were equally effective in attracting the crabs ($G < 0.67$, $p > 0.05$, 1 *df*, for both flesh types; Figure 2). Hydrolysis of both flesh types with salivary gland homogenate was also as effective as *B. carica* flesh treated with trypsin ($G < 1.20$, $p > 0.05$, 1 *df*, for both flesh types; Figure 2).

In control tests, comparing the enzymes alone to whelk flesh plus trypsin, both trypsin-chymotrypsin (two crabs) and salivary gland homogenate alone (no crabs; see also Rittschof et al., 1990b) were unattractive ($G > 12$, $p < 0.01$, 1 *df*, for both enzymes).

Thus, all enzymatic treatments of whelk flesh generated responses by crabs that were comparable to responses generated by trypsinized whelk flesh. In contrast, *M. mercenaria* flesh did not attract significant numbers of crabs when frozen and thawed or when treated with trypsin. Clam flesh treated with chymotrypsin was attractive, but significantly less potent than whelk flesh treated with trypsin. Clam flesh treated with either the chymotrypsin–trypsin mixture or the salivary gland extract was as potent as trypsin-treated whelk flesh.

Mollusc Flesh Protein Characterization

Presentation of assay materials in dialysis bags limits crab attraction to molecules < 14 kD. Thus, characterization of proteins by gel electrophoresis detecting molecules > 14 kD is an indirect method of determining the amounts

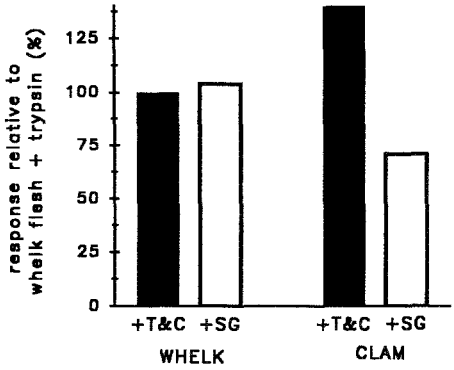

FIG. 2. Responses of *C. vittatus* to *B. carica* or *M. mercenaria* flesh when treated with enzyme mixtures. Field assays were conducted to compare the attractiveness of each treatment with *B. carica* flesh + trypsin. +T&C = +trypsin and chymotrypsin, +SG = +salivary gland homogenate. Actual number of crabs responding (treatment: *B. carica* + trypsin) were: whelk + T&C, 54:54 ($G = 0.00, p > 0.05$, 1 *df*), whelk + SG, 26:25 ($G = 0.02, p > 0.05$, 1 *df*), clam + T&C, 14:10 ($G = 0.67, p > 0.05$, 1 *df*); clam + SG, 17:24 ($G = 1.20, p > 0.05$, 1 *df*).

of material that become available for crab attraction. Densitometry tracings of the gels containing treatments of whelk flesh and clam flesh (Figure 3) were analyzed to determine major protein bands, sensitivity to enzymatic digestion, and potency of total peptides versus specific peptides (Table 1 and see below).

In gel analysis, fresh *B. carica*, unattractive to crabs (Rittschof et al., 1990b), provided a reference protein banding pattern. Fresh *B. carica* flesh contained eight major protein bands of 240, 210, 190, 170, 105, 60, 50, and 40 kD (Figure 3A). Freezing and thawing of flesh released more proteins into solution as indicated by the higher staining intensities. Only the 50 kD protein occurred in lower concentration in the frozen and thawed treatment than in the fresh flesh treatment. The commercially purified enzymes (trypsin, chymotrypsin, and trypsin–chymotrypsin mixture) effectively hydrolyzed all bands and digested over 90% of the total protein. The salivary gland homogenate hydrolyzed approximately 40% of the high molecular weight (>150 kD) proteins and over 90% of 50 kD protein (Table 1A).

Fresh *M. mercenaria* flesh, like fresh *B. carica* flesh, is unattractive to crabs. It provided a standard for protein composition and a reference protein banding pattern. Fresh *M. mercenaria* flesh contained major protein bands of 240, 210, 190, 150, 105, 90, 80, and 40 kD. Freezing and thawing of the flesh promoted minimal hydrolysis. Trypsin, chymotrypsin, and the trypsin–chymotrypsin mixture hydrolyzed all major bands and digested 50% of the proteins. Salivary gland homogenate caused minimal hydrolysis of the high

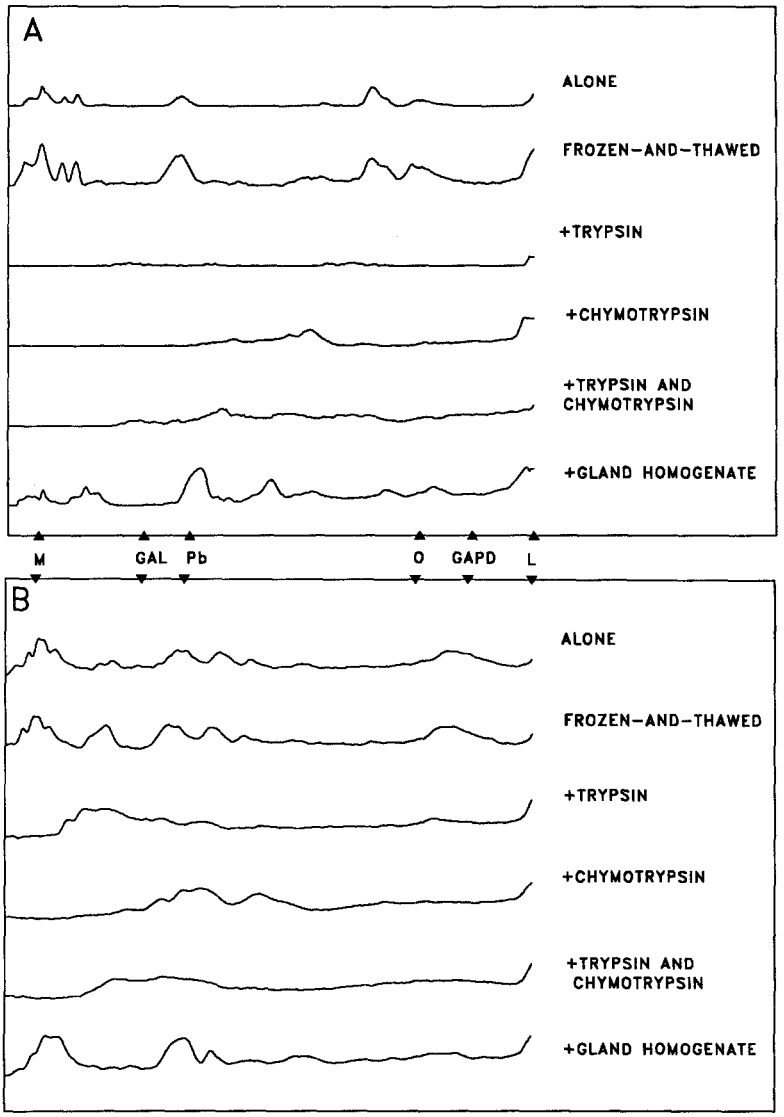

FIG. 3. Densitometry traces from SDS PAGE analysis of protein extracts. (A) *B. carica* proteins extracted from fresh flesh, frozen and thawed flesh, and fresh flesh after incubation for 90 min with catalytic amounts of enzymes. (B) *M. mercenaria* proteins treated as above. The purified enzymes, when presented alone in the same catalyztic amounts as used during incubation, gave no bands. Salivary gland homogenate, when presented similarly, showed bands in the 105–120 kD region. Position of marker proteins are provided between panels. M = rabbit myosin heavy chain, 212 kD, GAL = beta-galactosidase, 116 kD, Pb = phosphorylase b, 97 kD, O = chicken ovalbumin, 45 kD, GAPD = glyceraldehyde 3-phosphate dehydrogenase, 36 kD, L = α-lactalbumin, 14 kD.

TABLE 1. SENSITIVITY OF PROTEINS TO HYDROLYSIS AND EXPECTED AND ACTUAL POTENCY OF TREATMENTS[a]

Treatment	Protein hydrolysis: protein size and (hydrolysis level)	Estimated percent protein exclusion	Expected potency	Actual potency
A. *B. carica* flesh				
Alone	NA	0	Low	Low
Frozen and thawed	50 kD (+)	10	Low	High
+Trypsin	All (+ +)	>95	High	High
+Chymotrypsin	All (+ +)	90	High	High
+Trypsin and chymo.	All (+ +)	90	High	High
+Salivary gland homogenate	170–240 kD (+) 50 kD (+ +)	10	Low	High
B. *M. mercenaria* flesh				
Alone	NA	0	Low	Low
Frozen and thawed	190–240 kD (0)	5	Low	High
+Trypsin	All (+)	50	Moderate	Low
+Chymotrypsin	All (+)	50	Moderate	Moderate
+Trypsin and chymo.	All (+)	70	Moderate	High
+Salivary gland homogenate	190–240 kD (0) 40 kD (+ +)	10	Low	High

[a]Protein size and extent of protein hydrolysis (0 = minimal, + = moderate, + + = extreme) were determined from the desitometry tracings of gels (Figure 1). Percent of protein hydrolyzed to less than 14 kD (dialysis membrane exclusion limit) was estimated from the gels and used to predict expected potency of treatments. Treatments, with < 14 kD proteins comprising 0–20% of total protein, were predicted to be of low potency, 21–40%, moderate potency, and 41–60%, high potency. Predicted potency could be compared to actual biological potency as recorded in field assays (Figures 2 and 4). Treatments which elicited herrmit crab responses of 0–33% were considered to be of low potency, 34–68%, moderate potency, 69–100, high potency.

molecular weight proteins and 10% hydrolysis of the 40 kD protein. Comparison of bioassay data with gel analysis indicates that the level of crab attraction was not inversely proportional to the total amount of protein on the gel (Table 1B). Salivary gland homogenate had minor effects on the baseline protein banding patterns of both whelk and clam flesh but generated potent crab attractants. The frozen and thawed treatment had minor effects on protein banding patterns and effectively generated attractants from whelk flesh, but not from clam flesh. In contrast, trypsin strongly affected the protein banding patterns of both flesh types, but trypsin-treated clam flesh did not attract crabs. Treatment of clam flesh with either chymotrypsin or the trypsin–chymotrypsin mixture altered banding patterns and attracted crabs. Alteration in the 50-kD protein band in whelk flesh and the 40-kD band in clam flesh appeared to correlate with crab attractant potency.

This first series of experiments suggested that both the enzyme and the substrate were important in generating crab attractants. The whelk substrate (the more potent of the mollusc substrates) was composed of two major components, muscle proteins, and blood proteins. In the next series of experiments, each of these components was separated into two fractions and digested with trypsin to determine which fraction produced the most potent attractants when treated with the enzyme.

Attraction to Digests of B. carica *Muscle and Blood Proteins*

The following experiments attempted to further characterize the specific trypsin substrate within *B. carica* flesh. When equal amounts of the fractions were digested by trypsin and presented in field assays, muscle proteins were far more effective substrates than hemolymph or hemocyanin (Figure 4). The intermediate ionic strength muscle precipitate, treated with trypsin was over 2.5 times as potent as flesh treated with trypsin ($G = 9.15$, $p < 0.01$, 1 df). The low ionic strength muscle precipitate treated with trypsin was equally as effective in attracting crabs as flesh treated with trypsin ($G = 0.017$, $p > 0.05$, 1 df). Both precipitates contain proteins of 40–50 kD that are hydrolyzed by both trypsin and salivary gland homogenate (Rittschof et al., 1990a,b). Trypsinized blood proteins, hemolymph and hemocyanin, were significantly less attractive than trypsinized whelk flesh ($G = 12.08$, $p < 0.01$, 1 df; $G = 29.13$, $p << 0.01$, 1 df).

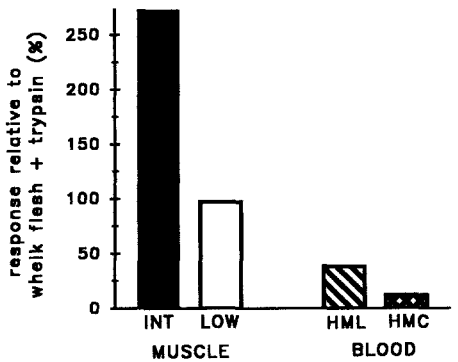

FIG. 4. Responses of *C. vittatus* to *B. carica* muscle and blood proteins after treatment with trypsin. Field assays were conducted to compare the attractiveness of each treatment with the attractiveness *B. carica* flesh + trypsin. Actual number of crabs responding (treatment: *B. carica* + trypsin) were: INT = intermediate ionic strength precipitate, 30:11 ($G = 9.15$, $p < 0.01$, 1 df), LOW = low ionic strength precipitate, 29:30 ($G = 0.017$, $p > 0.05$, 1 df), HML = hemolymph, 16:42 ($G = 12.08$, $p < 0.01$, 1 df), HMC = hemocyanin, 5:42 ($G = 29.13$, $p << 0.01$, 1 df).

Attraction to Digests of Ovalbumin

If the specificity of crab attraction resides in the enzyme, then any substrate of sufficient quantity and complexity, digested by the appropriate enzyme, should attract crabs. Ovalbumin was chosen as a test substrate for this hypothesis. Ovalbumin is approximately the same molecular size as the potential cue substrates—40 kD band from clam and 50 kD band from whelk. Ovalbumin was digested with trypsin, chymotrypsin, a mixture of trypsin and chymotrypsin, and salivary gland homogenate. All treatments were tested in field assays.

All enzymes were effective in cleaving ovalbumin into smaller units which collected in the dye front of the gel (Figure 5). Chymotrypsin was most effective. It eliminated the native ovalbumin band at 45 kD, generating >90% protein < 14 kD. Trypsin and the trypsin–chymotrypsin mixture were moderately effective, yielding 20% and 40% protein < 14 kD.

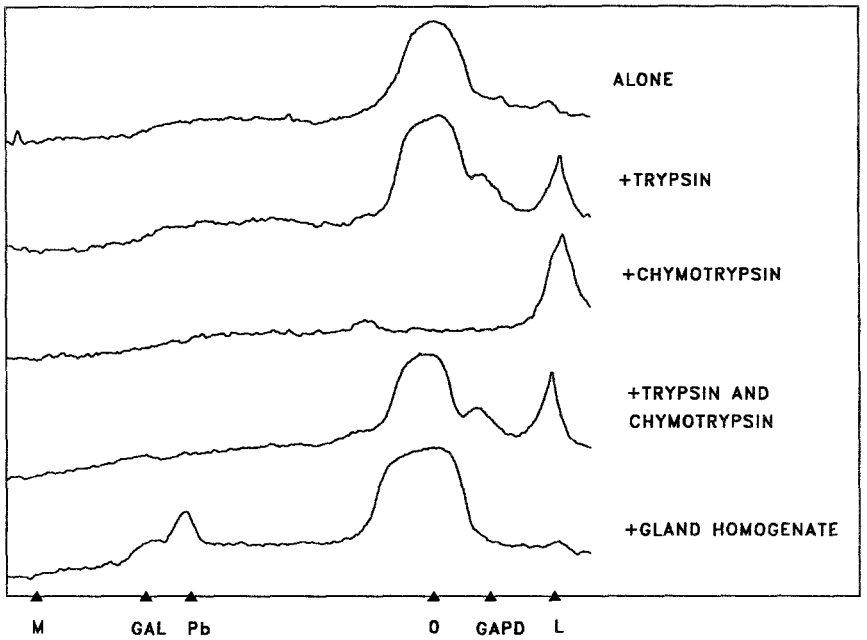

FIG. 5. Densitometry traces from SDS PAGE analysis of ovalbumin. Ovalbumin is presented alone and after incubation for 90 min with catalytic amounts of enzymes. Catalytic amounts of purified enzymes, when presented alone, gave no bands. The salivary gland homogenate, when presented similarly, showed bands in the 105–120 kD region. Position of marker proteins are provided below the panel. M = rabbit myosin heavy chain, 212 kD, GAL = beta-galactosidase, 116 kD, Pb = phosphorylase b, 97 kD, O = chicken ovalbumin, 45 kD, GAPD = glyceraldehyde 3-phosphate dehydrogenase, 36 kD, L = α-lactalbumin, 14 kD.

Overall, in field assays, none of the ovalbumin treatments was as effective as *B. carica* flesh + trypsin in attracting the crabs (Figure 6). Ovalbumin hydrolyzed by chymotrypsin was not attractive ($G = 28.88$, $p << 0.01$, $1df$) even though over 90% of the protein was cleaved to molecules smaller than the dialysis bag exclusion limit. Ovalbumin cleaved with trypsin did not attract crabs even though an amount of the protein was available for detection. In contrast, ovalbumin hydrolyzed by the salivary gland homogenate and ovalbumin treated with the trypsin–chymotrypsin mixture were minimally attractive, attracting 14 crabs ($G = 7.90$, $p < 0.01$, 1 *df*) and 22 crabs ($G = 15.33$, $p < 0.01$, 1 *df*), respectively.

Attraction to Specific Peptides Generated by Proenzyme Activation

Many proteolytic enzymes are activated from proenzymes by proteolytic cleavage that generates small peptides. The next two series of experiments tested the hypothesis that peptides, released upon activation of proenzymes from the predatory snail, could be crab attractants. The proenzymes used in the experiments are well characterized and the cleavage peptides released are known. Two proenzymes, trypsinogen (Figure 7) and chymotrypsinogen, were tested in field assays. *C. vittatus* was attracted to trypsinogen only when activated by enterokinase, generating the hexapeptide, Val-$(Asp)_4$-Lys ($G = 0.224$, $p > 0.05$, 1 *df*). *C. vittatus* was not attracted to the reactants alone nor to other product mixtures ($G > 5.88$, $p < 0.05$, 1 *df*, for all assays). *C. vittatus* was not attracted

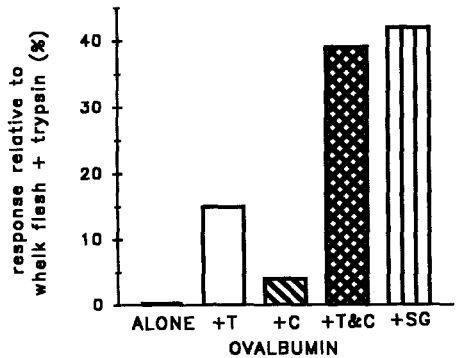

FIG. 6. Responses of *C. vittatus* to ovalbumin when presented alone or when treated with enzymes. Field assays compared the attractiveness of each treatment with the attractiveness of *B. carica* flesh + trypsin. Actual number of crabs responding (treatment: *B. carica* + trypsin) were: ovalbumin alone, 0:16 ($G = >20$, $p < .01$, 1 *df*), +T = +trypsin 3:20 ($G = 14.07$, $p < 0.01$, 1 *df*), +C = +chymotrypsin, 1:26 ($G = 28.88$, $p << 0.01$, 1 *df*), +T&C = +trypsin and chymotrypsin, 22:56 ($G = 15.33$, $p < 0.01$, 1 *df*), +SG = +salivary gland homogenate, 14:33 ($G = 7.90$, $p < 0.01$, 1 *df*).

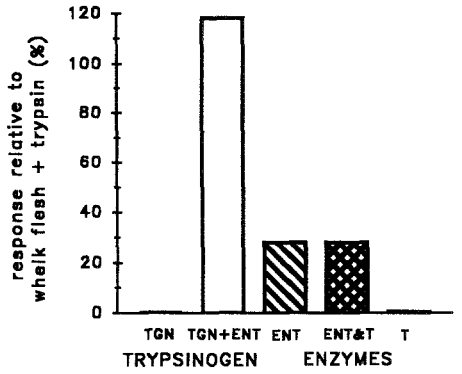

FIG. 7. Responses of *C. vittatus* to trypsinogen–enterokinase incubation, generating Val-(Asp)4-Lys. Five field assays were conducted to compare response to the standard (*B. carica* flesh + trypsin) with response to treatments. Actual number of crabs responding (treatment: *B. carica* + trypsin) were: TGN = trypsinogen alone, 0:24 ($G = 33.27$, $p < 0.01$, 1 *df*), TGN + ENT = trypsinogen activated by enterokinase, 20:17 ($G = 0.244$, $p > 0.05$, 1 *df*), ENT = enterokinase alone, 4:14 ($G = 5.88$, $p < 0.05$, 1 *df*), ENT&T = enterokinase and trypsin, 4:14 ($G = 5.88$, $p < 0.05$, 1 *df*), T = trypsin, 4:64 ($G > 6$, $p < 0.01$, 1 *df*).

in any of the chymotrypsinogen preparations, including the chymotrypsinogen–trypsin incubation (generating serylarginine and threonylasparagissl; Bohinski, 1987), the reactants alone, or the products alone ($G > 13$, $p < 0.01$, 1 *df*, for all assays).

DISCUSSION

The main purpose of this study was to extend our understanding of the substrate/enzyme interactions that generate hermit crab attractant peptides. The experiments show that generation of attractant cues by trypsin and chymotrypsin is substrate dependent. Experiments with endogenous enzymes of frozen and thawed flesh also support this assertion. All three types of enzymes generate attractants from whelk flesh, but not from clam flesh. Analysis of attractive properties of partially purified whelk muscle and blood proteins treated with trypsin (see also Rittschof et al., 1990b) shows that there are at least several protein substrates within whelk flesh that can be cleaved by trypsin to generate crab attractants. Muscle is more effective than blood as a substrate for attractants. Evolutionarily, muscle protein has two obvious advantages over blood protein as substrate: (1) collectively, muscle proteins are far more abundant and diverse than blood proteins, (2) tryptic digestion of muscle proteins generates many small peptides, each capable of escaping the dialysis bag as a chemical

messenger (Rittschof et al., 1990a,b) whereas tryptic digestion of hemocyanin (approximately 90% of total blood protein) generates only two large peptides of 50 kD and 55 kD (Brouwer et al., 1979) molecules, too large to escape from the dialysis bag and, thus, unable to act as chemical messengers.

Single enzyme additions have specific substrate requirements for the effective generation of crab attractants. Trypsin cleaves after arginine and lysine whereas chymotrypsin cleaves after aromatic amino acids (Bohinski, 1987). Specific substrate requirements are relaxed significantly by the use of enzyme mixtures. Mixtures of chymotrypsin and trypsin produce attractants equally well from both clam and whelk flesh. Similar to the effects of single enzymes on clam flesh, digestion of ovalbumin with either trypsin or chymotrypsin alone does not produce crab attractants. Digestion of ovalbumin with the enzyme mixtures generates crab attractants. Enzyme mixtures may generate different peptides (not just more peptides, see gel analysis). This suggests that complex enzyme mixtures can work on a broad spectrum of protein substrates to generate attractants. Enzymatic addition of snail salivary gland homogenate, containing a complex mixture of digestive enzymes (R.L., Ohio Wesleyan and D.R., Duke University, in preparation) produced crab attractants from both clam and whelk flesh as well as from ovalbumin.

Gel analysis shows that there is substantial variability in sensitivity of the major mollusc flesh proteins to enzymatic degradation. The 40 kD proteins and 50 kD proteins of *B. carica* and *M. mercenaria*, respectively, are likely candidates as substrates for cue generation. Crabs were attracted to the treatments in which these proteins were obviously degraded: frozen and thawed whelk flesh, whelk flesh + salivary gland homogenate, and clam flesh + salivary gland homogenate. Purification of the 50 kD protein from *B. carica* and purification and characterization of salivary gland enzymes are planned future studies for determining native crab attractants.

Coupling the above observations with electrophoretic analysis of protein degradation indicates that it is not the absolute amount of protein degradation that attracts crabs, but rather it is the generation of specific peptides (Table 1). This conclusion is supported by the experiments showing that treatments with extensive protein degradation are not always potent and that the single hexapeptide, Val-$(Asp)_4$-Lys, released in low concentration during trypsinogen activation, is as effective as whelk flesh + trypsin at attracting crabs. Although complex mixtures of peptides may function in crab attraction in the native system, a single peptide fragment can serve as a potent crab attractant.

In contrast to trypsinogen activation, which releases a single hexapeptide, chymotrypsinogen activation releases two dipeptides. These dipeptides do not attract *C. vittatus*. They may be too small or have a sequence that does not convey the correct information. Dipeptides are potent cues in other crustacean

systems (for a review, see Rittschof, 1990). Thus, it is more likely that the sequence information is incorrect.

Shell attractant responses have been studied in many species of hermit crabs (see Table 5 in Rittschof, 1980b). In each case, responses of hermit crabs are highly specific. Each species of crab responds only to cues generated from the flesh of certain species of gastropod (McLean, 1974; Rittschof, 1980a). Although it is unclear exactly how such information is stored in the signal molecules, it is clear from the data presented here that detailed discrimination is possible.

There are several molecular mechanisms that could explain how crabs discriminate between shell species by peptide released from flesh. Discrimination could be based upon differences in the relative proportions of peptides. Alternatively, specificity could reside within the peptide sequence, as has been shown for scores of peptide hormones (Litwack and Norman, 1987), for leukocyte attractants (Shiffman, 1982; Unson et al., 1984), and for peptide mimics of crustacean larval release pheromones (Rittschof et al., 1985, 1989, 1990a; Forward et al., 1987; De Vries et al., 1989) and barnacle settlement pheromones (Tegtmeyer and Rittschof, 1989). Studies that use pure peptides and that identify native crab attractant cues will resolve this issue.

(Received March 25, 1991; accepted July 29, 1991)

Abstract—*Oreina cacaliae* (Chrysomelidae) sequesters in its elytral and pronotal defensive secretion the *N*-oxides of pyrrolizidine alkaloids (PA *N*-oxides) from its food plant *Adenostyles alliariae* (Asteraceae). [^{14}C]Senecionine *N*-oxide was applied for detailed studies of PA *N*-oxide sequestration. An average of 11.4% of total radioactivity is taken up by individual beetles which had received [^{14}C]senecionine *N*-oxide with their food leaves 8 days before. An average of 28.9% of the ingested radioactivity could be recovered from the defensive secretions collected twice, i.e., 5 and 8 days after tracer feeding. The tracer transfer into the secretion seems to be a slow but progressive process as indicated by the high percentage of tracer still recovered from the secretion sampled after 8 days. Chromatographic analysis revealed that [^{14}C]senecionine *N*-oxide is the only labeled compound in the defensive secretion. Beetles that fed on tertiary [^{14}C]senecionine sequestered only trace amounts of radioactivity (exclusively present as labeled *N*-oxide) in their secretions. *O. speciosissima*, a species also adapted to PA containing food plants, was shown to sequester [^{14}C]senecionine *N*-oxide with the same efficiency as *O. cacaliae*. *O. bifrons*, a specialist feeding on *Chaerophyllum hirsutum* (Apiaceae), rejected PA treated leaf samples already at very low PA concentrations (10 nmol/leaf piece). In both *O. cacaliae* and *O. speciosissima*, [^{14}C]senecionine *N*-oxide applied by injection into the hemolymph is rapidly transferred into the glands. *O. bifrons*, not adapted to

pyrrolizidine alkaloid containing plants was unable to sequester [^{14}C]-senecionine *N*-oxide in the secretion but rapidly eliminated the tracer with the frass. Again, only traces of labeled [^{14}C]senecionine *N*-oxide were found in the defensive secretions of the two PA adapted species if labeled senecionine was injected. It is suggested that the beetles are adapted to the *N*-oxide form of PAs, similarly as their food plants, and that they lack the ability to efficiently *N*- oxidize tertiary PAs. No indication for *de novo* PA synthesis by the beetles was found in tracer feeding experiments with the biogenetic PA precursor putrescine.

Key Words—*Oreina*, Chrysomelidae, leaf beetle, defensive secretion, alkaloid sequestration, pyrrolizidine alkaloid *N*-oxides, tracer feeding, [^{14}C]senecionine *N*-oxide.

INTRODUCTION

Pyrrolizidine alkaloids (PAs) are a group of plant secondary compounds which are receiving much attention in the study of insect–plant relationships (see Boppré, 1986, 1990; Schneider, 1987). Although it is likely that they are produced by plants as protective agents against herbivory, some plant feeders have evolved to cope with these compounds or even use them for their own protection or as pheromone precursors. Well-known examples are the arctiid moths and the danaid and ithomiine butterflies.

The leaf beetle *Oreina cacaliae* (Chrysomelidae) was recently shown to sequester plant-derived PAs in the form of their *N*-oxides (PA *N*-oxides) in its defensive glands (Pasteels et al., 1988a). This is the first time that PAs have reported to be involved in exocrine chemical defense. Leaf beetles are specialist herbivores and chemically defended, but sequestration of plant chemicals for defense has been established unambiguously in only a few of them (Pasteels et al., 1988b), e.g., the sequestration in hemolymph and eggs of cucurbitacins and conjugates by cucumber beetles (Galerucinae, Luperini; Ferguson and Metcalf, 1985).

In the subfamily Chrysomelinae, defensive compounds are typically biosynthesized *de novo* and stored in pronotal and elytral glands (Pasteels et al., 1988b). *Oreina cacaliae* was the first example of host plant influence on these secretions. It feeds on *Adenostyles alliariae*, *Senecio fuchsii*, and to a lesser extent on *Petasites paradoxus* (all members of the Asteraceae) but sequesters in its secretions exclusively PA *N*-oxides derived from *A. alliariae* (Rowell-Rahier et al., 1991). *O. cacaliae* does not synthesize the cardenolides found in the secretions of all the other species of the genus and of most members of the related genus *Chrysolina* (van Oycke et al., 1987, 1988; Rowell-Rahier et al., unpublished). Most interestingly, a second species, *O. speciosissima*, feeding on the same host plants as *O. cacaliae*, was also found able to sequester PA

N-oxides from *A. alliariae* but to still possess the capability for *de novo* cardenolide biosynthesis (Rowell-Rahier et al., 1991).

In this study, we investigated by means of ^{14}C-labeled senecionine and its *N*-oxide the ability of *O. cacaliae* to sequester PAs. Labeled PAs were offered either orally or administered by injection into the hemolymph in order to circumvent the gut barrier. In addition, the ability to sequester and *N*-oxidize the tertiary PAs and to synthesize PAs *de novo* was tested. For comparison, *O. speciosissima* and the related *O. bifrons*, a species not adapted to PA-containing plants which feeds on *Chaerophyllum hirsutum* (Apiaceae), were included in the experiments.

MATERIAL AND METHODS

Insects

The beetles were collected in May and June 1988/89 and kept at room temperature on their host plants or at 4°C for 1 to 3 weeks until use.

O. cacaliae specimens originated from Wasserliesen (Vosges, France) and Zastler (Schwarzwald, Germany), *O. speciosissima* from La Lécherette (Vaud, Switzerland) and Zastler (Schwarzwald, Germany), and *O. bifrons* from Hohwald (Vosges, France).

Radioactive Tracers

[^{14}C]Senecionine (1.07 GBq/mmol) and its *N*-oxide were prepared biosynthetically from [1,4-^{14}C]putrescine (4.4 GBq/mmol) using root cultures of *Senecio vulgaris* according to Ehmke et al. (1988). Labeled putrescine was obtained from Amersham Buchler (Braunschweig, Germany).

Tracer Feeding Experiments

The beetles were placed individually in Petri dishes (5 cm diam.), kept at room temperature (20–22°C) and fed during 24 hr with a disk (1 cm diam.) or a piece of host plant leaf treated with 10 μl of a methanolic solution of [^{14}C]senecionine *N*-oxide (8.3 kBq/μl) or [^{14}C]senecionine (8.7 kBq/μl). After 24 hr, the frass and leaf remains were collected, and the beetles were transferred to fresh untreated host plant leaves. This transfer was repeated every day until the end of the experiment. Frass and defensive secretions were collected at the time intervals given in the results section. At the end of the experiment, the beetles were deep frozen prior to chemical extraction.

Injection of Labeled Compounds

An ethanolic solution (0.5 μl) of [^{14}C]senecionine *N*-oxide (1.0 kBq/μl) or 1 μl of [^{14}C]senecionine (0.8 kBq/μl), or 1 μl of [1,4-^{14}C]putrescine (2.1 kBq/μl) was injected into the abdominal cavity of the beetles with a 1 μl-microsyringe (Hamilton) or a individually calibrated micropipette. The beetles were subsequently treated as described above.

Collection of Defensive Secretions

The beetles were manipulated with fine forceps in order to provoke emission of the secretion which was collected on filter papers and immediately placed in MeOH until analysis.

Alkaloid Extraction

Individual deep-frozen beetles were ground with 2.0 ml acidic MeOH (1% HCl) and quartz sand in a mortar for 10 min. The homogenate was suspended in a total volume of 5.0 ml acidic MeOH and after centrifugation the supernatant was used directly for analysis of total radioactivity by scintillation counting or TLC-analysis. Frass samples were extracted in the same way.

Thin-Layer Chromatography (TLC)

MeOH solutions of secretions and crude MeOH extracts of beetles and frass were analyzed by TLC and evaluated quantitatively by means of a TLC multichannel analyzer (Rita-32a, Raytest). Separation was obtained on Silica gel 60 Merck) using the solvent system: CH_2Cl_2:MeOH:NH_4OH (25%) (82:15:3, by vol).

High Pressure Liquid Chromatography (HPLC)

Reverse-phase ion-pair HPLC (Wagner et al., 1986) was used to separate PA *N*-oxides according to Hartmann et al. (1988). ^{14}C-labeled PA *N*-oxides were detected with the HPLC radioactivity monitor LB-506D (Berthold) equipped with a 2 ml flow-cell and the split-mixer LB-5035.

RESULTS

Sequestration of Orally Fed [^{14}C]Senecionine N*-Oxide and [^{14}C]Senecionine by* O. cacaliae

In order to study the efficiency of PA uptake and storage, leaf-disks of *A. alliariae* treated with [^{14}C]senecionine *N*-oxide and [^{14}C]senecionine were offered individually to *O. cacaliae* beetles. The beetles consumed the leaf-disks

usually within 24 hr and were subsequently allowed to feed on untreated food leaves. Specimens with pre-emptied glands were employed. The defensive secretions were collected 5 days after the beginning of the experiment and in the *N*-oxide feeding experiment again 3 days later and were analyzed and compared with the MeOH-soluble radioactivity found in the frass and the bodies of the beetles (Table 1). In spite of great individual variation which is probably mainly due to differences in feeding behavior and activity, the data clearly show that a considerable proportion of the tracer is ingested by the beetles, i.e., an average of 11.4% (senecionine *N*-oxide) and 4.8% (senecionine). Only trace amounts of radioactivity could be recovered from the secretions of beetles that fed an tertiary [^{14}C]senecionine, whereas an average 28.9% of ingested radioactivity was found in the secretions of beetles that fed on [^{14}C]senecionine *N*-oxide. The tracer transfer into the secretion seems to be a slow and progressive process as indicated by the high percentage of tracer still recovered from the second secretion sampled after 8 days. Chromatographic analysis of the secretions revealed absolutely pure [^{14}C]senecionine *N*-oxide. Not even traces of labeled tertiary senecionine or any other metabolite could be detected (Figure 1A). Reversed-phase ion-pair HPLC confirmed the purity; neither labeled seneciphylline *N*-oxide nor any other potential derivative of senecionine *N*-oxide could be detected. On the other hand in crude beetle extracts, [^{14}C]senecionine *N*-oxide was always found to be accompanied by at least trace amounts of labeled senecionine and polar metabolites ($R_f < 0.1$; Figure 1B).

TABLE 1. DISTRIBUTION OF MeOH-EXTRACTABLE RADIOACTIVITY (MEAN % ± *SD*) AFTER INGESTION OF EITHER [^{14}C] SENECIONINE *N*-OXIDE OR [^{14}C] SENECIONINE BY *O. cacaliae*. EACH INDIVIDUAL BEETLE WITH PRE-EMPTIED GLANDS WAS FED WITH 8.3 kBq ([^{14}C] SENECIONINE *N*-OXIDE) OR 8.7 kBq ([^{14}C] SENECIONINE) DEPOSITED ON LEAF-DISCS (*A. alliariae*). AFTER 24 hr, THE BEETLES WERE ALLOWED TO CONTINUE FEEDING ON UNTREATED LEAVES

Percent in secretion[a]		28.9 ± 11.4	

[a] 100% = Total radioactivity in the beetles (secretions + beetle extracts).

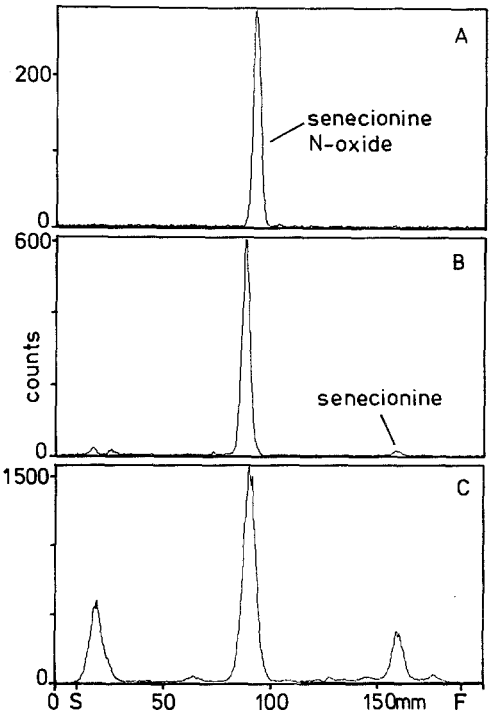

FIG. 1. Sequestration and elimination of [^{14}C]senecionine *N*-oxide fed orally to *O. caliae*. TLC separation of crude MeOH extracts of A: defensive secretion, B: beetle extracts, C = frass (24 hr) extracts. Detection: TLC radioscanning.

The trace amount of radioactivity found in the secretions of [^{14}C]senecionine fed beetles was exclusively in the *N*-oxide form, whereas extracts of these beetles were found to contain mainly tertiary [^{14}C]senecionine and only a small proportion of the *N*-oxide (ca. 20% of total alkaloid in the body).

The total amount of MeOH soluble radioactivity eliminated by the beetles with the frass during 2 days was on average 23.9% (*N*-oxide fed) and 22.3% (senecionine fed), respectively. Most of the radioactivity was eliminated during the first 24 hr (Table 1, Figure 1). Within two days, the elimination of radioactivity decreased to a level of less than 1% per day (Figure 1). Chromatographic analysis of frass extracts showed that during gut passage considerable amounts of [^{14}C]senecionine *N*-oxide were reduced to tertiary senecionine and degraded to polar metabolites (Figure 1C). Only trace amounts of the *N*-oxide form were detected in frass extracts of beetles that fed on [^{14}C]senecionine.

The proportion of total radioactivity recovered as MeOH soluble com-

pounds from secretions, beetles, and frass is on average only about 27% of radioactivity given (Table 1). Apparently, considerable proportions of the tracers fed are transformed into MeOH insoluble material. The fate of insoluble radioactivity has not been followed in the course of the present experiments; however, in comparable feeding studies with *Tyria jacobaeae* (Biller et al., unpublished), the loss of labeled senecionine *N*-oxide into insoluble material occurred most probably during the gut passage, and its endproducts were found to be associated with the frass.

In a second experiment, designed in the same way as that shown in Table 1, ten beetles that were "milked" prior to the tracer feeding were compared to ten individuals that were not "milked." The results show that the incorporation into the secretion is significantly lower (ten times) in the beetles with full glands (1.6% ± 1.1) than in those with empty glands (13.9 ± 8.4) (data not shown).

Sequestration of Orally Fed [^{14}C]senecionine N-*oxide by* O. speciosissima *and* O. bifrons

With *O. speciosissima* beetles fed on labeled senecionine *N*-oxide, results were obtained which are comparable to those described above for *O. cacaliae*. *O. bifrons*, a specialist feeding on *Chaerophyllum hirsutum* (Apiaceae), that during its life history never gains access to pyrrolizidine alkaloids, behaves differently. At alkaloid *N*-oxide concentrations of 10 nmols per leaf disk, the concentration at which the tracer was applied, nine out of ten beetles rejected their alkaloid-treated host plant, whereas control beetles fed well on untreated leaves. No radioactivity was found in the secretions collected from the one individual that was willing to feed on a treated leaf.

Sequestration of Injected [^{14}C]Senecionine N-*Oxide by* O. cacaliae, O. speciosissima, *and* O. bifrons

To test the ability of the three species to sequester and excrete senecionine *N*-oxide, ^{14}C-labeled *N*-oxide was directly injected into the hemolymph of the beetles. The distribution of radioactivity in frass, secretion, and beetle was analyzed (Table 2). The results are given individually for nine specimens in each series, to demonstrate the variability between replicates. To some extent, this variability is due to the difficulty of reproducibly injecting 0.5 μl into the abdominal cavity of the beetle. Nevertheless, the results clearly show that 5 days after injection, considerable amounts of radioactivity are in the defensive secretions and bodies of *O. cacaliae* and *O. speciosissima*. Another part of the radioactivity is rapidly eliminated with the frass. This elimination seems to be more rapid in *O. cacaliae*. Here, only trace amounts of radioactivity were detected in the frass collected on the second day, whereas in *O. speciosissima*, substantial amounts of radioactivity were measured in the frass of the second

TABLE 2. DISTRIBUTION OF MeOH-EXTRACTABLE RADIOACTIVITY AFTER INJECTION OF [^{14}C] SENECIONINE *N*-OXIDE INTO *O. cacaliae*, *O. speciosissima*, AND *O. bifrons*. THE BEETLES (NINE INDIVIDUAL SPECIMENS WITH EMPTY GLANDS) WERE EACH INJECTED WITH 0.6 µl TRACER (ca. 0.5 kBq) AND WERE ALLOWED TO CONTINUE FEEDING ON THEIR RESPECTIVE HOST PLANTS

day. *O. bifrons*, not adapted to pyrrolizidine-containing plants, is, as expected, unable to sequester [^{14}C]senecionine *N*-oxide either in the body or in the secretion. It is, however, as efficient as the other two species in eliminating injected alkaloid from its body. Most of the radioactivity is voided with the frass within the first 24 hr (Figure 2).

Analysis of the different fractions again revealed [^{14}C]senecionine *N*-oxide as the only labeled compound in the defensive secretions, whereas in beetle extracts, a considerable amount of unknown labeled polar metabolites was detected in addition to the *N*-oxide.

Only trace amounts of [^{14}C]senecionine *N*-oxide were found in the secretions of *O. cacaliae* if labeled senecionine was injected instead of its *N*-oxide.

Injection of [^{14}C]*Putrescine into* O. cacaliae

To test the ability of the beetle to synthesize *de novo* pyrrolizidine alkaloids, ten beetles were injected with labeled putrescine, a known alkaloid precursor. In none of the beetles was activity found in the secretions, nor could any traces of alkaloid be detected.

DISCUSSION

[^{14}C]senecionine *N*-oxide is efficiently taken up by *O. cacaliae* and translocated via the exocrine glands into the defensive secretion. On its way from the gut into the secretion, it has to pass at least two sets of membrane barriers,

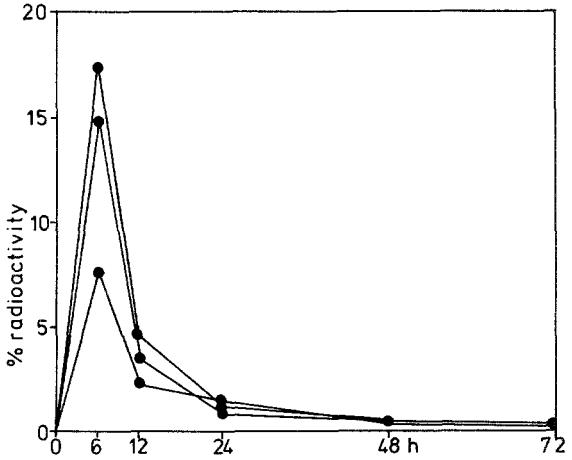

FIG. 2. Time course of occurrence of radioactivity in the frass of *O. cacaliae* following administration of [^{14}C]senecionine *N*-oxide. The tracer was fed orally on *A. alliariae* leaf disks.

the gut epithelium and the gland cell membranes. The rapid uptake of the PA *N*-oxide from the gut and its accumulation in the beetle seems to be followed by a slow and continuous transfer into the defensive glands (see Table 1). This transport is highly specific in two respects: (1) [^{14}C]Senecionine *N*-oxide is recovered from the defensive secretion in a virtually pure state. No labeled transformation or degradation products are detectable. This is in accordance with the observation that PA *N*-oxides from food plants such as *Adenostyles alliariae* and *Senecio fuchsii* are taken up rather unspecifically by the beetle, but only the PA *N*-oxides acquired from *A. alliariae* are transferred into the glands (Rowell-Rahier et al., 1991). (2) Only the *N*-oxide form is translocated into the secretion, not even traces of the tertiary form being detectable (see Figure 1A). This is in good agreement with the identification exclusively of PA *N*-oxides in the secretions of *O. cacaliae* collected in nature (Pasteels et al., 1988a; Rowell-Rahier et al., 1991). In this respect, *O. cacaliae* behaves like other specialized PA sequestering insects, e.g., *Tyria jacobaeae* (Ehmke et al., 1990) and *Creatonotos transiens* (von Nickisch-Rosenegk et al., 1990; Hartmann et al., 1990). In contrast to these insects, however, which easily transform tertiary PAs into the respective *N*-oxides and thus are able to sequester the tertiary form with the same efficiency as the *N*-oxide, *O. cacaliae* does not possess this ability. If labeled senecionine is offered orally or administered by injection into the hemolymph, only traces of radioactivity (exclusively [^{14}C]senecionine *N*-oxide) are detected in the secretions.

This once again emphasizes the physiological importance of the *N*-oxide form of the pyrrolizidine alkaloids in plants as well as in adapted insects. Plants are known to synthesize PAs as *N*-oxides (Hartmann and Toppel, 1987) and to use the polar, salt-like *N*-oxide as the molecular form for specific transport and cellular accumulation (Hartmann et al., 1989). Carrier-mediated membrane transport has been demonstrated for PA-containing plants (*Senecio vulgaris*) (Ehmke et al., 1988) as well as for PA-sequestering insects (*Creatonotos transiens;* Wink and Schneider, 1988). Characterization of the two different carrier systems present in *O. cacaliae* and *O. speciosissima*, i.e., of the gut epithelia cell membranes and the gland cell membranes, will be challenging tasks.

