is little or no contact between adult does and adult bucks except during the autumn breeding season (Marchinton and Hirth, 1984). Various aspects of marking behavior performed by males during the breeding season have been extensively examined (Moore and Marchinton, 1974; Miller et al., 1987a,b; Marchinton et al., 1990). White-tailed deer behavior suggests that urine could be a source of chemical signals indicating estrous status of the female (Moore and Marchinton, 1974). Female urine elicits a flehmen response from males. Additionally, Whitney et al. (1992) have presented evidence that vaginal mucus or other secretions from the reproductive tract are the source of a signal(s) indicating female reproductive status. They argue that urinalysis via vomeronasal stimulation likely affects the animal's reproductive physiology, whereas volatiles from the reproductive tract that are detected by the main olfactory system elicit approach and courtship behaviors.

Clearly, chemosignals from urine and vaginal secretion play important roles in the reproductive physiology of white-tailed deer. In this study we have investigated the urinary and vaginal mucus volatile compounds excreted by female white-tailed deer during the breeding season. Qualitative changes and concentrations of volatiles at estrus and mid-cycle as well as concentration changes in relation to the presence of ovarian hormones were investigated.

METHODS AND MATERIALS

Subject and Sample Collection. Samples of urine and vaginal mucus were collected from four adult (≥ 2 years old) female deer, housed in individual stalls (3×6 m) at the University of Georgia's Whitehall Deer Research Facility. Females were fed ad libitum a commercial feed (Omolene 300, Purina Mills, Inc.). Bermuda grass (*Cynodon dactylon*) or alfalfa (*Medicago sativa*) hay was also provided ad libitum.

Voided urine and vaginal secretions from estrous and mid-cycle females and urine from ovariectomized females were collected during the breeding season (i.e., October–January). Each female was allowed to associate daily with a mature, sexually experienced, epididymectomized male. Behavioral patterns of white-tailed deer indicative of estrus have been described by Warren et al. (1978) and Brown and Hirth (1979). Estrus was identified as the day(s) on which the male displayed courtship behaviors toward the female and the female was receptive to mounting by the male. Mid-cycle was identified as the midpoint between consecutive periods of estrus during the 26-day estrous cycle (Knox et al., 1988).

Mucus was collected by flushing the vagina/cervical area with 10 ml of sterile physiological saline. Voided urine was collected from four intact and three ovariectomized females. Studied animals were sedated using a mixture of

xylazine hydrochlorine and ketamine hydrochloride as described by Mech et al. (1985) and placed in a modified transport crate fitted with a screened bottom. Anesthesia was reversed with yohimbine hydrochloride and the females were held in the crate until urination. The mean time until urination was 3 hr 10 min. Immediately after urine and mucus collection, three 1.5-ml samples of each type were frozen and stored at −20°C until analyzed.

Procedure. Urinary and vaginal mucus volatiles were concentrated on porous polymer, Tenax GC, using the modified headspace technique developed by Novotny et al. (1974) and McConnell et al. (1979). To give each sample (1.5 ml) the same high ionic strength, 0.4 g of $(NH_4)_2SO_4$ was added. Next, the sample was absorbed on 0.6 g of glass wool. Purified helium gas at a flow of 30 ml/min was then passed through the glass wool for 30 min to purge the volatiles from it. The headspace sampling was performed at 50°C. After passing through a cooled condenser, installed to reduce water mist originating from the sample, the volatiles were trapped on a 4-mg Tenax GC precolumn packed into the injection port glass liner of a gas chromatograph.

After the headspace sampling procedure, the precolumn with trapped volatiles was inserted into the modified injection port of a Hewlett-Packard model 5980A gas chromatograph–mass spectrometer (GC-MS). The volatiles were desorbed at 200°C and retrapped cryogenically for 15 min to compress the desorbed sample at the column inlet. The column used was a glass capillary column (30 m × 0.25 mm ID) that had been statically coated with UCON-5-HB-200 (Supelco Inc., Bellefonte, Pennsylvania). Column temperature was programmed from 30 to 160°C at a rate of 2°C/min. Volatile constituents were identified through their mass spectra, using electron impact ionization at 70 eV. Peak areas were evaluated using a GC-MS data station. The identification of volatile components was verified by retention time measurements of authentic compounds.

Statistical Analysis. Statistical comparison of the concentration of excreted volatiles (expressed by integrated peak areas) was performed by using one-way analysis of variance (F at $P < 0.05$) with the Tukey test for equal sample size ($P < 0.02$). Because of the heteroscedastic data, the inequality of variance was "corrected" by logarithmic transformation of the original X values (integrated peak areas in arbitrary units) to $X' = \log X + 1$ values (Zar, 1984).

RESULTS AND DISCUSSION

Headspace analysis of the volatile compounds from the test materials revealed a large number of common compounds. Some varied considerably in concentration among samples. Others, present at constant levels, commonly

accounted for more than half of the total number of compounds observed in the samples. Only a few tended to peak consistently in relation to reproductive state and hormonal change.

Volatiles identified in both vaginal mucus and urine of female deer include alcohols, aldehydes, furans, ketones, alkanes, and alkenes. Pyrans, amines, esters, and phenols were present in the urine but not in the vaginal mucus. Conversely, aromatic hydrocarbons were characteristic of the vaginal mucus only. Several classes of volatiles that we observed in white-tailed deer have been reported from the urine of other mammals including mice, voles, and humans (Albone, 1984; Novotny et al., 1990).

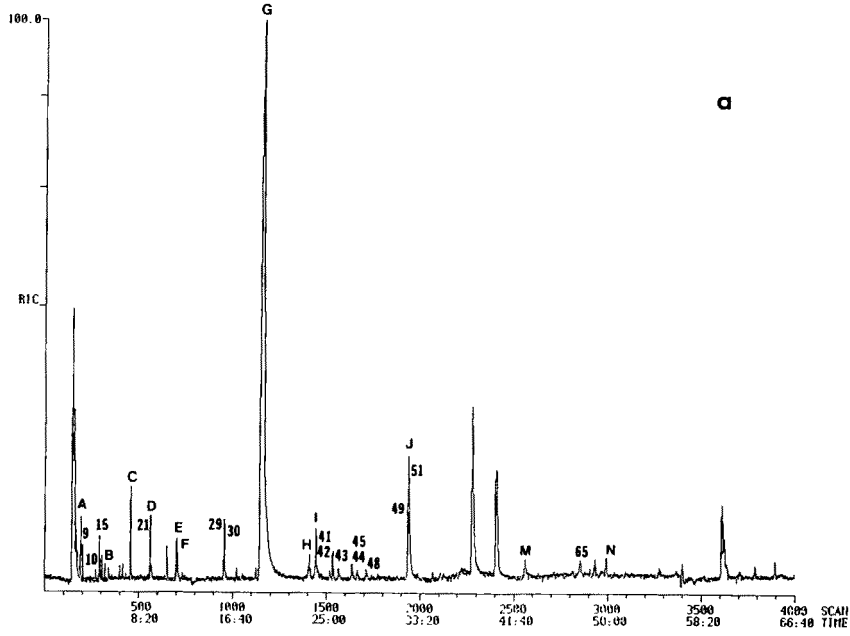

FIG. 1. GC-MS profiles of volatile compounds from (a) mucus and (b) voided urine of white-tailed deer females. (a) Not all peaks representing the identified compounds were numbered. The numbers in Tables 1 and 2 correspond to the numbers in the chromatogram. The peaks marked by letters represent compounds characteristic for estrous mucus only. The numbered peaks represent compounds common for mucus and urine. (b) Not all peaks representing the identified compounds were numbered. The numbers in Tables 3 and 4 correspond to the numbers in the chromatogram. All numbered peaks in the chromatogram represent ovary-dependent compounds. The numbered peaks marked additionally with filled dots represent compounds characteristic for estrous urine only.

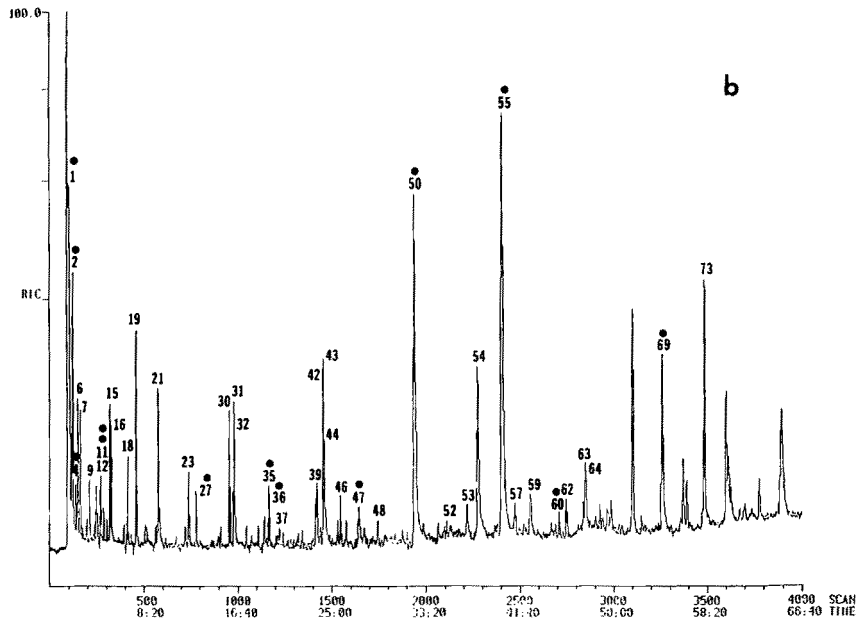

FIG. 1. Continued

The GC-MS recording shown in Figure 1a is typical of the volatile profiles obtained from the vaginal mucus of estrous females. Forty-four volatiles (Tables 1 and 2 and Table 5 below) occurred in vaginal mucus in measurable quantities; the majority of them were tentatively identified. Fourteen of these compounds, however, were found to be characteristic of the vaginal mucus only (Table 1). The composition of these characteristic compound mixtures depended upon the phase of the females' reproductive cycle. Estrous females discharged a mucus that was richer in the characteristic volatiles than that of the females in mid-cycle (Table 1). Nine of the 14 characteristic compounds (64%) were produced only by estrous females, whereas only two (14%) were produced by the females exclusively during mid-cycle. Certain aromatic hydrocarbons, whose presence may or may not be significant, along with two alcohols (2-propanol and 2-propyl-1-decanol) and two ketones (2-hexanone and methylacetophenone) occurred only in estrous vaginal samples (Table 1). Since estrous vaginal secretion, but not mid-cycle secretion, has been shown to elicit courtship behavior in male white-tailed deer (Whitney et al., 1992; Murphy et al., 1994), these compounds may represent behaviorally important chemosignals. Behavioral

experiments on these compounds should be conducted to evaluate their role, if any, in white-tailed deer communication.

Three of the 14 characteristic compounds occurred at similar levels in both estrous and mid-cycle mucus samples. These included two alcohols (2-butanol, cyclohexanol) and a ketone (cyclohexanone). Interestingly, cyclohexanone was present in both estrous and mid-cycle samples and at far higher concentration (40–92%, $P < 0.02$), than other compounds (Table 1).

The remaining 30 vaginal mucus volatiles also were found in urine samples (Table 2 and Table 5 below). Concentration of these compounds did not vary significantly between estrus and mid-cycle urines ($P > 0.05$; Table 2 shows the mean urinary value for each compound). In the mucus, 15 of these compounds varied depending on whether the mucus was discharged by estrous or mid-cycle females and tended to be lower than in the urine (Table 2). These volatiles included alcohol, aldehyde, alkane, and ketone structural classes, and all were ovarian hormone-dependent. Concentrations of 11 compounds in the estrous mucus were lower ($P < 0.02$) when compared to mid-cycle mucus, but concentration of only four mid-cycle mucus compounds was lower ($P < 0.02$) when compared to estrous mucus (Table 2). Only 1-octen-3-ol (peak 51) from

48[c]	2-nonanone	1.65 ± 0.01a	0.45 ± 0.00c	0.72 ± 0.01b

[a] The value of integrated peak areas X (in arbitrary units) was transformed to $X' = \log(X + 1)$. Means in the same row not followed by the same letter are significantly different [$F(2,6)$; $P < 0.02$)].

[b] Concentration of the urinary compounds listed in this column did not vary significantly between estrus and mid-cycle samples ($P > 0.05$); thus for comparison of urine with mucus samples, the mean urinary value was used for each compound.

[c] These volatiles were not present in the urine of ovariectomized females even in trace quantities.

estrous mucus and 3-methyl-1,3-butanediol (peak 44) from mid-cycle mucus were significantly greater (45% and 43%, respectively; $P < 0.02$) in concentration than urinary level (Table 2).

In addition to the 15 volatiles previously described, common for mucus and urine (Table 2), we found 33 more compounds that were consistently present only in urine (Tables 3 and 4). The GC-MS recording shown in Figure 1b is typical of the volatile profiles obtained from estrous female urine. Of the total 63 investigated urinary compounds (Tables 2–5), 46 occurred in both reproductive stages; 13 were present in estrous urine only and four in mid-cycle samples

[a] Urinary volatiles listed in this table were not present in the urine of ovariectomized females even in trace quantities.
[b] The value of integrated peak areas X (in arbitrary units) was transformed to $X' = \log (X + 1)$.
[c] Compound not present in the sample even in trace quantities.

only (Table 3). Volatiles occurring exclusively in estrus urine represented a variety of chemical groups including alcohols, aldehydes, alkanes, alkenes, furans, and ketones. Those characteristic of mid-cycle urine belonged to the furan, ketone, and pyran groups (Table 3).

Many of the urinary compounds appeared to be hormone-dependent. Thirty-eight of 63 compounds (60%) were absent, not found even in trace quantities, from urine of ovariectomized females (Tables 2–4). The only compounds with significantly greater concentration in ovariectomized females were an alcohol [1-octen-3-ol (peak 51)] and an alkane [1,2,4,-trimethylcyclopentane (peak 10)]. Those compounds are common for both mucus and urine samples (Table 2).

Among the volatiles identified in mucus (total 44) and urine (total 63), several compounds were present in all investigated samples. Concentrations of these volatiles were similar in all samples (i.e., 1.24–2.73 log of integrated peak areas in arbitrary units), were relatively high, and were not dependent on ovarian hormones or animals' reproductive stage (Table 5).

[a]They demonstrated relatively constant concentration in samples of all investigated females.

Limited research has been conducted on the urinary volatiles of cervids. Bakke and Figenschou (1990) reported 70 volatile substances in adult red deer (*Cervus elaphus elaphus*) from gas chromatography of a methylated acidic fraction of urine, a technique different from the methods used in the present study. Their substances were mainly carboxylic acids and their derivatives, in addition to some aromatic compounds. They did not observe any systematic variation in volatile excretion during different seasons. In black-tailed deer (*O. hemionus hemionus*), Muller-Schwarze et al. (1978) presented evidence that a urinary γ-lactone, (Z)-6-dodecen-4-olide, is involved in social communication. Thus, the results presented here provide additional chemical background information for the future testing of animal behavior.

CONCLUSIONS

Certain compounds present in vaginal mucus are not paralleled in the urine of white-tailed deer. In addition, several compounds found in estrous mucus were not found in mid-cycle samples. Other volatiles were found in both urine and vaginal mucus, but their concentration tended to be lower in mucus samples. These overlap compounds found in both mucus and urine (for both phases of the female reproductive cycle) suggest that some compounds in mucus sample may have originated from urine contamination.

Our study documents for the first time that: (1) the composition of volatiles in white-tailed female deer changes according to the stage of the reproductive cycle; (2) estrous mucus and urine have more characteristic compounds (9 and 13, respectively) then mid-cycle mucus and urine samples (2 and 4, respectively), and these compounds may be used to identify a particular stage of the deer's reproductive cycle; and (3) numerous urinary compounds exhibit strong dependence on ovarian hormones.

Further biological and behavior research is needed to determine which chemical compounds identified in this study (if any) are important in communicating sexual/reproductive status.

Acknowledgments—B.P. Murphy and numerous students of the Warnell School of Forest Resources assisted in sample collection. This project was supported by a donation from Wellinton Outdoor, Madison, Georgia, and McIntire-Stennis Project GEO-00490MS-A.

Editors' Note

The papers in this issue were presented at the 11th Annual Meeting of the International Society of Chemical Ecology, Inc. (ISCE), held in Syracuse, New York, June 4–8, 1994. The meeting was organized and hosted by R.M. Silverstein, John Simeone, and Francis X. Webster, and it marked the 20th anniversary of the founding, and editorship, of the *Journal of Chemical Ecology* by Milt Silverstein and John Simeone.

We thank Fran Webster for serving as the Guest Editor for these papers. Fran took charge of soliciting typed copies, having each paper peer reviewed, requesting revisions, and attending to most of the little details of preparing manuscripts for the printer and publisher. We are sure that Fran would want us to recognize and thank Eleanor Zaccaria, who helped with the editorial duties of this issue, and served as secretary for the journal for Milt and John for 20 years. In addition we thank our secretary here in Gainesville, Lori Clark, who also contributed to this issue.

Milt and John were very forward looking when they founded the *Journal of Chemical Ecology* in 1974. They subsequently were major forces in the development of the field of chemical ecology, especially in maintaining high standards of scholarship and excellence in the papers published for 20 years in the *Journal of Chemical Ecology*. We are confident the 12 papers in this issue are in that tradition of excellence, and are a worthy tribute to honor Robert Milton Silverstein and John B. Simeone, Founding Editors of the *Journal of Chemical Ecology*.

ONTOGENIC DEVELOPMENT OF CHEMICAL DEFENSE BY SEEDLING RESIN BIRCH: ENERGY COST OF DEFENSE PRODUCTION

JOHN P. BRYANT[1,*] and RIITTA JULKUNEN-TIITTO[2]

[1]*Institute of Arctic Biology, University of Alaska, Fairbanks Fairbanks, Alaska 99775-7000*
[2]*Department of Biology, University of Joensuu Joensuu SF-80101 Finland*

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Whether production of chemical defenses by plants is or is not an energetically costly process is an important, but unresolved, question in chemical ecology. We suggest studies of the ontogenetic development of plant defense systems can help resolve the question. As an example of this approach to the cost question, we explore the problems associated with production of immobile chemical defenses that defend juvenile resin birches against browsing by mammals. From this exploration we draw two conclusions: (1) Shortly after germination, production of chemical defenses by small-seeded species, such as birch, is energetically costly. (2) Opposing selection for defense versus competitive ability in the seedling stage of birch has resulted in a trade-off in allocation of carbon to production of immobile chemical defense versus allocation of carbon to production of storage reserves. We suggest this trade-off results in a large indirect cost of defense because carbon used for production of immobile chemical defenses is unavailable for support of growth in the future, but stored carbon can be used to support future growth.

Key Words—Plant chemical defense, storage, seedling, cost, ontogeny.

INTRODUCTION

Research on plant chemical defense has increased dramatically in the past two decades. From the early 1970s to the mid-1980s the number of primary publications dealing with chemical defense against insect herbivory increased from about 20 per year to about 200 per year (Scriber and Ayers, 1988), and recent review of this topic (Feeny, 1992; Roitberg and Isman, 1992; Bernays, 1994)

*To whom correspondence should be addressed.

0098-0331/95/0700-0883$07.50/0 © 1995 Plenum Publishing Corporation

indicate this rate of growth is continuing. Study of chemical defense against vertebrate herbivory in terrestrial ecosystems and chemical defense against herbivory in marine ecosystems started later, but recent reviews of these subjects indicate a similar rate of growth (Hay and Fenical, 1988; Palo and Robbins, 1991; Bryant et al., 1992; Hay and Steinberg, 1992).

This research explosion has been fueled by a succession of theoretical models (coevolution, optimal defense, resource availability, carbon/nutrient balance, growth/differentiation balance) that attempt to explain the evolution and ecology of plant antiherbivore defense systems (Ehrlich and Raven, 1964; Feeny, 1976; Rhoades and Cates, 1976; Rhoades, 1979; Bryant et al., 1983a; Coley, 1983; Coley et al., 1985; Lorio, 1986; Herms and Mattson, 1992). Although each model has increased our knowledge of plant antiherbivore defense, empirical research has now identified deficiencies in all models. Thus, plant defense theory is beginning a period of revision. The objective of this symposium was to identify research topics that are likely to provide direction to this revision.

The general area of research we have selected for discussion is the early ontogenetic development of plant defense systems. We suggest that research on this subject will further development of plant defense theory for the following reasons. The seedling stage is generally considered to be of paramount importance in understanding plant population dynamics and adaptations (Harper, 1977), and studies of plant population of dynamics have shown the direct negative effect of herbivory on survival of plant genets is generally greatest when herbivory occurs during juvenile stages of development (Watkinson, 1986). Thus, selection for chemical defense by herbivores should be comparatively strong in juvenile developmental stages (Bryant et al., 1983a; Langeheim and Stubblebein, 1983; Kearsely and Whitham, 1989). Yet, in comparison to what we know of chemical defense systems of mature plants, we know virtually nothing about the early ontogenetic development of plant defense systems (Simms, 1992).

The specific research problem we focus on is the energy cost paid by juvenile plants to produce chemical defenses. In this paper we suggest three hypotheses that could help resolve this question of cost, which is central to plant defense theory (Feeny, 1976; Rhoades and Cates, 1976; Rhoades, 1979; Bryant et al., 1983a; Coley et al., 1985; Bazzaz et al., 1987; Lorio, 1986; Herms and Mattson, 1992; Zangerl and Bazzaz, 1992):

Hypothesis I. In many species, juvenile developmental stages are more chemically defended than the mature stage.

Hypothesis II. In the specific case of species that reproduce by small seeds, the energy cost paid by young seedlings for formation of chemical defense is very high. Thus, production of immobile chemical defenses, sensu Coley et al. (1985), is minimal shortly after seed germination.

Hypothesis III. Opposing selection for chemical defense versus competitive ability (Herms and Mattson, 1992) in the seedling stage of small-seeded species

has resulted in a biochemical trade-off in allocation of carbon to formation of immobile antiherbivore defenses versus allocation of carbon to formation of storage reserves sensu Chapin et al. (1990). The outcome of this trade-off is a large indirect cost of defense (Bloom et al., 1985; Gulmon and Mooney, 1986; Herms and Mattson, 1992; Zangerl and Bazzaz, 1992) because carbon used for formation of immobile defenses cannot be used to support growth in the future, but carbon allocated to storage reserves can be used to support growth for defense in the future (Kozlowski and Keller, 1966; Kozlowski, 1971; Chapin et al., 1990).

These hypotheses are explored in the following sections.

HYPOTHESIS I

It has long been known that seedlings, saplings, and the mature developmental stages of woody plants differ predictably in one or more distinctive morphologic, anatomic, physiologic, and biochemical traits (Knight, 1795; Schaffalitzky de Muckadell, 1954, 1969; Waring, 1959; Sax, 1962; Kozlowski, 1971; Borchert, 1976). Among traits that change predictably during ontogeny as a result of meristem-based changes in gene expression (Kozlowski, 1971) are traits that have been assigned a defensive function. For example, woody species that produce thorns or spines are usually most thorny or most spinescent when juvenile (Schaffalitzky de Muckadell, 1969; Kozlowski, 1971). Similarly, the secondary chemistry of juvenile stages often differs either qualitatively or quantitatively from the secondary chemistry of the conspecific mature stage (Kozlowski, 1971).

The best documentation that chemical antiherbivore defenses of woody plants can change dramatically during ontogeny comes from studies of the interaction between woody plants and hares (*Lepus*) in subarctic forests (Bryant, 1981, 1987; Bryant et al., 1983a,b, 1985a,b, 1989, 1994; Reichardt et al., 1984, 1990; Tahvanainen et al., 1985; Clausen et al., 1986; Sinclair et al., 1988; Swihart et al., 1994). In the taiga and boreal forest of North America and Eurasia, winter-dormant twigs of juvenile trees and juvenile shrubs are less palatable to hares (*L. americanus* and *L. timidus*, respectively) than winter-dormant twigs of their conspecific mature stage. In every case that has been well-studied chemically, the low palatability of twigs of the juvenile stage has been related to increased production of specific feeding deterrent secondary metabolites (reviewed by Bryant et al., 1991, 1992). For example, Reichardt et al. (1984) found that winter-dormant internodes of juvenile Alaska paper birch (*Betula resinifera*) are defended against hare browsing by high concentrations of terpene resins such as papyriferic acid that are not even present in internodes of mature *B. resinifera*.

Other studies have provided evidence that chemical defense of the juvenile stage against browsing is widespread among both mammals and biomes. Basey et al. (1988) found juvenile quaking aspen (*Populus tremuloids*) in the Great Basin of North America is more defended against beaver by phenolics than is mature quaking aspen. Circumstantial evidence for this hypothesis comes from studies of willow (*Salix* spp.) and microtine rodents (Danell et al., 1987) and those of birch and moose (*Alces alces*) (Danell et al., 1990) in the boreal forest of Sweden, Monterey pine (*Pinus radiata*) and jackrabbits (*Lepus*) in California Mediterranean woodlands (Libby and Hood, 1976), Douglas fir (*Pseudotsuga menzesii*) and black-tailed deer (*Odocoileus hemionus columbianus*) and snowshoe hare in the coastal evergreen forest of northwestern North America (Dimock, 1974; Dimock et al., 1976), several birches and aspens and snowshoe hare in the temperate deciduous forests of eastern North America (Swihart et al., 1994), and several trees and elephant (*Loxodonta africana africana*) in the miombo woodland of Africa (Jachman, 1989).

Juvenile woody plants and mature woody plants can also differ in chemical defense against insect herbivory. Langenheim and her students have demonstrated seedlings of some Brazilian trees have better constitutive defenses (terpene resins) than the conspecific mature stage (Langenheim and Stubblebine, 1983; Macedo and Langenheim, 1989), and Wagner (1988) found the short-term inducible defense of Ponderosa pine (*Pinus ponderosa*) to be restricted to saplings. Results of Kearsely and Whitham (1989) suggest chemical defenses of *Populus angustifolia* change during ontogenetic development, but defenses of different developmental stages have different efficacies against different insects.

In comparison to woody species, virtually nothing is known about the ontogenetic development of chemical defense of herbaceous species, but what is known indicates chemical defenses of herbs also change during ontogeny. For example, in a particularly elegant study of *Plantago lanceolata*, Bowers and Stamp (1993) found young plants to be more defended by iridoid glycosides against both generalist insects and specialists insects than the mature stage, and plant age explained about twice as much of the variation in leaf iridoid glycoside concentration as did plant genotype. Gershenzon (unpublished data) has found young mint (*Mentha*) contain less monoterpene than does older mint.

These data suggest two generalizations. First, chemical defenses change during plant ontogenetic development. Second, in many cases, juvenile stages of development are more defended than the conspecific mature stage. They further suggest enhanced chemical defense of the juvenile stage may be more consistent in the case of mammalian herbivory than in the case of insect herbivory. We suggest comparative studies of effects of mammalian herbivory versus insect herbivory on plant recruitment in pristine ecosystems will be needed to determine the relative contributions of these two groups of herbivores to the evolution of chemical defenses of juvenile plants.

HYPOTHESIS II

The energy cost of producing antiherbivore defenses should be highest in periods of the life cycle when competition for carbon between chemical defense and other plant functions is intense. It is generally recognized that the onset of reproduction may be such a period (Bazzaz et al., 1987). In the case of small-seeded plants, it is likely that another such period is when energy reserves of the seed have been exhausted, and the plant first has to rely totally on photosynthesis for growth (Bryant et al., 1991, 1992). In these plants, growth of the radicle depletes energy reserves of the seed to such an extent that when the epicotyl emerges above the soil further growth is almost entirely dependent on the seedling's rate of carbon acquisition (Ingestad, 1962; Kozlowski, 1971). Thus, at this stage of seedling development, allocation of photosynthate to substances such as immobile chemical defenses that do not immediately support growth would be selectively disadvantageous, because it would greatly limit seedling establishment (Bryant et al., 1991, 1992). This is the reason we have predicted production of immobile chemical defenses by plants that grow from small seeds will be minimal when the epicotyl emerges from the soil.

We are testing this hypothesis by studying the ontogeny of chemical defense against browsing by mammals in birch. The birches we are focusing on are *B. resinifera* and *B. pendula* family E1970 × E1980 (Finnish Foundation for Tree Breeding, Helsinki). By the sapling stage, *B. resinifera* is more defended by terpene resin than is *B. pendula* (Bryant et al., 1989), and the resin concentration of juveniles of *B. pendula* family E1970 × E1980 is the lowest yet reported for a *B. pendula* family (Rousi et al., 1991, 1993).

We are studying these birches and their chemical defenses against browsing in winter for the following reasons: (1) Mammal browsing in winter is a major cause of death of recruitment of these birches (Rousi, 1990; Bryant, unpublished data), so juveniles of these birches should have evolved defenses against winter browsing. (2) Birch produces small seeds (mass about 0.6 mg), so energy limits the growth of young birch seedlings (Ingestad, 1962, 1970, 1971, 1979; Ingestad and Lund, 1979; Ingestad and McDonald, 1989) for reasons given above. (3) *B. resinifera* and *B. pendula* use triterpenes such as papyriferic acid and sesquiterpenes to deter browsing in winter (Reichardt, 1981; Reichardt et al., 1984; Bryant et al., 1989; Lapinjoki et al., 1991; Vainiotalo et al., 1991; Rousi et al., 1991, 1993; Taipale and Lapinjoki, 1992). These defensive substances are energetically expensive to produce for two reasons. First, the mass of glucose (Glc) used to produce a gram of defense is comparatively high for secondary metabolites: In the case of papyriferic acid it is 2.72 g Glc/g product, and in the case of sesquiterpenes it ranges from 3.34 to 3.54 g Glc/g product. By comparison, the glucose cost of producing tannin ranges from 1.28 g Glc/g product to 2.08 g Glc/g product (Gershenzon, 1994). Second, the resin glands

that secrete these defensive substances onto the epidermis of birch seedlings (Lapinjoki et al., 1991) are also energetically costly to produce (Gershenzon, 1994). Moreover, because these substances can occur in high concentrations in internodes of juvenile birch, their cost of production per gram tissue can be very high (Table 1). For example, Gershenzon (1994) has calculated *B. resinifera* saplings use 307 g Glc/g tissue to defend current-year-growth internodes with papyriferic acid, and papyriferic acid is only one third of the defensive resin found in current-year-growth internodes of sapling *B. resinifera* (Reichardt et al., 1984). (4) These substances appear to have no other function than defense against browsing by mammals in winter (Bryant et al., 1992), so the energy cost of producing them is not offset by use for other functions (Seigler and Price, 1976; Simms, 1992), (5) Finally, these defenses are immobile, sensu Coley et al. (1985), because they are deposited by resin glands on the surface of the epidermis (Reichardt et al., 1984; Lapinjoki et al., 1991).

In our experiments, seedlings were grown in pots in a mix of vermiculite and perlite (1 : 2 v/v) in a glasshouse. Light and temperature were characteristic of the environments in which these birches grow, which are essentially the same and seedlings were fed a nutrient solution developed by Ingestad specifically for growing birch seedlings in pots (Ingestad, 1962). This solution provided nitrogen at an optimum level (140 ppm N as NH_4NO_3). Other macronutrients and micronutrients were adjusted to N as recommended by Ingestad. Pots were sufficiently large to prevent root binding, and pots were drenched daily with nutrient solution to prevent desiccation and salt accumulation.

TABLE 1. HIGHEST RAW MATERIALS (GLUCOSE) COSTS ESTIMATED BY GERSHENZON (1994) FOR PRODUCTION OF CLASSES OF DEFENSE COMPOUNDS[a]

Chemical class	Plant species	Defense compound	Cost per gram of plant tissue (mg glucose/g)
Terpenoids	*Betula resinifera*	Papyriferic acid	307
Phenolics	*Isocoma acradenia*	Apigenin	103
Alkaloids	*Camellia sinensis*	Caffine	72
Cyanogenic glycosides	*Amelanchier alnifolia*	Prunasin	7.8
Glucosinolates	*Cleome serrula*	Methyl glucosinolate	20
Nonprotein amino acids	*Leucaena leucocephala*	Mimosine	42
Protinase inhibitors	*Lycopersicon esculantum*	Inhibitor 1 from tomato	0.27

[a]Estimates take into account all the starting materials and cofactors needed for biosynthesis.

For seven weeks after the epicotyl emerged above the soil, we followed production of resin glands in the upper 2 cm of internodes for 50 seedlings of each birch. These measurements were made for the first 2 cm below the apical meristem, because in these birches internode resin glands differentiate from the primary epidermis just below the apical meristem (Lapinjoki et al., 1991). To avoid destructive sampling before final harvest, we made rank estimates of the density of resin glands in weeks 1, 2, 3, 5, and 7. A rank of zero indicated no observable resin glands, and each higher rank indicated an increase of about 25–30 glands per square centimeter of internode epidermis. In week 7 we measured the seedlings' net photosynthetic rates, and then harvested them. After harvest, for each seedling we measured its height, its total leaf area, and the dry masses of its leaves, shoot, and roots. We also used the photographic procedure of Rousi et al. (1991, 1993) to count the number of resin glands in the top 2 cm of internode epidermis.

The epicotyls of both birches emerged above the soil at the same time, about one week after planting. At this time, neither birch produced internode resin glands (Figure 1A). *B. resinifera* began producing resin glands in week 2, and *B. pendula* began producing resin glands three weeks later. For both birches, resin gland production increased as the birches increased in size and their leaf area increased. This result was expected, because as the leaf area of a seedling birch increases, so does its ability to acquire carbon (Ingestad, 1962; Ingestad and Lund, 1979; Ingestad and McDonald, 1989). Thus, production of resin glands by both birches was minimal shortly after germination (Figure 1A). Furthermore, *B. resinifera* seedlings always produced more resin glands than did *B. pendula* seedlings (Figure 1A and B; $P < 0.0001$).

Similar results have been obtained for other birches and other small-seeded species. In a set of comparisons of eight birch species based on 12 secondary metabolites (96 total comparisons), R. Julkunen-Tiitto (unpublished data) found the concentrations of the 12 metabolites in CAG internodes of seedlings were less than those found in CAG internodes of saplings in 94 of the 96 comparisons. Reichardt and Chapin (unpublished data) found production of condensed tannin by CAG internodes of *Salix alaxensis* seedlings, production of pinosylvin and pinosylvin methyl ether by CAG internodes of *Alnus crispa* seedlings, and production of monoterpenes by CAG internodes of *Picea glauca* seedlings was low in comparison to production of the same substances by CAG internodes of conspecific saplings, respectively. In the case of herbaceous species, D. Bowers (personal communication) has found production of iridoid glycosides by *Plantago lanceolata* is minimal shortly after seed germination, and J. Gershenzon (personal communication) has obtained the same result for production of monoterpenes by mint (*Mentha*).

Our interpretation of these results is that the direct energetic cost of producing defensive resins is high enough that seedlings of small-seeded plants

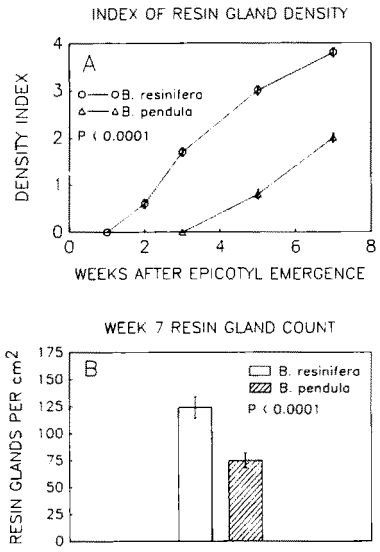

FIG. 1. Production of resin glands by seedlings of two birches, *B. resinifera* and *B. pendula* family E1970 × E1980. Mean ± 1 SE presented. $N = 50$ seedlings for each birch.

such as birch are unable to produce much of these substances. This conclusion contrasts with the suggestion of Rousi et al. (1991, 1993) that in the case of seedling resin birch, the direct energetic cost of producing terpene resins is negligible. Since this conclusion, and recent similar conclusions by others (e.g., Simms and Rausher, 1987, 1989; Simms, 1992; Karban, 1993), challenge the widely accepted hypothesis that production of chemical defense has an energetic cost, it is useful to examine the basis for the conclusion of Rousi et al. (1991, 1993).

In their experiments, Rousi et al. (1991, 1993) correlated the density of resin glands on internodes of 1-year-old birch seedlings with two measures of seedling growth, height (Rousi et al., 1991) and biomass accretion (Rousi et al., 1993). In both studies they are unable to demonstrate a negative correlation between defense (density of resin glands on internodes) and seedling growth. Similarly, in our experiments with birch seedlings, we also failed to find a negative correlation between resin gland density (Figure 1) and these two measures of growth (Table 2). Such failures to find negative correlations between simple measures of plant growth such as plant size or biomass accretion have often been interpreted to mean that production of chemical defense has no energy cost (Simms, 1992). Thus, it is not surprising that Rousi et al. (1991, 1993) reached their conclusion.

TABLE 2. SEEDLING HEIGHT, TOTAL LEAF AREA, DRY BIOMASS, AND NET PHOTOSYNTHETIC RATE[a]

Birch	Height (cm)	Leaf area (cm^2)	Biomass				Photosynthesis ($\mu mol/m^2$ sec)
			Leaf (g)	Shoot (g)	Root (g)	Total (g)	
B. resinifera	26 ± 0.9	433 ± 23	1.3 ± 0.1	0.4 ± 0.1	1.1 ± 0.1	2.8 ± 0.1	18.8 ± 0.5
B. pendula	27 ± 0.1	414 ± 23	1.4 ± 0.1	0.5 ± 0.1	1.1 ± 0.1	2.9 ± 0.1	18.6 ± 0.5

[a]Mean ± 1 SE presented.

We suggest conclusions drawn from this approach to testing the "energy cost of defense hypothesis" should be viewed with caution for three reasons. These simple estimates of growth do not take into account: (1) differences in the ability to acquire carbon, (2) differences in maintenance respiration, or (3) biochemical trade-offs in partitioning of carbon between chemical defense and competing plant functions. Yet these differences are the physiological and biochemical basis for the energetic cost of producing chemical defense (Gulmon and Mooney, 1986; Chapin et al., 1990; Bryant et al., 1991, 1992; Herms and Mattson, 1992; Zangerl and Bazzaz, 1992).

Our experiment with *B. resinifera* and *B. pendula* indicates a difference in the ability to acquire carbon is unlikely to explain why birch seedlings that differ in defense can accrete biomass at the same rate. We found that seedlings of *B. resinifera* and seedlings of *B. pendula* that differed in production of resin glands (Figure 1A and B; $P < 0.001$) and that had the same biomass after seven weeks of growth (Table 2), also had the same ability to acquire carbon (Table 2). We further suggest a difference in maintenance respiration is unlikely to explain why birch seedlings that differ in defense can accrete biomass at the same rate, because maintenance respiration has a minimal effect on patterns of carbon allocation by birch seedlings (Ingestad and McDonald, 1989; Ingestad and Agren, 1991).

HYPOTHESIS III

These conclusions suggest that if birch seedlings pay an energy cost to defend themselves against browsing in winter, this cost is an indirect cost resulting from trade-off in allocation of carbon between defense and storage. Two observations from common garden experiments support this hypothesis: (1) In contrast to 1-year-old *B. pendula* seedlings, when Rousi et al. (1991) examined

8-year-old *B. pendula* saplings they found a negative correlation between defense (resin gland density) and growth (sapling height). This result is expected if there is a trade-off between defense and storage in juvenile stages of *B. pendula*, and juvenile *B. pendula* is polymorphic for this tradeoff. (2) After two to three years of growth in common gardens in Finland (M. Rousi, personal communication) and Michigan (M. Herms, personal communication) the comparatively heavily defended saplings of *B. resinifera* are growing at less than half the rate of saplings of the less-defended *B. pendula*.

RECOMMENDATIONS FOR FUTURE RESEARCH

Two further experiments are needed to verify that seedlings of small-seeded plants subject to differences in the intensity of selection for defense and the intensity of selection for competitive ability are polymorphic for partitioning of carbon between immobile chemical defense and storage reserves. In the one experiment, mass balance measurements should be used to document biochemical carbon partitioning by seedlings of congeners or conspecifics grown in a common environment. In this experiment, masses of carbon allocated to production of immobile defenses and to production of storage compounds (e.g., starch, storage protein, fatty acids) as well as masses of carbon allocated to growth and maintenance (e.g., sugars, amino acids, enzymes), and to structure (e.g., cellulose, lignin) should be determined using the biochemical approach suggested by Chapin et al. (1990). Assuming no differences in carbon acquisition, maintenance respiration, and allocation of carbon to other functions, evidence for a trade-off between defense and storage would be a negative correlation between the amount of glucose used to produce immobile chemical defense and the amount of glucose used to produce storage substances. Furthermore, this trade-off should become more noticeable in later stages of seedling ontogeny, because according to our second hypothesis, shortly after germination allocation of carbon to any function that competes with immediate growth should be minimal. Thus, for later stages of seedling ontogeny we expect "defense-selected" seedlings will have comparatively small storage reserves, and "competition-selected" seedlings will have comparatively poor chemical defenses.

In the other experiment, $^{14}CO_2$ pulse labeling should be used to measure the flow of carbon competing plant functions within a few hours of acquisition. In this experiment, evidence for a "defense-storage" polymorphism would be provided by the following two observations: (1) After production of defenses and storage reserves begins, the short-term flow of carbon into immobile chemical defense will be greatest for "defense-selected seedlings." (2) Conversely, the short-term flow of carbon into storage reserves will be greatest for "competition-selected" seedlings.

CONCLUSIONS

Competition and herbivory are two of the greatest challenges faced by juvenile plants (Harper, 1977; Tilman, 1982; Watkinson, 1986; Huntly, 1991). Increased ability to deter herbivory is often achieved by increased allocation of resources to chemical defense, and increased competitive ability is generally associated with rapid growth. Thus, in the juvenile stage, plants that have evolved in environments with varying levels of herbivory and competition should be polymorphic for partitioning of carbon between defense and growth (Herms and Mattson, 1992). In this paper we have suggested that studies of the early ontogenetic development of defense systems by plants are needed to test this hypothesis. We have further suggested the focus of this research should be a search for a trade-off in allocation of carbon to immobile defense versus formation of storage reserves in the seedling stage of species that grow from small seeds. This research will help resolve a central question of current plant defense theory: when is production of chemical defense energetically costly?

PLASTICITY IN ALLOCATION OF NICOTINE TO REPRODUCTIVE PARTS IN *Nicotiana attenuata*

IAN T. BALDWIN* and MICHAEL J. KARB

Department of Biological Sciences
SUNY, University at Buffalo
Buffalo, New York 14260

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Although little is known about the patterns of chemical defense allocation in reproductive tissues, optimal defense theory predicts a high constitutive allocation due to the tissues' high fitness value. To examine this prediction, we quantified the short- and long-term changes in the nicotine pools of reproductive tissues in response to both floral and leaf damage. Recently opened flowers (stage 5 capsules) do not alter their nicotine pools within a day in response to herbivory by *Manduca sexta* larvae or mechanical damage to the corolla. Similarly, leaf damage during both vegetative and reproductive growth does not influence the nicotine pools of the first three stage-5 capsules produced. However, the nicotine pools of capsules produced later in reproductive growth were significantly larger (1.2- to 1.9-fold) on plants with leaf damage. These differences in floral nicotine pools were a result of both increases in nicotine pools of capsules on damaged plants and decreases in the nicotine pools of capsules on undamaged plants during reproductive growth. Leaf damage did not affect the rate of capsule maturation or the mass of stage-5 capsules at any time during reproductive growth. An allometric analysis of nicotine pools and biomass of reproductive parts in all stages of development from damaged and undamaged plants demonstrates that damaged plants allocated a significantly larger quantity of nicotine to reproductive parts in all stages of development than did undamaged plants. Given that nicotine is thought to be synthesized in the roots and transported to leaves and reproductive parts, nicotine could be allocated to reproductive parts in proportion to the number of developing capsules on a plant. We excised the first 27 stage-5 capsules on plants with and without leaf damage, with the expectation that plants with fewer capsules would allocate a larger amount of nicotine to the remaining capsules. In contrast to the prediction of this passive allocation model, floral excision did not affect nicotine pools on plants with or without leaf damage. These results demonstrate that the allocation of nicotine to reproductive parts is more strongly influenced by damage to vegetative rather than reproductive tissues. Reproductive parts are constitutively defended

over the short term, but the set points for defense allocation are apparently increased by damage to vegetative tissues during reproductive growth. The decrease in allocation of nicotine to reproductive parts in undamaged plants during reproductive growth suggests an optimization of resource allocation as plants realize their potential fitness.

Key Words—Nicotine, defensive allometry, *Nicotiana attenuata*, flowers, reproductive parts, optimal defense theory.

INTRODUCTION

Leaves are functionally plastic in the face of herbivory: after attack by herbivores, they change their allocation of resources to both their primary function, carbon gain, and to chemicals used in defense (Welter, 1989; Baldwin, 1993). Few studies have examined the coordination of herbivory-induced changes in defense allocation and photosynthetic capacity (Baldwin and Ohnmeiss, 1994; Zangerl, 1986, Zangerl and Bazzaz, 1992), but the pattern that has emerged is consistent with the predictions of optimal defense (OD) theory (Rhoades, 1979, 1983; McKey, 1974, 1979). OD theory holds that plant tissues contributing more to plant fitness and those more likely to encounter herbivore attack should be allocated higher levels of resources for defense than other plant tissues. For example, the increase in photosynthetic capacity induced by damage and the induced increase in nicotine concentrations are highly coordinated in the leaves of *Nicotiana sylvestris*, and the coordination changes with nitrogen supply rates (Baldwin and Ohnmeiss, 1994).

In contrast to leaves, reproductive tissues are decidedly more determinate in growth form, and for these tissues, OD theory predicts a high constitutive allocation of defense metabolites, given the importance of reproductive parts to the realization of a plant's fitness. OD theory also predicts that the chemical defenses present in immature fleshy fruits should be neutralized in order to increase the attractiveness of mature fruit to dispersers. The latter prediction has received substantially more attention than the former; the changes in palatability that accompany ripening are legend and well described. For example, as a tomato ripens, glycoalkaloids are degraded (Heftmann and Schwimmer, 1972) and the production of proteinase inhibitors (Pearce et al., 1988) ceases, resulting in fruits that are less well defended than their immature counterparts. Much less is known about the allocation of defenses to the reproductive parts of plants that do not produce fleshy fruits, and wild parsnip (*Pastinaca sativa*) is one of the better studied plants in this regard. The concentrations of furanocoumarins in fruits are not affected by floral damage in either damaged flowers or in flowers produced after damage (Nitao, 1988). This lack of variation in floral furanocoumarin concentrations contrasts with the dramatic increases in leaf furanocoumarin concentrations that are induced locally by damage (Zangerl, 1990).

Hence, despite wild parsnip's ability to compensate for floral damage by producing more secondary umbels (Hendrix and Trapp, 1981), its allocation of defense appears to be unchanged in response to damage. Here we examine whether the allocation of nicotine to reproductive parts is similarly unaffected by damage in a species, *Nicotiana attenuata*, in which leaf damage is known to increase the concentrations of nicotine both locally in damaged leaves and systemically throughout the plant (Baldwin and Ohnmeiss, 1993).

However, first we need to consider how best to quantify changes in defense allocation in growing tissues. These issues of quantification are particularly germane to the analysis of the predictions of OD theory, which weighs the costs of producing secondary metabolites against the benefits of resistance resulting from the use of the secondary metabolite. For growing plants, costs can be envisioned as the diversion of resources from growth because reproductive output is frequently size-dependent (Samson and Werk, 1986). Hence, rigorous tests of the predictions of OD theory require secondary metabolite production to be quantified in the context of growth.

Changes in allocation of secondary metabolites in growing tissues can be described by an allometric analysis: the metabolite pool in the plant or plant part is regressed against the metabolite-free biomass of the plant or plant part from a series of harvests taken at many stages during development. If the metabolite pool reflects metabolite production (e.g., there is little or no metabolite turnover), then, borrowing the terminology from the literature on heterochronic growth (McNamara, 1986), metabolite production can be envisioned as having onset and offset times. The slope of this relationship describes how a plant partitions resources to defense during growth. Changes in allocation to defense and growth could therefore be quantified as changes in slopes and onset and offset times in the allometric relationship, and allometric relationships found in undamaged plants can serve as a null model against which damage-induced plasticity can be compared. Ohnmeiss and Baldwin (1994) used an allometric analysis to describe the changes in nicotine pools of damaged and undamaged *N. sylvestris* plants during vegetative growth. Although damage did not significantly affect plant growth, it did increase the accumulation of nicotine for approximately 10 days after damage; consequently, the slope of allometric relationship increased. The slopes of plants harvested more than 10 days after damage were the same as those of undamaged plants. The larger intercept of this allometric relationship reflected the earlier period of increased production (Figure 1). We can conclude that leaf damage causes vegetatively growing plants to move from one allometric relationship to another.

In this study we examined the plasticity in nicotine allocation to reproductive parts in *N. attenuata* Torr. ex Watson. This plant is a herbaceous annual native to North America found in dry washes and recently disturbed or burned areas throughout the Great Basin desert. It produces a central racemose or nar-

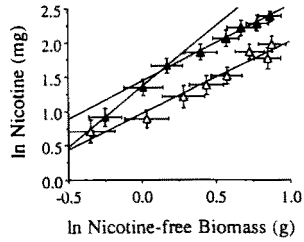

FIG. 1. An allometric analysis of nicotine pools in vegetatively growing *N. sylvestris* plants that were either undamaged (open symbols) or damaged once (closed symbols). Damaged plants increased their accumulation rates for the first 10 days after the damage event (three harvests) but then returned to the same nicotine accumulation rate as undamaged plants (data from Ohnmeiss and Baldwin, 1994).

rowly peniculate indeterminate inflorescence with self-compatible perfect flowers that mature into green capsules that contain 10–300 small (120–160 μg/seed) wind- and water-dispersed seeds (Goodspeed, 1954). The calyx is covered by many trichomes and contains approximately 80% of the nicotine of the entire reproductive part at all developmental stages. A large proportion of the nicotine in the calyx is located in the trichomes, and a single large trichome (of which there may be 27 per capsule) contains between 1.3- and 3.6 μg of nicotine (I. Baldwin, M. Karb, E. Schmelz, N. Blenk and M. Euler, unpublished data). In contrast to the calyx, seeds contain very little nicotine. We found a range of 0–1.2 ng nicotine/seed from seeds collected from pods at different stages of development and grown under a variety of conditions. Hence, the amount of nicotine found in all the seeds of a pod represents a maximum of only 18% of nicotine found in a single large trichome.

We ask the following two questions in two experiments: (1) Does the amount of nicotine in a mature flower increase rapidly in response to floral damage, as has been demonstrated for leaves? (2) Does damage to leaves influence the quantity of nicotine allocated to reproductive parts? These questions examine the prediction from OD theory that reproductive parts will be constitutively defended and examine the plasticity in defense allocation both over the lifetime of a flower and the lifetime of the plant. Few studies have examined the effect of damage to vegetative tissues on the defensive allocation in reproductive tissues despite the clear physiological reliance of reproductive tissues on the resources acquired during vegetative growth. The changes in the allocation over a plant's lifetime deserve attention because most of the nicotine in a reproductive capsule is stored in trichomes on the calyx. Trichomes are cell types that are active early in capsule development (Gershenzon and Croteau, 1991), and damage-induced changes may be constrained to the capsules initiated

after damage. Additionally, because nicotine is synthesized in the roots and transported in the shoot in all nicotine-producing *Nicotiana* species studied to date (Baldwin, 1989), we examined the possibility that the allocation of nicotine to reproductive parts may occur simply as a function of the number of capsules on a plant and the amount of nicotine produced by the roots.

METHODS AND MATERIALS

Plant Growth. N. attenuata seeds were soaked in an aqueous extract of wood smoke in 9.8 mM KNO_3 in order to stimulate germination (Baldwin et al., 1994b). Seeds were from the third generation of glasshouse-grown plants grown from seed collected from plants in 1988 on the DI Ranch in southwestern Utah (T40S R19W section 9). Approximately one week after germination, seedlings were transferred to Jiffypots (Jiffy Products Ltd., Canada), which were subsequently planted into 4- and 0.75 liter plastic pots containing Cornell mix A potting soil (Boodley and Sheldrake, 1977) for plants used in experiments 1 and 2, respectively. All plants were grown in a glasshouse and received supplemental lighting from 400-W high-pressure sodium vapor lamps for 14 hr/day.

Extraction and Quantification of Nicotine. Reproductive parts were cut from the pedicel at the base of the calyx with a razor blade, weighed, frozen at −40°C, and extracted in alkaloid extraction solution (40% methanol in 0.1% HCl) for a minimum of 2.5 days (the time necessary for complete nicotine extraction from frozen flower samples). The corollas of reproductive parts in developmental stage 5 (Table 1) were analyzed separately from the rest of the flower and are reported on in a companion paper (Euler and Baldwin, unpublished data); here we report the nicotine pools of the entire reproductive part. Twenty-four capsules from each developmental stage from one plant were

TABLE 1. CLASSIFICATION OF DEVELOPMENT IN *Nicotiana attenuata* CAPSULES

Stage	Description
1	Corolla completely within calyx
2	Corolla greenish and beginning to emerge from calyx
3	Corolla greenish and fully elongated
4	Corolla white, fully elongated but closed
5	Corolla open
6	Corolla senesced and pistil swollen

weighed, dried at 45–50°C, and reweighed for the calculation of stage-specific percentage dry mass conversion factors. Nicotine was separated by HPLC (Baldwin, 1988), quantified with external standard curves run every 50 samples, and expressed as micrograms of nicotine per capsule.

Experiment 1. This experiment examined the effect of mechanical damage and herbivory to the corolla on capsule nicotine pools. Each afternoon we chose capsules in stage 4 (Table 1) on five plants that would open their corolla tube that evening (and enter stage 5) and haphazardly assigned them to the following three treatment groups on each plant: undamaged, razor damage, and caterpillar damage. Capsules in the razor-damaged treatment received one incision half the length of the corolla tube. One second- or third-instar *Manduca sexta* was placed on the corolla of each capsule in the caterpillar herbivory treatment. Caterpillars remained on the corolla until they had initiated feeding at least once before being removed. Caterpillars that did not feed within the first 30 min were replaced with others until the corolla was damaged. Capsules were damaged in the afternoon and harvested 26–28 hr later. Capsules that aborted before this time were not included in the analysis. Undamaged capsules aborted 7% of the time (3 of 46); 23% of the razor-damaged capsules aborted (11 of 48); and 36% of the caterpillar-damaged capsules aborted (19 to 53).

Experiment 2. This experiment examined the changes in nicotine pools in reproductive parts induced by damage to leaves both over the course of capsule ontogeny and over the reproductive phase of growth for the plant. We harvested capsules at the same stage in development (stage 5) at specified intervals of capsule production on each plant (capsules 1–3, 14–16, and 27–29) in order to track the developmental stage of each plant. Moreover, we included an additional pair of treatments in which the first 26 maturing capsules were excised and predicted that if nicotine is allocated to reproductive parts passively as a function of the total amount of nicotine produced by the vegetative tissues, the nicotine pools of capsules 27–29 of these plants would be larger than those from treatments that did not have their capsules excised.

Forty plants in the early stages of stalk elongation were randomly assigned to the four following treatment groups: (1) both leaf damage and capsule excision, (2) capsule excision only, (3) leaf damage only, and (4) neither leaf damage nor capsule excision. Leaves were damaged every day throughout the period of stalk elongation and flowering. One row of evenly distributed pattern-wheel (Dritz, Spartanburg, South Carolina) damage was made across the length of the lamina on either the left or right side of the midrib on every other leaf of plants in the leaf-damage treatment groups. On average, pattern-wheel damage resulted in 4.5 1-mm^2 holes/cm of leaf. Holes were produced by crushing leaf tissue between the blunt spokes of the pattern wheel and a plastic card, and resulted in undetectable leaf dry mass loss (Ohnmeiss and Baldwin, 1994). Pattern-wheel damage was applied to all fully expanded leaves except the senescing leaves.

Corolla tubes of stage-5 capsules open in the evening and remain open for two to three nights. Plants were inspected every evening between 8:30 and 11:30 PM for capsules with recently opened corrola tubes. The number of stage-5 capsules was recorded and the first 26 stage-5 capsules produced on plants in the flower excision treatments were removed. The first three and the fourteenth to sixteenth stage-5 capsules produced on the two nonexcision treatments were harvested for nicotine quantification. The twenty-seventh, twenty-eighth, and twenty-ninth stage-5 capsules of plants in all four treatments were harvested for nicotine analysis.

An allometric analysis of nicotine contents in reproductive parts in all stages of development was conducted on the first five plants to produce 29 stage-5 capsules in treatments 3 and 4 (e.g., the two nonexcision treatments). Five capsules from each of six ontogenetic stages, for a total of 30 capsules per plant, were harvested for nicotine quantification.

Statistical Analysis. Two-way ANOVAs with damage and plant as the main effects were performed on micrograms of nicotine per capsule and gram capsule mass data of experiment 1. Two-way ANOVAs with damage and excision as the main effects were performed on the third harvest of stage-5 capsules (numbered 27–29) of experiment 2. A repeated-measures one-way ANOVA with leaf damage as the main effect was performed on the three harvests of stage-5 capsules from the two nonexcision treatments of Experiment 2. The ln-transformed amounts of nicotine per capsule were analyzed with an analysis of covariance with ln-transformed amounts of nicotine-free biomass per capsule as the covariate and with individual regressions on the data from each plant. A test of homogeneity of slopes (parallelism) was conducted to determine whether the slopes of these relationships differed between plants with and without leaf damage. Data analysis was performed with the MGLH module of the SYSTAT statistical package (Evanston, Illinois).

RESULTS

Experiment 1. The amount of nicotine in stage-5 capsules with caterpillar (37.4 ± 3.4 μg nicotine/capsule) or mechanical damage (36.3 ± 3.5 μg nicotine/capsule) to their corollas did not differ from that found in undamaged capsules (37.9 ± 3.1 μg nicotine/capsule) as determined by two-way ANOVAs (damage treatment $F_{2,98} = 0.061$; $P = 0.94$). Significant differences between plants were found ($F_{4,98} = 2.66$; $P = 0.037$), and the damage $\times$ plant interaction term was not significant ($F_{8,98} = 0.16$; $P = 0.99$). No significant differences were found in any of the flower biomass data (Ps > 0.40; two-way ANOVA).

Experiment 2. Neither the leaf damage treatment nor the floral excision treatment significantly influenced the biomass of any of the stage-5 capsules

from any of the harvests as determined by the one-way repeated-measures ANOVA or the two-way ANOVA on the twenty-seventh to twenty-ninth stage-5 capsules produced on each plant (Table 2; Figure 2). Similarly, the floral excision treatment did not significantly affect the amount of nicotine in the twenty-seventh to twenty-ninth stage-5 capsules produced on plants as determined by a two-way ANOVA (Table 2; Figure 2). Leaf damage had no significant effect on the amount of nicotine found in the first three stage-5 capsules ($F_{1,17} = 1.15$; $P = 0.30$; one-way ANOVA; Figure 2) produced on each plant; however, leaf damage dramatically increased the amount of nicotine in capsules produced later during reproductive growth as determined by the repeated-measures one-way ANOVA and the two-way ANOVA (Table 2; Figure 3). By the third harvest (capsules numbered 27–29), stage-5 capsules on plants with leaf damage had nicotine pools that were three times those produced by undamaged plants at the same stage of development. This difference in nicotine pools is due in part to a significant decrease in nicotine of capsules produced on undamaged

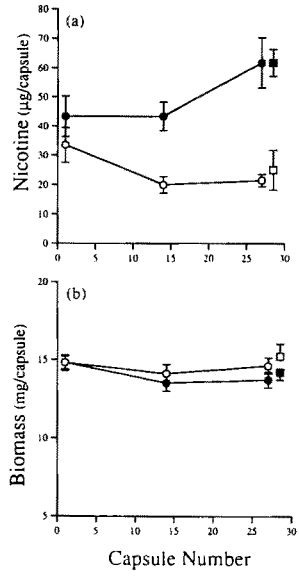

FIG. 2. Mean (±SEM) capsule (a) nicotine and (b) biomass at three stages during reproductive growth of 10 undamaged (open circles) plants and nine plants with leaves damaged during vegetative and reproductive growth (solid circles). Samples are of stage-5 capsules (see Table 1) numbered 1–3, 14–16, and 27–29 on all plants where capsule 1 was the first capsule to reach stage 5. The nicotine and biomass pools of stage-5 capsules numbered 27–29 from an additional nine undamaged (open squares) and nine plants with leaves damaged during vegetative and reproductive growth (solid squares) are also depicted. These plants are from the floral excision treatment which had their first 1–26 stage-5 capsules excised.

plants ($F_{1,27} > 4.56$; $P < 0.042$; one-way ANOVA contrasts between the first and second and first and third harvests). Neither leaf damage nor flower excision affected the plants' phenologies; the rates of flower production as determined by the time to produce 3, 14 or 27 stage-5 capsules did not differ among the treatment groups ($F_{1,33} < 2.62$; $P > 0.11$; two-way ANOVAs).

Reproductive parts at all stages in development from plants with and without leaf damage used in the allometric analysis had significantly ($F_{1,286} = 180.33$; $P < 0.00001$; one-way ANOVA on ln micrograms of nicotine) more nicotine than those from undamaged plants (Figure 3). Biomass values were not significantly different ($F_{1,286} = 0.013$; $P = 0.91$; one-way ANOVA on capsule ln dry mass). The relationship between nicotine pools and capsule biomass as determined by a test of homogeneity of slopes (parallelism) did not differ sig-

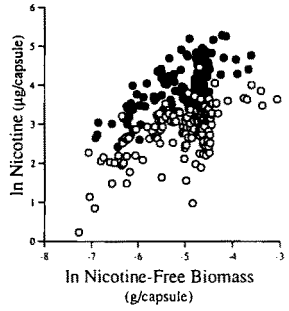

FIG. 3. Natural log transformed nicotine pools plotted against the ln-transformed nicotine-free biomass of five capsules from each of the six developmental stages described in Table 1. Capsules were sampled from five undamaged (open circles) plants and five plants with leaves damaged during vegetative and reproductive growth (solid circles). All plants were sampled after producing 30 stage-5 capsules and hence were at the same stage in their reproductive phase as those plants in the third harvest of Figure 1. See Table 3 for the regression statistics for each individual plant and the text for the ANCOVA analysis.

4	0.840	6.678 ± 0.294	0.644 ± 0.057
5	0.505	5.694 ± 0.414	0.422 ± 0.081

[a] Natural log-transformed nicotine pools in five capsules for each of the six developmental stages described in Table 1 were regressed against ln-transformed nicotine-free dry biomass for each plant. Plants were either undamaged or had their leaves damaged throughout the reproductive phase of growth.

nificantly ($F_{1,288} = 0.115$; $P = 0.735$) between damaged and undamaged plants. Because the assumption of homogeneity was not violated, an analysis of covariance (ANCOVA) with ln nicotine as the dependent variable and ln nicotine-free biomass as the covariate was performed, revealing that undamaged and damaged plants differed significantly ($F_{1,289} = 72.3$; $P < 0.001$). Within-plant regressions revealed the same pattern as the ANCOVA (Table 3). The *y*-intercept values were significantly higher for damaged plants ($F_{1,8} = 5.93$; $P = 0.041$; one-way ANOVA on ln-transformed values), while the slopes of the individual plant regressions were not significantly different ($F_{1,8} = 0.58$; $P = 0.47$; one-way ANOVA on ln-transformed values). In addition, the relationships between ln-transformed nicotine pools and biomass tended to have less scatter with damaged plants than with undamaged plants (mean $R^2 = 0.618$ and 0.402 for damaged and undamaged plants, respectively; Table 3).

DISCUSSION

The results of these experiments revealed some of the "rules" that govern how nicotine is allocated to reproductive parts. First, nicotine is not passively allocated to reproductive parts as a function of the amount of nicotine produced in roots and the number of capsules on a plant. The nicotine content of stage-5 capsules on plants that had the vast majority of their maturing capsules excised did not differ from those which did not have capsules excised (Figure 2). The excised stage-5 capsules contained between 20 and 60 μg of nicotine, depending on whether they developed on plants with or without leaf damage. Had these capsules remained on the plant through maturity, they would have accumulated 60–160 μg of nicotine, respectively. Hence, the excision treatment should have doubled or tripled the nicotine pools or stage-5 capsules if the passive allocation model was correct. This deduction assumes that nicotine accumulation reflects nicotine production in *N. attenuata* as has been demonstrated in *N. sylvestrius* (Baldwin et al., 1994a) and that nicotine was not stored in other plant parts for allocation to capsules later in reproductive growth. Second, the allocation of nicotine to a capsule is not influenced by herbivory or mechanical damage to the corolla (experiment 1) or to the removal of other reproductive parts (experiment 2). Third, in contrast to damage to reproductive parts, damage to leaves dramatically increases the allocation of nicotine. Fourth, the allocation of nicotine to reproductive parts follows an allometric relationship that has less scatter in damaged plants, as indicated by the higher R^2 of the individual regressions (Table 3), and has a higher intercept. The effect of leaf damage on the nicotine–biomass allometry appears similar to that found in vegetatively growing *N. sylvestrius* plants (Figure 1). The long-term effect is to move plants from one allometric relationship to another with similar slopes but different intercepts.

The *N. sylvestris* data set clearly showed that damaged plants moved from one allometric relationship to another by briefly increasing their rate of nicotine production during growth and, hence, increasing the slope of the relationship. A similar mechanism could be operating in *N. attenuata* reproductive parts, although leaf damage may have initiated the production of capsules with higher nicotine accumulation set points at the beginning of capsule growth. Fifth, leaf damage does not appear to alter the allometric set points for nicotine accumulation for the first reproductive parts produced by a plant, and these apparent set points appear to decline during the later stages of reproductive growth in undamaged plants. These patterns of nicotine allocation underscore the important regulating influence that vegetative tissues have on the defense of reproductive tissues.

Many of these patterns are broadly consistent with the predictions of OD theory. First, defense is constitutively allocated to individual reproductive parts as a function of capsule mass. OD theory predicts that defensive plasticity should be reserved for those tissues that are functionally plastic, such as leaves that are capable of physiologically rejuvenilizing and tissues whose contribution to plant fitness vary over ontogeny. Second, defense allocation to the first capsules produced on an undamaged plant appear to be higher than those produced later (Figure 2). For plants growing in unpredictable environments, the first offspring produced represent a larger proportion of realized fitness than those produced later and hence would be predicted to receive a larger defensive allocation. Moreover, if inducible defense allocation provides a means of conserving resources that could be otherwise used for offspring production, the inducible allocation of defense to offspring produced later during reproductive growth, as plants realize their potential fitness, is also consistent with the cost–benefit paradigm of OD theory. Whether or not plants that produce more defense in herbivore-free environments consequently produce fewer offspring of lower quality remains to be demonstrated.

TRACKING VARIABLE ENVIRONMENTS: THERE IS MORE THAN ONE KIND OF MEMORY

FREDERICK D. PROVENZA

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Three kinds of memory help herbivores track changes in the environment. The first is the collective memory of the species with genetic instructions that have been shaped by the environment through millennia. This includes skin and gut defense systems. Auditory and visual stimuli and sensations of pain impinge upon the skin defense system that evolved in response to predation. The taste of food and the sensations of nausea and satiety are an integral part of the gut defense system that evolved in response to toxins and nutrients in plants. The second kind of memory in social mammals is represented by the mother, a source of transgenerational knowledge, who increases efficiency and reduces risk of learning about foods and environments. The third kind of memory is acquired by individual experience. Postingestive feedback from nutrients and toxins enables individuals to experience the consequences of food ingestion and to adjust food preference and selection commensurate with a food's utility. The three memories interact, each linking the past to the present, and collectively shape the present and future of every individual. Thus, the dynamics of foraging involves appreciating the uniqueness of individuals and subgroups of animals, each with their own genetic and behavioral history, and recognizing that foraging behaviors may not be stable, optimal, or even predictable in the conventional sense.

Key Words—Evolution, ecology, learning, memory, foraging, habitat, spotted owl.

INTRODUCTION

Organisms rely on experience and memory to cope with hazards in the environment. In the absence of memory, every facet of the environment would ceaselessly be experienced for the first time and immediately forgotten. As Luis Bunuel lamented while in the process of losing his memory: "You have only

0098-0331/95/0700-0911$07.50/0 © 1995 Plenum Publishing Corporation

to begin to lose your memory, if only in bits and pieces, to realize that memory is what makes our lives. Life without memory is no life at all . . . . Our memory is our coherence, our reason, our feeling, even our action. Without it, we are nothing . . . (I can only wait for the final amnesia, the one that can erase an entire life, as it did my mother's . . .)" (in Sacks, 1990, Chapter 2).

There are three kinds of memory. The first is the collective memory of the species, the genetic instructions that have been shaped by the environment throughout millennia. The second is represented in social mammals by the mother, who is a source of transgenerational knowledge. The third kind of memory is acquired by individual experience. The three memories interact and link consequences of behavior from the past to the present and shape the present and future of every individual. This paper discusses the three types of memories and how they are related.

EVOLUTION AS MEMORY

Genes are the cumulative memory of how environment has shaped the species through millennia. Skin and gut defense systems are part of these genetic instructions in species are diverse as fruit flies, snails, fish, lizards, tiger salamanders, pigeons, hawks, rats, cats, dogs, sheep, baboons, and humans (Garcia et al., 1985; LeDoux, 1994; Provenza, 1995). Auditory and visual stimuli and sensations of pain associated with the skin defense system evolved in response to predation. The taste of food and sensations of nausea and satiety are part of the gut defense system evolved in response to toxins and nutrients in plants. As Garcia (1989) suggests "all organisms evolved coping mechanisms for obtaining nutrients and protective mechanisms to keep from becoming nutrients" too soon.

Evolution has created skin and gut defense mechanisms that facilitate interactions with a virtually infinite variety of objects in the environment. Each system is underlain by two kinds of memory; one provides the emotional content of the experience, whereas the other renders specific details about objects and events. Collectively, these systems are designed to interact with and to be shaped by the environment during each animal's lifetime. This flexibility increases the likelihood of survival of the individual and of the species, given the fact that the environment is ever-changing and that the average lifetime of a species is several million years (Wilson, 1992). This plasticity is clearly one of the most important outcomes of evolution.

The way skin and gut defense systems work is illustrated in experiments in which hawks were fed distinctively colored or flavored mice (Brett et al., 1976; Garcia and Garcia y Robertson, 1985). Hawks fed white mice with impunity, but occasionally given a black mouse followed by an injection of the toxicant lithium chloride (LiCl), would not eat either black or white mice,

because both mice tasted the same. But when a distinctive taste was added to black mice, hawks learned to avoid black mice on sight after a single black mouse toxicosis event. The taste cue potentiated the color cue.

Such experiments show that not all cues are readily associated with all consequences. Cue–consequence specificity refers to the fact that when animals are made ill following exposure to audiovisual and taste cues, they show much stronger aversions to the taste than to the audiovisual stimuli. In contrast, if they receive foot shock following the same cues, they show much stronger aversions to the audiovisual than to the taste cues (Garcia and Koellin, 1966). The same kind of response has been demonstrated for food and place aversions. Toxins like LiCl cause strong food aversions, but they do not cause rats to avoid the place where they ate a particular food (Lett, 1985; Coil et al., 1978). Conversely, compounds such as gallamine, which causes muscular paralysis, causes rats to avoid the place where they ate but they do not stop rats from eating the food (Lett, 1985).

The incorrigible nature of such responses is illustrated further by the fact that animals acquire aversions even when they know the food did not cause the illness (Garcia and Garcia y Robertson, 1985; Provenza et al., 1994a). For instance, many of us remember acquiring an aversion to a particular food, even though we knew the illness (e.g., nausea caused by flu, reaction to a vaccine, seasickness, chemotherapy) was not related to food. This knowledge does not alter the newly acquired aversion to the taste and odor of the food.

Such seemingly irrational responses occur because gustatory and visceral afferent nerves converge at common central neural pathways that are generally distinct from audiovisual and somatosensory integrative neural systems (Garcia et al., 1985; LeDoux, 1994). Olfactory pathways have access to both skin and gut defense systems. Odor cues are associated with taste cues (i.e., taste potentiates odor) during a meal, and these two senses provide information concerning the flavors of particular foods. Conversely, odors of predators serve as warnings for the skin defense system. Thus, evolution arranged the central nervous system in a manner that affords relatively direct and independent integration of skin defense and gut defense systems.

Skin and gut defense systems were designed differently to accomplish different objectives. The skin defense system functions on a scale of milliseconds to seconds; rapid responses are required to avoid predation (LeDoux, 1994). Conversely, the gut defense system integrates information about tastes (and potentiated odors) of foods and the postingestive effects of nutrients and toxins over time frames of minutes to hours; digestion and absorption are relatively slow processes (Garcia et al, 1985; Provenza, 1995).

Skin and gut defense systems are also mutually inhibitory. Fear abolishes appetite and gastric motility, whereas a large meal is followed by drowsiness and muscular relaxation. As Robert Capa (*Newsweek*, May 23, 1994) noted in

his diary on D-Day: "The mess boys of the *U.S.S. Chase* wore immaculate white jackets and served hot cakes, sausages, eggs and coffee with unusual zest and politeness. But the pre-invasion stomachs were preoccupied, and most of the noble effort was left on the plates . . . ."

Two kinds of memory underlie skin and gut defense systems, one renders specific details about objects and events, whereas the other provides the emotional or affective content of the experience (LeDoux, 1992, 1994). Declarative (cognitive) memory is the process by which earlier conscious experiences are recalled. The original learning and remembering are conscious events mediated by the hippocampus. Memories of snakes (skin defense) and various foods (gut defense) and locations where they have been encountered are examples. In contrast, emotional (noncognitive) memory operates independently of conscious awareness, and it is mediated by the amygdala. Fear (skin defense), nausea and satiety (gut defenses) are examples. Emotional memory may be stored within declarative memory, which can activate emotional responses through the amygdalic system. Thus, emotion is not merely unconscious memory, rather it exerts a powerful influence on declarative memory and on behavior.

Emotional and declarative memories provide insights into the distinction between food preferences and food selection. Neurally mediated interactions between the senses (i.e., taste and smell) and the gut (i.e., nausea and satiety caused by toxins and nutrients) cause changes in food preferences that do not involve cognitive processes (i.e., they constitute an emotional memory). The noncognitive aspect of this phenomenon has been verified in a variety of species under various conditions, e.g., animals acquire food aversions when anesthetized (Roll and Smith, 1972; Bermudez-Rattoni et al., 1988; Provenza et al., 1994a), tranquilized (Forthman Quick, 1984), and when their electrocortical activity is depressed (Davis and Bures, 1972; Buresova and Bures, 1973). In contrast, animals use declarative memory to select (avoid) particular foods and foraging locations.

THE MOTHER AS MEMORY

The mother as a memory shapes food and habitat selection by her offspring and increases their likelihood of survival. The importance of this transgenerational link is clearly illustrated in instances when wild and domesticated ruminants are moved to unfamiliar environments. Compared with animals reared in the environment, naive animals spend more time foraging but ingest less forage; they spend more time walking and walk for greater distances; they suffer more from predation, malnutrition, and ingestion of toxic plants (reviewed in Griffith et al., 1989; Provenza and Balph, 1990).

The mother increases efficiency of learning about nutritious foods (Provenza, 1994). Lambs exposed to wheat with their mothers for as little as 1 hr/day for five days ingested more wheat than did lambs exposed to wheat without their mothers; intake of wheat was nearly 10 times higher as many as three years later with no intermittent exposure (Lynch et al., 1983; Green et al., 1984). Likewise, lambs exposed to the shrub *Amelanchier alnifolia* and to barley with their mothers ingested considerably more of these foods than did lambs who were exposed without their mothers (Thorhallsdottir et al., 1990). Finally, lambs who ate either of two palatable shrubs (*Cercocarpus montanus* or *Amelanchier alnifolia*), showed a marked preference for the shrub they ingested with mother (Nolte et al., 1990).

In the same manner, the mother reduces the risk of overingesting toxic foods (Provenza, 1994). For instance, a lamb learns quickly to avoid harmful foods and to select nutritious alternatives, when with its mother who exhibits this behavior (Mirza and Provenza, 1990, 1992). As a result of such interactions, a lamb acquires preferences for foods its mother eats, and avoids foods its mother avoids (Mirza and Provenza, 1994).

Experiences early in life with the mother also shape habitat preferences of offspring. Wild herbivores of the same species often occupy different home ranges within an area (Gruell and Papez, 1963; Geist, 1971; Fiesta-Bianchet, 1986a,b, 1988; Cederlund and Okama, 1988; Cederlund et al., 1987; Porter, 1992). This phenomenon also occurs in livestock (sheep: Hunter and Milner, 1963; Lawrence, 1990; cattle: Yeates and Schmidt, 1974; Martin, 1979; Reinhardt and Reinhardt, 1981; Roath and Krueger, 1982; Hall, 1988; Howery et al., 1995a; goats: O'Brien, 1984). Cross-fostering experiments with sheep (Key and MacIver, 1980) and cattle (Howery et al., 1995b) show that habitat selection preferences are transferred from mother to offspring. For instance, lambs whose mothers preferred native pastures were cross-fostered with lambs whose mothers preferred seeded pastures. After weaning, the lambs strongly preferred the location where their foster mothers had foraged. Individuals reared in different environments often have disparate dietary habits (Biquand and Biquand-Guyot, 1992), which in turn affects their preferences for foraging locations (Scott et al., 1995).

As a result of selecting particular foods and foraging in certain locations, the preferences of individuals can become quite rigid, to the degree that they appear to be genetically fixed. This phenomenon is illustrated in field studies of Criollo goats grazing savannas of Martinique, French West Indies (Biquand and Biquand-Guyot, 1992). The diets of mature female goats, which came from four different locations, strongly reflected their area of origin on the island, despite grazing a common area for four years. These mothers produced four lots of female offspring. Diets of the cohorts born in successive years were strongly affected by experiences early in life, which were a reflection of the

diets of their mothers and peers, as well as differences in plant species that were available the year they were born.

Research on moose provides another example of the persistence of behaviors learned from the mother (Andersen, 1991; Histol and Hjeljord, 1993). A population of moose in central Norway migrates from low-lying summer areas to winter areas situated at higher altitudes, which is contrary to the general pattern of migration to lower elevations near the sea. Archeological evidence along the migration route shows that the migratory behavior of this population has not changed since 5000 BP, despite deterioration in the quality of their winter range. The low calf production of the population (0.6 calves/cow) compared with neighboring populations (0.8–1.3 calves/cow) evidently reflects the poor winter ranges. Migratory traditions passed on from mother to offspring are inflexible, and changing migratory routes to utilize better quality range may take many generations, if it ever occurs.

THE INDIVIDUAL AS MEMORY

Experience is the memory of the consequences of behavior to the individual. The importance of individual experience in foraging is illustrated in experiments with the mother and her offspring. For instance, when a lamb experiences mild toxicosis from eating a food its mother prefers, the lamb acquires an aversion to the food even though its mother continues eating the food avidly (Provenza et al., 1993a). Thus the mother may facilitate the acquisition of foraging behaviors by her offspring, but continuation of the behaviors depends on the consequences to the individual (Galef, 1988).

Postingestive feedback enables individuals to experience the consequences of food ingestion, and it causes changes in preference for the flavor (taste and odor) of particular foods (Provenza, 1995). Animals acquire preferences for flavors of foods that cause satiety, the pleasant sensation that occurs when animals ingest adequate kinds and amounts of nutritious foods. Conversely, animals acquire aversions for the flavors of foods that cause malaise, the unpleasant feelings of physical discomfort that occur from ingesting excesses of nutrients and toxins and from nutrient deficits. What constitutes excesses, deficits, and satiety depends on the animal's nutritional requirements, which vary with age, physiological state, and environmental conditions. Thus, postingestive feedback adjusts food preferences commensurate with the food's utility. In the absence of flavor–feedback interactions, animals are not likely to select a nutritious diet because they generally can not directly taste and smell nutrients and toxins in foods.

Flavor–feedback interactions cause changes in preference (affective value), and changes in preference cause changes in food selection (Garcia, 1989; Provenza, 1995). Taste plays the pivotal role in both cases. Affective processes

integrate the taste of food and its postingestive consequences, aversive or positive, thereby causing changes in incentive to eat particular foods; they involve neurally (i.e., primarily brain stem and limbic system) mediated interactions between the sense of taste and the body, and they are noncognitive. Cognitive processes involve use of the senses of smell, sight, and hearing to select foods that cause positive consequences and to avoid foods that cause malaise; they involve interactions between higher cortical centers and the limbic system. Affective and cognitive processes function in parallel to regulate the internal environment. The taste of food is continuously calibrated according to its effect on the internal environment, and on that basis animals select foods that are nutritious and avoid those that are toxic.

Affective and cognitive processes both operate when animals forage, for instance when goats choose between current season's (CSG) and older growth (OG) twigs from the shrub blackbrush (*Coleogyne ramosissima*). Even though CSG contains more nitrogen (1.04% vs. 0.74%) than OG and is more digestible (48% vs. 38%), goats prefer older twigs containing lower levels of a condensed tannin that causes a learned food aversion (Provenza et al., 1990). When both types of twigs are offered to goats who have never consumed blackbrush, goats do not exclusively choose either type, but when they finally eat more CSG than OG in a meal (44 g and 16 g) and eat enough CSG to acquire an aversion (about 44 g), they ingest less CSG from then on (Provenza et al., 1994b). Thus, the relative amount of food eaten within a meal controls the acquisition of an aversion to CSG. The change in preference for CSG involves the brain stem and limbic system and requires no cognitive ruminations on the part of the goat, whereas the change in food selection by the goat involves the senses of sight and smell and higher cortical centers.

An animal's experiences, particularly early in life, exert a profound influence on food preference (Provenza and Balph, 1990; Provenza, 1994). As a result of eating particular foods and not eating others, young animals acquire dietary habits. They prefer familiar foods, and they become reluctant to eat novel foods. Accordingly, familiarity and novelty come to control taste-feedback interactions within meals. For instance, when animals eat a meal of novel and familiar foods and experience malaise, they avoid the novel foods (Revusky and Bedarf, 1967; Burritt and Provenza, 1991), and they exhibit the same response when the flavor of a familiar food changes (Launchbaugh and Provenza, 1993; Provenza et al. 1993a, 1995). Furthermore, when they eat a meal of only novel foods and experience malaise, they avoid the foods that are most novel (Kalet and Rozin, 1970, 1971; Kalat, 1974; Provenza et al. 1994b). For instance, lambs fed rolled barley (familiar food), with a low and a high concentration of a flavor, consume small amounts of both foods, regardless of flavor concentration (Launchbaugh et al. 1993); but after they eat a meal of both foods, and then receive a mild toxin dose, they avoid the barley with the highest concen-

tration of the flavor (i.e., the barley that is most different (novel) from plain barley). Conversely, when animals experience mild malaise following a meal of familiar foods, they avoid foods eaten too frequently or in excess (Provenza et al. 1993b, 1994b; Phy and Provenza, 1995; Burritt and Provenza, 1995). Thus, eating any familiar food to satiety is apt to cause mild malaise, which will cause animals to eat a varied diet (Provenza, 1995).

Young ruminants remember foods that provided either aversive (Lane et al., 1990; Burritt and Provenza, 1990) or positive (Green et al., 1984; Squibb et al., 1990) consequences for at least one to three years without intermittent exposure, and they sample novel foods cautiously (Chapple and Lynch, 1986; Chapple et al., 1987; Thorhallsdottir et al., 1987; Burritt and Provenza, 1989, 1991). The ability to discern novel from familiar foods is illustrated in experiments when lambs were given 10 different foods during a seven-month period (Provenza et al., 1995). Any time lambs were offered a food they had previously eaten, their initial intake was high (e.g., >600 g in 30 min). Conversely, when they were offered a novel food, their intake was low initially (e.g., <50 g in 30 min) and gradually increased over several days. Intake decreased (increased) any time a novel (familiar) flavor was added to a familiar (novel) food. Thus, lambs remembered at least 10 foods, a number similar to that typically comprising the diets of animals foraging on rangelands. For instance, goats encounter over 100 species/ha in tropical savannas, but they eat only seven species in significant amounts (10% or more of the diet), and five species constitute 65% of their diet (Biquand and Biquand-Guyot, 1992).

Animals discriminate among novel foods to the degree dictated by the environment. Goats first introduced to blackbrush-dominated rangelands sample all foods in the area during the first few hours, including potentially toxic plants like *Juniperus osteosperma* (bark and green leaves), *Gutierrezia microcephala* (a forb), and *Marrubium vulgare* (a forb), as well as nontoxic shrubs like *Prunus fasciculata* and *Purshia tridentata*. They also sample and learn to distinguish among different plant parts, for instance, current season's and older growth twigs from the shrub blackbrush. Within a few days, however, goats discriminate among and ingest different amounts of various foods, evidently on the basis of neurally mediated interactions between taste and postingestive feedback (Provenza et al., 1994b; Provenza, 1995). Considering the importance of food for survival, the design of the central nervous system, and the fact that ruminants spend as many as 8–12 hr foraging every day, it should not be surprising that herbivores can learn to discriminate among several novel foods on the basis of flavor–feedback interactions.

CONCLUSION

One of the most important outcomes of evolution is the plasticity to be shaped by the environment during an animal's lifetime. Beliefs concerning evo-

lution should be tempered with the realization that food and habitat selection are dynamic processes, adapted to environmental change. Learning is vital for adaptation, and it involves elements of history and change such as prior experiences; social interactions; neuro-, morpho-, and physiological feedbacks and feedback time lags; individual variability in responses to nutrients and toxins; forage sampling; and random events. It is prudent to recognize that learning can activate a self-perpetuating series of consequences that are nonoptimum, sensitive to perturbation, difficult to predict, and resistant to change (Provenza and Cincotta, 1993). Accordingly, food and habitat selection should be studied as dynamic behavioral processes rather than as static events that reside at some optimum.

Conservation and management programs should operate with this kind of dynamic in mind. The spotted owl is an excellent example. There is growing evidence that the spotted owl is not endangered. Instead, it occurs from British Columbia to Mexico in habitats as disparate as young- and old-growth forests and desert scrub (Easterbrook, 1994). Recent studies suggest that the DNA is no different in individuals in any of those populations. What differ are the experiences of individuals with the environment, but that does not make them different species. As Easterbrook points out: "If local variation in climate and diet convert creatures to different species, a black man who lives in Seattle, gets rained on and eats salmon would be a different species from a white man who lives in stifling humidity in Louisiana and dines on gumbo. By this theory the human race contains hundreds of species." The distinction between what has been shaped by the environment during an animal's lifetime and what has been shaped by evolution over millennia makes all the difference in the world concerning understanding of the status of spotted owls.

Acknowledgments—This paper is based on a talk given at the 11th Annual Meeting of the International Society of Chemical Ecology as part of a symposium titled "Plant-Herbivore Interactions: Quo Vadimus?" It is published with the approval of the Director, Utah Agricultural Experiment Station, Utah State University, Logan, as Journal Paper number 4628. The work was supported by grants from the Cooperative States Research Service and the Utah Agricultural Experiment Station.

TURNABOUT IS FAIR PLAY: SECONDARY ROLES FOR PRIMARY COMPOUNDS

MAY R. BERENBAUM

Department of Entomology
University of Illinois at Urbana-Champaign

Urbana, Illinois 61801-3785

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Chemically based resistance of plants to herbivorous insects is today essentially synonymous with allelochemically based resistance; the importance of plant secondary compounds in determining patterns of host-plant utilization has been established in a wide variety of insect-plant interactions. In contrast, primary metabolites, those involved in fundamental plant physiological processes, are rarely considered to be major determinants of host-plant resistance despite the fact that, as insect nutrients, they can have profound effects on behavior and physiology. The degree to which variation in plant primary metabolism results from the selective impact of herbivory may be greatly underestimated in that the biosynthetic and structural diversity of primary metabolites and the consequences of that diversity on herbivores are rarely taken into account in most studies of insect preference and performance. Qualitative and quantitative variation in the production of primary metabolites can result from herbivore selection pressure if production of primary metabolites is under genetic control and if plant fitness in the presence of herbivores is associated in a predictable way with genetically based primary metabolite variation. Variation in primary metabolism is likely to be particularly effective as a defense against highly oligophagous herbivores with limited mobility, especially those confined to structures containing allelochemicals that could neutralize the benefits associated with compensatory feeding.

Key Words—Secondary compounds, primary compounds, plant resistance, herbivory.

INTRODUCTION

Over the last 40 years, as chemical techniques for the separation, identification, and quantification of secondary chemicals have become increasingly more sophisticated and accessible, interest on the part of ecologists in the chemistry

0098-0331/95/0700-0925$07.50/0 © 1995 Plenum Publishing Corporation

of primary constituents of plants has virtually disappeared. With few exceptions, chemical ecologists have, for the most part, relegated the precise identification and quantification of primary plant metabolites (with the exception of elemental nutrients) to physiologists. In point of fact, however, amino acids, vitamins, sterols, and other herbivore nutrients are chemical constituents of plants that are synthesized, sequestered, or metabolized as are alkaloids, coumarins, phenylpropanoids, and the other more "secondary" metabolites. Moreover, considerable evidence exists that they play an essential role in determining host-plant suitability for herbivores and that herbivores detect and process them in ways very similar to the manner in which secondary metabolites are detected and processed.

There is a clear need, then to differentiate between the terms "secondary substance" and "allelochemical"—the two terms are not really synonymous or interchangeable. Just as some secondary substances may have primary physiological functions (Seigler, 1977), some primary substances may function as allelochemicals. By the same token, it must be emphasized that the terms "nutrient" and "allelochemical" are not necessarily exclusive and opposite (Slansky, 1992); whether a substance is nutritive or toxic is entirely dependent upon context (Reese, 1979; Janzen, 1979) and not upon biosynthetic origin. Although it is now widely accepted that allelochemicals may function in some instances as nutrients (Bernays and Woodhead, 1982; Rosenthal and Bell, 1979), the allelochemical function of erstwhile nutrients is rarely considered.

To a great extent, the relative lack of emphasis on primary metabolites of plants in current discussions of plant–insect interactions is largely the result of historical precedent; methodologies and technologies now exist, however, that make the analysis of primary metabolism in an ecological context more tractable. Such analyses stand to make substantial contributions to understanding the chemical bases for host-plant choice in insects and the evolutionary responses of plants to herbivory.

HISTORICAL BACKGROUND

The chemical characterization of plants began in earnest in the nineteenth century, and it rapidly became apparent that, while certain plant constituents, such as chlorophyll or sucrose, are virtually universal in distribution, other types of plant constituents are restricted in distribution to individual families, individual genera within families, individual species within genera, and even individual populations within species. Such idiosyncratic distributions suggested that compounds that are not universally distributed are not essential to the physiological function of the plant. Kossel (1891, as translated by Mothes, 1980) proposed "calling . . . essential components of the cell primary components, and those which are not found in every cell capable of developing, secondary."

TABLE 1. DATA FOR CHEMICAL CHARACTERIZATION OF REPRESENTATIVE PRIMARY AND SECONDARY METABOLITES (WINDHOLZ, 1983)

Primary metabolites		Secondary metabolites	
Tryptophan	1901	Cocaine	1885
Vitamin A	1913	Coniine	1886
Methionine	1922	Nicotine	1893
Vitamin E	1936	Mescaline	1896
Vitamin B_{12}	1948	β-Pinene	1896

This dichotomy was rapidly embraced and prevailed for the next century, although variously modified over the years; as more constituents were characterized, they were, for the most part, readily characterized as either primary or secondary metabolites. Surprisingly, the chemical characterization of many nutritive substances lagged behind that of many secondary metabolites (Table 1), at least in part because some essential nutrients, such as vitamins, are present in plants in concentrations even lower than are most secondary compounds; the word "vitamin," for example, was not even coined until 1912. In some ways, the choice of the word "secondary" was unfortunate; although it for the most part accurately depicts the biosynthetic dependence of secondary metabolites on intermediates of primary metabolism (referred to by Bonner and Galston (1952) as the byways and highways of plant metabolism, respectively), it also connotes inutility or expendability. Over the next century, various unflattering epithets, including "excretory products" (Goris, 1921, cited by Robinson, 1930), "metabolic waste products" (Muller, 1969), "unnecessary metabolites" (Robinson, 1974), even "flotsam on the metabolic beach" (Mothes, 1980), were applied to these compounds to emphasize the fact that they did not appear to play a role in the daily physiological demands of plant life.

Relatively early on, however, Stahl (1888) suggested that such compounds play a vital role in protecting plants against biological stress agents, referring to them as *Schutzexcrete*, or protective excretions. Stahl's suggestion that the function of the so-called secondary compounds is primarily ecological was not widely accepted until 1959, when Fraenkel (1959) reintroduced the idea to the scientific community, accompanied by a compelling body of evidence attesting to the behavioral and physiological effects of these compounds on herbivorous insects. In full recognition of the fact that secondary compounds are essential in the sense that they allow plants to survive in their biotic milieu, Whittaker and Feeny (1971) coined the less judgmental term allelochemic (from *allelo*, Greek for "one another") to describe compounds with primarily ecological functions; "most allelochemical interactions involve the diverse secondary sub-

stances . . . which do not occur in all living matter but appear sporadically throughout the living world. They are contrasted with the primary subtances, such as various proteins, carbohydrates, nucleic acids, and fats, which are of general occurrence." It is interesting to note that Whittaker and Feeny (1971) did not equate "allelochemical" with "secondary substances" but carefully noted that secondary substances do function as such in "most" cases.

Dissatisfaction with the notion that a clear dichotomy of function exists between primary and secondary compounds has arisen many times over the last century; indeed, even Kossel (1891, cited in Mothes, 1980), in proposing the terms primary and secondary metabolite, acknowledged the difficulties of distinguishing between them. Seigler (1977) and Seigler and Price (1976) suggested that secondary compounds may well play a role in primary physiological processes by serving as biosynthetic intermediates, as growth regulators, or as rather elaborate storage molecules for elements in short supply. Consistent with this function is the phenological, ontogenetic, and diurnal variation in abundance that characterizes virtually all secondary compounds. The idea that secondary compounds can function as storage molecules for elements in excess supply is, in fact, at the foundation of the carbon–nutrient balance hypotheses currently in vogue (according to which excesses of nutrients in the form of either carbon or nitrogen allow for the accumulation of either carbon-based or nitrogen-based allelochemicals, respectively) (Bryant et al., 1983; Coley et al., 1985).

Primary constituents, however, were not completely forgotten in all of this discussion. Because many biochemical and physiological processes are identical in plants and animals, it was assumed from the beginning that primary compounds produced by plants serve as nutrients for plant-feeding animals (including humans) when they are ingested. That the nutrient content of plants determines in part the suitability of plants to herbivorous insects was clearly recognized by Painter (1936), who stated that the "possible lack of specific food materials, especially proteins" could be critical to plant food quality, leading to, among other things, changes in longevity, size, fecundity, and death rates in herbivorous insects. He also ruefully noted that, at that time, "the development of insects with respect to specific food substances or mineral elements is almost an untouched field." The development of defined artificial diets and aseptic rearing techniques in the next decade allowed for tremendous gains in identifying the essential amino acid, vitamin, and other dietary requirements of insects in general and phytophagous insects in particular (Lipke and Frankel, 1965).

By mid-century, some investigators were proposing that both nutrients and secondary chemicals were important in determining patterns of host-plant utilization. This idea was perhaps best stated by Kennedy (1953, 1958), in his "dual discrimination hypothesis," according to which secondary chemicals are involved principally in host-plant recognition and nutrients principally in feeding-site selection within a plant. That both nutrients and secondary chemicals

should play a role in determining host-plant preferences was not an unreasonable supposition, according to Thorsteinson (1958), because "physiologically there is little basis for distinguishing between perception of token stimuli and nutrients since both are manifestations of the chemotactic sense." In his work with *Plutella xylostella*, Thorsteinson himself had demonstrated that the feeding-stimulant properties of sinigrin, a secondary compound typical of crucifers, were greatly enhanced in the presence of sucrose (Thorsteinson, 1960).

This synthetic view was largely forgotten, however, when Fraenkel proposed that allelochemicals, rather than nutrients, are exclusively responsible for determining plant utilization patterns by herbivorous insects—stating boldly that "there is little reason to suppose that differences in chemical composition with respect to the 'primary' substances (which occur in all living matter) can be responsible for the choice of food plant on the part of the insect" (Fraenkel, 1959). Although Fraenkel eventually softened this view (somewhat) in a later paper (Fraenkel, 1969, ". . . it would be illogical to expect that extreme changes in nutrients would leave the insect entirely unaffected"), the later paper never had the impact of the first, which went on to become a classic cited over 200 times between 1959 and 1984 (Current Contents, March 12, 1984). During that critical period in the development of insect–plant interaction theory, discussions of the impact of insect herbivory on plant evolution focused primarily on plant secondary metabolism.

LOW NUTRIENT QUALITY AS DEFENSE

Plant nutritional quality reemerged as an important element of coevolutionary studies in 1976, when both Feeny (1976) and Rhoades and Cates (1976) described allelochemicals with antinutritive, or digestibility-reducing, properties. The suggestion was made that low nutrient quality, arising either through antinutritive alleochemicals, such as tannins and resins, or through reduced amounts of essential nutrients, such as proteins, could function as a plant defense. There were perceived theoretical shortcomings with this position, however, articulated by both Moran and Hamilton (1980) and Price et al. (1980)—namely, that reduced nutrient quality could potentially lead to increased damage to plants due to the propensity of certain herbivores to compensate for low nutrient levels by ingesting some food. Moran and Hamilton (1980) conceded that low nutritive quality could function as a defense under special conditions—if herbivores are able to detect low nutrient quality and are sufficiently mobile to move to avoid it, if successive generations of extremely sedentary herbivores on the same host experience reductions in size as a result of reduced nutrient quality, or if prolonged development in early stages as a result of low nutrient quality increases the risk of predation or disease.

Over the past decade, although the effects of nutrient variation on herbivore preference and performance have been studied extensively (Slansky and Rodriguez, 1987; Slansky, 1992; Simpson and Simpson, 1990), the idea that low nutrient quality can evolve as a plant defense has garnered little attention. Neuvonen and Haukioja (1984) attempted to examine the hypothesis in the context of delayed inducible resistance in *Betula pubescens* in response to repeated defoliation by *Epirrita autumnata*; resistance in this system took the form of increased levels of foliar phenolics and decreased amounts of foliar nitrogen. These authors concluded that, due to the presence of multiple confounding variables, "one cannot say that low nutritive quality in itself is defensive." Lundberg and Astrom (1990) elaborated upon the idea of low nutritive value as a plant defense in a theoretical paper focused on repercussions of variable nutrient quality on movements of vertebrate herbivores. These authors assumed for purposes of discussion that low nutritive quality could be defined as "N primarily total nitrogen weight per unit of biomass," which they considered to be "a positive currency common to both the plant and the herbivore."

In none of these more recent studies, however, is nutrient quality ever assessed in a rigorous manner. Purported tests of the idea that low nutritive quality can confer resistance against herbivores have completely ignored the tremendous chemical variability that exists among primary metabolites; that secondary chemicals, such as tannins, phenolics, or resins, may have antinutritive effects is almost beside the point. Plant nutritional quality in ecological studies is almost invariably measured as or equated with total protein (or, even less definitively, total nitrogen content) and water content (Scriber, 1984). While these values may well be correlated with herbivore performance, it is extremely unlikely that herbivores are capable of responding physiologically to "total nitrogen." Nitrogen is at best a surrogate for nutritional value (Simpson and Simpson, 1990) and, for nitrogen in particular, it can be argued that it is not at all the same currency as far as plants and herbivores are concerned, since plants take in nitrogen in forms that are completely unutilizable by herbivores. Even for plants, which can utilize atmospheric nitrogen with the assistance of symbiotic microbes, the form in which nitrogen enters the system affects its utilizability (Fitter and Hay, 1983). As for herbivores, the efficiency with which nitrogen can be utilized depends critically on the form in which it is ingested; free amino acids, for example, are for more readily utilized than are complex proteins (Cockfield, 1988) and ureides, frequently found in legumes symbiotically associated with nitrogen-fixing bacteria, are even less readily utilized by insects (Wilson and Stinner, 1984). Due to differential needs, the efficiency with which amino acids can be utilized depends critically on their relative abundance and proportional representation (Rock, 1972; Reese, 1979). As well, vitamins, carbohydrates, lipids, and a host of other synthesized materials are as important

as, if not more important than, nitrogen per se for insect nutrition. The hypothesis that plant primary metabolism can be influenced by herbivore selection pressure effectively remains untested.

TESTING THE HYPOTHESIS

That plant primary metabolites can confer resistance against herbivores, or, alternatively, that insect selection pressure can effect changes in the content and composition of plant primary metabolites, is an eminently testable hypothesis. In order to demonstrate that plant defense is a "raison d'être," as it were, for quantitative or qualitative variation in the production of particular primary metabolites, certain conditions must be met: (1) primary metabolite content must be variable among potential host plants; (2) variation in primary metabolite content must be at least partly genetically based and thus available for selection; and (3) plant fitness (reproductive success) in the presence of the herbivore must be associated in a predictable way with that genetically based primary metabolite variability (Haukioja et al., 1991).

If these three conditions are met, then the potential exists for insects, by differential herbivory, to effect changes in the content or composition of primary metabolites in their host plants. There is one other criterion to consider as well. Insect herbivores may act as selective agents on plant primary metabolism only indirectly if variation in the content of a particular primary metabolite is genetically correlated with variation in the content of a secondary metabolite, which is the trait under direct selection, for example. Direct selection can act efficiently on plant primary metabolites only if those metabolites are themselves responsible for a change in herbivore physiology or behavior that in turn alters plant fitness.

Although it may seem a daunting task to identify particular nutrients likely to respond to herbivore pressure, it is probably less daunting than identifying particular allelochemicals likely to respond to herbivore pressure, at least in part because there may be fewer primary metabolites of ecological relevance to insects in plants than there are secondary metabolites. According to Fraenkel (1969), "Thirty to forty such substances [necessary nutrients] (according to whether one counts the amino acids individually, and making allowance for the discovery of new factors) are involved in the nutrition of insects"; by contrast, essential oils of individual plants may contain hundreds of terpenoid and phenylpropanoid constituents (Guenther, 1948). The task may be simplified further because many phytophagous insects appear to have similar nutritional requirements. All phytophagous insects, for example, have an absolute sterol requirement, although there is variation in the extent to which different plant sterols can be utilized (Chapman, 1972; Grunwald and Kogan, 1981). Although carbohydrates occur in many forms throughout the plant kingdom, simple sugars

tend to be of greater importance for folivorous insects than are complex sugars or starches (Dadd, 1963). Although not universal by any means, the dietary requirement for ascorbic acid is practically a defining trait for phytophages, among other insects (as is the case in mammals, in which frugivorous species and other species with high dietary intakes of ascorbic acid have apparently lost the capacity to synthesize it). All insects also share a dietary requirement for unsaturated fatty acids, which, for phytophagous insects, is generally satisfied by unsaturated C_{18} fatty acids, particularly linolenic acid (Thompson, 1973).

Proteins and their constituent amino acids are among the primary metabolites most likely to be influenced by insect herbivory. The protein content and composition of plants are dramatically different from that of herbivores and, in fact, this difference is widely regarded as a major nutritional barrier to utilizing plant food (Hinton, 1976). Most phytophagous insects have an absolute requirement for the same 10 amino acids that are required by the vast majority of animal species: these are arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine (Chen, 1966). According to Chen (1966), some insects contain levels of amino acids upwards of 30 times higher than levels recorded from other animals. Why their amino acid demands are so great is unclear—amino acids appear to play a role in osmoregulation, in detoxification (e.g., conjugation with glycine for export), and in energy conservation. Certain activities may impose higher amino acid demands on certain insects, relative to other species. The parsnip webworm *Depressaria pastinacella*, for example, invests approximately 20% of its nitrogen intake into the production of a silken web. The amino acid composition of the silk is radically different from that of parsnip fruits, the principal food of the webworms; levels of glutamic acid, serine, and glycine in silk far exceed proportionately the levels in fruits. In turn, the composition of silk is radically different from that of the body of the webworm itself (Figure 1). The quantities of histidine, arginine, and methionine, all essential amino acids, are notably low

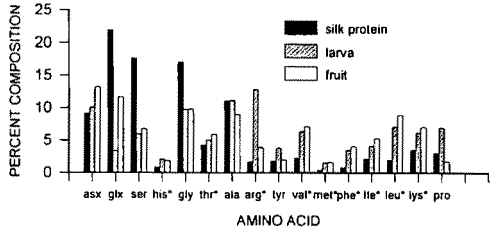

FIG. 1. Amino acid composition of parsnip webworm silk, webworm bodies with silk glands removed, and green fruits of wild parsnip. Amino acids essential for insects are marked with an asterisk (Rock, 1972).

in parsnip fruits relative to the amino acid profile of the webworm. While larval body contents may not necessarily reflect dietary needs, these disproportions between insect and plant proteins may impose a considerable nutritional stress on the insect and leave it vulnerable to deficiencies in its food plant.

The effects of variability in the amino acid composition of protein on plant suitability to insects have been demonstrated by Broadway and Duffey (1988), who found a 16-fold variation in larval weights of *Spodoptera exigua*, depending on the source of dietary protein. The most significant influence on larval growth rates was amino acid profile (in particular, the content of lysine + arginine and of sulfhydryl-containing amino acids). As storage molecules, many plant proteins appear to be effectively physiologically inactive—it is only when they are hydrolyzed to component amino acids that they enter into plant primary physiological processes (Mothes, 1980). It seems likely, then, that the amino acid composition of these storage proteins could vary among genotypes with little physiological impact on the plant. Moreover, genetic variations is known to exist for protein concentration (Moser and Frey, 1993; McFerson and Frey, 1991; Hansen et al., 1992; Sullivan and Bliss, 1983; Caradus, 1992) and composition (Axtell, 1981) and thus would potentially be available for selection by herbivores.

Evidence also exists that there is a predictable association between quantitative variation in amino acid content and plant resistance to insects in some systems. Maltais and Auclair (1957) demonstrated that *Pisum sativum* lines resistant to *Acyrtosiphon pisum* were 11.5–37.1% lower in amino acids and 16–47% higher in free sugars (such that the ratio of sugar to nitrogen in resistant lines was 23–64% higher, a critical factor for a phloem-feeding insect that relies on high throughput for extracting sufficient amounts of protein from a protein-poor food resource). Auclair et al. (1957) also demonstrated that amino acid content tended to be higher in susceptible varieties; Weibull (1994) showed that *Hordeum vulgare* resistance to *Rhopalosiphum padi* is associated with variation in glutamic acid content in the sense that low glutamic acid levels are associated with reduced aphid weights. Amino acid imbalance was also implicated by Janzen (1977) in the inability of *Callosbruchus maculatus* to thrive on diets high in tryptophan, cystine, and methionine, relative to levels in their normal host *Vigna unguiculata*. While these studies involve effectively sedentary specialists [stipulated by Moran and Hamilton (1980) as particularly prone to nutritional defenses], Waldbauer et al. (1984) have shown that in at least one more mobile species, *Heliothis* (=*Helicoverpa*) *zea*, insects can detect and respond to protein deficiencies in their diet by self-selection and avoidance of nutritionally inadequate food.

The content and composition of plant sugars appear to play an important role in resistance of plants to insects as well. In studies of Douglas fir, *Pseudotsuga menziesii*, resistance to *Choristoneura occidentalis*, Clancy (1992)

showed in artificial diet studies that optimal sugar concentrations were about 6% and survivorship actually declined when sugar levels exceeded this amount even slightly; natural levels range from 5.7 to 18.4%, thus potentially exceeding optimal concentrations by a large margin. Excess amounts of sugar may hinder growth because its processing diverts energy away from growth (Waldbauer et al., 1984). In this system, sugar composition plays a role as well; Zou and Cates (1994), upon noting that 78% of total sugar in Douglas fir was galactose, determined that 6% galactose increased mortality and decreased growth relative to comparable amounts of glucose and fructose in diets. Sugar content and composition are known to be under genetic control in certain crop plants (Simon et al., 1982, Freeman and Simon, 1983; Poehlman, 1979) and have been extensively modified by artificial selection (Stommel and Simon, 1989).

Of all plant primary constituents, vitamins are probably among the most variable in terms of distributive and quantity. Ascorbic acid content, for example, differs by an order of magnitude or more among cultivars of squash, peppers, tomatoes, muskmelons, apples, pears, and mangoes (Mozafar, 1994), and β-carotene varies by almost two orders of magnitude among varieties of carrots, sweet potato, and cassava (Mozafar, 1994). Many cases can be cited of successful breeding programs designed to increase the vitamin content of fruits or foliage of crop plants (Bittenbender and Kelly, 1988). There is at least one example of an association between vitamin content of plant tissue and susceptibility to an insect herbivore—ascorbic acid content of fruits is positively correlated with amount of damage inflicted by *Heliothis armigera* (Singh et al., 1982, cited in Mozafar, 1994)—and numerous other studies demonstrate an association between ascorbic acid content and resistance to microbial pathogens. Felton and Summers (1993) have cogently argued that ascorbate oxidase, a plant enzyme that can convert ascorbic acid into the unstable and potentially toxic oxidized derivative dehydro-L-ascorbic acid in the insect gut, is effectively a defense-related protein in that it renders ascorbic acid unusable by the insect as a dietary nutrient or antioxidant. Low levels of ascorbic acid in plant tissues, independent of the activity of ascorbate oxidase, may serve a similar defensive function. That phytophagous insects are capable of responding behaviorally as well as physiologically to vitamin imbalances in their food was demonstrated by Schiff et al. (1988), who showed that *Heliothis zea* larvae can self-select optimally between diets complete except for lipids or vitamins.

INTERACTIONS BETWEEN PRIMARY AND SECONDARY METABOLITES

In that a herbivorous insect almost inescapably ingests both primary and secondary metabolites when it feeds, the potential exists for toxicological and and physiological interactions between these classes of compounds. Examples

of mitigation of allelochemical toxicity by primary metabolites are numerous. High levels of protein, for example, can reduce the toxicity of trypsin inhibitors of glycoalkaloids (Slansky, 1992); antioxidants such as vitamins A, C, and E can reduce the phototoxicity of photosensitizing allelochemicals (Aucoin et al., 1990; Green and Berenbaum, 1994). Allelochemicals can also exacerbate the effects of low nutrient concentrations. Diet dilution can elicit compensatory feeding behavior, which in the presence of a toxin can lead to ingestion of a lethal dose (Slansky and Wheeler, 1992). In addition, the vitamin content of the diet can influence the detoxification capacity of an herbivore; in other systems, for example, there have been suggestions that vitamin C inhibits or otherwise alters metabolic transformations catalyzed by cytochrome P-450 (Sinclair et al., 1993; Suzuki et al., 1993), the principal enzyme system involved in insect detoxification of plant secondary metabolites (Brattsten, 1992).

BENEFITS AND COSTS OF NUTRIENT-BASED DEFENSE TO THE PLANT

One conceivable advantage to a plant of a defense system based on altered levels of plant primary metabolites is that autotoxicity may not pose as great a risk as it does in defense systems based on secondary metabolites. Secondary metabolites often target fundamental physiological processes, and, as such, absent a system for localization or sequestration, pose as much of a danger to the plants producing them as they do to insects consuming them. Presumably, systems for the rapid synthesis or degradation of primary metabolites are already in place to meet the physiological demands of the plant; such systems may require little modification to permit plants to store comparatively high levels of a nutrient that, if ingested by a herbivore, due to its differing physiological needs, could create a lethal nutritional imbalance. Nutritional defenses can be expected to arise most frequently in those cases in which the nutritional needs of plant and animal diverge most dramatically. Nutrient-based defenses would be unlikely to arise in developing seeds, for example. Developing seeds utilize plant nutrients in much the same way that heterotrophic organisms do, whereas photosynthetic source tissues can synthesize needed components. Indeed, seedling success in terms of competitive ability, growth rate, or germination rate is often correlated with nutrient content of the seed (Varis and George, 1985; Rahman and Goodman, 1983; Parrish and Bazzaz, 1985).

Even in those cases in which plant and animal nutritional requirements differ dramatically, plant nutrient content cannot decrease to such a point that plant function is impaired. Plants require proteins, lipids, carbohydrates, vitamins, and micronutrients to grow and reproduce, and reductions in the amounts of these constituents may compromise a plant's physiological capabilities at the same time they decrease attractiveness to herbivores. To date, there is abundant

evidence of the impact of quantitative variation in plant elemental nutrients such as nitrogen on photosynthesis (Field and Mooney, 1986; Sinclair and Horie, 1989) and seed phosphorus on seedling success (Austin and Longden, 1965; Bolland and Paynter, 1990; Zhang et al., 1990), but little information exists as to whether similar limitations exist with respect to primary metabolites synthesized by the plant.

All things considered, low nutrient value is unlikely to evolve as a defense under many, possibly even most, circumstances, and it is certainly unlikely to be selected for by herbivores that can compensate for low nutrient content by increasing consumption rates (in the absence of toxins) or by herbivores whose susceptibility to predators or pathogens is unaffected by growth rates or nutritional state. However, low nutrient value may well be selected for by highly oligophagous herbivores with physiological requirements for certain nutrients that differ dramatically from the requirements of their host plants or with limited mobility such that they must complete development on a single plant, or even a single plant part, with no opportunity to compensate for nutritional deficiencies by switching host plants. Primary metabolites acting as nutrients under these circumstances may be most effective in conferring resistance against herbivores in the presence of toxic secondary metabolites, in that such toxins may offset compensatory feeding responses by increasing toxicity as intake increases (Slansky and Wheeler, 1992). There are undoubtedly innumerable plant–insect relationships in which these conditions pertain, but in the absence of any systematic investigation of either the primary metabolite content of host plants or nutrient requirements of herbivores it is impossible to speculate whether nutrient-based defenses are rare or common.

APPLICATIONS

Demonstrations of the efficacy of nutrient-based defense have implications beyond theories of insect–plant interactions. There is currently tremendous interest in developing novel mechanisms to reduce pest problems in agroecosystems and at the same time reduce chemical inputs (both synthetic and natural) without reducing yields. Because humans do not feed exclusively on a single plant species for sustenance, as do many phytophagous insects, selective breeding for altered nutrient levels may lead to increased resistance to insects in the absence of chemical inputs with little or no adverse impact on human consumers (Slansky, 1990). This strategy has already been exploited in controlling pests of stored products that, because they are consumed by humans, are not ideally protected with synthetic organic insecticides. Prepared food, such as pudding mixes, have been formulated such that key vitamins, fatty acids, and other insect nutrients are in short supply; this strategy has proved successful in causing mortality of

flour beetles (Mansingh, 1981). Whether such a strategy will work under field conditions, for a suite of herbivores that may have differing nutrient requirements, remains to be seen.

Acknowledgments—I thank Arthur Zangerl for his considerable insights into all matters botanical as well as for comments on the manuscript and assistance with the figure. I also thank Francis Webster for the opportunity to contribute to this volume; this manuscript provides me with an opportunity to thank Robert Silverstein and John Simeone for a publication that has provided me with endless hours of thought-provoking and often utterly absorbing reading over the past 16 years. This work was supported by NSF DEB91-19162.

(Received February 14, 1995; accepted March 10, 1995)

Abstract—North American beaver (*Castor canadensis*) were observed to sniff from the water and make land visits to some synthetic chemical components of castoreum placed on experimental scent mounds (ESM). In previous analysis, the elicitation (presence/absence), completeness, and/or strength (number, duration) of these key responses served as separate measures of biological activity. In this paper, we used principal components analysis (PCA) to combine linearly six related measures of observed response and one index of overnight visitation calculated over all trials. The first principal component accounted for a majority of the variation and allowed ranking of the samples based on their composite bioactivity. A second PCA, based only on response trials (excluding trials with no responses), showed that responses to the synthetic samples, once elicited, did not vary greatly in completeness or strength. None of the samples evoked responses as complete or strong as the castoreum control. Castoreum also elicited more multiple land visits (repeated visits to the ESM by the same individual or by more than one family member) than the synthetic samples, indicating that an understanding of the castoreum chemosignal requires consideration of responses by the family unit, and not just the land visit by the initial responder.

Key Words—Beaver, *Castor canadensis*, castoreum, communication, neutral compounds, phenolic compounds, principal components, social odors, territory.

INTRODUCTION

The North American beaver (*Castor canadensis*) is a large, monogamous rodent that lives in family units. A beaver family typically consists of an adult pair and two to four offspring from two years of births (Bergerud and Miller, 1977; Novak, 1977; Svendsen, 1980b, 1989). Beaver are primarily nocturnal and are considered territorial. Through the construction of mud mounds marked with a chemically complex secretion from their castor sacs, called castoreum, beaver may advertise their defended area. This functional role for scent marking by beaver has been supported by two types of studies. First, resident beaver will destroy and often overmark scent marks from nonresident beaver (Hodgdon, 1978; Müller-Schwarze and Heckman, 1980; Svendsen, 1980a). Second, vacant beaver sites marked with castoreum by human researchers are colonized to a lesser degree than unmarked sites (Welsh and Müller-Schwarze, 1989). Thus, castoreum appears to play an important role in intraspecific communication between individuals from different family units. The roles that particular chemicals serve in this territorial signal are not understood.

The chemical composition of castoreum has been examined (Walbaum and Rosenthal, 1927; Stevens, 1943; Lederer, 1946, 1950; Valenta et al., 1960) but not in conjunction with biological investigations. In separate behavioral bioassays, progressive fractionation of castoreum evoked steadily decreasing responses from beaver (Müller-Schwarze et al., 1986). The phenolic and neutral components of castoreum elicited responses, but the amines and carboxylic acids did not (Svendsen and Huntsman, 1988). Recently, we initiated a combined study of the chemical make-up of these active fractions of castoreum (Tang et al., 1993, 1995) and the biological activity of the identified components (Müller-Schwarze and Houlihan, 1991; Schulte et al., 1994).

Our behavioral assay focuses on the response of resident beaver to foreign scent marks placed within their home site by humans. Resident beaver will sniff the experimental scent mound (ESM) from the water, go on land to the mound, and sniff it. Beaver may then reenter the water or paw at the mound, walk over it, and often deposit their own castor fluid on the ESM (Hodgdon, 1978; Bollinger, 1980; Müller-Schwarze and Heckman, 1980; Svendsen, 1980a; Houlihan, 1989; Schulte, 1993). Behavioral responses are composed of several stages (i.e., "sniff from water," land visit, overmarking), and vary in their likelihood of occurrence, as well as their duration, number of responses, and the number of beaver in a family that respond during one trial. Therefore, creating a single measure of biological activity by which to compare different chemical compounds and mixtures (broadly referred to as samples) is problematic. In a companion paper (Schulte et al., 1994), we presented the analysis of the individual measures of response to 10 different single compounds (nine phenolic compounds and one neutral compound, borneol) present in castoreum (Tang et al.,

1993, 1995) and 10 mixtures, composed of 4–26 compounds. Using these same data, we present the results and interpretation of our multivariate analysis of bioactivity.

Multivariate analyses have been used to study complex chemical communication systems (Smith et al., 1985; Natynczuk, 1990; Singer et al., 1992; Sunnerheim-Sjöberg and Hämäläinen, 1992). Our application involved creating one or two uncorrelated response variables from seven intercorrelated measures of beaver responses to synthetic chemical samples. These uncorrelated variables would provide a relative measure of overall bioactivity among the samples.

Our second objective in this study was to integrate repeated responses by one individual and responses by more than one animal of a social group into our measure of bioactivity. Social odors (or components thereof) that evoked repeated responses by one individual and/or responses by more than one member of the social unit may be particularly important elements for communication. Signals sent between social units may have both multiple senders and multiple recipients. For instance, beaver mounds may be marked by more than one family member (Hodgdon, 1978), and different age/sex classes of beaver may potentially receive this signal. Therefore, a measure of response made at the individual and the family level was incorporated into our data compilation.

METHODS AND MATERIALS

The field methods were described in detail in an earlier paper (Schulte et al., 1994) and are only summarized here. A more complete description is provided for the format of the data and statistical analyses.

Study Area, Field Procedures, and Chemical Samples. All bioassays were conducted during the months of May–September during 1989–1992 at 16–20 beaver sites each year in Allegany State Park, Cattaraugus County, New York State. The beaver population at Allegany State Park has been unharvested for 20 years. The average number of beavers per site over the four years was 5.5 (SD = 2.9). Beavers have been live-trapped, ear-tagged, and observed since 1985. Captured beavers were sedated; sexed; ear-tagged; weighed; measured for body length, girth, and appendage dimensions; and assigned to an age class (adult, 2-year-old, 1-year-old, kit) based on their weight and size. As of spring 1992, 245 beavers had been processed and individually marked using this procedure. During observations, untagged beavers were identified by distinguishing physical marks and assigned to an age class based upon their relative size.

Over the four years of field bioassays, 10 different single compounds (one at four concentrations) and 10 different mixtures of compounds (three at two concentrations) were tested for biological activity. Each of these compounds has been identified as a major component of castoreum (Tang et al., 1993, 1995).

The chemical identity of single compounds, concentration assayed, and composition of mixtures are shown in Table 1. The ratio of compounds in mixtures was based on their ratio in a sample of 16 pooled, male beaver castor sacs (Tang et al., 1993). Ethanol was used as the solvent for all samples. An experimental scent mound (ESM) was constructed (30 cm diameter, 10 cm high) approximately 50 cm from water's edge using mud from the pond bottom. A size 18 cork was placed in the center of the mound, and the sample was applied to the cork with a disposable pipe. As done by Svendsen (1980a), half a tongue depressor (applicator) was placed adjacent to the cork in order to detect subtle disturbances to the mound overnight. The placement of the applicator does not interfere with beaver inspecting or re-marking the mound. Observations began immediately after building the ESM at approximately 17:00 hr and ended with fading daylight (20:00 to 21:30 hr except in September 1989, 19:00–20:00 hr). The behaviors of all beavers were recorded continuously with a Tandy 102 portable computer. When one or more beavers approached the sample, observations were focused on these individuals. The responses by beaver to a single ESM with one applied sample were observed such that a trial was equivalent to a single-day, single-site assay. Each sample was tested at 8–16 different beaver sites in a given year.

Except for the neutral compound, borneol, and the controls, all tested compounds were phenolics. Castoreum was presented either dissolved in ethanol (1989) or in a dried, ground form known as quill (1990–1992). Responses to these two forms of castoreum did not differ significantly. A control using ethanol only on the ESM was included each year. Blank ESMs with no sample applied were used as an additional control in 1991 and 1992.

In addition to direct observations, the ESM was checked the next morning for signs of visitation during the night, then removed and destroyed. These signs were divided into four categories as follows: (1) intact; (2) paw prints on an otherwise undisturbed ESM; (3) scratch marks, displacement of the applicator, or removal of the cork; and (4) flattening of, or fresh castoreum odor on the mound. For the purposes of data analysis, a trial was assigned to only the category of most complete response. Except when overmarked with castoreum by beaver, the observer could detect the sample's odor on the cork during this inspection.

Measures of Response. Sniffing from the water and land visits were measured in three ways: response elicitation (yes or no), completeness, and strength. A complete response was defined as a flattening/overmarking of the ESM and numerically assessed by determining the proportion of trials in which a complete response was observed for each sample. Response strength was measured by the duration and number of responses and proportion of beavers responding. In 68% of the trials, the beaver did not respond at all, even though they passed near the samples. This high percentage of zero values affects the measures of completeness and strength of sniffing and land visits. Since many zero values

TABLE 1. CONTROLS AND SYNTHETIC SAMPLES FROM BEAVER CASTOREUM, ABBREVIATIONS, AND ASSAY YEAR AT BEAVER SITES IN ALLEGANY STATE PARK, NEW YORK, 1989–1992

	Name	Abbreviation	Assay year
A.	Single compounds (mg/trial)	s

C.	Controls	c	
	Castoreum (expected maximum response)	CA	1989–1992
	Ethanol (expected minimum response)	OH	1989–1992
	Blank (no applied odor)	BL	1991;1992

[a] Assayed amounts of mixtures were 1/30 gland equivalents, except for three fivefold concentrates, with the ratio of compounds based on those in 16 pooled, male castor sacs (Tang et al., 1993).

[b] The 12 neutral compounds were borneol, benzaldehyde, benzyl alcohol, 6-methyl-1-heptanol, *trans*- and *cis*-linalool oxide, 4,6-dimenthylheptane-1-ol, *trans*-pinocarveol, isopinocamphone, verbenone, (1*R*)-myrtenol, and 3,4-dimethyoxy-acetophenone.

not only lower the means for the responses, but also result in means that primarily reflect elicitation, we analyzed the data first with, and then without, the "no response" trials. For instance, in a hypothetical example, if a sample was assayed for 16 trials and in 10 trials beaver did not respond, then $N_1 = 16$ (all trials) and $N_2 = 6$ (only trials with responses).

In 1992 beavers passed within 5 m of the ESM in 58.6% of the no-response trials. Within this distance directed sniffing towards the ESM was easily observed when it occurred. The lack of sniffing or land visits for these trials appeared to indicate true absence of a response. In 20.7% of the trials, the ESM was less than 15 m from the active lodge under favorable weather and wind conditions for detection by beavers. Hence, in at least 79% of the trials with no responses in 1992 beavers probably could detect the odor source, but failed to respond to it visibly. Distance of detection will vary depending on wind direction, velocity, humidity, and other factors.

Format of Data and Statistical Analysis. We used six response measures from the observations and an index of response completeness for the overnight visitation data. Two types of responses were observed: sniffs from the water that were directed towards and within 5 m of the ESM, and land visits to the ESM. Three response variables for each response type were generated: average duration and average number of responses per trial, and the proportion of the total number observed of beaver responding. Only land visit durations from the first beaver visit per trial were used for the analysis. This was done because scent deposition by the first beaver may affect the likelihood or duration of response by subsequent beavers. The average response per trial was calculated for all six measures, first for all trials, then for only those samples and only those trials with a response (sniff from the water, land visit, or both). In addition, two overnight indices were generated: The first is the proportion of trials with any overnight response for each sample (overnight index 1). The second overnight index was the proportion of trials with overnight visits in which the ESM was flattened/overmarked, representing a complete land visit response (overnight index 2).

To create a single, relative measure of bioactivity, principal components analysis (PCA) was utilized. PCA does not test hypotheses, but it can be used to reduce multiple independent variables to one or a small set of variables (Dunteman, 1989). A first PCA used the mean responses to each sample for the three sniff-from-water and three land-visit variables for all trials along with overnight index 1. The mean of each response variable for each sample was used to prevent confounding of the within- and between-group variation (James and McCulloch, 1990). This PCA included all of the samples assayed. The responses to each control (castoreum, ethanol, blank) were combined across years. The four concentrations of 4-ethylphenol tested in 1990 were treated as one sample (EH, Table 1) because previous analysis indicated no significant

differences among the concentrations (Schulte et al., 1994). A second PCA was performed using only those samples that evoked sniffs from the water, observed land visits, and/or flattening/overmarking of the ESM during overnight land visits (index 2) in at least one trial each. Only 17 samples fulfilled this criterion. Plots of the first two principal components for each PCA were made to spatially separate samples based on their relative bioactivities.

Because beaver live in family units, responses at the level of the social unit were measured as "observed multiple land visits." A multiple visit occurred when: (1) one beaver visited an ESM more than one time, or (2) more than one beaver visited an ESM in a single trial. A contingency table was formed from a subset of these data. These categories are not mutually exclusive, and the number of times both types of multiple visits occurred during a single trial was also tabulated.

The Statistical Analysis System (SAS, Cary, North Carolina) and the BIOM Package of statistical programs (Rohlf, 1987) were used for all data analyses.

RESULTS

Responses to All Samples for All Trials. The principal components analysis successfully reduced the number of response variables conducive to characterizing the general bioactivity of the samples. The proportion of trials with an overnight land visit (index 1), the three sniff-from-water and the three observed-land-visit variables were linearly combined to yield a first principal component that accounted for 75% of the variation in the data (Table 2). The correlation of the response variables with the first principal component (the component loading) was high for each variable. Therefore, principal component 1 may be interpreted as a general measure of response. The second component, accounting for 12.6% of the variation, contrasted sniff duration and number with the observed land visits.

The relative bioactivity of the samples can be determined by comparing the distribution of samples along the first component axis (Figure 1). Note that the scales of the two axes are not identical and the position of the samples along the first component is the most relevant in terms of bioactivity. As expected, the castoreum control has the largest positive value (high activity) along component 1. The ethanol and blank ESMs, along with several other samples, are positioned toward the negative (low activity) end of component 1. The 26-compound mixtures (5P5N and PN) and the high concentrations of the 14-phenolics (5P) and 12-neutrals (5N) mixtures are somewhat separate from the other samples along component 1. A second group is evident, comprised of the lower concentration of the 14 phenolics (P91; P92) and 14 neutrals (N), a four (FP) and a six (SP) phenolic mixture, and two single compounds, 4-ethylphenol

TABLE 2. PRINCIPAL COMPONENT ANALYSIS OF CONTROLS AND SYNTHETIC SAMPLES KNOWN FROM BEAVER CASTOREUM FOR ALL TRIALS (RESPONSE AND NO RESPONSE): LOADINGS AND CUMULATIVE PERCENT VARIANCE EXPLAINED[a]

Variables	PC 1	PC 2
Overnight index 1	0.78	0.25
Sniff		
Duration	0.84	0.37
Number	0.81	0.46
Response proportion	0.92	0.17
Land visit		
Duration (first)	0.90	−0.35
Number	0.90	−0.38
Response proportion	0.89	−0.41
Cumulative variation (%)	75.0	87.6

[a]Only two factors were retained by the mineigen criterion in SAS. Principal component 1 (PC 1) correlates positively and highly with all the response variables and is interpreted as an index of responsiveness [PC 1 = response (+) to no response (−)]. PC 2 contrasts "sniff from water" number and duration (+) with the observed land visit responses (−). A plot of the first two canonical variables is shown in Figure 1. The response variables are described in the text.

(EP) and 4-methylguaiacol (MG). The remaining samples are rather tightly grouped, although their positions along the first component would permit a linear ranking based on overall bioactivity. The spread among the samples along the second principal component is exaggerated in Figure 1 because of the scale, but sniffing from the water relative to low levels of observed land visits was most prevalent to the six-phenol (SP) mixture and 4-ethylphenol (EP).

Responses to 17 Samples for Response Trials Only. In an attempt to rank the samples based upon the strength (observed variables) and completeness (overnight index 2) of the elicited responses, a second PCA was performed using means calculated from response trials only (Figure 2).

Of extreme interest is that of the original 32 samples, only 17 elicited sniffing from the water, observed land visits, and overnight flattening/overmarking of the ESM in at least one trial (but not necessarily the same trial). Most of the retained samples are positioned to the right (more active) of the dropped samples along component 1 in Figure 1 (retained samples are demarcated by an asterisk in Figure 1). For instance, the blank (BL) mounds never elicited an overnight visitation in 29 trials over two years. While the ethanol (OH) control did elicit all three types of responses, these never occurred together during the same trial or even in the same year.

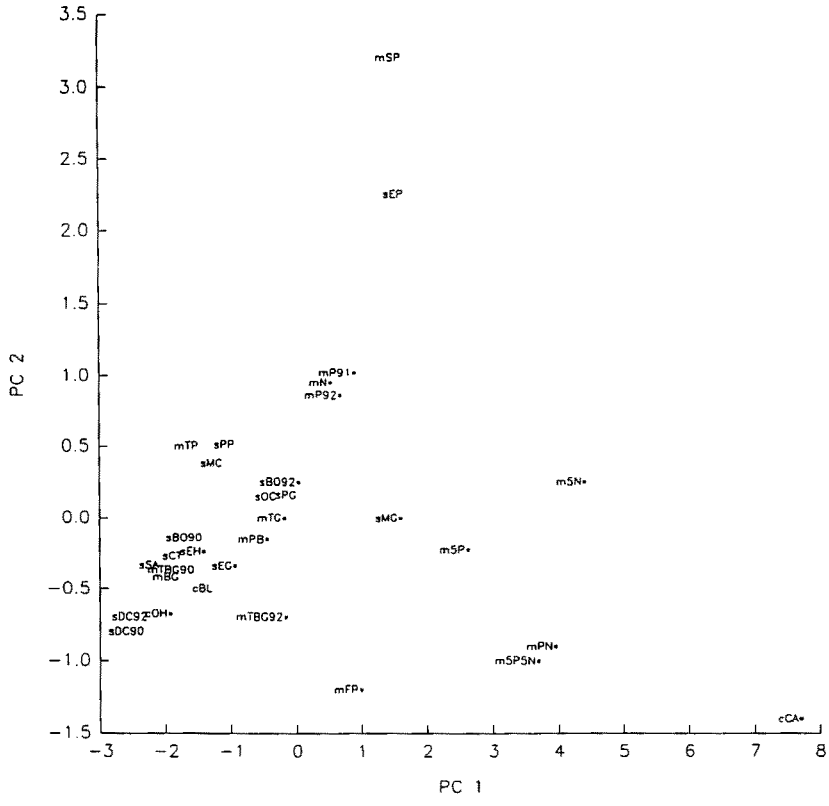

FIG. 1. Plot of first two principal component canonical variables: controls and synthetic compounds and mixtures, 1989–1992, all trials. The location of each sample is at the center of its abbreviation (see Table 1 for key to abbreviations of samples). The lowercase letter (s = single compound; m = mixture; c = control) designates the type of sample. The asterisk demarcates those samples that met the response criterion and were retained for the second PCA (Figure 2). Principal component 1 (PC 1) correlates positively with all seven response variables and represents an index of responsiveness. PC 2 contrasts sniff from water number and duration (+) with the observed land visit responses (−) (Table 2).