It is surprising that *O. speciosissima* sequesters orally fed or injected [^{14}C]senecionine *N*-oxide with same efficiency as *O. cacaliae*, but it confirms previous findings (Rowell-Rahier et al., 1991). In nature, *O. speciosissima* feeds preferentially on *Petasites paradoxus*, the leaves of which contain no PAs or at least amounts undetectable with our analytical methods (Rowell-Rahier et al., 1991). Specimens collected in nature are reported to sequester either no PA *N*-oxides (Pasteels et al., 1988a) or only very small amounts, which represent the PA pattern found in *A. alliariae* (Rowell-Rahier et al., 1991). On the other hand, in contrast to *O. cacaliae*, *O. speciosissima* still synthesizes cardenolides (Rowell-Rahier et al., 1991). Why does not *O. speciosissima* use in nature its ability to sequester PAs, and why has it evolved if it is not used? These are

intriguing questions which must await a better understanding of the biological significance of this sequestration.

Sequestration in the glands does not seem to have evolved as a detoxification mechanism, since the absolute amount sequestered is negligible compared to the amount ingested and excreted. Furthermore, the mechanisms which eliminate the polar *N*-oxides from the body via the gut seem to be as efficiently developed in unadapted beetles, e.g., *O. bifrons*, as demonstrated by the injection experiment (see Table 2).

The role of PA *N*-oxide sequestration in defense is suggested by the facts that it occurs in secretions which are known to be defensive in related chrysomelids, and that in *O. cacaliae* PAs have completely replaced the production of other toxins, i.e., cardenolides. PA *N*-oxide concentrations as high as 0.3 mol/l reported for the secretion of *O. cacaliae* (Rowell-Rahier et al., 1991) should ensure an efficient protection, judging by the concentrations found in other sequestering insects. In caterpillars of *Tyria jacobaeae* the PA *N*-oxide concentrations may reach concentrations of 10 mmol/kg fresh weight (Ehmke et al., 1990). The tissue concentrations are somewhat higher if we consider the integument as the major site of PA *N*-oxides storage. PAs are said to be strong repellents for a wide range of animals (Boppré, 1986). A convincing example is the giant tropical orb spider *Nephila clavipes*, an important potential predator of butterflies. *Nephila* cuts out field-caught Ithomiinae unharmed from its web, but readily eats freshly emerged adults, which are still free of PAs (Brown, 1984). A *Nephila* bioassay is now used, because the spider rejects sensitively PA-protected butterflies, but eats most other "unpalatable" aposematic insects. *O. bifrons* used in the experiments described here is a second example. Amounts of senecionine *N*-oxides as low as 10 nmol offered with a piece of food leaf prevented the beetles from feeding. For comparison, no feeding deterrency was observed when senecionine or monocrotaline and their *N*-oxides were offered in amounts of 40 μmol per leaf disk to the PA-adapted *O. cacaliae* and *O. speciosissima* (Rowell-Rahier et al., 1991).

The PA *N*-oxides found in the defensive secretions are acquired defensive chemicals which are exclusively derived from the food plant. There is no indication of *de novo* synthesis of PA *N*-oxides by the beetles. Furthermore, there is no evidence for chemical modification of acquired PA *N*-oxides, as documented recently for insect-specific PA *N*-oxides. The callimorphines in *Tyria jacobaeae* (Ehmke et al., 1990) and the creatonotines of *Creatonotos transiens* (Hartmann et al., 1990) are synthesized by the insects from a necine base acquired from the plant, esterified with a necic acid of insect origin.

Abstract—The glandular trichome/methyl ketone-mediated insect resistance of the wild tomato, *Lycopersicon hirsutum f. glabratum* C.H. Mull, accession PI 134417, to *Manduca sexta* (L.) and *Leptinotarsa decemlineata* (Say) was shown to affect adversely *Trichogramma pretiosum* Riley. Adult *T. pretiosum* were killed by direct contact with PI 134417 foliage and by exposure to its volatiles. This effect was greatly reduced or eliminated by removing the exudate of the glandular trichomes from the foliage. 2-Tridecanone, a principal consituent of the foliar glandular trichomes of PI 134417, was toxic to adult *T. pretiosum* at concentrations similar to those associated with PI 134417 foliage. Incubation of parasitized *Helicoverpa (=Heliothis) zea* (Boddie) eggs on PI 134417 foliage or 2-tridecanone-treated filter paper significantly reduced the proportion of eggs producing adult parasitoids. Similarly, incubation of parasitized *H. zea* eggs on filter paper treated with 2-undecanone, another constituent of the glandular trichomes of PI 134417, caused an increase in the percentage of host eggs containing dead parasitoid pupae.

Key Words—*Lycopersicon hirsutum f. glabratum*, tomato, glandular trichomes, *Trichogramma pretiosum*, Hymenoptera, Trichogrammatidae, plant-insect interaction, 2-tridecanone, 2-undecanone.

INTRODUCTION

Host plant resistance and biological control have often been cited as compatible tactics in pest management programs (Bergman and Tingey, 1979; Obrycki, 1986). Although host plant resistance is compatible with, and may enhance, biological control of insect pests in many situations, there are many situations in which they are not compatible. Recent research has identified a number of cases in which plant defense characters adversely affect organisms of the third trophic level (Campbell and Duffey, 1981; Duffey and Bloem, 1986; Obrycki, 1986; Price, 1986; van Emden, 1986). Indeed, adverse effects extending to organisms of the fourth trophic level have been demonstrated (Orr and Boethel, 1986). Thus, alteration of plant characters to achieve resistance to insect pests can affect the level of biological control of not only the resisted species, but also other pests not directly affected by the resistance (Kauffman and Kennedy, 1989a,c). Consequently, pest management programs using insect resistant varieties as one component must take into account possible adverse effects on biological control.

Plant resistance characters can affect natural enemies either directly, through contact with the resistant plant, or indirectly, through plant effects on the herbivores that render them more or less suitable as hosts or prey for their natural enemy. Among the parameters that cause direct effects, foliar morphology (Obrycki and Tauber, 1984; Keller, 1987) and plant volatiles (Altieri et al., 1981; Boethel and Eikenbary, 1986) are characteristics that have been shown to adversely affect predators and parasitoids. Perhaps the most consistent pattern to emerge from research on tritrophic level interactions is that high densities of foliar trichomes interfere with the effectiveness of small parasitic or predaceous arthropods (Obrycki, 1986; Kauffman and Kennedy, 1989b).

Foliage of the wild tomato, *Lycopersicon hirsutum f. glabratum* C.H. Mull, accession PI 134417, is characterized by a high density of Type VI (Luckwill, 1943) glandular trichomes, that mediate resistance to the tobacco hornworm, *Manduca sexta* (L.) (Lepidoptera: Sphingidae), and the Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae). Resistance to these insects is due largely to the presence of the 13-carbon methyl ketone, 2-tridecanone, in the tips of these trichomes (Kennedy and Yamamoto, 1979; Williams et al., 1980; Dimock and Kennedy, 1983; Kennedy and Dimock, 1983; Kennedy and Sorenson, 1985, Kennedy et al., 1985; Fery and Kennedy 1987; Kennedy and Farrar, 1987). The trichomes also confer a limited degree of resistance to the tomato fruitworm, *Helicoverpa* (=*Heliothis*) *zea* (Boddie) (Lepidoptera: Noctuidae), although higher levels of resistance to this pest are conferred by lamellar-based factors (Kennedy and Dimock, 1983; Dimock and Kennedy, 1983; Kennedy, 1986; Farrar and Kennedy, 1987a, 1991). The foliar trichomes of PI 134417 do contain quantities of 2-tridecanone that are poten-

tially lethal to *H. zea.* However, because of the means by which exposure to this chemical occurs (primarily through vapors) neonate *H. zea* larvae experience only a narcotizing dose, from which ca. 80% of them soon recover (Kennedy and Dimock, 1983; Kennedy, 1984; Kennedy et al., 1987). The 11-carbon methyl ketone, 2-undecanone, also found in type VI trichomes of PI 134417, is active against *H. zea* and several other pest species (Dimock et al., 1982; Farrar and Kennedy, 1987b, 1988; Lin et al., 1987). 2-Undecanone is both less abundant than 2-tridecanone in PI 134417 (Kauffman and Kennedy, 1989a,b) and less acutely toxic to *H. zea* (LD_{50} = 64.19 $\mu g/cm^2$ on filter paper vs. 17.05 $\mu g/cm^2$ for 2-tridecanone; Dimock et al., 1982). 2-Undecanone however, synergizes the activity of 2-tridecanone against neonate *H. zea*, and also causes high rates of pupal mortality in *H. zea* (Farrar and Kennedy, 1987b, 1988).

Kauffman and Kennedy (1989b) found that parasitism by *Trichogramma* spp. (Hymenoptera: Trichogrammatidae) was a major cause of egg mortality for *H. zea* on cultivated tomato, *L. esculentum* Mill., in the field in North Carolina, but was significantly reduced on resistant PI 134417 plants. They also found reduced levels of parasitism on plant lines with elevated densities of glandular trichomes but no methyl ketones, indicating a likely inhibition of *Trichogramma* by physical effects of trichome densities. However, the lowest rates of parasitism were on PI 134417 and other lines with both methyl ketones and the highest trichome densities. Therefore, they could not determine whether this reduction in parasitism was due entirely to increased trichome density or if the methyl ketones were also involved. Recently, Kashyap et al. (1991) found that rates of movement of *T. pretiosum* Riley on PI 134417 were greatly reduced, and entanglement of wasps in trichome exudate greatly increased, compared to insect-susceptible plant lines. These findings suggest that physical effects of the trichomes could potentially explain all or most of the inhibition of *Trichogramma* on PI 134417 foliage. One implication of these findings is that it may be possible to reduce these effects in insect-resistant tomato cultivars by selecting for decreased trichome density but increased levels of 2-tridecanone per trichome.

Despite the evidence for physical effects of the glandular trichomes of PI 134417 on *Trichogramma*, there remains the potential for toxic or repellent effects of 2-tridecanone and 2-undecanone. Kauffman and Kennedy (unpublished data), using chemically treated filter paper, found an LC_{50} for 2-tridecanone to *T. pretiosum* of approximately one-tenth of the concentration found on PI 134417 foliage. There are, therefore, levels of 2-tridecanone in PI 134417 foliage that are potentially lethal to *Trichogramma*. A reduction in physical effects achieved by breeding for fewer trichomes but more 2-tridecanone per trichome could thus be negated by toxic or repellent effects of 2-tridecanone. This study was therefore undertaken to further evaluate the potential of 2-tridecanone and 2-undecanone to kill or repel *T. pretiosum*.

MATERIALS AND METHODS

H. zea eggs were obtained from a stock culture initiated from field-collected insects and maintained on semi-synthetic diet (Burton, 1970) for less than 1 year. *T. pretiosum* was obtained from a laboratory culture maintained on *H. zea* eggs. In all tests, 0- 24-hr-old *T. pretiosum* adults were used.

Foliage of PI 134417 and *L. esculentum* cv. "Better Boy" was obtained from plants raised in the greenhouse using a commercial soil mix (Metro Mix 220®). Plants were watered daily and fertilized weekly (Peters Professional® fertilizer, 20-20-20 (N-P-K) at 2.8 g/plant). Natural daylengths were supplemented to 16 hr by light from metal halide lamps.

Direct Effects of Foliage on Adult T. pretiosum. The effect of resistant PI 134417 foliage on the mortality of adult *T. pretiosum* was studied by confining parasitoid adults on foliage with the exudate of the glandular trichomes removed or with the trichomes intact. Young, fully expanded foliage was collected from 8- to 10-week-old plants. To remove the trichome exudate, the foliage was first gently wiped on both surfaces with a dry cotton ball, then with a cotton ball soaked in a 0.1% aqueous solution of Triton X-155® (a non-phytotoxic emulsifying agent), then rinsed, first in a 0.1% Triton X-155 solution and finally in clean water.

Leaflets were removed from the petiole and placed on moist filter paper (Fisher brand #8®) in the inverted lid of a 5.5 cm Petri dish. The dish was then placed in a 1.0-l glass jar. Adult *T. pretiosum* were transferred in shell vials from the culture, anesthetized with carbon dioxide, and counted under a stereomicroscope. After they revived, 25 wasps were released into each jar, which was then sealed with filter paper across the top. Jars were held horizontally. Each of the four treatments, i.e. (1) PI 134417 with intact trichomes, (2) PI 134417 with trichome exudate removed, (3) Better Boy, and (4) no foliage (filter paper only), was replicated ten times. Each replicate of each treatment was in a separate jar. Jars were held at 27°C and, after 4 hr, mortality of adult parasitoids was recorded. The data were normalized using an arcsine $\sqrt{\%}$ transformation and subjected to analysis of variance (ANOVA). The Least Significant Difference (LSD) was used to test for differences among treatment means.

Because 2-tridecanone vapors are associated with PI 134417 foliage (Dimock and Kennedy, 1983; Kennedy, 1984), a study was conducted to determine if foliar volatiles from PI 134417 caused mortality of *T. pretiosum*. A moist 5.5 cm filter paper disk was folded and placed in a 30-ml clear plastic cup. One leaflet was placed in the cup and the cup was covered with a piece of nylon organdy cloth (33 × 33 threads/cm). Twenty-five anesthetized *Trichogramma* adults were transferred quickly into another cup (a small amount of a 50% honey solution was wiped on the inside as a food source) which was then inverted over the organdy cloth. The cups were held together with Parafilm® to

avoid the loss of parasitoids, moisture, and leaf volatiles. Wasps were thus separated from the foliage by the organdy. The same four foliage treatments as above were included and were replicated ten times. The test was held at 27°C and the mortality of wasps was recorded at 4 hr and 24 hr. The data were analyzed as above.

Effects of Methyl Ketones on Immature Stages of Trichogramma *in Host Eggs.* Parasitized eggs were obtained by exposing *H. zea* eggs on cheesecloth to several hundred adult *T. pretiosum* for 24 hr. Eggs were then transferred with a small brush onto excised foliage. The foliage was then placed on moist filter paper in a Petri dish and the dish was sealed with Parafilm. The same foliage treatments as above were included. Each of the foliage treatments was replicated ten times with a replicate consisting of 25 parasitized eggs on an excised leaflet. All treatments were held at 27°C. Foliage was replaced with fresh foliage at 2- to 3-day intervals. On 8 and 12 days after the initiation of the test, the number of eggs from which adult *T. pretiosum* emerged was recorded. The experiment was repeated twice.

The effects of 2-tridecanone and 2-undecanone on survival of *T. pretiosum* within *H. zea* eggs were investigated in separate experiments. Parasitized *H. zea* eggs were obtained as above. Groups of 25 parasitized eggs were placed on chemically-treated 5.5-cm filter paper disks in Petri dishes. Treatments included 2-tridecanone (Fluka Chemical Corp., Hauppauge, New York 11788) at concentrations of 22.5, 45.0 or 90.0 $\mu g/cm^2$, or 2-undecanone (Pflatz and Bauer, Inc., Stamford, Connecticut 06902) at concentrations of 4.47, 8.94, or 17.88 $\mu g/cm^2$. The methyl ketones were applied to the filter paper disks as acetone solutions at a volume of 21 $\mu l/cm^2$ and the acetone allowed to evaporate. Controls, consisting of disks similarly treated with acetone only, were included in both experiments. The rates of 45 $\mu g/cm^2$ 2-tridecanone and 8.94 $\mu g/cm^2$ 2-undecanone roughly correspond to the mean levels associated with PI 134417 foliage (Kennedy, 1986).

Treated filter paper disks and parasitized eggs were placed in inverted 5.5-cm Petri dishes and the dishes covered and sealed with Parafilm. Filter papers were replaced with freshly treated papers every third day. After 12 days at 27°C, the number of parasitized *H. zea* eggs producing adult parasitoids, as evidenced by emergence holes, was recorded. No honey was placed in the dishes since it was unnecessary to maintain emerged parasitoids. Treatments were replicated ten times.

A second experiment involving 2-undecanone was conducted and was identical to the above experiment in every respect except that the host eggs were subjected to parasitism by exposing them to *T. pretiosum* adults for only 4 hr. This was done to minimize variation in the time the eggs were parasitized. After 12 days, all eggs were dissected and examined for the presence of dead parasitoid pupae. (Preliminary examinations indicated the presence of dead pupae

in 2-undecanone-treated eggs but not in 2-tridecanone-treated eggs.) Treatments were replicated five times. Data from both of these experiments were normalized by arcsine $\sqrt{\%}$ and analyzed by ANOVA for effects of methyl ketone concentration.

Effects of Methyl Ketone on Rates of Parasitization. The effects of 2-tridecanone on rates of parasitization were studied in both no-choice and choice experiments. In the no-choice experiment, unparasitized *H. zea* eggs were placed on filter paper disks treated with 2-tridecanone (0, 45.0 or 90.0 $\mu g/cm^2$). Groups of 50 eggs were placed with ca. 40 unsexed adults of *T. pretiosum* in 1-l glass jars as above. A small amount of honey was streaked on the side of the jar to provide food for the parasitoids.

After 4 hr, mortality of *T. pretiosum* adults was recorded and each group of *H. zea* eggs was randomly divided into two groups of 25. One group was transferred to filter paper treated with 2-tridecanone at the same concentration as that to which the initial group of 50 eggs was exposed; the other group was transferred to filter paper that had been previously treated only with acetone. The chemical treatments on which the groups of 25 eggs were held are hereafter referred to as post-treatments. This procedure allowed for comparison of long- and short-term exposure periods. Eggs were held at 27°C in covered Petri dishes sealed with Parafilm. Filter papers were replaced with freshly treated papers every 3 days. The proportion of eggs producing adult *T. pretiosum* was recorded after 8 days. This experiment was replicated ten times and the data were transformed to arcsine $\sqrt{\%}$ prior to factorial ANOVA. Because a significant interaction between initial treatment and post-treatment was found, post-treatment effects were also analyzed separately.

The choice experiment was conducted as above except that each glass jar contained both 25 unparasitized *H. zea* eggs on an acetone-treated filter paper disk and 25 unparasitized eggs on a disk treated with 2-tridecanone at one of four concentrations (22.5, 45.0, 67.5, or 90.0 $\mu g/cm^2$). After 4 hr, mortality of parasitoid adults was recorded and the *H. zea* eggs were placed individually in gelatin capsules (#2 Eli Lilly and Co., Indianapolis, Indiana 46285). The eggs were held at 27°C for 14 days, and, beginning at day 7, examined daily for parasitoid emergence. Only eggs from which parasitoids emerged were classified as parasitized.

The effects of 2-undecanone on parasitization were also examined in a choice test. The procedures were identical to those described for 2-tridecanone except that the concentrations of 2-undecanone tested were 0, 4.47, 8.94, 13.41, and 17.88 $\mu g/cm^2$.

In all experiments, percentage parasitization data were transformed to arcsine $\sqrt{\%}$ and subjected to ANOVA. Data on developmental times (days from parasitization to adult wasp emergence) were also subjected to ANOVA.

RESULTS

Direct Effects of Foliage on Adult T. pretiosum. Exposure of *T. pretiosum* adults to contact with PI 134417 foliage or its volatiles caused significant mortality within 4 hr (Table 1). In the experiment in which the wasps contacted foliage, removal of the exudate of the glandular trichomes resulted in a significant reduction in mortality, but did not completely eliminate the effect of PI 134417 foliage. In the experiment in which wasps were exposed only to foliar volatiles, there was no difference in mortality between PI 134417 foliage without trichome exudate and Better Boy foliage. However, in this experiment, mortality on PI 134417 foliage without trichome exudate was greater after 24 hr than that in the experimental control (no foliage). Although visual inspection of PI 134417 foliage indicated that virtually all of the exudate of the glandular trichomes was removed, it is possible that the elevated mortality observed was due to traces of trichome constituents that were not completely removed during the washing process. Type VI glandular trichomes in tomato do not regenerate exudate after they are ruptured.

Effects of Methyl Ketones on Immature Stages of Trichogramma *in Host Eggs*. Incubation of parasitized *H. zea* eggs on PI 134417 foliage with intact glandular trichomes resulted in a significant reduction in the percentage of eggs yielding adult parasitoids in both runs of the experiment. Removal of the trichome exudate eliminated this effect (Table 2).

TABLE 1. MORTALITY OF *T. pretiosum* ADULTS FOLLOWING DIRECT CONTACT WITH FOLIAGE OR EXPOSURE TO FOLIAR VOLATILES OF TOMATO GENOTYPES RESISTANT AND SUSCEPTIBLE TO *H. zea*

[a] Test I—January, 1989; Test II—June, 1989. Eggs were on a neutral substrate when exposed for 24 hr to parasitization by adult T. *pretiosum*. Eggs were then transferred to foliage treatments for incubation.

[b] Means separation vertical; means with the same letter are not significantly different at $P \leq 0.05$ (LSD), $df = 2$.

In the experiments in which parasitized eggs were incubated on methyl ketone-treated filter paper, 2-tridecanone significantly reduced the percentage of host eggs yielding adult *T. pretiosum* (Table 3). However, the effect was seen only at the highest rate (90 $\mu g/cm^2$) tested, which represents twice the mean level commonly associated with PI 134417 foliage (Kennedy, 1986).

When eggs were subjected to parasitization by *T. pretiosum* for 24 hr and then incubated on 2-undecanone-treated filter paper, there was no significant effect on the percentage of host eggs yielding parasitoid adults (Table 3). In contrast, when eggs were subjected to parasitism for only 4 hr prior to incubation on a 2-undecanone-treated substrate, significant treatment effects were seen (Table 3). Fewer of these eggs produced one or more adult parasitoids, although the overall effect was not quite statistically significant ($F = 4.15$, $df = 1$, $P = 0.0533$). However, the effect on the percentage of eggs containing dead pupae was highly significant ($F = 15.13$, $df = 1$, $P = 0.0007$).

Effects of Methyl Ketones on Rates of Parasitization. In the no-choice test in which *H. zea* eggs on substrates treated with different concentrations of 2-tridecanone were exposed to parasitism by adult *T. pretiosum*, there was significantly greater mortality of *T. pretiosum* adults in the 2-tridecanone treatments than in the untreated controls (Table 4). There was a significant reduction in the percentage of eggs yielding adult parasitoids by the presence of 2-tridecanone during exposure of the eggs to the wasps. This effect was seen in both the 2-tridecanone and acetone only post-treatments. However, there was a highly significant treatment × post-treatment interaction (Table 4). This interaction

		4.47	7.2	82.4
		8.94	37.6	52.8
		17.88	11.2	80.0

[a]For effect of 2-tridecanone rate, $B = -0.0121$, $df = 1$, $F = 138.64$, $P = 0.0001$.
[b]For effect of 2-undecanone rate, $B = -0.0054$, $df = 1$, $F = 0.31$, $P = 0.5800$.
[c]For effect of 2-undecanone rate, $B = 0.0875$, $df = 1$, $F = 4.15$, $P = 0.0533$.
[d]For effect of 2-undecanone rate, $B = -0.1540$, $df = 1$, $F = 15.13$, $P = 0.0007$.

appears attributable to a greater reduction in the percentage of eggs producing adult *T. pretiosum* when eggs were incubated on 2-tridecanone-treated filter paper than when they were incubated on acetone-treated filter paper, indicating that immature parasitoids exposed within the host egg to 2-tridecanone died prior to emergence from the egg. These results are consistent with those of the above experiment in which eggs were parasitized on a neutral substrate and then placed on 2-tridecanone-treated filter paper.

When *T. pretiosum* adults were given a choice between *H. zea* eggs on filter paper disks treated with 2-tridecanone or acetone, they parasitized significantly fewer eggs on 2-tridecanone-treated filter paper ($F = 9.61$, $df = 1$, $P = 0.0027$; Table 5). There was a significant positive relationship between mortality of adult *T. pretiosum* and the amount of 2-tridecanone on the treated disk in the choice arena. This increasing mortality is reflected in the reduced percent parasitism of *H. zea* eggs on both the 2-tridecanone- and the acetone-treated disks (Table 5). In this experiment, increasing concentrations of 2-tridecanone on the disk on which the eggs were exposed were associated with a small but statistically significant increase in the time of emergence of adult *T. pretiosum* ($F = 115.3$, $df = 1$, $P \leq 0.0001$; Table 6).

TABLE 4. EFFECT OF 2-TRIDECANONE ON *T. pretiosum* ADULT MORTALITY AND ON EMERGENCE OF *T. pretiosum* FROM PARASITIZED *H. zea* EGGS HELD IN THE PRESENCE OR ABSENCE OF VARIOUS CONCENTRATIONS OF 2-TRIDECANONE (POST-TREATMENT)

Pre and post-treatment 2-tridecanone conc. ($\mu g/cm^2$)	(%) Adult parasitoid mortality	(%) Eggs producing adult parasitoids on post-treatment[b, c]

[a] Filter papers treated with acetone were held with 2-tridecanone treated filter papers in a 1-1 glass jar. Eggs were held on treated filter papers only during the 4 hr period of exposure to adult *T. pretiosum* after which they were transferred to gelatin capsules for incubation in the absence of 2-tridecanone.
[b] Plant rate (Dimock and Kennedy, 1983).

In a similar choice test involving eggs on 2-undecanone or acetone treated substrates, there were no significant differences in the percent parasitization of eggs on either substrate over the range of 2-undecanone concentrations tested, although there was a trend toward lower parasitization of eggs on substrates treated with higher concentrations of 2-undecanone (Table 7). There was, however, a significant positive relationship between wasp mortality and 2-undecanone concentration on the treated disk (Table 7). There was no effect of this

[a] Filter papers treated with acetone were held with 2-undecanone treated filter papers in a glass jar (1.0 1). Eggs were held on treated filter papers only during the 4 h period of exposure to adult *T. pretiosum* after which they were transferred to gelatin capsules for incubation.
[b] Plant rate (Dimock and Kennedy, 1983).

brief exposure (up to 4 hr) to 2-undecanone on development time of *T. pretiosum* ($P \geq 0.05$).

DISCUSSION

These results suggest at least a potential role for methyl ketones in the reduction of parasitism of *Heliothis* eggs on PI 134417 by *Trichogramma* spp., including *T. pretiosum*, as previously reported by Kauffman and Kennedy (1989b). Adult *T. pretiosum* contacting PI 134417 foliage or exposed to foliar volatiles of PI 134417 suffered elevated levels of mortality, an effect that was greatly reduced or eliminated by removing the glandular trichomes from the foliage. The effect of foliar volatiles is a strong indication of effects of the methyl ketones beyond physical effects of the trichomes.

In addition to effects on adult *T. pretiosum*, incubation of parasitized eggs on PI 134417 foliage resulted in fewer eggs producing parasitoid adults, apparently because of mortality of immature parasitoids within the eggs. This mortality did not occur when parasitized eggs were incubated on PI 134417 foliage from which the glandular trichomes had been removed or on *L. esculentum* foliage. These effects are also likely attributable to the methyl ketones, although it is possible that physical coating of the eggs with trichome exudate could also be a factor.

Effects similar to those associated with PI 134417 foliage were caused by methyl ketone-treated filter paper. 2-Tridecanone at concentrations commonly found associated with PI 134417 foliage caused mortality of adult *T. pretiosum* and immature *T. pretiosum* within the eggs. 2-Undecanone at rates comparable to those in PI 134417 also caused significant mortality among adult *T. pretiosum* and among developing parasitoids within host eggs. However, significant effects of 2-undecanone on immature parasitoids were seen only when host eggs were exposed to 2-undecanone following a 4-hr exposure, on a neutral substrate, to adult parasitoids, not after 24-hr exposure (Table 3). This difference may indicate that *T. pretiosum* is sensitive to 2-undecanone during its early stages of development. By way of comparison, Farrar and Kennedy (1987b, 1988) found that *H. zea* is sensitive to the toxic effects of low concentrations of 2-undecanone only if it is exposed to the chemical during the fifth larval instar. In the case of *H. zea*, the toxic effects of 2-undecanone are manifest as mortality during the larval/pupal molt and the pupal stage. The presence of dead *T. pretiosum* pupae in host eggs held on 2-undecanone-treated filter paper (Table 3) may indicate a similar pupal toxicity in *T. pretiosum*. The similarity of effects of chemically treated filter paper with those of foliage is further evidence of the potential of the methyl ketones in PI 134417 foliage to adversely affect *T. pretiosum*.

There is thus the potential for 2-tridecanone, and, to a lesser extent, 2-undecanone, in the foliage of PI 134417 to adversely affect *T. pretiosum*. The findings of Kashyap et al. (1991) indicate that, on intact foliage, these effects may be largely masked by physical effects such as inhibition of movement or entanglement of wasps. It may be possible to reduce physical effects of resistant cultivars by selecting for fewer trichomes per unit area but more 2-tridecanone per trichome. However, given the potential effects of 2-tridecanone on *T. pretiosum*, this approach would probably be of limited value.

These findings further substantiate previous findings that the methyl ketone-based resistance of PI 134417 can adversely affect organisms of the third trophic level. In the case of *H. zea*, most of the resistance factors are in the leaf lamella and are not related to methyl ketones (Farrar and Kennedy, 1987a, 1991). In cultivars with methyl ketone-based resistance, biological control of *H. zea* could thus be disrupted, so that in localities where *H. zea* is a major pest, it would thus be necessary to use cultivars with *H. zea* resistance as well. These findings should aid both in understanding the nature of tritrophic level interactions and in the successful integration of host plant resistance and biological control into pest management programs.

Abstract—Two species of termites, *Reticulitermes* (*lucifugus*) *grassei* and *R.* (*l.*) *banyulensis*, show a high degree of aggressivity toward each other. The epicuticular signature, recognized by contact, can be extracted using organic solvents, and the removal of the signature abolished all types of aggressive behavior. The signature can be transferred to lures, where it triggers interspecies aggression. It was found to be mainly present in the apolar fraction of the cuticular extracts, which contained only hydrocarbons, are determined by GC/MS techniques. Chemical recognition contributes towards isolation of the two species belonging to the *R. lucifugus* complex.

Key Words—Interspecific recognition, Isoptera, termites, *Reticulitermes*, cuticular hydrocarbons, aggression.

INTRODUCTION

In 1903, A.M. Fielde noticed that recognition between insects, such as ants, required antennal contact, and suggested that a system of chemical recognition (Fielde, 1904), and a "specific and progressive" odor exists (Fielde, 1905). Clément (1981a, 1982) described the sequences of contacts among termites

*To whom correspondence should be addressed.

0098-0331/91/1200-2397$06.50/0

Reticulitermes which release aggression, and proposed that substances present on the cuticle were involved.

The cuticle of many insects has been described in detail by Wigglesworth (1933, 1990), and the cuticular lipids have been the subject of numerous reviews (Blomquist and Jackson, 1976; Howard and Blomquist, 1982; Lockey, 1988). They describe the exoskeleton of insects as being covered in a thin layer of lipids, consisting mostly of hydrocarbons, which can be extracted using an organic solvent and separated with chromatographic methods.

These hydrocarbons, as well as serving to protect the insects against dessication, toxins of predators or invasion by microorganisms, play a part in interspecific and intraspecific recognition (Blomquist et al., 1987). They were described in terms of chemical signature among social insects by Howard and his colleagues in 1982 (1982b). Bonavita-Cougourdan et al. (1987) have demonstrated their role in recognition between individuals of *Camponotus vagus* (Scop.). Subsequent studies by Morel et al. (1988) on *Camponotus floridanus* (Buckley), and by Nowbahari et al. (1990) on *Cataglyphis cursor* (Fonsc.), have confirmed this intraspecific function among other ants.

Howard et al. (1980b, 1982a) have shown that some species of termitophiles, such as the staphylinids (*Trichopsenius frosti* Seevers, *T. depressus*, *Philotermes howardi*, etc.) which are associated with termites (*R. flavipes* Kollar and *R. virginicus* Banks) chemically mimic the cuticle of their hosts. Howard et al. (1990a) have also observed a chemical mimicry of the ant *Camponotus modoc* (Wheeler) by a dipteran parasite (*Microdon albicomatus* Novak). Recently, Howard et al. (1990b) have also proved a synthesis *de novo* of hydrocarbons by the same parasite, who mimics another ant, *Myrmica incompleta* (Prov.).

Cuticular signals are used as "camouflage" in order to penetrate termite or ant colonies with impunity. This "exceptional similarity" has also been noted among ant inquilines by Franks et al. (1990).

Espelie and Hermann (1988) have noted another example of chemical convergence between a wasp (*Parachartergus aztecus* Willink), a species of parasitic ant (*Pseudomyrmex ferrugineus* Smith) and their host plant (*Acacia collinsii* Safford). Espelie et al. (1990) have likewise observed a similarity of the cuticular hydrocarbons of a wasp (*Polistes metricus* Say) and the walls and pedicel of its nest.

Obin (1986) conducted laboratory tests on the ability of *Solenopsis invicta* (Buren) ants to distinguish between a familiar and foreign signal, but the behavioral data were not very convincing. Among these Hymenoptera, the glandular signals are very strong and may have masked the cuticular signals or be added to the cuticular hydrocarbons. The studies by Jaffe (1980) suggest that the volatile glandular secretions of *Atta cephalotes* (L.) may play an important part in the recognition mechanism. Today, many authors agree as to the presence on

the cuticle of a signal for specific, colonial, and individual recognition (Blum, 1987; Hölldobler and Carlin, 1987).

Haverty and Thorne (1989), working with different phenotypes of *Zootermopsis* (Isoptera, Termopsidae), noted a correlation between aggressive behavior and cuticular phenotypes, which has led to the separation of two subspecies of *Z. nevadensis* (Hagen), namely *Z. (n.) nevadensis* and *Z. (n.) nuttingi*. With the exception of the work of Howard et al. (1982b), Bonavita-Cougourdan et al. (1987), Morel et al. (1988), and Nowbahari et al. (1990), however, there has been little experimental proof that cuticular extracts are really active in recognition between individuals. On the other hand, these organic extracts can contain polar compounds (ethers, alcohols) and other substances not suitable for gas chromatography (steroids, amino-acids, sugars) which accompany the hydrocarbons when placed on a lure. The volatile secretions of non-cuticular glands may also be spread all over the cuticule (Howse, 1975; Blum, 1987).

The aim of this study was to examine the chemical signals responsible for recognition between the two species of the super-species *Reticulitermes lucifugus* (Rossi). These two species are at the two extremes of a circular cline in Europe (Clément, 1981b), and show aggressive behavior toward each other (Clément, 1978). *Reticulitermes (lucifugus) grassei* (Clément) inhabits southwest France, *R. (l.) banyulensis* (Cl.) southeast France; they are genetically and physiologically isolated (Clément, 1981b).

In order to understand this interspecific aggression, an ethological and chemical study was carried out, using on the one hand, various behavioral tests with living or dead individuals, and lures covered with different organic extracts separated into fractions of different polarities, and, on the other hand, chemical determination of the extracts carrying the specific signature of the termites.

METHODS AND MATERIALS

Biological Material. Colonies of *R. (l.) grassei* were collected near La Rochelle (Forêt de la Coubre, Ile d'Oléron, Charente Maritime, France), in 1986, 1987, and 1988, and colonies of *R. (l.) banyulensis* were collected near Perpignan (Banyuls, Pyrénées Orientales, France), in 1987, 1988, and 1989.

Behavioral Tests. Two series of tests were carried out. The frequencies of eight defined actions (behavioral items) were quantified and the median for each item calculated from ten replicates. At the end of each test the percentage occurrence of each of the eight actions was calculated in relation to the total number of actions. These actions were either antennal (antenna to antenna, antenna to head, antenna to body), palpating (palps to head, palps to body), the number of openings of the mandibles, the number of bites, and the number of trembling

actions. In each case, the confrontations were between a stranger introduced into an arena with 30 resident workers, randomly chosen. For each nest used in the experiment, the level of the aggressive behavior between species was quantified, using the threshold described by Clément in 1986.

Each test was followed by a control test in which a worker of the same species was introduced instead of the stranger. The worker termites were selected from the same advanced larval stage (stage 7 or 8).

In the lure experiment, the chemical extract came from the same colony as the individuals used to control the level of aggression of the resident colony.

The arena consisted of a Petri dish repeatedly washed with acetone in which was placed a filter paper kept humid. The 30 residents were placed in the arena 24 hr before the test, which was the time calculated as being necessary for them to become accustomed to it.

Series 1: Introduction of a Stranger Living, Dead, or Dead and Washed

Living individuals of the stranger species were dyed blue for the first series of tests. This was done by placing part of the colony in a dish containing a filter paper impregnated with a solution of Cresyl-blue in distilled water. The intestines of the termites become stained through their licking and eating some of the paper, and since their cuticle is transparent, the color can be easily seen. This dying technique was described by Goldberg (1971) and used by Guille-Escuret (1981), but with Neutral-red which is too similar to the natural rosy color of the termites. Preliminary tests showed that on being introduced into a group from its own colony, one of these stained individuals is totally accepted and slowly loses its coloring. The various colonies used in the test have the same level of aggressive behavior according to the threshold described previously (Clément, 1986). The stain, therefore, has no effect upon the termites' behavior. The observation period with live individuals was 5 min, because the exchanges are extremely rapid.

Tests were carried out with dead individuals, asphyxiated by nitrogen or carbon dioxide. The observation time for this test was 15 min. The dead individual was placed at the center of the arena.

Tests were also carried out with individuals killed as above. They were then rinsed in three baths of organic solvent (1 ml each) for 5 min.

The observation period was again 15 min. A preliminary study was carried out to determine the type of solvent to be used, the most appropriate extraction time, the number of individuals to be used for extraction purposes, and the amount of solvent required (Bagnères, 1989). The most suitable solvent was found to be pentane, a non-polar solvent which nevertheless extracts other more polar substances, such as fatty acids, in addition to the hydrocarbons. This solvent was then used for the washing experiments and for the following series in which extracts were obtained and deposited on another insect.

Three kinds of tests were carried out each time in both directions: with one *R.* (*l.*) *grassei* and 30 *R.* (*l.*) *banyulensis* (with one *R.* (*l.*) *banyulensis* as control), and with one *R.* (*l.*) *banyulensis* and 30 *R.* (*l.*) *grassei* (using one *R.* (*l.*) *grassei* as control). The 12 replicate tests described above (six for each species: three tests + three controls) were repeated ten times.

Series 2

In a second series of tests, a stranger was asphyxiated, washed, and dehydrated (by critical point drying/CO_2 at 72.9 atm. pressure, 31.2°C). This technique was used to avoid the problem of brittleness of the body after immersion in a solvent and was first used by Howard et al. (1982b) and then readapted by us for this study. Control chromatograms were obtained to check that all the signals from the cuticle had disappeared when a typical extract was produced. The critical-point-dried (CPD) lures (from *R.* (*l.*) *grassei* and *R.* (*l.*) *banyulensis*) were kept in a dry atmosphere in a container with Actigel (silicic acid). A single lure was used only once and received either no treatment (blank) or one kind of treatment, namely either pentane (10 μl) (true control) or a pentane extract (10 μl) of one or the other species, so that each lure was covered with the equivalent of an extract from five workers, since we calculated that in the recovery of this extract about 4/5 of the total was lost (Killian, 1989). These extracts were either total pentane extracts, or the polar fraction, or the non-polar fraction of the total extract of each species (*R.* (*l.*) *grassei* and *R.* (*l.*) *banyulensis*). The nature of these extracts is described in the section on chemical analysis. The deposition of the extract was made with a Hamilton 10 μl syringe. Each test was repeated about ten times.

Statistical Analysis. Various statistical analyses were carried out using a Statgraphics software (version 3.0). The first series of summary statistics was performed to calculate the medians of percentages together with the lower quartiles and the upper quartiles. The fit with the normal distribution was calculated for each set. To compare the various medians, the Mann–Whitney non-parametric test was chosen.

Chemical Analysis. Groups of 100 workers at the same stage were extracted with pentane (2 ml) for 5 min to obtain the extract for the ethological tests. The extracts were adjusted to a volume of 1 ml before fractionation. The extracts were either used as such when deposited on a lure or separated into fractions. Silica Sep-pak (Millipore, Waters Ass.) were used as microcolumns. The non-polar fraction was eluted first with pentane, followed by a further pentane washing, and then the polar fraction was eluted with methanol.

For the identification and quantification of the chemicals in the total extract, in both species, individual workers were counted and weighed, and 35 extracts of 100 workers each were made with each of the two species. Ten portions of

100 μl were made from each extract, to which were added 100 μl of a solution of an internal standard (800 ng of heneicosane, nC21).

The extracts were analyzed by gas chromatography (GC) on a Delsi 300 instrument equipped with a flame ionization detector (FID), a split/splitless injector (maintained splitless for 15 sec after injection), and a capillary column (25 m $\times$ 0.35 mm) coated with a 0.12 μm film of CP Si15. The carrier gas was helium at 1 bar. The temperature was isothermal at 150°C for 5 min and then programmed at 5°C/min to 320°C. The results were collected in an Enica 21 integrator.

The double-bond position in alkenes was determined by the methoxymercuration-demercuration method (Plattner et al., 1976; Blomquist et al., 1980).

Thin layer chromatography was carried out on silica impregnated with 10% silver nitrate, and developed with benzene:hexane (8:92) to separate alkanes and alkenes (Howard et al., 1978).

Compounds were identified by coupled gas chromatography-mass spectrometry (GC-MS). An identical chromatograph to that described above was coupled to a Nermag R1010C quadrupole mass spectrometer, and the data fed into an IBM PC computer using Spectral 30 software. Analysis by electron impact (at 70 ev) was followed by examination under chemical ionization using methane (0.1 Torr, 100 ev). Equivalent chain length (ECL) is calculated for each compound, using a mixture of internal standards from C20 to C38 coinjected with the total extract, and data compared with Howard et al. (1978, 1980a), Lockey (1988, 1991), Lockey and Metcalfe, (1988), Nelson et al. (1988) and Pomonis et al. (1989).

The quantification of each substance (absolute quantity and percentage of the total) was performed using a Lotus software in which the area of each peak was corrected with a response coefficient K for the FID detector (see Bagnères et al., 1990) where $K = 0.042 \times nC + 0.11$ (nC is the number of carbon atoms per molecule of the substance).

RESULTS OF TEST 1

Introduction of a Living Stranger (Table 1)

When two results on the same line have different letters beside them, the difference between them is statistically significant at least at the 95% significance level according to the Mann–Whitney test. If, on the other hand, two results on the same line have one or more letters in common beside them, the difference is not significant at the level chosen. It can be seen from these results that when a stranger-dyed individual was introduced into the group, the last five items described, but particularly the biting, increased greatly, and therefore provided the best index to measure the aggression level. The sequence occurred

very rapidly, and nine times out of ten, it ended in the death of the introduced stranger, whereas the control-dyed (from the same colony) individual in both cases was incorporated into the group immediately.

When the arena was filled with a group of *R. (l.) banyulensis* workers, they displayed a number of activities and reacted more violently than a group of *R. (l.) grassei* workers (30 biting items giving a highly significant difference between control and stranger of $p < 7 \times 10^{-5}$; 6 openings of mandibles, significantly different at $p < 3 \times 10^{-4}$). When the arena was filled with *R. (l.) grassei* workers, the difference between the scores was equally significant, but this species seems to be a little less aggressive. The experimental conditions did not affect the natural aggressive behavior between the two species.

Introduction of a Dead Stranger (Table 2)

Upon introducing a dead stranger, the same aggressive behavior was observed, but with less intensity than with the living stranger. When the arena was filled with *R.* (*l.*) *banyulensis*, the wounding score was reduced to 18, compared with 30 (above) when alive, but this was still significantly different from the controls at $p < 2 \times 10^{-4}$, and the mandible opening score dropped from 6 (above) to 2. Because the lure was immobile, the duration of the test was prolonged (5 to 15 min), so that more contacts could take place. The chemical signal which triggered aggression was therefore not due to any activities of

the stranger, but the signal lost some of its strength because the dead lure was not moving among the group in the arena and did not actively elicit aggression.

Introduction of an Individual Washed with Pentane (Table 3)

An extracted termite produced very little aggressiveness (seven biting items observed in an arena filled with *R. (l.) banyulensis* in 150 min of observation). On the other hand, this lure elicited more contacts or "grooming" with the palps, so that the remaining actions corresponded more to a preliminary feeding than to true aggression.

These results confirm the hypothesis that species recognition is based upon a chemical signal of the contact pheromone type, and not upon any movement recognition. When an individual was washed with pentane, it was not perceived differently from a control: the substances responsible for recognition are therefore soluble in pentane. In order to prove this hypothesis, however, it was necessary to transfer these substances.

RESULTS OF TEST 2

A CPD lure covered with different extracts was introduced in an arena filled with *R.* (*l.*) *banyulensis* workers. This species was chosen because it is the more aggressive of the two. First, we checked with the controls (no solvent or just pentane on the lure) compared with total extract from workers of one or the other species, that the extract from foreign *R.* (*l.*) *grassei* elicited significant aggression while that from *R.* (*l.*) *banyulensis* did not. We then proceeded to test the different fractions (either total, non-polar, or polar) on the two types of lures (Table 4a and 4b).

The tests showed that with the total extract, the origin of the lure (same or different species) did not affect the results, so that they were satisfactory tools for our tests. The washing process effectively removed all traces of the signal. Covering with an extract of workers of the same species elicited some biting, but this was nothing like the number of woundings inflicted in the case of true aggression (1% and 1.5%). Finally, covering the lure with an extract from the opposite species produced significantly more cases of biting (3.5% and 4.5%).

The extract consisting of non-polar lipids from an alien species (*R.* (*l.*) *grassei*) provoked much more aggression in every case, not only in comparison with the polar fraction, but also with the total extract (6.5% and 5%). The tests with the alien polar extract produced a significantly weaker response (2.5% and 2%).

In our first experiments, we did not collect an intermediate fraction between the non-polar and polar portions and therefore traces of hydrocarbons were carried over into the polar fraction. Aggression was then proportional to the remaining quantity of hydrocarbons. We therefore made sure that not more than 1% of the hydrocarbons remained in our polar fraction (Killian, 1989).