PCA was performed with the 17 samples that satisfied the response requirement. The six observed response variables and the values from overnight index 2 were linearly combined to yield seven principal components. The first two components accounted for 60.5% of the variation in the data (Table 3). The third component explained an additional 12.7% of the variation, but only two

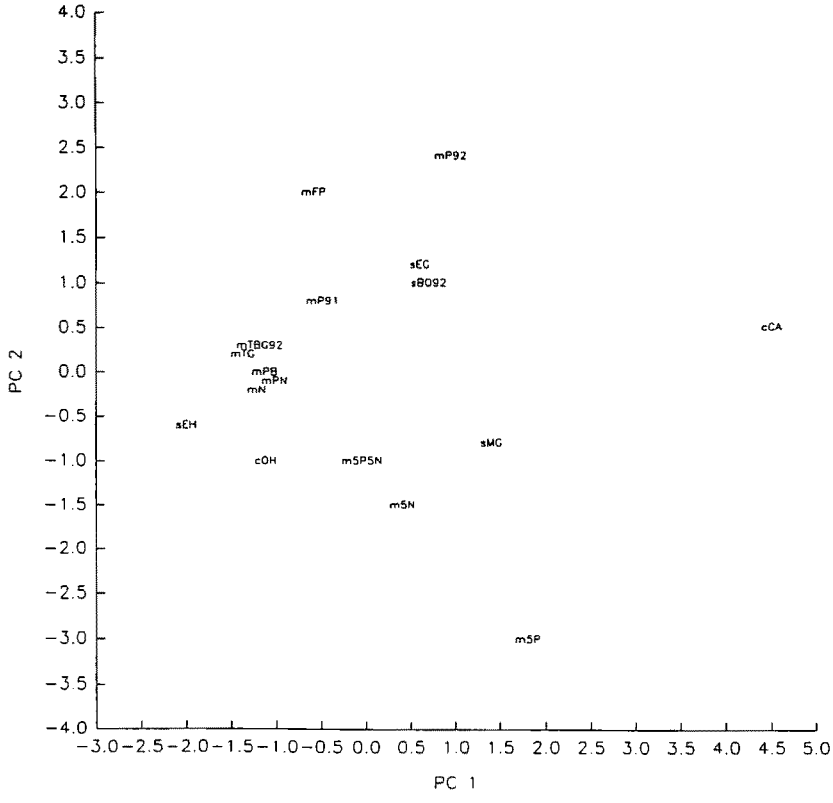

FIG. 2. Plot of first two principal component canonical variables: controls and synthetic compounds and mixtures, 1989–1992, response trials only. The location of each sample is at the center of its abbreviation (see Table 1 for key to abbreviations of samples). The lowercase letter (s = single compound; m = mixture; c = control) designates the type of sample. Principal component 1 (PC 1) correlates positively with all seven response variables and represents an index of response strength. PC 2 contrasts sniff from water proportion and overnight visitation (+) with the observed land visit duration and number and with sniff duration (−) (Table 3).

components were retained using the mineigen criterion in SAS. The correlations between the components and the response variables (loadings) permitted interpretation of the components. Principal component 1 was positively correlated with all of the response variables, especially the six observed measures (Table 3). This axis can be interpreted as an index of response strength, from weak to strong. Component 2 contrasts overnight visitation and the proportion of beaver

TABLE 3. PRINCIPAL COMPONENT ANALYSIS OF ONLY THOSE CONTROLS AND SYNTHETIC SAMPLES KNOWN FROM BEAVER CASTOREUM THAT ELICITED SNIFF, LAND VISIT, AND OVERNIGHT RESPONSES: LOADINGS AND CUMULATIVE PERCENT VARIANCE EXPLAINED[a]

Variables	PC 1	PC 2
Overnight index 2	0.12	0.67
Sniff		
Duration	0.55	−0.40
Number	0.59	0.29
Response proportion	0.46	0.68
LV		
Duration (first)	0.64	−0.52
Number	0.77	−0.42
Response proportion	0.78	0.39
Cumulative variation (%)	35.5	60.5

[a]Two components were retained based on the mineigen criterion in SAS. Principal component 1 (PC 1) correlates positively with all the response variables and represents a continuum of response strength from weak to strong. PC 2 contrasts overnight flattening/overmarking of the ESM and sniff proportion (+) with land-visit duration and number and with sniff duration (−). A plot of the first two canonical variables is shown in Figure 2. The response variables are described in the text.

that sniffed from the water (+) with land visit duration and number, and sniff duration (−). Of importance in this second PCA is the comparably low percentage of variation explained by only two components (60.5% vs. 87.6% in the first PCA) and the more even contribution of both the first (35.5%) and second (25%) components in explaining this variation.

The spatial distribution of the samples along these two components is shown in Figure 2. The castoreum control was distinct from all the samples along component 1, the index of response strength, and centered along component 2. Many of the less-active samples (OH, EH, TG, TBG92, PB), as determined from their location on component 1 in Figure 1, are located toward the less active (−) end of component 1 in Figure 2. However, the lower concentration of the 26-compound mixture (PN) and the 12-compound neutral mixture (N) are grouped with these largely inactive samples in Figure 2. The high concentration of the 26-compound mixture (5P5N) is spatially quite distant from castoreum (CA) in Figure 2 compared to Figure 1.

Multiple Land Visits. Most samples were visited only once per trial (Table 4). Beavers that visited the ESM treated with castoreum returned to the ESM in 15 of all 45 trials (33.3%), and in 15 of the 28 trials (53.6%) with an

TABLE 4. MULTIPLE OBSERVED LAND VISITS (LV) TO ESM BY BEAVER AT ALLEGANY STATE PARK IN FIELD BIOASSAYS OF CONTROLS AND SYNTHETIC SAMPLES KNOWN FROM BEAVER CASTOREUM[a]

m5P5N	1	2	1	22.2 (9)
cCA	15	20	13	48.9 (45)

[a]The values in columns 2–4 are number of trials. The values in the final column are percentages with the total number of trials for that row given in parentheses. Multiple visits occurred when one beaver visited the ESM more than one time (exit water to ESM, visit ESM, reenter water = one visit), or more than one beaver visited the ESM during the course of observations. The columns are not mutually exclusive and the final column's values may be greater than any value in the other columns (e.g., cCA 22/45 trials = 48.9%).

[b]Abbreviations explained in Table 1, where prefix s = single compound; m = mixture; c = control.

[c]SGA = all single compounds assayed (see Table 1), except those listed separately in this table.

[d]MXA = all mixtures assayed (see Table 1), except those listed separately in this table.

observed-land-visit response. The high concentration of the mixture of 14 phenolics (5P) had the next greatest "multiple visits by one beaver" value (22.2%, two of nine trials, but 66.7% of those with a land-visit response). Only two other samples, both mixtures (5P5N and 5N) and in both of these the higher of the two concentrations assayed, were revisited by the first beaver to make a land visit. In 20 trials at least two different beavers visited the castoreum ESM (44.4% of all trials and 71.4% of trials with land visit responses). Only two single compounds, 4-methylguaiacol and borneol, and six mixtures received visits by more than one beaver in a single trial. For castoreum, both types of multiple visits were recorded in 13 of 45 total trials (28.9%) and 46.4% of trials with a land visit. The three high concentrations of the mixtures (5N, 5P, and

5P5N) had one trial each of both types of multiple visits (11.1%). These were the only samples to have both types of multiple visits occur in the same trial.

DISCUSSION

Principal components analysis can be utilized to provide an overall picture of relative bioactivity of single compounds present in castoreum and their mixtures. The two PCAs performed in this study revealed important differences in the spatial distributions of the samples. When all trials (and all samples) were included in the analysis, the mean values for the six observed response measures were heavily weighted by the absence of responses (numeric value of zero). For many samples, there were no observed responses in a majority of the trials. Thus, the individual response measures, such as mean duration of first land visits, were influenced greatly by whether land visits were elicited at all. Yet, using the mean values, PCA provided a reasonable separation of the samples based upon their position along the first principal component (Figure 1), which was positively correlated with all of the response measures (Table 2). By evaluating only those trials in which responses were recorded, the sniff-from-water and land-visit variables now reflected response strength. Stronger responses were defined as those that lasted longer, occurred in greater number, and by a larger proportion of the beaver in the family. In the second PCA (Table 3), the first component is still an indicator of responsiveness, but it accounts for much less of the variation in the data than in the first PCA. The spatial distribution of the samples in this plot of the first two components (Figure 2) cannot be as easily interpreted in terms of their bioactivity.

Our previous analysis (Schulte et al., 1994) revealed that the 26-compound mixture elicited responses similar in completeness, yet weaker, and evoked less often than responses to castoreum; in general, mixtures elicited greater responsiveness than single compounds. This trend may be illustrated by comparing the presence/absence of mixtures and single compounds and their spatial positions in Figures 1 and 2.

The implication from the results of principal components analysis is that particular chemicals (and possibly mixtures relative to single compounds) may influence the likelihood of a beaver responding more than they affect the extent of the response elicited. A probable explanation is that single compounds or mixtures of interest to beaver trigger an investigatory response that shows little variation (the ethological notion of "typical intensity"). Only when more complete cues are available, such as from the castoreum control, are longer or more elaborate responses evoked. Therefore, it appears reasonable to examine separately and together the elicitation of general responses (e.g., land visits), the completeness of that response (sniff the ESM, paw, overmark), and the strength

of response (duration, number, proportion of beaver visiting). Here, we have attempted to combine these various measures of bioactivity, while in a companion paper we dealt with them separately (Schulte et al., 1994). Clearly, the operational definition of bioactivity is critical to its evaluation. Bioactivity, as defined by the likelihood of eliciting a response (see Figure 1), may differ from activity determined from the strength of the response (see Figure 2).

A further consideration in investigating the chemically complex structure of many mammalian chemosignals is targeting the key behaviors in the bioassay. For beaver, responses have been measured primarily at the level of the individual, and generally only the first response by an individual (Hodgdon, 1978; Svendsen and Huntsman, 1988; Müller-Schwarze and Houlihan, 1991). By also looking at repeated land visits by the same individual and land visits by the entire beaver family, we were able to evaluate the bioactivity of chemical components of castoreum. Multiple visits to any one sample were never observed in more than 25% of the trials. However, multiple visits to castoreum were observed in 49% of the trials. Thus, the synthetic samples, even the 26-compound mixture, appeared to lack components that would evoke a strong family-level response. Only the fivefold higher concentrations of the three mixtures elicited both types of multiple visits within a single trial (once each). A more thorough study of the effect of concentration of mixtures on the responsiveness of beaver is currently being planned.

Interestingly, multiple visits do not parallel ESM destruction or overmarking during the first visit. Beavers may overmark foreign, their own, or other family members' scent marks to eliminate the scent, to freshen the odor, or to create a family scent (Hodgdon, 1978; Houlihan, 1989). Other possibilities may also exist. In response to the ESM, once a resident beaver obliterated and/or overmarked the foreign scent, the ESM became another resident scent mound. If this stimulated further land visits by the same or other beaver, an endless succession of land visits could theoretically follow. This system apparently does operate in wolves (*Canis lupus*). In some situations fresh scent marks stimulated re-marking at greater rates than older marks (Mech and Peters, 1977).

Additional land visits by beavers, or re-marking by wolves, may be in response to the first visitor's behaviors and not the sample or scent mark's odor. Multiple land visits were not examined by Hodgdon (1978) based on this reasoning. In the current study, flattening or overmarking of the castoreum-marked ESM was observed in nine of the 22 trials with multiple visits. For the eight synthetic samples that elicited multiple visits (Table 4), flattening or overmarking was observed in six of the 12 trials with multiple visits. For the synthetic samples and castoreum, repeated land visits occurred even in the absence of overmarking or flattening of the ESM during the first land visit. This does not prove that family members are not responding to the ESM as a result of the first

beaver's visit, but they are certainly not always responding to a scent mark deposited by this first visitor.

Furthermore, flattening/overmarking of the ESM often transpired during an ensuing land visit. For castoreum, flattening/overmarking was observed in only nine of 28 trials with observed land visits. In another eight of these trials and in six trials in which land visits were not observed, the ESM was eventually flattened/overmarked. Why is scent marking not an immediate but commonly an eventual outcome when a beaver visits a foreign castoreum scent?

Two related explanations are offered. Following a land visit to the castoreum ESM, a beaver usually appeared excited. Typically, this individual would begin to swim rapidly around the perimeter of the pond (termed patrolling behavior). The beaver would usually be lost from view during much of this activity. Upon reappearance, the beaver would often revisit the ESM in a very directed manner. The beaver may have been searching for further signs of an intruder before overmarking the scent. A second possibility, not mutually exclusive of the first, may explain visits by additional beavers. Leaving the foreign scent intact, until other members of the family have investigated it, may be advantageous. This may alert the entire family to a stranger's presence and "identity." Scent matching (Gosling, 1982, 1986, 1990) could then occur if the strange beaver were encountered.

Thus, a scent mark by a social mammal may truly be a social odor both in its creation and its intended addresses. In the case of beavers, an appropriate measure of scent response behavior (and thus bioactivity) should be determined at the individual and family level, as was done in this study. This may be relevant in investigations of other mammalian social odors.

In cases where social behavior is regulated by chemical cues, it has to be determined whether species-wide compounds control specific responses, or multicomponent odor images (Albone, 1984) characterize individuals. The former are the traditional "pheromones," while the latter serve in recognition and scent matching. These alternatives may not be mutually exclusive. The chemical images in the secretions of social mammals may contain functional pheromones. Information about the individual may modify an otherwise typical response to a pheromone. Wilson (1975), in discussing the numerous substances found in the castoreum of beavers, stated, "although no behavioral function has yet been demonstrated, it is likely that a deliberate testing of the idea will reveal some of the substances to be pheromones" (p. 188). The continued research on the composition of beaver scent marks and the elicited responses may assist in the general understanding of signal structure in mammalian chemical communication.

Acknowledgments—We thank the management and staff of Allegany State Park for their cooperation in our study. Thanks go to P. Houlihan and C. Sack for the creation and modification

of the behavioral recording and analysis programs. K. Bakinsky, T. Brockway, C. Calamita, S. Heerkens, M. Marion, J. Orlowski, M. Rehberg, R. Robichaud, C. Rubeck, D. Schulte, B. Speicher, L. Sun, and T. Schwender assisted with the field research. Gratitude is extended to Drs. L.E.L. Rasmussen, S.V. Stehman, and L.L. Wolfe for their critical evaluations of the research design, statistical analyses, and manuscript. SUNY College of Environmental Science and Forestry furnished a field camp at Allegany State Park. Support for this research was provided by National Science Foundation grant BNS-8819981 to D.M.S. and F.X.W., and a grant to B.A.S. from the Theodore Roosevelt Fund.

PHEROMONE-MEDIATED MATING IN THE APHID PARASITOID, *Aphidius nigripes* (HYMENOPTERA: APHIDIDAE)

JEREMY N. McNEIL[1,*] and JACQUES BRODEUR[2]

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Mating in the aphid parasitoid, *Aphidius nigripes*, is mediated by a female sex pheromone that stimulates both upwind flight and courtship behavior by males. There is no evidence of any overt behavior associated with the release of the pheromone, but bioassay results, using female extracts, suggest that the pheromone is produced in the abdomen, although it may be actively released from the entire body surface. Age does not appear to have a major influence on either pheromone production by the female or on male responsiveness. However, field data suggest the presence of a strong diel periodicity in the emission of and/or receptivity to the pheromone. Laboratory bioassay results indicated diel changes in the male response but more refined techniques are needed to determine if such periodicity exists in pheromone production by females. Following mating, female pheromone production is significantly reduced. The potential use of the parasitoid sex pheromone in integrated management of aphids is discussed.

Key Words—Aphid parasitoid, pheromone, mating.

INTRODUCTION

Mackauer and Völkl (1993) postulated that the inefficacy of primary aphid parasitoids is, to a large extent, associated with certain aspects of their foraging behavior. If true, then the rational deployment of infochemicals that modify foraging offers a possible approach for increasing the impact of aphid parasitoids on host densities. There are several avenues of aphid parasitoid chemical ecology

*To whom correspondence should be addressed.

0098-0331/95/0700-0959$07.50/0 © 1995 Plenum Publishing Corporation

that could be exploited from a multitrophic perspective, particularly with respect to establishing parasitoid populations in agroecosystems early in the growing season before the pest populations become well established (Pickett et al., 1991; Lilley et al., 1994). Infochemicals of plant origin may have a significant impact on parasitoid foraging behavior (Vet and Dicke, 1992; Tumlinson et al., 1993), and there is evidence that this is the case for aphid parasitoids (Powell and Wright, 1992; Hardie et al., 1994; Pettersson et al., 1994). At the level of the herbivore, both aphid honeydew and the aphid sex pheromone may serve as kairomones for parasitoids (Bouchard and Cloutier, 1984, 1985; Budenberg, 1990; Hardie et al., 1991, 1994a; Budenberg et al., 1992; Powell et al., 1993; Lilley et al., 1994).

Aphidius nigripes (Ashmead), the most abundant of the parasitoids attacking the potato aphid, *Macrosiphum euphorbiae* (Thomas) in northeastern North America is not considered to have a significant impact on the density of its host (Shands et al., 1965) despite having many attributes of an effective biological control agent (Cloutier et al., 1981). Host–parasitoid asynchrony was proposed as an explanation for the low impact of *A. nigripes*, based on the assumptions that the parasitoid was unable to overwinter and immigrants arrived after the aphid populations had already become well established in the potato ecosystem (Spencer, 1926; Shands et al., 1965). However, recent research has clearly shown that *A. nigripes* enters diapause as a prepupa and is well adapted to survive the prevailing weather conditions in Québec, Canada (Brodeur and McNeil, 1989, 1994a). Furthermore, both parasitoid and host colonize potato fields at the same time in spring (Brodeur and McNeil, 1994a), indicating that asynchrony is really not a plausible explanation for the low impact that *A. nigripes* has on *M. euphorbiae*. More probable causes relate to parasitoid foraging and/or the levels of hyperparasitism (see Brodeur and McNeil, 1994b).

An interdisciplinary project on the chemical ecology of this multitrophic system has been initiated to determine the feasibility of using different infochemicals to increase the efficacy of *A. nigripes*. There is clear evidence that aphid honeydew influences *A. nigripes* female foraging behavior (Bouchard and Cloutier, 1984, 1985), and these studies, together with the work of Brodeur and McNeil (1994a), have demonstrated the existence of a female parasitoid sex pheromone. In the present paper we present a description of *A. nigripes* mating behavior, together with data from laboratory and field experiments examining certain aspects of female pheromone production and male receptivity. This work is the first step towards the identification of the female sex pheromone, which may be used to monitor parasitoid populations (Brodeur and McNeil, 1994a), attract males into the agroecosystem, and possibly modify foraging behavior if, as in certain Lepidoptera (Palaniswamy and Seabrook, 1978; Noguchi and Tamaki, 1985), females are able to detect and react to the pheromone of conspecifics.

METHODS AND MATERIALS

All insects used in these experiments were from laboratory colonies, established and renewed annually using *M. euphorbiae* and *A. nigripes* collected from commercial potato fields near Québec City. Aphids, kept on Norland variety potato seedlings, and parasitoids were reared at 20 ± 1°C, 60 ± 10% relative humidity under a 16L:8D photoperiod. The *A. nigripes* used in the experiments were obtained by exposing potato plants, infested with third-instar aphid nymphs, to parasitoids for a 24-hr period. Mummies were collected and held in individual gelatin capsules so that all adults were virgins, of known age, and, in the case of males, naive with respect to the female sex pheromone.

In order to eliminate any visual effects in pheromone bioassays, 1 μl of a methylene chloride extract of individual virgin females was applied to a 0.38-cm^2 filter paper disk, air dried for 20 sec to allow the solvent to evaporate, and then introduced into a 8-dram shell vial containing one virgin male. Two variables were measured in all laboratory experiments: the proportion of males that respond and the time that receptive males take to respond to the stimulus. Males were considered responsive if there was evidence of rapid wing-fanning (the first step in the courtship behavior) within 60 sec following the introduction of the disk. Unless otherwise stated, each extract was obtained by soaking an individual 0- to 24-hr-old virgin female in 100 μl of methylene chloride and testing 1 μl [0.01 female equivalent (FE)] on a minimum of 20 virgin, naive, 24-to-48-hr-old males during the first 3 hr of the photophase. Room temperature remained at 20–22°C for all experiments. Newly emerged females were used for extracts, as all previous laboratory observations showed that females generally mate soon after emergence, shortly after the onset of the photophase.

The first experiments were carried out to determine optimal extraction time by soaking one female in 100 μl of methylene chloride for periods of 10–600 sec. The highest response, and the shortest reaction time, was observed with 480-sec extracts (Figure 1), and all subsequent experiments were carried out using this extraction time.

Laboratory Work. A description of *A. nigripes* mating behavior was obtained by continuous observations of individual couples, comprised of virgin adults 0 to 48 hr old, held in #000 gelatin capsules. The duration of different components of the mating sequence were also obtained.

To determine if the pheromone originated from a specific zone or was released from the entire body, newly emerged females were sectioned, and extracts obtained from the head/thorax and abdomen were tested. Three replicates were carried out.

Variability in pheromone production by different individuals was examined by testing the level of response of males to the extracts of 15 different 0 to 24-hr-old virgin female extracts.

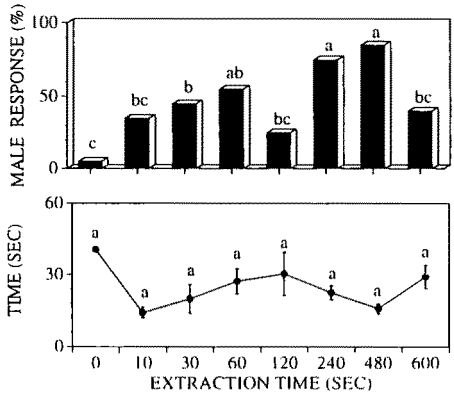

FIG. 1. The effect of extraction time on the proportion of *Aphidius nigripes* males responding and the reaction time of responding males to an 1-μl (0.01 FE) methylene chloride extract of 0- to 24-hr-old virgin females.

The diel periodicity of pheromone emission and/or male receptivity was examined by extracting 0 to 24-hr-old females 1 hr (09:00) and 7 hr (15:00) after the onset of the photophase. In this experiment, in contrast to all others, we used three females to obtain each extract, thereby minimizing any effect of individual variability in pheromone content. However, as in all other cases, bioassays were carried out using 0.01 FE. These times of extraction were chosen as copulations are most frequently observed soon after the lights-on signal. Each extract was tested at both hours of extraction, giving four combinations. Extracts to be tested at times other than at the actual hour of extraction were kept at −20°C until required.

The effect of female age on pheromone production was evaluated using extracts of individual 0-, 2-, 4-, 6-, 8-, 10-, and 12-day-old virgin females. A similar experiment was carried out to test the effect of age on male responsiveness to a female pheromone extract. Twenty 0-, 2-, 4-, 6-, 8-, and 10-day-old virgin males were tested using a 0.01-FE extract obtained from three 0- to 24-hr-old females. In the interval between emergence and time of extraction (females) or testing (males), individuals were held in isolated cages and provided 20% sugar water daily.

Field Work. Eight Delta sticky traps, each containing one newly emerged virgin female (Brodeur and McNeil, 1994a), were placed in a commercial potato field at Ste-Catherine, Québec, approximately 50 m apart and 40 cm above the crop canopy at 20:00 hr. The following day, trap catches were determined at 2 hr intervals from 04:00 to 22:00 hr (observations were terminated at sundown as preliminary experiments had indicated that no males were captured during

the scotophase) to determine if there was any diel periodicity in parasitoid mating. In addition, the total number of males captured by each female was noted, to compare the relative attractiveness of different females. This experiment was repeated over three days.

To examine the effect of mating on the attractiveness of females, eight Delta traps were placed in the field, four containing virgins and four with females mated in the 24 hr following emergence. The number of males captured by each female was recorded every two days over a 12-day period. In all cases, females were provided with a 20% sugar water solution.

Statistical Analyses. Data on the reaction time of receptive males and the number of males captured by different virgin females were analyzed by one-way ANOVA and means compared using the Tukey-Kramer unplanned test. For the comparison of different aged virgin and mated females, the data were analyzed using a two-way ANOVA. When necessary data were transformed ($\sqrt{X + 0.5}$ or $1/\sqrt{X}$) to stabilize variance. All values are presented as $\bar{X} \pm$ SE. The proportion of males responding was analyzed using chi-square and, in the case of significant differences, the contingency tables subdivided using the STP procedure ($\alpha = 0.05$).

RESULTS

In the presence of a virgin female, the first evident sign of short-distance male response to pheromone is a series of wing vibration bouts and an increase in general locomotory activity. The frequency of wing vibrations increases as the male approaches the female and is more or less continuous by the time contact occurred. The male contacts the female, usually from the side or from behind, and unreceptive females often fly away at this point. If she remains, the male mounts the female, moves forward, and grasps her around the thorax and abdomen with his fore- and mid-legs. He places his antennae between those of the female and moves them rapidly from side to side, bringing them repeatedly into contact with the female's antennae. There is also an up–down movement of the male's antennae, and on the downward stroke they touch the female on the head. If the female does not accept the male, she continues moving her antennae, flits her wings, and pushes the male with her hind legs. This is most often accompanied by the female lowering her head and curving her abdomen forward between her mid- and forelegs. In contrast, a receptive female lowers her antennae and holds them immobile lateral to her head, while raising her abdomen. When the female takes the acceptance position, the male moves backwards, curving his abdomen downwards to make contact with the female's genitalia. At this time his forelegs are either wrapped around the female's thorax or supported on her hind legs while his mid-legs are in contact with either the

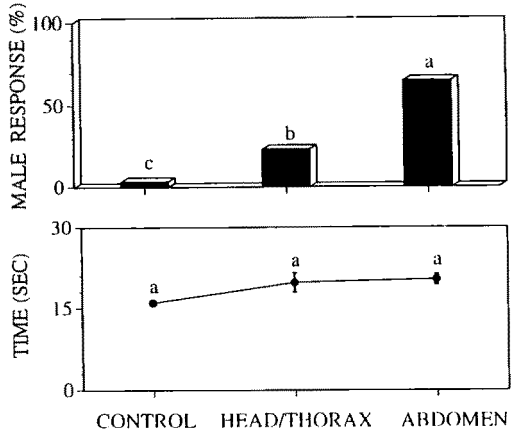

FIG. 2. The proportion of *Aphidius nigripes* males responding and the reaction time of responding males to an 1-μl (0.01 FE) methylene chloride extract from different body parts of 0 to 24-hr-old virgin females.

females wings or hind legs. In cases where the female was receptive ($N = 21$) the initial antennal interaction lasted 16.7 ± 0.7 sec and the actual copulation for 82.5 ± 2.0 sec. At the beginning of the copulation period, the male exhibits a rhythmic antennal movement, with his antennae coming into contact with the female's head at the base of her antennae, but for the last 41.7 ± 4.2 sec the male holds his antennae together, immobile above his head. Once mating has terminated, induced by the female walking forward and moving her antennae, the male dismounts and leaves.

The site of pheromone production would appear to be located in the abdomen (Figure 2). There was, however, some response to the head/thorax extract, and the mean reaction of responding males was similar for all extracts (Figure 2). There was considerable interfemale variability in pheromone production, as evidenced by differences in the proportion of males responding to the individual female extracts in the laboratory bioassay (Figure 3) and the number of males captured by different virgins in the field (Figure 4). The highest variability in the male reaction time in laboratory bioassays was observed with extracts from those females that elicited responses from the fewest males, although there was no evident trend between the proportion of males responding and the mean response time (Figure 3).

The proportion of males responding to female extracts changed with the time of the day that the bioassay was carried out, indicating the possibility of a diel periodicity in male receptivity to the female sex pheromone (Figure 5). The

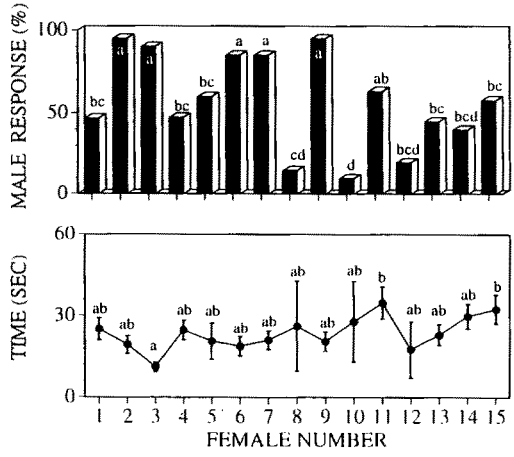

FIG. 3. The proportion of *Aphidius nigripes* males responding and the reaction time of responding males to an 1-μl (0.01 FE) methylene chloride extract from different 0 to 24-hr-old virgin females.

time of day at which the female extract was obtained did not have any significant effect on the results of the bioassay (Figure 5). There was clear evidence of a diel periodicity in the number of males captured by virgin females on the day when weather conditions permitted high levels of parasitoid activity, with the majority being caught between sunrise and 10:00 hr (Figure 6). On the two

other days, there was nearly continuous rain, and while more males were captured in the early morning, the numbers were insufficient to carry out any meaningful treatment of the data.

In the laboratory bioassay, the attractiveness of extracts from different aged females remains reasonably high for the first eight days, after which there is a

slight decline, suggesting that pheromone production may decrease with age (Figure 7). This idea is supported by the slight increase in the mean reaction time of males to extracts obtained from older females (Figure 7). However, in the field, while there was considerable variability (probably the result of variable weather conditions), there was no significant age effect with respect to the number of males attracted to virgin females in the field (Figure 8). On the other hand, there was a significant decrease in female receptivity following mating ($F = 42.8$; $P = 0.0001$) with virgins attracting an average of 18.6 $\pm$ 2.4 males

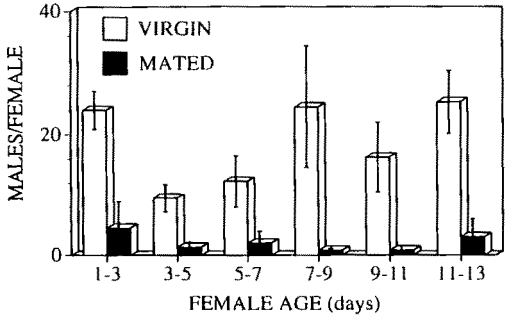

FIG. 8. The number of *Aphidius nigripes* males captured every 48 hr in sticky traps baited with either individual virgin or mated (once in the 24 hr following emergence) females over a 12-day trapping period at Ste-Catherine, Québec.

per trapping period compared with 2.0 $\pm$ 0.9 by mated individuals during the whole period.

No consistent pattern of change was noted in the responsiveness of different aged virgin males to a standard female extract (Figure 9). Again, the differences observed in mean reaction times did not show any clear relationships to the number of males responding in the different assays (Figure 9).

DISCUSSION

The results of both field and laboratory experiments clearly demonstrate that mating in *A. nigripes* is modulated by a female sex pheromone, as reported for several other species of aphid parasitoid (Decker et al., 1993; Reed et al., 1994). It was clear from direct field observerations during our trapping experiments that males exhibit upwind flight towards virgin females placed in sticky traps and the bioassays show that at short distance the pheromone elicits male courtship behavior. There is no evidence of any specific behavior associated with the release of the pheromone, either a specific calling position or the extrusion of a specialized gland, as seen in the calling behavior of many Lepidoptera. This suggests that the pheromone may be released from the cuticular surface, as reported for the short-distance pheromone of certain flies (Carrière and McNeil, 1990) and the contact pheromone in the German cockroach (Schal et al., 1990). The strongest response was obtained with abdominal extracts, suggesting that this is the site of pheromone production, although release may

occur from the entire body surface, as there is some response to the head/thorax extracts. However, it is possible that the response elicited by the head/thorax extract may be the result of pheromone being moved from the abdominal surface to other parts of the body during the frequently observed female grooming behavior. Obviously, additional work is required to locate the sites of both pheromone production and emission and to determine the factors determining the high interfemale variability observed.

In the laboratory, males exhibit courtship behavior when in close proximity of freshly killed females. However, in the field, three sticky traps baited with live females captured 34.3 $\pm$ 2.7 males, while those containing dead females captured none. This would suggest that pheromone release is an active rather than passive process. There is, however, an alternative explanation: that there are two pheromones, one that serves to attract males over considerable distances and a second short-range one that elicits the actual courtship behavior. Once female specific compounds have been identified, this matter will be clarified.

The field results clearly demonstrated a diel periodicity with a peak early in the morning that coincides with the time that we observe most matings in the laboratory. Reed et al. (1994) also reported that the majority of *A. colemani* found in female-baited traps were captured before noon. While the bioassay data would suggest that this periodicity is mainly the result of changes in male receptivity, this conclusion should be viewed with a certain degree of caution. The extraction technique may remove pheromone from sites within the body (Blomquist and Dillworth, 1985; Carrière and McNeil, 1990) and thus not reflect the amount released by the female at the time extraction. Again, once the identification of the sex pheromone has been completed, then the question of periodicity will be resolved by quantifying both the amount of pheromone released by females and the response of males to known doses of pheromone at different times during the day. This will be examined under a range of different conditions, as it is very clear from our laboratory studies that mating success of pairs reared under identical conditions vary considerably from one day to the next. One possible cause is changing atmospheric pressure, as suggested for the spruce budworm (Miller and McDougall, 1973), a factor known to influence parasitoid oviposition behavior (Roitberg et al., 1993).

There appears to be no marked effect of age on either male receptivity or pheromone production by females, although in the laboratory bioassays a slight decline was noted in older females. Again, it is possible that the whole-body extraction technique used may mask age-related changes in the actual amount of pheromone released. However, based on the field trapping data, high pheromone production by virgins is maintained during the period of the female's life when oviposition is at its maximum (Cloutier et al., 1981). Mating results in a marked decrease in female attractivity and of the 49 males captured in traps baited with mated females, 46 were attracted to one female. Thus, further work

is required to determine the factors that modify pheromone production following mating and the duration of the refractory period. The effect of previous mating history on male receptivity must also be evaluated. The mean reaction time will also be reexamined, as the results of the present study suggest that this parameter remains relatively constant for males that respond.

As suggested by Decker et al. (1993), and demonstrated by Brodeur and McNeil (1994a), a female sex pheromone provides a potential means of estimating parasitoid populations. In addition, it may be used to enhance the impact of parasitoids on aphid populations. The sex pheromone of aphids appears to attract female parasitoids but not males (Hardie et al., 1994a), so its use in management may result in a very strong female-biased sex ratio if parasitoids are drawn in from the surrounding habitat. If this bias reduces the probability of females mating and results in a high production of male progeny, then there would be a lower number of effective biological control agents in the next generation. However, the use of the parasitoid sex pheromone simultaneously with that of the aphid may ensure that both sexes are attracted into the habitat, thereby increasing parasitoid efficacy. Obviously, as is the case with aphid sex pheromones (Hardie et al., 1994a), we need a much better basic understanding of the factors affecting both female production of, and male receptivity to, the sex pheromone of parasitoids such as *A. nigripes* before we can meaningfully evaluate their potential in management programs.

(Received February 14, 1995; accepted March 10, 1995)

Abstract—The bean bug, *Riptortus clavatus* lays scattered eggs (as opposed to the egg masses of pentatomids) on host as well as nonhost plants. Therefore, the first feeding stage (second-instar) nymphs emerging from eggs laid on nonhost plants need a signal that enables them to locate a food source at the lowest energy cost. Male-released (*E*)-2-hexenyl (*E*)-2-hexenoate, (*E*)-2-hexenyl (*Z*)-3-hexenoate, and myristyl isobutyrate play the double role of attractant pheromone for adults as well as aggregation pheromone, which enables the second-instar nymphs to find the host food plant. These male-specific semiochemicals are released only when foodstuff is available. On the other hand, females of *Ooencyrtus nezarae*, the most effective parasitoid of the host in Kumamoto, Japan (where the field experiments were conducted), utilize these semiochemicals as kairomones in order to locate the potential host community. Field experiments revealed that the synthetic pheromone rivaled 10 live males in the attraction of adults and second-instar nymphs. Captures of the egg parasitoid *O. nezarae* females in cylindrical sticky traps were signif-

icantly higher in traps baited with the synthetic semiochemicals than in control traps. The number of females captured was significantly higher than the number of males, although the captures in the sticky suction trap system revealed that the populations of male and female were not significantly different.

Key Words—*Riptortus clavatus*, *Ooencyrtus nezarae*, Alydidae, Encyrtidae, attractant pheromone, aggregation pheromone, kairomone, (*E*)-2-hexenyl (*E*)-2-hexenoate, (*E*)-hexenyl (*Z*)-3-hexenoate, myristyl isobutyrate.

INTRODUCTION

The bean bug, *Riptortus clavatus* (Thumberg), is an economically important soybean pest in Japan. Females lay single eggs on nonhost as well as host plants. The selective pressure of egg parasitoids probably contributes to this habit of scattering eggs. It is important to the first feeding stage (second-instar) nymphs to have a signal to locate a food source plant. Surveys conducted inside soybean fields indicated that the population of second-instar nymphs is much higher than both the number of eggs and the population of first-instar nymphs because second-instar nymphs moved from nonhost to host plants (Nakamori et al., 1994).

It has been demonstrated by field experiments that males induced aggregation of adult bugs (Kadosawa, unpublished data) and that this aggregation was semiochemically mediated (Numata et al., 1986). In the course of a study of the attractant pheromone of the bean bug, we found that the same semiochemicals are utilized by the second-instar nymphs to locate their host plants. In addition, the signal is used as a long-range kairomone by an egg parasitoid of the bean bug, *Ooencyrtus nezarae*.

METHODS AND MATERIALS

Chromatographic, Mass, and Infrared Spectral (MS, IR) Analyses

Gas chromatographic (GC) analyses were performed on a Hewlett-Packard 5890 equipped with one of the following capillary columns: DB-23 (30 m × 0.25 mm; 0.25 μm), DB-wax (30 m × 0.25 mm; 0.25 μm), or an HP-1 (12 m × 0.2 mm; 0.33 μm), operated in splitless mode either at 50°C for 1 min programmed at 4°C/min to 180°C, held at this temperature for 1 min, programmed again at 10°C/min to 230°C and held at this temperature for 20 min [in short, 50(1)-180(1)/4-230(20)/10 or 50(1)-210(10)/10]. Mass spectra were recorded on a Hewlett-Packard 5891 mass selective detector using the same type of capillary columns under the same conditions as described for the GC. This was operated either in the electron impact (EI) or chemical ionization (CI) mode

using ammonia. Gas chromatography–Fourier transform infrared (GC-FTIR) was done on a Hewlett-Packard 5965B equipped with a DB-23 capillary column operated at 50(1)-210(10)/8. The light pipe and the transfer line were operated at 250°C.

Gas Chromatography–Electroantennographic Detector (GC-EAD)

The responses of *R. clavatus* antennae were recorded with a GC-EAD system with silver wire electrodes (Struble and Arn, 1984). Separations were achieved on a DB-23, DB-wax, or HP-1 capillary column operated at 50(1)-210(10)/10, 50(1)-180(1)/4-230(20)/10, and 70(1)-170(1)/3-250(10)/10, respectively.

Extracts

The airborne volatiles of adult bugs confined in an all-glass aeration apparatus and fed on soybean seeds (or deprived of food) were collected on a Tenax TA column, eluted with hexane, and concentrated. Whole-body extracts of adults and nymphs were obtained by immersing at least five individuals in hexane for 3 min. Hexane extracts of soybean and horse bean seeds were prepared by macerating the seeds before immersing in hexane.

Isolation of Pheromone

Crude airborne extracts of male bugs were separated on a silica gel column (Wako C-200) by successively eluting with hexane–ether (100:0, 95:5, 90:10, 80:20, 50:50, and 0:100) mixtures. Further purification was done by collecting small fractions from a silica gel–silver nitrate (10%) column eluted with hexane–ether (95:5 and 90:10).

Chemical Derivatizations

Dimethyl disulfide (DMDS) adducts of the active unsaturated esters were obtained by reaction with dimethyl disulfide (DMDS, 100 μl) catalyzed by iodine. The mixture was stirred for 50–60 min at 65°C in a 1-ml conical vial containing a magnetic spin vane and closed with a Teflon-lined cap. After the mixture was cooled to room temperature, hexane (200 μl) was added, and iodine was removed by washing with sodium thiosulfate. The organic phase was dried over anhydrous sodium sulfate, concentrated to 50 μl, and analyzed by EI-MS using either a DB-wax or an HP-1 capillary column operated at 100(1)-230(20)/10 and 100(1)-230(30)/5, respectively.

Hydrolysis was done with potassium hydroxide in methanol at 60°C for 2 hr. The solvent was distilled off, the residue redissolved in ether, washed with

hydrochloric acid 2 M, dried over anhydrous sodium sulfate, concentrated, and analyzed by EI-MS.

Hydrogenation (catalyzed by PtO_2) was carried out in a 1-ml conical vial containing a magnetic spin vane and equipped with a Claisen head fitted with a rubber balloon and Teflon-lined cap.

Synthesis

(E)-*2-Hexenyl* (E)-*2-hexenoate.* To a solution of (*E*)-2-hexenoic acid (34 g) in dry benzene (90 ml), oxalyl chloride (75 g) was added dropwise at 45–50°C. After stirring at 65°C for 2 hr, the solvent was evaporated and the crude material was distilled to yield (*E*)-2-hexenoyl chloride (32.5 g; bp 62–63°C/20 mm Hg). This acid chloride (30.3 g) was added dropwise to an ice-cooled mixture of (*E*)-2-hexenol (20 g) and pyridine (23.7 g) in dry chloroform (100 ml). The reaction mixture was refluxed for 1 hr, cooled to room temperature, water was added, and the organic layer was washed with sodium carbonate, dried over anhydrous sodium sulfate, evaporated, and distilled to give (*E*)-2-hexenyl (*E*)-2-hexenoate (28 g, bp 79–80°C/0.7 mm Hg).

(E)-*2-Hexenyl* (Z)-*3-hexenoate.* (*Z*)-3-Hexenoyl chloride (bp 50–51°C/19 mm Hg) was prepared by the reaction of oxalyl chloride with the corresponding acid. The reaction of this acyl chloride with (*E*)-2-hexenol yielded (*E*)-2-hexenyl (*Z*)-3-hexenoate (bp 82–83°C/1.7 mm Hg).

Myristyl Isobutyrate. Reaction of myristyl alcohol with isobutyryl chloride gave myristyl isobutyrate (bp 127–128°C/0.7 mm Hg). The other esters were prepared in small scale by the reaction of acid chlorides and alcohols without solvent, followed by distillation of the products.

Insects

R. clavatus adults were collected in soybean fields and kept in cages (15 × 12 × 10 cm) in the laboratory (25°C, 70% relative humidity, and 16:8 LD photoperiod) and fed on a mixture of soybean and horse bean. Adults were transferred to other cages after a reasonable number of eggs were laid. Nymphs obtained from these eggs were kept together, but the emerged adults were segregated by sex.

Field Experiments

Preliminary field tests were conducted in Tsukuba (latitude 36°05′N, longitude 140°10′E) in the fall of 1992. Further evaluation of the synthetic attractant pheromone was carried out in Kumamoto (latitude 32°53′N, longitude 130°45′E) from September 7 to November 11, 1993.

The chemical lure (100 mg), incorporated into plastic pellets (4–5 mm in diameter) made of polyethylene–vinyl acetate, was placed in plastic cages (13 × 9.5 × 8 cm), set at 3 cm above the water surface of a hand-made, blue water-pan trap (16 cm × 35 cm ID). Insect baits were prepared with males (10 individuals) placed in plastic cages supplied with water and dry soybean seeds. Control and baited traps were randomly distributed around a soybean field inside Kyushu National Agricultural Experiment Station (Kyushu Noshi).

Kairomonal response of egg parasitoids to the synthetic attractant pheromone was investigated with cylindrical sticky traps made from two sticky plates (30 × 30 cm; Shin-Etsu Chemical Co., Tokyo) folded to form a cylinder (ca. 15 cm ID). Plastic pellets incorporated with the chemical lure (50 mg) were placed inside small plastic bottles (Fuji Flavor Co., Japan) and set on the top of the sticky cylinder traps. These traps were set on plastic plates placed randomly in the ground around a soybean field inside Kyushu Noshi. Number and sex of the egg parasitoids, *O. nezarae*, captured were determined under a binocular microscope. The population of the egg parasitoid was monitored in a nearby soybean field using a sticky suction trap system (Tokyo A&S Co., Tokyo).

Statistical Analyses

Field capture data were transformed to log $(x + 1)$ before differences between means were tested for significance by the Tukey-Kramer honestly significant difference test at a 5% level. Throughout this paper, treatments labeled with the same letters are not significantly different.

RESULTS AND DISCUSSION

Identification of Sex Pheromone

GC-EAD analyses of the airborne volatiles collected from *R. clavatus* males (using female or male antenna as a sensing element) showed the occurrence of four EAD-active peaks, which appeared not only on the polar columns, DB-23 (Figure 1) and DB-wax, but also on a nonpolar HP-1 column. After separation on a silica gel column, the four compounds were recovered in the hexane–ether (95:5) fraction. Peak I has been previously identified as (*E*)-2-hexenyl hexanoate, the alarm pheromone of the bean bug (Leal and Kadosawa, 1992) and was found in the airborne volatiles of male and female bugs. The other three EAD-active peaks (II, III, and IV) were detected in the (airborne or whole-body) extracts of male bugs, but they were not present in the female extracts or in the foodstuff. Collection of volatiles from the same group of males for a whole day with foodstuff followed by one-day collection without foodstuff (and vice versa) revealed that the three compounds were released only by males provided with

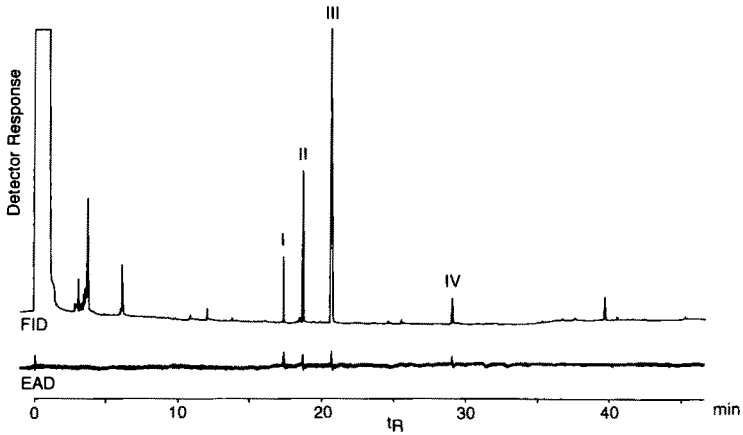

FIG. 1. Coupled GC-EAD response of female *R. clavatus* antenna to the airborne volatiles of male bugs separated on a DB-23 capillary column. The same response was detected with male antenna as a sensing element.

foodstuff. It is unknown, however, whether the bugs release the semiochemicals only when they are feeding. Compounds I, II, and III were not detected either by FID or EAD in the airborne extracts from starved males. These data suggested that compounds II, III, and IV were constituents of the attractant pheromone of *R. clavatus*.

EI-MS analyses of the male-specific, EAD-active compounds II, III, and IV gave their base peaks at *m/z* 55, 97, and 89, respectively (Figure 2). Although the molecular ion of compound II was missed in EI measurements, it was confirmed to be 196 from the quasi-molecular ion obtained at *m/z* 214 by chemical ionization with ammonia. Likewise, the molecular ions of compounds III and IV were corroborated to be *m/z* 196 and 284, respectively.

Hydrogenation of II and III gave hexyl hexanoate, suggesting that these two compounds were isomers. Vapor-phase IR (Figure 3) of III gave a profile of a conjugated ester (νC=O, 1740 and νC=C, 1655 cm^{-1}). The profiles of II (νC=O, 1755 cm^{-1}) and IV (νC=O, 1751 cm^{-1}) indicate that these compounds were nonconjugated esters. The fact that the C—H stretching band of IV was predominant over the carbonyl stretching band suggested that this ester had at least one long carbon chain.

Alkaline hydrolysis of II gave 2-hexenol and 3-hexenoic acid, whereas the products of the hydrolysis of III were 2-hexenol and 2-hexenoic acid.

EI-MS of the DMDS adduct of II displayed a base peak at *m/z* 89 along with the molecular ion M^+ 290, indicating that the unsaturation of the

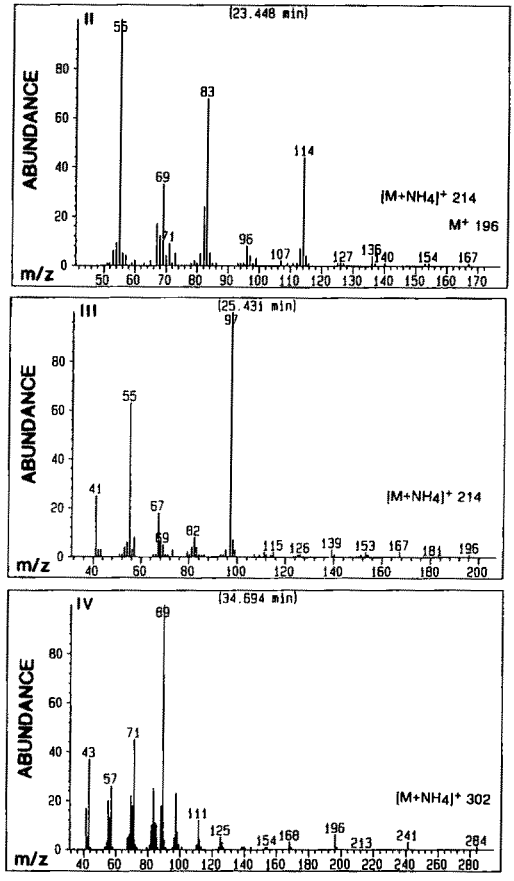

FIG. 2. Electron impact-mass spectra of the three constituents (II, III, and IV) of *R. clavatus* attractant pheromone. The quasi-molecular ions $[M+NH_4]^+$ obtained by chemical ionization with ammonia are also displayed.

acid moiety of II was in position 3 [$CH_3CH_2CHSMe^+$, *m/z* 89; $CH_3CH_2CH(SMe)CH(SMe)CH_2CO^+$, 191(5%)]. It remained to be determined what the configuration of the two double bonds was. The IR spectrum had a band characteristic of the *E* configuration, which suggested that at least one of the double bonds would be in that configuration. Synthetic (*E*)-2-hexenyl (*Z*)-3-hexenoate gave the same retention times as the natural product on three different capillary columns and showed identical MS. On the other hand, (*E*)-2-hexenyl (*E*)-3-hexanoate had longer retention times on polar capillary

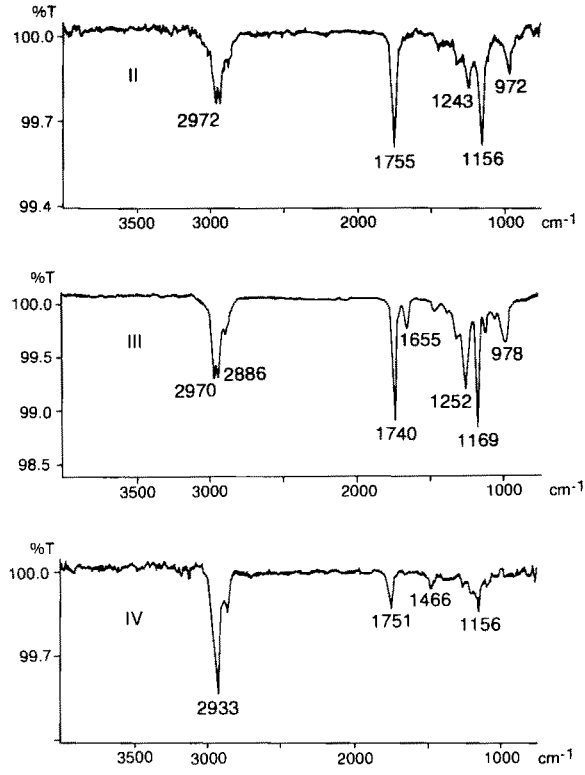

FIG. 3. Vapor-phase IR data for the three components (II, III, and IV) of the attractant pheromone system of *R. clavatus*.

columns and gave an MS with the base peak at *m/z* 55, but having a different profile: 114 (72%), 83 (55), and 69 (50). Therefore, compound II was identified as (*E*)-2-hexenyl (*Z*)-3-hexenoate.

The partial DMDS derivative of peak III gave the base peak at *m/z* 97 ($CH_3CH_2CH_2CH{=}CHCO^+$), the second peak (75%) at *m/z* 103 ($CH_3CH_2CH_2CHSMe^+$) and the molecular ion at M^+ 290. These data and the occurrence of an *E* configuration band (978 cm^{-1}) in the IR spectrum (Figure 3), suggested that compound III was (*E*)-2-hexenyl (*E*)-2-hexenoate. The synthetic ester was identical to the natural product in the retention times on three capillary columns and spectral data. Although (*Z*)-2-hexenyl (*E*)-2-hexenoate showed an MS profile very close to that of the natural product, it had a shorter retention time on polar capillary columns. Thus, compound III was identified as (*E*)-2-hexenyl (*E*)-2-hexenoate.

The facts that hydrolysis of IV gave myristyl alcohol, that IV did not undergo hydrogenation, and that the MS of IV had a base peak at *m/z* 89 (M^+ 284), suggested that this compound was either myristyl *n*-butyrate or myristyl isobutyrate. These two esters were almost indistinguishable from their MS, but myristyl *n*-butyrate showed much longer retention times on polar capillary columns, whereas myristyl isobutyrate was identical to the natural product. Therefore, the attractant pheromone of *R. clavatus* was identified as a mixture of (*E*)-2-hexenyl (*Z*)-3-hexenoate, (*E*)-2-hexenyl (*E*)-2-hexenoate, and myristyl isobutyrate, in short E2HZ3H, E2HE2H, and MI. These three compounds were found in an average ratio of 1:5:1.

Field Evaluation of Attractant Pheromone

Preliminary experiments in Tsukuba indicated that the major component (E2HE2H) alone was inactive and that there was no significant difference between catches of *R. clavatus* in traps baited with males and those in traps using the synthetic attractant pheromone mixture (100 mg) as a lure. Further experiments in Kumamoto corroborated that the attractancy of the synthetic attractant pheromone (E2HZ3H, E2HE2H, and MI: 1:5:1; 100 mg) to *R. clavatus* was not significantly different from that of 10 caged males (Figure 4). In addition, the field results with synthetic chemicals showed that there was a significant difference in catches of male and female *R. clavatus*.

Despite the fact that in the field male and female adults are attracted to the male-released pheromone of *Nezara viridula* (Harris and Todd, 1980; Aldrich et al., 1987), the semiochemicals involved are often referred to as "sex pheromones," probably because a correlation between attraction and mating was

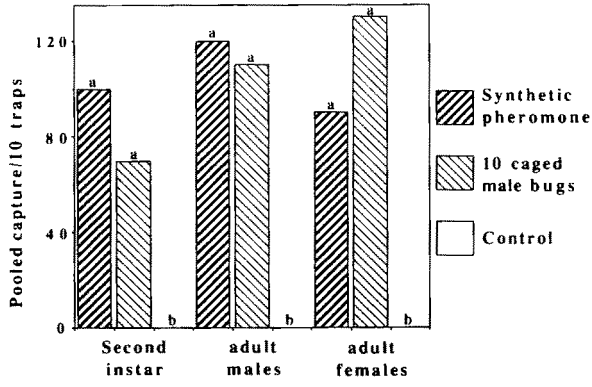

FIG. 4. Captures of second instars and male and female adults of *R. clavatus* in traps baited with synthetic attractant pheromone and 10 caged males (control = no lure).

found in the laboratory (Borges, 1987). Recently, it has been reported that the male-released volatiles act as a sex pheromone mediating mate finding and that aggregation observed in the field may be mediated by other factors (Brézot et al., 1993). The male-released pheromone system of *R. clavatus*, however, was confirmed with synthetic chemicals (as opposed to live insects or volatiles collected from them) to be an attractant pheromone.

Ecological Significance of Semiochemicals to Second Instars

Field tests showed that traps loaded with the synthetic mixture (E2HZ3H, E2HE2H, and MI; 1:5:1; 100 mg) were equally effective in attracting second-instar nymphs of the bean bug as male-baited traps. The significance of these chemicals to the ecology of *R. clavatus* is not limited to their involvement in the aggregation of male and female bugs, which is relevant for reproduction of the bean bug.

As this species lays eggs on host and nonhost plants, it is important to the first feeding stage (second-instar) nymphs to have a signal that enables them to locate a food source at the lowest energy cost. The facts that the attractant pheromone is only released by feeding males and specifically attracts the second instars (the other stages are not attracted) substantiate its involvement in food source location. Whether the later stages (third, fourth, and fifth instars) lose the ability to respond to these semiochemicals is not known, but nymphs in these stages may not need the information as they would have already reached the host food plant, or they would have starved to death.

GC-MS analyses revealed that none of these semiochemicals is present in the whole-body extracts of nymphs. In the extracts of first, second, and third instars only 2-(*E*)-octenal was detected, whereas fourth and fifth instars had a second component tentatively identified as 4-oxo-2-hexenal. These chemicals may be involved in the alarm and defensive systems of *R. clavatus* nymphs.

The use by the second instars of semiochemicals emitted by male bugs to locate host plants is an important feature of the biology of the bean bug. This is novel in the chemical ecology of hemipterans and seems to have evolved in response to selective pressure from the parasitoid. Due to the lack of terminology, we use the term "aggregation pheromone" to refer to the use of these semiochemicals in this unique context.

Kairomonal Activity of Attractant Pheromone

The possible attraction of egg parasitoids to the host's attractant pheromone was investigated in the field. In order to rule out the possibility that stimuli from bugs initially captured were used by egg parasitoids as cues for host location, we used cylindrical sticky traps in which the bean bug could not be captured. This type of trap, however, could catch the most effective egg parasitoid of the

bean bug in Kumamoto (Japan), *O. nezarae* Ishii (Hymenoptera: Encyrtidae). Experiments conducted from September 21 to October 17, 1993, revealed (Figure 5) that, although the numbers of male and female *O. nezarae* captured in sticky suction trap were not significantly different, significantly more female parasitoids were caught in the traps baited with the synthetic attractant pheromone (E2HZ3H, E2HE2H, and MI; 1 : 5 : 1; 50 mg) than in control traps. Catches of female *O. nezarae* were also significantly higher (5.5-fold) in the traps baited with the attractant pheromone than in the sticky suction trapping system. The synthetic bait was not attractive to male *O. nezarae*.

These findings confirm that the attractant pheromone of *R. clavatus* is utilized by females of the egg parasitoid *O. nezarae* as a long-range attractant kairomone. It is also likely that the bean bug has developed the strategy to lay eggs on nonhost plants to escape egg parasitoids. *O. nezarae* has evolved the ability to respond to semiochemicals produced by males that allow second instars to locate host food plants. Because the semiochemicals are released only by fed (or feeding) males, eggs laid on nonhost plants are probably less prone to attack by *O. nezarae* than those laid on host plants, unless the parasitoid can also detect other stimuli associated with females, hosts, or eggs.

Parasitoids have been reported to respond (as reviewed in Whitmann, 1988) to the host's body odor; the sex, epideitic, and aggregation pheromone; salivary constituents; excretory products; webbing; honeydew; body scales; and eggs. Recently, it has been reported that the egg parasitoid *Trissolcus basalis* utilizes a defensive substance produced by its host bug, *Nezara viridula*, as a long-range attractant kairomone (Mattiacci et al., 1993). The experimental evidence,

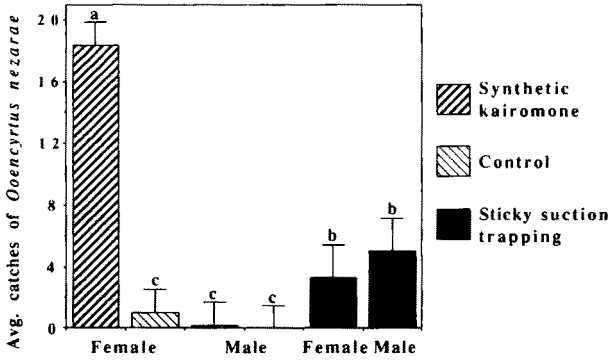

FIG. 5. Response of the egg parasitoid *O. nezarae* to the attractant pheromone of the host *R. clavatus* compared to catches of the egg parasitoid in a sticky suction trapping system.

however, for the long-range attraction is based only on the fact that female *T. basalis* spend significantly more time in the arm of an Y-olfactometer baited with the defensive substance. Attraction of parasitoids to the pheromone of host bugs is not novel. In fact, it has been previously reported that an egg parasitoid, *Telonomus* sp., was attracted to the male-released pheromone of the predatory spined soldier bug, *Podisus maculiventris* (Aldrich et al., 1984).

Field observations demonstrated that significantly more eggs of *Piezodorus hybneri* have been parasitized by *Telonomus triptus* when egg masses were placed close to caged adult bugs than egg masses alone (Higuchi, unpublished), leading to the conclusion that egg parasitoids are attracted to the vicinity of the eggs in response to a cue emanating from the host. Nevertheless, egg parasitoids usually appear later in the field than their hosts, and thus the host's first-laid eggs usually escape parasitoid attack (Higuchi, 1993). Therefore, the use of kairomones to synchronize the parasitoid population at the beginning of the host flight season may pave the way for the development of invaluable tools in integrated pest management programs.

QUANTITATIVE HIGH-RESOLUTION GAS CHROMATOGRAPHIC DETERMINATION OF STEREOISOMERIC COMPOSITION OF CHIRAL VOLATILE COMPOUNDS IN THE PICOGRAM RANGE BY EC-DETECTION

ANN-BRITT WASSGREN and GUNNAR BERGSTRÖM*

Department of Chemical Ecology
Göteborg University
Reutersgatan 2 C, S-413 20 Göteborg, Sweden
(Received February 14, 1995; accepted March 10, 1995)

Abstract—A gas chromatographic method using electron capture detection for determination of the stereochemical composition of chiralolatile compounds, e.g., pheromones, at the picogram level is described. Substances of interest are analyzed as pentafluorobenzoate derivatives on fused silica capillary columns coated with CP Sil-88. This method was developed primarily for the quantitative analyses of stereoisomerism of the pheromone precursor, diprionol, in female sawflies, *Neodiprion sertifer*. It was possible to separate the stereoisomers showing (2*S*, 3*S*, 7*R*) and (2*S*, 3*S*, 7*S*) configurations. Resolution of the (2*S*, 3*S*, 7*S*)- and (2*S*, 3*R*, 7*R*)-diastereomers was high enough to allow the quantification of these stereoisomers. A quantitative analysis of the diprionol production in individual *N. sertifer* females yielded 7.5–9.7 ng/female.

Key Words—Chiral separation, HRGC, stereoisomers, diastereomers, enantiomers, electron capture detection, pentafluorobenzoates, pheromones, volatile compounds.

INTRODUCTION

Methods for identifying substances in biological material can be greatly facilitated by the conversion of a functional group to a suitable derivative according to the mode of determination. For example, detection of various phenols and carboxylic acids as pentafluorobenzoyl derivatives has been satisfactory using a tritium foil ECD, and analyses at trace concentrations have been successfully

*To whom correspondence should be addressed.

0098-0331/95/0700-0987$07.50/0 © 1995 Plenum Publishing Corporation

performed by Kawahara (1968). Methods for determining the composition and concentration of carboxylic acids and phenols in water using derivatives have been described by Fogelqvist et al. (1980). Esterification with halogenated alcohols has been used for the identification of pesticides at nanogram levels (Satter and Paasivirta, 1979). The determination of trace amounts of different estrogens, in the form of heptafluorobutyric esters, has made it possible to measure picogram amounts by using ^{63}Ni ECD, according to Kern and Brander (1979).

Selective analysis of enantiomers of chiral compounds in biological material presents an interesting problem. In the oldest and most commonly used GC procedures for enantiomeric separations, an optically pure chiral reagent is employed to convert enantiomers into their diastereomeric derivatives, which are then separated on a nonchiral stationary phase. These methods were described by, among others, Ställberg-Stenhagen (1970). Today it is customary to perform determinations of enantiomeric compositions by chiral GC analysis on modified cyclodextrin phases, and in some cases it is possible to derivatize the compounds to trifluoroacetyl (TFA) derivatives (König et al., 1990). Separations of underivatized enantiomers and diastereomers on chiral metal chelate dissolved in an achiral stationary phase is described by Schurig and Weber (1984).

In the present report, pentafluorobenzoate was chosen as a derivatizing agent. It introduces an electron capturing moiety into the molecule, which provides good response to a ^{63}Ni detector and is suitable for gas chromatographic separation at the picogram level, as exemplified by the analysis of diprionol (2*S*, 3*S*, 7*S*)-3,7-dimethyl-2-pentadecanol, the pheromone precursor in *Neodiprion sertifer* (Geoffr.) (Hymenoptera: Diprionidae) females. Since some of the stereoisomers of diprionol occur in picogram amounts only, their determination requires sensitive methods. The gas chromatographic separation of diprionol has been performed earlier using two different methods, which we have described in Högberg et al. (1990). In both methods, the substances were derivatized, either to isopropyl carbamates or to benzoates. The isopropyl carbamates were separated on a chiral column CP-XE-60-(*S*)-valine-(*S*)-2-phenylethylamide (König, 1982; König et al., 1982) and detected by N/P detection (Wassgren and Bergström, 1984; Bergström, et al., 1992), while the benzoates were separated on a fused silica column coated with Sil-88 and detected by a flame ionization detector. Previously, we separated the diastereomers showing (2*S*, 3*S*, 7*R*)-configuration from the (2*S*, 3*S*, 7*S*) pair in synthetic diprionol as benzoates on a Sil-88 column, but problems arose when identifying small amounts in biological materials, i.e., in the picogram range (Högberg et al., 1990).

The objective of this work was to develop a convenient, sensitive method for the identification and quantification of the enantiomeric composition of diprionol from natural material in the picogram range and the quantification of the production of diprionol in single females. We think that this method may be of general interest in connection with separations of small amounts of many different chiral natural compounds.

METHODS AND MATERIALS

Biological Material. Females of *N. sertifer* were collected in 1991 in Värmland, Sweden, from two populations.

Chemical Materials. All synthetic references were synthesized in high stereochemical purity (see Högberg et al., 1990). The substances are the following: (2*S*, 3*S*, 7*S*)-3,7-dimethyl-2-tridecanol, (C_{15}-*SSS*), (2*S*, 3*S*, 7*S*)-3,7-dimethyl-2-tetradecanol, (C_{16}-*SSS*), (2*S*, 3*S*, 7*S*)-3,7-dimethyl-2-pentadecanol, (C_{17}-*SSS*), (2*S*, 3*R*, 7*R*)-3,7-dimethyl-2-pentadecanol, (C_{17}-*SRR*), (2*S*, 3*S*, 7*R*)-3,7-dimethyl-2-pentadecanol, (C_{17}-*SSR*), and (2*S*, 3*S*, 7*S*)-3,7-dimethyl-2-hexadecanol, (C_{18}-*SSS*). The solvents were of high analytical quality, containing no halogenated compounds. Ethyl acetate was obtained from American Burdick & Jackson, Fluka AG, Switzerland; pentane was distilled in our laboratory, and the water was Millipore-distilled. Other solvents and reagents, such as pyridine, methanol, pentafluorobenzoyl chloride, and isopropyl isocyanate were of Fluka analytical reagent grade. Chromabond polypropylene columns containing silica gel (SiOH) (Skandinaviska GeneTec AB), 1 ml volume, were used for sample preparation.

Preparation of Extracts. Single female *N. sertifer* were extracted in about 100 μl ethyl acetate at room temperature for 72 hr. The sample was transferred to a test tube and 50 ng of (2*S*, 3*S*, 7*S*)-3,7-dimethyl-2-hexadecanol was added as internal standard. In addition, two standards were made with 10 and 20 ng, respectively, of (2*S*, 3*S*, 7*S*)-3,7-dimethyl-2-pentadecanol, with 50 ng internal standard in each. Two blank samples containing only pentane were treated in a similar manner. The solvent was concentrated to about 20 μl by evaporation under a slow stream of nitrogen; the residue was then immediately dissolved in 50 μl pentane for subsequent liquid chromatography.

Liquid Chromatography. The cleanup was performed with solid-phase extraction on a Chromabond SiOH column (1 ml). The chromatography was initiated by wetting the adsorbent material with the eluent, in this case pentane; the material was then placed on the column and a gradient elution was applied (Wassgren et al., 1992) by increasing the polarity with 1–9% ethyl acetate in pentane, with 150 μl elution volume in each fraction. Fractions 7 and 8 were mixed in a small conical glass tube with a stopper before evaporation to dryness.

Preparation of Pentafluorobenzoates. The sample was dissolved in 3 μl of a mixture consisting of 2 μl pentafluorobenzoyl chloride in 20 μl pyridine, and the closed reaction tube was kept in a water bath at 60–70°C for 2 min. The solvent and excess reagent were then evaporated to dryness with water suction for 0.5–1 hr. The yellow residue was dissolved with 3 μl methanol, and 3 μl Millipore-redistilled H_2O was added. The pentafluorobenzoate was extracted twice with pentane (2 × 25 μl). The organic phase was washed twice with Millipore-redistilled H_2O, dried with Na_2SO_4, and concentrated to about 20 μl for GC analyses.

GC-ECD. Gas chromatography was performed with a Chrompack model CP-9000 gas chromatograph equipped with an electron capture detector, model 902A, which contains a foil of radioactive ^{63}Ni, a splitless injector, and a HP3396A integrator. The gas chromatograph was fitted with a 1.5-m × 0.32-mm-ID methyl deactivated silica retention gap, connected with a Quick-Seal column connector to fused silica columns coated with Sil-88 (Chrompack, the Netherlands) with the following dimensions: (a) 30 m × 0.15 mm ID, d_f = 0.24 μm; (b) 25 m × 0.25 mm ID, d_f = 0.22 μm; (c) 50 m × 0.25 mm ID, d_f = 0.22 μm. A setup of oxygen trap, molecular sieve, and charcoal filter was placed before the gas inlet. Separations of pentafluorobenzoates of the synthetic enantiomeric mixture of diprionol and the corresponding chiral homologs were carried out by tandem GC. The deactivated retention gap was fitted with a Quick-Seal column connector to the first fused silica capillary column Sil-88 (30 m × 0.15 mm ID). The second fused silica column was also coated with Sil-88 (25 m × 0.25 mm ID). Nitrogen was used as carrier gas at a pressure of 145 kPa, as well as make-up gas and purge gas at flows of 40 ml/min and 35 ml/min, respectively. The oven temperature were 250° and 275°C, respectively. The ECD was working in range 0, and attenuation 0.1.

Individual analyses of *N. sertifer* samples were also performed on Sil-88 columns, namely a 50-m × 0.25-mm column coupled to a 25-m × 0.25-mm column in series. The carrier gas pressure was 90 kPa, and the oven temperature 150°C.

RESULTS AND DISCUSSION

It has always been a special problem to isolate and identify biologically active components in extracts of whole insects. Such extracts, which are complex mixtures of volatile and nonvolatile compounds, usually require cleanup with solid sorbent extraction. This is a rapid isolation technique for compounds such as the alcohols present in pine sawflies. The recovery in this case, when we used the extract of an individual female, was 90%.

In earlier studies we presented the quantification of the amount of diprionol in extracts containing 20 females by using a flame ionization detector. This detector is not sufficiently sensitive to detect diprionol from single individuals or for determining possible homologs. We have therefore improved the method by using a selective electron capture detector (ECD), which is used for very sensitive detection of components with high electron affinity, especially halogenated hydrocarbons. The alcohols were transformed to pentafluorobenzoates with pentafluorobenzoyl chloride, which gives high sensitivity on ECD. The derivatizing procedure is quantitative, and it is therefore possible to perform the whole procedure *in vitro*; in this manner the loss of material is exceedingly small; recovery is 80% after the derivatization procedure. The reproducibility

and accuracy of this approach were determined in an experimental series of standards consisting of diprionol, 10 and 20 ng, respectively, with 50 ng internal standard in each. The pentafluorobenzoyl derivatives of diastereomericdiprionols were separated on commercially available high-polar fused-silica capillary columns, CP Sil-88.

The stationary phase unfortunately is not chemically bonded, since the relatively active cyanate groups (CN^-) do not allow cross-linking without vinyl groups. It is therefore necessary to inject a reference mixture at regular intervals, to check retention time, and carry out coinjection of the material with pure, known stereoisomers. This ensures that the stereoisomers elute at the same time. The uncoated retention gap avoids problems with solvent condensation that occur with splitless injection. One of the main problems we encountered was the occurrence of residual water after extraction, because water both distorts the chromatography and severely reduces the sensitivity of the ECD; anhydrous sodium sulfate can be used to remove residual water. It was also possible to use this gas chromatographic method for the quantification of low concentrations of diprionol its stereoisomers and occurring homologs in both natural and synthetic material (Figure 1). The detection limit is below 1 pg of diprionol homologs and diastereomers. Furthermore, Figure 1 shows the separation of a mixture of known stereochemical composition of isomeric diprionols and homologs. The *erythro*-isomers of the C_{15}- and C_{16}-homologs which have the (S, S, S)-configuration have the same retention time as the (R, R, R)-isomers (Högberg et al., 1990). The *erythro*-isomers (S, S, S) and (R, R, R) were separated as N-isopropylcarbamates. The separations of (2*S*, 3*S*, 7*R*)-diprionol from (2*S*, 3*S*, 7*S*)-diprionol by a 1.5-min retention difference and the resolution between (2*S*, 3*S*, 7*S*)-diprionol and (2*S*, 3*R*, 7*R*)-diprionol are sufficient to identify and

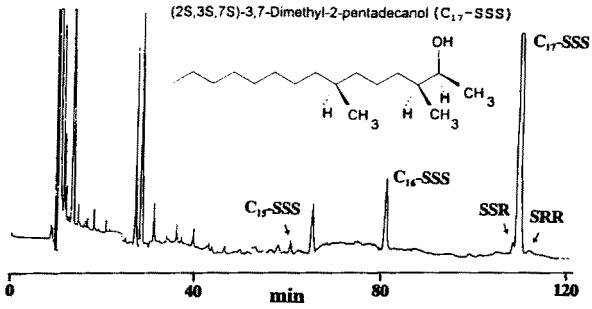

FIG. 1. Enantiomer separation of diprionols as pentafluorobenzoate derivatives, detected by ECD. Columns: fused silica capillary columns, 30 m × 0.15 mm and 25 m × 0.25 mm coated with CP-Sil-88; d_f = 0.22 μm, coupled in series. Oven temperature, 150°C; inlet temperature, 145 kPa nitrogen. C_{15}-*SSS* (2 pg); C_{16}-*SSS* (10 pg); C_{17}-*SSS* (200 pg); C_{17}-*SSR* (4 pg) and C_{17}-*SRR* (2 pg).

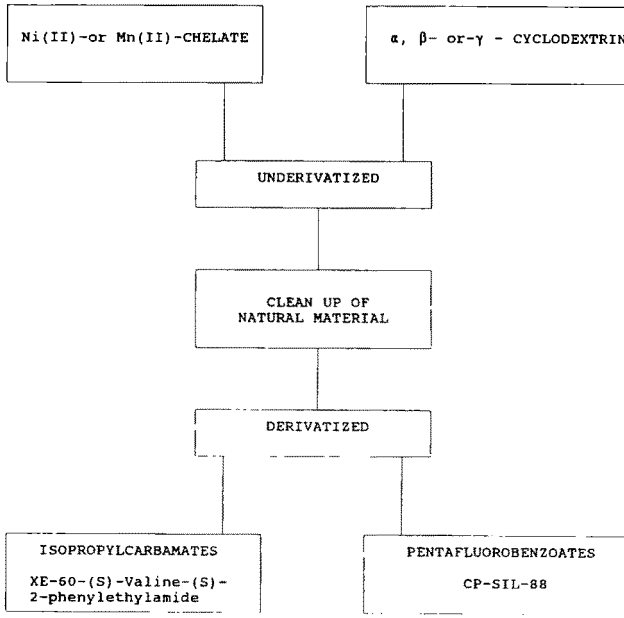

SCHEME 1. Summary of procedures used in chiral analyses of sawfly and antlion volatiles.

quantify them. With this derivatization method we can determine the configuration at the 7-position for *erythro* isomers of diprionols. Scheme 1 shows, in summary, the procedure we have used for the analysis of chiral volatiles from sawflies and antlions. We refer here especially to Högberg et al. (1990) and Bergström et al. (1992), respectively.

The analytical results of the quantification of diprionol from single individuals of *N. sertifer* are presented in Figure 2A, which shows a GC-ECD chromatogram of natural material. Two females from the same population were analyzed, and we found 7.5 and 8.2 ng per individual, respectively. A female from another population produced 9.7 ng diprionol. The second chromatogram presents a standard with 10 ng diprionol (Figure 2B). For each quantification, a standard curve was plotted using the peak area of the diprionol per internal standard. This standard curve for diprionol, i.e., the curve obtained by plotting the ratio between the gas chromatographic peak area of the substance being analyzed and the internal standard against the amount of substance determined, was linear. The blank sample, which was prepared equivalently to the other samples, contained extraneous peaks from the reagents and solvents used (Figure 2C).

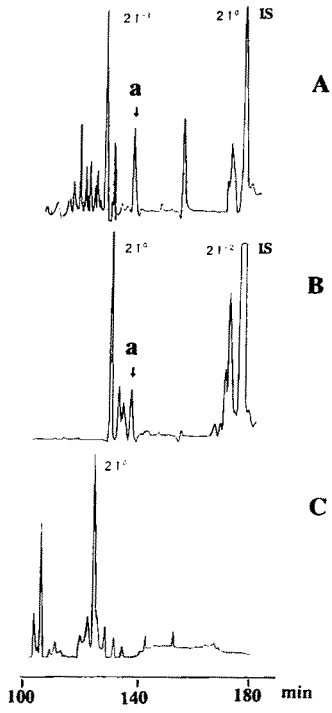

FIG. 2. Quantitative GC-ECD analysis of diprionol in an individual *N. sertifer* female. Column: fused silica capillary columns 50 m × 0.25 mm coupled to 25 m × 0.25 mm coated with Sil-88; d_f = 0.22 μm. Oven temperature, 150°C; carrier gas, nitrogen (90 kPa); injector temperature, 250°C; EC-detector temperature, 275°C. (A) Derivatized LC fractions 7 and 8 from one female: C_{17}-*SSS* (a), internal standard C_{18}-*SSS* (IS), attenuation: $2\uparrow^{-1}$ and $2\uparrow^{0}$. (B) Standard mixture; 10 ng C_{17}-*SSS* (a), C_{18}-*SSS* internal standard (IS), attenuation: $2\uparrow^{0}$ and $2\uparrow^{-2}$. (C) A blank chromatogram with the disturbed peaks from the reagent, attenuation: $2\uparrow^{0}$.

The results demonstrate that complexation gas chromatography can be used as an effective method for stereochemical analyses of molecules that contain suitable functional groups for derivatization. This method may prove generally useful for determination of stereochemical composition.

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Thirty-five populations of *Ips pini* (Say) and one population each of *Ips avulsus* (Eichhoff) and *Ips bonanseai* (Hopkins) were analyzed for the enantiomeric composition of ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol). Populations of *I. pini* occur as at least two distinct regional pheromone variants: New York type [32%-(−) to 56%-(−)-ipsdienol] and California type [94%-(−) to 98%-(−)-ipsdienol]. A third phenotype may occur in southeastern British Columbia, Idaho, and Montana [91%-(−) to 95%-(−)], possibly indicating a zone of hybridization. Populations of the New York type occur in southwestern British Columbia, Alberta, Saskatchewan, Minnesota, and Wisconsin suggesting a continuum through the Canadian provinces and Lake States. The presence of the New York type in western Canada is likely linked to the Quaternary history of the transcontinentally distributed host, *Pinus banksiana* Lamb. Male *I. avulsus* [−25%-(−)] and male *I. bonanseai* [−29%-(−)] both produce ipsdienol, but not ipsenol. Production of ipsdienol by male *I. pini* was evaluated in six different *Pinus* spp. hosts. Following transfer of male *I. pini* to hosts other than the host of origin, the percentage of the (−)-enantiomer of ipsdienol declined when compared to production in the host of origin.

Key Words—Insecta, Coleoptera, Scolytidae, *Ips pini*, *Ips avulsus*, *Ips bonanseai*, ipsdienol, 2-methyl-6-methylene-2,7-octadien-4-ol, aggregation pheromone, enantiomeric composition.

INTRODUCTION

North American pine engraver beetles in the *pini* subgeneric group include *Ips avulsus* (Eichhoff), *Ips bonanseai* (Hopkins), and *Ips pini* (Say) (S.L. Wood, 1982). Morphological similarities also support the placement of the palearctic species, *Ips mannsfeldi* (Wachtl), in this group (S.L. Wood, 1982). In an exhaustive biosystematic study, Lanier (1972) investigated morphological, karyological, and behavioral (mating and pheromone attraction) characteristics of the North American species. Through a survey of collection records, he also delineated the currently accepted distributions of these species.

I. pini, an economically important pest in certain regions of its extensive range, has been the topic of numerous studies of pheromone biology (Anderson, 1948; Lanier et al., 1972, 1980; Vité et al., 1972; Young et al., 1973; Birch, 1974; Piston and Lanier, 1974; Birch and Wood, 1975; Lanier and Wood, 1975; Stewart, 1975; Plummer et al., 1976; Birch and Light, 1977; Birch et al., 1977, 1980; Angst and Lanier, 1979; Furniss and Livingston, 1979; Mustaparta et al., 1980, 1985; Miller et al., 1989, 1990; Raffa and Klepzig, 1989; Gries et al., 1990; Miller, 1990; Miller and Borden, 1990; Teale, 1990; Herms et al., 1991; Raffa, 1991; Teale et al., 1991, 1994; Teale and Lanier, 1991; Vanderwel, 1991; Seybold, 1992; Seybold et al., 1992; Hager and Teale, 1994). The original impetus for the isolation of the aggregation pheromone of *I. pini* in California was because it colonized the same host niche (i.e., phloem layer of *Pinus ponderosa* Laws.) in sympatry with *Ips paraconfusus* Lanier, but was in a different subgeneric group (Wood, 1970; Birch, 1978). Lanier et al. (1972) first described geographic variation in pheromone production and response for populations of *I. pini* from California, Idaho, and New York. The variation in production was later attributed to the enantiomeric composition of the male-produced terpene alcohol pheromone component, ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) (Birch et al., 1980; Lanier et al., 1980). Isolation studies and field assays showed that a population in California produced and responded to (4*R*)-(−)-ipsdienol (Young et al., 1973; Stewart, 1975; Birch et al., 1980), while a population in New York produced and optimally responded to a mixture of the two enantiomers (Stewart, 1975; Lanier et al., 1980). In an analysis of hingut extracts from individual male *I. pini*, Miller (1990) characterized the enantiomeric composition of ipsdienol produced by six populations of *I. pini* in British Columbia in addition to the populations from California and New York. Miller et al. (1989) documented substantial intrapopulational variation of the enantiomeric composition of ipsdienol and found that interpopula-

tional variation ranged from 91%-(−) in California and 89%-(−) in southeastern B.C. to 43%-(−) in New York and 34%-(−) in southwestern B.C.

More recently, geographic variation in *I. pini* pheromone production and response has also been associated with the terpenoid-based ketone, lanierone (2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one), a second pheromone component (Teale et al., 1991; Seybold et al., 1992). Lanierone is produced by a New York, but not a California, population of *I. pini*. Teale et al. (1991) demonstrated that lanierone and racemic ipsdienol together elicit a dramatically higher response from New York *I. pini* than either component alone (> 10-fold increase in trap catch). Lanierone significantly increases the response of California *I. pini* when compared to the response to (−)-ipsdienol alone (0.4-fold increase in trap catch), but lanierone is not as strong a synergist with ipsdienol for this population as it is in New York (Seybold et al., 1992).

The pheromone biologies of *I. avulsus*, *I. bonanseai*, and *I. mannsfeldi* have not been investigated to the extent that any geographic variation is evident. By gas chromatographic (GC) analysis of hindgut extracts, Vité et al. (1972) first demonstrated that fed male *I. avulsus* and *I. bonanseai* produced ipsdienol. *I. avulsus* also produced ipsdienol when exposed to myrcene vapors (Hughes, 1974). However, the enantiomeric composition of the ipsdienol produced by either species has not been reported. Nonetheless, in several field behavioral assays in eastern Texas, *I. avulsus* responded to treatments containing racemic ipsdienol (Renwick and Vité, 1972; Hedden et al., 1976). Based on results from assays with 90%-(−)-ipsdienol in Lufkin, Texas, Vité et al. (1978) predicted that (−)-ipsdienol would be produced by *I. avulsus*. In east Texas, Smith et al. (1990) also reported responses of *I. avulsus* to treatments containing the enantiomers of ipsdienol [96%-(−); 94%-(4*S*)-(+)]. Although the trap catches were low in these studies, *I. avulsus* preferred treatments containing racemic and (−)-ipsdienol over those with (+)-ipsdienol.

While assays with isolated semiochemicals have not been conducted with *I. bonanseai*, Lanier (1972) found in the laboratory that the male-produced frass of *I. bonanseai* from the Santa Catalina Mountains in Arizona elicited a walking response from female *I. pini* originating from western North America. This response was lower than the responses to frass produced by male *I. pini* from eastern or western North America. An investigation of hindgut extracts from male *I. mannsfeldi* indicated that 96.5%-(−)-ipsdienol and 99.5%-(4*S*)-(−)-ipsenol (2-methyl-6-methylene-7-octen-4-ol) occurred in an approximate ratio of 1.5 : 1 (Kohnle et al., 1993). Limited field studies conducted 200 km northeast of Madrid, Spain, demonstrated that predominantly male *I. mannsfeldi* responded maximally to the combination of the two racemic compounds, with negligible responses to either compound alone.

I. pini is distributed both boreally and australly, and it has coevolved with a wide variety of *Pinus* spp. These characteristics, when combined with a simple

aggregation pheromone that is easily collected and analyzed, make *I. pini* an ideal model animal to study the evolution of geographic variation in pheromone production. Because the enantiomeric composition of ipsdienol plays a central role in the aggregation behavior and, thus, the mating biology of *I. pini*, we analyzed North American populations of *I. pini* for this character. Single populations of *I. avulsus* and *I. bonanseai* were included in the survey for comparative purposes. The effect of the *Pinus* spp. host on the enantiomeric composition of male-produced ipsdienol was also investigated for populations from British Columbia, California, and New York. We envisioned that the phenotypic trait of ipsdienol enantiomeric composition could be used to organize the variable populations of *I. pini* into geographically coherent pheromone subgroups that might later be recognized as taxonomic units. Through this analysis, we also hoped to identify areas of sympatry where populations of different pheromone subgroups might be in the process of introgression or divergence. In addition, the information provided by this survey would be useful for forest pest managers concerned with trapping or monitoring populations of *I. pini*. Experience with populations of *I. pini* from California and New York has shown that each population generally responds maximally to its locally produced enantiomeric blend of ipsdienol. Similar, and in some cases, identical pheromone extracts will be analyzed for the presence and absence of lanierone and the results will be summarized in a future paper.

METHODS AND MATERIALS

Insects. Ips species were collected in pine logging debris and reared to adults (Browne, 1972). The sexes were separated using morphological secondary sexual characters (Lanier and Cameron, 1969). Adults were held at 5°C on moist filter paper until they were introduced into logs for ipsdienol collection. Collection localities are given in Table 1 and summarized geographically in Figure 1.

Collection of Vapors. Volatiles associated with tunneling adult beetles of each species were collected by artificially colonizing recently cut logs from *Pinus* spp. and trapping the vapors on Porapak Q (Byrne et al., 1975) (50/80 mesh size, Supelco Inc., Bellefonte, Pennyslvania). Since male *Ips* are generally the first sex to colonize the host (see Kirkendall, 1990 for an exception) and are generally thought to be the only sex to produce ipsdienol (see Seybold, 1992, for an exception), we introduced adult males into fresh logs (~28 cm length × 12 cm diameter) by drilling shallow holes through the bark approximately 3 cm apart on the surface. One male was inserted per hole, and then secured with screen. The method was repeated with separate logs for females and, in some cases, for the host alone. Depending on the availability of a given pop-

[a] All entries represent collections of *Ips pini* except where *Ips avulsus* or *Ips bonanseai* are indicated in brackets. n.d. = not determined.
[b] PB = *Pinus banksiana* Lamb., PCl = *Pinus contorta latifolia* (Engelm. *ex* Wats.), PCm = *Pinus contorta murrayana* (Balf.), PCo = *Pinus coulteri* D. Don, PH = *Pinus hartwegii* Lindl., PJ = *Pinus jeffreyi* Grev. & Balf., PP = *Pinus ponderosa* Laws., PR = *Pinus resinosa* Ait., PS = *Pinus strobus* L., and PT = *Pinus taeda* L. Volatiles from male and female *I. pini* were collected separately from artificially colonized logs of the local host in which the population was collected.
[c] Asterisk indicates recent sample; see text.
[d] In dates, Roman numeral is the month: I = January, . . . , XII = December.
[e] Determined as 23.7%-(−) by chiral GC.
[f] Determined as 98.0%-(−) by chiral GC.
[g] Determined as 58.2%-(−) by chiral GC.
[h] Determined as 31.8%-(−) by chiral GC.

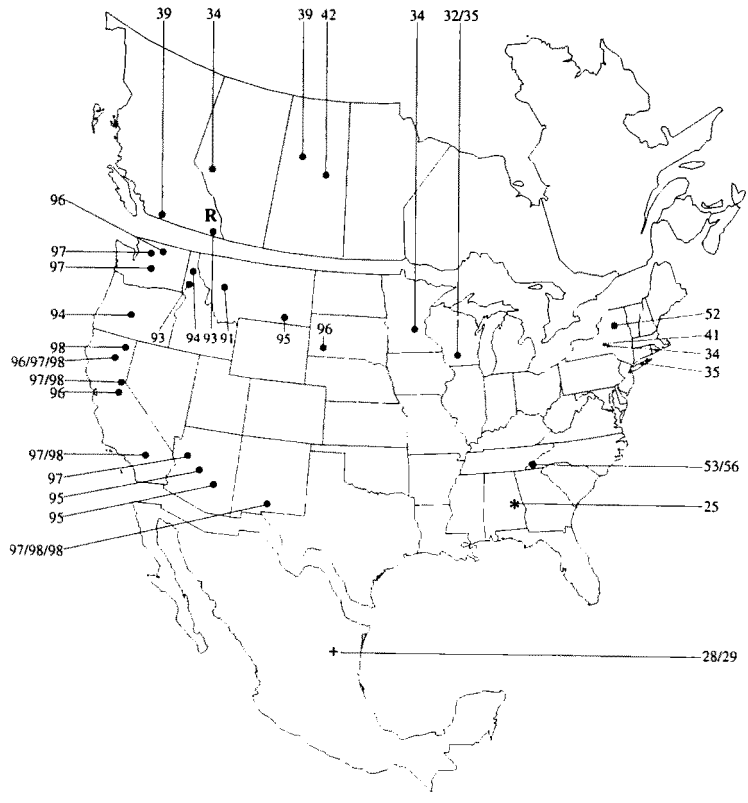

FIG. 1. The enantiomeric composition of ipsdienol [in percentage-(−)] isolated from (*) *Ips avulsus* (Eichhoff), (+) *Ips bonanseai* (Hopkins), and (●) *Ips pini* (Say) from collection sites in North America. R denotes Radium, British Columbia.

ulation, we attempted to use at least 100 insects per aeration. The technique results in an initial colonization density of ~1 insect/4 cm^2.

The artificially colonized logs were incubated at room temperature for 24 hr to allow for frass production and then placed into 19-liter silylated glass carboys (Sylon CT, Supelco Inc., Bellefonte, Pennsylvania) for collection of volatiles. The volatiles were collected for 168 hr by drawing air from the carboys at a rate of 4 liters/min through 15 g Porapak Q. After the collection period, the logs were dissected to determine the number of insects that excavated feeding galleries.

Extraction and Analysis. Compounds were extracted from the Porapak with ~350 ml pentane. Quantitative analysis of ipsdienol present in the extract was performed using one of two methods. In the first samples analyzed, a 10-μl

aliquot of the crude, unconcentrated pentane extract was analyzed for presence and quantity of ipsdienol using silica-phase high-performance liquid chromatography (HPLC). Because of the difficulty in obtaining an internal standard with suitable retention time and UV absorbance, quantities were estimated using a calibration curve derived from the injection of known quantities of authentic ipsdienol (Product #P407, Bedoukian Research Inc., Danbury, Connecticut). Measurement was based on the mean of three sample injections. Recent samples (indicated by an asterisk in Table 1) were analyzed by adding an internal standard of *n*-octanol (Aldrich Chemical Co., No. 36,056-2, Milwaukee, Wisconsin) to the 350-ml crude extract prior to Kuderna-Danish evaporative concentration to 10 ml. A 1-μl aliquot of the concentrated crude extract was analyzed for the presence and quantity of ipsdienol using gas chromatography (GC). In this case, measurement was based on the mean of six sample injections. Enantiomeric analysis that followed both methods of quantitative analysis utilized a fractionated 1-ml aliquot of the 10-ml concentrated crude extract.

The enantiomeric composition of the naturally occurring ipsdienol was determined following isolation by silica-phase preparative HPLC. In the first samples analyzed, isolated ipsdienol was converted to diastereomeric esters and the esters were resolved by silica phase analytical HPLC (Kubo et al., 1986; Seybold, 1992). Integration of peak areas for each diastereomer and calculation of the peak area ratio yielded the enantiomeric composition. The chiral acid used for the esterification of ipsdienol was (1*S*)-camphanic acid [Aldrich Chemical Co., No. 32,822-7, CP = 99%, $[\alpha]_D^{20} = 25°$ (c = 1, dioxane)]. The enantiomers of isolated ipsdienol were thus resolved as the (4*R*)- and (4*S*)-ipsdienyl-(1*S*)-camphanates (Seybold, 1992). In more recently analyzed samples (indicated by an asterisk in Table 1), enantiomeric composition of isolated ipsdienol was determined by chiral GC (Seybold et al., 1992). Selected samples were analyzed by both methods (Table 1) to determine if the methods gave comparable results. Measurement of the enantiomeric ratio for each compound using either technique was based on the mean of five sample injections.

Chromatography. Thin-layer chromatography (TLC) for monitoring reactions utilized silica gel Polygram Sil G/UV254 precoated 4 × 8-cm plastic sheets (0.25 mm, Macherey-Nagel, Duren, Germany) developed with ethyl acetate-hexane (2:1, v/v).

Silica-phase HPLC for quantitative analysis of ipsdienol and resolution of ipsdienol diastereomeric esters employed a Jasco 880-PU pump (Jasco, Tokyo, Japan) equipped with an Eyela UV-9000 Detector (Tokyo Rikakikai Co., Tokyo, Japan); column: Partisil PXS 5/25 (Whatman Inc., Clifton, New Jersey), 25 cm × 5 mm; mobile phase: hexane–acetone (100:2, v/v); flow rate 1.5 ml/min; and UV 225 nm. Silica-phase preparative HPLC for isolation of ipsdienol was conducted with a Japan Analytical Industry model LC-908 instrument equipped with UV and refractive index (RI) detectors. The column and

conditions for isolation of ipsdienol were Nucleosil 50-5 (50 × 10 cm) (Alltech Applied Science, Deerfield, Illinois); mobile phase: hexane–acetone (94:6, v/v); flow rate: 1.6 ml/min; and UV 235 nm.

Gas chromatography (GC) for quantitative analysis of ipsdienol was performed on a Hewlett Packard Series 5890A gas chromatograph. A fused silica capillary (Durabond-5, J&W Scientific, Folsom, California; 30 m × 0.25 mm ID, 0.25-μm film thickness; helium carrier gas 31 cm/sec) was temperature programmed (70°C for 29 min and 70°C to 180°C at 5°C/min) for resolution of ipsdienol from *n*-octanol and a myriad of crude extract components. Injection and detection temperatures were set at 200°C and peak areas were integrated using an HP-3393A integrator. GC conditions for determination of enantiomeric composition of ipsdienol were as previously described (Seybold et al., 1992).

Spectroscopy. High-resolution gas chromatography–mass spectrometry (HRGC-MS) utilized a Hewlett-Packard Series 5790A gas chromatograph interfaced with an HP Series 5970A mass selective detector (MSD). This system was operated under electron impact (70 eV) conditions. A fused silica capillary (Durabond Wax, J&W Scientific; 30 m × 0.25 mm ID, 0.25-μm polyethylene glycol film; helium carrier gas 25 cm/sec) was temperature programmed (75°C to 130°C at 10°C/min, 130°C to 150°C at 2°C/min, and then 150°C to 250°C at 10°C/min) for resolution of ipsdienol. Ipsdienol was unambiguously identified in selected extracts by comparison with the retention time and spectrum from the commercially available authentic standard and by matching retention time of the standard with the retention time of the base peak (ipsdienol m/z = 85) determined by selective ion monitoring of selected extracts.

RESULTS

A total of 35 populations of *I. pini*, one population of *I. avulsus*, and one population of *I. bonanseai* were examined in this survey; in some cases identical populations were subsampled and analyzed twice. The enantiomeric composition of ipsdienol isolated from male *I. pini* in its local host ranged from 32.0%-(−) (Sauk County, Wisconsin) to 98.5%-(−) (Lassen County, California, and Otero County, New Mexico) (Table 1). Male *I. avulsus* (Lee County, Alabama) produced 25.0%-(−)-ipsdienol [23.7%-(−) when measured by chiral GC], while male *I. bonanseai* (Galeana, Nuevo Leon, Mexico) produced 28.3%-(−)- and 29.0%-(−)-ipsdienol in separate analyses of the same population (Table 1). Populations of *I. pini* can be organized into three basic pheromone groups, based on their geographic distribution. Populations from the southwest and the Pacific coast of the United States produced ipsdienol that ranged in enantiomeric composition from 94.2%-(−) (Deschutes County, Oregon) to 98.5%-(−) (Lassen County, California, and Otero County, New Mexico) (Figure 1). Populations

from southeastern British Columbia, Idaho, and Montana produced ipsdienol that varied in enantiomeric composition from 91.2%-(−) (Missoula County, Montana) to 94.6%-(−) (Rosebud County, Montana). Populations from the eastern United States, southwestern British Columbia, Alberta, and Saskatchewan produced ipsdienol with an enantiomeric composition between 32.0%-(−) (Sauk County, Wisconsin) and 55.9%-(−) (Clay County, North Carolina) (Figure 1). An isolated population from the Black Hills of South Dakota (Pennington County) produced 96.4%-(−)-ipsdienol (Figure 1). There was general agreement between results obtained using the HPLC and GC techniques (Table 1). The most pronounced difference was with measurements of ipsdienol isolated from *I. pini* from Clay County, North Carolina: 55.9%-(−) by HPLC; 58.2%-(−) by GC.

When populations of male *I. pini* were transferred to other host pines for ipsdienol production, the percentage of the (−)-enantiomer declined when compared to the percentage produced in the host of origin (Table 2). Host transfers to *P. ponderosa* resulted in absolute reductions of 7.5% (Manning Park, British Columbia from *P. contorta latifolia*); 1.6% (Jaffray, British Columbia from *P. contorta latifolia*); 3.1% (Essex County, New York from *P. resinosa*); and 0.3% (Onondaga County, New York from *P. resinosa*). California populations of *I. pini* collected in *P. jeffreyi* and *P. contorta murrayana* (both Lassen County) showed absolute reductions of 3.4% and 2.0%, respectively, when they were aerated in *P. ponderosa*. A California population of *I. pini* collected in *P. ponderosa* (Shasta County) showed an absolute reduction of 2.5% in the percentage of the (−)-enantiomer when transferred to *P. jeffreyi* and a 0.6% drop when transferred to *P. contorta murrayana* (Table 2). Nonetheless, the ranges for these three California populations in the three hosts were fairly small (*P. jeffreyi*—3.4%; *P. contorta murrayana*—2.5%; and *P. ponderosa*—2.5%).

If we consider the populations from British Columbia, California, and New York as a random sample from the distribution of *I. pini*, then a paired *t* test of the reductions of the (−)-enantiomer can be performed. For biological reasons, we chose to analyze the six cases where *P. ponderosa* was the host of aeration, but not the original host. We also included the single case (Shasta County, California) where the closely related *P. jeffreyi* was the host of aeration and *P. ponderosa* was the original host. The analysis indicated that the 95% confidence interval around the mean reduction in the percentage of the (−)-enantiomer does not include zero, thus the reduction is significant ($\bar{X} = -2.914$; 95% confidence interval = −5.013, −0.816; $N = 7$) (Minitab, Release 8.2, 1991, State College, Pennsylvania).

The structure of ipsdienol was confirmed by mass spectral analysis in samples from the following populations of *I. pini:* Obed, Alberta; Jaffray, British Columbia; El Dorado County, California (Fallen Leaf Lake); Lassen County, California (Ladder Butte); Modoc County, California; San Bernardino County,

[a] First host entry is host for collection, while second host entry is host for aeration. Hosts include: PCl = *Pinus contorta latifolia* (Engelm. *ex* Wats.), PCm = *Pinus contorta murrayana* (Balf.), PJ = *Pinus jeffreyi* Grev. & Balf., PP = *Pinus ponderosa* Laws., and PR = *Pinus resinosa* Ait. For populations from British Columbia and New York, the alternate host (*P. ponderosa*) originated from Shasta Co., California. For populations from California, the alternate hosts originated from Lassen or Shasta Cos., California.

California (Shake Creek); Latah County, Idaho; Clay County, North Carolina; Deschutes County, Oregon; Meadow Lake, Saskatchewan; Prince Albert, Saskatchewan; Pennington County, South Dakota; Okanogan County, Washington (Winthrop); and Sauk County, Wisconsin.

DISCUSSION

Within the *pini* subgeneric group in North America, all three species produce ipsdienol, but not ipsenol. The palearctic consubgeneric species *I. mannsfeldi* is an exception (Kohnle et al., 1993). The two populations of *I. avulsus* and *I. bonanseai* that we sampled produced surprisingly similar enantiomeric blends of ipsdienol [~25%-(−) and ~29%-(−), respectively] that differed markedly from the majority of *I. pini* populations studied [32%-(−) to 98%-(−)]. Although evaluation of this character alone may suggest similarity of the two southern species, Lanier (1972) concluded that *I. pini* and *I. bonanseai* were more closely related for reasons of morphology, karyology, and interfertility. However, he did not include *I. avulsus* in either interbreeding or pheromone cross-attraction studies, stating that the extreme (morphological?) differences of *I. avulsus* made experiments unnecessary. Lanier (1972) noted that the male genitalia of *I. avulsus* resemble those of *I. bonanseai*, as well as those of species in the *emarginatus* subgeneric group.

It is unclear whether interspecific breeding isolation and competition for host material (Wood, 1970; Lanier and Burkholder, 1974; Lanier and Wood, 1975) or phylogenetic divergence (Lewis and Cane, 1990) better explains current pheromonal specificity among *Ips* spp. However, the similarity in enantiomeric composition of ipsdienol produced by male *I. avulsus* and *I. bonanseai* may not indicate phylogenetic similarity as much as it does similar competitive interactions with *I. pini*. *I. avulsus* and *I. pini* share a zone of sympatry in southern Appalachia (Ciesla and Bell, 1968; Lanier, 1972; S.L. Wood, 1982), while *I. bonanseai* and *I. pini* are sympatric in the northern Mexican state of Chihuahua (Lanier, 1972). Additional populations of *I. pini* may be present in more southerly Mexican states like Durango, providing the possibility of more extensive sympatry for *I. bonanseai* and *I. pini* (J. Flores, personal communication). In these zones, both *I. avulsus* and *I. bonanseai* may have evolved to produce and detect enantiomeric blends of ipsdienol that would minimize the possibility of a wasted mating attempt with *I. pini*. Since the behavioral assays conducted to date in eastern Texas implied a preference by *I. avulsus* for (−)-ipsdienol (Vité et al., 1978; Smith et al., 1990), it is surprising that we found that male *I. avulsus* from Lee County, Alabama produced predominantly (+)-ipsdienol. There could be geographic variation for this character in *I. avulsus* between the disjunct Alabama and Texas populations (Lanier, 1972). Both *I. avulsus* and *I.*

bonanseai may also produce other aggregation pheromone components, possess proximal chemical or auditory cues, or even have different host preferences that provide for interspecific discrimination in the respective zones of sympatry with *I. pini*.

For *I. pini* this study indicated the presence of geographically specific trends in ipsdienol stereochemistry. Birch et al. (1980) and Lanier et al. (1980) showed a clear difference in enantiomeric composition between eastern and western North American populations. Ipsdienol is produced in the east in a wide range of enantiomeric percentages [32%-(−) to 56%-(−)], increasing as populations were sampled from more easterly and southerly localities. In general for eastern populations, the percentage of the (−)-enantiomer tends toward that produced by the consubgeneric species *I. avulsus* and *I. bonanseai*. Anderson (1948) made pioneering observations of the aggregation behavior of *I. pini* on jack pine, *Pinus banksiana* Lamb., in Minnesota. Although the Minnesota population that we analyzed came from red pine, *P. resinosa* Ait., it is likely that Anderson's original observations were made on a population of males that produced ~34%-(−)-ipsdienol and that population was representative of much of eastern North America (see query in D.L. Wood, 1982).

The regional situation in western North America is more complex. Miller et al. (1989) found a particularly interesting regional variant of *I. pini* in *P. contorta latifolia* Engelm. ex Wats. located in southwestern British Columbia near Manning Provincial Park. This population produces an enantiomeric blend of ipsdienol normally associated with *I. pini* in eastern North America (e.g., New York). Surprisingly, this population occurs only 70 km north of a western population [97%-(−)] (Okanogan County, Washington, Winthrop, *P. ponderosa*) and 100 km northwest of a second western population [96%-(−)] (Okanogan County, Washington, Tonasket, *P. contorta latifolia*). This variant population is likely to be contiguous with populations included in this study from Alberta and Saskatchewan (Meadow Lake and Prince Albert), which are also more "New York-like." In addition, populations from southeastern British Columbia, Idaho, and Montana tend to produce an enantiomeric percentage of (−)-ipsdienol that is slightly lower [91%-(−) to 95%-(−)] in our study than that produced by populations from the southwestern and Pacific coast states [94%-(−) to 98%-(−)]. Miller et al. (1989) found a lower population mean for the population from southeastern British Columbia [89%-(−)], while Plummer et al. (1976) reported 100%-(−) for "Idaho" *I. pini*. The latter study was an early attempt at determining the enantiomeric composition of insect pheromone alcohols using NMR chiral shift reagents. This technique may not have been as accurate as currently available chromatographic methods. The existence of a third regional variant in western North America (Idaho/Montana) is generally supported by cuticular hydrocarbon phenotypes (Seybold et al., unpublished)

and by field behavioral responses to ipsidenol and lanierone (Miller et al., unpublished) that differ from those in northern California and New York.

The complexity outlined by this investigation in northwestern North America suggests that further sampling in British Columbia, Alberta, and the central Rocky Mountain region will be important. Perhaps significantly, Swaine (1918) recognized a taxon in southern British Columbia named *Ips interpunctus* Eichhoff [now synonymized with *Ips perturbatus* (Eichhoff) (Wood, 1977; Wood and Bright, 1992)]. Although found most frequently in spruce (*Picea* spp.), *I. interpunctus* was considered closely related to *I. pini* because it was observed in the same galleries with, intergraded morphologically with, and apparently crossed with *Ips oregonis* Eichhoff [a synonym for western populations of *I. pini* (Hopping, 1964; Wood and Bright, 1992)] (Swaine, 1918). The seemingly confusing interspecific taxonomic situation in this area alluded to by early researchers may have foreshadowed the intraspecific complexity presented in the current analysis. Indeed, Lanier and Burkholder (1974) also understood the significance of this region for *I. pini* when they observed that, "The pheromonal differences (between populations of *I. pini*), like the slight morphological differences in both the insect (Hopping, 1964) and its parasitic mites (Lindquist, 1969), probably intergrade in the Rocky Mountains of the northern U.S.A. and Canada." Several possible zones of sympatry between pheromone types of *I. pini* must exist in the northwest, and they would make ideal locations for studies of naturally occurring, interpopulational aggregation and mating behavior. These zones include possible California and New York phenotypes in northern Washington and southwestern British Columbia; Idaho/Montana and possible New York phenotypes in southeastern and southwestern British Columbia; and Idaho/Montana and possible California phenotypes in northern Idaho and northern Washington.

Among the critical questions to be answered by examining the behavior of the populations in these possible zones of sympatry is whether the southwestern British Columbia population has the behavioral and biochemical characteristics of the well-studied New York population. Cross-attraction studies in this area with *I. pini* from California and New York similar to those conducted by Lanier et al. (1972) are needed to address this question. Reciprocal tests in California and New York with southwestern British Columbian *I. pini* would establish whether the latter has New York behavioral traits. Production of lanierone and the dose–response to the highly pure enantiomers of ipsdienol are also key factors to be investigated for this population. However, differences in the cuticular hydrocarbon phenotypes from the New York and southwestern British Columbian populations indicate that these populations are not entirely identical (Seybold et al., unpublished).

If the population in southwestern British Columbia is demonstrated to have

the full complement of New York behavioral attributes, then its origin is of interest: whether through human introduction or natural postglacial migration with *P. banksiana* and *P. contorta* (Critchfield, 1957, 1984, 1985; Mathews, 1979; Seybold et al., 1992). Since male *I. pini* collected from Alberta [34%-(−)]; Meadow Lake, Saskatchewan [39%-(−)]; Prince Albert, Saskatchewan [42%-(−)]; and Minnesota [34%-(−)] all produce an enantiomeric composition of ipsdienol similar to the southwestern British Columbia population [39%-(−)], it is likely that a transcontinental continuum of the New York ipsdienol phenotype exists through the Canadian provinces. Because *P. banksiana* is the only species of pine whose distribution spans the Lake States and most of the Canadian provinces (Critchfield and Little, 1966), the late Quaternary history of *I. pini* in this area is undoubtably linked to the history of this host (Critchfield, 1985). During the Holocene Epoch (the current interglacial episode), *P. banksiana* may have recolonized the Canadian provinces from a principal refugium in southeastern North America or from intraglacial corridors or refugia (Critchfield, 1985). The current distribution of *P. banksiana* ends in a zone of hybridization with *P. contorta latifolia* in northern Alberta, northeastern British Columbia, and southwestern MacKenzie (Critchfield, 1984, 1985). However, throughout the repeated glacial–interglacial sequences of the Pleistocene Epoch, *P. banksiana* and *P. contorta* have experienced increased genetic variation due to multiple alterations in geographic distribution, including periods of genetic contact during earlier interglacials (Critchfield, 1984). For example, there is evidence for introgression of *P. banksiana* into the northern interior range of *P. contorta latifolia*, extending northwest from western Montana to the Yukon (Critchfield, 1984). These genetic traits have been documented to occur to the west of the current zone of hybridization and are separated from this zone by populations of pure *P. contorta latifolia*. Their presence in these locations has been attributed to previous contacts between the species during earlier interglacials (Critchfield, 1984).

Critchfield's (1984) themes of long periods of geographic isolation with possible genetic differentiation, shifting and expansion of the range, and reestablishment of genetic contact with populations from other refugia might apply to historical populations of *I. pini* as well as to its hosts. However, comparable genetic studies of the associated regional populations of *I. pini* that might reveal similar disjunct occurrences of genetic influence have not been conducted. Furthermore, the only currently known, direct fossil evidence related to the Quaternary history of *I. pini* consists of body fragments excavated near Kitchener, Ontario, from peat/marl lacustrine sediments at a depth of 1.75–3.28 m and dated ~9000 BP (Schwert et al., 1985). The sediments indicated that at that time the area was a pine-dominated vegetative zone with floral and faunal conditions similar to those present in southern Ontario today. To our knowledge,

there are no fossil records from the area of interest in the western Canadian provinces.

It is intriguing that while the current distribution of *P. banksiana* ends in a zone of hybridization with *P. contorta latifolia* in northern Alberta, northeastern British Columbia, and southwestern Mackenzie, the distribution of the New York ipsdienol phenotype of *I. pini* continues in *P. contorta latifolia* through southwestern British Columbia to the border of Washington. This asymmetry between the distribution of the New York phenotype of the beetle and the host that it may have followed from the east could be explained by invasion of New York-type *I. pini* into the habitat and host once occupied solely by the western form or by a more rapid postglacial recolonization rate by the eastern host, *P. banksiana.* Miller (1990) studied the enantiomeric composition of ipsdienol produced by males from six populations in British Columbia and the response to the enantiomers in four populations. One population (Radium in southeastern British Columbia, Figure 1) has a distribution of ipsdienol enantiomeric composition that appears to be intermediate between east and west, suggesting possible introgressive hybridization.[4] However, the response of the Radium population of *I. pini* to the enantiomers of ipsdienol appears to be similar to the New York type (Miller, 1990). In our study, the slightly lower enantiomeric compositions of ipsdienol [in percentage-(−)] produced by populations from southeastern British Columbia, Idaho, and Montana may indicate that, similar to the situation with the two hosts, the zone of introgression for the two beetle populations extends south of the international border. Alternatively, the New York type of *I. pini* may have had more rapid entry into northern British Columbia during the present interglacial. Macrofossil data (Critchfield, 1985) and pollen-dating studies (Critchfield, 1985; MacDonald and Cwynar, 1985; Prentice et al., 1991) suggest that *P. banksiana* may have recolonized the area vacated by the receding Laurentide and Cordilleran ice sheets more rapidly than *P. contorta.*

Although the species of pine host used for ipsdienol production did not radically alter the enantiomeric composition of ipsdienol isolated from any *I. pini* population in our study, it is interesting that the enantiomeric composition [in percentage-(−)] was consistently lower when males were placed in any other host compared to their host of origin. These reductions were small when compared to the differences measured from the New York and California phenotypes, but comparable to the differences measured from the Idaho/Montana and California phenotypes. These small reductions might be due to a nutritional effect of feeding in a biochemically different pine species or simply attributable

[4]This area of North America has also been recognized as a site of complex intrapopulational pheromone variation for *Ips tridens* (Mannerheim) (Lanier and Burkholder, 1974).

to variation in our technique. One source of variation is the number of individuals included in the aeration sample. This is related to the inherent variation in the enantiomeric composition between individuals in the population (Miller et al., 1989; Miller, 1989). For example, in a study of gut extracts made from 62 individual male *I. pini* collected in Shasta County, California, Miller et al. (1989) found that 10–20% of the individuals had ipsdienol with enantiomeric compositions lower than 90%-(−) and several individuals had an enantiomeric composition less than 50%-(−). The distribution mean was 91%-(−), which is lower than results obtained by trapping ipsdienol from all individuals simultaneously in the volatile headspace from a similarly-sized population from the same locality (Tables 1 and 2, Figure 1). The slightly lower result noted by Miller et al. (1989) may also be due to host effects. Insects from their study were collected in *P. ponderosa* and analyzed in *P. contorta latifolia*. Real differences associated with their gut extraction technique and our volatile entrapment method may also exist.

Another source of variation may be related to the quantity of ipsdienol produced or collected for analysis. Thus, the number of individuals included in each aeration sample may affect the measurement of the enantiomeric composition. However, we have found that including 20–25 individuals in an aeration sample gives an enantiomeric composition that is repeatable with larger numbers of insects. For example, in four separate aerations of four coastal California populations of male *Ips mexicanus* (Hopkins) (29, 61, 111, and 200 individuals), the enantiomeric compositions of ipsdienol were: 88.9, 90.9, 91.3, and 88.9%-(−), respectively (Seybold, 1992). Similar results were obtained in the present study (see populations of *I. pini* from Shasta and Lassen Counties, California; Table 2).

A third source of variation in our technique involves run-to-run variation in the extraction and chemical analytical procedures. Two similarly-sized samples of male *I. pini* from Sauk County, Wisconsin, of male *I. pini* from Otero County, New Mexico, and of male *I. bonanseai* from Nuevo Leon, Mexico (Table 1) were analyzed. The measurement differed by 3.0% in absolute terms for Wisconsin *I. pini*, yet by only 0.5% for New Mexico *I. pini* and 0.7% for *I. bonanseai*, indicating the possibility for substantial run-to-run variation, although different individuals were also included in each run. Due to these three sources of variation, a larger number of samples will be required to separate the northern Rocky Mountain (i.e., Idaho/Montana) unequivocally from the Pacific coast/southwestern United States variant. Our analysis has been a first-level, bulk aeration assessment. Further sampling in these areas of interest should involve measuremnts of within-population variation by analyzing volatiles trapped from individuals.

Acknowledgments—We dedicate this paper to the memory of Gerald N. Lanier, who recognized both that, "In some instances the entities revealed by pheromonal differences will prove to

be sibling species" and research on the role of optical rotation in pheromone specificity could clarify the role of pheromones in the evolution of the Coleoptera (Lanier and Burkholder, 1974). We wish to thank the following cooperators who assisted us with collections of live populations of *I. pini* and host material: C.W. Berisford, J.H. Borden, B. Borys, J.H. Cane, A. Cognato, R. Dorsett, T. Eager, T. Eiber, J.W. Fox, M.M. Furniss, C. Garza, K. Gibson, P.F. Kolb, D.W. Langor, G.N. Lanier, J. Flores Lara, R.L. Livingston, L.D. Merrill, D.R. Miller, D. Milligan, K.F. Raffa, M.E. Schultz, P.J. Shea, and S.A. Teale. J.L. Tupy, S.T. O'Keefe, M. Kuenzli, D.R. Quilici, and J.A. Tillman provided essential laboratory support for this study. H. Rappaport provided assistance with graphics, and J. Baldwin provided statistical advice. We thank B.B. Kinloch, C.I. Millar, and D. Vanderwel for reviews of the manuscript. This research was supported by the University of California at Berkeley, a National Science Foundation Graduate Fellowship to S.J.S., National Science Foundation Dissertation Improvement Grant BSR-8914625 to S.J.S., and USDA Forest Service Pacific Southwest Research Station Cooperative Research Agreement #PSW-92-0014CA with D.L.W. A substantial portion of this survey was completed by S.J.S. with the support of and at the facilities of the Insect Chemical Ecology Laboratory of the USDA Forest Service, Pacific Southwest Research Station, Albany, California.

WHY NOT BE A QUEEN? REGIOSELECTIVITY IN MANDIBULAR SECRETIONS OF HONEYBEE CASTES

E. PLETTNER,[1] G.R.J. SUTHERLAND,[1,3] K.N. SLESSOR,[1,*] and M.L. WINSTON[2]

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Both female castes of the honeybee (*Apis mellifera* L.) synthesize hydroxylated 2(*E*)-decenoic acids in their mandibular glands. Queens produce 9-hydroxy-2(*E*)-decenoic acid as part of their primer pheromone, while workers produce the regioisomeric 10-hydroxy acid, probably as a larval food source and an antiseptic secretion. Both workers and queens are biosynthetically competent to produce the other caste's dominant hydroxylated compound, as both isomers can be detected in queens and workers. We investigated the source of the caste-determined regioselectivity of hydroxy acid biosynthesis by investigating the production and interconversion of these compounds in isolated worker honeybee mandibular glands with specifically deuterated precursors. Gas chromatographic-mass spectroscopic identification of the labeled product indicates that octadecanoic acid is converted into 10-hydroxy-2(*E*)-decenoic acid with higher efficiency than either hexadecanoic or decanoic acids. 10-Hydroxydecanoic acid is readily converted into 10-hydroxy-2(*E*)-decenoic acid as expected in the β-oxidation process. The saturated and unsaturated 10-hydroxy acids are oxidized to the corresponding ten carbon diacids.

Key Words—Hymenoptera, Apidae, *Apis mellifera* L., mandibular gland secretion, hydroxydecenoic acids, hydroxydecanoic acids, deuterated precursors, gas chromatography-mass spectroscopy, biosynthetic precursors.

INTRODUCTION

There are two female castes in a honeybee (*Apis mellifera* L.) colony: the queen and several thousand workers. The queen's main function is reproduction,

although she also heads the colony by producing primer/releaser pheromones that mediate many aspects of worker behavior and partially inhibit worker reproduction. The workers perform many nonreproductive tasks, such as brood rearing, guarding, and foraging (Winston, 1987), and generally only lay eggs following two to three weeks of queenlessness and broodlessness. Beekeepers and scientists have been fascinated by the differences between queens and workers because fertilized eggs have the potential to follow different developmental pathways leading to worker or queen adults. This process of caste differentiation ultimately results in morphological and physiological differences between adult queens and workers.

One such physiological difference is the composition of the mandibular gland secretion, a blend of several compounds produced in the mandibular glands of female honeybees. Among the many compounds found in their mandibular glands, both queens and workers produce a group of oxygen functionalized 10- and 8-carbon fatty acids. The fatty acids characteristic of queens have the functional group at the penultimate ($\omega - 1$) position in the chain, while the acids typical of workers are functionalized at the last (ω) position. The major component of queen mandibular pheromone (QMP) is 9-keto-2(*E*)-decenoic acid (ODA); the second most abundant is 9-hydroxy-2(*E*)-decenoic acid (9-HDA) (Slessor et al., 1988, 1990). The most abundant component of the worker mandibular blend is 10-hydroxy-2(*E*)-decenoic acid (10-HDA), followed by 10-hydroxydecanoic acid (10-HDAA). The 8-carbon homolog, 8-hydroxyoctanoic acid (8-HOAA), is a minor worker component, as are the diacids corresponding to 10-HDA and 10-HDAA, 2(*E*)-decenedioic acid ($C_{10:1}$ DA) and decanedioic acid ($C_{10:0}$ DA), respectively.

The function of these caste-specific blends also differs. The queen-produced blend is a releaser pheromone that attracts nearby workers to the queen, giving rise to a retinue of workers around the queen (Slessor et al., 1988), among other effects (Winston and Slessor, 1992). The queen pheromone also is a primer pheromone, since it inhibits queen rearing by workers (Winston et al., 1990) and its major component, ODA, inhibits juvenile hormone III biosynthesis in workers (Kaatz et al., 1992). The worker mandibular components are not known to function as semiochemicals, but 10-HDA is found in royal jelly (Weaver et al., 1968), the worker-produced queen food and the 10-carbon diacids, $C_{10:1}$ DA and $C_{10:0}$ DA, are found in honey (Plettner, unpublished observation). Blum et al. (1959) reported antibacterial and antifungal activity for 10-HDA, and Boch et al. (1979) reported the volatile acids present as antibacterials, so this secretion may be involved in food preservation.

Even though the mandibular acids of both castes appear to have important functions in honeybee colonies, their biosynthesis has not been studied. However, the catabolism of ODA in workers was followed with radiolabeled material, in an effort to understand how the workers clear their system of the queen-

produced attractant and primer (Johnston et al., 1965). The results indicated that the ODA was reduced to 9-HDA and to the saturated analogs, 9-ketodecanoic- and 9-hydroxydecanoic acids (ODAA and 9-HDAA). This process appeared to take place mainly in the gut of the workers. The authors speculated that the catabolites of ODA might accumulate in the worker-produced royal jelly and could thus be recycled back to the queen, who would convert the catabolites back to ODA. However, analyses of royal jelly have revealed that it does not contain 9-HDA, 9-HDAA, or ODAA (Weaver et al., 1968), and the biosynthesis of mandibular acids has not been studied since. The objective of our work was to study interconversion among mandibular blend components and to find which precursor is functionalized to give the hydroxy acids, using deuterated potential intermediates and precursors and following their incorporation by gas chromatography–mass spectroscopy. We wished to understand how the caste-specific regioselective functionalization of the hydroxy acids is regulated and chose to initially study workers, since these are more readily available than queens.

The composition of queen and worker mandibular glands had been thought to be mutually exclusive, until it was found that some workers can produce ODA under queenless conditions (Ruttner et al., 1976). Further work led to the realization that this overlap does not occur under special circumstances. Even queenright workers have a small amount of 9-HDA in their mandibular glands, the ratio of 10-carbon hydroxy acids, 10-HDA–10-HDAA–9-HDA being ca. 30:10:1 (Plettner et al., 1993). We have taken advantage of this occurrence of 9-HDA in workers to study its biosynthesis simultaneously with the ω-hydroxy acids. The overlap in gland composition is not restricted to workers; mated, laying queens always have trace amounts of 10-HDAA and variable amounts of 10-HDA, along with ODA and 9-HDA, which are more abundant than the worker acids (Crewe, 1982, Plettner et al., unpublished observation). While workers retain the same ratio of mandibular components throughout their life, queens gradually change from a blend dominated by 10-HDA in newly emerged queens to a blend with mostly ODA and 9-HDA. Both castes experience an increase in the total amount of acids in the mandibular glands as they age (Slessor et al., 1990) (Figure 1). Knowledge of the mandibular gland ontogeny was useful for this project, since young individuals have low levels of endogenous material, which makes labeled products easier to detect.

METHODS AND MATERIALS

Gland Isolation and Treatment

The bees used for the assay were 1–5 days old and were kept caged in an incubator (34°C) with honey and water until required. Both glands were freshly

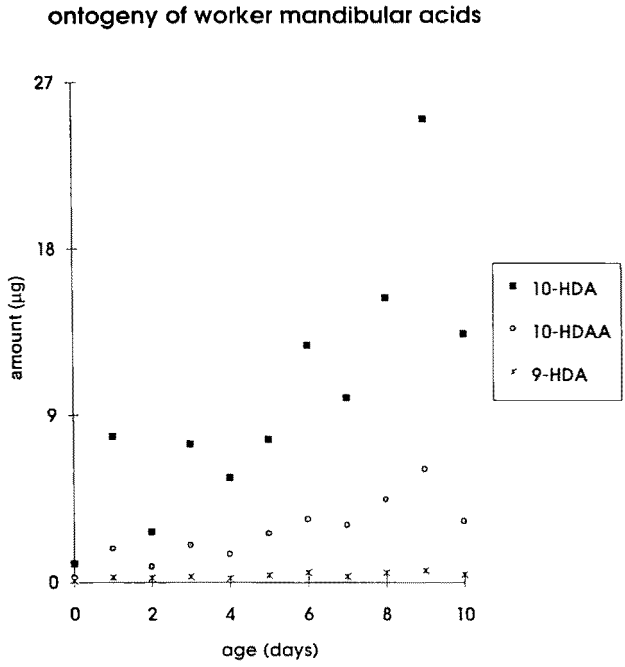

FIG. 1. Ontogeny of three hydroxy acids found in worker mandibular glands: 10-hydroxy-2(*E*)-decenoic acid (10-HDA), 10-hydroxydecanoic acid (10-HDAA), and 9-hydroxy-2(*E*)-decenoic acid (9-HDA). Data represent the total amount of compound found in a pair of mandibular glands, as determined by gas chromatography (Slessor et al. 1990). Each point is an average of three samples.

removed, washed in Tris-buffered physiological saline (pH 6.5–7.5), blotted dry with a piece of tissue, and exposed to a solution of the test substrate in DMSO. The gland was placed in an Eppendorf tube and left to perfuse at room temperature for 5–20 min, washed with physiological saline, blotted dry, and placed in methanol (13 µl) containing 10-undecenoic acid (0.2 µg/µl) as internal standard, crushed, and centrifuged at low speed. The supernatant was removed and the pellet extracted with a further portion of methanol (13 µl) containing internal standard.

Analysis

Two aliquots (2 µl) of mandibular extract were evaporated and trimethylsilyated with bistrimethylsilyltrifluoroacetamide (2 µl of neat reagent, Sigma Chemical Co., St. Louis, Missouri) for at least 40 min at room temperature (Slessor et al., 1990). One sample was diluted with hexane (to 30 µl) and

analyzed by splitless capillary gas chromatography (GC) on a Hewlett-Packard 5890A equipped with a flame ionization detector and a 30 m × 0.25 mm, (film thickness 0.25 μm) DB-1 column (program: 100°C, 1 min; 10°/min to 185°C, 4 min; 3°/min to 200°C, 0 min; 25°/min to 260°C, 20 min), head pressure 120 kPa, flow: 30 ml/min. Response was calibrated with standards of known concentration.

The second sample was diluted such that ca. 10–20 ng of the most abundant component would be injected and analyzed on a Varian 3400 GC interfaced with a Varian Saturn ion trap mass spectrometer (MS), equipped with a 30-m × 0.25-mm, (film thickness 0.25 μm) DB-5 column (program: 100°C, 1 min; 10°/min to 200°C, 3°/min to 220°C, 2.5°/min to 225°C, (15 min), head pressure 105 kPa, flow 20 ml/min. The ionization mode was EI with a filament emission current of 10 μA at 70 eV, a target value of 5500, with the automatic gain control (AGC) on and with 1 scan/sec.

Data Analysis and Statistics

Three evaluations of substrate incorporation were investigated: percentage of label incorporated, quantity of labeled product formed, and rate of incorporation. Small overlapping peaks from artifacts in GC-MS made the latter two evaluations less reliable than percentage label.

The usually dominant $(M\text{-}15)^+$ fragment, arising from loss of a methyl group from the trimethylsilyl derivative of the parent ion, was used to determine the percentage label for each compound of interest. The ion currents for the $(M\text{-}15)^+$ and $(M\text{-}15 + n)^+$ (n = number of D atoms in the compound) were recorded for each scan across the GC peak without prior background subtraction. The percentage of labeled material was obtained from a calibration curve in which the ratio of $\Sigma(M\text{-}15 + n)/\Sigma(M\text{-}15)$ had been plotted against the percentage of label, using prepared mixtures of labeled and unlabeled standard. This correction minimized the effect of overlapping ions, especially $(M\text{-}15 + nD) - n$ signal on the unlabeled (M-15) signal at higher labeling concentrations. With the AGC on, correction parameters varied only slightly with concentration of 0.1–100 ng of injected sample.

The data were analyzed by a one-way ANOVA (SAS statistical package, SAS Institute Inc., Cary, North Carolina) for differences between treatments and blanks (pairwise comparisons). Points were only rejected if a known experimental problem existed with the sample, or if they were strong outliers by the fourth spread criteria (Devore, 1991).

Labeled Substrates

General. TLC was performed on 0.25-mm-thick films of silica gel (Merck, Kieselgel 60G for TLC) on glass plates. Acidic TLC plates were prepared with 2% H_3PO_4 instead of water and were used to monitor reactions and purifications

involving free acids. Silica gel columns were prepared with Merck Kieselgel 60 (230–400 mesh). Acidic gel was prepared by suspending the silica in 2% aqueous H_3PO_4 (silica–aqueous acid 1:2 w/w), leaving the silica to settle, decanting the supernatant, and drying the slurry in an oven at 100°C. Acidic silica gel was used to purify compounds possessing free carboxylic acid functionalities to minimize streaking. Esters dissolved in methanol were hydrolyzed by adding 5% aqueous NaOH and stirring overnight. Hydrolyzates were acidified with 10% HCl and extracted twice with ether, the ether washed with brine, and dried over sodium sulfate. ^{1}H NMR spectra were measured in $CDCl_3$ at 400 MHz on a Bruker WM-400. Both ^{1}H NMR and GC-MS were used to confirm the structure and assess the extent of deuteration in intermediates and products. All deuterated products showed physical properties and retention times identical to the unlabeled compound, except for the differences in the ^{1}H NMR and MS fragmentation expected for the deuterium substitution pattern.

(9,9,10) D_3-10-Hydroxydecanoic Acid (D_3 10-HDAA). 10-Oxodecanoic acid was obtained from 10-undecenoic acid by OsO_4-mediated oxidation with $NaIO_4$ (Graham and Williams, 1966). This material was refluxed 4 hr under Ar at 105°C with D_2O–pyridine (6:7), to give (9,9) D_2-10-oxodecanoic acid (96% D_2). Reduction with $NaBD_4$ in methanol gave (9,9,10) 10-hydroxydecanoic acid (94% yield, 94% labelled).

(4,4) D_2-2(E)-Decenoic Acid [D_2 $C_{10:1}$ 2(E)]. Octanal was deuterated with D_2O–pyridine (1:1, 3 hr, 100°C) to give (2,2) D_2-octanal (93% D_2). Reaction with the ylide of trimethylphosphonoacetate produced by treatment with NaH (Kandil and Slessor, 1985), gave methyl (4,4) D_2-2-decenoate (ca. 86% *E* and 14% *Z*). Chromatography on silica gel (hexane–ether, 5:1) provided an enriched methyl ester fraction (ca. 95% *E*, 30% yield). The methyl ester was base hydrolyzed to yield the free acid (77% yield).

(4,4) D_2-10-Hydroxy-2(E)-Decenoic Acid (D_2 10-HDA). The tetrahydropyranyl derivative of 8-hydroxyoctanal (Chiron, 1982) was deuterated with pyridine–D_2O (1:1, 16 hr, reflux), to give (2,2) D_2-8-THPO-octanal (94% D_2). Condensation with the ylide of trimethylphosphonoacetate gave the THP derivative of methyl (4,4) D_2-10-hydroxy-2-decenoate (ca. 80% *E* and 20% *Z*). Removal of the THP group under acidic conditions (methanol–water–10% HCl, 1:4:10, room temperature for 1.5 hr) and silica gel purification resulted in methyl (4,4) D_2-10-hydroxy-2-decenoate enriched in the *E* isomer (93% *E*, 50% yield, 94% D_2). Base hydrolysis of the methyl ester gave the free acid (58% yield).

(4,4) D_2-2(E)-Decenedioic Acid (D_2 $C_{10:1}$ DA) and (2,2) D_2-Decanedioic Acid (D_2 $C_{10:0}$ DA). Small portions of D_2 10-HDA and D_2-10-oxodecanoic acid were oxidized with pyridinium dichromate (PDC) (Corey and Schmidt, 1979) to the corresponding diacids D_2 $C_{10:1}$ DA and D_2 $C_{10:0}$ DA, respectively.

(12) D_1-Octadecanoic Acid (D_1 $C_{18:0}$). Oxidation of methyl 12-hydroxy-

octadecanoate (Sigma) with pyridinium chlorochromate (PCC) gave the 12-keto compound, which was treated directly with *p*-tolylsulfonylhydrazine (2 hr reflux in MeOH) and reduced with $NaBD_4$ (2 hr 50°C in MeOH) to give methyl 12-D octadecanoate in 5% yield. The methyl ester was hydrolyzed to the free acid (83% D_1).

(7,7) D_2-8-Hydroxyoctanoic Acid (D_2 8-HOAA). Oxidation of monoacetyl 1,8-octanediol (Babler and Coghlan, 1979) with PDC gave 8-acetoxy octanoic acid. The acetate group was removed to give 8-hydroxyoctanoic acid and oxidized with PCC to the 8-oxo acid. The oxo acid was deuterated twice with pyridine–D_2O (1 : 1, 17 hr reflux, 65% D_2) and reduced with $NaBH_4$ in MeOH to give the deuterated ω-hydroxy acid.

(7,7,8,8) D_4-Decanoic Acid (D_4 $C_{10:0}$). 7-Decynoic acid was prepared by the condensation of 6-bromohexanoic acid and 1-butyne in the presence of 2.5 eq. of *n*-butyl lithium, converted to the methyl ester with BF_3–MeOH, and deuterated with deuterium and $RhCl_2[P(phenyl)_3]_2$ as a catalyst (room temperature, 1 atm) to give methyl (7,7,8,8) D_4 decanoate. Hydrolysis gave deuterated decanoic acid.

RESULTS

Treatment with labeled 10-HDAA or 10-HDA led to labeling of 8-HOAA, suggesting that both 10-carbon hydroxy acids can be shortened to 8-HOAA (Table 1). Furthermore, application of labeled 10-HDA resulted in labeling of 10-HDAA and vice versa, indicating that 10-HDA and 10-HDAA can be interconverted. Finally, treatment with labeled 8-HOAA led to no significant labeling

TABLE 1. PERCENTAGE OF LABELED PRODUCT FORMED IN INTERCONVERSION AMONG ω-HYDROXY ACIDS IN WORKER MANDIBULAR GLANDS

Treatment	Incubation time (min)	*N*	Product (means ± SE)[a] 8-HOAA	10-HDAA	10-HDA
D_2 8-HOAA	10	9	**73.4 ± 1.2 a**	1.5 ± 0.1 a	4.0 ± 1.4 a
Blank		10	6.3 ± 1.8 b	3.6 ± 0.2 b	4.1 ± 0.4 a
D_3 10-HDAA	15	9	22.6 ± 11.1 a (N = 8)	**86.0 ± 4.0 a**	15.5 ± 7.0 a
Blank		9	1.3 ± 0.7 b	0.3 ± 0.1 b	0.5 ± 0.1 b
D_2 10-HDA	20	8	48.0 ± 5.0 a	27.0 ± 4.0 a	**89.7 ± 5.1 a**
Blank		9	1.3 ± 0.7 b	0.3 ± 0.1 b	0.5 ± 0.1 b

[a]Treatments were compared to their corresponding blanks. Means within a column followed by the same letter do not differ significantly by Tukey's test ($P < 0.05$).

of the 10-carbon hydroxy acids, which suggests that 8-HOAA was not chain lengthened.

In the D_3 10-HDAA treatment, labeled 8-HOAA accumulated over time. In 1 min, 7.1 ± 3.3 ng of labeled 8-HOAA formed, while in 15 min, 120 ± 62 ng formed. In the same experiment, labeled 10-HDA did not accumulate with time; 12.6 ± 2.2 ng formed in 1 min and 9.2 ± 2.8 ng formed in 15 min. The accumulation of 8-HOAA with time and its failure to convert to other compounds suggests that it may be an end point in the hydroxy acid biosynthetic pathway. By contrast, 10-HDA did not accumulate with time and appears to be converted to other compounds. The percentages of labeled 10-HDA and 10-HDAA formed from 10-HDAA and 10-HDA, respectively, were similar (Table 1), as were the amounts formed during the 15- to 20-min treatments (data not shown). This indicates that in young workers desaturation of 10-HDAA to give 10-HDA occurs more or less at the same rate as the reverse reaction.

Apart from interconversion, the 10-carbon hydroxy acids were oxidized to their respective diacids in both queens and workers. Treatment with D_3 10-HDAA led to significant incorporation in $C_{10:0}$ DA and $C_{10:1}$ DA, while treatment with D_2 10-HDA resulted in significant labelling of $C_{10:1}$ DA, but not of $C_{10:0}$ DA.

No incorporation of label from the ω hydroxy acids into ω-1 hydroxy acids was found. The reverse incorporation of label from a labeled 9-HDA into the 10 hydroxy acids was not observed (data not shown). Both observations suggest that the ω and ω-1 hydroxy acids do not interconvert.

TABLE 3. INTERCONVERSION AMONG POTENTIAL PRECURSORS TO HYDROXY ACIDS IN WORKER MANDIBULAR GLANDS[a]

Treatment	Product			
	$C_{10:0}$	$C_{10:1}$	$C_{16:0}$	$C_{18:0}$
D_4 $C_{10:0}$		+	n.s.	n.s.[b]
D_2 $C_{10:1}$	n.s.		n.s.	+++
D_3 $C_{16:0}$	++	++		+++
D_1 $C_{18:0}$	n.s.	++	+	

[a]Plus signs indicate significant incorporation of label into the product as compared to the blank ($P < 0.05$, Tukey's). Data corresponding to the compounds used for treatment were left blank. +, up to 20% label; ++, between 20% and 40%; +++, between 40% and 60%; n.s., not significant.
[b]The mass spectra show a small amount of label.

Of the possible precursors to the hydroxy acids tested, D_1 $C_{18:0}$ was incorporated with the greatest efficiency into both ω-1 and ω hydroxy acids (Table 2). This was followed by D_3 $C_{16:0}$, which was incorporated significantly only into 8-HOAA. D_2 $C_{10:1}$ was not incorporated significantly into any of the hydroxy acids, while D_4 $C_{10:0}$ was only weakly incorporated into 10-HDA. Furthermore, application of D_2 $C_{10:1}$ and D_3 $C_{16:0}$ resulted in significant labeling of $C_{18:0}$ (Table 3). Treatment with D_4 $C_{10:0}$ did not lead to significant labeling of $C_{18:0}$, but a small amount of the expected label was seen in the mass spectra. These results suggest that unfunctionalized fatty acids with less than 18 carbons were lengthened to $C_{18:0}$ before functionalization.

DISCUSSION

A study of the possible interconversion among ω-hydroxy 10-carbon acids demonstrated that there was ready interconversion between the saturated and the 2(*E*)-unsaturated ω functionalized species in isolated worker mandibular glands. In addition, the two 10-hydroxy 10-carbon acid substrates were readily chain shortened to the saturated 8-carbon ω acid. Both observations are in accord with the ability of these hydroxylated compounds to enter the β-oxidation pathway. 10-HDAA would first be desaturated to 10-HDA, presumably through activation as its CoA-ester. Our results indicate this to be a reversible process. Hydration of the 2–3 double bond would give a 3,10-dihydroxydecanoate. The final steps are the oxidation of the 3-hydroxy group to a keto moiety, attack of the keto group by free CoA-SH, and displacement of the acetyl-CoA head portion, giving

8-HOAA-CoA. At each step a portion could be hydrolyzed, giving rise to the corresponding free acid. Presumably, a significant proportion of the 10-HDA-CoA gets hydrolyzed, since 10-HDA is the major hydroxy acid component of the worker mandibular gland secretion. Free 3,10-dihydroxydecanoic acid appears to be a minor component of worker mandibular extracts and has been found in royal jelly, along with the other ω-hydroxy acids (Weaver et al., 1968).

In addition to β-oxidation of 8- and 10-carbon hydroxy acids, the glands have the capability to oxidize ω-hydroxy acids to diacids. While 10-HDA was oxidized only to its corresponding diacid ($C_{10:1}$ DA), 10-HDAA was converted to both its corresponding diacid ($C_{10:0}$ DA) and $C_{10:1}$ DA. The latter conversion could have occurred by desaturation of 10-HDAA to 10-HDA, followed by oxidation to the diacid, or vice versa, oxidation to $C_{10:0}$ DA preceding desaturation to $C_{10:1}$ DA. No experiment with labeled $C_{10:0}$ DA was performed to evaluate these two possibilities.

We investigated decanoic acid ($C_{10:0}$) as a potential precursor to find the fatty acid subtrate that is regioselectively oxygenated through caste-determined control. We compared incorporation of labeled straight-chain fatty acids of different chain lengths in the whole gland assay. The results indicated that D_1 $C_{18:0}$, and not D_4 $C_{10:0}$, was incorporated most efficiently into both ω and ω-1 10-carbon components. Furthermore, interconversion among precursors indicated that $C_{10:0}$, $C_{10:1}$, and $C_{16:0}$ were lengthened to $C_{18:0}$, suggesting it to be the entry point to the hydroxy acid pathway. For $C_{10:0}$ to be incorporated into mandibular acids, it must be lengthened to $C_{18:0}$ prior to functionalization, requiring the largest number of steps and experiencing considerable dilution. $C_{18:0}$ would require the smallest number of steps and would experience the smallest isotopic dilution in the final products. The somewhat low incorporation of D_3 $C_{16:0}$ may be due to a primary isotope effect, since one of the deuterium atoms would be removed during ω-functionalization. Our results are consistent with $C_{18:0}$ being the entry point to the hydroxy acid biosynthetic pathway, with either free and/or lipid-bound $C_{18:0}$ constituting a precursor reservoir that ensures continuous hydroxy acid biosynthesis by the mandibular gland.

Two routes are possible to convert $C_{18:0}$ into 10-carbon ω and ω-1 hydroxy acids, which differ only in the order in which functionalization and chain shortening take place. Functionalization may occur at the $C_{18:0}$ (or its CoA ester) stage to give 18-hydroxyoctadecanoic acid (or its CoA ester) followed by chain-shortening by β-oxidation to the 10-carbon length (Figure 2). Alternatively, after chain shortening, a bound $C_{10:0}$ intermediate is functionalized. Both routes have been observed in the biosynthesis of fatty acid-derived semiochemicals. The major component of the sex pheromone of the cabbage looper (*Trichoplusia ni*), (*Z*)-7-dodecenyl acetate, is biosynthesized from $C_{16:0}$-CoA by Δ11 desaturation to give (*Z*)-11-$C_{16:1}$-CoA followed by chain-shortening to (*Z*)-7-$C_{12:1}$-CoA, the immediate precursor (Jurenka and Roelofs, 1993). Chain-shortening

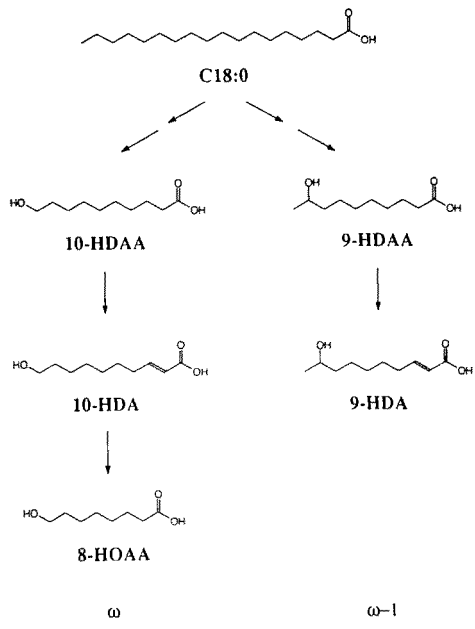

FIG. 2. Formation of ω and ω-1 hydroxy acids from octadecanoic acid ($C_{18:0}$) in worker mandibular glands. The ω hydroxy acids are: 10-hydroxydecanoic acid (10-HDAA), 10-hydroxy-2(*E*)-decenoic acid (10-HDA), and 8-hydroxyoctanoic acid (8-HOAA); the ω-1 hydroxy acids are 9-hydroxydecanoic acid (9-HDAA) and 9-hydroxy-2(*E*)-decenoic acid (9-HDA).

before functionalization is found in the red-banded leafroller moth (*Argyrotaenia velutinana*), where the major sex pheromone component, (*Z*/*E*)-11-tetradecenyl acetate, is made by $C_{18:0}/C_{16:0}$-CoA chain shortening to $C_{14:0}$-CoA, followed by Δ11 desaturation to give (*Z*/*E*)-11-$C_{14:1}$-CoA. (Jurenka and Roelofs, 1993). We are currently investigating which route is responsible for hydroxy acid biosynthesis in honey bee mandibular glands.

One requirement of being a queen is the regioselective functionalization of a fatty acid, or its derivative, at the ω-1 position in the production of the queen's primer pheromone. Our results indicate that the free fatty acid entry point for this caste-determined capability is $C_{18:0}$. As no evidence was found for the interconversion of ω and ω-1 hydroxy acids, two distinct functionalization reactions must be operative: ω for workers and ω-1 for queens. The positional selectivity of this hydroxylation to form hydroxy decenoic acids in the mandibular gland is one of the important developmentally derived characters that differentiate queens from workers. An understanding of the control system reg-

ulating this regioselectivity will provide a better appreciation for the caste differentiation processes in this highly social insect.

Insect Chemical Ecology Laboratory, USDA-ARS, Bldg 007
Agricultural Research Center-West
Beltsville, Maryland 20705

(Received February 14, 1995; accepted March 10, 1995)

Abstract—Males of the spined soldier bug, *Podisus maculiventris* (Heteroptera: Pentatomidae), produce an attractant pheromone that is exploited as a host-finding kairomone by a complex of parasitic species. The capability to catch hundreds of a generalist tachinid fly parasitoid, *Euclytia flava*, alive in traps baited with the pheromone of *P. maculiventris* provided an opportunity to test the premise of the "new associations" biological control concept. The hypothesis that host species newly associated with a parasitoid are maladapted relative to native-native associations was tested by giving *E. flava* females a choice between native and exotic stink bugs (Heteroptera: Pentatomidae). Wild *E. flava* females preferred to oviposit on exotic pentatomid species rather than indigenous, known host species, both in field traps baited with the pheromone of a native host and in the laboratory. Data presented here demonstrate that an invader may be vulnerable to native parasitoids in one aspect of the parasitism process (acceptance), yet go unrecognized as a potential host.

Key Words—Parasitoid, Tachinidae, Pentatomidae, *Nezara*, *Podisus*, biological control, pheromone, kairomone, exotic host.

INTRODUCTION

Classical biological control has emphasized old associations, seeking natural enemies in the native regions of pests for introduction into areas where target species are out of control (Nechols and Kauffman, 1992). However, coevolution between a parasitoid and its hosts may lead to a physiological equilibrium that could prevent such long-associated parasitoids from being effective biological control agents (Pimentel, 1963). Indeed, the probability of success in biological control is reportedly 75% higher in programs employing new associations than

0098-0331/95/0700-1031$07.50/0 © 1995 Plenum Publishing Corporation

those based on long-evolved parasite–host or predator–prey associations (Hokkanen and Pimentel, 1984). These authors proposed that new exploiter–victim associations should be the preferred type of biological control agents in the future. This proposal proved to be controversial among biological control specialists (Greathead, 1986; Hokkanen and Pimentel, 1989; Nechols et al., 1992) but, in their reanalysis of the data on the new association approach for selecting biological control agents, Hokkanen and Pimentel (1989) again concluded that the concept is ecologically and statistically sound. Moreover, they reemphasized that newly associated biological control agents are "virtually the only type of agents for the classical biocontrol of native pests" (Hokkanen and Pimentel, 1989).

The initial controversy over the merits of the new associations approach in biological control has escalated into a lively debate over the wisdom of importing exotic species to control native pests (e.g., Carruthers and Onsager, 1993; Lockwood, 1993a). An overriding concern with the use of exotics to control native species is whether the risk of adverse affects to innocuous and beneficial endemic species is worth the potential benefit of controlling the pest (Howarth, 1991; Pimentel and Hunter, 1992; Lockwood, 1993a,b). Officials in the U.S. Department of Agriculture, Animal and Plant Health Inspection Service (USDA-APHIS) are keenly aware of environmental issues involved in biological control with exotic agents (C.P. Schwalbe, USDA-APHIS, personal communication), and the regulations governing the importation of exotic species are currently under review (M. Firko, USDA-APHIS, personal communication).

Data gleaned from the literature for Tachinidae indicate that biological control efforts involving this group support the new associations concept more clearly than do data for some other groups (Hokkanen et al., 1994). Large numbers of the endemic generalist pentatomid parasitoid, *Euclytia flava* (Diptera: Tachinidae), can be caught alive in traps baited with pheromone for the common North American generalist predator known as the spined soldier bug, *Podisus maculiventris* (Heteroptera: Pentatomidae) (Aldrich et al., 1984). This capability has provided an unprecedented opportunity to test the premise of the "new association" biological control concept. The hypothesis that host species newly associated with a parasitoid are maladapted relative to native–native associations was tested by giving *E. flava* females a choice between native and exotic pentatomids to determine their relative susceptibility to parasitoid oviposition.

METHODS AND MATERIALS

Host Insects. Table 1 lists the pentatomids used for host-choice experiments, the origin of individuals to start colonies, the native ranges for these

TABLE 1. PENTATOMIDS USED FOR HOST-CHOICE TESTS WITH *Euclytia flava* (Diptera: Tachinidae), AND THEIR CLASSIFICATION AS EXOTIC (E) OR NATIVE (N) RELATIVE TO RANGE OF *E. flava*

Species	Class	Collection locality	Native range
Predaceous			
Posisus maculiventris	N	Beltsville, Maryland	North America
P. neglectus	N	Beltsville, Maryland	North America
P. distinctus	E	Brasília DF, Brazil	South America
Phytophagous			
Nezara viridula	E	Stoneville, Mississippi	Africa
Euschistus obscurus	N	Weslaco, Texas	Central America, southern U.S.
E. tristigmus	N	Beltsville, Maryland	North America
E. servus	N	Beltsville, Maryland	North America
Acrosternum hilare	N	Beltsville, Maryland	North America
A. pennsylvanicum	N	Beltsville, Maryland	eastern North America
Thyanta accerra	N	Weslaco, Texas	eastern North America

species (McPherson, 1982; Thomas, 1992), and whether they are exotic or native relative to the range of *E. flava* (British Columbia and California, to Maine, and south to Texas) (Stone et al., 1965). *Nezara viridula*, a native of the Ethiopian region (Hokkanen, 1986; Jones, 1988), now has a cosmopolitan distribution, but Maryland is at least 350 km north of the limit of the range of this species in the eastern United States (Todd, 1989). *Euschistus servus*, *Euschistus tristigmus*, *Acrosternum hilare*, and *Acanthocephala terminalis* (Coreidae) adults used for experiments were collected in May and June, 1993 and 1994, from empress trees (Scrophulariaceae: *Paulownia tomentosa*). *Acrosternum pennsylvanicum* males used in the study were collected in June, 1993, from bracken fern (Filicopsida: Dennstaedtiaceae: *Pteridium aquilinum*) (Aldrich et al., 1989). Adults of other species were from laboratory colonies maintained as previously described (Aldrich et al., 1984, 1987).

Parsitoids. Adult *E. flava* females used for host choice tests were field-collected in traps baited with a simplified formulation (described below) of the synthetic pheromone for *P. maculiventris* (Aldrich et al., 1984). Flies in 1993 were collected from June 3 to 16, and flies in 1994 were collected from April 24 to May 14 in traps deployed at the Research Center.

Pheromone. A three-component blend was used to bait traps to catch *P. maculiventris* and *E. flava*. (*E*)-2-Hexenal (Aldrich Chemicals, Milwaukee, Wisconsin), racemic α-terpineol (Hercules Inc., Wilmington, Delaware), and benzyl alcohol (Aldrich Chem.) were mixed in a molar ratio of 1 : 0.843 : 0.061,

respectively. Batches of 40 ml of pheromone (17.6 ml hexenal, 21.4 ml α-terpineol, 1 ml benzyl alcohol) were normally prepared. A 20% (w/w) formulation of pheromone in plasticized polyvinyl chloride (PVC) was prepared by mixing 107 g of powdered PVC (Tenneco, Piscataway, New Jersey) with 53 ml of dioctyl phthalate (Aldrich), then adding the pheromone (Fitzgerald et al., 1973). The pheromone–PVC mixture was poured into test tubes (to the top), heated at 110°C for 30 min, removed from the tubes, and stored in sealed vials in a freezer until use. Pheromone for *Podisus neglectus* was prepared in a similar manner except linalool (Aldrich Chem.) was substituted for α-terpineol (Aldrich et al., 1986).

Trapping. Traps were made of transparent cylindrical containers having either white or transparent lids (20.2 × 19.7 cm; Tri-State Molded Plastics, Inc., Dixon, Kentucky) by cutting two holes (9 cm diameter) in opposite sides, and covering each hole with an inwardly projecting screen funnel. The containers were turned upside-down, so that the normal top of the container became the trap button, small drainage holes were made in the bottom, and the bottoms were held in place by two elastic cords hooked into each screen funnel. Traps were hung from branches about 1.7 m from the ground, at least 50 m apart, bordering oak-dominated deciduous forest at the Beltsville Agricultural Research Center-East. Each trap was baited with ca. 350 mg of pheromone–PVC material every three to four days. *E. flava* females were removed from traps by first flushing the trap with CO_2 to anesthetize the insects and then placing the flies in cotton-stoppered vials for transport to the laboratory.

Induced Parasitoid Oviposition in the Field. To determine if native tachinids could be induced to oviposit on adults of the southern green stink bug, *N. viridula*, a preliminary experiment was performed as follows in June 1989. A 20 × 20-cm cylinder was made from 1/4-in. mesh screen (large enough for tachinid flies to pass through), and the top and bottom were attached as for the traps described above. Ten laboratory-reared *N. viridula* males were placed inside the cage with a dose of *P. maculiventris* synthetic pheromone, and the cage was hung in the field.

A more extensive experiment was carried out from June 11 to 27, 1993. In this experiment, one or two newly emerged (<48-hr-old) laboratory-reared southern green stink bug males were placed inside traps baited with pheromone for *P. maculiventris*. Traps ($N = 20$) were monitored every one to three days, *Nezara* males exposed to parasitism were removed for examination in the laboratory, and fresh *N. viridula* males were put in the traps. The number and position of tachinid eggs on the *Nezara* males from pheromone-baited traps were counted under a dissecting microscope (tachinids known to use pentatomid pheromones as kairomones lay macro-eggs on their hosts' cuticle). Males were placed in half-pint cartons and held in the insectary for parasitoid emergence.

Host-Choice Bioassays. The same type of plastic containers used to make pheromone traps were used for the host-choice bioassays. Container lids were modified for ventilation by cutting a hole in the top (15-cm diameter) and gluing fine mesh nylon screen over the holes. Vaseline was applied to the upper, inner rim of each bioassay cage to prevent bugs from walking onto the lid, and each cage was provisioned with a water bottle, three green beans propped up against the cage wall, one mealworm pupa per predator if *Podisus* spp. were being tested, and honey was smeared on the screen mesh for the flies to feed upon.

Bioassays involving live bugs were usually performed with three or four wild *E. flava* females collected the same day as the bioassay was initiated, and three males and three females of each of the two heteropteran species were exposed to parasitoids. However, several bioassay experiments deviated from this standard, depending on the number of host specimens and flies available on any given day. In general, lower numbers of bugs and flies were used when the number of individuals for one of the three required species was limiting. The bugs to be tested were added to the bioassay cage, and then *E. flava* females that had been chilled in a refrigerator for 5–10 min were added. Each choice test lasted ca. 24 hr, after which the bugs were removed to count the eggs laid on them and held for parasitoid emergence. Some flies and unparasitized bugs were bioassayed on successive days.

Two choice-tests were performed using dead *Nezara* males treated with cuticular extracts. Six *N. viridula* males (killed by freezing) were mounted on pins in a circle, alternately dipped in extracts (purified through silica gel) of either *E. obscurus* or *N. viridula* males (9 adults/ml pentane/replicate), and placed in cages with six to eight 1-day-old flies.

Data Analysis. Bioassays of live bugs sometimes used flies on successive days and/or fewer than the normal number of bugs; therefore these data were analyzed by chi-square; all extract bioassays used 1-day-old flies and were analyzed by paired Student's *t* test.

RESULTS

Induction of Parasitoid Oviposition in the Field. The preliminary experiment exposing adult *N. viridula* males to parasitoids in the field showed that native tachinids attracted to the vicinity of the cage by *P. maculiventris* pheromone would, in fact, readily oviposit on southern green stink bugs. However, no parasitoids emerged from these *Nezara* males.

In the follow-up experiment in 1993, newly emerged *N. viridula* males with incompletely sclerotized cuticle were used because it seemed possible that the failure of tachinids to develop in the earlier experiment could have been due

to an inability of the first-stage larvae to penetrate the host cuticle. Again, southern green stink bugs males received many tachinid eggs (8.26 ± 0.79 eggs/male; $N = 72$), and about three times more eggs were laid ventrally on the bugs than dorsally (Table 2). However, no tachinid larvae emerged from *Nezara* males with tachinid eggs, including several individuals having only one or two eggs.

Host-Choice Bioassays. A total of 317 living adult heteropterans, representing 11 species, were offered to 123 wild *E. flava* females in host-choice bioassays. These *Euclytia* females oviposited 1339 eggs.

Data for host-choice experiments involving live pentatomids are summarized in Figure 1A. Of the 12 choices included in Figure 1A, four combinations offered *E. flava* females a clear-cut choice between an exotic species (black bars) and a native, known host species (white bars): (1) *N. viridula/P. maculiventris*, (2) *P. distinctus/P. maculiventris*, (3) *N. viridula/T. accerra*, and (4) *N. viridula/E. tristigmus*. In all four of these exotic–native host choices, significantly more eggs were laid on the exotic species. In the experiment comparing the acceptability of the *P. distinctus* (Brazilian) versus *P. maculiventris* (No. 2), no eggs were oviposited on *P. maculiventris*. In *N. viridula/P. maculiventris* (No. 1) pairings, well over twice as many eggs were laid on *N. viridula* (508, range 10–57) than *P. maculiventris* (224, range 1–21) ($P < 0.001$). *Nezara viridula* adults were moderately, but significantly, preferred over *T. accerra* ($P < 0.05$) (No. 3), whereas *N. viridula* was greatly preferred over the known host, *E. tristigmus* ($P < 0.001$) (No. 4). Other pairings involving the exotic species, *N. viridula*, and native species not known to be naturally parasitized by *E. flava*, also showed ovipositional patterns heavily skewed toward *N. viridula:* (7) *N. viridula/E. obscurus* ($P < 0.001$), (10) *N. viridula/A. hilare* ($P < 0.001$), and (11) *N. viridula/A. pennsylvanicum* ($P < 0.05$). *Euclytia*

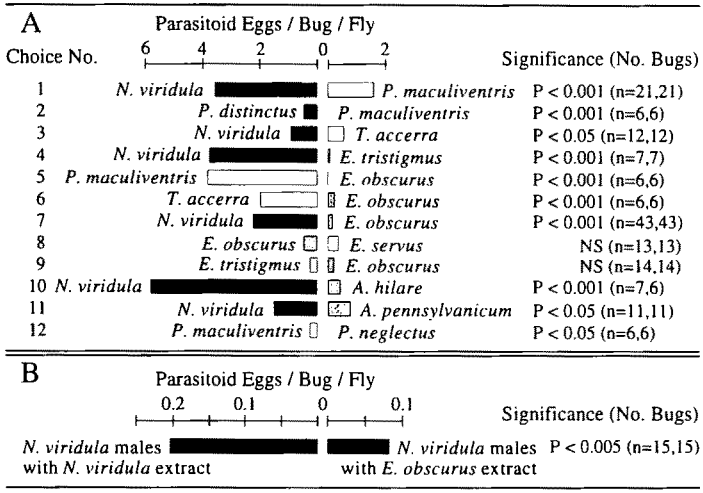

FIG. 1. Oviposition by *Euclytia flava* (Diptera: Tachinidae) given a choice (A) between two species of live Pentatomidae (black bars = exotic species; white = native, known host; gray = native, unknown host status) or (B) dead *Nezara* males treated with cuticular extracts.

flava females did not discriminate among *Euschistus* spp. (Nos. 8 and 9), and laid relatively few eggs on these bugs (Nos. 4 to 9). In the choice-test involving *P. maculiventris* and another native, but comparatively rare, known *Podisus* host, *P. neglectus* (No. 12), no eggs were laid on the latter species. Finally, in the only comparison between a pentatomid and a coreid (not shown in Figure 1), 18 eggs were laid on one *N. viridula* female while no eggs were laid on the *A. terminalis* female.

Euclytia flava females laid significantly more eggs on the ventral versus the dorsal surface of *N. viridula*, *P. maculiventris*, *E. obscurus*, and *A. pennsylvanicum* individuals (Table 3). However, the reverse was true for *T. accerra* individuals; significantly more *E. flava* eggs were laid dorsally. For three species, significantly more eggs were deposited on male bugs than females: *N. viridula*, *P. maculiventris*, and *A. hilare* (Table 3).

For two species, *P. maculiventris* ($P = 0.0082$), and *N. viridula* ($P = 0.0042$) (2×2 chi-square contingency test), there was a significant interaction between the position of *E. flava* eggs on the host body and the sex of the host. For *P. maculiventris*, the distribution of tachinid eggs on the ventral body surface did not differ significantly from the expected for males and females ($P = 0.6529$), whereas the distribution of eggs laid on the dorsal surface was signif-

TABLE 3. DISTRIBUTION OF *Euclytia flava* EGGS OVIPOSITED ON HETEROPTERA.

Species	No. Eggs (*N*)	Position (%)			Sex (%)		
		Dorsal	Ventral	*P*	Male	Female	*P*
N. viridula	965	23.9	76.1	0.001	58.9[a]	41.1[a]	0.0001
P. maculiventris	230	39.6	60.4	0.01	58.4[a]	41.6[a]	0.01
P. distinctus	11	36.4	63.6	NS	36.4	63.6	NS
E. obscurus	61	26.2	73.8	0.001	49.9	50.1	NS

A. hilare	4	25.0	75.0	NS	62.5	37.5	0.05
A. pennsylvanicum	23	4.3	95.7	0.0001	[b]		
T. accerra	85	65.9	34.1	0.01	58.8	41.2	NS

[a]Normalized for unequal sample sizes.
[b]No female *A. pennsylvanicum* were tested.

icantly greater for males than for females ($P = 0.00018$). For *N. viridula*, significantly more eggs were laid on both the dorsal and ventral surfaces of males versus females than expected ($P < 0.0000001$ and $P < 0.0005$, respectively).

Bioassays using frozen *N. viridula* males treated with cuticular extracts showed that the factor supporting *E. flava* oviposition on *E. obscurus* could be transferred (Figure 1B). Dead *Nezara* males treated with cuticular wash from *E. obscurus* had significantly fewer eggs than did males treated with *N. viridula* extract ($P < 0.005$).

DISCUSSION

Exposing the exotic pest species, *Nezara viridula*, to parasitoids attracted in the field to *P. maculiventris* pheromone resulted in a level of multiple tachinid oviposition beyond that commonly observed for trapped spined soldier bugs. Of the two common tachinid parasitoids attracted to the pheromone of the spined soldier bug (*E. flava* and *Hemyda aurata*), only *E. flava* will enter this type of trap (Aldrich et al., 1984; Aldrich, 1985). Therefore, it was inferred that *N. viridula* males were being attacked by *E. flava* and, in fact, this species was frequently observed in and around the traps. Although no *E. flava* emerged from the southern green stink bug, the surprising degree of oviposition suggested that this exotic species is actually exceptionally attractive at close range to females *E. flava*. In the laboratory, wild *E. flava* females given a choice between *P.*

maculiventris adults and *N. viridula* adults did, indeed, prefer to oviposit on the exotic species rather than the native, known host whose pheromone was used to catch the flies for the experiments.

In the three other offerings where *E. flava* females could choose between an exotic species and a native, known host species, the flies also significantly preferred to oviposit on the exotic species. The *P. maculiventris/P. distinctus* combination is particularly interesting because the South American predator, *P. distinctus*, is congeneric, and males of this species produce a pheromone blend that contains the same compounds as the pheromone of *P. maculiventris* (Aldrich et al., 1991b) (*P. connexivus* redetermined as *P. distinctus* by D. Thomas, unpublished data). In this case, three *E. flava* females were given a choice between three males and three females of each *Podisus* spp.; they laid 11 eggs on *P. distinctus* individuals, and no eggs on *P. maculiventris*. Similarly, *Nezara* and *Acrosternum* are closely related genera whose species produce distinctive blends of the same sesquiterpene hydrocarbon and epoxide isomers (Aldrich et al., 1989). In fact, it is likely that the only Nearctic tachinid (*Trichopoda pennipes*) to naturally adopt *N. viridula* as a host in the 200 years or so since its arrival in the United States did so because it was preadapted to respond to the sesquiterpenes of the native *Acrosternum* spp. (Aldrich et al., 1989). Nonetheless, in close proximity to *N. viridula* and *Acrosternum* spp., *E. flava* females strongly discriminate between these bugs in favor of the exotic species, *N. viridula*.

The distribution data of parasitoid eggs on the bugs used for host-choice experiments give some added insights into the ovipositional behavior of tachinids. In seven of the nine pentatomid species, *E. flava* females laid more eggs ventrally than dorsally, with significant differences in four of these species. However, significantly more eggs were laid dorsally on *T. accerra* than ventrally. *Thyanta accerra* adults were noticeably smaller (ca. 9 mm long; McPherson, 1982) than all of the other pentatomids included in these experiments except for *E. tristigmus*, which showed an equal but nonsignificant positional distribution of eggs. Therefore, small body size may make it more difficult for *E. flava* to oviposit ventrally.

Tabulation of the laboratory ovipositional data by the sex of the host revealed that *E. flava* females laid significantly more eggs on males than females of *P. maculiventris*, *N. viridula*, and *A. hilare*. For the latter species, the sample size was small, and significant at only the 5% level. For *P. maculiventris* and *N. viridula*, large numbers of eggs were laid, and the preferences for males were highly significant. It is not unexpected that the female flies are preferentially stimulated to oviposit on *P. maculiventris* males because *E. flava* uses the male-produced pheromone of the spined soldier bug as a host-finding kairomone. In fact, the significant interaction between egg position and host sex that was detected for *P. maculiventris* is largely accounted for by the significantly greater

than expected number of eggs on the dorsal surface of males, and the pheromone is emitted from dorsal abdominal glands.

It does seem surprising that *E. flava* females prefer males over females for an exotic species. One possible explanation for this behavior is that *Acrosternum* spp. are occasional hosts such that *E. flava*, like *T. pennipes*, is preadapted to recognize the pheromone components of *N. viridula*. This possibility is supported by the finding that male *A. hilare* are preferred over females by ovipositing *E. flava* and that the egg position by sex interaction detected for *N. viridula* is partially accounted for by an excess of eggs on the ventral surface of males. In contrast to *Podisus* spp., the attractant pheromones of *Nezara*, *Acrosternum*, *Euschistus*, *Thyanta*, and most other phytophagous pentatomids are evidently released ventrally from scattered cells in the abdominal epidermis of males (Carayon, 1981; Aldrich, unpublished data).

Euclytia flava has been reared from eight species of pentatomoid bugs, including four species used in the host-choice experiments described here: *P. maculiventris*, *E. servus*, *E. tristigmus*, and *T. accerra* (Aldrich et al., 1991a; Buschman and Whitcomb, 1980; Eger and Ables, 1981; Jones et al., 1994; Jones and McPherson, 1980; Oetting and Yonke, 1971). The female flies exploit the pheromones of their hosts to locate them (Aldrich et al., 1991a; Aldrich, 1995), and these pheromones to some extent stimulate acceptance. However, native hosts appear to have somehow retaliated, perhaps by secreting repellent or masking compounds on their cuticle. This interpretation is substantiated by the demonstration that dead *Nezara* males treated with cuticular wash from *E. obscurus* had significantly fewer eggs than did males treated with *N. viridula* extract.

The two exotic species examined here, *N. viridula* and *P. distinctus*, evidently have no immunity to oviposition by *E. flava*. Most of the *Nezara* individuals that were attacked died, and oviposition by *E. flava* on *N. viridula* is a reproductive waste. By comparison, the *E. flava*–native pentatomid combinations tested here have evolved toward commensalism. Thus, the preference of *E. flava* females for exotic species substantiates the theoretical premise of the new associations hypothesis (Pimentel, 1963; Hokkanen and Pimentel, 1984, 1989).

A multitude of new host–enemy associations are automatically created when a species invades a foreign territory. The data presented here demonstrate that an invader may be maladapted and vulnerable to native parasitoids in one aspect of the parasitism process (acceptance), yet go unrecognized as a potential host. Of the existing community of natural enemies, there likely are some native species capable of becoming successful biological control agents if only they could find the exotics. Perhaps in the future it will be possible to accomplish biological control by "teaching" physiologically competent endemic beneficials to recognize alien hosts. In other words, can artificial selection regimes be

devised, based on appropriate semiochemical information, to speed up the natural process of host shifts?

The upheaval surrounding the use of exotic species for biological control of endemic pests makes managing native beneficials more important than ever (Howarth, 1991). The idea that native natural enemies might be "taught" to accept foreign hosts is a reversal of classical biological control. Today, such an unclassical approach is probably more environmentally and sociologically acceptable than classical biological control.

Acknowledgments—I thank Drs. John Simeone and Milt Silverstein for their devotion to our science and inspiration over the years. Dr. Walker Jones (USDA-ARS, Weslaco, Texas) kindly supplied material to start colonies of some pentatomids. I am also very grateful to Ms. Jennifer Graf and Mr. Tev M. Barros for invaluable help in preparing this manuscript. Permits for importation of exotic species were obtained from the appropriate state and federal agencies. Mention of commercial products does not constitute an endorsement by the U.S. Department of Agriculture.

(Received February 14, 1995; accepted March 10, 1995)

Abstract—A brief survey is given about recent results in the identification of semiochemicals in bark beetles: Males of *Ips sexdentatus* (Boern.), stressed by the attack on resinous trees produce large amounts of (3*S*)-1-methyl-5-(1-hydroxy-1-methylethyl)-cyclohexa-1,3-diene. The compound appears to be derived from Δ^3-carene and acts as a repellent. Males of *Ips typographus* (L.), stressed through the attack on unsuitable host material release 3-methyl-7-methylene-1,3(*E*), 8-nonatriene, which seems to act as a repellent. The odor bouquet of three species of *Pityogenes* is described. The occurrence of (+)-grandisol and other compounds related to weevil pheromones points to a close relation between Scolytidae and Curculionidae. Females of *Dendroctonus simplex* (Le Conte) use (−)-frontalin as the main pheromone. 6-Methyl-6-hepten-2-one, a minor component among the volatile compounds released by the females, is regarded as a possible precursor of frontalin. Similarly, (2*R*,5*S*)-2(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran, pityol, a pheromone of *Pityophthorus* spp., is regarded to at least share a common biogenetic precursor with 6-methyl-5-hepten-2-ol, sulcatol. A new bicylic acetal, 2-ethyl-1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane, is described as an aggregation pheromone of the beech bark beetle, *Taphrorychus bicolor* (Herbst). Structural relationships between bark beetle pheromones and plant volatiles are discussed.

Key Words—Bark beetle, identification, pheromone, *Dendroctonus*, *Ips*, *Pityogenes*, *Pityophthorus*, *Taphrorychus*.

INTRODUCTION

As compared to Lepidoptera, chemical communication in bark beetles appears to be much more complex. While host odors play a major role in host selection, the beetles use so-called aggregation pheromones (Vité and Francke, 1976) to mass attack selected trees. These chemical messages are produced by the habitat-selecting sex (in most polygamous species the males) to attract both males and females. In some species, however, the signals also show certain characters of sex pheromones since the opposite sex is attracted in higher numbers. When females select the host, as in many monogamous species, the arriving males may contribute in a "dialogue" by producing signals that balance the sex ratio or which repel other individuals. Mass attack actually is the outcome of an intriguing system of intra- and intersexual communication, which in many respects appears to be more closely related to communication among social insects than to the sex pheromone systems of moths. The pheromone biology and chemical ecology of bark beetles have been extensively reviewed (D.L. Wood, 1982; Borden, 1989; Byers, 1989; Vité and Baader, 1990); syntheses of pheromones have been carefully compiled by Mori (1992).

While many chemical compounds have been identified from bark beetles, only a few proved to be truely behavior mediating. With the exception of the structures of *Scolytus* pheromones, which seem to be polyketids made up by propanoate units, bark beetle pheromones are represented by either mevalogenins (terpenoid carbon skeletons) (Francke and Vité, 1983) or acetogenins (unbranched carbon skeletons). The structures of 21 known, relevant compounds are depicted in Figure 1.

In the present paper, we present our recent results on the identification of behavior mediating compounds from bark beetles. Some new chemical structures will be presented and some (structural/biogenetic) relations will be discussed.

RESULTS AND DISCUSSION

Ips De Geer

Typical pheromones of many *Ips* species are the male-produced ipsdienol (VIII) and ipsenol (X) (Silverstein et al., 1966). While myrcenol (VII) was found to be a synergistic component of the aggregation pheromone of *Ips duplicatus* (Sahlb.) (Byers et al., 1990b), amitinol (IX), a possible rearrangement product of ipsdienol, appeared to be behavior mediating in *I. sexdentatus* (Boern). (Kohnle et al., 1988). The structures of these compounds suggest a biogenesis from the host terpene, myrcene, as a precursor (Hughes, 1974; Hendry et al., 1980); however, recent results also show that a *de novo* synthesis by the beetles may occur, at least in some species (Ivarsson et al., 1993). While the hemiter-

pene, 2-methyl-3-buten-2-ol (III), is an important pheromone of *I. typographus* (L.) (Bakke et al., 1977) and *Orthotomicus erosus* (Woll.) (Giesen et al., 1984), its isomers, 4-methyl-3-buten-1-ol (IV) and 3-methyl-3-buten-1-ol (V), are pheromones of the larch bark beetle, *I. cembrae* (Heer) (Stoakley et al., 1978) and *Polygraphus rufipennis* (Kirby), respectively (Bowers et al., 1991). The almost ubiquitous bicyclic terpenol, (*S*)-*cis*-verbenol (XI), is a particularly important compound in *I. typographus*, while its oxidation product, verbenone (XIII), acts as a repellent in many species, including *Dendroctonus*.

Ips sexdentatus (Boern.). Investigations concerning the pheromone system of *Ips sexdentatus* have been carried out earlier (Francke et al., 1986; Kohnle et al., 1988). In continuation of these studies, we analyzed the volatile compounds produced by beetles boring in highly resinous trees. Using a fused silica capillary coated with the polar stationary phase FFAP, pentane extracts of excised

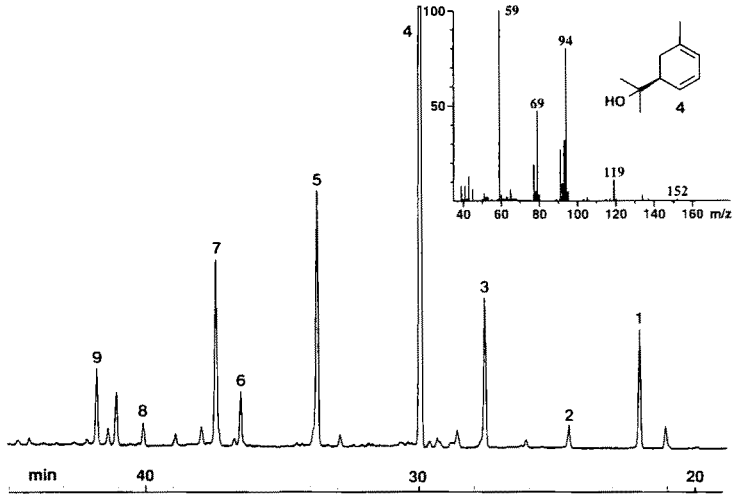

FIG. 2. Gas chromatogram of hindguts of *Ips sexdentatus* males boring in highly resinous pine trees; for conditions see text. Insert: 70-eV EI-MS of (3*S*)-(−)-1-methyl-5-(1-hydroxy-1-methylethyl)-cyclohexa-1,3-diene.

hindguts of males produced the gas chromatogram shown in Figure 2. Structure assignment of peaks was based on GC-MS investigations (a Hewlett-Packard HP 5890 was linked to a double-focusing mass spectrometer, Vacuum Generators VG 70-250SE, 70 eV) and comparison of data obtained with authentic reference samples. A list of identified compounds is shown in Table 1; peak numbers in Figure 2 and numbers in the corresponding table are congruent.

5. (+)-Myrtenol (85% ee)
6. *m*-Cymen-8-ol
7. *trans*-Myrtanol
8. β-Phenylethanol
9. 3-Caren-10-ol

[a]Compound numbers refer to peak numbers in Figure 2.

The main compound (peak 4) proved to be 1-methyl-5(1-hydroxy-1-methylethyl)-cyclohexa-1,3-diene, a *m*-mentha-4,6-dien-8-ol, which had been described earlier from *Ips* (Renwick et al., 1976) and *Dendroctonus* (Pierce et al., 1987). The compound shows a mass spectrum (see insert in Figure 2), which is indistinguishable from the corresponding *p*-menthadienol, α-phellandren-8-ol, and which can be separated from the latter only by a rather selective column. Such coincidences may cause misinterpretations concerning *m*- and *p*-menthadienes—including our own report (Francke et al., 1986). Actually, the *m*-menthadienol may be much more widespread than is known today. Optically active samples of the compound were prepared according to Gollnick et al. (1966). Using a 30-m FS capillary coated with a 1:1 mixture of 2,6-di-*O*-methyl-3-*O*-pentyl-β-cyclodextrin as the stationary phase, programmed from 80 to 140°C at a rate of 2°C/min, the stereoisomers of the hydrogenated natural product could be separated and compared with synthetic samples. As a result, the *Ips*-volatile proved to show (5*S*)-configuration with an enantiomeric excess (ee) of ca. 99%.

Although the biosynthesis of the compound has not yet been investigated, it is likely that it is produced from 3-carene, since exposure of the beetles to resin with high amounts of 3-carene resulted in the production of high amounts of the (5*S*)-enantiomer of the *m*-mentha-4,6-dien-8-ol.

During field tests, enantiometrically pure samples showed strong repellent effects, which may indicate a function as a warning signal to avoid the attack of healthy (high resinous) trees with a high content of the (poisonous) monoterpene hydrocarbon, 3-carene.

Apart from the (5*S*)-(−)-*m*-mentha-4,6-dien-8-ol, the first compound of this type to show biological activity, its corresponding dehydrogenation product, the aromatic *m*-cymen-8-ol (6), was also found, which, however, did not exhibit behavior-mediating properties.

In the present samples, ipsdienone (1) and ipsdienol (3), which besides myrtenol (5) usually represent major products in the hindguts of successfully boring beetles, were found to be much less abundant. Chiral gas chromatography, using the cyclodextrin phase mentioned above, proved the myrtenol to show (1*S*)-configuration (85% ee), while the ipsdienol was represented by a 4:1 mixture of (−):(+). The latter result is in contrast to our earlier report (Francke et al., 1986), where we found almost racemic ipsdienol, produced by successfully boring *I. sexdentatus* males.

Ips typographus (L). The chemistry of the pheromone system of *I. typographus* has been described by Bakke et al. (1977). Kohnle et al. (1991) hypothesized that 2-methyl-3-buten-2-ol and (*S*)-*cis*-verbenol play a major role as contact pheromones, while (−)-ipsdienol and (+)-ipsenol, two behavior-mediating components that are produced at a later stage of the attack, are frass pheromones.

We were interested in investigating the pheromone production of male beetles under stress and forced them to bore into rather thin, rapidly drying logs of Norway spruce and collected headspace volatiles on charcoal filters by closed loop stripping (Grob and Zürcher, 1976). As a result, the beetles did not release any volatiles known as attractants. A typical gas chromatogram (50-m fused silica capillary coated with FFAP and programmed from 60 to 200°C at a rate of 3°C/min) is shown in Figure 3. The identified compounds are listed in Table 2; the numbers are congruent. Identifications are based on GC-MS and synthetic reference samples (see above). Besides an array of monoterpene hydrocarbons and a few sesquiterpenes known as host constituents, some oxygenated monoterpenes were found. Upon high-resolution GC-MS, a compound eluting between the monoterpene hydrocarbons and the region of oxygenated monoterpenes proved to be a hydrocarbon, $C_{11}H_{16}$. The compound (mass spectrum shown as an insert in Figure 2) could be hydrogenated to $C_{11}C_{24}$, which suggested an open chain. The base peak *m/z* 81 pointed to the methylene-homologue of *m/z*

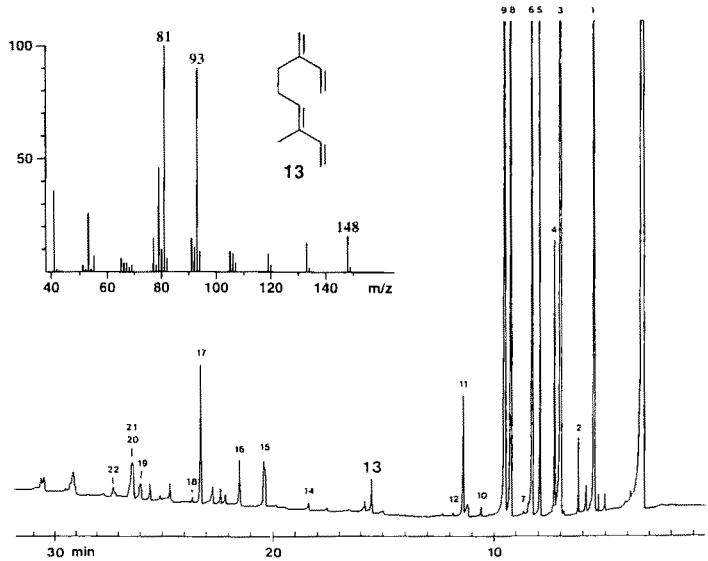

FIG. 3. Gas chromatogram of headspace volatiles collected from *Ips typographus* males boring in Norway spruce; for conditions see text. Insert: 70-eV EI-MS of 3-methyl-7-methylene-1,3(*E*),8-nonatriene. NMR data of this compound obtained with a Bruker AMX 400 are as follows: ^{1}H NMR (400 MHz, $CDCl_3$) δ = 1.85 (s, 3H); 3.03 (d, J = 7 Hz, 2H); 4.90 (s, 2H); 5.03 (s, 1H); 5.08 (s, 1H), 5.10 (d, J = 10.8 Hz, 1H); 5.24 (d, J = 18 Hz, 1H); 5.72 (td, J = 16 Hz, J = 7 Hz, 1H); 6.20 (d, J = 16 Hz, 1H) 6.43 (dd, J = 18 Hz, J = 10.8 Hz, 1H).

69, which is characteristic for the typical dimethyl allyl terminus of open chain terpenes. In fact, the natural product proved to be 3-methyl-7-methylene-1,3(*E*),8-nonatriene (13), which could be easily synthesized from myrcenal (Büchi and Wuest, 1967) by Wittig reaction with triphenylmethylene phosphorane.

The carbon skeleton of the new homoterpene is the same as in the homoocimene, 3,7-dimethyl-1,3,6-nonatriene, identified from army ants (Keegans et al., 1993), and resembles that of juvenile hormones. A possible biosynthesis suggests homomevalonate to be involved.

Preliminary laboratory bioassays showed a repellent effect of 3-methyl-7-methylene-1,3(*E*),8-nonatriene, indicating a possible function as a warning signal to avoid unsuitable host material.

Pityogenes Bedel/Pityophthorus Eichhoff

Little is known about the pheromone systems in these two genera, since only two species, *Pityogenes chalcographus* (L.) and *Pityophthorus pityographus* (Ratz.) have been investigated so far.

The acetogenin, chalcogran (XIX), has been identified as the principal pheromone component produced by male *Pityogenes chalcographus* (Francke et al., 1977) synergized by methyl (*E*,*Z*)-2,4-decadienoate (XX) (Byers et al., 1990a). The natural spiroacetal shows (2*S*)-configuration (Schurig and Weber, 1984), and the (2*S*,5*S*)-diastereomer proved to be nonattractive (Byers et al., 1989). The structure of chalcogran suggests a formation from five acetate units and loss of one carbon atom: it would not be too surprising if chalcogran and its synergist, the decadienoic acid ester, share a common precursor or if a long-chain unsaturated fatty acid were involved in the biosynthesis. Chalcogran as well as the isomeric spiroacetal, 7-methyl-1,6-dioxaspiro[4.5]decane (XVIII) (see below), are not made up by three propanoate units, as suggested by Vanderwel and Oehlschlager (1987), since such a biosynthesis would yield a compound showing characteristic methyl branching pattern as represented in multistriatin (II).

In a continuation of our earlier investigations, we analyzed the volatiles emitted by males of *P. quadridens* (Hartig), *P. calcaratus* (Eichh.), and *P. bidentatus* (Herbst). Gas chromatograms are shown in Figure 4 and 5A and B; a corresponding list of identified compounds is given in Table 3. Peak attribution was based on GC-MS using synthetic reference samples (see above).

P. quadridens shows an interesting bouquet (Figure 4); while expectedly it contains chalcogran and 1-hexanol, just like *P. chalcographus*, it also exhibits

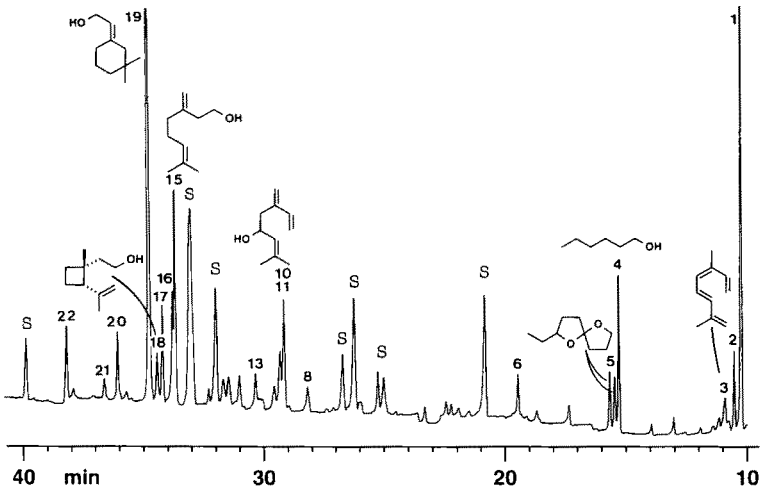

FIG. 4. Gas chromatogram of a pentane extract of *Pityogenes quadridens*; 50-m × 0.25-m-ID glass capillary, coated with WG 11, programmed from 60 to 200°C at a rate of 3°C/min; S = sesquiterpene.

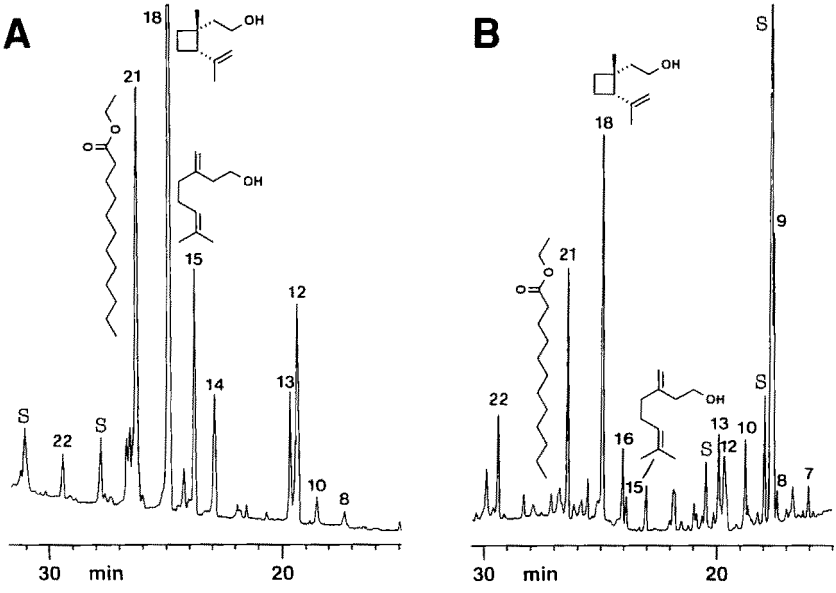

FIG. 5. (A) Gas chromatogram of a pentane extract of *Pityogenes calcaratus*; 50-m × 0.25-mm-ID fused silica column coated with FFAP and programmed from 60 to 200°C at a rate of 3°C/min; S = sesquiterpene. typical features of *Ips* pheromones: ipsdienol—absolute configuration unknown—accompanied by traces of 2-methyl-6-methylene-1,3(*E*),7-octatriene (not listed), a possible elimination product formed from either ipsdienol or amitinol. The dehydroocimenes, 2,6-dimethyl-1,3(*E*),5(*Z*),7-octatetraene (3) and traces of its 5(*E*) isomer were also found.

A particularly surprising set of compounds points to close relationships between Scolytidae and Curculionidae: γ-isogeraniol (15), (*E*)-3,3-dimethyl-$\Delta^{1,\beta}$-cyclohexaneethanol (19) and grandisol (18)—absolute configurations unknown—could be identified. The *cis*-isomer of 19 and grandisol are pheromone compounds of the boll weevil, *Anthonomus grandis* (Boheman) (Tumlinson et al., 1969).

During bioassays with *P. quadridens*, mixtures of chalcogran (15), (+)-grandisol (18), and 19 proved to be attractive in the field (E. Baader, unpublished). The samples obtained from *P. calcaratus* males were dominated by grandisol (Figure 5A). Enantiomeric separation of its trifluoroacetate on 2,3,6-tri-*O*-pentyl-β-cyclodextrin proved the natural product to be the (+)-enantiomer showing ca. 99% ee. It was accompanied by trace amounts of grandisal. Both

grandisal and grandisol have been described as pheromones of pine weevils, *Pissodes* spp. (Booth et al., 1983). (+)-Grandisol and γ-isogeraniol were also identified in males of *P. bidentatus* (Figure 5B). All three *Pityogenes* species discussed so far contained ethyl dodecanoate (22).

With respect to chemical functionalities, structural relations between γ-isogeraniol and grandisol are similar to those between ipsdienol and lineatin (VI), the aggregation pheromone of the ambrosia beetle, *Trypodendron lineatum* (Oliv.) (Borden et al., 1979). Formation of the cyclobutane ring may follow the same biogenetic mechanism.

While γ-isogeraniol was prepared according to Brown et al. (1963), (*E*)-3,3-dimethyl-$\Delta^{1,\beta}$-cyclohexaneethanol was obtained by reduction of the corresponding aldehyde (Bedoukian and Wolinsky, 1975). Bioassays with *Pityogenes* species using synthetic compounds are not yet finished.

It is interesting to note that (+)-grandisol was also found in *Pityophthorus pityographus* (Ratz.). In this species, the tetrahydrofuran derivative, pityol (XV), represents the most active pheromone component (Francke et al., 1987). The gas chromatogram (FFAP; standard conditions see above) depicted in Figure 6 shows the relative proportions between pityol, grandisol, and inactive com-

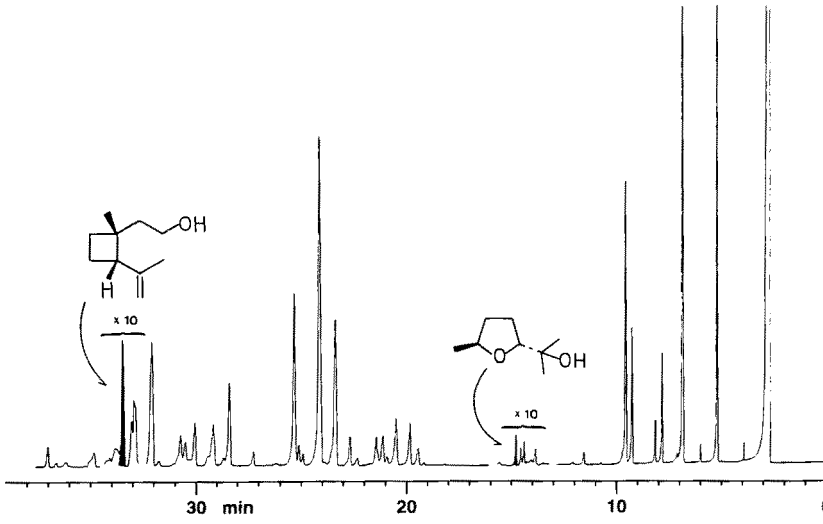

FIG. 6. Gas chromatogram of a pentane extract of *Pityophthorus pityographus*. For conditions see Figure 4.

pounds, which may form a kind of matrix for the active principle. In addition, (2*R*,5*S*)-pityol was identified from some American *Pityophthorus* species and proved to be highly attractive in the field (D. Wood, S. Seybold and W. Francke, unpublished). In pine cone borers, *Conophthorus* spp., the same compound represents a strong female specific attractant (Birgersson et al., 1995).

Although the biosynthesis of pityol is unclear, a degradation of a monoterpene precursor (geraniol or a derivative thereof) is suggested as the initial step, to yield 6-methyl-5-hepten-2-one. Reduction of this ketone would yield sulcatol (XIV), which is known as an aggregation pheromone of the ambrosia beetle, *Gnathotrichus sulcatus* (Le Conte) (Byrne et al., 1974). Enzymatic epoxidation of the double bond of sulcatol by an mfo-system and ring closure would lead to either pityol or vittatol, which had been identified from the elm bark beetle, *Pteleobius vittatus* (F.) (Klimetzek et al., 1989). The stereochemistry of the resulting 2,5-disubstituted tetrahydrofrun would be determined by the stereoselectivity of the reduction step and the stereoselectivity during epoxidation.

The spiroacetal (*E*)-7-methyl-1,6-dioxaspiro[4.5]decane (XVIII), which was first described from common wasps (Francke et al., 1979), could be identified in some *Pityophthorus* spp. (W. Francke, unpublished), in *Conophthorus* spp. (Birgersson et al., 1995), in *Cryphalus piceae* (Ratz.), and in the ash bark beetle, *Leperisinus varius* (F.). In all three species it acts as a male-produced repellent (Birgersson et al., 1995; Kohnle et al., 1992). Using chiral gas chro-

matography (40-m FS capillary coated with 2,3,6-tri-*O*-hexyl-α-cyclodextrin, programmed from 50 to 100°C at a rate of 2°C/min) in some species the natural product could be shown to exhibit (2*S*,5*S*)-configuration, just as in *Paravespula vulgaris* (W. Francke, unpublished). The synthesis of the optically active spiroacetals, used as reference samples and in field tests, followed the procedure described by Jacobsen et al. (1982).

Dendroctonus Erichson

The oxygenated monoterpenes, *trans*-verbenol and verbenone, have been frequently described as behavior-mediating volatiles from *Dendroctonus* spp. The terpenoid, frontalin (XVI) (Kinzer et al., 1969), and the acetogenin, brevicomin (XVII) (Silverstein et al., 1968), play a major role in the communication systems of many species. The compounds are secreted by different sexes and contribute to the above-mentioned dialogue. The isomers of brevicomin are obviously used both with respect to enantiomeric compositions as well as diastereomeric proportions.

In addition to the widespread monoterpenes and bicyclic acetals, 3-methyl-2-cyclohexen-1-one (Kinzer et al., 1971) and its reduction product, 3-methyl-2-cyclohexen-1-ol (XXI) (Vité et al., 1972) as well as 1-methyl-2-cyclohexen-1-ol (Libbey et al., 1983) were specifically found to be pheromones of *D. pseudotsugae* (Hopkins). Although the substituted cyclohexenone might be biosynthesized from a straight-chain precursor (e.g., 2,6-heptanedione or derivative thereof), it appears more likely that it represents a degradation product of a terpene (via a *m*-menthane derivative; see above). The tertiary alcohol may well be a product of an allylic rearrangement of 3-methyl-2-cyclohexan-1-ol, the chemical relations between these two compounds being the same as between ipsdienol and amitinol.

Dendroctonus simplex *(Le Conte)*. Besides the usual array of monoterpene and sesquiterpene hydrocarbons and some oxygenated monoterpenes, four female-specific compounds could be identified in *D. simplex*. The gas chromatogram depicted in Figure 7 and Table 4 show identical numbering; identifications are based on GC-MS using synthetic reference samples (see above). The major sex specific compound was identified to be (−)-frontalin (ca. 95% ee as determined by chiral gas chromatography on the above-mentioned 2,3,6-trihexyl-α-cyclodextrin). The pure enantiomer proved to be highly attractive in the field (J.P. Vité, unpublished). In addition to frontalin, three structurally related terpenoid ketones, 6-methyl-6-hepten-2-one, 6-methyl-5-hepten-2-one, and 6-methyl-3(*E*),5-heptadien-2-one, were found. Close biogenetic relations between these ketones and known bicyclic acetals are suggested.

Bicyclic acetals showing a 6,8-dioxabicyclo[3.2.1]octane system represent

cryptic ketodiols or products of intramolecular cyclizations of epoxy ketones. (Z)-6-Nonen-2-one, which besides *exo*-brevicomin had been identified from the ash bark beetle, *Leperisinus varius* (Francke et al., 1979), was postulated as a precursor to form *exo*-brevicomin upon epoxidation and ring closure (Francke, 1981). Recently, careful investigations by Vanderwel et al. (1992) proved this hypothesis to be true for *D. ponderosae* (Hopkins). Reactions similar to those that lead from 6-nonen-2-one to brevicomin would produce frontalin from 6-methyl-6-hepten-2-one (Figure 8). The stereoselectivity of the epoxidation would determine the stereochemistry of the final product.

It should be noted that 6-methyl-5-hepten-2-one is widespread among bees and ants and that epoxidation and ring closure of this ketone (Figure 8) may similarly be involved in the biosynthesis of 1,3,3-trimethyl-2,7-dioxabicyclo[2.2.1]heptane, which has been found in some ant species (Keegans et al., 1993).

Taphrorychus Eichhoff

Our earlier investigations on the pheromone system of the only species investigated so far revealed the presence of large amounts of acetophenone (Kohnle et al., 1987) along with other beetle-specific volatiles. We now wish to give a more complete list of volatile compounds and report on the identification of the male produced aggregation pheromone.

Taphrorychus bicolor (Herbst). The gas chromatogram depicted in Figure 9 and Table 5 show identical numbering; identifications were based on GC-MS using synthetic reference samples (see above). Pentane extracts of frass produced by boring beetles served as substrate. A most interesting mass spectrum was obtained from the male-specific peak 3, which eluted shortly after nonanal. Its EI-MS is shown as an insert in Figure 9. As determined by high-resolution GC-MS, the molecular formula was found to be $C_{10}H_{18}O_2$. The substance could not

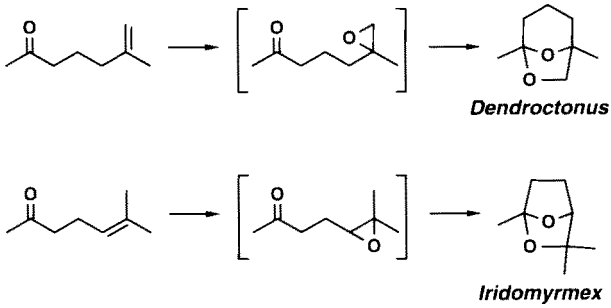

FIG. 8. Possible formation of bicyclic acetals from terpenoid precursors.

be hydrogenated and did not react with silylation reagents. According to known mass spectrometric fragmentation patterns (Gore et al., 1976), the structure of a bicyclic acetal was suggested. Although initially the intense signal of *m/z* 82 (C_6H_{10} as determined by high-resolution MS) could not be satisfactorily interpreted, the characteristic fragments at *m/z* 43 and *m/z* 128 (M-42) pointed to a substituted 5-methyl-6,8-dioxabicyclo[3.2.1]octane. The ^1H NMR spectrum of

a small sample of the natural product obtained by preparative gas chromatography showed two shifted methyl singlets and a methyl triplet as well as two shifted protons in α-positions to oxygen. On the basis of this information, the fragment *m/z* 82 suggested an ethyl group at position 2 and a second methyl group at position 1. Thus, the compound proved to be 2-ethyl-1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane, the 2-ethyl bishomolog of frontalin. Using optically active reference samples, chiral gas chromatography (25-m FS capillary coated with 2,6-di-*O*-methyl-3-*O*-pentyl-β-cyclodextrin programmed from 60 to 150°C at a rate of 3°C/min) proved the natural product to show (1*S*,2*R*,3*R*)-configuration.

The compound that we named bicolorin was highly attractive in the field. After brevicomin, frontalin, and multistriatin, which together with (3*S*,4*S*)-4-methyl-3-heptanol (I), plays a major role in pheromone systems of *Scolytus multistriatus* (Marsh.) (Pearce et al., 1975), bicolorin is the fourth substituted 6,8-dioxabicyclo[3.2.1]octane identified as a bark beetle pheromone. Although sharing the same parent system, the four compounds seem to originate from very different precursors. Details on the synthesis of the stereoisomers of bicolorin and results of bioassays will be given in a separate paper.

REMARKS AND REFLECTIONS

Since the identification of the first bark beetle pheromone by Silverstein et al. (1966), a lot has been learned about the chemistry and function of behavior-mediating compounds among the scolytids. Although many of the known intra- and interspecific signals proved to be highly characteristic, a closer look at the chemical structures of the components that make up such chemical messages reveals many compounds that are by no means unique. Only a few of the substances depicted in Figure 1 have not yet been found in a non-bark beetle context. The hemiterpenes III, IV, and V are known from plants and Hymenoptera; and III is the alarm pheromone of European hornets, *Vespa crabro* (Veith et al., 1984). The bicyclic terpenes XI, XII, and XIII are typical constituents of many essential oils and have been known for quite some time. Furthermore, the occurrence of the myrcene derivatives is not restricted to bark beetles. "Ipsdienone," the oxidation product of ipsdienol (VIII) had already been mentioned by Naves (1948; he called it myrcenone) as a constituent of the Verbenacea, *Lippia asperifolia*. Our own analysis of the essential oil of *L. javanica* from South Africa (W. Francke and H. Meyer, unpublished) revealed high proportions of ipsdienone and ocimenone accompanied by small amounts of other monoterpenes including ipsdienol and 6,7-epoxymyrcene. Ipsdienol has also been described as a component of the fragrance of orchids that are pollinated by euglossine bees (Whitten et al., 1988). Amitinol (IX) is a constitutent of the

essential oil of *Ledum palustre* (Schantz et al., 1973). Sulcatol (XIV) and the corresponding ketone are particularly widespread among the secretions of animals (including mammals); they are produced by microorganisms as well as by plants. The orchid *Aerides lawrenceae* produces a nice "bark beetle bouquet" by emitting both sulcatol and 2-methyl-3-buten-2-ol (III) (Kaiser, 1993). Although grandisol has not yet been reported from sources other than beetles, its *trans* isomer, fragranol, has been identified from *Artemisia fragrans* (Bohlmann et al., 1973). Methyl (*E*,*Z*)-2,4-decadienoate (XX), which along with the corresponding ethylester ("pear ester") is known to account for the typical aroma of Bartlett pears, was also found in orchids (Kaiser, 1993). Even the famous bicyclic acetals XVI, XVII, and XIX do not represent "unique beetle chemistry." We found *endo*-brevicomin in the scent of the orchid *Ophrys speculum* (W. Francke and D. Erdmann, unpublished), while 3,4-dehydrobrevicomin proved to be a pheromone of mice (Novotny et al., 1984). Chalcogran (XIX) was identified in flowers of orchids, *Liparis viridifoli*, *Eria hyacinthoides*, and *Oncidium ornithorhynchum*. Along with the isomeric spiroacetal (XVIII) it also occurs in *Dracaena fragrans* (Kaiser, 1993). The latter compound is also widespread among common wasps and was detected both in cork oak and spruce (W. Francke, unpublished). What do *Dendroctonus* and *Elephas* have in common? The "typical" bark beetle pheromone, (1*S*)-frontalin is a constituent of the temporal gland secretion exuded by male Asian elephants, during their musth cycles (Rasmussen et al., 1994). The list of parallels is long and certainly does not exclude polyketides such as the "*Scolytus* pheromones," 4-methyl-3-heptanol (I), which is known from ants, too.

Degradation and elimination of the signal with time and space is a principal feature of pheromones, and one may speculate about the environmental impact on the fate of the bark beetle pheromones once they are released. Oxygenated monoterpenes may undergo acid-catalyzed or UV-induced rearrangements, and in addition their structures may be changed by elimination of water or further oxidation. Verbenone is easily rearranged to chrysantheone and 2,4,4-trimethylbicyclo[3.3.1]hept-2-en-6-one (Hurst and Whitham, 1960). In our own investigations we found that this reaction may take place under the conditions of a sunny warm day. During our irradiation experiments (400 W, Heraeus), isopiperitone as well as (*E*)- and (*Z*)-ocimenone were produced. Formation of the acyclic ketones is similar to the conversion of α-pinene to ocimenes as described by Kropp (1969). Although verbenols show a less suitable chromophore, allylic rearrangements to the corresponding bicyclic alcohols and ring-opening to *cis*-isopiperitenol and *cis*-3-methyl-6-(1-methylethenyl)-3-cyclohexen-1-ol follows the same mechanisms as in the case of verbenone. Irradiation of ipsenol and ipsdienol affects the butadiene moiety, yielding 1-substituted cyclobutenes. While 1-(2-hydroxy-4-methyl)-butylcyclobutene is formed from ipsenol, ipsdienol leads to 1-(2-hydroxy-4-methyl)-but-3-enylcyclobutene and

bicyclic alcohols. The composition of the mixture of alcohols formed from these alcohols corresponds to the mixture of hydrocarbons obtained from irradiation of myrcene (Liu and Hammond, 1967 and references cited therein). Interestingly, we identified 1-(2-hydroxy-4-methyl)-but-3-enylcyclobutene as a new natural product in some bark beetle species; however, no bioassays have yet been carried out. It would be interesting to know more about degradation products form (bark beetle) pheromones and to learn something about their (possible) bioactivities.

Some of the known systems of bark beetle pheromones look rather primitive, being made up of simple oxygenated monoterpenes that are indistinguishable from products of autoxidation processes, while other species developed elaborate biosynthetic pathways to produce and use highly sophisticated compounds. This may suggest at least a certain trend in the evolution of bark beetle pheromones. However, with respect to production and use of relevant compounds, there is no correlation between chemical structures of bark beetle pheromones and the position of the corresponding species within the phylogenetic tree, described by Steven Wood (1982). Chemical communication seems to follow higher principles, as is thought today. It makes use of a wealth of chemical compounds that seem to develop specificity through the formation of unique blends that are used in a specific biological context. With respect to bark beetles, we are just starting to learn how chemical ecology works.

(Received September 23, 1994; accepted March 13, 1995)

Abstract—When the nine identified components in the effluvium of calling female codling moths were compared to pure synthetic (*E,E*)-8,10-dodecadien-1-ol in flight-tunnel tests, equal responses were obtained over a concentration range of 300-fold. When synthetic (*E,E*)-8,10-dodecadien-1-ol was compared to extract of female sex pheromone glands by a male wing-flutter bioassay, or in flight-tunnel tests, equal responses were obtained over a concentration range of 1000-fold. The sum total of these and previous studies indicate that the codling moth sex pheromone consists of only one component.

Key Words—Codling moth, *Cydia pomonella*, sex pheromone, (*E,E*)-8,10-dodecadien-1-ol.

INTRODUCTION

Sex pheromones of insects are generally multicomponent (Wood et al., 1967; Roelofs, 1977; Silverstein, 1977). The codling moth sex pheromone was originally identified as the single component, (*E,E*)-8,10-dodecadien-1-ol by Roelofs et al. (1971). Subsequently, data from flight-tunnel tests and male wing-flutter bioassays indicated that dodecan-1-ol and tetradecan-1-ol were synergistic components of the sex pheromone (Einhorn et al., 1984, 1986; Arn et al., 1985; Bartell et al., 1988), but in later flight tunnel tests the activity of these compounds could not be substantiated (McDonough et al., 1993).

The lack of substantiation of pheromonal activity for dodecan-1-ol and

*To whom correspondence should be addressed.

tetradecan-1-ol did not rule out the possibility that other undiscovered active components existed. Arn et al. (1985) identified nine components in the effluvium of calling females and many of these components had not been tested. Using a male wing-flutter bioassay, Bartell and Bellas (1981) reported that extract of female sex pheromone glands produced a stronger response than synthetic (*E,E*)-8,10-dodecadien-1-ol.

To define the sex pheromone of the codling moth more accurately, we conducted tests in a flight tunnel comparing the natural ratio of known components of the effluvium of calling females with synthetic (*E,E*)-8,10-dodecadien-1-ol and a comparison of sex pheromone gland extract to synthetic (*E,E*)-8,10-dodecadien-1-ol by wing-flutter and by flight-tunnel bioassays. None of these tests indicated the presence of sex pheromone components other than (*E,E*)-8,10-dodecadien-1-ol.

METHODS AND MATERIALS

Insects. Pupae were obtained from a laboratory colony reared on artificial diet (Howell, 1972; Toba and Howell, 1991). Individual pupae were placed in 15 × 50-mm vials and maintained at 20°C and 65% relative humidity under constant light. Males for wing-flutter or flight-tunnel bioassays were used three days after eclosion and 0.25–2.5 hr after darkening the room.

Extracts of Sex Pheromone Glands. Female moths (2–3 days old) in individual vials were collected 0.5 hr after the beginning of darkness and placed in a refrigerator to inactivate them. They were removed individually, and their terminal abdominal segments containing the sex pheromone gland were severed and steeped for 15–60 min in ca. 200 μl dichloromethane. The dichloromethane extract was removed with a syringe and kept in a freezer until needed.

Chemicals. (*E,E*)-8,10-Dodecadien-1-ol, decan-1-ol, dodecan-1-ol, tetradecan-1-ol, hexadecan-1-ol, and octadecan-1-ol were purchased from Aldrich Chemical Co. (Milwaukee, Wisconsin). (*E,E*)-8-10-Dodecadien-1-ol was purified by three low-temperature recrystallizations from pentane, and the isomeric purity was 99.7% (ca. 0.1% *ZE* and 0.2% *EZ*) by gas chromatographic analysis. (*E*)-9-Dodecen-1-ol was purchased from the now-defunct Farchan Division of Story Chemical Corp. (Willoughby, Ohio). All of these chemicals were at least 98% pure by GC analysis, and (*E*)-9-dodecen-1-ol contained less than 1% of the *Z* isomer. (*E,Z*)-8,10-dodecadien-1-ol was synthesized by the method of McDonough and Smithhisler (1989) for the synthesis of (*E,Z*)-10,12-tetradecadien-1-ol except that 1,8-octandiol was used in place of 1,10-decandiol. The isomeric purity was 96% (ca. 1% *ZE* and 3% *ZZ*).

Pheromone Dispensers. In flight tunnel tests, two types of dispensers were used. When (*E,E*)-8,10-dodecadien-1-ol was compared to extract of sex pher-

omone gland, a piece of cotton dental roll (6 mm thick × 6 mm diameter) was used. The test materials were applied as dichloromethane solutions in doses of 0.3, 1.0, 3.0, 10.0, 30.0, 100.0, and 300 ng of (*E,E*)-8,10-dodecadien-1-ol. The amount of (*E,E*)-8,10-dodecadien-1-ol in the extract was determined by gas chromatographic analysis and was usually about 3 ng/female. When (*E,E*)-8,10-dodecadien-1-ol was compared to the nine known components of the effluvium of calling females (Arn et al., 1985), gray elastomer septa (Brown and McDonough, 1986) were used. The test compositions were applied as dichloromethane solutions, and for the nine component mixtures, in ratios that would reproduce the vapor ratios reported by Arn et al. (1985). The ratios applied were calculated in the manner previously reported (McDonough et al., 1993) from known relative half-lives (McDonough, 1991). The applied ratios were: (*E,E*)-8,10-dodecadien-1-ol, 100; (*Z,E*)-8,10-dodecadien-1-ol, 0.3; (*E,Z*)-8,10-dodecadien-1-ol, 5.6; (*E*)-9-dodecen-1-ol, 9.08; decan-1-ol, 0.25; dodecan-1-ol, 43.9; tetradecan-1-ol, 46.9; hexadecan-1-ol, 704; octadecan-1-ol, 6,340. The doses applied of (*E,E*)-8,10-dodecadien-1-ol were: 0.1, 0.3, 1.0, 3.0, 10.0, 30.0 μg.

Wing-Flutter Bioassay. The 10 males for testing were placed in a pint fruit jar. The metal jar tops were pierced with a small hole that just allowed the insertion of a 3-mm-diameter glass rod. Between tests, a piece of tape over the hole prevented odors from entering the jar. The test room was dimly lighted by red lights. A 3-mm-diameter glass rod was inserted to a depth of 6 mm into the test solution. As soon as the solvent evaporated from the rod, it was inserted into the jar. The number of males making a circling motion while wing fanning were counted. Each concentration was tested three times. The concentrations tested in female sex pheromone gland equivalents per milliliter and in grams of codlemone per milliliter were 0.01 and 3×10^{-11}; 0.1 and 3×10^{-10}; 1.0 and 3×10^{-9}; and 10 and 3×10^{-8}, respectively.

Flight Tunnel. A flight tunnel constructed as described by Miller and Roelofs (1978) was used. The flight compartment was 210 cm in length. The air speed directly downwind of the dispenser was 12 cm/sec, and the temperature was maintained at 23°C. The tunnel was dimly lighted overhead by red lights controlled by a rheostat. The effluvium from the flight tunnel was evacuated directly into a fume hood.

Flight Tunnel Bioassay. There were two observers, one at each end of the flight tunnel. Test mixtures in their dispensers were held in place at the upwind end of the flight tunnel by a bent wire. At the downwind end of the tunnel, five male codling moths in a small covered dish were placed on a platform in the middle of the airstream. After 1 min, the cover was removed and behavior was observed. If a male did not flutter its wings, it was considered nonviable. The number of males tested for each data point was 25. When sex pheromone gland extract was tested, a fresh extract was used for each test of five males. Upwind

flights culminating in contact with the dispenser were recorded. Once a male contacted the dispenser, it was removed from the flight tunnel via a tube connected to a vacuum.

RESULTS

Flight Tunnel Tests of Components of Effluvium of Calling Female Codling Moths. Figure 1 shows a graph of log dose versus male response to synthetic (*E,E*)-8,10-dodecadien-1-ol and to the nine components of the effluvium of calling females over a dosage range of 0.1–30.0 μg of (*E,E*)-8,10-dodecadien-1-ol. The nine components were formulated in gray elastomer septa in ratios that would reproduce ratios in the vapor equal to those Arn et al. (1985) found in the effluvium of calling females. The two curves are superimposable and indicate that none of the known components of the effluvium of calling females other than (*E,E*)-8,10-dodecadien-1-ol elicited behavioral activity in these tests.

Wing-Flutter Bioassay. The results of the wing-flutter bioassay are shown in Table 1. The response of males to synthetic (*E,E*)-8,10-dodecadien-1-ol varied from zero for the blanks to almost 100% for a concentration of 3×10^{-8} g/ml. The responses of males to the sex pheromone gland extract were quite similar to synthetic (*E,E*)-8,10-dodecadien-1-ol and well within the standard errors of the means. Thus, in these tests, there is no indication of active components in the extracts other than (*E,E*)-8,10-dodecadien-1-ol.

Flight Tunnel Tests of Extract of Female Sex Pheromone Glands. Male response in flight tunnel tests to synthetic (*E,E*)-8,10-dodecadien-1-ol and to

Concentration		% Response ± SE (N = 3)	
Female eq/ml	g/ml	SPG extract	Synthetic
10	3×10^{-8}	93.0 ± 12.1	96.5 ± 4.9
1	3×10^{-9}	71.5 ± 6.4	66.5 ± 9.2
0.1	3×10^{-10}	38.6 ± 5.0	43.5 ± 24.7
0.01	3×10^{-11}	15.3 ± 16.6	20.5 ± 20.5
0.0	0.0	3.9 ± 3.4	0.0

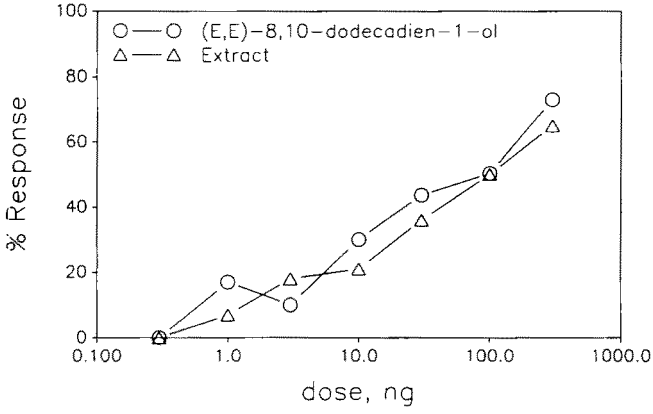

FIG. 2. Flight-tunnel bioassay comparing (*E,E*)-8,10-dodecadien-1-ol with extract of female codling moth sex pheromone glands.

extract of female sex pheromone glands as a function of log dose is shown in Figure 2. Over the dosage range of 0.3–300 ng of (*E,E*)-8,10-dodecadien-1-ol on a cotton dental roll dispenser, the response curves were superimposable. Thus, in these tests also there is no indication of active components in the extracts other than (*E,E*)-8,10-dodecadien-1-ol.

DISCUSSION

Generally, it is expected that insect sex pheromones will consist of two or more components (Silverstein et al., 1966; Wood et al., 1967), but although

the evidence is not rigorous, there is little doubt that the sex pheromone of the codling moth consists of only one component. None of the identified components in the effluvium of calling females, when released in the natural ratio to (*E,E*)-8,10-dodecadien-1-ol, elicited greater responses in flight tunnel tests than (*E,E*)-8,10-dodecadien-1-ol alone, either in this study or in our previous study (McDonough et al., 1993). Furthermore, in both the wing-flutter and the flight-tunnel bioassays, synthetic (*E,E*)-8,10-dodecadien-1-ol elicited responses identical to extracts of female sex pheromone glands containing an equivalent amount of (*E,E*)-8,10-dodecadien-1-ol. In flight tunnel tests a higher response was elicited by synthetic (*E,E*)-8,10-dodecadien-1-ol than by five calling females, and male responses to synthetic (*E,E*)-8,10-dodecadien-1-ol emitted at the low rate of about 3–5 ng/hr were equivalent to the responses to the five caged females (McDonough et al., 1993). Several authors have suggested that the codling moth sex pheromone is inadequate as a mating disruptant because the pheromone was incomplete. A more likely reason for the unsatisfactory results is the ease of oxidative degradation (McDonough et al., 1992), which greatly reduces the amount of (*E,E*)-8,10-dodecadien-1-ol available to disrupt mating. Based on the evidence now available, male codling moths are highly sensitive to their single component sex pheromone.

Abstract—We evaluated several approaches to developing a simple, sensitive, and reliable laboratory bioassay of responses of overwintered adult plum curculios (PCs), *Conotrachelus nenuphar* (Herbst), to host fruit odor or its attractive components. A high proportion of assayed PCs responded positively to odor of wild plums under no-choice, moving-air conditions in a wind tunnel and under dual-choice, still-air conditions in enclosed Petri dishes. Positive response to controls lacking host odor, however, was much greater in the wind tunnel, arguing in favor of bioassays under dual-choice conditions in still air to provide greater PC discrimination. Response to host odor (from wild plums or hexane extract of wild plums or Liberty apples) in Petri dish bioassay chambers proved greatest: (1) during the scotophase of PCs under total dark or dim red light conditions, (2) when Petri dishes were completely enclosed, (3) when PCs were starved for 24 or 48 hr, and (4) when PCs were tested within seven weeks after apple tree petal fall. Neither the sex of a PC nor the direction in which a PC was obliged to move to find the source of host odor (upward through a port in the Petri dish lid or downward through a port in the base) had a substantial effect on level of response to host odor or discrimination of host odor from a nonodorous control. We conclude that an enclosed Petri dish bioassay chamber of the type described here should be a valuable asset in the process of chemically identifying components of host fruit odor attractive to PCs.

Key Words—Fruit odor, bioassay methods, *Conotrachelus nenuphar*.

INTRODUCTION

The plum curculio (PC), *Conotrachelus nenuphar* (Herbst), is among the most damaging of all insect pests of stone and pome fruit in eastern and central North America (Racette et al., 1991). Despite this economic importance, currently there exists no effective trap for monitoring the appearance, abundance, or disappearance of PC adults in commercial orchards (Racette et al., 1992; Prokopy et al., 1993).

In contrast, effective monitoring traps are available for essentially all other key frugivorous insect pests of North American stone and pome fruit orchards (Prokopy and Croft, 1994). They also are available for several other economically important Curculionidae. For example, traps baited with pheromone in combination with host plant volatiles are used to monitor the cotton boll weevil, *Anthonomus grandis* Boheman (Dickens, 1989), the palm weevil, *Rhynchophorus palmarum* (L.) (Jaffé et al., 1993; Oehlschlager et al., 1993), the palmetto weevil, *Rhynchophorus cruentatus* (Fabricius) (Giblin-Davis et al., 1994), and the rice weevil, *Sitophilus oryzae* (L.) (Phillips et al., 1993). Traps baited with pheromone alone are employed in monitoring the sweetpotato weevil, *Cylas formicarius* (Fabricius) (Jansson et al., 1992), legume-infesting *Sitona weevils* (Neilsen and Jensen, 1993) and the pepper weevil, *Anthonomus eugenii* Cano (Eller et al., 1994), while traps baited with host plant volatiles alone have been used to monitor *Hylobius* and *Pachylobius* weevils in pine forests (Hunt and Raffa, 1989).

The principal native host of PC is suspected to be wild plum, *Prunus americana* (Maier, 1990). Within the past 150 years, however, PC has expanded its host range onto introduced commercial apple, pear, plum, peach, and cherry trees (Maier, 1990). Following eclosion in mid-summer, adults feed on host fruit somewhat briefly and then migrate to hibernation sites in nearby woods or hedgerows (Lafleur et al., 1987). In spring, overwintered adults move toward host trees, beginning when apple buds are in the tight cluster stage of development and peaking several weeks later at fruit set (Lafleur and Hill, 1987). Until petal fall, activity within host trees is largely nocturnal, with adults spending a majority of daylight hours in the ground cover beneath trees (Racette et al., 1991). After petal fall, activities of feeding and egg-laying on host fruit occur both diurnally and nocturnally but tend to be concentrated from mid- or late afternoon until dawn the next day (Racette et al., 1991).

Our ultimate goal is to develop an effective monitoring trap for PC adults that incorporates both attractive odor and attractive visual stimuli. Toward this end, we have found that overwintered PC adults respond positively to the odor of intact developing host fruit under both field (Butkewich and Prokopy, unpublished data) and laboratory (Butkewich and Prokopy, 1993) conditions and that adults respond positively to odor of the same or opposite sex (Prokopy and

Cooley, unpublished data). Identification of host fruit or pheromonal chemicals eliciting attraction cannot proceed efficiently, however, without a simple, sensitive, and reliable laboratory bioassay procedure. The laboratory assay approach we had employed until now involved hanging candidate fruit or cotton wicks containing fruit extracts from ends of wooden crosspieces enclosed in clear plastic cylinders, allowing an introduced adult to climb the central stem supporting the crosspiece, and continuously observing the response pattern of the adult thereafter (Butkewich and Prokopy, 1993). Although reasonably sensitive and reliable, this bioassay procedure proved too cumbersome for use on a large scale.

Our objective here was to develop an efficient approach to bioassaying response of PC adults to attractive host fruit odor. To this end, we assessed PC responses to fruit odor under wind-tunnel versus still-air conditions, under photophase versus scotophase conditions, and under various modified still-air conditions. We also assayed responses of adults of varying physiological states with respect to hunger and age and responses of females versus males. The result has been development of a still-air, choice-test bioassay approach that is simple, sensitive, and reliable.

METHODS AND MATERIALS

PCs used in the assays were obtained as adults from unmanaged apple trees from mid-May (petal fall) to early June by tapping tree limbs and collecting fallen adults on sheets of cloth placed beneath the trees. Collected and unsexed PCs were placed in groups of 20–30 in waxed, lid-covered paper cups (500 cc), maintained in the laboratory at 26°C and 80% relative humidity, and provided with several fresh-picked wild plum or apple fruit that were renewed every other day. Unless stated otherwise, the scotophase in the maintenance room extended from 10:00 to 18:00 hr, and fruit were removed from the cups 24 hr before testing. Owing to the limited number of available PCs, the same PCs were used in more than one experiment, but never in more than one experiment per week. Individuals used in experimental treatments were chosen at random from the available pool of PCs.

Intact fruit used in assays were wild plums, picked fresh (when 11–13 mm diam.) about two weeks after petal fall. For several assays, we used a hexane extract of unsprayed domestic plums cv. Fellenberg or domestic apples cv. Liberty. For extracts, fruit were picked fresh about one week after petal fall (when 0.7 g in weight) and were soaked in hexane (1 g fruit/1 ml hexane) for 24 hr at 25°C. In tests, 50 μl of raw extract was applied using a micropipet to a 1-cm^3 piece of cotton dental wick (Absorbal, Wheat Ridge, Colorado) and allowed to evaporate for 4 min before use. As a control treatment, we used

either 12-mm-diam wooden beads painted with green artist pigment to approximate the color of wild plums or 1-cm^3 pieces of cotton dental wick, each treated with 50 μl of hexane and allowed to dry for 4 min before use.

The wind tunnel (Phelan, unpublished) consisted of a 78-cm-long × 34-cm-wide × 10-cm-high Plexiglas box that was open at both ends and divided into four 7-cm lanes by Plexiglas dividers. Air, purified by a charcoal filter, was blown through the lanes at 0.4 m/sec by a fan attached to the filter by a plastic bag. The tunnel was illuminated by fluorescent white light (130 lux) or by an incandescent red lamp (1 lux). Assays were conducted under no-choice conditions. Five minutes before a trial, a treatment or control substance was placed 3 cm downwind of the filter at the upwind end of a lane, separated from the lane by wire mesh. Within 30 sec of the start of a trial, a single PC was introduced into the midway point of each lane, immediately after which the downwind end was closed with wire screen. Each PC was observed continuously until it reached the upwind screen (recorded as a positive response) or until 5 min elapsed without reaching the upwind screen (trial terminated).

Still-air test chambers consisted of plastic Petri dishes (90 mm diam × 15 mm high) modified in the following way (Figure 1). Two holes, 10 mm diam. and 40 mm apart, were bored through a Petri dish lid using a heated cork borer. A tapered disposable polyethylene micropipet tip, 10 mm diam. at the base, 30 mm tall, and 7 mm diam at the tip (after cutting) was fitted snugly into each

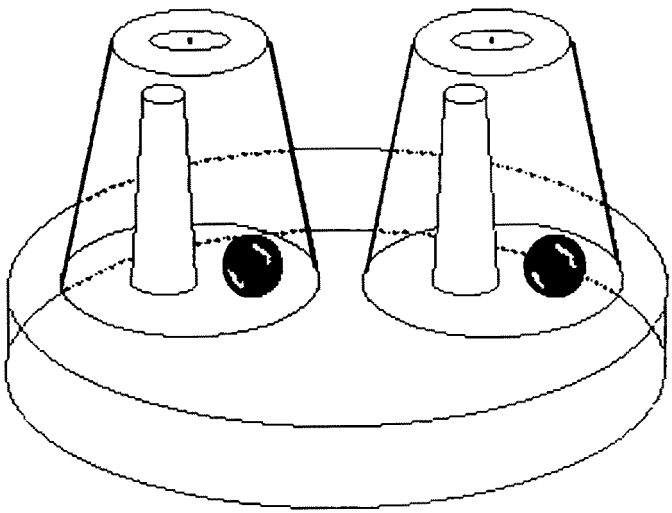

FIG. 1. An enclosed dual-choice Petri dish bioassay apparatus in standard orientation. The dark spheres represent a wild plum (left) and a wooden model of a plum (right).

hole so that the base was flush with the lid of the dish and the tip protruded above the lid. A 35-ml transparent polystyrene cup was centered over each tube, enclosing it. One of the cups contained a treatment inserted within 5 min of the start of a trial. The other cup contained an appropriate control. Within 2 min of the start of a trial, a single PC was placed in the bottom of the dish. It could choose to remain in the dish or to crawl up the inner surface of one of the two tubes and enter a cup containing a treatment or control. In initial tests, the location of each PC was observed every 15 min up to 4 hr. Thereafter, it was observed only at 3 hr.

Data were analyzed according to a G test ($P < 0.05$) (Sokal and Rohlf, 1981) in which the number of PCs that entered a treatment cup was compared with the number that entered a control cup. In addition, to provide a common criterion for judging the power of a treatment to attract PCs under various Petri dish assay conditions, we adopted a response index (RI) used by Phillips et al. (1993) for assessing laboratory attraction of rice weevils to odors of grain. $RI = [(T - C)/\text{total}] \times 100$, where T is the number of PCs responding to a treatment, C is the number of PCs responding to the control, and total is the number of PCs evaluated in the test.

RESULTS

Wind-Tunnel versus Still-Air Conditions. In wind-tunnel assays conducted under white light 8–12 hr after the onset of the photophase of PCs (4–8 hr before the scotophase), 3% of PCs responded positively to a wild plum and 3% to a wooden plum model within 1 min (Table 1, experiment 1). Response levels at 5 min (the end of a trial) were 27 and 20%, respectively. Even though substantial numbers of PCs in nature have been observed to feed and oviposit during this part of the photophase (Owens et al., 1982; Racette et al., 1991), we speculated that response to host fruit might be greater during the scotophase. Indeed, this proved to be so. In assays carried out under dim red light 0–4 hr after the onset of the scotophase, 40% of PCs responded positively to a wild plum and 13% to a wooden plum model within 1 min (Table 1, experiment 2). Response levels at 4 min were identical to those at 5 min: 67% to a wild plum and 30% to a wooden plum model. Response to hexane extract of plums compared with hexane alone under the same conditions as experiment 2 yielded results very similar to those of experiment 2 (Table 1, experiment 3).

Despite the significantly greater proportion of PCs responding to intact plums or plum extract compared with controls during scotophase under wind-tunnel conditions, we believed that this bioassay lacked sufficient discrimination and was too time-consuming to be useful when conducting large numbers of assays associated with identification of chemical components of fruit or sex odor.

TABLE 1. PC RESPONSE TO WILD PLUM (WOODEN MODEL AS CONTROL) OR HEXANE EXTRACT OF PLUMS (HEXANE AS CONTROL) UNDER WIND-TUNNEL OR STILL-AIR (PETRI DISH) TEST CONDITIONS DURING PHOTOPHASE OF PC (WHITE LIGHT) OR SCOTOPHASE OF PC (RED LIGHT)[a]

	Assay condition					PC responding (%)

[a]Thirty PCs were tested per experiment.
[b]Treatments are significantly different from control at $P < 0.05$.

In particular, PCs were prone to move upwind even in clean air. We reasoned that a choice test under still-air conditions might prove more rewarding.

Using still-air Petri dish test chambers, we repeated the treatments of the three wind-tunnel experiments. In each case, PC discrimination between treatment and control exceeded that in the comparable wind-tunnel experiment. Thus, when tested during the photophase, 47 vs. 17% of PCs had responded positively to a wild plum compared with a wooden plum model by 4 hr (Table 1, experiment 4). In a similar test during the scotophase, response levels at 4 hr were 73 vs. 10%, respectively (Table 1, experiment 5). When hexane extract of plums was compared with hexane alone during the scotophase, response levels at 4 hr were 63 vs. 3%, respectively (Table 1, experiment 6). For experiments 5 and 6, we provide response levels at 30, 60, 120, 180, and 240 min. In each experiment, response to treatment as well as control reached a maximum at 3

hr. In each experiment, 3% of the PCs assayed changed location from a treatment cup to a control cup or vice versa between observation periods.

We concluded from this set of six experiments that assays conducted in still air in Petri dishes under dim red light early in the scotophase of PC permitted a substantially greater level of PC discrimination than assays carried out in a wind tunnel or during the photophase of PC. Unless stated otherwise, all remaining assays were conducted in still air in Petri dishes.

Photophase versus Scotophase Conditions. To confirm and expand our conclusions with respect to effects of photophase versus scotophase on PC response levels, we conducted two additional experiments in which PCs were evaluated under photophase or scotophase conditions using plum extract as the treatment substance. When assayed early in the scotophase, PCs responded identically under conditions of dim red light or total darkness: 61% to plum extract versus 3% to control, respectively (Table 2, experiment 1). For PCs entrained for one week to a photophase from 18:00 to 10:00 hr the next day, response levels to plum extract versus control were 60 vs 4% when the assay was initiated at 10:00 hr under red light but 25 vs. 2% when initiated at 10:00 hr under white light (Table 2, experiment 2). For PCs entrained for one week to a photophase from 05:00 to 21:00 hr, response levels to plum extract versus control were 23 vs. 6% when the assay was initiated at 10:00 hr under red light and 27 vs. 2% when initiated at 10:00 hr under white light (Table 2, experiment 2). These results show that PC response to host odor under dim red light does not differ from that in total darkness and confirm that response to host odor is substantially greater when assays are initiated at the beginning of scotophase under dim red light (or total darkness) than otherwise. All remaining assays were conducted under this condition.

Closed versus Open-to-Air Petri Dishes. We hypothesized that the level of PC response to host odor in Petri dish test chambers might be even greater if air were allowed to pass into the chambers rather than maintaining closed air conditions. We reasoned that PCs might be less likely to adapt or habituate to host odor in dishes that permitted exchange of interior with exterior air. Results showed, however, that discrimination between plum extract and control was slightly greater in Petri dishes that were closed (58 vs. 8%) than in Petri dishes having an entirely screened bottom that permitted entry of air from below when dishes were raised 2 cm above floor level (56 vs. 19%) (Table 2, experiment 3).

Orientation of Petri Dishes. We asked whether PC response to host odor differed according to whether PCs in closed Petri dishes were obliged to crawl upward through tubes to reach sources of host odor in cups resting upon lids of dishes (our standard orientation) or were obliged to crawl downward through tubes to reach sources of host odor in cups when dishes, tubes, and cups were flipped 180 degrees so that dishes rested on cups beneath. Results revealed little

[a] Standard assays employed mixed sexes of PCs starved for 24 hr and were conducted early in the scotophase of PC under dim red light conditions in enclosed Petri dishes in which fruit-odor-containing and control cups were placed on lids of dishes and no Fluon was used to coat the exterior of micropippet tubes. All assays except experiment 7 were conducted between June 1 and June 30.

[b] Treatments are significantly different from control at $P < 0.05$.

[c] Response index; see text for definition.

response difference between these two assay conditions: 62% to plum extract versus 8% to control under the standard orientation compared with 64 and 14%, respectively, under the reverse orientation (Table 2, experiment 4). Because it was substantially less effort to set up Petri dishes for assays under the standard dish orientation, we adopted this position rather than the reverse orientation for all tests.

Clean versus Fluon-Coated Micropipet Tubes in Petri Dishes. Even though

only 3% of assayed PCs were observed to change cups during the course of experiments 5 and 6 of Table 1, we speculated that coating the outside of each micropippet tube with Fluon (polytetrafluoroethylene), a substance to which insect tarsi cannot adhere, might prevent any PCs whatsoever from changing location. Unexpectedly, results showed that PC response was only 38% to apple extract (versus 13% to control) under such assay conditions compared with 68% to apple extract (versus 9% to control) under standard conditions with clean micropipette tubes (Table 2, experiment 5). Observations indicated that oftentimes PCs that had climbed up inside surfaces of tubes to reach open tips were reluctant to crawl down Fluon-coated outside surfaces to reach sources of odor.

Physiological State of PCs. Under standard Petri dish assay conditions, we compared response patterns of PCs in varying physiological states with respect to hunger or age. For PCs deprived of all food for 0, 24, 48, or 72 hr before testing, proportions responding to an intact plum versus a wooden plum model were 38 vs. 40%, 73 vs. 13%, 75 vs. 8% and 35 vs. 0%, respectively (Table 2, experiment 6). For PCs collected in late May (within two weeks of apple tree petal fall), proportions responding to apple extract versus control were 69 vs. 11% on May 31, 64 vs. 6% on July 5 and 47 vs. 14% on July 19 (Table 2, experiment 7). We conclude from these tests that nonstarved PCs do not discriminate between fruit odor and control, that PCs starved for 72 hr are perhaps too weak to respond strongly to fruit odor, and that response to fruit odor begins to fade by two months after apple petal fall, when collected overwintering PCs held under laboratory conitions begin to die in substantial numbers. We further conclude that deprivation of food for 24 hr rather than 48 hr is likely to pose less threat to the long-term survival of collected PCs and is the deprivation period of choice where the intent is maximizing PC response to host odor while preserving the health of PCs for future testing.

Sex of PCs. Using Thomson's (1932) criterion for determining the sex of PCs, we attempted to segregate females from males before testing but were unable to do so effectively without injuring some PCs. We did kill and sex 100 assayed PCs after termination of a test of response to apple extract and found 69 to be females. Among the 69 females, response to apple extract versus control was 70 vs. 10%. Among the 31 males, response was 68 vs. 10%, respectively (Table 2, experiment 8). Thus, females and males appear to respond similarly to host odor.

DISCUSSION

Our findings indicated that about 65% of PCs assayed in a wind tunnel early in the scotophase moved upwind in an airstream flowing at 0.4 m/sec in response to odor of wild plums or hexane extract of wild plums before the

proportion responding reached a plateau. Similarly, about 68% of PCs assayed in still-air Petri dishes early in the scotophase responded positively to such host odor before reaching a plateau. The principal difference between the results of these two bioassay approaches was the degree of PC response to controls, which averaged 34% in the wind tunnel but only 7% in Petri dishes. It should not be surprising that PCs responded to a similar extent to host fruit odor under wind-tunnel and still-air conditions given that PCs appear to use host odor as an informational cue both when locating host trees under windy field conditions (Butkewich and Prokopy, unpublished data) and when locating individual host fruit within a tree under calm conditions (Butkewich and Prokopy, 1993). The lower level of response of PCs to controls in closed Petri dish bioassays than in wind-tunnel bioassays argues in favor of conducting bioassays in still air to maximize PC discrimination.

Petri dishes proved to be convenient still-air test chambers. We estimate it requires about 70 min for one person to set up 100 Petri dishes for assay (each dish containing a test substance, a control substance, and a single PC) and about 40 min to record the data 3 hr later and disassemble the dishes. We do not recommend introducing more than one PC per Petri dish owing to the array of sounds emitted by PCs that could attract, repel, or otherwise affect PCs (Webb et al., 1980).

Use of response indices (Table 2) facilitates comparison among experiments. Response indices were greater for PCs assayed at the beginning of scotophase under dim red light than during photophase or under white light, were no different for assays under dim red light or total darkness, were greater for Petri dishes that were enclosed than for Petri dishes whose bottom was screened and open to incoming air, were no different for Petri dishes in which PCs crawled upward to reach cups than for Petri dishes in which PCs crawled downward to reach cups, were greater for bioassays without Fluon compared to bioassays where Fluon was used, were greater for PCs starved for 24 or 48 hr before testing than for unstarved PCs or PCs starved for 72 hr, were greater for overwintered PCs tested two or seven weeks after petal fall than for PCs tested nine weeks after petal fall, and were no different for females and males.

Laboratory procedures reported recently for bioassaying responses of curculionid adults to host odor or pheromonal stimuli include use of an olfactometer under moving air for assaying palm weevils during photophase (Jaffé et al., 1993) and a variety of olfactometers under still-air, two-choice conditions for assaying palm weevils (Rochat et al., 1991), rice weevils (Phillips et al., 1993), and banana weevils, *Cosmopolites sordidus* (Germar), (Budenberg et al., 1993) during scotophase. Our results support the latter approach as being the most effective for PCs.

Currently, we are attempting to identify the compound(s) in host fruit odor attractive to PCs. Such a compound(s) alone, or in combination with pheromonal

components, might serve as an effective odor stimulus for use in traps for monitoring or possibly even directly controlling PCs.

Abstract—The allelopathic potential of *Ipomoea tricolor*, a plant used in Mexican agriculture to control weeds, and tricolorin A, the major phytogrowth inhibitor present in the so-called "resin glycosides" of this plant, have been evaluated by testing leachates of the plant and the compound on the germination and radicle growth of *Amaranthus hypochondriacus*, *Echinochloa crus-galli*, *Senna uniflora*, *I. tricolor*, and *I. purpurea*. The allelopathic potential of *I. tricolor* was evaluated in a greenhouse experiment with dry *I. tricolor* mixed with sterile and nonsterile soil in pots. *A. hypochondriacus* was sown in pots containing *I. tricolor*, 2-chloro-4-(ethylamino)-6-(isopropylamino)-1,3,5 triazine (Gesaprim) or 1-glyphosphate, and the glyphosphate salt of isopropylamine (Faena), two different commercial herbicides used as a comparison to *I. tricolor*. Number and dry weights of different monocotyledonous and dicotyledonous weeds and *A. hypochondriacus* growing in the different treatments were measured. *Ipomoea* and Faena herbicide had a similar inhibitory effect on monocots.

Key Words—Allelopathy, *Ipomoea tricolor*, Convolvulaceae, tricolorin A, resin glycosides, herbicides.

INTRODUCTION

The phytotoxic effect of plant residues on the growth of crops and weeds is an aspect that has been extensively studied in allelopathy. Extracts of decomposing

*To whom correspondence should be addressed.

field residues of barley, rye, broccoli, broadbean, wheat, rice, vetch, and sudangrass, among other crops and weeds, were found to be toxic to the growth of different test species. The challenge is to find plants and residues that are selectively phytotoxic to weeds and with an adequate safety margin on crops (Chou et al., 1977; Altieri and Doll, 1978; Anaya and del Amo, 1978; Ramos et al., 1983; Anaya et al., 1987, 1988; Einhellig and Leather, 1988).

Ipomoea tricolor Cav. (Convolvulaceae) is extensively used in Mexico in folk medicine and agriculture for many purposes. The seeds, with a high content of ergot-type alkaloids, have been used as a hallucinogenic agent in ritual ceremonies by members of the Zapotec and Chatin Indians in Mexico. Other species of the morning glory family are used traditionally all over the world as powerful cathartics. This purgative action is a consequence of the presence of glycosidic resins in foliar tissues, especially in roots and rhizomes of the species belonging to the Convolvulaceae family (Wagner, 1973). In the tropical zones of Mexico, farmers promote the growth of *I. tricolor*, other species of this genus, and some semidomesticated legumes, e.g., *Stizolobium* spp., to protect the soil and to control the growth of weeds. In the sugar cane fields of the state of Morelos, México, *I. tricolor* is grown extensively as a cover crop, especially from August to October. After this time, the whole plant is cut and incorporated into the soil as a green manure. Bioactivity-directed fractionation of organic extracts of the plant led to the isolation of a mixture of resin glycosides with high phytotoxic effects (Anaya et al., 1990). Tricolorin A, the major phytogrowth inhibitor present in the active fraction of the $CHCl_3$ extract (Figure 1) inhibited the radicle growth of *Amaranthus hypochondriacus* and *Echinochloa*

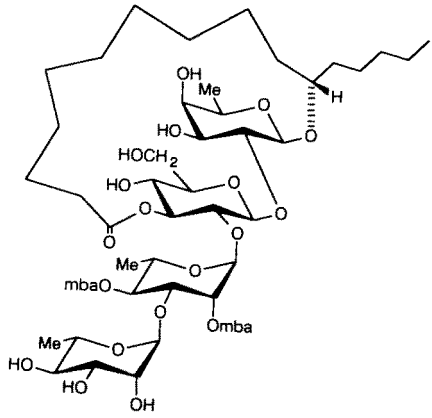

FIG. 1. Structure of tricolorin A (mba, 2-methylbutyroyl).

crusgalli with IC_{50} values ranging from 12 to 37 μM. This bioactive glycolipid displayed a broad range of activities, including antimicrobial and cytotoxic effects and inhibition of protein kinase C activity (Pereda-Miranda et al., 1993).

An objective of the present study was to compare the phytotoxicity of *I. tricolor* leachates and tricolorin A in vitro with that of two commercial herbicides on the germination and growth of *A. hypochondriacus* (Amaranthaceae) and *E. crusgalli* (Poaceae). A second objective was to compare the effect of dry *I. tricolor* incorporated into the soil (sterile and nonsterile) in pots with that of two commercial herbicides on the number and growth of weeds, and the growth of *A. hypochondriacus* (Amaranthaceae).

METHODS AND MATERIALS

Whole plants of *I. tricolor* were collected in Cañón de Lobos, Morelos, México, in March 1993. The plant material was air dried and crushed by hand.

Comparative Bioassays for Phytotoxicity. A bioassay was performed to determine the phytogrowth inhibitory effect of the leachate (2%) of *I. tricolor* mixed (50:50) with 1.5% pure agar. Osmotic pressure was checked to prevent the use of a highly concentrated leachate. Tricolorin A, and two commercial herbicides, 2-chloro-4-(ethylamino)-6-(isopropylamino)-1,3,5 triazine (Gesaprim, Ciba-Geigy), and 1-glyphosate and the glyphosate salt of isopropylamine (Faena, Monsanto) in concentrations of 10, 50, 100, 150, and 200 μg/ml were tested. Phytogrowth inhibitory activity was determined by seed germination and radicle growth tests on *A. hypochondriacus*, *E. crusgalli* (Poaceae), *Senna uniflora* (Fabaceae), *I. tricolor*, and *I. purpurea*. Distilled water plus methanol (9.9:0.1) mixed with 1.5% agar (50:50) was used as control.

The bioassay was performed in Petri dishes (10 seeds per dish for *A. hypochondriacus*, *E. crusgalli*, *I. tricolor*, and *I purpurea*, and eight seeds for *Senna uniflora*) with four repetitions per treatment in a complete block design. Petri dishes were incubated in darkness at 27°C. Percent germination and radicle growth were obtained after 24 hr for *A. hypochondriacus* and 48 hr for the rest of the test species. Data were analyzed by an ANOVA and Tukey's test.

Greenhouse Experiment. Soil for pots was collected in a crop field recently tilled from a farming community where *I. tricolor* is used as a cover crop for weed control, in the locality of Yautepec, near Cañón Lobos, Morelos, in July 1993. The soil was passed through a 2-mm sieve and divided in two parts. One part was sterilized before the addition of treatments. The experiment was performed in a complete random block design with four blocks. Each block contained 16 representative pots for a total of 64 pots. The pots contained 3 kg of soil and were rotated every three weeks to ensure uniform sunlight. The following treatments were used.

Abbreviations	Treatments
1VS	Sterile soil + 2.5% of vermiculite (control 1)
2VS	Sterile soil + 5% of vermiculite (control 2)
1VNS	Nonsterile soil + 2.5% of vermiculite (control 3)
2VNS	Nonsterile soil + 5% of vermiculite (control 4)
1IS	Sterile soil + 2.5% of *I. tricolor* (dried and milled)
2IS	Sterile soil + 5% of *I. tricolor* (dried and milled)
1INS	Nonsterile soil + 2.5% of *I. tricolor* (dried and milled)
2INS	Nonsterile soil + 5% of *I. tricolor* (dried and milled)
1GS	Sterile soil + 2.5% of vermiculite + 0.4% of Gesaprim
2GS	Sterile soil + 5% of vermiculite + 0.8% of Gesaprim
1GNS	Nonsterile soil + 2.5% of vermiculite + 0.4% of Gesaprim
2GNS	Nonsterile soil + 5% of vermiculite + 0.8% of Gesaprim
1FS	Sterile soil + 2.5% of vermiculite + 0.4% of Faena
2FS	Sterile soil + 5% of vermiculite + 0.8% of Faena
1FNS	Nonsterile soil + 2.5% vermiculite + 0.4% of Faena
2FNS	Nonsterile soil + 5% of vermiculite + 0.8% of Faena

Gesaprim is a 1,3,5-triazine herbicide with a selective pre- and postemergent action used to control annual weeds. Faena is a phosphonic acid product, a glyphosate that acts as a nonselective, nonresidual postemergent herbicide (Worthing, 1991; Draber and Fujita, 1992). The tested concentrations of herbicides were designed to be similar and higher than the mean content of Tricolorin A in *Ipomoea tricolor* (Pereda-Miranda et al., 1993).

Five seeds of *A. hypochondriacus* were sown in each pot. After two weeks, pots were thinned to one seedling of *A. hypochondriacus*. Five seeds of *E. crusgalli* and *S. uniflora* were sown in each pot that contained sterile soil. Number of monocotyledonous and dicotyledonous weeds in the nonsterile soil treatments was recorded five times during the experiment. Numbers of *E. crusgalli* and *S. uniflora* were recorded in the sterile soil treatments. The number of *I. tricolor* seedlings in the four treatments that contained this plant incorporated into the soil (sterile and nonsterile) was recorded four times during the experiment. Pots were watered when necessary. Basins were placed underneath each pot in order to collect drainage water, which was refrigerated for further bioassays and chromatographic analysis. After 45 days the experiment was completed. Plants were removed and separated into monocot and dicot weeds and *A. hypochondriacus*. Plants were dried and weighed. Data were analyzed by an ANOVA, contrasts, and Tukey studentized range tests (Méndez et al., 1992).

Bioassays with Drainage Water from Pots. A bioassay was performed to determine the effects of the drainage water from pots containing each of the treatments in the greenhouse experiment. In this bioassay, the drainage water

of the pot with the 2.5% proportion was mixed with that of the pot with 5% proportion of each treatment to make only eight treatments. These drainage waters were tested on germination and radicle growth of *A. hypochondriacus* and *E. crusgalli*. Bioassay was performed in a complete block design with four repetitions in Petri dishes with Whatman filter paper (No. 42), 10 seeds per treatment. Petri dishes were placed under the same conditions as the comparative phytotoxicity bioassay. Data were analyzed by ANOVA and Tukey's test.

Soil Analysis. Soil samples before and after the greenhouse experiment were analyzed at the Center of Ecology at UNAM in order to measure physical and chemical properties.

RESULTS AND DISCUSSION

Comparative Bioassays for Phytotoxicity

Results of the bioassays in Petri dishes testing aqueous leachates of *I. tricolor*, tricolorin A, and the two herbicides, Gesaprim and Faena, on the germination of *A. hypochondriacus*, *E. crusgalli*, *Senna uniflora*, *Ipomoea tricolor*, and *I. purpurea* are shown in Table 1. Aqueous leachates of the plant significantly inhibited germination of *E. crusgalli* and *I. tricolor*. Tricolorin A was the only treatment that strongly inhibited germination of *A. hypochondriacus*, and to a lesser extent, *E. crusgalli*. Tricolorin A slightly inhibited *I. tricolor* and *I. purpurea* germination, as all other treatments had no effect, on *S. uniflora*, a species that coexists with *I. tricolor* in the same habitat. Both herbicides slightly inhibited germination of *A. hypochondriacus* and *E. crusgalli*. Germination of *I. tricolor* was significantly inhibited by tricolorin A (100–200 μg/ml) and Faena herbicide. Germination of *I. purpurea* was slightly affected by tricolorin A and Faena.

Results of the bioassays in Petri dishes, which tested the same treatments on the radicle growth of test species, are shown in Table 2. Leachate of *I. tricolor* strongly inhibited the radicle growth of *A. hypochondriacus* and had a slight effect on *E. crusgalli* and *S. uniflora*, but it showed no effect on the radicle growth of the two *Ipomoea* species tested. Tricolorin A displayed a strong inhibitory effect on radicle growth of *A. hypochondriacus* and *E. crusgalli*. However, this bioactive compound had no effect on *S. uniflora*. Tricolorin A significantly inhibited radicle growth of *I. tricolor* at 150 and 200 μg/ml. This inhibitory effect was stronger on *I. purpurea*. The effect of the two herbicides tested in Petri dishes was different to that in the soil. Gesaprim significantly inhibited (34%) the radicle growth of *A. hypochondriacus* at 150 and 200 μg/ml. It stimulated *A. hypochondriacus* at 10 μg/ml, and had no effect on *E. crusgalli* and *S. uniflora*. Gesaprim caused a significant stimulation of radicle

TABLE 1. EFFECTS OF AQUEOUS LEACHATE AND TRICOLORIN A OF *Ipomoea tricolor* AND GESAPRIM AND FAENA HERBICIDES ON GERMINATION OF FIVE SPECIES

Treatments	Germination (%)				
	Amaranthus hypochondriacus	*Echinochloa crusgalli*	*Senna uniflora*	*Ipomoea tricolor*	*Ipomoea purpurea*

[a]Differences statistically significant ($P < 0.05$) with respect to control using a HSD Tukey's test.

growth of the two *Ipomoea* species tested. Faena had an inhibitory effect on radicle growth of *E. crusgalli*, *S. uniflora*, *I. tricolor*, and *I. purpurea* starting at 10–50 μg/ml. This herbicide did not affect the growth of *A. hypochondriacus*.

Greenhouse Experiment

Number of Seedlings of I. tricolor in Pots. The dry *I. tricolor* that was mixed with sterile and nonsterile soil (1IS, 2IS, 1INS, 2INS), contained some seeds of the species that went unnoticed until they germinated in the pots. The number of seedlings that emerged in these four treatments was recorded four times during the experiment and then was completely eliminated to avoid its competitive effect on the other plants. The split-plot ANOVA made with the logarithms of the number of these seedlings in the four dates recorded showed a significant effect for the interaction date–treatment.

[b]Number in parentheses indicates stimulation.

The analysis of interaction of treatments by dates on number of seedlings of *Ipomoea* is shown in Figure 2. There was a significant difference in the number of seedlings of *I. tricolor* in sterile (1IS and 2IS) and nonsterile (1INS and 2INS) treatments, particularly in the first date. There was a significant difference between 1INS treatment (prepared with the low proportion of *I. tricolor* added to soil) and the other three treatments in the second, third, and fourth measurements. Probably, in nonsterile soil, microorganisms quickly attack the seed population of *I. tricolor*, diminishing the possibility of germination and survival. Absence of microorganisms in sterile soil may have favored the integrity of *Ipomoea* seeds and their probability of survival and germination. With time, conditions of soil sterility were lost, and the number of germinated seeds came to be similar in all treatments, except in the 1INS. It is possible that in natural conditions, *I. tricolor* inhibits germination and growth of its own seeds.

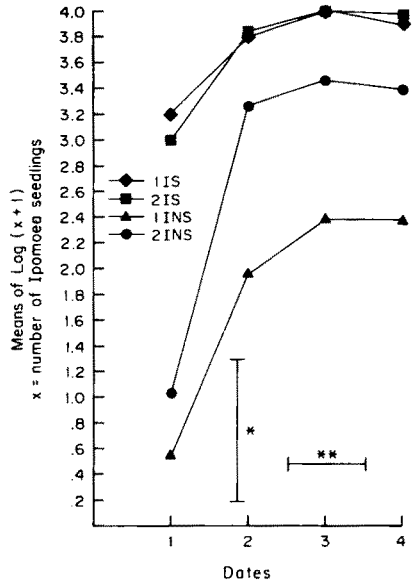

FIG. 2 Study of the interaction treatments by dates on number of seedlings of *Ipomoea* (all experimental data). *HSD for comparing treatments; **HSD for comparing dates.

The phytotoxic activity of the leachates and/or residues could be an autocontrol mechanism of the population. These seeds are rich in alkaloids and other important secondary metabolites, including resin glycosides, so it is also important to explore the ecological role that these compounds play in the establishment of biotic interactions, especially with predators and microorganisms.

Effects of Treatments on Number of Echinochloa *(Monocot) and* Senna *(Dicot) Plants in Sterile Soil.* The number of plants for each pot was recorded five times during the experiment. ANOVA showed that there was a significant difference among treatments. For both plant types, it is also possible to observe a significant effect for the interaction treatments–dates.

Tukey's studentized range test for the means of the logarithm of number of *Echinochloa* (monocot) plants in sterile soil (Table 3) shows that the number of plants is higher in control 2VS compared with the other treatments. There was no difference among IVS, 1IS, 2IS, and 2FS. These four treatments were different from 1FS, 1GS, and 2GS. These last two treatments were statistically different from each other and from 1IFS. The number of *Echinochloa* was significantly diminished by both Gesaprim treatments and treatment with Faena in low concentration (1FS).

TABLE 3. TUKEY'S STUDENTIZED RANGE TEST FOR LOGARITHM OF NUMBER OF *Echinochloa* (MONOCOT) AND *Senna* (DICOT) PLANTS IN STERILE SOIL[a]

Echinochloa (monocot)		*Senna* (dicot)	
Treatment	Mean	Treatment	Mean
2VS	1.40 ± 0.61 a	2VS	1.56 ± 0.38 A
2FS	1.30 ± 0.75 ab	2FS	1.40 ± 0.34 A
1VS	1.28 ± 0.73 ab	2IS	1.35 ± 0.48 AB
2IS	1.25 ± 0.72 ab	1VS	1.33 ± 0.75 AB
1IS	1.21 ± 0.71 ab	1IS	1.31 ± 0.19 AB
1FS	1.08 ± 0.73 bc	1FS	1.02 ± 0.32 BC
2GS	0.87 ± 0.74 cd	2GS	0.70 ± 0.78 DC
1GS	0.66 ± 0.64 d	1GS	0.35 ± 0.40 D

[a]Numbers with different letters are significantly different ($p < 0.05$).

The number of *Senna* (dicot) (Table 3) was the same in the control 2VS and Faena in high concentration (2FS). The control 1VS and the treatments 1IS and 2IS are not different from each other. The other treatments (1FS, 2GS, and 1GS) were significantly different. In fact, the number of *Senna* plants was significantly diminished by the two treatments with Gesaprim and Faena in low concentration. *Ipomoea* treatments affected the number of *Senna* only when compared with 2VS control and Faena in high concentration. The effect of Faena was unexpected when the results of the low and high concentrations were compared. The number of *Senna* and *Echinochloa* seedlings was affected only by the low concentration of Faena.

The analysis of interaction of treatments by dates on number of *Echinochloa* (monocot) plants in sterile soil is shown in Figure 3. Faena at low concentration (1FS) had the lowest number of seedlings at the second and third dates. There was a significant difference between both Gesaprim treatments and the other treatments at the fourth and fifth dates.

The analysis of interaction of treatments by dates on number of *Senna* (dicot) plants in sterile soil is shown in Figure 4. Regarding differences among treatments, Gesaprim and Faena at low concentration had low numbers of *Senna* plants at the third and fourth dates. At these same dates, control 2VS had the higher number of plants. Both concentrations of Gesaprim (1GS and 2GS) were significantly different from the other treatments in the fourth and fifth dates. Gesaprim and Faena at low concentration (1GS and 1FS) had a stronger effect on the number of *Echinochloa* and *Senna* plants compared with the high concentration (2GS and 2FS).

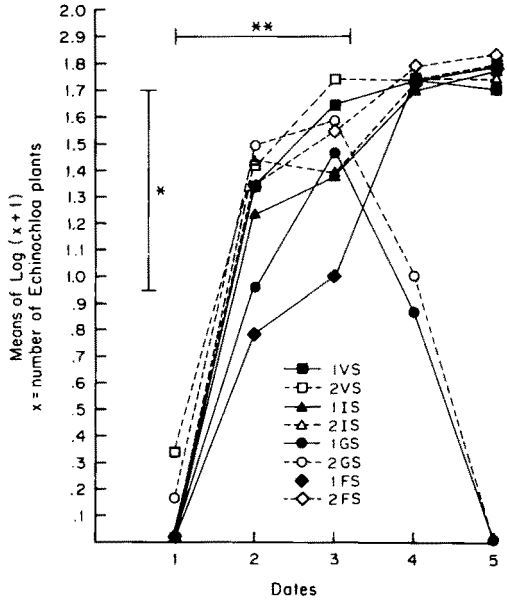

FIG. 3 Study of the interaction treatments by dates on number of *Echnochloa* plants (only data for sterile soil). *HSD for comparing treatments; **HSD for comparing dates.

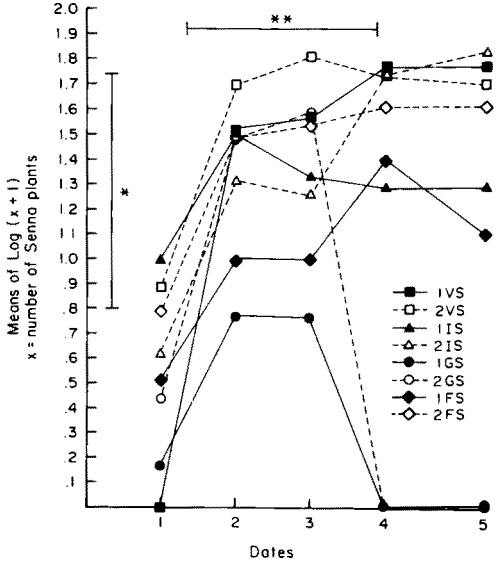

FIG. 4 Study of the interaction treatments by dates on number of *Senna* plants (only data for sterile soil). *HSD for comparing treatments; **HSD for comparing dates.

TABLE 4. TUKEY'S STUDENTIZED RANGE TEST FOR LOGARITHM OF NUMBER OF MONOCOTYLEDONOUS AND DICOTYLEDONOUS PLANTS IN NONSTERILE SOIL[a]

Monocotyledonous plants		Dicotyledonous plants	
Treatment	Mean	Treatment	Mean
2VNS	1.09 ± 0.42 a	1VNS	2.26 ± 0.23 A
1VNS	1.09 ± 0.40 a	2VNS	2.24 ± 0.12 A
1FNS	0.97 ± 0.64 a	1FNS	1.53 ± 0.33 B
1INS	0.73 ± 0.49 ab	1INS	1.41 ± 0.27 B
2INS	0.52 ± 0.41 bc	2INS	1.24 ± 0.34 B
2FNS	0.37 ± 0.23 bcd	2FNS	0.81 ± 0.26 C
2GNS	0.10 ± 0.23 cd	1GNS	0.55 ± 0.69 C
1GNS	0.07 ± 0.15 d	2GNS	0.54 ± 0.68 C

[a]Numbers with different letters are significantly different ($p < 0.05$).

Effects of Treatments on Number of Monocotyledonous and Dicotyledonous Plants in Nonsterile Soils. The split-plot ANOVA with the logarithms of the number of monocotyledonous and dicotyledonous plants in nonsterile soils showed that there was a significant difference between treatments. In the case of the number of dicotyledonous plants, there was a significant effect for the interaction treatments–dates. Tukey's studentized range test for the logarithm of the number of monocots in nonsterile soil (Table 4) showed that the two controls (1VNS, 2VNS) and 1FNS are not different. The rest of the treatments were different from each other. The number of monocots was significantly diminished by *Ipomoea* and Faena in high concentration; this effect was stronger with Gesaprim in both concentrations. In relation to the number of dicots, it was observed that treatments 1FNS, 1INS, and 2INS were significantly different from the controls. Treatments 2FNS, 1GNS, and 2GNS had a strong phytotoxicity on the number of dicots.

The analysis of interaction of treatments by dates on the number of monocotyledonous plants in nonsterile soil is shown in Figure 5. The two controls maintained the higher number of monocots from the beginning of the experiment. At the fourth and fifth dates, this is true also for Faena at low concentration. The two treatments with *Ipomoea* had a low number of monocots from the first to the fourth dates. Both treatments with Gesaprim differed from the other treatments from the third date to the final date. Faena at high concentration was significantly different from Faena at low concentration. It is possible to see that the effect of *Ipomoea* treatments is stronger compared with Faena at low concentration.

The analysis of interaction of treatments by dates on the number of dico-

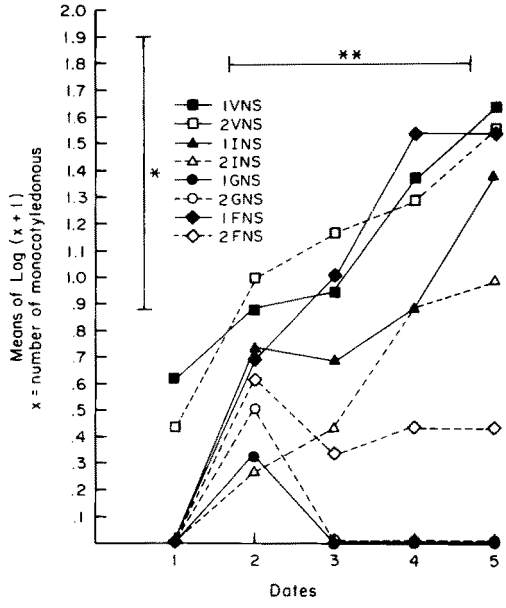

FIG. 5 Study of the interaction treatments by dates on number of monocotyledonous (only data for non-sterile soil). *HSD for comparing treatments; **HSD for comparing dates.

tyledonous plants in nonsterile soil is shown in Figure 6. Both controls had the higher number of dicots at the five dates recorded. At the first date both *Ipomoea* treatments and Gesaprim at the low concentration had the lower numbers of dicots. *Ipomoea* treatments and Faena at low concentration showed a similar effect on the number of dicots from the second date to the fifth date. From the third date to the end of the experiment, 2FNS and both Gesaprim concentrations had a strong phytotoxic effect on dicots.