The decrease in the frequency of aggressive acts can be seen from the experiments to have been due to the fact that it was impossible to reproduce perfectly the natural situation: the immobility of the introduced specimen, or other parameters arising from the difficulty of transferring these substances in a natural manner, or with the accurate concentration of cuticular substances, lowers the aggression scores and raises the scores for palpations. Nevertheless, the total mixture of lipids constituted a true chemical signature for the *Reticu-*

[a] The percentages are the median number of items of each kind. A letter occurring more than once on the sam line means that the difference was not significant (Mann–Whitney test, $p < 5\%$). Numbers in parenthese refer to quartiles (lower and upper).

litermes workers, and this signature is contained to a large extent in the non-polar fraction extracted with pentane.

Results of the Chemical Investigations on the Cuticular Extracts (Table 5). These results supplement those by Lange et al. (1989). The non-polar chemical signature of *R.* (*l.*) *banyulensis* (Figure 1a) is composed of 48 hydrocarbons containing from 23 to 36 atoms per molecule, and the non-polar chemical signature of *R.* (*l.*) *grassei* (Figure 1b) is composed of 37 hydrocarbons containing from 25 to 33 carbons atoms. These hydrocarbons are principally saturated, and only a very small portion of the total are alkenes (3% in *R.* (*l.*) *b.*, and 2% in *R.* (*l.*) *g.*). The largest group are the monomethylalkanes (63% in *R.* (*l.*) *b.*, and 61% in *R.* (*l.*) *g.*), followed by the *n*-alkanes (29% in *R.* (*l.*) *b.*, and 23% in *R.* (*l.*) *g.*) and then the dimethylalkanes (5% in *R.* (*l.*) *b.* and 14% in *R.* (*l.*) *g.*). It is the latter group which differentiates most the two signatures, followed by the length of the carbon chains. The quantitative results (percentages and absolute quantities) are given in Table 5. It can be seen that 40% of the substances are common to both species, but for the greater part of these common substances, the quantities are quite different, as for example, in the case of pentacosane, 5-methylpentacosane, 5-methylheptacosane, and 5,17-dimethylheptacosane.

DISCUSSION AND CONCLUSION

This study demonstrates the following points:

1. A specific chemical signature exists on the epicuticle, and this can be extracted with pentane and transferred to a lure. This signature provokes aggression between the two species of *Reticulitermes*.

[a]The diagnostic ions of monoenes are given after methoxymercuration-demercuration, and chemical ionization (CI) was effected under (a) methane and (b) ammoniac. Percentages and quantities (ng/mg ins.) are given with the standard deviations in parentheses. CN = Carbon number, MW = molecular weight, ECL = equivalent chain length.

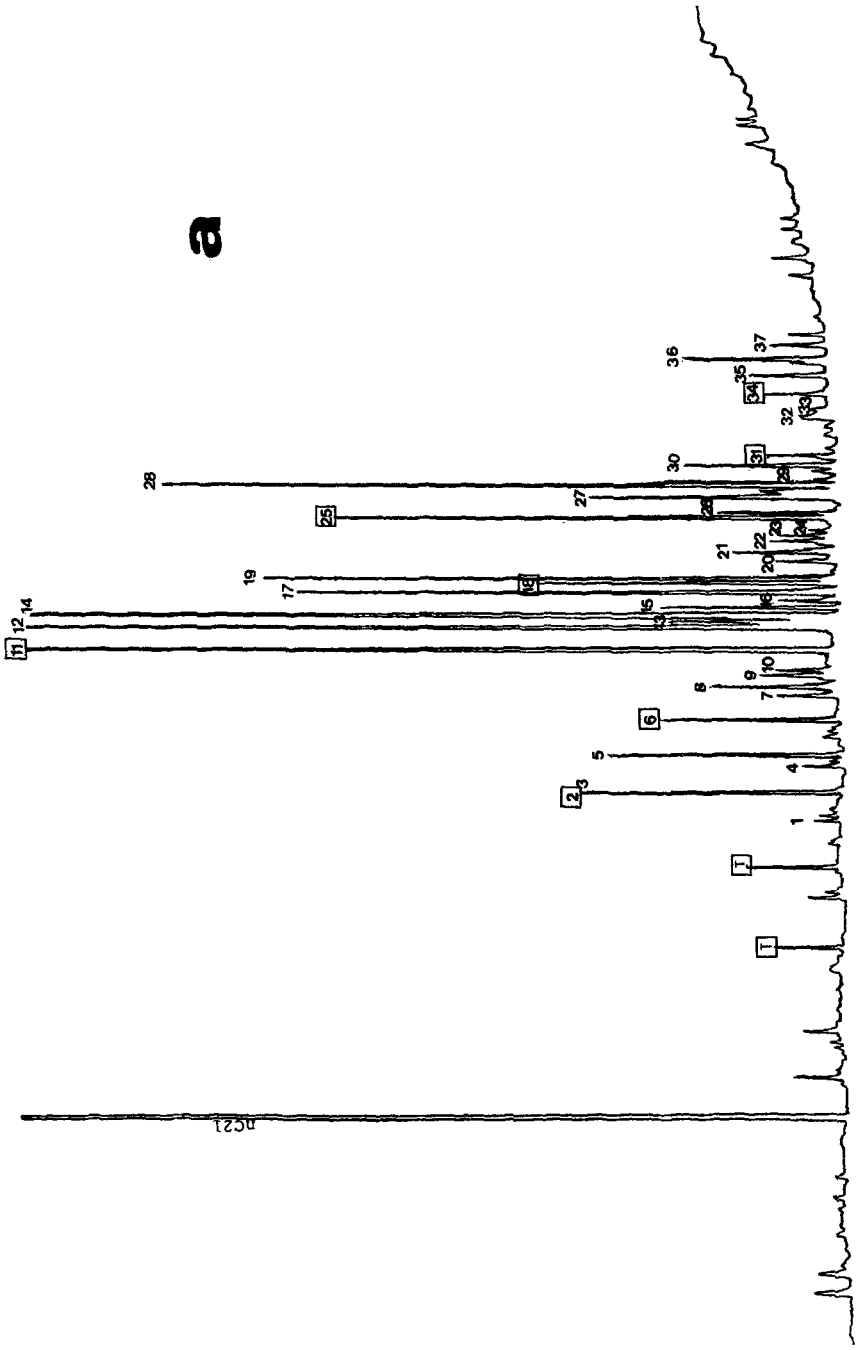

FIG. 1a. Gas chromatogram of cuticular hydrocarbons from *Reticulitermes (lucifugus) grassei*.

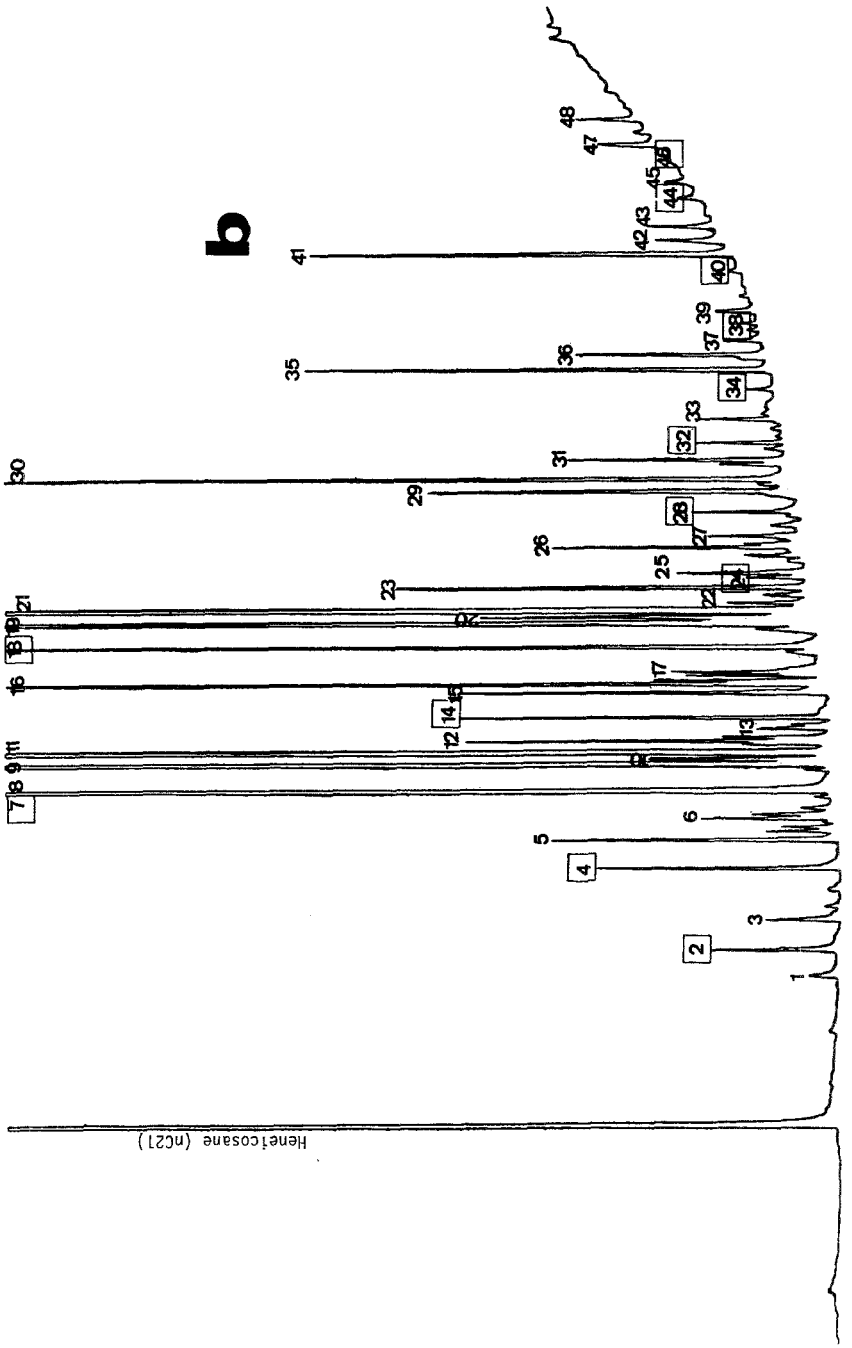

FIG. 1b. Gas chromatogram of cuticular hydrocarbons from *Reticulitermes (lucifugus) banyulensis*.

2. This signature is contained chiefly in the non-polar fraction of the epicuticular extract, which contains only hydrocarbons.

3. Contact is necessary for recognition to occur, but it is preferable for an introduced individual to be mobile, and for a natural encounter to take place.

A few studies have been published previously on aggressive behavior in termites. Those by Clément (1986) on the European *Reticulitermes* provided us here with a basis for the aggression tests, since the author measured the degree of agonism displayed by two intra- or interspecific groups brought into contact. As the result of the investigations by Howard et al. (1982b), the hypothesis was put forward that hydrocarbons may play a role in interspecies recognition between two American *Reticulitermes* species; but the most innovative findings on termite aggression were published by Nel in studies on the closure of *Hodotermes mossambicus* and *Trinervitermes trinervoides* societies (Nel, 1968). The latter author showed that in the former species the aggression displayed by a colony differs significantly depending on whether it is a natural (highly aggressive) colony, or one which has been raised under artificial conditions (non-aggression). Springhetti and Amorelli (1982) have even reported differences in the competitive behavior of *Kalotermes flavicolli* and *Reticulitermes lucifugus*, in the field and in the laboratory with opposite results in the two cases. This conclusion was not confirmed in the present study. It has been observed by us on the contrary, that *Reticulitermes* colonies or species withdraw to their galleries to avoid confrontation with strangers (Bagnères et al., 1990).

As B.L. Thorne (1982) has remarked, "the intensity of agonist encounters depends on which species, colonies and castes (and the respective ratios) are involved."

It does seem likely that hydrocarbons may be a fairly universal factor in insect inter- and intraspecies recognition. Henderson et al. (1990) have reached the same conclusion for the ant *Formica montana*, starting with a hypothesis which seems contradictory to those of most others authors, namely, that in these ants, aggression might be a raising of an inhibition created by the hydrocarbons, in which case these substances would no longer serve as triggering signals as we ourselves have concluded in the present study. The present data certainly showed that in *Reticulitermes*, no aggression is triggered when the recognition signals are missing. Aggression is actively induced by differences in the kind or the proportions of the signals, which are probably compared with a reference mixture which was memorized at emergence.

Some 10 years ago, various authors began to consider, indeed, that cuticular mixtures of hydrocarbons serve as specific markers (Carlson and Service, 1980), and up to the present, many articles have appeared on the chemotaxonomy of numerous species (Flies: Hoppes et al., 1990; Luytens, 1982; Nelson and Carlson, 1986; Nelson et al., 1988; Crickets: Castner and Nation, 1986;

Grunshawn et al., 1990; Beetles: Lockey, 1991; Page et al., 1990). The hydrocarbons have also been dealt with in a number of studies on termites, such as these on *Coptotermes* by Haverty et al. (1990a, 1991, submitted), Su and Haverty (pers. comm.), Brown et al. (1990), on *Zootermopsis* by Blomquist et al. (1979), Haverty et al. (1988), on *Nasutitermes* by Howard et al. (1988) and Haverty et al. (1990b, submitted), and on *Reticulitermes* by Howard et al. (1978, 1982b), Clément et al. (1985, 1986, 1988), Bagnères et al. (1988, 1990), and Haverty et al. (1991).

Very little is known about the mechanisms of regulation involved in chemical signatures and their genetics. Vander Meer et al. (1985), by hybridizing two species of *Solenopsis* (*S. invicta* and *S. richteri*) saw that the cuticular profiles of the hybrids were intermediate between those of the two parents.

The origin of the variations in the spectrum of the cuticular hydrocarbons of *Solenopsis* (and incidentally, the composition of the venom) has been studied by Ross et al. (1987). Bagnères et al. (1991) have observed that the hydrocarbons of the specific signatures of two species of ant were modified when these ants were kept in artificially mixed colonies, in a way that permitted them to live together in the same nest without provoking any aggression (Corbara and Errard, 1991). Likewise, Bonavita-Cougourdan et al. (1989) have transferred larvae of *Camponotus vagus* from one nest to another nest, then these larvae acquired an odor close to that of their new nest and thereby become part of it. There is therefore in these cases a possible plasticity in the specific odor and the colonial odor, or an active transfer of cuticular hydrocarbons from the postpharyngeal gland (Bagnères and Morgan, 1991).

The regulation of these processes no doubt has two origins which are not incompatible. There is a genetic or epigenetic origin and an origin through transfer, because it emerges from our work, both published and unpublished, and from the published work of others (see Howard et al., 1990b), that the secretion of cuticular hydrocarbons is clearly the direct expression of the genome, but that this can be modified through the social environment.

The modifications in this case may be due either to passive transfer (contact and rubbing) or by active transfer (licking and grooming), or to a change in the hydrocarbons synthesis (throught feedback inhibition). Among ants, the products of the postpharyngeal gland may be involved here (Bagnères and Morgan, 1991), but in termites no equivalent gland has ever been described.

It is striking to note that in spite of all the different cuticular profiles, the majority of insect species have somewhat similar profiles, which suggests that evolution of this order has favored a kind of chemical homogeneity, due perhaps to a uniformity at the level of their synthesis and regulation. This may help to explain how the degree of closure or opening of insect societies may depend on the recognition of a complex signal which can sometimes vary very subtly.

The exact sites of synthesis, the mechanisms involved in the transport of precursors and products are not yet fully understood, nor are the receptor sites and the operations taking place at a more central level of control.

To complete the present study, it is necessary to know if mixtures of some compounds are more effective than others, and to carry out tests on the insects. Thus far, a discrimination analysis between hydrocarbons and ethological results within a single superspecies (*R.* (*l.*) *g.*) and (*R.* (*l.*) *b.*) has not led to any conclusive results; it even seems that the whole mixture plays some part (Bagnères, 1989).

Acknowledgments—This study is part of a thesis of the University of Paris VI (U.P.M.C.), France, for the graduation of A.G.B. as "Docteur de l'Université P. et M. Curie," and that of A.K. with a "Diplome d'Etude Approfondie" (D.E.A.). We acknowledge the help of Mrs. C. Joulie, G. Lelait, and A. Poveda. We thank Prof. E.D. Morgan (University of Keele, U.K.) for the English translation, and also J. Blanc.

(Received May 1, 1991; accepted July 22, 1991)

Abstract—In a wind-tunnel, male Hessian flies flying toward a source of the female-produced sex pheromone exhibited flight maneuvers very similar to those described for male moths. Upwind flight, consisting of zigzagging and straight flight upwind, was initiated within seconds after flies were placed in the odor plume. This upwind flight was sometimes interrupted by casting, which consisted of wide excursions in the horizontal plane ranging 10–35 cm across the central zone of the tunnel. Comparison of the flight maneuvers of males exposed to ten female equivalents of a hexane extract of female ovipositors and males exposed to 20 ng of (2S)-(*E*)-10-tridecen-2-yl acetate (SE10-13:OAc), which has been identified as a component of the Hessian fly sex pheromone, indicated that the sex pheromone probably contains additional components. However, SE10-13:OAc elicited upwind flight and source location by a significant number of males, even at dosages as low as 2 ng on filter paper. At the highest dosage of SE10-13:OAc tested (200 ng on filter paper), there was a significant decrease in net flight velocity and a slight, but not significant, reduction in the number of males contacting the odor source. The addition of increasing amounts of the R enantiomer to the S enantiomer resulted in increased inhibition of upwind flight and source contact by males.

Key Words—Hessian fly, *Mayetiola destructor*, Diptera, Cecidomyiidae, flight, anemotaxis, orientation, olfaction, enantiomer, mating.

INTRODUCTION

During the last decade, scientists studying the responses of various species of Lepidoptera to sex pheromones have made significant progress toward understanding how male moths locate odor sources (Baker, 1989). By manipulating concentrations and blends of pheromone components and altering pheromonal plume characteristics, they have shown that behavioral thresholds are lowest for the natural blend of components (Linn et al., 1986, 1987) and that there are two main mechanisms for odor source location (Baker, 1986; Kennedy, 1986), optomotor anemotaxis, i.e., steering with respect to the wind, and self-steered counterturning. Most of these studies have been carried out using a sustained-flight tunnel, an arena that enables the researcher to measure flight responses under controlled conditions.

In contrast to moths, many other insects are either less tractable in the wind tunnel or exhibit a different set of responses to pheromones of conspecifics. Some species of beetles, for example, must fly for a certain time before they become responsive to aggregation and sex pheromones (Choudhury and Kennedy, 1980), whereas others must be starved (Bartelt et al., 1990). However, recent successes with beetles flying in the wind tunnel (Birch and White, 1988; Bartelt et al., 1990; Domek et al., 1990) indicate that behavioral mechanisms used in the location of odor sources by some species of Coleoptera may be similar to those used by moths.

In the Diptera, orientation to sex pheromones over long distances is more common in the so-called primitive flies (suborder Nematocera) than in the more advanced flies (Blomquist et al., 1987). Thus, in the families Sciaridae and Cecidomyiidae, males exposed to sex pheromones move upwind in y-tube olfactometers or individual glass cylinders (Kostelc et al., 1980; Alberts et al., 1981; Williams and Martin, 1986), whereas many species in the suborder Cyclorrhapha produce sex pheromones that do not appear to elicit long-range orientation but rather release short-range courtship (Shorey and Bartell, 1970) and copulatory behaviors (Carlson et al., 1984) or increase mating strike activity (Mackley and Broce, 1981). The exception to this trend within the Cyclorrhapha is the tephritid *Dacus oleae* (Haniotakis et al., 1977); in this species, males respond over distances of > 1 meter to the female-produced sex pheromone.

It has been known for many years that male Hessian flies, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae) respond to virgin females over distances of several meters by flying upwind (Cartwright, 1922). The utilization of a sex pheromone by this species was demonstrated by McKay and Hatchett (1984), who showed that males placed in a y-tube olfactometer responded to hexane extracts of ovipositors of virgin females. Recently, Foster et al. (1991) identified a chemical, (2S)-(*E*)-10-tridecen-2-yl acetate (SE10-13:OAc), from

an extract of Hessian fly ovipositor, that elicited upwind movement by male Hessian flies in a y-tube olfactometer.

Further work characterizing the sex pheromone of the Hessian fly required a more discriminating assay. The y-tube olfactometer, although convenient during isolation and identification of sex pheromone components, only indicates whether the addition of a compound to an airstream elicits more upwind movement than an airstream without the compound. Therefore, for studying the efficacy of sex pheromone blends and observing the actual maneuvers used by insects to locate an odor source, this technique is inadequate. The sustained-flight tunnel is a much more discriminating assay (Baker and Linn, 1984) and is especially useful for measuring subtle effects of pheromone components on flight behavior.

Herein, we describe the pheromone-mediated behavior of male Hessian flies in a sustained flight tunnel. Responses to SE10-13:OAc vs. hexane extracts of female ovipositors were compared to determine whether the sex pheromone of the Hessian fly consisted of a blend of chemicals rather than a single component. Responses of males to the R enantiomer were also of interest, because only SE10-13:OAc, and not (2R)-(*E*)-10-tridecen-2-yl acetate (RE10-13:OAc), is found in the natural pheromone (Foster et al., 1991). Finally, because the sex pheromone of the Hessian fly did appear to be a blend consisting of SE10-13:OAc plus at least one other chemical, we measured the responses of male Hessian flies to binary blends of SE10-13:OAc and three racemic mixtures of three other chemicals, (*Z*)-10-tridecen-2-yl acetate (Z10-13-2:OAc), (*E*)-10-tridecen-2-ol (E10-13-2:OH), and tridecen-2-ol (13-2:OAc), which have also been found in the active fraction of extracts of female Hessian flies (Foster et al., 1991).

METHODS AND MATERIALS

Insects. Puparia were collected in the fall of 1986 from wheat fields in Ellis County, Kansas. Although the Great Plains biotype predominates in Ellis County, other biotypes occur at low frequencies and may have been used in these experiments (biotype A and very low frequencies of B) (J. Hatchett, personal communication). However, allozyme studies on Hessian fly biotypes suggest that gene flow is not restricted among biotypes (Black et al., 1990), and hence the sex pheromone of the different biotypes is likely to be the same. This original culture was increased using the techniques outlined in Harris and Rose (1990). Virgin males and females were obtained from single sex progenies. Males emerged between 15.00 and 21.00 hours and were held overnight in groups of 20–30 in cages (10 cm diam. × 20 cm high) located in an environmental chamber (15°C and ca. 70% RH) before use in experiments. Sex pher-

omone extract was prepared by excising the ovipositors of 0-3-hr-old virgin females and extracting the ovipositors in hexane. Both adult males and females were maintained in a 15:9 (L:D) photoperiod, with lights on at 6.00 hours.

Chemicals. Racemic (*E*)-10-tridecen-2-yl acetate (E10-13-2:OAc), Z10-13-2:OAc, SE10-13:OAc, and RE10-13:OAc were synthesized by Dr. J.G. Millar (Millar et al., 1991). E10-13-2:OH was synthesized by reaction of E10-13-2:OAc with 0.5 M KOH in methanol. Racemic 13-2:OAc was supplied by Dr. R.W. Howard (U.S.D.A.-ARS, Manhattan, Kansas). Hexane solutions of the various mixtures tested in the wind tunnel (Figure 4) were prepared with the dosage of SE10-13:OAc held constant at 20 ng and were checked by capillary gas chromatography prior to use. The ratios used in these mixtures were designed to cover the range observed in extracts of Hessian fly ovipositors (Foster et al., 1991). In contrast, the mixtures of SE10-13:OAc and RE10-13:OAc (also based on a constant dosage of 20 ng SE10-13:OAc) were prepared by weight (and subsequent volumetric dilution) and were not checked by gas chromatography because of the inability of the capillary column (30 m × 0.25 mm Supelcowax, Supelco Inc., Bellefonte, Pennsylvania) to resolve the enantiomers.

Testing Protocol. Pheromone-mediated behaviors of male Hessian flies were quantified in a sustained-flight tunnel based on the design of Miller and Roelofs (1978). The Plexiglass™ tunnel was 182 cm in length, 42 cm in height, and 50 cm wide, with a ca. 1 cm layer of moist soil on the bottom. Soil was used because Hessian fly males are small (ca. 0.5 mg and 4 mm in length) and susceptible to entrapment by electrostatic charges on Plexiglas surfaces. Illumination was provided by a series of six Verilux (Greenwich, Connecticut) full-spectrum fluorescent tubes mounted directly above a light diffusing screen. Light intensity on the floor of the tunnel was measured at 290 microwatts/cm^2 by a United Detector Technology Model 61 Radiometer (Hawthorne, California). The wind speed in the tunnel was measured at 0.3 m/sec (Model AB-27 Teledyne hot-wire anemometer, Teledyne Hastings-Raydist, Hampton, Virginia). The plume, which was visualized with smoke generated from burning incense, was located in the middle of the bottom of the tunnel and contacted the soil surface throughout its length. Widths of the plume, just downwind of the source and upon exiting the tunnel, were ca. 1.5 and 15 cm, respectively. Room temperature was held at 22 ± 1°C.

Males (10–18 hrs old) were allowed to acclimate to the temperature of the wind tunnel room for at least 1 hr before being tested between 07.00 and 10.00 hours. This test period was chosen because it corresponds with the time at which (1) males show higher levels of spontaneous flight activity, and (2) females call, thereby emitting sex pheromone (Bergh et al., 1990). An individual male was removed from a cage using an aspirator and placed in a brass screen cylinder (2.5 cm diam × 3.5 cm length) that had screening at one end and was open at the other end. The cage was then placed (open end upwind) in the center of the

wind tunnel, 85 cm downwind of the odor source. The odor source consisted of a rectangular strip of filter paper (ca. 0.5 × 2 cm) mounted on a partially straightened paper clip, 3 cm above the soil surface. Synthetic pheromone or ovipositor extract was applied to the downwind edge of the paper strip. Males were scored for: taking flight out of the cage (activation), apparent within-plume flight for >10 cm, upwind displacement to within 50, 15, and 2 cm of the source, and source contact. Wing fanning, a pre-flight behavior commonly observed in studies of pheromone-mediated responses of moths, was not evident in male Hessian flies. Observations were terminated when the male (1) remained still in the cage for more than 1 min, (2) contacted the walls of the tunnel, or (3) flew out of the back of the tunnel. Preliminary observations showed that Hessian fly males that lost the pheromone plume typically flew to the side of the tunnel and sat for periods of at least 5 min, and exhibited little, if any, sexual activity. The times from the introduction of the fly into the odor plume to (1) taking flight out of the cage, and (2) to contacting the source were also recorded. Once males contacted the odor source, they were removed from the wind tunnel and were not tested again.

Because of the relatively rapid release rates of volatile chemicals from filter paper sources, only five males were tested for each filter paper source; this procedure was usually completed within ca. 5 min. After each group of five males was tested, a thin layer of fresh soil was added to the tunnel floor and sprayed with a fine mist of water. Flies were tested in a randomized complete block design with five successive males per block per treatment. After testing hundreds of males, we found no evidence to suggest that the soil substrate became contaminated with sex pheromone during the five successive flights to a single source; that is, the last male flying to the source was not more or less likely to contact the source than the first male. Between 45 and 75 males were tested with each of the extracts, chemicals, and chemical blends.

Mean latencies to taking flight and to contacting the source were compared by one-way ANOVA. When the ANOVA indicated significant differences among treatments, 95% confidence intervals were used to separate means. Differences in the distributions of males in response categories were tested using G tests or 2 × 2 or R × C tests of independence using the G statistic, with adjusted G's when there were only two treatments being compared (Sokal and Rohlf, 1969), or by logistic ANOVA (McCullagh, 1980) when variances were sufficiently small to warrant such an analysis.

RESULTS

Description of the Flight Maneuvers of Male Hessian Flies. When placed in the odor plume of ovipositor extract, male Hessian flies took flight within ca. 6 sec and initiated upwind flight. This flight occurred at a height of ca.

2–6 cm above the soil surface and varied, sometimes consisting of narrow zigzags (counterturning with significant resultant progression; see Kennedy, 1986) and at other times appearing to be straight flight upwind (track angles near 0°). Upwind flight was sometimes interrupted by casting (counterturning with no significant net progression upwind; see Kennedy, 1986), which, in the male Hessian fly, consisted of wide sweeps in the horizontal plane, ranging ca. 10–35 cm across the central zone of the tunnel. Frequently, casting was followed by the male again locating the odor plume and flying upwind. Upwind flight was also interrupted when males (1) flew out of the plume without casting, or (2) alighted on the soil beneath the odor plume. Males exhibiting the former behavior generally left the odor plume by flying upward. Once out of the plume, these males typically flew near the upper or side walls for several seconds, and then alighted on the sides of the tunnel, where they remained for at least several minutes. Upwind flight followed by alighting on the soil occurred at a lower frequency (ca. 0.5% of all males). However, when it occurred, the male faced upwind and either resumed upwind flight or flew out of the odor plume. Upon contacting the odor source, all males continued to fan their wings and arch their abdomen, thereby bringing the tip of the abdomen into contact with the filter paper in what appeared to be a copulatory attempt. The few males that flew past the filter paper (without landing) initiated casting after flying upwind 5–10 cm beyond the source, and, then, always regained the odor plume after drifting downwind of the odor source. The shortest and longest flight times from the release cage to the odor source (85 cm) were 6 and 131 seconds, respectively, which are equivalent to average net up-tunnel velocities (Kuenen and Baker, 1982) of 14.2 and 0.65 cm/sec.

Flight Maneuvers in Response to Extract of Sex Pheromone Glands of Females and Synthetic Pheromone. Male Hessian flies exposed to ovipositor extract (ten female equivalents) or to synthetic SE10-13 : OAc (20 ng) exhibited the same maneuvers but with different frequencies. With either odor source, most males took flight (activated) after being placed in the tunnel (Figure 1). Males that took flight did so with a similar latency for both treatments, ranging from 1–51 sec ($x \pm SE = 6.9 \pm 1.8$) for males exposed to extract and 1–17 sec ($x \pm SE = 4.0 \pm 0.6$) for males exposed to SE10-13 : OAc. Only rarely did males that took flight exit the odor plume without exhibiting upwind flight (Figure 1). However, after this stage, a larger number of the males exposed to SE10-13 : OAc lost the odor plume as they progressed up the tunnel to the pheromone source. Having reached the 2-cm point, no male, whether exposed to extract or SE10-13 : OAc, failed to continue upwind and contact the odor source. The overall result of these maneuvers was that 39/45 (87%) of the males exposed to extract contacted the source in contrast to only 25/45 (56%) of the males exposed to SE10-13 : OAc ($G_{adj} = 10.02$, $df = 1$, $P < 0.01$). To compare the overall responses of males to extract vs. SE10-13 : OAc, males were categorized

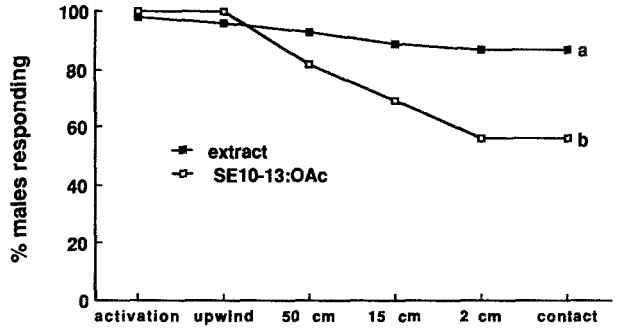

FIG. 1. Flight maneuvers of male Hessian flies exposed to 10 FE sources of extract of female ovipositors (solid squares) and 20 ng sources of (2S)-tridecen-2-yl acetate (SE10-13:OAc-open squares). Activation refers to the percent of males taking flight. Numbers of males contacting the two sources were significantly different at $P < 0.01$ (G test). Number of males tested to each source = 45.

as (1) those that did not exhibit upwind flight, (2) those that exhibited upwind flight but did not contact the source, and (3) those that exhibited upwind flight and contacted the source. Using these response categories, we found that the distribution within these categories differed significantly for males exposed to extract compared to those exposed to SE10-13:OAc (3×2 test of independence, $G = 17.54$, $df = 2$, $P < 0.001$). Net up-tunnel velocities (time from taking flight to contacting the odor source) were similar to extract or to SE10-13:OAc, ranging from 1.0 to 12.1 cm/sec ($x \pm SE = 3.7 \pm 0.4$) and from 1.1 to 8.5 cm/sec ($x \pm SE = 3.5 \pm 0.5$), respectively.

SE10-13:OAc Dose-Response Relationships. Males that flew out of cages after being exposed to 2, 6, 20, 60, and 200 ng of SE10-13:OAc did so with similar latencies, 5.95, 3.33, 5.55, 7.13, and 7.83 sec, respectively ($F_{(4,210)} = 1.50$, $P < 0.20$). Numbers of males contacting the source were also not significantly different for the range of dosages (38%, 49%, 53%, 51%, and 38% for 2, 6, 20, 60, and 200 ng, respectively, $G_{(4)} = 4.56$, $P < 0.50$). However, fitting a quadratic response curve to these data yielded a significant improvement over a linear response curve (chi square = 4.02, $df = 1$, $P < 0.05$), an indication that the number of males contacting the odor source reached a maximum and then decreased with increasing dosage. In addition, in comparison to males flying to the 20 ng source, males exposed to the lowest dosage (2 ng) exited the odor plume during upwind flight more frequently, whereas males exposed to the highest dosage (200 ng) appeared more likely to exit the odor plume before exhibiting upwind flight (Figure 2). Net up-tunnel velocities for males contacting the odor source (Figure 3) were significantly faster with 20 ng than with 200 ng ($F_{(4,98)} = 3.53$, $P < 0.01$, 95% confidence intervals).

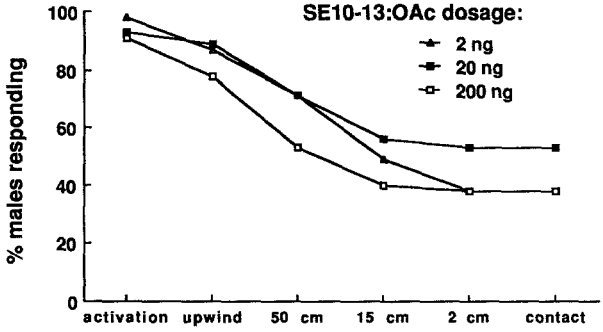

FIG. 2. Behaviors of male Hessian flies exposed to three different dosages of SE10-13:OAc. Males were also exposed to 6 and 60 ng sources; however, these results are not shown. Activation refers to the percent of males taking flight. Numbers of males contacting the source were not significantly different at $P < 0.05$ (G test). Numbers of males tested to each source = 45.

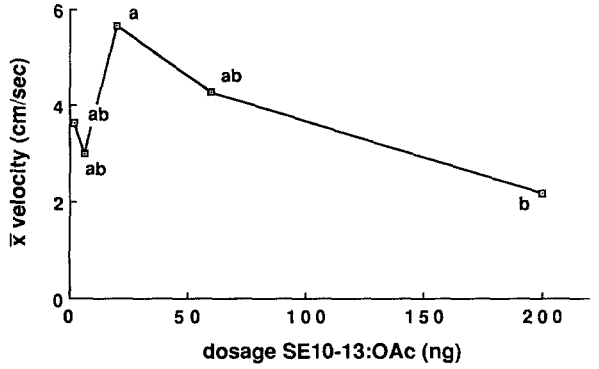

FIG. 3. Net up-tunnel velocities of male Hessian flies flying upwind to and contacting filter paper with different dosages of SE10-13:OAc (2, 6, 20, 60, and 200 ng). Means accompanied by the same letter are not significantly different at $P < 0.05$ (one-way ANOVA, 95% confidence intervals).

Binary Blends of SE10-13:OAc and Other Chemicals Found in an Extract of Female Ovipositors. Similar numbers of males (Figure 4) contacted the odor source when the dosage of SE10-13:OAc was held constant at 20 ng and ratios of Z10-13-2:OAc in SE10-13:OAc ($G_{(3)} = 1.36$, $P < 0.80$), ratios of E10-13-2:OH in SE10-13:OAc ($G_{(2)} = 1.18$, $P < 0.50$), and ratios of 13-2:OAc in SE10-13:OAc ($G_{(3)} = 0.90$, $P < 0.99$) were presented to males. With all binary blends, flight times were not significantly different.

Flight Responses to Mixtures of R and S Enantiomers. The addition of

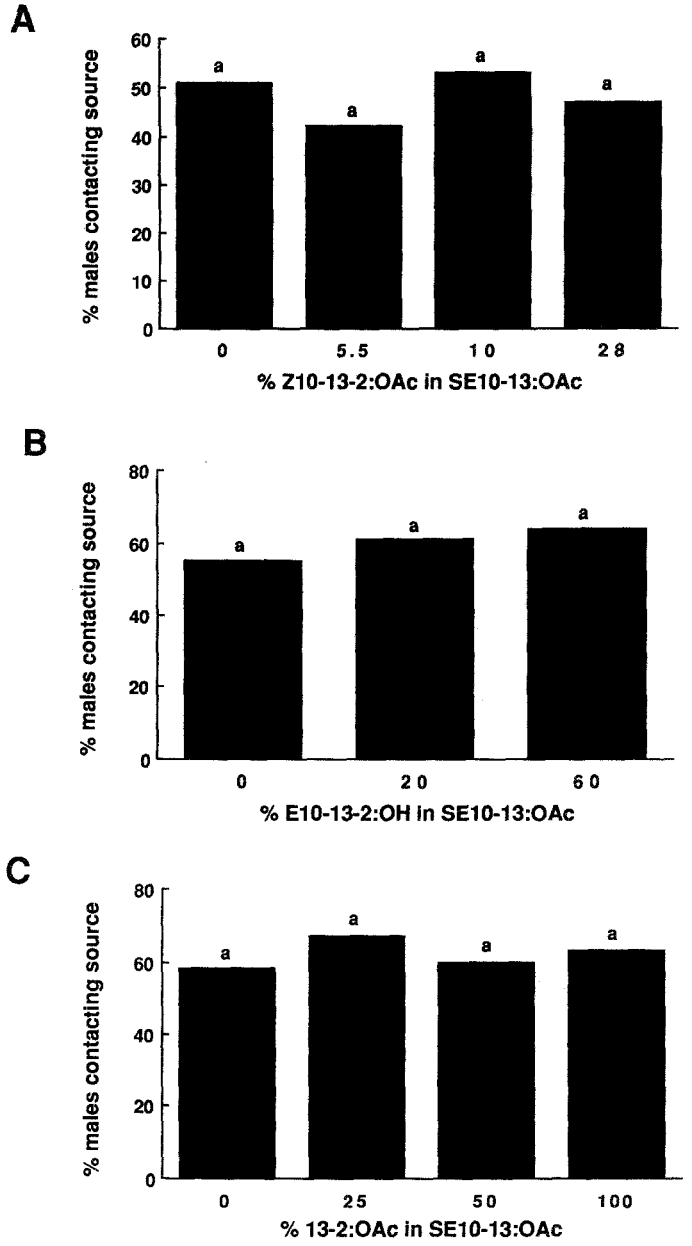

FIG. 4. Percentages of male Hessian flies contacting the odor source given (A) ratios of Z10-13-2:OAc in SE10-13:OAc, (B) ratios of E10-13-2:OH in SE10-13:OAc, and (C) ratios of 13-2:OAc in SE10-13:OAc (acronyms as in text). In all tests, the dosage of SE10-13:OAc was held constant at 20 ng. Within each graph, numbers of males contacting the source were not significantly different at $P < 0.05$ (G test). Numbers of males tested were (A) = 45, (B) = 75, and (C) = 60.

either 20% or 100% RE10-13:OAc to SE10-13:OAc (Figure 5) resulted in more males losing the odor plume during upwind flight and fewer males contacting the odor source (logistic ANOVA, $P < 0.05$). Net up-tunnel velocities towards the 100% S, 100:20 S:R, and 100:100 S:R sources were 3.13, 2.54, and 2.96 cm/sec, respectively, and were not significantly different at $P < 0.05$. A small number of males (4/60) also flew upwind to and contacted the 100% RE10-13:OAc odor source. Males never contacted the source when presented with a filter paper source treated with hexane (Figure 5, blank).

DISCUSSION

The flight maneuvers of male Hessian flies in the presence of the female-produced sex pheromone were very similar to those described for male moths (see reviews, Kennedy, 1986; Baker, 1989). As with moths, flight responses of male Hessian flies varied, sometimes consisting of narrow zigzags and at other times appearing to be straight flight upwind. Casting, a maneuver exhibited by moths when contact with the odor plume is lost, was sometimes exhibited by Hessian fly males flying upwind toward the odor source and also occurred when males flew upwind of the odor source. Upon contacting the source, male Hessian flies arched the abdomen in what appeared to be a copulatory attempt.

To determine whether SE10-13:OAc could account for much or all of the behavioral activity of the sex pheromone, flight maneuvers were contrasted for Hessian fly males flying to SE10-13:OAc vs. a hexane extract of female ovi-

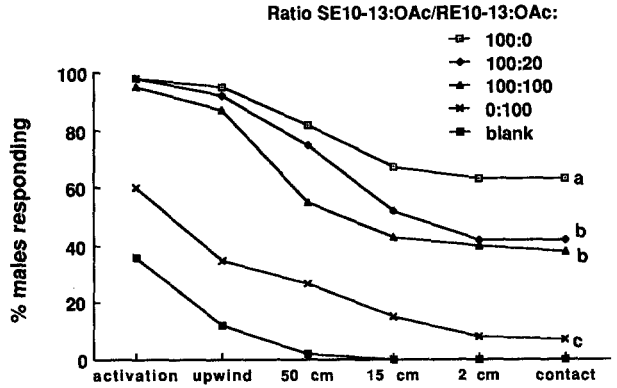

FIG. 5. Behaviors of male Hessian flies exposed to various ratios of the S and R enantiomers of E10-13:OAc. The dosage of SE10-13:OAc was held constant at 20 ng for the first three treatments listed. Activation refers to the percent of males taking flight. Numbers of males contacting the source were not significantly different if accompanied by the same letter ($P < 0.05$, G test). Numbers of males tested with each source = 60.

positors. A ten-female equivalent dosage of extract was contrasted with 20 ng of SE10-13:OAc because females contain, on average, ca. 2.0 ng of SE10-13:OAc (Foster et al., 1992). In contrast to males exposed to female extract, males flying to SE10-13:OAc typically did not fly as far upwind (Figure 1). As a result, only 56% of the males contacted the SE10-13:OAc source, compared to 87% of the males that contacted the female extract source. These data suggest that the sex pheromone of the female Hessian fly consists of a blend of two or more components, rather than just SE10-13:OAc alone. The larger number of male Hessian flies exhibiting upwind flight and source contact to the extract could indicate lower behavioral thresholds for the true pheromone blend and a greater response to the blend at all distances from the odor source as has been shown in several species of moths (Linn et al., 1986, 1987). The alternative explanation, that SE10-13:OAc elicited less upwind flight because of the 1% impurity of the R enantiomer, seems less likely, given the relatively small effect that a larger amount of the R enantiomer had when presented with SE10-13:OAc (Figure 5).

Three other chemicals identified in the extract of female ovipositors, Z10-13-2:OAc, E10-13-2:OH, and 13-2:OAc (Foster et al., 1991), were also tested in binary mixtures with SE10-13:OAc. However, the addition of any of these chemicals to SE10-13:OAc did not affect the percentage of males flying upwind and contacting the odor source. Although it is possible that these components interact, i.e., that tertiary or quaternary blends including SE10-13:OAc would elicit responses in more males (see Linn et al., 1984), we currently have no data to support these chemicals being classified as pheromone components.

That the sex pheromone of the Hessian fly probably consists of a blend of chemicals is not surprising. Blends of chemicals are the rule rather than the exception in the sex pheromones of Lepidoptera and Coleoptera. However, in many insects that use blends of chemicals to locate mates, a single component, when presented by itself, either does not elicit source location and/or upwind flight or only elicits these maneuvers at very high dosages, and even then, only in a small number of males (Linn et al., 1986). This does not appear to be the case with the Hessian fly, at least not within the range of dosages we tested. In the presence of even relatively small dosages of SE10-13:OAc (2 ng, ca. 1 female equivalent), significant numbers of males exhibited activation (98%), upwind flight (62%), and source contact (38%). Thus, male Hessian flies appear to have extremely low thresholds for activation and orientation (Linn and Roelofs, 1989) in response to this component.

At the highest dosage of SE10-13:OAc tested (200 ng/filter paper), there was a slight, but not significant reduction in the number of Hessian fly males flying upwind and contacting the odor source (38% for 200 ng vs. 53% for 20 ng sources). However, net up-tunnel velocities (times in flight from leaving the cage to contacting the source) of the males that did locate the 200 ng source

were two times slower than those of males flying to 20 ng (Figure 3). Kuenen and Baker (1982), studying the effects of pheromone concentration on the flight behavior of the oriental fruit moth, also found a decrease in net up-tunnel velocity with higher concentrations. By analyzing flight tracks, they determined that moths flying to pheromone sources of higher concentration turned more frequently and did so a shorter distance away from the longitudinal axis of the pheromone plume. In-flight arrestment, consisting of long looping turns and movement downwind and out of the plume, was also exhibited more frequently by moths flying towards sources with higher concentration. Although we did not record flight tracks of male Hessian flies (it would be difficult because of the small size of males), upwind flight of males flying to sources loaded with 200 ng of SE10-13:OAc seemed to be interrupted more frequently by bouts of casting (counterturning with no significant net progression), which included looping turns and frequent downwind displacement. Although some of these males subsequently exited the back of the tunnel or alighted on the walls of the tunnel, others relocated the odor plume and eventually contacted the odor source, albeit after significantly longer flight times.

Hessian fly females produce only the S enantiomer and not the R enantiomer of the sex pheromone component E10-13:OAc (Foster et al., 1991). Thus, responses to the other enantiomer were also of interest. Silverstein (1988), in a review of chirality in insect communication, states that there are five possible responses to another enantiomer in insects that produce a single enantiomer: (1) less active or inactive, (2) equally active, (3) more active, (4) synergistic, and (5) inhibitory. The first of these responses is the most common, with several cases of inhibition also reported. When inhibition does occur, it often takes only small amounts of one enantiomer to strongly inhibit or virtually block responses to the other enantiomer (Tumlinson et al., 1977; Birch et al., 1980).

Inhibition of behavioral responses with the addition of the R enantiomer to the S enantiomer also occurred in the Hessian fly (Figure 5). However, relatively large amounts of the R enantiomer were necessary to inhibit flight responses of males; even with 100:100 ratios of S:R, 38% of the males contacted the source, in contrast to the 63% of all males flying toward the 100:0 S:R sources. These data suggest that male Hessian flies have olfactory receptors that detect the R enantiomer. However, whether the R enantiomer interacts with the S-receptor cell or with its own specific receptor cell is not known.

The apparently contradictory result of a small percent of male Hessian flies (6.7%) flying to the source loaded with nominal 100% R enantiomer is probably explained as the combination of the relatively weak inhibitory effect of the R enantiomer and the small impurity of the S enantiomer present in our sample. It is not unreasonable that the impurity of the S enantiomer (1% = 0.2 ng) could have triggered orientation responses in 6.7% of the males, given the rel-

atively high percentage of males (38%) flying upwind to and contacting the source with 2 ng of the S enantiomer.

It has been suggested that studies on insects in orders other than the Lepidoptera may reveal that optomotor anemotaxis and self-steered counterturning are not the only mechanisms available to insects flying towards pheromone sources (Cardé, 1986). Our study of the Hessian fly and recent studies of Coleoptera (Bartelt et al., 1990; Domek et al., 1990) suggest that the converse may also be true, i.e., that many insects in distantly related orders may have evolved behavioral mechanisms similar to those that have been so rigorously studied in the Lepidoptera. Further studies on insects such as the Hessian fly will help to determine if the orientation mechanisms they use differ in any way from those used by moths, and whether, given the constraints of sensory and central processing systems in insects and the vagaries of odor plumes in natural environments, flying insects have additional behavioral options for odor source location.

Acknowledgments—Our thanks to Dr. Chris Bergh for building the wind tunnel, conducting initial studies on male flight responses to female sex pheromone, and for rearing Hessian flies, to Susan Rose for technical help, to Mr. John Maindonald (D.S.I.R. Physical Sciences, Auckland) for advice on statistical analyses, to Dr. Jocelyn Millar (U.C. Riverside) for synthesizing several of the chemicals used in this study, and to Eileen Schofield (Kansas Agricultural Experiment Station) for editorial comments. This work was supported by KAES Hatch funds and is contribution No. 91-238-J from the Kansas Agricultural Experiment Station, Manhattan.

(Received June 10, 1991; accepted August 5, 1991)

Abstract—The female-produced sex pheromone of the Hessian fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae), has been identified as (10*E*)-tridecen-2-yl acetate. A flexible synthetic route was developed which allowed access to the chiral and racemic forms of the pheromone, and to the 10*Z* stereoisomer of the pheromone. The natural compound was determined to have the 2*S* configuration by hydrolysis of the acetate function, derivatization of the resulting alcohol with (2*S*)-2-acetoxypropionyl chloride, and capillary gas chromatographic comparison of the derivative with the corresponding derivatives prepared from the synthetic enantiomers. Trace amounts of the 10*Z* isomer of the pheromone have also been detected in extracts of female Hessian fly ovipositors, along with (10*E*)-tridecen-2-ol and 2-tridecanyl acetate. Due to the small quantities of these compounds available from ovipositor extracts, the chirality of the trace components has not yet been determined.

Key Words—(10*E*)-tridecen-2-yl acetate, (10*Z*)-tridecen-2-yl acetate, sex pheromone, Diptera, Cecodomyiidae, Hessian fly, *Mayetiola destructor*.

INTRODUCTION

Wheat is an important cereal crop in many countries of the world, providing some 20% of the food calories consumed by mankind (Feldman, 1976). One of the most destructive insect pests of wheat is the Hessian fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae). Current methods of controlling Hessian fly damage include breeding of resistant wheat varieties, using cultural practices such as rotation of crops and delaying planting of wheat until late fall, and occasionally use of systemic insecticides (Foster et al., 1986). In addition, natural enemies of the Hessian fly often build up late in the season, but by this time most of the crop damage has already occurred (Foster et al., 1986).

It has been known for many years that adult female Hessian flies produce a sex pheromone which is attractive to male flies over distances of at least several meters (Cartwright, 1922; Mackay and Hatchett, 1984). The identity of an attractive sex pheromone component from female Hessian fly was very recently reported as (2*S*,10*E*)-tridecen-2-yl acetate in a preliminary communication (Foster et al., 1991). We report here the details of the synthesis of the racemic and chiral forms of the pheromone, and the synthesis of a geometric isomer of the pheromone. We also report the details of the determination of the chirality of the pheromone.

EXPERIMENTAL

Proton NMR spectra ($CDCl_3$) were recorded on a GE-300 NMR spectrometer, at 300 MHz. IR spectra were recorded as films of neat compounds on NaCl plates, with a Perkin–Elmer 137 spectrometer. Mass spectra (electron impact, 70 eV) were recorded with a Hewlett–Packard (H–P; Avondale PA) 5970 mass selective detector, interfaced to a H–P 5890 capillary GC. An HP-1 capillary column (12.5 m × .2 mm ID, 0.33 micron film; H–P) was used for all gas chromatography-mass spectrometry (GC-MS) work. Routine gas chromatography (GC) runs were carried out with an H–P 5890 instrument with flame ionization detection (FID), fitted with a DB-5 column (20 m × .32 mm ID, 0.25 micron film; J&W Scientific, Folsom CA) in split mode, using He carrier gas. GC signals were integrated with an H–P 3396A integrator. Optical rotations were measured with a Perkin–Elmer Model 241 polarimeter, using a 1 decimeter cell with a volume of approx. 1 ml.

All reagents were obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin) or Fisher Scientific (Pittsburgh, Pennsylvania) unless otherwise stated.

Unless otherwise stated, reaction mixtures were extracted three times with the stated solvent, and the combined extracts were washed with brine, dried over anhyd. Na_2SO_4, and concentrated on a rotary evaporator under water aspi-

rator vacuum. Flash chromatography was carried out with 230–400 mesh silica gel (Aldrich Chemical Co.).

Enantiomeric excesses (e.e.) of alcohols 3–5 and 8 were determined by derivatization of the alcohols with (2*S*)-2-acetoxypropionyl chloride. Thus, two equivalents of the acid chloride were added to dilute solutions (~0.1 M) of the alcohols (1 equivalent) in a mixture of ether and triethylamine (approx. five equivalents) at room temperature. The mixtures were mixed thoroughly, and allowed to stand overnight. The mixtures were then washed thoroughly with excess saturated aqueous $NaHCO_3$, the organic portions were dried over anhyd. Na_2SO_4, and the resulting solutions of diastereomeric esters were analyzed by capillary GC on the DB-5 column as described above. Enantiomeric excesses were determined by comparison of the integrated peak areas of the diastereomers. In all cases, baseline separation of the two diastereomers was achieved. In addition, there was no trace of the alcohol starting material, ensuring that the chirality determination had not been distorted by diastereoselective kinetic effects during the derivatization.

Insects and Extracts. Hessian flies were from a laboratory culture originally established from collections from wheat fields in Ellis County, Kansas in fall of 1986. These insects were probably of the Great Plains biotype, although there may also have been low numbers of biotypes A and B. The insects were reared on Newton wheat in the 2–3 leaf stage (Harris and Foster, 1991). As the majority of Hessian fly females lay all male or all female progenies (Gallun et al., 1961), virgin male or female insects were harvested off the individual wheat plants shortly after they emerged, at approx. 15–21:00 hr (for males) and 4:30–7:30 hr (for females). Males were stored in cages in an environmental chamber at 15°C and 70% relative humidity, and 15:9 light:dark cycle until used the following morning.

For analyses of natural pheromone, and for use in olfactometer tests, the terminal abdominal segments of females, 0–3 hr old, were dissected under a binocular scope, placed in hexane, and allowed to extract for at least an hour before use.

The double bond geometry of the pheromone component in the extract was determined by comparison of its retention times with those of synthetic standards on the DB-5 column (70–200°C @ 5°C/min) and on a 30 m × 0.25 mm ID SP2340 column (Supelco, Bellefonte, Pennsylvania; same temperature program as for DB-5 column). (4*E*)-Tridecenyl acetate was used as an internal standard.

The chirality of the Hessian fly-produced compound was determined by hydrolysis of an extract of 200 female abdominal tips (0.5 M KOH in MeOH), and reaction of the resulting free alcohol with excess (2*S*)-2-acetoxypropionyl chloride in 10% pyridine in ether for approx. 24 hr at ambient temp. (Slessor et al., 1985). The retention time on the DB-5 column and the mass spectrum

of the reaction product were compared with those of the compounds obtained from reaction of the synthetic enantiomers of (10*E*)-tridecen-2-ol with (2*S*)-2-acetoxypropionyl chloride.

Bioassays. The Y-tube olfactometer was similar to that described by Chaudhury et al. (1972). The two equivalent arms of a glass Y-tube were attached to two straight glass tubes (2.9-cm diam.) which functioned as traps for the responding male flies. These glass tubes were attached to two larger tubes (4-cm diam. × 15-cm long) into which the sample being tested and a solvent blank were placed (one into each of the respective arms). The sample consisted of the appropriate amount of chemical in *n*-hexane absorbed onto a quadrant of filter paper (2.5-cm radius); the blank consisted of an equal amount of *n*-hexane absorbed onto a similar piece of filter paper. The third arm of the Y-tube was attached to a large glass chamber (19-cm long × 6.3-cm diam.) into which male flies were introduced at the commencement of the test. Air, purified by passage through activated carbon filters and subsequently humidified by being passed through water, was pumped through the olfactometer at a rate of 250 ml/min/arm. Each test was run for 10 min. At the end of each test, the number of males in the sample trap, the blank trap, the Y-tube, and the introduction chamber were recorded. Twenty-five insects were used in each test, and each assay was replicated six times, with the exception of the bioassay of the ovipositor extract, which was run with ten insects/replicate, and four replicates. All tests were run between 6–10 a.m., with freshly emerged insects, under fluorescent light, and at ambient air temperatures (~20–25°C). Data on the distribution of flies between the control and test stimulus arms of the olfactometer were compared against equal distributions of flies between the two arms using Chi-square tests.

Synthesis

4-Undecyn-2-ol 3. n-BuLi (60 ml of a 2.5 M solution in hexanes, 150 mmol) was added dropwise to a cooled (< −10°C) solution of 1-octyne 1 (16.5 g, 150 mmol) in THF (250 ml). The mixture was stirred for 30 min, then cooled to −20°C. HMPA (50 ml) was added, followed by dropwise addition of racemic propylene oxide 2 (10.15 g, 175 mmol). The solution was warmed to 20°C overnight, then poured into water and extracted with hexane, and worked up as described above. The crude product was distilled under vacuum, yielding alcohol 3 (24.18 g, 96%), bp 68–70°C (0.2 mm Hg). Lit bp, 65–72°C (0.2 mm Hg) (Oehlschlager et al., 1985). ^{1}H NMR δ: 3.90 (m, 1H; H-2), 2.37 (ddt, 1H, J = 16.4, 4.9, 2.4 Hz; H-3), 2.27 (ddt, 1H, J = 16.4, 6.8, 2.3 Hz; H-3′) 2.15 (tt, 2H, J = 6.9, 2.4 Hz; H-6), 1.98 (d, 1H, J = 4.7 Hz; -OH), 1.55–1.44 (m, 2H; H-7), 1.43–1.25 (m, 6H; H-8,9,10), 1.23 (d, 3H, J = 6.2 Hz; H-1), 0.89 (t, 3H, J = 6.8 Hz; H-11). IR λ max cm^{-1}: 3350 (s, broad),

2960 (s), 2860 (m), 1465 (m), 1375 (w), 1075 (m), 945 (m). The NMR and IR spectral data were a good match with literature data (Utimoto et al., 1984). MS *m/z* (rel. abundance): 124 (2, M^+-CH_3COH), 109 (3), 96 (15), 95 (23), 82 (17), 81 (21), 68 (31), 67 (39), 54 (100), 45 (68).

The reaction was repeated, substituting *S*-(−)-propylene oxide (Fluka Chemical Corp., Ronkonka, New York) for racemic propylene oxide, yielding (2*S*)-4-undecyn-2-ol (2*S*-3) in 68% isolated yield, $[\alpha]_D^{28} = +20.4 \pm 0.3°$ (c 1.22, $CHCl_3$), and an enantiomeric excess (e.e.) of 98.3%, as determined by capillary GC (190°C, isothermal) of the diastereomeric ester formed by derivatization of 2*S*-3 with (2*S*)-2-acetoxypropionyl chloride. Spectra and chromatographic retention times of 2*S*-3 matched those of racemic 3.

10-Undecyn-2-ol 4. Lithium wire (5.21 g, 750 mmol) was dissolved in approx. 250 ml of 1,3-diaminopropane. The resulting blue solution was heated at 65°C until the blue color was discharged (approx. 2 hr). The resulting white slurry was cooled to 20°C, and potassium *t*-butoxide (66 g, 590 mmol) was added in one portion. The orange slurry was stirred 30 min, followed by dropwise addition of racemic alcohol 3 (21.0 g, 125 mmol). The mixture was stirred 45 min (reaction complete by GC), poured onto 1 kg of ice, and extracted with hexane. The hexane extracts were backwashed with 1 M HCl, then worked up as usual. The crude product was distilled under vacuum, giving alcohol 4 (19.63 g, 93%), bp ~65–70°C (0.18 mm Hg). ^{1}H NMR δ: 3.79 (m, 1H; H-10), 2.17 (td, 2H, J = 7.0, 2.7 Hz; H-3), 1.93 (t, 1H, J = 2.7 Hz; H-1), 1.50 (m, 2H; H-9), 1.45–1.22 (m, 11H; H-4 to H-8, −OH), 1.19 (t, 3H, J = 7.8 Hz; H-11). IR λ max cm^{-1}: 3350 (s, broad), 3300 (m), 2940 (s), 2860 (s), 2135 (w), 1470 (m), 1375 (w), 1135 (m), 1105 (m), 1065 (m). MS *m/z* (rel. abundance): 135 (1, M^+-CH_3-H_2O), 125 (1), 107 (4), 95 (8), 93 (12), 81 (23), 79 (18), 67 (36), 55 (34), 45 (100), 41 (55).

The reaction was repeated on smaller scale with 3.07 g of 2*S*-3 (18.3 mmol), yielding 2*S*-4 in 78% yield, $[\alpha]_D^{30} = +7.2 \pm 0.3°$ (c 0.54, $CHCl_3$), with e.e. > = 98.3% by capillary GC (190°C isothermal) of the diastereomeric derivatives formed as for 3 above. Spectra and chromatographic retention times of 2*S*-4 matched those of racemic 4.

10-Tridecyn-2-ol 5. *n*-BuLi (9 ml of a 2.5 M solution in hexanes, 22.5 mmol) was added to a cooled (<0°C) of alkynol 4 (1.68 g, 10 mmol) in 25 ml of THF. The resulting slurry was cooled to −40°C, HMPA (5 ml) was added, followed by dropwise addition of ethyl bromide (1.42 g, 15 mmol) in THF (5 ml). The mixture was warmed to 20°C overnight, poured into water and extracted three times with hexane. After workup as usual, the residue was purified by flash chromatography (15% EtOAc in hexane), giving alkynol 5 (1.73 g, 88%). NMR δ: 3.79 (m, 1H; H-2), 2.14 (m, 4H; H-9,12), 1.55–1.23 (m, 13H; H-3 to H-8, -OH), 1.19 (d, 3H, J = 6.2 Hz; H-1), 1.12 (t, 3H, J = 7.4 Hz; H-13). IR λ max cm^{-1}: 3400 (s, broad), 2950 (s), 2865 (s), 1465 (m),

1375 (m), 1330 (m), 1135 (m), 1065 (m). MS *m/z* (rel. abundance): 163 (1, M^+-H_2O-CH_3), 149 (5), 135 (5), 121 (10), 107 (22), 93 (37), 82 (31), 81 (41), 79 (49), 67 (100), 55 (56), 45 (99), 41 (98).

Compound 2*S*-5 was prepared in identical fashion in 91% yield, $[\alpha]_D^{31} = +5.7 \pm 0.2°$ (c 0.76, $CHCl_3$), with an e.e. of 98.1%, as determined by capillary GC (210°C isothermal) of the diastereomeric derivatives, formed as for 3 above. Spectra and chromatographic retention times of 2*S*-5 matched those of racemic 5.

(10Z)-tridecen-2-yl acetate 7. Nickel acetate tetrahydrate (63 mg, 0.25 mmol) was dissolved in 10 ml of 95% EtOH. Under a strong flush of argon, 250 μl of a 1 M solution of $NaBH_4$ in EtOH was added in one portion. The flask was flushed with H_2 and ethylene diamine (33 μl, 0.5 mmol) was added, followed by alkynol 5 (0.5 g, 2.55 mmol). The mixture was stirred under a slight positive pressure of H_2 until the reduction was complete (~2 hr). The mixture was then filtered with suction through a plug of activated charcoal, rinsing the charcoal well with ethanol. The filtrate was concentrated, taken up in hexane, washed with 1 M HCl, and worked up as usual. The crude product 6 (0.37 g, 74%) was 98% pure by capillary GC, and so was used without further purification.

Alcohol 6 was taken up in ether (25 ml), cooled in an ice bath, and triethylamine (1 ml) and acetyl chloride (0.29 ml, 4 mmol) were added sequentially. The mixture was warmed to room temperature overnight, poured into hexane, washed with 1M HCl, and worked up as usual. The crude product was purified by flash chromatography on 10% $AgNO_3$ on silica gel, eluted with 5% ether in hexane. The purified acetate was Kugelrohr-distilled (oven temp. 110°C, 0.2 mm Hg), yielding 0.27 g (44% from 5) of acetate 7, >99.5% chemically pure by capillary GC. NMR δ: 5.33 (m, 2H; H-10,11), 4.88 (m, 1H; H-2), 2.02 (s, 3H; acetate CH_3), ~2.02 (m, 4H; H-9,12), 1.6–1.4 (m, 2H; H-3), 1.4–1.25 (m, 10H; H-4 to H-8), 1.20 (d, 3H, J = 6.3 Hz; H-1), 0.96 (t, 3H, J = 7.5 Hz; H-13). IR λ max cm^{-1}: 2950 (s), 2865 (s), 1750 (s), 1465 (m), 1370 (m), 1250 (s, broad), 1070 (m, broad). MS *m/z* (rel. abundance): 225 (trace, M^+-15), 180 (3, M^+-CH_3COOH), 138 (5), 124 (5), 110 (8), 96 (17), 82 (41), 68 (47), 55 (36), 43 (100), 41 (56).

(10E)-tridecen-2-yl acetate 9. Sodium pellets (0.52 g, 23 mmol) were dissolved in 40 ml of a 1:1 solution of THF:liquid NH_3. Alcohol 5 (0.41 g, 21 mmol) was added, and the mixture was stirred under reflux for 5.5 hr. The reaction was quenched by addition of solid NH_4Cl (5 g) and the NH_3 was allowed to evaporate overnight. The residue was taken up in water and extracted with hexane, followed by the usual workup, giving crude alcohol 8 (0.41 g). The alcohol was acetylated and purified as described for 6 above, giving acetate 9 (0.39 g, 78% from 5). NMR δ: 5.40 (m, 2H; H-10,11), 4.88 (m, 1H; H-2), 2.02 (s, 3H; acetate CH_3), 1.97 (m, 4H; H-9,12), 1.6–1.4 (m, 2H; H-3), 1.4–1.25 (m, 10H; H-4 to H-8), 1.20 (d, 3H, J = 6.3 Hz; H-1), 0.96 (t, 3H, J =

7.4 Hz; H-13). IR λ max cm^{-1}: 2950 (s), 2860 (s), 1755 (s), 1465 (m), 1370 (m), 1250 (s, broad), 1030 (broad), 972 (m). MS *m/z* (rel. abundance): 180 (5, M^+-CH_3COOH), 138 (5), 124 (6), 110 (9), 96 (17), 95 (17), 82 (45), 68 (55), 55 (38), 43 (100), 41 (57).

2*S*,10*E*-tridecen-2-ol [2*S*-8], $[\alpha]_D^{31} = +5.8 \pm 0.1°$ (c 1.32, $CHCl_3$), and 2*S*,10*E*-tridecen-2-yl acetate [2*S*-9], $[\alpha]_D^{31} = +0.8 \pm 0.2°$ (c 0.80, $CHCl_3$) were prepared in identical fashion from 2*S*-5, in 87% yield overall. The e.e. of 2*S*-8 was determined as before to be ≥96.7% (GC temp., 210°C isothermal). Spectra and chromatographic retention times of 2*S*-8 and 2*S*-9 matched those of racemic 8 and 9 exactly.

(2R,10E)-tridecen-2-yl acetate (2R-9). Methanesulfonyl chloride (0.52 g, 4.5 mmol) was added to an ice-cold solution of (2*S*,10*E*)-tridecen-2-ol (0.594 g, 3.0 mmol) in 20 ml of 20:1 CH_2Cl_2:triethylamine. The solution was stirred at 0° for 1 hr, then washed twice with cold saturated aqueous $NaHCO_3$, once with brine, then dried and concentrated *in vacuo* (0.2 mm Hg) for 2 hr, yielding 2*S*-10 as a yellow oil (0.82 g, 98%), chromatographically homogeneous by silica gel TLC (20% EtOAc in hexane). The oil was used without further purification.

Cesium propionate:propionic acid complex (~1:1 complex; 500 mg, ~1.5 mmol; Aldrich) was added to a solution of mesylate 2*S*-10 (0.44 g, 1.5 mmol) in dry DMF (15 ml, dried over activated 3 Angstrom molec. sieve). The mixture was stirred for 33 hr at 40°C under Ar, then poured into water (100 ml). The mixture was extracted three times with hexane, and the combined hexane extracts were worked up as usual. The residue was flash chromatographed (7.5% EtOAc in hexane), yielding propionate 2*R*-11 (0.33 g, 87%).

A mixture of the propionate 2*R*-11 (0.21 g, 1.22 mmol) and NaOH (25 mg) were stirred in MeOH (10 ml) for 36 hr. Water (0.5 ml) was added, and the mixture was stirred a further 16 hr. The mixture was concentrated, taken up in hexane, washed with water, and worked up as usual. The residue was flash chromatographed (20% EtOAc in hexane), yielding (2*R*)-tridecen-2-ol (2*R*-8, 200 mg, 83%), $[\alpha]_D^{31} = -5.3 \pm 0.3°$ (c 0.34, $CHCl_3$), with an e.e. of ≥96.4%, determined as described for 2*S*-8 above.

The purified 2*R*-8 was acetylated as described above for the 2*S* enantiomer, yielding 2*R*-9 (92%), $[\alpha]_D^{32} = -0.5 \pm 0.2°$ (c 0.80, $CHCl_3$). Spectra and chromatographic retention times of 2*R*-8 and 2*R*-9 matched those of racemic 8 and 9.

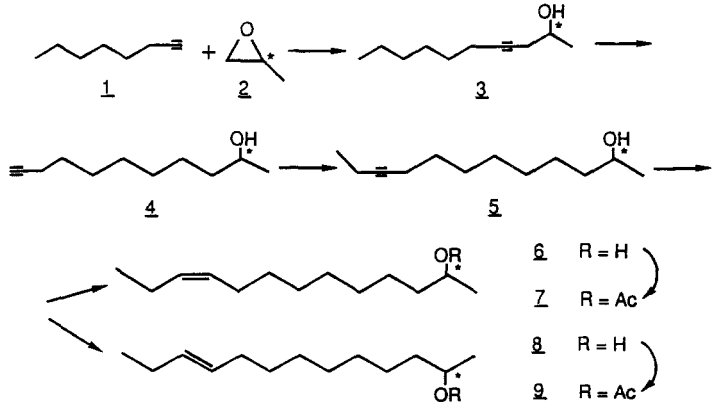
RESULTS AND DISCUSSION

The female-produced sex pheromone of the Hessian fly consists of 2*S*,10*E*-tridecen-2-yl acetate, which contains one disubstituted double bond and one chiral center. Natural pheromone was only available in very small quantities

from extracts of female ovipositors, and it was not possible to ascertain either the double bond geometry or the configuration of the chiral center by analytical chemistry methods alone. Consequently, a synthetic route was devised that would give access to all possible stereoisomers of the basic structure of the Hessian fly pheromone in high stereoisomeric purity, and which could be readily scaled up to obtain multigram yields if required. The synthesis shown in Scheme 1 had the required flexibility. The synthesis was carried through with racemic material initially, and the double bond geometry of the natural pheromone was determined by comparison of the retention times of the synthetic *Z* and *E* isomers with that of the insect-produced material. The synthesis was then repeated with (*S*)-(−)-propylene oxide, to produce the enantiomers of the pheromone.

Thus, the lithium salt of 1-octyne 1 was reacted with racemic propylene oxide 2 in THF-HMPA, to give alkynol 3 (Oehlschlager et al., 1985). The triple bond was then isomerized to the terminal position using the modified acetylene zipper reaction (Abrams and Shaw, 1988), yielding alkynol 4 (Oehlschlager et al., 1985). The lithium salt of 4 was alkylated with ethyl bromide in THF-HMPA, completing the carbon skeleton. Reduction of the product 5 with sodium in liquid ammonia (Henrick et al., 1982), or P-2 nickel and hydrogen (Brown and Ahuja, 1973), gave (10*E*)- and (10*Z*)-tridecen-2-ols 8 and 6, respectively. Acetylation of the alcohols with acetyl chloride and triethylamine gave the racemic forms of the two possible pheromone structures 7 and 9. The isomers were readily distinguishable by capillary GC (DB-5 and SP2340 columns). The retention time of the major component of the natural pheromone extract exactly matched that of the 10*E* isomer 9, confirming the double bond geometry as *E*.

With the question of the alkene geometry settled, the enantiomers of 9



SCHEME 1

were prepared by the same route, substituting (*S*)-(−)-propylene oxide [*S*-(−)-2] for racemic 2 in the first step. Ring opening of the epoxide was accomplished with little or no loss of chirality (Brandsma, 1971), yielding 2*S*-3 with an enantiomeric excess (e.e.) of >98% (vide infra). 2*S*-3 was then carried through the same synthetic steps as racemic 3, with similar yields, and minimal loss of chirality, yielding (2*S*,10*E*)-tridecen-2-yl acetate, 2*S*-9.

2*R*-9 was synthesized via the intermediate alcohol, 2*R*-8, which in turn was prepared by inversion of the chiral center in alcohol 2*S*-8 by Kruizinga's method (Kruizinga et al., 1981; Johnston and Oehlschlager, 1984; Scheme 2). Thus, 2*S*-8 was converted to mesylate 2*S*-10 by the usual conditions (MesCl/triethylamine in methylene chloride), followed by stereoselective nucleophilic displacement of the mesylate with cesium propionate in DMF. Base hydrolysis of the propionate 2*R*-11 gave alcohol 2*R*-8 (e.e. >96%), which was acetylated as before, giving 2*R*-9, with minimal loss of chirality.

Enantiomeric excesses of alcohols 3–5 and 8 were determined by derivatization with (2*S*)-2-acetoxypropionyl chloride (Slessor et al., 1985). The resulting diastereomeric esters were readily resolved to baseline by capillary GC (DB-5 column). This method was also used to determine the chirality of the insect-produced compound. Thus, a preparative GC fraction of ovipositor extract containing the active compound was hydrolysed with 0.5M KOH in methanol, and the resulting alcohol was derivatized as described above. Only the 2*S* enantiomer was detectable from the insect extract (detection limit of 2*R* enantiomer estimated at <1% of the 2*S* enantiomer).

In Y-tube olfactometer bioassays, the 2*S* enantiomer was shown to be the attractive enantiomer (Table 1). The 2*R* enantiomer was much less attractive, with the residual activity possibly being due to the small amount of 2*S* contaminant present in the synthetic enantiomer. In addition, the racemic mixture was as attractive as the 2*S* enantiomer alone, indicating that the 2*R* enantiomer was not significantly inhibitory.

The Hessian fly ovipositor extract also contained lesser amounts of several related compounds (Foster et al., 1991), including the double bond isomer (10*Z*)-tridecen-2-yl acetate, which was present in amounts equal to approximately 10% of the biologically active *E* isomer, and the saturated analog tri-

decan-2-yl acetate. (10*E*)-Tridecen-2-ol and tridecan-2-ol were also detected in extracts. However, in bioassays, the racemic forms of these compounds were not significantly attractive, nor did they increase the response of male flies when added to lures containing the attractive pheromone (Harris and Foster, 1991). The absolute configuration of the minor components has not yet been determined because of the trace levels at which they were present in the natural extract.

Kelaniya, Sri Lanka

(Received January 3, 1991; accepted August 12, 1991)

Abstract—A mixture of *trans*-2-hexenal; *n*-tridecane (60:40, w/w), the natural combination present in the defensive secretion of *Coridius janus* (Hemiptera; Pentatomidae) was shown by comparison with similar aldehyde mixtures having longer and shorter chain *n*-alkanes, to be the optimal combination as a fumigant and a repellent against three test insect species, *Anoplolepis longipes*, *Sitotroga cerealella*, and *Culex quinquefasciatus*. Toxic values obtained for the three insects, respectively: $1/LC_{50}$, 1.72, 4.54, and 6.66 ppm while repellencies were 63%, 50%, and 69%. This study revealed that among *t*-2-hexenal: *n*-alkane combinations those with medium carbon chains, *viz* C-11 and C-12, also possessed high toxicities and repellencies comparable to that of the natural combination while those with shorter and longer *n*-alkanes possessed lower activity. Toxicities and repellencies of *n*-alkane series were only moderate to low showing highest toxic values for *n*-tridecane at $1/LC_{50}$, 0.39, 2.32, and 2.32 ppm and repellencies at 31%, 30%, and 32% for the three test insects, respectively. This series, nevertheless, showed similar variation, medium length chains, C-11, C-12, and C-13 showing comparatively higher activity than other alkanes of shorter and longer chains. This study also revealed that the fumigant property of both alkane and aldehyde are of equal importance while repellency is heavily dependent on the aldehyde.

Key Words—*Coridius janus*, Pentatomidae, Hemiptera, Defensive secretion, *n*-alkanes, acetates, toxicants.

INTRODUCTION

A self-protective role against their predators as the primary function of insect defensive secretions has been established (Blum, 1964; Peschke and Eisner, 1987; Roth et al., 1956). Often these secretions are multicomponent, presumably relating to their specific function/s described as repellents, deterrents, toxicants, alarm, or aggregation pheromones (Staddon, 1979; Aldrich, 1988). Hydrocarbons are a frequently found in insect defensive secretions with structural diversity ranging from simple *n*-alkanes to cyclic, mono-, di-, tri-unsaturated, and branched molecules (Weatherston and Percy, 1978). One of the characteristic features of hemipteran defensive secretions is that they often consist of one or more deterrents accompanied by alkanes or acetates (Aldrich, 1988; Eisner et al., 1961; Dettner, 1984). Pentatomidae and Coreidae, the two most thoroughly studied families of Hemiptera conform to the above, possessing simple alkanes and acetates, respectively, as accompanying compounds (Weatherston and Percy, 1978; Weatherston, 1967). Besides serving as solvents that modulate evaporation of volatile irritants, these accompanying compounds act synergistically as spreading and penetrating agents as shown by Staddon (1979) and Remold (1962).

In our previous study, the toxicity of the defensive secretion of *Coridius janus* Fabricius (Hemiptera; Pentatomidae) was shown toward three household pests: *Anoplolepis longipes* (Formicidae), *Culex quinquefasciatus* (Culicidae), and *Sitotroga cerealella* (Gelechiidae) (Gunawardena and Herath, 1991). A mixture of *t*-2-hexenal and *n*-tridecane (60/40, w/w), the two major components of the above secretion was shown to be responsible for the toxic action. Our interest was to examine the effectiveness of the above natural formula against other similar mixtures having longer and shorter chain *n*-alkanes as accompanying compounds. Is there an optimum chain length for effectiveness? What is the contribution of *n*-alkanes toward overall toxicity and repellency of the mixture? These aspects of accompanying compounds have not been studied before.

MATERIALS AND METHODS

Chemical Samples and Chemical Analyses

n-Alkanes were purchased from Fluka Chemicals, Switzerland, and *t*-2-hexenal from Aldrich Chemicals Co. Ltd., U.K. Purity of these chemicals was found to be 99.9% by GLC analysis. Gas Liquid Chromatography was carried out on a Shimadzu GC-6A instrument with FID, a He flow of 30 ml/min., temperature program of 40–225°C at 8°C/min, 240°C detector and injector temperature, glass columns (0.25mm id × 30M; SPB 1 stationary phase fused silica).

Bioassay of n-*Alkanes or* t-2-*Hexenal*/n-*Alkane Mixtures for Toxicity by Fumigant Action*

Test insects, *Anoplolepis longipes* (Formicidae), a natural enemy of *C. janus*, females of *Culex quinquefasciatus* (Culicidae) and *Sitotroga cerealella* (Gelechiidae), a storage product pest, were collected from their respective natural habitats a few hours prior to the experiments and were fed with sugar solutions, avian blood, and paddy grains, respectively, before being subjected to bioassay. Batches consisting of 20–30 insects were confined to test tubes (20 ml) just before the experiment. Test mixtures were prepared by first mixing neat liquids of *t*-2-hexenal and *n*-alkanes in the ratio of 60:40 (w/w) until a single phase was obtained and weighing out from these solutions appropriate amounts (Table 1) in small glass vials (2 ml). A large glass jar (5L) with a small opening at the bottom was used as the fumigating chamber. Glass vials filled with test mixtures (Table 1) were inserted partially into the fumigating jar

[a] All mixtures were in the ratio 60:40 (w/w) and in single phase.
[b] All experiments were carried out in 5L fumigating chamber and for the calculation of LC_{50} values complete evaporation of compounds were assumed by weighing empty vials before introducing compounds into them and after evaporation of compounds from them. Each dose was tested in three replicates.

through the opening at the bottom in such a manner that the volatiles were allowed to escape into the chamber. The bottom of each vial was heated slowly until all the test compounds/mixtures evaporated into the jar. Complete evaporation was assumed by weighing empty vials before the introduction of chemicals and after their evaporation into the fumigating jar. Subsequently, the test insects were introduced into the jar through the same opening and the jars were tightly closed. During all bioassays, temperature was maintained between 30–31°C. Blank experiments were conducted under the same conditions using only pure water and without any other liquid. Dead insects were separated and kept under observation for a further 24 hr, before mortalities were recorded. In the calculation of mean LC_{50} values, three doses (Table 1) of each test compound/mixture were subjected to three assays.

Repellency Assay

Preliminary tests indicated neat liquid mixtures of *t*-2-hexenal : *n*-tridecane (w/w) repel test insects with 100% efficiency. A 15% solution of *n*-alkane or *t*-2-hexenal/*n*-alkane mixture in paraffin oil was therefore used in all experiments. For each assay, 20–30 test insects were used, at a constant temperature of 30–31°C and 5μl of each *n*-alkane or *t*-2-hexenal/*n*-alkane mixture tested in three replicates. Blank experiments were conducted using pure water, paraffin oil and without any other liquid.

Anoplolepis longipes

Insects were confined to a glass tube (30 cm long × 5 cm ID) with both ends open by spreading a sugar solution inside the tube. This tube was kept in parallel direction to a slow stream of air. After 10 min, the outer surface of a glass funnel was treated with 5 μl of test compounds/mixtures, as 15% solutions in paraffin oil and inserted into one end of the tube. The air flow could thus carry the repellent throughout the tube. This arrangement was deemed most satisfactory since the loss of repellent against the direction of the air flow was minimized. The number of insects in the original tube was counted 5 min after the introduction of test compounds/mixtures.

Sitotroga cerealella

A long glass tube (50 cm long × 3 cm ID) was divided in the middle and the two parts marked A and B. Test insects were introduced into this tube in a dark room and were phototropically lured into part A. The test compound/mixture (5 μl), spread in a glass funnel as above, was introduced into tube A. The number of insects in the tube A was counted 10 min after the introduction of test compounds.

Culex quinquefasciatus

A long glass tube (50 cm long × 3 cm ID) was divided similarly into two parts A and B and the former was covered with black paper. Test insects were introduced into this end and were allowed to settle down. Afterward, the compounds/mixtures (5 μl) were introduced as above from the same end A. The number of mosquitoes in part A was counted 10 min after the introduction of test compounds.

RESULTS

Toxicity Assay

Plot of toxicity (given in 1/LC50 ppm) vs. *t*-2-hexenal: *n*-alkane (60:40, w/w) combinations showed high toxicities for those of *t*-2-hexenal: C-11, *t*-2-hexenal: C-12 and, *t*-2-hexenal: C-13 (Figure 1). The highest toxicity, however, was exhibited by the natural combination, *t*-2-hexenal: *n*-tridecane which gave toxic values of (1/LC 50 ppm) 1.72, 4.54, and 6.66 ppm for *A. longipes*, *S. cerealella*, and *C. quinquefasciatus*, respectively.

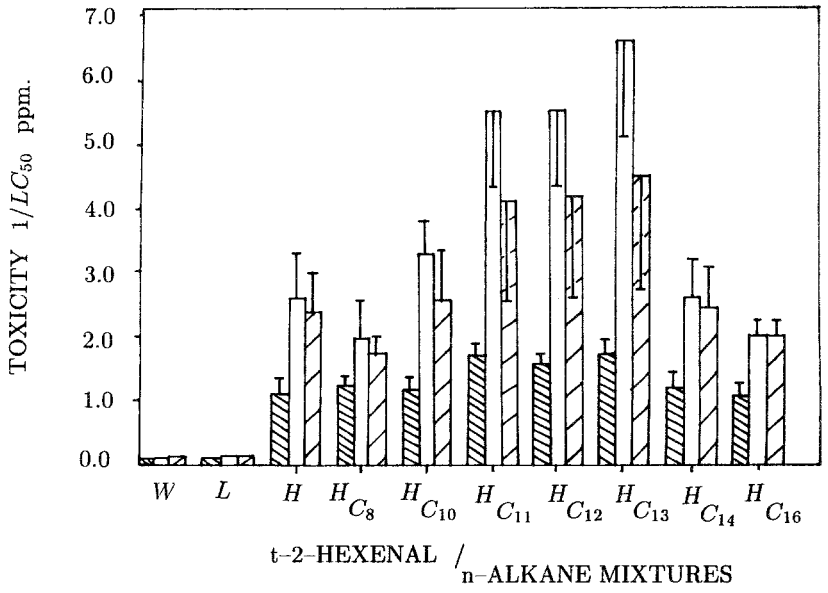

FIG. 1. Variation of toxicities with 60:40 (w/w) *t*-2-hexenal/*n*-alkane combinations. In Fig. 1–4, each column is a mean of three replicates. Vertical bars indicate ∓ SEM. *A. longipes* ≡ ▨, *C. quinquefasciatus* ≡ □, *S. cerealella* = ▨, *t*-2-hexenal = H, paraffin oil = P, distilled water = W, without liquid = L.

n-Alkane series also showed a similar profile with maxima around C-11, C-12, and C-13 but with comparatively lower toxicities than those of their respective combinations (Figure 2). Highest toxicity was shown by tridecane having 1/LC50 values of 0.395, 2.32, and 2.32 ppm for *A. longipes*, *S. cerealella*, and *C. quinquefasciatus*, respectively. Toxicity of *t*-2-hexenal was somewhat higher than those of *n*-alkanes, the 1/LC50 value being 1.14, 2.43, and 2.56 ppm for the three test insects in the above order.

Repellency Assay

Our data showed that repellencies of both series, *t*-2-hexenal: *n*-alkane (60:40, w/w) combinations, and *n*-alkanes varied in a similar manner, only the latter showing somewhat lower values. These variations were quite parallel to those obtained in toxicity assay. High repellencies of combinations from 2-hexenal: C-11 alkane up to 2-hexenal: C-13 alkane were observed with a maxima at the mixture of 2-hexenal: C-13 giving % repellencies of 63, 55, and 65 for *A. longipes*, *S. cerealella*, and *C. quinquefasciatus*, respectively. Along the *n*-alkane series, highest activity was obtained for tridecane, repelling 30%, 31%, and 32% of test insects in the above order. *t*-2-Hexenal, however, was shown to be far superior in its repellent properties compared with hydrocarbons

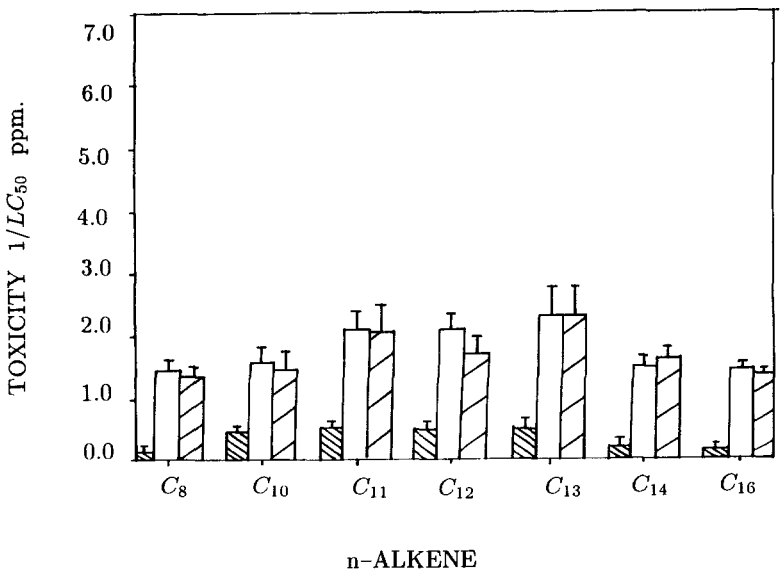

FIG. 2. Variation of toxicities with *n*-alkanes (see Figure 1 legend for explanation of symbols).

as it repelled 44%, 44%, and 55% of *A. longipes*, *S. cerealella*, and *C. quinquefasciatus*, respectively (Figures 3 and 4).

DISCUSSION

Synergistic action of all combinations of *t*-2-hexenal: *n*-alkane (60:40, w/w) is shown by this study. The natural combination, *t*-2-hexenal: C-13 (60:40, w/w) is shown to be the optimal fumigant compared to other possible aldehyde combinations with longer and shorter *n*-alkanes in the ratio 60:40 (w/w). It is also apparent from this study that among other combinations, those with medium carbon chains C-11 and C-12 are much more effective than those with shorter and longer chains.

n-Alkanes, although moderate to low in toxicity, showed similar variation along the series suggesting that *n*-alkanes also contribute directly toward toxicity of the defensive secretions. It is also interesting to note that 2-hexenal by itself is only a little more toxic ($1/LC_{50}$ 1.14, 2.56, and 2.43 ppm for *A. longipes*, *C. quinquefasciatus*, and *S. cerealella*, respectively) than *n*-tridecane, the most toxic alkane in the series ($1/LC_{50}$ 0.395, 2.32, and 2.32 ppm for the above insects, respectively). It is clearly shown from our results that for overall

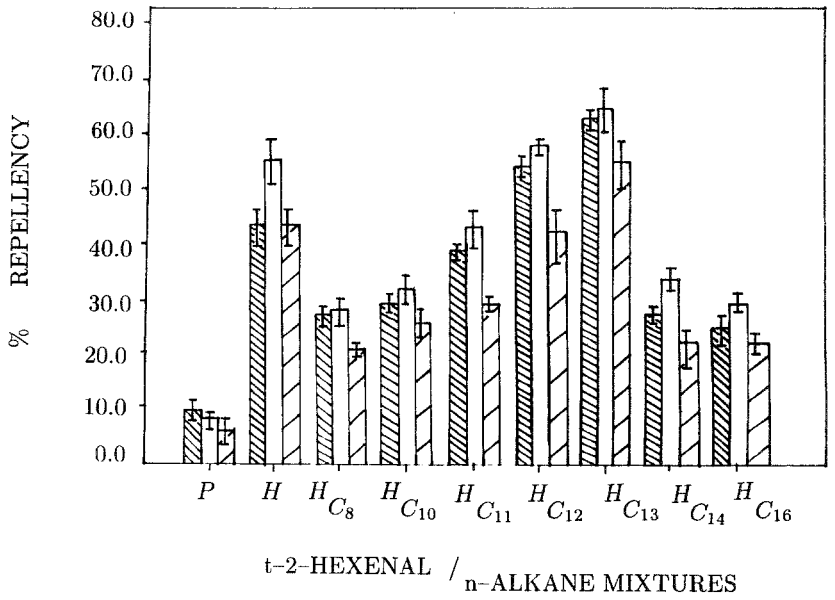

FIG. 3. Variation of repellencies with *t*-2-hexenal/*n*-alkane combnations (see Figure 1 legend for explanation of symbols).