Gesaprim herbicide eliminated all plants in the pots at the two concentrations used at the end of the experiment. The effect of Gesaprim on growth of plants in sterile and nonsterile soil was opposite to its effect in Petri dishes. In general, Gesaprim did not affect germination and growth of the test species in Petri dishes bioassays. Undoubtedly, the mediator role of the soil is a fundamental factor for the phytotoxic expression of this herbicide. On the other hand, Faena did not affect germination and growth of *Amaranthus* in vitro, nor the germination of *Senna*, but it inhibited significantly the radicle growth of *Echinochloa*, *Senna*, *Ipomoea tricolor*, and *I. purpurea* seedlings in these Petri dish bioassays.

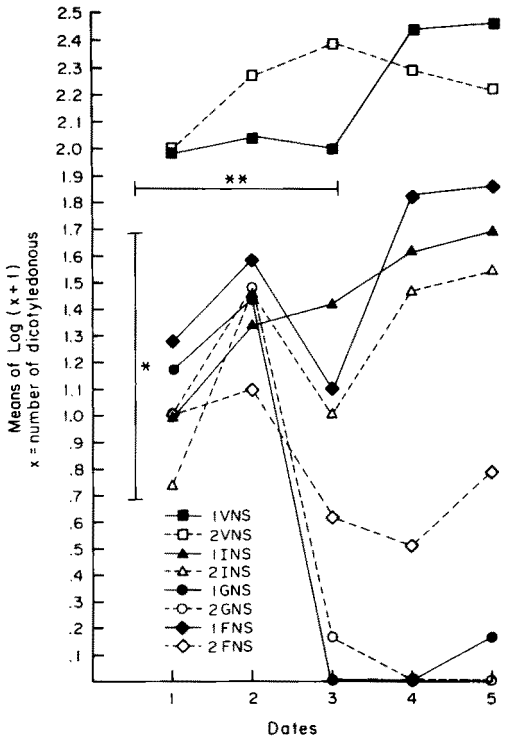

FIG. 6 Study of the interaction treatments by dates on number of dicotyledonous (only data for non-sterile soil). *HSD for comparing treatments; **HSD for comparing dates.

Effects on Echinochloa *and* Senna *Biomass in Sterile Soils and Monocot and Dicot in Nonsterile Soils.* Biomass, expressed as dry weight, was evaluated at the end of the experiment. Mean weights of *Echinochloa* (monocot) and *Senna* (dicot) in sterile soil, and monocots and dicots in nonsterile soil are shown in Table 5. Gesaprim eliminated all the plants at the two concentrations tested in sterile and nonsterile soils. In relation with sterile soil, the significant difference between treatments is focused on the effect of *Ipomoea* mixed in the soil and on biomass of *Echinochloa*. In relation with nonsterile soils, there was no significant difference in the biomass of monocots and dicots in the control, *Ipomoea*, and Faena treatments. On the other hand, there were no significant differences in the biomass of *Aviaranthus hypochondriacus* among all the treatments (data not shown).

Results of Bioassay with Drainage Water from Pots

The results from this bioassay are shown in Table 6. Effects of the drainage water from sterile and nonsterile soil treatments on radicle growth of *A. hypochondriacus* and *E. crusgalli* were different. It is possible to see that there was a specific response of each species to the treatments. ANOVA and Tukey's test showed that significant effects, particularly stimulations, were produced only by drainage water from nonsterile soils. The water from pots with *I. tricolor* produced a significant stimulation of radicle growth of *A. hypochondriacus*. Drainage water from Faena treatments significantly inhibited the growth of this species.

TABLE 6. EFFECTS OF THE LEACHATES FROM THE POTS ON THE RADICLE GROWTH OF *Amaranthus hypochondriacus* AND *Echinochloa crusgalli*.

Treatment	Inhibition (%)	
	Amaranthus hypochondriacus	*Echinochloa crusgalli*
Sterile soil

VNS	0	0
INS	(24)[a]	(54)[a]
GNS	9	(47)[a]
FNS	44[a]	(36)

[a]Differences statistically significant ($P < 0.05$) with respect to control using a HSD Tukey's test. Numbers in parentheses are stimulations.

On the other hand, *E. crusgalli* was significantly stimulated by water from pots with *I. tricolor*, Gesaprim, and Faena. Neither of the phytotoxic agents from the different treatments, except that from Faena, was leached out by the drainage waters. If we compare the results of the bioassays in Petri dishes (Table 2) with these of the drainage waters bioassays (Table 6), we can observe the essential effect of the soil on the expression of phytotoxicity and allelopathy. In relation to this, the effectiveness of a soil-applied herbicide depends on its adsorption in the soil. Organic matter is the predominant adsorbing component in it, so the amount of organic matter in the soil is a determining factor (Johnston, 1986; Rowell, 1994). The selectivity of triazines, for instance, results from their low solubility in water and their high colloidal absorption grade in the soil, so they have relatively long-term activity in the soil. This could explain the strong phytotoxicity of Gesaprim in the soil of the experiment that was rich in organic matter (Gerber et al., 1970; Addiscot and Wagenet, 1985).

Table 7 shows some physical and chemical properties of soil before and after the experiment. In general, conditions of the soil before and after the experiment change slightly. Before the experiment, sterilization of the soil increased total nitrogen and total phosphorus. After the experiment, the pH tended to be neutral. The soil was not saline, but *Ipomoea* and Gesaprim caused a small increase in the electrical conductivity of it. Organic matter is higher in sterile and nonsterile soil with *Ipomoea* and in soil of the nonsterile control and

[a]Before the experiment: SSBE, sterile soil; NSSBE, nonsterile soil. After the experiment: VS, soil of the sterile control; VNS, soil of the nonsterile control; IS, sterile soil with *Ipomoea*; INS, nonsterile soil with *Ipomoea*; GS, sterile soil with Gesaprim; GNS, nonsterile soil with Gesaprim; FS, sterile soil with Faena; FNS, nonsterile soil with Faena.

nonsterile soil with Faena. Potassium was increased in *Ipomoea* treatments and in nonsterile soil with Gesaprim. Nitrogen was increased in sterile soil before the experiment and in both treatments with *Ipomoea*. Phosphorus is higher in almost all the sterile soils compared with the nonsterile ones.

In the greenhouse experiment, the biomass of *Echinochloa crusgalli* (sterile soil) was significantly diminished by the incorporation of *I. tricolor* into the soil, and also, the number of monocots and dicots in nonsterile soil. In fact, the number of monocots and dicots tended to diminish starting from the third date recorded in the greenhouse experiment in both *Ipomoea* treatments. It is possible to see that this tendency is stronger comparing these two treatments with Faena at low concentration. In the field, it is possible that the weed control effect of *Ipomoea tricolor* takes place in two stages, first, by the combination of the allelopathic potential of the living plant expressed through rain leachate and competition (interference); and second, when the plant is cut and incorporated into the soil. Decomposition of its residues acts as the second weed control factor before the sowing of sugar cane, corn, or other crops.

(Received August 1, 1994; accepted March 15, 1995)

Abstract—*Holcus lanatus*, a temperate grass, was found to contain low but measurable concentrations of condensed tannins (CT), according to the vanillin-HCl and the butanol-HCl methods. The variation in CT concentrations between different types of tissue including leaf age and reproductive versus nonreproductive tissue was examined. There was no evidence that floral tissue contained more CT than nonreproductive tissue. A sequential extraction and analysis procedure showed a decreasing proportion of free-unbound CT and greater preponderance of protein-bound and fiber-bound CT with increasing leaf age and in dead matter. Samples collected from an agricultural pasture on two sampling dates, January 24 and March 5, 1993, showed short-term temporal variation in free-unbound CT.

Key Words—Condensed tannin, *Holcus lanatus*, flowering, vegetative, seasonal variation.

INTRODUCTION

Despite having no known role in primary metabolism, evidence has accumulated that plant secondary metabolites may have adaptive value in the ecological interactions of the plant, often providing effective defense against herbivores or pathogens (Zucker, 1983; Rhoades and Cates, 1976). Current theories of plant

chemical defense predict that tissues of greatest value should be most heavily defended (Rhoades, 1979). In fitness terms, the influorescences are among the most valuable of plant tissues, representing a large investment of resources in reproduction. Flower pigments of plants, whose role is usually considered to be attraction of pollinators, often contain phenolic compounds (Harborne, 1988). This factor can confound comparisons of the extent to which flowering tissue versus vegetative tissue is chemically defended by phenolics. Although condensed tannins (CT) are generally considered to be absent from temperate or high-latitude grasses (Jung et al., 1979; Bernays et al., 1989), Yorkshire fog (*Holcus lanatus* L.) is reported to contain small but measurable amounts (Terrill et al., 1992; Douglas et al., 1994). Since grasses are wind pollinated, this permits comparison of concentration of CT in flowering and vegetative tissue, without confounding the possible defensive functions of phenolics in influorescences with the insect attractant function.

Although there is much information on the variation in concentration of phenolic compound in woody plants, both temporally and between plant parts (Feeny, 1970; Palo et al., 1985; Iason et al., 1993), little is known about the distribution of tannins in grasses. The development of techniques to quantify the amounts of free-unbound, versus protein- and fiber-bound CT in plants (Terrill et al., 1992) permits examination of these different forms of CT and enhanced interpretation of their ecological roles. In this study, wild *H. lanatus* and a cultivar, *H. lanatus* (cv. Massey Basyn), were used to address the following specific aims: (1) to investigate variation in the concentrations of free-unbound, protein-bound, and fiber-bound CT between different leaf ages and between vegetative and reproductive parts of *H. lanatus*; and (2) to examine the variation in CT concentration of vegetative shoots of *Holcus lanatus* cv. Massey Basyn, between two different sampling dates in the growing season, independently of flowering.

METHODS AND MATERIALS

Vegetation Sampling. Differences in chemical composition between vegetative and reproductive tissues of *H. lanatus* were compared using samples collected on February 28, 1993, from separate sites, 40 m apart along an unmown roadside verge at Aokautere, 10 km NW of Massey University, Palmerston North, New Zealand. Each sampling site was at least 2 m from the road edge, well drained, and consisted of at least 70% ground cover of *H. lanatus*. The *H. lanatus* plants were dissected into flowering stems, inflorescences, live vegetative stems, dead leaf, and live leaves 1, 2, and 3. Leaf 1 was defined as the youngest leaf that had emerged from the sheath by at least 1 cm. Leaves 2 and 3 were the two next oldest leaves, respectively.

In order to examine temporal variation in the tannin concentration of the vegetative tissue of *H. lanatus*, two sets of herbage samples were collected from a quadrat placed at random in each of four 0.2-ha plots of *H. Lanatus* cv. Massey Basyn, on January 24, 1993 and six weeks later on March 5, 1993. The plots were at Massey University, New Zealand, and were each grazed continuously by weaned lambs to a target sward height of 5 cm from December 1992 until after the second sampling date, as part of a larger study of the nutritive value of *H. lanatus* for sheep. These samples were harvested at ground level and aerial tissue above the highest node with adventitious roots was separated into live leaf, dead leaf, and live stem.

Material was stored in sealed bags at 4°C for a maximum of three days after harvesting while being dissected. Only about 30 g was dissected at any time to prevent air drying during this process. All sorted samples were stored at −20°C prior to freeze drying and subsequent milling to pass a 1 mm sieve.

Chemical Analyses. CT were measured using the sequential extraction procedure described by Terrill et al. (1992) in which the CT present in each of the free-unbound, protein-bound, and fiber-bound forms were determined using the butanol–HCl procedure (the proanthocyanidin assay) of Porter et al. (1986). Free-unbound CT was extracted with aqueous acetone and diethyl ether and partitioned into the aqueous phase to exclude chlorophyll. Subsequent extraction with boiling sodium dodecyl sulfate (SDS)/mercaptoethanol solution yielded protein-bound tannin. The residue from this extraction was boiled with SDS and butanol–HCl reagent to yield fiber-bound CT. Additionally, the free-unbound tannin fraction was analyzed for CT by the vanillin–HCl assay (Broadhurst and Jones, 1978). Vanillin reacts with end-flavanoid units only, whereas in the butanol–HCl procedure CT is depolymerized and anthocyanidin color pigment can be formed from any flavonoid unit in the CT (Hagerman and Butler, 1989). Results are expressed as proportions of dry matter relative to a standard of purified CT, extracted from *Lotus pedunculatus*, which was made up in either water (free-unbound CT) or SDS solution (protein- and fiber-bound CT).

Holcus lanatus is known to contain low concentrations of anthocyanin pigments (Beddows, 1961), which can cause some color development in assays for CT (Watterson and Butler, 1983). Consequently, for each fraction of each sample, a sample blank was prepared by either replacing the HCl in the reagent with the same volume of water (butanol–HCl assay), or replacing the vanillin/methanol with methanol only (vanillin assay). These blanks were otherwise treated in exactly the same way as the sample. Any color development was subtracted from that of the normally assayed sample.

Samples were also analyzed for total nitrogen, using a Kjeldahl technique. Due to a shortage of material, samples of each type of tissue were pooled across plots or sites prior to analysis for neutral detergent fiber (NDF) according to the system of Van Soest and Wine (1967).

Statistical Analyses. Statistical comparisons of chemical composition were made using Genstat 5 (1987). One-way analysis of variance was used to compare between plant tissues or leaf ages, and when data were available on different harvest dates, a two-way analysis of variance was used entering plant tissue and date as factors. Data were blocked within plots for *H. lanatus* on the grazed pasture or within sampling sites for wild *H. lanatus*. The protected least significant difference (LSD) method was used to make comparisons between individual classes where overall F tests showed significant heterogeneity (Snedecor and Cochran, 1980).

RESULTS

Changes in Composition with Age of Leaf. There were significant differences in concentration of free-unbound, protein-bound, fiber-found, and total CT between different types of shoot tissue as measured by the butanol–HCl assay ($P < 0.01$, Table 1). Although leaves 1–3 did not contain significantly different concentrations of total CT, there was a significantly higher concentration of CT in dead versus living leaf. There was a gradual decrease of free-unbound CT with leaf age, as shown by both the vanillin–HCl and the butanol–HCl assays (Table 1). Free-unbound CT formed 55% of total CT in leaf 1 but only 9% of total CT in dead leaf tissue. Although there were no significant differences, both protein-bound and fiber-bound CT tended to increase with leaf age. Protein-bound and fiber-bound CT were significantly ($P < 0.05$) higher in dead than living leaf material (Table 1). As a percentage of total CT, protein-bound CT represented 45% in leaf 1, 54% in leaf 2, 62% in leaf 3, and 69% in dead leaf. The corresponding percentages of the total CT formed by fiber-bound CT were 0%, 3%, 6%, and 22%. Total nitrogen concentration declined with leaf age. It was significantly lower in leaf 3 than leaves 1 and 2 ($P < 0.05$) and declined markedly in the dead leaf matter (Table 1). Although no statistical comparisons were possible, there was no indication that cell wall content (NDF) changed progressively with leaf age, although dead leaf material contained a higher concentration than living leaf (Table 1).

Analysis of the samples collected on different dates from the grazed pasture confirmed the overall pattern of decrease in total nitrogen and increase in CT and NDF as a proportion of dry matter with leaf senescence. The shift in the form of the CT from free-unbound to the protein- and fiber-bound forms with leaf senescence was also confirmed (Table 2).

Reproductive versus Nonreproductive Tissue. The concentration of fiber-bound CT was higher in flowers than in leaf 1, and the concentration of free-unbound CT was lower in flowers than leaves 1 or 2 according to the butanol–HCl assay ($P < 0.05$, Table 1) and lower than leaf 1 according to the vanillin assay. There was no significant difference in the concentration of total CT

between flowers and live leaf tissue (Table 1). In general, stem tissue contained lower levels of total CT than other types of tissue (Table 1), and the reproductive stem contained lower concentrations of total CT measured by butanol–HCl than vegetative stem.

Total nitrogen concentrations in the samples of flowers were significantly lower than in leaves ($P < 0.05$) and NDF was greater in flowers and reproductive stems than in vegetative parts (Table 1).

Chronological Differences. Total CT concentration did not differ between sampling dates (Table 2), although free-unbound CT was lower in March than in January ($P < 0.01$) and the ratio of vanillin–HCl/butanol–HCl for free-unbound CT was higher in March ($P < 0.05$). Total nitrogen was lower on the earlier sampling date ($P < 0.05$) but only in the live leaf tissue (Table 2).

DISCUSSION

Although other phenolics are present (Morrison, 1974; Mole and Joern, 1993), grasses are generally reported to contain no CT (Rhoades and Cates,

1976; Jung et al., 1979). Rather than defending themselves against herbivory with carbon-based secondary metabolites, they usually respond to defoliation by herbivores with rapid regrowth (Bryant et al., 1983; McNaughton, 1983). Wild *H. lanatus* grows under a wide range of nutrient and ecological conditions (Watt, 1978), and in agricultural pastures it has the potential for rapid regrowth after grazing that is typical of grasses (Haggar, 1976). However, low concentrations of CT in *H. lanatus* has been confirmed in the present study, using two analytical methods working on different principles (vanillin–HCl and butanol–HCl).

The overall higher concentrations of total CT with leaf age, particularly in senescent leaves, are due partly to a concentrating effect as soluble and mobile constituents are withdrawn from the leaf prior to abcission. Insoluble, nonmobile constituents such as CT (Rhoades and Cates, 1976) and cell-wall polymers, measured here as NDF, are hence increased relative to dry matter. The pattern of change of free-unbound, protein-bound, and fiber-bound tannin with leaf age suggests that the greater proportion of fiber-bound CT, and to a lesser extent of protein-bound CT in older and dead leaf material, is due to progressive complexation of free-unbound CT. This greater binding of CT to cell wall in senescing leaves may inhibit microbial degradation (Swain, 1979), leading to slow rates of decomposition and the accumulation of litter in *Holcus*-dominated grasslands (Watt, 1976).

Condensed tannin concentrations may increase (Feeney, 1970; Mauffette and Oechel, 1989) or decrease (Baldwin et al., 1987) with age of leaf in trees. Most studies only measure free-unbound tannin, and in *H. lanatus* this form of tannin declined with leaf age, although total CT did not change consistently. As well as reflecting greater binding of tannins with increasing leaf age, the decrease in free-unbound CT is probably also associated with a decrease in the production of CT in the older leaves. These leaves are lower in the canopy and receive less incident light, an environmental factor that has been shown consistently to lead to strong reductions in phenolic levels (Waterman and Mole, 1989; Nichols-Orians, 1991; Iason and Hester, 1993). Because of the rapid leaf turnover in grasses throughout the season of growth, a sustained trend of increasing or decreasing concentration of CT in the live tissue would not be expected except as a result of changes in the proportions of young leaf. Indeed, differences in free-unbound CT between the two dates sampled in the grazed pasture are low in comparison to the differences between tissues and leaf ages. Temporal effects may also result from variation in climatic conditions causing short-term changes in growth or photosynthetic rate. The total CT concentration in flowering tissue did not differ significantly from that in live leaf tissue of any age (Table 1), and the observed differences in the form of the CT are consistent with the greater maturity of the inflorescences relative to the young leaf ages.

In those environments where tannin levels are high and plant nutrients and protein levels are low, tannins may cause avoidance by herbivores (Mole and

Waterman, 1987) and are considered to inhibit forage digestion by complexing with plant proteins and digestive enzymes (Robbins et al., 1987). In contrast, nutrient levels and net primary production of plants in some natural communities and most intensively managed agricultural systems are higher than in less intensively managed communities. In these nutrient-rich grazing systems, low levels of CT in forages are thought to be of benefit to grazing ruminants, enhancing animal performance by complexation with protein and protecting it from wasteful microbial degradation in the rumen (Barry, 1989). The low levels of CT in *H. lanatus* are within the range that results in a positive effect on performance of ruminant herbivores (<20 g/kg dry matter; Barry, 1989). Furthermore, CT have no effect as digestion inhibitors in insects (Bernays et al., 1989; Feeney, 1992). In summary, it is unlikely that the low levels of CT in *H. lanatus* have a digestion-inhibiting effect on herbivores, but the possibility that they act as a defense against pathogenic attack from fungi and bacteria (Rhoades, 1979) cannot be dismissed.

(Received August 1 1994; accepted March 15 1995)

Abstract—Brown-rotted wood has been used as a source of lignin to investigate further the antialgal effects of lignocellulosic materials such as decomposing barley straw. The antialgal activity of brown-rotted and white-rotted wood has been determined in a laboratory bioassay. Using pyrolysis gas chromatography–mass spectrometry, the lignin of the rotted wood samples has been compared and the significance of the structure of the lignin in antialgal activity is discussed.

Key Words—Antialgal compounds, brown-rotted wood, white-rotted wood, lignin, macromolecular analysis, pyrolysis GC-MS, *Chlorella*, *Microcystis*.

INTRODUCTION

Barley straw rotting, submerged and well-aerated, in water has been shown to release substances that inhibit the growth of a range of algae and cyanobacteria (Gibson et al., 1990; Newman and Barrett, 1993). Indeed, this effect is being exploited widely for the control of nuisance algae in waterbodies. We have suggested that the antialgal factor(s) is derived directly from the straw per se (Pillinger et al., 1992) and may be phenolic, particularly polyphenolic, in origin (Pillinger et al., 1994). Straw contains some 15% by weight of the polyphenolic structural material lignin. We report the effect of lignin on the growth of an alga and a cyanobacterium in a laboratory bioassay.

Unfortunately, no method is available that permits the extraction of total

lignin (Lewis and Yamamoto, 1990); different forms of lignin reflect the method by which they have been isolated. The lignin extract that best reflects unchanged native lignocellulose is "enzymatically liberated lignin" (Ander and Eriksson, 1975), formed by the action of brown-rot fungi on lignocellulose, whereby cellulose is preferentially utilized leaving a brown powder highly enriched in lignin (Kirk and Adler, 1970). Brown-rotted wood is readily available in nature, and for this reason we have investigated initially the effect of lignin derived from wood rather than from straw. Although brown-rot lignin is representative of the original lignin of the wood, minor chemical changes cannot be ruled out (Kirk and Adler, 1970). On the other hand, a group of specialized fungi that are able to effect white-rotting of lignocellulose substrates do so by metabolizing lignin. The action of fungi on wood has been reviewed by Levy (1987). Mulder et al. (1991) demonstrated that a thoroughly white-rotted wood did not contain lignin moieties, only those of cellulose. We thus chose to use white-rotted wood in antialgal tests as a control to the lignin-enriched brown-rotted wood.

We have used on-line pyrolysis gas chromatography–mass spectrometry (Py-GC-MS) to compare the lignin in each of the rotted wood samples. This technique increasingly is being employed to study lignocellulose (e.g., Scheijen and Boon, 1991; Galletti and Reeves, 1991) and was recently summarized by Boon (1989). Macromolecular lignin-rich material can be analyzed directly avoiding selective (Lapierre et al., 1989) and time-consuming chemical extractions. The solid sample is thermally disrupted in the absence of air, the subcomponents separated by conventional gas chromatography, and identified by their characteristic mass spectra.

METHODS AND MATERIALS

Algal Toxicity Experiments. A unicellular green alga, *Chlorella vulgaris* Beijerinck (CCAP 211/12), and the cyanobacterium (blue–green alga) *Microcystis aeruginosa* Kutz, emend Elenkin 1924 (CCAP 1450/6), were maintained in liquid culture as below with weekly subculturing. The growth of either organism in the absence (control) and presence of rotted wood (see Table 1 below for details) in algal culture medium was assessed using a laboratory bioassay (Pillinger, 1993). Briefly, an aliquot (1 ml) of stock culture in the exponential phase of growth was added to 50 ml modified Jaworski's medium, buffered with 20 mM HEPES at pH 8.2, in a conical flask and incubated at random in continuous light at 20°C with daily shaking to maintain aeration. All controls and treatments were replicated five times. A comparison of the growth of the organisms between the controls and treatments was obtained by quantifying the chlorophyll *a* content after three to four days of incubation. The absorbance due to chlorophyll *a* of a methanolic extract (10 ml) of the dry biomass retained on

a glass-fiber filter (pore size 1.2 μm) was measured at 665 nm (less a background reading taken at 750 nm). In some experiments the growth of *Chlorella* was measured by counting algal cells using a hemacytometer. Preliminary data indicated a linear correlation between the two methods. All data are reported as percentage of the control growth, allowing comparison between experiments conducted under slightly varying conditions, and, where quoted, standard errors of the mean of the normalized values. The significance of the treatment value ($N = 5$) as compared to the respective control ($N = 5$) was determined by an unpaired t test.

Analytical Pyrolysis Gas Chromatography–Mass Spectrometry. A sample of dried, pulverized wood of between 1 and 2 mg was weighed accurately into a Pelletiser (Scientific Glass Engineering, SGE, Milton Keynes, U.K.) and gently compressed. The pellet was introduced into the quartz liner of the furnace (SGE Pyrolyser) maintained at a preset temperature (500°C). A slight positive pressure of helium in the furnace keeps pyrolysis time constant and reduces secondary pyrolysis; pyrolysis products were thus swept onto the column of the gas chromatograph (GC). The GC (Hewlett Packard HP5890 Series II) was fitted with a WCOT 50-m × 0.32-mm capillary column column coated with 0.5 μm film of 5% phenyl methyl silicone. The initial oven temperature was set at 50°C and programmed to rise at 10°C/min to 100°C after a 1-min hold, then at 5°C/min to 300°C, after which it was isothermal; the complete run lasted for 60 min. Pyrolysis subcomponents were detected using a mass selective detector (HP 5971 series MSD); electron impact ionizing voltage was 70eV with continuous scanning from 50 to 500 mass units. Identification was based on computer matching of mass spectra.

The experimental conditions, including the temperature of pyrolysis, gave an acceptable separation of the subcomponents. Blank runs confirmed that memory effects of the pyrolyzer system were negligible. Preliminary analyses indicated a good measure of reproducibility with a kraft lignin standard, Indulin AT (Sigma), and replicate analyses of a white-rotted wood sample (Pillinger, 1993).

Pyrolysis is not a highly quantitative method (Faix et al., 1987). However, where similar weights of comparable samples are pyrolyzed under identical conditions within a short time period to reduce effects of instrumental variability, then a quantitative estimate of the various pyrolysis fragments can be made. This was achieved by determining the computer-integrated peak areas of interest as a ratio of a chosen peak that occurred in each sample.

RESULTS

Antialgal Effect of Brown- and White-Rotted Wood. Both brown-rotted (BRW) and white-rotted (WRW) sycamore wood were significantly (t test, P

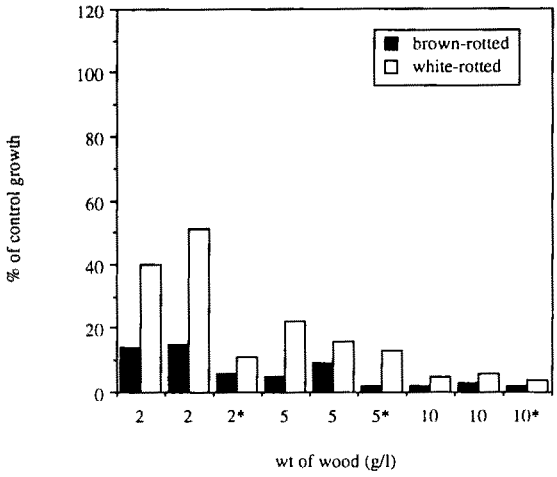

FIG. 1. Effect of brown- and white-rotted sycamore wood on growth of *Chlorella* in vitro. Algal growth quantified by cell counts. The asterisk denotes that the wood was autoclaved in the algal medium prior to the bioassay, otherwise wood was tested without autoclaving. All treatments ($N = 2$) significantly (t test, $P < 0.001$) inhibitory compared to controls ($N = 2$).

< 0.001) inhibitory to the growth of *Chlorella*, although it can be seen from Figure 1 that BRW was consistently more inhibitory than WRW. The results shown in Figure 1 represent the data from duplicate experiments in which wood was included in the algal bioassay at a dose equivalent to 2, 5, and 10 g/liter (g/dm^3) respectively. In a third experiment (denoted by an asterisk in Figure 1), similar dose rates of wood were used, but the wood was autoclaved in the algal bioassay medium prior to the experiment. Autoclaving increased the antialgal activity of both types of wood, discernible only at the lower dose rates. Microscopic examination of the WRW (sycamore) indicated that the sample was not homogeneously rotted.

When compared to the data for sycamore, a greater antialgal effect of brown- and white-rotted elm was recorded and thus the elm samples were selected for chemical analysis. The latter sample was well rotted and homogeneous on microscopic examination. WRW (elm) was not significantly inhibitory compared to control growth at the three dose rates tested (1, 2, and 4 g/liter whereas BRW (elm) was highly inhibitory to *Chlorella* (Figure 2). In all cases, the wood was autoclaved in the medium previously shown (Figure 1) to result in greater algal toxicity than with wood not exposed to the period of hot aqueous extraction afforded by autoclaving.

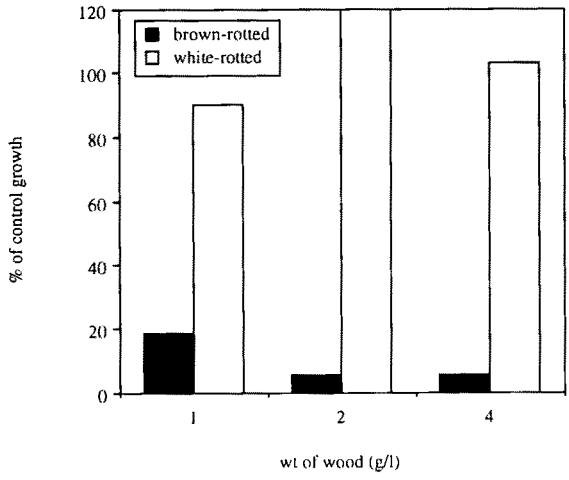

FIG. 2. Effect of brown- and white-rotted elm wood on growth of *Chlorella* in vitro. Algal growth quantified by chlorophyll *a* estimation.

A heartwood sample from the white-rotted elm trunk (Table 1) was quite brown in color, although the wood had the texture of WRW. The lack of antialgal activity of the elm heartwood sample was similar to that of the white-rotted fraction, namely 1 g/liter wood resulted in 140% (SE $\pm$14.7) of the control growth; 2 g/liter in 130% (12.6); and 4 g/liter in 98% (6.0). On autoclaving the elm heartwood sample in algal medium prior to the bioassay, a brown coloration was imparted to the medium as occurred also with BRW. The resulting inactivity of the white-rotted, but brown-colored, elm wood towards *Chlorella* indicated that reduced light penetration was not responsible for the algal toxicity observed with BRW.

Two further white-rotted wood samples, birch and hazel, were not inhibitory to *Chlorella* (Table 2). However, both samples were inhibitory to the growth of the cyanobacterium *Microcystis* (Table 2). The data in Table 2 also show the results of the bioassay of WRW (elm) against *Microcystis*; it can be seen that this white-rotted sample, which was not toxic towards *Chlorella* (Figure 2), significantly inhibited the growth of *Micocystis* at the same three dose rates.

Pyrolysis GC-MS of Wood. Quantitative and qualitative differences in the lignin of brown- and white-rotted woods were determined using pyrolysis GC-MS. Figure 3 shows the total ion current (TIC) chromatogram, or pyrogram, generated by the mass spectrometer in response to the intensity of ions of the

TABLE 1. PROVENANCE AND DESCRIPTION OF WOOD SAMPLES[a]

Wood sample	Location, UK	Type of rot
Sycamore, *Acer pseudoplatamus* L.	old woodland, Lancashire	brown
	old woodland, Lancashire	white (partial)
Elm, *Ulmus minor* Miller	old woodland, Cambridgeshire	brown
	old farmland hedge, Cambridgeshire	white (well-rotted)
	old farmland hedge, Cambridgeshire	heartwood (brown) from white (well-rotted) log
Birch, *Betula* sp.	parkland, Berkshire	white (well-rotted), *Coriolus* (*Trametes*) *versicolor* fruiting on surface
Hazel, *Corylus avellana* L.	twig from parkland, Berkshire	white (well-rotted) under bark, *Merulius corium* fruiting on surface

[a]All samples were air dried, homogenized in a laboratory blender, and sieved to <2 mm. Samples for pyrolysis GC-MS were further sieved to <125 μm and stored in glass vials in a desiccator.

TABLE 2. EFFECT OF WHITE-ROTTED WOOD ON GROWTH OF *Chlorella* AND *Microcystis*

Wood	Weight of wood (g/liter) in algal medium	% of control growth (±SE)[a]

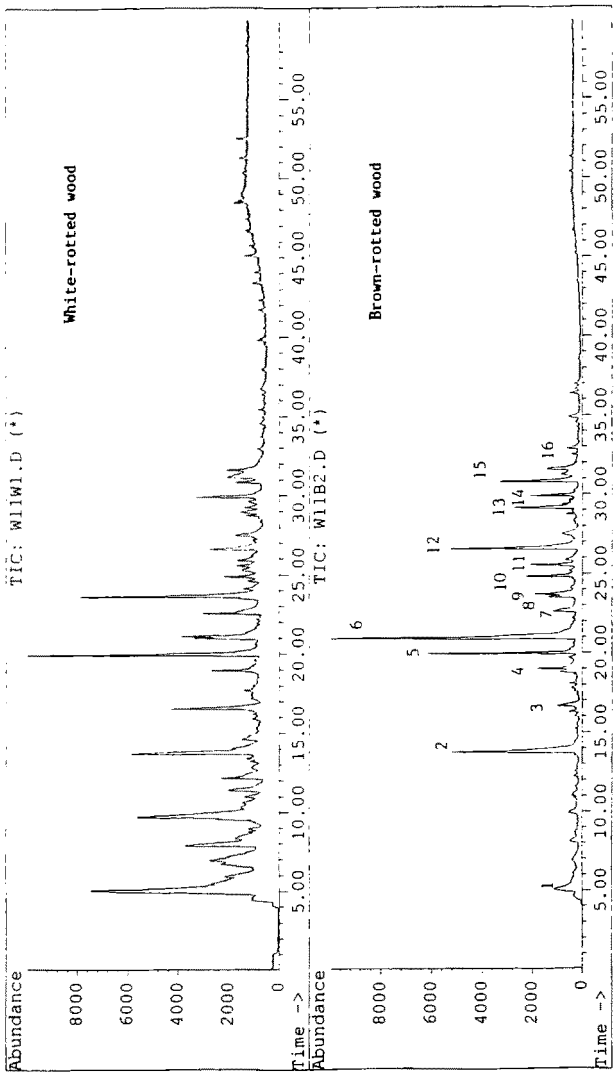

FIG. 3. Comparison of pyrograms of brown-rotted and white-rotted elm wood. Weight of WRW pyrolyzed = 1.52 mg, BRW pyrolyzed = 1.20 mg. Peaks 1–16 on the BRW trace refer to Figure 4 for quantitative comparison and Table 3 for identification.

various pyrolysis subcomponents of the white-rotted and brown-rotted elm samples. The trace for the WRW (elm) shows pyrolytically produced subcomponents of short retention time, which, together with their mass spectra, indicates they were derived from polysaccharide (Boon, 1989; Kivaisi et al., 1990). Such peaks were typically lacking from the BRW (elm) pyrogram. In BRW (elm) and WRW (elm), the area of the peak due to the simplest monomethoxy fragment, methoxy phenol or guaiacol, was remarkably similar (peak number 2 on Figure 3). Thus the integrated areas of other peaks for which spectra were obtained were normalized to that of methoxy phenol.

Figure 4 graphically shows the normalized distribution of the 16 major peaks in the BRW (elm) sample compared to the normalized values of the peaks of the same (as determined by their mass spectra) fragments where present in WRW (elm). The tentative identification of the peaks is given in Table 3. The convention of describing lignin subcomponents as either G (guaiacyl unit, with one methoxy group) or S (syringyl unit, dimethoxylated) has been adopted.

It can be seen from Figure 4 that peak 6 (2,6-dimethoxyphenol) was some six times more abundant in BRW than WRW. A greater abundance of dimethoxy to monomethoxy substitution was reflected in the overall pattern of the BRW compared to WRW. The ratio of S/G lignin subcomponents in BRW (elm) was

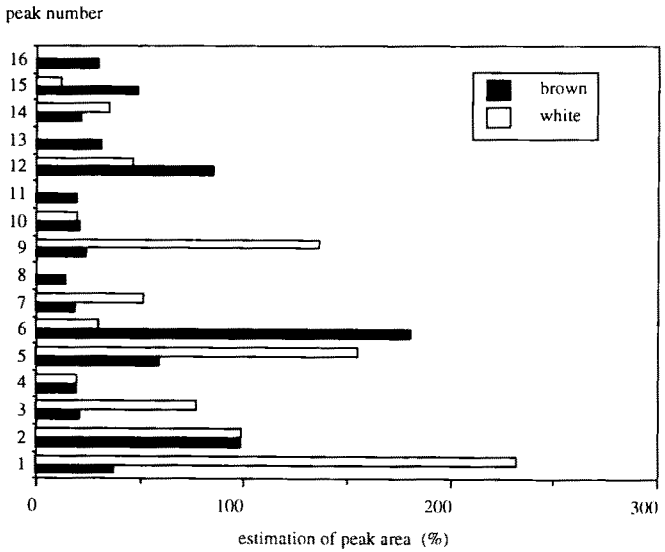

FIG. 4. Comparison of peak areas obtained by pyrolysis GC-MS of brown-rotted and white-rotted elm wood. Computer-integrated peak areas are normalized to the area of peak number 2, identified as methoxyphenol, arbitrarily set at 100%. Peaks 1–16 refer to the pyrograms shown in Figure 3 and identification is shown in Table 3.

TABLE 3. IDENTIFICATION OF PEAKS IN PYROGRAM OF BRW ELM

Peak number	Retention time (min)	M+[a]	Base peak[b]	Other peak	G or S[c]	Identification or partial identification[d]
1	5.08	60				unidentified
2	13.76	124	109		G	methoxyphenol

calculated as 1.8, whereas in the WRW (elm) it was 0.3. Both hazel and birch WRW samples had S/G ratios of less than 0.5. The heartwood sample of white-rotted elm, which was ineffective against *Chlorella*, had a pyrogram typical of the WRW (elm). The S/G ratio of the elm heartwood sample was calculated to be 0.1, consistent with depletion of syringyl lignin following white-rotting, irrespective of the brown coloration typical of BRW.

DISCUSSION

Brown-rotted wood, elm or sycamore, was consistently more inhibitory to the growth of *Chlorella* than was white-rotted wood. The partial inhibitory

effects of sycamore WRW may be explained by the poor degree of homogeneity of the white-rotting as noted on microscopic examination. Extensively white-rotted wood (three species) did not prevent the growth of *Chlorella*. Based solely on the response of *Chlorella*, it is tempting to conclude that the lignin enrichment of BRW is responsible for antialgal activity. These data support our hypothesis that, of the lignocellulose content of straw, it is indeed the lignin portion that has antialgal potential.

White-rotted wood (three species), however, significantly prevented the growth of *Microcystis*. Cyanobacteria are reportedly more sensitive than green algae to barley straw (Newman and Barrett, 1993), although the possibility that the prokaryote and eukaryote are adversely affected by different factors cannot be ignored.

Pyrolysis GC-MS has allowed us to compare the lignin from a range of rotted wood samples. In general, components with short retention times and mass spectral identification indicating a polysaccharide origin were recorded only in the WRW samples, consistent with the typical action of white-rot fungi, which deplete lignin while preserving holocellulose. Lignin-derived subcomponents were observed in both BRW and WRW; the latter results are in contradiction to those reported by Mulder et al. (1991). A measure of the extent of white-rotting is obviously critical for the interpretation of analytical data relating to the persistence of ligninaceous material.

Analysis by pyrolysis GC-MS does not allow us to quantify the total phenolic macromolecular material remaining in the two types of rotted wood, so we cannot discount the possibility that antialgal activity is dependent only on the amount of total lignin, the more resistant *Chlorella* being unaffected by lower levels of lignin in WRW. However, it is also possible that the structural difference in lignin as identified by Py GC-MS is a significant factor in determining antialgal activity. The pyrograms of the elm wood, rotted in the two distinct fashions, allows a comparison of the nature of the lignin in each. BRW [regarded as closely repesentative of the native (unrotted) wood lignin] shows a high proportion of syringyl to guaiacyl lignin subcomponents, presumably reflecting the distribution of S to G lignin prior to pyrolysis. The action of brown-rot fungi in modifying the native lignin (Mulder et al., 1991; Kirk and Alder, 1970) may account partially for an increase in S units reflected in the S/G ratio of BRW. The pyrogram of WRW, on the other hand, indicates the presence of G units of lignin. Overall the S/G ratio of the two elm samples, supported by the data from other WRW samples, reflects the structurally different lignin resulting from brown- or white-rot processes.

The preferential utilization of syringyl lignin during white-rotting, which is limited to specialized fungi, is well documented (Dare et al., 1988). Niemann et al. (1991), however, have suggested that overall reduction in S lignin in some cases may result from the fungal preference for secondary cell walls, which are

higher in S lignin than primary cell walls, rather than specific action on S lignin. Likewise chemical extraction is selective; Scheijen and Boon (1991) cautioned that the Bjorkman method preferentially extracts secondary cell walls high in S lignin units. Such reports underline the value of the in toto analysis afforded by Py-GC-MS.

Under alkaline and oxygenated conditions, precisely those that exist in both field sites and laboratory bioassays where the antialgal effect of barley straw has been demonstrated, phenolic groups would readily autoxidize to quinones that are antialgal (Pillinger et al., 1994). We have proposed (Pillinger et al., 1994) that the process of oxidation of phenolic hydroxy groups increases the antialgal activity of phenolic or polyphenolic substrates. Detailed studies of chemical processes associated with wood pulping have shown that syringyl lignin components have a greater tendency to undergo abiotic oxidation than do guaiacyl units (Kempf and Dence, 1975). Furthermore, the toxicity of a range of phenylpropanoid compounds towards a green alga, *Selenastrum capricornutum*, increased with increasing methoxy substitution, and the position of the methoxy groups also influenced sensitivity (Della Greca et al., 1992). The digestibility of forage crops containing similar amounts of lignin was found to be greater in those feeds with lower syringyl lignin (Jung and Himmelbach, 1989 and references therein), suggesting that microbial action is reduced by the dimethoxy substitution of the lignin. It is conceivable, therefore, that lignin with increased dimethoxy groups as compared to a high proportion of monomethoxy substitution could be a significant factor in the efficacy of lignin to reduce the growth rate of algae and cyanobacteria. The greater antialgal activity shown by brown-rotted wood over white-rotted wood may be accounted for, at least partially, not only by the total amount of lignin present, but also by the increased potential for oxidation offered by syringyl lignin compared to guaiacyl lignin. Softwood lignin is typically of the guaiacyl type, with negligible dimethoxy substitution (Sarkanen and Ludwig, 1971); preliminary studies in our laboratory suggest that brown-rotted conifer wood is indeed less toxic towards *Chlorella* than that of hardwoods.

CONCLUSIONS

Brown-rotted wood inhibits the growth of two freshwater microorganisms, a green alga, *Chlorella*, and a cyanobacterium, *Microcystis*. White-rotted wood, however, was not inhibitory to the green alga but significantly inhibited growth of the cyanobacterium. Lignin was still present in the white-rotted samples, detected by on-line pyrolysis followed by combined gas chromatography–mass spectrometry. Quantification of data from pyrolysis studies must be treated with caution, but nevertheless the method provided a valuable comparison of the type

of lignin in similar samples. The lignin remaining in the white-rotted samples had a lower proportion of syringyl (dimethoxy substituted) to guaiacyl lignin than in the brown-rotted wood. Apparently, lignin rich in syringyl units shows greater antialgal activity, possibly as a result of the greater case of phenolic oxidation afforded by the presence of dimethoxy groups compared to monomethoxy ones.

Acknowledgments—Dr. J.A. Cooper is thanked for helpful discussions and mycological advice and Dr. J.R. Newman for continuing collaboration and critically reading the manuscript. John Walters and Tina Wardhaugh are thanked for biological technical support. We thank two anonymous reviewers for their thoughtful comments.

(Received September 6, 1994; accepted March 28, 1995)

Abstract—The aim of the present study was to investigate the regulation and the homogeneity of the chemical signature between members of *Camponotus vagus* after experimentally changing the cuticular chemical signature by topically applying hydrocarbons. Topical application of pentane (solvent) to the cuticle of isolated workers led to a significant decrease in the quantities of the cuticular hydrocarbons measured within 3 hr, followed by an increase within the following 3 hr and a period of relative stability from 9 hr to 14 days. On the other hand, after topical application to isolated workers of *n*-tetracosane, a hydrocarbon existing only in trace quantity in this species, the quantity of this hydrocarbon measured over time in the epicuticular wax tended to level out at about 14 days after treatment. In contrast, topically applied (Z)-9-tricosene, an unsaturated hydrocarbon not normally synthesized by this species, decreased dramatically within a few hours and had completely disappeared within 14 days. (Z)-9-Tricosene applied to one member of a group was present in the postpharyngeal glands of the other members from 30 min to seven days of cohabitation. The highest levels were recorded in all six workers in each group after one day. GC-MS analyses showed that (Z)-9-tricosene was present in the cuticles of some untreated workers only after four and seven days of cohabitation with a treated worker. These data suggest: (1) that the deposited (Z)-9-tricosene decreased very quickly on the cuticle of the treated worker, although the total amount was spread over the cuticle and postpharyngeal gland and (2) that it was absorbed by the nontreated workers via the postpharyngeal glands during licking or grooming activities and reincorporated into the cuticle at four and seven days. When the treated worker

was separated from the other ants by a wire mesh, (Z)-9-tricosene was detected neither in the cuticle nor in the postpharyngeal gland of nontreated workers.

Key Words—Cuticular hydrocarbons, chemical signature, postpharyngeal glands, nestmate recognition, Hymenoptera, ant, *Camponotus vagus*.

INTRODUCTION

It was suggested long ago by Fielde (1904) that a colony odor might exist among ants. Hölldobler and Michener (1980) more recently suggested that individuals might produce signals or discriminators that are learned by the members of a colony and that subserve the recognition and discrimination processes at work in the colony. Several studies subsequently focused on the nature and the source of these colony signatures. It has been established that qualitative and quantitative differences in the cuticular hydrocarbon mixtures are used for interspecies recognition purposes by the termites *Reticulitermes* (Howard et al., 1982b; Bagnères et al., 1988, 1991a) and *Zootermopsis* (Haverty et al., 1988). The cuticular hydrocarbons play a role in recognition among colony members in the ants *Camponotus vagus* (Bonavita-Cougourdan and Clément, 1986; Bonavita-Cougourdan et al., 1987; Clément et al., 1987), *C. floridanus* (Morel and Vander Meer, 1988), and *Cataglyphis cursor* (Nowbahari et al., 1990) and possibly also in social bees (Page et al., 1991; Getz and Page, 1991; Breed and Stiller, 1992) and social wasps (Espelie et al., 1990; Bonavita-Cougourdan et al., 1991).

Colony odor may be important to the mechanisms whereby termitophiles and myrmecophiles are integrated into colonies of termites and ants, respectively. Howard et al. (1980, 1982a) established that the termitophiles, *Tricopsenius frosti*, *T. depressus*, and *Philotermes howardi*, chemically mimic the cuticular profiles of their respective termite hosts (*Reticulitermes flavipes* in the case of *Tricopsenius frosti* and *R. virginicus* in that of the other two termitophiles). A similar mimetic chemical process occurs in the parasitic dipteran *Microdon piperi*, which facilitates its integration into colonies of *Camponotus modoc* ants (Howard et al., 1990a). Although *de novo* biosynthesis of hydrocarbons occurs among *Microdon albicomatus* parasites living in *Myrmica incompleta* ant colonies (Howard et al., 1990b), Vander Meer and Wojcik (1982) reported that the myrmecophile beetle *Martinezia duterteri* (=*Myrmecaphodius excavaticollis*) initially has its own cuticular profile, but acquires the cuticular hydrocarbons characteristic of the host ant species, *Solenopsis richteri* or *Solenopsis invicta*. Vander Meer et al. (1989a) observed that the larvae of the eucharitid parasitoid, *Orasema* spp., which becomes closely integrated into colonies of the fire ant, *solenopsis* spp., has a cuticular hydrocarbon signature that is qualitatively identical and quantitatively very similar to that of its host.

A hybrid cuticular signature was developed by workers of the species *Man-*

ica rubida and *Formica selysi* that were placed together at emergence and formed a heterospecific colony (Errard and Jallon, 1987; Errard et al., 1989; Errard and Jaisson, 1991; Bagnères et al., 1991b). The hybrid signature differed both qualitatively and quantitatively from the original species' profiles. *Camponotus vagus* ant larvae (Bonavita-Cougourdan et al., 1989) that were adopted and tended by workers in an unknown colony showed changes in proportions of cuticular hydrocarbons as the result of the change of social environment.

Three hypotheses have been put forward to account for the mechanisms whereby hydrocarbon components may be acquired and/or chemical signatures modified in this way (Bonavita-Cougourdan et al., 1989); (1) larvae may be able to synthesize hydrocarbons of their brood-tenders that they have perceived via the olfactory pathway, (2) larvae may synthesize hydrocarbons constituting the colony signature from precursors provided by workers in variable quantities from one colony to another, or (3) hydrocarbons synthesized by brood-tenders may be transmitted orally to a larva, and these may be transferred to the latter's cuticle.

Some investigations on ants have shown that the postpharyngeal glands are involved in the absorption of ingested alimentary lipids (Peregrine et al., 1972, 1973; Peregrine and Mudd, 1974; Delage-Darchen, 1976). Others have established that the main components of the postpharyngeal glands are hydrocarbons (for example: Thompson et al., 1981; Attygalle et al., 1985). Hydrocarbons present on the cuticle and in the gland are qualitatively identical and quantitatively similar, at least in the case of some species (Bonavita-Cougourdan et al., 1987; Clément et al., 1987; Bagnères and Morgan, 1991). Hefetz et al. (1992) reported that the postpharyngeal glands of *Manica rubida* living in mixed associations with *Formica selysi* contained some of the latter's specific cuticular hydrocarbons in addition to their own.

The present paper reports studies of chemical interactions occurring in a social group and analyzes the mechanisms possibly regulating the homogeneity of chemical signals. First, we reinvestigated the nature of the cuticular hydrocarbons carried by the ant *Camponotus vagus* (Scop.). Secondly, we studied the variations with time of (*Z*)-9-tricosene, an exogenously added hydrocarbon not normally synthesized by this species, and an endogenous hydrocarbon, *n*-tetracosane, existing only in trace amounts in this species. The third aspect studied was the chemical composition of the cuticles and postpharyngeal glands to determine whether transfer of (*Z*)-9-tricosene occurred over time within small groups containing one worker topically treated with (*Z*)-9-tricosene and five untreated workers. We chose (*Z*)-9-tricosene because it is an unsaturated hydrocarbon known to exist in other insects, but not in the ants with which we worked. It was described as the sex pheromone of the common housefly (Carlson et al., 1971) and as one of the cuticular hydrocarbons carried by termites of the genus *Reticulitermes* and by ants of the genus *Formica* (Bagnères, 1989).

METHODS AND MATERIALS

Insects. We used colonies of the carpenter ant *Camponotus vagus* (Scop.), a monogynous species living in stumps and fallen trees. All the colonies were collected in the same biotope, at Nans les Pins, 45 km from Marseille, France. At the laboratory, the colonies were reared in Plexiglas boxes connected to two well-aired compartments, where food consisting of honey and crickets was provided. The ants were reared and maintained with a 12L:12D photoperiod at approximately 22°C and 70% relative humidity.

Experiment 1 (Control). First we studied the ants' cuticular hydrocarbons and their variations with time in response to topical application of solvent (pentane). Nine sets of five workers each were used for this purpose. With a 1-μl Hamilton syringe, 1 μl of pentane was deposited on the thorax of these separately housed sets of workers. Cuticular extracts of the five workers in each set were analyzed with gas chromatographic technique (GC) at 0, 1, 3, 6, 9, 24, 48, 168, and 336 hr after application of pentane. We recorded as a function of time the amounts (in nanograms) of the main hydrocarbon families present (*n*-alkanes, monomethylalkanes, and dimethylalkanes) in the workers' cuticular profiles.

Experiment 2. We studied as a function of time the variations in added quantities of an endogenous cuticle component, *n*-tetracosane (*n*-C_{24}), and an exogenous compound, (*Z*)-9-tricosene ($C_{23:1}$), applied to the thorax of workers. One microliter (0.5 μg/μl) of a solution of (*Z*)-9-tricosene was applied to the cuticle of a single individual in each set of workers. The cuticular extract of each individual was then analyzed by GC at 0 ($N = 2$), 1 ($N = 10$), 3 ($N = 11$), 6 ($N = 10$), 9 ($N = 9$), 24 ($N = 10$), 48 ($N = 9$), 168 ($N = 11$), and 336 ($N = 10$) hr after application of (*Z*)-9-tricosene.

In a separate series, 1 μl of *n*-tetracosane solution (0.8 μg/μl in pentane) was applied to the cuticle of a single individual in each set of workers ($N = 5$ individuals per set), and the cuticular extract of each individual was then analyzed by GC at the same time intervals as in the (*Z*)-9-tricosene experiment above. The solutions of (*Z*)-9-tricosene were prepared from a 97% solution of (*Z*)-9-tricosene (Aldrich Inc., St Quentin Fallavier, France) and pentane (Atrasol 99%), and the *n*-tetracosane solution was prepared from a pure *n*-tetracosane solution (PolyScience Corp., Niles, USA).

Experiment 3. One worker was topically treated with 1 μl of the solution of (*Z*)-9-tricosene (1 μg/μl in pentane), marked with a metal belt (diameter 0.06 mm) placed around its petiole (Provost, 1983), immediately isolated for 1 hr, and then placed with five nontreated workers in a transparent plastic box (12 × 8 × 2 cm). The cuticular profile of each of the six individuals in the group was analyzed after 0, 0.5, 1.5, 9, 24, 48, 96, 168, 264, and 336 hr of cohabitation. In this experiment, we also analyzed by GC-MS a blend of eight cuticular extracts from the eight untreated individuals taken at a cohabitation time of 96 hr.

Experiment 4. The purpose of this experimental series was to evaluate the amounts of (Z)-9-tricosene present over time in the postpharyngeal glands of a worker topically treated with (Z)-9-tricosene, and in those of the five nontreated workers with which it cohabited. The same experimental procedure was used as in experiment 3, except that the postpharyngeal glands were dissected from each worker in distilled water, extracted with pentane, and then analyzed by GC. The same periods of cohabitation were used as above with five groups for each time period with the exceptions of six groups for 9 hr, nine groups for 48 hr, and four groups for 264 hr and 336 hr. In experiment 4, we analyzed by GC-MS a blend of two cuticular extracts from two treated individuals and blends of postpharyngeal gland extracts from treated and untreated individuals at each cohabitation time, except at 48, 264, and 336 hr.

Experiment 5. A worker treated with 1 $\mu g/\mu l$ of (Z)-9-tricosene as above was separated by a double layer of wire mesh for 24 hr from five nontreated workers. This experiment was repeated five times with different workers. The postpharyngeal glands were then dissected from all individuals, each extracted separately (pentane), and analyzed by GC.

Chemical Analysis. Prior to dissection and/or extraction, ants were killed by freezing. Either the dissected postpharyngeal glands or whole ants were immersed for 5 min in 1 ml pentane in a Weaton tube. An internal standard of 200 ng *n*-docosane was then added. Each extract was completely evaporated under a stream of nitrogen, and 40 μl of pentane added to extracts of postpharyngeal glands and 30 μl to cuticular extracts. Samples of 2 μl were analyzed by GC on a Delsi 200 DN GC coupled to an Enica 31 integrator and equipped with a flame ionization detector (FID) and a Chrompack CPSil5 WCOT column (25 m $\times$ 0.25 mm). The injector was of the split-splitless type, and the injection was performed within 15 sec in the splitless mode. The temperature program was from 180°C to 320°C at 5°C/min. The carrier gas was helium at a pressure of 1 bar.

A silver nitrate silica microcolumn (20% silver nitrate on silica, 6 cm $\times$ 6 mm) was used to separate (Nelson et al., 1981) (Z)-9-tricosene from the cuticular hydrocarbons synthesized by *Camponotus vagus* after a period of 168 hr. Saturated hydrocarbons were eluted from the column with 30 ml of hexane, and then 10 ml (in 2-ml portions) of ether–hexane (1 : 20) was added to elute (Z)-9-tricosene. The eluates obtained were analyzed by GC to determine the purity and the efficiency of the separation technique. In our experiments, 10 ml of ether–hexane sufficed to collect (Z)-9-tricosene, and no further (Z)-9-tricosene was detected by GC after further washing of the microcolumn.

The gas chromatography–mass spectrometry (GC-MS) analyses were performed on a Hewlett-Packard 5890 GC coupled to a 5989A MS. The whole system was controlled by a HPUX MS Chemstation. The analyses were first performed in an electron impact mode (EI; 70 eV) over the mass range *m/z* 30 to *m/z* 600 amu (atomic mass units), with a scan time of 1 sec. Positive chemical

ionization (CI; 150 eV/CH_4^+) was then used over the mass range *m/z* 100 to *m/z* 600 amu at a rate of approximately 1 scan/sec. The GC contained an HP5 column (30 m × 0.25 mm). The injection was made in the splitless mode (1 min). Helium was used as the carrier gas at a pressure of 2 bars. During chemical ionization, the methane was at a pressure of 1.5 bars. For hydrocarbon identification, the GC oven was programmed from 70°C to 180°C at 30°C/min and then to 320°C at 3°C/min with a 5-min isotherm at 320°C. For (*Z*)-9-tricosene determinations, the oven was programmed from 70°C to 200°C at 30°C/min and then to 240°C at 5°C/min, and again to 320° at 10°C/min with a 10-min isotherm at 320°C.

Confirmation of Typical Hydrocarbon Pattern of C. vagus. Some of the cuticular hydrocarbons of *C. vagus* have been previously identified by GC-MS (Bonavita-Cougourdan et al., 1987). For confirmation and reference, we prepared a cuticular extract by immersing 80 workers in pentane for 5 min. The apolar fraction was separated from the polar fraction with a silica microcolumn (6 cm × 6 mm), and the apolar fraction was analyzed by GC-MS. This enabled us to confirm that no (*Z*)-9-tricosene was present among the endogenous substances, to check which substances (such as *n*-tetracosane) were present only in trace amounts, and to look more closely at some of the cuticular hydrocarbons previously found to be present, but whose identity was doubtful. Our identifications were compared with the previously published results (Bonavita-Cougourdan et al., 1987; Lange et al., 1989; Bagnères and Morgan, 1991).

Detector response to the hydrocarbon series was corrected with a response coefficient defined for the flame ionization detector used (Bagnères, 1989). A coefficient of 0.9 was used for (*Z*)-9-tricosene.

Statistical comparisons were made by using the Mann-Whitney two-tailed *U* test and the Jonckeere test (Jonckeere, 1954).

RESULTS

GC-MS Identification of Cuticular Hydrocarbons

Chemical analyses based on the GC-MS data confirmed that the extracts from *C. vagus* (Table 1 and Figure 1) mainly consisted of saturated hydrocarbons with 21–39 carbon atoms (59 peaks), but two unsaturated compounds represented by peaks 19 and 24 were found. The saturated hydrocarbons were *n*-alkanes, monomethylalkanes, dimethylalkanes, and trimethylalkanes. Some further hydrocarbons were identified in addition to those previously described (Bonavita-Cougourdan et al., 1987; Lange et al., 1989). These included monomethylalkanes, dimethylalkanes, and trimethylalkanes. The latter is a new hydrocarbon class that has not been detected previously in *C. vagus*. Hydrocarbons with 21–24 carbon atoms (peaks 0–5) were present only in trace amounts (Table 1) and were not included in Figure 1.

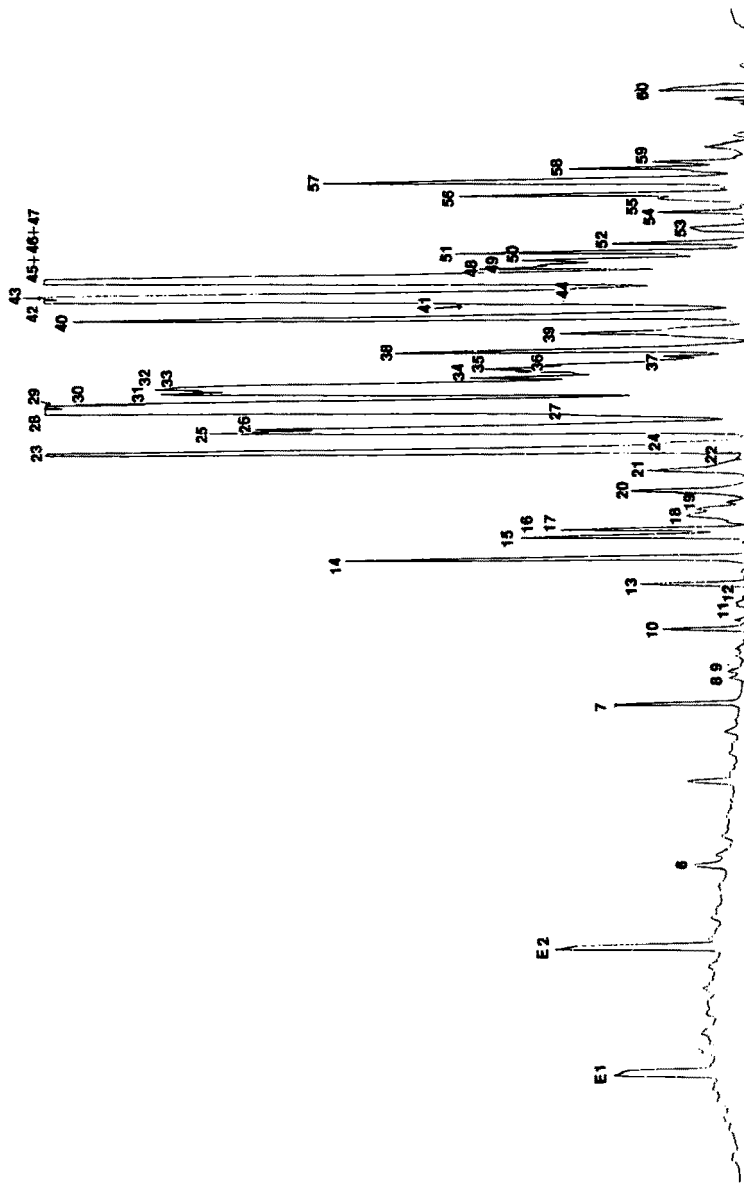

FIG. 1. Cuticular hydrocarbon profile of a worker ant of *C. vagus*. E1 (*n*-docosane) and E2 (*n*-tetracosane) were internal standards. Analyses were conducted on a fused silica capillary column with a temperature program from 180°C to 320°C programmed to rise at 5°/min. The carrier gas was helium and the injection mode was splitless (15 sec).

TABLE 1. DETERMINATION BY GC-MS OF CUTICULAR HYDROCARBONS OF *C. vagus*[a]

[a]CN represents the number of carbon atoms and ECL the equivalent chain length.

Variations in Cuticular Components as a Function of Time and Treatment

Experiment 1. To determine the effect of applying the solvent (pentane) alone to the workers' thorax on the cuticular hydrocarbon profiles, we quantitatively analyzed peaks 23, 26, 28, and 42, and the incompletely separated compounds represented by peaks 45–47 as a function of the time elapsed after the application of solvent. At t_{0+3} hr (Figure 2), the quantities decreased 3.1, 3.3, 3.8, 4.3, and 4.7 times for peaks 23, 26, 28, 42, and 45 + 46 + 47, respectively. Comparisons between the values recorded at t_{0+3} hr and those recorded at t_{0+1} hr and t_0 hr using Jonckeere's test (Jonckeere, 1954) showed that the quantities of all tested compounds decreased significantly ($P < 0.05$). The statistical test was carried out separately on each peak with the five values recorded at each of the times considered. At t_{0+6} hr, a significant increase (6.3, 5.8, 9.5, 7.1 and 8.6 times in the case of peaks 23, 26, 28, 42, and 45 + 46

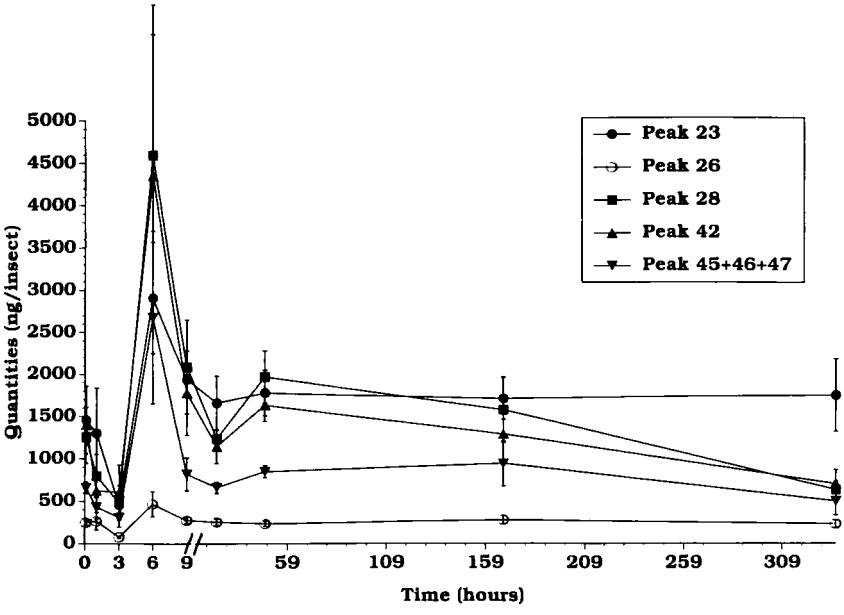

FIG. 2. GC analysis of cuticular hydrocarbons in workers topically treated ($N = 5$) with 1 μl of pentane. Points represent means and bars the standard error (SE). For each time period, five workers were analyzed. Peak 23 = 4/2-me-C_{30}; peak 26 = n-C_{31}; peak 28 = 15-me-C_{31} + 13-me-C_{31} + 11-me-C_{31}; peak 42 = 15-me-C_{33} + 17-me-C_{33}; and peaks 45 + 46 + 47 = 1 mixture of 13,17-dime-C_{33} + 13,19-dime-C_{33} + 13,21-dime-C_{33}, 11,17-dime-C_{33} + 11,19-dime-C_{33} + 11,21-dime-C_{33} and 9,17-dime-C_{33} + 9,19-dime-C_{33} + 9,21-dime-C_{33} + 9,23-dime-C_{33}.

+ 47, respectively) in the quantities of all five peaks occurred compared with the values at t_{0+3} hr ($P < 0.05$; Mann-Whitney two-tailed U test). The quantities recorded at t_{0+6} hr were conspicuously higher than at t_0. The differences were significant in the following cases: peak 23 (twofold increase); peak 28 (3.6-fold increase), and peak 45 + 46 + 47 (4.1-fold increase) ($P < 0.05$; Mann-Whitney two tailed U test). The quantities of the methylated products had increased at least two fold at t_{0+6} hr. From t_{0+9} hr onwards, values tended to return to the initial levels; they no longer differed significantly from values recorded at t_0.

The mean weight of the hydrocarbons present in the cuticular mixture at t_0 was 11.4 μg/individual; assuming that all the cuticular products behaved in the same way as the five peaks investigated here. Based on the same assumptions, the total hydrocarbons present at t_{0+3} hr were estimated to be 4.4 μg/individual (which is 2.6 times less than the level measured at t_0). At t_{0+6} hr after the solvent was applied, it was estimated that there would be 34 mg/individual, or more than three times the amount measured at t_0.

The data show that in response to the application of pentane alone, the quantity of hydrocarbons decreased about 2.6-fold during the first 3 hr after the application of pentane, then increased to about three times their initial level during the following 3 hr, and finally returned to normal at about t_{0+9} hr.

Experiment 2. The changes with time in the percentages (Figure 3) of *n*-tetracosane and (*Z*)-9-tricosene measured on the cuticles with respect to the

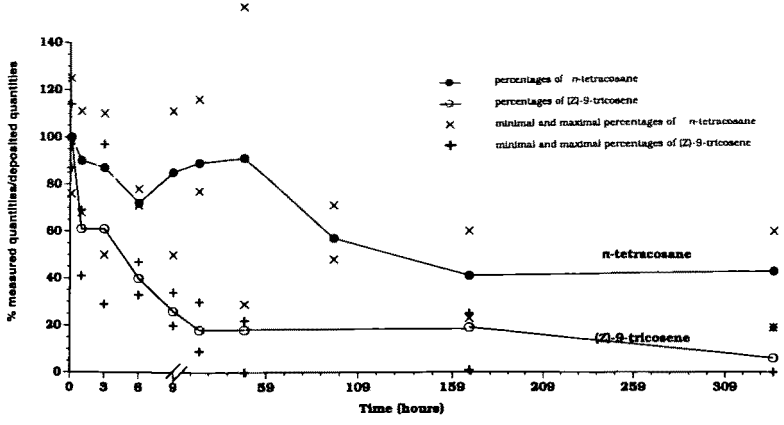

FIG. 3. Percentages of *n*-tetracosane and (*Z*)-9-tricosene measured in topically treated workers isolated at different time periods and cuticular extracts analysed by GC. The *n*-tetracosane was deposited at 800 ng in 1 μl of pentane and the (*Z*)-9-tricosene at 500 ng in 1 μl of pentane. The percentages were calculated from quantities initially deposited at t_0.

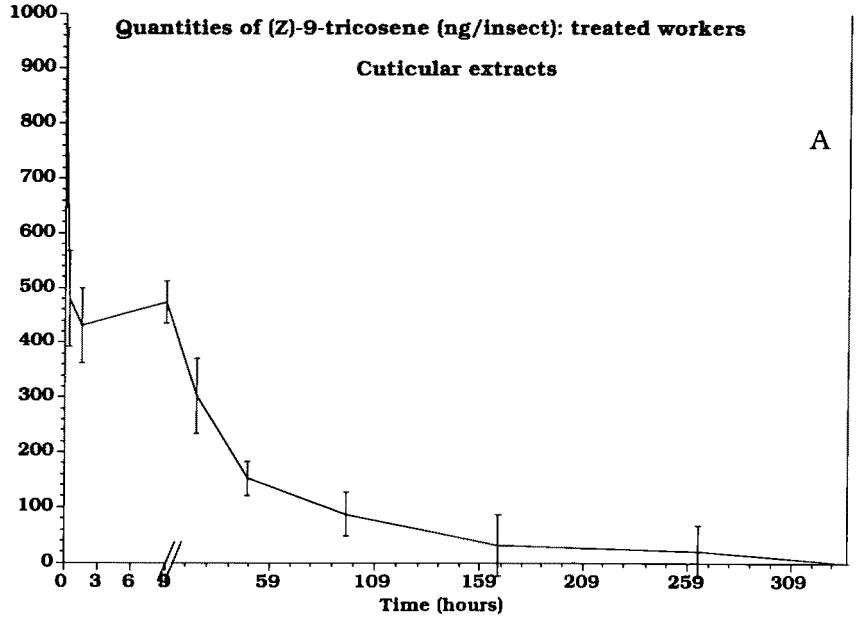
amounts initially deposited at t_0 showed the occurrence of a slower decrease of *n*-tetracosane (half of the amount deposited remained between t_{0+96} and t_{0+168} hr), and a faster decrease of (*Z*)-9-tricosene (half of the amount deposited remained between t_{0+3} and t_{0+6} hr). From t_{0+48} to t_{0+336} hr, the percentage levels of *n*-tetracosane stabilized, whereas those of (*Z*)-9-tricosene tended to decrease.

Changes with Time in Quantities of Added (Z)-9-*tricosene on Cuticles and in Postpharyngeal Glands of a Group Consisting of One Treated and Five Untreated Workers*

Experiment 3. The mean quantity of (*Z*)-9-tricosene applied in this test was 890 ng (SD = 89). The mean quantity of (*Z*)-9-tricosene measured on the cuticle at time t_0 (at the beginning of cohabitation, 1 hr after application) was 810 ng/insect (SD = 168) (Figure 4A). The quantity decreased to 474 ng/insect (SD = 40), about half the initial level, after cohabitation period of 9 hr, and then continued to decrease with time. At 336 hr, the amount of (*Z*)-9-tricosene remaining on the cuticle was practically zero.

(*Z*)-9-Tricosene was detected on the cuticles of the nontreated workers (Figure 4B) only after cohabitation periods of 96 and 168 hr. After 96 hr, the cuticular extracts of 32% of the nontreated workers (eight of the 25 nontreated workers in the five groups studied) contained on average 30 ng/insect (SD = 11); the mean level measured on all 25 nontreated workers was 10 ng (SD = 15). The total amount of (*Z*)-9-tricosene (243 ng) present in the nontreated workers was confirmed by the GC-MS data. After 168 hr of cohabitation, the cuticles of 24% of the nontreated workers (six of 25) contained on average 40 ng/insect (SD = 15), and the mean calculated for all 25 workers studied was 10 ng (SD = 18). At t_{0+168} hr, the total amount of (*Z*)-9-tricosene recorded, 241 ng, was confirmed by the data obtained using the silica–silver nitrate microcolumn followed by the GC and GC-MS. The (*Z*)-9-tricosene subsequently disappeared completely from the cuticles of nontreated workers (cohabitation times of 264 and 336 hr).

Experiment 4. The mean quantity of (*Z*)-9-tricosene deposited on the thorax of the treated workers was 867 ng (SD = 140). The results (Figure 4C) show that the mean quantities of (*Z*)-9-tricosene present in the postpharyngeal glands of some of the treated and nontreated workers amounted to 69 ng (SD = 66), i.e., to 9% of the total amount deposited; whereas in other cases mean values of 43 ng (SD = 28) equal to 5%, and 53 ng (SD = 36) equal to 7%, of that initially deposited were recorded after periods of cohabitation of 30 min (10 workers from five groups), 90 min (five workers from five groups) and 9 hr (10 workers from six groups). The highest levels recorded were those obtained on the whole set of treated and nontreated individuals belonging to the five groups under investigation at a cohabitation time of 24 hr. Low levels were observed



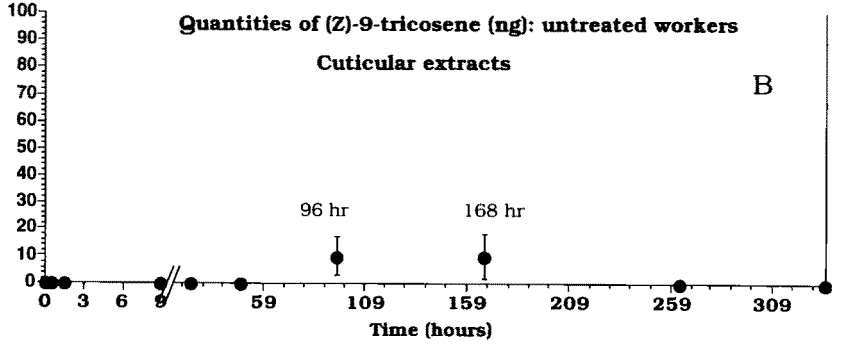


FIG. 4. Mean quantities of (Z)-9-tricosene measured with time in groups of workers. A worker was topically treated with 1 μl of the (Z)-9-tricosene solution at 1000 ng/μl pentane approximately, isolated 1 hr, and then placed with five untreated workers to form a group. Cuticular extracts were analyzed after various time periods, and (Z)-9-tricosene was quantified in treated workers (A) and in untreated workers (B). Extracts from postpharyngeal glands were analyzed from treated and untreated workers (C) for the same time intervals. Bars represent the 95% confidence intervals.

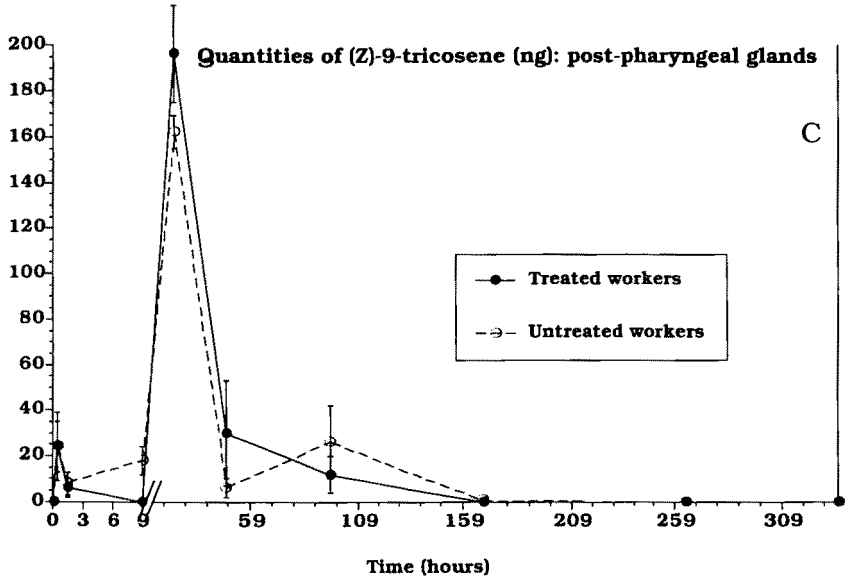

FIG. 4. Continued.

at 48 and 96 hr of cohabitation (five of 54 workers and 12 of 30 workers, respectively), and the levels tended towards zero at cohabitation periods of 168, 264, and 336 hr (Figure 4C). The presence of (Z)-9-tricosene was confirmed by the GC-MS data obtained on a mixture of two cuticular extracts from two individuals chosen at random among the set of treated workers.

In order to determine the combined amounts of (Z)-9-tricosene present over time in a small group of individuals, the mean totals present on the cuticles and in the postpharyngeal glands of treated and nontreated workers were measured (Figure 5). Three phases were distinguished in this way: first, it was observed that at cohabitation times of 30 and 90 min and 9 hr, the mean total quantities of (Z)-9-tricosene measured both on the cuticles and in the postpharyngeal glands of the workers were lower than those measured at t_0 (at the beginning of cohabitation) (Figure 5); at the same time, the quantities measured in the postpharyngeal glands were low and amounted to only 18%, 6% and 12%, respectively, of the levels measured at the beginning of cohabitation. An overall loss of (Z)-9-tricosene therefore occurred during cohabitation, amounting to the difference between the total amounts measured at both loci and those measured at the beginning of cohabitation. This loss amounted to around 23%, 41%, and 30% at the above respective cohabitation times.

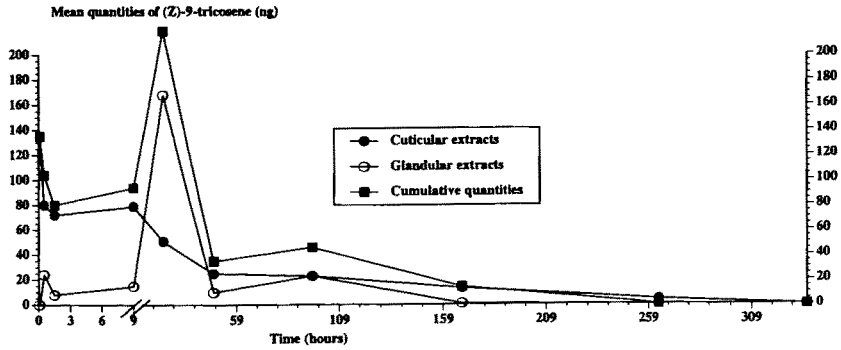

FIG. 5. Mean of the total quantity of (Z)-9-tricosene measured with time in cuticular extracts (experiment 3) and postpharyngeal glands extracts (experiment 4) in groups of workers. A worker was topically treated with 1 μl of the (Z)-9-tricosene solution at 1000 ng/μl pentane approximately, isolated 1 hr, and then placed with five untreated workers to form a group. Cuticular and glandular extracts were analyzed after several time periods, and the (Z)-9-tricosene was quantified in treated and untreated workers. The total quantity was calculated by group, and the mean calculated on all groups for each time period.

During the second phase, which corresponded to 24 hr of cohabitation (Figure 5), the mean total amount of (Z)-9-tricosene recorded per individual was similar to that observed at t_0. During the same period, the total amounts of (Z)-9-tricosene recorded reached a maximum in the postpharyngeal glands.

From cohabitation periods of 48–336 hr (third phase) (Figure 5), the mean combined quantities of (Z)-9-tricosene per individual decreased to zero, and the differences in comparison with the amounts initially deposited gradually increased.

Experiment 5. In the experiments where the treated worker was separated from the nontreated workers in the group by a double layer of wire mesh, the mean amount of (Z)-9-tricosene present in the cuticular extracts of the treated workers (in the case of the five groups studied for 24 hr) was 264 ng (SD = 82). (Z)-9-Tricosene was detected in the postpharyngeal glands of two of the five treated workers (10 ng and 71 ng). Among the nontreated workers, which were separated from the treated member of the group by the wire mesh, not even a trace of (Z)-9-tricosene was detected either in the cuticular extracts or in the extracts obtained from the postpharyngeal glands. When no physical contact was possible between the treated and nontreated individuals, (Z)-9-tricosene was therefore neither transferred nor synthesized.

DISCUSSION

The application of an apolar solvent (pentane) to the cuticle of a *Camponotus vagus* worker led to a significant decrease (2.6-fold) within 3 hr in the amounts of the cuticular products investigated. A threefold increase in the levels of these substances then occurred with respect to the initial levels (t_0) during the t_{0+3} to t_{0+6} hr period, followed by a return to the initial values and a period of relative stability that persisted for up to two weeks. The rebound and increase in cuticular hydrocarbons between 3 and 6 hr after treatment may be due to enhancement of biosynthesis. In ants, the site of hydrocarbon biosynthesis is probably located in the oenocytes, as hypothesized in the case of *Apis mellifera* (Piek, 1964) and other insects (Lockey, 1988).

The data showed that a very fast decrease occurred in applied (Z)-9-tricosene, which is not normally synthesized (according to the GC-MS identification of the extracts analyzed with a threshold of sensitivity of 1 pg/ant). The (Z)-9-tricosene curve was that of an exponential function in the case of single treated individuals during the experiment as well as in that of mixed groups. Half of the amount deposited had disappeared (ie., "half-life" was reached) in about 6 hr after application. It was no longer detectable after a period of 14 days. In contrast, a substance synthesized by the species in small quantities, *n*-tetracosane, stabilized at lower levels than that deposited on the cuticle, but at much higher levels than occurred naturally in cuticular wax. Half of the quantity of *n*-tetracosane deposited disappeared within 140 hr [as compared with 6 hr in the case of (Z)-9-tricosene]. These data show that differences existed depending on the nature of the cuticular hydrocarbon. When the component was normally present among the cuticular hydrocarbons, its quantity decreased but became stable at a particular level; when the component was not normally present, it disappeared quickly.

Added (Z)-9-tricosene may have been mostly metabolized. It probably cannot be resynthesized by *C. vagus*, which seems unlikely to possess the appropriate enzymatic system for synthesizing this substance. Blomquist et al. (1984) suggested that when (Z)-9-tricosene, the sexual pheromone of the female housefly, is deposited on the cuticle of the male, which does not normally synthesize it, the pheromone may be internalized and metabolized into epoxide and ketone products that are then incorporated into the cuticle. The eight-hour "half-life" of added (Z)-9-tricosene recorded in their study of male houseflies is similar to what we have found when it is added to the cuticle of *C. vagus*. Blomquist and Jackson (1973) reported that in the grasshopper, *Melanoplus sanguinipes*, *n*-alkanes with 21 to 29 carbon atoms administered to the cuticle surface were quickly metabolized; the lighter ones were more readily metabolized than the heavier ones, and around 30% of the *n*-tricosane, for example,

was metabolized into secondary alcohols within 18 hr. In our study with *C. vagus*, *n*-tetracosane with a "half-life" of about 140 hr may possibly be resynthesized.

All the treated and nontreated workers at t_{0+24} hr had (*Z*)-9-tricosene in their postpharyngeal glands, and the amounts detected were related to that deposited on the treated worker in contact with a group of nontreated ones. Between 24 and 96 hr, few workers had (*Z*)-9-tricosene in their postpharyngeal glands, and none carried this substance on their cuticle. Only after 96 and 168 hr did we detect small quantities of (*Z*)-9-tricosene on the cuticles (around 1% on average of the amount initially administered). These results suggest that in a treated worker (*Z*)-9-tricosene applied to the cuticle may have been transported to the postpharyngeal glands via the hemolymph. The presence of (*Z*)-9-tricosene in the postpharyngeal glands of nontreated workers after 24 hr of cohabitation with the treated one suggests that (*Z*)-9-tricosene must have been transferred from the one treated individual to the others. The transfer probably occurred during interactions such as trophallactic exchanges and licking activities. Separation of the treated individual from nearby workers by the presence of a double wire mesh prevented these exchanges from occurring. During trophallactic exchanges, (*Z*)-9-tricosene must have been transferred from the postpharyngeal glands of the treated worker to those of the nontreated workers, and during licking activities, this substance must have been transferred from the cuticle of the treated worker to the postpharyngeal glands of the nontreated workers. The fact that no (*Z*)-9-tricosene was detected during the first few hours of cohabitation on the nontreated workers' cuticles shows that the transfer was never effected simply by a cuticle-to-cuticle contact between treated and untreated workers. Large quantities of (*Z*)-9-tricosene were detected in postpharyngeal glands of nontreated workers at a cohabitation time of 24 hr, followed by small quantities only at later times. No traces of (*Z*)-9-tricosene were detected on the cuticles of the ants. It seems reasonable to hypothesize that (*Z*)-9-tricosene may have traveled from the postpharyngeal glands to the cuticle via an internal pathway. Vinson et al. (1980) established that triolein, a triglyceride, was transferred by the hemolymph partly via the postpharyngeal glands of the *Solenopsis invicta* queen. In a recent study, Soroker and Hefetz (poster at the congress held in Tampa, Florida, in 1993) established that the postpharyngeal glands of *Cataglyphis niger* stored hydrocarbons that were synthesized at the cuticular level and not by the postpharyngeal glands themselves. Zylberberg et al. (1974) suggested that the postpharyngeal glands may be involved in selectively absorbing ingested lipids present in nutrients, and thus may play an alimentary role.

It has been established that recognition signals of genetic origin, or discriminators as they have been called, can be produced either mainly by the workers (Morel et al., 1990) or mainly by the queens (Carlin and Hölldobler, 1986). The genetically determined hydrocarbons may be stored in the post-

pharyngeal glands and transferred between the members of a social group during trophallaxis, licking, and grooming activities, according to a gestalt model (Crozier and Dix, 1979) where individuals may consistently regulate and adjust their chemical signals so as to homogenize the substances involved in the recognition processes. Regulatory processes of this kind may constitute one of the mechanisms whereby social cohesion is maintained. They may help to give us a better understanding of the mechanisms involved both in the cohabitation that occurs in artificially mixed colonies of *Manica rubida* and *Formica selysi* (Bagnères et al., 1991b), in the changes observed with time in some of the hydrocarbons carried by *Solenopsis invicta* (Vander Meer et al., 1989b), and in the synchronous patterns of change occurring with time in the cuticular hydrocarbon mixture of *Leptothorax lichtensteini* (Provost et al., 1993).

INDOLE AS AN OLFACTORY SYNERGIST FOR VOLATILE KAIROMONES FOR DIABROTICITE BEETLES

ROBERT L. METCALF,* RICHARD L. LAMPMAN, and LESLEY DEEM-DICKSON

Department of Entomology, University of Illinois Urbana-Champaign, Illinois 61801

(Received October 4, 1994; accepted April 6, 1995)

Abstract—Olfactory synergism, where combinations of plant volatile kairomones are quantitatively more attractive to insects than the sum of attraction of the individual components, is an important but little-studied phenomenon in host plant selection and feeding and in pollination ecology. Diabroticite beetles (Coleoptera: Chrysomelidae) are strongly attracted to *Cucurbita* blossoms, and 2- to 3-fold olfactory synergism has been demonstrated in four species by combinations of the key blossom volatiles, 1,2,4-trimethoxybenzene, indole, and (*E*)-cinnamaldehyde. This TIC mixture represents an optimized *Curcurbita* blossom volatile kairomone mixture useful in monitoring Diabroticite populations and in studying their behavior and ecology. Indole, which exhibits a spectrum of attraction to these beetles ranging from moderate for *Diabrotica virgifera virgifera* and *Acalymma vittatum* to very weak for *D. barberi*, is the primary synergistic component. Indole combined with 4-methoxycinnamaldehyde was significantly synergistic to *D. v. virgifera* at a ratio of 1:300 and produced 4-fold synergism at a ratio of 1:1. Indole combined with 4-methoxyphenethanol was less synergistic to *D. barberi* with 1.5- to 2-fold synergism at a 1:1 ratio. These consistent variations in diabroticite beetle olfactory responses presumably indicate evolutionary divergences in the numbers of relict indole antennal receptors.

Key Words—Kairomonal attractants, Diabroticite beetles, Coleoptera, Chrysomelidae, olfactory synergism, trimethoxybenzene, indole, cinnamaldehyde, 4-methoxycinnamaldehyde, 4-methoxyphenethanol.

INTRODUCTION

Abundant evidence from chemical ecology supports the viewpoint that diabroticites (Coleoptera: Chrysomelidae: Luperini) coevolved with plants of the fam-

ily Cucurbitaceae (Metcalf, 1986, 1994; Metcalf and Lampman, 1989c). The preponderance of species for which host records are available were collected from foliage, blossoms, and fruits of this family. This, combined with the fact that the tetracyclic triterpenoid cucurbitacins, characteristic of the Cucurbitaceae, are arrestants and phagostimulants for *Diabrotica* spp. in quantities as small as 5×10^{-12} to 1×10^{-9} g (Metcalf et al., 1980; Peterson and Schalk, 1985), indicates a coevolutionary relationship. The aggregations of diabroticite beetles commonly found in *Cucurbita* blossoms, where they feed avidly on pollen, are the result of concerted attraction from an array of blossom volatiles that increases the arrival rate acting together with the arrestant properties of the cucurbitacins that delay departure (Andersen and Metcalf, 1987; Metcalf and Lampman, 1989c, 1991; Lewis et al., 1990). Coleoptera are considered to be the most primitive pollinators of the angiosperms and were probably associated with open bowl-shaped flowers, where the beetles fed on floral secretions, nectar, and pollen (Kevan and Baker, 1983). *Diabrotica* spp. are among the most important pollinators of *Cucurbita* spp. (Avila et al., 1989).

The blossoms of *Cucurbita maxima* Duchesne produce an array of more than 40 volatile chemicals (Andersen and Metcalf, 1986, 1987), of which 22 have been identified by GC-MS (Andersen, 1987). Extensive field evaluations have shown that at least 10 of these volatile compounds are kairomone attractants for both sexes of diabroticites (Lampman et al., 1987; Metcalf, 1994; Metcalf and Lampman, 1989a–c). Most of these volatiles are phenyl propanoids formed through the shikimic acid pathway from phenyl alanine to cinnamic acid, which is produced in relatively large amounts during pollen maturation in blossoms (Wierman, 1981).

All of the four diabroticites examined in field studies are attracted to chemically related phenyl propanoids; however, each species has an intrinsic and characteristic pattern of response when exposed to an array of *Cucurbita* blossom volatiles (Lampman and Metcalf, 1988; Metcalf and Lampman, 1991; Metcalf, 1994). Indole is a condensed phenyl propanoid that is a major component of the rich, heavy aroma of squash blossoms and is attractive to the western corn rootworm, *D. virgifera virgifera* LeConte, and to the striped cucumber beetle, *Acalymma vittatum* (F.). However, indole alone is only slightly attractive to the southern corn rootworm *D. undecimpunctata howardi* Barber and is unattractive to the northern corn rootworm *D. barberi* (Smith and Lawrence) (Andersen and Metcalf, 1986; Lewis et al., 1990; Metcalf, 1994). During the summers of 1986–1994, we evaluated more than 30 combinations of volatile components identified from the blossom aroma of *C. maxima* (Andersen and Metcalf, 1987; Andersen, 1987) as attractants for adult diabroticites and found indole to be a key component of blossom volatile mixtures that were strongly attractive to all four species investigated (Metcalf et al., 1993) (Figure 1). Thus the role of indole as a diabroticite host plant kairomone is complex.

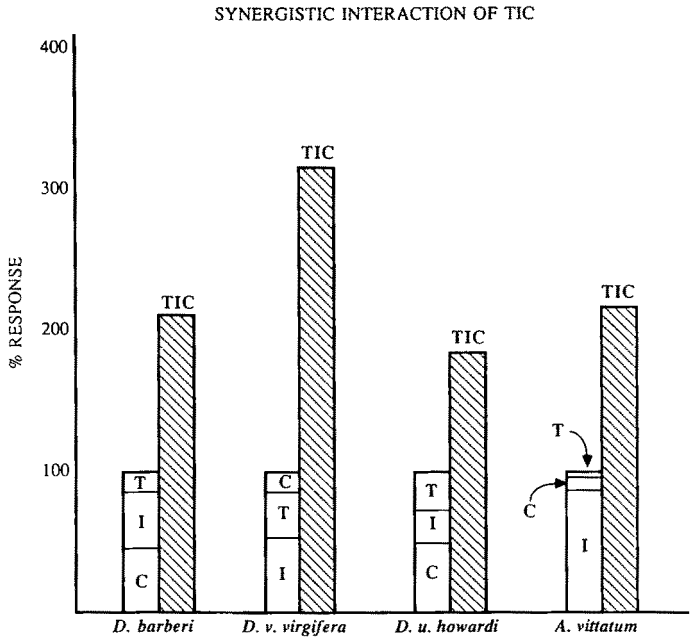

FIG. 1. Synergistic interactions of 1,2,4-trimethoxybenzene (T), indole (I), and (*E*)-cinnamaldehyde (C) to four species of diabroticites. Each compound at 20 mg/trap, separately (open), combined (shaded).

A mixture of equal parts of veratrole, indole, phenyl acetaldehyde, anethole, and eugenol (VIPAE) applied at 100 mg/sticky trap, showed a mean trap catch of *D. u. howardi* adults of 28.0 ± 1.8 times that of the unbaited controls ($N = 4$) (Lampman and Metcalf, 1987). The relationship between log dosage of VIPAE and mean beetle catch was linear over a range of 1–300 mg of lure per trap ($r^2 = 0.98$, $P < 0.001$). Further evaluation of the role of each of the components led to simplification of the lure mixture to equal parts of veratrole, indole, and phenyl acetaldehyde (VIP), which was approximately as attractive to *D. u. howardi* as the VIPAE mixture. However, the catch of *D. v. virgifera* adults by the VIP mixture was not greater than that of indole alone (Lampman and Metcalf, 1987). Further elaboration of the volatile components of *C. maxima* blossoms suggested the substitution in the VIP mixture of 1,2,4-trimethoxybenzene (T) for veratrole, and (*E*)-cinnamaldehyde (C) for phenyl acetaldehyde. These, combined in equal proportions with indole (I), formed the TIC mixture that was as attractive to *D. u. howardi* adults as the VIP mixture and was equally attractive to *D. v. virgifera* adults (Lampman and Metcalf, 1987). Used at 60

mg/trap in experiments conducted during 1986–1989, the TIC mixture showed a mean trap catch of *D. u. howardi* of 35.9 ± 54.1 times that of the unbaited controls ($N = 5$) and for *D. v. virgifera* of 43.7 ± 66.3 times that of the unbaited controls ($N = 8$) (unpublished data). The TIC mixture was also strongly attractive to *Acalymma vittatum* adults and, when applied at 60 mg/trap, showed a mean catch of 14.3 ± 10.9 times that of the unbaited controls ($N = 8$) (Lewis et al., 1990).

From these investigations, we concluded that the TIC mixture represents an optimized *Cucurbita* blossom volatile kairomone that is highly attractive to diabroticite species. In this report we further characterize the role of indole as an olfactory synergist for kairomone lures to various species of Diabroticites.

METHODS AND MATERIALS

Attractants and Field Trapping. The chemicals evaluated as lures were all 98% pure by GC and were purchased from Aldrich Chemical Co., Milwaukee, Wisconsin; except for 4-methoxycinnamaldehyde, which was obtained from Chemical Dynamics, Plainfield, New Jersey. The multicomponent TIC lure was a 1 : 1 : 1 mixture of 1,2,4-trimethoxybenzene, indole, and (*E*)-cinnamaldehyde. Solid lures such as indole and 4-methoxycinnamaldehyde were diluted with reagent-grade acetone before application.

The relative effectiveness of the various lures was determined by baiting white, 1-liter cylindrical paper cartons coated with TangleTrap insect adhesive (Tanglefoot Company, Grand Rapids, Michigan). These traps were inverted over 1-m lath stakes placed approximately 10 m apart in a linear randomized complete block design at the edge of hybrid corn fields infested with adult *Diabrotica* corn rootworms. The lures were dispensed quantitatively from capillary micropipets onto cotton dental wicks (Table 1) or onto 5 × 5-cm squares of blotting paper (Tables 2 and 3), affixed to the top center of the sticky trap. The individual lure components were applied to separate sections of wick or blotting paper, to obviate interference with volatility. The three components of TIC were thoroughly mixed and applied as a mixture. Under each experimental date, four replicate traps were run at each dose together with four untreated control traps. The adult beetle catch was counted at either 4 or 24 h after treatment, depending upon the densities of the beetle populations.

Statistical Analyses. The significance of the treatments in the experiments reported was determined by two-way ANOVA on transformed data [log (x + 1)], and where appropriate, individual means were separated by Fisher's protected least significant difference test (PLSD) (Statview, 1992; Norusis, 1988). For evaluation of dose–response data, linear regression analysis of the mean number of beetles per trap as a function of logarithm of dose was computed (Statview, 1992; Sokal and Rohlf, 1973).

Olfactory synergism is defined as the more than additive response of diabroticite beetles (trap catch) to a mixture as compared with the summed responses to its component parts and is illustrated in Figure 1. The synergistic ratio (SR) is the ratio of the mean trap catch of the mixture (control subtracted) to the summation of the mean trap catches of the components (controls subtracted).

RESULTS AND DISCUSSION

Olfactory Synergism of Indole with Cinnamaldehyde and Trimethoxybenzene. Several years of extensive investigations (Metcalf and Lampman, 1989c; Metcalf, 1994) have demonstrated that indole is the key component of *Cucurbita* blossom volatiles in promoting olfactory synergism among the several species of Diabroticites. The experiments summarized in Table 1 show the synergistic ratio (SR) for catches of *D. v. virgifera* on cylindrical sticky traps baited with 20 mg of the several components of the TIC mixture. As shown in Table 1, indole together with trimethoxybenzene (TI) was strongly synergistic with a

[b]Means for each test date followed by different letters are significantly different ($P < 0.05$) by Fisher's PLSD test.

mean SR for three investigations of 3.5 ± 2.7. Indole together with cinnamaldehyde (CI) was also synergistic, with a mean SR for four evaluations of 1.9 ± 0.9. However, in contrast cinnamaldehyde together with trimethoxybenzene (TC) showed no evidence of olfactory synergism.

The three components—indole, cinnamaldehyde, and trimethoxybenzene—used together (TIC) were strongly synergistic, with a mean SR for four evaluations of 2.3 ± 0.9. It should be evident that synergism between an active component and an inactive component may produce higher synergistic ratios than that between two active components, e.g., indole and cinnamaldehyde.

Olfactory Synergism to Several Diabroticite Species. Indole is the key *Cucurbita* blossom volatile, producing olfactory synergism not only to *D. v. virgifera*, as demonstrated in Table 1, but also to other related species, all of which feed on pollen in *Cucurbita* blossoms. The dose–responses of the several species to indole alone in field experiments with cylindrical sticky traps ranges from a limit of response (LR) of approximately 1 mg per trap for *D. v. virgifera* and *Acalymma vittatum* to 20 mg for *D. u. howardi* and to 200 mg for *D. barberi* (Andersen and Metcalf, 1986; Lewis et al., 1990; Metcalf, 1994). However, the TIC mixture is synergistic to all four species, as shown in Figure 1 from data of typical field experiments (Lewis et al., 1990, unpublished data) where the sum of the trap catches for the individual TIC compounds, at 20 mg

each was normalized to 100 and compared to the normalized catches of the TIC mixture at 60 mg/trap. Figure 1 portrays synergistic ratios of 2.1 for *D. barberi* (July 7, 1988), 3.2 for *D. v. virgifera* (July 2, 1988), 1.8 for *D. u. howardi* (Sept. 13, 1986), and 2.1 for *A. vittatum* (Aug. 2, 1988) (Lewis et al., 1990).

Olfactory Synergism of Indole with Methoxycinnamaldehyde. Methoxycinnamaldehyde (MCA) is the most effective single component kairomone-type lure yet found for adult *D. v. virgifera* (Metcalf and Lampman, 1989a). It is an effective lure for both sexes and the male/female trap catch was 108/356 = 0.30 (Aug. 8, 1987) and was 62/37 = 1.67 (Aug. 25, 1993). In 23 comparisons ($N = 4$ traps each) in hybrid corn conducted during July, August, and September of 1987–1993, the one-day mean capture of *D. v. virgifera* beetles on 1-liter cylindrical sticky traps baited with 100 mg of MCA was 182.5 ± 82.0 as compared with a mean of 7.1 ± 12.0 beetles captured on an equal number of unbaited control traps. Therefore the MCA-baited traps captured a mean of 25.7 times more *D. v. virgifera* adults than the controls. MCA is an almost specific lure for *D. v. virgifera* adults, and in 18 comparisons over the same years, the MCA-baited traps captured a mean of only 2.5 ± 3.4 *D. barberi* beetles as compared with a mean of 2.7 ± 3.9 for unbaited controls. In 16 comparisons, the MCA-baited traps captured a mean of only 0.9 ± 2.0 *D. u. howardi* beetles as compared with a mean of 0.7 ± 1.2 for unbaited controls.

The limit of response for *D. v. virgifera* to MCA is approximately 0.03 mg/trap as compared to 1.0 mg for indole (Andersen and Metcalf, 1986; Metcalf and Lampman, 1991). Although MCA has not been isolated from *Cucurbita* blossoms, it is a widely distributed natural product (Metcalf and Lampman, 1991) and is likely to be present in *Cucurbita* blossom aroma because of the presence there of relatively large amounts of cinnamaldehyde, di- and trimethoxybenzene, and 4-methoxybenzaldehyde (Andersen, 1987).

Methoxycinnamaldehyde has a relatively low volatility and has a release rate of only about 0.012 that of indole (Metcalf and Lampman, 1991). Despite this nearly 100-fold disparity in release rates, when MCA and indole were compared at 20 mg/cylindrical sticky trap as lures for *D. v. virgifera* beetles, the mean trap catches from four experiments averaged 10.0 ± 6.7-fold greater for MCA than for indole ($N = 4$) as shown in Table 2. Similar experiments comparing MCA at 20 mg with TIC at 20 mg (ca. 7 mg indole) showed that the mean trap catches of *D. v. virgifera* were almost equal, with an average MCA/TIC ratio of 0.98 ± 0.22 for four experiments ($N = 4$ traps each). This information provides further demonstration of the remarkable olfactory synergism of the TIC mixture.

The ranges of olfactory synergism of mixtures of MCA and indole to *D. v. virgifera* beetles were compared using 20 mg of MCA and a range of doses of indole, from 0.02 to 20 mg, applied to separate sections of blotting paper squares in simultaneous experiments with cylindrical sticky traps (Table 2).

When applied in equivalent doses of 20 mg in four experiments, the mean trap catches for the mixture as compared to the additive catches of the separate components (controls subtracted) showed a mean synergistic ratio (SR) of 4.0 ± 1.3. Further comparisons (Table 2) using MCA at 20 mg and decreasing the amounts of indole, showed only a gradual reduction in SR, which averaged 2.7 at 20 mg:2 mg, 1.6 at 20 mg:0.2 mg, and 1.0 at 20 mg:0.02 mg. Linear regression of the synergistic ratio versus the log dose of indole in the MCA/indole mixtures evaluated in a single field over a short period of time (August 6–17, 1993), shows a highly significant relationship (Figure 2).

The appreciable olfactory synergism (Table 2, Figure 2) at a trap dose of 100 parts of MCA to 1 part of indole appears to result from the approximately 100-fold difference in the release rates of the two lures, so that approximately equal concentrations of MCA and indole were present throughout the "active space" downwind from the baited traps. However, since even at equivalent trap doses, MCA was approximately 10 times more attractive than indole as a lure for *D. v. virgifera* (Table 2), concentrations of indole throughout the MCA active space ranging from 1- to 100-fold greater than those of MCA must have an indirect effect in modifying the *D. v. virgifera* behavior, presumably by central nervous system interactions (Mustaparta, 1990).

Olfactory Synergism of Indole with Methoxyphenethanol. Methoxyphenethanol (MPE) is an effective single-component kairomone lure for adult *Diabrotica barberi*. It is a lure for both sexes and the male/female trap catch was

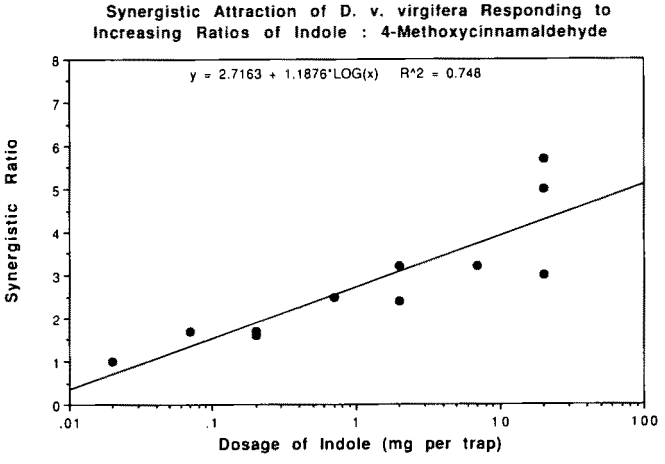

FIG. 2. Relationship between synergistic ratio and dose of indole together with 20 mg 4-methoxycinnamaldehyde per sticky trap ($N = 4$) to *Diabrotica v. virgifera* (1993 data from Table 2). Regression line is significant at $P = 0.01$.

7/45 = 0.16 (Aug. 16, 1989) and 29/135 = 0.4 (Sept. 9, 1993). In 27 comparisons (N = 4 traps each) conducted during July, August, and September of 1989–1993, the one-day captures of *D. barberi* beetles on cylindrical sticky traps baited with 100 mg of MPE had a mean value of 117.8 ± 156.7 as compared with 5.6 ± 8.1 for an equivalent number of unbaited control traps. Therefore, the MPE-baited traps captured a mean of 21.0 times more *D. barberi* adults than the unbaited control traps. MPE is a highly specific lure for *D. barberi* and in 17 identical comparisons over the same four-year period, the MPE baited traps captured a mean of 3.3 ± 4.4 *D. v. virgifera* adults as compared to a mean of 3.5 ± 4.7 for unbaited control traps. No significant numbers of *D. u. howardi* were captured by the MPE baited traps.

The limit of response of *D. barberi* beetles to traps baited with MPE was approximately 0.1 mg (Metcalf and Lampman, 1991). In contrast, indole is not appreciably attractive to *D. barberi* adults at trap doses as high as 200 mg (Lampman and Metcalf, 1987). When MPE and indole were compared at equivalent 20 mg doses (Table 3), mean trap catches of *D. barberi* averaged 46.0 ± 55.0-fold greater for MPE than for indole (N = 5). The mean trap catches of *D. barberi* with a 1:1 mixture of indole and MPE showed some evidence of olfactory synergism (Table 3); however, the SR values were substantially lower than those recorded for corresponding mixtures of MCA and indole to *D. v. virgifera*. This is to be expected, as indole has consistently been less effective in producing an olfactory response in *D. barberi* either alone or in the TIC mixture.

Atmospheric Behavior of Synergistic Mixtures. The TIC attractant mixture diffuses downwind and produces directed anemotactic flight behavior in diabroticite species that is superficially indistinguishable from that of single-component kairomone odorants. There is, for example, a highly precise relationship between mean beetle trap catch and log dose TIC for *D. v. virgifera* and for *D. u. howardi* (Figure 3), using data from Lampman and Metcalf (1987). These responses of the two *Diabrotica* spp. are virtually identical. A similar relationship was shown for *A. vittatum* (Lewis et al., 1990). Such log dose–odorant response curves are also observed with single odorants such as 4-methoxycinnamaldehyde to *D. v. virgifera* (r^2 = 0.984, P = 0.01) and 4-methoxyphenethanol for *D. barberi* (r^2 = 0.937, P = ca. 0.05) (calculated from Metcalf and Lampman, 1991). These plots are useful in determining the approximate limit of response (LR), which for TIC is about 0.5 mg/trap for *D. v. virgifera* and about 1 mg/trap for *D. u. howardi* (Figure 3). These values compare with that of MCA to *D. v. virgifera* of 0.03 mg/trap and for MPE to *D. barberi* of about 0.1 mg/trap (Metcalf and Lampman, 1991).

Experiments with sticky traps baited with 100 mg of TIC or MCA and placed in newly mowed alfalfa stubble devoid of western corn rootworm beetles and adjacent to corn infested with *D. v. virgifera*, have demonstrated directed

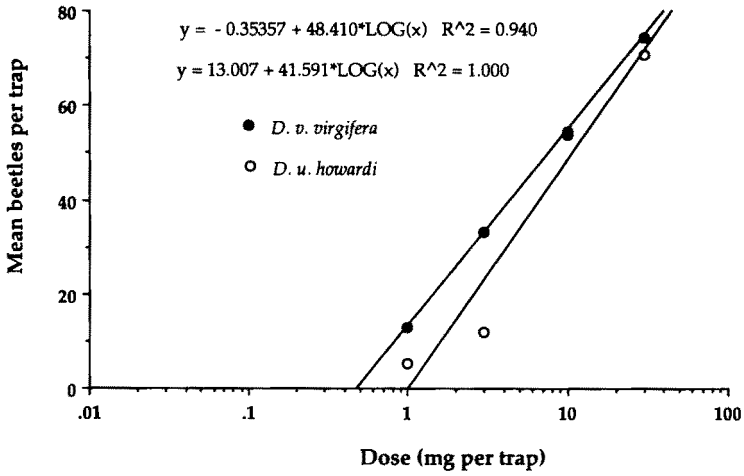

FIG. 3. Relationship of mean trap catch (N = 4) to trap dose for TIC attractant, for *Diabrotica v. virgifera* (P = 0.0001) and *Diabrotica u. howardi* (P = 0.03).

anemotactic searching over distances of at least 100 m in winds of 2–6 m/sec. The mean capture rates for attractant baited/unbaited traps (N = 4, at each distance) were: 10 m TIC 49×, MCA 59×; 30 m TIC 14×, MCA 30×; and 100 m TIC 16×, MCA 20×. The differences in mean capture rates for each lure over the three distances were significant at P = 0.001 (Metcalf and Metcalf, 1992).

The responses of insects to semiochemical odorants are a function of the Q/K ratio, where Q is the release rate of odorant in molecules per second and K is the insect behavioral threshold in molecules per cubic centimeter (Bossert and Wilson, 1963; Metcalf and Metcalf, 1992). Release rates from 20-mg films of the several lures have been measured at 22–24°C and an airflow of 75 cm/sec as: trimethoxybenzene 1.9×10^{14}, indole and cinnamaldehyde both as 1.4×10^{15}, 4-methoxycinnamaldehyde (MCA) as 1.6×10^{13}, and 4-methoxyphenethanol (MPE) as 1.2×10^{14} molecules/sec (Metcalf and Metcalf, 1992). Thus the release rates of indole and cinnamaldehyde, the most volatile of the components of the TIC mixture are approximately 80-fold greater than that of MCA. From this disparity and the 33-fold greater sensitivity of *D. v. virgifera* to MCA (LR 0.03) as compared to indole (LR 1.0) it appears that MCA has a chemosensory activity of about 2750-fold greater than indole (Metcalf and Lampman, 1991).

From these facets of evidence, how can we account for the impressive long-range attractivity of the TIC mixture and the demonstrated synergistic

response of *D. v. virgifera* to indole–MCA mixtures at ratios as low as 0.003? Calculations using the point source atmospheric diffusion model of Bossert and Wilson (1963), where $Q/K = 0.125\ uX_{max}^{7/4}$, indicate that under the conditions noted above, the maximum downwind "active space" (X_{max}) is almost congruent at a ratio of indole/MCA = 0.01. For example, with K assumed as 1×10^5 (Metcalf and Metcalf, 1992) and a wind (u) of 100 cm/sec, the calculated X_{max} for 20 mg of MCA is 32.5 m and for 0.2 mg of indole is 30.0 m (unpublished). Therefore, we suggest that exposure of diabroticites to low levels of indole may stimulate the anemotactic response to search upwind, thus leading them into the odor corridor of the primary kairomone attractant.

The observations discussed above emphasize the complex role of indole as a kairomone for various diabroticites. Indole is a component in *Cucurbita* blossom aroma (Andersen and Metcalf, 1986). This association is a very primitive one, and antennal kairomone receptors to indole must have developed very early in the coevolutionary association of diabroticites and Cucurbitaceae. The presence of indole along with a few other prominent odorants from *Cucurbita* blossoms provided a chemical fingerprint leading diabroticites toward a readily accessible source of nectar and pollen. The indole receptor appears to have been conserved for over 30 million years of diabroticite evolution (Krysan et al., 1989), and remains functional in representatives of both the nondiapausing *fucata* group and in the diapausing *virgifera* group of species. However, evolutionary processes have substantially tempered the nature of the behavioral patterns elicited by depolarization of the indole receptors, probably by reducing the relative numbers of responsive sensilla. In species as diverse as *D. v. virgifera* and *A. vittatum*, there is a clearly defined behavior response to indole, which is much less evident in the sibling species of *D. v. virgifera*, i.e., *D. barberi* and *D. cristata*. In *D. u. howardi*, which probably most clearly resembles the *fucata* group ancestor (Krysan et al., 1989), there is a strong EAG response to the presence of indole but the corresponding behavioral response is suppressed (Andersen and Metcalf, 1986; Lampman et al., 1987).

These interesting evolutionary anomalies can be assessed in a preliminary way by considering the two basic components of the insect nervous system involved in semiochemical communication. The antennal receptors and their associated peripheral nervous system represent the detection system that feeds information into association centers of the CNS where directed behavioral responses are generated (Mustaparta, 1990). As the conservation of the indole receptors has been inferred in the range of species discussed, it appears that evolutionary modifications during speciation have preferentially modified the first integration process in the antennal lobes of the CNS. The extent and magnitude of the synergistic effect resulting from kairomone mixtures containing indole suggest that exposure to very low levels of this kairomone may stimulate

the anemotactic response resulting in upwind searching behavior. It is obvious that the phenomenon of olfactory synergism needs further intensive study.

(Received August 19, 1994; accepted April 6, 1995)

Abstract—The pronotal and elytral defensive secretions of 10 *Oreina* species were analyzed. Species feeding on Apiaceae, i.e., *O. frigida* and *O. viridis*, or on Cardueae (Asteraceae), i.e., *O. bidentata*, *O. coerulea*, and *O. virgulata*, produce species-specific complex mixtures of autogenous cardenolides. *O. melanocephala*, which feeds on *Doronicum clusii* (Senecioneae, Asteraceae), devoid of pyrrolizidine alkaloids (PAs) in its leaves, secretes, at best, traces of cardenolides. Sequestration of host-plant PAs was observed in all the other species when feeding on Senecioneae containing these alkaloids in their leaves. *O. cacaliae* is the only species that secretes host-derived PA N-oxides and no autogenous cardenolides. Differences were observed in the secretions of specimens collected in various localities, because of local differences in the vegetation. The other species, such as *O. elongata*, *O. intricata*, and *O. speciosissima*, have a mixed defensive strategy and are able both to synthesize de novo cardenolides and to sequester plant PA N-oxides. This allows a great flexibility in defense, especially in *O. elongata* and *O. speciosissima*, which feed on both PA and non-PA plants. Populations of these species were found exclusively producing cardenolides, or exclusively sequestering PA N-oxides, or still doing both, depending on the local availability of food-plants. Differences were observed between species in their ability to sequester different plant PA N-oxides and to transform them. Therefore sympatric species demonstrate differences in the composition of their host-derived

secretions, also resulting from differences in host-plant preference. Finally, within-population individual differences were observed because of local plant heterogeneity in PAs. To some extent these intrapopulation variations in chemical defense are tempered by mixing diet and by the long-term storage of PA N-oxides in the insect body that are used to refill the defensive glands.

Key Words—*Oreina* spp., Coleoptera, Chrysomelidae, Asteraceae, Senecioneae, Cardueae, Apiaceae, chemical defense, cardenolides, pyrrolizidine alkaloids, sequestration.

INTRODUCTION

Adult *Oreina* leaf beetles are chemically protected by a secretion oozing from elytral and pronotal glands. Such glands are characteristic of leaf beetles belonging to the Chrysomelinae and some other leaf beetle taxa (reviewed in Pasteels et al., 1988a, 1994). Although only six *Oreina* species have been previously studied, these can be classified into three categories according to their defensive chemistry, exemplifying different defensive strategies.

First *O. gloriosa*, feeding exclusively on *Peucedanum ostruthium* (Apiaceae), relies for its defense on de novo synthesis of cardenolides from a sterol precursor (Van Oycke et al., 1988; Eggenberger et al., 1992). The mixture of cardenolides produced is complex and shows high interindividual variability. Individual variation is in part correlated with physiological factors such as age and mating status (Eggenberger and Rowell-Rahier, 1993), but a strong heritability of the proportions of compounds was demonstrated by full-sib and mother–offspring correlations (Eggenberger and Rowell-Rahier, 1992). Significant differences in the proportions of the cardenolides making up the defensive mixtures also were observed between different alpine populations. These differences were correlated with the genetic distances (estimated from allozyme data) and the geographic distances separating the populations (Eggenberger and Rowell-Rahier, 1991). Three other species, *O. bifrons*, *O. speciosa*, and *O. variabilis*, feeding on Apiaceae, similarly secrete mixtures of cardenolides. The average mixtures are species specific, and their level of similarity correlates with the genetic distances between the species (allozyme electrophoresis) (Rowell-Rahier and Pasteels, 1994). Thus, chemical defense is able to evolve rapidly, possibly in part by genetic drift. In this context, it should be noted that *Oreina* species apparently form metapopulations, the genetic structure of which has been analyzed in two species, *O. cacaliae* and *O. speciosissima* (Rowell-Rahier, 1992). The secretion of cardenolides is considered to be plesiomorphic in the genus, since it is frequently observed in other genera belonging to the same subtribe Chrysolinina (i.e., in the genera *Chrysolina* and *Ambrostoma*) or to a related subtribe, the Doryphorina (genera *Calligrapha* and *Zygogramma*) (Pasteels et al., 1994).

Secondly, *O. cacaliae*, feeding exclusively on members of the Senecioneae (Asteraceae), secretes sequestered plant pyrrolizidine alkaloid N-oxides (PA N-oxides) for defense (Pasteels et al., 1988b; Ehmke et al., 1991). In the beetles studied from the Vosges (France) and the Black Forest (Germany), only PA N-oxides from *Adenostyles alliariae* were sequestered in the defensive secretion, but not PAs from *Senecio fuchsii*, another food plant in the field. PAs from both plants, however, were sequestered in the body (Rowell-Rahier et al., 1991).

Finally, *O. speciosissima*, also feeding on Senecioneae, has a mixed defensive strategy, being able to synthesize cardenolides and to sequester PAs. Interestingly, although the beetles readily sequestered PAs when fed with *A. alliariae* in the laboratory, pooled secretions of beetles collected from two different localities contained, at best, trace amounts of PAs (Rowell-Rahier et al., 1991). In the field, these beetles fed mainly on *Petasites albus*, which is devoid of PAs in its leaves, although *A. alliariae* was equally frequent in one locality. The mixed strategy possibly illustrates an intermediate evolutionary stage, but the flexibility it allows could be selectively advantageous in its own right.

Our ultimate goal is to understand the evolution of chemical defense in the genus. Independent phylogenies based on molecular data will be presented elsewhere. Here, we will focus on the distribution of the three defensive strategies within the genus (i.e., de novo synthesis, sequestration, and mixed strategy) and limit ourselves to adult defense. Larval defense is described by Dobler and Rowell-Rahier (1994a) and Ehmke et al. (in preparation). In the present paper, 10 species will be examined (*O. cacaliae*, *O. speciosissima*, and eight previously unstudied species), bringing the total of species studied to 14, i.e., the majority of species occurring in the Swiss and French Alps. Two main questions will be addressed: How are the different strategies linked to host-plant affiliation, i.e., Apiaceae or Asteraceae, and among the latter, Senecioneae or Cardueae? In sequestering species, how is the defensive chemistry influenced by the local host-plant community? The emphasis will be on the defensive chemistry of beetles collected in the field. Laboratory feeding experiments with a specific food plant will be described only when necessary to confirm the beetles' ability for sequestration.

METHODS AND MATERIALS

Collecting Sites and Host Plants

Unless specified otherwise host-plant affiliations are based on direct observations of feeding beetles. Beetle nomenclature follows Bourdonné and Doguet (1991), and plant nomenclature, Flora Europaea. The species with their host plants are listed in Table 1.

TABLE 1. DISTRIBUTION OF DE NOVO SYNTHESIZED CARDENOLIDES AND SEQUESTERED PAs IN DEFENSIVE SECRETIONS OF *Oreina* spp.

Species	Defensive compound	Host plants	Localities
O. viridis	cardenolides	*Meum athamanticum* (Apiaceae)	Tschiertschen
O. frigida	cardenolides	*Meum athamanticum* (Apiaceae)	Hörnlihütte, Engstligenalb
O. bidentata	cardenolides	*Leuzea rhapontica* (Asteraceae-Cardueae)	Bosco Gurin
O. coerulea	cardenolides	*Centaurea nemoralis* (Asteraceae-Cardueae)	Calmbach, Bad Liebenzell

[a] At best traces; needs confirmation.

Species Feeding on Apiaceae. O. frigida (Weise) was collected at Hörnlihütte above Arosa (Graubünden, Switzerland, 2600 m) and Engstligenalb (Berner Oberland, Switzerland, 2000 m). This species was found under stones at the first location and on *Cirsium spinosissimum* (L.) Scop. (Asteraceae, Cardueae) at the second. In the laboratory, it fed on *Meum athamanticum* Jacq.

(Apiaceae), but also on *Adenostyles alliariae* (Gouan) Kern. (Asteraceae, Senecioneae) and not on *C. spinosissimum*, *Doronicum clusli* (All.) Tausch, or *Petasites albus* (L.) Gaertn. (both Asteraceae, Senecioneae). The food plant of this species was not yet reported.

O. viridis (Duftschmid) was collected at Tschiertschen (Graubünden, Switzerland, above the tree line, 2000 m) under stones. The host plant reported in the literature is *M. athamanticum* (Bourdonné and Doguet, 1991), which is accepted in the laboratory as are other Apiaceae, but no Asteraceae.

Species Feeding on Asteraceae. O. bidentata Bontems was collected at Bosco Gurin (Tessin, Switzerland, 1600 m) on *Leuzea* (=*Centaurea*) *rhapontica* (L.) J. Holub (Asteraceae, Cardueae).

O. cacaliae (Schrank) was collected at Tschiertschen on *A. alliariae* and *Senecio nemorensis* L. (s.str.) (Asteraceae, Senecioneae).

O. coerulea (Olivier) was collected at Calmbach (Black Forest, Germany, 550 m) and Bad Liebenzell (Black Forest, Germany, 550 m) both on *Centaurea nemoralis* Jordan (Asteraceae, Cardueae).

O. elongata (Suffrian) was collected at Col du Lautaret and Col du Petit St. Bernard. (near Briançon, France, 2000 m) on *A. alliariae* and *Adenostyles alpina* (=*glabra*) (L.) Bluff & Fingerh.; Mattmark dam (Valais, Switzerland, 2400 m) on *C. spinosissimum*; and Vallée des Merveilles (Parc National du Mercantour, France, 2500 m) on *Adenostyles leucophylla* (Wild.) Reichenb. and *C. spinossissimum*.

O. intricata (Germar) was collected at Tschiertschen on *S. nemorensis*.

O. melanocephala (Duftschmid) was collected at Hörnlihütte. This species was found under stones, close to *D. clusii*. The beetles fed on *D. clussi*, but not on other Asteraceae or Apiaceae present in the same location. *Doronicum* spp. are the host plants reported in the literature for this *Oreina* by Bourdonné and Doguet (1991).

O. speciosissima (Scopoli) was collected at Tschiertschen mostly on *P. albus*; and occasionally on *S. nemorensis* and *A. alliariae*, and at Zinal (Valais, Switzerland, 1800 m) on *A. alliariae*.

O. virgulata (Germar) was collected at Engstligenalb and Hörnlihütte on *C. spinosissimum*.

Detection and Quantification of Cardenolides in Secretion

For most species, secretions of five or more beetles were collected on pieces of filter paper or in glass capillaries and pooled in methanol. Only two specimens of *O. frigida* and three of *O. melanocephala* were available for study. The methanol extract of pooled secretions was evaporated under vacuum, the residue redissolved in acetonitrile–water 1 : 10, and analyzed after filtration by reverse-phase HPLC [two pump system (Waters 510); detector: photodiode array (Waters

994), 220 nm; column: Macherey-Nagel cartridge, C18, 3 mm, 4 × 130 mm; eluent: chromatography grade acetonitrile (Baker) and water (Merck), 15–42% acetonitrile linear in 36 min, 0.45 ml/min; data analysis system: Maxima 820 data station]. Cardenolides were recognized by their UV spectra. For quantitative analyses, known volumes of secretion were processed and 2 mg ouabain was used as internal standard during HPLC analysis. Quantification of cardenolides was based on peak area measurements and expressed in milligram ouabain equivalents.

Alkaloid Extraction

Individual beetles previously kept frozen at −20°C were ground with quartz sand in 4 ml acidic MeOH (1% HCl) in a mortar for 10 min. After centrifugation the supernatant was divided into two aliquots, which were evaporated under reduced pressure. One aliquot was redissolved in 2 ml of dilute NH_4OH and directly applied to an Extrelut column (3 ml, Merck). PAs were eluted with 20 ml of CH_2Cl_2. After evaporation, the residue was redissolved in 0.1–0.5 ml MeOH. This extract provided the fraction occurring as tertiary PAs in the beetle. To obtain the fraction of total PAs (tertiary PAs and PA N-oxides), the remaining aliquot was redissolved in 2 ml of 0.1 M H_2SO_4 and mixed with Zn dust in excess. The mixture was stirred at room temperature for 4 hr, then the solution was made alkaline and treated as described above. Methanolic extracts of secretions were evaporated to dryness and the residue redissolved in 5 ml of 1 M HCl. Aliquots of 2 ml each were treated to reduce PA N-oxides in tertiary PAs as described above.

Plant leaves were preserved by freezing (−18°C) as soon as possible after harvesting in the field. Following freeze-drying, 0.5–1.0 g of the powdered material was extracted in 25 ml of 0.05 M H_2SO_4 for 3–4 min (Ultra-turrax) and left to stand for 30 min. After centrifugation, one part of the supernatant was adjusted to pH 11 with NH_4OH and applied to an Extrelut column as above. For total PA analysis, part of the acidic supernatant was adjusted to 0.25 M H_2SO_4, mixed with Zn dust, and further processed as described above.

Alkaloid Analysis

PAs were separated and analyzed quantitatively by capillary GC on quartz columns (WCOT, 15 × 0.25 mm DB-1, J & W Scientific) using a Hewlett Packard 5890 series II. Conditions: injector, 250°C; temperature program, 150–300°C at 6°C/min; split ratio, 1:20; injection vol., 1–2 μl; carrier gas, He 0.75 bar; detection, flame ionization and nitrogen detectors. Atropine was used as internal standard. The GC response factors of the major PAs analyzed in these experiments were shown to be almost identical. Retention indices were calculated from cochromatographed hydrocarbon standards.

GC-MS. A Carlo Erba Mega 5160 gas chromatograph, equipped with a quartz column (30 m × 0.32 mm) as specified above, was directly coupled to a quadripole mass spectrometer Finnigan MAT 4515. GC conditions were as specified above (Witte et al., 1993).

RESULTS

Species Secreting Cardenolides and No PAs. All species feeding on Apiaceae as well as those feeding exclusively on Cardueae secrete complex mixtures of cardenolides (Table 1). At least 14 cardenolides were observed in the secretion of *O. bidentata*, 15 in that of *O. coerulea*, 5 in *O. frigida*, 15 in *O. viridis*, and 19 in *O. virgulata*. The secretions of *O. coerulea* from both sites in the Black Forest are very similar, not only in the different compounds observed, but also in their proportions. By contrast, the secretion of *O. bidentata* differs markedly from that *O. coerulea* in the proportions of the constituents. The two species are morphologically very similar (Kühnelt, 1984), but the difference in the composition of the secretions confirms the separation into different species, as in general our analyses show that cardenolide mixtures offer discriminating taxonomic characters (Rowell-Rahier and Pasteels, 1994).

Interestingly, no PAs were observed in the secretion of *O. frigida*, although the beetles accepted *A. alliariae* in the laboratory. Either the beetle is unable to sequester PAs or it mainly fed on *M. athamanticum* in the field. Only a few beetles were available for study, and more experiments are needed to answer this question.

Similarly, PAs were not observed in the secretion of *O. melanocephala* feeding on *D. clusii*. Although PAs were observed in some *Doronicum* (e.g., *D. macrophyllum* and *D. pardalianches*) (Hartmann and Witte, 1994), no PAs were found in *D. clusii* (by TLC analysis of 2 g of dried leaves material). Intriguingly, no or only traces of cardenolides were observed in the few available secretions. More secretion of this rare species is needed for determining what it actually secretes.

Besides cardenolides, all these species may secrete ethanolamine and tyrosine betaine, as do the other previously studied *Oreina* (Pasteels et al., 1994). No attempt was made to identify unambiguously these constituents of unknown function, or to identify the structure of the different cardenolides detected in the secretions.

Species Secreting Sequestered PA N-Oxides and No Cardenolides. O. cacaliae is the only species that secretes host-plant-derived PAs but no autogenous cardenolides. Only PA N-oxides were observed in the beetles' secretions and stored in their bodies, confirming our previous observations (see above). For simplicity, PAs will be designated by their names, omitting the fact that they are in the form of N-oxides.

In Tschiertschen, the beetles were found on both *A. alliariae* and *S. nemorensis*, which grew in close proximity. The glands of wild caught specimens were experimentally emptied, and then the animals were fed for five days on one or the other host plant. After this feeding period, their secretions were collected and both the secretions and the beetles were analyzed for PAs (Table 2). The chemical defense of the beetles depended on the plant on which they fed, but did not exactly mirror food-plant chemistry. The beetles that fed on *A. alliariae* secreted and had in their bodies seneciphylline and senecionine, as did the beetles from the Vosges studied previously (Rowell-Rahier et al., 1991). However, contrary to the latter, they contained traces of other PAs, e.g., doronenine and bulgarsenine, which must have been acquired from *S. nemorensis* in the field. By contrast, beetles fed in the laboratory with *S. nemorensis* secreted

doronenine as the major constituent and also contained in their body significant amounts of bulgarsenine, the major constituent of *S. nemorensis*. Only traces of bulgarsenine were found in the secretions, however, and significant amounts of seneciphylline were observed in both bodies and secretions, possibly sequestered from *A. alliariae* in the field. These data demonstrate that the beetles selectively sequester (and probably metabolize to some extent) certain PAs more than others (Hartmann et al., in preparation). Heterogeneity in the plant community causes heterogeneity in beetle defense. It should be emphasized, however, that the analyses were performed on pooled secretions and the beetles fed for some time in the laboratory. Individual secretions and beetles from the field must be analyzed in order to perceive fully the variation in beetle defense due to plant diversity and heterogeneity.

Species Secreting Both De Novo Synthesized Cardenolides and Host-Derived PA N-Oxides. The mixed defensive strategy was observed in *O. speciosissima* as already reported (Rowell-Rahier et al., 1991), and also in *O. intricata* and *O. elongata* (Table 1). At least 13 cardenolides were observed in the secretion of *O. intricata*, but, as for all species secreting PAs, the presence of PA N-oxides interferes with the detection of cardenolides in HPLC. In Tschiertschen, the beetles fed mainly on *S. nemorensis*, and doronenine was found both in their secretion and their bodies (Table 3), as observed in *O. cacaliae* fed on *S. nemorensis*. However, when this beetle was observed on *A. alliariae* in the field, seneciphylline was sequestered in secretion and body. Both seneciphylline and doronenine were found in the body of one beetle. This beetle presumably had a mixed diet in the field. The body of another beetle contained 255.3 μg/g of seneciphylline and only traces of doronenine, showing that the PA composition may greatly depend on the diet in the field.