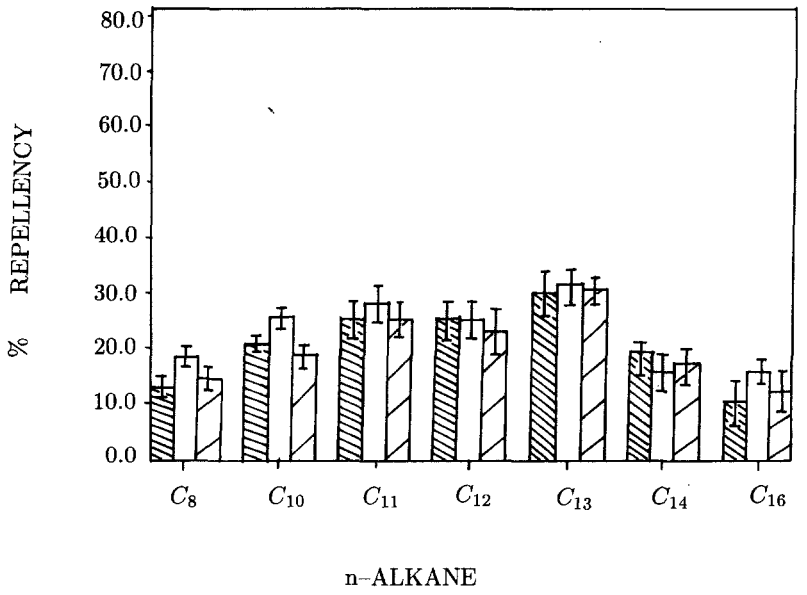

FIG. 4. Variation of repellencies with *n*-alkanes (see Figure 1 legend for explanation of symbols).

high toxicity of the combinations both *n*-alkane and the aldehyde seem to be equally important. Accordingly, the role of hydrocarbon in the defensive secretion of *C. Janus* could be twofold: while acting as a toxicant by itself, it could also enhance the toxicity of the major toxicant, probably by acting as the carrier, as was shown by Remold (1962). For both purposes, medium chain *n*-alkanes, undecane, dodecane, and tridecane seem to be ideally suited.

Repellencies of both series again followed more or less the similar pattern to those of toxicities, the natural combination having the highest repellency (*A. longipes:* 63%, *C. quinquefasciatus:* 65%, and *S. cerealella:* 55%) while those combinations with C-11 and C-12 also showed high activity. Unlike toxicities, however, overall repellency of the combination seems to be entirely derived from *t*-hexenal having repellencies 44%, 55%, and 44% for insects in the above order. This could presumably be the reason for the natural occurrence of *t*-2-hexenal without any accompanying compounds in the defensive secretions of some hemipterans as well as other arthropods (Weatherston and Percy, 1978). Alkenal probably becomes the only constituent when repellency is the only desired mode of defense of an insect. Presence of alkanes in the defensive secretion is known to delay the evaporation of volatile alkenal and this could obviously be unfavorable in some situations (Aldrich, 1988).

These findings on the importance of medium chain *n*-alkanes were com-

pared with their frequency of natural occurrence in defensive secretions. Our search of 25 hemipteran species which use alkanes as accompanying compounds in their defensive secretions revealed that *n*-tridecane occurs exclusively (100%) in all cases. More interestingly, it was found to be the major or the only alkane in 95% of the sample. Other *n*-alkanes found in combination with tridecane were indeed C-11 and or C-12 (50%) while some of the species use, in addition to C-13, C-12, and C-11, some C-15 (14%). No other *n*-alkanes were found as accompanying compounds in the above sample (Weatherston and Percy, 1978; Aldrich et al., 1984, 1986; Staddon, 1979; Kathuria et al., 1975; Remold, 1962; Taketoshi, 1974; Prestwich, 1976).

In conclusion, this study reveals two aspects clearly, *viz*, the natural combination in the defensive secretion of *C. janus* which employs *t*-2-hexenal: tridecane is the most effective toxicant and repellent compared to other combinations of the alkenal having shorter and longer *n*-alkanes. Second, in addition to functions already attributed to alkanes, they contribute to defensive function in their own right. This effect is most significant in the medium chain *n*-alkanes undecane, dodecane, and tridecane which are often found naturally in the defensive secretions of hemipterans.

Abstract—We required an experimental system in which to explore elements of the chemical legacy hypothesis, according to which molecules of environmental chemicals may persist on or in the body or immediate surroundings of larval or pupal insects and influence their habitat preferences in adulthood by affecting the maturation of the chemosensory pathways. Using a purpose-built apparatus which exploited the geotactic and phototactic behavior of *Drosophila melanogaster*, we examined the pattern of responses to a range of dilutions of geraniol, a terpene of plant origin. Fruit flies avoided the geraniol at high concentrations. Although attraction at low doses and reduced aversion after larval, pupal, or early adult exposure to geraniol have been reported, we did not find either. Thus, we failed to generate the phenomenon described as "pre-imaginal conditioning" required for the model system. We discuss the results in relation to designing suitable assays for testing the Chemical Legacy Hypothesis.

Key Words—Chemical legacy hypothesis, pre-imaginal conditioning, Hopkins host-selection principle, *Drosophila melanogaster*, Diptera, Drosophilidae, geraniol.

INTRODUCTION

According to the chemical legacy hypothesis, correlations between adult habitat preferences and larval rearing experiences in insects may arise from direct

chemical intervention in development of the chemosensory machinery (Corbet, 1985). Minute traces of chemicals from the larval environment persisting on the surface of the animal's body or cocoon might influence chemosensory development, perhaps acting at or soon after adult emergence (Herard et al., 1988). Corbet (1985) and Vet et al. (1990) reviewed evidence for such plasticity of behavioral responses in insects, but the mechanism underlying this process has not yet been elucidated. We wanted to see whether the effect of early exposure on adult responsiveness could be interpreted in terms of a change in chemosensory threshold, reflected in a shift of a humped dose-response curve along the dose axis. We therefore sought a system showing dose-dependent reversal of response, with attraction at low doses and aversion at high ones, and modification of adult chemosensory responses to a compound by exposure to it in the pre-imaginal or immediately post-emergence environment.

Systems reported to show these features include *Drosophila* with peppermint oil (Hershberger and Smith, 1967; Jaenike, 1982) and geraniol (Manning, 1967). We chose geraniol, a terpene of plant origin, because it is a pure substance whereas peppermint oil is a mixture. In adults of an unnamed species of *Drosophila*, Manning (1967) reported attraction to geraniol at low concentrations and aversion at high concentrations with reduced aversion in flies reared as larvae in agar to which the chemical had been added.

Here, we describe our assay and conditioning methods, and report our failure to find attraction at low concentrations or to modify the adult response to geraniol. We discuss this result in relation to designing suitable model systems for exploring the chemical legacy hypothesis.

METHODS

Drosophila melanogaster were reared on a maizemeal/sugar/agar medium under a 12L:12D lighting regime at 25°C. Since the testing procedure exploited the negative geotaxis and positive phototaxis of adult fruitflies, we waited until flies were 36 hours post-emergence and had reached physical maturity (Ford, et al. 1989) before using them.

Odorant was presented in chambers constructed from the barrels of 7-ml nonsterile polyethylene Pasteur pipettes (Elkay Eireann). We cut off and discarded the tubular portion of each pipette approximately 2 mm below the barrel, and inserted the mouth of the barrel into a hole of 7.5-mm diameter drilled through 3-mm thick perspex. Six barrels were fitted like this in a 35-mm diameter circle on a 100 × 75-mm piece of perspex which had been painted black on the upper side.

To form the testing arena, this barrel assembly was placed face down on a flared plastic dish (volume 85 ml, upper diameter 65 mm, lower diameter

55 mm) coated on the outside with black insulating tape (Figure 1). Each arena was used once, after which the perspex and dish were washed and the barrels were discarded and replaced with new ones for the next test.

Testing was conducted at 25°C under twin fluorescent lights. The barrel assembly was inverted while 5 μl diethyl ether was pipetted into alternate barrels (controls) and 5 μl of a solution of geraniol in ether was pipetted into the remaining three barrels (tests). The barrel entrances were marked "control" or "test" using a water-soluble felt-tip pen. The droplets of both ether and the geraniol solution visibly evaporated while the assembly was in this position.

Approximately 50 flies were drawn from a culture bottle and held in the pooter while the barrel assembly was inverted over the plastic dish. With the barrel assembly in place we pooted the flies into the dish and left the apparatus undisturbed for 30 sec. After that time, an acetate sheet was slipped under the perspex to trap the flies in the barrels, and the entire apparatus was secured with a rubber band. Flies were killed by freezing and then counted by removing each barrel. During the testing process, the experimenter was unable to identify the test or the control tubes.

The geraniol solution was prepared by dissolving geraniol (Sigma Chemical Company) in diethyl ether. We used dilutions from 0.1 to 0.0000001, and express them as log concentration on figures and tables to follow. Since the assay procedure depended on the solvent, ether, evaporating from the barrels and leaving geraniol behind, we checked whether geraniol influenced the evaporation of ether by weighing a sample of barrels to 0.00001 g continuously for

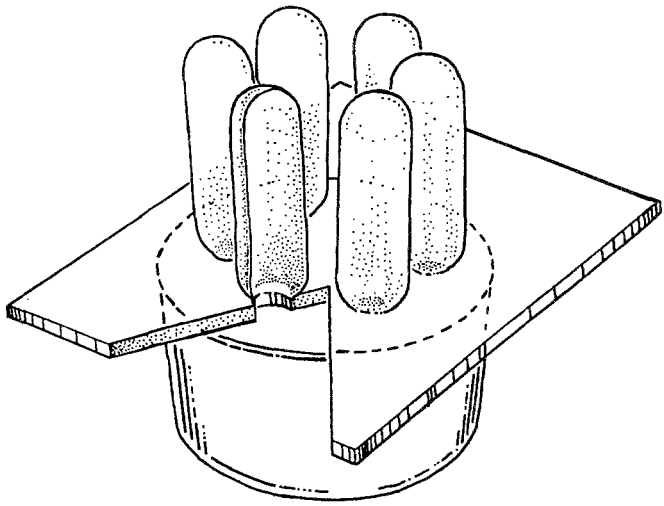

FIG. 1. The testing apparatus.

300 sec while 5 μl of 0.1 geraniol solution or diethyl ether evaporated. We found that evaporation indicated by weight loss was significantly slower in the presence of geraniol at intervals up to 150 sec (Table 1).

We checked whether these differences in evaporation kinetics influenced the proportion of flies entering geraniol-scented barrels by presenting 0.43–0.56 μl droplets of neat geraniol in alternate barrels and leaving control barrels blank. The results for ten such replicates were compared with ten replicates using 5 μl of 0.1 geraniol solution in the test barrels and 5 μl ether in the control barrels, and were significantly different (Mann–Whitney, $U = 55.0$, $P < 0.05$). On average, 41% of respondents entered geraniol tubes in the absence of ether, and 27% entered scented tubes when ether was used as the solvent.

We inferred that geraniol acted as a "keeper" delaying evaporation of ether and that the flies' apparent aversion to the geraniol–ether solution may have resulted, at least in part, from a differential response to persisting traces of the solvent, perhaps aversion to excess ether in the test barrels or attraction to excess ether in the controls.

To guard against this effect during testing, we delayed introducing flies into the arena after pipetting solvent and solution into the barrels, and used a weaker geraniol solution when testing whether flies had reduced aversion to geraniol after pre-imaginal exposure. We assumed that the "ether-holding" property of geraniol would reduce as the concentration of the solute reduced.

We gave flies prior exposure to geraniol in two ways. Flies collected within 30 min of emergence were placed in a small vial stoppered with cotton wool with 5 μl neat geraniol on a small disk of filter paper. After 30 min exposure to geraniol, the flies were transferred to normal culture jars. They were tested at 48 hr post-emergence. We also prepared geraniol-agar by mixing 0.25% geraniol by volume into the agar during the cooling stage, and flies reared in this

medium were collected either at the moment of emergence or 12 hr later and held in clean vials with damp cottonwool for 5 hr before testing.

RESULTS

We tested about 5000 flies in 93 replicates over seven concentrations of geraniol ranging down to a dilution of 10^{-7} in ether. Like Dudai et al. (1976) and Manning (1967), we found that *Drosophila melanogaster* avoided geraniol at relatively high concentrations. At lower concentrations, the flies did not discriminate between test and control barrels (Figure 2), and unlike Manning (1967), we did not observe any behavior consistent with attraction to geraniol. A polynomial regression model incorporating a cubic term adequately described the dose–response function (Table 2). Response values predicted by the model are shown in Figure 2.

When newly emerged flies were exposed for 30 min to 5 μl neat geraniol, their response to 0.01 geraniol when tested 48 hr later was not significantly different from that of flies without prior exposure ($t = 1.157$, $df = 32$, $P > 0.05$). We conclude that exposure of up to 30 min immediately after emergence had no detectable effect on subsequent adult responsiveness.

Flies raised on agar tainted with geraniol and tested 5 or 17 hr after emergence did not exhibit reduced aversion to 0.01 geraniol ($F_{2,35} = 0.19$, $P > 0.05$), and like the controls, were equally likely to approach scented and unscented barrels when tested with 10^{-4} geraniol ($F_{2,32} = 2.52$, $P > 0.05$) and 10^{-6} geraniol ($t = 0.704$, $df = 19$, $P > 0.05$). We therefore found no

evidence for an effect of pre-imaginal exposure on the adult response to geraniol.

DISCUSSION

In our study, fruit flies appeared unable to detect geraniol diluted below 10^{-3}. We therefore used 10^{-2} geraniol as a test stimulus after prior exposure to geraniol to see whether a change in responsiveness had been induced by a chemical legacy.

Manning (1967) showed that flies reared as larvae and maintained as adults in the presence of geraniol found this compound less aversive than flies reared as larvae and maintained as adults in its absence. The finding that this effect was almost abolished if all flies were removed to geraniol-free vials at emergence indicates that at least part of the effect of early exposure on adult behavior depends on post-emergence exposure to geraniol. Further evidence came from the finding that when flies were reared as larvae on uncontaminated medium, those exposed to geraniol on emergence for 18 hr found geraniol less aversive in subsequent tests than did those kept in unscented vials after emergence.

These results are compatible with the postulate of the chemical legacy hypothesis that effects of chemicals from the larval medium on adult behavior may involve persistent chemical cues acting on the development of the chemosensory machinery in the adult during a "sensitive period" at or soon after emergence (Corbet, 1985). To elucidate the mechanism by which experience of a compound from the larval medium might modify the subsequent responsiveness of adult flies to it, we wanted to see how the adult dose–response curve would be affected by exposure to a compound in the larval medium. We chose the geraniol/*Drosophila* system because it involves a pure substance rather than

a mixture, because exposure to geraniol in the larval medium had been reported to reduce adult aversion to that compound (Manning, 1967), and because Manning (1967) reported a dose-dependent reversal of response, with aversion at high doses and attraction at low ones (see Knight and Corbet, 1991).

We did not find any evidence for attraction to geraniol at low doses, or for effects of pre-exposure before or up to 12 hr after emergence on the proportion entering scented barrels in subsequent tests. The failure of our fly/geraniol bioassay system to reveal phenomena reported by Manning prompts us to consider the features that are desirable in a model system designed to explore the mechanism by which chemicals from the larval environment might influence adult chemosensory responses. First, we consider properties of suitable chemical stimuli.

Natural materials, such as fruits, are mixtures of compounds. Even if natural materials are more appropriate when the ecological implications are being explored (Jaenike, 1983; Papaj and Prokopy, 1988), pure substances are preferred for studies of the mechanism of this effect (Manning, 1967; Jaenike, 1982). In nature, the effect may often depend on persistence of chemical cues on or near the insect's body until adult emergence. With some possible exceptions (ethanol; Jaenike, 1982; perhaps sinigrin), candidate compounds will have features associated with environmental persistence: low solubility in water, and relatively low volatility. In general, the effect on adult responsiveness has been clearest when the stimulus chemical is initially aversive or of low attraction; the response to highly attractive chemicals is less susceptible to changes (Jaenike, 1983, 1988; Vet et al., 1990). Further, the dose–response curve is expected to be more informative if there is initial attraction at very low doses. This has been demonstrated for some compounds (e.g., Rodrigues, 1980), but we have not been able to corroborate the claim that it applies to geraniol.

The manner in which the stimulus chemical is presented to insects may also be critical. The range of doses required for the construction of a dose–response curve is often achieved by diluting the candidate compound in a more volatile solvent such as diethyl ether (e.g., Borst, 1983; Quinn et al., 1974), and it is usual to wait until the solvent can no longer be smelled by the experimenter before conducting the bioassay. It is then assumed that any difference in the insect's response to the test chemical and the solvent control is due to the test chemical itself, and not to persistent traces of the solvent. However, this assumption might not be valid if the test chemical were to affect the evaporation kinetics of the solvent. That this may sometimes be so can be inferred from the perfumers' practice of using fixatives in the formulation of scents to delay evaporation (Moncrieff, 1967), and from the finding of Kaib and Dittebrand (1990) that less volatile components of an ant pheromone delayed evaporation of limonene. We found an effect of geraniol on the rate of evaporation of ether, and modified our procedure in the hope of minimizing it. If traces of solvent remain

in the test chamber, the flies' apparent response to the test chemical might be modified by, or dominated by a response to the solvent. Such solvent–solute interactions are not usually taken into account.

The allelochemicals acting as cues to specialized herbivorous insects in nature are often toxic to non-adapted insects (Spencer, 1988), but if there is substantial mortality during pre-exposure in these experiments, any treatment effects on adult responsiveness may be due to differential survival, rather than to modification of a chemosensory pathway (Jaenike, 1982, 1983). Manning (1967) reported reduced adult aversion to geraniol in a sample of 56 fruitflies reared in agar medium containing 0.5% geraniol by volume. We found that adult flies died in culture jars with medium containing geraniol at that strength, so we halved the geraniol concentration to 0.25%. Even then, flies in geraniol-agar delayed oviposition by about 3 days compared with flies in unadulterated medium.

We also suspect that the timing of exposure and testing may be critical. According to the chemical legacy hypothesis, some effects on adult responsiveness are attributable to exposure of the new adult to chemicals derived from the pre-imaginal environment during a "sensitive period," at or near the time of emergence from the pupa or cocoon, as illustrated by the elegant experiments of Jaenike (1982) and subsequently Herard et al. (1988). In these cases, the behavioral induction is not strictly pre-imaginal, although caused by chemical cues associated with the pre-imaginal environment. To eliminate these cues by washing pupae until no statistically significant effect remains is difficult (Thorpe, 1939; Hershberger and Smith, 1967), but not impossible (Jaenike, 1982). In experiments on modification of adult chemosensory responsiveness, the exact age at exposure of "newly emerged" adults may prove to be important. In our experiments, adults were collected as they left the puparium, but other workers may have timed emergence less precisely, using adults within perhaps a few hours of emergence. It is not yet clear how critical the timing of exposure in relation to emergence may be. The timing of testing is also important; for example, the effect of early exposure to a chemical stimulus wanes over succeeding days of adult life in *Drosophila* (Hershberger and Smith, 1967) and in the ant *Camponotus floridanus* (Carlin and Schwartz, 1989).

The extent to which the design of the bioassay apparatus influences the results remains unknown. Some experiments on olfactory conditioning in *Drosophila* have involved oviposition, being scored in terms of the numbers of eggs laid on two or more different substrate types available at the same time. Others depended on displacement of flies, by walking or in flight, sometimes taking advantage of geotactic and/or phototactic responses. They have used moving air in a Y-tube (Manning, 1967; Fuyama, 1976; Hershberger and Smith, 1967; Kikuchi, 1973) or two-way (Tully and Quinn, 1985; Tully, 1987) or four-way olfactometers (Vet et al., 1983), or still air offering flies a choice between two

chambers (Borst, 1983; Dudai et al., 1976). In some bioassays, some flies are allowed not to respond (e.g., Fuyama, 1976). In our experiments, the proportion of nonrespondents varied with the conditions.

Compounds attractive at low concentration may repel at high concentration (Knight and Corbet, 1991). A fly approaching a scent source in still air will encounter a concentration gradient. It will encounter a progressive increase in concentration of the test chemical, and may experience an aversive dose before reaching the source. At the same time, its chemosensory threshold may be elevated as a result of continuing exposure. The net effect on the fly's displacement is expected to depend on the form of the dose–response curve, the concentration gradient and the rates of approach and sensory adaptation, and on whether or not a non-return valve prevents departure from the source. These complications may not affect the result in cases where the entire gradient within the flies' arena is aversive, but may do so if it spans both concentrations high enough to repel and concentrations low enough to be neutral or attractive. A moving air olfactometer can be arranged so that concentration gradients are less steep, reducing this source of error.

Few experimenters have drawn conclusions on the basis of a single run (Manning, 1967). More often, runs are replicated for each treatment. These often reveal high variability, perhaps due to the numbers of flies per run, or the presence of one or both sexes of flies. Given an estimate of the mean and the variance in the response, it would be possible to calculate the number of runs required to establish a difference of a given magnitude at a given probability level (Elliott, 1977, p. 129).

Finally, chemosensory responsiveness varies throughout the 24-hr period such as in moths (Linn and Roelofs, 1986). Tests to be compared should therefore be run at about the same subjective biological time each day. We ran ours 3 hr after the onset of subjective dawn. Because of the need for thorough cleaning or replacement of the apparatus between tests to avoid scent contamination, this means that multiple copies of the equipment must be available if several tests are to be performed each day. Ideally, then, the apparatus on which the experimental model is based should be inexpensive and/or disposable.

Abstract—Seven volatile compounds identified from the headspace of whole wheat bread dough were investigated for their role in attracting *Glischrochilus quadrisignatus* and *G. fasciatus* in the field. Traps baited with either whole wheat bread dough or a synthetic seven-component bread dough odor caught similar numbers of these beetles, suggesting that the seven-compound combination could simulate the behavioral effect of bread dough. A series of trials using traps baited with various combinations of these chemicals showed that five compounds were significantly active in attracting *G. quadrisignatus* and *G. fasciatus*, but not all were essential for maximum response. The simplest blend eliciting a level of response comparable to the seven-component combination included ethyl acetate, acetaldehyde, ethanol, and racemic 2-methylbutanol, of which ethyl acetate, ethanol, and acetaldehyde were essential and 2-methylbutanol was replaceable with 2-methylpropanol for *G. quadrisignatus* attraction. Ethyl acetate and ethanol were essential for comparable attraction of *G. fasciatus*. The chemical mediation of food finding in *G. quadrisignatus* and *G. fasciatus* is discussed in the context of volatile blends characterized for other nitidulid species.

Key Words—Coleoptera, Nitidulidae, *Glischrochilus quadrisignatus*, *Glischrochilus fasciatus*, field traps, volatile attractants, host volatiles.

INTRODUCTION

Glischrochilus quadrisignatus (Say) and *G. fasciatus* (Olivier) are insect pests of many small fruits and vegetables. Severe damage to corn, strawberry, cane

*To whom correspondence should be addressed.

berry, and tomato caused by *Glischrochilus* species throughout the continental United States and Southern Canada frequently have been reported (Pree, 1969; Foott and Hybsky, 1976; Miller and Williams, 1981). In addition, nitidulid beetles are considered the primary vectors of oak wilt disease (Appel et al., 1986), and *G. quadrisignatus* and *G. fasciatus* are among the principal insect species associated with oak wilt-infected trees (Dorsey and Leach, 1956; Juzwik and French, 1983). *G. quadrisignatus* is also associated with *Fusarium* pathogens of corn roots, stalks, and ears (Windels et al., 1976), and is capable of transmitting conidia and ascospores of *Gibberella zea* (the perithelial state of *Fusarium graminearum*) causing rot to corn ears (Attwater and Busch 1983). Furthermore, *Glischrochilus* species can be a considerable nuisance by disrupting picnics and other outdoor activities (Luckmann, 1963; Miller and Williams, 1981).

Glischrochilus species are attracted to a variety of host odors and traps baited with foods have been used in monitoring these and other nitidulid beetles (Foott and Hybsky, 1976; Alm et al., 1985, 1986, 1989; Peng and Williams, 1991). Given that these beetles attack fruits and vegetables late in the maturation process, conventional pesticide control may be unacceptable. Mass trapping using odor baits has been conducted for control and has been suggested as an alternative to broadcast application of pesticides to control these pests (Warner, 1960; Pree, 1969; Foott and Hybsky, 1976); however, the chemical basis of nitidulid food finding is incompletely understood. Our laboratory has recently characterized volatiles mediating food-finding in two other nitidulids, *Carpophilus hemipterus* and *C. lugubris* (Phelan and Lin, 1991; Lin and Phelan, 1991). In this study, we sought to elucidate chemicals mediating food finding in *Glischrochilus quadrisignatus* and *G. fasciatus* to allow a broader interspecific comparison of this process among members of this group of insect herbivores, and more specifically to aid in the development of monitoring tools and alternative control strategies for these insects.

MATERIALS AND METHODS

Odor Baits. Natural odor baits used in this study were either 30 g of whole wheat bread dough inoculated with baker's yeast (Lin and Phelan, 1991) or 30 g of banana inoculated with the yeast *Saccharomyces cerevisiae* (Phelan and Lin, 1991). Although a variety of fruits and vegetables were attractive to *Glischrochilus quadrisignatus* and *G. fasciatus*, whole wheat bread dough was one of the most attractive substrates (Blackmer, 1991). Thus, bread dough odor was used as model for synthetic odor. Yeast-inoculated banana, another attractive substrate, was tested in the first trial to confirm that bread dough and yeast-inoculated banana were equally effective in attracting these beetles.

Headspace volatile profiles of whole wheat bread dough and synthetic blends were analyzed using a Tenax-based volatile-collection device integrated

into a Hewlett-Packard 5890A capillary gas chromatograph (GC) and a Hewlett-Packard 5970C Mass Selective Detector (MS). Methods for collection and analysis of bread dough odor have been previously described (Lin and Phelan, 1991). GC separations were conducted on a DB-1 capillary column (30 m × 0.32-mm ID, 5.0-μm film thickness; J & W Scientific, Folsum, California) with a temperature program of 30–200°C, increased at 10°C/min.

Based on our previous chemical characterization of bread dough odor (Lin and Phelan, 1991), a synthetic odor bait was generated based on seven compounds: acetaldehyde, ethyl acetate, ethanol, propanol, 2-methylpropanol, 2-methylbutanol and 3-methylbutanol. A racemic mixture of 2-methylbutanol was used in this study. Chemicals were purchased from Aldrich Chemical Co. (Milwaukee, Wisconsin) and were diluted individually with mineral oil, except ethanol, which was diluted by double-deionized water due to its insolubility in mineral oil. Synthetic odor blends were created by adjoining 1.2-mL glass vials (9 mm ID × 30 mm H), each of which contained 1 mL of an individual component solution. This method effectively prolonged the release of the chemicals and enabled us to change the resultant odor by removing or manipulating the release rate of individual components without altering the release rate of other odor components. Through repetitively adjusting the concentration of each component solution, we generated a synthetic odor profile that closely mimicked that of whole wheat bread dough using the synthetic-blend composition listed in Table 1. The release rate of components in the synthetic blend were

TABLE 1. COMPOSITION OF A SYNTHETIC BREAD DOUGH ODOR, RELEASE RATES OF INDIVIDUAL COMPONENTS, AND COMPARISON OF THEIR HEADSPACE CONCENTRATIONS WITH THOSE OF NATURAL BREAD DOUGH ODOR[a]

Components		Synthetic odor composition[b]	Release rate[c] (mg/24 hr)	SY:BD[d] (absolute quantity)			
Abbr.	Identity			12 hr	24 hr	36 hr	Mean
EtAc	Ethyl acetate	1 ml, 0.25%	0.58	1.67	1.19	1.25	1.37

2MBOH	2-Methylbutanol	1 ml, 0.5%	2.38				

[a] Measurements of release rates were conducted in the laboratory under conditions of 25–28°C and 65–75% RH.
[b] Solution (v/v) in mineral oil except ethanol, which was diluted with distilled water.
[c] Based on the total release rate in 48 hr ($N = 3$).
[d] Ratio between absolute concentration of each component in the headspace of the synthetic blend (SY) relative to bread dough (BD) at 12, 24, and 36 hr, respectively ($N = 3$).
[e] 3-Methylbutanol and 2-methylbutanol were combined due to unresolved GC peaks.

compared to those in the natural odor after 12, 24, and 36 hr by comparison of GC peak areas. The release rates of 2-methylbutanol and 3-methylbutanol were measured in combination due to their similar retention time in our GC/MS analysis (Lin and Phelan, 1991). The cumulative release over time of each of these seven compounds was measured individually using an electronic balance (Mettler H54AR, $d = 0.01$ mg). Traps for volatile collection and measurement were set in the laboratory at 25–28°C and 65–75% RH. Vials filled with 1 mL mineral oil and with 1 mL double-deionized water were set under the same conditions and their weight losses were also measured as control.

Field Trap and Experimental Procedure. Skalbeck traps (Skalbeck, 1976) were used in this study, because of their trapping efficiency and economy compared with other trap designs (Peng and Williams, 1991). Briefly, the trap consisted of a pint-size canning jar, a screen cap, a hardboard rain shield over the screen cap, and a plastic funnel-shaped cup with the bottom removed placed in the jar underneath the screen cap. The odor bait was held in a small plastic cup covered with fine-mesh organdy to keep beetles out, and the cup was placed at the bottom of the jar. Bread dough was incubated in a plastic bag at room temperature for about 12 hr and the synthetic combinations were prepared immediately prior to trap deployment. Traps were set up in early afternoon and removed after 48 hr.

The trials were conducted in an abandoned apple orchard at Wooster, Ohio, in July and August of 1990. Traps were set at ground level, which was shown to be the height most effective in trapping *Glischrochilus* species (Alm et al., 1989; Peng and Williams, 1991). A randomized complete-block design was used in all trials. Original data were subjected to the transformation of $\log(x + 1)$ before analysis of variance, and Duncan's multiple range test was used for comparing means where the ANOVA indicated a significant F value (SAS Institute, 1985).

RESULTS

Odor Samples. Using the synthetic composition listed in Table 1, the average release rate of individual components over 48 hr ranged from 0.58 mg/24 hr (ethyl acetate) to 236.6 mg/24 hr (ethanol; Table 1). Concentrations of the seven components above the headspace of the synthetic blend and bread dough were similar at 12, 24, and 36 hr after trap setup, and mean ratios of individual compounds between the synthetic blend and bread dough ranged from 0.86–2.22, which we regarded as very good considering the dynamic nature of fermenting bread dough (Table 1).

Beetle Attraction. The mean numbers of *G. quadrisignatus* and *G. fasciatus* caught in traps baited with the synthetic odor of seven compounds was not significantly different from those trapped with bread dough (Figure 1), suggesting that the synthetic blend was equally as effective in attracting both these

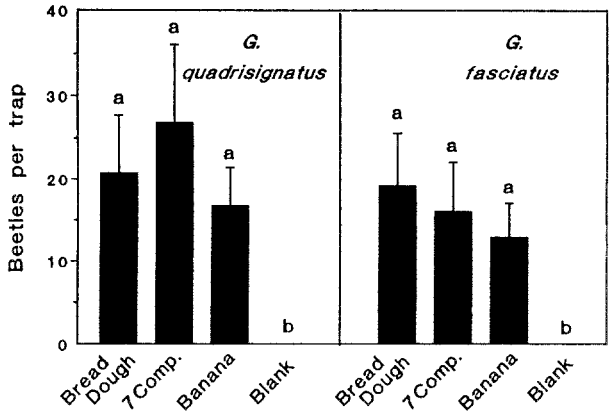

FIG. 1. Catch of *G. quadrisignatus* and *G. fasciatus* ($\bar{x} \pm$ SEM) from traps baited with bread dough (Dough), the synthetic bread dough odor (7 Comp.), or yeast-inoculated banana (Banana), and from blank traps. Bars marked by the same letter are not significantly different (Duncan's multiple-range test, N = eight traps, $P < 0.05$).

species as natural bread dough odor. Beetle responses to bread dough or to the blend of seven compounds were not significantly different from that to yeast-inoculated banana, confirming that bread dough and yeast-inoculated banana were equally attractive to these two species. Blank traps used throughout this study never caught any beetles.

When components of the synthetic odor blend were removed selectively, based on chemical functionality, the absence of acetaldehyde (AcAl), ethyl acetate (EtAc), or all five alcohols (5OH) reduced the beetle response, although the reduction in *G. fasciatus* response caused by the removal of acetaldehyde was not statistically significant (Figure 2). These results suggested that acetaldehyde, ethyl acetate, and one or more alcohols were required for a full-level attraction of *G. quadrisignatus* and *G. fasciatus*.

Next, two sets of trials focused on the relative activity of bread dough odor alcohols. For both species, the addition of individual alcohols to the basic combination of ethyl acetate and acetaldehyde did not significantly enhance beetle response (Figure 3). The addition of ethanol as the only alcohol significantly reduced the catch of *G. quadrisignatus*, with a similar nonsignificant trend for *G. fasciatus* (Figure 3). However, in the subsequent experiment, in which individual alcohols were removed from the seven-component blend, only the combination lacking ethanol caught significantly fewer individuals of either species than the full blend (Figure 4). In both cases, this treatment was not significantly different from that of the two-component blend lacking all alcohols. These results suggested that ethanol was an essential component and that some of the other alcohols were required for a full attraction of both *G. quadrisignatus* and *G. fasciatus*.

In the final trial, the addition of 2-methylbutanol or 2-methylpropanol to

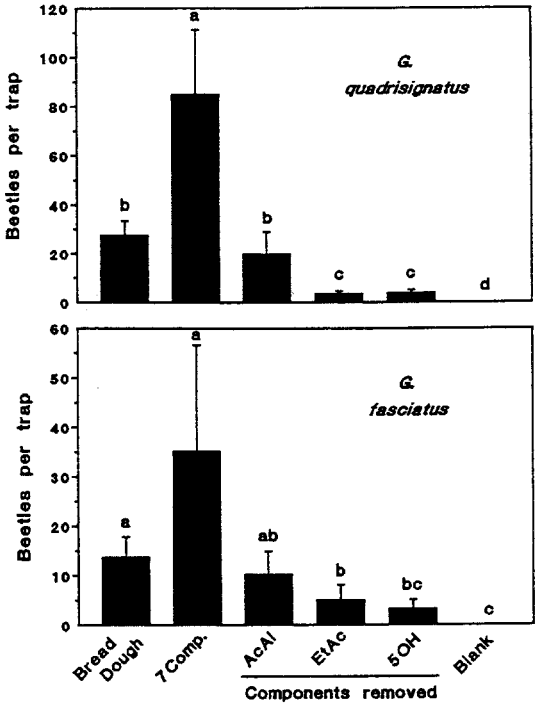

FIG. 2. Catch of *G. quadrisignatus* and *G. fasciatus* ($\bar{x} \pm$ SEM) from traps baited with bread dough, the synthetic bread dough odor (7 Comp.), or synthetic blends with components selectively removed, and from blank traps. Bars marked by the same letter are not significantly different (Duncan's multiple-range test, N = eight traps, $P < 0.05$; see Table 1 for explanation of compound abbreviations).

the three-compound blend of ethyl acetate, acetaldehyde, and ethanol significantly improved the attraction of *G. quadrisignatus* to the level of the seven-component blend (Figure 5). The addition of either propanol or 3-methylbutanol did not significantly enhance trap catch above that of the three-component blend, and the addition of 2-methylpropanol plus 3-methylbutanol to the three-component blend was no more effective than the addition of 2-methylpropanol alone. The response of *G. fasciatus* to these synthetic blends was similar in trend, although some of the differences in trap catch were not significant, probably due to the very low catch overall for this species. This trial demonstrated that at least one bread dough odor alcohol in addition to ethanol was required for full attraction of *G. quadrisignatus*, and probably for *G. fasciatus* as well.

DISCUSSION

In this study, we demonstrated that traps baited with whole wheat bread dough and the seven-component synthetic blend mimicking bread dough odor

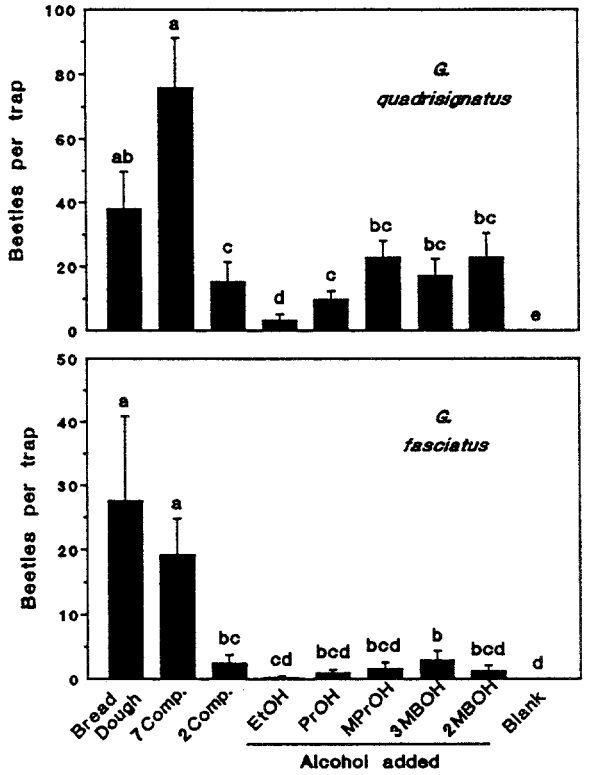

FIG. 3. Catch of *G. quadrisignatus* and *G. fasciatus* ($\bar{x} \pm$ SEM) from traps baited with bread dough, the synthetic bread dough odor (7 Comp.), a base blend of acetaldehyde and ethyl acetate (2 Comp.), or synthetic blends with each bread dough odor alcohol added to the base blend, and from blank traps. Bars marked by the same letter are not significantly different (Duncan's multiple-range test, N = eight traps, $P < 0.05$; see Table 1 for explanation of compound abbreviations).

caught comparable numbers of *G. quadrisignatus* and *G. fasciatus* in the field (Figure 1). In a series of trials that employed the removal and addition of individual components from the seven-component synthetic blend, both species demonstrated a similar trend in response. The effect of ethyl acetate was clear for both species, as its absence significantly reduced the beetle catch (Figure 2). Beetle catch was also reduced by the removal of acetaldehyde, although this reduction was not statistically significant for *G. fasciatus* (Figure 2). Among the bread dough odor alcohols, ethanol represented a third essential component as its removal significantly reduced capture of both species (Figure 4); however, a minimum of one remaining alcohols was also needed for full beetle attraction and it was at least partially interchangeable in this role (Figures 3 and 5).

Alm et al. (1985, 1986, 1989) tested a number of short chain esters, alcohols, and acids individually using traps in the field and found that butyl acetate,

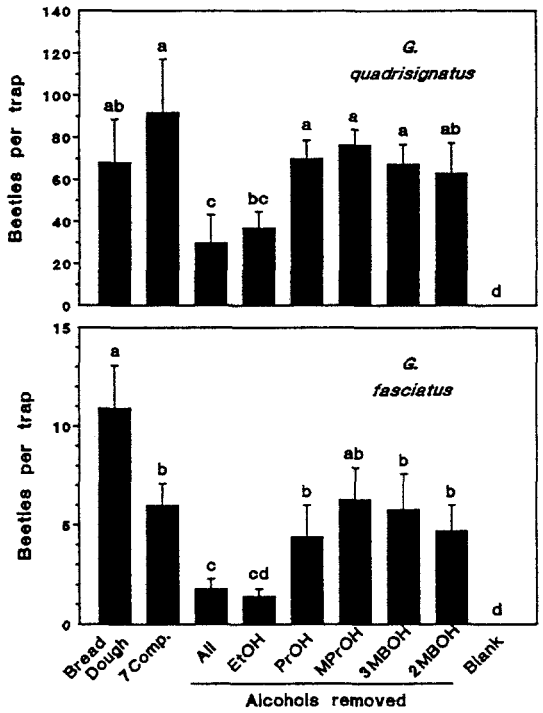

FIG. 4. Catch of *G. quadrisignatus* and *G. fasciatus* ($\bar{x} \pm$ SEM) from traps baited with bread dough, the synthetic bread dough odor (7 Comp.), or synthetic blends with each bread dough odor alcohol removed, and from blank traps. Bars marked by the same letter are not significantly different (Duncan's multiple-range test, N = eight traps, $P < 0.05$; see Table 1 for explanation of compound abbreviations) .

propyl propionate, and allyl propionate were attractive to *G. quadrisignatus*. However, the role of these three components for host finding of *G. quadrisignatus* in nature is not clear, because the release rates used in these studies were 0.061–2 ml/24 hr, which were considerably higher than from natural odor sources. Butyl acetate also was identified in the headspace above yeast-inoculated banana (Phelan and Lin, 1991), but it was not found in bread dough odor (Lin and Phelan, 1991). The beetle catch with yeast-inoculated banana was not significantly different from that with bread dough or the synthetic bread dough odor (Figure 1), suggesting that butyl acetate does not play a major role in the attraction of *G. quadrisignatus* at the rate of release from yeast-inoculated banana.

Bread dough was used as a positive control throughout this study. The response of *G. quadrisignatus* seemed to be lower to bread dough than to the seven-component blend, and the difference was statistically significant in one trial (Figure 2); however, the response of *G. fasciatus* was significantly higher to bread dough than to the seven-component blend in two trials (Figures 4 and

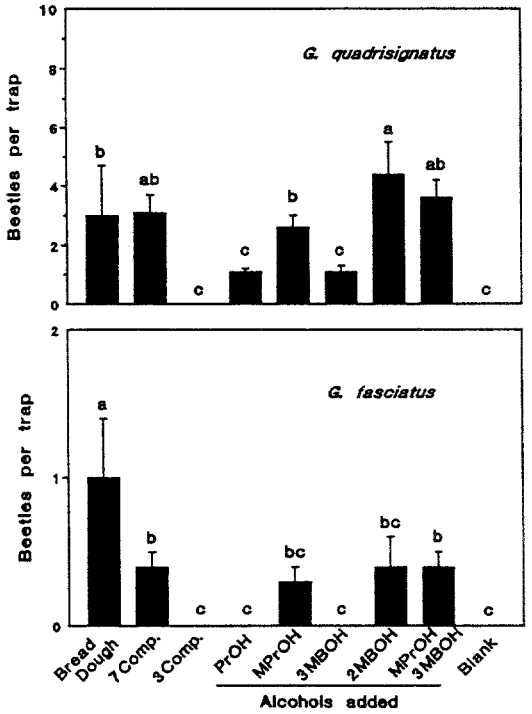

FIG. 5. Catch of *G. quadrisignatus* and *G. fasciatus* ($\bar{x} \pm$ SEM) from traps baited with bread dough, the synthetic bread dough odor (7 Comp.), a base blend of acetaldehyde, ethyl acetate, and ethanol (3 Comp.), or synthetic blends with bread dough odor alcohols added to the base blend, and from blank traps. Bars marked by the same letter are not significantly different (Duncan's multiple-range test, $N = 20$ traps, $P < 0.05$; see Table 1 for explanation of compound abbreviations).

5). This suggests that volatile components mediating the host-finding behavior of these two closely-related species are not identical and that some additional unidentified minor constituents in bread dough odor may be important for *G. fasciatus*, although both species demonstrated a similar trend in response to the seven bread dough odor constituents tested. Alm et al. (1985) also found the difference of these two species in response to volatile chemicals in the field: *G. quadrisignatus* was attracted to butyl acetate, and *G. fasciatus* was not, although both species were attracted to natural substrates.

Agriculturally-related sap beetles including *Glischrochilus* species are attracted to a variety of fruits, vegetables, and foods in the field and in the laboratory, and bread dough was one of the most attractive and commonly used substrates (Pree, 1969; Foott and Hybsky, 1976; Alm et al., 1985; Blackmer, 1991; Peng and Williams, 1991). Volatile components produced by bread dough are also identified from fruits and vegetables, although bread dough odor consists of fewer components than the others (Phelan and Lin, 1991; Lin and

Phelan, 1991). By closely simulating the release rate for each of the volatile constituents identified from bread dough or from a fruit substrate, we were better able to identify the active components attracting the beetles, and to deduce the relative complexity of interactions between components in the mediation of the beetles' host-finding behavior. Food odor attractants for four nitidulid species now have been identified as summarized in Table 2. In general, the active components are short-chain compounds with various functionalities, and they can be clustered into groups based on behavioral activity. Eliciting maximum beetle attraction requires a blend including one or more components from each group. Components within a group may be partially or fully interchangeable in eliciting beetle orientation, while those in different groups are not. Relative effectiveness of components within a group may be the result of qualitative differences or of quantitative differences, since compounds were tested at the concentrations measured in the natural odors.

Acetaldehyde plays an important role in attracting all four species of sap beetles (Table 2). The role of acetaldehyde was replaceable in part by a combination of the banana odor ketones for *C. hemipterus*. This relationship has not been investigated for the other three species, since ketones were not present in bread dough odor. The role of ethyl acetate is clear: it is essential in attracting *C. hemipterus* and two *Glischrochilus* species, but its activity in attracting *C.*

TABLE 2. ACTIVITY GROUPS OF FOOD VOLATILE CONSTITUENTS FOR FOUR NITIDULID SPECIES[a]

Volatile constituents	*C. hemipterus*[b]	*C. lugubris*[c]	*G. quadrisignatus*	*G. fasciatus*
Aldehyde ketones				
Acetaldehyde	1	1	1	1
2-pentanone	1	nt	nt	nt
3-hydroxy-2-butanone	1	nt	nt	nt
Esters				
Ethyl acetate	2	2	2	2
Alcohols				
Ethanol	ne	2,3	3	3
Propanol	3	2,3	4	4
2-methylpropanol	3	3	4	4
3-methylbutanol	3	3	4	4
2-methylbutanol	nt	3	4	4
Butanol	3	nt	nt	nt
2-pentanol	4	nt	nt	nt

[a] For each species, constituents with the same number are at least partially interchangeable and those with numbers not shared with other components are essential in eliciting attraction. An "ne" indicated that the component did not significantly enhance attraction and an "nt" indicated that the component was not tested for the species.
[b] From Phelan and Lin (1991).
[c] From Lin and Phelan (1991).

lugubris is partially replaceable with ethanol and also probably propanol (Table 2). Although seven more ester compounds were identified in the banana odor, they showed no effect on the attraction of *C. hemipterus* and had not been tested for the other three species.