The mixed defensive strategy is best illustrated in *O. speciosissima* and *O. elongata*. *O. speciosissima* was observed in Tschiertschen mostly on *P. albus*, which is devoid of PAs in its leaves, but also to a lesser extent on *S. nemorensis* and *A. alliariae*. The beetles sequestered PAs from both *Adenostyles* and *Senecio*, suggesting that they had a mixed diet in the field, like *O. intricata* and probably *O. cacaliae*. In Zinal, *O. speciosissima* fed exclusively on *A. alliariae*. Preliminary analysis by HPLC of secretion from this location indicates that it contains, at best, traces of cardenolides, but the presence of sequestered PAs (characteristic of *A. alliariae*) was obvious.

Striking differences in chemical defense between populations as the result of local differences in the distribution of food plants were also observed in *O. elongata*. Beetles from Mattmark dam fed exclusively on *C. spinosissimum*; no other potential food plants were observed in the vicinity. As expected, they secreted only cardenolides (more than 15 compounds), as no PAs are present in *C. spinosissimum*. This patch of beetles probably has been isolated on *Cirsium* since the building of the dam in 1970. The beetles, however, have kept their

ability to sequester PAs, as proved by feeding them on *A. alliariae* in the laboratory. In contrast, no cardenolides could be detected in the secretion of specimens from the Col du Lautaret, which fed on *A. alliariae*. The secretion contained, however, significant amounts of PAs (Table 4). When the beetles were fed for two weeks on *C. spinosissimum*, after their glands had been emptied before the experiment and again after one week, the renewed secretion at the end of the two weeks contained only PAs obviously mobilized from their body reservoir (Pasteels et al., 1992). Nevertheless, *O. elongata* from the Col du Lautaret do have the capacity to synthesize cardenolides, since cardenolides were found in their eggs and larvae (Dobler and Rowell-Rahier, 1994a). Finally, *O. elongata* collected in the Vallée des Merveilles on either *A. alliariae* or *C. spinosissimum* secreted both cardenolides and PAs. The beetles collected on *Cirsium* contained nearly as much PAs in their secretion and body as those collected on *Adenostyles*, demonstrating that they had also fed on *Adenostyles* (Table 4). A mixed diet in these beetles is not surprising, both plants are growing intimately intermixed in the field.

Interestingly, although the food plants of *O. elongata* contained seneciphylline as a major constituent (Table 5), the secretion and body of the beetles

also contained significant amounts of senecionine and a new PA derivative, oreine (Table 4) (Hartmann et al., in preparation). A similar pattern of PAs was found in the secretion of beetles from a third population, collected in the Col du Petit St Bernard. This contrasts with the PA composition of secretion of *O. cacaliae* fed on the same host plant, where no oreine and less senecionine compared to seneciphylline was found. The amounts of PAs sequestered in the body of *O. elongata* are much larger than the amounts sequestered by the other *Oreina* species (compare data in Table 4 with those in Tables 2 and 3).

O. elongata collected in the Vallée des Merveilles on *Adenostyles* had an average of 3.5 μg (ouabain equivalent) of cardenolides/secretion ($N = 15$, pooled secretions); those collected on *Cirsium*, 2.7 μg ($N = 5$). This is somewhat less, but within the same order of magnitude, as the amount of PAs sequestered in the secretion (Table 4). However, sequestration of PAs in the glands seems to occur much faster than synthesis of cardenolides, as proved by the following experiment. The glands of beetles ($N = 10$) collected on *Adenostyles* were emptied. The beetles were then fed during nine days in the laboratory on *Cirsium* and their secretion collected again. The mean amount of cardenolides was only 0.04 μg (ouabain equivalent)/secretion, but that of PAs was 16.3 μg/secretion, although *Cirsium* does not contain PAs in its leaves. Clearly, PAs stored in the body can be mobilized in the glands before significant amounts of cardenolides could be synthesized.

DISCUSSION

Relation Between Host-Plant Use and Defensive Chemistry. All species studied here, except *O. cacaliae* and possibly *O. melanocephala*, secrete cardenolides. As in the other leaf beetles studied to date, complex mixtures of cardenolides are produced, the mixture being species specific.

PAs are sequestered from species of the tribe Senecioneae, and species feeding exclusively on Apiaceae or Cardueae only secrete autogenous cardenolides in addition to ethanolamine and tyrosine betaine. All species feeding on Senecioneae containing PAs seem able to sequester some plant PAs, sometimes after transformation. Only PA N-oxides are observed in beetles' secretions and stored in their bodies, confirming our previous observations (Ehmke et al., 1991).

Although ethanolamine and tyrosine betaine were not systematically searched for, so far tyrosine betaine was found in all species producing cardenolides with or without PAs, but is clearly absent in *O. cacaliae*, which does not secrete cardenolides. Ethanolamine was detected in all secretions in which it was looked for, not only in the genus *Oreina* (i.e., *O. cacaliae*, *O. gloriosa*, *O. speciosissima*), but also in the Chrysolinina and Doryphorina (Pasteels et al., 1988a, 1994).

Additional experiments are needed to determine if *O. frigida* and *O. melanocephala* conform to these general rules. First, *O. frigida* collected in the field did not secrete PAs, although it is able to feed on *Adenostyles* in the laboratory. The absence of PAs in this species could simply result from the fact that the few beetles collected did not feed on *Adenostyles* in the field or could be due to an inability to sequester. Second *O. melanocephala*, which fed on *Doronicum* devoid of PAs, did not secrete cardenolides or secreted only in trace amounts. More material of this rare species is needed for a better understanding of its secretion and for deciding with confidence if it has lost the ability to synthesize cardenolides, as did *O. cacaliae*.

Sources of Variation in Defensive Chemistry. As expected, important within-species differences are observed in those beetles that sequester PAs, because of local differences in the vegetation. The secretion of *O. cacaliae* from Tschiertschen contained a spectrum of PAs including compounds characteristic of both *A. alliariae* and *S. nemorensis*, whereas the secretion of specimens collected in the Vosges or the Black Forest contained only PAs from *A. alliariae* (Rowell-Rahier et al., 1991). In these localities, *S. nemorensis* is substituted by *S. fuchsii*, which, instead of macrocyclic PAs, contains open-chain mono- and diesters. The beetles from Tschiertschen sequestered PAs from *S. nemorensis* in both their bodies and secretions, whereas the beetles from the Vosges only sequestered PAs from *S. fuchsii* in their bodies, but not in their secretion. PAs from *A. alliariae* were sequestered in both the bodies and secretion of beetles from both localities.

Individual variation in sequestered defense within a population is also to be expected, since the various host plants with different secondary chemistry are distributed in patches of various sizes, and since beetles have low vagility for long periods of time (S. Knoll, unpublished observation). Our results indicate, however, that mixed diets occur in the field. Sequestration and storage of

large quantities of PAs for long periods occur in the body from which refilling the glands is possible. This could temper individual variation in host-derived defense (Pasteels et al., 1992).

Interpopulation variation in chemical defense is even more obvious in the beetles with the mixed defensive strategy, illustrating the flexibility of this mode of defense. In both *O. speciosissima* and *O. elongata*, populations were observed that practically only sequestered PAs or that secreted only autogenous cardenolides or that did both. Of course, this reflects local variation in host-plant distribution, but intrinsic genetic differences between beetles from distant populations adapted to local vegetation cannot be excluded, and has been suggested in *O. elongata* populations (Dobler and Rowell-Rahier, 1994b). As already stated, *Oreina* species form metapopulations and morphological differences between populations have been reported that justify for some taxonomists the subdivision of species into subspecies or even different species. For example, *O. speciosissima* from Zinal and other alpine populations differ from beetles from lower altitudes in details in their morphology to the point that they were considered as a distinct species: *O. perenei* (e.g., Freude et al., 1966). However, this distinction does not appear to be valid (for detailed taxonomic discussion, see Kühnelt, 1984). Morphological differences also exist between *O. elongata* from the Col du Lautaret, the Vallée des Merveilles, and Mattmark dam, possibly reaching subspecies level. The two first populations belong to *O. elongata occidentalis* Ruffo and the latter to *O. elongata ruffoi* Franz (e.g., Kühnelt, 1984).

The same exocrine glands that store and possibly synthesize autogenous cardenolides also store and possibly transform sequestered PAs. We do not know how these two processes interfere with each other, but it is tempting to speculate that sequestration competes with the secretion of cardenolides. At least in *O. elongata*, our data indicate that the refilling of the glands with sequestered PAs is much faster than with autogenous cardenolides. If sequestration competes with de novo synthesis, it could explain why beetles feeding exclusively for many generations on *Adenostyles* have their production of cardenolides suppressed. If this suppression becomes constitutive, a situation similar to that observed in *O. cacaliae* would be reached. This could occur by genetic drift the more easily as no selective force can act on the synthesis of cardenolides, which is not expressed anymore. Furthermore, experiments demonstrated that naïve red-winged blackbirds more often rejected *O. cacaliae*, which only sequesters PAs, than *O. gloriosa*, a species which is very similar in both size and color, but only produces cardenolides (Rowell-Rahier et al., 1995).

It would be too simplistic, however, to consider the production of both cardenolides and PAs as a transitory evolutionary step towards exclusive plant-derived defense. The advantages of one or the other defense is difficult to assess and depends not only on the distribution of natural enemies and their answer to

both kinds of compounds, but also on the distribution of plants and of their nutritional value. The mixed strategy is observed in three species, but only a single species relies solely on sequestered PAs.

Interspecific differences in host-derived defenses is, of course, even greater that intraspecific variation in both allopatric and sympatric situations. Not only do the different *Oreina* exhibit differences in their host-plant preferences, but they handle PAs from the same plant species in different ways. For example, *O. elongata* feeding on *A. alliariae* sequester higher proportions of senecionine compared to seneciphylline, than *O. cacaliae* or *O. speciosissima* feeding on the same plant, and above all produce significant quantities of oreine, which is not detected or is detected only as traces in the other species. Oreine is not present in *A. alliariae*, and it must be derived from seneciphylline (Hartmann et al., in preparation). Similarly, among PAs belonging to the same structural group (see Hartmann and Witte, 1994, for a classification of PAs) doronenine is the major PA found in *O. cacaliae*, *O. speciosissima*, and *O. intricata*, feeding on *S. nemorensis*. In *S. nemorensis*, the only possible source of such PAs, doronenine is not very abundant and bulgarsenine is far more abundant. Either these beetles are very selective in their sequestration, or they transform bulgarsenine into doronenine (Hartmann et al., in preparation).

Strong inter- and intraspecific variations in host-derived defense resulting from local heterogeneity in phytochemistry, differences in plant communities, and differences in processing plant compounds by insects are of course not surprising; they are already well documented in other insects, predominantly in butterflies and moths (Brower, 1970; Bowers, 1992; Rowell-Rahier and Pasteels, 1992; Hartmann and Witte, 1994). In *Oreina* species, the full description of allopatric and sympatric variations in host-derived defense requires further analysis of individual beetles freshly collected in the field. The real challenge, however, will be to evaluate the consequences for beetle fitness of this diversity and flexibility of defense.

(Received December 9, 1994; accepted April 6, 1995)

Abstract—The rice looper, *Plusia festucae*, is a defoliator of the rice plant. Chromatographic behavior, chemical reactions, and GC-MS analyses of the female sex pheromone revealed that the main component was (*Z*)-5-dodecenyl acetate (Z5-12:OAc, component I). The GC-MS analysis also indicated that the pheromone gland extract included another three monounsaturated components, (*Z*)-5-dodecen-1-ol (Z5-12:OH, component II), (*Z*)-7-tetradecenyl acetate (Z7-14:OAc, component III), and (*Z*)-7-tetradecen-1-ol (Z7-14:OH, component IV) in the following ratio: I:II:III:IV = 100:6:15:1. In a paddy field, the mixture of synthetic I, II, and III in a ratio of 100:6:15 showed stronger attractancy than the virgin female, while the role of IV was unknown.

Key Words—Sex pheromone, lepidopterous pheromone, rice looper, *Plusia festucae*, (*Z*)-5-dodecenyl acetate, (*Z*)-5-dodecen-1-ol, (*Z*)-7-tetradecenyl acetate

INTRODUCTION

The rice looper, *Plusia festucae* (L.) (Lepidoptera: Noctuidae: Plusiinae), is a defoliator of rice plants. The larvae of the first generation appear in paddy fields in the Tokyo area from late May to mid-June, and the adult moths emerge from late June to July. Although traps baited with virgin females that were reared in

*To whom correspondence should be addressed.

our laboratory attracted male moths in the paddy field in September, the larvae of the second generation could not be found on the leaves of rice plants in August (Kokuryu et al., unpublished). In order to reveal ecological aspects of this species, we have defined the female sex pheromone, which is expected to be a useful tool for monitoring the population of adult males.

METHODS AND MATERIALS

Insects. Larvae of *P. festucae* were collected in the experimental paddy field of Tokyo University of Agriculture and Technology (Fuchu-shi, Tokyo) during June 1993. Three generations were reared on the artificial diet prepared mainly from kidney bean powder for *Acanthoplusia agnata* (Kawasaki et al., 1987) at 25°C and on a 16:8-hr light–dark cycle. Abdominal tips containing the pheromone glands were removed from about 500 female moths (2–3 days old) 4 hr after the beginning of scotophase, and these were soaked in *n*-hexane for 30 min to extract the pheromone. In order to examine how the attractancy of the virgin female compares with the synthetic pheromone, the larvae were collected again in 1994 and reared on the same diet.

Electroantennogram (EAG) Method. EAG activities of the natural pheromone and synthetic compounds were measured by modifying the method described for the pheromone study of the rice green caterpillar (Ando et al., 1980; Roelofs, 1984). The head of a *P. festucae* male moth was also removed, and the responses produced on one of the two antennae were recorded with a handy recorder (model 8K30; Nippondenki-Sanei, Co., Tokyo, Japan) instead of a cathode ray oscilloscope.

Chemical Reactions with Pheromone Extracts. Crude extract from 50 virgin females was treated with $NaBH_4$ (5 mg) in 2-propanol (0.2 ml) for 3 hr at room temperature. After mixing with water (2 ml), crude products were extracted with *n*-hexane and the EAG activity was measured. Catalytic hydrogenation of the pheromone extract (50 females) was carried out with 10% Pd-C (2 mg) in *n*-hexane (0.5 ml) for 1 hr at room temperature. After filtration of the catalyst and evaporation of the solvent, the hydrogenated products were used for the EAG assay. Another pheromone extract from 100 females was treated with 1 N methanolic KOH (0.5 ml) for 1 hr at room temperature. After neutralization with 1 N HCl, the hydrolyzed products were extracted with *n*-hexane. Half of this extract was offered in the EAG assay, and the remainder was treated with pyridine (0.1 ml) and acetic anhydride (0.1 ml), after removing the *n*-hexane. This mixture was added to water (1 ml), and reacetylated product, which was extracted with *n*-hexane, was offered in the EAG assay. To determine the double bond position of the pheromone, ozone was added to a *n*-hexane solution (50 μl) of the crude extract (100 females), which was cooled in a dry ice–acetone bath. An aliquot of this solution was analyzed by GC-MS to determine

the thermal decomposition products from the ozonide of the pheromone components.

Chromatography. EAG activities of the fractions obtained by TLC of 50 female extracts on a normal-phase plate (silica gel, Merck GF_{254}, 0.25 mm) using *n*-hexane–benzene (1 : 10) were measured. Under these conditions, R_f values of authentic compounds, (*Z*)-5-dodecenyl acetate (Z5-12 : OAc)** and the parent alcohol, were 0.67 and 0.16, respectively. Another 50 female extracts were injected into a reverse-phase HPLC column (Deverosil ODS-5, 8 mm ID × 15 cm, Nomura Chem. Co., Seto-shi, Japan), using an acetonitrile–water (97 : 3) solvent system at a flow rate of 1.5 ml/min, and the elutions were collected every minute to measure the EAG activity. Under these HPLC conditions, authentic compounds showed the following R_t: Z5–10 : OAc 6.0 min; Z5–12 : OAc 7.8 min; Z7–14 : OAc 14.1 min; Z11–16 : OAc 21.3 min.

GC-MS Analyses. Electron impact (EI) GC-MS was achieved using a JEOL JMS-SX102A mass spectrometer with DB-23 and DB-1 capillary columns (0.25 mm ID × 30 m, J & W Scientific). The former column was used for the natural pheromone and synthetic standards, and the column temperature program was 80°C for 1 min and 8°C/min to 210°C. The latter column was used for the ozonolysis products, and the temperature program was 40°C for 1 min, 50°C/min to 150°C, and finally 8°C/min to 300°C. The ionization voltage of every measurement was 70 eV. The ion source temperature was 240°C. The spectra (*m/z* 50–800) were measured twice per minute in a cyclic scan mode lasting from 5 to 20 min after the sample injection.

Field Tests. Sticky-type traps (30 × 27 cm bottom plate with a roof, Takeda Chemical Ind., Ltd., Osaka, Japan) were set at a height of 0.4 m in the paddy field where the larvae were collected. Synthetic chemicals (>97% purity) were applied to natural rubber septa [8 mm OD, white rubber (Aldrich)] as dispensers, which were set at the center of the traps and used without renewal during the experiments. Attractancy of the female for the male moths was examined using the trap baited with two virgin females in a plastic cup with wire-screen windows (3 × 5 cm). The females were replaced every day.

RESULTS

EAG Analyses. The chemical and chromatographic characteristics of the *P. festucae* pheromone were examined using an EAG technique as the bioassay. Reduction with $NaBH_4$ had little effect on the EAG activity of the crude extract. On the other hand, the activity of the crude extract was completely lost by catalytic hydrogenation, but not completely lost by treatment with methanolic potassium hydroxide. Acetylation of the crude alkaline hydrolyzed mixture with

**Other monoene compounds are abbreviated in the same manner (Arn et al., 1992).

acetic anhydride–pyridine restored the original activity. Furthermore, on preparative TLC with a normal-phase plate, an acetate fraction (R_f 0.6–0.8) showed the strongest EAG activity. The activity of an alcohol fraction (R_f 0.1–0.2) was weak but not negligible, and no other fractions showed remarkable activities. It has been reported that reverse-phase chromatography is available to examine the carbon length of straight-chain compounds (Ando et al., 1986). Strong activity was observed in a fraction (R_t 7–9 min), from which C_{12} monoene acetates were recovered. Figure 1 shows the EAG profiles of a series of C_{12} monoene acetates. Dodecenyl acetate with a (*Z*)-double bond at the 5 position produced the strongest response of the tested compounds. These experiments indicate that the main component of the female pheromone is Z5–12:OAc.

Identification by GC-MS. A GC-MS analysis of one female sex pheromone extract from *P. festucae* on a polar capillary column (DB-23) produced the total ion chromatogram (TIC) shown in Figure 2A. This analysis covers the volatility range of C_{10}–C_{16} alcohols and their derivatives (acetate and aldehyde). Monoene acetates and alcohols with straight chains of the same length showed characteristic fragment ions ($[M-AcOH]^+$ and $[M-H_2O]^+$]) with the same mass number after the elimination of the acetic acid and water, respectively, from molecular ions. Figures 2B–E are mass chromatograms to detect the monoene compounds that monitor fragment ions at *m/z* 222 for C_{16}, *m/z* 194 for C_{14}, *m/z* 166 for C_{12}, and *m/z* 138 for C_{10} chain compounds. Mass chromatogram monitoring of an ion at *m/z* 61 (Figure 2F) was performed to detect acetates. As shown in Figure 2 the pheromone extract included four monoene compounds, C_{12} acetate (component I, R_t 10.91 min), C_{12} alcohol (component II, R_t 11.19 min), C_{14} acetate (component III, R_t 13.10 min), and C_{14} alcohol (component IV, R_t 13.76 min), in a ratio of 100:6:15:1. GC-MS analysis of a mixture of the natural pheromone and synthetic standards showed that the most abundant component (I) had the same R_t and mass spectrum as Z5–12:OAc, as shown in Figure 3.

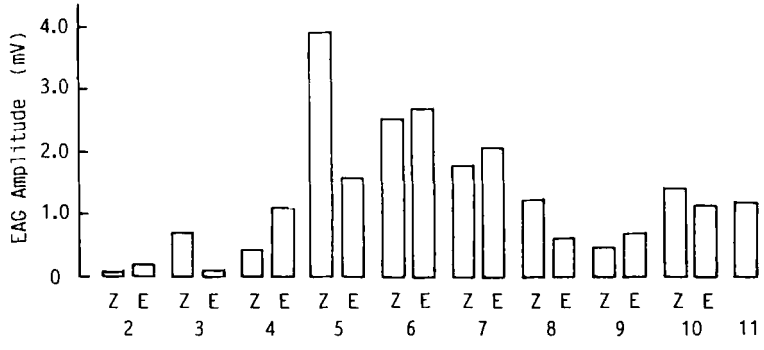

FIG. 1. EAG responses of male *P. festucae* to 1 μg of C_{12} monoene acetates.

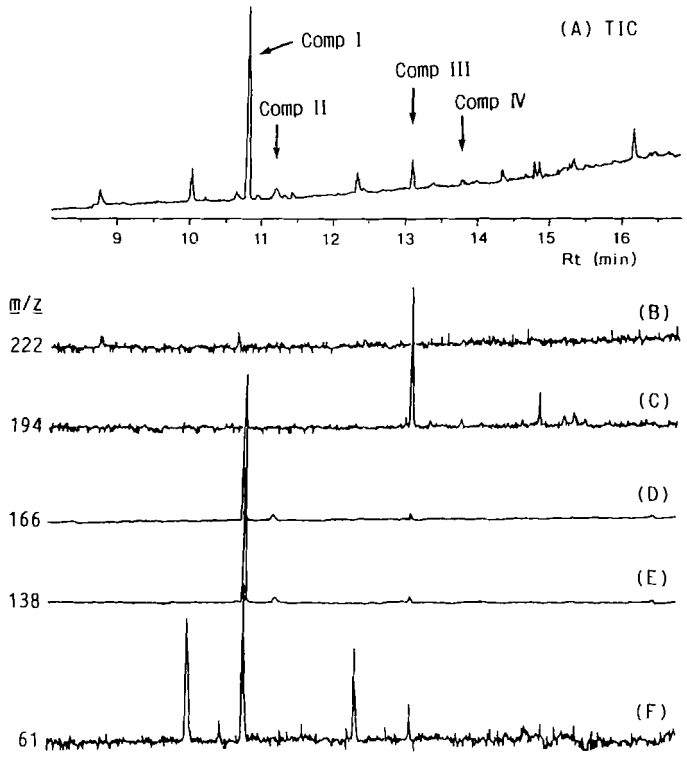

FIG. 2. GC-MS analysis of the pheromone gland extract (one female equivalent) of *P. festucae*. (A) Total ion chromatogram (TIC); (B–F) mass chromatograms monitoring the fragment ions at *m/z* 222, 194, 166, 138, and 61.

The peak height of component I in the TIC (Fig. 3A) indicates that one female possessed ca. 20 ng of Z5–12:OAc. The double-bond positional isomer Z7–12:OAc, a common pheromonal component of Plusiinae pheromones (Arn et al., 1992), had a different R_t (11.06 min) and spectrum and was not detected in the *P. festucae* pheromone extract. Further cochromatographic experiments revealed that the synthetic Z5–12:OH, Z7–14:OAc, and Z7–14:OH had the same R_t as components II, III, and IV, respectively. No other related components were observed in the extract, while the GC-MS data were examined in detail by mass chromatogram, which monitored $[M\text{-AcOH}]^+$ for saturated acetates; $[M-H_2O]^+$ for saturated alcohols, saturated aldehydes, and monoene aldehydes; and molecular ions $[M]^+$ for diene compounds.

The double bond position of component I was furthermore confirmed by an ozonolysis experiment with the pheromone extract. GC-MS analysis of the

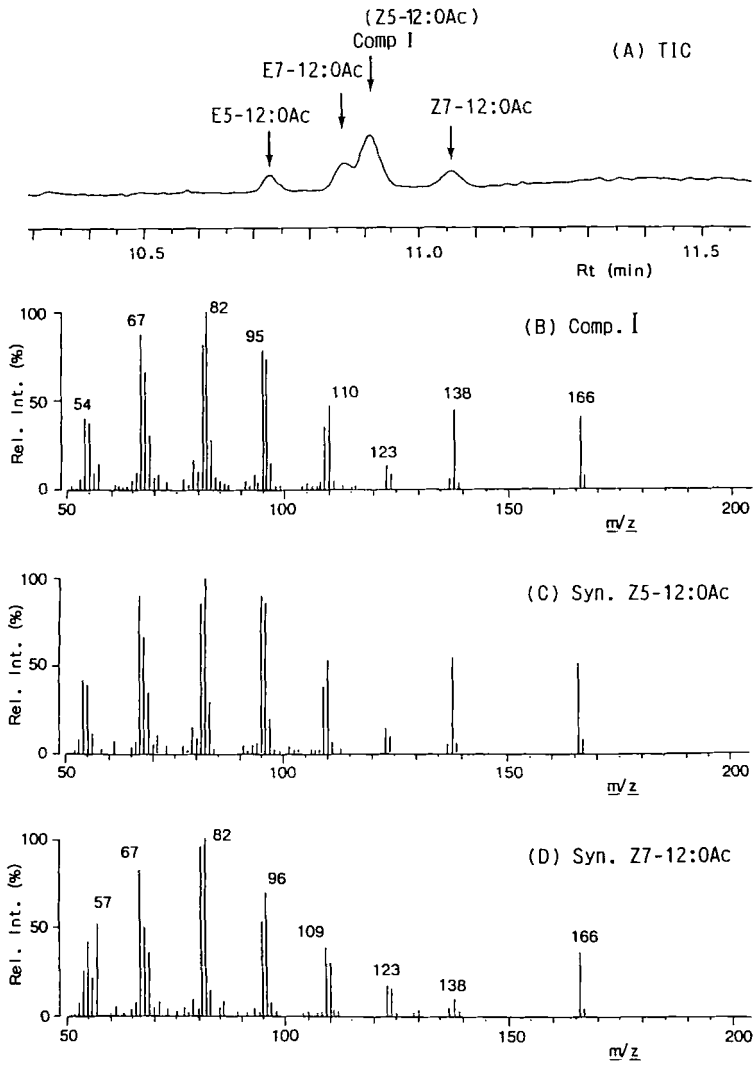

FIG. 3. GC-MS analysis of *P. festucae* pheromone and synthetic standards. (A) TIC of pheromone gland extract (one female equivalent) mixed with some synthetic monoene acetates (10 ng each); (B) mass spectrum of I; (C) mass spectrum of synthetic Z5-12:OAc; (D) mass spectrum of synthetic Z7-12:OAc.

crude products showed 5-acetoxypentanal (R_t 3.54 min) with diagnostic fragment ions at *m/z* 101, 87, and 73. No other acetoxyaldehydes were detected in the ozonolysis products.

Average Fitness Indexes. Kuwahara et al. (1986) proposed an identification method for a double-bond position using the newly devised average fitness index, which was computed with the mass spectral data of a series of synthetic isomers. The fitness index was calculated by dividing the absolute difference between the intensity ratio of the fragment ion-pair of a synthetic isomer and the corresponding ratio of the natural pheromone by the latter. All the index values were summed from each isomer and averaged to determine the similarity to the pheromone. The smallest average among the isomers indicates the best fit to a natural pheromone. Based on the published data (Horiike et al., 1981; Horiike and Hirano, 1982, 1984), the smallest values of the indexes for components I, II, and III were obtained with Z5–12 : OAc (19.6), Z5–12 : OH (76.3), and Z7–14 : OAc (41.6), respectively (Table 1). Since the published data were

TABLE 1. AVERAGE FITNESS INDEXES OF NATURAL PHEROMONE COMPONENTS (I–III) TO SYNTHETIC MONOENES[a]

Pheromone component	Position of (Z)-double bond						
	5-ene	6-ene	7-ene	8-ene	9-ene	10-ene	11-ene
I (C_{12} acetate)[b]	19.6 (5.0[f])[e]	36.6 (41.1)[e]	62.7 (38.9)[e]	38.3	53.3	73.8	57.1
II (C_{12} alcohol)[c]	76.3 (13.1)[e]	79.6 (14.1)[e]	83.1	80.3	101.5	123.6	96.8
III (C_{14} acetate)[d]	44.1	56.1	41.6 (10.3[g])[e]	62.9	59.9	41.8 (34.2)[e]	81.0

[a] Fitness index (%) = |(ratio of an ion-pair/corresponding ratio of the pheromone) − 1| × 100 (Kuwahara et al., 1986). Mass spectra of the natural pheromone components were measured by a JEOL JMS-SX102A mass spectrometer operated at 70 eV ionization voltage.

[b] Calculated using the published ratios (Horiike and Hirano, 1982) of the following seven ion pairs [(*m/z*)/(*m/z*)] by a Shimadzu-LKB 9000 spectrometer at 70 eV; 54/55, 55/68, 67/68, 68/95, 81/82, 81/95, and 95/96.

[c] Calculated using the published ratios (Horiike and Hirano, 1984) of the following eight ion pairs [(*m/z*)/(*m/z*)] by a Shimadzu-LKB 9000 spectrometer at 70 eV; 54/69, 55/67, 56/83, 68/81, 68/82, 69/81, 81/82, and 67/68.

[d] Calculated using the published ratios (Horiike et al., 1981) of the following six ion pairs [(*m/z*)/(*m/z*)] by a Shimadzu-LKB 9000 spectrometer at 50 eV; 67/68, 68/96, 95/96, 67/82, 55/82, and 109/110.

[e] Calculated using the spectral data of the natural and synthetic compounds measured by the same instrumental condition.

[f] Significant at the 1% level by the *t* test.

[g] Significant at the 5% level by the *t* test.

measured with different instrumental conditions from those for the natural pheromone, these smallest indexes are still rather large. The values in parentheses in Table 1, which were calculated with data measured by the same instrument, were much smaller than those calculated with the published data. Because of the spectral similarity of Z5-12:OH and Z6-12:OH, determination of the double-bond position of component II was difficult even though the indexes in parentheses (13.1 and 14.1) were compared each other. The R_t of Z6-12:OH (11.28 min) disqualified this candidate. With component III, the index of Z7-14:OAc (41.6) was almost the same as that of Z10-14:OAc (41.8), but the difference between their indexes increased until they were large enough to be distinguished from each other (10.3 and 34.2), when the calculation used data that were measured with the same instrument. The amount of component IV was so small in the pheromone extract that the mass spectrum was not available for calculating the indexes.

Field Attraction. In order to examine whether the four compounds are real pheromone components, their attractive activities were evaluated in a paddy field. Table 2 shows results of the field tests with the synthetic pheromones carried out in the suburbs of Tokyo from June to July 1994. A rubber septum containing a mixture of Z5-12:OAc (I), Z5-12:OH (II), and Z7-14:OAc (III) in a ratio of 100:6:15 attracted male moths of *P. festucae* more strongly than two virgin females. The trap baited only with Z5-12:OAc, a major component of the natural pheromone, caught no males, and Z7-14:OAc, one of the two

minor components, was shown to be indispensable for the attraction. Z5-12:OH, another minor component, had an important role in strongly attracting the males. Z7-14:OH (IV) is not necessary for attraction.

DISCUSSION

Chromatographic behavior, chemical reactions, and GC-MS analyses of the pheromone gland extract conclusively show that the *P. festucae* female pheromone is composed of Z5-12:OAc, Z5-12:OH and Z7-14:OAc. This conclusion was confirmed by a field test in a paddy field. The attractancy of the mixture in a ratio found in the extract (100:6:15) was stronger than that of virgin females. The role of Z7-14:OH, the most minor component identified so far, was unknown because the activity of three-component lure did not increase after the addition of this forth component.

To date, sex pheromones of 13 species in the subfamily Plusiinae have been identified (Arn et al., 1992). Nine species among the above insects secrete Z7-12:OAc or Z7-12:OH as a major component of their sex pheromones, and only one species, *Autographa nigrisigna* Walker, utilizes Z5-12:OAc. *P. festucae* is the second species in this subfamily, the pheromone of which is constituted mainly of Z5-12:OAc. Considering that *A. nigrisigna* males were attracted to the lure baited with Z5-12:OAc, Z7-12:OH, Z7-12:OAc, and Z7-14:OAc in a ratio of 100:62:2:4 (Sugie et al., 1991), Z7-14:OAc seems to be another key component of the Plusiinae pheromones.

Chemical analysis of the double-bond position of a minor component is difficult. The positional isomers are, however, distinguishable by carefully examining the relative intensities of some fragment ions in their EI-MS without any chemical modifications. When a mass spectrum of the minor component is recorded with no confusing background, the identification is easily accomplished based on the chromatographic and spectral data measured with a capillary GC-MS and comparing them with those of a series of authentic compounds. Even if the authentic standards are not available, the double-bond positions can be estimated using the average fitness indexes calculated with the published spectral data. In these experiments, structures of II and III were focused in an interesting way by the data measured with a different mass spectrometer.

We are now investigating *P. festucae* using the pheromone traps, and the results will be reported elsewhere.

(Received September 23, 1994; accepted April 9, 1995)

Abstract—Using gas chromatography–mass spectrometry in conjunction with ancillary techniques such as chemical ionization with different reactant gases, determination of the position of double bonds by means of dimethyl disulfide derivatization, and finally gas chromatographic and mass spectrometric comparison with authentic synthetic material, 75 constituents were identified in the preorbital secretion of the male oribi, *Ourebia ourebi*. The secretion contains compounds with long-chain, unbranched structures similar to those found in many other preorbital secretions but with a finite volatility range, in contrast to the seemingly endlessly increasing chain lengths typical of other preorbital secretions.

Key Words—*Ourebia ourebi*, Bovidae, mammalian semiochemicals, mammalian pheromones, exocrine secretion, preorbital secretion, dimethyl disulfide derivatization, skipped dienes, chemical-ionization mass spectrometry, NMR.

INTRODUCTION

Cutaneous glands producing odoriferous substances that act as semiochemicals occur in most mammalian species. They are common in carnivores, rodents, and in most ungulate groups, but are also found in many other orders (Schaffer, 1940). The glands may be situated in many different regions of the body, and they may have different functions. For example, the scent glands described in

*To whom correspondence should be addressed.

[1] The heading of the series has been changed as the semiochemical activity of these secretions cannot always be demonstrated.

the black-tailed deer, *Odocoileus hemionus columbianus*, include preorbital (Albone, 1984), interdigital, metatarsal (Müller-Schwarze, 1971), and tarsal glands (Müller-Schwarze, 1971; Müller-Schwarze and Müller-Schwarze, 1975).

Volatile substances may be released into the air by diffusion from the gland, but in most cases described, objects are marked with secretions from these glands. Scent marking with glandular exudate is often associated with territorial behavior (Eisenberg and Kleiman, 1972) and many bovid species utilize secretions from their preorbital glands for this purpose.

The exocrine secretions of several South African antelope species have been studied in considerable detail in the Laboratory for Ecological Chemistry at the University of Stellenbosch. Some of them, such as the grysbok and the grey duiker cause considerable damage in vineyards, orchards, and pine plantations in parts of South Africa (Bigalke, 1974). A research program was therefore initiated to identify the semiochemicals produced in these preorbital glands and to investigate the feasibility of reducing damage by the use of synthetic pheromones. The first stage of the program was the chemical characterization of the preorbital gland secretion of the grysbok. Although the ritual involved in marking objects with preorbital gland secretions undoubtedly plays an important part in the behavior of male grysbok, no experimental evidence could be found that the olfactory stimuli released from the deposited material serve as deterrents signalling territorial occupancy to other males (Novellie et al., 1984).

Preliminary behavioral studies with other antelope species indicated that the response-guided strategy (Albone, 1984) was unlikely to lead to a complete understanding of the function of the various constituents of the preorbital secretions of these animals in their territorial and social behavior, and it became clear that more background information would be needed on the preorbital secretions from individual conspecific animals, as well as from related and unrelated species.

One of the species selected for this purpose is the oribi, *Ourebia ourebi*, which belongs to the tribe Raphicerini. Other members of this tribe are the grysbok, *Raphicerus melanotis*, and the steenbok, *R. campestris*. The oribi normally inhabits grasslands, open plains, and thickly bushed country (Kenmuir and Williams, 1975) and is found in the eastern Cape, Natal, southeastern Transvaal, Mozambique, and southeastern Zimbabwe (Walker, 1982). They are normally seen in pairs or in small groups (Kenmuir and Williams, 1975).

There are six scent glands on the oribi's body, namely preorbital glands, tracts of glandular skin on the forelegs covered with long hair and on the hindlegs covered with shorter brushes, inguinal glands, pedal glands, as well as ear glands (Kingdon, 1982). In the oribi, marking with the preorbital glands is associated mainly with territorial and sexual activity (Kingdon, 1982). Only males mark with their well-developed preorbital glands (Smithers, 1986), while females induce the male's marking behavior (Kingdon, 1982). The male oribi's preor-

bital secretion consists of a mucoid emulsion containing black insoluble material and small quantities of volatile organic compounds.

In this paper, the identification of the volatile organic constituents of the preorbital gland secretion of the oribi, and the synthesis of some of them, are reported.

METHODS AND MATERIALS

General. All Pyrex glassware used in the handling of biological material and extracts, as well as in the preparation of reference compounds, was heated to 500°C in an annealing oven to remove any traces of organic material. Dichloromethane (Merck, Residue Analysis Grade) was analyzed gas chromatographically and found to be pure enough for extraction purposes when used in small quantities. Syringes, stainless-steel needles, etc., were cleaned by rinsing with this solvent.

Analytical Methods. Gas chromatographic (GC) analyses were carried out with Carlo Erba 4200 and 5300 gas chromatographs equipped with flame ionization detectors, Grob split-splitless injectors, and glass columns coated by the Laboratory for Ecological Chemistry with a 0.25-μm film of the apolar stationary phase PS-089, a silanol-terminated 95% dimethyl-5% diphenylsiloxane copolymer. Helium was used as carrier gas at a linear velocity of 28.6 cm/sec at 40°C. The flame ionization detector was operated at 280°C and the injector was normally used at 220°C. Samples were injected in the split mode, and the volatiles entering the column were thermally focused at ca. 30°C and subsequently analyzed using a temperature program of 2°C/min. For the analysis of synthetic products and intermediates, a 4°C/min programming rate was used. Methyl heptanoate was used as an internal standard in a quantitative analysis of the preorbital secretion.

Electron impact (EI) mass spectra were recorded at 70 eV on a Carlo Erba QMD 1000 GC-MS instrument, using the column and conditions described above. Chemical ionization (CI) mass spectra were obtained with methane and nitric oxide as reactant gases.

^{1}H and ^{13}C NMR spectra of synthesized compounds were obtained on a Varian VXR-300 spectrometer operating at 299.9 MHz for the observation of ^{1}H and at 75.42 MHz for the observation of ^{13}C, respectively. All spectra were recorded at 25°C. ^{13}C Multiplicities were determined by means of the APT technique. Two-dimensional ^{1}H–^{1}H correlation spectra (COSY) were obtained using the pulse sequence: D1-90°-(t1 + D3)-60°-AQ (Bax et al., 1981), with D3 = 0.06 sec to enhance long-range coupling effects. Two-dimensional ^{1}H–^{13}C correlation spectra (HETCOR) were obtained by means of the pulse sequence as described previously (Wilde and Bolton, 1984). Where necessary

^{13}C assignments were verified by means of a long-range ^{1}H–^{13}C heteronuclear correlation experiment (Reynolds et al., 1989). The ^{13}C spectrum of the whole, unprocessed secretion was obtained using a 67° pulse angle and a pulse repetition time of 0.8 sec. A total of 29,600 transients were accumulated. The ^{13}C chemical shifts were measured in benzene-d_6 as lock solvent relative to tetramethylsilane as internal reference.

Infrared spectra were recorded on a Mattson Galaxy Series FT-IR 3000 instrument, equipped with a Roland DXY-1100 plotter.

Collection and Sample Preparation. Preorbital gland secretion was collected from a netted, sexually mature male animal by scooping the exudate from the preorbital cavity with a tubular PTFE scoop fitted with a PTFE plunger with which the material was ejected from the scoop into a Reacti-Vial. The organic volatiles were extracted by stirring each collected sample with dichloromethane (ca. 100 μl), using a thin (0.5 mm) glass rod to produce a homogeneous suspension, centrifuging the suspension at 2000–3000 rpm for ca. 15 min, removing the dichloromethane extract from underneath the supernatant water and mucus layer with a 100-μl syringe, and transferring it to a clean Reacti-Vial. Most extracts could be used without subsequent concentration. When more concentrated solutions were required, the solvent was removed in a slow stream of purified (activated charcoal) nitrogen.

Dimethyl Disulfide Derivatization. The derivatization was carried out using two methods. Following the method described by Buser et al. (1983), an aliquot (10 μl) of a dichloromethane extract of the preorbital secretion was concentrated in a 1-ml Reacti-Vial using a slow stream of purified nitrogen. The residual material was dissolved in hexane (50 μl) and treated with 5 μl of iodine solution (60 mg/ml of diethyl ether) and 50 μl of dimethyl disulfide (DMDS). The Reacti-Vial was sealed using a PTFE-faced rubber septum and the reaction mixture left at 40°C for 15 hr in the oven of a gas chromatograph. The reaction was quenched with an aqueous solution of sodium thiosulfate (5%). The organic and aqueous layers were separated by centrifuging for a few minutes at 2000 rpm, after which the organic layer was transferred to a clean Reacti-Vial. The solution was concentrated to 5 μl for GC-MS analysis. In the alternative method, described by Vincenti et al. (1987), a similar procedure is employed except for the substitution of hexane with carbon disulfide as solvent, a higher reaction temperature (60°C), and a longer reaction time (40 hr).

Reference Compounds. Compounds required for comparison with constituents of the preorbital secretion that are not commercially available were synthesized from authentic starting materials.

(4*Z*,7*Z*)-4,7-Tridecadien-1-ol, **30,** was synthesized according to Scheme 1. Partial hydrogenation of 2-octyn-1-ol 1-**1** (Taylor and Strong, 1950) with Lindlar catalyst (Augustine, 1965) gave pure (*Z*)-2-octen-1-ol 1-**2** in 80% yield; bp 97–

98°C (14 mm Hg); ^{13}C NMR ($CDCl_3$): Table 1. Bromination of the octenol 1-**2** with phosphorus tribromide in the presence of pyridine (Taylor and Strong, 1950) gave (Z)-1-bromo-2-octene 1-**3**, containing 9.8% of the *E* isomer (GC-MS), in 81% yield; bp 89–90°C (16 mm Hg). 5-Tetrahydropyranyloxy-1-pentyne 1-**5** was synthesized from 1-bromo-3-tetrahydropyranyloxypropane 1-**4** and sodium acetylide according to the method of Vaughn et al. (1937) in 60% yield; bp 116–118°C (28–30 mm Hg); ^{13}C NMR ($CDCl_3$): Table 1. Coupling of the bromooctene 1-**3** with the acetylenic Grignard reagent 1-**6** in the presence of CuCl, according to the method described by Osbond et al. (1961), gave 1-tetrahydropyranyloxy-7-tridecen-4-yne 1-**7** in 72% yield; ^{13}C NMR ($CDCl_3$):

Table 1. Partial hydrogenation of 1-tetrahydropyranyloxy-7-tridecen-4-yne with Lindlar catalyst followed by deprotection of the resulting skipped diene derivative with hydrochloric acid (Le Roux, 1980), gave 5.84 g (38% overall yield from 1-**1**) of a mixture of 4,7-tridecadien-1-ol isomers containing 32% of the required Z,Z isomer **30**. Chromatography on 7% $AgNO_3$-coated silica gel gave pure (GC) (4Z,7Z)-4,7-tridecadien-1-ol **30**: ^{13}C NMR ($CDCl_3$): Table 2.

(6Z,9Z)-6,9-Pentadecadien-1-ol, **49**, was prepared according to Scheme 2. Treatment of 5-bromo-1-pentanol 2-**1** with isobutene and Amberlyst H-15 as catalyst (Alexakis et al., 1988) gave 5-bromo-1-*tert*-butoxypentane 2-**2** in quan-

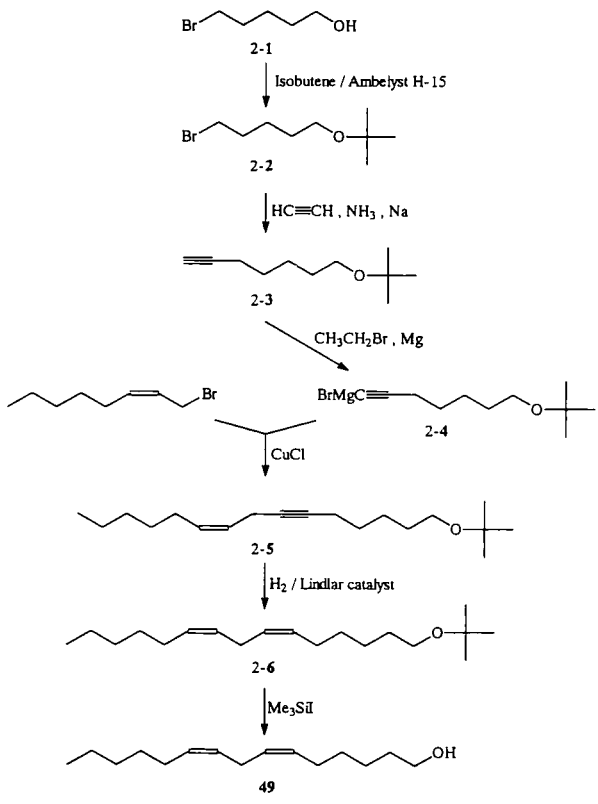
titative yield; ^{13}C NMR ($CDCl_3$): Table 3. 1-*tert*-Butoxy-6-heptyne 2-**3** was synthesized from 2-**2** in a manner analogous to the preparation of 1-**5** in 97% yield; ^{13}C NMR ($CDCl_3$): Table 3. 1-*tert*-Butoxy-(*Z*)-9-pentadecen-6-yne 2-**5** was prepared from the acetylenic Grignard reagent 2-**4** and 1-bromo-2-octene by the procedure used for the preparation of 1-**7** in 87% yield; ^{13}C NMR ($CDCl_3$): Table 3. Partial hydrogenation of 2-**5** with Lindlar catalyst gave 1-*tert*-butoxy-6,9-pentadecadiene as a mixture of *Z,Z*, *Z,E*, *E,Z*, and *E,E* isomers containing 62% of the *Z,Z* isomer 2-**6**; ^{13}C NMR ($CDCl_3$): Table 3. Deprotection of the mixture of 1-*tert*-butoxy-6,9-pentadecadiene isomers with Me_3SiI according to the method of Jung and Lyster (1977), proceeded quantitatively to give 3.40 g of the isomeric 6,9-pentadecadienols in an overall yield of 68% from the starting compound 5-bromo-1-pentanol 2-**1**. Column chromatography on 7% $AgNO_3$-coated silica gel gave the pure (6*Z*,9*Z*)-6,9-pentadecadien-1-ol **49**; ^{13}C NMR ($CDCl_3$): Table 2.



SCHEME 2. Synthesis of (6Z,9Z)-6,9-pentadecadien-1-ol.

(9Z,12Z)-9,12-Octadecadien-1-yl formate, **74,** was synthesized in 92% yield by the reduction of linoleic acid methyl ester with $LiAlH_4$ followed by the esterification of the resulting (9Z,12Z)-9,12-octadecadien-1-ol with formic acid at room temperature for 5 hr. The reaction product was purified by bulb-to-bulb distillation to give (9Z,12Z)-9,12-octadecadien-1-yl formate **74** in 95% yield; bp 165°C (0.015 mm Hg). The ^{13}C NMR data for this and other formates synthesized according to this method, are given in Table 4.

(9Z,12Z)-9,12-Octadecadien-1-yl acetate, **77**, was prepared by the esterification of (9Z,12Z)-9,12-octadecadien-1-ol with acetyl chloride in the presence of pyridine in 99% yield; bp 159°C (0.007 mm Hg). The ^{13}C NMR data for

this and other acetates synthesized according to this method are listed in Table 5.

(4Z,7Z)-4,7-Tridecadienal, **22,** was obtained by the oxidation of the dienol **30** on pyridinium chromate-silica gel in 57% yield according to the procedure described by Singh et al. (1979). The ^{13}C NMR data for the aldehydes synthesized for comparison by this method, are given in Table 6.

RESULTS AND DISCUSSION

Although the oribi enjoys a widespread distribution in the eastern parts of sub-Saharan Africa, its distribution is patchy, and it is therefore a relatively rare

to $(M+30)^+$ in the CI(NO) mass spectra of the saturated formates was used to determine the molecular mass of the formates. This ion is formed by addition of a nitrosonium ion to the formate. The M^+ and $(M-46)^+$ ions are the base peaks in the mass spectra of the di- and monounsaturated formates, respectively. Formates were distinguished from other long-chain constituents by the presence in their CI(CH_4) mass spectra of a $(M+1-HCOOH)^+$ ion, which forms the base peak.

The acetates present in the secretion were characterized by a characteristic ion at *m/z* 61 (Sharkey et al., 1959; Beynon et al., 1961). In addition, the saturated acetates also have an ion at *m/z* 116, formed by cleavage of the bond between C-3 and C-4 with rearrangement of one hydrogen atom. The presence of an acetate moiety was confirmed by the presence of $(M+1-CH_3COOH)^+$ ions in the CI(CH_4) mass spectra of these compounds. The $(M+1)^+$ and $(M+NO)^+$ ions in their CI(CH_4) and CI(NO) spectra, respectively, were used to determine the molecular mass of these constituents.

The aldehydes present in the secretion were distinguished by an ion at *m/z* 44 accompanied by $(M-CH_2{=}CH_2)^+$ and $(M-CH_2{=}CHOH)^+$ ions in the high mass range of their EI mass spectra. The $(M-1)^+$ ion constitutes the base peak in these CI(NO) mass spectra, which also contain $(M+NO)^+$ and $(M-H_2O)^+$ ions, whereas the ion at *m/z* 44 has a very low abundance (<ca. 1%) in the spectra of the mono- and diunsaturated aldehydes.

The position of the double bonds in the monounsaturated alcohols, aldehydes, formates, and acetates present in the secretion was determined by GC-MS analysis of an extract of the secretion that had been subjected to the dimethyl disulfide (DMDS) derivatization procedure described by Buser et al. (1983). A total ion current chromatogram of organic material extracted from the secretion and subjected to DMDS derivatization is shown in Figure 2. The EI mass spectra of the bis(methylthioether) derivatives exhibited easily recognizable molecular and less abundant $(M-CH_3S)^+$ ions. The position of the double bonds was derived using the diagnostic ions A^+, B^+, and C^+, as shown in Table 7.

The configuration of the double bonds was established by coinjection of an extract of the secretion with a number of synthetic reference compounds after it had been confirmed that the *E* and *Z* isomers of these compounds could be separated on the available capillary column. Although the concentration of many of the unsaturated compounds in the preorbital secretion is below the detection limit of the NMR instrument, it was possible to confirm the presence of a double bond with *Z* configuration in the major constituents because of a resonance at δ 27.2 in the ^{13}C NMR spectrum of the whole secretion and the total absence of a resonance at δ ca. 33. It is known that the carbon atoms of the allylic methylene group in long-chain unbranched compounds resonate at δ ca. 27 in the *Z* isomers and at δ ca. 33 in the *E* compounds (Breitmaier et al., 1979; Wenkert et al., 1976).

Attempts to determine the position of the double bond in the unsaturated alcohols were unsuccessful as their DMDS derivatives could not be found in the total ion chromatogram of the derivatized secretion. This was probably due to the low concentration of these alcohols in the secretion. The assumption, based on the structures of the other constituents of the secretion, that the double bond in these compounds is situated between C-6 and C-7 from the methyl end of the carbon chain, was confirmed by retention time comparison of the natural constituents with the authentic synthetic alcohols.

In the EI spectrum of component **60,** the $(M-HCOOH)^+$ ion at *m/z* 222 is weaker than the molecular ion at *m/z* 268, and the base peak appears at *m/z* 70. These two phenomena distinguish this monounsaturated formate from other alkenyl formates present in the secretion. The $(M+1)^+$ and $(M+1-HCOOH)^+$ ions at *m/z* 269 and 223 in its CI(NO) spectrum as well as the $(M+NO)^+$, M^+, and $(M-HCOOH)^+$ ions at *m/z* 298, 268, and 222, respectively, in its CI(NO) spectrum confirm that component **60** is a monounsaturated hexadecen-1-yl formate. In the EI spectrum of its DMDS derivative, the presence of the diagnostic ions at *m/z* 159, 203, and 157 suggested the presence of a C-8–C-9 double bond. Synthetic (*Z*)-8-hexadecen-1-yl formate was coinjected with the oribi secretion, and the retention time of component **60** was found to be much shorter than that of the reference compound. On account of this difference in retention time, component **60** was assumed to be a branched monounsaturated formate. According to Brown et al. (1954), Friedel et al. (1956), Dolejs et al. (1968), and Bowen and Maccoll (1984), the base peak in the EI mass spectra of anteisoalcohols appears at *m/z* 70. Component **60** was therefore assumed to be an anteisoformate and, by combining all the relevant information, was identified as 13-methyl-(*Z*)-8-pentadecen-1-yl formate. This was not, however, confirmed by comparison with synthetic material.

According to the EI, CI(CH_4), and CI(NO) mass spectra, component **59** was assumed to be a pentadecen-1-yl acetate. The DMDS derivative of 7-pentadecen-1-yl acetate was found in the EI total ion chromatogram of the derivatized oribi preorbital secretion. In addition, the retention time of component **59** is shorter than the retention time of component **61,** (*Z*)-9-pentadecen-1-yl acetate, the difference between the retention times of these two components being only slightly longer than the difference between the retention times of (*Z*)-8- and (*Z*)-10-hexadecen-1-yl acetate, components **67** and **68**, respectively. It was therefore reasonable to assume that component **59** could be 7-pentadecen-1-yl acetate. However, the retention time of the (*Z*)-7-pentadecen-1-yl acetate reference, which was coinjected with oribi secretion, was longer than that of component **59.** The question arises as to why the DMDS derivative of 7-pentadecen-1-yl acetate was unequivocally identified in the EI total ion chromatogram of the DMDS-derivatized secretion but could not be detected in the EI total ion chromatogram of the secretion itself. The reason may possibly be that

7-pentadecen-1-yl acetate is actually present in the secretion, but in a low concentration and that it is obscured in the EI total ion chromatogram by other components. However, component **59** is not 7-pentadecen-1-yl acetate and could therefore only be characterized as an unidentified pentadecenyl acetate.

The molecular mass and functionality of the diunsaturated compounds present in the secretion were determined from EI, CI(CH_4), and CI(NO) mass spectral data.

The DMDS derivatization method for the determination of the position of double bonds as described by Buser et al. (1983) produced only two mono-DMDS derivatives of a single diunsaturated acetate, component **50.** Their EI spectra both have a molecular ion at *m/z* 346. Typical diagnostic ions appear at *m/z* 171 (A^+), 175 (B^+), 115 ($B^+ - CH_3COOH$) in one of the spectra, suggesting that one double bond in component **50** is in the 5 position. The diagnostic ions appear at *m/z* 131 (A^+), 215 (B^+), and 155 ($B^+ - CH_3COOH$) in the spectrum of the second DMDS derivative, indicating that the other double bond in component **50** is in the 8 position. Component **50** was therefore concluded to be 5,8-tetradecadien-1-yl acetate. The formation of the mono-DMDS derivative of a diunsaturated acetate has been described by Tonini et al. (1986) in a paper on the sex pheromone of the leopard moth. The DMDS derivatization procedure described by Vincenti et al. (1987), in which a higher reaction temperature and a longer reaction time are used, was therefore employed as an alternative method. According to Vincenti et al. (1987) and Carlson et al. (1989), the structures of the DMDS derivatives of compounds containing a diene system depend on the number of carbon atoms between the two double bonds. Information furnished by the partial derivatization of the skipped diene system of component **50,** 5,8-tetradecadien-1-yl acetate, according to Buser et al. (1983), proved useful in the interpretation of the more complex results produced by the complete derivatization according to Vincenti et al. (1987).

The reaction of a skipped diene with two molecules of DMDS gives four-membered cyclic thioethers substituted with two alkyl chains, each containing a methylthio group α to the ring. The mass spectrometric fragmentation of the DMDS derivatives of constituents containing a skipped diene system is shown in Table 8.

Information on the molecular mass and functionality of a number of alkadienals was supplied by the presence of $(M+1)^+$ and $(M+1-H_2O)^+$ ions in their CI(CH_4) mass spectra. However, only one DMDS derivative of an alkadienal, that of 5,8-tetradecadienal **32,** could be detected in the total ion current chromatogram of the derivatized secretion. The molecular ion, which is absent from the mass spectra of the derivatized alkadienyl acetates and formates, appears at *m/z* 334 in the mass spectrum of the derivatized dienal **32.** The ion at *m/z* 287 is formed by the loss of a methylthio radical from the molecular ion. The diagnostic ions at *m/z* 203 [AB^+ and BC^+], 155 [$(AB-CH_3SH)^+$ and

$(BC-CH_3SH)^+$], and 131 [A^+ and C^+] provide evidence that the double bonds are in the 5 and 8 positions. Component **32** was therefore identified as a 5,8-tetradecadienal. All of the alkadienals were found to contain a skipped diene system. Their structures and the configuration of the double bonds were confirmed by GC retention time comparison with synthetic compounds, employing coinjection techniques.

The EI mass spectra of the four components, **30, 40, 49,** and **57,** are similar to those of the alkadienals except for the presence in their spectra of the ion at *m/z* 31, which is typical for alcohols and formates. The prominent $(M+1)^+$ and $(M+1-H_2O)^+$ ions in their CI(CH_4) spectra indicated that they could be alkadienols. Although the $(M-3)^+$ ion, normally present in the CI(NO) spectra of primary alcohols, does not appear in an appreciable abundance in their CI(NO) mass spectra, the presence of a primary hydroxyl function in these compounds is confirmed by the presence of $(M-1)^+$ and $(M-2+NO)^+$ ions and the absence of a $(M-OH)^+$ ion. No DMDS derivative of an alkadienol could, however, be located in the total ion chromatogram shown in Figure 2 and, as a working hypothesis, these compounds were assumed to contain skipped diene systems similar to those found in the formates and acetates. This assumption was confirmed by coinjection of the secretion with the synthetic compounds.

In contrast to the other compound types, only saturated carboxylic acids are present in the secretion. The compounds identified in the preorbital secretion of the oribi are listed in Table 9 together with quantitative data and information on the methods used in their identification.

(4*Z*,7*Z*)-4,7-Tridecadien-1-ol, **30,** was synthesized using published procedures as outlined in Scheme 1. The bromination of the alkenol 1-**2** with phosphorus tribromide and pyridine gave (*Z*)-1-bromo-2-octene 1-**3** containing 10% of the *E* isomer. Condensation of this bromide with an excess of the acetylenic Grignard reagent 1-**6** in the presence of CuCl under reflux conditions, followed by partial hydrogenation and acid catalyzed removal of the protective groups, gave a mixture of 4,7-tridecadien-1-ol isomers. Column chromatography on 7% $AgNO_3$-coated silica gel was used to separate the product isomers and to isolate (4*Z*,7*Z*)-4,7-tridecadien-1-ol, **30.**

(6*Z*,9*Z*)-6,9-Pentadecadien-1-ol, **49,** was synthesized according to Scheme 2. In this synthesis the alcohol function was protected as its *tert*-butyl ether (Alexakis et al., 1988). The use of Ac_2O and $FeCl_3$ for the conversion of *tert*-butyl ethers to the corresponding acetates has been reported (Alexakis et al., 1988; Ganem and Small, 1974; Gross and Watt, 1987; Alexakis and Duffault, 1988). However, this method proved unsuccessful in this synthesis. Me_3SiI as deprotection reagent (Jung and Lyster, 1977), chosen for its reported high yield and limited reaction time, afforded complete cleavage of the ether in 6 min at room temperature. Column chromatography on 7% $AgNO_3$-coated silica gel was used to isolate pure (6*Z*,9*Z*)-6,9-pentadecadien-1-ol, **49.**

The formates were prepared by esterification of the corresponding alcohols with formic acid at room temperature, and the acetates were obtained by acetylation of the alcohols with acetyl chloride and pyridine in ether. The unsaturated aldehydes were prepared by oxidation of the corresponding alcohols with pyridinium chromate on silica gel in dichloromethane in the presence of a small quantity of acetic acid.

(Received December 16, 1994; accepted April 11, 1995)

Abstract—Volatile compounds elicited by insect herbivore feeding damage in five cotton cultivars and one naturalized cotton variety were examined by allowing beet armyworm larvae to feed overnight on leaves and collecting volatiles from the plants in situ. Of 23 compounds identified from larval damaged leaves, terpenes and lipoxygenase–hydroperoxide lyase-derived volatiles predominated. No pronounced differences in the levels of volatile emission were noted from leaves of undamaged plants of the different varieties. However, average volatile emission from damaged leaves of the naturalized variety was almost sevenfold higher than from damaged leaves of the commercial cultivars. This was despite the fact that larvae preferred feeding on the leaves of commercial cultivars over those of the naturalized variety in choice tests.

Key Words—Beet armyworm, *Spodoptera exigua*, cotton, *Gossypium hirsutum*, volatile compound, terpene, plant–insect interaction.

INTRODUCTION

The chemical composition of the cotton plant, *Gossypium hirsutum* L. (Malvaceae) has been extensively studied because of its economic importance and its susceptibility to a wide array of pests and diseases. Numerous investigations have been concerned with the volatile terpenoids found in the leaves and flower buds (Thompson et al., 1971; Chang et al., 1988) that may serve as attractants and/or feeding deterrents (Harborne, 1988) for pests. In the past, isolation of

these compounds usually relied on solvent extraction and/or steam distillation, which may have given unrepresentative aroma profiles due to artifact formation and cellular compartment disruption. Newer technology relies on the use of dynamic headspace techniques in which volatile compounds are entrained in a stream of air and adsorbed on porous polymers like Tenax or Porapak Q. These techniques allow volatiles to be collected from living plants and thus provide more accurate assessments of the composition of volatiles emitted by plants in response to various stimuli (Heath and Manukian, 1992; Surburg et al., 1993).

Recently, we analyzed the volatile compounds emitted by cotton (var. McNair 235) seedlings (with four to six leaves) damaged by feeding corn earworm, *Helicoverpa zea* (Boddie) larvae (McCall et al., 1994). Volatiles emitted by damaged seedlings that had been cut and detached from the base of the stem were found to serve as cues for the location of hosts by the parasitoid *Microplitis croceipes* (Cresson), which attacks corn earworm larvae (McCall et al., 1993).

Given the increasing awareness of the role that plant volatiles may play in herbivore/predator relationships and a need to study these phenomena in situ, we undertook the present study to determine whether significant differences might occur in volatile emissions from more mature specimens of different commercial cotton cultivars subjected to feeding damage by lepidopterous larvae. For this study we chose four varieties commonly planted in the coastal plain and piedmont areas of Georgia. For comparison we also chose a nectariless variety and a naturalized variety from south Florida. Beet armyworm *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae) larvae were used as test insects. They are pests of considerable economic importance in the southern United States on a variety of agronomic and horticultural crops such as beets, corn, and soybeans in addition to cotton.

METHODS AND MATERIALS

Cotton Varieties and Insects. Cotton varieties examined in the present study were Delta Experiment Station 119 (DES119), Delta Pineland 90 (DPL90), Stoneville 453 (SV453), Stoneville 213 nectariless (SV213), KC311, and a south Florida naturalized cotton, Texas accession no. 2259 (TX2259). Plants were grown in 30-cm pots in a 1 : 1 : 1 mixture of topsoil, vermiculite, and peat moss. Plants analyzed in these experiments were mature plants that had set squares (flower buds). Beet armyworm larvae were reared by the method of King and Leppla (1984).

Volatile Collections from Damaged Leaves of Cotton Varieties. Larvae were allowed to feed on cotton leaves overnight by enclosing a single leaf in a lightweight muslin bag in the late afternoon along with two late second-instar beet armyworms. A fully expanded leaf occupying a position near the apical

end of a branch was used in all studies. The following morning, about 2 hr after sunrise, the bag and larvae were removed from the plant. The branch holding the damaged leaf, still attached to the plant, was inserted into a 15-cm-diameter × 40-cm-tall glass sleeve sampling chamber of the volatile collection apparatus (Heath and Manukian, 1992; Heath et al., 1992). Air was forced through multiple layers of charcoal-infused fabric at the top of the sleeve, and the purified air passed down over the branch at a rate of 40 liters/min. This high flow rate was required to prevent intrusion of unfiltered air into the bottom of the sampling apparatus, which was not constricted. Volatiles were collected on 50 mg of Super Q adsorbent (Alltech Associates, Deerfield, Illinois) contained in a glass volatile collection trap (4 mm ID × 40 mm long) (Heath and Manukian, 1992) placed downstream from and adjacent to the damaged leaf. Air was pulled through the trap at a rate of 2 liters/min by a vacuum pump. Volatiles were collected for 2 hr beginning approximately 2 hr after sunrise. The experiments were replicated six times for each variety to obtain mean values. Leaves from an undamaged plant were sampled in a similar fashion, replicated four times for each variety, for comparison.

Feeding Choice Tests with Cotton Varieties. Larval preference for feeding on the different cotton varieties was tested by placing two second-instar beet armyworms in an 18-cm covered dish with a mature leaf of TX2259 and one of the commercial cultivars. Between 3:00 and 3:30 PM the leaves were cut from undamaged plants at the midpoint of the petiole, weighed, and the ends of the petioles wrapped in moistened cotton to prevent desiccation. Immediately, the larvae were placed in the dishes with the leaves and allowed to feed overnight. At about 7:00 AM the next day the larvae were removed and the leaves were weighed again to determine percent mass of the leaf eaten. The experiments were repeated six times for each cotton cultivar.

Analytical Methods. At the end of the sampling period, volatiles were eluted from the Super Q in each volatile collection trap with 150 μl of methylene chloride, 600 ng each of *n*-octane and *n*-nonyl acetate were added as internal standards, and each sample was analyzed by capillary gas chromatography on a methyl silicone column (Quadrex, New Haven, Connecticut, 50 m × 0.25 mm ID, with a 0.25-μm-thick bonded stationary phase) in a Varian model 3400 gas chromatograph equipped with a split/splitless injection system and a flame ionization detector. Injections were made in the splitless mode, and the injector was purged after 30 sec. The column was connected to the injector with a 5-m × 0.25-mm deactivated fused silica retention gap and operated under the following conditions: 50°C for 3 min, then programmed at 5°C/min to 180°C, injector 220°C, detector 240°C, helium linear flow velocity 21 cm/sec.

Volatiles from each cotton variety were analyzed by gas chromatography–mass spectroscopy using a 50-m methyl silicone column, operated as before, and interfaced to a Finnigan-MAT ITS 40 (ion trap) mass spectrometer operated

in the electron impact mode. Compounds were identified by comparison of spectra with those in the EPA-NIH data base and by comparison of GC retention times with those of authentic standards on the methyl silicone column and on a 50-m × 0.25-mm CPS-1 column (Quadrex, New Haven, Connecticut) operated under the following conditions: 30 sec splitless delay after injection, oven temperature 60°C for 1 min then programmed at 5°C/min to 180°C, injector 220°C, detector 260°C, helium linear flow velocity 19 cm/sec.

RESULTS AND DISCUSSION

The predominant components in the volatiles collected from leaves of undamaged plants of the various cotton cultivars were terpenoids, including the monoterpenes α-pinene, myrcene, and (*E*)-β-ocimene, the homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene, and the sesquiterpene caryophyllene (Table 1). There were no pronounced differences in the composition of the volatiles collected from undamaged leaves of the commercial cultivars and the naturalized cotton TX2259. These results are in good agreement with those of McCall et al. (1994) for detached cotton plants, in that monoterpenes comprised the majority of compounds collected. Similarly, Chang et al. (1988) reported that the monoterpenes were the most abundant compounds in the volatiles collected from detached cotton flower buds. Thus, it appears that detached flower buds and leaves may not differ from intact living plants in volatile emission. However, it is possible that the release of some or all of these compounds in our experiments was caused by slight damage incurred when the branch was placed in the sampling apparatus.

Compounds emitted by leaves that had been damaged by beet armyworm larvae feeding overnight are presented in Table 2 and are summarized by biosynthetic class in Figure 1. A total of 23 compounds, representing approximately 90% of the trapped volatiles, were identified. A number of other compounds, notably sesquiterpene hydrocarbons, were not identified because of insufficient spectral data and/or lack of reference standards. The majority of the volatile components consisted of monoterpene and sesquiterpene hydrocarbons, with the most abundant components being the monoterpenes α-pinene and (*E*)-β-ocimene and the sesquiterpene caryophyllene. More unusual terpenes identified were (*E*)-4,8-dimethyl-1,3,7-nonatriene and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. These compounds, which are usually referred to as homomonoterpenes and homosesquiterpenes, result from oxidative cleavage of the sesquiterpenoid nerolidol and diterpenoid geranyllinalool, respectively (Gäbler et al., 1991).

Most cotton cultivars accumulate large amounts of terpenoids in specialized glands present in the leaf and flower buds (Elzen et al., 1985). Therefore, it is

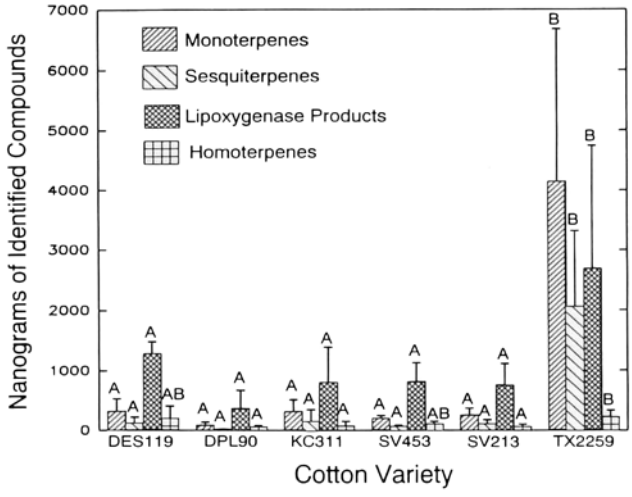

FIG. 1. Total identified volatiles, divided by biosynthetic class, from cotton varieties damaged by beet armyworm larvae. Data represent the means of six experiments ± standard deviation. Within a biosynthetic class, bars with the same letter are not significantly different by Duncan-Waller's multiple range comparison at $P = 0.05$.

possible that the terpenes released by the damaged plants in this study came from glands that were physically disrupted by the larvae. However, many of these terpenes, including (*E*)-4,8-dimethyl-1,3,7-nonatriene and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene have previously been shown to be emitted in response to arthropod feeding damage in corn and lima bean (Turlings et al., 1990; Dicke et al., 1990). In a subsequent study (Loughrin et al., 1994) we found that larval damaged plants released significantly greater quantities of acyclic terpenes such as ocimene and the homoterpene and homosesquiterpene during the mid- to latter part of the photophase than during the scotophase or early photophase. However, cyclic terpenoids such as α-pinene and caryophyllene were not released in significantly greater amounts during the photophase than during the scotophase. Therefore, the time of the photoperiod during which volatiles are collected from a plant may have a significant effect on the composition of the volatile blend. In this study, volatiles were collected from all the cultivars at the same time of the photoperiod to allow valid comparison of the composition and quantities of the volatiles.

For most of the cotton cultivars studied, the greatest quantity of volatiles emitted by damaged plants consisted of lipoxygenase–hydroperoxide lyase products (Vick and Zimmerman, 1987). This class of compounds, formed by the

hydroperoxidation of fatty acids containing a *cis,cis*-1,4-pentadiene moiety, are known to be induced by damage (Hatanake et al., 1987) and are largely responsible for the odor of cut grass. While the majority of the lipoxygenase-derived volatiles identified in the present study are commonly associated with damaged leaves, a number of less commonly encountered esters of (*Z*)-3-hexen-1-ol were also identified in the volatiles from the leaves damaged by larvae. These were previously identified in volatiles collected from detached cotton seedlings damaged by *Helicoverpa zea* Boddie larvae (McCall et al., 1994). In the latter work it was also demonstrated that the emission of esterified forms of the lipoxygenase products was more favored from leaves with old damage than from freshly damaged plants. While the butanoic acid esters of (*Z*)-3-hexenol are less common than the acetate esters, (*Z*)-3-hexenyl butanoate and related esters are common floral headspace components (Knudsen et al., 1993).

Another compound identified in the volatiles from damaged cotton leaves, *cis*-jasmone, likely resulted from the action of a hydroperoxide dehydrase (Vick and Zimmerman, 1987) rather than hydroperoxide lyase on the hydroperoxide formed by lipoxygenase. This compound probably resulted from the β-oxidation and subsequent decarboxylation of jasmonic acid, a plant messenger known to be synthesized in response to insect damage and responsible for mediating responses such as the accumulation of proteinase inhibitors (Farmer and Ryan, 1990). Thus, this compound may have been formed in direct response to the damage incurred by the insect feeding.

When the quantities of compounds emitted by damaged leaves of the different cotton cultivars were summed by biosynthetic class and subjected to statistical analysis as shown in Figure 1, no significant differences were seen among the commercial cotton cultivars. However, TX2259 emitted substantially more volatiles of all biosynthetic classes, except the homoterpenes, than the other varieties.

The standard deviations noted in these experiments were quite large. These may have been caused by variations in the amount of damage done by the larvae, differences in environmental parameters such as light and relative humidity for each individual experiment, and/or variations in the stage of development of each individual leaf. Although visual inspection indicated that a similar amount of damage was inflicted by the larvae on all the varieties, we were not able to determine accurately the amount of damage to each plant. Therefore, to determine whether the higher levels of volatile emission from the variety TX2259 could have been due to greater feeding damage by the larvae to this variety, feeding choice tests were conducted. Larvae were given the opportunity to feed on a leaf of either a commercial cultivar or a TX2259 leaf. The results of these experiments (Figure 2) indicate that beet armyworm larvae consistently preferred to feed on leaves of the commercial cultivars when given a choice. Whether these results are due to greater amounts of terpenoids and other secondary metab-

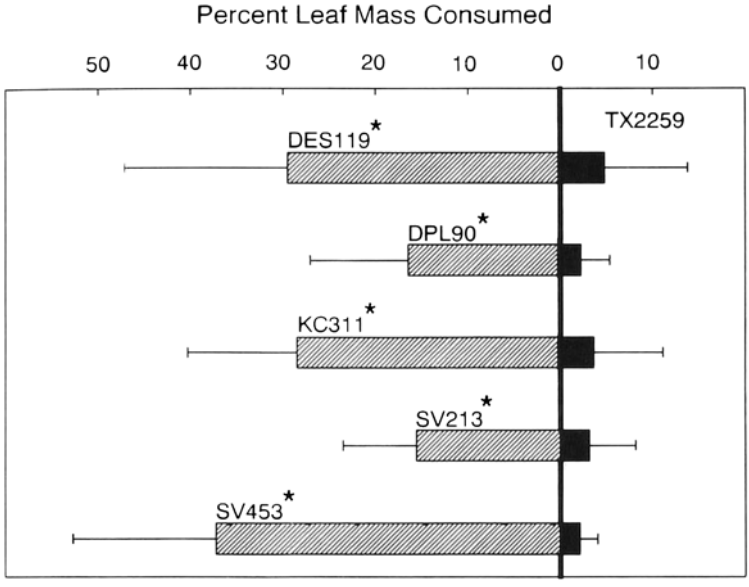

FIG. 2. Beet armyworm preference for feeding on leaves of commercial cotton cultivars versus those of TX2259 leaves. Two second-instar beet armyworms were provided with a mature leaf of TX2259 and a mature leaf of one of the commercial cultivars in an 18-cm covered dish. Solid bars to the right indicate mean percent of leaf mass of TX2259 consumed and hatched bars to the left indicate mean percent of leaf mass of the commercial cultivar leaf consumed in each choice test. $N = 6$ for each feeding choice test. Error bars represent standard deviation. An asterisk after a variety name indicates significant preference for feeding on the leaves of that variety (Student's t test).

olites or the presence of a specific feeding deterrent in TX2259 is unknown. However, the results suggest that beet armyworm larvae are not likely to cause more damage by feeding on TX2259 than on the other varieties, and thus the greater volatile emission by damaged TX2259 leaves was probably not due to greater damage incurred by this variety.

The volatiles released by cotton leaves damaged by feeding larvae may serve as indicators of the presence of hosts to potential biological control agents such as parasitic wasps (Elzen et al., 1984; Tumlinson et al., 1992). Of course, previous research has also implicated cotton volatiles in the attraction of pests such as the boll weevil (Gueldner et al., 1970; Dickens, 1990). Even given the low levels of terpenes released by undamaged leaves, the air over a cotton field should contain detectable amounts of these compounds. More likely, insect herbivore-induced compounds (Loughrin et al., 1994), which are released in

much greater amounts from herbivore-damaged plants than from mechanically damaged or undamaged plants, act as a beacon to draw parasitoids to plants with potential hosts.

In summary, the leaves of the cotton varieties we studied emitted only relatively low quantities of volatiles unless damaged by feeding larvae. This was true even for a naturalized cotton variety, but the latter emitted markedly greater amounts of terpenes from damaged leaves than the commercial cultivars studied. The implication for these findings may be that biological control using predators and parasitoids would be enhanced by developing strains of cotton that release greater amounts of volatile compounds when attacked by insect herbivores.

Book Review

Beetle–Pathogen Interactions in Conifer Forests. T.D. Schowalter and G.M. Filip, (eds.). London: Academic Press, 1993. UK £50.00 hardcover. 252 pp. ISBN 0-12-628970-0. Applied Botany and Crop Sciences Series. Series editors R.W. Snaydon and J.M. Barnes.

This book contains an integrated synthesis of the current research and knowledge base developed by a multidisciplinary group of scientists organized under the former United States Department of Agriculture Regional Research Project W-110. The original 23-year project consisted of over 30 technical experts and explored the role of bark beetles and pathogens (predominantly fungal) as agents of stress on conifers in North American forest ecosystems. The text summarizes the contributions of 24 of these experts and their colleagues to that project. The project was renewed for an additional five-year period in late 1994 as Regional Research Project W-187: "Interactions Among Bark Beetles, Pathogens, and Conifers in North American Forests."

The book's twelve chapters are organized into six sections. Excluding the first and last sections, which introduce and summarize the book, the section topics advance sequentially from organismal to ecological and managerial levels (e.g., systematics, factors influencing interactions, effects of interactions, and management of interactions). The authors and editors have generously supplemented the work with black-and-white photos, figures, and tables. The photos appropriately illustrate the text, and many were photographed, and apparently chosen by the editors themselves. Schowalter and Filip also wisely chose to present the scientific and common names of all of the organisms discussed in the text in four appendices. The appendices pertaining to trees, insects, and pathogens (fungi, bacteria, nematodes, and parasitic higher plants) are all based on accepted checklists or reference works of nomenclature. An index based on key words and common and scientific names has been included and is very useful. An index of authors of the literature cited throughout the text would have been a useful addition to the book.

The theme of the text is that species interactions are of paramount importance to the productivity and stability of integrated forest ecosystems. The 252-page volume focuses on the systematics, physiology, biology, and ecology of scolytid bark beetles, ascomycete and deuteromycete fungi, and, to some extent, their pinaceous host plants. Nonetheless the effects of predacious and parasitic insects, mites, nematodes, and bacteria on the colonization of host conifers by

0098-0331/95/0800-1229$07.50/0 © 1995 Plenum Publishing Corporation

bark beetles and pathogenic fungi are also considered in this treatment of forest ecology. Furthermore, the effects of biotic and abiotic agents that predispose host trees to bark beetle and fungal colonization are also discussed. All of these species and factors are considered to be integral to the function of forested terrain from the ecosystem perspective.

With the current focus on environmental health and biodiversity issues in ecology, the value of the material in this book to ecologists is self-evident. This well-studied and integrated system provides an ecological case study of considerable breadth and depth. The book serves as an entry point into an ecological literature that is often avoided by students because of the sheer number of research papers on bark beetle–fungal interactions. Some of the ecological relationships described in the book are simply stunning. Two species of tarsonemid mites, which are flightless associates of the southern pine beetle, *Dendroctonus frontalis*, possess specialized morphological structures to carry ascospores of species of plant pathogenic *Ophiostoma* fungi, and this fungal–acarial interaction ostensibly assists *D. frontalis* in its colonization of its primary host, loblolly pine, *Pinus taeda* (Stephen et al., p. 142).

To chemists or chemical ecologists, the value of this book is more subtle. Chapters entitled "Environmental Stress and Whole-Tree Physiology," "Strategies and Mechanisms of Host Colonization by Bark Beetles," and "Host Response to Bark Beetle and Pathogen Colonization" all contain significant portions devoted to chemical mediation of the beetle–pathogen–host triangle. In the latter chapter, Nebeker et al. (pp. 164–166) not only discuss a variety of phytochemicals involved in the induced defensive response of conifers to fungal colonization, but also review the literature related to a group of hydroxy isocoumarins that are thought to be toxic fungal metabolites involved in overcoming tree resistance and eventually killing the tree. They follow this (p. 168) with an interesting discussion of iron chelation chemistry that might be involved in the blue sapwood discoloration that is the signature of blue-stain fungi ubiquitous in trees colonized by phloeophagous and xylophagous insects.

Moreover, the book is replete with biological and ecological vignettes that could provide the basis for many studies of chemical ecology. For example, Stephen et al. (pp. 138–141) discuss the phenomenon of phoresy by wingless mites that ride on bark beetles or other flying associates to disperse to new subcortical tissue of conifers. Since the phoretic relationship between mite and bark beetle host can sometimes be quite species-specific, these interactions might provide interesting models for the study of host recognition through contact chemoreception between the arthropodous classes Arachnida and Insecta. Although Stephen et al. do not raise the subject in their discussion of bark beetle–fungal mutualism (pp. 142–144), one could envision a role for ingested fungal cellulose-degrading enzymes in digestion of phloem and xylem tissue by

scolytids. This would be analogous to the elegant work on xylophagous cerambycid beetles and siricid woodwasps in the laboratory of M.M. Martin. In another example, conifers that are damaged by lightning strike or fire exhibit elevated levels of bark beetle and pathogen colonization (Paine and Baker, pp. 64–67). When compared to controls, lightning-struck *P. taeda* have different relative amounts of specific monoterpenes as well as other biochemical differences (Nebeker et al., p. 160). One wonders which biochemical changes, and in particular which monoterpenes, are primarily responsible for the enhanced colonization rate by bark beetles following a lightning strike and whether the same chemical phenomena apply to fire-damaged trees. Lastly, both Raffa et al. (p. 111) and Nebeker et al. (pp. 157–158) review the behavioral basis for feeding stimulation in bark beetles and preliminary attempts at chemical characterization of the relevant semiochemicals. This is an area that is woefully understudied and deserves the attention of insect behaviorists and chemists skilled in modern preparative and analytical techniques. Clearly, the curious chemical ecologist would find fertile subject matter for research among the organismal interactions introduced and explored in this book.

In general the chapters are interwoven quite skillfully by the many authors. They frequently and smoothly allude to each other's chapters throughout the book. However, problems inherent with chapters written by teams of experts do surface from time to time. For example, Stephen et al. (p. 137) write "All parasitoids of bark beetles are wasps (Hymenoptera)." However, two pages later in a discussion of mites associated with bark beetles, the same authors write "Although **mite parasitoids** tend to be the most specific, practically all ride more than one host (bark beetle) species." Nonetheless, due perhaps to excellent technical reviews of the entire book by R.L. Edmonds and D.L. Wood, these occurrences are rare in a text that amalgamates the input of a large number of experts. The positive effect of the collective expertise far outweighs any minor oversights of coordination.

As a chemical ecologist interested in the colonization behavior of bark beetles and the role of aggregation pheromones in that behavior, I dwelled on Chapter 6: "Strategies and Mechanisms of Host Colonization by Bark Beetles." The chapter, written by K.F. Raffa and two colleagues, is a masterful and complete update of a 1982 review of the same topic by D.L. Wood. Undoubtedly this chapter will be the new classic of citation for the next generation of bark beetle chemical ecologists. A section on pheromone biosynthesis by scolytids is particularly well written. While the authors emphasize conversion of host monoterpenes to monoterpene alcohol and ketone pheromone components by bark beetles, they also discuss the possibility that cyclic ketal and some monoterpene alcohol pheromone components might arise from *de novo* synthesis. The open-minded approach of this review is critical to its enduring nature,

as recent results in our laboratory demonstrate that the model species *Ips paraconfusus* and *I. pini* can both produce hydroxylated monoterpenes *de novo* from radiolabeled acetate.

As I read this book I noted that it has a marked regional emphasis. Nineteen of the 24 authors are from the western and southern regions of the United States, and the book is centered on model organisms and systems that occur in these regions. There is less coverage of the Lake States (central) region and even less of the eastern region. For example, Filip and Schowalter (p. 231) summarize the significance of bark beetles and root pathogens to human utilization of timber resources by stating that they cause a loss of volume of 0.9–1.1 billion m^3/year in **western** North America. This regional influence likely resulted because the membership of Project W-110 was drawn primarily from the western and southern regions of the United States, which in turn reflects the economic impact of coniferous forests in these regions and the research priorities of the relevant state agricultural experiment stations.

It is likely that some portions of *Beetle–Pathogen Interactions in Conifer Forests* will not capture the attention of all chemical ecologists. Chapters on topics such as abiotic and biotic predisposition of conifers to attack by bark beetles and pathogenic fungi, computer modeling of beetle–pathogen–tree interactions, and management of root disease and bark beetle impacts on forest resources, while interesting, are typically not in the mainstream reading of nonforest ecologists. However, enough of this book deals with chemically related ecological issues and interactions to justify careful scrutiny by the readers of the *Journal of Chemical Ecology*. The book, and especially selected chapters (1, 5, 6, 7, 8, 9, and 12), would be very suitable as discussion matter for a graduate level seminar or supplementary course reading in general ecology or chemical ecology. This book provides a valuable window into a voluminous and often intimidating primary literature that will aid research scientists, instructors, and students in chemical ecology, general ecology, forestry, and resource management.

Announcement

BIOLOGY OF COMMUNICATION AWARD

The Jean-Marie Delwart Foundation will award in 1996 a prize for research or a series of researches, individual or collective, in the field of chemical communication. The award will recognize the discovery of a new signaling function of one or several substances particularly in the relations between animal species (including humans) as well as between animal and plants.

The research or researches should be fundamental and original.

The prize of $10,000 will be awarded for works written in or translated into French or English.

Candidates should attach to their documents an application letter, addressed to the Jean-Marie Delwart Foundation, as well as their curriculum vitae and a complete list of their publications. Applications should reach the:

Fondation Jean-Marie Delwart
Château de Pellenberg
B-3212 Pellenberg
Belgium

by December 31, 1995.

The jury is composed of members of the scientific committee of the Jean-Marie Delwart Foundation and of members of the Académie Royale des Sciences de Belgique.

The prize will be awarded in December 1996 at the Public Session of the Académie Royale des Sciences de Belgique.

PRESERVING LEAVES FOR TANNIN AND PHENOLIC GLYCOSIDE ANALYSES: A COMPARISON OF METHODS USING THREE WILLOW TAXA

COLIN M. ORIANS[1]

Department of Biology, Williams College
Williamstown, Massachusetts 01267

(Received November 10, 1994; accepted April 8, 1995)

Abstract—Members of the Salicaceae often produce phenolic glycosides and condensed tannins. There is much debate on the best method for the preservation of leaf material prior to chemical analysis. Published results indicate freeze-drying, a method commonly used for tannin analysis, may be inappropriate for phenolic glycosides, unless done in a manner to prevent thawing during the drying process. Another commonly employed method, air-drying, is appropriate for phenolic glycosides but inappropriate for condensed tannins. I present evidence using willow leaves that demonstrates that: (1) leaves freeze-dried in external flasks without temperature control contain lower concentrations of phenolic glycosides (salicortin and 2′-cinnamoylsalicortin), (2) air-dried leaves have reduced concentrations of condensed tannins, while (3) vacuum-dried fresh leaves have high concentrations of both phenolic glycosides and condensed tannins. Freeze-drying caused salicortin and 2′-cinnamoyl salicortin concentrations to drop by 20 mg/g and 4 mg/g, respectively. Salicin, a product of salicortin and 2′-cinnamoyl salicortin degradation, is absent in vacuum-dried leaves, present in air-dried leaves and very high in freeze-dried leaves. Thus, the presence of salicin in this system is an artifact of the preservation technique. Condensed tannin concentrations dropped nearly 20 mg/g when leaves were air-dried. Thus, vacuum-drying fresh leaves allows researchers to quantify phenolic glycosides and condensed tannins from the same leaf material.

Key Words—Salicaceae, willows, phenolic glycosides, salicortin, 2′-cinnamoyl salicortin, salicin, condensed tannins, leaf preservation.

INTRODUCTION

Willows and other Salicaceous plant species produce two main secondary chemicals: phenolic glycosides and/or condensed tannins (Julkunen-Tiitto, 1986,

[1]Present address: Dept. of Biology, Tufts University, Medford, MA 02155.

2751-3028/95/0900-1235$07.50/0 © 1995 Plenum Publishing Corporation

1989; Lindroth et al., 1987). The concentrations of the phenolic glycosides may vary among individuals (Nichols-Orians et al., 1993) and in some cases influence the susceptibility of plants to both insect and mammalian herbivores (Rowell-Rahier, 1984; Tahvanainen et al., 1985; Basey et al., 1988; Lindroth and Peterson, 1988; Lindroth et al., 1988; Clausen et al., 1989; Lindroth, 1992). Condensed tannins are bioactive as well, especially against microbes (Schultz, 1989; Nichols-Orians, 1991a).

Salix sericea Marshall and *Salix eriocephala* Michx. produce different secondary chemicals. *S. sericea* produces two main phenolic glycosides, salicortin and 2′-cinnamoylsalicortin (Nichols-Orians et al., 1992) and very low concentrations of condensed tannins. *S. eriocephala* produces high concentrations of condensed tannins and no phenolic glycosides. Interestingly, these species hybridize and *S. sericea* × *S. eriocephala* hybrids produce both tannins and phenolic glycosides at intermediate concentrations (Orians and Fritz, 1995). When studying the bioactivity of these secondary chemicals, it is critical that leaves be preserved in a manner that prevents degradation.

Salicortin is quite labile and when improperly preserved it degrades to salicin (Lindroth and Pajutee, 1987; Julkunen-Tiitto and Meier, 1992). Even relatively nonlabile chemicals like tannins are lost when improperly preserved (Hagerman, 1988). Given the bioactivity of both these chemical types, it is of interest to determine the method of preservation that will prevent their degradation (Lindroth and Pajutee, 1987; Hagerman, 1988; Julkunen-Tiitto and Gebhardt, 1992; Julkunen-Tiitto and Meier, 1992).

Julkunen-Tiitto and Meier (1992) have suggested that air-drying at low temperatures is sufficient to prevent the degradation of phenolic glycosides. However, air-drying leaves is known to result in the degradation of tannins (Hagerman, 1988). Van Sumere et al. (1983) suggest that lyophilization (freeze-drying) is inappropriate for low- and intermediate-molecular weight phenolics. When drying leaves for tannin analysis, Hagerman (1988) recommends fresh extraction or freeze-drying prior to extraction. The exact method depends upon the species and time of year. Thus, the method appropriate for one set of chemicals is often inappropriate for another. The lack of a standard technique has made it difficult to compare studies and has hindered researchers in their efforts to determine the bioactivity of foliar chemicals. This study was initiated after preliminary results indicated that vacuum-drying was appropriate for both phenolic glycosides and tannins.

Here I compare three methods of preservation (air-drying, freeze-drying, and vacuum-drying). Based on studies by Hagerman (1988), Van Sumere et al. (1983), and Julkunen-Tiitto and Meier (1992), I expected concentrations of phenolic glycosides to be lowest in freeze-dried leaves and concentrations of condensed tannins to be lowest in air-dried leaves. The results indicate that air-drying results in a loss of tannins, freeze-drying causes extensive conversion of

salicortin and 2′-cinnamoylsalicortin to salicin, while vacuum-drying preserved both the phenolic glycosides and the tannins. Thus, of the three methods, vacuum-drying is superior for both chemicals.

METHODS AND MATERIALS

Plants. Salix sericea Marshall and *Salix eriocephala* Michx. are abundant in the northeastern United States and eastern Canada (Argus, 1986). They produce leaves continuously from May until September at our field site near Milford, New York, and adult plants reach a height of 3–4 m. *S. sericea* × *S. eriocephala* hybrids are abundant at the field site.

Cuttings from field plants at the study site were brought back to Williams College. Cuttings were rooted, potted, and then placed in a common garden on Williams College campus. I used a total of 36 one-year old cuttings for this study (12 of each plant species). Four plants of each species were randomly assigned to each treatment. Thus all the leaves removed from one plant were processed the same way.

Leaf Material. Two adjacent leaves (the first two fully mature leaves) from eight different shoots were collected from each plant. The methods of collection were as follows. For freeze-drying, leaves were immediately frozen in liquid nitrogen, transported to the lab, placed in flasks and attached to a Labconco (model 77500) freeze-drier. Care was taken to limit thawing once frozen. This freeze-drier has external flasks (that cannot be temperature regulated) attached to a central vacuum. Therefore it was impossible to prevent thawing completely prior to sublimation.

For air-drying, leaves were put into a cooler containing ice, transported back to the lab, and air-dried at 60°C for 24 hr.

For vacuum-drying, leaves were put into the ice cooler, transported back to the lab, and immediately vacuum dried (a freeze-dryer was used but the leaves were never frozen). Once dry, leaves were ground in a Wiley mill (size 30 mesh), weighed, and stored in the freezer until chemical analyses were performed.

Chemical Analysis. The phenolic glycosides were assayed using standard techniques (Nichols-Orians et al., 1992, 1993). Briefly, leaf powder (30 ± 3 mg) was extracted in cold MeOH (10 mg leaf powder/1 ml MeOH) with sonication for 10 min. Cold water was constantly flushed through the sonicator to prevent the heating of samples. Extracts were centrifuged and filtered (0.45 μm) then placed in crimp-top vials. Extracts were kept in the freezer until analysis (48 hr or less). The concentration of glycosides was quantified with an HPLC (Hewlett-Packard) and a UV detector set at 274 nm. A reverse-phase Nova-Pak C_{18} (4 μm) column (Waters) and a gradient system of distilled water and MeOH

was used. The samples were injected through an LS-3200 automated sampler (SGE). 1,3-Dimethoxybenzene was used as the internal standard. Purified standards of salicin, salicortin, and 2′-cinnamoylsalicortin were used to determine concentrations.

The condensed tannins also were extracted using standard techniques (see Nichols-Orians, 1991a,b). Briefly, approximately 300 mg leaf powder was washed with ether and extracted with 70% acetone for 3 hr in a 40°C water bath. Acetone was removed under reduced pressure and all extracts were diluted to 8 ml with distilled water. Two techniques were used to quantify condensed tannin concentrations: the butanol/HCl method and the vanillin method (Bate-Smith, 1977; Butler et al., 1982; Hagerman and Butler, 1989). The concentration of the condensed tannin (milligrams per gram dry leaf) in each species was determined using purified tannins collected from each of the species.

RESULTS AND DISCUSSION

The method of preservation had a statistically significant effect on the concentrations of the phenolic glycosides (see treatment effect in Table 1). As expected, freeze-dried *S. sericea* or hybrid leaves had the lowest concentrations of salicortin and 2′-cinnamoylsalicortin (Figure 1A and B) (*S. eriocephala* does not produce phenolic glycosides). The difference in phenolic glycoside concentration between air-dried and vacuum-dried leaves was not significant. However, the presence of a breakdown product, salicin, is the best indicator of salicortin or 2′-cinnamoylsalicortin degradation. No salicin was present in the vacuum-dried leaves but was present in both the air-dried and freeze-dried *S. sericea* leaves (Figure 1C).

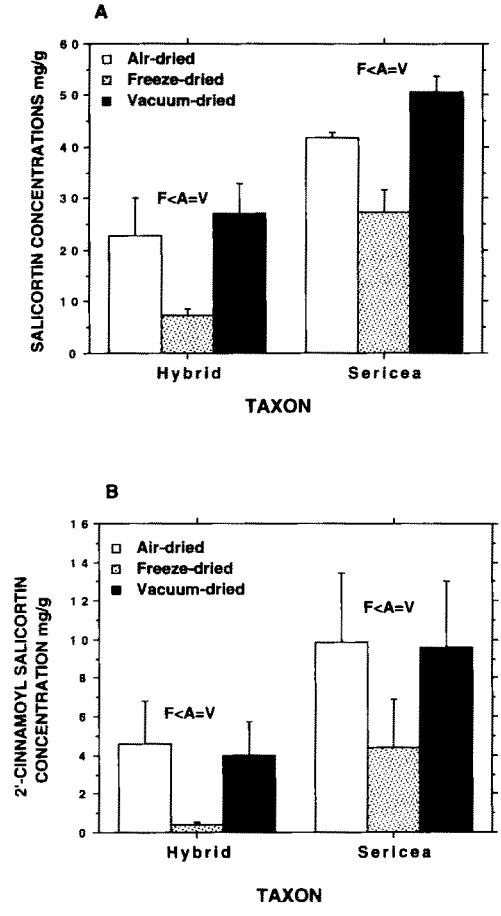

FIG. 1. The concentration (milligrams per gram dry leaf) of (A) salicortin, (B) 2'-cinnamoylsalicortin, and (C) salicin as a function of plant taxon and preservation treatment. Data were ln transformed prior to analyses and the Bonferroni method was used to determine which treatments were significantly different. A = air-dried, F = freeze-dried, V = vacuum-dried.

When vacuum-dried, the mean concentration of salicortin was 50 mg/g in *S. sericea* leaves and 27 mg/g in hybrid leaves. When freeze-dried, the mean concentration dropped to approximately 27.5 mg/g in *S. sericea* and 7.4 mg/g in hybrid leaves. Salicin concentrations increased from zero in vacuum-dried leaves to approximately 21 mg/g and 10 mg/g in *S. sericea* and hybrid freeze-dried leaves, respectively.

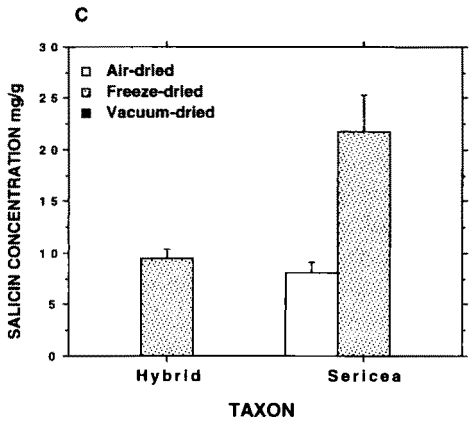

FIG. 1. Continued.

If samples are placed in a freeze-dryer with a temperature-regulated drying chamber (set below freezing), degradation can be prevented (Lindroth, personal communication). It is critical, therefore, not to use freeze-driers with external flasks when analyzing phenolic glycosides. Many researchers have reported the presence of salicin in their study species, yet my results show that its presence may be merely an artifact of the preservation technique.

Condensed tannin concentrations also varied with preservation technique (Table 2). As expected, both the vanillin and the butanol/HCl method show that concentrations are lowest in air-dried leaves and highest in the freeze- and

TABLE 2. SIGNIFICANCE OF EFFECTS OF LEAF PRESERVATION TECHNQIUE ON CONCENTRATIONS OF CONDENSED TANNINS IN LEAVES USING TWO-WAY ANALYSIS OF VARIANCE WITH PLANT TAXON AND PRESERVATION TECHNIQUE AS MAIN EFFECTS[a]

[a]Concentrations were LN transformed prior to analyses.

vacuum-dried leaves (Figure 2A and B). The loss of tannin with air-drying is consistent with the results of Hagerman (1988). It is standard methodology to freeze-dry leaves prior to tannin analysis. I found no difference in concentration between freeze-dried and vacuum-dried leaves. Clearly vacuum-drying is an excellent method when quantifying the concentrations of condensed tannin.

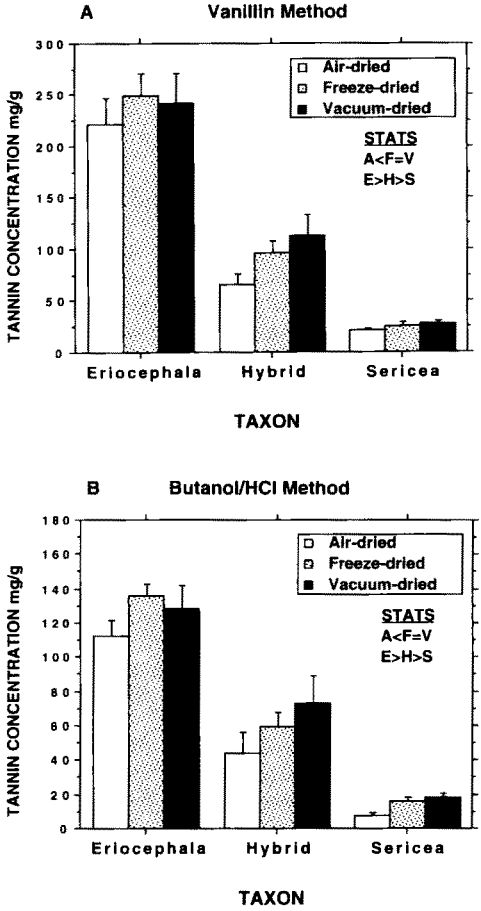

FIG. 2. The effects of plant taxon and preservation treatment on the concentration of condensed tannin (milligrams per gram dry leaf) as determined with the (A) vanillin method and (B) butanol/HCl method. Data were transformed prior to analyses and the Bonferroni method was used to determine which taxa and treatments were significantly different. A = air-dried, F = freeze-dried, V = vacuum-dried, E = *S. eriocephala*, H = hybrid and S = *S. sericea*.

Overall, this technique allows researchers to quantify both phenolic glycosides and condensed tannins from the same leaf material. For plants that contain both chemical types, such as *S. sericea*, *S.s.* × *S.e.* hybrids, and most *Populus* sp., this technique would be ideal. Further study will be required to determine if vacuum-drying will be the method of choice for other chemicals, such as hydrolyzable tannins and alkaloids. Van Sumere et al. (1983) suggest that some phenolics might be lost during freeze-drying under high-vacuum conditions because many of the volatile phenolics are concentrated on the ice trap. Whether these same chemicals would be lost in the absence of freezing is unknown. If vacuum-drying proves to be generally appropriate, it would alleviate the need for liquid nitrogen and facilitate research in remote sites. I conclude that researchers studying salicaceous species should adopt this preservation technique as it prevents the degradation of both phenolic glycosides and condensed tannins and avoids the need for liquid nitrogen—a cooler of ice and a vacuum pump will do.

Acknowledgments—I thank Len and Ellie Sosnowski and the New York State Department of Environmental Conservation for permitting me to collect plants from their property. Cynthia Huang and Rebecca Barnes provided invaluable assistance. Early versions of the manuscript benefited from the comments of Gretchen Meyer, Karl Kleiner, and Robert Fritz. (Received November 10, 1994; accepted April 8, 1995)

Abstract—*Salix sericea* and *S. eriocephala* differ markedly in secondary chemistry. *S. sericea* produces phenolic glycosides, salicortin and 2′-cinnamoylsalicortin, and low concentrations of condensed tannin. In contrast, *S. eriocephala* produces no phenolic glycosides, but high concentrations of condensed tannins. Hybrid chemistry is intermediate for both types of chemicals, suggesting predominantly additive inheritance of these two defensive chemical systems from the parental species. However, there is extensive variation among hybrids. This variation may be due to genetic variation among parental genotypes, which genes were passed on, or to subsequent back-crossing. The differences in chemistry are likely to exert a strong effect on the relative susceptibility of hybrid and parental willows to herbivores.

Key Words—Salicaceae, willows, hybrids, hybridization, phenolic glycosides, salicortin, 2′-cinnamoylsalicortin, condensed tannins.

INTRODUCTION

Hybridization among plants is very common (Barton and Hewitt, 1985; Rieseberg and Brunsfeld, 1992; Reiseberg and Ellstrand, 1993). The ubiquity of hybrids has important implications to plant speciation and could affect the evolution of plant phytophages. In fact, the study of herbivores in plant hybrid

zones has recently gained attention (Whitham, 1989; Boecklen and Spellenberg, 1990; Whitham et al., 1991, 1994; Aguilar and Boecklen, 1992; Floate and Whitman, 1993; Paige and Capman, 1993; Fritz et al., 1994). While some have argued that hybrids typically have higher densities of herbivores and thus may serve as ecological and evolutionary sinks (sensu Whitham 1989), others have argued that the relative abundance of herbivores and hybrids and parental taxa is more variable; densities may be greater, less, or equal to the parental species (Boecklen and Spellenberg, 1980; Aguilar and Boecklen, 1992; Fritz et al., 1994).

The different patterns of herbivore abundance could be due to the specifics of the plant system; Boecklen and colleagues study oaks, Whitham and colleagues study cottonwoods, and we have been studying willows. The morphology and chemistry of hybrids will differ among systems (Meier et al., 1989; O'Donoughue et al., 1990; Levy and Milo, 1991; Reiseberg and Ellstrand, 1993). However, differences in abundance could merely be due to variation among herbivores in their response to plant traits (Rowell-Rahier, 1984; Tahvanainen et al., 1985a; Marquis, 1990).

The effects of hybridization on plant morphology are well researched (Whitham, 1989; Boecklen and Spellenberg, 1990; O'Donoughue et al., 1990; Levy and Milo, 1991; Reiseberg and Ellstrand, 1993), but the effects of hybridization on foliar chemistry are less understood (Rabotyagov and Akimov, 1987; Huesing et al., 1989; Meier et al., 1989; Reiseberg and Ellstrand, 1993). Willows and other salicaceous plant species produce two main secondary chemicals: phenolic glycosides and condensed tannins (Julkunen-Tiitto, 1986, 1989; Lindroth et al., 1987). In this system, *S. sericea* produces high concentrations of phenolic glycosides, especially salicortin (Nichols-Orians et al., 1992, 1993) and phenolic glycosides are well known to influence the susceptibility of plants to both insect and mammalian herbivores (Rowell-Rahier, 1984; Tahvanainen et al., 1985a,b; Basey et al., 1988; Lindroth and Peterson, 1988; Lindroth et al., 1988; Clausen et al., 1989; Denno et al., 1990; Kolehmainen et al., 1994). Preliminary results indicated that *S. sericea* produces low concentrations of condensed tannins, while *S. eriocephala* produces high concentrations of condensed tannins, but no phenolic glycosides. Since condensed tannins can be bioactive as well, especially against microbes (Zucker, 1983; Schultz, 1989), the patterns of inheritance of these two chemicals could have strong effects on the relative resistance of hybrids to phytophages.

Here we report on the concentrations of condensed tannin and phenolic glycosides in *Salix sericea*, *Salix eriocephala*, and hybrids of the two species. To avoid confounding environmental effects (Bryant et al., 1987; Price et al., 1989; Julkunen-Tiitto et al., 1993), we grew the hybrids and the two parental taxa in a common garden.

METHODS AND MATERIALS

Plants. Both *Salix sericea* Marshall and *Salix eriocephala* Michx. are abundant in the northeastern United States and eastern Canada (Argus, 1986). They produce leaves continuously from May until September at our field site near Milford, New York, and adult plants reach a height of 3–4 m. Hybrid and parental plants are abundant within our field site. In March 1993 we took leafless budsticks (cuttings) from seven *S. eriocephala*, eight hybrid, and eight *S. sericea* field plants. These plants were far apart from one another and therefore likely represent different genotypes.

Cuttings were dipped in Rootone and planted in a soiless medium until roots formed. In May the plants were transplanted into pots containing soil, peat moss, and vermiculite (3 : 1 : 1). For this experiment one cutting from each of the field plants was used. Plants were replaced in a common garden on the Williams College campus, and fertilized weekly with 120 ml of 3.2 g/liter 20–20–20 Agway complete fertilizer. On July 20, leaves were collected for chemical analyses.

Leaf Material. Leaf developmental age can have pronounced effects on leaf chemistry (unpublished data). Therefore it is important to compare leaves of similar age. The results reported here are based on the chemistry of the first fully mature leaf. In order to get enough leaf material for both tannin and phenolic glycoside analyses, we collected 10 different leaves (the first fully mature leaf on 10 different shoots). Leaves were cut at the petiole, placed on ice, transported to the laboratory and vacuum-dried. Vacuum-drying of leaves has been shown to prevent the loss of both condensed tannins and phenolic glycosides (Orians, 1995).

Chemical Analysis. The phenolic glycosides were assayed using standard techniques (Nichols-Orians et al., 1992, Orians, 1995). Briefly, leaf powder (30 $\pm$ 3 mg) was extracted in cold MeOH (10 mg leaf powder/ml MeOH) with sonication for 10 min. Cold water was constantly flushed through the sonicator to prevent the heating of samples. We centrifuged and filtered (0.45 μm filter) each sample before placing extracts in crimp-top vials. Extracts were kept in the freezer until analysis (48 hr or less). We quantified the concentration of glycosides with an HPLC (Hewlett-Packard) and a UV detector set at 274 nm. A reverse-phase Nova-Pak C_{18} (4 μm) column (Waters) and a gradient system of distilled water and MeOH was used. We injected samples through an LS-3200 automated sampler (SGE). 1,3-Dimethoxybenzene was used as the internal standard. Standard curves were determined for salicortin and 2′-cinnamoylsalicortin.

The condensed tannins also were extracted using standard techniques (Orians, 1995). Briefly, approximately 300 mg leaf powder was washed with ether

and extracted with 70% acetone for 3 hr in a 40°C water bath. Acetone was removed under reduced pressure, and all extracts were diluted to 5 ml with distilled water. The butanol/HCl method was used to quantify tannin concentrations (Hagerman and Butler, 1989). The concentration of the condensed tannin (milligrams per gram dry leaf) was determined using purified tannins collected from the two willow species and the hybrids. For reference we have included results using quebracho tannin as a standard.

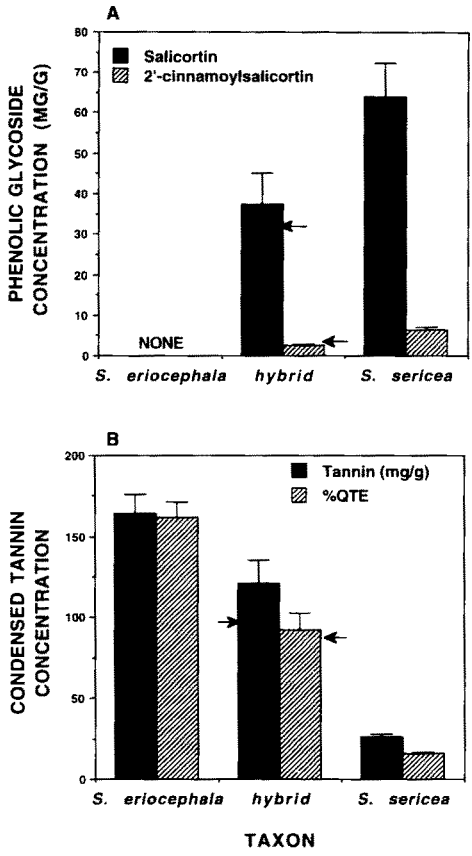

FIG. 1. The concentration (milligrams per gram dry leaf weight) of (A) phenolic glycosides and (B) condensed tannins in parental and hybrid willows. Arrows represent midpoint concentrations.

RESULTS AND DISCUSSION

The concentrations of condensed tannins and phenolic glycosides differ among the three taxa (ANOVA, $P \leq 0.03$) (Figure 1). *S. sericea* contains high concentrations of salicortin and 2′-cinnamoylsalicortin and low concentrations of condensed tannins. Conversely, *S. eriocephala* produces high concentrations of condensed tannins but no phenolic glycosides. The concentrations of these two types of chemicals are intermediate in the hybrids. We performed contrasts to determine whether the concentrations in hybrids are statistically different from the parental midpoint. We found no significant difference for condensed tannins ($P \geq 0.06$), salicortin ($P = 0.51$) or 2′-cinnamoylsalicortin ($P = 0.39$). The intermediate concentrations of these chemicals suggests additive inheritance [a result consistent with other studies (Meier et al., 1989; Reiseberg and Ellstrand, 1993] or balanced ambidirectional dominance. Deviation from the midpoint would have indicated some directional dominance.

The concentrations of both condensed tannins and phenolic glycosides among hybrids are quite variable. In general, the coefficients of variation resemble *S. eriocephala* for tannin concentration and *S. sericea* for phenolic glycoside concentration (Table 1). Thus, overall, hybrids are more variable and the lack of significant differences, on average, from the mid-parent reflects the plants we chose to study. Condensed tannin concentrations in hybrids range from 78 to 171 mg/g dry leaf weight, and salicortin and 2′-cinnamoylsalicortin concentrations range from 10 to 70 and from 0.75 to 5.6 mg/g dry leaf weight, respectively.

The variation among hybrids may reflect parental variation in chemistry.

TABLE 1. COEFFICIENT OF VARIATIONS FOR CONCENTRATIONS OF PHENOLIC GLYCOSIDES AND CONDENSED TANNINS IN *S. sericea*, HYBRID AND *S. eriocephala* LEAVES

	Taxon		
Chemical	*S. sericea*	Hybrid	*S. eriocephala*
Phenolic glycosides			
Salicortin	46.1	42.5	NA
2′-Cinnamoylsalicortin	59.5	39.9	NA
Condensed tannin			
Absolute concentration	3.5	38.6	28.9
%QTE*	2.0	32.1	30.4

* %QTE = % quebracho tannin equivalents.

A hybrid may produce a low concentration of 2′-cinnamoylsalicortin if its *S. sericea* mother does. We know that phenolic glycoside concentrations vary extensively within *S. sericea* (Nichols-Orians et al., 1993), and have found that *S. sericea* female #61 and its *S. sericea* progeny contain low concentrations of 2′-cinnamoylsalicortin (unpublished data). We are currently testing the correlation between parental and offspring chemistry for both intraspecific and interspecific crosses. There could also be between-progeny variation because a parent passes on half its genes to each offspring. Finally, variation among hybrids could be due to whether the hybrid is F_1, F_2, or back-crossed to one of the parental species. We do not know the status of these hybrids, but are currently collaborating with Stephen Brunsfeld to evaluate the effects of back-crossing on the chemistry.

Interestingly, we found an inverse correlation between tannin and phenolic glycoside concentration among the hybrids (Figure 2A and B). (No negative correlation was found within *S. sericea*.) This negative phenotypic correlation indicates that it may be impossible for hybrids to produce high concentrations of both phenolic glycosides and condensed tannins (sensu Berenbaum et al., 1986). Future studies will evaluate the basis of this trade-off and its effect on hybrid–herbivore interactions.

Differences in chemistry can strongly affect the resistance of salicaceous plants to herbivores (Rowell-Rahier, 1984; Tahvanainen et al., 1985a; Basey et al., 1988; Lindroth and Peterson, 1988; Lindroth et al., 1988; Clausen et al., 1989; Denno et al., 1990; Kolehmainen et al., 1994). For example, Tahvanainen et al. (1985a) found that herbivory by several willow-feeding beetles varied as a function of the phenolic glycoside content of different willow species. They found that the response of each beetle species depended upon its adaptations to phenolic glycosides. Previously we reported (Fritz et al., 1994) that many herbivore species differ in their response to *S. eriocephala*, *S. sericea*, and *S.e.* × *S.s.* hybrids. Depending on the herbivore, hybrids were less resistant, intermediate in resistance, or as resistant as one of the parental taxa. Since we know phenolic glycosides and tannins differentially affect herbivores (Rowell-Rahier, 1984; Tahvanainen et al., 1985a; Schultz, 1989; Denno et al., 1990), plant chemistry may be one factor that explains the varied herbivore responses. There is, however, no a priori reason to expect hybrids to be more or less resistant than either of the parental taxa.

The apparent additive inheritance of these secondary chemicals in hybrids has further implications for the resistance of hybrids to herbivores. Whitham (1989) suggests that back-crossing might lead to the further breakdown of resistance traits of backcross plants compared to parents or F_1s. However, if a resistance trait were additively inherited, back-crossing to the parent with the higher concentration should lead to the recovery of resistance traits of the parent. This

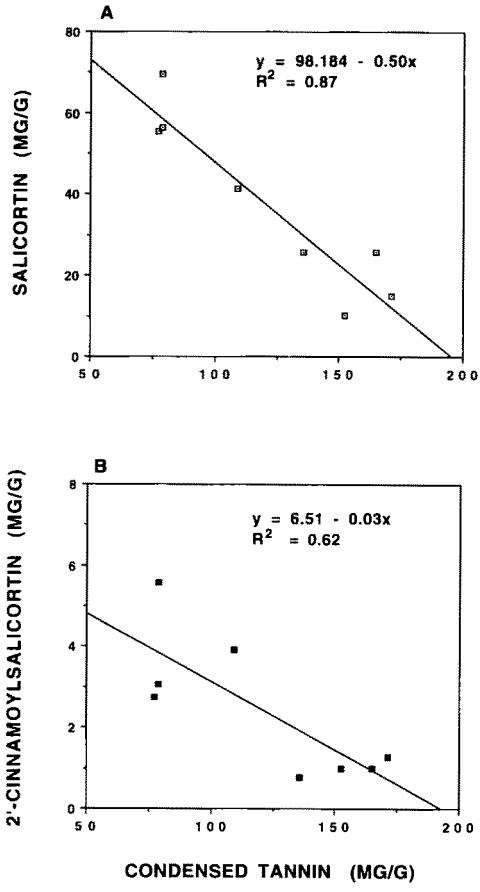

FIG. 2. The relationship between (A) condensed tannin and salicortin concentration, and (B) condensed tannin and 2'-cinnamoylsalicortin concentration in hybrid leaves.

in turn should result in a parallel herbivore response rather than further breakdown. We are currently studying both the inheritance of chemical variation and resistance in backcross plants to test this hypothesis.

Acknowledgments—We thank Len and Ellie Sosnowski and the New York State Department of Environmental Conservation for permitting us to collect plants from their property. (Received October 7, 1994; accepted April 17, 1995)

Abstract—A bioassay-guided fractionation of the aerial parts of *Senecio palmensis* resulted in the isolation of two sesquiterpenes, 2,10-bisaboladien-1-one and 11β-acetoxy-5-angeloyloxy-silphinen-3-one. The bisabolene and the silphinene represented 0.012% and 0.024% of the plant dry weight, respectively. Both compounds showed antifeedant activity against *Leptinotarsa decemlineata* larvae and adults in short-term choice and no-choice bioassays. Both compounds were also tested against different species of phytopathogenic fungi. The beetles were more sensitive to these compounds in choice than in no-choice assays, with a gradient of increasing sensitivity from second instars to adults. Bisabolene was 45 times less active as an antifeedant than juglone, which was tested as a positive control. The silphinen was more active than the bisabolene, with a range of activity similar to juglone. Furthermore, exposure of fourth instars to these compounds over a 24-hr period resulted in reduced feeding and growth rates. To distinguish between antifeedant and toxic effects, growth efficiencies were calculated as the slope of the regression of relative growth rate on relative consumption rate. The comparison of these

results with those of antifeedant simulation and contact toxicity bioassays indicates that feeding inhibition is the primary mode of action of the bisabolene, while the silphinene shows both antifeedant and toxic effects.

Key Words—*Senecio palmensis*, Asteraceae, *Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae, antifeedant, toxic, sesquiterpenes.

INTRODUCTION

The chemical control of the Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say.), with synthetic insecticides has induced a rapid development of resistance of bettle populations to most of these chemicals, including some natural insecticides such as avermectins and the δ-endotoxin of *Bacillus thuringiensis* (Brattsten, 1991; Whalon et al., 1993).

Insect antifeedants of plant origin may provide an attractive alternative to control this insect since their use may reduce the development of cross-resistance. Furthermore, substances that exert both behavioral (antifeedants) and physiological (toxins) effects would be more useful in reducing the development of resistance (Jermy, 1990).

Plant sesquiterpenes and other terpenoids are major determinants of insect-plant interactions (references in Mullin et al., 1991). Inhibitory cyclic sesquiterpenes and diterpenes for insect herbivores have been identified from at least 28 genera of the terpenoid-rich Asteraceae (Mullin et al., 1991). Additionally, species belonging to the Asteraceae family are an important source of CPB antifeedants (Jermy et al., 1981; Hough-Goldstein, 1990). This family also offers numerous examples of insecticidal and/or antifeedant plant metabolites with additional fungicidal activity (Picman, 1986; Miles et al., 1990). As a result of our ongoing search for natural agrochemicals among Canarian endemic plant species in the Asteraceae, we found that an ethanolic extract of *Senecio palmensis* (Chr. Sm.) had a strong antifeedant activity against *Leptinotarsa decemlineata* larvae.

Here we report the isolation of two sesquiterpenes from a biologically active fraction of *S. palmensis*, along with their antifeedant and antifungal activity against *L. decemlineata* larvae and adults and six species of phytopathogenic fungi. Juglone, a natural compound with insecticidal, antifeedant (Hassanali and Lwande, 1989; Bernays and Cornelius, 1992), and antifungal activity (Marston et al., 1993) was included in the experiments as a positive control. We also report on the effects of those compounds on feeding and growth of fourth-instar *L. decemlineata* larvae and the study of their mode(s) of action through antifeedant simulation.

METHODS AND MATERIALS

Plant Material

Flowering plants were collected in Arico, Tenerife (July 1992). A voucher specimen has been deposited in the Centro de Investigación y Tecnología Agraria (CITA), Tenerife.

General

IR spectra were recorded in CH_2Cl_2 solutions using a Perkin-Elmer spectrometer. ^1H and ^{13}C NMR spectra in $CDCl_3$ were measured in a Bruker AMX 400 MHz spectrometer (chemical shifts reported are relative to residual $CDCl_3$, 7.26 ppm for ^1H and 77.0 ppm for ^{13}C). Mass spectra were obtained at 70 eV on a VG micromass ZAB-2F instrument. Optical rotations were recorded with a Perkin Elmer 241 polarimeter. HPLC chromatography was performed on a Beckman System Gold apparatus. The GC-MS analysis was done on a Perkin-Elmer Sigma 3B with a Supelco capillary silica column SPB-1 (30 m × 0.25 mm and 0.25 μm mesh) and the conditions were as follows: temperature gradient 110–250°C and 150–280°C with 5°C/min increments for compounds **1** and **2**, respectively.

Isolation of Compounds

Dried aerial parts of *S. palmensis* (4.7 kg) were exhaustively extracted with EtOH in a Soxhlet apparatus. The extract (808.75 g) was chromatographed on a silica gel vacuum liquid chromatography column (VLC column 9 × 5 cm, packed with silica gel 5–40 μm mesh) with an *n*-hexane–ethyl acetate–methyl alcohol gradient to give one biologically active fraction A (6.35 g, *n*-hexane–EtOAc, 9:1). This fraction was further chromatographed on silica gel (VLC column 7 × 5 cm, packed with silica gel 5–40 μm mesh) and eluted with an *n*-hexane–EtOAc gradient to provide two biologically active fractions, A1 (1.41 g, *n*-hexane–EtOAc, 6:4) and A2 (2.10 g, *n*-hexane–EtOAc 2:8). Both fractions were subsequently purified by preparative normal-phase HPLC using a 250 × 20 mm silica column (Gasukuro Kogyo Inertsil ODS-2, 5 μm particle size) and an isocratic system of Cl_2CH_2–CH_3CN, 93:7, at a flow rate of 12 ml/min. Peaks were detected at 254 nm. Two pure bioactive compounds (**1**, 475 mg; and **2**, 850 mg) were obtained from fractions A1 and A2, respectively, as a result of the HPLC purification.

Insect Bioassays

The *L. decemlineata* colony was reared on potato foliage (cv. Desirée) and maintained at 24 ± 1°C, >70% relative humidity with a photoperiod of 16:8 hr (L:D) in a growth chamber.

Short-Term Choice and No-Choice Feeding Assays: These experiments were conducted with a newly emerged second (L2) and fourth instar (L4) *L. decemlineata* larvae and adults. Potato leaf disks (1 cm^2) were treated on the upper surface with 10 μl of the test substance. For choice assays, four treated and four control disks were arranged alternatively on five 2.5% agar-coated Petri dishes (9 cm diameter); for no-choice assays, eight treated or control disks were used per dish. Ten second instars, three fourth instars, or three adults were placed in each dish following three hours of starvation and allowed to feed in a growth chamber (environmental conditions as described above). Feeding was terminated after consumption of 50–75% of the control disks, and the uneaten leaf disk surfaces were measured according to Escoubas et al. (1993) with a computer-interfaced scanner (Escoubas, personal communication).

Calculations of amounts of treated and control disks eaten were made by subtracting the surface area of the remaining portion from the initial surface for the appropriate test. Percent feeding reduction (%FR) was determined for each arena by the equation %FR = [1 − (treatment consumption/control consumption)] × 100 (Bentley et al., 1984). For the crude extract and its fractions, an arbitrary level of %FR > 75 was considered indicative of a strong feeding deterrency.

The two isolated compounds and commercial juglone (Sigma) were tested in a dose–response experiment to calculate their relative potencies (EC_{50} values, the effective dose for 50% feeding reduction), which were determined from log

probit analysis (Finney, 1971). Two dose series were used: 10, 25, 50, 75, and 100 $\mu g/cm^2$ for compound **1** and 0.1, 0.25, 0.50, 0.75, 1.0, 10 and 25 $\mu g/cm^2$ for compound **2** and juglone.

Long-Term Feeding Assays. These experiments were performed under the same environmental conditions as above. One L4 larva (less than 24 hr old) and eight potato leaf disks (1 cm^2) were placed on 2.5% agar-coated Petri dishes (9 cm diam.). The upper surfaces of the disks were treated with either 10 μl of the test solution or the solvent carrier alone (acetone control), and 15 plates per treatment were used in all feeding experiments.

To distinguish between the antifeedant and toxic effects of these compounds, antifeedant simulation assays with different levels of starvation and dose–response assays were run simultaneously (Blau et al., 1978). At the end of the feeding experiments larval feeding indexes and growth efficiencies were calculated.

Feeding Indexes and Growth Efficiency. The feeding indexes were calculated on a dry weight basis. Initial larval dry weights were estimated from the regression of fresh on dry weight of additional newly molted L4 larvae. Initial dry weight of food was calculated similarly using additional leaf disks. At the end of the feeding experiments, the remaining food and larvae were lyophilized and weighed.

The relative consumption rate (RCR) and the relative growth rate (RGR) were calculated according to Farrar et al., (1989). Growth efficiency (GE) was calculated as the slope of the regression of RGR on RCR, assuming a common intercept determined by the RGR of the starved control larvae (Blau et al., 1978). The relative chemical consumption (RC) was estimated as RCR $\times$ dose (in milligrams) (Liu et al., 1990).

Antifeedant Simulation. Fifteen individually weighed *L. decemlineata* L4 larvae were fed for 24 hr on zero, two, four, six, and eight preweighed potato leaf disks (1 cm^2). At the end of the experiment, the weights of larvae and remaining leaf disks were recorded. With these data, a calibration curve was constructed by calculating the regression of RGR on RCR ranging from total starvation to abundance.

Dose–Response Experiments. Fifteen individually weighed L4 CPB larvae were fed during 24 hr on eight preweighed leaf disks treated with 0, 10, 25, 50, 75, and 100 $\mu g/cm^2$ of each terpene. At the end of the experiment, uneaten food and live larval weights were recorded. To study the posttreatment growth, the same larvae were allowed to feed ad libitum on untreated potato foliage for another 24 hr and then reweighed.

Contact Toxicity. The contact toxicity of the compounds was investigated by topical application using 15 preweighed L4 larvae. A drop (2 μl) of each compound (20 μg) dissolved in acetone was applied to the back of each larva. Treated larvae were fed on eight preweighed potato leaf disks (1 cm^2) for 24

hr, and then reweighed, along with the remaining food, to calculate their relative consumption and growth rates as above.

Antifungal Activity Assays

The antifungal activity of the terpenes isolated was tested against six species of plant pathogens (*Fusarium moniliforme*, *F. oxysporum*, *F. solani*, *Botrytis cinerea*, *Phytophthora syringae*, and *Ascochyta lentis*) and estimated as mycelial growth inhibition (Murabayashi et al., 1991). The test substances were dissolved in acetone and incorporated in a PDA culture medium (5% final concentration of solvent). For each experiment, 2-cm-diameter disks were cut from the corresponding culture medium and inoculated with the appropriate fungal species. Eight replicates of each culture were incubated at 27°C in darkness and the colony diameters measured after 48 hr. Control experiments consisted of inoculated untreated culture-medium incubated under the same conditions. EC_{50} values were determined from log probit analysis (Finney, 1971). Two dose series were used: 0.01, 0.05, 0.1, 0.25, and 0.5 mg/ml for compounds **1** and **2**; and 0.005, 0.01, 0.025 mg/ml plus the same as above for juglone.

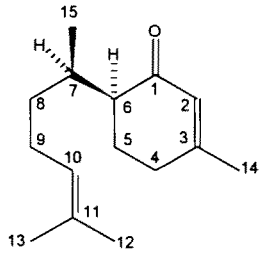
Statistical Analysis

All dry weight measures were log-transformed prior to ANOVA analysis to test for treatment effects on the feeding indexes, chemical consumption, and contact toxicity. Differences between treatment means were checked with Duncan's multiple range test. The toxicity of these compounds was determined by regressing RGR on RCR and comparing each treatment slope with the control slope (antifeedant simulation experiment) (Blau et al., 1978; Berenbaum and Feeny, 1981; Miller and Feeny, 1983). The slopes of the regression lines were compared with a *t* test for parallelism (Tallarida and Murray, 1981). The basic assumption of this analysis is that the RGR of starved larvae does not differ among treatments within an experiment. Treatments in which the slope of the regression is significantly lower than that of the calibration curve can be categorized as toxins. The slope of the regression of RGR on RCR is one estimate of growth efficiency (GE) on any particular treatment.

RESULTS

Bioassay-Guided Isolation of Compounds. The crude alcoholic extract of the aerial parts of *S. palmensis* was a strong antifeedant against *L. decemlineata* fourth instars in choice tests (97 ± 3% feeding reduction at 100 $\mu g/cm^2$). A bioassay-guided fractionation of the extract resulted in the isolation of two active sesquiterpenes (**1** and **2**, Figure 1) by VLC column, normal-phase column, and

Compound 1



Compound 2

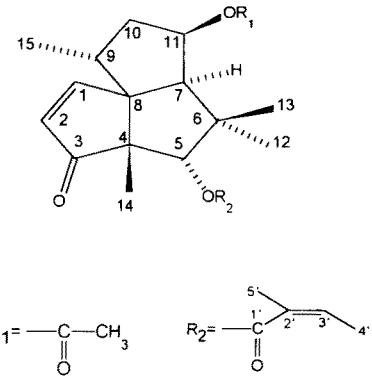


FIG. 1. Structures of compounds isolated from *S. palmensis*.

normal-phase HPLC chromatography. Their structures were established by IR, mass (EI-MS) GC-MS, and ^{1}H and ^{13}C NMR spectroscopic experiments, including two-dimensional methods (HMCQ and HMBC) (Table 1), and by comparison with previously reported data.

Compound **1** was identified as (6*S*)-2,10-bisaboladien-1-one, previously isolated from *Stevia purpurea* and *Cymbopogon citratus* (Asteraceae) (Bohlmann et al., 1976; Abegaz and Yohannes, 1983). Compound **2,** two times more abundant in the plant than **1,** was identified as 11β-acetoxy-5-angeloyloxy-silphinen-3-one (see Table 1), previously isolated from *Cineraria geifolia* var. glabra (Asteraceae) (Jakupovic and Abraham, 1985).

Antifeedant Effects of Sesquiterpenes. Both chemicals strongly deterred feeding of CPB larvae (98% feeding reduction at 100 $\mu g/cm^2$ in choice assays). Their relative potencies (EC_{50}) are presented in Table 2 along with that of juglone. The degree of antifeedant activity of the chemicals tested varied with the insect's developmental stage, in agreement with previous reports (Bentley et al., 1988; Liu et al., 1989; Hough-Goldstein, 1990). In general, a gradient of increasing sensitivity from second instars to adults was shown. Larvae and adults generally appeared more selective in choice than in no-choice experiments, in contrast with the effect of limonin (Alford et al., 1987), and similar to the effect of polygodial and warbuganal (Caprioli et al., 1987).

Compound **1** showed the lowest antifeedant activity (Table 2) with a relative potency range similar to limonin, a known CPB antifeedant with EC_{50}

TABLE 2. RELATIVE ANTIFEEDANT POTENCIES OF COMPOUNDS **1** AND **2** AND JUGLONE (JU) AGAINST *L. decemlineta*

values of 34.92 and 9.34 $\mu g/cm^2$ against L4 larvae in choice and no-choice tests, respectively (Alford et al., 1987).

Compound **1** decreased *L. decemlineata* consumption and growth rate. The responses were not dose-dependent, but significant reductions of RGR at 100 $\mu g/cm^2$ and RCR at 75 and 100 $\mu g/cm^2$ were observed (Table 3). The effects of compound **1** on posttreatment growth rate and consumption were similar (Table 3).