Seven alcohols were identified from banana odor and five were identified from bread dough odor, their roles in attracting these beetles are very diverse (Table 2). We did not find ethanol to be attractive for *C. hemipterus* when presented at the concentration in inoculated banana odor (Phelan and Lin, 1991), although Smilanick et al. (1978) did suggest that it was active when presented in combination with ethyl acetate and acetaldehyde in equal ratio. In attracting *Glischrochilus* species, ethanol is an essential component and its activity is not replaceable with any other bread dough odor components. For *C. lugubris*, ethanol demonstrated dual roles: it is partially interchangeable with ethyl acetate, and it also is active in the role played by the other bread dough odor alcohols. All other bread dough odor alcohols play the same role in attracting these four species at various levels. The fourth role in the attraction of *C. hemipterus* is played by 2-pentanol. It was not detected in bread dough odor and this was not tested for other three species, but it is unlikely to play an essential role in attracting the other three species, because bread dough elicits a response from *C. lugubris* (Blackmer, 1991) and from the two *Glischrochilus* species (this study) comparable to that of yeast-inoculated banana.

Our present and previous studies on food odor attractants of four nitidulid species suggest that the host-finding behavior of each species is mediated by broad overlapping blends of common volatile constituents from fruits and vegetables. This chemically-mediated response mechanism is consistent with the broad host ranges exhibited by all four species, and with their demonstrated response to a variety of food substrates. Further work is required to determine if the subtle difference in optimal blends for each species serves any adaptive function, such as in determining levels of substrate decomposition.

Acknowledgments—The authors thank Dr. R.W. Williams for providing traps and D. Fickle for assistance in data collection in some of the trials. Critical reviews of the manuscript were made by Drs. R.K. Lindquist, T.L. Ladd, Jr., and R.W. Williams. AGE-RELATED RESPONSE OF MALE MELON FLIES *Dacus cucurbitae* (DIPTERA: TEPHRITIDAE) TO CUE-LURE

TIM T.Y. WONG,* D.O. McINNIS, MOHSEN M. RAMADAN, and JON I. NISHIMOTO

Tropical Fruit and Vegetable Research Laboratory

(Received April 17, 1991; accepted August 19, 1991)

Abstract—Laboratory-reared and wild adults of the melon fly, *Dacus cucurbitae* Coquillett, were tested for response to cue-lure at various ages. Virgin laboratory (4, 6, 8, 10, 12, and 14 days old) and wild (10, 12, 14, 16, 18, 20, and 22 days old) flies were released into outdoor field cages and trapped from 0800 until 1600 hr. Response of males to cue-lure increased with age and corresponded with sexual maturity for each strain. Females of both strains were relatively nonresponsive to cue-lure. Failure to eradicate in past male annihilation programs against *D. cucurbitae* may be explained in part by the fact that only older males, which may have already mated with gravid females, respond to cue-lure.

Key Words—*Dacus cucurbitae*, Diptera, Tephritidae, melon fly, cue-lure, age effects, pheromone.

INTRODUCTION

Cue-lure, a synthetic lure for male melon flies, *Dacus cucurbitae* Coquillett, has been in use since 1960 (Beroza et al., 1960). It is still the most effective attractant available for survey and detection of this insect (Keiser et al., 1973, Harris et al., 1986, Wong et al., 1989b). Cue-lure also attracts other tephritids. Drew (1974) and Drew and Hooper (1981) reported over 80 species of Dacini responded to cue-lure. The possible use of cue-lure in male annihilation programs against *D. cucurbitae* has been demonstrated in several large area field

*To whom correspondence should be addressed.

tests. Cunningham and Steiner (1972) and Cunningham et al. (1970, 1975) reported reductions of up to 99% of male melon flies in plots up to 15 km^2. However, these test populations were only semi-isolated; therefore, as a result, the tests could not demonstrate eradication. Furthermore, in the 10-km^2 plot test, a meaningful reduction in the infestation rate of *D. cucurbitae* in its wild host fruit, *Momordica charantia* L., failed to occur (Cunningham and Steiner, 1972). Bateman et al. (1966a,b) failed to reduce fruit infestation rates by the Queensland fruit fly, *Dacus tryoni* (Froggatt), in semi-isolated populations in small towns in Australia. Bateman (1973) did, however, achieve eradication of *D. tryoni* from Easter Island by using a combination of protein bait sprays and cue-lure male-annihilation treatments.

Here we report studies on the response to cue-lure of various ages of *D. cucurbitae* reared in the laboratory on artificial diet (Tanaka et al., 1969, 1982) compared with wild flies from naturally infested fruits. Also, we compare the present data with sexual maturation data of *D. cucurbitae* from Wong et al. (1986).

METHODS AND MATERIALS

Laboratory-reared melon flies used in the study had been in culture for over 400 generations (at least 33 years, with about 12 generations per year). Throughout the testing period from 1984 to 1985, wild flies were collected as mature larvae and pupae from naturally infested squashes, *Cucurbita pepo* L., and melons, *Cucumis melo* L., from Waimanalo, Oahu, Hawaii. Two days before eclosion, pupae were dyed with powdered pigments (Day-Glo Neon Red, Day-Glo Signal Green, Day-Glo Saturn Yellow, Day-Glo Blaze Orange, Day-Glo Invisible Blue, Calco Blue, and Tinopal SFG) using different colors for different ages of flies. Dyed pupae were placed in (61 × 38 × 37 cm) screened cages separated by age group and provided with ICN hydrolyzed protein (Nutritional Biochemical, Cleveland, Ohio), sugar, honey, and water, as needed for survival of newly emerged adults (Keiser and Schneider, 1969). One day after eclosion, virgin flies were separated by sex while immobilized in a refrigerated room (5–7°C) and then transferred to screened cages and held at ambient room condition (average temperature 26°C, range 24.5–28°C, 66–76% relative humidity under natural daylight supplemented with fluorescent light) until ready for testing. Previous laboratory tests using the same laboratory strain and the same wild population (Wong et al., 1986) had shown differences (both sexes) in physiological ages of the two strains of flies, i.e., sexual maturation of 90% or more was reached under these conditions in 12 days with laboratory-reared flies and in 20 days with wild flies. Therefore, in this study, tests were made when laboratory flies were 4, 6, 8, 10, 12, and 14 days old and when wild flies

were 10, 12, 14, 16, 18, 20, and 22 days old. The tests were made in two outdoor screened cages (2.5 × 2.5 × 2.5 m). In each of two cages, we released 100 unmated flies of each sex and age, laboratory-reared flies in one and wild flies in the other. Water and sugar were provided in each cage. All releases were made at 0745 hr. A plastic trap (Steiner, 1957) containing a 10-ml mixture of 99% cue-lure and 1% naled by volume in a cotton wick (4 cm long × 2 cm diam.); (Keiser et al., 1973) was placed in each outdoor cage at 0800 hr, then replaced with another identical baited trap containing cue-lure and naled hourly until 1600 hr. The flies become inactive at night and during this time are not attracted to cue-lure (Nakagawa, unpublished data). Therefore, we did not continue the experiment beyond 1600 hr. The test was replicated ten times. Total flies trapped for each testing day were recorded. Temperature and relative humidity ranged from 17° to 32°C and from 56 to 88%, respectively, during testing days. Mean percentages of flies captured were transformed using the arcsine procedure before analysis (Snedecor and Cochran, 1967). Mean captures, by age class, within laboratory or wild classes were compared with Duncan's multiple-range test at $P = 0.05$ level (SAS Institute, 1985).

Sexually mature virgin females of some tephritids respond strongly to certain synthetic male lures when males are scarce or absent. Steiner et al. (1965) reported this behavior for females of the oriental fruit fly, *Dacus dorsalis* Hendel, and Nakagawa et al. (1970, 1981) for females of the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann). We therefore conducted two cage tests to determine the response of mature virgin female *D. cucurbitae* to cue-lure in the absence of males. In one test, 500 6- to 18-day-old virgin laboratory-reared females were released in an outdoor cage. This was repeated six times, each on different dates. In another test, 300 20- to 26-day-old virgin wild females were released into a cage. This test was repeated four times, each on different dates. Testing procedures for these two tests were similar to previous tests with males and females.

RESULTS AND DISCUSSION

In the first experiment involving the releasing of both sexes, captures of males of both fly strains by traps baited with cue-lure increased gradually as adults increased in age (Table 1). A few (5.3%) laboratory males were caught in traps at age 4 days., more than 60% at age 8 days, and over 96% at age 14 days. However, males of the wild strain required a much longer period before they responded to cue-lure: only 27% at age 10 days, 57% at age 14 days, and full response (>93%) was not reached until age 22 days. Females of both strains were seldom attracted to the cue-lure (Table 1). Maximum average female capture was 1.0 (10 days old) and 0.6 (18 days old) for laboratory and

[a] Numbers of laboratory-reared or wild flies trapped between the hours of 0800–1600 in a single day. Means based on ten replicates of 100 flies per sex per strain released into cages. Means followed by the same letter within the same sex and strain are not significantly different ($P = 0.05$; Duncan's (1955) multiple range test). Data were arcsine transformed before analysis of variance; untransformed means are presented.

wild flies, respectively. Female and male flies caught in traps were observed nearly touching the wick treated with cue-lure but never observed to be feeding on it.

Response of males to cue-lure increased with age and corresponded with sexual maturity within each fly strain (Figure 1). Best fitting linear regressions for percentage response (Y) of laboratory-reared and wild males of different ages (X) to traps baited with cue-lure are: $Y = 8.69\ (X) - 15.5\ (r = 0.91, df = 59, P \leq 0.05)$ and $Y = 5.65\ (X) - 28.7\ (r = 0.87, df = 69, P \leq 0.05)$, respectively, and for laboratory-reared and wild males mated at different ages are: $Y = 12.19\ (X) - 34.1\ (r = 0.89, df = 79, P \leq 0.05)$ and $Y = 9.1\ (X) - 73.0\ (r = 0.91, df = 109, P \leq 0.05)$, respectively. When males were older (7-day-old laboratory and 12-day-old wild males), response to the lure matched sexual maturation rates for each strain. Of the 3762 laboratory-reared and 4317 wild *D. cucurbitae* males recovered from traps baited with cue-lure, 97.4 and 98.6%, respectively, were captured during the first 3 hr of the daylight period. Responses of *D. cucurbitae* to cue-lure were highest during the first hour of testing ending at 0900 hr (80.9% for laboratory-reared and 64.2% for wild

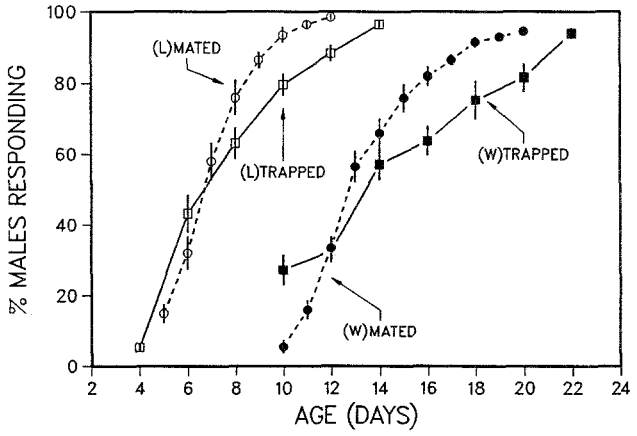

FIG. 1. Response of laboratory-reared (L) and wild (W) *Dacus cucurbitae* males of different ages to traps baited with cue-lure and 1% naled in outdoor cages, Honolulu, Hawaii. Values are arcsine transformed percentage means for five replicates (trapped) and ten replicates (mated). Line at each point represent ±2 standard errors. Data on mating of laboratory-reared and wild flies obtained from Wong et al. (1986).

males), followed by the second hour ending at 1000 hr (12.4% laboratory-reared and 28.2% for wild males). Trap catches dropped sharply after 1000 hr with no response after 1500 hr. These data indicate that the pattern of response for the laboratory-reared flies was very similar to that of the wild flies. The pattern of fly response during the morning hours could be attributed to the release of flies during those hours. However, similar diurnal patterns of lure response are known for field populations of melon fly (Nakagawa and Urago of this laboratory; unpublished data). They found that the peak response period of wild *D. cucurbitae* males occurred in the morning from 0830 to 1030 hr with no response occurring after 1530 hr.

The finding that newly-emerged, sexually immature males of *D. cucurbitae* did not respond to cue-lure differs from that of an earlier study. Beroza et al. (1960) observed responses by immature *D. cucurbitae* to cue-lure. The relation between response to male lure and sexual maturity has been studied previously in other *Dacus* species, but reports on the nature of this relationship are also conflicting. Fitt (1981) found that in male *Dacus opiliae*, the development of the behavioral response to methyl eugenol was related directly to reproductive development. Similarly, *D. tryoni* males do not respond to cue-lure (Monro and Richardson 1969; Fletcher, 1974) until some days after emergence. Steiner (1952) and later Wong et al. (1989a) reported that sexually immature *D. dorsalis* males responded to methyl eugenol. However, Umeya et al. (1973) and

Ito and Iwahashi (1974) found that attraction of *D. dorsalis* males commenced some days after emergence and was correlated with sexual maturation.

Of the six releases of laboratory-reared virgin melon fly females consisting of 2800 individuals (6–18 days old) and four releases of 900 wild virgin females (24–27 days old) released into cages without males, only 14 laboratory females (0.5%) and no wild females were caught in the cue-lure traps. Thus, we conclude virgin, gravid melon fly females are not responsive to cue-lure at any age.

The use of cue-lure against melon fly as a male annihilation technique would probably be much more difficult than is the highly effective use of methyl eugenol against the oriental fruit fly. The problem is that with the melon fly, males respond to cue-lure at a later stage in their sexual maturation than oriental fruit fly males do to methyl eugenol. Wong et al. (1989a) reported that 40–50% of male oriental fruit flies are attracted to methyl eugenol-toxicant mixtures and killed before any became sexually mature. Also, whereas methyl eugenol attracts virgin female oriental fruit flies in the absence of males, cue-lure does not attract virgin female melon flies. With methyl eugenol in male annihilation applications, female oriental fruit flies respond and are killed in ever greater numbers as the male population is depleted, but cue-lure can not do the same with the melon fly.

(Received June 13, 1991; accepted August 19, 1991)

Abstract—Field plots of three accessions of *Nicotiana glutinosa* L. (*Nicotiana* species accessions 24, 24A, and 24B) at Oxford, North Carolina and Tifton, Georgia were heavily damaged by natural populations of tobacco budworms, *Heliothis virescens* (F.), during 1985–1989. Experiments in outdoor screen cages demonstrated that all accessions of *N. glutinosa* were as prone to oviposition by *H. virescens* moths as was NC 2326, a commercial cultivar of flue-cured tobacco, *N. tabacum* L. However, in greenhouse experiments, tobacco budworm larvae did not survive or grow as well when placed on plants of *N. glutinosa* as they did when placed on plants of NC 2326. Four labdane diterpenes (manool, 2-hydroxymanool, a mixture of sclareols, and labda-13-ene-8α,15-diol [labdenediol]) and two sucrose ester fractions (2,3,4-tri-*O*-acyl-3′-*O*-acetyl-sucrose [G-SE-I] and 2,3,4,-tri-*O*-acyl-sucrose [G-SE-

*To whom correspondence should be addressed.

II]) were isolated from green leaves of the three accessions of *N. glutinosa*. These components were bioassayed for their effects on the ovipositional behavior of tobacco budworm moths using small screen cages in a greenhouse at Oxford, North Carolina. Labdenediol, manool, and both sucrose ester fractions stimulated tobacco budworm moths to oviposit on a tobacco budworm-resistant Tobacco Introduction, TI 1112 (PI 124166), when these materials were sprayed onto a leaf.

Key Words—Insecta, Lepidoptera, Noctuidae, *Heliothis virescens*, tobacco budworm, *Nicotiana*, ovipositional stimulants.

INTRODUCTION

Nicotiana glutinosa L. is a coarse-viscid pubescent annual in the family Solanaceae (Subgenus Tabacum, Section Tomentosae). It is native to Peru and southern Ecuador, where it has adapted to semi-arid areas such as rocky slopes and ditch banks (Goodspeed, 1954; Tatemichi, 1990). There are three accessions of *N. glutinosa* (accessions 24, 24A, and 24B) in the USDA-National Plant Germplasm System Collection at the Crops Research Laboratory in Oxford. The Section Tomentosae ($2n = 24$) is the group of *Nicotiana* species most closely related to cultivated tobacco, *N. tabacum* L. (Subgenus Tabacum, Section Genuinae; $2n = 48$). *N. glutinosa* is currently used as a source of desirable traits in tobacco-breeding programs, and chromosomes from this species have been incorporated into commercial tobacco cultivars by conventional breeding techniques (Gerstel, 1945).

N. glutinosa is resistant to tobacco mosaic virus (TMV), powdery mildew, *Erysiphe cichoracearum* DC (Cohen et al., 1983), and cyst nematodes, *Globodera solanacearum* (Miller & Gray) Behrens. It is the source of resistance to TMV in all commercial tobacco cultivars (Stavely, 1979). However, *N. glutinosa* is susceptible to several other diseases (Stavely, 1979), and it is also attacked by most common insect pests of tobacco in the United States, including the tobacco hornworm, *Manduca sexta* (L.), the tobacco aphid, *Myzus nicotianae* Blackman, and the tobacco budworm, *Heliothis virescens* (F.) (Thurston, 1961; Thurston et al., 1966; Parr, 1967; Parr and Thurston, 1968; Burk and Stewart, 1969, 1971; Greene and Thurston, 1971). *N. glutinosa* is preferred for oviposition by moths of tobacco hornworms and tobacco budworms over tobacco, most *Nicotiana* species, and tomato, *Lycopersicon esculentum* Mill. (Thurston et al., 1966; Parr, 1967; Greene and Thurston, 1971; Jackson and Severson, 1989; Jackson et al., 1988, 1989; Severson et al., 1990).

N. glutinosa does not produce the cuticular duvane diterpenes found on *N. tabacum* and *N. sylvestris* Spegazzini & Comes, but it does produce labdane diterpenes (Colledge et al., 1974; Reid, 1979). Severson et al. (1990) listed ten

cuticular labdanes produced by the *Nicotiana* species. The primary labdanes of *N. tabacum* are (12*Z*)-labda-12,14-dien-8α-ol (*cis*-abienol) and (13*E*)-labda-13-ene-8α,15-diol (labdenediol) (Reid, 1974; Severson et al., 1985b). One accession of *N. glutinosa* (acc. 24) produces (13*R*)-labda-8,14-dien-13-ol (manool), (13*R*)-labda-8,14-dien-2-oxy-13-ol (2-oxymanool), (13*R*)-labda-8,14-diene-2α,13-diol (2-hydroxymanool), (13*R*)-labda-14-ene-8α,13-diol (sclareol), (13*S*)-labda-14-ene-8α,13-diol (13-episclareol), and labdenediol. The second accession of *N. glutinosa* (acc. 24A) produces only the sclareols and labdenediol, while the third accession of *N. glutinosa* (acc. 24B) does not produce labdanes (Severson et al., 1988a; Figure 1).

An epimeric mixture of sclareol and 13-episclareol inhibits the growth of a wide range of fungal species (Bailey et al., 1974, 1975). Cohen et al. (1983) reported that oxymanool suppresses the emergence of conidial germ tubes of *E. cichoracearum*, and thus inhibits development of powdery mildew. *Cis*-abienol from *N. tabacum*, and 2-hydroxymanool, manool, oxymanool, sclareol, and the eutectic mixture of sclareol and 13-episclareol from *N. glutinosa* inhibit the growth of wheat coleoptiles (Cutler et al., 1977). We previously reported that *cis*-abienol does not stimulate oviposition by tobacco budworm moths (Jackson et al., 1986).

All three accessions of *N. glutinosa* produce sucrose esters (SE), which were isolated and characterized by Arrendale et al. (1990). They classified the SE from *Nicotiana* species based upon the position of the acetyl moieties on the sucrose molecule. The SE from *N. glutinosa* in this paper are designated G-SE-I (2,3,4-tri-*O*-acyl-3′-*O*-acetyl-sucrose) and G-SE-II (2,3,4-tri-*O*-acyl-sucrose), while the SE from *N. tabacum* (6-*O*-acetyl-2,3,4-tri-*O*-acyl-sucrose; Severson et al., 1985b, 1990) is designated T-SE-I. Severson et al. (1990) listed a total of eight SE types and two types of glucose esters (GE) in a survey of all of the *Nicotiana* species. The SE from *N. tabacum* (TI 165, PI 405002) (Cutler et al., 1986) and *N. glutinosa* (Severson et al., 1990) inhibit growth of wheat coleoptiles and the growth of some gram positive bacteria. We previously reported that the sugar esters from *N. tabacum* (TI 165) (SE), *N. kawakamii* Ohashi (SE & GE), *N. alata* Link & Otto (SE), and *N. trigonophylla* Dunal (SE & GE) stimulate oviposition by tobacco budworm moths (Jackson et al., 1989; Severson et al., 1990). However, oviposition by tobacco budworm moths is not affected by simple sugars such as sucrose, glucose, or fructose (Jackson et al., 1989).

Because the cuticular components from *N. glutinosa* may be transferred to *N. tabacum* during the development of tobacco breeding lines, it is of interest to know how these components affect the behavior of associated insect pests. In this paper, we describe the effects that cuticular components from *N. glutinosa* have on the ovipositional behavior of tobacco budworm moths.

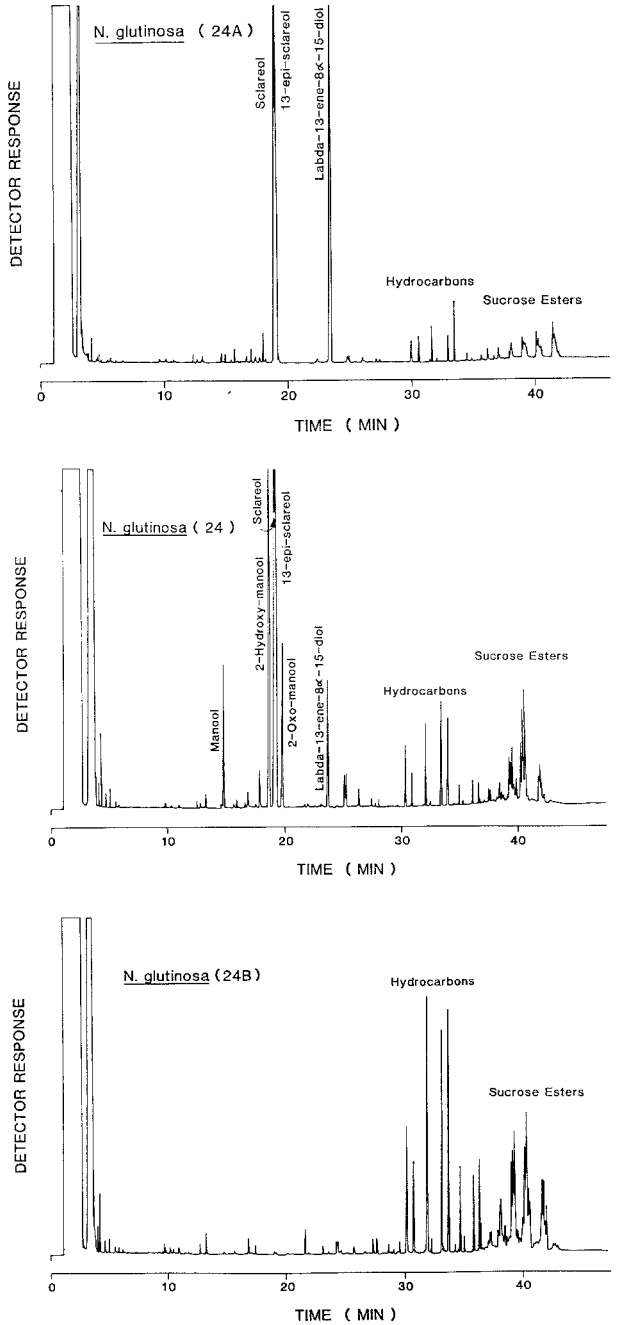

FIG. 1. Capillary gas chromatograms of the cuticular components from the green leaves of three accessions of *Nicotiana glutinosa* grown in field plots at Oxford, North Carolina, 1985.

MATERIALS AND METHODS

Field Plots

Seventy accessions of 66 *Nicotiana* species (including the three accessions of *N. glutinosa*) were grown in 20-plant plots at Tifton, Georgia and Oxford, North Carolina during 1985 and 1986. Plots were arranged in a randomized complete block design with three replications. Fields were fumigated with methyl bromide before planting to control soil-borne diseases. Napropamide (Devrinol 50WP®, ICI Americas Inc., Wilmington, Delaware) and metalaxyl (Ridomil 2E®, Ciba-Geigy Corp., Greensboro, North Carolina) were incorporated into the soil 2 weeks before transplantation for control of weeds and blue mold, *Peronospora tabacina* D. B. Adam. Plots were cultivated, fertilized, and irrigated as needed. The numbers of tobacco budworm larvae on each plant were counted at peak infestations 1–2 times each year at each location.

Field plants were sampled for cuticular components once each season at each location. One leaf disk (2-cm diam) was removed from each of five plants per treatment, with two replications per location per year. Disks were taken from the center (including midrib) of a fully expanded but not senescent leaf near the top of each plant. Leaf disks were briefly dipped ten times in succession into 10 ml of methylene chloride (distilled-in-glass grade, American Burdick & Jackson, Muskegon, Michigan) in scintillation vials. Samples were chilled on dry ice and kept at −17°C until analyzed by gas chromatography (GC).

Ovipositional Choice Experiments with Whole Plants

Whole plants of *N. glutinosa* were bioassayed for tobacco budworm ovipositional preference in choice tests vs. NC 2326, a commercial flue-cured tobacco cultivar, using 16 outdoor screen cages (2.4 × 2.4 × 2.0 meters high; Jackson et al., 1983, 1984, 1986). Each cage had a wooden floor and waterproof gabled roof. Three 7.5 watt light bulbs were positioned over the center of each cage and aimed upward under the roof. Lights were shaded from below by 30.5-cm diam. metal pans, and they were controlled by a central rheostat so that the light intensity was equal within all cages. The cages were three meters apart and they were located in an isolated area of the Tobacco Research Station in Oxford, where there were no extraneous light sources within view of moths inside the cages. These experiments were conducted July 3–31, 1984 and May 31–August 15, 1985. Maximum daytime temperatures ranged from 22 to 37°C and minimum nighttime temperatures ranged from 8 to 23°C during these periods.

Plants used in these experiments were germinated in the greenhouse (ambient photoperiod, temperature maintained below 35°C) and later transplanted to 12.7-cm diam. plastic pots containing sterilized soil and a time-release

fertilizer (14-14-14, N-P-K) (Osmocote®, Sierra Chem. Co., Milpitas, California). At transplantation, each seedling was treated with 0.04 ml of metalaxyl (Ridomil 2E) in 100 ml water to prevent fungal diseases. Plants were grown in the greenhouse for an additional 2 weeks then moved to a shady area of mowed grass until they were large enough for testing at 5–7 weeks after transplantation. When aphids were a problem, plants were sprayed with pirimicarb (Pirimor 50 W®, ICI Americas Inc., Wilmington, Delaware) at 0.01 g per plant.

Tobacco budworms were from a laboratory colony started each fall from larvae collected in tobacco fields near Oxford. This colony was cultured for 7–10 generations on an artificial diet (Baumhover, 1985) before the start of these experiments. Female moths were 3–4 days old after eclosion, and they were caged together as groups of ten female and ten male moths in 3.8-liter paper cartons for two nights before testing to insure mating. The mating containers and colony moths were kept in rooms at ca. 25°C, ca. 70% RH, and a photoperiod of 14 : 10 (L : D).

For choice experiments, four *N. glutinosa* plants were placed in one corner of a cage, and four NC 2326 plants of a similar size were placed in the opposite corner of the cage. Plants ranged in height from ca. 15–30 cm. Ten female tobacco budworm moths were placed into each cage a few hours before sunset. Moths were provided water, but no food. The following morning, the total number of tobacco budworm eggs on the four plants of each entry was counted. Each cage-night was treated as one replication. Data were analyzed by paired *t*-tests (Steel and Torrie, 1960). For no-choice experiments, eight plants of a treatment and eight plants of the control (NC 2326) were placed in separate cages set up as pairs, and the data were analyzed by paired *t*-tests.

Ovipositional Bioassays of Cuticular Components

Manool, hydroxymanool, labdenediol, a sclareol mixture (sclareol plus episclareol), two SE fractions (G-SE-I and G-SE-II), and a mixture of α-+ β-4,8,13-duvatriene-1,3-diols (duvatrienediols) were bioassayed for ovipositional response by tobacco budworm moths in "hoop cages" (0.46 × 1.31 × 0.46 meters high). Twelve hoop cages were located inside a glass greenhouse (7.3 × 9.1 × 4.9 meters high). The walls of this greenhouse were covered with black plastic to block extraneous lights, but the gabled roof was left uncovered. No artificial light sources were used for these experiments. The greenhouse was maintained at 25–30°C during the test period, and the humidity was kept high by hosing down the concrete floor several hours before each experiment. Each hoop cage had a rectangular plywood floor (0.46 × 1.31 meters) and two semicircular end pieces (0.46 meters high). It was covered with 0.32-cm hardware cloth. In the center of the floor of each cage was a trap door large enough to

introduce potted plants and moths. Cages were painted flat black. In the center of each plywood end piece was a 10.2-cm diam. hole through which was pushed the end of a frustum (11.7-cm diam. bottom, 9.5-cm diam. top, and 8.9-cm high) formed from a 12.7-cm black plastic pot with the end removed. A detached leaf was placed over the end of an intact 12.7-cm plastic pot, and the frustum was pushed over the end of the pot to secure the leaf in place so that its abaxial surface was exposed. After the exposed surface of the leaf was treated with a cuticular component, the frustum was pushed through the hole in the end of the cage and held fast with Velcro® fasteners so that the leaf protruded into the cage ca. 2 cm. For a choice test, a frustum with attached leaf was pushed into each end of the cage. Thus, the two excised leaves at opposite ends of the cage each exposed a circular area of 71 cm^2 to ovipositing moths.

Leaves from Tobacco Introduction (TI) 1112 (PI 124166) were used in these experiments. TI 1112 has glandless trichomes on its leaves and, in contrast to most tobacco cultivars and *Nicotiana* species, it has negligible levels of the common leaf surface constituents (Severson et al., 1984). Plants were grown in 12.7-cm diam. plastic pots under high pressure sodium lights in a greenhouse. Plants grown under these lights are similar in physical and chemical characteristics to field-grown plants (Severson et al., 1985b).

Tobacco budworm moths were reared and prepared for bioassay in the same manner as those for the outdoor cage experiments described above. Five female moths were introduced into each cage in the late afternoon after temperatures in the greenhouse had fallen below 30°C. Eggs on each exposed leaf surface were counted the following morning.

Each cuticular component was bioassayed in a choice test vs. a solvent blank (SB) (0.5 mL methylene chloride in 1.5 mL of 3:1 acetone:water) and vs. duvatrienediols. We previously reported that duvatrienediols are strong ovipositional stimulants for tobacco budworm moths (Jackson et al., 1986, 1989). Spray applications were made in the late afternoon with a small air brush (Model 250, Badger Air-Brush Co., Franklin Park, Illinois). This apparatus had a 20-mL reservoir, a Teflon® delivery tube, and it was attached to an air compressor that would deliver up to 200 kPa. About 35 kPa were optimal for spraying the plants, because that pressure produced a fine mist that did not run off the leaves. One milliliter of a cuticular component was mixed with 1.0 mL of 1:1 acetone:distilled water. Control plants were sprayed with 2.0 mL of SB or with 1.0 mL duvatrienediols plus 1.0 mL of 1:1 acetone:water. Thus, 2.0 mL of spray was applied to the surface of each leaf. Leaf disks were allowed to air-dry (ca. 30 min) before they were inserted into the oviposition cage. The following morning after tobacco budworm eggs had been removed, four 2-cm diam leaf disks were taken from each excised leaf. These disks were dipped ten times each into scintillation vials containing 10 mL of methylene chloride (dis-

tilled-in-glass grade, American Burdick & Jackson). Samples were frozen on dry ice and kept frozen at −17°C until they were analyzed for chemical components by capillary GC.

Before analysis of variance (ANOVA) for each experiment, data were transformed first to a percentage of the total eggs counted per replication (x), and then transformed to arcsine (square root x). Preference for egg laying on a particular treatment vs. the control was determined using a paired t-test for each experiment (SAS Institute, 1985).

Feeding Experiment

In order to determine how well tobacco budworm larvae survive and develop on the three *N. glutinosa* accessions vs. NC 2326, greenhouse-grown plants were artificially infested with second instars. Plants were grown in the greenhouse under supplemental high pressure sodium lights for 6–8 weeks after transplantation from seed pots in a manner similar to that used to produce plants for ovipositional cage bioassays described above. Five-second instars of *H. virescens* from the laboratory colony described above were placed on the terminal leaf bud of each plant. Larvae were allowed to feed for 1 week, then they were weighed.

Extraction of Cuticular Components for Bioassays

Cuticular components were extracted from all three accessions of *N. glutinosa* from field plots at Oxford and Tifton. Plant tops (ca. 6–10 weeks old) were cut off and dipped ten times into 4-liter beakers of methylene chloride (Resi-analyzed reagent grade, J.T. Baker Chemical Co., Phillipsburg, New Jersey; Jackson et al., 1984, 1986). Approximately 100 plants were extracted with ca. 3 liters of solvent. These crude extracts were cooled with dry ice and stored at −17°C until needed. After warming to room temperature, the extracts were filtered through folded filter paper containing anhydrous Na_2SO_4, and the solvent was removed on a roto-evaporator under vacuum at 40°C.

Isolation of Labdanes and Sucrose Esters

The cuticular extract from *N. glutinosa* (acc. 24A) (10.9 g) was dissolved in 1:1 hexane:methylene chloride, deposited onto 50 g of silicic acid, and loaded onto a 50-g silicic acid column. The column was eluted with hexane (500 mL), 1:3 hexane:methylene chloride (750 mL), methylene chloride (400 mL), 1:9 acetone:methylene chloride (400 mL), and 1:4 acetone:methylene chloride (1000 mL). Fractions rich in the sclareol mixture (2.1 g, 99+%) eluted in the third 100 mL portion of the 1:9 acetone:methylene chloride fraction. Re-crystallization from hexane yielded a constant melting mixture of sclareols

(1.8 g, melting point [*mp*] 96–97°C, 99+%) (reported literature *mp* = 95°C; Reid, 1974). Combination of the last 100 mL of the 1:9 acetone:methylene chloride and the first 400 mL of the 1:4 acetone:methylene chloride elutants produced 5.8 g of the sclareols plus labdenediol mixture. A portion of this mixture (2.8 g) was chromatographed on a Sephadex LH-20 column (2.54 cm id × 100 cm) using chloroform (0.75% EtOH as preservative) as the eluting solvent, and 5 mL fractions were collected. After solvent removal and re-crystallization, fractions 77–84 produced 0.9 g of the sclareol-episclareol mixture (*mp* 96–97°C, 99+%). Solvent removal and re-crystallization of fractions 95–107 produced 99+% labdenediol (*mp* 131–132°C) (reported literature *mp* = 131–131.5°C; Reid, 1974).

Cuticular extract from *N. glutinosa* (acc. 24) (6.2 g) was deposited onto 50-g silicic acid, loaded into a 50-g silicic acid column, and eluted with hexane (150 mL), 3:1 hexane:methylene chloride (200 mL), hexane:methylene chloride (1000 mL), and 1:19 acetone:methylene chloride (1000 mL). The first 200-mL elutant of the 1:19 acetone:methylene chloride fraction yielded 1.7 g of a mixture of 2-oxymanool (9%), sclareols (53%), and 2-hydroxymanool (28%). This mixture was re-chromatographed on the Sephadex LH-20 column as described above. After solvent removal and re-crystallization, combinations of fractions 95–100 yielded 99+% 2-hydroxymanool (0.22 g, *mp* = 131–133°C).

The G-SE-I and G-SE-II fractions were isolated as described by Arrendale et al. (1990). Manool was obtained from Aldrich Chemical Company (Milwaukee, Wisconsin). The duvatrienediols were isolated as described by Severson et al. (1988b).

Gas Chromatography

Chemical samples were analyzed by capillary GC and GC/MS as described by Severson et al. (1984, 1985a,b). Cuticular extracts, fractions, and isolates were taken to dryness under N_2 in a micro autosampler vial (100 μL), then 50 μL of 1:1 N-*O-bis*(trimethylsilyl)trifluoroacetamide:dimethylformamide (Pierce Chemical Company, Rockford, Illinois) was added. The vial was capped and heated at 76°C for 45 min to convert hydroxylated components to trimethylsilyl ethers. After cooling, the samples were analyzed on a Hewlett Packard 5880 gas chromatograph equipped with a splitless injector (injector temp. 250°C, purge activation time of 1.5 min) and flame ionization detector (detector temp. 350°C) using a 0.3-mm id × 30-m bonded SE54 fused silica capillary column (Arrendale and Martin, 1988). A temperature program was run at 100°C for 5 min, followed by a temperature increase of 10°C/min to 170°C, 3°C/min from 170–220°C, and 5°C/min from 220–290°C. The final temperature was held at 290°C until all components had eluted.

RESULTS AND DISCUSSION

Results from field plots showed that *N. glutinosa* was one of the *Nicotiana* species most frequently infested with tobacco budworm larvae (Table 1). Although numerically lower, the percentage infestations on the three accessions of *N. glutinosa* were not significantly different from infestation levels seen on *N. tabacum* cultivars such as NC 2326 and Samsun, an oriental tobacco (Severson et al., 1985b). *Nicotiana kawakamii* was the only species that had a significantly higher average infestation rate in the field than *N. glutinosa* (Table

TABLE 1. PERCENTAGE INFESTATION BY NATURAL POPULATIONS OF LARVAE OF THE TOBACCO BUDWORM ON SINGLE ROW PLOTS OF 70 ACCESSIONS OF 66 *Nicotiana* SPECIES AT OXFORD, NORTH CAROLINA AND TIFTON, GEORGIA, 1985–1986

1). However, data from field infestation rates must be interpreted cautiously since they are only a relative measure of host suitability (Jackson and Severson, 1989). This is because several mortality factors (predation, abiotic factors, plant antibiosis) may kill eggs or larvae of *H. virescens* once they are on a plant. Oviposition by moths of *H. virescens* may be heavy on certain tobacco types, but they may show little insect damage in the field because of high larval mortality due to their antibiotic defenses (Jackson et al., 1988, 1989; Jackson and Severson, 1989). However, because larvae of *H. virescens* seldom leave the plants upon which they hatched (Jackson et al., 1989), we may assume that a plant type heavily damaged in the field is highly susceptible to oviposition. The three accessions of *N. glutinosa* fall in this latter group, making them quite susceptible to oviposition by tobacco budworm moths.

The propensity of female tobacco budworm moths to oviposit on *N. glutinosa* was confirmed by both choice and no-choice oviposition cage experiments when compared with the highly susceptible *N. tabacum* cv. NC 2326 (Table 2). In no-choice tests, *N. glutinosa* (acc. 24) was equally acceptable as an ovipositional site as NC 2326 with no significant difference in the number of eggs that were laid on either host. Similarly, when given a choice between one of the accessions of *N. glutinosa* and NC 2326, tobacco budworm moths deposited equal numbers of eggs on each plant type despite their differences in cuticular chemical profiles (Figure 1). This probably indicates that more than one cuticular component is utilized by moths of *H. virescens* as ovipositional stimulants.

TABLE 2. OVIPOSITIONAL RESPONSE OF FEMALE TOBACCO BUDWORM MOTHS TO THREE ACCESSIONS OF *Nicotiana glutinosa* IN SCREEN FIELD CAGES, OXFORD, NORTH CAROLINA, 1984–1985

	Choice experiments[a]			No-choice experiments[b]		
Species accession	Percent of eggs on *N. glutinosa*	Total no. of eggs	No. of reps	Percent of eggs on *N. glutinosa*	Total no. of eggs	No. of reps
N. glutinosa (24)	50.6 NS[c]	5489	20	46.3 NS[c]	4452	15
N. glutinosa (24A)	45.7 NS	2624	10	—[d]	—	—
N. glutinosa (24B)	51.6 NS	2749	10	—	—	—

[a] Paired choice tests with four plants of *N. glutinosa* vs. four plants of *N. tabacum* cv. NC 2326 flue-cured tobacco in the same cage.
[b] Paired no-choice tests with eight plants of *N. glutinosa* in one cage vs. eight plants of NC 2326 in a separate cage.
[c] Paired *t*-test; NS = not significant. For no-choice experiments, data from separate cages containing either NC 2326 or an *N. glutinosa* accession were paired.
[d] Not tested.

While there did not appear to be any difference between *N. glutinosa* and NC 2326 for ovipositional preference, feeding tests using greenhouse-grown plants showed that tobacco budworm larvae survived and grew better on NC 2326 than on any of the accessions of *N. glutinosa* (Table 3). This result differs from Burk and Stewart (1971) who listed only one of the accessions of *N. glutinosa*, 24A, as inducing significantly higher mortality on tobacco budworm larvae than those feeding on a flue-cured control. Differences in survival rates of larvae may help explain the lower percentages of *N. glutinosa* plants infested with tobacco budworm larvae in the field compared to *N. tabacum* cultivars (Table 1). Reasons for lower survival and developmental rates for tobacco budworm larvae on *N. glutinosa* have not been studied, but differences in cuticular components or internal leaf components such as flavanols (Jurzysta, 1983; Snook et al., 1986) or pyridine alkaloids (Sisson and Severson, 1990) may be important. These classes of compounds are known to be toxic to larvae of *H. virescens* (Lukefahr and Martin, 1966; Shaver and Lukefahr, 1969; Granzow et al., 1985; Jackson et al., 1989; Gunasena et al., 1990). Interestingly, *N. glutinosa* is not resistant to feeding by tobacco hornworm larvae (Parr and Thurston, 1968).

Chromatograms of the cuticular components of the three accessions of *N. glutinosa* are given in Figure 1, and levels of duvanes, labdanes, and SE found on *N. glutinosa* and *N. tabacum* in the field are shown in Table 4. Both SE fractions (G-SE-I and G-SE-II), manool, and labdenediol stimulated tobacco budworm oviposition when these compounds were sprayed onto TI 1112 leaves (Table 5). These components stimulated oviposition to a level not significantly

TABLE 3. AVERAGE SURVIVAL AND WEIGHT GAIN AFTER 1 WEEK FOR SECOND INSTAR *Heliothis virescens* LARVAE PLACED ON GREENHOUSE-GROWN *Nicotiana glutinosa* PLANTS COMPARED TO THOSE PLACED ON FLUE-CURED TOBACCO, NC 2326 AT OXFORD, NORTH CAROLINA, 1985–1986

[j] *N. glutinosa*: G-SE-I (2,3,4-tri-*O*-acyl-3′-*O*-acetyl-sucrose) and G-SE-II (2,3,4-tri-*O*-acyl-sucrose); *N. tabacum*: T-SE-I (6-*O*-acetyl-2,3,4-tri-*O*-acyl-sucrose).

different from the effects of the duvatrienediols (Table 5), known ovipositional stimulants for *H. virescens* (Jackson et al., 1986). The mixture of sclareols gave conflicting results in the two types of paired tests. Although comparison of sclareol-treated leaves vs. solvent blank-treated leaves indicated no ovipositional activity (statistically nonsignificant), comparison of sclareol-treated leaves vs. duvatrienediol-treated leaves indicate activity similar to that of the duvatrienediols (Table 5). We have no suitable explanation for this apparent discrepancy. Hydroxymanool had no effect on oviposition by tobacco budworm moths, as indicated by the nonsignificant difference from the solvent blank and by the significantly lower egg deposition when compared with the duvatrienediol-treated leaves.

In this paper, we have demonstrated that three accessions of *N. glutinosa* are attacked by larvae of *H. virescens* in the field, but that infestation levels of tobacco budworm larvae on these accessions are slightly less than are found on

TABLE 5. OVIPOSITIONAL RESPONSE OF TOBACCO BUDWORM MOTHS TO CUTICULAR COMPONENTS ISOLATED FROM *Nicotiana glutinosa* AND APPLIED TO TI 1112 LEAVES IN CHOICE TESTS IN SMALL SCREEN CAGES IN A GREENHOUSE SECTION, OXFORD, NORTH CAROLINA, 1988

oriental or flue-cured tobacco cultivars. We have also shown that each of the accessions of *N. glutinosa* is equally susceptible to oviposition by tobacco budworm moths as is a standard flue-cured cultivar, NC 2326. Differences in the infestation levels of tobacco budworm larvae on tobacco and *N. glutinosa* appear to be due to larvae not surviving or developing as well on the accessions of *N. glutinosa* as they do on tobacco cultivars.

We have also shown that two labdane diterpenes and two SE types from the cuticulae of *N. glutinosa* accessions stimulate oviposition by tobacco budworm moths in cage bioassays. We previously reported (Jackson et al., 1989) that GE and SE type compounds from other *Nicotiana* species also stimulate oviposition by these insects. There are additional labdanes and GE and SE compounds from the *Nicotiana* species (Severson et al., 1990) that we have not bioassayed for ovipositional activity. Several of the *Nicotiana* species possessing these untested components are also susceptible to tobacco budworm damage in the field (Table 1) and to oviposition by tobacco budworm moths (Jackson

et al., 1989; Severson et al., 1990). Sucrose esters from the *Nicotiana* species differ not only in esterification positions on the sucrose molecule, but also in the acid moiety compositions which vary considerably within the genus (Severson et al., 1990). For example, the major acid moieties of the SE from *N. tabacum* (T-SE-I from TI 165) are methylpentanoics, whereas the major acid moieties of the SEs from *N. glutinosa* (G-SE-I and G-SE-II) are methylhexanoics (Table 6). Thus, it appears that several different SE fractions from the genus *Nicotiana* elicit the same behavioral response, oviposition, by tobacco budworm moths. We are investigating how structural differences and variations in the acid compositions of the SE types from the *Nicotiana* species affect the ovipositional response of tobacco budworm moths. The components tested in this study and those listed by Severson et al. (1990) might also affect pest or beneficial insects other than tobacco budworms which are associated with tobacco culture, and we are investigating these interactions.

Acknowledgments—We thank James S. Cheatham, James M. Hobgood, Jr., Linda Smith, Brenda King, and Sara J. Mueller for their excellent technical assistance.