The growth efficiencies of CPB larvae treated with different concentrations of **1** were similar to those of the starved control (Table 3). Each treatment dose gave significant linear relationships between RCR and RGR (0 $\mu g/cm^2$: $r = 0.88$; $P < 0.00001$; 10 $\mu g/cm^2$: $r = 0.87$; $P < 0.00001$; 25 $\mu g/cm^2$; $r = 0.71$, $P < 0.00001$; 50 $\mu g/cm^2$: $r = 0.78$; $P < 0.00001$; 75 $\mu g/cm^2$: $r = 0.57$, $P = 0.00075$; 100 $\mu g/cm^2$: $r = 0.88$, $P < 0.00001$) and parallel to the calibration curve (Figure 2, Table 3).

Since the growth efficiencies of larvae treated with **1** were similar to those of the starved control, we conclude that feeding inhibition at the behavioral level is the primary mode of action of **1**. Additionally, this compound did not show contact toxicity (Table 4).

The antifeedant effect of the 24-hr assay with compound **1** (50% feeding inhibition at 100 $\mu g/cm^2$) was lower than that of short-term (<6 hr) no-choice

[g]ANOVA parameters (F statistic and probability level, P).

tests (95% feeding reduction at 100 μg/cm^2). An explanation of the decreased effect of antifeedant **1** with longer exposure time (over 6 hr) could be a behavioral desensitization. A similar effect has been described for behavioral desensitization of *Spodoptera frugiperda* to aristolochic acid in no-choice situations (Raffa and Frazier, 1988).

Compound **2** showed higher activity levels than compound **1** (Table 2). Compound **2** strongly deterred adult beetles from feeding and had relative potencies within the range of juglone. When compared with limonin, compound **2** was 23 times more active against L4 larvae in choice tests, but less active in no-choice tests, with an effective dose of **2** that was 1.5 times higher than

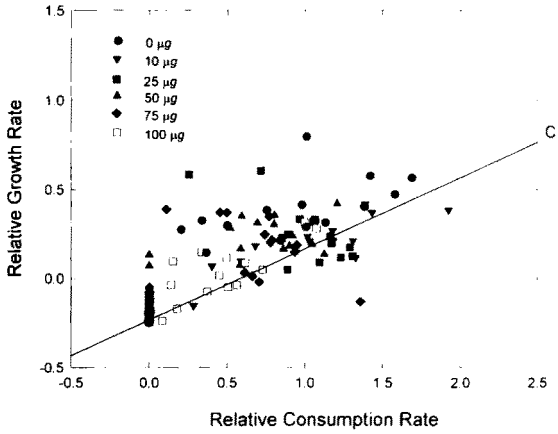

FIG. 2. Plot of the relative growth rate (RGR) on the relative consumption rate (RCR) for *L. decemlineata* L4 larvae fed for 24 hr on leaf disks treated with compound **1**. The line represents the calibration curve ($y = 0.371x - 0.220$, $r = 0.84$, $P < 0.0001$).

limonin (Alford et al., 1987). The activity of juglone was also stronger than limonin (42 and 2.2 times stronger against L4 larvae in choice and no-choice tests, respectively) (Alford et al., 1987). Therefore, commercial juglone can be considered an effective CPB antifeedant suitable for use as a positive control.

Compound **2** showed a strong and significant reduction in feeding and growth of *L. decemlineata* larvae with increasing concentrations, with 100%

TABLE 4. FEEDING INDEXES MEAN VALUES AND STANDARD ERRORS OF FOURTH-INSTAR CPB LARVAE ($N = 15$) TOPICALLY TREATED WITH 20 μg OF COMPOUNDS **1** AND **2**

Treatment	RCR[a]	RGR[b]
1	0.75 (0.03)	0.12 (0.01)
2	0.65 (0.07)	0.09 (0.02)
Control	0.72 (0.04)	0.13 (0.02)
F[c]	1.028	1.397
P	0.366	0.266

[b] As in Table 3.
[c] See footnote *g* in Table 3.

feeding inhibition at the maximum dose tested (Table 5). The posttreatment larval relative growth rate decreased without following a dose response pattern and was significantly lower than the control starting from a dose threshold of 25 $\mu g/cm^2$ (Table 5). The chemical consumption of **2** peaked at 50 $\mu g/cm^2$, decreasing to zero at 100 $\mu g/cm^2$ (Table 5).

The growth efficiencies of the larvae treated with **2** were significantly lower than the starved control, also starting from a dose threshold of 25 $\mu g/cm^2$. We could not calculate the growth efficiency for the highest dose of **2** (100 $\mu g/cm^2$) since the corresponding RCR was zero (Table 5). For compound **2**, the linear relationships between RCR and RGR were not always significant (0 $\mu g/cm^2$: $r = 0.51$, $P = 0.003$; 10 $\mu g/cm^2$: $r = 0.91$, $P < 0.00001$; 25 $\mu g/cm^2$: $r = 0.61$, $P < 0.001$; 50 $\mu g/cm^2$: $r = 0.40$, $P = 0.001$; 75 $\mu g/cm^2$: $r = 0.22$, $P = 0.14$), and their slopes were lower than the slope of the calibration curve at a dose of 25 $\mu g/cm^2$ (Figure 3, Table 5), indicating that compound **2** has a toxic action.

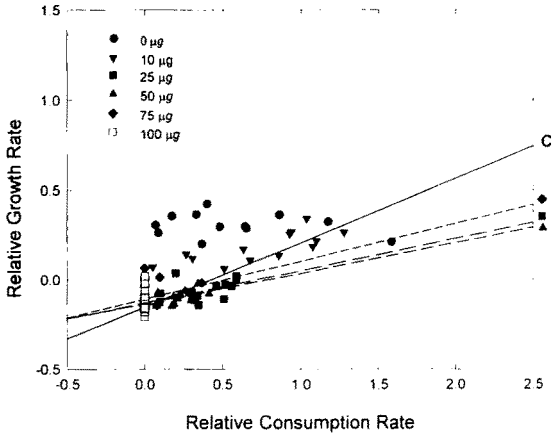

FIG. 3. Plot of the relative growth rate (RGR) on the relative consumption rate (RCR) for *L. decemlineata* L4 larvae fed for 24 hr on leaf disks treated with compound **2.** Represented are the lines of the calibration curve C ($y = 0.376x - 0.156$, $r = 0.82$, $P < 0.00001$) and the treatment lines with slopes significantly different from the control C.

Antifungal Activity: Both terpenes were tested against soil-borne (*Fusarium* sp.) and foliar (*Botrytis*, *Phytophthora*, and *Ascochyta* sp.) phytopathogenic fungi. They showed only mild activity against *B. cinerea* (EC_{50} values of 0.15 and 0.03 for **1** and **2**, respectively) and *A. lentis* (EC_{50} values of 0.19 and 0.33 for **1** and **2**, respectively). Juglone showed the highest overall antifungal activity (EC_{50} values of 0.007 and 0.04 for *B. cinerea* and *A. lentis*, respectively).

DISCUSSION

Two effective CPB sesquiterpene antifeedants have been isolated from *S. palmensis*. Compound **1** belongs to the chemical class of bisabolenes and has an antifeedant action lower than juglone but similar to limonin. Compound **2** is a silphinene sesquiterpene with an activity level similar to juglone and higher than limonin. Both compounds showed mild antifungal activity, suggesting a target-specific interaction.

Bisabolenes are a class of sesquiterpenoids mainly isolated from Asteraceae plants (Kreiser, 1991). In contrast, silphinenes have only been described in the genera *Cineraria* and *Callilepis* (Bohlmann and Zdero, 1982; Jakupovic and Abraham, 1985) and in *Silphium* sp. along with some bisabolenes (Bohlmann and Jakupovic, 1980).

This is the first report of an antifeedant silphinene (compound **2**). In con-

trast, some natural bisabolenes are effective antifeedants. For example bisabolangelone, isolated from *Angelica silvestris*, has strong antifeedant properties against several insect species including *L. decemlineata* (Muckenstrum et al., 1981; Nawrot et al., 1984).

Another bisabolene structurally related to compound **1**, zingiberene, appears to be responsible for the toxicity of the wild tomato plant *Lycopersicon hirsutum* f. *hirsutum* to CPB and represents a potential new source of insect resistance in the cultivated tomato *L. esculentum* (Carter et al., 1989). The search for structurally related natural bisabolenes could be a promising source of new leads for the development of CPB host-plant resistance.

These two compounds were more effective in choice that in no-choice tests, indicating behavioral avoidance, in addition to their deterrent effect. The greater effect that both compounds had against adult CPB indicates that these chemicals may alter the host selection process through behavioral avoidance by the adults, which are more mobile and are the primary finders of hosts (Hough-Goldstein, 1990).

Furthermore, compound **1** and the starvation simulation test both had a similar effect of reduction in the growth and feeding of the larvae, which suggests an antifeedant effect at the behavioral level. The association between larval feeding and growth reduction caused by compound **2** did not parallel that of the starved control, indicating both antifeedant and toxic effects. Additionally, larval contact with compound **2** was associated with detrimental effects. We also observed a decrease in larval posttreatment growth rate that did not correlate with chemical consumption. These observations suggest that the toxic action of **2** is not postingestive, in contrast to limonin, an antifeedant and toxic limonoid with a negative postingestive effect on *L. decemlineata* larvae associated with relative chemical consumption (Mendel et al., 1991). Compound **2**, with antifeedant and toxic activity, could be more promising than compond **1** as a control agent against CPB because both activities together require behavioral and physiological adaptations in order to develop resistance (Jermy, 1990). Further research is needed in order to understand the toxic mode of action of **2**.

(Received October 28, 1994; accepted April 17, 1995)

Abstract—Benzoic (BEN) and cinnamic (CIN) acids are commonly found in soils and are considered as strong allelochemicals. Published information suggest that BEN and CIN and other phenolic acids decrease plant growth in part by suppressing nutrient absorption. However, studies on the mechanism of action were not conclusive. We examined the effects of BEN and CIN on the cell plasma membrane in intact soybean (*Glycine max* L. cv. Maple Bell) seedlings. Treating intact root systems with BEN or CIN rapidly increased electrolyte leakage and ultraviolet absorption of materials into the surrounding solution. After 12 hr of treatment, BEN and CIN lowered the extracellular sulfhydryl group content in roots. The two allelochemicals induced lipid peroxidation, which resulted from free radical formation in plasma membranes, inhibition of catalase and peroxidase activities, and sulfhydryl group depletion. Oxidation or cross-linking of plasma membrane sulfhydryl groups is the first mode of action of both compounds. The BEN- and CIN-induced decrease in soybean nutrient absorption may be a consequence of damage to cell membrane integrity caused by a decrease in sulfhydryl groups followed by lipid peroxidation.

Key Words—Allelochemicals, lipid peroxidation, sulfhydryl groups, leakage, plasma membrane, superoxide dismutase, catalase, peroxidase.

INTRODUCTION

Numerous phenolic derivatives of benzoic acid (BEN) and cinnamic acid (CIN) have been identified in soil, and several of these compounds markedly inhibit

growth and development of plants (Rice, 1984; Vaughan and Ord, 1991). Several investigations have found a lower mineral content in plants treated with phenolic acids (Glass, 1974; Lee, 1977; Baziramakenga et al., 1994). Because a membrane is the first living tissue that comes in contact with any allelochemical, it is likely to be the first damaged. Allelochemicals can damage cell membranes through direct interaction with a constituent of the membrane or as a result of an impairment of some metabolic function necessary to the maintenance of membrane function (Rice, 1984). An impairment of lipid or protein metabolism by phytotoxins could lead to membrane disturbance (Keck and Hodges, 1973), but studies of this type have not been conclusive.

BEN induced K^+ and NO_3^- leakage from roots of *Hordeum vulgare* L. (Lee, 1977). Salicylic acid was reported to induce K^+ efflux from yeast (Scharff and Perry, 1976; Hoeberichts et al., 1980). Glass (1974) presented evidence suggesting that the inhibition of mineral uptake by phenolic derivatives of BEN and CIN is linked to their lipid-solubilizing capacity. Studies conducted with artificial lipid membranes showed that phenolic compounds caused disruption of the integrity of the phosphatidylethanolamine monolayers (Kaye and Proudfoot, 1971) and increased fluidity of lipid alkyl chains in phospholipids (Singer and Wan, 1977).

On the other hand, it was established that phenolic compounds applied exogenously stimulated hydrogen peroxide production in the cell wall of *Armoracia lappathifolia* Gilibb (Gross et al., 1977). Oxidation of phenolic compounds can generate superoxide and hydroxyl radicals with high reactivity for biological substances such as unsaturated lipids and proteins, causing enzyme inactivation, membrane lipid peroxidation, and strand break in DNA (Appel, 1993).

Ion transport across membranes is thought to be mediated by intrinsic membrane proteins and the altered ion uptake in phenolic-treated plants may be due to a disruption of the functions of these proteins (Vaughan and Ord, 1991). Sulfhydryl groups play an essential role in the function of transport proteins (Nelson et al., 1975; Lucas and Alexander, 1980; Ramaiah and Mookerjee, 1981). Numerous environmental toxins such as heavy metals and toxic chemicals can reduce the sulfhydryl group content (Spring and Hager, 1982; Ayers et al., 1986). Depletion of the sulfhydryl groups could therefore lead to the inactivation of enzymes, which depend on such reduced sulfhydryl groups.

The objective of our work was to determine the effects of BEN and CIN on electrolyte leakage, lipid peroxidation, and depletion in sulfhydryl groups in roots of *Glycine max* L. cv. Maple Bell. BEN and CIN were selected because they have been frequently isolated in soil (Chou and Patrick, 1976; Baziramakenga et al., 1995) and exudates of plants (Yu and Matsui, 1994). Our previous investigation indicated that they alter ion uptake by roots of soybean (Baziramakenga et al., 1994), but their mechanisms of action have not been elucidated.

Information of this kind will provide a better understanding of how these compounds reduced mineral uptake by plants.

METHODS AND MATERIALS

Plant Materials. Soybean (*Glycine max* L. cv. Maple Bell) seeds were surface-sterilized in 5% hypochlorite for 10 min, soaked for 6 hr in distilled water, and allowed to germinate on sterilized vermiculite saturated with 1 mM $CaSO_4$. Plants were grown in a controlled environment chamber with a 28:20°C day–night temperature, a light–dark regime of 16:8 hr, irradiance of 280 μmol/m^2/sec, and 70% relative humidity. After three days, seedlings of uniform size were transferred to 2-liter buckets filled with nutrient solution (μM): 750 KNO_3, 325 $Mg(NO_3)_2$, 10 KH_2PO_4, 1000 $CaSO_4$, 8 H_3BO_3, 0.2 $MnSO_4$, 0.2 $ZnSO_4$, 0.2 $CuSO_4$, and 0.2 $(NH_4)_6Mo_7O_{24}$ at pH 5.8 (Cakmak and Horst, 1991). Seedlings were allowed to acclimate to hydroponic conditions for three days and were subsequently transferred to similar medium supplemented with various concentrations of BEN or CIN. The roots were exposed to allelochemicals for 12, 24, 48, and 96 hr. Controls received no allelochemical. The solutions were changed daily.

Leakage. Changes in membrane permeability due to benzoic or cinnamic acids were assayed by measuring leakage of solutes and ultraviolet absorbing materials. After washing for 10 min in total with four changes of deionized water (50 ml each), the roots were resuspended in 20 ml of deionized water for 4 hr to test leakage at room temperature. Conductivity of the solution bathing intact roots was measured with a Dorian conductivity bridge. The leaked ions were analyzed for K^+ and Ca^{2+} by atomic absorption spectrometry and for Cl^-, NO_3^-, PO_4^{3-}, and SO_4^{2-} by ion chromatography. The UV-absorbing materials (e.g., amino acids, nucleotides, polypeptides, etc.) were determined by measuring the absorbance at 260 nm on a Varian DMS 100 spectrophotometer.

Lipid Peroxidation. The level of lipid peroxidation was followed by measuring malondialdehyde (MDA) accumulation, a product of unsaturated fatty acid peroxidation, by the method of Dhindsa et al. (1981). Samples consisting of root tips (250 mg) were homogenized in 5 ml of 0.1% of trichloroacetic acid (TCA) in sodium phosphate buffer (pH 7.2) with a Polytron (Kinematica CH-600 Kriens W) and centrifuged at 15,000*g* for 15 min. An aliquot of 1 ml of the supernatant was added to 4 ml of 0.5% of thiobarbituric acid (TBA) in 20% TCA. The mixture was placed in a water bath at 90°C for 10 min and then quickly cooled on an ice-bath for 15 min. Samples were centrifuged at 15,000*g* for 5 min. The A_{532} of the supernatant was measured on a Hitachi U-1000 Spectrophotometer, and this value was subtracted from the nonspecific A_{600}

reading value. The MDA contents were calculated with the extinction coefficient value of 155 mM^{-1} cm^{-1}. MDA values were expressed as millimoles per gram fresh weight of root tissue.

Enzyme Activities. Root tips (500 mg) were quickly homogenized in 10 ml of 50 mM HEPES-KOH buffer (pH 7.8) containing 0.1 mM EDTA with a Polytron (Cakmak and Horst, 1991). All operations were performed at 0–4°C. The homogenate was centrifuged at 15,000*g* for 15 min and the supernatants were stored at −20°C until enzyme activity determination.

Superoxide dismutase (SOD) activity was assayed by its ability to inhibit the photochemical reduction of nitroblue tetrazolium (NBT) by the procedure of Beauchamp and Fridovich (1971). The assay medium (3 ml) contained 50 mM HEPES-KOH buffer (pH 7.8), 0.1 mM EDTA, 50 mM Na_2CO_3, 12 mM L-methionine, 2 μM riboflavin, 75 μM NBT, and 300 μl of crude root extract. Riboflavin was added last. The tubes were shaken and placed under two 25-W fluorescent lamps at room temperature. The reaction was initiated and terminated by turning the light on and off. The A_{560} was measured on a Hitachi U-1000 Spectrophotometer. Tubes containing the assay mixture without the root extract were illuminated to determine maximum A_{560}. Each root extract A_{560} value was subtracted from the control A_{560} value; the mathemical difference was then divided by the maximum and multiplied by 100 to obtain the percentage of inhibition of NBT reduction.

Peroxidase activity was measured at 460 nm using guaiacol as hydrogen donor (Yamanoto and Tani, 1986). The reaction mixture contained 2.5 ml of potassium phosphate buffer (pH 6.80), 0.125 ml of 120 mM guaiacol, and 0.125 ml of crude extract. The reaction was initiated by the addition of 0.250 ml of 0.1% H_2O_2 in potassium phosphate buffer. The absorbance was measured after 5 min, and the activity expressed as percentage of the control.

Catalase activity was assayed by following the disappearance of H_2O_2, its substrate from the assay mixture (Chance and Machly, 1955). The reaction mixture contained 25 mM potassium phosphate buffer (pH 6.8) and 10 mM H_2O_2. Root extract (0.1 ml) was added to 2.9 ml of the reaction mixture to initiate the reaction. The tubes were shaken for 10 min at room temperature and the decrease in H_2O_2 was measured as the decline in A_{240} on a Varian DMS 100 spectrophotometer. Catalase activity was expressed as percentage of the control.

Sulfhydryl Groups. The concentration of sulfhydryl groups was determined by Ellman's reagent, 5,5′-dithio-bis-2 nitrobenzoic acid (DTNB) according to the method of Welch and Norvell (1993). Seedlings treated with the allelochemicals were soaked in 100 ml of the reaction mixture containing 0.2 M Tris HCl and 0.2 M Na EDTA (pH 8.2). One milliliter of 10 mM DTNB in methanol was added to the reaction mixture. The control reaction mixture received 1 ml of methanol. After 15 min, the roots were removed from reaction buffer, and

2.0 ml of the reaction buffer was assayed for reactive sulfhydryl groups at 412 nm on a Hitachi U-1000 Spectrophotometer. The coefficient of extinction used for measuring the sulfhydryl group was 1.36×10^4 M^{-1} cm^{-1} (Prudêncio-Ferreira and Arêas, 1993).

Statistical Analysis. All experiments were conducted as completely randomized designs. Treatments were replicated three times except in the lipid peroxidation (four) and sulfhydryl group (five) studies. Each experiment was conducted three times. Data were subjected to analysis of variance and treatment means ± standard error were determined.

RESULTS AND DISCUSSION

BEN and CIN induced electrolyte leakage as determined by the conductivity of bathing medium (Figure 1). After 96 hr of treatment, the conductance of

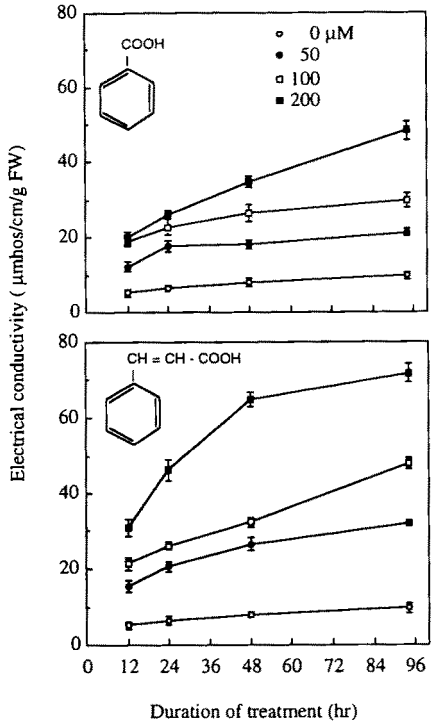

FIG. 1. Effect of different concentrations of BEN and CIN on electrolyte leakage as determined by conductivity of bathing medium.

the bathing solution of treated roots was two to eight times more than that of the control plants. Leakage of electrolytes from treated seedlings increased with time, indicating that cell permeability is affected by time of exposure of the tissues to the allelochemicals. Roots treated with CIN showed more electrolyte leakage than those treated with BEN. After 12 hr of treatment, the loss of electrolytes in CIN-treated tissue was 1.5 times greater than that of the roots treated with BEN.

Roots of BEN- or CIN-treated soybean seedlings leaked larger amounts of K^+ (Figure 2) and Cl^- (Figure 3) than did roots of control plants. Exposure to BEN or CIN for 12 hr, even at high concentrations, did not markedly affect efflux of K^+ and Cl^-. The increase of efflux became more distinct after 24 hr of treatment. Leakage of Ca^{2+}, PO_4^{3-}, and SO_4^{2-} from treated roots occurred at approximately 1/10th of the rate of K^+ leakage (data not shown). No NO_3^- efflux was detected under BEN or CIN treatments. K^+ and NO_3^- leakage have

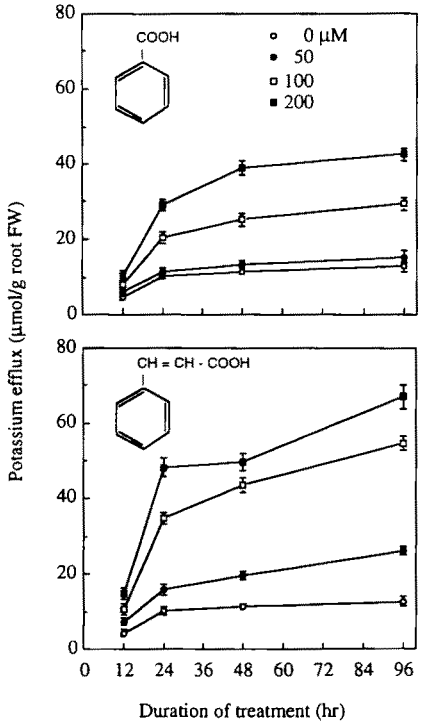

FIG. 2. Time course of K^+ release from soybean roots treated with different concentrations of BEN and CIN.

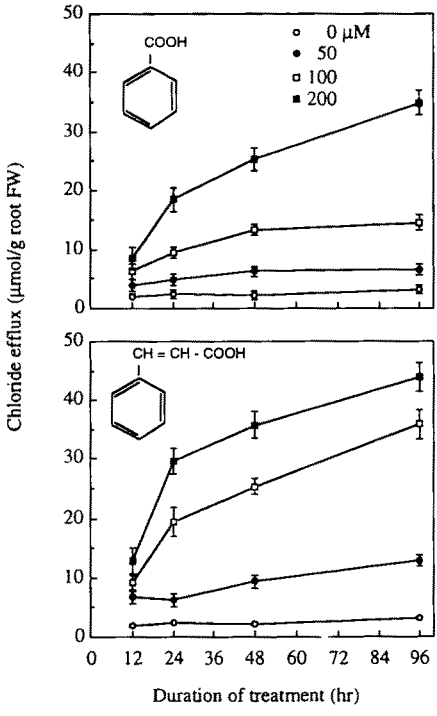

FIG. 3. Time course of Cl^- release from soybean roots treated with different concentrations of BEN and CIN.

been noted in intact roots of barley treated with BEN (Lee, 1977). The leakage of NO_3^- in barley and not in soybean is difficult to explain. This may be a situation in which species differences are involved. Leakage of Cl^-, assumed to be accumulated within cell vacuoles (Drew and McLaren, 1970), is clear evidence that change in cell permeability due to BEN or CIN is not limited to epidermal cells but extends deeply into the tissue. Our data support the hypothesis of membrane disruption by phenolic compounds (Rice, 1984). Chipley (1982) proposed that the undissociated form of BEN may diffuse freely through the cell membrane and then ionize in the cell to yield protons that delocalize the negative charge of ions within the interior of cell. If the pH-controlling capacity of the cytoplasm is exceeded, its pH may decrease sufficiently to inhibit active uptake of ions and their normal retention by the cell (Lee, 1977).

Leakage of ultraviolet-absorbing materials from seedlings treated with BEN or CIN followed a pattern similar to that of the electrolytes (Figure 4). At 200

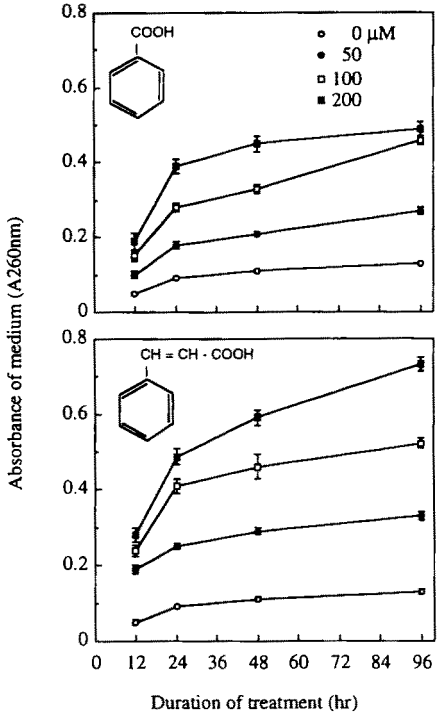

FIG. 4. Effect of varying concentrations of BEN and CIN on the loss of UV-absorbing materials from soybean roots.

μM, the leakage of organic components as measured by the absorbance of the medium at 260 nm increased five and seven times over the control when tissues were treated with BEN and CIN, respectively. The efflux of nonelectrolytes evidences a loss of membrane integrity in soybean roots.

We may postulate two categories of alterations in membrane function and structure following BEN or CIN treatment: (1) changes in membrane lipids and (2) changes in membrane proteins. In fact, solute transport across biological membranes is based on diffusion through lipids via aqueous pores or in association with carriers and on transport systems such as pumps, carriers, or channels (Novacky, 1983; Iswari and Palta, 1989; Briskin, 1994).

Changes in the membrane lipids involve solubilization of undissociated acids within the lipid of membrane or lipid degradation (Jackson and St. John, 1980). We investigated the effects of the two allelochemicals on the lipid degradation by means of lipid peroxidation. The level of TBA-reactive materials,

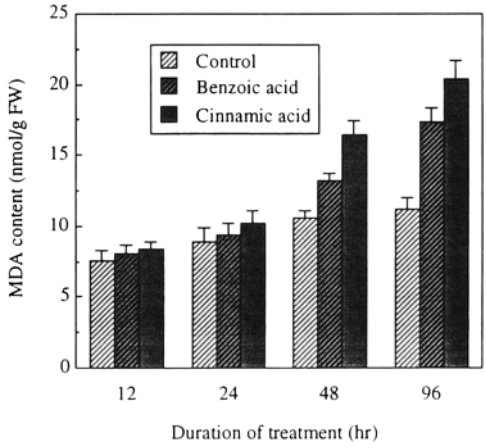

FIG. 5. Lipid peroxidation assayed as malondialdehyde (MDA) content in soybean root treated with 100 μM of BEN and CIN.

mainly MDA, in roots of seedlings treated with BEN and CIN is expected to be higher than in the control. The effect of BEN or CIN on lipid peroxidation became more apparent after incubation for 48 hr (Figure 5) and was concentration dependent (Figure 6). The striking increase in MDA seen in roots of treated

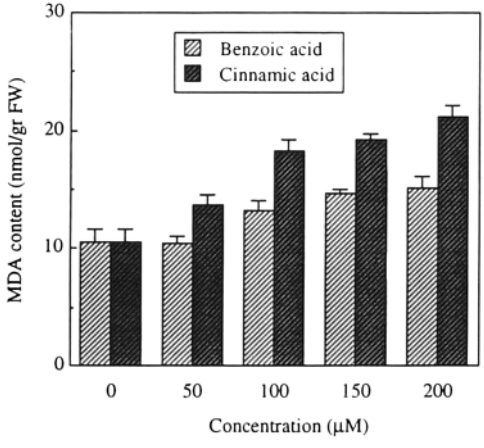

FIG. 6. Lipid peroxidation in root tips as dependent on the concentration of BEN and CIN after 48 hr of treatment.

plants suggests changes in peroxide-scavenging activity. In view of this, radical- and peroxide-scavenging enzymes were assayed. SOD, peroxidase, and catalase activities were affected by BEN or CIN (Figure 7). SOD activity in treated seedlings was slightly higher than that in controls. Peroxidase activity was stimulated at 50 μM of CIN, but inhibited at 200 μM for both allelochemicals. Catalase activity was reduced at all concentrations, and this effect was more pronounced for CIN than for BEN.

Increased SOD activity suggests an increased production of peroxides in allelochemical-treated root tips. The inactivation of peroxidase (at high concentrations) and catalase suggests that H_2O_2 might accumulate in the presence of the allelochemicals. This could induce damage in the cell either directly or

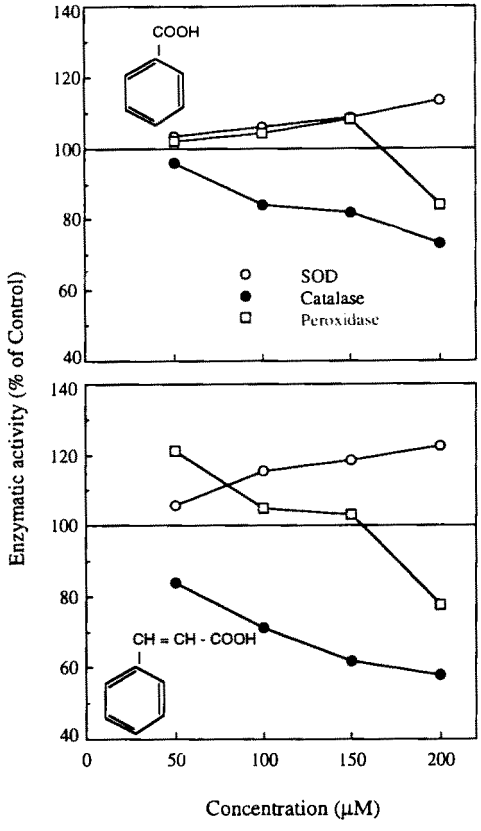

FIG. 7. Effect of BEN and CIN on activities of superoxide dismutase (SOD), catalase, and peroxidase in root tips of soybean plants after 48 hr of treatment.

through the formation of hydroxyl radicals or other oxygen radicals, leading to peroxidation of the unsaturated fatty acids in the cellular membrane (Mehdy, 1994). It is well established that phenolic acids catalyze peroxide formation (Elstner, 1987). In *Escherichia coli* cell cultures, SOD activity was increased by the addition of quinones at concentrations of more than 100 μM (Hassan and Fridovich, 1979). Our results do not support the hypothesis that BEN can serve as a scavenger of free radicals (Chipley, 1982; Epperlein et al., 1986). However, derivatives of BEN, and specifically salicylic acid, inhibit catalase activity and induce an increase of H_2O_2 in tobacco leaves (Chen et al., 1993). It is likely that BEN is converted to biologically active phenolic compounds (Pridham, 1965). Peroxidase activity was inhibited by *p*-coumaric and *p*-hydroxybenzoic in wheat roots (Vaughan and Malcolm, 1979) and by *p*-hydroxybenzoic acid in *Nicotiana tabacum* tissue cultures (Pickering et al., 1973). Gamborg et al. (1961) reported no effect of CIN on horseradish and pea epicotyl peroxidase activities. The reduced enzyme activity may be related to a reduction of solubility of the enzyme by forming insoluble protein–phenolic complexes or direct inhibition of the enzymes by forming a soluble but inactive enzyme inhibitor complex (Firenzuoli et al., 1969).

It has been suggested that phenolic compounds can interfere directly with carrier proteins (Booker et al., 1992). We examined the influence of the two allelochemicals on sulfhydryl groups in root. Roots treated with BEN or CIN for 12 hr contained lower concentrations of sulfhydryl groups than roots of control seedlings (Figure 8). Since the plasma membrane is relatively imperme-

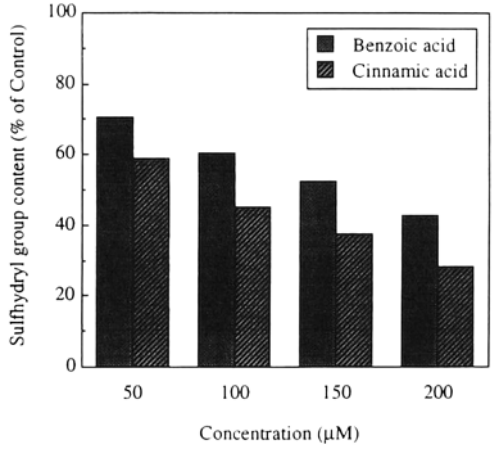

FIG. 8. Effect of BEN and CIN on sulfhydryl group contents in root of soybean plants after 12 hr of treatment.

able to the DTNB (Welch and Norvell, 1993), there is evidence that BEN and CIN affect essential sulfhydryl groups located at the plasma membrane.

A change in ion transport following BEN or CIN treatment could be explained in terms of reaction with sulfhydryl groups of membrane carrier proteins, ion pumps, or channels that may be required for the maintenance or modification of the plant cell membrane potential or the proton electrochemical gradient involved in the transport of ions or solutes. Studies with Ca^{2+}-ATPase and Na^+, K^+-ATPase of the sarcoplasmic reticulum indicated the participation of sulfhydryl groups in ATP recognition (Schoner et al., 1982). Sulfhydryl groups are implicated in phosphate transport (Jeanjean et al., 1975; Poder and Penot, 1986). Phenolic acids and their oxidation products can effectively tie up proteins, modify enzymatic active sites and decrease their activity, and even create artifactual enzymes by blocking ionic amino acid residues (Chalker-Scott and Fuchigami, 1989). Allelochemicals such as sesquiterpene lactones were reported to bind irreversibly to SH groups involved in auxin–auxin receptor (Spring and Hager, 1982) or to the sulfhydryl groups of enzymes (Fisher and Quijano, 1985).

Comparative physiological changes occurring in roots of soybean treated with BEN or CIN indicate that the earliest detectable effects of the two allelochemicals are the decline of sulfhydryl groups. In this regard, it seems likely that CIN and BEN cause intramolecular changes in protein sulfhydryl that could result in enhanced permeability of cellular membranes and subsequent electrolyte leakage. It has been suggested that depletion of cellular sulfhydryl groups implies a lowered internal defense against free radicals (Ayers et al., 1986), which in turn may lead to enhanced peroxidation of membrane lipids and loss of cell integrity. In contrast to other measured parameters that were markedly affected after 12 hr, 48 hr were necessary to observe an effect of BEN and CIN on lipid peroxidation. Thus, the leakage and lipid peroxidation observed in our experiments could be interpreted as secondary responses in the phytotoxic actions of BEN or CIN.

However, given the high reactivity of most allelochemicals with soil matrix, it should not be difficult to appreciate the significance of our data in terms of field conditions in the absence of data on the fate of BEN and CIN in soil environment. A sufficient pool of allelochemicals could be maintained in the rhizosphere through exudation from living plant tissues, decomposition of plant residues, or microbial metabolism. In this view, Haider and Martin (1975) concluded that after one week 39–63% of phenolic acids added to a sandy loam soils was decomposed. Although the recovery of phenolic acids from soils varied with soil type, horizon, and the particular kind of phenolic acid added, 30–75% was recovered after 32 days (Dalton et al., 1989).

The work presented here provides evidence that BEN and CIN alter ion uptake by affecting membrane properties. We propose that BEN- or CIN-induced

damage to the permeability of roots can be ascribed to direct action on membrane sulfhydryl groups. The intramolecular changes by oxidation or cross-linking in plasma membrane protein sulfhydryls is the first damaging effect of phenolic acids. Increased electrolyte leakage and lipid peroxidation, coupled with reduced of peroxidase and catalase activities, is a secondary response.

BIOLOGICAL ACTIVITY OF CHEMICALS IDENTIFIED FROM EXTRACTS AND VOLATILES OF MALE *Rhagoletis cerasi*[1]

D. RAPTOPOULOS,* G. HANIOTAKIS, A. KOUTSAFTIKIS,[2] D. KELLY,[3] and V. MAVRAGANIS

Biology Department, N.R.C. "Demokritos" Aghia Paraskevi Attiki, Greece

(Received November 14, 1994; accepted April 19, 1995)

Abstract—Fractions obtained by chromatographic separation of extracts and volatiles from male *Rhagoletis cerasi* flies were tested for biological activity on females under laboratory conditions. During the bioassays, the number of incoming flies as well as the time spent by individual flies on the area of stimulus were taken under consideration. Two distinct types of female behavior were observed, i.e., attraction and arrestant behavior. GC-MS analysis of biologically active fractions resulted in tentative identification of 75 compounds. EAG screening for 27 of these compounds was performed, and subsequent laboratory bioassays resulted in the confirmation of arrestant activity for various mixtures of eight fatty acids (octadecanoic, nonadecanoic, eicosatetraenoic, eicosapenaenoic, eicosaenoic, heneicosanoic, docosahexenoic, and docosanoic). Following EAG tests and laboratory bioassays, a possible mode of chemical communication of this species with sex pheromones is proposed.

Key Words—*Rhagoletis cerasi*, cherry fruit fly, Diptera, Tephritidae, EAG, volatiles, extracts, sex pheromone.

INTRODUCTION

Cherries constitute a crop of economic importance for a number of regions in Greece. They are harvested in spring, a period during which no other fruit is in season, and consequently they are sold at high prices. A limiting factor in cherry

production is the cherry fruit fly, *Rhagoletis cerasi*, Linne (Diptera: Tephritidae).

The conventional control method for this pest is cover sprays with organophosphorus insecticides. The short period between the time of effective spray applications and fruit harvesting frequently results in detectable levels of pesticide on the fruit.

A number of alternative possibilities for the control of this pest have been explored with encouraging results, but for various reasons none has been adopted by cherry growers. The use of behavior modifying agents for the development of alternative control methods is at the center of attention. Mass trapping with visual traps, which are commercially available today, may effectively protect the crop (Russ et al., 1973). Mass trapping with insecticide-treated wood boards baited with food attractants and bait sprays are also effective (Haniotakis et al., 1989, 1991). Oviposition-deterring pheromones identified in this species have been tested for control with promising results (Katsoyannos, 1975; Boller et al., 1987; Boller and Aluja, 1992.). The existence of sex pheromones has also been reported (Katsoyannos, 1982). Sex pheromones and host kairomones seem to play an important role in the ecological behavior of the species, including host selection, mating site selection, and oviposition site selection. Host odors, for example, act as long-range attractants for sexually mature males and females to the host plant, where sex pheromones are responsible for mating. This combination of kairomones and male-produced sex pheromones is considered as a highly specialized recognition system, which is an important element for both evolution and speciation (Metcalf, 1990).

We report here a detailed analysis of the extracts and volatiles emitted by the male cherry flies and results of laboratory behavioral bioassays and EAG studies to determine biological activity of some of the compounds identified.

METHODS AND MATERIALS

Insects. The insects used in this study were collected as larvae from infested cherries from the regions of Pelion and Crete (Greece).

Headspace Sampling. Biologically active compounds were collected using the total condensation cold trap (Browne et al., 1974; Haniotakis et al., 1977). Approximately 100 live 4-day-old males were placed in cylindrical air-tight glass chambers (20 cm × 12 cm ID). Sugar and water were provided as food. Incoming air was purified through two filters: one of activated charcoal (Fluka AG, Buchs SG), and the other of Porapak Q. The outlet of the insect chamber was connected via glass tubing to a cylindrical flask (30 cm × 9 cm ID) immersed in liquid nitrogen. The system was tested without insects to ensure its proper functioning. Volatiles were collected from insects from the 6th to the 10th hour

of the photophase each day, during their mating period (Katsoyannos, 1982). A total of 150 ml liquefied air was collected each day. Subsequently the air was allowed to evaporate slowly at 25°C, and, prior to its total evaporation, 50 ml methylene chloride was slowly added. The collection procedure lasted for six consecutive days. In this way, it was calculated that a total of 2400 male-hour equivalents were collected. The end product (0.5 liters of methylene chloride solution) was dried by adding anhydrous magnesium sulfate, and evaporated under a Vigreux column (13 cm length) to a total volume of 1 ml, which was kept at 4°C.

Extraction Procedure. Two hundred sexually mature males were extracted in methylene chloride–methanol (3:1), for 4 hr at room temperature at the seventh hour of photophase on the sixth day of their adult life. The extract (20 ml) was evaporated under a Vigreux column to a volume of 1 ml and kept at 4°C.

Laboratory Bioassays. Bioassays were performed in a Plexiglass cage (30 × 50 × 80 cm), with its two small sides covered with wire screen (1-mm mesh). During the bioassays, 100 virgin, sexually mature females one to two weeks old were present in the cage. The bioassays were conducted between the 7th and the 10th hour of the photophase in an insect-free well-ventilated room, under uniform light (3000 lux), 25 ± 2°C, and 60 ± 5% relative humidity. Samples of the crude extract or male volatiles, and the fractions obtained therefrom during the purification procedure (estimated to ten male-hour equivalents), as well as samples (10 μg) of the compounds identified and various combinations of them, were pipetted onto a piece (2 × 2 cm) of Whatman No. 1 filter paper that was suspended upstream about 3 cm below the top of the cage. A weak airstream was directed through the cage by means of a small fan (Mazomenos and Haniotakis 1985). The bioassays lasted for 5 min. Ten minutes was allowed between two consecutive bioassays for full recovery of the insects. Filter paper impregnated with solvent only was used as control. Two types of behavior, i.e., attraction and arrestment, as well as the overall behavior of the females in the cage were recorded, e.g., excessive insect mobility. Bioassays were video-taped and the time spent by individuals on the filter paper was measured by replaying tapes of the experiments. Incoming and outgoing individuals were timed, and during replay the elapsed time was calculated.

EAG Studies. Preliminary EAGs were obtained from antennae excised from male and female *R. cerasi* heads. Since no difference was observed in the degree of response between males and females, replications for statistical analysis were limited to females only. For this purpose, the indifferent glass capillary microelectrode was positioned in the hemocoel of the cranial cavity, while the recording electrode made contact with the distal end of the funiculus. The microelectrodes used (GC150F-10, Clark Electromedical Instruments) contained Ag electrodes, and 0.1 N aqueous solution of KCl as electrolyte (van der Pers et

al., 1984). The electrodes were connected to a high-impedance amplifier (Un-03 Syntech General Research Instruments, Borneolaan 4, NL-1217 HA Hilversum, Netherlands). Aliquots (10 μl) containing 10 μg of the compounds tested were pipetted on filter paper (1 × 2 cm), which, after solvent evaporation, was placed inside a Pasteur pipet. Air purified by means of an activated charcoal trap was "puffed" through the pipet by an air pump (CS-27, Syntech), and onto the preparation. Stimulus duration was adjusted to 6 liters/min for 0.7 sec, and the constant air current was 5 liters/min. A valve diverted the air current into the pipet at the onset of the signal. The antenna signals were recorded, digitized, stored, and analyzed on a PC, using the EAG v.3 program (Syntech). The various stimuli were randomly presented to the insect. An interval of 60 sec between two consecutive stimuli was found to be necessary for full recovery of the antenna. Each compound was tested on at least five individuals.

Extracts of male insects and male insect volatiles were tested. In addition, a series of compounds (aldehydes, ketones, terpenes) that were either identified in the volatiles of the male insects or are known to be part of the "general green leaf volatile complex" (Guerrin et al., 1982; Jang et al., 1989; Levinson et al., 1990; Light et al., 1988, 1992), or compounds identified from cherry volatiles (Mattheis et al., 1992), and pheromone compounds of other tephritids (Mazomenos and Haniotakis, 1981; Heath et al., 1991) were also examined.

The insects' response to the compounds tested was evaluated by the maximum negative deflection (−mV) produced by every compound after subtracting the control. The final values obtained in this way (mV) were transformed to percentages (%) relative to 6-methyl-5-hepten-2-one (100%). This compound was selected because it was identified both in cherry (Mattheis et al., 1992) and insect volatiles, and its EAG response was similar in magnitude to that of the male volatiles.

Isolation and Identification of Components of Biologically Active Samples. For the determination of the polarity of the active compounds present in the male extracts and their initial separation, TLC was used. A system of diethyl ether–hexane (40:60) was used to elute Silica Gel 60 TLC plates (Merck). Four fractions were collected: TLC-1 at R_f0.0, TLC-2 between R_f0.0 and 0.5, TLC-3 between R_f0.5 and 0.75, and fraction TLC-4 between R_f0.75 and 1.

Large-scale separation of the male-produced volatiles was obtained using HPLC (Binary LC Pump 250 Perkin Elmer) with a Techsil silica 10 column (250 mm × 4.6 mm ID), using methylene chloride–methanol (99:1) as solvent system. The HPLC was operated isocratically for 40 min with a flow rate of 1 ml/min. Subsequently, the ratio of methanol in the system was increased up to 40%, with the same flow rate. Column effluent was monitored by a UV/Vis LC-235 diode array detector (Perkin Elmer) at λ = 210 nm and 235 nm. Four fractions were collected, HPLC-1 to HPLC-4, each containing 20 ml. All fractions were concentrated in a Vigreux column to a total volume of 1 ml and kept at 4°C.

The active fractions obtained by either TLC or HPLC were analyzed on a Varian model 3300 capillary gas chromatograph equipped with flame ionization detector and an on-column injector. The fractions were injected onto DB-35, 30 m × 0.32 mm ID and DB-17, 30 m × 0.32 mm ID fused silica columns (J&W Scientific, Folsom, California). The column temperature program for DB-5 was 50–180°C at 15°C/min, held for 10 min, and then programmed to 250°C at 25°C/min. For DB-17 the temperature program was 50–190°C at 8°C/min. The injector temperature was set at 200°C and the detector temperature at 260°C. Helium was the carrier gas, the column flow rate was adjusted to 2 ml/min. and the make-up flow rate to 30 ml/min. Sample aliquots (2 μl) of each active fraction were injected, and the retention times of the components on the two columns were compared to those of the available synthetic compounds.

Tentative mass spectral identification of the components of active fractions was performed on a GC-MS VG-Trio-1000 (VG-MassLab, Manchester, UK) spectrometer system in the electron impact (EI) mode, equipped with a DB-5, 30 m × 0.32 mm ID chromatographic capillary column (J&W Scientific), held at 50°C for 1 min., then programmed at 25°C/min to 250°C.

RESULTS AND DISCUSSION

EAG Results. Figure 1 shows the EAG responses of female antennae to various amounts of male extracts and male volatile emissions ranging from 10^{-3} to 5 male equivalents, and 10^{-3} to 5 male-hour equivalents, respectively. Unfortunately, experiments with higher concentrations of male equivalents were not

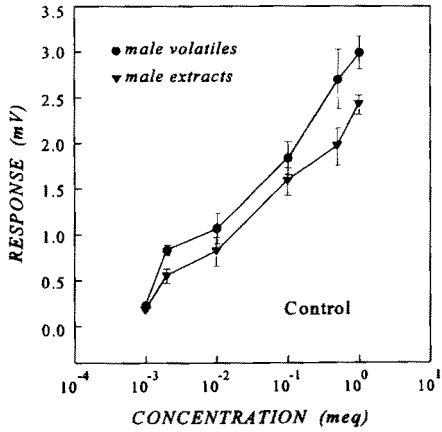

FIG. 1. EAG response of the female antenna to various concentrations of male produced volatiles, and male extracts.

possible due to the unavailability of biological material. These figures show that female flies have the ability to detect chemicals present in male volatiles at very low concentrations.

Laboratory Bioassays. The fractions collected from the TLC (male solvent extracts) and HPLC (male trapped volatiles) were tested for biological activity under laboratory conditions. Table 1 summarizes the results obtained from the bioassays and shows that there are two distinct groups of compounds: those acting as "attractants," attracting large numbers of females (such is the case of HPLC-2), and the second acting as "arrestants," stimulating incoming individuals to stay for a long time on the area of the stimulus (such is the case of HPLC-4, and TLC-1). Solvent extraction of the male seems to remove compounds belonging to the arrestant group, while in the case of volatile collection, compounds belonging mainly to the attractant group are obtained.

Analysis of Male Extracts and Headspace Volatiles. The GC-MS analysis of the male extracts and the male produced volatiles is summarized in Table 2. The various compounds identified were arbitrarily arranged into three abundance classes (major, intermediate, and trace), based upon visual examination of the reconstructed gas chromatograms from individual GC-MS runs.

Laboratory Bioassays of Synthetic Compounds. Based mainly on ranking of EAGs, 44 chemicals were tested in bioassays. A list of the compounds tested for their behavioral activity under laboratory conditions is given in Tables 2 and 3.

[a]Aldrich was the source of tested compounds.
[b]Positive sign (+) refers to arrestant behavior. Negative sign (−) refers to no response.

None of the compounds marked in Table 2 elicited any behavioral response to the female flies similar to that of the male volatiles or extracts when tested individually. Indication for biological activity appeared when 3-heptanone and 4-decanone were tested. Females seemed excited and flew vigorously, but did not land on the filter paper.

Arrestant behavior was observed when combinations of fatty acids were tested in bioassays (Table 3). Of these acids, octadecanoic was identified in fractions TLC-1 and HPLC-4. Gas chromatograms with standards of the acids listed in Table 3 indicated the possible presence of these acids in the polar fractions TLC-1 and HPLC-4, but since no reliable mass spectra were obtained, they could not be positively identified. However, bioassays with these acids and

some of their combinations were carried out. Ohinata et al. (1977) and Levinson et al. (1990) reported the existence of a similar group of acids in the male emitted volatiles of *Ceratitis capitata*, and their combination elicits a behavioral response by the females.

Some of the compounds identified have been also reported as components of the pheromone blend of other tephritids. Geranyl acetate and α-*E*-*E*-farnesene, for example, are constituents of the pheromone blend of *Ceratitis capitata* (Heath et al., 1991), and α-pinene, of *Bactrocera oleae* (Mazomenos and Haniotakis, 1981).

In summary, we believe that two different types of precopulatory behavior in *R. cerasi* are governed by chemical stimuli. One group of compounds attracts females to the stimulus area, and the other has arrestant properties. The fatty acids tested belong to the second group of compounds and may play a significant role in the communication system of this insect.

More work needs to be done to identify the compound(s) responsible for the attraction observed.

Acknowledgments—The authors would like to thank Dr. B.E. Mazomenos for his valuable assistance in various phases of the laboratory work, and the technical staff of the Entomology laboratory of "Demokritos" for their skillful technical assitance.

(Received September 15, 1994; accepted April 21, 1995)

Abstract—The spatial distribution of the pheromone of the grape vine moth, *Lobesia botrana* (Lepidoptera: Tortricidae), was measured in vineyards treated for mating disruption by using an electroantennogram technique (EAG). Five hundred dispensers per hectare, each containing 0.1 g of the main component of the sex pheromone (*E,Z*)-7,9-dodecadienyl acetate (*E7,Z9*-12:Ac) were evenly distributed in the experimental vineyards. The EAG amplitudes measured in the experimental plots were transformed into relative pheromone concentrations by means of a calibration curve. Mean relative pheromone concentrations in the center of a treated plot reached 2.31×10^{-4} relative units. No significant differences in the mean relative pheromone concentrations were found between replicate plots ($P > 0.01$). The mean relative pheromone concentrations measured within one plot along a transect at 5-m intervals also showed no significant differences between the sites. These results indicate that inside the borders of treated areas the pheromone was evenly distributed. No sites with significantly lower pheromone concentrations, frequently assumed to be the cause for higher trap catches in some areas, were found. However, the mean relative pheromone concentration rapidly declined more than 100-fold outside the border of the treated plot. At 10 m from the treated area, the EAGs showed no significant difference compared to the EAGs recorded in an untreated area. A rapid drop in the mean relative pheromone concentration was also found on a vertical transect through the canopy of the vineyard. Measurements in an untreated control block gave a mean antennal response approximately 1000-fold lower than in a nearby pheromone treated plot. The significance of the variation in the pheromone distribution for the success of the mating-disruption method is discussed.

Key Words—Lepidoptera, Tortricidae, *Lobesia botrana*, sex pheromone, pest control, mating disruption, electroantennogram, field EAG, vineyard.

INTRODUCTION

Pest control by mating disruption has been applied successfully for control of a number of pest insects worldwide (Ridgeway et al. 1990; Jutsum and Gordon, 1989; Suckling, 1993). The aim of this method is to reduce the mating success of the pest insects by applying large quantities of its sex pheromone, or parts of the sex pheromone blend, in the area to be protected. While the effectiveness of the method has been proven for a number of pest insects (e.g., Arn et al., 1979; Charmillot and Vickers, 1991; Suckling and Shaw, 1992), mating disruption has failed to function as an appropriate means for pest control for other species or in other situations. The reasons for these differences in the success are not always fully understood and are subject of investigation.

Methods widely used to monitor the success of mating disruption are male catch in traps baited with synthetic pheromone baits or virgin females and crop damage assessment. In the first case, the number of males caught indicates the effectiveness of the method, assuming that male insects would not be capable of reaching the pheromone baited traps if the mating disruption was successful. However, the number of male insects caught is not always correlated to fruit damage. In addition, the number of males caught within a treated area can differ significantly between traps, so the question arises whether the higher number of trap catches in some traps is caused or supported by a reduced pheromone concentration in the vicinity of that trap. Monitoring mating disruption through crop damage assessment gives a good indication of the success of the pheromone application but has the disadvantage that any potential problems in the control of the pest insect that arise during the pheromone application will not become obvious until harvest and therefore cannot be addressed. The use of a field EAG apparatus (Baker and Haynes 1989; Sauer et al.; 1992; Karg and Sauer, 1992; Bengtsson et al., 1994; Karg et al., 1994; Suckling et al., 1994) is useful as an additional monitoring method. Its application could contribute to improving the success of the mating disruption technique in two ways. Firstly, field EAG could function as a monitoring system for (a) the pheromone concentration achieved in mating disruption plots during the season, (b) the spatial and temporal distribution of the pheromone, and (c) the longevity of the dispensers. Secondly, information concerning the spatial distribution of the pheromone in the area to be protected contributes to knowledge regarding the mechanisms underlying mating disruption by describing the olfactory environment in which a male insect has to find his partner. This information can be used to adjust the pheromone application method to the specific circumstances during the flight period of the pests.

The primary aim of this work was to measure relative pheromone concentrations and gain insight into the three-dimensional spatial distribution of the pheromone applied in vineyards under ambient conditions. We aim to describe the olfactory environment in which a male moth has to find his female counterpart. Consequences for the mechanisms of mating disruption are discussed.

METHODS AND MATERIALS

Insects. Grape vine moths, *Lobesia botrana* (Lepidoptera: Tortricidae), were reared in the laboratories of the Landwirtschaftliche Versuchsanstalt of BASF, Limburgerhof, Germany, and supplied as pupae. The purpae were sexed and, after eclosion, kept in a refrigerator at 9°C until used. All experiments were performed with antennae from 2 to 4-day-old males.

Pheromones. For calibration purposes, the main component of the pheromone of *Lobesia botrana* (*E,Z*)-7,9-dodecadienyl acetate ((*E,Z*)-7,9–12 : Ac) (Buser et al., 1974) was used. Different pheromone concentrations were obtained by dissolving different amounts of pheromone in paraffinoil (Merck, No. 7161, Uvasol). The vials containing the different pheromone–paraffinoil mixtures (from 10^{-2} to 10^{-7}) were kept inside 20-ml glass syringes. The equilibrium concentrations of the volatile pheromone inside these syringes above the pheromone–paraffinoil mixture depended on the concentrations of pheromone in the solutions (Raoult's law). While not in use, the pheromone solutions were kept in a freezer at −20°C. The pheromone dispensers in the field were standard pheromone dispensers as used by BASF, containing 0.1 g (*E,Z*)-7,9–12 : Ac.

Experimental Setup. The dispersion and the concentration of pheromones were measured by using electroantennograms (EAG). The measuring system and evaluation of the data are described in more detail by Sauer et al. (1992), Bengtsson et al. (1994), and Karg et al. (1994). A suction pump generated a continuous airstream across an antenna, which was mounted on an antenna holder, inside a glass chamber isolated from ambient air in the vineyard. A removable charcoal filter with a low flow-resistance was attached to the inlet of the measuring chamber to remove pheromones and other odors from the incoming ambient air. This filtering system was necessary for measuring the resting potential of the antenna in clean air and during calibration. For calibration purposes, 0.75 ml of air from a syringe loaded with a known pheromone concentration (10^{-4}) was injected into a continuous airstream (42 ml/sec) by a step-motor-driven device in a 0.2-sec puff. The pheromone concentration reaching the antenna was called the relative pheromone concentration, as this reflects the pheromone concentration above the pheromone–paraffinoil mixture as transported to the antenna by the main airstream. Different relative pheromone concentrations, necessary to measure the dose–response curve of the antenna to pheromone, were generated with different pheromone–paraffinoil mixtures in the

syringes. In order to measure the relative pheromone concentration in the ambient air, the charcoal filter was removed. Thus the ambient air containing pheromone was sucked across the antenna. Removal of the charcoal filter alone did not affect the flow rate over the antennae, as monitored with a flowmeter.

EAG signals were amplified, frequency modulated, and recorded on a tape recorder (see Sauer et al., 1992). To prevent contamination of the apparatus, glass parts were washed in acetone and heated with a Bunsen burner between subsequent measurements.

Estimation of Pheromone Concentrations. The measurement of three to five calibration pulses was followed by at least three measurements of the airborne pheromone concentration. The mean antennal response to the calibration pulses and to the ambient air measurements was determined and normalized by dividing the mean response to the ambient air measurements by the mean response to the calibration pulses (this equals one measurement), giving the normalized EAG amplitude. Normalization was necessary because of differences between antennae in the absolute antennal sensitivity to pheromone, as well as to compensate for the loss of responsiveness of individual antennae due to signal degradation and antennal fatigue. This procedure was repeated 3–15 times at every site. A single antenna was used for all related measurements, if possible. Antennae were replaced when only approximately 30% of the initial amplitude to a calibration pulse could be measured.

The relative pheromone concentration in the field was estimated by comparing the normalized EAG amplitudes generated by the ambient air with the normalized EAG amplitude elicited by the calibration pulses. The normalized EAG amplitude measured in ambient air could be transformed to the normalized calibration curve and converted to the corresponding relative pheromone concentration value (see Figure 1 below).

Field Experiments. All experiments were carried out in summer (1989 and 1990) during the flight season of the second generation of *Lobesia botrana*, in vineyards near Billigheim and Wachenheim, Rhineland-Palatinate, Germany. The plot sizes were 0.3–5 ha. Five hundred dispensers per hectare were applied, each containing 0.1 g of (*E*,*Z*)-7,9-12 : Ac. During the measurements the field EAG was always placed in the center of the four nearest pheromone dispensers. All related measurements began in an untreated control vineyard of the same grape variety (Scheurebe) approximately 1 km (Wachenheim) or 350 m (Billigheim) upwind from the pheromone-treated fields. The control vineyards had been treated conventionally with insecticides, ensuring that the possible interference of pheromones related by calling females was minimized. The EAG system was then transported to the pheromone-treated plots for subsequent measurements.

For comparison of the mean relative pheromone concentrations of different plots, the field EAG system was placed close to the center of the treated areas. At least seven antennae were used in the center of every plot. The measurement

of the transect along an axis of a treated plot began at the upwind edge (see Fig. 5 below, 2 m on x axis, 17 m on y-axis). Measurements were taken initially following one row. The field EAG system was transported towards the center of the plot, with measurements taken at 5-m intervals. On two occasions (at 17 and 32 m inside the treated vineyard) the EAG system was transported in an orthogonal direction (right angle to the previous axis), again with measurements taken in 5-m intervals, with the distance varying slightly depending on the interrow distances. For all related measurements, only one antenna was used. Measurements were repeated with five antennae. The measurements of the vertical distribution of the pheromone began above the canopy and continued in steps through the canopy. Measurements were taken at approximately 3.1, 2.8, 2.3, 1.8, 1.3, and at 0.8 m above ground level.

RESULTS

Calibration of Antennal Response. Figure 1 shows the mean normalized calibration curve of antennae of male *Lobesia botrana* to pheromone stimuli

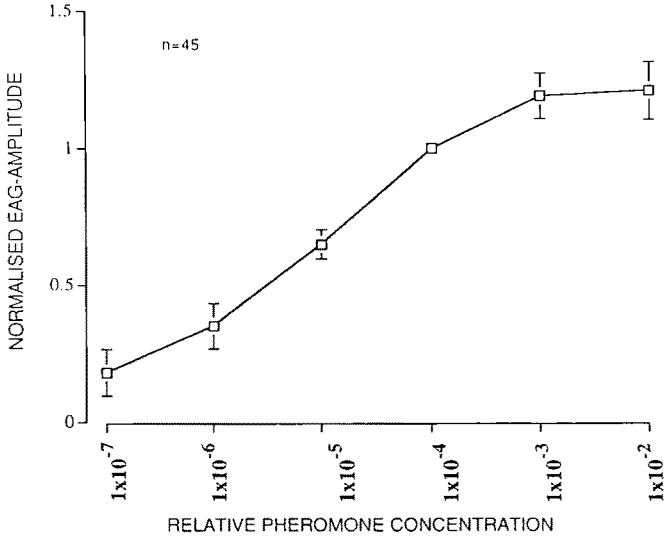

FIG 1. Dose—response curve of male antenna of *Lobesia botrana* to sex pheromone (*E,Z*)-7,9-dodecadienyl acetate. The dose-response curves of 45 antennae of male insects were normalized ot the antennal response to a stimulus of 1×10^{-4} relative pheromone concentration (pheromone–paraffin oil). The bars indicate the standard deviation. The normalized EAG amplitude elicited by the ambient air (y axis) can be converted to the corresponding relative pheromone concentration value (x axis) with the help of the normalized calibration curve.

from syringes containing vials with different pheromone–paraffinoil mixtures from 1×10^{-7} to 1×10^{-2}. The dose–response curves of 45 antennae were normalized to the response of a stimulus of 1×10^{-4} (relative pheromone concentration) and then averaged. With the help of the calibration curve, the normalized EAG amplitude measured in a pheromone-treated plot could be transferred to its corresponding relative pheromone concentration (Figure 1).

Comparison of Pheromone-Treated and Untreated Fields. The comparison of the mean relative pheromone concentrations measured in the center of a treated plot (Billigheim) and an untreated control plot, approximately 350 m upwind, is shown in Figure 2. The measurements were carried out in August 1989, with temperatures of 22°C and at a mean wind speed of <2 m/sec. The relative pheromone concentration measured in the treated area ranged from 4.5×10^{-5} (relative units) to 3.0×10^{-4} with a mean relative pheromone concentration of 2.31×10^{-4} ($N = 24$). The antennal response to the ambient air in this field thus had the same amplitude as it would have had to a calibration pulse from a syringe with a 2.31 : 1000 pheromone–paraffinoil solution. The EAG amplitude elicited in an untreated area was significantly lower (approximately 1000-fold) ($P < 0.001$) compared to the treated area. The mean relative pheromone concentration calculated from the EAG amplitude here reached a mean value of 1.98×10^{-7} ($N = 22$).

The EAG measured in untreated plots cannot be elicited by pheromone molecules but is the antennal response to other volatiles present in the ambient

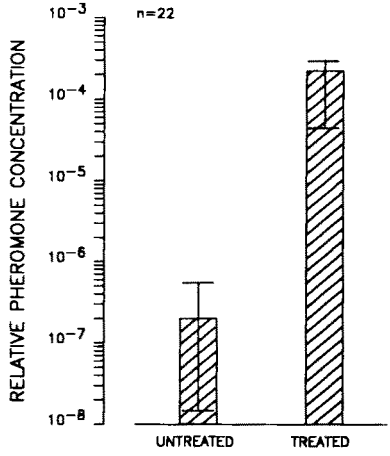

FIG. 2. Comparison of the relative pheromone concentrations in a treated area (Billigheim) and an untreated control plot (350 m upwind). The mean relative pheromone concentrations were 2.31×10^{-4} ($N = 24$) in the treated area and 1.98×10^{-7} ($N = 22$) (relative units) in the untreated area. The bars indicate the range of the measured values.

air, such as plant volatiles or other environmental odors. This is corroborated by results of Suckling et al. (1994) and Rumbo et al. (1995). The EAG elicited by these odors appears at first to be rather high, but if one takes the logarithmic relationship between the pheromone concentration and the elicited EAG into account, the contribution of environmental odors can be neglected (see Sauer et al., 1992).

Comparison of Pheromone Concentrations Measured in Replicate Pheromone-Treated Plots. Figure 3 shows the mean relative pheromone concentrations measured in replicate treated plots in Rhineland-Palatinate in 1989. Plots 1 and 2 were both located in the center of a 5-ha treated vineyard in Wachenheim. Plot 3, located in Billigheim, had a size of approximately 1.2 ha and was situated on a slope (6%). Mean relative pheromone concentrations in the center of three plots were measured on several days under similar weather conditions, with temperatures of 20–23°C and mean wind speeds of <2.5 m/sec.

The mean relative pheromone concentration estimated according to the dose–response curve (Figure 1) was 3.31×10^{-5} ($N = 24$) in plot 1 in Wachenheim, with measurements ranging between 2.3×10^{-5} and 6.9×10^{-5} (relative units). In plot 2 in Wachenheim the mean relative pheromone concentration was 5.25×10^{-5} ($N = 9$) (range 2.25×10^{-5}–12.8×10^{-5}) and in

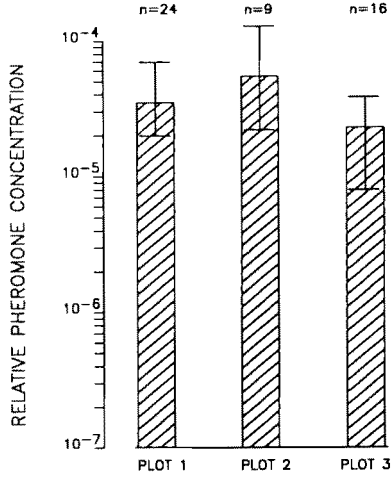

FIG. 3. Comparison of the relative pheromone concentrations in different treated plots in Billigheim and Wachenheim. The mean relative pheromone concentrations were 3.31×10^{-5} ($N = 24$) in plot 1 in Wachenheim, 5.25×10^{-5} ($N = 9$) in plot 2 in Wachenheim and 2.18×10^{-5} in the center of plot 3 in Billigheim ($N = 16$). There was no significant difference in the mean relative pheromone between the plots. The bars indicate the range of the values.

the center of plot 3 in Billigheim a mean relative pheromone concentration of 2.18×10^{-5} (range 0.94×10^{-5}–3.81×10^{-5}) was measured ($N = 16$). There was no significant difference in the mean relative pheromone concentration between the three replicate plots ($P > 0.01$).

Measurement of Pheromone Concentrations at Different Sites within Treated Plots. The spatial distribution of pheromone was repeatedly measured at different sites within the boundaries of treated plots along an axis. The results of the measurements carried out in Billigheim on August 3, 1989, are shown in Figure 4. The mean relative pheromone concentrations measured at the different sites ranged from 1.74×10^{-5} at the edge of the treated plot to 4.51×10^{-5} at 30 m inside the plot. There was no significant difference in the mean relative pheromone concentration within the treated plot ($P > 0.01$). In Figure 5 the mean relative pheromone concentrations measured inside a pheromone-treated plot in Billigheim on July 11, 1990, are shown. The mean relative pheromone concentrations again were not significantly different between the measurements ($P > 0.01$).

These results suggest that the pheromone is rather homogeneously distributed within the treated areas. No reductions in the mean pheromone concentration, frequently assumed to be the cause for higher trap catches in some areas, were found on any occasion.

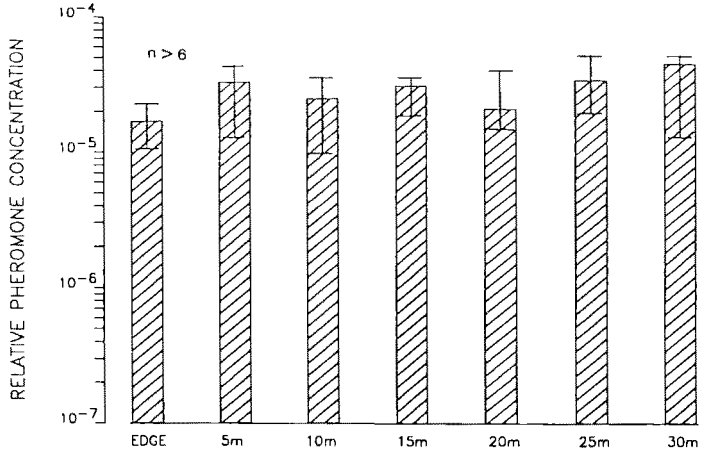

FIG. 4. Relative pheromone concentration within a treated area in Billigheim on August 3, 1989. The mean relative pheromone concentrations ranged from 1.74×10^{-5} to 4.51×10^{-5}. There was no significant difference in the mean relative pheromone concentrations measured within the boundaries of this treated area. The bars indicate the range of the values.

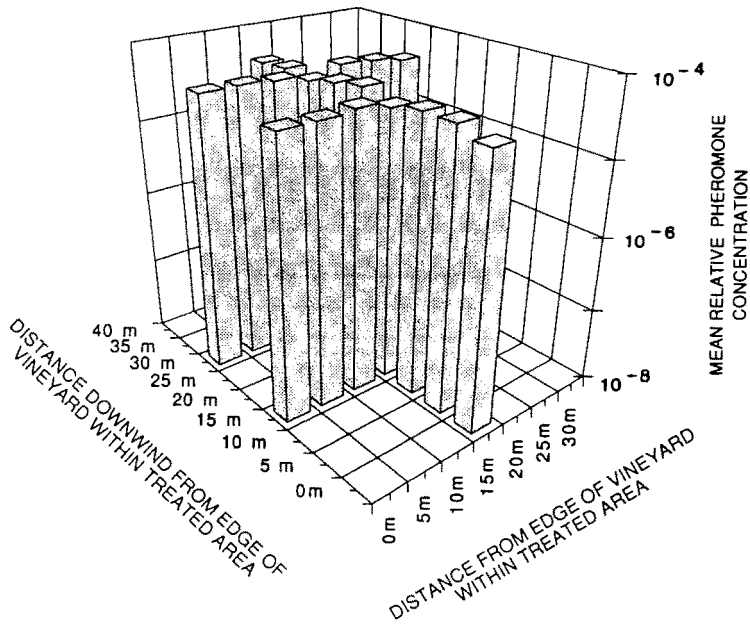

FIG. 5. Relative pheromone concentration within the treated area in Billigheim on July 11, 1990. The values ranged from 1.95×10^{-5} to 2.83×10^{-5}. There was no significant difference between the mean relative pheromone concentrations measured on several axes in the pheromone-treated vineyard. Distances are in meters.

Pheromone Concentrations outside the Borders of a Treated Vineyard. The mean relative pheromone concentration rapidly declines with increasing distance from the edge of the treated area (Figure 6). The mean relative pheromone concentrations measured inside a treated area on July 20, 1989, in Wachenheim was 8.43×10^{-5} (range $1.36 \times 10^{-5} - 8.6 \times 10^{-5}$) and dropped significantly to 3.41×10^{-7} (range $2.1 \times 10^{-7} - 1.1 \times 10^{-6}$) just 10 m outside the plot ($P < 0.001$) (Figure 6A). The antennal response at 10 m outside the treated plot was comparable to an EAG elicited in an untreated area. Measurements were repeated several times with similar results. Figure 6B and C show the results of measurements from August 8, 1989, and from July 11, 1990 in Billigheim. The decline of the mean relative pheromone concentration took place in all directions from the treated area, independent of wind direction, although the pheromone concentration seemed to be slightly biased towards the downwind direction.

Pheromone Concentrations along a Vertical Transect through a Treated Plot. The decline of the mean relative pheromone concentration with height is shown in Figure 7. The highest mean relative pheromone concentration of

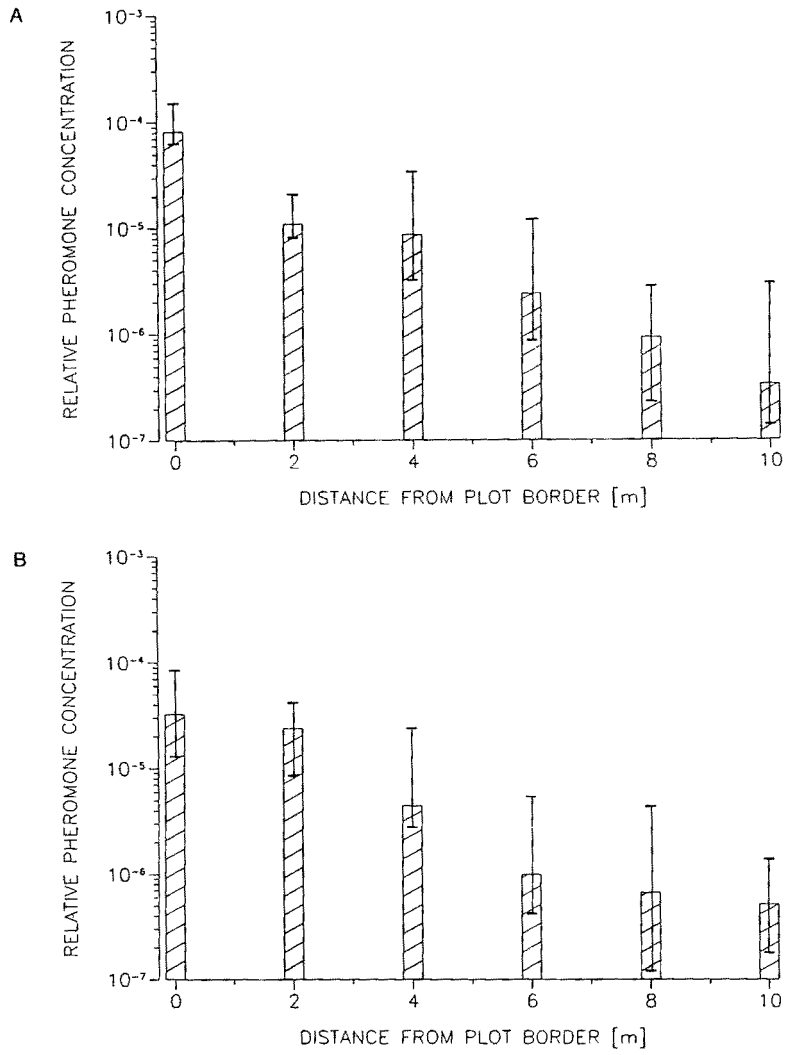

FIG. 6. Decline of the mean relative pheromone concentration with increasing distance from the edge of the treated plot. The mean relative pheromone concentration measured at the edge of a treated plot on July 20, 1989, in Wachenheim was 8.43×10^{-5} and dropped significantly at 3.41×10^{-7} only 10 m, outside the plot ($P < 0.001$) (A). This antennal response was comparable to an EAG elicited in untreated areas. The response measured at increasing distances did not change significantly. (B and C) The results of the measurements from August 21, 1989 in Billigheim and from July 11, 1990, in Billigheim.

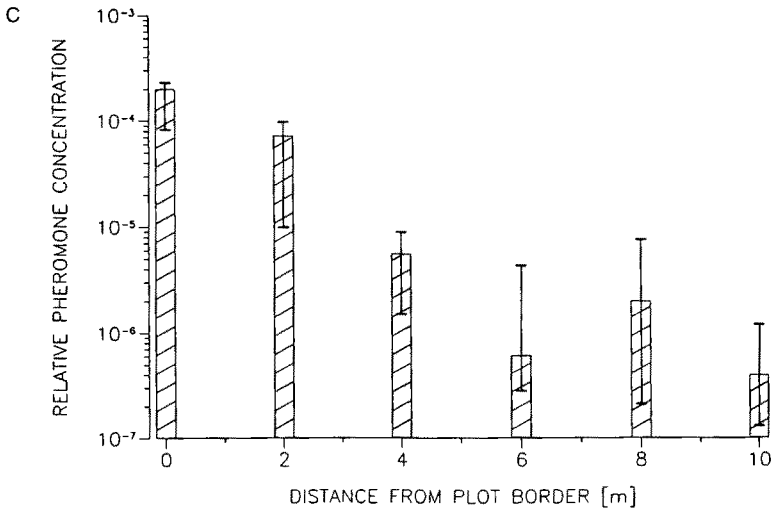

FIG. 6. Continued.

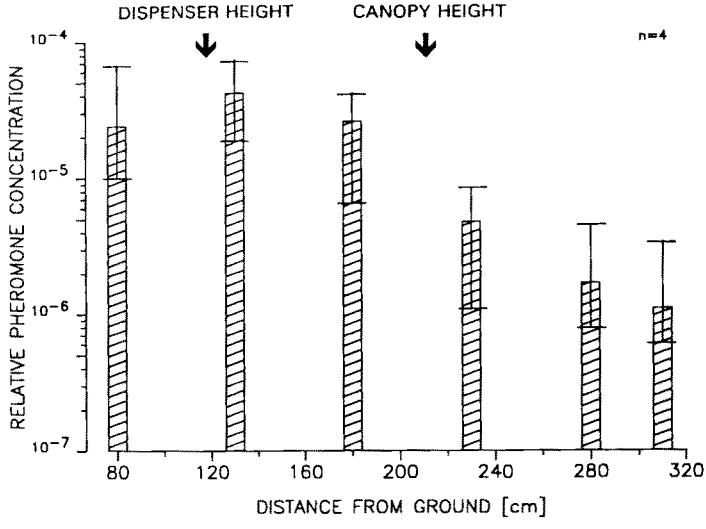

FIG. 7. Decline of the mean relative pheromone concentration along a vertical transect through a treated vineyard. The mean relative pheromone concentration declines rapidly approximately 30-fold from 2.42×10^{-5} to 7.42×10^{-7} at 3.1 m above the canopy of the treated area.

4.22×10^{-5} (range 2.3×10^{-5}–6.7×10^{-7}) was measured at 1.3 m, the same height the pheromone dispeners had been applied. The mean relative pheromone concentration was lower both below and above 1.3 m and declined approximately 30-fold with increasing height to 7.42×10^{-7} at 3.1 m.

DISCUSSION

Information concerning the distribution of airborne pheromone in mating disruption trials will be helpful in understanding the mechanisms on which mating disruption is based. Three different techniques are commonly used to measure pheromones in the field: (1) sampling of ambient air with collection of airborne volatiles on filters (e.g., Tenax) and subsequent chemical analysis (e.g., Caro et al., 1980, 1981) (2) field EAG measurements (e.g., Baker and Haynes, 1989; Sauer et al., 1992; Karg and Sauer 1992; Bengtsson et al., 1994; Karg et al., 1994; Suckling et al., 1994), and (3) single sensillum recordings (van der Pers and Minks, 1993).

Absolute, but time averaged, pheromone concentration can probably most accurately be measured by using air-sampling methods, followed by chemical analysis (Caro et al., 1980, 1981). This approach has not been attempted for *Lobesia botrana*, but preliminary results from another species (*Cydia nigricana*) show that the estimated aerial pheromone concentration from areas treated for disruption, as measured with EAG, compare closely with the value achieved by chemical analysis of field samples collected on a Tenax filter (Witzgall, unpublished data.).

The advantage of the field EAG system is the instantaneous nature of the measurements (on-line measurements) and the high temporal resolution (Karg et al., 1990a; Karg and Sauer, 1992; Bengtsson et al., 1994), which gives insight into the possible spatial and temporal fluctuations of the pheromone concentration. In addition, the portability of the EAG system allows repetitive measurements and measurements at different sites within only a short time period, and the high sensitivity of the antenna to pheromones enables us to gain information concerning the three-dimensional distribution of pheromone in mating disruption trials. However, the method has some disadvantages that hinder the interpretation of electroantennogram measurements (Sauer et al., 1992; Bengtsson et al., 1994; van der Pers and Minks, 1993). The major drawbacks are the interaction of pheromone and host-plant detection (Karg et al., unpublished data, Rumbo et al., 1995), the variance between individual antennae (Suckling et al., 1994), and the nonlinearity of the detector. The importance of these problems varies from species to species. In the case of *Lobesia botrana*, the response to environmental volatiles or host-plant volatiles are of minor importance (Sauer et al., 1992). Separation of the antennal preparation from the ambient air through

the surrounding glassware in the EAG system of Sauer et al. (1992) has the advantage that repetitive calibration of the antennal response in clean air is possible. Continuous sampling of ambient air through the glassware with a constant flow rate by a suction pump possibly distorts the EAG signal. However, fluctuations in an artificial pheromone plume, generated with the help of a fan and pheromone plumes released from a dispenser in an open field can readily be measured (Karg and Sauer, unpublished data).

In single sensillum recording techniques (van der Pers and Minks, 1993) neural responses of individual pheromone-specific sensilla are recorded. The advantage of this technique compared to the EAG method is that the presence of environmental volatiles does not usually interfere with the recordings from pheromone receptors. The major disadvantage of this technique is the comparably more difficult and fragile preparation that hampers its use in field measurements. In addition, the information acquired from recordings made from single olfactory hairs might be insufficient for the interpretation of sensory input (van der Pers and Minks, 1993), especially when the insects use a pheromone blend.

Our results show that the spatial distribution of the pheromone in the treated plots can best be described as a dense pheromone cloud, which is characterized by a high relative pheromone concentration. The pheromone cloud has well-defined edges outside which the pheromone concentrations decrease rapidly, and there are comparatively small internal variations in the mean pheromone concentration. Distinct trails generated by pheromone dispensers, often assumed to be present in treated vineyards, were not found.

The high relative pheromone concentration with little internal structure has two causes. Firstly, the higher temperatures in summer lead to higher release rates by the pheromone dispensers. Secondly, the plant canopy has a strong effect on the pheromone concentration obtained (Karg et al., 1990b). The foliage reduces mean windspeeds within the canopy (Uchijiama, 1988) and thereby decreases pheromone transport. In addition adsorption and release of pheromone by foliage has a significant impact on the atmospheric pheromone concentration in mating disruption trials (Karg et al., 1994) and probably also contributes to the even distribution of the pheromone within the treated area. Areas with significantly lower pheromone concentrations, often assumed to be responsible for increased trap catches or infestation (Krieg and Netter, personal communication), were not detected. The rapid decline of relative pheromone concentration outside the boundaries of the treated area is one possible cause for failure of mating disruption. Immigration of females mated in the surrounding areas with low pheromone concentration can lead to high infestation and fruit damage, even though disruption is successful within the treated area. Therefore, it is important to treat a sufficient distance outside the area to be protected with pheromone. The decline above the vineyard is less critical, as flight and ori-

entation takes place only within the canopy of the vineyards (Schneickhart, 1989; Netter, 1993).

Male *Lobesia botrana* attempting to find a female partner in a "pheromone cloud" as described above are most likely to undergo adaptation and/or habituation processes, which require sustained and/or repetitive simulation of the olfactory system (Rothschild, 1981; Bartell, 1982; Cardé, 1990). In our experiments discrimination between adaptation and habituation was not possible. Both sensory adaptation and habituation elicit changes in male behavior that can be registered in field observations. Only limited flight activity of *Lobesia botrana* males was found in pheromone-treated areas, whereas rather high flight activity was recorded in untreated fields (Netter, 1992; Schneickart, 1989; Karg, unpublished data). This reduction of male activity probably leads to a decrease in mate contact and can be responsible for the success of mating disruption of male *Lobesia botrana*. If distinct odor plumes or trails were present in the treated area, then sensory adaptation alone would be very unlikely to lead to disruption (Cardé, 1990) since the receptor neurons are known to regain their initial sensitivity to the pheromone within less than a second if returned to clean air (Rumbo, 1981). However, in a pheromone cloud characterized by high concentrations and a lack of fluctuations, sensory adaptation alone could explain the success of mating disruption.

Our results do not support the false trail following hypothesis as an explanation for the success of mating disruption of the second generation of *Lobesia botrana*. According to the false trail following hypothesis, pheromone plumes generated by the pheromone dispensers in the mating disruption trails compete with the plumes generated by calling females (Sanders, 1981; Bartell, 1982). The reduction of mating success is assumed to be due to the increased number of plumes (both artificial and natural), thus reducing the rate of success in finding a partner. In our experiments, no such odor plumes were ever found inside the borders of the treated fields.

Acknowledgments—We gratefully acknowledge the help of BASF AG, Ludwigshafen, who supplied the insects and the pheromone dispensers. Thanks are due to Drs. Max Suckling, Bill Hansson, and John Byers for critical revision of the manuscript and many helpful comments. We would like to express our special thanks to Prof. Ulrich Bässler, who supported the project and took a constant interest in its progress. Thanks to Elke Grimm for all her support.

(Received December 16, 1994; accepted April 21, 1995)

Abstract—The volatile plant sesquiterpenoids farnesene, nerolidol, and farnesol were tested to determine their effect on European corn borer, *Ostrinia nubilalis*, oviposition during the first six nights of the adult stage. Adult European corn borers were released into cages designed to encourage oviposition on eight glass plates randomly arranged on top of the cage: four coated with either 80 $\mu g/cm^2$ farnesene, nerolidol, or farnesol, and four coated with the solvent methylene chloride. The setup was used as a binary choice test. Farnesene was preferred by females because they deposited significantly more egg masses on plates coated with the compound. Nerolidol had no effect. Farnesol, by contrast, deterred oviposition: the number of egg masses was significantly lower on plates covered with that compound. These data show that structural modification at a single terminal functional group in these compounds affects the ovipositional behavior of European corn borer females.

Key Words—Farnesene, farnesol, nerolidol, European corn borer, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, oviposition, behavior, egg masses, digital analysis technique.

INTRODUCTION

The European corn borer (ECB), *Ostrinia nubilalis* (Hübner), is a highly mobile, polyphagous, primary pest of corn, and females deposit an average of two to

three egg masses each night throughout their ovipositional period, which ranges from 9 to 14 days, depending on environmental conditions (Caffrey and Worthley, 1927). Unidentified volatiles of injured corn plants repelled ECB oviposition and odors of undamaged plants attracted females (Schurr and Holdaway, 1970), but little is known about how individual volatile compounds might influence ECB oviposition. Volatile emission of the corn natural products (*E*)-β-farnesene and (*E*)-nerolidol increased due to larval feeding of the beet armyworm, *Spodoptera exigua* (Hübner) (Turlings and Tumlinson, 1992). A combination of these and other herbivore-induced plant odors attracted the host-seeking parasitic wasp *Cotesia marginiventris* (Cresson), and the authors suggested that release of host plant volatiles after damage also might deter host-seeking phytophagous insects from ovipositing on plants (Turlings et al., 1990). While farnesene acts as an ovipositional stimulant and larval attractant for the codling moth *Laspeyresia pomonella* (L.) (Sutherland and Hutchins, 1973; Wearing and Hutchins, 1973), its impact on ECB females is unclear. We evaluated the effects of the structurally related sesquiterpenoids farnesene, nerolidol, and farnesol on the ovipositional behaviors of ECB in the laboratory and found that these compounds could mediate ECB ovipositional behaviors.

METHODS AND MATERIALS

Insects. ECB were reared according to the methods of Reed et al. (1972), with modifications for the adult stage as described. Adults eclosed in specially designed cages (58.7 × 58.7 × 63.7 cm) made of angle and strap aluminum frame (1.9 cm and 2.3 cm, respectively) covered on the sides and bottom with 16 × 18 mesh brass cloth. Each cage was constructed so the wire cloth, which discourages oviposition, covered the inside surface of the cage, except for a section in the front, which was replaced by a cloth sleeve (Figure 1). The top of the cage was covered with 5-mesh galvanized cloth, which permitted oviposition on the underside of surfaces placed on top of the cage. Two feeding stations were included in each cage. One feeder was a cotton pad suspended from a brass wire 19.5 cm from the top of the cage and moistened daily with water. The other feeder, a molded plastic unit (10.3 cm^2) with 16 wells (3 ml), was located on the bottom of the cage and its wells were filled with 1.4% (w/v) agar gel containing 39.4% sucrose (w/v). Adult feeding was not restricted during the tests.

Oviposition Tests. The ovipositional tests were designed to examine ECB reproductive behaviors during the peak ovipositional period in a laboratory environment that simulated natural conditions in Iowa (16L : 8D, 24.5 : 18.5°C, 96% humidity). Females and males eclosed in the emergence cages; mating probably occurred soon after adult emergence. Within 15 hr of eclosion, 100 each of males and females were collected separately by using a small vaccum apparatus

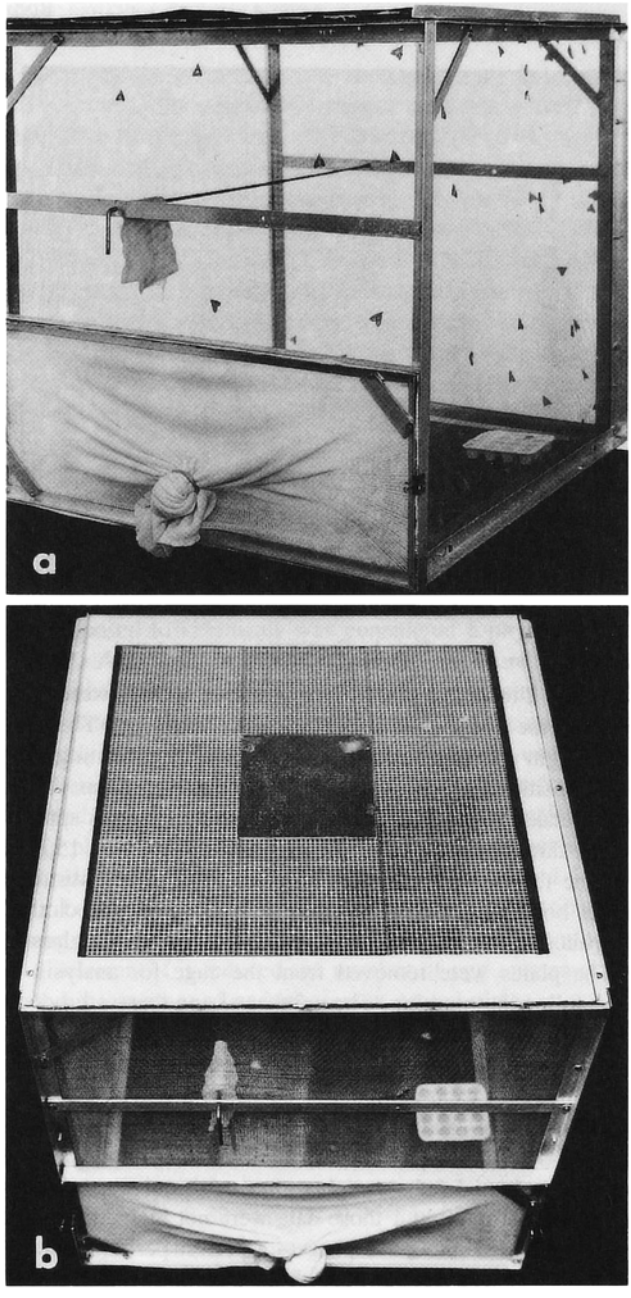

FIG. 1. Oviposition cage for *O. nubilalis* adults: (a) front view, (b) top view showing the position of the glass oviposition plates, (c) one oviposition plate covered with egg masses.

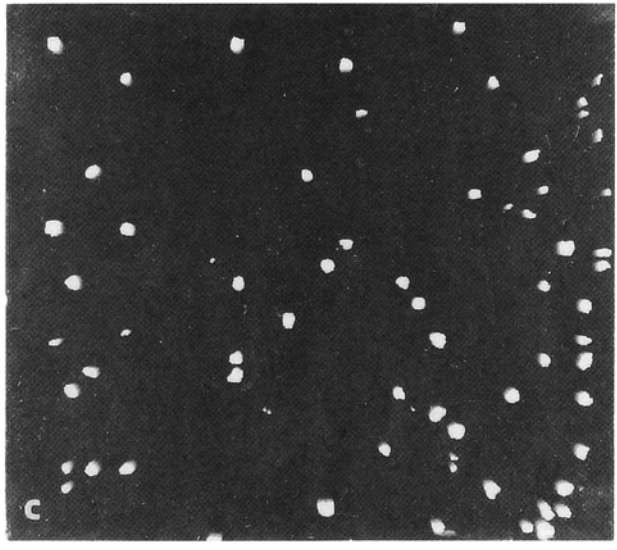

FIG. 1. Continued.

and released inside a test cage placed in a chamber. Adults were free to walk, fly, or mate within the ample confines of the cage (Figure 1a). These large cages allowed limited flight and ample mobility during posturing (mating movements), mating, and oviposition, which maximized reproductive efforts. There was no noticeable preference by the adults for any side, and the adults apparently were dispersed evenly throughout the cage. Eight glass plates (17 × 15.3 × 0.3 cm) positioned on the top of the cage were used as oviposition substrates (Figure 1b). A Plexiglas border and the central plate were covered with cloth to prevent oviposition on those surfaces. Females deposited eggs on the glass during the scotophase. The plates were removed from the cage for analysis during the photophase the following morning. The number of egg masses produced nightly and their size were monitored with a digital image analysis system described below. The plates were randomly arranged for each replicate (cage), and three replicates were made for each compound.

Farnesene, nerolidol, and farnesol were tested separately to determine if they stimulated or deterred oviposition or had no effect. Ovipositional behaviors for females were evaluated for six nights after eclosion, but because few egg masses were deposited on night 1 those data were not included in the analysis. The analysis was divided into three phases: a pretest period without chemical on night 2, a binary choice test period with chemicals on nights 3 and 4, and a posttest period without chemical on nights 5 and 6. The pretest period on night 2 following eclosion monitored uncoated plates to determine two factors: (1)

the total number of egg masses produced, which was expected to fall in a predicted range of 250–400 on that night if females were healthy, and (2) whether the number of egg masses distributed between plates 1–4 and 5–8 was equal, indicating that there was no bias in the random positioning of the plates. If the number and distribution of egg masses were as expected, the analysis advanced to the binary choice test period with chemical. Each chemical, dissolved in methylene chloride, was coated (80 $\mu g/cm^2$) on plates 1–4, and methylene chloride was coated on plates 5–8. The plates were monitored on nights 3 and 4 to determine if the plant compound influenced oviposition, as indicated by the number of egg masses deposited on the coated plates. The posttest period monitored oviposition on uncoated plates again on nights 5 and 6 to determine if there was a residual effect from the compound that might keep total oviposition reduced or elevated and to distinguish behavioral responses if oviposition was as expected.

The effect of the compound on oviposition was interpreted as toxicological if the total number of egg masses was significantly below the number expected from the same number of females not exposed to chemicals. A number of egg masses equal to or greater than the number expected from the same number of females not exposed to chemicals was considered a physiological response to the compound. A change in oviposition from exposure to a compound was interpreted as a behavioral response if two criteria were met: (1) the total number of egg masses was as expected on nights 3 and 4, but the number of egg masses was significantly higher or lower than expected on plates coated with farnesene, farnesol, or nerolidol; and (2) the total number of egg masses was as expected on nights 5 and 6. This type of response showed that females could not distinguish among plates before exposure to the compound, but were behaviorally sensitive to plates coated with chemical during nights 3 and 4. Additional evidence for a behavioral response occurred if females distributed egg masses evenly among the uncoated plates on nights 5 and 6. A compound was described further as a deterrent if it reduced the number of egg masses or as a stimulant if it increased the number of egg masses on coated plates.

Some volatile compounds could have indirectly affected oviposition by causing the premature death of adults. Therefore, mortality was monitored throughout the experiment.

Chemicals. The purity of each sample was analyzed by gas chromatography–mass spectrometry (GC-MS) by using a Hewlett Packard 5892 Chem Station, including a Wiley data base of spectra for reference. Each sample was injected on a 30-m × 0.32-mm-ID, 0.25-μm film thickness, DB-225 50% cyanopropylphenyldimethylpolysiloxane column (J & W Associates, Folsom, California); gas flow rate for He: 1.0 ml/min; temperature program: 35°C for 1 min then to 200°C at 20°C/min; EI at 70 eV. Analysis of the samples showed that farnesene was composed of two isomers and several unidentified impurities,

while there were four isomers of farnesol and two isomers of nerolidol. Evaporation and decomposition of farnesene, farnesol, and nerolidol was evaluated by gas chromatography–flame ionization detection (GC-FID). Glass plates were coated with each sample, stored in the conditions as described for oviposition tests, and extracted with methylene chloride after 0, 24, and 48 hr. An aliquot of each sample was injected on a 30-m × 0.25-mm-ID, 0.25-μm film thickness, DB-5 5% phenyl methyl silicone column (J & W Associates); gas flow rate for He: 1.3 ml/min; temperature program: 100°C for 1 min then to 200°C at 20°C/min. The integrated areas of each sample at 0, 24, and 48 hr were compared to standard curves to determine the amount of evaporation or decomposition.

Analysis. Each egg mass deposited on the glass plates was measured with a digital analyzer system (Decagon Industries Monochrome Ag Vision Imaging System, Pullman, Washington). A glass plate containing the egg masses was positioned under the camera of the digital analyzer and lighted from below. The resulting image appeared on the video monitor as a bright background with the egg masses showing as dark spots. This system digitized the video camera image (CCD 512 × 488 pixels) for each egg mass, and these data were stored as a separate record in a common-separated value (CSV) file for each glass plate. CSV files were then converted into an XLS file of the MS-DOS-driven spreadsheet program, Microsoft Excel. Once the data were transferred to the spreadsheet program, further statistical analyses were completed. Egg masses varied in size and therefore number of eggs. Egg masses with fewer than five eggs were not considered in this analysis because often the digital analyzer would mistake imperfections in the glass (nicks, scores, etc.) for egg masses, and small egg masses were sometimes missed entirely by the analyzer.

Statistical Analyses. Effects of each chemical on oviposition were analyzed with a two-tailed t test (Ott, 1984). Values were expressed as the mean and standard deviation (SD) ($N = 3$).

RESULTS

Female ECB were attracted to smooth surfaces for oviposition and deposited most of their egg masses on the underside of the glass plates resting on the top of the cage. Glass plates were convenient for the application of the test compounds and the easy quantification of egg masses by digital analysis. A few egg masses were deposited on the smooth surface of the plastic feeder. These spurious masses represented less than 1% of the total number of egg masses produced and were disregarded. No egg masses were deposited on the central plate or on the perimeter border.

The egg masses typically appeared evenly distributed on the plates (Figure 1c). Females deposited few eggs on the night following eclosion, but thereafter

females produced two to three egg masses/night/female for approximately one week. After one week, the insects' fecundity markedly declined.

Females distinguished between plates coated with the sesquiterpenoid plant volatiles and plates coated with the solvent methylene chloride for two of three compounds tested. Use of sesquiterpenoids modified at the terminal position provided three structurally related analogs: farnesene with a congugated terminal unsaturation, nerolidol with an unconjugated terminal unsaturation and an adjacent tertiary hydroxyl, and farnesol with a terminal hydroxyl moiety. There was substantial evaporation and decomposition of the compounds during the exposure period of the test, but even after 48 hr some of each compound was still detectable by gas chromatography (Table 1). While females responded to each of the compounds differently, there was little mortality from exposure to the compounds on nights 3–4 (Figure 2).

Plates coated with farnesene were moderately preferred by ECB females. Females deposited significantly more egg masses on plates coated with 80 $\mu g/cm^2$ of farnesene (plates 1–4) during nights 3 and 4 following eclosion (Table 2). There was no bias due to the position of the coated plates because on night 2, when none of the plates were coated, there were equal numbers of egg masses deposited on plates 1–4 and on plates 5–8; these plates were maintained in the same position throughout the experiment whether or not they had been coated with volatile plant compounds. When the coated plates were removed from the system and uncoated plates tested again on nights 5 and 6, females could not distinguish among the plates and deposited as many egg masses on plates 1–4 as on plates 5–8 (Table 2).

Females showed no preference for plates coated with nerolidol. There was no significant increase or decrease in the number of egg masses deposited on plates 1–4 coated with 80 $\mu g/cm^2$ nerolidol (Table 3). No bias was detected due

TABLE 1. TOTAL RECOVERY OF FARNESENE, NEROLIDOL, AND FARNESOL FROM GLASS PLATES EXPOSED TO AIR FOR VARIED TIMES[a]

Exposure time (hr)	Amount recovered (μg)		
	Farnesene	Nerolidol	Farnesol
0	2.4	1452.3	2530.0
24	3.4	1.6	167.0
48	1.8	1.5	71.6

[a]Each plate was coated with 20.8 mg of a compound. Amount recovered was measured by GC-FID, limit 50.0 ng/μl farnesene, 3.0 ng/μl nerolidol, and 22.0 ng/μl farnesol. Incubation conditions were as described for oviposition tests in Methods and Materials.

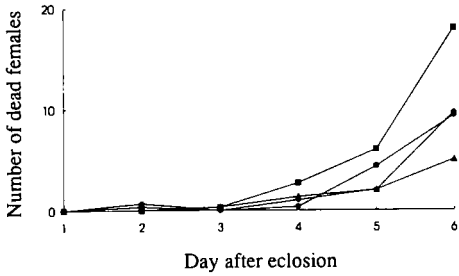

FIG. 2. Mortality of newly eclosed *O. nubilalis* females before, during, and after exposure to the plant volatiles farnesene (square), nerolidol (triangle), and farnesol (diamond) on nights 3 and 4. An untreated group (circle) is also shown. Because 100 pairs were used for each test, the values also represent percent mortality. Each value is the average of three replicates.

to the random positioning of the plates on nights 2, 5, and 6; there was no significant increase or decrease in the number of egg masses deposited on plates 1–4 (Table 3).

Farnesol deterred the females. Significantly fewer egg masses were deposited on plates 1–4 on nights 3 and 4 (Table 4). No difference in egg mass placement was detected from the random positioning of the plates on night 2,

TABLE 2. EFFECT OF FARNESENE ON OVIPOSITION OF EUROPEAN CORN BORER, *Ostrinia nubilalis*[a]

Night after eclosion	Glass treatment	Egg masses observed (mean ± SD)[b]		
		Plates 1–4	Plates 5–8	Total
2	No	137 ± 20 Farnesene	131 ± 36 Control	267 ± 54
3	Yes	211 ± 16	145 ± 23	356 ± 20
4	Yes	178 ± 24	115 ± 8	293 ± 28
5	No	108 ± 16	97 ± 14	205 ± 28
6	No	88 ± 30	72 ± 28	160 ± 57

[a] Oviposition was observed on nights 2–6. Plates were treated on nights 3 and 4 with farnesene (20.8 mg/plate) or solvent only (control).

[b] Few egg masses were observed on night 1 because of mating and premating behaviors, so they were not included. Oviposition was significantly higher on farnesene-treated plates (two-tailed t test, $\alpha = 0.05$, $N = 3$).

TABLE 3. EFFECT OF NEROLIDOL ON OVIPOSITION OF EUROPEAN CORN BORER, *Ostrinia nubilalis*[a]

Night	Glass treatment	Egg masses observed (mean ± SD)[b]		
		Plates 1–4	Plates 5–8	Total
2	No	180 ± 44 Nerolidol	187 ± 17 Control	367 ± 27

[a]Oviposition was observed on nights 2–6. Plates were treated on nights 3 and 4 with farnesol (20.8 mg/plate) or solvent only (control).

[b]Few egg masses were observed on night 1 because of mating and premating behaviors, so they were not included. Oviposition was significantly lower on farnesol-treated plates and on subsequent nights for plates in positions where farnesol had been present during nights 3 and 4 (two-tailed t test, $\alpha = 0.05$, $N = 3$).

DISCUSSION

Volatile emissions detected from corn leaves are composed of complex mixtures of aliphatic aldehydes, ketones, alcohols, and esters as well as terpenoids and other aromatic compounds (Buttery and Ling, 1984). These volatiles mark the aroma of the plant and are used as cues by the parasitic wasp *Cotesia marginiventris* to recognize appropriate host sites (Turlings et al., 1990). In this study, we found that farnesene, one of the chemicals in the blend that is attractive to *C. marginiventris*, enhanced ECB oviposition. Use of analogs of farnesene modified at the terminal functional group to make either farnesol or nerolidol affect ECB adults by reducing oviposition or having no influence, respectively. Thus, we could mediate oviposition positively or negatively simply by exposing the adults to closely related compounds with different terminal functional groups.

Farnesene is a common sesquiterpenoid plant natural product (Teranishi et al., 1993) and its release is induced at rates as high as 120 ng/hr following injury from the armyworm, *Spodoptera exigua* (Turlings and Tumlinson, 1992). Even though the high rate of release of farnesene is not sustained for more than 24 hr (Turlings and Tumlinson, 1992), we used it as a guide to determine the quantity of mixed isomers of farnesene to apply on the plates in our oviposition assay. Herbivore-damaged corn plants might release as much as 2.9 μg in a 24-hr period. Our tests, conducted with 80 $\mu g/cm^2$, represent a total exposure of 83 mg/cage/night or an approximately 29,000-fold higher amount over that expected from exposure to the corn plant. Since the isomers readily evaporate or decompose from the plate at a rate as high as 0.86 mg/hr and leave as little as 1.6 mg on each plate after 24 hr, we believe the females are exposed to similar amounts of the compounds on plates in the laboratory as they might experience from an injured plant. Therefore, their movements and activities during oviposition probably reflect the same responses to chemical stimuli as those expected on exposure to the injured plant itself.

Farnesene readily influenced ECB oviposition but females do not distinguish among plates once the chemical is removed. Farnesol, by contrast, has a residual effect because ECB females distinguished among the plates, even two days after exposure to the chemical. A simple explanation to account for this observation is that some of the compound dispersed on to the metal screen of the cage, was present during subsequent days during the test, and females were still able to perceive the deterring compound by olfaction or gustation or both. Residual amounts of the compound could have remained on the cage for several days because we found that farnesol evaporated or decomposed less readily than the other compounds during a 48-hr period.

Physiological effects from exposure to either farnesene or farnesol also can never be completely eliminated as a cause of the changes in ECB oviposition, but neither farnesene nor farnesol increased mortality and, even though females

were exposed to chemicals, they produced the expected total number of egg masses during the experiment. Because there were not overt symptoms of a physiological problem, we interpreted the results of our studies as behavioral modulation of ECB oviposition.

Farnesene, farnesol, and nerolidol are important molecules in insect communication and development. Stereoisomers of farnesene are alarm pheromones for numerous species of aphids (Bowers et al., 1972; Montgomery and Nault, 1977; Pickett and Griffiths, 1980), trail pheromones for ants (Attygalle and Morgan, 1984), and feeding stimulants for larvae and attractants for adults of the codling moth *Cydia pomonella* (Sutherland and Hutchins, 1973; Wearing and Hutchins, 1973). Farnesene and farnesol are feeding stimulants for the sand fly *Lutzomyia longipalpis* (Tesh et al., 1992). Farnesol and nerolidol possess high juvenilizing activity against the mealworm, *Tenebrio molitor*, while reduced farnesol, the analog without unsaturation, and farnesane lose all activity (Bowers and Thompson, 1963). Farnesol, a powerful juvenoid, acts as a gonadotropic hormone in some adult insects (Slama, 1985), but its role in the physiology of ECB adults during this study seems to be minimal.

Commercial samples of farnesene, farnesol, and nerolidol evaluated by GC-MS showed that they are composed of several isomers, and for farnesene, several impurities. Isomers and structural analogs of these compounds are known to stimulate different activities in insects. For instance, geometrical stereoisomers of 3,7,11-trimethyldodeca-2,6,10-triene, structurally related analogs of the natural aphid alarm pheromone, (*E*)-β-farnesene, show differential activity: (*E*)-2,6,10-trimethylundeca-1,5,9-triene is approximately 1000-fold more active than its stereoisomer (*Z*)-2,6,10-trimethylundeca-1,5,9-triene against the aphid *Acyrthosiphon pisum* (Harris), but both are less effective at triggering an alarm response than the natural pheromone (Nishino and Bowers, 1976; Nishino et al., 1976). Farnesene- and farnesol-related structural isomers of sesquiterpene ovipositional stimulants, (+)-(*E*)-*endo*-β-bergamoten-12-oic acid and (−)-(*E*)-*endo*-α-bergamoten-12-oic acid, which differ only in the position of a double bond, elicit contrasting responses from gravid females of *Helicoverpa zea* (Boddie): (+)-(*E*)-*endo*-β-bergamoten-12-oic acid is more attractive to females than (−)-(*E*)-*endo*-α-bergamoten-12-oic acid (Coates et al., 1988). These studies illustrate that differences in biological activities are evoked from stereochemical changes in molecular structure and we speculate that structural isomers and stereoisomers of farnesene, farnesol, nerolidol, and related compounds may similarily modulate ovipositional behaviors of ECB females.

Prominent differences in ovipositional behaviors of ECB females from exposure to farnesene and farnesol may arise because they vary the use of olfactory and gustatory sensory mechanisms to distinguish between plates coated with the sesquiterpenoid plant volatiles and plates coated only with solvent. A combination of olfaction and gustation are used during resource selection and

host location in many insects (Ahmad, 1983; Bell, 1991; Metcalf and Metcalf, 1992; Renwick and Chew, 1994), but further studies on ECB behaviors such as searching, orientation, and landing behavior are needed. Females also respond to volatile aromatics (Cantelo and Jacobson, 1979), and nonvolatile carbohydrates on the leaf surface of corn (Derridj et al., 1993). Studies of interactions of the ECB adults at the corn leaf surface will show if herbivore-induced release of these compounds will affect their orientation and ovipositional behaviors on a natural host and if they have potential to be employed to disrupt oviposition.

(Received July 11, 1994; accepted April 24, 1995)

Abstract—The hydrocarbons of honeybee comb wax vary significantly between colonies. This variation is explained in part by genetic (familial) differences among colonies. Even though significant differences in wax hydrocarbons exist among families, there is a high level of consistency within and among families in a correlation analysis, indicating structural constancy in comb wax. The significance of these results in interpreting the potential role of comb wax in the nestmate recognition system of the honeybee is discussed.

Key Words—Honeybee, comb wax, hydrocarbons.

INTRODUCTION

The comb wax of the honeybee serves as a source of recognition cues that are used in discriminating nestmates from nonnestmates (Breed et al., 1988ab, 1995; Breed and Stiller, 1992). Exposure to wax for periods as brief as 5 min radically alters the recognition phenotype of a bee (Breed et al., 1988b), superimposing the wax-derived cues on cues found on the cuticle of bees (Breed, 1983). The purpose of this paper is to present an analysis of the hydrocarbon component of comb wax and to test the hypothesis that comb wax could convey genetic information that might be used in nestmate recognition.

Comb wax is chemically complex (Hepburn, 1986; Tulloch, 1980), containing hydrocarbons, esters, free acids, and alcohols. It may also serve as a repository for compounds brought into the colony with foodstuffs. For example, Breed et al. (1988a) showed that anise extract, when placed in a waxy medium, could be used by honeybees as a recognition cue. Bowden and Breed (unpublished) have recently shown that a number of other compounds found in flowers, such as anethole, citral, and linalool, can function as recognition cues. Breed and Stiller (1992) showed that the alkanes hexadecane and octadecane can serve as recognition cues. Our focus in this paper on the hydrocarbons is justified by the biological activity shown by these alkanes; subsequent studies (Breed et al., 1995) will deal with other comb wax components.

In addition to the investigations of Tulloch (1980) and Hepburn (1986) on the chemistry of comb wax, Carlson (1988) compared the comb waxes of European and African honeybees, with the objective of developing a method of identifying Africanized bees. The finding of interracial variation in comb wax composition suggests genetic variation. Blomquist et al. (1980) investigated the synthetic pathways leading to bee's wax.

There is, however, considerable information available on honeybee cuticular hydrocarbons. Cuticular hydrocarbons have been implicated in nestmate recognition in a number of social insect species (reviews: Howard, 1993; Smith and Breed, 1995). Most relevant to our study is the work of Page et al. (1991), who showed that there is a genetic component of the variation among bees in cuticular hydrocarbon profiles. Other studies include those of Carlson and Bolton (1984) and Smith (1990), who compared African and European bees, and Francis et al. (1985, 1989), who characterized the cuticular hydrocarbons of European bees. Singer and Espelie (1992) implicated cuticular hydrocarbons in nestmate recognition in social wasps, and Clement et al. (1987) made a similar argument for an ant. Cuticular hydrocarbons also have been hypothesized as signals in species or sex identification in nonsocial insects (Howard, 1993; Markow and Toolson, 1990).

We obtained comb wax from 40 colonies representing nine families. We analyzed the results by chromatographic analyses of the wax to determine the extent of variation within and among families and to assess whether adequate variation exists for wax hydrocarbons to function as recognition cues. We then placed our findings in the context of other studies of recognition cue chemistry.

METHODS AND MATERIALS

Comb Production. Combs produced by sets of sister colonies were collected from the University of California, Davis, apiaries. Colonies for comb production were derived from 18 colonies headed by naturally mated parental queens. Nine

queens were designated queen mothers (Q1–Q9), and nine other queens were designated drone mothers (D10–D18). Virgin queens and drones were raised, and virgin queens from each queen mother were mated to a single, different drone from each colony, using the following scheme: Q1 × D10, Q2 × D11, Q3 × D12, etc. This resulted in families designated 1–9.

Parental queens were naturally mated. We assumed that sister queens were half-sisters, rather than supersisters, because queens mate naturally with an average of about 17 drones (Adams et al., 1977). We also assumed that all queen and drone mothers were unrelated. With these assumptions, workers within colonies had pedigree coefficients of relatedness (Pamilo and Crozier, 1982) of $G = 0.75$. Workers between colonies with sister queens (same family) were related to $G = 0.31$, and workers of different families were unrelated. The mean number of colonies sampled per family was 4.4 (SE = 0.58) and the range was 2–7.

To collect comb samples, instrumentally inseminated queens were installed in single-story Langstroth hives in a single apiary containing nine standard frames and about 8000 workers. Colonies were allowed to develop for at least 60 days, during which time the original workers died and were replaced by worker progeny of the queens. After this time a single comb constructed on an empty frame without foundation was removed from the boxes and colonies were stimulated to construct a new comb. Empty, newly constructed combs were collected and frozen for analysis. Comb from a single colony is considered, in this paper, to be a sample. Each colony is represented by a single sample in our dataset.

Extraction Procedures for Comb Wax. Comb wax (50.0 mg) was added to a clean 4-ml glass vial with a Teflon liner on the lid, 2.0 ml of dichloromethane was added, and the sample was mixed thoroughly and allowed to sit over night. The sample was then mixed thoroughly again and 80 μl added to 0.5 ml dichloromethane. To remove undissolved materials and other high-molecular-weight material, the contents of the second vial were passed through a silica gel column. The column was made from a 14.6-cm disposable Pasteur pipet containing a glass wool plug to which a slurry of dichloromethane and silica gel was added to within 5 cm of the top. Dichloromethane was added to the column until a total of 4 ml of eluate was collected. An internal standard (20 μg *n*-octadecane) was added to the 4-ml solution. After this procedure, the solution contained 1 μg/μl of total wax (based on the amount of wax at start) and an internal standard (*n*-octadecane) at a concentration of 5 ng/μl. In preliminary results, chromatograms from wax solutions that had gone through silica gel were identical to those that had not, indicating that volatile materials were not left on the silica gel.

Gas Chromatography. Chemical separations were made with an RSL-150 methyl silicone capillary column (25 m × 0.25 mm ID, 0.25 μm film) in a

Hewlett-Packard 5890 gas chromatograph with splitless injector and flame ionization detector. The injector temperature was set at 250°C and the detector temperature at 290°C. The inlet purge of the splitless injector was turned on at 0.75 min. The initial oven temperature was set at 150°C for 1 min, then programmed at 10°C/min to a final temperature of 280°C. These conditions resulted in good separation of volatile wax components within a time frame of 25 min. Larger compounds (alkanes > C_{29}) may not have been detected in the same proportion as lower-molecular-weight compounds; this factor does not affect the analysis as each peak is used as an independent variable.

Statistical Analyses. All analyses were performed using the Statview II statistical package. After using the octadecane standard to standardize the data, separate analyses of variance (ANOVA) were performed between families for each compound. To determine levels of association between colonies, parametric correlation analyses were performed using the 25 peaks as independent measures for each colony; this procedure yielded a matrix of between-colony correlation coefficients. For example, each colony in family 1 was represented by a correlation coefficient with each other colony in family 1, as well as by correlation coefficients with each colony in the other families. An ANOVA was then used to test whether the between-colony correlation coefficients were higher within families than among families. Correlation coefficients were also calculated between peaks; in this analysis the correlations between peak 1 and peak 2, peak 1 and peak 3, and so on, were calculated.

RESULTS

Peak Separation. Twenty-five peaks were resolved, in addition to the internal standard (Table 1). Mean concentrations, in nanograms per microgram of wax, varied from 0.3 to 27.9. The standard errors are not large with respect to the mean. The small standard errors indicate a relatively high level of homogeneity among the samples. The major *n*-alkenes were identified and are indicated in Table 1.

ANOVAs of Wax Concentration Variation among Families. Each of the 25 compounds resolved was subjected to an analysis of variance to determine whether significant differences in concentration existed among families (Table 1). Of the 25 ANOVAs, seven, representing compounds 6, 8, 9, 12, 20, 23, and 26, were significant. Compounds 1, 5, 6, 14, 18, and 24 were present either in very low concentrations or were not detected in many samples. Six other ANOVAs yielded probabilities between 0.05 and 0.10 (compounds 3, 4, 10, 11, 13, and 25), suggesting that further significant variation may have been resolved with larger sample sizes. There is no obvious relationship between the magnitude of the mean peak for a given compound (Table 1) and the significance

TABLE 1. SELECTED PEAK IDENTIFICATIONS, MEAN CONCENTRATION, AND ANOVA AMONG FAMILIES FOR 25 PEAKS ANALYZED[a]

Peak	Peak Identification	Concentration (ng/μg wax) Mean	SE	F	P

[a] N = 40 samples for each peak. F values are calculated based on 8 degrees of freedom in the denominator and 31 in the numerator, and a total sample size of 40 colonies. Probabilities <0.05 are indicated with an asterisk.

of the ANOVA. The number of significant ANOVAs indicates substantial differentiation among samples and supports the hypothesis of genetic differentiation in wax among families.

Correlation Analyses. Two types of correlation analyses were performed. The first is between compounds, i.e., does the variation in concentration of one compound have value in predicting the variation in other compounds or are the concentrations of the different compounds unrelated? Second, correlations were

calculated between colonies to determine if the familial similarity shown in the ANOVAs was reflected in higher correlations among colonies within families than among colonies between families. These correlations tested the level of association among colonies and are analyzed to determine if intrafamilial association is higher than interfamilial association.

Correlations among Compound Concentrations. Is the variation in any one compound associated with the variation in any other compound? The result of this analysis is a 25 × 25 half matrix. Ninety-seven of the 600 (ignoring autocorrelations) correlation coefficients were significant. The first four peaks had only five significant correlations, while the remaining peaks were more highly intercorrelated.

Important to the interpretation of correlations is a consideration of the percentage of variation explained by the correlations (r^2); the critical value for significance of the correlation coefficients in this analysis was 0.40, which explained only 15.7% of the variation. Relatively highly correlated (more than 50% of the variation explained) compounds are listed in Table 2. Compounds

TABLE 2. RELATIVELY HIGHLY CORRELATED ($r^2 > 50\%$) COMPOUND PAIRS[a]

Compound	Compound	% variation explained ($r^2 \times 100$)
9	6	57.5
9	7	70.1
10	7	60.5

25	17	56.7
25	22	51.4
26	23	61.3

[a]Pairs are presented with the compound having the higher retention time first.

with close retention times are highly associated in the data set (Spearman rank correlation between the retention times in Table 2, $r = 0.93$, $P < 0.0001$).

Intercolonial Correlations. Are related colonies similar in their wax hydrocarbon profiles? The second correlation analysis, between colonies, yielded much higher correlation coefficients. All but five of the correlations in this 40 × 40 half matrix were 0.90 or higher; coefficients this high explained 81% or more of the variation in the relationship. The five lower coefficients (between 0.80 and 0.89) involved the same colony and may indicate a pathology in that colony or a problem in the handling of that particular sample. An ANOVA between the within and between correlations showed no significant difference between the within-family correlations (mean = 0.974 ± 0.003, $N = 80$) and among-family correlations (mean = 0.973 ± 0.0009) ($F = 0.297$, $P = 0.58$, $N = 800$). This level of homogeneity precluded further analysis.

DISCUSSION

Intercolony variation in wax hydrocarbons appears to be adequate for these compounds to function as nestmate recognition cues. However, the statistical significance among family groups for any given compound is a little difficult to interpret in terms of functional significance in the recognition system. How large a concentration difference is necessary for perceptual differences to exist? Which of these compounds are actually used by bees in the recognitive context? And how do the bees make efficient use of the many possible recognition cues that are present in wax? Much additional work will be needed to elucidate the role of these compounds in nestmate recognition (Getz and Page, 1991).

Page et al. (1991) performed a similar analysis of surface hydrocarbons on bees that had not been exposed to comb as adults. They analyzed the 20 largest gas chromatographic peaks obtained from hexane extracts run through a methylsilicone column. These 20 peaks included 11 alkanes (C_{23} to C_{33}) and nine unidentified compounds—"probably . . . unsaturated and methylated derivative compounds" (Page et al., 1991). Smith (1990) identified cuticular hydrocarbons from European and African honeybees; he found that the smaller peaks associated with the alkanes were primarily alkenes, with the exception of two prominent C_{33} alkadienes. Based on his analysis and our mass spectrometry, the peaks immediately preceding each alkane are probably the corresponding alkenes, although we did not determine the location of the double bonds in these compounds. These identifications have some importance, as three of the seven significant differences among families involve these compounds. We have also analyzed polar compounds in the wax (Hibbard et al., unpublished); long-chain free fatty acids are a significant wax component (Blomquist et al., 1980).

Page et al. (1991) found that a significant proportion of the variation among bees in surface hydrocarbons was attributable to genetic factors. This led to the

conclusion that adequate information was available from surface hydrocarbons for kin recognition to take place. Page et al. (1991) analyzed correlation coefficients between colonies for cuticular hydrocarbons, as we have done here for wax hydrocarbons. Similar to our results, they found high correlation coefficients both within and between genetic groups (0.90 and higher). This high level of uniformity among samples for cuticular hydrocarbons and wax hydrocarbons may be due either to genetic canalization of the biosynthetic pathways or to the function that these compounds have in the biology of the honeybee. On the surface of an insect, large deviations from the norm might result in failure of cuticular waterproofing (Hadley, 1989); the physical properties of the comb may also be sensitive to major changes in composition.

In addition to similarity among individuals driven by waterproofing or structural functions of the hydrocarbons, similarity may also be affected by their use as signals. Under certain circumstances selection can favor loss of diversity in kin recognition cues and a consequent loss of signal information (Ratnieks, 1991). Conversely, random genetic variation could yield usable signals in the absence of selection for a signal function. Bees are capable of using a wide variety of compounds as recognition cues—alkanes, acids, esters, terpenoids—and they seem to exploit whatever cues are available.

Unlike the present findings, Page et al. (1991) found correlation coefficients for cuticular hydrocarbons were significantly higher within bee families than between families. Our correlation analysis indicates that sets of chemically similar compounds (e.g., an alkane and the alkenes of the same chain length) often have highly correlated concentrations in wax. This suggests that if these compounds are used as recognition cues, the information conveyed is redundant within these groupings. This is particularly true of the group of compounds from C_{29} to C_{33}.

The inability of the correlation analysis to yield predictive factors concerning familial relationship is interesting. However, it should be noted that nestmate recognition depends on intercolonial differences and optimally would function equally well, whether colonies are related or not.

Behavioral experiments (Breed et al., 1988a, 1995; Breed and Stiller, 1992) have clearly shown that whatever cues are present in the cuticular hydrocarbons are overridden by cues acquired from the comb in the nestmate recognition context. There is some evidence that the cuticular hydrocarbon recognition cues persist and are used in other behavioral contexts (e.g., Oldroyd et al., 1991). Given the close correspondence between comb wax and cuticular hydrocarbons, the issue is raised as to the salient differences (see Page et al., 1991, for a listing of the cuticular compounds). Breed et al. (1995) have shown that certain compounds, such as the C_{27} alkane, the C_{29} alkane, and tetradecanoic acid, are relatively easily transferred from comb to the bees, while others, such as the

C_{31} alkane, do not transfer in statistically significant amounts. This suggests compounds that might be tested for activity in recognition bioassays.

The chemistry of honeybee nestmate recognition is quite complicated, with a plethora of candidate compounds from diverse sources present in the bee's environment. The results of this paper support the suggestion that comb wax is a possible source of compounds for use as recognition cues and points to compounds that differ enough in concentration among colonies to make them worthwhile targets of further testing.

Acknowledgments—This research was supported by grants from the National Science Foundation to M.D.B. (IBN 9209016), R.E.P. (IBN 9213463), and L.B.B. (IBN 9210463). Supported in part by the Colorado Agricultural Experiment Station (L.B.B.) and in part by the California Department of Food and Agriculture (R.E.P.). We thank Kim Fondrk for performing the instrumental inseminations and Dave Nelson for collecting the comb samples.

(Received January 24, 1995; accepted April 24, 1995)

Abstract—The metabolism of platyphylloside [(5*S*)-5-hydroxy-1,7-bis-(4-hydroxyphenyl)-3-heptanone-5-O-β-D-glucopyranoside]—known to reduce digestibility—was studied *in vitro* in sheep rumen liquor. Platyphylloside is hydrolyzed to 5-hydroxy-3-platyphyllone [(5*S*)-5-hydroxy-1,7-bis-(4-hydroxyphenyl)-3-heptanone], which is reduced to centrolobol [1,7-bis-(4-hydroxyphenyl)-3-heptanol], via 3-platyphyllone [7-bis-(4-hydroxyphenyl)-3-heptanone]. The digestibility-reducing effect was shown to be correlated with the concentration of centrolobol.

Key Words—Phenols, platyphylloside, 5-hydroxy-3-platyphyllone, 3-platyphyllone, centrolobol, metabolites, digestibility, rumen liquor, birch.

INTRODUCTION

Birch—like other plants—produces a large number of secondary metabolites, some of which can be regarded as part of a chemical defense against foraging animals. Defense compounds can have pheromonal properties, and they can be toxic, unpalatable, or digestibility reducing (Harborne, 1988, and references cited therein). Hares fed solely on birch twigs lose weight and have a negative sodium balance (Pehrson, 1983). Caged rabbits fed on fine birch twigs or a commercial diet sprayed with a phenolic birch extract showed increased sodium losses in the urine, and the *in vitro* digestibility of hay in rumen liquor from birch-fed goats was severely reduced as compared to hay-fed controls (Palo,

*To whom correspondence should be addressed.

1987). In a previous study (Sunnerheim-Sjöberg *et al.*, 1988), it was shown that the phenol platyphylloside [(5*S*)-5-hydroxy-1,7-bis-(4-hydroxyphenyl)-3-heptanone-5-O-β-D-glucopyranoside] isolated from birch twigs (*Betula pendula* Roth.) could explain about 80% of the observed depression of *in vitro* organic matter digestibility (IVOMD). Platyphylloside also reduces palatability and digestibility *in vivo* (Palo, personal communication).

Preliminary studies have shown that platyphylloside (I) is hydrolyzed to 5-hydroxy-3-platyphyllone (II) in rumen liquor and that platyphyllane [1,7-bis-(4-hydroxyphenyl)-heptane] is excreted with feces from moose and goat fed on birch (Palo, 1987; Palo *et al.*, 1989; Sunnerheim-Sjöberg, 1991). Platyphyllane was also detected after enzymatic hydrolysis of urine from rabbits and hares fed on birch (Palo, 1987). It was not shown, however, how II is further metabolized or if platyphyllane actually is a metabolite from I, and if so, whether it is formed in the rumen or later in the digestive system.

Platyphylloside (I) and 5-hydroxy-3-platyphyllone (II) were first isolated from *Betula platyphylla* by Terasawa et al. (1973). They named II platyphyllonol. Sasaya and Izumiyama (1974) and Nomura et al. (1981) isolated II from *Alnus hirsuta* Turcz. and *Alnus japonica*, respectively, and called it hannokinin.

The aims of the present study were to: (1) study the metabolism and identify the metabolites of platyphylloside *in vitro* in rumen liquor, and (2) identify the compound/compounds—platyphylloside or any of its metabolites—correlated to IVOMD inhibition in rumen liquor.

METHODS AND MATERIALS

Digestibility Experiment

IVOMD was determined according to the method originally described by den Braaver and Eriksson (1967) and modified by Palo (1985). Rumen liquor was sampled from a canulated sheep fed on hay (800 g/day plus mineral supplement).

Sample Preparation. Three types of samples were prepared: (1) with hay and with I: to each of 18 tubes containing 500 mg milled hay, 2.0 ml of a solution of I in 96% aqueous ethanol (12.00 g/liter) was added; (2) with hay but without I (control samples): to each of 18 tubes containing 500 mg milled hay, 2.0 ml of 96% aqueous ethanol was added; (3) without hay but with I: to each of 5 tubes, 2.0 ml of a solution of I in 96% aqueous ethanol (12.00 g/liter) was added.

The solvent was allowed to evaporate at 40°C for 12 hr. To each of the 41 tubes, 50 ml buffer (pH 6.8 ± 0.1) (den Braaver and Eriksson, 1967) and 1.0 ml rumen liquor were added. Tubes were incubated at 37°C.

After incubation (6, 12, 24, 48, 72, 96 hr), hay residues were removed

from the liquid by suction filtration. The hay residue was washed twice with 25 ml acetone. The combined solutions were evaporated to dryness, and resuspended in 10.0 ml 48% aqueous ethanol and stored at −20°C for one to four days, filtered through cotton, and analyzed with high-performance liquid chromatography (HPLC).

Chromatography

Thin-layer chromatography (TLC) was performed on Merck HF-254 silica gel plates. Column chromatography was performed on silica gel (Riedel-de-Haën, 0.032–0.063 mm). The following eluents were used for TLC: (I) chloroform–methanol–water, 240 : 15 : 1; (II) toluene–acetonitrile, 2 : 1; (III) ligroin–ethyl acetate–acetic acid, 4 : 2 : 1. The TLC-plates were inspected under UV light at 254 nm. Spray reagents used were: (i) 4-diazobenzene-sulfonic acid (Fluka AG, CH 9470) dissolved in 10% aq. sodium carbonate, followed by 50% sulfuric acid (v/v) (for phenols) and (ii) dinitrophenylhydrazine reagent (for carbonyl groups).

HPLC was performed on a Merck-Hitachi chromatograph equipped with a UV detector. Detection was made at 280 nm. The column was a LichroCart 125-4 Lichrospher 100 RP-18 (5 μm) (Merck). The mobile phase consisted of solvent A: phosphate buffer (0.01 M, pH 2.8) and solvent B: acetonitrile. The gradient program was 1–3 min: 5% B, 3–50 min: linear gradient from 5 to 50% B. The flow rate was 1.5 ml/min; 10 μl/sample was injected. Peak retention times and areas were monitored and integrated automatically.

Spectroscopy

^{1}H and ^{13}C NMR spectra were recorded at 300 MHz on a Varian XL-300 and/or at 400 MHz on a Varian VXR-400 spectrometer. Chemical shifts (δ) are given relative to solvent peak as internal reference. Mass spectra were recorded at 70 eV with a Finnigan 4000 spectrometer using a direct insertion probe. Optical rotation was recorded at 22°C with a Perkin-Elmer 241 polarimeter.

Statistical Methods

For multivariate analysis, partial least square regression (PLSR), Unscrambler 4.0, CAMO AA/S, Norway, was used.

Isolated Substances

Platyphylloside (I), [(5S)-5-hydroxy-1,7-bis-(4-hydroxyphenol)-3-heptanone-5-O-β-D-glucopyranoside]. This was isolated from the inner bark of *Betula pendula* according to Smite et al. (1993) and was identical with previously isolated platyphylloside (Sunnerheim-Sjöberg et al., 1988). ^{1}H NMR:

(CD_3OD)δ: 1.75(m, 1H, 6-H), 1.83 (m, 1H, 6-H), 2.59 (m, 3H) and 2.75–2.84 (m, 5H), (1, 2, 4, and 7-H), 4.17 (m, 1H, 5-H), 6.67 (two d, 4H, J = 8.5 Hz, Ar-H), 6.99 (d, 2H, J = 8.5 Hz, Ar-H), 7.01 (d, 2H, J = 8.6 Hz, Ar-H), glucose moiety: 3.14 (1H, 2-H), 3.25 (1H), 3.70 (dd, 1H, J = 12 and 5 Hz), 3.86 (dd, 1H, J = 12 and 2 Hz), 4.29 (d, 1H, J = 8 Hz, H-1'), one H hidden under the solvent peak. ^{13}C NMR: (CD_3OD) δ: 29.8, 31.4, 38.5, 46.4, 62.7, 71.6, 75.2, 76.2, 77.8, 78.0, 103.5, 116.0, 116.2, 130.3, 130.4, 133.2, 134.3, 156.3, 156.6, 211.9.