(Received June 26, 1991; accepted August 19, 1991)

Abstract—Chemical analysis of the venom of the myrmicine ant *Megalomyrmex foreli* from Costa Rica revealed the presence of four major alkaloidal components. Two of these, 2-butyl-5-(*E*, 1-heptenyl)-5-pyrroline **(3)** and 2-butyl-5-(*E*, *E*, 1,3-heptadienyl)-5-pyrroline **(4)**, constitute a new functional class of ant venom alkaloids, whose structures were assigned from their spectral and chemical behavior and unambiguous syntheses. The function of these compounds is suggested by field observations of the behavior of *M. foreli*, its sting morphology, and the relative toxicity of **3** and **4** against termite workers.

Key Words—*Megalomyrmex*, Hymenoptera, Myrmicinae, venom, alkaloids, ants, pyrrolines, alarm behavior, stridulation, toxicity.

INTRODUCTION

The venoms of many species of the two related myrmicine genera *Solenopsis* and *Monomorium* have been shown to contain 2,5-dialkylpyrrolidines. These compounds have been found in some *Solenopsis* (*Diplorhoptrum*) species and in nearly every species of *Monomorium* where alkaloids have been detected

*To whom correspondence should be addressed.

0098-0331/91/1200-2507$06.50/0

(Jones et al., 1982). Recently, we have also found 2,5-dialkylpyrrolidines in two *Megalomyrmex* species (Jones et al., 1991). In a number of cases, smaller amounts of 1-pyrrolines may also be also present (Fales et al., 1980; Pedder et al., 1976; Jones et al., 1982, 1988a,b) although they may be instrumental artifacts. The only other unsaturation detected in the naturally occurring 2,5-dialkylpyrrolidines has been the presence of one or more terminal double bonds on the alkyl groups (Jones et al., 1982).

Other species in the genus *Megalomyrmex* have been found to produce saturated 2,5-dialkylpyrrolidines, and in one case, a 3,5-dialkylpyrrolizidine (Jones et al., 1991). In the present paper, we report the elucidation of two novel 1-pyrrolines with conjugated unsaturation, produced by workers of *M. foreli*. Some insight into the chemical ecology of this species has been gained from field observations and consideration of its sting morphology and the topical toxicities of its venom alkaloids.

METHODS AND MATERIALS

Chemical Analyses. Gas chromatographic analyses were carried out using a Shimadzu GC-9A equipped with a 30 m × 0.5 mm i.d. open DB-17 column (1 μm film thickness). The temperature for the analyses was programed from 60–215°C at 10°/min, and the carrier gas flow rate was 15 mL/min. On a given day, retention temperatures were reproducable to 1°C. Preparative gas chromatography was conducted with a Varian model 1400 gas chromatograph equipped with a 2 m × 5 mm i.d. column packed with 10% OV-17 on 100–120 mesh Supelcoport. IR spectra were obtained using a Hewlett–Packard model 5965A FTIR. ^{1}H and ^{13}C NMR spectra were obtained from $CDCl_3$ solutions using a Varian XL-200 spectrometer. ^{13}C assignments were made on the basis of standard 2D COSY and HETCOR experiments. Electron impact mass spectra were obtained using a LKB-9000 GC/MS equipped with a 30 m × 0.52 mm i.d. open DB-17 column (1 μm film thickness), a LKB-2091 equipped with a 25 m × 0.31 mm i.d. HP-5 column, or a Finnigan ion trap model 800 equipped with a 25 m × 0.31 mm i.d. HP-5 column. High resolution mass spectra were obtained using a VG 7070F instrument in the EI mode at an ionizing voltage of 70 eV.

Ants. Collections and observations on *Megalomyrmex foreli* were made at Jardin Botanico Wilson, San Vito de Java, Puntarenas Province, 1100 m in southwestern Costa Rica. Intermittent observations on *M. foreli* behavior were made from February 1990 through March 1991 on nine separate colonies. These were: five colonies with ca. 100 individuals/nest found in the sheathing stems of *Calathea* spp. (Marantaceae) from 0.5–1 m above the ground in secondary forest, and four subterranean nests in open second growth: three at the base of

shrubs and one in a rock wall. None of the subterranean nests had any tumulus at the entrance, and overall colony sizes were estimated to range from 100–300 individuals. Ants were immediately placed in glass vials containing 1–2 ml of CH_2Cl_2. Specimens of *M. foreli* were deposited in the collection of the Los Angeles County Museum of Natural History, Los Angeles, California, and have been accessed by Roy R. Snelling. For analysis, these mixtures were reduced to ca. 0.2 ml with a slow stream of nitrogen. GC/MS and GC/FTIR analyses revealed the presence of four **(1–4)** nitrogen containing components in a 2 : 1 : 7 : 5 ratio with the following spectral data: **1:** IR 1644 cm^{-1}; MS *m/z* (relative intensity) 223 (M^+, 2), 222 (2), 208 (2), 194 (4), 180 (7), 166 (14), 152 (23), 139 (44), 124 (4), 110 (7), 96 (14), 83 (13), 82 (100), 69 (6), 68 (6), 67 (8), 55 (23), 41 (34). **2:** MS *m/z* (relative intensity) 225 (M^+, 2), 169 (3), 168 (65), 127 (10), 126 (100), 109 (10), 95 (10), 82 (15), 67 (30), 55 (40). **3:** IR 1648, 1594, 1459, 1331, and 973 cm^{-1}; MS *m/z* (relative intensity) 221 (25, M^+), 179 (24), 178 (72), 166 (14), 165 (87), 164 (100), 150 (29), 122 (37), 109 (15), 108 (77), 106 (18), 94 (58), 80 (33), 79 (21), 67 (32), 55 (52), 54 (34), 53 (23), 41 (97). **4:** IR 1622, 1578, 1459, 1330, and 987 cm^{-1}; MS *m/z* (relative intensity) 219 (25, M^+), 190 (29), 177 (26), 176 (99), 163 (45), 162 (45), 148 (22), 134 (44), 132 (18), 121 (22), 120 (100), 119 (29), 118 (29), 107 (18), 106 (27), 105 (12), 94 (13), 93 (18), 91 (26), 80 (24), 79 (31), 77 (25), 67 (19), 65 (18), 55 (25), 53 (17), 41 (60).

In addition, a small quantity (<5% of **4**) of an earlier eluting isomer of **4** was also detected, with a mass spectrum identical to that of **4,** and the following infrared spectrum: IR 1642, 1458, 1320, 989, and 887 cm^{-1}.

Hydrogenation. A slow stream of hydrogen was passed through a small portion of the extract containing ca. 5 mg of PtO_2 for 5 min. Reexamination by GC/MS revealed only two major nitrogen containing components whose gas chromatographic retention times, and infrared and mass spectra were identical to those of a sample of synthetic *cis/trans* **2.**

2-Butyl-5-methyl-5-pyrroline (5). A solution containing 5.26 g (40 mmol) of 1-nitropentane and 3.7 ml of methyl vinyl ketone in 70 ml of benzene was cooled to 0°C and treated with 0.2 g of tributylphosphine. The mixture was stirred overnight, treated with 0.5 ml of iodomethane, and filtered through a short overnight, treated with 0.5 ml of iodomethane, and filtered through a short Florisil column. Gas chromatographic analysis revealed the presence of one product. The solution was heated to reflux under a Dean–Stark trap with 5 ml of ethylene glycol and 0.3 g of *p*-toluenesulfonic acid for 3 hr until the formation of water ceased. The mixture was cooled, washed with saturated $NaHCO_3$, dried over anhydrous $MgSO_4$, and filtered. GC/MS analysis showed the presence of one major long retention time component, **2,** MS *m/z* 206 (8, $M-CH_3$), 99 (11), 88 (5), 87 (100), 55 (10), and 43 (58). After the solvent was removed, the residue was taken up in EtOH and hydrogenated over 5 g of 10%

Pd/C at 3 atm pressure for 3 days. After filtration, the solvent was removed, and the residue was stirred with 70 ml of 10% HCl containing 1 ml of 60% $HClO_4$ for 2 hr. The aqueous solution was washed with ether, and carefully made alkaline with 10% NaOH. The aqueous solution was extracted with ether (4 × 50 ml), and the combined ether layers were dried over anhydrous K_2CO_3. Distillation provided 3.2 g (58% from 1-nitropentane) of **5**, bp 65–68°/13 mm Hg: IR 1652 cm^{-1}; [^{1}H] NMR δ = 3.9 (1H, m), 2.48 (2H, m), 2.05 (1H, m), 2.02 (3H, s), 1.7 (1H, m), 1.5–1.3 (4H, m), 0.9 (3H, br t), ^{13}C NMR δ = 173.57, 72.93, 38.84, 36.52, 29.17, 29.02, 22.89, 19.81, 14.08; MS *m/z* (relative intensity) 139 (6, M^+), 124 (3), 97 (20), 96 (37), 83 (78), 82 (100), 81 (8), 69 (10), 68 (46), 55 (38), 54 (13), 53 (11), 43 (6), 42 (82), 41 (59), 39 (39); HRMS *m/z* 139.1355 ($C_9H_{17}N$ M^+, calcd. 139.1361).

2-(Diethylphosphonomethyl)-5-butyl-2-pyrroline ***(6).*** A solution containing 0.14 g of **5** in 2 ml of THF was added over 15 min to a solution containing 2 mmol of diisopropylamide at −78°C in 5 ml of THF (from 0.28 ml of diisopropylamine and 1.3 ml of 1.6 M *n*-butyllithium) under a nitrogen atmosphere. After 1 hr, a solution containing 0.14 ml of diethyl chlorophosphate in THF was added slowly and the mixture was stirred for 3 hr. The reaction was quenched with 1 ml of saturated $NaHCO_3$ and warmed to room temperature. After the addition of 10 ml of ether, the aqueous layer was separated, and the organic mixture was dried over anhydrous $MgSO_4$. Kugelrohr distillation (210–220°/0.3 mm Hg) of the filtered mixture provided 0.25 g (90%) of **6** as a yellow oil: IR 3316, 1619, 1279, 1040, 950, and 787 cm^{-1}; ^{1}H NMR δ = 7.13 (br s), 4.12 (m), 3.95 (m), 3.6 (m), 3.5 (d, J = 14.3 Hz), 3.0 (d, J = 22.3 Hz), 2.55 (m), 2.0 (m), 1.5–1.2 (m), 0.8 (m); ^{13}C NMR δ = 168.3, 167.4, 72.90, 64.30, 62.12, 60.69, 60.35, 59.36, 38.18, 36.04, 33.42, 33.06, 31.46, 29.08, 28.92, 28.68, 28.47, 22.71, 16.35, 16.16, 13.91; MS *m/z* (relative intensity) 275 (7, M^+), 219 (26), 218 (76), 190 (23), 162 (22), 144 (28), 138 (30), 137 (32), 136 (16), 122 (27), 82 (86), 81 (26), 80 (100), 55 (19); HRMS *m/z* 275.1657 ($C_{13}H_{26}NO_3P$ M^+, calcd. 275.1650).

2-Butyl-5-(E,1-heptenyl)-5-pyrroline ***(3).*** A solution containing 0.4 g (1.45 mmol) of **6** in 10 ml of THF was cooled to −78°C under a nitrogen atmosphere and treated with 0.9 ml of 1.6 M *n*-butyllithium in hexane. After 30 min, a solution containing 0.145 g of hexanal in 2 ml of THF was added and the mixture was allowed to warm to room temperature over 12 hr. The mixture was acidified with 10% HCl, and after separation, the aqueous phase was washed once with ether. The aqueous solution was then made alkaline with 10% NaOH and extracted 2 × 10 ml with ether. The combined ether extracts were dried, filtered, and the solvent removed *in vacuo*, to provide 0.14 g (45% yield) of **3** as a single component by GC analysis. The IR and mass spectra, and gas chromatographic retention time of **3** were identical to those observed for natural **3** from *M. foreli*. ^{1}H NMR δ = 6.34 (1H, d, J = 16 Hz), 6.12 (1H, d of t, J =

16, 6.6 Hz), 3.92 (1H, br m), 2.6 (2H, complex m), 2.1 (2H, m), 1.95 (1H, m), 1.7 (1H, m), 1.5–1.2 (13H, m), 0.85 (6H, m); ^{13}C[NMR δ = 172.33 (C=N), 141.99 ($\underline{C}H_2$–CH=), 127.55 (=$\underline{C}$H–C=N), 72.65 (C=N–$\underline{C}$H), 36.47 (N–CH–$\underline{C}H_2$–*n*-propyl), 33.59 ($\underline{C}H_2$–C=N), 32.76 ($\underline{C}H_2$–CH=), 31.34 ($\underline{C}H_2$–CH_2–CH=), 29.02, 28.46 ($\underline{C}H_2$–CH_2–C=N), 28.32, 22.83 ($\underline{C}H_2$–CH_3), 22.44 ($\underline{C}H_2$–CH_3), 13.99 (CH_3), 13.90 (CH_3); HRMS *m/z* 221.2155 ($C_{15}H_{27}N$ M^+, calcd. 221.2144).

2-Butyl-5-(E,E,1,3-heptadienyl)-5-pyrroline ***(4).*** In the same manner as described for **3,** a solution containing 0.4 g (1.47 mmol) of **6** in 10 ml of THF was treated sequentially with *n*-butyllithium and E-2-hexenal, and the reaction was worked up as described above to give 0.12 g (37% yield) of **4** as a single component by GC analysis. The IR and mass spectra, and gas chromatographic retention time of **4** were identical to those of natural **4** from *M. foreli*. ^{1}H NMR δ = 6.56 (1H, d of d, J = 15.8, 9.8 Hz), 6.38 (1H, d, J = 15.8 Hz), 6.17 (1H, d of d of t, J = 15.0, 9.8, 1.2 Hz), 5.90 (1H, d of t, J = 15.0, 7.1 Hz), 4.0 (1H, m), 2.6 (2H, m), 2.1 (2H, m), 1.7 (1H, m), 1.5–1.3 (9H, m), 0.9 (6H, br t); ^{13}C NMR 172.4 (C=N), 139.49 (CH_2–$\underline{C}$H=), 138.92 (CH_2–CH=CH–$\underline{C}$H=), 130.13 (CH_2–CH=$\underline{C}$H), 126.68 (=$\underline{C}$H–C=N), 72.91 (C=N–$\underline{C}$H), 36.47 (N–CH–$\underline{C}H_2$–*n*-propyl), 34.92 ($\underline{C}H_2$–CH=), 33.58 ($\underline{C}H_2$–C=N), 29.00, 28.53, 22.86 ($\underline{C}H_2$–CH_3), 22.25 ($\underline{C}H_2$–CH_3), 14.02 ($\underline{C}H_3$), 13.62 ($\underline{C}H_3$); HRMS *m/z* 219.1989 ($C_{15}H_{25}N$ M^+, calcd. 219.1987).

Toxicity Determinations. The toxicities of **3** and **4** were determined from topical application bioassays against *Reticulitermes speratus* collected near Yokkaichi Mie prefecture, Japan, as previously described (Jones et al., 1988a). The LD_{50} of **3** was 1.06 $\pm$ 0.93 μg/mg termite, and the LD_{50} of **4** was 2.39 $\pm$ 0.69 μg/mg termite.

RESULTS

Field Observations. The diet of *M. foreli* consisted mainly of secretions produced by plants and insects. Workers were observed consistently to harvest secretions from at least three species of Membracidae (Homoptera), extrafloral nectar of *Cassia* sp., *Inga* spp. (Leguminoseae), and secretions of the (both Riodinidae). Just after dawn, some workers also occasionally harvested dead arthropods that had collected under a porch light. Although workers foraged throughout a 24-hr cycle, typically the greatest abundance of individual workers per colony was at night, and there was no indication that any foraged more than 3–5 m from the nest entrance. When nests located in *Calthea* stems were broken into, there was a rapid scatter response; individuals ran excitedly over the stems, dropped to the ground, or retreated further into the stem. While in this state, individuals produced stridulations ranging from 500 to 2100 Hz at 20–25 pulses/sec (DeVries, 1991a).

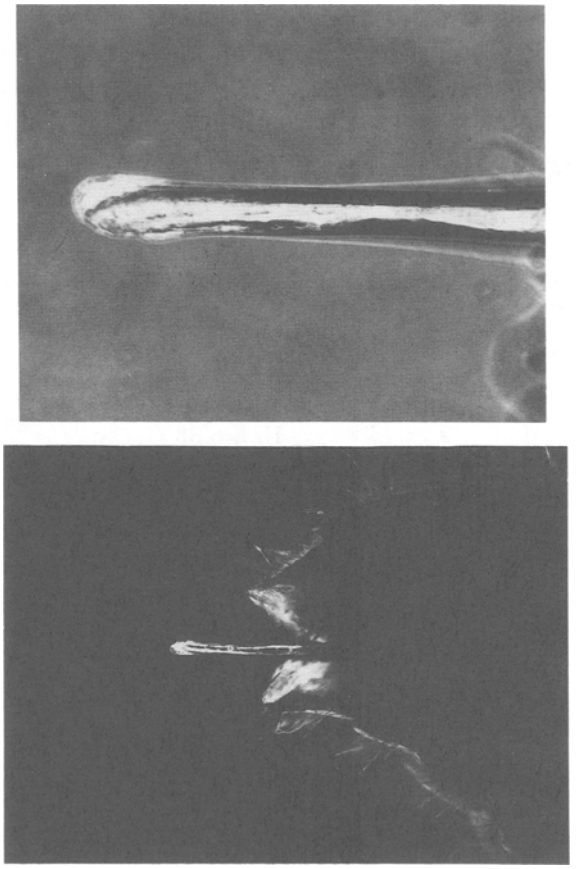

FIG. 1. The spatulate sting of *Megalomyrmex foreli* (Bottom: × 50; top × 200).

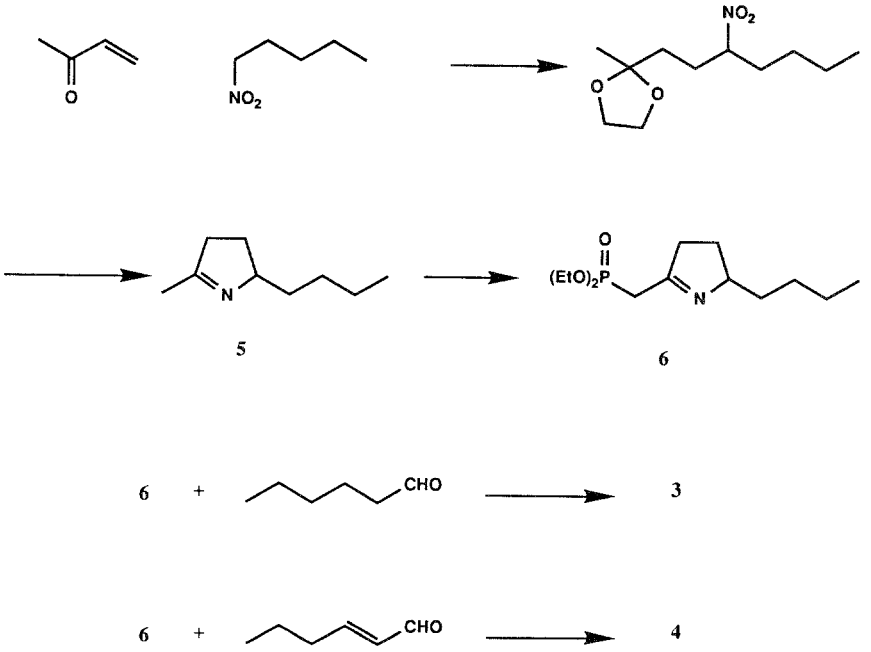
The easily visible sting was angled slightly dorsally and was extruded when an individual was held between two fingers, although restrained individuals of *M. foreli* did not sting readily. Apparently, the sting could not pierce the callous tissue at the fingertips. A microscopic examination of the sting revealed the spatulate nature of its lancets (Fig. 1).

Alkaloid Analysis. Analysis of the methylene chloride extracts from all of the collections of *Megalomyrmex foreli* revealed the presence of four major alkaloidal components in a 2:1:7:5 ratio with parent ions at m/z = 223, 225, 221, and 219, respectively. Comparison of their mass and infrared spectra and retention times to those of authentic samples showed that the first two components were 2-butyl-5-heptyl-5-pyrroline **(1)** and *trans*-2-butyl-5-heptylpyrrolidine **(2)** (Jones et al., 1982). Hydrogenation of a portion of the extract over

PtO_2 gave an isomeric mixture of *cis/trans* **2,** demonstrating that the carbon–nitrogen skeleton of **2** was common to the remaining alkaloids. The longer retention times and the pair of strong bands between 1650 and 1550 cm^1 in the infrared spectra of the third and fourth eluting alkaloids indicated the presence of one or two units of conjugated unsaturation in these compounds. In addition, strong out-of-plane bending bands at 973 and 987 cm^{-1}, respectively, were evidence for the *E* geometry of the added double bonds in these compounds. The mass spectra of the third and fourth eluting compounds both showed ions attributable to loss of propene $(M\text{-}42)^+$ and the loss of C_4H_9 that would be expected if they were unsaturated analogues of **1** such as 2-butyl-5-(*E*,1-heptenyl)-5-pyrroline **(3)** and 2-butyl-5-(*E*,*E*, 1,3-heptadienyl)-5-pyrroline **(4)** (Fig. 2).

In order to confirm these assignments, pyrroline **3** and **4** were synthesized as shown in Scheme I. The ethylene ketal of the nitro ketone formed by the addition of 1-nitropentane to methylvinylketone (Miyakoshi, 1986) was hydrogenated, and following acidification, this sequence provided 2-butyl-5-methyl-5-pyrroline **(5)** in nearly 60% yield. Reaction of the kinetic enolate of **5** with diethyl chlorophosphate gave a good yield of the pyrroline phosphonate **6.** The condensation of the anion of **6** (*n*-butyllithium, −78°) with hexanal or *E*,2-



SCHEME 1.

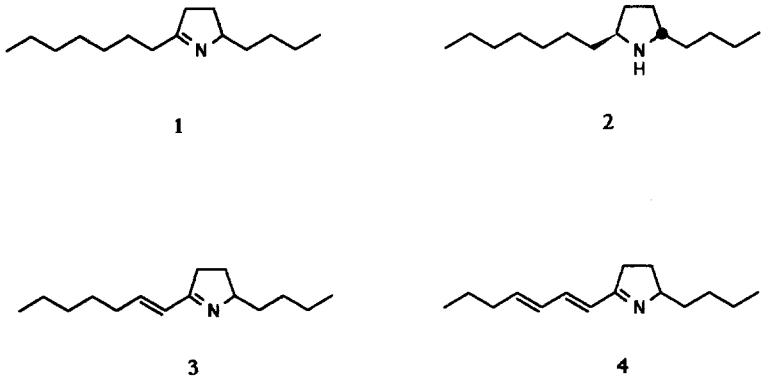


FIG. 2. The major alkaloids from the venom of *Megalomyrmex foreli*.

hexenal in a Wadsworth–Emmons-type reaction formed **3** and **4**, respectively, in moderate yield. In their ^{1}H NMR spectra, the olefinic coupling constants of 16 Hz in **3** and 15.8 Hz and 15.0 Hz in **4** confirm the *E* geometry of the side chain double bonds in these products. The retention times as well as the infrared and mass spectra of **3** and **4** were identical to those of the third and fourth eluting alkaloids from *M. foreli*.

Finally, a minor component with a retention time between that of **3** and **4** and a mass spectrum identical to that of **4** was detected. The band at 887 cm^{-1} in the infrared spectrum of this compound along with its retention time suggested that it was very likely a geometrical isomer of one of the double bonds of **4**.

Since **3** and **4** are new ant venom alkaloids, their toxicity against termites (*Reticulitermes* spp.) in topical application bioassays was determined. At 1.06 μg/mg and 2.39 μg/mg of termite, respectively, the LD_{50}'s of **3** and **4** were within the range of those found for other ant-venom-derived 1-pyrrolines (Escoubas et al., 1988; Jones et al., 1988a). For comparison, the LD_{50} of nicotine is 0.5 μg/mg termite. No "knock-down" effect was observed, even when the mortality became 100%.

DISCUSSION

The venom alkaloids **1–4** (Fig. 2) present in *M. foreli* share a common carbon–nitrogen skeleton, and the presence of pyrrolidine **2** suggests employment of the venom as a repellent, since this compound has been shown to have a strong repellent effect on other ants (Blum et al., 1980). *M. leoninus* produces only **2** in its venom (Jones et al., 1991), which may emphasize its taxonomic

relationship to *M. foreli*, as *M. foreli* is a member of the *M. leoninus* species group (Brandao, 1990). Saturated 2,5-dialkylpyrrolidines, including **2**, are frequently encountered venom components in other myrmicine species (Jones et al., 1982), and it may be that the pyrrolines **1**, **3**, and **4** are the result of an incomplete or modified biosynthetic pathway to **2**.

The unsaturated pyrrolines **3** and **4** constitute a new functional class of ant venom alkaloids. Their conjugated imine groups are reminiscent of the vinyl ketones produced in the defensive secretions of some termites, e.g., *Schedorhinotermes* spp., whose toxicity has been attributed to their strongly, electrophilic nature (Quennedey et al., 1973; Prestwich and Collins, 1982; Prestwich et al., 1975). The toxicities of **3** and **4** in topical application against termites (*Reticulitermes* spp.) are similar to those found for other ant-derived 1-pyrrolines, and are somewhat less than those reported for the corresponding pyrrolidines (Escoubas et al., 1988; Jones et al., 1988a, 1989). It is not surprising that the more polar **3** and **4** are not exceptionally toxic to termites compared to other more lipophilic ant venom alkaloids, since topical activity requires cuticular penetration. Our observations suggest that termites and *M. foreli* seldom, if ever, have strong interactions. Thus, it is unclear if these results can be taken as an indication that *M. foreli* evolved as a defense against termites. On the other hand, the functionally analogous vinyl ketones, produced by termites (*Schedorhinotermes*) for defense, have demonstrable *in vivo* toxicity (Spanton and Prestwich, 1981; Prestwich and Collins, 1982), and are inhibitors of *in vitro* pheromone degradation (Prestwich et al., 1989; Tasayco and Prestwich, 1990a,b). As defensive chemicals, the unsaturated pyrrolines **3** and **4**, functioning as irreversible electrophiles, may be used by *M. foreli* as a defense by disrupting the enzymatic degradation of chemical signals in the antennal sensilla of would be predators in a similar fashion.

The reluctance of *M. foreli* to sting led to an examination of the sting apparatus. The terminal lobate portion of the sting (Fig. 1) indicates some function other than piercing, and fortifies the suggestion that *Megalomyrmex* stings may be used as a chemical applicator (Kugler, 1979). Indeed, as has been observed in the genus *Tetraponera*, a characteristic of ants with well-developed chemical defenses may be replacement of stinging by some other mode of defense (Kugler, 1979; Braekman et al., 1987). The alarm-defense behaviors in *M. foreli* parallel those of other ant taxa. The rapid scatter response and stridulations produced by these ants when they are disturbed are similar to such responses commonly observed in the genera *Azteca*, *Dolichoderus*, *Tapinoma* (Dolichoderinae), *Oecophylla*, *Camponotus* (Formicinae), and in the myrmicine genus *Crematogaster* (DeVries, personal observation), all taxa with vestigal stings and highly evolved chemical defenses (Hölldobler and Wilson, 1990). Additionally, it is well established that alkaloid producing ants can utilize these compounds in the form of an aerosol (Obin and Vander Meer, 1985).

Taken together, the rapid scatter response, apparently non-penetrating sting, and relatively low topical toxicity of **3** and **4**, along with their electrophilic functionality, suggest that the venom of *M. foreli* may be deployed in much the same way.

The most recent review (Hölldobler and Wilson, 1990) indicates that little is published on the natural history of *Megalomyrmex*. It has been observed that some species of *Megalomyrmex* are apparently xenobiotic parasites of its nearest relatives, *Cyphomyrmex* and *Sericomyrmex*, and that in some species in the *M. leoninus* group, reproduction, or the queen caste, has been taken over by the workers (Brandao, 1987; Hölldobler and Wilson, 1990). The present observations of *M. foreli* suggest that the unique venom chemistry and modified sting play a role in the foraging and defense behaviors of these ants. Furthermore, these behaviors converge upon other, distantly related ant taxa that posses highly developed chemical defenses. Since plants and insects that form associations with ants receive survival benefit from the symbiotic interaction (Way, 1963; Beattie, 1985; Pierce, 1987; DeVries and Baker, 1989; DeVries, 1991b), it is likely that the *E. lycisca* and *N. cachrus* caterpillars reported here benefit from forming symbioses with *M. foreli*. Thus, although the defensive chemistry in *M. foreli* undoubtedly evolved in response to specific selective pressures, totally unrelated organisms like plants and other insects may benefit from the unique venom alkaloids of this ant.

Acknowledgments—We wish to thank Dr. H.M. Garraffo and Mr. Noel F. Whittaker of the laboratory of Bioorganic Chemistry, NIDDK for FTIR and high resolution mass spectra, respectively, and Dr. R.J. Highet of the laboratory of biophysical chemistry, NHLBI for the NMR spectra. We also thank Mr. R. Dreyfuss of the medical arts and photography branch, NIH, for the photomicroscopy. PJD would like to thank J. Longino, B. Hawkins, J. Clark, and the MacArthur Foundation for field assistance, and dedicate this paper to the work of P. Martino.

RELATIONSHIP BETWEEN DETERRENCE AND TOXICITY OF PLANT SECONDARY COMPOUNDS FOR THE GRASSHOPPER *Schistocerca americana*

E.A. BERNAYS

Department of Entomology and Center for Insect Science
University of Arizona
Tucson, Arizona 85721

(Received July 29, 1991; accepted August 19, 1991)

Abstract—A variety of plant secondary compounds, several of which are quite widespread in nature were tested for their deterrence to the generalist grasshopper *Schistocerca americana* in short-term behavioral assays. The compounds were coumarin, salicin, tannic acid, gramine, nicotine, quinine, carvone, geraniol, abietic acid, umbelliferone, and ursolic acid. These were then tested for their post-ingestional effects over the whole of the last larval instar. Different methods were employed to mask the taste of compounds that were deterrent in order to ensure that any effects were not due to reduced feeding. In no case was there any indication of a detrimental effect or any trend suggesting one. In two cases, there was a significant increase in growth rate with the addition of the secondary compound to the diet. The evolutionary implications of these findings are discussed.

Key Words—*Schistocerca americana*, Orthoptera, Acrididae, deterrence, toxicity, plant defense, diet breadth.

INTRODUCTION

The possible evolutionary reasons for deterrent effects of plant secondary compounds on herbivores are numerous, but usually it is assumed that avoidance of chemicals or plants is an evolutionary response to some noxious quality of these materials. Yet many deterrent responses appear to be unrelated to post-ingestional toxicity (Cottee et al., 1988; Bernays and Chapman, 1987; Bernays and Graham, 1988). The question needs answering on a series of different insect species and plant compounds because, if behavioral deterrence is not associated with post-ingestional toxicity, the evolutionary reasons for the behavioral sen-

0098-0331/91/1200-2519$06.50/0

sitivity need reevaluation with respect to whether they are primarily ecological or physiological. Among grasshoppers, deterrence of chemicals in non-host plants appears to be the primary basis for rejection of plants as food (Bernays and Chapman, 1977, 1978; Chapman and Bernays, 1977; Chapman et al., 1988), and there is interest in whether rejection responses are indicators of unsuitability. The aim of this paper is to examine the behavioral effects of a range of plant secondary compounds and then to examine whether measurable noxious effects follow ingestion of them, using the acridid *Schistocerca americana* Drury. This species is polyphagous but many native American plants tested are quite unacceptable, or become so after the initial meal (Chapman and Sward, unpublished).

METHODS AND MATERIALS

Stock colonies of *Schistocerca americana* Drury (Orthoptera: Acrididae) were reared in rectangular metal cages of 64 L capacity according to the procedures used at the Centre for Overseas Pest Research (Hunter-Jones, 1961). Each day, individuals that had newly molted to the sixth instar were removed and kept in 8 L cylindrical plexiglass cages in an environment chamber kept at L:D, 12:12 and temperature, 32:28°C. They were fed on seedling wheat.

Behavioral Choice Tests. Chemicals were tested for their deterrence on 3-day-old sixth instar nymphs by presentation in choice tests on sucrose-impregnated glass fiber disks, with sucrose-only control disks for 3–4 hr at 30°C (Navon and Bernays, 1978). Experiments were also carried out in which the chemicals were presented on wheat blades, but the measurements on acceptability were done by relative amounts of leaf area removed in a 5-hr period.

Chemicals chosen for experiments were expected to be deterrent at some concentration. The ten compounds and their commercial sources are listed in Table 1. For application to wheat blades, concentrations were made up either in water with detergent, in acetone, or in alcohol, such that an appropriate dry weight concentration of the desired level was achieved. This was found to vary by about 20% around the mean value, which was considered a realistic level of variation that could occur naturally. Concentrations tested were at about the maximum recorded levels found naturally, and at one fifth of that concentration.

Performance Tests. To test the potential effects of ingestion of the plant secondary compounds, various techniques were employed. For those that had no deterrent effect on feeding behavior (tannic acid, coumarin, abeitic acid, and carvone), the material was simply added to leaves as described above (Table 1) while the controls had solvent-only treated leaves. In each experiment, each individual was fed daily on either wheat leaves with an added chemical, or control wheat leaves without the chemical. Insects were weighed and selected

for each treatment in such a way that there was considerable overlap in the weight range and no significant difference between the test and control groups. They were kept individually in 5 L tubs with gauze lids. Conditions were the same as for the sorted and aged insects described above. The amounts of leaf material given to each insect each day were approximately of the same weight as the insect. In this way, most or all of the food was eaten each 24 hr except toward the end of the instar (Bernays, 1990). There were usually at least ten test and ten control insects in an experiment. The insects were weighed daily and the dry weight measured after the final ecdysis. The growth rate and efficiency of conversion of ingested food to body mass (ECI) were calculated in the usual way (e.g. Scriber, 1978).

In some cases (umbelliferone, gramine, and nicotine) insects were dosed daily using semimicro gelatin capsules prepared as described by Szentesi and Bernays (1984). The feeding regime was as described above, but twice daily a capsule containing the chemical under test, or an empty capsule, was inserted under the labrum and between the bases of the mandibles, from which it was swallowed. The amounts of the chemical in the capsules were calculated to give the approximate percentage dry weight of food assuming all food was eaten (Table 2).

With geraniol, we attempted to mask the taste by inclusion in betacyclodextrin, as described by Usher et al. (1989). This appeared to be successful

since no more food remained in the tubs at the end of each day relative to controls.

Crystals of salicin and methylene blue dye (mixed together) were wax-coated in a simplified version of the fluid-bed Wurster chamber process (see Usher et al., 1989 for details of this chamber). Crystals were placed in a hand-pulled funnel made from glass tubing 2 cm in diameter with a plug of glass wool at the bottom. Warm air was fed into the upright funnel from below, and this airstream suspended the particles at a level somewhat above the region where the diameter expanded to that of the tubing which extended about 10 cm above. From the top of the tubing, a solution of beeswax in chloroform was sprayed onto the moving particles using a chromatographic spray. The air stream was continued for about 5 min and then turned off allowing the newly-coated particles to fall onto the plug. Blue color was not observed at this stage. When the resulting wax-coated particles were extracted with chloroform, it was found that the salicin made up about 10% of the total weight. A behavioral assay was used to test deterrency by giving individuals a choice test between wax-coated cellulose and methylene blue crystals, and wax-coated salicin and methylene blue crystals, spread on sucrose-impregnated filter paper disks. The concentration was determined to be approximately 2% dw. No deterrency was detected

and subsequent dissection showed that the dye had been released in the gut. Wax-coated particles were tested for post-ingestional effects over the instar by spreading them onto leaves using a thin layer of office glue stick material. Coated cellulose (a carbohydrate that is not digested) was used as the control. Concentrations of salicin were approximately 1–3% dw of the leaf.

Finally, with ursolic acid, gelatin walled microcapsules were prepared by complex coacervation (Thies, 1986). Afterward, these were spread as an aqueous slurry onto the wheat leaves and allowed to dry. The difficulty of controlling the concentration obtained, and of variable levels of agglomeration, meant that the amounts ingested probably varied between about 0.1 and 0.5% of the dry weight of the leaf.

RESULTS AND DISCUSSION

Eight of the ten compounds deterred feeding at some concentration, although in only four cases were there significant effects at concentrations in the likely natural range, while three were significantly phagostimulatory at lower concentrations (Table 2). In no case was there any significant depression of growth rate or efficiency of conversion of food to body mass when insects ingested the chemicals over a whole instar (Tables 3 and 4). On the contrary, tannic acid and salicin appeared to cause slight increases in growth rates (Table 3). Similarly, Cottee et al. (1988) found a singular lack of oral toxicity in eight

plant secondary compounds when tested with the related species, *Schistocerca gregaria* (the desert locust), and Bernays (1990) found no detrimental post-ingestive effects of several deterrents for *Locusta migratoria*.

The lack of postingestive effects of the secondary compounds tested precluded the establishment of a meaningful ranking so that correlation analyses between deterrence and toxicity were not really possible. Cottee et al. (1988) demonstrated a weak correlation between behavioral deterrence of compounds and their toxicity following injection into the hemolymph in both *Locusta migratoria* and *Schistocerca gregaria* (when this is re-analyzed and Spearmans rank correlation done, $p < 0.05$). On the other hand, when compounds were administered by cannulation into the midgut, no correlation was found when deterrence was compared with oral toxicity.

In a comprehensive study by Harley and Thorsteinson (1967) on another polyphagous grasshopper, *Melanoplus bivittatus*, results with steroids and alkaloids also indicate a total lack of correlation between deterrence and toxicity. Interestingly, in that study, care was taken to use plant chemicals occurring in the habitat in which the insect occurs.

Although these experiments were undertaken to examine components of fitness, the tests are obviously not definitive. Feeding on such chemicals over a lifetime may be detrimental while feeding over one instar is possibly not long enough for effects to be seen. However, it might be expected that with below optimal levels of food, additional stresses involved would render insects vulnerable to any deleterious effects of plant secondary compounds. For example, protein shortage may lead to less effective detoxification processes and water

shortage to less effective excretion via the Malpighian tubules. Experiments by Boys (1981) in which *Locusta migratoria* was dosed with gramine at several concentrations covering the natural range, showed no effects on growth rate, fecundity, or longevity. Usher et al. (1989) also found that grindelic acid was deterrent to *Schistocerca americana*, but that when the taste was masked and the food eaten, no detrimental effects could be detected. Tannic acid has been tested with the related *Schistocerca gregaria* and also found to have no detrimental effects even when it is ingested at relatively high levels for the whole of nymphal life (Bernays et al., 1980).

Perhaps, if levels are high enough, detrimental effects would ensue (Cottee et al., 1988), but there is an interesting possibility that grasshoppers are much more highly sensitive behaviorally to plant secondary compounds, than is required for reasonable protection from ingestion of them.

From the evolutionary point of view, a poor correlation between deterrency and oral toxicity would indicate that avoidance responses may often have evolved under selective pressures unrelated to post-ingestional toxicity. Similarly, the tendency toward restriction of host range observed in insect herbivores may be unrelated to their inability to tolerate plant secondary compounds. Host range may be restricted for quite diverse and ecological reasons rather than for mainly physiological reasons. In such a case, non-host plants may become deterrent and unacceptable even when they are chemically suitable for growth and development (Bernays and Chapman, 1987; Bernays and Graham, 1988).

Abstract—In two studies using the electroantennogram (EAG) technique, bark beetle- and tree-produced semiochemicals were presented to *Dinotiscus dendroctoni* (Ashmead), a larval parasitoid of *Dendroctonus frontalis* Zimm. In the first study, 20 test compounds and a standard mixture of oxygenated monoterpenes were presented individually at one concentration to the parasitoids. In the second study, the nine compounds that elicited the greatest EAGs in study 1 were then tested as serial dilutions of 10 to 0.0001 $\mu g/\mu l$. The individual compounds did not elicit responses greater than the standard mixture of oxygenated monoterpenes. Males and females exhibited similar dose responses, although females showed lower thresholds of response than males to frontalin, terpinen-4-ol, *E,Z*-chalcogran, and *exo*-brevicomin. In both studies, pino-/isopinocamphone elicited the greatest responses at high concentrations. Tests of different ratios of the camphone mixture indicated that pinocamphone elicited the greatest response. Most of the test compounds elicited similar responses which suggests that several of the compounds may be used together by *D. dendroctoni* in habitat and/or host community location.

Key Words—*Dendroctonus frontalis*, Coleoptera, Scolytidae, *Dinotiscus*

INTRODUCTION

Numerous parasitoid species are associated with bark beetles in the family Scolytidae (Dahlsten, 1982). The ability of these natural enemies to locate their hosts has, in many cases, been determined to be mediated by semiochemicals (Borden, 1982; Payne, 1989; Mills et al., 1991). For the southern pine beetle, *Dendroctonus frontalis* Zimm., parasitoids generally begin arriving on beetle-attacked trees about 3 weeks after initial attack by their host (Camors and Payne, 1973). This coincides with the presence of *D. frontalis* brood in the late larval stadia (Thatcher and Pickard, 1967; Mizell and Nebeker, 1978), the host stage attacked by most of its parasitoids (Berisford, 1980).

Parasitoids arrive after peak pheromone production. Thus, it has been suggested that they may respond to pheromones remaining in the frass after initial attack by the bark beetles (Berisford and Franklin, 1971; Dixon and Payne, 1980) and/or olfactory stimuli from larvae feeding under the bark (Camors and Payne, 1973; Kudon and Berisford, 1981). Other possibilities include pheromones of *D. frontalis* produced later in the attack phase, i.e., verbenone and *exo*-brevicomin, and compounds produced by yeasts (Leufvén and Birgersson, 1987) and fungi (Birgersson and Leufvén, 1988) that are carried into the trees by the beetles.

Dinotiscus (=*Cecidostiba*) *dendroctoni* (Ashmead) (Hymenoptera: Pteromalidae), one of the more abundant species found parasitizing *D. frontalis* (Hetrick, 1940; Dixon and Payne, 1980; Goyer and Finger, 1980), is attracted to *D. frontalis*-infested loblolly pine *Pinus taeda* L. traps in the field (Camors and Payne, 1973). The specific olfactory cues used by this and other bark beetle parasitoid species are unknown. The following studies were conducted to determine the receptivity and sensitivity of the antennal olfactory receptor system of *D. dendroctoni* to potential semiochemicals.

METHODS AND MATERIALS

Insects. Pitch pine, *Pinus rigida* Mill., logs from Georgia, infested with heavily parasitized *D. frontalis* brood, served as our source of *D. dendroctoni* adults. Logs were stored in a cooler at 4°C. As adults were needed, logs were placed in rearing/emergence chambers (Browne, 1972). The chambers were checked daily and emerged adults were placed individually in 1 dram screw-top vials with a 30 × 7 mm section of filter paper moistened with a 1 : 1 honey–water solution. Adults were stored at 4°C in a domestic refrigerator without

photoperiodic control, for no longer than 21 days. To allow the adults to feed on the honey solution, they were removed from the refrigerator daily and exposed to room temperature (ca. 23°C) for 30 min. The procedure prolonged the lives of the parasitoids.

Compounds. Twenty bark beetle- and tree-produced compounds were tested in the study. The source and purity of the compounds are listed in Table 1. All compounds were diluted in redistilled pentane. Pino-/isopinocamphone was oxidized from precursor isopinocampheol with CrO_3/H_2SO_4 (Jones reagent). Due to changes in oxidizing procedures, the ratio of pino-/isopinocamphone varied from 3:2 (used in study 1), to 1:2 and 1:19 (used in study 2). The relative heights of the peaks obtained from GC-MS analysis were used to determine the ratio of pinocamphone to isopinocamphone.

Electrophysiology. Electroantennogram (EAG) techniques (Dickens and

Payne, 1977) were modified from earlier techniques (Schneider, 1957; Payne, 1970, 1975). Glass capillary, Ag-AgCl electrodes filled with insect Ringer's solution (Barbosa, 1974) were used. A scalpel was used to sever the tip of the distal flagellum segment from the insect's antenna. The recording electrode was then inserted into the open end of the segment; the indifferent electrode was inserted into the insect's oral cavity. EAGs were displayed on a Tektronix 5223 digitizing oscilloscope and recorded on a Soltec x–y plotter. Stimuli were delivered at 5 min intervals as 5 μl aliquots on filter paper (20 $\times$ 7 mm) placed into glass cartridges (75 mm long, 5 mm ID), and oriented toward the antennal preparation from ca. 1 cm. Stimulus duration was 1 sec in a 1 liter/min airflow filtered through activated charcoal. The initial depolarization upon stimulation was recorded as response to a given stimulus.

Study 1. A screening study was undertaken, in which all compounds were presented to *D. dendroctoni* at one of two concentrations (10 or 100 μg/μl), except for pino-/isopinocamphone (3:2) which was presented at 1 μg/μl. The pentane solvent (5 μl on filter paper) was used as a control. A standard stimulus was used as a basis against which to normalize parasitoid response to the compounds. This helped control for variation between and within preparations over time (Payne, 1975). The standard consisted of an oxygenated mixture of several volatiles emanating from trees containing heavily parasitized *D. frontalis* brood. The mixture contained *E,Z*-chalcogran (16 μg/μl), fenchone (93 μg/μl), camphor (96 μg/μl), bornyl acetate (122 μg/μl), pino-/isopinocamphone (1:2) (90 μg/μl), terpinen-4-ol (91 μg/μl), 4-allylanisol (98 μg/μl), *trans*-verbenol (91μg/μl), borneol (98 μg/μl), verbenone (99 μg/μl), and myrtenol (88 μg/μl).

Each insect was exposed to all test compounds randomly. Both the control and the standard were presented to the insect after every four stimulations by candidate compounds. Response to each compound was calculated as a percent of the response to the standard closest in sequence. Not all insects survived to be stimulated by all compounds. Therefore, on several occasions more than one insect was needed to complete a replicate. Essentially, equal numbers of males and females were tested for each compound.

Responses to compounds were ranked into four "tiers." Compounds eliciting EAGs greater than or equal to those elicited by the standard were ranked in the first and second tier, respectively. The third tier consisted of compounds which elicited EAGs not significantly different from the lowest ranking tier 2 compound. Tier 4 compounds elicited EAGs significantly lower than the lowest ranking tier 2 compound.

Study 2. Serial dilutions of compounds ranked in tiers 1–3 were tested in concentrations ranging from 10 to 0.0001 μg/μl. The dilution series for each randomly-assigned compound were presented to the insects randomly. Pentane solvent was used as the control. The same standard mixture used in study 1 was used here, except all compounds in the mixture were diluted to ca. 10 μg/μl.

The control and standard stimuli were presented to the insect after each dilution series. Response to each dilution in the series was calculated as a percent of the mean of the two closest responses to the standard. Ten females and nine males were tested for each dilution series.

Statistical Analysis. Study 1 was designed as a randomized complete block, with each insect representing a block. Blocks were nested within sex and analyzed as an incomplete block design using the General Linear Models (GLM) procedure in SAS (SAS, 1985). Mean comparisons, using least square means ($P \leq 0.05$), were determined *a priori* to compare all compounds in tiers 1–3 to the standard. Mean comparisons were not run on tier 4 compounds.

Dose-response to serial dilutions in study 2 were first analyzed by determining the low threshold of response. This was calculated, relative to the standard, as the minimum stimulus concentration at which the percent EAG to the stimulus was significantly greater ($P \leq 0.05$) than the percent EAG to the corresponding pentane control, as determined by *t*-test comparisons. The GLM procedure was used to compare percent response values between compounds for each sex at and above the low threshold (SAS, 1985). Means were separated using the Student–Newman–Kuels' test. The *t*-test was used to compare percent response values between sexes for each compound at each dose.

RESULTS AND DISCUSSION

Study 1. EAGs were not significantly different between male and female *D. dendroctoni* in response to the candidate compounds ($F_{1,493} = 1.05$; $P > 0.05$), relative to the EAGs elicited by the standard for each sex. In addition, male and female EAGs elicited by the standard were also not significantly different ($t_{(106)} = 0.45$; $P > 0.05$). Therefore, the data were pooled. This is surprising, since male parasitoids normally mate on the tree from which they emerge, aggregating to sites where females emerge (Mills, personal communication). After mating, only females are attracted to scolytid infested trees (Camors and Payne, 1973).

The only compound to elicit significantly greater response than the standard was pino-/isopinocamphone (3:2) (tier 1 compound), which elicited EAGs of 126% relative to the standard (Table 2). Tier 2 compounds consisted of frontalin, *E,Z*-chalcogran, *E*-7 methyl-1,6-dioxaspiro[4.5]decane (MAD), with mean EAG responses ranging from 92 to 107%. Compounds ranked in the third tier were *exo*-brevicomin, *alpha*-pinene, *alpha*-terpineol, and terpinen-4-ol, with mean EAGs ranging from 77 to 82%.

Study 2. Electroantennograms between sex for each compound were similar except for two compounds, *alpha*-terpineol and frontalin at 1 $\mu g/\mu l$ (Figure 1). However, females had lower response thresholds than males for several

[a] Means followed by different letters are significantly different from each other, based on *a priori* comparisons (LS means; $p < .05$). Tier 4 compounds were not subject to mean comparisons; therefore, those means are not followed by letters.

[b] Standard is a mixture of *E,Z*-chalcogran, fenchone, camphor, bornyl acetate, pino-/isopinocampone (1:2), terpinen-4-ol, allylanisol, *trans*-verbenol, borneol, verbenone, and myrtenol.

compounds; *exo*-brevicomin, *E,Z*-chalcogran, frontalin, and terpinen-4-ol (Table 3). Lowest response thresholds for females were elicited by terpinen-4-ol and frontalin, followed by *E,Z*-chalcogran. Dickens (1981) suggested that compounds which elicited responses to low concentrations and wider concentration ranges may function in long-range orientation of the insects to the host or host habitat.

The standard elicited significantly higher EAGs from both sexes than any individual compound tested at 1 $\mu g/\mu l$ (Table 4). The ranking of EAGs to compounds at 10 $\mu g/\mu l$ was quite similar to the ranking at 1 $\mu g/\mu l$, except for MAD which elicited relatively low EAGs at 1 $\mu g/\mu l$ and relatively high EAGs at 10 $\mu g/\mu l$, and terpinen-4-ol which elicited similar responses at both concen-

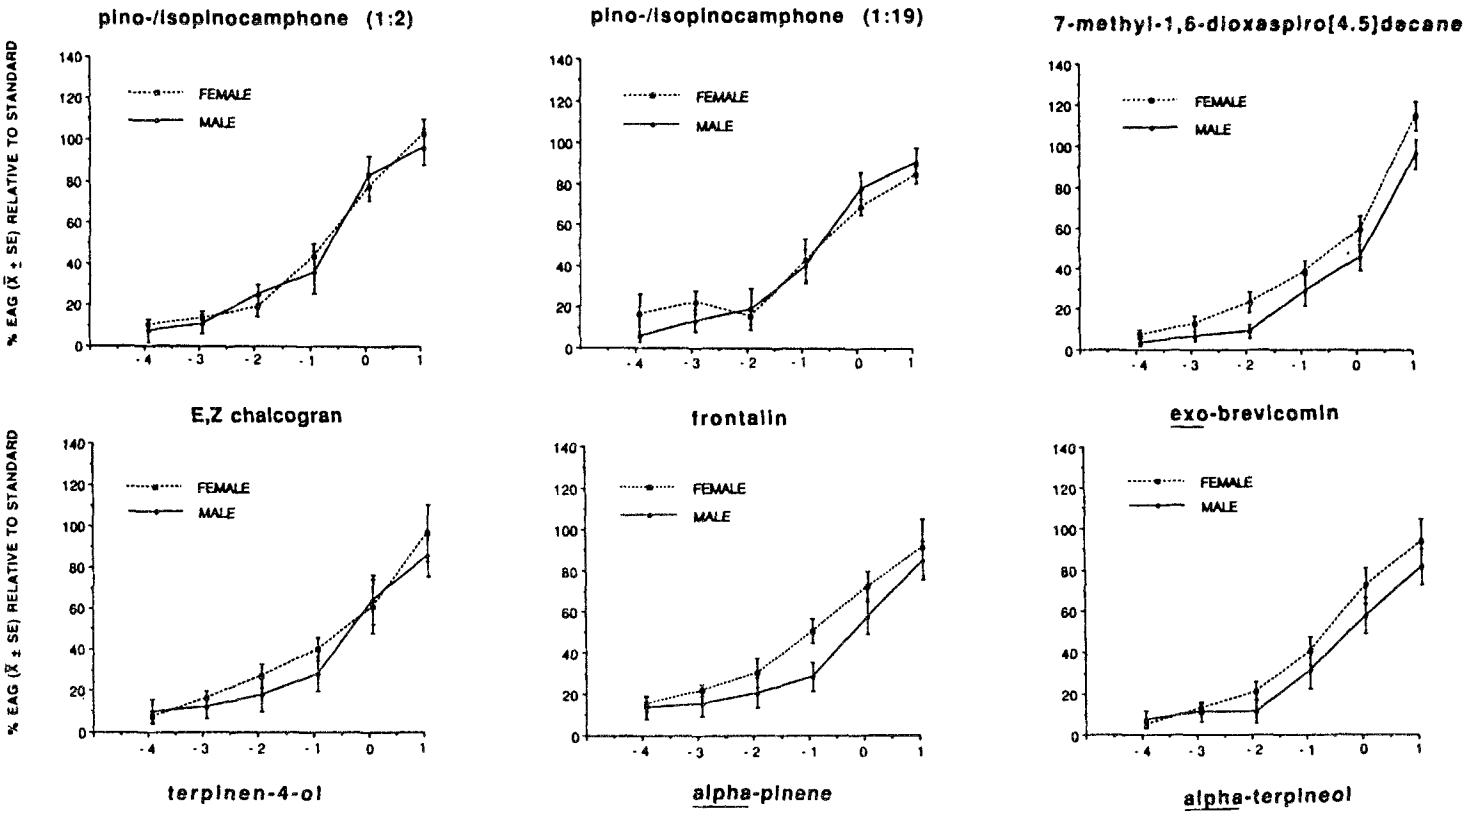

FIG. 1. Mean percent EAGs ± SE from *Dinotiscus dendroctoni* to bark beetle pheromones and tree-produced volatiles, relative to EAG responses by each sex to the standard mixture of oxygenated monoterpenes. Each concentration was presented as 5 μl aliquots.

trations (Table 4). Pino-/isopinocamphone (1:2) consistently ranked first or second for both males and females at both concentrations, yet responses to the compound were only significantly different from a few of the other compounds. Pino-/isopinocamphone (1:19) consistently ranked lower than the (1:2) mixture. In study 1, pino-/isopinocamphone (3:2) elicited higher responses than did the standard, even though its concentration was 1/100th the standard. The data suggest that *D. dendroctoni* is more sensitive to pinocamphone than isopinocamphone.

An exponential increase in EAGs, at the highest concentrations tested, was recorded for males and females exposed to MAD and *alpha*-pinene, and for females exposed to *E,Z*-chalcogran (Figure 1). This pattern suggests that *D. dendroctoni* may use the increasing concentration gradients of one or all of these compounds as directional cues for close range orientation of the insect to its host.

The results show that *D. dendroctoni* has receptors for many of the oxygenated monoterpenes collected from host trees containing *D. frontalis* brood. Based on our electrophysiological data, where most of the compounds elicited similar EAGs, it can be suggested that several of the compounds may be used by *D. dendroctoni* as cues in habitat and host community location. In field tests, the standard mixture attracted *D. dendroctoni* and other parasitoid species at a level comparable to crude extracts taken from *D. frontalis*-infested trees exhibiting high levels of parasitism (Birgersson et al., unpublished data). This is consistent with studies of parasitoids of other plant-inhabiting insect host spe-

cies that have been found to use a complex of insect and plant-produced compounds as habitat and host community location cues (Vinson, 1981, 1984; Lewis and Martin, 1990).

Subtractive assays of the standard mixture, used to evaluate parasitoid attraction, revealed that parasitoids were most attracted to traps baited with the complete standard mixture blend and less so to the blends missing one of the compounds (Birgersson et al., unpublished data). No one compound tested was predominantly attractive to parasitoids. Additionally, most parasitoids attracted to these blends were female. This suggests that although males respond similarly to these compounds as females at the sensory level, they may respond differently or not at all at the behavioral level.

One compound that has consistently been extracted from *D. dendroctoni* oviposition sites may serve as a short range oviposition cue for the parasitoid

(Birgersson et al., unpublished data). Unfortunately, it has not yet been identified. Sensory and behavioral experiments with the compound, as well as behavioral studies with the test compounds from this study, need to be carried out to further identify the semiochemicals used by *D. dendroctoni* during the host-searching process.

(Received July 8, 1991; accepted August 26, 1991)

Abstract—The present set of experiments was designed to explore avian insensitivity to capsaicin. Based upon a molecular model of avian chemosensory repellency, we hypothesized that structural modifications of the basic capsaicin molecule, which is itself not aversive to birds, might produce aversive analogues. To this end, European starlings (*Sturnus vulgaris*) and Norway rats (*Rattus norvegicus*) were given varied concentrations of synthetic capsaicin and four analogues (methyl capsaicin, veratryl amine, veratryl acetamide, vanillyl acetamide) in feeding and drinking tests. The results agreed with a model that we are developing to describe the chemical nature of avian repellents. Synthetic capsaicin and vanillyl acetamide were not repellent to birds, owing to the presence of an acidic phenolic OH group. Conversely, veratryl acetamide was aversive, due to the basic nature of this compound. For rats, repellent effectiveness among compounds was reversed: synthetic capsaicin was the best repellent while veratryl acetamide was the worst. We speculate that this taxonomic reversal may reflect basic differences in trige-

*To whom correspondence should be addressed.

minal chemoreception. In any case, it is clear that chemical correlates of mammalian repellents are opposite to those that predict avian repellency.

Key Words—Capsaicin, chemosensory, irritation, rat, *Rattus norvegicus*, starling, *Sturnus vulgaris*, trigeminal.

INTRODUCTION

Avoidance of a chemical can be learned by associating sensory features of the chemical with post-ingestional effects, e.g., sickness (Riley and Clarke, 1977). Alternatively, avoidance of a chemical can occur in the absence of learning, provided that the chemical stimulates trigeminal free nerve endings (Parker, 1912) in the nose, eyes, or mouth. While the morphological organization of the trigeminal system in birds is not very different from that found in mammals (Dubbeldam and Veenman, 1978), there appear to be dramatic behavioral discrepancies (Kare and Mason, 1986). Although the avian trigeminal system responds to odorants (e.g., Walker et al., 1979, Mason and Silver, 1983) and mediates avoidance of avian irritants, e.g., methyl anthranilate (Mason et al., 1989), it does not respond to strong mammalian irritants. Thus, pigeons (*Columba livia*) and grey partridges (*Perdix perdix*) are indifferent to ammonia (Soudek, 1929), and parrots (*Amazona* spp., Mason and Reidinger, 1983), pigeons (Szolcsanyi et al., 1986), red-winged blackbirds (*Agelaius phoeniceus*; Mason and Maruniak, 1983), European starlings (Mason and Clark, 1990), cedar waxwings (*Bombycilla cedrorum*), and house finches (*Carpodacus mexicanus*; D. Norman, unpublished observation) , are insensitive to capsaicin, the pungent principle in *Capsicum* peppers.

The finding that birds are unresponsive to capsicum is especially interesting, because mammals uniformly avoid this substance. The present set of experiments was designed to explore this instance of avian insensitivity. On the basis of a model relating avian repellency with chemical structure (Mason et al., 1991; Clark and Shah, 1991; Clark et al., 1991; Shah et al., 1991), we hypothesized that structural modifications of the basic capsaicin molecule might produce analogues that were aversive to birds. To this end, starlings and Norway rats (*Rattus norvegicus*, laboratory strain) were given varied concentrations of capsaicin and four analogues (methyl capsaicin, veratryl amine, veratryl acetamide, vanillyl acetamide) in feeding and drinking tests.

Our choice of analogue structures was guided by the following considerations. First, methyl capsaicin was selected because its additional OCH_3 group (Figure 1) made it more basic than capsaicin, and molecular basicity is positively associated with avian repellency (Clark and Shah, 1991). Second, vanillyl acetamide was chosen because the removal of the alkyl group (relative to capsaicin) should enhance repellency by contributing to the electron richness of

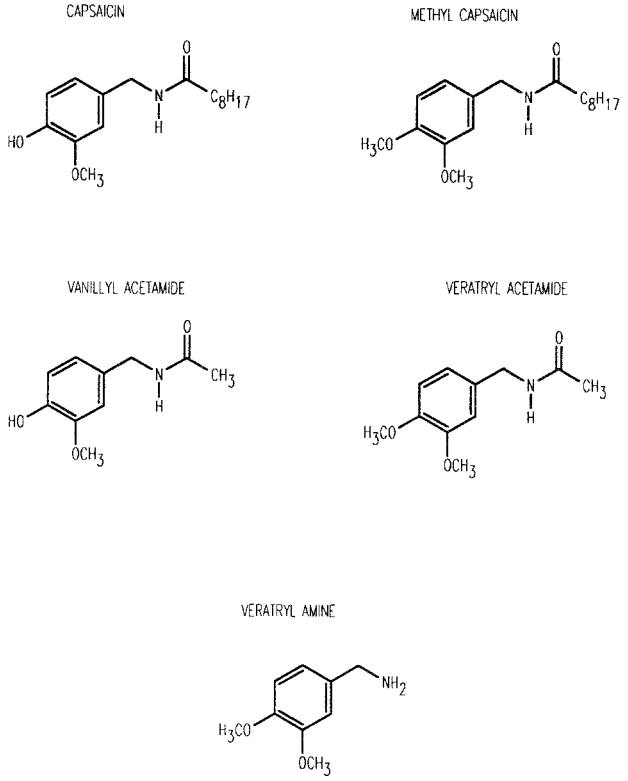

FIG. 1. Molecular structure of synthetic capsaicin, methyl capsaicin, veratryl amine, vanillyl acetamide, and veratryl acetamide.

the phenyl ring (Shah et al., 1991). Third, veratryl amine was evaluated because it is more basic than capsaicin and because there is no possibility of side chain interference in effectiveness, e.g., no possibility of electronic interference (Clark et al., 1991). Finally, we selected veratryl acetamide both because it is basic relative to capsaicin or vanillyl acetamide, and because it is more lipophilic than veratryl amine. Because lipophilicity is positively correlated with repellency (Mason et al., 1989), we predicted that veratryl acetamide should be the most effective bird repellent of the derivatives tested.

MATERIALS AND METHODS

Subjects. Adult European starlings (*Sturnus vulgaris*) were decoy-trapped in Pilesgrove township, Salem County, New Jersey, and transported to the laboratory. Birds were held for 3 weeks prior to testing. We chose to use this

species because (1) they show good chemical sensing ability (e.g., Clark and Mason, 1987), and (2) comparable data exist concerning the responses of starlings to other repellents, e.g., anthranilate derivatives (Mason et al., 1989) and mammalian irritants, e.g., piperine, zingerone, allyl isothiocyanate, and gingerol (Mason and Otis, 1990).

Upon arrival, the birds were individually caged (61 × 36 × 41 cm) under a 12:12 light-dark cycle with light onset at 0700 hr. Food and grit [Purina Flight Bird Conditioner (PFBC) and medicated oyster shells] were available *ad libitum*; apples were provided twice a week. Before experiments began, birds were permitted free access to tap water.

Sixty-day-old Sprague–Dawley Norway rats were obtained from the Vassar College colony. The rats were individually caged (17.7 × 24.2 × 17.7 cm) under a 12:12 light/dark cycle (light onset 0700 hours). During a 2-week adaptation period prior to testing, all rats were permitted free access to crumbled Purina rat chow and tap water.

Chemicals. Veratryl amine was purchased from Fluka Chemical Co. (Buchs, Switzerland), while synthetic capsaicin was obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin). Vanillyl acetamide was synthesized according to the method described by Helson (1919). Methyl capsaicin (corresponding to synthetic capsaicin, i.e., veratryl nonamide) and veratryl acetamide were synthesized by a simple acetylation procedure, as follows. Veratryl amine (10 g) was dissolved in triethylamine (20 ml) and the solution was cooled to 0°C. The nonanoyl chloride or acetic anhydride (two equivalents) was added dropwise and the solution was allowed to stand at room temperature for 1 hr. The reaction mixture was poured into ice water (50 ml) and extracted with dichloromethane (2 × 25 ml). The organic layer was successively washed with 5% HCl (25 ml), 11% sodium hydrogen carbonate (25 ml), and water (25 ml), dried and evaporated under reduced pressure. The residue was purified by column chromatography (on silica gel) to obtain pure samples of veratryl nonamide and veratryl acetamide.

For the bird experiments, each chemical constituted an independent test for both the feeding and drinking experiments. For each chemical in drinking trials, stimuli were dissolved in water to prepare the following concentrations (w/v): 0.001, 0.005, 0.01, 0.05, 0.1, and 1.0%. For each chemical in feeding trials, stimuli were first dissolved in ether, and the solutions applied to bird feed. The ether was then evaporated (Jakubas et al., 1991). Chemical concentrations used in the bird feeding trials were: 0.001, 0.01, 0.1, and 1.0% (w/w).

Procedures. In *drinking trials*, one-bottle tests similar to those described by Clark and Shah (1991) were used. Briefly, water consumption for starlings was monitored for a total of 6 hr for each of 3 days. At the end of this period, individuals whose variance was $> \pm 1$ standard deviation of the population vari-

ance were excluded from the trials. Those birds with stable daily water consumption were ranked according to mean water consumption and assigned to one of the six treatment concentration groups (hereafter called concentration group). That bird with the highest water consumption was assigned to the 0.5% concentration group, that bird with the second highest consumption, to the 0.1% concentration group, and so forth, until all birds were assigned to a group. This assured that all concentration groups were balanced with respect to drinking when trials began. A total of 36 birds was used for each experiment, with six birds per concentration group. During any given experiment, only a single chemical was tested.

After assignment to a concentration group, a 1-day pre-treatment drinking trial began. At 0930, tap water consumption for birds within each concentration group was measured every 2 hr for a total of 6 hr. These measures served as the control level of water consumption. After the pre-treatment trial, drinking tubes were switched (to maintain consistent protocol) and the birds were provided free access to fresh tap water. The following day, at 0930, tap water was replaced with a preassigned concentration of chemical in water, and consumption was recorded every 2 hr for the next 6 hr. After the test, birds were again provided free access to tap water. Consumption of tap water was monitored overnight. Overnight consumption was monitored to evaluate whether birds made up for any water deficits resulting from experiments. During the post-treatment trial, tap water consumption was monitored every 2 hr for a total of 6 hr. Mean posttreatment water consumption within concentration groups was compared with mean pre-treatment water consumption to determine whether consumption had returned to pre-treatment levels; i.e., were there carryover effects due to consumption of treated water? If pre-treatment consumption was equal to posttreatment consumption, then the next compound was tested following the above procedures. During subsequent experiments with other chemicals, each group was assigned a different concentration, as determined by a counterbalanced predetermined schedule. This was done to minimize the possibility that strength of stimulus, rather than quality *per se* affected drinking behavior. Previous experience suggested that these precautions were adequate, though we did not specifically test for this effect.

Protocol specified that an individual's intertrial water consumption be maintained within ± 1 standard error of its pre-treatment value. If this were the case, the bird was used in the next experiment; otherwise, it was replaced with a new bird whose baseline water consumption was matched for the group mean. Individual birds showed remarkable consistency for water consumption. Only one bird was replaced throughout the drinking trials.

Birds were checked for health condition after each daily trial, e.g., unusual inactivity, vent fouling, and piloerection. There were no mortalities, and birds were released to the wild at the end of the experiment. Naive birds were not

used for each test because it was impractical to capture the 180 starlings required for all trials.

In *feeding trials*, 24 starlings were used with each chemical. In every test, the birds were given a 4-day pre-treatment period, during which each was presented with a cup containing 50 g of feed during the first 2 hr following light onset. Consumption was then assessed and birds were left with undisturbed access to the maintenance diet until lights were out. Feed was removed from the cages overnight so that the birds were moderately food deprived. On the fourth day, birds were assigned to four concentration groups ($n = 6$/group) on the basis of consumption. That bird with the greatest consumption was assigned to the first group, that with the second highest was assigned to the second group, and so forth.

A 4-day treatment period immediately followed pre-treatment. During the first 2 hr following light onset, each bird was given 1 cup containing 50 g of feed. The feed was adulterated with one of the stimulus chemicals, and different groups were presented with different concentrations. As in pre-treatment, consumption was measured after 2 hr, and birds were food-deprived overnight.

Rat feeding trials were similar to starling feeding trials, with two differences. First, rats were given only one concentration of each chemical (1.0%, w/w). We had planned to use the same range of concentrations presented to birds, but only capsaicin was aversive in pilot testing at a concentration of 0.1%. Second, a control group that received untreated chow during the treatment period was included. Drinking trials were not conducted because 1.0% concentrations of the chemicals were near the limit of solubility in the drinking trials with birds.

Analyses. For starling drinking trials, data were transformed using a difference score to control for individuals' pre-treatment water consumption, i.e., treatment–pre-treatment, and posttreatment–pre-treatment. Difference scores were evaluated in a two-factor analysis of variance (ANOVA), with repeated measures between difference scores (two levels). The independent factor was treatment concentration group. Missing data was only a problem for the drinking experiments. At times, individuals would rest atop the drinking tubes and spill water. If this occurred during any of the test periods (pre-treatment, treatment, or posttreatment), that individual's consumption was not included in the analysis.

For starling feeding trials, mean consumption was evaluated using three-factor ANOVAs with repeated measures between periods (two levels: pre-treatment, treatment) and among days (four levels). The independent factor was concentration group (four levels).

For rat feeding trials, mean consumption during the treatment period was assessed in a two-factor ANOVA with repeated measures among days. The independent factor was chemicals (six levels, the five chemicals, and a control).

In all cases, Tukey *b post-hoc* tests were used to isolate significant differences among means ($P < 0.05$). Unless otherwise indicated, all data were tested and found to be homogeneous using Bartlett's-Box method.

RESULTS

Avian Drinking Trials

Synthetic Capsaicin. There were no significant concentration, treatment period (block), or interaction effects (Figure 2A).

Methyl Capsaicin. The interaction between concentration groups and period was significant ($F = 5.3$; 5,29 df; $P < 0.001$). *Post-hoc* tests showed that, relative to posttreatment, there was a significant, albeit slight reduction in treatment difference scores for the highest methyl capsaicin concentration group (Figure 2B).

Vanillyl Acetamide. The interaction between concentration groups and period was significant ($F = 6.3$; 5,29 df; $P < 0.001$). *Post-hoc* tests showed that the mean treatment difference score for the highest concentration group was significantly less than the mean posttreatment score for that concentration group (Figure 2C).

Veratryl Amine. The interaction between concentration groups and period was significant ($F = 5.5$; 5,29 df; $P < 0.001$). *Post-hoc* tests showed that the treatment difference scores for the two highest concentrations of veratryl amine were smaller than the posttreatment difference scores for these concentrations. The highest concentration produced the greater effect (Figure 2D).

Veratryl Acetamide. The interaction between concentration groups and period was significant ($F = 14.4$; 5,29 df; $P < 0.001$). *Post-hoc* tests showed that while posttreatment difference scores remained constant or became larger, treatment scores decreased with increasing concentration. The two highest concentrations produced a drop from pre-treatment consumption that was significantly greater than the drop produced by any other concentration (Figure 2E).

Avian Feeding Trials

Synthetic Capsaicin. There were no significant differences for concentration, treatment period, day, or the interaction effects (Figure 3A).

Methyl Capsaicin. The day by period by concentration interaction was significant ($F = 3.0$, 9,60 df, $P < 0.005$). *Post-hoc* tests showed that the profile for consumption for the first day of pre-treatment differed from all other profiles. Indeed, all interaction terms and main effects involving days pointed to decreased consumption on the first day. However, more importantly to the hypothesis of interest, there was no period effect ($P = 0.789$), even though the

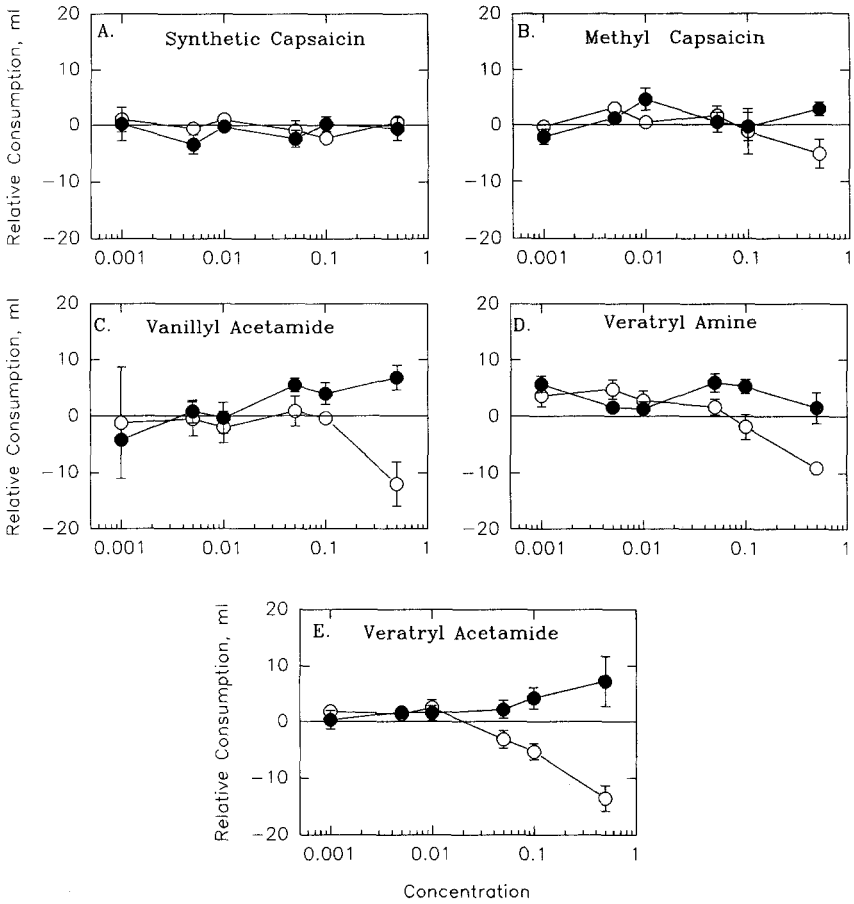

FIG. 2. Mean consumption of synthetic capsaicin and the four capsaicin analogues in avian drinking trials. Open circles represent treatment–pre-treatment values, while filled circles represent mean posttreatment–pre-treatment values. Capped vertical bars represent standard errors of the means.

period by concentration profiles differed ($F = 5.4$, 3,20 df, $P < 0.007$; Figure 3B).

Vanillyl Acetamide. Again, there were no significant effects for treatment ($P = 0.51$), concentration ($P = 0.23$), or their interaction ($P = 0.69$; Figure 3C).

Veratryl Amine. Overall, the consumption of food was less during the treatment period relative to the pre-treatment period ($F = 635.4$; 1,20 df; $P < 0.001$). Inspection of the concentration by period interaction (Figure 3D) showed

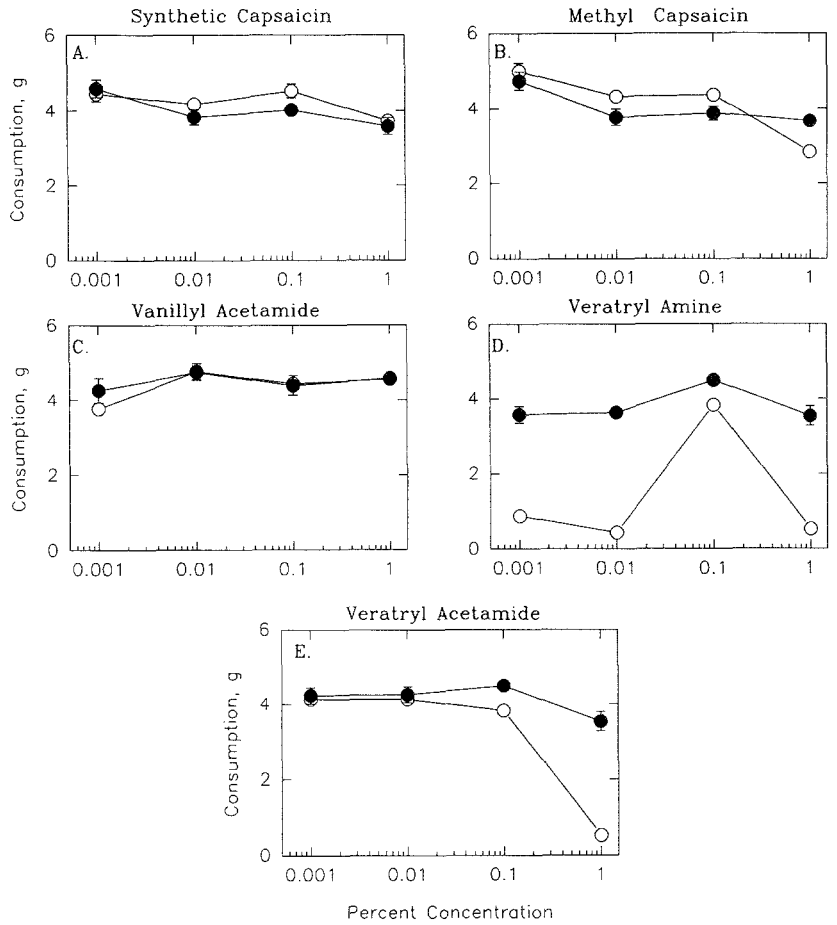

FIG. 3. Mean consumption of synthetic capsaicin and the four capsaicin analogues in avian feeding trials. Open circles represent treatment consumption while filled circles represent pre-treatment consumption. Capped vertical bars represent standard errors of the means.

that this relationship held down to the limits of concentrations tested, i.e., 0.001% ($F = 44.62$; 1,20 *df*, $P < 0.001$). *Post-hoc* tests showed that consumptions for birds assigned to the 0.1% concentration group did not differ between treatment periods.

Veratryl Acetamide. This compound did not appear to be as effective as veratryl amine, but was more effective than capsaicin, methyl capsaicin, and vanillyl acetamide. Overall, the treatment period consumption was less than the pre-treatment control ($F = 67.15$; 1,20 *df*; $P < 0.001$). The interaction of

period by concentration profiles indicated that the reduction in consumption of treated food was accentuated at higher concentrations (Figure 3E; $F = 33.63$; 3,220 df; $P < 0.001$). *Post-hoc* tests indicated that only the 1% concentration differed from pre-treatment levels and the lower levels of treated food.

Rodent Feeding Trials

Synthetic Capsaicin, Methyl Capsaicin, Veratryl Amine, Veratryl Acetamide, and Vanillyl Acetamide. There were significant differences among compounds ($F = 2.8$; 5,18 df; $P < 0.05$). *Post-hoc* examination of this effect indicated that synthetic capsaicin significantly reduced consumption relative to consumption by the group that received untreated feed. The least effective repellent was vanillyl acetamide; consumption by rats given this substance was significantly higher than the consumption exhibited by control group rats (Figure 4).

DISCUSSION

Although the peripheral trigeminal system in birds and mammals is morphologically similar, there are broad functional differences between the taxa. Birds are uniformly unresponsive to most (if not all) mammalian sensory irri-

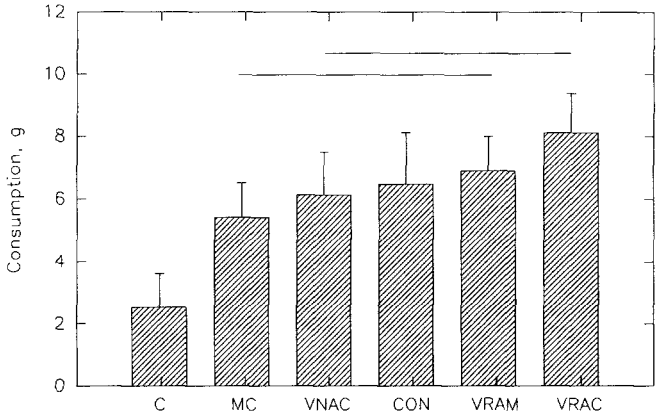

FIG. 4. Mean consumption in rat feeding trials with synthetic capsaicin and the four capsaicin analogues. All chemicals were presented at a concentration of 1.0% (w/w). Capped vertical bars represent standard errors of the means. The horizontal lines depict homogeneous group means as determined by a *post-hoc* Tukey's *b* test. tants at biologically relevant concentrations. The present set of experiments was designed to explore avian insensitivity.

Overall, the present results are consistent with our model describing the chemical nature of avian repellents (Clark et al., 1991; Clark and Shah, 1991; Mason et al., 1991; Shah et al., 1991). According to that model, the electron richness of the phenyl ring and basicity are positively related to repellency, whereas acidic functionalities are negatively associated with effectiveness. Hence, vanillyl amides, i.e., synthetic capsaicin and vanillyl acetamide, should be weakly repellent (if at all), owing to the presence of the acidic phenolic OH group. Conversely, the veratryl amides should be aversive.

Veratryl amine and veratryl acetamide were aversive to birds in both drinking and feeding trials. The former substance was the most basic of the compounds tested. These data agree with our earlier work on vanillyl and cinnamyl alcohol derivatives. In those experiments (Shah et al., 1991; Jakubas et al., 1991, respectively), veratryl alcohol was more active than vanillyl alcohol and dimethoxy cinnamyl alcohol and its benzoate were more active than the corresponding coniferyl derivatives.

Methyl capsaicin was not significantly repellent to birds in the present experiments, although the data hint that it may be aversive, relative to capsaicin, but only at very high concentrations. The higher activity of veratryl acetamide compared to veratryl nonamide (methyl capsaicin) may be due to stereoelectronic factors. For example, the nine-carbon chain on the amino group may sterically hinder the molecule's activity, e.g., structural and conformational effects. Alternatively, this long chain could effectively block electronic effects of the electron-rich phenyl ring. However, steric effects alone are not sufficient to explain the inhibition of repellency. Indeed, the feeding experiments indicate that vanillyl acetamide was ineffective as a repellent. The fact that vanillyl acetamide was aversive at the highest concentration in drinking trials may reflect the tendency for drinking trials to be more sensitive (Clark et al., 1991), possibly because the active ingredients in solution have greater access to receptors than those attached to particles of food.

The interaction of steric and basic effects may be important for repellency. It is worthwhile to note that, structurally, both veratryl amine and veratryl acetamide have short (two-carbon) or no side chains. At present, the nature of the assay (feeding vs. drinking) precludes solution of which of these points is more important. Molecular modeling may clarify the importance of steric and electronic effects of the side chain on the basic molecule, as well as the importance of hydrophobic and hydrophilic interactions.

In mammals, repellent effectiveness among compounds was essentially reversed. Capsaicin was the best repellent while veratryl acetamide was the worst. These results are consistent with the available evidence. We speculate that this taxonomic reversal may reflect several factors, e.g., differences in tri-

geminal chemoreception. In any case, it is clear that chemical correlates of mammalian repellents are opposite to those that predict avian repellency. Thus, acidity, a long side chain (lipophilicity), and an electron-poor phenyl ring may correlate positively with mammalian irritancy. According to the results obtained in this study and also the available data on the mammalian repellency of capsaicin derivatives (e.g., Green et al., 1990), the former two factors can be substantiated. More experiments are needed to test the third attribute.

POSTEMBRYONIC DEVELOPMENT AND REPRODUCTION IN *Corcyra cephalonica* (STAINTON) (LEPIDOPTERA: PYRALIDAE) ON EXPOSURE TO EUCALYPTUS AND NEEM OIL VOLATILES

P.H. PATHAK and S.S. KRISHNA*

(Received June 27, 1991; accepted September 4, 1991)

Abstract—Postembryonic development and adult emergence of *Corcyra cephalonica* (Stainton) were adversely affected in varying degrees when individuals were reared for the first 2 weeks of larval life or for a similar duration from the sixteenth day of their lives in an environment of eucalyptus oil volatiles. This was, however, not so in the progeny of parents exposed to these volatiles for only 5 min. Exposure of this pest to neem oil volatiles during larval stages for similar periods failed to produce such adverse effects. A marked decline in the reproductive potential, in terms of egg output and egg hatchability, of the moth was observed when the larvae were reared for the first 15 days in the presence of eucalyptus oil volatiles or when the parents were exposed for 5 min to such an environment during adult life. Thus, a "carry over" of the detrimental effect of the volatile(s) of this oil on the reproductive potential of the pyralid was indicated.

Key Words—Plant oils, *Eucalyptus*, neem, postembryonic development, reproductive potential, *Corcyra cephalonica*, Lepidoptera, Pyralidae.

INTRODUCTION

The rice moth *Corcyra cephalonica* (Stainton) is a major pest of stored commodities in the tropics (Piltz, 1977). Information on the effects of volatiles of selected plant-derived stored food products (Krishna and Mishra, 1985; Kumar

*To whom correspondence should be addressed.

0098-0331/91/1200-2553$06.50/0

and Krishna, 1991) or of specified plant components (Pathak and Krishna, 1985, 1992; Ansari and Krishna, 1987) on the insect's reproductive biology, particularly egg output and egg hatchability, have been reported. However, nothing is known about the changes that are likely to occur in the postembryonic development and reproduction of the insect following programmed exposure of individuals to the volatiles from such sources during rearing or breeding. We present our findings on these aspects with respect to eucalyptus and neem oils.

METHODS AND MATERIALS

Insects

A culture of *C. cephalonica* was maintained in the laboratory on a diet composed of "Jowar" (*Sorghum bicolor* (L.) Moench) and 5% yeast (Mishra and Krishna, 1979). Newly emerged larvae of males and females (<24 hr old) were drawn from the culture for this investigation. The oil of eucalyptus tested was a commercial brand (M/S Vivek Pharma, Mazagon, Bombay, India) and that of neem was a product extracted from the decorticated seeds of locally grown Indian neem trees (*Azadirachta indica* A. Juss).

Larval Exposure to the Oils

For assessing the impact of the volatiles of these oils on the postembryonic development, adult emergence and subsequent reproductive potential of the pest, two series of tests were conducted, each comprising five sets of 20 larvae (a set constituting a replicate). These larvae were housed in glass containers (70 mm diameter; 90 mm height) covered on the top by black muslin fastened by elastic bands and provided with an adequate quantity of the same diet mixture as that used in the culture. In one series, the larvae were maintained for the first 15 days of their lives, in a chamber permeated by the volatiles emanating from 6 ml of eucalyptus or neem oil contained in glass vials (23 mm bottom diameter and 13 mm top open end diameter; 35 mm height) placed on the floor of the chamber. In the second series, the larvae were similarly exposed to the volatiles but commencing from the sixteenth day after hatching. The number of adult males and females that finally emerged and their total postembryonic developmental period were recorded in all the sets of both series of experiments.

Reproductive performance of these moths was then evaluated by holding a freshly emerged male and a female (<24 hr old and both belonging to the same series) in single pairs for mating and egg laying inside clean and empty black muslin-covered glass containers described above. The number of eggs deposited by the females was recorded daily for the first 4 days, the period when the females were generally prolific in their egg laying, and the hatchability of the

eggs were also noted. The data, pooled from five (four in one case only) independently run tests, were subjected to *t*-tests (Paterson, 1939; Snedecor, 1956) to ascertain statistical significance between treatments.

Adult Exposure to the Oils

To examine the effects of exposure of adults to eucalyptus oil volatiles on the postembryonic development and breeding efficiency of the progeny, five newly emerged males and females were arranged in single pairs. They were exposed inside parafilm-covered glass containers to the vapors of the oil for 5 min. Longer exposure led to their death. The oil was held in wire-mesh capped glass vials kept at the base of the containers. The vapor-exposed pairs were transferred to another set of clean, similar glass containers with their top ends closed by black muslin for copulation and subsequent oviposition. Eggs laid on the first day were removed from all the containers and arranged in rows on a glass petri dish for hatching. One hundred larvae that hatched from this pooled egg mass were divided into five lots of 20 each, and individuals of every such lot were then kept on the culture diet in glass containers. Numbers of adult males and females that emerged, the total postembryonic developmental period and reproductive potential, in terms of egg output and egg hatchability, of the mated females were recorded as described before.

All the tests, performed at 27°C ± 2°C under 85% ± 5% r.h., were accompanied by appropriately designed controls wherein the insects were not exposed to the oil vapors.

RESULTS AND DISCUSSION

Considerable lengthening of total postembryonic developmental period and substantial reduction in the numbers of adults that finally emerged were characteristically noticed in both sexes of *C. cephalonica* that passed their first 2 weeks of larval life in an environment laden with eucalyptus oil vapor (Table 1). Presumably the volatile(s) released from eucalyptus oil detrimentally affected the basic insect development regulating neuroendocrinal mechanisms (Wigglesworth, 1972; Chapman, 1982) in these treated individuals. Deferment of the oil vapor treatment to the growing caterpillars to a later period commencing from the 16th day of their life for 15 days failed to produce any adult (data relating to this treatment not shown in Table 1). Possibly, these mature larvae, whose orientation behavior changed from one of remaining deep within the diet to that of emerging to the surface of the food in search of favorable sites for pupation, became easily subjected to the adverse effect of the oil vapor leading to their death. The same did not occur when this pest, during larval rearing, likewise interacted with neem oil vapor or in the progeny of parents exposed to eucalyptus

TABLE 1. POSTEMBRYONIC DEVELOPMENT PERIOD AND EMERGENCE OF ADULT MALES AND FEMALES OF *Corcyra cephalonica* EXPOSED OR UNEXPOSED TO EUCALYPTUS/NEEM OIL VAPORS (DATA POOLED FROM FIVE REPLICATES OF 20 LARVAE EACH PER TEST)[a]

Treatment	*N*	Adult score: mean nos. emerging (±SE)		Mean no. of days to adult stage ± SE	
		M	F	M	F
I Eucalyptus oil:

[e] Larvae of the progeny.

oil vapor, as adults, for only 5 min; however, curiously enough, in the latter situation, a statistically significant reduction ($P < 0.05$) was noticed in the postembryonic developmental period of females.

There was a marked decline both in egg output and egg hatchability in reproductive pairs whose larval development for the first 15 days took place in an eucalyptus oil environment ($P < 0.01$; Table 2). A similar reduction in the moth's reproductive potential was again noticed in the breeding pairs of progeny whose parents were exposed during their adult life to this oil vapor for only 5 min. These observations reflect a "carry over" of the deleterious effect of the volatile(s) from this oil on the reproductive fitness of the insect. Data comparisons of larval treatments involving neem oil did not manifest this outcome although Pathak and Krishna (1985) reported a significant fall in egg yield and egg hatchability in this species following a 30-min exposure of adults to vapors arising from 160 μl of this oil.

ANNOUNCEMENT

International Society of Chemical Ecology

The 9th annual meeting of the International Society of Chemical Ecology will take place in Kyoto, Japan, July 6–9, 1992. Sessions will consist of 30 min presentations by invited speakers and 12 min presentations by contributing speakers, with five min and three min discussion periods, respectively. Thus far, organizers have planned sessions on the Chemical Ecology of Medicinal Plants (K. Fuji), Allelopathy (C.H. Chou), Aqueous Biosphere (D. Daloze), Natural Products (K. Mori, K. Nakanishi, A.B. Smith III), and Fruit Flies (J.L. Nation). Poster presentations on session themes, as well as general chemical ecology, are invited.

An abstract is required for oral and poster presentations, and should include author's name, title, organization, and address, paper title, and subject matter. A form for this purpose should be requested. Program details, abstract forms, registration forms, and accommodation applications are available from