5-Hydroxy-3-platyphyllone (II), [(5S)-5-Hydroxy-1,7-bis-(4-hydroxyphenyl)-3-heptanone]. This was obtained from enzymatic hydrolysis of platyphylloside and was identical with that previously isolated (Sunnerheim-Sjöberg et al., 1988). TLC; eluent I: R_f = 0.30, eluent II: 0.38; eluent III color with reagent (i): a red center with blue–green contour. Color with reagent (ii): yellow. ^1H NMR (CD_3OD) δ: 1.65 (m, 2H, 6-H), 2.48–2.66 (m, 4H, 4-H and 7-H), 2.73 (m, 4H, 1-H and 2-H), 4.00 (m, 1H, 5-H), 6.67 (d, 2H, J = 8.5 Hz, 3'-, 5'-H), 6.68 (d, 2H, J = 8.4 Hz, 3"-, 5"-H), 6.98 (d, 4H, J = 8.4 Hz, 2'-, 6'-, 2"-, 6"-, 2"-H, and 6"-H). ^{13}C NMR (CD_3OD) δ: 29.8 (I-C), 31.9 (7-C), 40.5 (6-C), 46.4 (2-C), 51.3 (4-C), 68.3 (5-C), 116.1 and 116.2, (3'-, 5'-, 3"-, and 5"-C), 130.2, 130.3 and 130.4 (2'-, 6'-, 2"-, and 6"-C), 133.3 (1'-C), 134.1 (1"-C), 156.4 (4'-C), 156.6 (4"-C), 211.9 (3-C).

3-Platyphyllone [1,7-Bis-(4-hydroxyphenyl)-3-heptanone] (III) and Centrolobol [1,7-bis-(4-hydroxy-phenyl)-3-heptanol] (IV). These were isolated from rumen liquor samples that had been incubated for 48 hr. The rumen liquor was concentrated by evaporation below 40°C, and the two compounds were obtained by flash chromatography on silica gel; two columns: length = 18 cm, ID = 5 cm, eluent I, followed by one column; length = 29 cm, ID = 1.5 cm, eluent II. The progress of the separation was followed by TLC with eluents I and II.

Compound III was further purified by flash chromatography on silica gel; length = 29 cm, ID = 1.5 cm, eluent II. Ten milligrams with small amounts of impurities was obtained. TLC: Eluent I R_f = 0.57, eluent II R_f = 0.68. Color with reagent (i): a red center with blue–green contour. Color with reagent (ii): yellow. ^1H NMR ($CDCl_3$) δ: 1.55 (m, 4H, 5- and 6-H), 2.38 (t, 2H, J = 6.8 Hz), 2.51 (t, 2H, J = 6.9–7.3 Hz), 2.67 (t, 2H, J = 7.5 Hz) and 2.81 (t, 2H, J = 7.3–5 Hz) (1-, 2-, 4-, and 7-H), 6.73 and 6.74 (each: d, 2H, J = 8.4 Hz, Ar-m-H), 6.99 and 7.03 (each: d, 2H, J = 8.4 Hz, Ar-o-H). ^1H NMR (CD_3OD) δ: 1.49 (m, 4H, 5- and 6-H), 2.39 (t, 2H), 2.46 (t, 2H), 2.66 (m, 2H) and 2.73 (m, 2H) (1-, 2-, 4-, and 7-H), 6.67 (two d, 4H, Ar-m-H), 6.94 and 6.97 (each: d, 4H, Ar-o-H). MS data were in accordance with those published by Nagai et al. (1990).

Compound IV was further purified by flash chromatography on silica gel; column 1: length = 28 cm, ID = 1.5 cm, eluent II, column 2: length = 26 cm, ID = 1.5 cm, eluent I. TLC: eluent I R_f = 0.26, eluent II R_f = 0.56. By

this means, 12 mg of IV containing small amounts of impurities was obtained. Color with reagent (i): blue–green contour with an orange center. No reaction with reagent (ii). ^{1}H NMR (CD_3OD) δ: 1.33 (m, 1H, 5-H), 1.45 (m, 3H, m, 4-, 5-H), 1.55 (m, 2H, 6-H), 1.64 (m, 2H, 2-H), 2.49 (m, 3H, 1-, 7-H), 2.64 (m, 1H, 1-H), 3.50 (m, 1H, 3-H), 6.67 (d, 2H, J = 8.80 Hz, Ar-m-H), 6.68 (d, 2H, J = 8.40 Hz, Ar-m-H), 6.96 (d, 2H, J = 8.40 Hz, Ar-o-H), 6.98 (d, 2H, J = 8.80 Hz, Ar-o-H). MS data were in accordance with those published by Craveiro et al. (1970). The isolated centrolobol had no optical activity when dissolved in methanol.

RESULTS AND DISCUSSION

Metabolism of Platyphylloside

Samples with Hay. When exposed to rumen liquor and hay *in vitro*, platyphylloside could not be detected after the initial 6 hr. The concentration of the hydrolysis product, 5-hydroxy-3-platyphyllone, was at its maximum after 12 hr of incubation. 3-Platyphyllone started to form between 6 and 12 hr and reached a maximum after 24 hr. Centrolobol emerged between 12 and 24 hr and increased throughout the experiment. Centrolobol is the final degradation product *in vitro* (Figure 1).

The analysis of the time dependency of the concentrations of the four compounds involved suggests the following main metabolic pathway of platyphylloside *in vitro* in rumen liquor: Platyphylloside → 5-hydroxy-3-platyphyllone → 3-platyphyllone → centrolobol (Figure 2.)

3-Platyphyllone (III) and centrolobol (IV) have previously been isolated from plant material as glycosides. Nagai et al. (1986, 1990) isolated two glycosides of III and one glycoside of IV from *Acer* and obtained the aglycone III by acid hydrolysis. They named III "acerogenin G." Craveiro et al. (1970) found the two enantiomers of the aglycone IV from two *Centrolobium* species. Smite et al. (1993) isolated a trisaccharide of IV from *Betula pendula*. The indicated configurations are solely based upon comparison of optical rotation

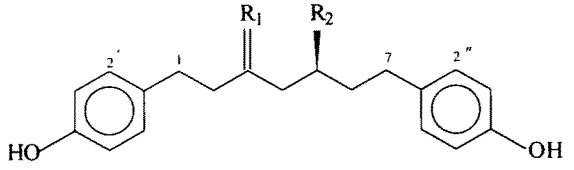

FIG. 1. The structure of compounds I, II, III, and IV. I: R_1 = O, R_2 = O-β-D-glucopyranoside; II: R_1 = O, R_2 = OH; III: R_1 = O, R_2 = H; IV: R_1 = H, OH, R_2 = H

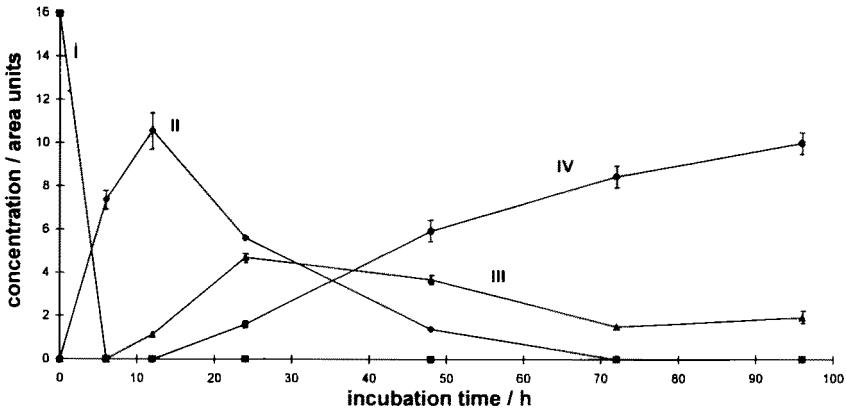

FIG. 2. Changes in relative concentrations with incubation time. I incubated with rumen liquor plus hay. I = platyphylloside, II = 5-hydroxy-3-platyphyllone, III = 3-platyphyllone, IV = centrolobol. Mean (±SD) of three replicates. (Some of the standard deviations are so small that they are not observable on this scale). *Note:* Response factors are not identical for the different compounds.

and ^{13}C NMR data with results of Ohta et al. (1985). Assignment of the absolute configuration of I was based on the application of the glycosidation shift rule of Seo et al. (1978). There has been some debate about the absolute configuration of IV (Nagai et al., 1986).

Samples without Hay. The hydrolysis of I in the samples without hay was as rapid as in the samples with substrate, but the subsequent reactions were slower. After 72 hr, considerable amounts of II remained, three times higher than the concentration of III. No IV was formed without substrate. Probably the microflora became exhausted with time due to lack of the hay substrate, and the reactions were thus slowed down.

Unidentified Metabolite. There was another unidentified metabolite, both in the samples with and without hay. The compound had a relatively high UV absorbance, but ^{1}H NMR showed that the concentration was very low. It reached a maximum after 6 hr and was not detectable after 24 hr. During that time, digestibility was not affected (see below). For this reason one can assume that this unidentified compound is not the active one.

Platyphyllane. Platyphyllane, 1,7-bis-(4-hydroxyphenyl)-heptane, found in feces from moose and goat fed on birch (Palo 1987; Palo et al., 1989) could not be detected in any of the samples in this *in vitro* experiment, which might indicate that a reduction of centrolobol to platyphyllane takes place after passage through the rumen.

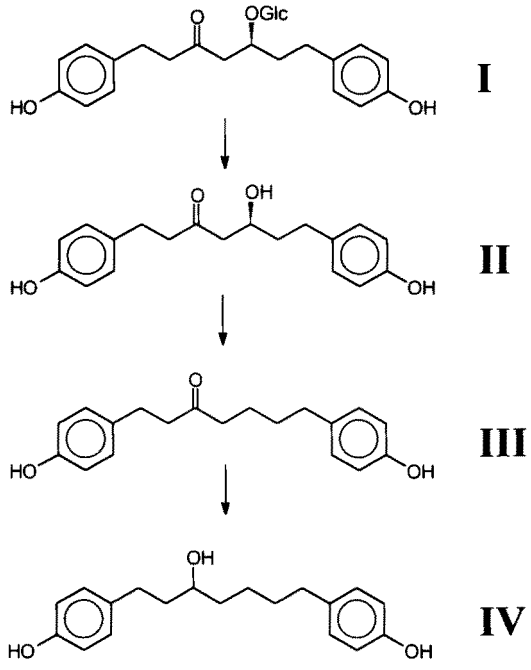

FIG. 3. Metabolism of platyphylloside *in vitro* in rumen liquor.

Digestibility Inhibition

IVOMD. During the initial 12 hr, no digestion difference between samples and controls was observed; in both, 67% of the organic matter was left. From 12 to 72 hr, however, there was a notable difference; in the control tubes organic matter decreased to 30%, while in the samples with platyphylloside 58% of the organic matter was left (Figure 3). The average digestion rate was 0.13%/hr in the platyphylloside-containing samples compared to 0.62%/hr in the control tubes. At the end of the experiment, the enzymatic activity might have decreased, leading to some uncertainty in the IVOMD values at 96 hr.

During the first 12 hr, when no digestibility difference between samples and controls was observed, no centrolobol could be detected. As centrolobol emerged, the rate of digestion decreased. As centrolobol concentration increased, the effect on digestion was more pronounced (Figures 1 and 3). The concentration of centrolobol was well correlated with digestibility reduction (Figure 4), measured as the IVOMD difference between samples and controls. It seems reasonable to conclude, but has yet to be proved, that centrolobol is the com-

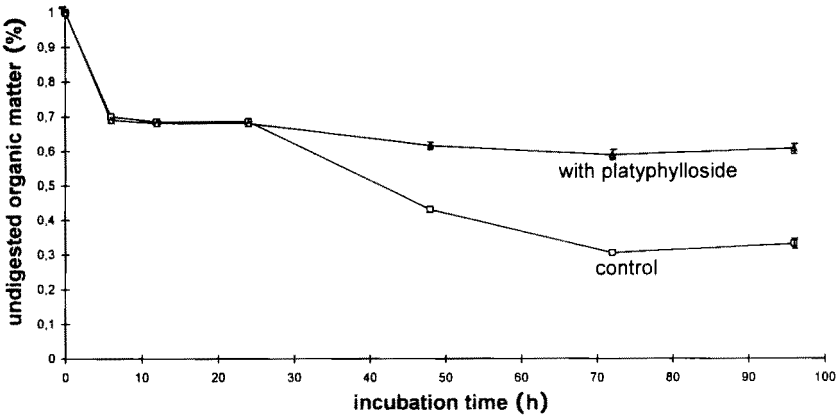

FIG. 4. Change in in vitro organic matter digestibility with incubation time. Mean (±SD) of three replicates. (Some of the standard deviations are so small that they are not observable on this scale).

pound responsible for the decreased digestibility. The slight deviation from a linear relation might be explained by the decreased activity of the microflora with time.

Multivariate Analysis. A partial least squares regression (PLSR) model confirms the correlation between centrolobol and digestibility reduction. Con-

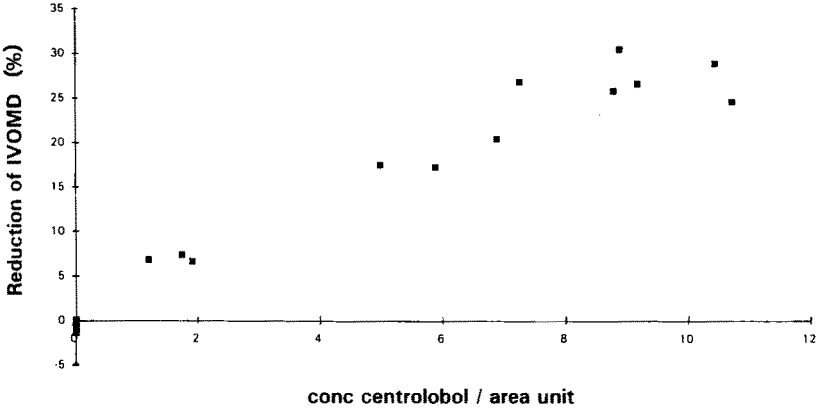

FIG. 5. Relation between concentration of centrolobol and reduction of IVOMD (differences between digestibility with and without platyphylloside).

centration of centrolobol had the highest positive loading, i.e., showed a strong correlation with IVOMD reduction, while 3-platyphyllone had a weak correlation and the other two compounds had small negative loadings, i.e., were weakly negatively correlated to IVOMD reduction. PLSR shows relations between the dependent variable (here IVOMD reduction) and all independent variables (here concentrations of all metabolites) simultaneously. [For a short presentation of multivariate analysis, see Sunnerheim-Sjöberg and Hämäläinen (1992) and references cited therein.]

Stereochemistry. Centrolobol isolated from the rumen liquor samples showed no measurable optical rotation, which was unexpected since most digestion reactions are enzymatic reactions. However, the sample was not absolutely pure, and the impurities might accidentally have the opposite optical rotation of the same magnitude. Further studies are in progress.

CONCLUSIONS

Platyphylloside is rapidly hydrolyzed to 5-hydroxy-3-platyphyllone *in vitro* in sheep rumen liquor, followed by reduction to 3-platyphyllone and finally to centrolobol. The reduction of digestion *in vitro* is correlated with the concentration of centrolobol in sheep rumen liquor.

Acknowledgments—This investigation was supported by a grant from The Swedish Research Council of Forestry and Agriculture, which is gratefully acknowledged. We thank Mrs. E. Fuchs for skillful technical assistance and Dr. E. Smite and Dr. L. Lundgren for providing a sample of platyphylloside-containing extract.

RESPONSES OF BEAVER (*Castor canadensis* KUHL) TO PREDATOR CHEMICALS

AXEL ENGELHART[1] and D. MÜLLER-SCHWARZE*

SUNY College of Environmental Science and Forestry
Syracuse, New York 13210

(Received January 6, 1995; accepted April 25, 1995)

Abstract—Free-ranging beaver (*Castor canadensis*) in two different beaver populations in New York State were exposed to predator chemicals to test feeding inhibition. Solvent extracts of feces were applied to stem sections of aspen, the preferred food tree of beavers, permitting smelling and tasting the samples. Predator odors were from wolf (*Canis lupus*), coyote (*Canis latrans*), dog (*Canis familiaris*), black bear (*Ursus americanus*), river otter (*Lutra canadensis*), lynx (*Lynx canadensis*), and African lion (*Panthera leo*). The experiment was repeated. The predator odors reduced feeding compared to untreated or solvent-treated controls. One population consumed 17.0% of the samples with predator odor and 27.0% of the controls in summer, and 48.4% and 60.0%, respectively, in autumn. The other population accepted 3.15% of the predator odor samples and 11.05% of the controls in summer. Coyote, lynx, and river otter odors had the strongest effects. Diesel oil and bitter-tasting neem extract had weaker effects. Predator odors are promising as feeding repellents for beaver.

Key Words—Adirondacks, Allegany State Park, allopatric, aspen, beaver, *Castor canadensis*, feeding inhibition, *Populus tremuloides*, predator odor, repellent, sympatric.

INTRODUCTION

Populations of the North American beaver (*Castor canadensis* Kuhl, 1820) are currently increasing because low pelt prices discourage fur trapping. The growing beaver populations cause considerable wildlife damage by flooding roads, forests, and fields and by cutting down valuable trees. This intensifies the need for effective beaver management. Among other means, environmentally com-

patible biological repellents are needed to keep beavers from sensitive areas or single trees. An obvious candidate for a natural repellent would be a potent predator odor (Müller-Schwarze, 1990).

Predator "sign," i.e., droppings, urine, scent marks, scrapes on the ground, scratches on objects, or rubbing sites, inform potential prey species about the presence, recent activity, and possibly diet of predators in an area. While avoiding predators, the prey species still has to operate in the same area. The use of predator odors as repellents is predicated on the assumptions that: (1) the prey species is merely alerted by the odor and avoids the particular spot or area in expectation of encountering a predator, and/or (2) the predator odor itself is aversive. In an application, the first case requires occasional reinforcement by an actual encounter with a predator. The second situation suggests a more lasting repellent effect, which also could be more general, across predator species. Sulfur-containing compounds, metabolites derived from protein, have been postulated to be the aversive agent common to many predator odors (Mason, et al., 1994; Nolte et al., 1994). Trimethyl thiazoline from feces of red fox (*Vulpes vulpes*) is aversive to rats (Vernét-Maury, 1992). Even plants rich in sulfur compounds, such as onion or leek, are avoided by herbivores such as black-tailed deer, *Odocoileus hemionus columbianus*, or goats (personal observations).

Previous predator odor studies on vertebrates have ranged from fish (Mathis and Smith, 1993) to mammalian herbivores such as black-tailed deer (Müller-Schwarze, 1972; Sullivan *et al.*, 1985b), white-tailed deer (Swihart *et al.*, 1991), red deer (Abbott *et al.*, 1990), and sheep (Arnould, 1992, Arnould and Signoret, 1993). Weldon (1990) has summarized the known responses of vertebrates to predator odors. Particularly relevant here are studies in lagomorphs (Sullivan and Crump, 1984; 1986; Sullivan *et al.*, 1985a; Boag and Mlotkiewicz, 1991, 1994), and rodents (Bäumler *et al.*, 1990; Sullivan *et al.*, 1988a,b, 1990a,b; Vernét-Maury, 1992).

The primary mammalian predators of North American beavers are the wolf (*Canis lupus*) and coyote (*C. latrans*), particularly during spring and summer (Theberge et al., 1978; Potvin *et al.*, 1988; Fuller, 1989) and when preferred prey such as white-tailed deer (*Odocoileus virginianus*) are less abundant (Pimlott *et al.*, 1969).

It is thought that the decline of the beaver population on Isle Royale in Lake Superior around 1980 was caused by increased wolf predation (Shelton and Peterson, 1983). In northern Manitoba, wolves have been observed to stalk beaver (Nash, 1951). In several studies various amounts of beaver remains were found in wolf scats. On Isle Royale in Lake Superior, Mech (1966) reported that about 11% of wolf scats contained beaver hair. This compares with 7% in the Rocky Mountain national parks of Canada (Cowan, 1947) and 10.5% in Ontario (Peterson, 1955). In Algonquin Provincial Park, Ontario, up to 62.8% of wolf scats contained beaver hair in summer, but only 11.5% in winter (The-

berge *et al.*, 1978). In Minnesota, however, 20–47% of wolf scats contained beaver remains in April and May, but only 2% in June and July (Fuller, 1989). In southern Québec, beaver constituted 29–44% of biomass in the diet of wolves from May through November but only 1–3% during the remainder of the year (Potvin et al., 1988). Indirect evidence for wolf predation on beaver comes from experimental wolf reduction in Québec, which resulted in an increase in beaver numbers and a decrease after the wolf population was allowed to grow again (Potvin *et al.*, 1992).

Coyotes have been observed to hunt and kill beaver in Rocky Mountain National Park, Colorado (Packard, 1940). In the Adirondacks, New York, coyotes also prey on beaver (Brundage and Brocke, personal communication).

At Allegany State Park, New York, our group observed black bears (*Ursus americanus*) taking beaver out of live-traps on at least two occasions (Houlihan, unpublished; Schulte, 1993). Observations of black bears trying to dig into beaver colonies were "fairly common" in northern Saskatchewan (Gunson, 1970). Substantial predation by black bears has only been reported from an island in Lake Superior (Smith et al., 1994). For grizzly bears (*Ursus arctos*) in Denali National Park, Alaska, Murie (1981) had "no observations suggesting bear predation on beavers." They may serve only as "occasional taste of carrion for the bears."

Fox (*Vulpes vulpes*), bobcat (*Lynx rufus*), and lynx (*Lynx canadensis*) prey little on beaver (Saunders, 1988). In a study in Maine, less than 5% of bobcat carcasses contained remains of beaver (Litvaitis *et al.*, 1986). Despite claims in the past, the river otter (*Lutra canadensis*) is not a predator of beaver. Beaver are rare in the diet of otter. In a northeast Alberta area with high beaver and otter densities, Reid (1984) found only five otter scats among 1140 (0.4%) that contained beaver remains. Otter may have fed on beaver carcasses. No beaver remains were found in seven other studies of otter droppings, cited by Reid (1984).

The exclusively herbivorous beaver most prefers bark and leaves of aspen (*Populus tremuloides* and *P. deltoides*) among tree species. In our study areas they also feed on beech (*Fagus grandifolia*), speckled alder (*Alnus rugosa*), red maple (*Acer rubrum*), yellow birch (*Betula alleghaniensis*), American hornbeam (*Carpinus caroliniana*), and other deciduous tree species. Conifers are rarely taken. Beaver also feed on grass, apples, ferns, and aquatic vegetation, depending on the season.

Beavers are monogamous animals that live in families (for a review see Chapman and Feldhamer, 1983). A typical family consists of an adult male and female and their offspring of the current and the past year. A family at a particular site created by damming up a stream is termed a "colony." For this study, a colony of beaver was the unit of experimental subjects.

In this study we seek answers to the following questions: Do predator odors

on or near food inhibit feeding by beaver? Are odors from certain predators more potent inhibitors than others? If so, are odors of predators sympatric with beaver more active than those from allopatric species?

METHODS AND MATERIALS

The study areas were Allegany State Park (ASP) in southwestern New York State and the Huntington Wildlife Forest (HWF) in the Adirondack Park in northern New York. The natural vegetation in both study areas is northeastern hardwood, with differences in the composition of the forest.

All odor samples except lion odor were prepared from excrement. The lion odor sample was prepared from a commercial lion urine extract (Imperial Chemical Industries PLC, Brachnell, England). All feces, except dog (a pet female black Labrador), were collected at the Burnet Park Zoo, Syracuse. For all samples, 1 part feces (by weight) was suspended in 2 parts pure methanol for 2 hr and then filtered with a vacuum filter. The filtrate was used for the experiment, the solid phase discarded. The odor samples were stored in glass jars with alcohol-proof plastic lids in a refrigerator.

The aspen sticks used as carriers for the odors were cut from aspen saplings in the study area. Stems with a diameter of 1–2 cm and with as few lateral twigs as possible were selected. The sticks were cut fresh on the first day of each trial, pruned, and cut into sections 30 cm long. To facilitate uptake of the methanol solutions, the bark of all sticks, except the "intact" control, was perforated by rolling them on a nailboard. The sticks were dried at room temperature for 2 hr and then scented by dipping them to two thirds of their length into the extracts for 2 sec (except those left blank). In addition to intact and perforated blanks, some sticks were soaked in bitter-tasting extract of seeds (main component azadirachtin) of the neem tree, *Azadirachta indica*, which inhibits feeding by small rodents (Bäumler *et al.*, 1990). Some sticks were soaked in diesel oil, also a repellent for small rodents (Bäumler *et al.*, 1990), and others were soaked in pure methanol as a solvent control. The sticks were dried for 2 hr before further handling.

For each trial we used 10 randomly chosen colonies. Twelve sticks, arranged in a row, were placed at the bank of each pond parallel to the water's edge near feeding places that were frequently visited by beavers. One stick each carried one of the seven predator odors, one neem extract, and diesel oil. The remaining three sticks served as controls: one was perforated and methanol-soaked, one perforated and untreated (blank), and one unperforated and untreated (intact). The distance between the sticks was 30 cm for the trials in June and July in ASP and in HWF. For the trials in October and November in ASP, the distance was increased to 1 m to determine whether distance affects the ability of the

beavers to distinguish the odors. The sticks were placed in a random order, determined by lot and the same pattern used for all 10 colonies. Each trial was five nights long, i.e., five beaver activity periods, without replacing any missing or altered sticks. This time period was long enough to assure the beaver had encountered the samples and short enough to minimize random influences such as heavy rains. First, a baseline trial with 12 intact, i.e., unperforated, untreated aspen sticks was run for three nights at 10 ASP colonies. At HWF, two such baseline trials were run (total number of sticks for baseline trials in both areas: 360). For treated samples, a total number of 2108 sticks were used. Their distribution over summer and fall, and ASP and HWF, the predator odors used, and the numbers of replications and colonies are listed in Table 1.

The results of the nocturnal beaver activity were recorded each morning. Sticks were classified into completely peeled, partially peeled, left intact and moved, and left intact and in place. Missing sticks (swept away or sunken) were regarded as consumed by beaver (aspen wood does not float on water for a long time). Beaver sample sticks and often discard partially peeled sticks. Sticks that were peeled less than 80% were regarded as rejected, as were sticks that were not taken after five activity periods.

TABLE 1. EXPERIMENTAL DESIGN: NUMBERS OF SAMPLES (NUMBERS OF TRIALS × NUMBERS OF COLONIES) USED AT TWO BEAVER POPULATIONS AND DURING DIFFERENT SEASONS

	Population and Season			
Treatment	ASP summer (5 × 10)	HWF summer (5 × 10 + 1 × 4)	ASP fall (8 × 10)	Total

Lion	50	54	80	184
Diesel oil	50	54	80	184
Neem	50	54	80	184
Methanol control	50	54	80	184
Intact		54	80	134
Blank	50	54	80	184
Number of treatments	10	12	12	
Total number of sticks	500	648	960	2108

As statistical tests of significance in the differences of numbers eaten vs. not eaten, we used the non-parametric Cochran and McNemar tests. They retain the pairwise comparison of simultaneous samples. χ^2 tests were also used.

RESULTS

Allegany State Park (ASP). In a three-nights-long baseline test at the beginning of the trials, 74 of 120 (i.e., 12 sticks at each of 10 ponds) or 61.7% of intact aspen sticks were taken. For the trials run in June and July (sample size: 50 for each of 10 treatments) the percentages of experimental sticks accepted by the beaver after one to five activity periods are given in Figure 1. Acceptance ranged from 10.0% for coyote odor to 32.0% for the perforated aspen control ($\chi^2 = 7.30$; $P < 0.01$). (Intact, i.e., untreated, unperforated aspen logs, and

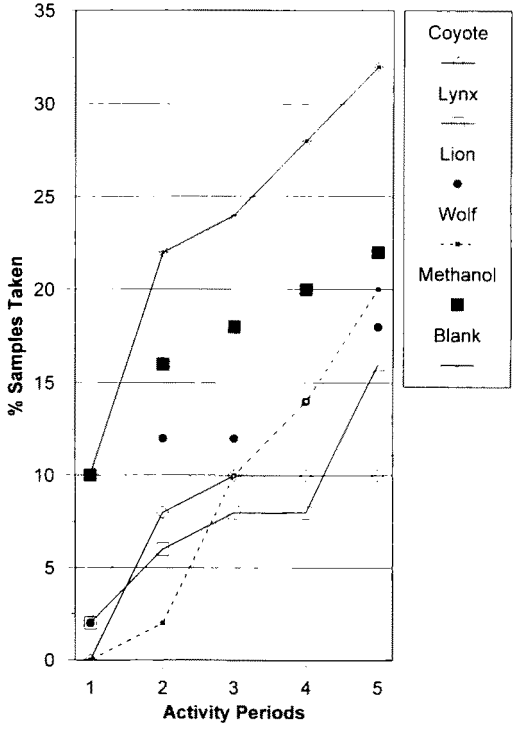

FIG. 1. Responses by beaver (% samples taken) at Allegany State Park in June/July 1993.

river otter odor had not been used at that time.) After coyote odor, the most active predator odors were lynx and black bear (16% of each accepted; χ^2 = 0.236 vs. control; NS; black bear data not shown in Figure 1). Thus, coyote odor inhibited feeding significantly, compared with untreated controls.

In the October/November trials, significantly more sticks were consumed (Figure 2). This was a time of provisioning for the winter and reinforcing lodge and dams. A total of 690 sticks were used. When only intact aspen sticks, 1 m apart, were offered, 48.7% were taken after three days. The most avoided odor was river otter (28% acceptance after three days; χ^2 = 10.98; $P < 0.001$; 42.5% after five days), and the most frequently taken samples were the perforated and methanol-treated aspen controls (63.7% each; difference between otter and each control: χ^2 = 7.26; $P < 0.01$). The wider spacing of 1 m between the sticks had no effect on the preference for the controls. The ratio between the numbers of predator odor samples and controls that were consumed was

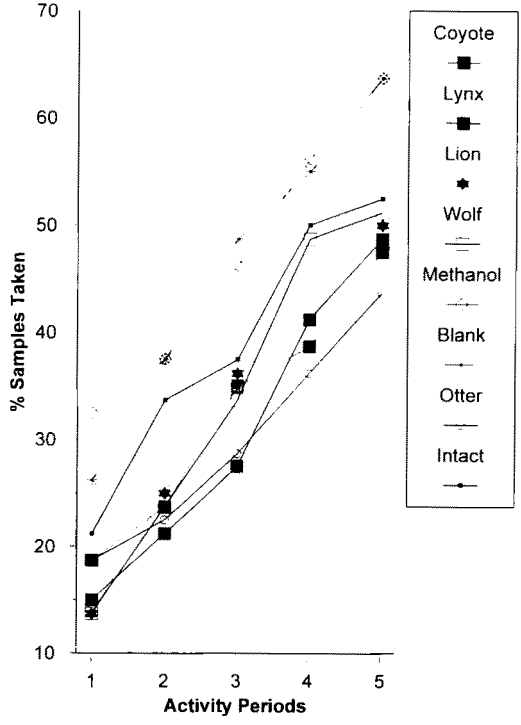

FIG. 2. Responses by beaver at Allegany State Park in October/November 1993.

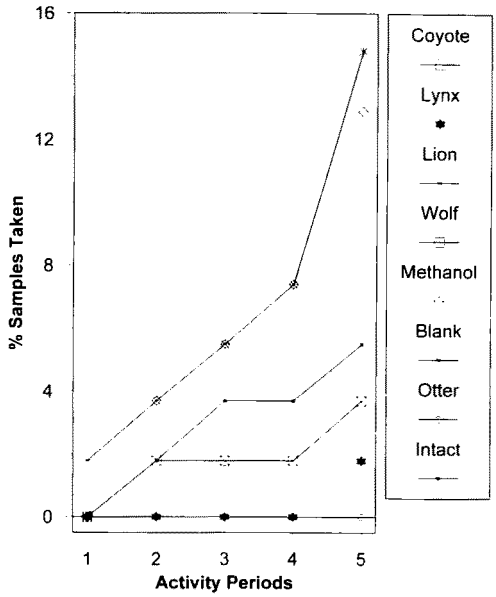

FIG. 3. Responses by beaver at Huntington Wildlife Forest in August/September 1993.

0.81 in October/November. For an interstick distance of 30 cm, this relation was 0.49 for ASP in June/July and 0.30 for HWF in August/September (difference not significant).

Huntington Wildlife Forest (HWF). At HWF (experiments during August/September) the beaver consumed fewer sticks than at ASP. The acceptance rate ranged from 0 for river otter odor to 14.8% for the perforated aspen control (Figure 3; $\chi^2 = 8.64$; $P < 0.025$). This compares with 32.5% and 34.2% in two trials with only untreated perforated aspen sticks as baseline test (difference to otter: $P < 0.001$).

The ratio between the percentages of consumed predator-treated and control sticks at HWF was 0.30. Because the data were collected during the summer, the experiment was influenced by the fact that the beaver at HWF could choose from a great variety of available food, notably large beds of floating watershield (*Brassenia* sp.) leaves.

Both Study Areas. Figure 4 summarizes the responses in all trials in both areas. The average acceptance rate of five predator odors (those shown in the graphs) changed from 8.3% on the first day to 26.6% on the fifth, while the average for the three controls was 14.7% on day 1 and 38.5% on day 5. The average acceptance of five predator odors as percent of the average of the three

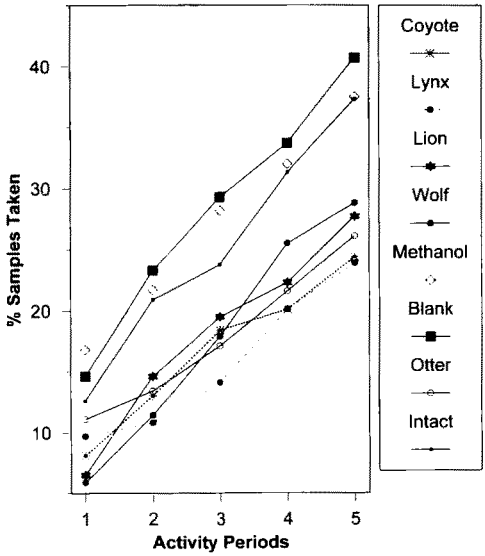

FIG. 4. Summary of all responses in both study areas. (No data for river otter and intact controls for June/July).

controls increased slightly from 56.5% on day 1 to 68.1% on day 5. The most avoided predator odor (different odors in different blocks of trials) as percent of the average for the three controls increased gradually from 40.1% on the first day to 67.7% on the fifth. Table 1 summarizes the experimental design for all replicates in both areas, and Table 2 summarizes the results for all replicates in both areas.

The significance levels of the differences in the responses of the beavers to the different samples after five activity periods for all trials are shown in Table 3. The greatest statistical differences ($P < 0.001$) between predator odors and controls were as follows: all seven predator odors vs. perforated, untreated sticks; coyote, dog, otter, lynx, and lion vs. neem; black bear, coyote, dog, and otter vs. methyl alcohol; and coyote, otter, and lynx vs. diesel oil. Also significant ($P < 0.01$) were: wolf, lynx, otter, and lion vs. methyl alcohol; bear and wolf vs. neem; and lion vs. diesel oil. Among the controls, only blanks (unperforated, untreated) were taken significantly less often than untreated, but perforated sticks ($P < 0.01$).

Generally, there were no significant differences between different predator odors. The exception is the odor of otter, which was slightly, but consistently, more potent ($P < 0.1$) than all other predator odors except lynx. Although river

TABLE 2. SUMMARY OF ALL RESPONSES IN BOTH AREAS (Cumulative % Eaten)

otter odor was the most avoided odor, there were treatments that were accepted less on average because river otter odor was not used for the June/July trials in ASP, when relatively few samples were taken. The only other slight differences among other predator odors occurred between coyote and lion odors ($P < 0.1$) and between lynx and lion odors ($P < 0.1$). The acceptance rates for neem and diesel oil were intermediate between predator odors and aspen controls (Table 2).

DISCUSSION

The responses toward the samples show that free-ranging beaver are able to distinguish between different odor treatments of food, which in this experiment included the opportunity to taste the samples. They did so in the presence of abundant alternate food. This type of field experiment contrasts with captivity or laboratory studies in which the experimenter provides the only food available and manipulates its amount. Examples are experiments with cattle (Pfister *et al.*, 1990), sheep (Arnould and Signoret, 1993; Pfister *et al.*, 1990), goats (Weldon *et al.*, 1993), or mountain beaver (Epple *et al.*, 1993). The three questions posed at the outset can be answered as follows. At least some predator fecal extracts inhibit feeding (the actual concentrations of active compounds are unknown at this point). The effects of different extracts did not differ significantly from one another. From this it follows that there was no significant difference between chemicals of predators that are sym- or allopatric with beaver.

The different responses to the samples by the beavers in the two regions may result from genetic differences between the two populations or environmental factors such as experience with predators or the composition of the food supply. Originally there were two different subspecies in the two respective study areas (Hall, 1981). The original subspecies in the Adirondacks was *Castor canadensis acadicus* Bailey and Doutt (Hall, 1981). The subspecies for western New York State, including ASP, is the nominate race. The beaver had been almost extirpated in the entire State of New York in the 19th century. The Adirondack population was restocked in 1905 with seven beaver from Canada (nominate race), and again in 1907, when 14 specimens from Yellowstone National Park (subspecies *C. c. missouriensis* Bailey) were released at Old Forge. After their extirpation, the first beavers at ASP were recorded in 1937 (Shadle and Austin, 1939). These beaver had come north from Pennsylvania where animals from Wisconsin had been introduced in 1917 and subsequent years (Hilfiker, 1991). Still, the genetic distance between the two current study populations is not known.

Since the two study areas also differ in the presence of potential predators, the effect of learning could be important. In general, ASP has fewer different predators. Felidae are totally missing (personal communication with local wildlife managers) and so are wolves. Black bear, coyote, and river otter occur in the park (personal observation of animals and tracks by both authors). By contrast, all North American predators whose odors were used, except wolf, occur in HWF. The lynx was extirpated in the Adirondacks in the late 19th century and recently reintroduced (Brocke *et al.*, 1991), but is still very rare. The closely related bobcat (*Lynx rufus*) also occurs in the Adirondacks (Saunders, 1988). Black bear tracks and droppings around beaver ponds have been seen in HWF by the author, as have three specimens of river otter and several coyotes. The

barking and howling of coyote packs was often heard. The abundance of predators in HWF could explain why the predator odors were avoided so strongly, as were the nearby control samples. Nevertheless, beavers did not avoid the odors of sympatric species significantly more than the odor of the allopatric lion. However, the slightly more avoided odors were those of species that are sympatric with each particular beaver population used in this study, such as river otter and lynx in HWF.

Other studies of predator odor effects on feeding by herbivores show consistent effects (e.g., Müller-Schwarze, 1972; Sullivan and Crump, 1984). Dog odor has no significant effect on the feeding behavior of snowshoe hare (Sullivan *et al.*, 1985a), but coyote odor decreases browsing by black-tailed deer significantly (Sullivan *et al.*, 1985b). Black-tailed deer avoid the odors of sympatric predator species more than those of allopatric species. This behavior may have a genetic basis but might be refined by learning (Müller-Schwarze, 1972). In this study beavers avoided the odors of sympatric predators such as river otter and coyote that actually occur within the range of the tested beaver slightly more than those of originally sympatric, but now absent, species such as the wolf. Lynx are in the same category as wolf (except for recent local reintroductions) (Brocke *et al.*, 1991), but their odor was still avoided. Furthermore, beaver do not discriminate between the odors of the allopatric lion and the sympatric wolf, nor did they distinguish between wolf and dog odor. Similarly, Mason et al. (1994) found that urine odors from dog, mink, bobcat, and coyote inhibited feeding by mountain beaver, *Aplodontia rufa*, equally well. These authors postulate that to herbivores, sulfur compounds constitute a general predator cue across carnivore species.

We have evidence that beavers actually encounter predators in our study areas. The authors observed river otters in beaver ponds in both regions. Black bear footprints and droppings close to beaver ponds were found in ASP and HWF. In our team's studies, a black bear took a beaver out of a Hancock live-trap in ASP on two occasions (Houlihan, unpublished; Schulte, 1993). Beavers might learn to avoid predator odors through direct encounters or witnessing attacks on other beaver. A beaver might also be conditioned by warning signals from conspecifics, even though the signal is associated only with a predator odor, not an encounter itself.

The seasonal differences in sample acceptance are most likely correlated with the changing abundance of palatable food. In summer beavers feed very little on tree bark. Beavers prefer to eat leaves and chew the bark of a twig only after all leaves are consumed. They also eat grass and forbs. This might explain the low interest in the aspen sticks in general at both ASP and HWF in summer. In September the situation changes dramatically. The beavers cut many trees to build food caches for the winter. Furthermore, beavers working on bulky food items such as branches might entirely ignore the relatively small aspen samples.

During this period they spend more time than usual on the shore and are more exposed to predators. They might be more alert and are consequently avoiding the predator odor more for both of these reasons. The responses at HWF dropped towards zero acceptance from the middle of September onwards. In late autumn the growing season is over, and beavers depend almost exclusively on bark in their diet. The aspen samples might then become more attractive again and the beaver less selective.

When the distance between the sticks was increased from 30 cm to 1 m, the beaver did not discriminate controls more from predator odors. Thus "olfactory overshadowing" may not have been important with our arrangement of the samples.

During some days in late October the ponds were frozen, and the beaver tended to either ignore or accept all samples. The ice cover affected the beavers' activities, and the low temperature of air and sticks could have impaired their ability to distinguish between different odors. The different amounts of rainfall in the course of the year could also play an important role. Since the predator odors were applied as alcoholic solutions, they are easily washed away by rain. Sticks with predator odor that had lain in the water for some time were eventually chewed. The same was true for initially rejected sticks with diesel oil. In other studies, such as that of black-tailed deer (Sullivan et al., 1985b), predator odors also became less effective after heavy rains. The strong feeding responses after rainfall indicate that the odor was washed away. This might be different for each odor, depending on original odor strength and other compounds present. For instance, wolf odor was more avoided than any other odor on the first day (Figure 1) but had no strong repellent effect later on. The reverse was true for river otter odor. That taste, in addition to olfaction, may be involved is shown by the fact that beaver often consumed more than half of the bark on a stick and then abandoned the rest.

Any application of repellents has to take into account which predator species are present in the area. Beaver exposed to a more diverse predator guild may avoid more strongly repellents based on predator odors. For lasting effects, the learning ability of beaver requires that other stimuli be used to reinforce the avoidance of predator odors. Furthermore, odors applied directly to food may trigger responses different from odors placed in the vicinity of food, and the senses involved determine the stimuli used. For an effective beaver repellent to last in the elements, a formulation with a hydrophobic carrier will be necessary. The next step is the chemical isolation and identification of the active compounds.

Acknowledgments—We thank Drs. Rainer Brocke and William Porter of the Adirondack Wildlife Program for partially funding this research; Mr. Richard Sage, Assistant Director of the Adirondack Ecological Center, and Mr. James Rich, Regional Director of ASP, for administrative support; Ms. Kathryn Buffington for arranging the loan of night vision goggles; Capt. Paul Cloutier

of the Division of Military and Naval Affairs in Latham for loaning night vision goggles; and Staff Sgt. Norman Provoncha of the Ticonderoga Armory for providing the goggles and instruction for their use. Messrs. Michael Rehberg and Lixing Sun helped with the field work and gave much useful advice. Mr. Allen Baker from Burnet Park Zoo provided predator samples, and Mr. Christopher Sack helped in the laboratory. Prof. Dr. R. Apfelbach, University of Tübingen, Germany, referred A.E. to ESF. We thank Drs. Robert M. Silverstein and Stephen Teale for critical reading of the manuscript.

ALLELOPATHIC POTENTIAL OF *Anthoxanthum odoratum* FOR INVADING *Zoysia*-GRASSLAND IN JAPAN

YOSHITO YAMAMOTO

Department of Ecology
National Grassland Research Institute
Nishinasuno Tochigi 329-27, Japan

(Received December 5, 1994; accepted May 8, 1995)

Abstract—The growth of *Zoysia japonica* surrounding *Anthoxanthum odoratum* on *Zoysia*-grassland in Japan was investigated in June 1990. The stem density of *Z. japonica* tended to decrease with short distances between two *A. odoratum* plants. This showed that the growth of *Z. japonica* surrounding *A. odoratum* was reduced. Basic, neutral, and acidic fractions extracted from *A. odoratum* plants inhibited the seedling growth of lettuce. In particular the neutral fraction showed the strongest activity among the three fractions. The main inhibitory compound obtained at R_f 0.6–0.7, on the thin-layer chromatogram of the neutral fraction, was isolated and identified as coumarin by means of GC-MS. Coumarin solution inhibited seedling growth of *Z. japonica* in low concentrations but, conversely, promoted seedling growth of *A. odoratum*. Coumarin was contained in all parts of *A. odoratum* and its concentration varied with the season and from one individual plant to another. In particular, coumarin was highly concentrated in the leaves, accounting for more than 2.5% of dry leaf weight in June. The inhibitory effect of these aqueous extracts was correlated to the amount of coumarin in *A. odoratum* leaves and coumarin was considered to be the main inhibitory compound.

Key Words—*Anthoxanthum odoratum*, allelopathy, coumarin, *Zoysia japonica*, allelochemicals, grassland.

INTRODUCTION

Zoysia japonica is one of the important native grasses mainly dominant in the seminatural grassland of Japan, but recently, the author observed that *Anthoxanthum odoratum* has invaded *Zoysia*-type vegetation and formed a pure stand. Judging from the distribution pattern of *A. odoratum* in *Zoysia*-type vegetation, the author hypothesized that allelopathy contributed to its aggressiveness. *A.*

odoratum was one of the pasture plants introduced from Europe as horse feed about 100 years ago, but it has escaped from pasture and spread all over Japan except for the Okinawa region. Several studies have been made on allelopathy of *A. odoratum*; for example, it was reported that the root exudate from *A. odoratum* affected the growth and phosphorus uptake (Newman and Rovia, 1975; Newman and Miller, 1977). However, the effects of allelochemicals and the allelopathic role of *A. odoratum* in grassland communities have not yet been studied. Therefore, the author started this research on the allelopathy of *A. odoratum*.

In this study, the growth of *Z. japonica* surrounding *A. odoratum* was investigated, and the main allelopathic substances of *A. odoratum* were isolated and identified. In addition, the allelochemical content of *A. odoratum* was measured, and the effects of this allelochemical on the growth of *Z. japonica* and *A. odoratum* were assessed.

METHODS AND MATERIALS

Field Survey of Growth of Zoysia japonica. The growth of *Z. japonica* surrounding *Anthoxanthum odoratum* in *Zoysia*-type vegetation was investigated in June 1990. First, two *A. odoratum* plants were selected in *Zoysia*-type vegetation, on the condition that there was no *A. odoratum* within a circle the diameter of which was the distance between the two plants. The stem numbers of the two *A. odoratum* plants were counted (Figure 1). A quadrat (10 × 10 cm) was set between the two *A. odoratum* plants, and the stem numbers of *Z. japonica* within the quadrat were counted. This investigation was carried out on a total of 22 circles.

Extraction of Active Substances from A. odoratum and TLC Fractionation. The plant top of *A. odoratum* was collected in March and freeze-dried. The extraction procedure used is shown in Figure 2. Thin-layer chromatography was carried out on a 20-cm × 20-cm silica gel plate (Whatman, Silica gel 60A PK6F) 1 mm thick using benzene–MeOH–acetic acid (45 : 8 : 4 v/v/v) as a developing solvent. After the TLC plate was dried, it was divided into 10 parts from the origin to front. Each fraction was eluted with MeOH for 12 hr at 25°C, and the eluates were filtered. These fractions were bioassayed using lettuce seedlings. Thirty seeds were placed on filter paper moistened with 1.6 ml of the test solution in a 20-mm-high × 55-mm-ID glass Petri dish. Lettuce seeds were incubated for four days in a growth chamber at 25°C in darkness. The average hypocotyl length of 10 germinated plants was compared with that of controls grown in distilled water.

Isolation and Identification of Allelochemical. An active compound separated by TLC was isolated and identified using a Shimadzu GCMS-QP1000S

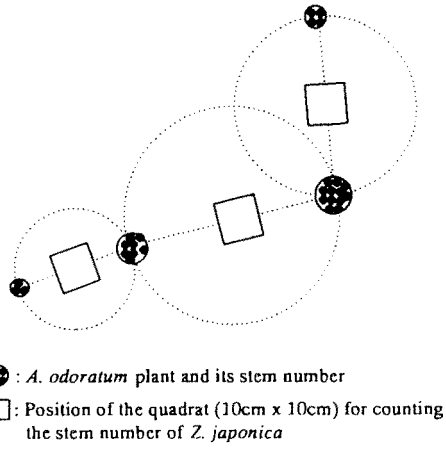

FIG. 1. Diagram showing procedure used to quantify stem density of *Z. japonica* and *A. odoratum* in *Zoysia*-type vegetation. The two *A. odoratum* plants were selected so that there was no *A. odoratum* within a circle the diameter of which was the distance between two plants. The distance between the two plants was measured, and then the stem number of each plant was counted. Next, the stem density of *Z. japonica* located between the two plants was counted.

gas chromatograph–mass spectrometer. The analytical conditions were as follows: column—Shimadzu fused silica capillary column CBP1-M25-0.25 (25 m length × 0.25 mm ID); carrier gas—He, 40 ml/min; temperature—column, 50–250°C, 5°C/min; injection, 250°C; detector, 250°C.

Seedling Growth Bioassay. Thirty seeds of *Z. japonica* or *A. odoratum* were placed on filter paper moistened with 2 ml of the known concentrations of the test water solution in a 20-mm-high × 55-mm-ID glass Petri dish. *Z. japonica* seeds were incubated in a growth chamber for 10 days under a cycle of 12 hr light (7.5×10^3 ergs/cm^2/sec) at 35°C and 12 hr dark at 25°C. *A. odoratum* seeds were also incubated for eight days in light at 30°C and in dark at 20°C. The percentage of germination of the 30 seeds and average length of shoot and root of 10 germinated plants were compared with those of controls grown in distilled water.

Measurement of Content of Allelochemical in A. odoratum. Four plants of *A. odoratum* were collected every month from April to November 1993 in a field plot. In this plot, cutting and nitrogen fertilization (1.42 g N/m^2/yr) were performed in March, July, and September. Each of the collected plants was separated into head, leaf, stem, stubble, root, and standing dead litter and then each part was freeze-dried and powdered. Each 1 g of powder was extracted

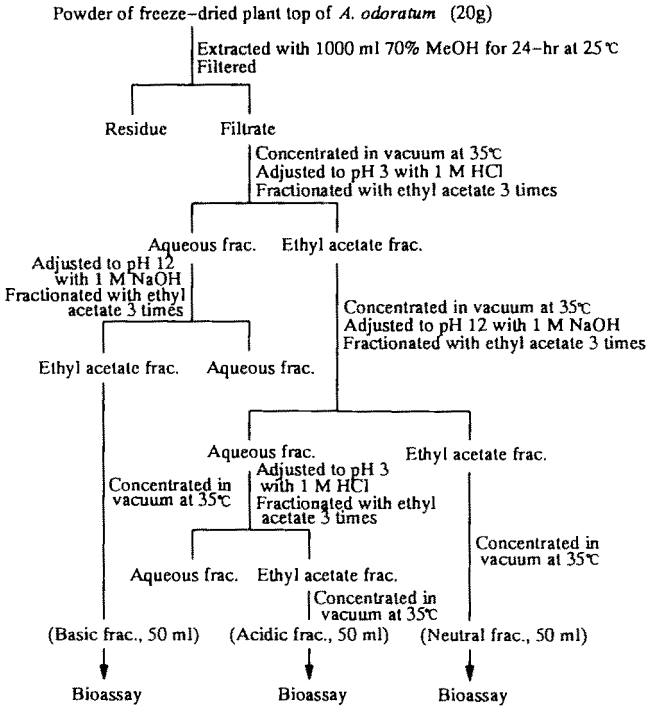

FIG. 2. Extraction procedure of active substances from *A. odoratum*.

with 50 ml MeOH for 12 hr at 25°C, and the extracts were filtered. The concentration of coumarin in these extracts was measured using a Shimadzu GC-15A gas chromatograph. The analytical conditions were as described in the section "*Isolation and Identification of Allelochemical.*" In addition, aqueous extracts of the leaf freeze-dried samples were bioassayed using *Z. japonica* seeds, as described above.

RESULTS

Field Survey of Growth of Zoysia japonica. The relationship of the distance between two *Anthoxanthum odoratum* plants and the stem density of *Zoysia japonica* between the two plants was unclear, but the effect of *A. odoratum* on the growth of *Z. japonica* seemed to depend on plant size of *A. odoratum*. When total stem numbers of the two *A. odoratum* plants were between 15 and 19, stem density of *Z. japonica* located between the two plants tended to decrease the shorter the distance between the two *A. odoratum* plants (Figure 3). This

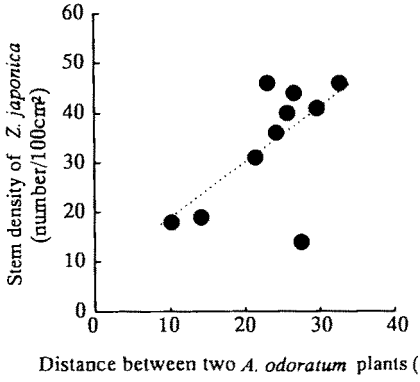

FIG. 3. Relationship between the distance of two *A. odoratum* plants and stem density of *Z. japonica* located between the two plants.

result showed that the stem density of *Z. japonica* surrounding *A. odoratum* was reduced.

Isolation and Identification of Allelochemical. Basic, neutral, and acidic fractions extracted from the plant top of *A. odoratum* inhibited the seedling growth of lettuce (Figure 4). Neutral and acidic fractions showed strong inhibitory activity at high concentrations, especially concentration 1, which completely inhibited germination of lettuce seeds. The neutral fraction showed the

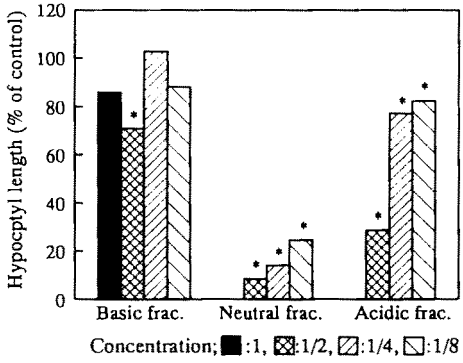

FIG. 4. Effect of the plant top extracts of *A. odoratum* on growth of lettuce. Concentration 1 was the 50-ml fraction obtained from 20 g of plant top of *A. odoratum* as shown in Figure 2. *Significant at $P < 0.05$ as compared with the distilled water control by using Student's *t* test. Lettuce did not germinate in concentration 1 of neutral and acidic fractions.

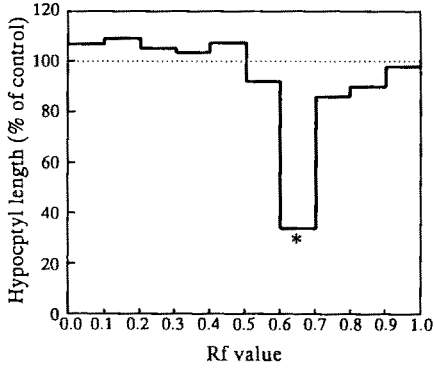

FIG. 5. Effect of thin-layer chromatogram fractions of neutral fraction on the growth of lettuce. Adsorbent: silica gel; developing solvent: benzene–MeOH–acetic acid (45 : 8 : 4, v/v/v). *Significant at $P < 0.05$ as compared with the silica gel control by using Student's t test.

strongest inhibitory activity of the three fractions. From the results of the bioassay using lettuce, significant growth inhibitory activity was exhibited by the neutral fraction at R_f 0.6–0.7 from the thin layer chromatogram (Figure 5). The main inhibitory compound at R_f 0.6–0.7 was isolated and identified as coumarin by GC-MS.

Seedling Growth Bioassay. Coumarin, which was identified as the main allelopathic compound from *A. odoratum*, inhibited the growth of *Z. japonica* and *A. odoratum*. The compound inhibited the seedling growth of *Z. japonica* even in low concentrations (Figure 6). In particular, root length was inhibited

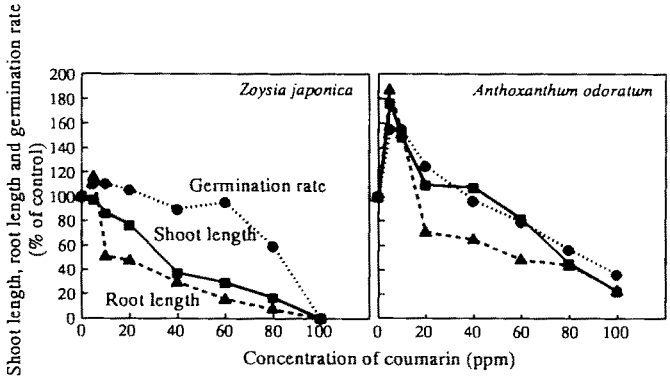

FIG. 6. Inhibitory effect of coumarin on the growth of *Z. japonica* and *A. odoratum*.

TABLE 1. SEASONAL CHANGES IN CONTENT OF COUMARIN IN *Anthoxanthum odoratum*

	Coumarin content (μg/g dry sample ± SD)					
Month	Root	Stubble	Leaf	Stem	Standing dead litter	Head
April	55 ± 13	860 ± 462	3998 ± 1078	2587 ± 727	93 ± 56	1306 ± 391
May	99 ± 41	151 ± 64	8988 ± 3302	2456 ± 1437	20 ± 9	252 ± 256
June	461 ± 62	1179 ± 401	26577 ± 4531	6558 ± 2112	281 ± 136	
July	291 ± 145	382 ± 337	7188 ± 2832	5599 ± 786	92 ± 46	
August	369 ± 218	522 ± 67	8199 ± 1158	4691 ± 728	440 ± 115	
September	163 ± 32	435 ± 116	6458 ± 1567	5397 ± 1913	348 ± 81	
October	51 ± 24	454 ± 196	7013 ± 1680	5597 ± 1104	354 ± 81	
November	47 ± 13	235 ± 183	2773 ± 956	2327 ± 98	75 ± 44	

by as little as 10 ppm coumarin solution. The seedling growth of *A. odoratum* was also inhibited by high concentrations of coumarin solution, but at low concentrations it was, conversely, promoted.

Measurement of Content of coumarin in A. odoratum. The concentration of coumarin in the head, leaf, stem, stubble, root, and standing dead litter of *A. odoratum* was quantified (Table 1). The concentration of coumarin contained

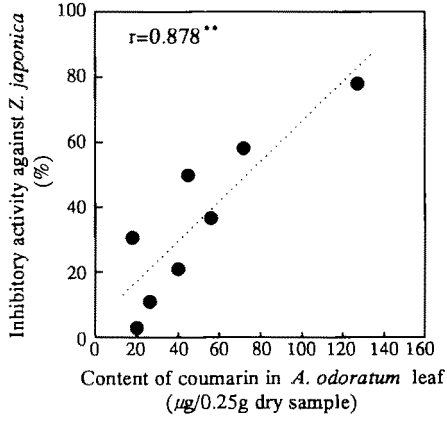

FIG. 7. Relationship between the content of coumarin of *A. odoratum* leaf collected from April to November and inhibitory activity of aqueous extracts against the root growth of *Z. japonica*. Inhibitory activity was calculated by subtracting treatment root length (as percentage of the control root length) from 100%. Correlation coefficient, 0.878, was significant at $P < 0.01$.

in all plant parts of *A. odoratum* varied with the month. Coumarin content in all parts tended to be highest during summer. The leaf and stem showed the highest concentrations and the leaf, in particular contained more than 2.5% dry weight of coumarin in June. Aqueous extracts of these leaves also inhibited the root length of *Z. japonica*.

The aqueous extracts of leaves with high coumarin content tended to show a high inhibitory effect (Figure 7). The correlation coefficient between inhibitory effect and content of coumarin was 0.878 ($P < 0.01$). Therefore, the coumarin contained in *A. odoratum* was considered to be the main inhibitory compound against *Z. japonica*.

DISCUSSION

Generally, *Zoysia japonica*, which dominated the experimental site, is the dominant species in seminatural grazing land in Japan. *Z. japonica* is a stoloniferous plant tolerant of grazing or cutting and deteriorates without these forms of management (Numata, 1975; Itow, 1975). However, it was found from a field survey that *Anthoxanthum odoratum* tended to invade *Zoysia* vegetation, and the stem density of *Z. japonica* surrounding *A. odoratum* was confirmed to be reduced (Figure 3). Regarding the mechanism of aggressiveness of *A. odoratum*, both allelopathy and competition for light, soil moisture, or plant nutrients were considered. As both *A. odoratum* and *Z. japonica* were grazed by cattle, there was less competition between these species for light. *Z. japonica* is drought resistant and is able to grow in sterile land without fertilizing. Therefore, it was possible that allelopathy contributes to the aggressiveness of *A. odoratum*. Allelopathy is well known to play a significant role in the dominance of grassland communities (Rice, 1984; Heisey and Delwiche, 1985; Chou, 1987; Chou and Lee, 1991).

Coumarin was isolated and identified as an inhibitory compound from the most active fraction of the extracts of *A. odoratum* (Figures 4 and 5). Coumarin is a known constituent of many kinds of plant species (Putnam, 1988). It is possible that coumarin in the germinated seeds of *Myroxylon peruiferum* could play an important role as an allelopathic factor (Oniki and Valio, 1992). *A. odoratum* contained coumarin in high concentrations, particularly in leaves (Table 1). Coumarin inhibited root growth in *Phleum pratense* (Avers and Goodwin, 1956) and *Hordeum vulgare* (Hu, 1985) and inhibited germination of *Medicago sativa*, *Lolium multiforum*, and *Abutilon theophrasti* (Dornbos and Spencer, 1990). In exudates from *Avena fatua* roots the compound also inhibited growth of *Triticum aestivum* (Perez and Ormeno-Nunez, 1991). In this study, coumarin inhibited the growth of *Z. japonica*, but promoted the growth of *A. odoratum*, at low concentrations (Figure 6). It was interesting that the sensitivity of the

two species to coumarin was different. The data suggested that the aggressiveness of *A. odoratum* might be due to the allelopathic effect of coumarin. Newman and Rovia (1975) reported that the growth of *A. odoratum* was promoted by its own root leachates compared with controls or with other species. If coumarin were leached from the root of *A. odoratum*, the promotion of the growth of *A. odoratum* can be understood. The amount of coumarin in the leaf of *A. odoratum* and the inhibitory effect of these aqueous extracts on the growth of *Z. japonica* were correlated. Therefore, coumarin was considered to be the main inhibitory compound in *A. odoratum*.

The aggressiveness of *A. odoratum* in *Zoysia* grassland may be the result of many factors, but judging from the results above, it is clear that coumarin in *A. odoratum* could play an important role in terms of its allelopathic qualities and its aggressiveness in *Zoysia* grassland.

Acknowledgments—The author wishes to express his gratitude to Dr. H. Kirita, Dr. E. Tsuzuki, Dr. K. Okamoto, and Dr. N. Kitahara for their critical reading of the manuscript and valuable comments. This study was supported in part by a Grant-in-Aid (Bio Cosmos Program) from the Ministry of Agriculture, Forestry and Fisheries (BCP95-II-A-1).

(Received October 31, 1994; accepted May 9, 1995)

Abstract—Treatment of potato leaf disks with four *neo*-clerodane diterpenes from *Teucrium* (eriocephalin, teucrin-A, teucvin, and teuscorolide) significantly reduced feeding by larvae of *Leptinotarsa decemlineata* (Colorado potato beetle). Choice and no-choice tests suggest that teuscorolide acts as a feeding deterrent, whereas the antifeedant activity of teucrin-A, teucvin, and eriocephalin is likely associated with a toxic mode of action. Nutritional tests, antifeedant simulation assays, and posttreatment studies confirmed that teucrin-A can be categorized by its mode of action as a toxin, rather than as a feeding deterrent.

Key Words—*Leptinotarsa decemlineata*, Colorado potato beetle, *Teucrium*, clerodane diterpenes, feeding behavior, antifeedants, toxins, feeding deterrents.

INTRODUCTION

The Colorado potato beetle, *Leptinotarsa decemlineata* (Say), is an economically important pest currently resistant to most classes of synthetic insecticides (Forgash, 1981, 1985). Despite widespread development of resistance, chemical insecticides remain the major control method (Casagrande, 1987; Hare, 1990). We are now in a situation where alternative pesticides are not always available, which may lead to a decline in potato production. Recently, interest has grown

in the search of antifeedants and toxins of plant origin as a promising source of new control agents (Alford et al., 1987; Hough-Goldstein, 1990).

Clerodane diterpenes have attracted interest in recent years on account of their biological activities against some economically important pests (review in Merritt and Ley, 1992). The most abundant sources of this kind of compounds are the plants belonging to the genus *Teucrium* (Labiatae), from which about 150 *neo*-clerodanes have been isolated (reviews in Piozzi et al., 1987; Merritt and Ley, 1992). Natural *neo*-clerodanes from *Teucrium* and some of their structural derivatives reduced feeding in larvae of some economically important lepidopterous pests (Miyase et al., 1981; Blaney et al., 1988; Simmonds et al., 1989; Simmonds and Blaney, 1992; Rodríguez et al., 1994) and the African migratory locust, *Locusta migratoria* (Hanson et al., 1982).

We report here the effects of four natural *neo*-clerodanes from *Teucrium* (eriocephalin, teucrin-A, teucvin, and teuscorolide) on the feeding behavior of larvae of the Colorado potato beetle. Choice and no-choice tests were used to assess the potency of each compound as an antifeedant. Teucrin-A was further investigated with the help of nutritional tests, antifeedant simulation assays, and posttreatment studies to distinguish between a feeding deterrent or toxic mode of action.

METHODS AND MATERIALS

Chemicals

The *neo*-clerodane diterpenes eriocephalin, teucrin-A, teuscorolide, and teucvin (Figure 1) were available from previous studies.

Insects

A colony of Colorado potato beetle was established by collecting over 50 adults from a potato field located in Zaragoza, Spain. The laboratory colony

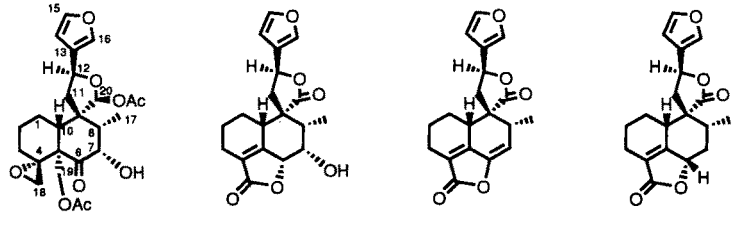

FIG. 1. Molecular structures of *neo*-clerodanes tested against Colorado potato beetle larvae.

was reared on potato plants, *Solanum tuberosum* cv. Kennebec, at 22 ± 2°C, 90 ± 10% relative humidity, and 16 L:8 D photoperiod in an environmental chamber. Fourth-instar larvae from the first generation were used in all feeding experiments.

Feeding Experiments

General. The arena for the assays consisted of plastic Petri dishes (15 × 90 mm), coated on their bottom half with about 20 ml of a 2.5% agar solution (Escoubas et al., 1993). Potato leaf disks (1.77 cm^2) were cut with a cork borer (No. 15) and each disk was fitted into a hole punched in the agar layer. The disks were treated on the upper surface with 10 μl of an acetone solution containing the test compound or the solvent carrier alone. After complete evaporation of the solvent, newly emerged fourth-instar larvae (less than 24 hr old and starved for 6 hr) were placed in each dish in a growth chamber at 26 ± 0.5°C and 85 ± 10% relative humidity, where they were allowed to feed.

Feeding and nutritional indexes were calculated on a dry weight basis. Initial and final larval dry weights were estimated from the ratio of fresh to dry weight calculated with 50 newly molted fourth-instar larvae. Initial dry weight of the leaf disks was estimated similarly using 100 leaf disks to calculate the ratio. At the end of the experiment, the uneaten leaf disks were oven dried at 60°C for two days and weighed.

Choice and No-Choice Feeding Assays. Potato leaf disks were treated with 0, 100, 300, or 1000 ppm concentrations of the test compounds. For the no-choice assays, six treated or control disks were placed in each arena. In the choice assays, three treated and three control disks were alternately arranged per arena. Arenas that contained six untreated leaf disks were simultaneously set and compared with the arenas of the choice assay (choice/no-choice test). Two newly emerged fourth-instar larvae were placed in each dish. In the choice assay, feeding was terminated after the consumption of 50% of the disks (control plus treated) or after 24 hr, whichever occurred first, and after the consumption of about 75% of the control disks in the no-choice assay (4 hr). Assays were conducted with 10 replications per treatment.

The antifeedant index (AI) was calculated in the no-choice assay by the equation $[(C - T)/C] * 100\%$ (Bentley et al., 1984) and in the choice assay by the equation $[(C - T)/(C + T)] * 100\%$ (Simmonds et al., 1989), where C and T represent the consumption of control and treated disks, respectively. The suppression index (SI) was determined in the choice/no-choice assay by the equation $[(C - T)/C] * 100\%$, where T represents consumption of both treated and untreated leaf disks in test arenas and C the consumption in control arenas that contain untreated leaf disks only (Raffa and Frazier, 1988).

Nutritional Indexes. Twenty newly emerged fourth-instar larvae were individually fed for 24 hr on eight potato leaf disks treated with 0, 10, 30, 100,

300, and 1000 ppm concentrations of teucrin-A. At the end of this period, 10 larvae per treatment were allowed to continue feeding on eight untreated potato leaf disks for another 24 hr. Nutritional indexes were calculated for the 24 hr that the larvae were feeding on treated leaf disks (treatment period), and for the following 24 hr that the larvae were feeding on untreated leaf disks (posttreatment period).

The relative consumption rate (RCR) and the relative growth rate (RGR) were calculated according to Farrar et al. (1989). Growth efficiency (GE) was calculated as the slope of the regression of RGR on RCR, assuming a common intercept determined by the RGR of starved larvae (Blau et al., 1978). The relative chemical consumption (RCC) was estimated as RCR $\times$ dosage, according to Liu et al. (1990).

An antifeedant simulation assay (Blau et al., 1978) was run simultaneously to distinguish between the deterrent or toxic effects of teucrin-A. A calibration curve for the effect of RCR on RGR at different levels of starvation was built by feeding larvae with different amounts of food, ranging from total starvation to surplus of food. Twenty larvae were individually presented for 24 hr with one of five different arrangements: zero, two, four, six and eight potato leaf disks.

Statistical Analysis

Significant differences between the consumption in control and treatment arenas in the no-choice assays and between the consumption in control (only untreated leaf disks) and test (with treated and untreated leaf disks) arenas in the choice/no-choice assays were tested using the Dunnett two-tailed test. Significant differences between the amount of control and treated potato disks eaten in choice tests were determined by Wilcoxon's matched pair test. Significant differences among nutritional index means (RCR, RGR, and RCC) were tested using the Student-Newman-Keuls test.

The potential antibiosis or antixenosis of teucrin-A was determined by regressing RGR on RCR and comparing each treatment slope with the slope of the calibration curve, assuming a common intercept determined by the RGR of starved larvae (Blau et al., 1978). Curves for deterrent substances would fall on the calibration line, although concentrated in the range of low consumption rate. Treatments in which the slope of the regression is significantly lower than that of the calibration curve (test of homogeneity of slopes) can be categorized as toxins.

We found that RCR, RGR, and GE were inversely proportional to the larval weight. Since the weight of the larvae after 24 hr feeding on treated leaf disks was different for each concentration, it was necessary to exclude the differential effect this would cause from the nutritional indexes in the posttreatment

period. We did this by calculating the regression of nutritional indexes (RCR, RGR, and GE) obtained over the posttreatment period on the larval weight at the end of the treatment period. From the regression the expected post-RCR, post-RGR, and post-GE were then calculated for each specimen according to its weight at the beginning of the posttreatment period. The difference between the observed and the expected postnutritional indexes are the residual postnutritional indexes, which represent the portion of the observed index that can not be explained by the initial weight and therefore should be due to the posttreatment effect of teucrin-A. Significant differences between residual means were tested using the Student-Newman-Keuls test.

RESULTS AND DISCUSSION

The four *neo*-clerodanes tested affected the feeding behavior of Colorado potato beetle larvae, showing some degree of antifeedant activity. The term "antifeedant" is used here as the capacity to reduce feeding, independently of a deterrent (antixenosis) or toxic (antibiosis) mode of action.

Teuscorolide significantly reduced feeding at 1000 and 300 ppm in the choice assay, but only at 1000 ppm in the no-choice assay, and it lacked suppression activity in the choice/no-choice assay (Table 1). The highest antifeedant activity in choice, as opposed to no-choice, tests suggests that this compound acts as a feeding deterrent, since it is able to deter larvae in a choice situation, but the larvae will feed on it when other resources are not available. Similar feeding behavior responses have been reported for other feeding deterrents tested with larvae and adults of Colorado potato beetle (Caprioli et al., 1987; Hough-Goldstein, 1990).

Teucrin-A and teucvin caused a significant dosage-dependent feeding reduction in the no-choice assay at all concentrations tested, indicating a potent antifeedant activity (Table 1). However, consumption of treated disks was only significantly reduced at the highest dose (1000 ppm) in the choice test, indicating low discrimination between treated and control disks (Table 1). A significant suppression of feeding by these two compounds at 300 and 1000 ppm in the choice/no-choice test suggest a noxious effects of these compounds (Table 1). The results observed in the choice situations might then be explained by the antibiosis of these compounds. When the larvae ingest a quantity of treated leaves large enough to evoke toxic responses, feeding activity decreases or ceases and the reduction in the amount of treated disks eaten would be rather small, since no control disk consumption occurred either. Only at 1000 ppm was there a significant reduction, because at this concentration the larvae only fed when control disks were found, but stopped feeding for several hours after they eat a small portion of a treated disk. The tetranortriterpene limonin, which

has been reported to act as a toxin against larvae of Colorado potato beetle, elicited similar responses in these types of tests (Alford et al., 1987; Mendel et al., 1991).

Eriocephalin significantly reduced feeding on treated leaf disks at 300 and 1000 ppm in no-choice assays, but only at 1000 ppm in choice assays, and lacked suppression activity in choice/no-choice assays (Table 1). The results from the no-choice test suggest an antifeedant activity for this compound, but the choice test indicates low discrimination between treated and control disks, similar in both cases to the results obtained with teucrin-A and teucvin. However, with eriocephalin, there was no suppression of overall consumption in choice/no-choice tests. These results suggest some degree of antibiosis associated with eriocephalin. This is exhibited only in no-choice tests after the larvae

have eaten several treated leaf disks. In choice/no-choice tests the assays are finished before the larvae have fed on sufficient treated disks to display any adverse effects.

Structure–activity studies have suggested that the C-12 β-substituted furan ring and the 4α,18-epoxide function of most natural *neo*-clerodanes from *Teucrium* are essential to keep the feeding reduction activity against larvae of *Spodoptera littoralis*. (Blaney et al., 1988; Simmonds et al., 1989; Rodríguez et al., 1994). We have found that eriocephalin, a *neo*-clerodane with both molecular moieties, also reduced feeding in larvae of the Colorado potato beetle. However, it was less active than teucrin-A and teucvin, two 19-*nor*-*neo*-clerodanes with a 18,6α-γ-lactone. Simmonds and Blaney (1992) found that at 100 ppm, eriocephalin and teucvin reduced feeding in larvae of *S. littoralis* and *S. frugiperda*, whereas teuscorolide was effective only against *S. littoralis* and teucrin-A lacked activity. Likewise, Simmonds et al. (1989) found that, at the same concentration, eriocephalin reduced feeding against *S. littoralis* but not against *H. armigera*, whereas teucrin-A lacked activity against both species. The differences of specificity observed among insect species (even within the same family) reveal the importance of targeting a broad range of insect pests in structure–activity studies.

The effect of teucrin-A on feeding behavior was further studied with the help of nutritional indexes to distinguish between a feeding deterrent or toxic mode of action. Teucrin-A was selected over the other *neo*-clerodanes because of its potent antifeedant activity, similar to that of teucvin, and the availability of this compound.

Feeding during 24 hr on potato leaf disks treated with teucrin-A significantly decreased consumption and larval growth at concentrations over 30 and 100 ppm, respectively (Table 2). The responses were dose-dependent and correlated with the chemical consumption (RCR vs RCC: $r = 0.57$, $P \leq 0.0001$; RGR vs RCC: $r = 0.68$, $P < 0.0001$). The growth efficiencies of larvae feeding on leaves treated with 300 and 1000 ppm of teucrin-A were significantly lower than that predicted by an antifeedant simulation–calibration curve with different levels of starvation (Figure 2 and Table 2). Since growth efficiencies for deterrent substances would fall on the calibration line and treatments with lower growth efficiencies can be categorized as toxins (Blau et al., 1978), our data suggest that toxic effects are the primary mode of action of this compound.

The larvae fed for 24 hr on potato leaf disks treated with teucrin-A were maintained on untreated leaf disks for another 24 hr to study if they were able to overcome the adverse effects observed during the treatment period. The resulting nutritional indexes were inversely proportional to the larval weight (Figure 3), and the weight of the larvae after 24 hr of feeding on treated leaf disks was different for each concentration (Table 3). Thus we excluded the effects of the different larval weights at the beginning of the posttreatment period by calcu-

[a] Residual postnutritional indexes were calculated as the difference between the observed and the expected ones. The observed post-RCR and post-RGR were calculated as in Table 2, and the observed post-GE was equal to (RGR/RCR) × 100. Expected post-RCR, post RGR and post-GE were calculated according to their initial larval weight by the regressions in Figure 3.

[b] Average larval weight at the beginning of the post-treatment period ± standard error (mg fresh weight).

[c] Average residual post-RCR ± standard error.

[d] Average residual post-RGR ± standard error.

[e] Average residual post-GE ± standard error.

[f] Column means followed by the same letter are not significantly different from each other (Student-Newman-Keuls test $P \leq 0.05$).

lating the residual post-RCR, post-RGR, and post-GE as the difference between the observed and the expected ones, according to the larval weight at the beginning of the posttreatment period (Table 3). We found that the residual post-RCR and post-RGR of treated larvae become more negative with increasing concentrations of teucrin-A and significantly different from those of control and starved larvae at concentrations over 30 ppm. A similar effect was found on residual post-GE, but was significantly different from the control and starved larvae only at 300 and 1000 ppm. These results showed that starved larvae reached the usual nutritional indexes once they started eating, whereas larvae feeding on leaf disks treated with 300 or 1000 ppm of teucrin-A for 24 hr were not able to recover during the following 24 hr. No mortality occurred when we continued rearing the larvae on untreated leaf disks until pupation, but the length of the instar of larvae treated with 1000 ppm of teucrin-A (5.6 ± 0.2 days) was significantly longer than that of starved larvae (5.1 ± 0.1 days) ($P \leq 0.05$). These data indicate that although ingestion of potato leaves treated with teucrin-A for 24 hr does not result in death, teucrin-A produces a postingestive toxic effect that affects nutritional indexes and delays larval growth.

In summary, we have found that four *neo*-clerodane diterpenes from *Teucrium* exhibit antifeedant activity against larvae of the Colorado potato beetle.

Antifeedant simulation assays and posttreatment studies indicate that teucrin-A can be primarily categorized as a toxin by its mode of action. Further research is in progress to elucidate which physiological functions are altered by the toxic action of teucrin-A.

(Received November 7, 1994; accepted April 10, 1995)

Abstract—Several wild and domestic ruminant species and horses apparently will not consume leafy spurge (*Euphorbia esula*) while grazing range and pasture lands. It has been demonstrated that leafy spurge can elicit conditioned food aversions in cattle and sheep, and the aversion-eliciting capacity of leafy spurge may account for why cattle seldom graze this nutritious plant and why sheep may not readily consume it at some locations. The identity of the aversive compound(s) in leafy spurge is unknown, but several different diterpenoid ingenol esters have been isolated from its tissues, and we suspect that one or more ingenol esters may be aversion-eliciting compounds in leafy spurge. The objectives of this study were to determine whether or not leafy spurge is aversive to laboratory rats and if a crude acetone extract of leafy spurge, presumably containing ingenol esters and other phytochemicals, could generate an aversive response in sheep and laboratory rats. An additional objective was to determine whether or not a particular ingenol monobenzoate, which may be similar to ingenol esters in leafy spurge, might also elicit an aversive response from rats. Rats exhibited food aversions associated with leafy spurge ($P < 0.05$). An acetone extract of leafy spurge induced condi-

tioned food aversions in both sheep and rats ($P < 0.01$). The ingenol 3-monobenzoate also induced conditioned food aversions in rats ($P < 0.01$). Our interpretation of these data is that rats can be used as a model for cattle and sheep with respect to their aversion to leafy spurge ingestion. Additionally, we suggest that one or more ingenol esters may be aversion-inducing agents in leafy spurge. However, others may exist in leafy spurge that are also aversive or are the only or prime aversive chemicals.

Key Words—Leafy spurge, *Euphorbia esula*, ingenol esters, diterpenes, weeds, conditioned food aversion, diet selection, cattle, sheep.

INTRODUCTION

Leafy spurge (*Euphorbia esula*), which is indigenous to Eurasia, has become a common member of many plant communities in the northern Great Plains and Intermountain regions of North America and is replacing native vegetation on over one million acres of range and pasture land in these regions. This forb has high levels of crude protein and low levels of indigestible fiber; therefore, animals that will consume it can realize valuable nutritional benefits (Landgraf et al., 1984; Fox et al., 1991; Hanson et al., 1994). However, cattle (*Bos tarus*), bison (*Bison bison*), elk (*Cervus elaphus*), mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*), and horses (*Equus caballus*) consume little if any leafy spurge (Marlow et al., 1984; Lacey et al., 1985; Lym and Kirby, 1987; Sullivan et al., 1988; Hein and Miller, 1992). In contrast, domestic goats (*Capra hircus*) readily consume leafy spurge in various locations (Hanson and Kirby, 1992, Hanson et al., 1994; Walker and Kronberg, 1992). Domestic sheep (*Ovis aries*) graze it more readily in some areas than in others (Landgraf et al., 1984; Lacey et al., 1984; Kronberg et al., 1992). It has been demonstrated that leafy spurge can elicit conditioned food aversions in cattle, and leafy spurge from an area where sheep generally graze it reluctantly has induced conditioned food aversions in sheep (Kronberg et al., 1993a; Kronberg and Walker, 1993; Kronberg et al., unpublished data). This may explain why cattle seldom consume this plant and why sheep will not readily consume it at some locations.

The identity of the aversive compound(s) in leafy spurge is unknown; however, several different diterpenoid ingenol esters have been isolated from leafy spurge tissues (Kupchan et al., 1976; Upadhyay et al., 1978; Seip and Hecker, 1982; Sorg and Hecker, 1982). One or more ingenol esters may be aversion-eliciting compounds in leafy spurge, possibly due to the capacity of ingenol or ingenol esters to activate the phosphorylating enzyme protein kinase C (PKC) by substituting for, with greater potency, the natural activator diacylglycerol (Aitken, 1987). Protein kinase C is ubiquitous in mammalian tissues (Smith and Meldrum, 1992), with relatively large amounts in the brain, and mediates cellular signal transduction for a large class of hormones and neuro-

transmitters whose effects are mediated through hydrolysis of phosphatidylinositol phosphates (Aitken, 1986, 1987). Adrenergic, histaminergic, muscarinic–cholinergic, and vasopressinergic receptors are involved in phosphatidylinositol hydrolysis (Aitken, 1986).

Activation of the hypothalamic–pituitary–adrenal (HPA) axis appears to be involved in the induction of food aversions by one or more chemicals in leafy spurge (Kronberg et al., 1993b) as well as by other compounds such as lithium (Ader, 1976; Hennessey et al., 1976; Smotherman, 1985), and there are several reports that link the activation of PKC with HPA activation. For example, the release of adrenocorticotropin (ACTH) from the ovine pituitary through stimulation by arginine vasopressin involves activation of PKC, and ACTH secretion appears to be partly regulated by PKC (Liu et al., 1992). Furthermore, the PKC pathway appears to be involved in regulation of gene expression for corticotropin releasing hormone (Van, 1993), which stimulates the release of ACTH. Additionally, dexamethasone, a synthetic glucocorticoid that can inhibit activity of the HPA axis, inhibits both the tumor-promoting and inflammatory activities of phorbol esters (Aitken, 1986) and food aversions caused by lithium and radiation (Hennessey et al., 1976, Revusky and Martin, 1988, Cairnie and Leach, 1982). Phorbol esters are PKC activators. Ingenol esters are closely related to the phorbol esters.

Laboratory rats have been used effectively to study the interactions of phytotoxins in larkspurs (*Delphinium* spp.) and snakeweeds (*Gutierrezia* spp.) with grazing ruminants (Olsen, 1977; Edrington et al., 1993). Therefore, laboratory rats may be a suitable animal model for studies of interactions of leafy spurge with ruminants.

The objectives of this study were to: (1) determine whether or not leafy spurge can elicit food aversions in laboratory rats; (2) determine if a crude acetone extract of leafy spurge, presumably containing diterpenoids along with other chemicals, could cause an aversive feeding response in sheep and rats; and (3) determine whether or not an ingenol monobenzoate with known capacity to activate PKC might also elicit a food aversion in rats.

METHODS AND MATERIALS

Trial 1. Twenty-four laboratory rats (Sprague-Dawley) were randomly divided into four groups (6/group). The subjects were 90 days old and weighed an average of 365 g. Each was individually housed and had continuous access to standard laboratory rat food (Purina Rat Chow)[7] throughout the study.

Subjects were allowed *ad libitum* access to water and food for three days after arrival. Water was then provided at the same time each day for 15 min

[7] Mention of trade names or companies does not constitute an implied warranty by the authors or by the USDA, Utah State University, or Montana State University.

per day for nine days. The final three days were used to compute a baseline on water intake. On the 10th day, saccharine (1.6 g) was stirred into the usual daily fresh water ration prior to the regular access time. Following 15 min of access to this saccharine-water, the treatment subjects were individually anesthetized (see below) and treated with 2 (treatment group 1; T1) or 4 ml (treatment group 2; T2) of a spurge-water slurry. Ground leafy spurge was administered by gavage via a polyethylene tube (2 mm outer diameter) attached to a 20-ml syringe. Thirty milliliters of spurge was suspended in warm tap water (1 : 1 v/v) to form a slurry of leafy spurge for administration.

The volume of liquid and care required for intubation was such that treatment could best be managed with the subjects lightly anesthetized. Each rat was placed in a 20 × 20 × 60-cm clear plastic box and CO_2 was delivered as the animal was closely observed. When the subject became immobile, it was quickly removed, treated, and returned to its home cage and observed during recovery. This process required approximately 3 min per animal and none was lost. Control subjects (treatment group 3; T3) were given saccharine-water on treatment day and were then gavaged with 2 ml of plain water. Subjects in the fourth treatment group (T4) were never offered saccharine-water but were treated with 2 ml of leafy spurge after drinking plain water on the treatment day.

Two days of baseline conditions were allowed for recovery following treatment before tests were conducted. The test session consisted of offering all subjects in all groups except T4 a single bottle of saccharine-water (plain water for T4) of the same composition for the same time as on the treatment day. Again, bottles were weighed and amount consumed was the dependent measure of any effects of the treatment.

Baseline and test intakes were compared within and between treatments by a split-plot design where individuals were nested within their treatment groups, and day (baseline intake on day 1, test intake on day 2) was the subplot treatment. When appropriate, individual means were compared with the protected LSD procedure (SAS, 1988).

Acetone Extraction. Rat chow and leafy spurge were extracted with acetone, and the residues from these extractions were used in trials 2, 3, and 4 (extracted rat chow for trial 2 and extracted leafy spurge for trials 3 and 4). The following procedure was used to prepare the extracts: the rat chow or leafy spurge was ground to pass a 1-mm screen and then stirred with acetone (1 : 5 w/v, substrate to acetone). The mixtures were stirred in a covered container for 24 hr at room temperature, then any fibrous material was removed by filtration and the soluble filtrate was placed under a fume hood until all acetone evaporated, leaving a greasy residue.

Trial 2. Five laboratory rats (Sprague-Dawley; average weight 340 g) were used to determine if an acetone extract of a known nonaversive material (i.e., rat chow) were aversive. Rats were housed individually and had continuous

access to standard rat chow throughout the trial. During the training period, fresh water was provided at the same time each day for 15 min per day for seven days. On the first day of the test period, which immediately followed the training period, saccharine-flavored water (0.10% saccharine, w/v) was offered to the rats for 15 min at the same time as for the training period. Intake of saccharine-water during this period was measured. Rats were then gavaged with the residue from the acetone-extracted rat chow, which was mixed with corn oil at a ratio of 1:10 (w/w) extracted residue to corn oil. This mixture was gavaged at a dosage of approximately 0.002 ml/g of body weight for each rat. On the second day of the test period, saccharine-water was offered to the rats again for 15 min at the normal time, and their intakes of the fluid were measured. Intakes of saccharine-water on both days of the test period were compared, using a *t* test (SAS, 1988), to determine if the rats had an aversive response to the novel-flavored fluid on the second day.

Trial 3. Fifteen laboratory rats (Sprague-Dawley; average weight 300 g) were used in a seven-day trial to determine if an acetone extract of leafy spurge would induce an aversive feeding response in rats. The rats were randomly divided into two groups with eight rats in the treatment group. The rats were housed individually and had continuous access to standard rat chow throughout the trial. During the training period, water was provided for 30 min per day at the same time each day for five consecutive days. On the first day of the test period, which immediately followed the training period, saccharine-water (0.10% saccharine, w/v) was offered to the rats for 30 min at the same time as for the training period. Rats were then gavaged with either the leafy spurge extract in corn oil or the corn oil vehicle (ca. 0.002 ml/g of body weight). The extract was mixed with corn oil (1:10 w/w, extracted residue to corn oil). After completion of the gavage procedure, all rats were offered water for 30 min to equilibrate their thirst since rats drank different amounts of the saccharine-water earlier in the day. On the second day of the test period, the saccharine-water was offered to the rats again for 30 min at the normal time, and their intake of the saccharine-water was measured to determine if the acetone extract of leafy spurge induced an aversion to it.

Intake of saccharine-water was compared using a split-plot design where individuals were nested within their treatment groups, and day was the subplot treatment. When appropriate, individual means were compared with the protected LSD procedure (SAS, 1988).

Trial 4. Fourteen ewes (average weight 60 kg) were used in a nine-day trial to determine if an acetone extract of leafy spurge would induce an aversive feeding response in sheep. The sheep were randomly divided into two equal-sized groups. They were housed individually and had continuous access to water throughout the trial. During the training period (first six days), alfalfa pellets were provided *ad libitum* from 0800 to 1800 hr each day. On the first day of

the test period, rolled oats were offered to all sheep from 0800 to 0900 hr. A gelatin capsule containing the acetone extract of leafy spurge was then placed down the throat of treatment sheep. Control sheep received an empty capsule. The dosage of extract given to each animal was based on the equation: dosage = body weight × 0.15% (aversive dosage for air-dried spurge; Kronberg et al., unpublished data) × 4.5% (acetone-extract residue recovered from air-dried leafy spurge, w/w). After completion of this procedure by 0930 hr, the sheep were offered alfalfa pellets *ad libitum* until 1700 hr. On the second day of the test period, the sheep were offered rolled oats from 0800 to 0900 hr, and their intake of the oats was measured. Intakes of oats on both days of the test period were compared to determine if pairing ingestion of rolled oats with introduction of the leafy spurge extract caused the sheep to develop an aversion to the oats. Data were analyzed as described for trial 3 except oat intake was the dependent variable for this trial with sheep.

Trial 5. Nine laboratory rats (BD-1V Hooded rats; average weight 170 g) were used to determine if an ingenol 3-monobenzoate would induce an aversive feeding response in rats. The rats were randomly divided into two groups with five in the treatment group. The rats were housed individually and had continuous access to standard rat chow throughout the trial. During the training period, water was provided for only 30 min per day at the same time each day for four consecutive days. On the first day of the test period, which immediately followed the training period, saccharine-water (0.10% saccharine, w/v) was offered to the rats for 30 min at the same time as used in the training period. Rats were then gavaged with either the ingenol ester or the ethanol vehicle. Four milligrams of the ingenol ester was dissolved in 8 ml of ethanol and this solution, as well as the vehicle alone, were gavaged at a dosage of 0.001 ml/g of body weight. After completion of the gavage procedure (about half an hour after completion of the drinking period), all rats were offered water for 30 min to equilibrate their thirst. On the second day of the test period, the flavored water was offered to the rats again at the normal time for 30 min to determine if the ingenol ester had induced an aversion to the novel fluid. Data were analyzed as described for trial 3.

RESULTS

Trial 1. Leafy-spurge treatment reduced ($P < 0.01$) saccharine-water intake relative to the control group of rats (Figure 1). The 4-cc dose of spurge (treatment group T2) was more effective ($P = 0.03$) than the 2-cc dose (treatment group T1) at reducing saccharine-water ingestion. Rats in the control group (T3) did not show ($P = 0.40$) suppressed ingestion of saccharine-water during test

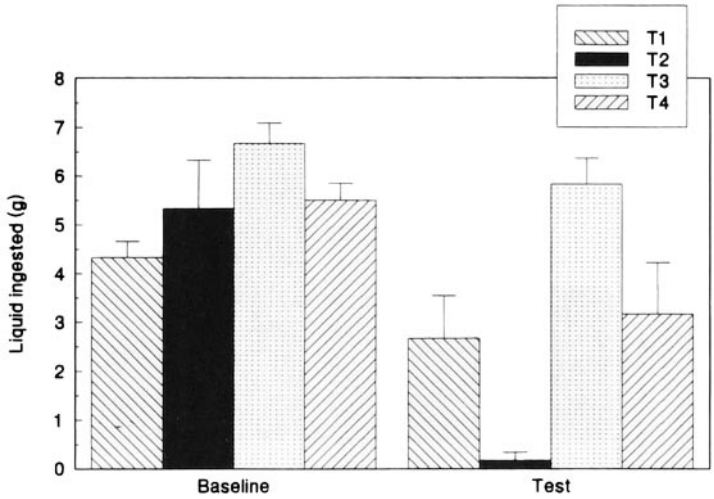

FIG. 1. Ingestion by rats of saccharine-water before and after receiving either 2 ml of leafy spurge (treatment 1, T1), 4 ml of leafy spurge (treatment 2, T2), or 2 ml of plain water (treatment 3, T3) and ingestion by rats of plain water before and after receiving 2 ml of leafy spurge (treatment 4, T4).

sessions. Rats that received spurge after drinking plain water (treatment group T4) reduced ($P = 0.02$) their subsequent intake of plain water.

Trial 2. The residue from acetone-extracted rat chow did not induce a food aversion in the rats. Rats consumed 13.0 (SE = 0.85) and 15.8 (SE = 1.3) ml of saccharine-flavored water on the first and second days of the test period, respectively, and these means were not different ($P = 0.11$).

Trial 3. Rats in treatment and control groups ingested similar ($P = 0.80$) amounts of the saccharine-water on the first day of the test period (Figure 2). However, rats that received a gastric infusion of the acetone extract of leafy spurge (treatment group SPUEXT) after ingesting the saccharine-water ingested less ($P < 0.01$) of this liquid than did control rats (treatment group CNTL) when it was offered to them a second time. The control rats increased ($P < 0.01$) their intake of the saccharine-water from the first to second days, but the treatment rats did not ($P = 0.28$).

Trial 4. Sheep in treatment and control groups ingested similar ($P = 0.99$) amounts of the rolled oats on the first day of the test period (Figure 3). Sheep that received a capsule containing the acetone extract of leafy spurge (treatment group SPUEXT) after ingesting the rolled oats ate less ($P < 0.01$) of them than

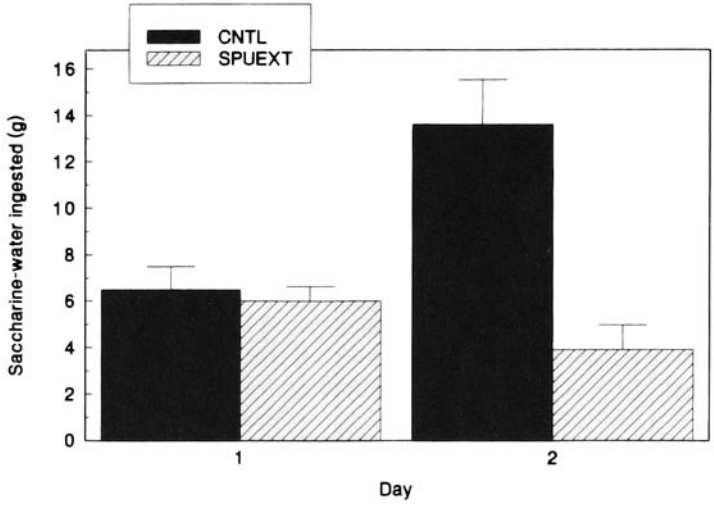

FIG. 2. Ingestion by rats of saccharine–water before and after they were gavaged with either an acetone extract of leafy spurge (SPUEXT) or only the vehicle (CNTL).

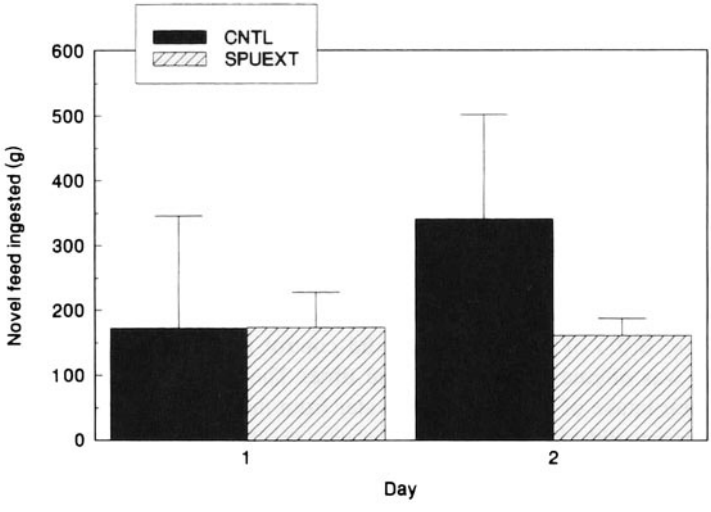

FIG. 3. Ingestion by sheep of rolled oats before and after they were bolused with either a gelatin capsule containing an acetone extract of leafy spurge (SPUEXT) or an empty gelatin capsule (CNTL).

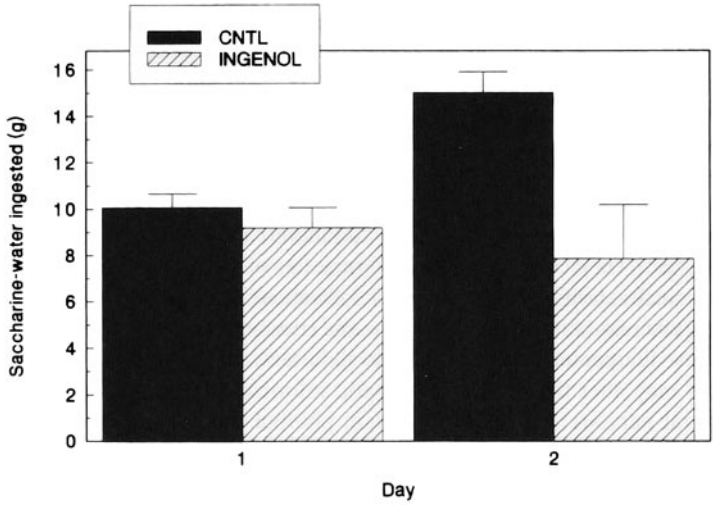

FIG. 4. Ingestion by rats of saccharine water before and after they were gavaged with either ingenol 3-monobenzoate (INGENOL) or only the vehicle (CNTL).

the control sheep (treatment group CNTL) when they were offered this food a second time.

Trial 5. Rats in treatment and control groups ingested similar ($P = 0.67$) amounts of the saccharine-water on the first day of the test period (Figure 4). However, rats that received a gastric infusion of ingenol 3-monobenzoate after ingesting the saccharine-water (treatment group INGENOL) ingested less ($P < 0.01$) of this solution than did control rats (treatment group CNTL) when it was offered to them a second time. The control rats increased ($P < 0.05$) their intakes of the liquid from the first to the second days, but the treatment rats did not ($P < 0.50$).

DISCUSSION

We interpret the results from the trials to suggest that leafy spurge can elicit an aversive feeding response in rats as it does in cattle and sheep (Kronberg et al., 1993a; Kronberg and Walker, 1993). Additionally, an acetone extract of leafy spurge can elicit an aversive feeding response in both rats and sheep; therefore, the aversive compounds in leafy spurge are apparently soluble in acetone. Given the results from the rat trials, we suggest that rats may be effective models for cattle and sheep with respect to studies on phytochemicals in leafy spurge that influence the feeding behavior of these livestock. Results

from the fifth trial indicate that an ingenol ester may be an aversion-inducing component of leafy spurge.

Ingenol and its esters vary considerably in their biological activity. Ingenol, the parent alcohol, has no to weak activity (Hirata 1975; Hirota et al., 1980; Hasler et al., 1992), certain ingenol esters exhibit inflammatory effects or tumor promotion (Upadhyay et al., 1978; Seip and Hecker, 1982; Sorg and Hecker, 1982), and another ingenol ester has antitumor activity (Kupchan et al., 1976). Hirota et al. (1980) found considerable variation in the toxicity of various ingenol esters to fish. They concluded that acyl moieties of ingenol ester were necessary for piscicidal activity. Certain ingenol 3,20-diesters had the greatest piscicidal activity; whereas certain ingenol mono- and triesters had weak toxicity. Ingenol, the parent diterpenoid, was not toxic to their fish. In addition to these findings, ingenols may alter the transfer of genetic information or have other effects on the central nervous system as do certain phorbol esters (Speroni et al., 1991; Cahill and Perlman, 1992; Emanuel et al., 1992; Van, 1993).

The type of ingenol esters contained in leafy spurge appears to vary as a function of environmental factors (Seip and Hecker, 1982) such that leafy spurge growing at two locations and/or times may exhibit different effects on the animals that ingest it. This may explain why the palatability of leafy spurge to sheep appears to vary as a function of location of the leafy spurge (Kronberg et al., 1992).

The capacity of ingenol and different ingenol esters to activate PKC is quite variable. Hasler et al. (1992) found that ingenol binds to and activates PKC weakly with a K_i of 30 μM. In contrast, ingenol 3-monobenzoate had an apparent K_i of 0.14 $\pm$ 0.04 nM for PKC, while ingenol 3,20-dibenzoate had a K_i of only 240 $\pm$ 9 nM for PKC (Winkler et al., 1993). This may explain why ingenol 3,20-dibenzoate did not elicit an aversion in sheep when it was injected into their blood stream after ingestion of a novel feed (Kronberg and Walker, 1993).

Lithium has induced food aversions in a large variety of animals (Riley and Tuck, 1985). Lithium chloride and phorbol 12-myristate 13-acetate (PMA, a compound that activates PKC and has a structure similar to that of the ingenol esters) appear to share a similar effect in certain mammalian cells. Both lithium and PMA inhibit gene expression for phosphoenolpyruvate carboxykinase and thereby inhibit gluconeogenesis (Chu and Granner, 1986; Bosch et al., 1992). Perhaps lithium and ingenol esters elicit aversion through related mechanisms. This may help to explain why both leafy spurge and lithium elevate blood cortisol levels and condition food aversions in certain mammals (Hennessey et al., 1976; Smotherman et al., 1976; Smotherman, 1985; Kronberg et al., 1993b).

Kronberg et al. (1993b) and others (Ader, 1976; Braveman, 1977; Smotherman, 1985) have argued that stress and activity of the hypothalamic-pituitary-adrenal (HPA) axis is involved in the development of conditioned aversions. Therefore, if ingenol esters exist in leafy spurge that can activate PKC, then

activity of corticotropin releasing hormone is likely stimulated (Van, 1993) and, consequently, the HPA axis is likely activated (Kronberg et al., 1993) when leafy spurge is ingested and ingenol esters are absorbed into the blood stream from the digestive tract. This process may lead to avoidance of leafy spurge by the offended animal.

In summary, we interpret our data to suggest that leafy spurge can elicit food aversions in rats as it does in cattle and sheep; consequently, rats can be used to model certain interactions of leafy spurge with these ruminant species. We also suggest that one or more ingenol esters may exist in leafy spurge that can elicit aversions in certain mammals and cause these mammals to avoid future ingestion of leafy spurge. However, other compounds may exist in leafy spurge that can also elicit conditioned food aversions or may be the only or primary aversive chemicals.

Acknowledgments—We thank J.D. Winkler for his generous gift of the ingenol monobenzoate used in the fifth trial and E. Carter for his assistance in conducting some of the trials. We also thank C. Dwivedi, D.C. McFarland, and anonymous reviewers for their comments on the manuscript.

(Received December 9, 1994; accepted April 24, 1995)

Abstract—Three volatile ketones, 2-tridecanone, (*E*)-3-tridecen-2-one and (*E*)-4-tridecen-2-one were identified in interdigital gland extracts from black-tailed deer, *Odocoileus hemionus columbianus*. The major compound, (*E*)-3-tridecen-2-one, inhibited the growth of several species of fungi and gram-positive bacteria. The bacterium, *Propionibacterium acnes*, and the fungus, *Trichophyton mentagrophytes* required a minimum concentration (MIC) of 12.5 μg/ml and 25 μg/ml, respectively, for inhibition. (*E*)-3-Tridecen-2-one represents a new class of lipid antibiotics found on animal skin. The second major compound is this secretion, 2-tridecanone, was not active against any of the organisms tested.

Key Words—Antibiotic lipids, antimicrobial activity, Cervidae, deer, gram-positive bacteria, fungi, interdigital gland, *Odocoileus hemionus columbianus*, 2-tridecanone, (*E*)-3-tridecen-2-one, (*E*)-4-tridecen-2-one.

INTRODUCTION

Interdigital glands are found in most species of deer (Cervidae), antelope (Bovidae), and pronghorns (Antilocapridae). There have been few investigations on the chemical composition of the secretion from this gland. A single Old World cervid, the reindeer, *Rangifer tarandus tarandus* (Andersson et al., 1979; Brundin et al., 1978; Brundi and Andersson, 1979; Sokolov et al., 1974) and one African antelope, the bontebuck, *Damaliscus dorcas dorcas* (Burger et al., 1976, 1977) have been investigated.

It has long been speculated that interdigital glands are involved in semiochemical communication. Lydekker (1898) suggested their function was "to leave a strong scent upon the ground over which their owner has passed." Research on reindeer interdigital gland secretion indicates that one function may be track-laying and track-following. Müller-Schwarze et al. (1978) showed that reindeer actively investigate interdigital gland secretion of conspecifics, and Brundin et al. (1978) indicated response to two short-chain acids of this secretion, isovaleric and isobutyric acids. The compounds identified from the interdigital (pedal) gland of the bontebuck have not been the subject of a comprehensive behavioral study. In preliminary tests, intense interest in these compounds was reported to have been elicited in two captive animals (Burger et al., 1976), but a later report indicated limited response of conspecifics to interdigital gland secretion or to its components (Bigalke and Novellie, 1979).

Black-tailed deer (*Odocoileus hemionus columbianus*) are a subspecies of mule deer that inhabit the Pacific coastal mountain ranges of North America from central California to central British Columbia and have well-developed interdigital glands in fore- and hind-feet. We investigated the volatile compounds of these glands and identified three ketones (Figure 1). Due to the difficulty of doing behavioral experiments on free-ranging animals and the fact that Müller-Schwarze (1971) had not observed any specific behavior associated with deer smelling the hoof prints of conspecifics, we investigated other possible natural functions of these compounds. Hoof rot has been reported to have a serious effect on the mortality of black-tailed deer in areas where they are forced to concentrate at muddy springs (Tabor and Dasmann, 1958). Since, to our knowledge, antimicrobial properties of mammalian exocrine gland secretions have been little investigated, we tested the two major compounds for activity. One compound, (*E*)-3-tridecen-2-one, showed antibiotic activity against fungi and gram-positive bacteria.

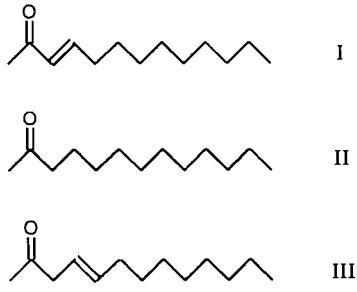

FIG. 1. The ketones identified from black-tailed deer interdigital glands: (*E*)-3-tridecen-2-one (I), 2-tridecanone (II), and (*E*)-4-tridecen-2-one (III).

METHODS AND MATERIALS

The interdigital gland secretion from five male and three female deer were obtained from animals taken by sport hunters or under depredation permits for crop damage. All animals were from Humboldt County, California. One was a yearling and the others were at least 2 years old.

Soon after harvesting, the secretion was scraped from the glands and extracted with dichloromethane. The resulting solution was filtered through glass wool and then analyzed by gas chromatography–mass spectroscopy (GC-MS). Fore- and hind-foot glands were examined separately to see if there was a difference in the secretions. As a control, samples of hair from fore- and hind-legs, twice the weight of the material from the gland, were removed 5 in. above the gland from two males and two females. This hair was extracted and analyzed as described for material from the gland.

GC-MS was performed using a Hewlett-Packard gas chromatograph (model 5890) fitted with a mass selective detector (model 5970) using a 12-m cross-linked methyl silicone capillary column (HP-1). The gas chromatography was programmed so the oven temperature was kept at 40°C for 4 min, then increased to a final temperature of 250°C at a rate of 30°C/min and kept at this temperature for 4 min. Mass spectral fragments below $m/z = 35$ were not recorded. The relative amount of each component is reported as the percent of the total ion current.

(*E*)-3-Tridecen-2-one (I) was synthesized by the method of Kologrivova and Belnov (1958). (*E*)-4-Tridecen-2-one (III) was a minor by-product in the synthesis of 3-tridecen-2-one. A pure sample was obtained by preparative gas chromatography using a Varion Aerograph model 90P TC gas chromatograph fitted with a 2-m × 8 mm 5% SE-30 column.

FT-IR was performed on a Perkin-Elmer 1600 and NMR on a Bruker QE Plus. Microozonolysis was accomplished as described by Beroza and Bierl (1966) and products were identified by GC-MS. The isomerization of (*E*)-4-tridecen-2-one to (*E*)-3-tridecen-2-one was effected by adding one drop of 12 M HCl to 2 mg of (*E*)-4-tridecen-2-one in 20 ml of diethyl ether. GC-MS analysis was executed at 1, 10 and 24 hr.

(*E*)-3-Tridecen-2-one and 2-tridecanone (Pfaltz & Bauer) were tested against the following strains of microorganisms purchased from the American Type Culture Collection (Rockville, Maryland): *Bacillus subtilis* ATCC 9372, *Brevibacterium ammoniagenes* ATCC 6872, *Staphylococcus aureus* ATCC 12598 (a methicillin-susceptible strain), *Streptococcus mutans* ATCC 25175, *Propionibacterium acnes* ATCC 11827, *Pseudomonas aeruginosa* ATCC 10145, *Enterobacter aerogenes* ATCC 13048, *Escherichia coli* ATCC 9637, *Proteus vulgaris* ATCC 133315, *Saccharomyces cerevisiae* ATCC 7754, *Candida utilis*

ATCC 9226, *Pityrosporum ovale* ATCC 14521, *Penicillium chrysogenum* ATCC 10106, and *Trichophyton mentagrophytes* ATCC 18748.

Except for *S. mutans*, bacterial cultures were grown in 0.8% nutrient broth (BBL), 0.5% yeast extract (Difco), and 0.1% glucose (NYG broth). *S. mutans* was cultured in 3.7% brain–heart infusion broth (Difco). All fungi, except *P. ovale* and *T. mentagrophytes*, were cultured in 2.5% malt extract broth (BBL). *P. ovale* was cultured in 1% bactopeptone (Difco), 0.5% yeast extract, 1% glucose, and 0.1% corn oil. For *T. mentagrophytes*, the culture medium consisted of 1% bactopeptone and 4% glucose.

Freeze-dried samples of microorganisms were prepared for testing as follows: *B. subtilis*, *S. cerevisiae*, *C. utilis*, and *P. ovale*, were cultured in shake flasks for two days at 30°C. *P. chrysogenum* and *T. mentagrophytes* were cultured in shake flasks for five days at 30°C. *B. ammoniagenes* and *E. aerogenes* were grown stationary at 30°C. *S. aureus*, *S. mutans*, *P. acnes*, *P. aeruginosa*, *E. coli*, and *P. vulgaris* were grown stationary at 37°C.

The minimum inhibitory concentration (MIC) of the 3-tridecen-2-one and 2-tridecanone was determined using a twofold serial broth dilution. Each test compound was dissolved in DMF and 20 μl of this sample was dissolved in 3 ml of the appropriate medium. A 30 μl sample of the previously described culture of each microorganism was added to the various media solutions. After two days the cultures of *B. subtilis*, *S. cerevisiae*, *C. utilis*, *B. ammoniagenes*, *E. aerogenes*, *S. aureus*, *S. mutans*, *P. acnes*, *P. aeruginosa*, *E. coli*, and *P. vulgaris* were examined for turbidity (OD at 660 nm). The fungi, *P. ovale*, *P. chrysogenum*, and *T. mentagrophytes*, were examined visually for growth at three days (*P. ovale*) and five days (*P. chrysogenum* and *T. mentagrophytes*). The MIC was determined to be the lowest concentration of each compound for which no growth was observed. The highest concentration used in these tests was 800 μg/ml.

RESULTS

The secretion is an unctuous material that covers the inner surface of the gland and adheres to the hair growing in the gland. It exudes from the gland and stains the hair on the dorsal surface of the foot and the hair between the hooves. GC-MS analysis of dichloromethane extracts of this secretion from both male and female showed the same major compound with a retention time of 9.45 min. The relative amount of compound varied considerably, but not consistently, between fore- and hind-foot extracts and between male and female. These amounts ranged from 8% to 57% of the volatiles, with an average of 31%.

This compound exhibited a molecular ion at $m/z = 196$, which suggested

a compound with a molecular formula of $C_{13}H_{24}O$, containing two sites of unsaturation. The base peak at $m/z = 43$ indicated that one site of unsaturation is due to a methyl ketone (CH_3-CO-). A fragment at $m/z = 69$ implied that a double bond is adjacent to the ketone ($CH_3-CO-CH=CH-$). A possible candidate compound, 3-tridecen-2-one, was synthesized (Kologrivova and Belnov, 1958) and found to have identical retention time and mass spectrum as the major compound in the gland. The natural sample of 3-tridecen-2-one was shown to be the *E*-isomer by the ^1H NMR coupling constant of 15.9 Hz for the olefinic protons and an IR absorption at 980 cm^{-1}. The spectral properties of this liquid are 300 MHz ^1H NMR ($CDCl_3$) $\delta = 6.81$ (dt, 1H, $J = 15.9$ Hz, 6.9 Hz), 6.06 (dt, 1 H, $J = 15.9$ Hz, $J = 1.48$ Hz), 2.24 (s, 3H), 2.22 (quart, 2H), 1.46 (m, 2H), 1.26 (m, 12H) and 0.88 (t, 3H); 75 MHz ^{13}C NMR ($CDCl_3$) $\delta =$ 198.80, 148.69, 131.24, 32.47, 31.85, 29.46, 29.37, 29.27, 29.17, 28.07, 26.79, 22.65, and 14.09; FT-IR (neat) 2925, 2854, 1700, 1677, 1628, 1467, 1360, 1253, 1189 and 980 cm^{-1}; and EI-MS $m/z = 196$ (M^+, 2), 181 (8), 97 (31), 96 (14), 83 (22), 81 (20), 71 (34), 69 (31), 55 (65), 43 (100), 41 (44). This is the first identification of 3-tridecen-2-one from a natural source.

A second compound with a retention time of 9.24 min was found in all samples and was the second most abundant volatile. The relative amount of the second compound varied considerably, but not consistently, between fore- and hind-foot extracts and between male and female. The amount ranged from a trace to 30% of the volatiles, with an average of 9.6%. This compound had a molecular ion at $m/z = 198$ that indicated a molecular formula of $C_{13}H_{26}O$ and one site of unsaturation. The base peak at $m/z = 43$ suggested a methyl ketone (CH_3-CO-). A major fragment at $m/z = 58$ due to a McLafferty rearrangement ($CH_3-CO-CH_3$) corroborates a methyl ketone. A possible candidate compound, 2-tridecanone, had the same mass spectrum and retention time as the compound from the deer's gland. The EI-MS of this compound was $m/z =$ 198 (M^+, 1.3), 96 (3.7), 85 (6.2), 71 (23), 69 (4.2), 59 (32), 58 (92), 55 (13), 43 (100), 41 (32) and 39 (8.1).

The number of other compounds seen in the gas chromatogram varied with each different extract. At the low end, one extract had three volatile components and at the high end there were 45 detectable compounds. While the number of volatile compounds varied considerably, there was no consistency between fore- and hind-foot or male and female. The identities of these minor compounds were not investigated except for a compound with a retention time of 9.21 min. This compound was observed in all samples but one and ranged in amount from a trace to 5% of the volatiles, averaging 1.2%.

This minor compound exhibited a molecular ion at $m/z = 196$ and a base peak at $m/z = 43$, suggesting it was an isomer of (*E*)-3-tridecen-2-one. The mass spectrum and retention time of this compound were identical to a minor component observed in the preparation of (*E*)-3-tridecen-2-one. A synthetic

sample of the compound was isolated by preparative gas chromatography. The FT-IR spectrum showed an unconjugated carbonyl absorption at 1718 cm^{-1} and an absorption at 968 cm^{-1}, indicating a *trans*-double bond. The double bond was shown to be at the 4 position by ozonolysis. Nonanal, one product expected on ozonolysis of a double bond at this position, was identified by comparison with an authentic sample using GC-MS. Also as expected, (*E*)-4-tridecen-2-one isomerized to the more stable (*E*)-3-tridecen-2-one on treatment with hydrochloric acid. The spectral properties of this liquid are FT-IR (neat) 2924, 2854, 1718, 1653, 1457, 1356, and 969 cm^{-1}, and EI-MS m/z = 196 (M^+, 0.4), 96 (4), 69 (5), 55 (10), 54 (6), 43 (100) and 41 (12). 4-Tridecen-2-one has not been reported previously in the chemical literature.

GC-MS analysis of extracts from the control samples of hair removed from the leg above the interdigital gland showed none of the ketones identified in the interdigital gland secretion. Clearly, the source of these compounds is the interdigital gland secretion.

In order to determine whether the two major interdigital gland ketones were active against microorganisms, these compounds were tested with various bacteria, yeast, and fungi. (*E*)-3-Tridecen-2-one showed activity [minimum inhibitory concentration (MIC)] against the gram-positive bacteria *Bacillus subtilis* (100 μg/ml), *Brevibacterium ammoniagenes* (100 μg/ml), *Staphylococcus aureus* (50 μg/ml), *Streptococcus mutans* (25 μg/ml), and *Propionibacterium acnes* (12.5 μg/ml). This compound was not active (MIC > 800 μg/ml) against the gram-negative bacteria *Pseudomonas aeruginosa*, *Enterobacter aerogenes*, *Escherichia coli*, and *Proteus vulgaris*. Activity against yeast was mixed; no activity (MIC > 800 μg/ml) was observed against *Saccharomyces cerevisiae* and *Candida utilis*, although *Pityrosporum ovale* was moderately inhibited (MIC, 100 μg/ml). Weak activity was observed with the fungus *Penicillium chrysogenum* (MIC, 800 μg/ml), while the fungus *Trichophyton mentagrophytes* was strongly inhibited at 25 μg/ml. 2-Tridecanone showed no activity against these microorganisms.

DISCUSSION

The ketones, (*E*)-3-tridecen-2-one, (*E*)-4-tridecen-2-one, and 2-tridecanone, from the interdigital gland of the black-tailed deer are similar to many compounds identified from other species. 1-Hydroxy-7-methyl-3-octanone, 7-methyl-1-octen-3-one, 7-methyl-3-octanone, and 6-methyl-2-heptanone are reported as constituents in the interdigital gland secretion of the reindeer (Andersson et al., 1979). The seasonal variation of three of these ketones was later studied by Brundin and Andersson (1979). Eight short-chain carboxylic acids were also found in reindeer interdigital gland secretions (Brundin et al., 1978).

The only other ungulate interdigital gland secretion that has been investigated is that from the bontebok, a rare antelope from South Africa (Burger et al., 1976, 1977). The major volatile constituent found in this gland was (*Z*)-5-undecen-2-one. Minor components from this gland included four methyl ketones: 2-heptanone, 2-nonanone, 2-undecanone, and 2,5-undecanedione.

It is widely believed that a major function of the interdigital glands is semiochemical communication with conspecifics. Two studies have shown that reindeer actively investigate interdigital gland secretion and that it may act as a trail pheromone for single animals separated from the herd (Müller-Schwarze et al., 1978; Brundin et al., 1978). Preliminary biological tests of synthetic compounds of bontebok interdigital gland secretion elicited intense interest by two captive animals (Burger et al., 1976.) A later report indicated limited response to interdigital gland secretion or to its components but suggested it might be used by conspecifics to indicate use or presence of other animals (Bigalke and Novellie, 1979).

In a report on the pheromones of black-tailed deer, Müller-Scharze (1971) observed deer investigating deep foot prints of conspecifics but saw no specific reaction to this behavior. There may be a connection between the interdigital gland secretion and forehead rubbing, another behavior reported by Müller-Schwarze. Black-tailed deer of both sexes mark dry tips of branches with their forehead. These scent-marked twigs are actively investigated by other deer and may help to mark territories, since introduced deer retreat upon smelling the twigs marked by inhabitants of the area. Müller-Schwarze observed deer rubbing their hind leg over their forehead. Since the secretion of the hind-foot interdigital gland stains the dorsal surface of the foot, it may be transferred to the head and become part of the forehead pheromone. We did not undertake behavioral studies of these compounds, and further studies are needed to determine the semiochemical role of these ketones.

The major compound from the interdigital gland shows a broad range of activity against microorganisms, suggesting that a major function of interdigital gland secretions might be to produce antibiotics. The speculation that the function of ungulate interdigital gland secretion is used primarily for semiochemical marking may need to be reinvestigated. Interdigital gland compounds may serve a dual function as semiochemical markers and antibiotics. It is also possible that antimicrobials may be included in animal exocrine gland secretions to keep semiochemicals from being metabolized by microorganisms.

Antibiotic lipids have previously been identified from the skin of animals. These compounds are fatty acids and their monoglycerol esters (Kabara et al., 1977; Bibel et al., 1989) and glycerosphingolipids and phopholipids (Bibel et al., 1989). To the best of our knowledge, (*E*)-3-tridecen-2-one represents a new class of lipid antibiotics found on animal skin. This ketone is water insoluble and would be adsorbed on skin, hair, and hoof. It is of note that *T. mentagro-*

phytes, the organism responsible for athlete's foot in humans and that also infects other animals, is strongly inhibited by this compound.

Acknowledgments—For obtaining the specimens, the authors thank Professors Mervin P. Hanson and Denis A. Potter of Humboldt State University, and Herb Pierce and Nick Albert of the California Department of Fish and Game.

(Received September 12, 1994; accepted May 16, 1995)

Abstract—The composition of the sex pheromone of *Sesamia grisescens* was investigated using gas chromatography, electroantennograms, and field trapping. (*Z*)-11-Hexadecenyl acetate and (*Z*)-11-hexadecenol were identified in field tests as the major attractants. Trapping trials identified a 3:2 blend of these compounds as the most effective bait. Gas chromatography indicated the presence of hexadecyl acetate, (*Z*)-9-hexadecenyl acetate, (*Z*)-9-hexadecenol, and (*E*)-11-hexadecenyl acetate in the pheromone gland, but these compounds had no significant effect on trap catches when added to the major components. Traps baited with the major components in a 1:1 ratio caught more male moths than traps baited with virgin females.

Key Words—Caneborer, sugarcane, trapping, electroantennogram, sex pheromone, attractant, Insecta.

INTRODUCTION

The noctuid borer, *Sesamia grisescens*, has been recorded from sea level to 1600 m above sea level on the Papua New Guinea (PNG) mainland and offshore islands (Szent-Ivany and Ardley, 1962; Bourke, 1968; Anon., 1969; Bourke et al., 1973). Known host plants include sugarcane, *Saccharum officinarum* L.; edible "pitpit," *Saccharum edule* Hassk; wild "pitpit," *Saccharum robustum* Brandes and Jeswiet ex Grassl (Bourke, 1968; Anon., 1969; Bourke

*To whom correspondence should be addressed.

et al., 1973; Young, 1982; Li, 1985); *Saccharum spontaneum*, *Pennisetum purpureum*, and *Panicum maximum* (Young and Kuniata, 1992).

S. grisescens is the most important insect pest of sugarcane in the Ramu Valley of Papua-New Guinea. Although the extent of damage varies from year to year, losses are always significant, and in 1987 were estimated at $A10 million (P. Sweet, Ramu Sugar Ltd., personal communication, 1991). Adult females deposit clusters of ca. 120 eggs beneath tightly folded leaf sheaths, from whence newly hatched larvae bore into the cane stems in which they complete their larval development and pupate before emerging as adults. Thus, no immature stage is amenable to control with contact insecticides. The systemic insecticide Furadan has proven ineffective and, so far, attempts at biological control with the larval parasite *Cotesia (=Apantales) flavipes* (Hymenoptera: Braconidae) have been of limited value. Lack of a suitable means of control, a risk of entry into Australia, and a desire by the Australian Quarantine Inspection Service for an effective means of detecting the presence of *S. grisescens* led to an attempt to identify the insect's pheromone, which could then be employed in traps for quarantine purposes and be evaluated as a mating disruptant for control.

Attractants or pheromones are known for four *Sesamia* species. *S. cretica* is attracted to a mixture of (Z)-9-tetradecenyl acetate (Z9-14:OAc) and (Z)-9-tetradecenol (Z9-14:OH) (Arsura et al., 1977). These two compounds, together with (Z)-11-hexadecenyl acetate (Z11-16:OAc) and (Z)-11-hexadecenol (Z11-16:OH), have been found in the pheromone gland of *S. calamistis* (Zagatti et al., 1988). Furthermore, Z11-16:OAc and Z11-16:OH have been found to be components of the pheromone of both *S. nonagrioides* (Sreng et al., 1985; Rotundo et al., 1985; Mazomenos, 1989) and *S. inferens* (Nesbitt et al., 1976; Wu and Cui, 1986; Zhu *et al.* 1987). It was considered likely that a combination of some or all of these compounds would also be attractive to *S. grisescens*.

MATERIALS AND METHODS

Insect Material. Pupae were collected from sugar cane at Ramu Sugar Ltd. plantations at Gusap in Papua New Guinea during the first week of August 1991. The male and female pupae (100 of each) were separated and packed in sealed containers, which were hand delivered to quarantine in Canberra, Australia (Whittle et al., 1993). The timing of the collection was chosen as an additional precaution against accidental release and establishment of the pest in Australia since it is unlikely that it could survive under the climatic conditions in Canberra at this time of year. Moreover, there are no known host plants in the vicinity of Canberra.

Male and female pupae were placed in separate cages in an environment cabinet with a relative humidity of 70–80% and temperatures of 25°C and 20°C, respectively, at 12L:12D. At the beginning of each photophase, emerged adults

were collected and held individually in waxed paper cups fitted with clear plastic lids and a feeding tube containing 5% honey solution. At no time were the insects permitted to mate. At the end of the investigation, apart from voucher specimens lodged with the Australian National Insect Collection, all insect material was destroyed.

Identification of Pheromone Gland Components. Observation of mating behavior in *S. grisescens* has shown that the moths become sexually active 1 hr before dawn (L.S. Kuniata, unpublished data). Ovipositors were excised from 3-day-old female moths 3–4 hr before the onset of photophase. The ovipositor was placed in a small test tube drawn from 4-mm-ID glass tubing and allowed to stand for 15 min in 15 μl of hexane (Waters Associates, HPLC grade). The hexane extract (and washings, 5 μl) was removed with a syringe and injected in 3-μl aliquots into a small glass tube packed with glass beads (60–80 mesh, 250 mg). Hexane was evaporated from each aliquot in a gentle stream of nitrogen (60 sec, 20 ml/min). Pheromone components were then evaporated from the glass beads under helium (5 ml/min) at 135°C for 10 min, and the effluent was trapped in a cooled (Dry Ice) glass capillary connected by glass-lined stainless steel tubing and PTFE sleeve. The trapped volatiles were washed from the capillary by injecting and then recovering a bead of hexane (2 × 10 μl). A reference mixture of normal hydrocarbons (C_{18}, C_{19}, C_{20}, C_{22}, C_{24}; or C_{17}, C_{19}, C_{21}, C_{23}; 10 ng/component) was added. The mixture was then examined by gas chromatography using Varian 3300 and Carlo Erba HRGC 5300 instruments fitted with splitless injectors and capillary columns (SGE BP20, polyethylene glycol, bonded phase 1.0 μm, 25 m × 0.32 mm, 170°C and SGE BP5, 5% phenyl siloxane, 95% dimethyl siloxane, bonded phase 1.0 μm, 12 m × 0.32 mm, 210°C, respectively; carrier gas was He). Injections were made at 40°C and isothermal conditions maintained for 4 min (inlet purged after 2 min). The column oven was then rapidly heated (50°C/min) to the operating temperature (170°C or 210°C) and the remainder of the run completed isothermally at that temperature. Under these conditions the log/linear relationship between retention time and carbon number still applies and computed Kovats indices are reproducible to ±0.3 units (Bellas, 1975; Guardino et al., 1976). Data were collected with a Hewlett Packard HP3392A integrator and a DAPA data system (DAPA Scientific Pty. Ltd., Western Australia). Peaks were assigned by coincidence with those obtained from known compounds.

Electrophysiology. Electroantennogram measurements were carried out as previously described (Rumbo, 1988), with a few small differences. Instead of using a glass electrode to connect to the tip of the antenna, the stump remaining after cutting off a few terminal segments from the tip of the antenna was covered with a conductive gel (Lectrogel, an electrosurgical preparation from Valleylab) and a Ag–AgCl electrode inserted into the gel. Lectrogel was similarly used to cover a slit made in the abdomen of the insect for the ground electrode.

Sets of sources containing 10 μg of *Z* and *E* isomers of C_{14} and C_{16} alkenyl

acetates were tested against the male antennae. A blank source was added to each set and sources within a set were presented at random as prompted by a microcomputer. Each set of sources was presented to the same insect three or four times depending on the life of the antenna. A different insect was used for each set. To compensate for aging effects and varying sensitivity between antennae, the measurements were normalized to an average response of unity.

Preparation and Analysis of Baits. All synthetic acetates and alcohols were of >99% purity by gas chromatography and obtained from the Research Institute for Plant Protection, Wageningen, The Netherlands, and Shin-Etsu Chemical Co. Ltd., Japan. Synthetic pheromone baits were prepared by dispensing 10 μl doses from stock solutions of candidate components onto 20 mm lengths of surgical rubber tubing (4.5 mm ID, 6.5 mm OD). The stock solutions contained the candidate mixture as a 10% v/v solution in toluene. Rubber tubing dosed with 10 μl of toluene alone provided blanks. The particular compounds or mixtures, together with ratios, are indicated in Tables 1 and 3 below.

In order to measure the volatiles released from a synthetic pheromone bait, five baits were threaded on a wire and placed in a glass tube through which was passed a stream of nitrogen at 60 ml/min. Volatiles in the nitrogen stream were trapped at the outlet with a small tube packed with glass beads (described above). After a collection time of at least 24 min, the trapped volatiles were desorbed and analyzed by gas chromatography as described above using an SGE BP10 column (14% cyanopropylphenyl siloxane, 86% dimethyl siloxane, bonded phase 0.5 μm, 12 m × 0.32 mm, 160°C).

Field Trials. Field trials were carried out using traps similar in design to the Pherocon 1CP trap (Zoecon Company, Palo Alto, California), hereinafter called wing traps. Synthetic pheromone baits were placed centrally on the bases of traps. Virgin female traps were baited with 2- to 3-day-old females obtained from field-collected pupae. They were placed individually in plastic tubes (75 × 26 mm) whose bases and lids had been replaced with fine copper mesh. One such tube was placed centrally on the base of each wing trap. Over the eight days of the trial, there were sufficient females available for a total of 14 trap nights, compared with 40 trap nights for each of the synthetic pheromone blends tested.

Field trials were carried out at Ramu Sugar Ltd. plantations at Gusap, Papua New Guinea. In all trails there were five replicates of each treatment, and the treatments were assigned randomly to traps set 10.5 m apart within and between rows of cane at a height of 1.3–1.5 m. Catches were recorded and cleared daily, and all traps were moved forward one position daily. The first trap in each row was at least 10.5 m from the edge of the crop. Representative moths caught at each treatment were retained for species identification.

Trial 1, using empirical blends (Table 1 below) was carried out in a 16.1-ha plot of variety Cadmus cane between July 25 and August 2, 1991. For trial

2 (Table 3 below), blends were evaluated in a field of variety Q127 cane between September 20 and October 10, 1991. Because of a diminishing population in that field, the trial was reset in another field of the same variety between October 15 and November 4, 1991. In trial 3 (Table 3 below), two blends were compared in a field of H56752 cane between January 1 and March 18, 1992 (trial 3A) and repeated between May 30 and June 8, 1992 (trial 3B). Trial 4 was carried out in fields of Q135 (April 5–June 10, 1993) and Q127 (June 11–August 10, 1993) cane. No blank or virgin female traps were incorporated in trials 2, 3A, 3B, or 4.

In a fifth trial wing traps were compared with more robust plastic delta and Hara traps (Hara Products, Swift Current, Saskatchewan, Canada). All were baited with 1 μl of a 1:1 ratio of Z11–16:OAc and Z11–16:OH and were evaluated in a field of Q127 cane from September 20 to October 10, 1991. Because of diminishing population levels, the trial was moved to another field of the same variety for the period October 15–November 4, 1991.

Trap data were subjected to an analysis of variance, and the significance of differences between means determined using Duncan's MRT. Missing values, which occasionally occurred when rats removed baits from some traps, were replaced with the mean catch of the remaining replicates for the night that the bait was missing. Means shown in Table 1 have been back-transformed following a reciprocal transformation of the original data.

RESULTS

Initial field trials were carried out with a range of compounds and mixtures based on known pheromones or attractants for *Sesamia* species. The results are shown in Table 1. Most moths were caught at a 1:1 combination of Z11–16:OAc and Z11–16:OH, although there was no significant difference between mean catch per trap with this bait and at the 3:1 ratio of the same components ($P < 0.05$). Combinations of Z9–14:OAc and Z9–14:OH were generally unattractive, and none of the single-component baits caught any *S. grisescens*. Over the period of these trials, virgin female traps were put out for a total of 14 trap nights (i.e., the sum of the number of traps on each night that trapping took place), during which three male *S. grisescens* were caught, for a mean of 0.2 males/trap/night. On the same nights, two synthetic blends, 3:1 and 1:1 ratios of Z11–16:OAc and Z11–16:OH, caught 0.5 and 0.4 males/trap/night, respectively. There were insufficient data to analyze for differences between these means.

Electrophysiological and chemical studies were made to confirm the active components of the pheromone and to determine the ratio of these materials in the sex pheromone gland. Electroantennogram responses from male antennae to

compounds of different carbon chain length, double bond position, and isomeric configuration produced significant profiles for tetradecenyl and hexadecenyl acetates (Figure 1). The lower response variability, as indicated by the standard deviations, for the hexadecenyl acetates and the greater response to Z11–16:OAc and E11–16:OAc suggests that one or both of these compounds may be present in the pheromone. The response from Z9–14:OAc is likely to be due to binding to the same active site on the antenna.

The gas chromatographic analyses of ovipositor extracts from individual virgin female moths showed peaks coincident with those for the compounds listed in Table 2. The average amount of the major component (Z11–16:OAc) per gland was 44 ng; however, amounts ranged from 4 to 176 ng. The corresponding alcohol, Z11–16:OH, occurred in significant quantities in all of the extracts examined, although the relative amounts ranged widely (142–2728) about the average value shown in Table 2. The relative amounts of hexadecanol (*n*16:OH) were also found to be extremely variable. This compound was not detectable in 18 of 21 analyses, but in one analysis *n*16:OH was found to be twice as abundant as Z11–16:OAc. A small peak consistent with E11–16:OAc was observed in four of 21 analyses. Similarly E11–16:OH was not usually detectable, but a small peak consistent with this compound was seen in two analyses. Analysis on the BP5 column showed peaks consistent with Z11–16:OAc, Z11–16:OH, and hexadecyl acetate (*n*16:OAc) as the major com-

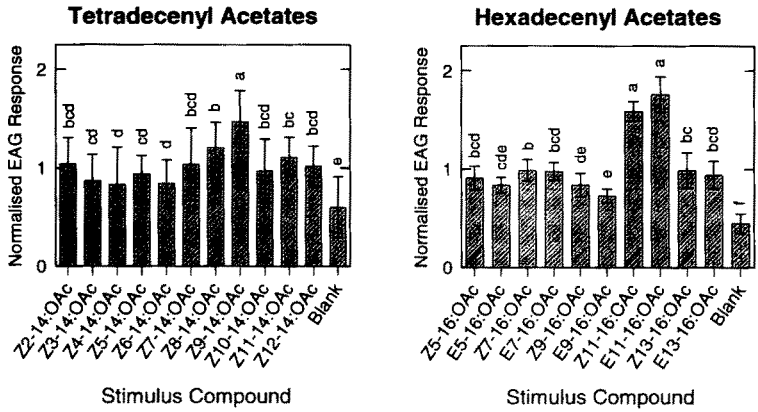

FIG. 1. Electroantennogram (EAG) responses of male antennae from *S. grisescens* to tetradecenyl (14-carbon) and hexadecenyl (16-carbon) acetates. Within each set, results are normalized to an average value of 1.0 and are shown for each double-bond position and isomer tested. Error bars are ± 1.0 SD. Responses not marked by the same letter are significantly different (Duncan's MRT $P < 0.05$).

ponents, although on this column *E* and *Z* isomers are not resolved. Half of one extract was treated with lithium aluminum hydride, which resulted in the disappearance of the acetate peaks in the gas chromatogram when compared to the untreated half of the extract.

The results from the field trial of empirical blends (trial 1, Table 1) sug-

gested that the optimum ratio of Z11-16:OAc to Z11-16:OH lies somewhere between 3:1 and 1:1, while gland content analysis indicated that the addition of Z9-16:OAc, Z9-16:OH, and *n*16:OAc might enhance the attractiveness of the two component mixture. Further trials with the blends shown in Table 3 were undertaken to identify the optimum blend for trapping purposes.

A 3:2 ratio of Z11-16:OAc/Z11-16:OH caught significantly more moths than the 1:1 ratio or the 1:1 blend with the addition of minor components ($P < 0.05$) (trial 2, Table 3). While the addition of the minor components to 3:2 and 1:1 blends of the major components resulted in fewer moths being caught than were taken at the two-component blends alone (trials 2, 3A, and 3B, Table 3), the differences were not significant. Because of the significant EAG response to *E*11-16:OAc and the detection of a peak corresponding to this compound in the gas chromatographic analyses of gland components, 3:2 blends of Z11-16:OAc/Z11-16:OH with and without a small amount of *E*11-16:OAc were compared (trial 4). There was no significant difference between mean catches at the two blends. The ratio of components emitted from baits loaded with a 3:2 mixture of Z11-16:OAc and Z11-16:OH was measured daily for 12 days. The emitted ratio was found to average 10:9.1 ± 0.8 SD.

[a] Mean catch of *Sesamia grisescens* at various mixtures of alkenyl acetates and alcohols. Within trials, means not followed by the same letter are significantly different (trial 2: $P < 0.05$, Duncan's MRT; trials 3 and 4: $P < 0.10$, t test).

In a fifth trial the wing traps were tested against plastic delta traps and Hara traps (using 1:1 Z11-16:OAc/Z11-16:OH as bait) and mean catches (±SD) of 6.8 (2.1), 4.4 (2.0), and 0.8 (1.3), respectively, were obtained. Mean catch at the wing and delta traps were not significantly different from one another, but both were significantly greater than the mean catch at the Hara traps.

In addition to *S. grisescens*, other moths were occasionally caught in the traps. For all trials involving mixtures of Z11-16:OAc and Z11-16:OH, the species caught were a pyralid, *Chilo terenellus* Pagenstecher (16), and three noctuids, *Sesamia inferens* (Walker) (3), a *Mythimna* sp. (2), and a *Hydrillodes* sp. (9).

DISCUSSION

The results from the field trials and chemical/electrophysiological investigations are consistent with the presence of Z11-16:OAc and Z11-16:OH as the principal components of the sex pheromone of *S. grisescens*. In this respect *S. grisescens* is similar to three of the four *Sesamia* species for which information is available. *S. cretica*, which is attracted to a mixture of Z9-14:OAc and Z9-14:OH is the exception. Although Z11-16:OAc is the predominant pheromone component, *S. grisescens* differs in having a far higher proportion of Z11-16:OH compared to the other *Sesamia* species. The gas chromatographic (GLC) analyses of individual pheromone gland contents suggested that the two major components are produced, on average, in a ratio close to 1:1. However there were large differences between individual moths, which indicated that male moths might respond to a range of mixtures, and in the field trials it was found that although baits loaded with a 3:2 ratio were the most attractive to male moths, significant catches were also obtained with 1:1 and 3:1 blends. The GLC analyses of the effluvia from the 3:2 baits showed an OAc-OH ratio of 10:9, close to the average ratio found in the gland and well within the range of values found in the pheromone glands for individual moths (Table 2). Nevertheless, the best definition of the optimum blend will require a study of the effluvia emitted by calling females, a study that was beyond the scope of the present investigation.

The saturated acetate *n*16:OAc was also identified as a pheromone gland component, but there was no evidence for any biological activity for this compound. Similarly, several compounds present in trace amounts were tentatively identified but, when added to the two principal components, failed to enhance the attractancy of the synthetic blend. This was unexpected, particularly with respect to *E*11-16:OAc, which elicited a very strong electrophysiological response from antennae of male *S. grisescens*. It may be that *S. grisescens* needs to discriminate between the *Z* and *E* isomers to ensure its reproductive isolation

from a sympatric species. However, if this is so, it would also be expected that the *E* isomer would have some inhibitory effect. For example, the tortricid *Epiphyas postvittana* shows strong EAG responses to both *E*11-14:OAc and *Z*11-14:OAc. While the *E* isomer is the major component of the pheromone blend, the *Z* isomer is not present in the pheromone gland and is inhibitory when mixed with the *E* isomer at 10% or greater (Rumbo et al., 1993). *E*11-16:OAc was not observed to be inhibitory for *S. grisescens*, and it is not yet known whether the male moth has separate sensory cells for the *Z* and *E* isomers.

The observation that the addition of secondary components to a 3:2 blend of *Z*11-16:OAc and *Z*11-16:OH had little effect on trap catches, and in fact marginally reduced them in one trial, can be compared with the results of Mazomenos (1989). He reported that while the addition of individual secondary components to the major pheromone component of *S. nonagrioides* (*Z*11-16:OAc) reduced male capture, a combination of the major and all secondary components was highly attractive. Although it is possible that further adjustment of ratios or addition of minor components in suitable proportions might provide an improved attractant for *S. grisescens*, the attractancy of the 3:2 blend is sufficient to provide a bait for monitoring purposes. Certainly the synthetic blend was found to be more attractive than a caged virgin female moth. The availability of the synthetic attractant will permit monitoring in Australia for accidental introduction of the pest and allow the natural distribution of the species to be mapped in PNG. Little is currently known about the distribution of *S. grisescens* and, hence, the climatic extremes across its range are unknown. Using weather data for Ramu Sugar Ltd. plantations at Gusap in Papua New Guinea and for the Australian mainland, a climate matching computer program (CLIMEX; Maywald and Sutherst, 1991) indicates that cane-growing areas in the north of Australia might provide a suitable habitat for *S. grisescens*. This model will be refined when further data on the range of the pest becomes available.

The use of the synthetic attractant in monitor traps for either quarantine or survey purposes will require further research. During trapping trials in PNG, other species that were occasionally found in traps included *S. inferens*, a *Mythimna* sp., and more often *C. terenellus* and a *Hydrillodes* sp. *S. inferens* has a distribution that includes New Guinea and has been found to be a pest on sugarcane, but this insect has not been a problem at the Ramu Sugar Ltd. plantations where its population density is very low. A total of three *S. inferens* were trapped during all trials at Gusap, PNG. In a preliminary trial in Australia the synthetic blend attracted single specimens of a noctuid, *Athenis reclusa* (Walker), and a geometrid, *Petelia medardaria* H-Sc. No other moths were trapped, but further trials will be necessary to determine the specificity of the monitor traps in Australia.

The use of synthetic attractants in traps to monitor populations of *S.*

grisescens in PNG may have only limited value in pest control strategies as the pest occurs in sugarcane in discrete generation cycles that are readily determined by sampling egg and larval numbers. However, there is potential for use of a synthetic blend as a mating disruptant, and trials are currently being planned to assess the suitability of a two component blend for this purpose. Control of *S. grisescens* may also assist in the containment of the weevil borer *Rhabdoscelus obscurus* Boisd, the larvae of which enter cane stalks through holes made previously by *S. grisescens*.

(Received December 19, 1994; accepted May 16, 1995)

Abstract—Leaf quality of the mountain birch (*Betula pubescens* ssp. *tortuosa*) for herbivores was studied at several hierarchical levels: among trees, among ramets within trees, among branches within ramets, and among short shoots within branches. The experimental units at each level were chosen randomly. The indices of leaf quality were the growth rate of the larvae of a geometrid, *Epirrita autumnata*, and certain biochemical traits of the leaves (total phenolics and individual phenolic compounds, total carbohydrates and individual sugars, free and protein-bound amino acids). We also discuss relationships between larval growth rate and biochemical foliage traits. Larval growth rates during two successive years correlated positively at the level of tree, the ramet, and the branch, indicating that the relationships in leaf quality remained constant between seasons both among and within trees. The distribution of variation at different hierarchical levels depended on the trait in question. In the case of larval growth rate, ramets and short shoots accounted for most of the explained variation. In the case of biochemical compounds, trees accounted for most of the variance in the content of total phenolics and individual low-molecular-weight phenolics. In the content of carbohydrates (total carbohydrates, starch, fructose, glucose, and sucrose) and amino acids, variation among branches was generally larger than variation among trees. Variation among ramets was low for most compounds. No single leaf trait played a paramount role in larval growth. Secondary compounds, represented by phenolic compounds, or primary metabolites, particularly sugars, may both be

important in determining the suitability of birch leaves for larvae. If phenols are causally more important, genet-specific analyses of foliage chemistry are needed. If sugars are of primary importance, within-genet sampling and analysis of foliage chemistry are necessary.

Key Words—Amino acids, *Betula pubescens* ssp. *tortuosa*, carbohydrates, *Epirrita autumnata*, larval growth, leaf biochemical traits, phenolics, sugars, within-tree variation.

INTRODUCTION

The plant modular structure (Harper, 1977, 1981; White, 1979; Vuorisalo and Tuomi, 1986) and partial physiological autonomy (Watson and Casper, 1984; Watson, 1986; Sprugel et al., 1991) of plant parts has been assumed to have ecological and evolutionary implications for plant growth patterns, resource allocation, and reproduction (Watson and Casper, 1984; Jerling, 1985; Tuomi et al., 1988a,b; Tuomi and Vuorisalo, 1989; Marquis, 1992). Modularity and partial autonomy may also modify interactions between plants and their herbivores and pathogens by increasing within-individual variation in plant quality (Whitham and Slobodschikoff, 1981; Denno and McClure, 1983; Gill and Halverson, 1984; Marquis, 1988; Edwards et al., 1990; Haukioja, 1991a; Suomela and Ayres, 1994; Suomela and Nilson, 1994).

Since food quality is important for herbivore growth, survival, and reproductive capacity (for reviews, see Mattson, 1980; Scriber and Slansky, 1981; Denno and McClure, 1983; Slansky and Rodriguez, 1987), among- and within-tree variation in leaf quality may affect performance of herbivores. Variation may also affect adult oviposition behavior (Thompson, 1988; Renwick and Chew, 1994) and larval search and feeding behaviors (Schultz, 1983). For researchers, variation has implications with regard to experimental design and sampling procedures (Suomela and Ayres, 1994).

In earlier studies we have demonstrated the occurrence of variation in the performance of larvae of the autumnal moth (*Epirrita autumnata*) and of sawfly species on leaves of the mountain birch (*Betula pubescens* ssp. *tortuosa*). There is considerable variation both among years (Hanhimäki et al., 1995) and according to the previous defoliation history of the trees (Hanhimäki, 1989; Ruohomäki et al., 1992). The performance of *E. autumnata* larvae on the mountain birch also varies both among trees growing at the same site and within individual trees. There are systematic within-tree differences in larval growth rate, e.g., among leaves of different sizes and on different positions on the crown (Suomela et al., 1995). In addition, even same-aged short shoot leaves, randomly sampled from a restricted part of the birch canopy, show pronounced within-tree variation in suitability as a food for *E. autumnata* larvae (Suomela and Nilson, 1994).

This may be related to the within-tree variation found in mountain birch leaf water content, specific weight, and toughness (Suomela and Ayres, 1994). Although these traits are only crude measures of plant quality, all of them have previously been claimed to be important for herbivore performance and have often been used to characterize foliage quality (Mattson, 1980; Scriber and Slansky, 1981; Coley, 1983; Ayres and MacLean, 1987; Ayres et al., 1987; Alliende, 1989; Basset, 1992). Detailed analyses of within-tree variation in the biochemical characteristics of mountain birch foliage have not been published.

In general, studies of within-tree variation among randomly or haphazardly sampled same-aged leaves are few (but see Schultz, 1982; Baldwin et al., 1987). However, within-individual variation in characters of the leaves and performance of the herbivores has been measured between leaves of different age or size (e.g., Whitham, 1981; Raupp and Denno, 1983; Meyer and Montgomery, 1987; Howard 1990; Stamp and Bowers, 1990; Bogacheva, 1994; Hikosaka et al., 1994) and between different parts of tree canopies (Jensen, 1988; Watt, 1992; Quiring, 1993).

In this paper we: (1) study the consistency of among- and within-tree variation in the growth rate of larvae of *Epirrita autumnata* on the same trees, ramets, and branches during two successive years; (2) compare patterns of among- and within-tree variation in different biochemical characters of the foliage in the same trees on which the larvae were reared, and (3) discuss the relationship between larval growth and the biochemical characters measured.

METHODS AND MATERIALS

Study Site and Organisms. Mountain birch [*Betula pubescens* Ehrh. ssp. *tortuosa* (Ledeb.) Nyman] forms the treeline in northwestern Europe. The trees (genets) are usually polycormic with several trunks (ramets), most of which originate from dormant basal buds (Kauppi et al., 1987). The growth type of mountain birch is indeterminate with two types of shoots: short shoots and long shoots (Clausen and Kozlowski, 1965). The short shoot leaves (usually three leaves per shoot) burst simultaneously in the spring and are thus of equal age. This is in contrast with the long shoot leaves, which are produced at the branch tips up to the late summer.

The experimental trees were located in a mountain birch forest on the slope of the Skallovaara fell, near the Kevo Subarctic Research Station (69°45′N, 27°E), in northern Finland.

The autumnal moth, *Epirrita autumnata* (Bkh.), is a univoltine polyphagous geometrid. The mountain birch is its most abundant host species in our study area, although the larvae also grow well on several other deciduous trees (Neuvonen et al., 1987; Haukioja et al., 1988a). The adults fly in the autumn

and the females oviposit on trees, where the eggs overwinter and hatch next spring at the time of birch budbreak. The larvae feed for about one month, after which they pupate in ground litter. *Epirrita autumnata* populations fluctuate cyclically at about 10-year intervals and can reach outbreak densities (Tenow, 1972; Haukioja et al., 1988a).

Larval Growth Experiments. We bioassayed leaf quality in the summers of 1990 and 1991 by measuring the growth rates of *E. autumnata* larvae at different hierarchical levels of the birch canopies. At the end of June 1990, we marked 20 mountain birches in a homogeneous semiopen mountain birch forest. We selected only trees that were 2–4 m tall and that had at least three ramets and two branches per ramet. Of these 20 birches, we randomly selected five trees for the experiment, using a random-numbers table. From each tree we randomly selected two ramets, from each ramet two branches, and from each branch a certain number of short shoots. To reduce effects of systematic within-canopy variation (Suomela et al., 1995), we used only branches that were at a height of 1–2 m from the ground and had at least 30 short shoots.

The larvae originated from a stock reared at the Kevo Station. They had always been reared on birch foliage; field-caught adult males were regularly used in matings to prevent inbreeding. During both study years the larvae were taken from several broods and randomly allocated to sample units. During the preexperimental period, larvae were reared individually in plastic vials, with birch leaves collected from trees growing outside the experimental plot.

At the beginning of July 1990 and 1991, we conducted growth trials with fifth-instar *E. autumnata* larvae, rearing them both years on leaves of the same trees, ramets, and branches. In both years we randomly sampled four short shoots per branch. We used different shoots in 1990 and 1991, since damage to leaves in an individual short shoot reduces the size of leaves in that shoot (but not in adjacent shoots) the next year (Ruohomäki et al., unpublished manuscript).

The leaves were excised at the middle of the petiole just before the beginning of the growth trial. The leaf lamina was not damaged, to avoid damage-induced responses in the foliage (Haukioja, 1991b). The leaves were taken to the laboratory in sealed plastic vials (with the leaves of each branch in a separate vial), protected from sunlight. We fed the *E. autumnata* larvae on the two largest leaves per short shoot (one larva per leaf) in the lab for about 24 hr. The number of larvae and leaves was thus 160 (five trees, two ramets per tree, two branches per ramet, four short shoots per branch, and two leaves per shoot) for each experiment. This means that, for very practical reasons, we had a large number of replicates at the lowest levels of the hierarchy but only five replicate trees.

Solitary larvae of *E. autumnata* are more sensitive to variation in food plant quality than larvae reared in groups (Haukioja et al., 1988b). For this reason we reared the larvae individually in 48-ml plastic vials. Leaf turgor was main-

tained by a 1-cm substrate of moistened plaster of Paris. We used larvae that had just molted to the fifth (ultimate) instar; they had, however, started to feed and had filled their guts.

At the start of the trial, each larva was weighed. Both the order of weighings and the order of leaves and vials on the rearing trays was randomized in each experiment. After 24 hr, the larvae were reweighed in the same order. The times of all weighings were recorded to an accuracy of 1 min.

Illumination was continuous, corresponding to natural summer light conditions at the latitude of Kevo. The temperature was +18°C in 1990 and during the first half of the experiment in 1991, but was reduced to +10°C for the second half of the 1991 trial to prevent the larvae from exhausting the leaves too quickly. Otherwise the methods used were similar in the two years.

As an index of leaf quality, we used the relative growth rate of the larvae. It was calculated as follows:

$$\text{Relative growth rate} = [\ln(m_e) - \ln(m_b)]/\text{time}$$

where m_b and m_e are the dry mass of a larva at the beginning and the end of the growth trial, respectively. Larval dry mass (DM) was calculated from the fresh mass (FM) as $DM = 0.125 \times FM^{1.113}$ (Neuvonen and Haukioja, 1984).

Biochemical Measurements. In 1991, we analyzed the contents of phenolics, carbohydrates, and amino acids in the birch leaves. From each branch used to feed the larvae, we clipped 25–30 short shoot leaves at the same time that we collected the leaves for the larval growth experiment. The leaves were collected on ice, transported immediately to the laboratory and freeze-dried.

The analyses were branch-specific. The shoot level had to be omitted, since the leaf mass on individual short shoots was too small to permit the collection of enough leaves for analyses at the shoot level.

The plant material was lyophilized, homogenized to a powder, and stored at +4°C. One gram of the resulting powder was suspended in 10 ml of 70% aqueous ethanol, allowed to stand for 3 hr at room temperature with continuous stirring, and centrifuged at 1500*g* for 15 min. The pellet was reextracted three times. The combined extracts were evaporated under low pressure at 40°C. The residue was redissolved in 10 ml of water and centrifuged (referred to henceforth as water extract).

The total content of phenolic compounds was measured using the Folin-Denis method as described in Marigo (1973) with gallic acid as a standard.

The contents of individual low molecular weight phenolics were determined by high-performance liquid chromatography (HPLC), using a Milichrom-4 chromatograph with a Separon C-18 column. The chromatographic data were used as the "fingerprints" of individual phenolics, since their contents were expressed in relative units: peak height (in millimeters) on the chromatogram per 1 g of dry matter.

The total content of carbohydrates was analyzed using the phenol–sulfuric acid method (Dubois et al., 1956). The contents of glucose, fructose, and sucrose were determined by gas–liquid chromatography. Two millimiters of the water extract containing 10–15 mg of soluble carbohydrates was evaporated at 40°C at low pressure. One milliliter of pyridine was stirred in, and the mixture was desiccated by evaporating three times under the same conditions. The residue was dissolved in 2 ml of pyridine for 12 hr and 0.6 ml of hexamethyldisilasane and 0.3 ml of trimethylchlorsilane (Sigma) were added and stirred for 10 min. After evaporation of pyridine, the residue was dissolved in 2 ml of *n*-hexane.

The contents of the sugars were measured with the Biochrom gas chromatograph, equipped with a flame ionization detector and a capillary column (20 m × 0.32 mm ID) with liquid phase SE-30. The column temperature was increased from 145° to 250°C at a rate of 8°C/min. The detector and injector temperatures were 280° and 190°C, respectively. Helium was used as the carrier gas. The internal standard was sorbitol.

Starch content was measured by the method of Humphreys and Kelly (1961).

To measure free amino acids, 6 ml of the water extract was applied to a column of Dowex HCR-S (70 × 15 mm ID, H^+-form; Sigma). The amino acids retained on the column were eluted with 3 N NH_4OH. The eluate was evaporated and dissolved in water (2.5 ml). The contents of free amino acids were determined by a standard procedure using a Microtechna amino acid analyzer T-339 M. Protein-bound amino acids were analyzed by the method of Lunderstädt (1976).

All biochemical measurements for each powder sample (representing the branch level) were repeated three times, and the mean was used in the statistical analyses. Since we took only one sample per branch, the reliability of the branch level values was checked beforehand by analyzing five separate samples taken from a homogeneous powder. The coefficients of variation among the samples were 2% for total phenolics, 4–23% for individual low-molecular-weight phenolics, 3% for total carbohydrates, 7–9% for sugars, 3–13% for free amino acids, and 0–6% for protein-bound amino acids.

Statistical Analysis. Due to the hierarchical design, the data were analyzed with nested ANOVA (Proc Nested, SAS Institute, 1990). In the larval growth trials the lowest hierarchical level (error variance) included variation within shoots, among larvae, and the measurement error. In the biochemical analyses, the lowest level included variation among branches within ramets plus variation within branches and measurement error.

The distribution of variation among different hierarchical levels was evaluated by comparing the proportions of total variance and the coefficients of variation. The proportions of total variance express the relative contributions of different hierarchical levels to the total variance. The coefficient of variation reveals variation as a proportion of the mean and is used to compare actual

variation between different characters. It was calculated in terms of percentages of estimated standard deviation from the mean (derived from the nested ANOVA model, Proc Nested, SAS Institute, 1990).

The relationships between larval growth and biochemical characters were tested with Pearson's correlation analysis and multiple regression analysis (Proc Corr and Proc Reg, SAS Institute, 1990).

We verified the assumption of normality of the data by evaluating the residuals of the second lowest level (short shoots and ramets in larval growth rate and contents of biochemical compounds, respectively) in nested ANOVA by Shapiro-Wilk's test (Proc Univariate, SAS Institute, 1990). Higher levels were generally not tested, since means follow a normal distribution better than individual values (Sokal and Rohlf, 1981). The distributions of a few biochemical compounds deviated from normal and could not be corrected by any transformations. The homogeneity of variances was tested with Cochran's test (Winer 1971); in a few biochemical compounds the variances differed significantly. There were, however, no deviations from normality or homoscedasticity in those compounds or at those hierarchical levels in which significant differences were found.

RESULTS

Larval Growth Experiments

Ramets (within trees) and short shoots (within branches) accounted for most of the explained variation in the growth rate of *E. autumnata* larvae (Table 1). Variation among trees and branches was smaller, whereas error variance accounted for over half of the total variance. Differences were significant at the shoot level, but insignificant at other levels (Table 1).

TABLE 1. RESULTS OF ANOVA, PROPORTION OF TOTAL VARIANCE (%), AND COEFFICIENTS OF VARIATION (CV) FOR DIFFERENCES AMONG TREES, AMONG RAMETS WITHIN TREES, AMONG BRANCHES WITHIN RAMETS, AND AMONG SHORT SHOOTS WITHIN BRANCHES IN GROWTH RATE OF *E. autumnata* LARVAE IN 1990 AND 1991

Source of variation	Error term	*df*	1990				1991			
			F	*P*	%	CV	F	P	%	CV
Trees	Ramets	4	2.1	ns	12	3.8	0.8	ns	0	0.0
Ramets	Branches	5	3.2	0.06	15	4.2	2.3	ns	15	6.3
Branches	Shoots	10	1.3	ns	3	2.0	1.9	0.06	10	5.3
Shoots	Error	60	1.5	0.04	15	4.1	1.6	0.03	17	6.8
Error		80			55	8.0			57	12.5

The coefficients of variation at other levels than among trees were higher in 1991 than in 1990. The proportion of the variance for branches was also higher in 1991, whereas the reverse was true for trees. The proportion of the variance for ramets and shoots was similar between years (Table 1).

The correlation coefficients in larval growth rates (Figure 1) between the years were positive (branch level, $r = 0.48$, $P < 0.05$, $df = 18$; ramet-level, $r = 0.60$, $P < 0.07$, $df = 8$; tree-level, $r = 0.87$, $P = 0.056$, $df = 3$). Because different shoots were used each year (see Methods and Materials), a correlation at the shoot level was not possible.

Biochemical Traits

Phenolic Compounds. In leaf total phenolic content, trees accounted for most of the variance (Table 2). The coefficients of variation at different levels ranged from 7 to 14% (Table 2). The differences were significant both among trees ($F_{4,5} = 5.4$, $P < 0.05$) and among ramets within trees ($F_{5,10} = 3.9$, $P < 0.05$). Detailed data are presented in Table 3.

Altogether 27 low-molecular-weight phenolic compounds were detected in the leaves (a representative HPLC trace is shown in Figure 2). Ten of these compounds could be identified using preparative HPLC and ^1H and ^{13}C NMR (Ossipov et al., 1995). The compounds identified were 1-*O*-galloyl-(2-*O*-acetyl)-glucopyranoside (no. 1), (+)-catechin (no. 6), chlorogenic acid (no. 8), 3-*O*-*p*-coumaroyl-D-quinic acid (no. 12), myricetin-3-*O*-(acetyl)-rhamnopyranoside (no. 21), quercetin-3-*O*-arabinofuranoside (no. 22), kaempferol-3-*O*-glucopyranoside (no. 23), quercetin-3-*O*-(4′-*O*-acetyl)-rhamnopyranoside (no. 24),

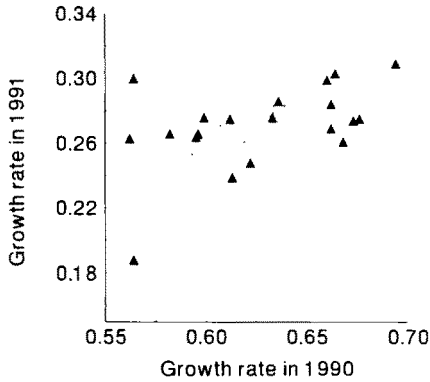

FIG. 1. Mean relative growth rate of *E. autumnata* larvae on individual trees (plus signs), on ramets within trees (squares), and on branches within ramets (triangles) during two consecutive years.

and kaempferol-glycosides (nos. 26 and 27). The contents of different compounds are given in relative units (peak height in millimeters per 1 g of dry matter). According to chromatographic observations at different wavelengths (250, 280, and 340 nm; data not shown), the main phenolic compounds were numbers 1, 8, 12, 21, 22 and 23 (Figure 2).

The 27 phenolic compounds were found in all leaf samples, i.e., there were no qualitative differences among or within trees. Trees accounted in general for most of the total variance in different phenolics (Table 2). In 24 of the 27 compounds, trees accounted for over 75% (in most cases over 90%) of the total variance.

Coefficients of variation among trees ranged from 4% (no. 17) to 164% (no. 26), being less than 50% for two thirds of the compounds. Coefficients of variation among ramets were low, ranging from 0% to 14%. Coefficients of variation among branches (including error variance) ranged from 6% to 24% (Table 2).

Differences among trees were significant in all compounds (in most cases at the $P < 0.001$ level, $F_{4,5}$ values ranging from 8 to 869), except for no. 17, in which most of the total variance was accounted for by branches (including error variance). Differences among ramets were low and mostly insignificant. Only in compounds 13, 16, and 26 were there significant differences among

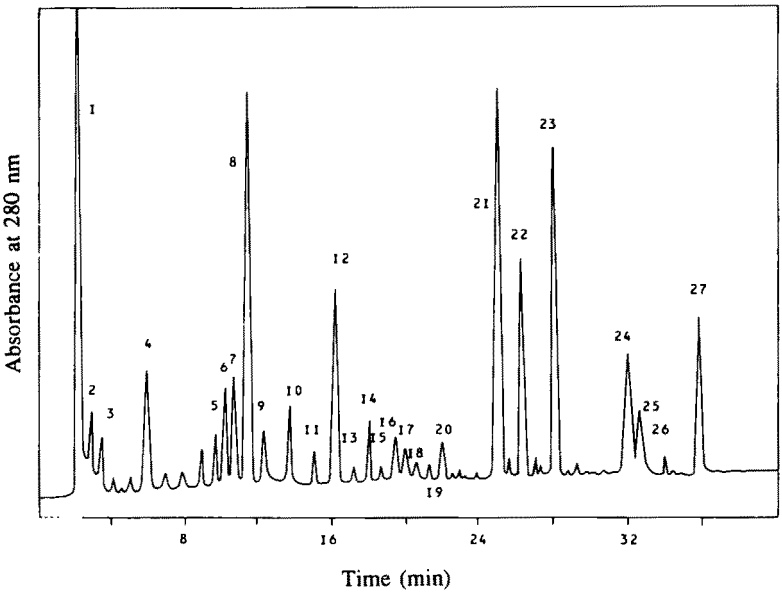

FIG. 2. A typical trace of HPLC analysis of individual low-molecular-weight phenolics (nos. 1–27) from birch leaves: 1, 1-*O*-galloyl-(2-*O*-acetyl)-glucopyranoside; 6, (+)-catechin; 8, chlorogenic acid; 12, 3-*O*-*p*-coumaroyl-D-quinic acid; 21, myricetin-3-*O*-(acetyl)-rhamnopyranoside; 22, quercetin-3-*O*-arabinofuranoside; 23, kaempferol-3-*O*-glucopyranoside; 24, quercetin-3-*O*-(4′-*O*-acetyl)-rhamnopyranoside; 26 and 27, kaempferol-glycosides. Separon C-18 column (64 × 2 mm I.D., 5 μm) at a flow rate of 50 μl/min. Two solvents were used: A, 5% aq. acetic acid; B, 96% aq. ethanol. The elution profile was 0–42 min, 0–95% B in A (linear gradient). Detection wavelength of 280 nm.

ramets within trees (at the $P < 0.05$ level, $F_{5,10}$ values ranging from 3.8 to 9.1).

Carbohydrates. In the total carbohydrate content of leaves, trees accounted for 40% and branches (including error variance) for about half of the total variance (Table 4). The coefficients of variation were low at every level (Table 4), and there were no significant differences at the $P < 0.1$ level. In leaf starch content, neither trees nor ramets differed significantly, while branches (including error variance) accounted for most of the total variation.

In monosaccharides and sucrose, and in their pooled contents (Table 4), branches (including error variance) accounted for most of the variation. Variation among trees was also considerable, but variation among ramets was low or nonexistent. Actual variation, at both the tree and the branch level, was highest in sucrose content and lowest in glucose content. The only significant differ-

TABLE 4. PROPORTIONS OF TOTAL VARIANCE AND COEFFICIENTS OF VARIATION OF TOTAL CARBOHYDRATE, STARCH, AND SUGAR CONTENTS AT DIFFERENT HIERARCHICAL LEVELS, AND GRAND MEAN FOR EACH COMPOUND

ence in the sugars was in leaf glucose content among trees ($F_{4,5} = 8.17$, $P < 0.05$). Detailed data on carbohydrates in each of the five trees are presented in Table 5.

Free Amino Acids. Glutamic acid was the most abundant free amino acid in all the trees. Branches (including error variance) accounted for most of the total variance in most amino acids. Exceptions were arginine, cisteic acid, citrulline, ethanolamine, γ-amino-*n*-butyric acid, and glutamic acid, in which most of the variance was accounted for by trees, and lysine and phenylalanine, in which about half of the variance was accounted for by ramets and half by branches (Table 6).

Coefficients of variation ranged from 0% to 69% among trees, from 0% to 28% among ramets, and from 15% to 64% among branches (Table 6). Differences among trees were significant in arginine, cisteic acid, citrulline, ethanolamine, and γ-amino-*n*-butyric acid (mostly at $P < 0.01$ level, $F_{4,5}$ values ranging from 10.2 (ethanolamine) to 27.2 (cisteic acid). The only significant difference among ramets was in glutamic acid ($F_{5,10} = 3.8$, $P = 0.03$). Details of amino acid contents in the five trees are presented in Table 7.

Protein-Bound Amino Acids. Glutamic acid, leucine, and lysine were the three most abundant protein-bound amino acids (Table 8). Branches (including

TABLE 5. CONTENTS OF CARBOHYDRATES IN LEAVES OF MOUNTAIN BIRCH[a]

[a] Tree means and values of branches with the lowest and highest value for each tree (in parentheses) are shown.

error variance) accounted for most of the total variance in all the protein-bound amino acids except for cysteine and methionine. Variation among trees ranged from 0 to 56% of the total variance, being in most cases lower than 25%. Variation among ramets was low or nonexistent in compounds other than cysteine. Coefficients of variation were, in general, highest among branches and lowest among ramets. The only significant difference was in methionine content among trees ($F_{4,5} = 10.4$, $P = 0.012$). The protein-bound amino acids in leaves from the five trees are shown in Table 9.

Relationships between Biochemical Characters and Larval Growth

Although our experiment was not designed to test for relationships between leaf biochemicals and larval growth, we did a tentative multiple regression analysis. Since the number of independent replicates (=trees) was five (see Hurlbert, 1984), we could include only a few biochemical compounds as independent variables into the model. Consequently, we included those two compounds that separately had the highest correlation coefficients with larval growth: (+)-catechin ($r = -0.87$ $P = 0.053$) and monosaccharides (=fructose + glucose) ($r = 0.87$, $P = 0.057$).

(+)-Catechin had a negative effect and monosaccharides a positive effect on larval growth. Neither of the compounds was quite significant, however (Table 10), possibly due to low sample size.

DISCUSSION

Variation in Larval Growth Rate. Ramets within trees and short shoots within branches accounted for most of the explained variation in larval growth rate. The variation was distributed similarly among the different levels during both years. Earlier findings show that during successive years individual mountain birches retain their relative rankings in chemical and morphological characters of the leaves, and as a diet for *E. autumnata* larvae (Haukioja et al., 1985a; Senn et al., 1992; Hanhimäki et al. 1995). The present results indicate that the same is also true at the level of the ramet and the branch. It also confirms that the methods used in this study, as well as earlier (Suomela and Nilson, 1994), are sufficiently reliable and reproducible for this kind of work.

Compared to earlier experiments (Suomela and Nilson, 1994), in which short shoots accounted for about 7% of total variance, the relative proportion of the short shoots in the present study was higher. As a proportion of the mean (coefficient of variation), however, variation among short shoots was lower or about the same as in the earlier experiments.

The constancy of leaf quality between successive years may result from intrinsic or extrinsic factors. Consistent differences may be due to somatic mutations (Whitham and Slobodchikoff, 1981; Antolin and Strobeck, 1985; but see Slatkin, 1985) or other intrinsic sources, such as the proximity of strong physiological sinks (Marshall, 1990; Wardlaw, 1990), which may remain relatively constant between years in different parts of the tree. They may also be due to persistent external factors, such as variation in solar irradiation or in shading by other branches or trees (see Suomela and Nilson, 1994).

Variation in Biochemical Characters. To our knowledge, these are the first findings partitioning variance in biochemical characteristics among and within trees, using same-aged, randomly chosen leaves. Our main finding was that the

proportion of variation attributable to different hierarchical levels and the coefficients of variation varied depending on the character. In total phenolics and individual low-molecular-weight phenolics, most of the variance was accounted for by trees. In carbohydrates and amino acids, it was the branch level (including

error variance) that generally accounted for most of the variance. In sugars and certain amino acids, a considerable part of the variation was also accounted for by trees (Tables 4, 6, and 8).

As indicated previously, variation among branches cannot be distinguished in the biochemical data from error variance, since we could only analyze one sample per branch. To estimate the reliability of branch-level measurements based on a single sample, we had checked beforehand the extent of variation in measurements among different samples derived from the same homogeneous powder (see Methods and Materials). In carbohydrates and amino acids, the coefficients of variation among different samples were clearly lower than coefficients of variation at the branch level (which include the measurement error) in the actual experiment (Tables 4, 6, and 8). This suggests that in carbohydrate and amino acid contents, in which variation was high at the lowest hierarchical level, a considerable proportion of variation was actually accounted for by the branches, not only by error variance.

Of the different biochemical compounds, the among-tree coefficients of variation were highest for the contents of phenolic compounds and lowest for protein-bound amino acids (Tables 2, 4, 6, and 8). The most extreme example of among-tree variation was the kaempferol-glycoside (phenolic no. 26), with a 50-fold difference among extreme trees (coefficient of variation 164%). At the ramet level, the coefficients of variation were generally low, being highest for free amino acids.

At the branch level, the coefficients of variation were highest for free amino acids and lowest for phenolics and protein-bound amino acids. Although the branch level relatively accounted for most of the total variance in protein-bound amino acids but for only a minor proportion in low-molecular-weight phenolic compounds, the coefficients of variation at this level were of about the same magnitude in both compound groups (on average 11.7% and 12.5% for amino acids and phenolics, respectively). This shows that it is essential to evaluate both the relative contributions of different hierarchical levels to the total variation

and the actual magnitude of variation (i.e., standard deviations or coefficients of variation).

The coefficients of variation for most biochemical compounds were clearly higher than those for larval growth rate, particularly at the levels of the tree and the branch. This suggests that, at least for short periods, the generalist *E. autumnata* larvae are able to handle relatively large biochemical variation in their food plants. This may be due, e.g., to changes in feeding rate or to flexibility of the digestive and detoxification systems of the larvae (Slansky, 1993 and references therein). It is possible, however, that younger larvae are more sensitive to biochemical variation than the late-instar larvae used in the present study (Gould, 1984; Slansky, 1993).

There are also some other studies in which variation among conspecific plant individuals has been estimated. The coefficients of variation of different phenolic compounds among trees in our study were of about the same magnitude as in the bark of winter-dormant *Betula pendula* seedlings representing several origins (Tahvanainen et al., 1991). Variation among individuals of several *Artemisia* species was also of the same magnitude (Wilt et al., 1992). In sugar contents the coefficients of variation among trees were lower than or about the same magnitude as in the bark of birch seedlings in Tahvanainen et al. (1991).

Generalizing, our findings indicate that there are differences in the among- and within-tree variation for the biochemical characteristics. Some compounds have a larger range than others, and the distribution of variance depends on the character. The large among-tree variation in the low-molecular-weight phenolics suggests that contents of these compounds in mountain birch leaves depend mainly on genetic factors and/or on relatively invariant microenvironmental or phenotypic factors. The contents of carbohydrates and amino acids seem to vary more than phenolics for phenotypic reasons, since in these compounds there was considerable variation within trees. This is consistent with the status of carbohydrates and amino acids as active metabolites, whose concentrations will vary depending, for instance, on the source-sink status of a particular plant part (Wardlaw, 1990). Furthermore, within-canopy differences in light conditions (DeJong and Doyle, 1985) or other environmental factors may have increased within-tree variation.

Since all 27 individual phenolic compounds were found in all 20 branches, the results do not lend support to the hypothesis of somatic mutations as an important source of qualitative variation in secondary chemistry within individual birches (Whitham and Slobodschikoff, 1981; Antolin and Strobeck, 1985).

Biochemical Characters and Larval Growth. Both phenolics [particularly (+)-catechin] and sugars seemed to affect larval growth, although the results were not quite significant. (+)-Catechin has earlier been found to have an adverse effect on bollworm (Noctuidae) larvae (Guerra et al., 1990). This com-

pound is a precursor of condensed tannins, and its negative effect on larval growth may take place via its interaction with proteins.

Although sugars have been largely overlooked in plant-herbivore studies, the contents of glucose and fructose (Zou and Cates, 1994), sucrose (Clancy, 1992), or total sugar content (Jensen, 1988) have been found to correlate positively with insect performance. Most of the experiments have been conducted with coniferous trees (Shaw et al., 1978; Jensen, 1988; Clancy, 1992) or with artifical diets (Rahbé et al., 1988; Clancy, 1992; Zou and Cates, 1994). Our results suggest that sugars may be important in deciduous trees also.

Total phenolic content of the mountain birch leaves has earlier been found to correlate negatively with growth of *E. autumnata* larvae on the mountain birch (Haukioja et al., 1985b). Also in the present study, there was a negative correlation between leaf total phenolic content and larval growth ($r = -0.74$, $P = 0.15$). However, the correlation between monosaccharides and total phenolics was negative ($r = -0.84$, $P = 0.07$). Thus, it is impossible to evaluate if total phenolics affected larval growth also in the present study but did not enter into the regression model due to their intercorrelation with sugars.

In summary, the relationships between biochemical characters and larval growth in the present study should be interpreted as suggestive only, since the number of trees in our study was low and we could include only few compounds into the model. However, the results indicate that both secondary metabolites, represented here by one phenolic compound, and primary metabolites, represented here by sugars, may be important for the growth of *E. autumnata* larvae.

Acknowledgments—We are grateful to Liinu Törvi for help in the field and to the staff of the Kevo Subarctic Research Station for all kinds of practical aid. The manuscript benefitted from comments by Seppo Neuvonen, Otso Suominen, and two anonymous reviewers. Ellen Valle kindly checked the English of the article. The work was funded by the Academy of Finland.

(Received January 31, 1995; accepted May 16, 1995)

Abstract—This study was conducted to determine whether avoidance of digitalis (*Digitalis purpurea*) by mountain beaver (*Aplodontia rufa*) is induced by toxic cardiac glycosides. High-performance liquid chromatography and behavioral assays were used to relate animal responses with the presence of common cardiac glycosides in several digitalis extracts. Statistical analyses of multiple-choice tests showed no correlation between cardiac glycoside content and mountain beaver avoidance of apple cubes treated with digitalis extracts. Therefore, we concluded that known toxic cardiac glycosides were not responsible for chemosensory cues that inhibited intake of food treated with digitalis extracts. These results suggest that digitalis is a source of an effective nontoxic herbivore repellent.

Key Words—*Aplodontia rufa*, avoidance, cardiac glycoside, digitalis, *Digitalis purpurea*, herbivore, mountain beaver, repellent

INTRODUCTION

Human and wildlife interactions are becoming more frequent, often with negative effects on both humans and wildlife. Current preventive measures such as trapping and lethal control are often not feasible or inappropriate in many management situations. Nonlethal repellents may provide viable alternatives.

Plants that are naturally avoided may be a source of aversive agents to inhibit browsing (Cardellina, 1988). For example, digitalis (*Digitalis purpurea*) plants are rarely harvested by mountain beaver (*Aplodontia rufa*), and prior studies indicate that even a preferred food is avoided when treated with water extracts of digitalis (Nolte et al., 1995). Unfortunately, toxins may render digitalis undesirable as a source of nonlethal aversive agents. The aversive cues, however, are not necessarily the toxic cardiac glycosides. Gustatory or olfactory cues of a food, and the specific compounds that cause aversive feedback, need not be synonymous (Provenza and Balph, 1990). We conducted a series of chemical and behavioral assays to determine whether the toxic glycosides common in digitalis are the aversive cues avoided by mountain beaver.

METHODS AND MATERIALS

Chemicals. High-performance liquid chromatography (HPLC) grade methanol, acetonitrile, and hexane were obtained from Fisher Scientific (Fair Lawn, New Jersey), and HPLC grade chloroform was obtained from Baxter (McGaw Park, Illinois). Water was either HPLC grade (Baxter) or purified in-house using the Milli-Q+ purification system (Millipore, Molsheim, France). Digitoxin and gitoxin were obtained from Sigma (St. Louis, Missouri).

Stimuli. Digitalis was collected in the vicinity where test animals were subsequently trapped. Samples were frozen and lyophilized for 48 hr. The lyophilized material was ground through a 20-mesh Wiley mill, mixed uniformly, and stored at 4°C.

Subjects. Experimentally naive (not previously tested) adult mountain beavers were trapped in the Capital State Forest, Grays Harbor County, approximately 30 km from Olympia, Washington. Animals were penned individually in outdoor pens (3 × 3 m) and given free access to pelleted feed (X-Cell Feed Company, Tacoma, Washington) and water throughout the trials. All animals were given a minimum of four days to adjust to captivity and the test regime prior to the onset of trials.

Extract Preparation. To derive a series of liquid–liquid extracts, two hot water digitalis extracts were prepared identically by placing 60 g of ground digitalis in 1.5 liters of water maintained at 85°C. The extraction was performed for 4 hr with periodic stirring followed by filtration through Whatman 114 coarse filter paper (Whatman International Ltd., Maidstone, Kent, U.K.). The liquid–liquid extracts were subsequently prepared by sequentially "washing" one of the filtered hot water digitalis extracts with 1.2 liters of hexane and 1.2 liters chloroform in a separatory funnel by manual shaking for 20 min. The hexane (L-L:H1) and chloroform (L-L:C2) phases, as well as the resultant filtrate (RF:A) were collected. This process was repeated with the other hot water

digitalis extract but the order of the hexane and chloroform washes was switched. Again, the chloroform (L-L:C1) and hexane (L-L:H2) phases were collected as was the resultant filtrate (RF:B).

Room temperature liquid–solid extracts were prepared by combining 60 g of ground digitalis with methanol (L-S:M), hexane (L-S:H), chloroform (L-S:C), or water (L-S:W) and shaking on a horizontal mechanical shaker for 30 min prior to filtration. Approximately 1.25 liters of filtrate was collected from each of the extraction processes.

Digitalis extracts were applied to apple cubes (1 cm^3) by submerging the cubes in the extracts for 1 hr immediately prior to tests. Apple cubes were similarly treated with the respective solvents for trials to determine whether mountain beaver were responding to cues emitted from digitalis or merely avoiding the solvents. Peeled apples were selected as the test food because they are readily ingested by mountain beavers.

Behavioral Assays. A series of multiple-choice tests were used to determine mountain beaver responses to extracts derived from digitalis. First, mountain beaver were given a choice of apple cubes treated with the liquid–liquid extracts (L-L:H1, L-L:H2, L-L:C1, L-L:C2) and the resultant filtrates (RF:A, RF:B) along with a water control. Response of mountain beavers to the liquid–solid extracts (L-S:H, L-S:C, L-S:M, L-S:W), one of the resultant filtrates (RF:B), and a water control was assessed in the second test. A third behavioral assay was conducted with the solvents (methanol, hexane, chloroform, and a water control) used to prepare the extracts.

During each of the tests, mountain beaver ($N = 10$) were presented with 20 untreated apple cubes placed in weigh-boats spaced at even intervals along the perimeter of their pens for four days of pretreatment. The number of apple cubes in each weigh-boat and within the immediate area (< 30 cm) was assessed after 24 hr. At that time, all remaining cubes were removed and another 20 fresh cubes were placed in the weigh-boats. A four-day treatment period immediately followed pretreatment. Treatment procedures were identical to those described for pretreatment except apples cubes were treated with the extracts as described above. Three tests were conducted sequentially as described above, and all treatments (extracts) within a test were offered simultaneously. Treatment locations were randomly selected each day.

Chemical Assays. All extracts were analyzed for digitoxin and gitoxin with a Hewlett Packard 1090M HPLC equipped with a diode array detector (Hewlett Packard Co., Palo Alto, California). Ultraviolet (UV) detection of the analytes was achieved at 220 nm. The analytical column was a 250 × 4.6 mm Keystone Octyl-H with a 10 × 4-mm guard of the same stationary phase (Keystone Scientific, Inc., Bellefonte, Pennsylvania). The mobile phase consisted of 68% water and 32% acetonitrile for 10 min, followed by a 15-min linear gradient of increasing acetonitrile concentration until a composition of 60% water and 40%

acetonitrile was achieved. For chloroform extracts only, the mobile phase consisted of a linear gradient from 100% water to 50% methanol/50% acetonitrile over 65 min. The flow rate was 1.0 ml/min and the injection volume was 10 μl.

Standards of digitoxin and gitoxin, prepared in methanol, were used for identification and quantitation.

Statistical Analyses. The data for each behavioral assay were assessed separately in single factor analyses of variance (ANOVA). A randomized block design was used where mountain beaver were blocks and food with the respective extracts were treatments. Tukey tests (Winer, 1971) were used to isolate significant differences among means subsequent to the omnibus procedures ($P < 0.05$).

RESULTS

Mountain beaver ($N = 9$) responses varied among treatments in the first behavioral assay ($P < 0.0001$) (Figure 1). One animal was not included in the

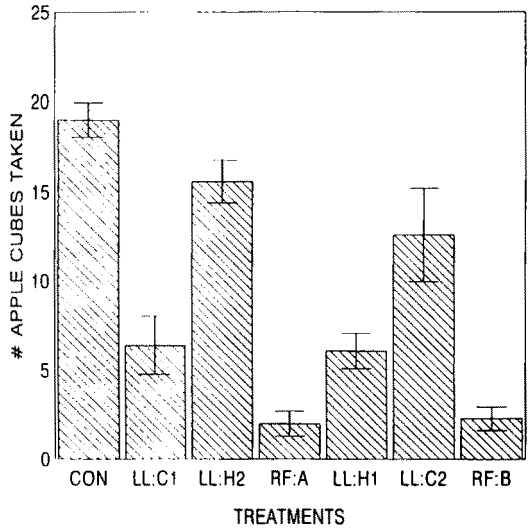

FIG. 1. Number of apple cubes take by moutain beaver during a multiple-choice test when the test food (20 apple cubes) was treated with one of six digitalis extracts prepared by a two-step liquid–liquid extraction or untreated (CON). The resultant filtrate (RF:A) was first collected after hexane (LL:H1) was followed by chloroform (LL:C2). Next the resultant filtrate (RF:B) was collected after chloroform (LL:C1) was followed by hexane (LL:H2).

analysis because it failed to ingest any treatment or control cubes throughout the assay. Mountain beaver took fewer ($P < 0.05$) apple cubes treated with either of the resultant filtrates (RF:A, RF:B) or the initial phase L-L extracts (L-L:H1, L-L:C1) than they did control cubes or cubes treated with the second phase liquid–liquid extracts (L-L:H2, L-L:C2). Mountain beaver responses were similar ($P > 0.05$) to L-L:H2 and L-L:C2 and to L-L:H2 extract and control cubes, but they took fewer ($P < 0.05$) cubes treated with the L-L:C2 extract than control cubes. Subsequently, we rated the mountain beavers' relative avoidance of each extract as: high, greater than control; low, similar to control; or moderate, greater than control but less than extracts rated as high (Table 1).

Responses of mountain beavers also varied with treatments in the second behavioral assay ($P < 0.0001$) (Figure 2). Animals ingested similar numbers of cubes treated with the hexane (L-S:H) or chloroform (L-L:C) extracts as they did control cubes ($P > 0.05$). Response to the water extracts (L-S:W or RF:B) and the methanol (L-S:M) extract were similar, and all of these extracts were substantially more aversive than the other treatments ($P < 0.05$). Mountain beavers' relative avoidance of these extracts was also rated as described above (Table 1).

None of the solvents used to prepare extracts were aversive. Mountain

TABLE 1. SUMMARY OF MOUNTAIN BEAVER RESPONSES TO TEST EXTRACTS AND ABSENCE OR PRESENCE OF CARDIAC GLYCOSIDES

Extract	Cardiac glycosides	Relative avoidance
Liquid–solid		
L-S:W	present	high
L-S:M	absent	high
L-S:C	absent	low
L-S:H	absent	low
Liquid–liquid		
L-L:C1	present	high
L-L:H2	absent	low
R-F:A	absent	high
L-L:H1	present	high
L-L:C2	present	moderate
R-F:B	absent	high
Solvents		
Water	absent	low

Hexane	absent	low

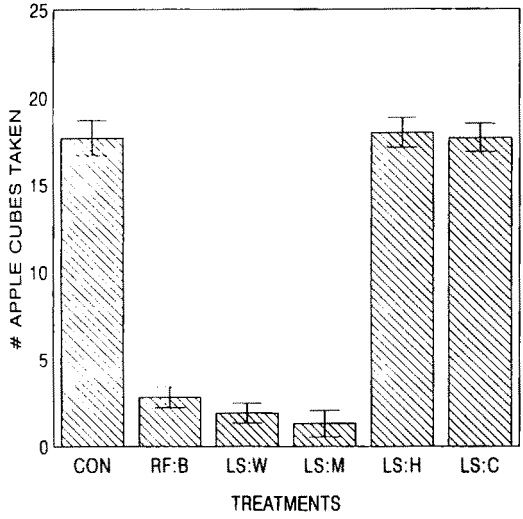

FIG. 2. Number of apple cubes taken by mountain beaver during a multiple-choice test when the test food (20 apple cubes) was treated with one of four liquid–solid digitalis extracts prepared with methane (LS:M), chloroform (LS:C), hexane (LS:H), water LS:W), or treated with the resultant filtrate (RF:B) from a chloroform/hexane liquid–liquid extract, or untreated (CON).

beaver ingested similar numbers of apple cubes in the third assay regardless of treatment ($P > 0.3$). The mean number of the 20 apple cubes treated with methanol, chloroform, hexane, or water taken by mountain beaver was 19.2, 19.7, 17.8, and 18.0, respectively.

Chemical Assays. All extracts were analyzed for digitoxin and gitoxin to determine if the cardiac glycosides were present (Table 1). Digitoxin and gitoxin were detected in the hot water liquid–solid extract prior to being subjected to the liquid–liquid extraction. HPLC analysis also indicated that digitoxin and gitoxin were present in both chloroform liquid–liquid extracts (L-L:C1 and L-L:C2), as well as the initial hexane liquid–liquid extract (L-L:H1) (Figure 3). Cardiac glycosides were not present in the second hexane L-L extract (L-L:H2) or either of the resultant filtrates (RF:A and RF:B) (Figure 4). Although the water liquid–solid extract contained digitoxin and gitoxin, neither of these cardiac glycosides were detected in the other liquid–solid extracts (L-S:M, L-S:H, L-S:C).

The detection limits, defined as the analyte concentration required to produce a chromatographic response equal to three times the chromatographic noise,

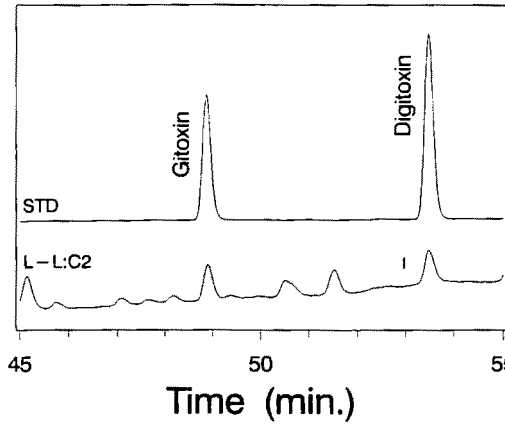

FIG. 3. Chromatograms of an extract (L-L:C2) in which digitoxin and gitoxin were detected and a standard mixture of gitoxin and digitoxin (STD). The y scale of L-L:C2 was amplified by fourfold for clarity. Chromatographic conditions are provided in the text.

were found to be 0.67 μg/ml and 0.48 μg/ml for digitoxin and gitoxin, respectively.

DISCUSSION

Aversive cues emitted by foxglove do not appear to originate from digitoxin or gitoxin. The methanol liquid–solid extract (L-S:M) and both resultant filtrates

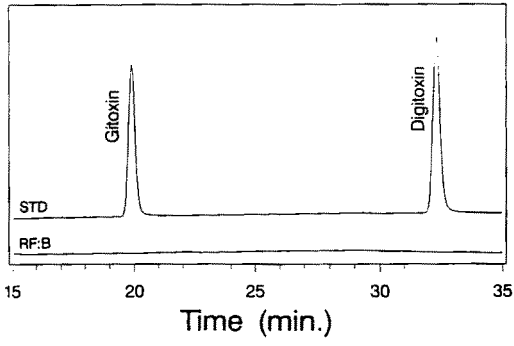

FIG. 4. Chromatograms of a resultant filtrate (RF:B) in which digitoxin and gitoxin were not detected and a standard mixture of digitoxin and gitoxin (STD). Chromatographic conditions are provided in the text.

were avoided by mountain beaver, although digitoxin and gitoxin were absent. In addition, avoidance of one of the liquid–liquid extracts that contained both digitoxin and gitoxin was only moderate.

The absence of cardiac glycosides in extracts was based on chromatographic analysis of the extracts for digitoxin and gitoxin, although other cardiac glycosides are known to be present in digitalis (Fujii et al., 1989). Digitoxin and gitoxin, however, should be good indicators of the cardiac glycosides present in digitalis. Digitoxin and gitoxin are two of the three main secondary glycosides formed from the primary glycosides that are present in living, undamaged digitalis plants. The polarities and solubilities of all the primary and secondary glycosides are similar. Therefore, we used the presence of digitoxin and gitoxin as "markers" for the presence of all possible cardiac glycosides. If neither digitoxin nor gitoxin were detected in an extract, it was assumed that no cardiac glycosides were present in the extract at our detection limit.

The combined assays indicate that the chemical cues avoided by mountain beaver were polar. Extracts prepared with polar solvents were aversive to mountain beaver, while extracts prepared with nonpolar solvents were generally not avoided. For example, in the second behavioral assay, apple cubes treated with the nonpolar hexane (L-S:H) and chloroform (L-S:C) extracts were taken, while cubes treated with the polar water (L-S:W) and methanol (L-S:M) extracts were avoided. Furthermore, the aversive resultant filtrates (RF:A, RF:B) were also derived from polar extracts of digitalis.

Generally, the polar extracts were avoided by mountain beaver on the first day of trials. Repellents that elicit initial avoidance are generally either irritants (e.g., capsaicin) or those that evoked "fear" response (e.g., predator scents) (Mason and Clark, 1992). The initial avoidance in these trials, however, may have reflected a conditioned food aversion. Conditioned food aversions occur when ingestion of a novel food is paired with gastrointestinal distress (Garcia and Koelling, 1966; Garcia, 1989). The mountain beavers in our trials likely had encountered digitalis prior to capture. Since the glycosides in digitalis induce nausea, it is possible that these animals learned to avoid digitalis through pairing the nontoxic cues with the toxins. Gustatory or olfactory cues of a food, and the specific compounds that cause aversive feedback, need not be and probably rarely are synonymous (Provenza and Balph, 1990).

Management Implications. Digitalis extracts may provide an effective source of aversive agents to inhibit herbivore damage in the Pacific Northwest. Nontoxic cues derived from the plant are avoided by mountain beaver. However, it is unclear whether the avoidance reflects a conditioned aversion. Regardless, the abundance of digitalis throughout the Pacific Northwest virtually ensures that if learning is required, animals will recognize its aversive properties through prior "natural" experiences. Further, herbivore familiarity with digitalis may

reduce habituation to its aversive cues. Animals that ignore cues normally emitted by the plant would risk exposure to its toxic properties.

(Received January 24, 1995; accepted May 17, 1995)

Abstract—The Japanese beetle is a polyphagous insect that typically aggregates on preferred host plants in the field. We studied the response of Japanese beetles to artificial damage, fresh feeding damage, and overnight feeding damage to test the hypothesis that beetles are attracted to feeding-induced volatiles. Crabapple leaves that had been damaged overnight by Japanese beetles or fall webworms attracted significantly more Japanese beetles than did undamaged leaves. Artificially damaged leaves or leaves freshly damaged by Japanese beetles, however, were not significantly more attractive than undamaged leaves. Leaves that had been damaged overnight by Japanese beetles or fall webworms produced a complex mixture of aliphatic compounds, phenylpropanoid-derived compounds, and terpenoids. In comparison, artificially damaged leaves or leaves with fresh Japanese beetle feeding damage generated a less complex blend of volatiles, mainly consisting of green-leaf odors. Feeding-induced odors may facilitate host location and/or mate finding by the Japanese beetle.

Key Words—*Popillia japonica*, Coleoptera, Scarabeidae, apple, *Malus* × *domestica*, attractant, induction, plant–insect interaction, semiochemical, terpene.

INTRODUCTION

Odors induced by arthropod herbivory on higher plants have recently been implicated as attractants of predators and parasitoids (Turlings et al., 1990). In the cases so far examined, volatiles were induced by arthropod feeding in a delayed manner, and the induced odors were typically a complex blend of aliphatics, terpenoids, and/or phenylpropanoid-derived compounds. The induced blends are often floral in character, which may increase the likelihood of predation on lepidopteran larvae in that many adult parasitic Hymenoptera are dependent on nectar for food (Leius, 1960).

Little is known, however, about the effects of these induced volatiles on the herbivores themselves. Still, evidence has been obtained for the additive or synergistic effects of host volatiles along with sex pheromones on insect aggregation. For example, female mountain pine beetles, *Dendroctonus ponderosae* Hopkins, convert the host-produced monoterpene α-pinene into *trans*-verbenol, which is an aggregation pheromone for this species. Verbenone, which is produced by microbial symbionts of *D. ponderosae*, serves as an anti-aggregation pheromone and terminates mass attacks on individual host trees (Borden, 1984; Hunt and Borden, 1990). In another example, fruit volatiles released by feeding of the green June beetle, *Cotinus nitida* L., were shown to be highly attractive to other green June beetles (Domek and Johnson, 1988). To our knowledge, however, no studies have examined feeding-induced volatile compounds from the leaves of woody angiosperms and their effect on aggregation of herbivorous insects.

The adult Japanese beetle (*Popillia japonica* Newman: Scarabaeidae) is a highly polyphagous insect that feeds upon nearly 300 plant species in 130 families (Fleming, 1972). Since its accidental introduction into New Jersey about 80 years ago, the beetle has become one of the most destructive pests of shade trees, fruit and vegetable crops, and ornamental plantings in the eastern United States. One of the more curious aspects of this insect's behavior is its tendency to congregate on individual hosts, often nearly defoliating them, while other suitable hosts in the vicinity often suffer only minimal damage (Van Leeuwen et al., 1928; Fleming, 1972). Males of this species are strongly attracted to the female sex pheromone, (Z)-5-(1-decenyl)-dihydro-2-(3H)-furanone (Tumlinson et al., 1977), but this alone cannot explain the aggregative behavior because females are normally mated on the ground at emergence, and mated females do not attract males at long range (Ladd, 1970). This has led to speculation of an aggregation pheromone (Adler and Jacobson, 1971; Iwabuchi and Takahasi, 1983).

We speculated that volatile compounds induced by feeding on leaves could act as aggregation kairomones for the Japanese beetle. The present study using

crabapple leaves (*Malus* × *domestica*), a highly preferred host of the Japanese beetle (Fleming, 1972), was undertaken to test this hypothesis.

METHODS AND MATERIALS

Insects and Plants. Japanese beetles were captured in the field using traps baited with commercial food-type lures (1 : 1.1 : 2.2 ratio of geraniol –phenethyl propionate–eugenol (Trécé Inc., Garwood, New Jersey). Fall webworms (*Hyphantria cunea* Drury: Arctiidae) were reared on wheat germ medium (Yearian et al., 1966) and then transferred to a diet of crabapple leaves at least one day before use in experiments. Third instars were used for the bioassays. Crabapple trees (cv. Dolgo) were maintained in nursery plots at the University of Kentucky's South Farm in Lexington, Kentucky.

The afternoon before an experiment, six to eight crabapple branches with an average of 12–15 leaves each were collected, immediately placed in clear plastic trays with lids, and held overnight. For investigation of the volatiles induced by overnight feeding damage, each tray received about 150 Japanese beetles or fall webworms. No insects were added to undamaged controls or leaves reserved for artificial or fresh beetle damage. In the case of artifical damage, leaves were damaged immediately before experiments by dragging a razor blade parallel to the midvein along the length of the leaf five times. For fresh beetle damage, about 150 beetles were allowed to feed in the trays for 2 hr prior to pitfall assays or volatile collections.

Pitfall Bioassays. Attraction of Japanese beetles to damaged or intact leaves was measured in a pitfall bioassay system because the beetles' extreme phototropism rendered use of a conventional wind tunnel impractical. Assays were conducted in choice-test arenas (Figure 1) consisting of six 125-ml Erlenmeyer flasks (mouth diam. 3.0 cm) in plastic trays (32 × 26 cm, 10 cm deep). The trays were filled with dry sand until the sand was level with the mouths of the flasks. Leaf treatments, consisting of a single damaged or undamaged leaf per flask, were placed in the flasks and the flasks were situated such that the beetles could enter by walking on the surface of the sand. Five comparisons were performed daily: a single crabapple leaf versus no leaf and the four types of damaged leaves (i.e., artificially damaged, freshly damaged by Japanese beetles, leaves with overnight feeding damage by Japanese beetles, and leaves with overnight feeding damage by fall webworms) versus undamaged crabapple leaves.

Preliminary trials indicated that male and female Japanese beetles did not differ significantly in their responses to leaves in the bioassay system. We therefore used both sexes in the pitfall bioassays in the same ratio (about 1 : 1) that

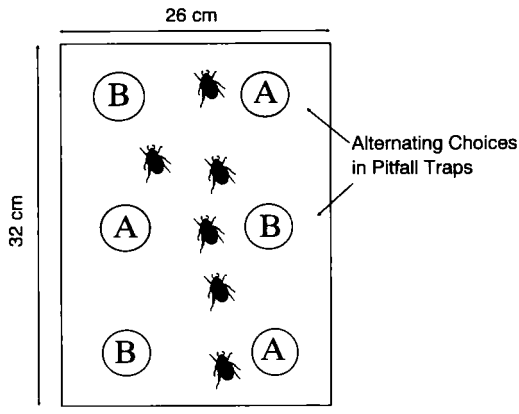

FIG. 1. Arena used for testing Japanese beetle attraction to damaged or undamaged leaves.

was captured in the traps baited with commercial food-type lures. This was intended to simulate attraction of a mixed-sex population as occurs to hosts in the field. Beetles were captured daily using traps baited with food lures and then held overnight without food. For each bioassay, 30 beetles were placed in the middle of the trays and allowed to choose between the two treatments. The bioassays were conducted at room temperature using overhead fluorescent lighting. Bioassays were allowed to proceed for 3 hr or until 25 beetles within a tray had been captured. Beetle counts were pooled for the three flasks of a particular treatment within each tray. Each comparison was replicated five times and numbers of beetles responding to each treatment were analyzed within treatment combinations by Wilcoxon signed-rank tests at $\alpha = 0.05$ (Hollander and Wolfe, 1973).

Volatile Comparisons. In the morning, about 5 g of leaves (detached at the base of the petiole) were collected from each tray of damaged or undamaged foliage. All insect–damage comparisons included 10 beetles or caterpillars that were placed in the volatile collection chambers along with the leaf samples.

The leaves were placed in a push–pull collection apparatus modified from the design of Cross (1980), with eight chambers for samples. Each chamber was a glass sleeve (40 cm long, 8 cm diam.) closed at each end with a no. 14 neoprene stopper adapted for copper tubing (0.635 cm OD), which served as air inlet or vacuum lines. The face of each stopper was covered with a Plexiglas plate attached with machine screws to reduce emission of volatiles from the neoprene. The air inlet side of the apparatus was furnished by the house air supply, which was passed through separate charcoal (500-ml) and Tenax (150-ml) filters for purification and then through an air scrubber filled with deionized

water to humidify the airstream and reduce desiccation of the leaves. From the air scrubber, the air passed through a manifold system to supply each chamber of the collection apparatus. The vacuum side of the apparatus was supplied by house vacuum via a manifold. Each port of the manifold was controlled by a separate flow controller. From the flow controllers, Tygon tubing led to glass tubes that served as collection traps and that contained 50 mg of Super Q absorbent (Alltech Associates, Deerfield, Illinois). The glass tubes were fitted to the collection chambers with Swagelok fittings and were rinsed prior to volatile collections with 2 ml of high purity CH_2Cl_2. During volatile collections, air was pulled through each chamber at 250 ml/min, and the entire system was kept slightly above atmospheric pressure as measured by a flow tube attached by means of a vent at the vacuum end of one of the volatile collection chambers.

After 4 hr, the collection traps were removed from the apparatus and compounds were eluted from the traps with 180 μl of an 80:20 v/v mixture of high purity hexane–CH_2Cl_2. Cumene (1000 ng) was added as an internal standard and compounds were quantitated by 2.0-μl injections onto a gas chromatograph operated in splitless mode and equipped with a 60-m × 0.32-mm Supelcowax 10 (polyethylene glycol) column. GC operating conditions were as follows: oven temperature 60°C for 1 min and then programmed at 2°C/min to 220°C; injector 220°C; FID 240°C; He carrier linear flow rate 21 cm/sec. Levels of individual compounds were pooled for individual treatments and contrasted between different treatments by Fisher's protected least significant difference test at $P = 0.05$ (Sokal and Rohlf, 1981).

Gas chromatography–mass spectroscopy was performed on a Hewlett-Packard mass ion detector operated in electron impact mode and interfaced to a GC equipped with a 30-m × 0.25-mm DB-5 column operated as follows: oven temperature 60°C for 1 min and then programmed at 2°C/min to 220°C; injector 220°C; He carrier linear flow velocity 21 cm/sec. Compound identification was performed by computer library searches and retention time matches of the natural plant products with authentic standards on the Supelcowax 10 column and a 30-m × 0.32-mm DB-5 column operated as described for GC-MS analyses. Authentic samples of volatile compounds were obtained from commercial sources except for (*E*)-4,8-dimethyl 1,3,7-nonatriene, which was donated by J.H. Tumlinson (USDA, Gainesville, Florida), (*E*,*E*)-α-farnesene isolated from the hydrocarbon fraction of ylang-ylang oil (Gaydou et al., 1986), and linalool oxide synthesized by the method of Cooper et al. (1990).

RESULTS AND DISCUSSION

For the pitfall bioassays to have value as a tool for investigating Japanese beetle discrimination between differing plant materials, one should be able to

demonstrate the beetle's ability to locate leaves of a preferred host within the bioassay system. Significantly more beetles were captured in flasks that contained a single undamaged leaf than in those that contained no leaf ($\alpha = 0.021$, Wilcoxon signed rank test, Figure 2). Moreover, significantly more beetles were attracted to leaves that had been damaged overnight by either Japanese beetles or fall webworms than to undamaged leaves ($\alpha = 0.022$ and 0.034, respectively). Leaves that had been artificially damaged or leaves with fresh Japanese beetle feeding damage were not significantly more attractive than undamaged leaves.

Representative chromatograms show that crabapple leaves that had been damaged overnight by Japanese beetles produced a more complex blend of volatiles than did undamaged or artificially damaged leaves (Figure 3). Nineteen compounds were identified from the insect-damaged leaves (Table 1).

The fact that a wider variety of volatile compounds was isolated from leaves that had received overnight feeding damage than from freshly damaged leaves parallels the findings of previous researchers (Turlings et al., 1995). Odor induction from angiosperm leaves due to insect feeding seems to occur in a delayed manner or perhaps requires that damage occurs at a certain time of the day (Turlings et al., 1990; Loughrin et al., 1994). In addition, the role of the insect in the production of the blend of induced odors should be stressed since artificial

Peak identities: 1, hexanal; 2, (*Z*)-3-hexenal; 3, (*E*)-2-hexenal; 4, (*E*)-β-ocimene; 5, hexyl acetate; 6, (*E*)-4,8-dimethyl 1,3,7-nonatriene; 7, (*Z*)-3-hexenyl acetate; 8, (*E*)-2-hexenyl acetate; 9, hexanol; 10, (*Z*)-3-hexenol; 11, (*E*)-3-hexenol; 12, (*Z*)-3-hexenyl butyrate; 13, a furan linalool oxide; 14, (*E*)-2-hexenyl butyrate; 15, linalool; 16, (*E*,*E*)-α-farnesene; 17, phenethanol; 18, phenylacetonitrile; 19, (*Z*)-3-hexenyl benzoate; IS = cumene internal standard.

damage alone does not seem to produce the same blend of volatiles as insect damage regardless of the age of the damage (Turlings et al., 1990).

Differences in induced volatiles may explain the beetle's attraction to leaves damaged by either Japanese beetles or fall webworms and their lack of preference for freshly damaged or artificially damaged leaves. Many of the compounds isolated from leaves that had received overnight feeding damage were either floral in character (e.g., phenethanol, linalool) or fruit-like [e.g., (*Z*)-3-hexenyl butyrate, (*Z*)-3-hexenyl benzoate). In contrast, artificially damaged leaves or leaves that had been freshly damaged by the beetles produced volatiles that were much more green-leaf in character (Hatanaka, 1993). Of the many essential oils and individual compounds that have been evaluated as Japanese beetle lures, those best described as floral or fruity are most effective (Schwartz and Hamilton, 1969).

The odors released by feeding damage on leaves of *Duranta repens* have been implicated as aggregation kairomones for adults of another scarabaeid

beetle, *Maladera matrida* Argaman (Harari et al., 1994). In this case, however, the chemistry of induction was not studied, and the authors assumed the insects were responding to general green-leaf odor components, such as leaf alcohols, aldehydes, and their derivatives. If so, this would be in contrast to our findings for the Japanese beetle, where attractiveness of leaves increased only after overnight feeding damage.

The terpene hydrocarbons (*E*)-β-ocimene, (*E*)-4,8-dimethyl-1,3,7-nonatriene, and (*E*,*E*)-α-farnesene were the most abundant of the compounds induced by insect feeding on crabapple. However, since compounds such as the various induced esters and phenylpropanoids have previously been shown to be attractive to Japanese beetles (Schwartz and Hamilton, 1969), the terpene hydrocarbons may not be important components of the beetle's response to damaged leaves.

Attraction of Japanese beetles to fall webworm damaged foliage was tested in order to compensate for possible residual sex or aggregation pheromone that might be present on the beetle-damaged leaves. A higher overall proportion of beetles was indeed attracted to the beetle-damaged leaves than to the fall webworm-damaged leaves (Figure 2, $\chi^2 = 11.03$ with 1 *df*, $P < 0.001$). This is likely explained, however, because leaves that had received beetle feeding damage were usually more heavily damaged than were webworm-damaged leaves, with overall volatile production about three times higher.

The Japanese beetle's tendency to congregate on individual host plants had led researchers to propose aggregation pheromone production by this insect (Adler and Jacobson, 1971; Iwabuchi and Takahashi, 1983). For instance, Iwabuchi and Takahashi found that either sex of Japanese beetles tethered singly to a grape leaf for 30 min attracted more males than did leaves alone. Ether extracts of females also attracted males to leaves. Extracts of males or visual cues (male or female dummies on a leaf) were not attractive. They suggested, from these observations, that an airborne substance is responsible for aggregation of males. Aggregations also included some females, but the basis of their response was not clarified.

We suggest that the argument for an aggregation pheromone in Japanese beetles is weakened by the fact that in Iwabuchi and Takahashi's study (1983), neither sex attracted additional beetles when tethered on yellow cardboard or on clear plastic plates attached to leaves. Similarly, traps baited with groups of mated females or males, without leaves, were no more attractive to other beetles than unbaited traps (Ladd, 1970). Iwabuchi and Takahashi (1983) did not indicate whether their tethered beetles produced feeding damage on the substrate leaves during the test period. Beetles used in their study were collected from a grape vineyard each morning and used immediately in tethering assays or were held overnight on grape leaves before being tethered or extracted. It is therefore also possible that the males contained traces of residual female sex pheromone or that both sexes carried traces of induced volatiles from grape leaves.

Several reasons may exist for the Japanese beetle's exploitation of damage-induced odors. Among these may be increased efficiency for mate finding. Although females cease production of sex pheromone shortly after their first mating (Ladd, 1970) and apparently do not require subsequent matings to produce a full complement of eggs (Ladd, 1987), they will frequently remate while feeding on host plants between oviposition bouts (Fleming, 1972). Ladd (1966) demonstrated that sperm displacement occurs in the Japanese beetle so that sperm contributed by a female's most recent partner is used to fertilize her eggs when she leaves a host plant to oviposit in the soil. Beetles often remain on damaged foliage overnight. So, by responding to induced plant odors, males may increase their chances of locating nonvirgin females and females may benefit by selectively remating with high-quality males.

Induced odors may also serve as reliable cues to beetles of a high-quality food source. Japanese beetles are attracted to a wide array of plant species regardless of their acceptability as hosts (authors' unpublished data). Induced odors may serve as more reliable indicators of host suitability than volatiles released constituitively from plants.

In summary, we have demonstrated odor induction due to insect herbivory on crabapple leaves and the delayed nature of this induction. The induced odors are attractive to Japanese beetles and may explain the aggregative behavior of this insect on its preferred host plans.

EARLY WARNING IN THE PREDATION SEQUENCE: A DISTURBANCE PHEROMONE IN IOWA DARTERS (*Etheostoma exile*)

BRIAN D. WISENDEN,* DOUGLAS P. CHIVERS, and R. JAN F. SMITH

Department of Biology, University of Saskatchewan 112 Science Place, Saskatoon, SK, S7N 5E2, Canada

(Received January 31, 1995; accepted May 17, 1995)

Abstract—The probability of prey avoiding a predator's attack should increase if the predator's presence is detected at an early stage in the predation sequence. In this study, we tested whether threatened Iowa darters (*Etheostoma exile*) release disturbance pheromones that warn conspecifics of the presence of predation threat. Pairs of aquaria were visually isolated from one another, but connected chemically by water circulating between them. Darters in one aquarium were observed before and after darters in the other aquarium were chased with a model predator. In control tests, the model was moved in the same manner but there were no darters in the upstream tank. Darters receiving water from threatened fish increased vigilance behavior and decreased movement. Vigilant fish raised their head above the substratum, propping themselves up on their pectoral fins and/or arching their neck dorsally, pointing the snout upward. Exposure to water from disturbed darters suppressed exploratory behavior and resulted in movement by short rapid hops that ended abruptly in a rigid, alert posture. This study suggests that Iowa darters release a disturbance pheromone that can provide conspecifics with an early warning of predation risk.

Key Words—Disturbance pheromone, alarm signal, predator-prey, predator avoidance, vigilance, Iowa darter, *Etheostoma exile*.

INTRODUCTION

In many situations in aquatic habitats, chemical information is more salient than visual information. For example, visual information may be of little use in highly

structured habitats, turbid water conditions, or at night. Furthermore, water serves as an excellent medium in which to dissolve and disperse chemical substances (Hara, 1992).

Chemical alarm signals occur in a wide range of aquatic taxa (gastropod mollusks, Atema and Stenzler, 1977; opisthobranchs, Sleeper et al., 1980; anemones, Howe and Sheik, 1975; decapods, Appleton and Palmer, 1988; fishes, Smith, 1992). Many fish have a well developed system of chemical alarm signaling (Smith, 1992). To date, study of alarm pheromones in fishes has focused on substances contained within the epidermis and released only by injury, including the *Schreckstoff* of ostariophysan species (von Frisch, 1938; reviewed in Pfeiffer, 1977; Smith, 1992). Conspecific skin extract invokes antipredator behavior in most ostariophysan fishes tested thus far and in nonostariophysan species such as brook stickleback, *Culaea inconstans* (Mathis and Smith, 1993b), darters (Smith, 1979, 1982), sculpins (Hugie et al., 1991), cyprinodontids (Reed, 1969) and gobies (Smith, 1989; Smith and Lawrence, 1991; Smith et al., 1991). Chemicals released by an injured conspecific serve as a reliable indicator of predation risk. Fathead minnows that have been "warned" by chemical alarm signals are significantly better at surviving in the presence of a predator (Mathis and Smith, 1993a).

Prewarned prey may be able to avoid an encounter with a predator. Prey that are subsequently detected by the predator are better able to avoid an attack by being in a state of readiness. The greater the degree of advance warning of a predator's presence, the greater the advantage to the prey. Therefore, there should be a selective advantage to individuals that can gain information about predation risk from a predator "disturbance" of a conspecific before the encounter escalates to a predator attack.

In birds and mammals, there are examples of visual, auditory, and chemical preinjury alarm signals that occur before prey capture (Caro, 1986b; Caro, 1986a,b; Klump and Shalter, 1984; Müller-Schwarze et al., 1984). In fishes, there are examples of preinjury visual alarm cues (e.g., goby bobbing, Smith, 1989; Smith and Smith, 1989; Sweatman, 1984) and auditory cues (e.g., squirrel fish, *Holocentrus rufus*, Winn et al., 1964; cod, *Gadus callarias*, Brawn 1961). However, among fishes, there are no documented cases of chemical alarm signals sent by uninjured individuals. Rainbow trout (*Oncorhynchus mykiss*) subjected to strong electric shock and other "stressors" release "chemical alarm signals" that increase stress in receivers, but no behavioral responses were measured (Lebedeva et al., 1994). Malyukina et al. (1983) reported that cod (*Gadus morhua*) detect and avoid chemical stimuli from stressed conspecifics. Tester (1963) found that grey sharks (*Caracharhinus menisorrah*) and black tipped sharks (*C. melanopterus*) were attracted to water from "agitated" and "distressed" groupers (*Epinephelus merra*), and black tipped sharks were attracted to distressed mullet (*Mugil cephalus*). These latter studies suggest that

distressed fish may release distinctive chemical stimuli, but they do not show a link between predation threat and the release of such chemicals or their detection and associated changes in vigilance by conspecifics.

Crayfish (*Orconectes virilis*) and hermit crabs (*Calcinus laevimanus*) respond to "disturbance pheromones" from conspecifics with antipredator behavior (Hazlett, 1985, 1990b). In addition, individuals of *O. virilis* respond to disturbance pheromones produced by other species of crayfish (*O. rusticus*, *Cambarus diogenes*), leeches (*Macrobdella decora*), newts (*Notopthalamus viridescens*), rock bass (*Ambloplites rupestris*), and the Iowa darter (*Etheostoma exile*) (Hazlett, 1985, 1989; 1990a).

If Iowa darters produce chemical stimuli when stressed (but not injured) to which crayfish respond, it follows that Iowa darters, themselves, may be able to detect these chemicals and respond with antipredator behavior. We conducted a laboratory experiment to investigate whether Iowa darters respond to chemical stimuli produced by disturbed conspecifics. We predicted that test individuals would increase vigilance behavior and suppress conspicuous behavior (movement) in response to chemical cues produced by sender conspecifics that were chased by a model predator in a separate, visually isolated aquarium.

METHODS AND MATERIALS

Two variations of this experiment were conducted at separate times by different investigators using fish from two different populations.

Experiment 1. We captured Iowa darters by seine in Eagle Creek, a tributary of the North Saskatchewan River, at a site approximately 50 km west of Saskatoon, Saskatchewan. Mean $\pm$ SE total lengths (TL) of a subsample of 15 females and 10 males were 43.1 $\pm$ 0.09 mm TL and 44.0 $\pm$ 0.11 mm TL, respectively. They were held in the laboratory at 15°C and fed a mixture of frozen brine shrimp and live food, including cladocerans, copepods, and mosquito larvae.

We placed pairs of 37-liter aquaria (50 $\times$ 30 $\times$ 25 cm high) end to end, separated by a small space and an opaque barrier. We used eight pairs in rotation. We connected the tanks by siphons at the abutting ends. Water was pumped from the distal end of the receiver tank into the distal end of the sender tank so that water flowed continuously through the siphons from senders to receivers. Flow rates averaged 1.2 liter/min. Each tank contained a substratum of several centimeters of silica sand.

Data were collected in May 1992 during daylight hours. Three darters (receivers) were placed in the receiver tank at least three days before the observation day. In experimental trials, 12 darters were placed in the sender tank at least three days before observation to ensure that they were well adjusted to the

laboratory setting. Both senders and receivers need to be in an undisturbed state for observers to detect a behavioral response to chemical cues (Hazlett, 1989; Smith, 1979). We buried a predator model in the sand of the sender's tank at least three days prior to the observations. The model was a fish lure 15 cm long and 2.5 cm high with hooks removed. A metal disc was glued to the underside of each model with silicone cement. The disc provided a heavy, stable platform to prevent the model from rolling or lifting off the substrate during the trial. The model was attached to monofilament line that led from the tank to the observation location. There was always live food present in both tanks on the observation day, and we fed the fish to satiation on the day before the observations. Darters do not respond to conspecific skin extract when they are hungry (Smith, 1981). Fish were used only once as receivers but were occasionally used more than once as senders. We drained and washed tanks between observations.

We quietly observed fish from about 1.5 m from the receiver tank. For 15 min before the fish model stimulus, we recorded the number of moves and head-up posture. In addition, we noted the time during which at least one of the three receivers was in the head-up posture. We then pulled the model out of the sand in the sender tank and moved it a short distance at 30-sec intervals for 5 min. No observations were made during this period. The above behaviors were similarly recorded for 15 min following exposure of the senders to the model predator. We conducted 10 experimental trials in which senders were present in the upstream tank. In 10 control trials, the upstream tank contained no sender fish, but we manipulated the model in the same manner as in experimental trials. This controlled for any stimuli produced by the movement of the model.

Iowa darters normally rest on the bottom. A move was scored each time a fish changed its location. A head-up posture was scored if a darter was stationary on the substratum with either the anterior part of its body propped up by its pectoral fins or if it arched its neck dorsally, pointing its snout upwards, or both. Head-up behavior is a component of the fright reaction of Iowa darters (Smith, 1982). Iowa darters are small, elongate benthic fish. Their body shape and habit leave these fish with a limited vantage point from which to view the surrounding area for predators and to sample water-borne chemical cues above the boundary layer (Moore and Atema, 1991; Moore et al., 1994). Head-up behavior would thus appear to be a cryptic, low-risk form of vigilance behavior.

Experiment 2. We collected adult and subadult darters (TL of subsample $= 48 \pm 1.5$ mm, $N = 4$) from a 1-ha pond on the University of Saskatchewan campus using minnow traps and a seine net. This population originated from the South Saskatchwan River in 1959. Darters in the laboratory holding tanks were provided with live cladocerans, mosquito larvae, and copepods ad libitum, supplemented occasionally with frozen brine shrimp.

We set up six pairs of 37-liter aquaria in the same manner as described for

experiment 1. The mean ± SE rate of flow was 2.9 ± 0.06 liters/min (N = 6 paired tanks). Food coloring added to the far end of upstream tanks was visible in the downstream tank to a human observer within 35 ± 7.7 sec (N = 6). Live food was always present in both tanks during the trials and for at least 1 hr before observations began.

Data were collected in June and July 1994 during daylight hours. We placed three receiver darters into the downstream tank. For experimental trials (N = 9), we placed 12 sender darters into the upstream tank. For control trials (N = 10), no darters were added to the upstream tank. All receiver fish were naive to the experiment and used only once as receivers. Some sender and receiver fish were used as senders in subsequent trials. Tanks were drained and washed between trials.

We videotaped all trials. Each trial lasted 35 min. At 10-sec intervals for 15 min, we scored the number of receiver fish with their head elevated above the substratum. After 15 min, a previously concealed model predator emerged from under a piece of black plastic in the upstream tank. In control trials the upstream tank contained no fish, but in experimental trials it contained sender darters. The model predator was similar to the one used in experiment 1. The model was attached to monofilament line through a system of pulleys, which enabled us to manipulate its position remotely (6 m from the receiver fish). The predator model moved from one end of the tank and back again every 15 sec, for 5 min. We then recorded the number of receiver fish in the head-up posture every 10 sec for 15 min.

Statistical Analyses. For statistical comparisons, we tested three behaviors (head-up posture, duration of time when at least one of three receivers was in head-up posture, and move frequency). We used the total frequency of each behavior exhibited by all three receivers in each trial to produce a single, independent datum before and after stimulus presentation per trial. We used Wilcoxon signed-rank tests (Siegel and Castellan, 1988) to compare darter behavior before and after model stimulus in the number of receiver fish performing head-ups for experimental and control trials separately.

RESULTS

Experiment 1. Darters significantly increased (Wilcoxon T^+ = 47, P = 0.048, two-tailed, N = 10) the frequency of their head-up postures from 15.7 ± 3.6 (mean ± SE) per 15 min before presentation of the predator model to 24.7 ± 3.7 per 15 min after model presentation, during which they were exposed to water from threatened conspecifics (Figure 1). In control trials, darters performed 17.7 ± 3.8 head-ups in the 15 min before the model emerged from the sand compared to 19.1 ± 3.2 during the final 15 min of each trial, which were

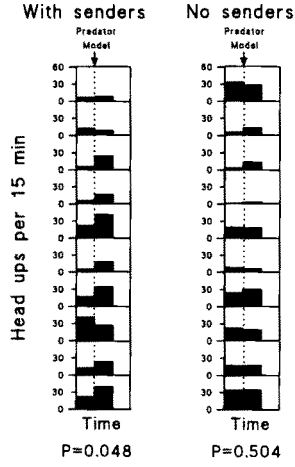

FIG. 1. Frequency of head-up posture by three receiver darters for 15 min before and after presentation of a model predator in an adjacent but visually isolated aquarium. Each cell represents a single trial. In experimental trials (left-hand column) sender darters were present in the adjacent aquarium with the model. In control trials (right-hand column) no sender fish were in the adjacent tank with the model. Below each column, significance of change between pre- and postpredator head-up frequency (Wilcoxon signed-rank test).

not significantly different (Wilcoxon $T^+ = 23.5$, $P = 0.504$, two-tailed, $N = 8$ excluding ties).

The duration of time in which at least one of the three receiver darters performed a head-up behavior significantly increased (Wilcoxon $T^+ = 33.5$, $P = 0.032$, two-tailed, $N = 8$ excluding ties) in experimental trials from 3.2 ± 0.8 min before the model was presented to 5.2 ± 0.8 min after sender darters were exposed to the model predator, but remained virtually unchanged (5.2 ± 0.5 vs. 4.7 ± 0.5 min) in control trials (Wilcoxon $T^+ = 13$, $P = 0.546$, two-tailed, $N = 8$ excluding ties, Figure 2).

In control trials, the number of moves per 15 min by the three receiver fish significantly increased (Wilcoxon $T^+ = 47.5$, $P = 0.044$, two-tailed, $N = 10$) from 97.7 ± 23.5 to 116.8 ± 20.9 after the model presentation. However, in experimental trials, move frequency did not change between the experimental treatments (115.8 ± 13.6 vs. 101.7 ± 11.1, Wilcoxon $T^+ = 35.5$, $P = 0.146$, two-tailed, $N = 9$ excluding ties, Figure 3).

Experiment 2. The number of receiver darters observed in the head-up posture significantly increased when exposed to water containing chemical cues of disturbed conspecifics (Figure 4). Overall, the number of individuals in the

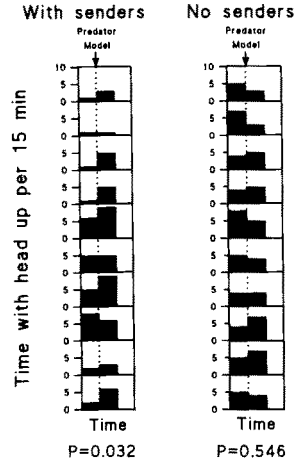

FIG. 2. Time, in minutes, in which at least one of the three receiver darters maintained a head-up posture before and after presentation of a model predator in the adjacent tank in the presence or absence of sender fish. Figure format as described for Figure 1.

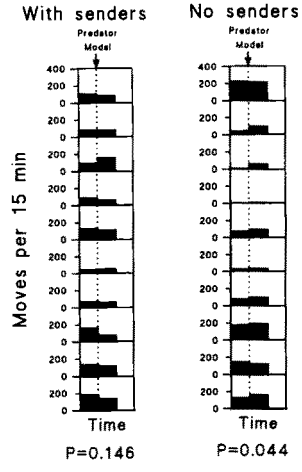

FIG. 3. Move frequency by three receiver darters before and after presentation of a model predator in an adjacent tank with or without sender fish. Figure format as described for Figure 1.

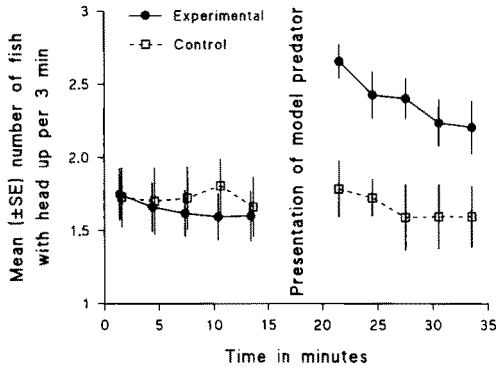

FIG. 4. Mean (±SE) number of fish exhibiting the head-up posture during each 3-min interval of the 15-min prepredator period and the 15-min postpredator period, separately. Data were not recorded during the 5-min interval while the model predator was active in the upstream tank.

head-up posture in the experimental trials increased from 1.64 ± 0.15 to 2.38 ± 0.15 (Wilcoxon $T^+ = 44$, $P = 0.008$, two-tailed, $N = 9$ excluding ties). In control trials, the average number of receivers in the head-up posture was 1.72 ± 0.21 before the model predator, and 1.66 ± 0.16 for the 15 min afterwards (Wilcoxon $T^+ = 22$, $P = 0.625$, two-tailed, $N = 10$).

Although we did not quantify the frequency of moves in the second experiment, we noted qualitative changes in fish movement during the postpredator period. Receiver fish in experimental trials changed position on the tank bottom with short rapid hops ending abruptly in a rigid, alert posture. These hops never took the fish very far above the substratum and the hops were separated by long intervals of motionlessness. In one extreme case, a fish buried itself in the sand during the 5-min interval when the model was being manipulated in the upstream tank and did not emerge until 6 min into the postpredator period. During the postpredator period, the behavior of control fish was similar to control and experimental fish in the prepredator period. Control fish moved about slowly, often swimming up into the water column and then gliding back to the tank bottom.

DISCUSSION

In both replications of this experiment, Iowa darters responded to water that had first passed over threatened conspecifics by increasing the frequency and duration of their head-up (vigilance) behavior. In a head-up position, darters

would likely be better able to view the surrounding area and sample chemical information.

We are reasonably confident that the disturbance signal was transmitted by a chemical cue. The two test tanks containing sender and receiver individuals were visually isolated and separated by a small space. Mechanical vibrations caused by movement of the model were present in both experimental and control trials. However, it is conceivable (we think remotely so) that darters may emit an alarm sound that could travel through the water in the siphon hose connecting the two test tanks. Further experiments are needed before this alternative modality can be excluded completely.

Motionlessness, or freezing, is a component of darter antipredator behavior (Radabaugh, 1989; Rahel and Stein, 1988; Smith, 1979). Darters exposed to water from threatened conspecifics did not decrease their frequency of movement. However, they did not increase movement as the control fish did (Figure 3). Movement by control fish may have been stimulated by the model's activity in the adjacent tank, perhaps stirring up particles and odors in the sand substratum. Thus, increased movement by control fish may represent exploratory behavior. The suppression of a similar increase in experimental fish may reflect a trade-off between information-gathering and cost of conspicuous behavior when under risk of predation.

Disturbance pheromones do not require injury and thus indicate a lower level of predation threat to receivers than injury-released pheromones. In crayfish, this is reflected by a behavioral response of lower intensity (Hazlett, 1985). In this study, response to disturbance pheromone did not include freezing behavior, characteristic of the response of darters to skin extract (Smith, 1979) or predators (Radabaugh, 1989) or of crayfish to conspecific hemolymph (Hazlett, 1994).

In nature, the release and detection of disturbance pheromones could occur before the predator detects the prey, hence the emphasis on crypsis. Head-up behavior is a relatively cryptic method of gathering information about predation risk. Decreased movement is a form of crypsis. Disturbance pheromones themselves may be a cryptic warning signal if the origin of a chemical signal is more difficult to localize than a visual or auditory signal, thus minimizing the signaler's conspicuousness to predators.

Hazlett (1989, 1990a) speculated that the disturbance pheromone in crayfish is ammonia, excreted under duress in urine or through the gills during periods of increased (metabolic) activity. The same may be true for Iowa darters. However, prestressed Iowa darters lose their ability to produce disturbance pheromones (Smith, 1979), suggesting that the pheromone supply can be exhausted. This evidence suggests that disturbance pheromone may be urinary in origin, rather than a metabolite excreted continuously from the gills.

The disturbance signal may not necessarily be an intentional warning to other fish but rather a normal physiological response to stress to which other individuals have become attuned. Urine released by nonthreatened individuals would constitute a false alarm. Some level of experience may be required for darters to associate predation threat with a sudden pulse of nitrogenous metabolites. In this study we compared the behavior of the recipient fish before and after the stimulus and thus controlled for any response of recipients to background level of urine released by nonstressed sender fish.

The evolution of a disturbance signal would involve selection pressures similar to the evolution of injury-released alarm signals (Smith 1992). There are greater possibilities for the signal sender to benefit from postsignal effects of a disturbance signal, because the sender of such a signal has a better chance of survival than a sender of injury-released pheromones. A possible postsignal benefit to the sender may be to induce group crypsis, which would reduce the chance of detection by the predator, thus benefiting both the signaler and receivers (Dawkins, 1976). Signal-senders may benefit by warning and increasing the survival of group members because retaining group members may reduce future predation risk to the sender (Smith, 1986). Reducing predator success in the signaler's home range may discourage future hunting in the region (Trivers, 1971). A disturbance alarm signal may also serve as an attack deterrent by informing the predator that prey are alerted to its presence and that further hunting is unlikely to succeed (Caro, 1986a,b).

From what is known about injury-released alarm pheromones, we predict that fish may be able to use disturbance pheromones to acquire predator recognition (Chivers and Smith, 1994a,c; Magurran, 1989) and avoid risky areas (Chivers and Smith, 1995) and may respond to disturbance pheromones produced by heterospecifics with which they share habitat and predators (Chivers and Smith, 1994b; Mathis and Smith, 1993b). Crayfish respond to disturbance pheromones from a range of heterospecifics (Hazlett, 1990a). Documenting the existence of disturbance pheromones increases the scope of chemosensory information in predator–prey relationships in fishes. Disturbance pheromones provide conspecifics, and possibly heterospecifics within the same prey guild, with an early warning of predation threat in advance of prey capture and hence earlier than the release of injury-released alarm pheromones. This should increase the probability that prey can avoid an encounter with a predator by either fleeing the area or employing crypsis. Increased vigilance will result in improved chances of escape should a predator initiate an attack.

Acknowledgments—Bee Wisenden and Dr. Brad Scandrett helped collect darters. Dr. Grant E. Brown made helpful comments on earlier drafts of this manuscript. This research was supported by the Natural Sciences and Engineering Research Council of Canada, and the University of Saskatchewan.

RATES OF URINE EXCRETION BY HOUSE MOUSE (*Mus domesticus*): DIFFERENCES BY AGE, SEX, SOCIAL STATUS, AND REPRODUCTIVE CONDITION

LEE C. DRICKAMER

Department of Zoology
Southern Illinois University
Carbondale, Illinois 62901

(Received December 29, 1994; accepted May 20, 1995)

Abstract—A series of five experiments was used to test hypotheses about factors affecting excreted urine output per day in male and female house mice (*Mus domesticus*). Urine was collected in metabolism cages over a 24-hr period. Male house mice excrete urine at a rate 1.5–2.0 times that of females. Daily average urine output increases with age for both sexes and for mice of the same age; urine output per day is correlated with body mass. Females in estrus produce more urine than females in diestrus. Urine output per day increases during the latter two thirds of pregnancy and remains high throughout lactation. Density does not influence urine output per day for either sex over the range of densities tested. Castration reduces urine output per day in male mice, but ovariectomy in females does not alter rates of urine production. Dominant males produce more urine than subordinate males, but there are no similar effects for female mice. The findings have potential implications for our understanding of the functional and ecological uses of urine by house mice.

Key Words—House mouse, *Mus domesticus*, urine, social status, urine marking.

INTRODUCTION

Many rodents use urinary odor cues as part of a complex system of signals that influences reproductive and social biology (Eisenberg and Kleiman, 1972; Brown, 1985a,b; Halpin, 1986; Hurst, 1987). For example, various rodents can use olfactory cues for recognition of gender, familiarity, kinship, stress, and individual identification (Bowers and Alexander, 1967; Carr et al., 1970; Davies and Bellamy, 1974; Hayashi and Kimura, 1974; Cox, 1984; Kareem and Bar-

0098-0331/95/1000-1481$07.50/0 © 1995 Plenum Publishing Corporation

nard, 1986; Winn and Vestal, 1986). Among such rodents, house mice have received, perhaps, the greatest attention by researchers (Brown, 1985a,b). Urine odor cues of house mice affect a variety of functions, including reproductive physiology, marking behavior, spatial relations, and possibly locating mates (Rose and Drickamer, 1975; Bronson, 1976; Harrington, 1976; Brown, 1979). Male house mice utilize urine to convey information about dominance status and aggression (Jones and Nowell, 1973a,b, 1977).

House mice engage in urine marking and countermarking under a variety of circumstances (Wolff and Powell, 1984) and produce accretions of urine termed urine posts by Welch (1953). Desjardins et al. (1973) reported that the patterns of urine marking were affected by dominance status. Male house mice urine mark more often (100–200 marks/hr) than females (25–95 marks/hr) (Maruniak et al., 1974; Powell and Wolff, 1982). Females mark more often in the presence of intact males than they do in the presence of other females or castrated males, but Maruniak et al. (1974) reported that there are no apparent variations in the amount of urine marking during different stages of the estrous cycle. Both males and females are attracted to urine odors from the opposite gender (Rowe, 1970; Davies and Bellamy, 1974; Drickamer, 1995). Female mice in estrus can discriminate the urine of dominant males from urine of subordinate males (Drickamer, 1992). Male mice discriminate male from female urine odor and also discriminate and prefer urine from females in estrus over females in diestrus (Rose and Drickamer, 1975; Sokolov and Kotenkova, 1976; Drickamer, 1995). Urine and related odors from pregnant and lactating females are avoided by most other mice, except for adult males (Drickamer, 1995). This avoidance is more pronounced for juvenile females and males and for estrous females.

Recently, Hurst conducted extensive studies on urine marking and related phenomena in house mice living in a poultry house and in laboratory enclosures (Hurst, 1989, 1990a–c). Adult males typically did not pay much attention to or countermark over urine from other adult males, although subadult males thoroughly investigated adult male urine. Adult males, adult females, and subadult females all countermarked female urine stimuli. Female urine was given great attention by all males and females, except by pregnant and lactating females. Females were attracted to urine from the resident dominant male, but avoided marks from males of neighboring territories or those of unfamiliar males.

One of the questions raised by these data on the use of urine cues by house mice concerns excreted urine output per day. Although mice must excrete urine to rid themselves of wastes, there may be differences in urine output per day attributable to a variety of other factors. How much urine do house mice of different genders and ages generate? What factors influence urine output per day by house mice?

Urine quantities have been recorded for rodents and other mammals, but

almost always in the context of metabolic studies. Two reports provide data on daily urine production under various conditions for albino laboratory strains of *Mus*; Bing and Mendel (1931) found excretion rates of 2.7–4.4 ml/day, and Chew and Hinegardner (1957) reported urine production of 10.5–12.0 ml/day, with a decrease with age and no gender differences. Data regarding urine production in deermice, *Peromyscus* (Chew, 1951, 1965), indicate that they urinate at a rate of 5.4–6.8 ml/day, with some of the variation attributable to differences in diet or ambient conditions.

These previous findings led me to an interest in possible variation in urinary output per day for house mice, and in particular, to consideration of a series of hypotheses regarding the factors that might affect such output. The first hypothesis concerned the possible differences by gender and age with regard to urine output per day. A second hypothesis concerned whether there were differences in urine output per day according to reproductive condition among females. Third, I tested whether there were any effects of density on urine output per day. Fourth, I asked whether gonadectomy affected urine output per day in either males or females. Finally, I tested the effects of social dominance status on urine output per day.

METHODS AND MATERIALS

General Methods. The mice used in these experiments were second through fourth generation from a stock of wild house mice (*Mus domesticus*) bred from animals trapped on farms in the area of Williamstown, Berkshire County, Massachusetts. Mice were housed in opaque polypropylene cages (28 × 15 × 15 cm deep) with fitted wire lids. A bedding of wood shavings was changed once each week. Food (Wayne Lab Blox) and water were provided ad libitum. Mice for the urine collection experiments were produced by individual female–male pairings. Mice were weaned at 23 days of age and housed individually until used in the experiments.

Urine collection was carried out in a series of four polycarbonate metabolism cages (overall dimensions = 28 cm diameter × 48 cm high; living area for mouse = 20 cm diameter × 14 cm; Maryland Plastics) placed on a table with wooden visual barriers between them. Food and water were available in small side chambers such that the mouse stuck its head, but not its hindquarters, into an opening to eat or drink. Each collection involved placing an individual mouse in the metabolism cage between 0600 and 0900 hr and leaving it there for 24 hr. After 24 hr, the urine in the receptacle was drawn into 1-ml and 5-ml hypodermic syringes and measured to the nearest 0.1 ml. Each metabolism apparatus was then cleaned thoroughly and dried before being used again.

Two methods issues must be addressed. First, how much could evaporation

from the surface of the urine that collected in the receptacle affect the results? Since the surface area from which urine could evaporate was the same at all times, this factor could result in disproportionately diminished estimates of urine quantity for mice with smaller amounts than those with larger amounts. Second, could seasonal differences in relative humidity in the room used for urine collection differentially affect the amount of evaporation from the surface of the urine collection receptacle? In the laboratory there is a tendency to have lower relative humidity in the winter and higher humidity during summer months. I attempted to alleviate both problems by placing 0.2 ml of vegetable oil in the receptacle at the outset of each collection period. This oil then floated on the surface of the urine as it collected and eliminated any significant evaporation. When the urine quantities were measured, I subtracted 0.2 ml from each value to account for the oil. For the second problem I also proceeded by testing mice for collection of urine in each treatment of the various experiments across all four seasons of the year; no more than 50% of the subjects were tested in any treatment during either the months of December through February (low humidity) or June through August (high humidity).

All colony cages and the urine collection metabolism apparatus were housed in a single room maintained at 21–25°C and 30–60% relative humidity on a 12-hr dark–12-hr light daily photoperiod regimen with overhead fluorescent lights on from 0600 to 1800 hr.

Experiment I: Gender and Age Effects. First, descriptive data concerning the quantities of urine according to age and gender were obtained. A total of 192 mice were used, 96 of each gender. Mice were tested at 25, 35, 45, 55, 75, 100, 125, and 150 days of age (N = 12 mice/treatment); different mice were used for each age period. Mice were tested at ± 2 days from the designated age on an as-available basis. Body mass was obtained for each mouse just prior to testing. No two mice of the same gender were tested from any single litter at the same age.

Initially, I used a two-way analysis of variance on urine quantity with two genders and six ages as main effects. Post-hoc analyses of treatment mean differences were tested using a Tukey-Kramer procedure with $\alpha = 0.02$ (Sokal and Rohlf, 1981); I elected to set the alpha level lower than the traditional 0.05 because of the large number of post-hoc tests conducted in the course of the various experiments and analyses. In addition, for this experiment, I tested whether there was any relationship between body mass and urine output per day. These data were used, in conjunction with the information on urine quantity, for each mouse in separate correlation analyses for each age and sex group.

Experiment II: Female Reproductive Condition. To test the effects of female reproductive condition on urine output per day, I used 112 adult female mice 110–170 days of age. There were eight treatments as follows (N = 14 mice/treatment): (1) females in estrus, (2) females in diestrus, (3) females in the first

six days of pregnancy, (4) females in the second six days of pregnancy, (5) females in the third six days of pregnancy, (6) females in the first week of lactation, (7) females in the second week of lactation, and (8) females in the third week of lactation. Different mice were used for each treatment. To obtain mice for treatments 1 and 2 individually caged females were monitored daily for reproductive cycle condition via wet-mount vaginal smears (Rugh, 1968; Drickamer, 1982). Only mice clearly in estrus or diestrus were placed in the metabolism cage for urine collection. To obtain females for treatments 3–5, females were placed with adult males and checked daily for vaginal plugs. Pregnancies were timed from the day of discovery of the vaginal plug. In some cases ($N = 9$ across the first two pregnancy treatments), I only determined after the fact that the female was not actually pregnant. Data from those mice were discarded and additional females were tested to obtain the required sample size. For treatments 6–8, pregnant females were monitored until parturition. The intervals for urine collection during lactation were timed from parturition until the completion of the three-week lactation period. Data were subjected to a one-way analysis of variance and post-hoc testing using a Tukey-Kramer procedure with $\alpha = 0.02$.

Experiment III: Crowding Effects. To test the possible effects of density on urine output per day, I used 576 mice, 288 of each gender. Adult mice, 130–170 days of age, were used in one of six treatments ($N = 12$ cages of each type for each gender): (1) housed individually, (2) housed 2 mice/cage, (3) housed 3 mice/cage, (4) housed 4 mice/cage, (5) housed 6 mice/cage, and (6) housed 8 mice/cage. Mice were placed into these housing conditions for 3 to 4 weeks prior to their use in urine collection. Cages with grouped mice were comprised of nonsiblings. For urine collection, only one mouse, selected at random, was tested from each cage. Data were subjected to a two-way analysis of variance with the two genders and six density treatments as the main factors.

Experiment IV: Gonadectomy Effects. To explore the effects of gonadectomy on urine output per day, I used 28 male and 28 female mice, all aged 125–165 days of age. There were four treatment groups ($N = 14$ cages of each type): (1) singly-caged intact males, (2) singly-caged castrated males, (3) singly-caged intact females, and (4) singly-caged ovariectomized females. Gonadectomies were performed under ether anesthesia when the mice were 110–140 days of age, and all operated mice were housed individually and given three weeks to recover prior to initiation of the treatment conditions. Data from males and females were subjected to separate t tests.

Experiment V: Social Status Effects. Possible effects of social status on urine output per day were tested using 12 groups of four mice each for males and for females. All mice were 110–140 days of age when dominance testing began. Groups were comprised of nonsiblings. In four instances, all with cages of males, aggression became so severe that I eliminated the group from the

experiment, substituted a new group of males, and separated the males in the original cage. Each mouse in a group received a small colored mark (red, green, blue, black) on its back at the base of the tail from a series of permanent ink marking pens. Marks were refreshed on the third and sixth days of observation. These identification marks were used during twice-daily 1-hr observations of the mice in their home cage to determine dominance status relationships. These observations were conducted for a minimum of five and a maximum of eight days to ascertain and confirm the dominance positions of the mice in each group. In all cases it was possible to assign the top and bottom rankings, but there was some question about assignment of the second and third ranking mice in some cages of each gender. Therefore, I elected to limit the treatment conditions to three: (1) most dominant individuals, (2) middle ranking mice, including both the second and third positions in the hierarchy, and (3) most subordinate individuals. Urine collection from all four mice in a cage was carried out on the same day, and the group was not reconstituted afterwards. Data from males and females were subjected to separate one-way analyses of variance and post-hoc testing for males was carried out using a Tukey-Kramer procedure with $\alpha = 0.02$.

RESULTS

Experiment I: Gender and Age Effects. Both the main treatment factors for gender ($F = 240.47$; $df = 1,176$; $P < 0.001$) and age ($F = 31.49$; $df = 7,176$; $P < 0.001$), as well as the interaction term ($F = 8.12$; $df = 7,176$; $P < 0.001$) were significant. Mean urine output per day within males was significantly lower at 25–45 days of age than at all subsequent ages (Table 1). Within females, there was an overlapping pattern of significant differences in mean urine output per day; in general, older females had higher output (Table 1). Males had higher mean urine output per day than females at all ages. The significant interaction was due to the fact that the ratio of urine output per day by males to that by females was approximately 1.5 : 1 at younger ages and shifted at about 2 : 1 at later ages. Correlations between body mass and urine output per day were significant for males at all ages (35 days of age: $r = 0.766$; $P = 0.0037$; 55 days of age: $r = 0.811$; $P = 0.0014$; 100 days of age: $r = 0.719$; $P < 0.0084$; 150 days of age: $r = 0.835$; $P < 0.0007$) and for females at all ages (35 days of age: $r = 0.923$; $P < 0.001$; 55 days of age: $r = 0.763$; $P = 0.0039$; 100 days of age: $r = 0.907$; $P < 0.001$; 150 days of age: $r = 0.910$; $P < 0.001$).

Experiment II: Female Reproductive Condition. There were significant differences in urine output per day according to reproductive condition ($F = 6.20$; $df = 7,104$; $P < 0.001$). Post-hoc comparisons revealed that females in diestrus had significantly lower urine output per day than all other treatments, including females in estrus (Table 2). There was a significant pattern within pregnant

TABLE 1. MEAN VALUES (± 1 SEM) OF URINE OUTPUT PER DAY BY MICE OF BOTH SEXES AND EIGHT DIFFERENT AGES[a]

Age (days)	Urine output (ml/day)	
	Males	Females
25	1.7 (0.2)A	1.1 (0.1)A
35	2.1 (0.2)A	1.4 (0.1)AB
45	2.4 (0.2)A	1.8 (0.2)ABC
55	3.6 (0.2)B	2.1 (0.2)BC
75	4.2 (0.2)B	2.1 (0.2)BC
100	4.4 (0.2)B	2.1 (0.2)BC
125	4.2 (0.2)B	2.0 (0.1)BC
150	4.4 (0.3)B	2.4 (0.2)C

[a]Those means in each column not marked with the same letter are significantly different at the $\alpha = 0.02$ level. $N = 12$ mice/treatment.

females; urine output per day was significantly less during early pregnancy compared to the final days of pregnancy.

Experiment III: Density Effects. The main treatment effect for gender was significant ($F = 174.31$; $df = 1,132$; $P < 0.001$), but neither the main treatment effect for density ($F = 1.98$; $df = 5,132$; P = NS) nor the interaction term ($F = 1.96$; $df = 5,132$; P = NS) were significant. As in experiment I, males had significantly higher urine output per day than females (Table 3).

TABLE 2. MEAN VALUES (±1 SEM) OF URINE OUTPUT PER DAY BY FEMALE MICE IN TWO DIFFERENT STAGES OF ESTRUS, THREE DIFFERENT INTERVALS DURING PREGNANCY, AND THREE DIFFERENT INTERVALS DURING LACTATION[a]

Treatment	Urine output (ml/day)
Female in estrus	2.6 (0.1)BC
Female in diestrus	1.8 (0.1)A
Pregnant female (days 1–6)	2.4 (0.2)B
Pregnant female (days 7–12)	2.9 (0.2)BCD
Pregnant female (days 13–18)	3.2 (0.2)CD
Lactating female (days 1–7)	3.1 (0.3)CD
Lactating females (days 8–14)	3.0 (0.2)CD
Lactating females (days 15–21)	3.0 (0.2)CD

[a]Those means not marked with the same letter are significantly different at the $\alpha = 0.02$ level. $N = 14$ mice/treatment.

TABLE 3. MEAN VALUES PER MOUSE (±1 SEM) OF URINE OUTPUT PER DAY BY MICE OF BOTH SEXES AND SIX DIFFERENT DENSITY TREATMENTS (N = 12 MICE/TREATMENTS)

	Urine output (ml/day)	
Density	Males	Females
1/cage	3.7 (0.2)	2.0 (0.2)
2/cage	4.0 (0.3)	2.4 (0.1)
3/cage	4.1 (0.2)	2.2 (0.2)
4/cage	3.8 (0.4)	2.4 (0.2)
6/cage	3.9 (0.5)	2.4 (0.2)
8/cage	4.4 (0.5)	2.6 (0.2)

Experiment IV: Gonadectomy Effects. For males, there was a significant effect of gonadectomy (t = 4.375; df = 26; $P < 0.001$) on urine output per day. Castration significantly reduced urine output (mean = 4.3 ± 0.3 ml/day for intact males and mean = 2.9 ± 0.2 ml/day for castrated males). For females, there was no effect of gonadectomy on urine output per day (t = 0.303; df = 26; P = NS) (mean = 2.4 ± 0.3 ml/day for intact females and mean = 2.5 ± 0.2 ml/day for ovariectomized females).

Experiment V: Social Status Effects. For males, there was a significant effect of dominance status on urine output per day (F = 40.22; df = 2,45; $P < 0.001$). The post-hoc analysis revealed that top ranked males had significantly higher urine output per day than middle ranking males, which, in turn, had significantly higher urine output per day than the lowest ranking males (Table 4). For females, there was no effect of dominance status on urine output per day (F = 2.00; df = 2,45; P = NS).

TABLE 4. MEAN VALUES (±1 SEM) OF URINE OUTPUT PER DAY BY MICE OF BOTH SEXES AND THREE DIFFERENT LEVELS OF DOMINANCE STATUS[a]

	Urine output (ml/day)	
Treatment (N)	Males	Females
Top ranked (12)	5.4 (0.2)C	2.7 (0.2)
Second and third ranked (24)	3.7 (0.2)B	2.3 (0.1)
Fourth ranked (12)	2.7 (0.2)A	2.2 (0.2)

[a]Those means in the first column not marked with the same letter are significantly different at the α = 0.02 level.

DISCUSSION

The foregoing experiments provide support for the following conclusions: (1) Male house mice excrete urine at a rate 1.5–2.0 times that of females. (2) Urine output per day increases with age for both genders. (3) For mice of the same age, urine output per day is correlated with body mass. (4) Females in estrus produce more urine per day than females in diestrus. (5) Urine output per day increases during pregnancy and remains high throughout lactation. (6) Density does not influence urine output per day for either gender over the range of densities tested. (7) Castration reduces urine output per day in male mice, but ovariectomy in females does not alter the rate of daily urine production. (8) Dominant males produce more urine per day than subordinate males, but there are no similar effects for female mice. These results can be interpreted in terms of the social biology and ecology of the mice, and, in some cases, in terms of their physiology.

Finding that urine output per day increases with age and with body mass is not surprising. The general rate of urine excretion is similar to the values from Bing and Mendel (1931), and the age-related changes reported here are in agreement with Chew and Hinegardner (1957). I do not have any explanation for my values being considerably less than those recorded by Chew and Hinegardner (1957), except possibly that the average body mass of their mice was higher than of the mice I tested. The significant difference between males and females in urine output per day differs from the findings of Chew and Hinegardner (1957), exceeds what would be expected based on any possible gender differences in body mass, and is consistently present at all ages tested. A key problem then is to explain the possible proximate and ultimate reasons for this gender difference.

That males excrete more urine per day than females is in accord with earlier reports that males urine mark at roughly twice the rate of females (Maruniak et al., 1975; Powell and Wolff, 1982). The extra marking by males could be related to the fact that they are more likely to be using urine to mark territory boundaries than are females. The higher levels of urine excretion by males appear to be testosterone dependent, as the volume drops to levels comparable to those recorded for females after males have been castrated. Further evidence of the role of testosterone comes from the data on dominance status and urine output per day. Since aggressiveness and dominance are related to testosterone in house mice (Barkley and Goldman, 1977a–c), we can predict that social dominance is associated with the tendency to establish and maintain a larger territory, corresponding with the need for more urine to mark the territory. Subordinate males, or those that are castrated and thus have lower testosterone, would have lower urine output per day and would mark less. Thus, higher testosterone and higher dominance status are linked (cause and effect cannot be readily separated) and, in some combination, they lead to greater quantities of urine production.

It is noteworthy that females in estrus excrete more urine than those in diestrus. If urine of females signals conspecifics about reproductive condition, then we might expect females in estrus to excrete additional urine to attract potential mates. This is supported by earlier reports that males prefer the odors of estrous to diestrous females (Rose and Drickamer, 1975; Sokolov and Kotenkova, 1976; Drickamer, 1995) and by Hurst's (1990b) finding that female mice advertise their status and condition through urine marks. Although dominant females may mark more (Hurst, 1990b), my findings indicate that, contrary to my previous logic concerning males, dominant females do not produce a significantly higher volume of urine per day than lower ranking females. I have no thorough explanation for the positive effects of dominance in males on their urine production versus that there is no such effect in females, although there are at least two possibilities. The first is that higher urine volume per day is related to higher levels of testosterone in male mice. Second, in the polygynous mating system of the house mouse and with a key function of urinary chemosignal cues in female mice being to signal their reproductive status, the subordinate females, when they come into estrus, may be competing for mates and thus they could have urine output per day similar to those of higher ranking females.

The somewhat higher rates of urine output per day for females that are pregnant may be due to purely physiological reasons. This notion is supported by the fact that females in the latter two thirds of gestation excrete more urine per day than those early in gestation. Females later in gestation are carrying larger fetuses and are providing the excretory function for those fetuses. Higher urine excretion rates for lactating females could, in addition to physiological reasons relating to the process of lactation and facilitation of excretion by the young, contribute to their use of that urine as a signal to other conspecifics to maintain their distance. Beginning near parturition and continuing through lactation, female mice are quite aggressive toward conspecifics, presumably as a measure of protection for their litter (Svare, 1981; Svare and Mann, 1983). Deposition of urine as a cue indicating their lactational status and as a warning to conspecifics could be an efficient means of avoiding more overt conflicts. These findings fit with evidence for avoidance of urine cues from pregnant and lactating females (Brown, 1985a; Drickamer, 1995). To my knowledge, no one has yet studied the rates of urine marking by pregnant or lactating female mice.

That density does not influence the rate of urine excretion per mouse is curious. Based on earlier work linking higher density with stress, and stress, in turn, with less urine excretion via the effects of vasopressin (Zikmund and Lichardus, 1961; Scharrer and Scharrer, 1963; Christian and Davis, 1964; Levine and Treiman, 1964; Levin et al., 1974; Drickamer and McIntosh, 1980), I might have predicted urine output per day per mouse to decrease with increasing density for one or both genders. I do not have an explanation for the lack of a

density effect, other than to suggest that it is likely that a number of interacting factors, including density-related stress and social status relationships among the mice could be affecting urine output per day. This suggestion concerning social status effects is supported, to some degree, by the fact that the standard errors for the mean daily urine output of male, but not female, mice in higher density cages are larger than for mice at lower cage densities. For males, the larger amount of variation could be attributable to the fact that there are dominance relationships among the males, with some, higher ranking males, excreting more urine and other, lower ranking males, excreting smaller amounts. It could also be the case that some critical or threshold density must be reached before density effects on urine output per day occur. This explanation seems less likely given the very high densities that already exist under the caging conditions used relative to any densities obtained in free ranging mice (Anderson, 1961).

Acknowledgments—I thank Williams College for providing the facilities for conducting these experiments and the farmers in the Williamstown, Massachusetts, area for permitting me to trap wild house mice. Lynn L. Gillie, Ami Sessions Robinson, Christopher Holmes, Sabine Schmid, and two anonymous reviewers kindly provided comments on an earlier draft of this manuscript.

(Received Feburary 1, 1994; accepted May 24, 1995)

Abstract—The substrate specificity of the acetyltransferase and the reductase enzyme systems used by *Ostrinia furnacalis* (Lepidoptera: Pyralidae) in pheromone biosynthesis was studied in vivo by topical application of precursors to pheromone glands. Each of the tetradecenols, varying in double bond position (from 7 to 13) and geometry of the double bond, was converted to the corresponding acetate by the acetyltransferase. The similarity in the conversion rates of all tested fatty alcohols indicated that the acetyltransferase has a low substrate specificity. Most of the corresponding tetradecenoic acids could also be converted to the respective acetates. However, very different conversion rates among the tested fatty acids demonstrated that the reductase system has a higher substrate specificity than the acetyltransferase. The conversion rates of most *E* isomers were higher than those of the corresponding *Z* isomers, except for the (Δ)-11-tetradecenoic acids, in which much more *Z* isomer was converted to the product. Saturated tetradecanoic acid was converted to the corresponding acetate at a high rate; the shorter homolog, tridecanoic acid, was converted at a lower rate (56%), and conversion to the respective acetates of the longer homolog, pentadecanoic and hexadecanoic acids, was insignificant (<5%). The results from the present study showed that specificity of pheromone production is to a large extent controlled by the pheromone gland reductase system.

INTRODUCTION

Many moths use *E/Z* isomers of monounsaturated acetates in specific ratios in their sex pheromones. The sex pheromone of *Ostrinia furnacalis* Guenée (Lepidoptera: Pyralidae), consists of (*E*)- and (*Z*)-12-tetradecenyl acetate (*E*12- and *Z*12-14:OAc) in a 47:53 ratio (Cheng et al., 1981). Two pheromone strains of the European corn borer, *Ostrinia nubilalis* Hübner, both have (*E*)- and (*Z*)-11-tetradecenyl acetate (*E*11- and *Z*11-14:OAc) as pheromone components but in different ratios: an *E/Z* ratio of 99:1 was found in *E* strain, whereas the same compounds were produced in a 3:97 ratio in the *Z* strain (Kochansky et al., 1975; Klun and Cooperators, 1975). Studies of the pheromone biosynthesis in both species showed a difference between isomeric ratios of acetates and the corresponding fatty acid precursors in the pheromone glands. In *O. furnacalis*, the ratio of (*E*)- and (*Z*)-12-tetradecenoate (*E*- and *Z*12-14:OAcyl) is about 12:88 (Zhao et al., 1990). Both the *E* and *Z* strains of *O. nubilalis* have a 70:30 *E/Z* ratio of Δ11-tetradecenoate (Δ11-14:Acyl) (Wolf and Roelofs, 1987; Jurenka and Roelofs, 1989). The specific *E/Z* ratio of acetates in *O. nubilalis* and *O. furnacalis* may thus be produced from the immediate fatty acid precursors by the selectivity of the postulated last two steps in the pheromone biosynthetic pathway: reduction and acetylation (Wolf and Roelofs, 1987; Zhao et al., 1990).

Recently, in vivo experiments demonstrated that the acetylation step has a very low substrate specificity in three noctuid species (Teal and Tumlinson, 1987; Bestmann et al., 1987; Dunkelblum et al., 1989). In contrast, an in vitro enzyme assay showed that the acetyltransferase exhibited some selectivity for the *Z* isomer of Δ11-tetradecenol (Δ11-14:OH) in *Argyrotaenia velutinana* Walker and three other species of tortricid moths, but not in *E*, *Z* and hybrid strains of *O. nubilalis*. Thus, in the later case, the *E/Z* acetate ratios produced may be due to the selectivity of the reduction step, whereas in *A. velutinana* the specific *E/Z* ratio may be controlled by the coupling of the reductase and the acetyltransferase (Jurenka and Roelofs, 1989). In general, the reductase system should be very important for the production of a specific ratio of acetates in many moth species, including tortricid moths (Morse and Meighen, 1987; Jurenka and Roelofs, 1989). However, so far the substrate specificity of the reductase in moth pheromone biosynthesis systems has not been experimentally investigated.

In the present study, we investigated the selectivity of the acetyltransferase and the reductase enzymes in *O. furnacalis* based on in vivo experiments using

a series of tetradecenols (Δ14 : OH) and tetradecenoic acids (Δ14 : Acid) as substrates.

METHODS AND MATERIALS

Chemicals. Tetradecenols, varying in double bond position from 7 to 13 as well as in geometry of the double bond, were purchased from the Research Institute for Plant Protection (Wageningen, The Netherlands). Gas chromatographic analyses using a BP-20 capillary column showed that the purity of the alcohols ranged from 96.3 to 99.4% and that the corresponding geometric isomer in each compound was less than 1%. Tetradecanol (14 : OH) and tridecanoic acid (13 : Acid) were available in our laboratory. [14,14,14-$^2H_3$]Tetradecanoic acid ([14-D_3]14 : Acid), [15,15,15-$^2H_3$]pentadecanoic acid ([15-D_3]15 : Acid), and [16,16,16-$^2H_3$]hexadecanoic acid ([16-D_3]16 : Acid) were purchased from Larodan Fine Chemicals, Malmö, Sweden.

Each of the tetradecenoic acids was prepared from the corresponding alcohol by a method modified from Corey and Smidt (1979): 45 μl of an alcohol, 600 mg pyridinium dichromate (PDC), and 2 ml dry dimethylformamide (DMF) were added to an 8-ml vial with a Teflon-lined screw cap. After 12 hr at 25°C without stirring, the reaction was stopped and the rest of the steps were performed as described by Corey and Smidt (1979).

The products were purified by centrifugal chromatography. Petroleum ether (60–90°)–ether–acetic acid (90 : 10 : 1) was used as the developing solvent at 3 ml/min flow rate. The fractions containing tetradecenoic acids were combined, and the solvent was removed with a stream of nitrogen. Capillary GC analyses of the fatty acids after conversion to methyl esters indicated that all were at least 96% pure and no corresponding alcohol or aldehyde was detected (the limit of detection was 0.1%). The yield for the different acids varied between 50 and 70%.

Deuterium-labeled pheromone precursors were synthesized by the procedures described below. High-resolution mass spectra of final products were recorded on a Jeol SX-102 mass spectrometer. ^1H NMR spectra were recorded on a Varian XL-300 spectrometer in $CDCl_3$ solutions with Me_4Si as the internal reference. Products were purified by flash chromatography (Taber, 1982) on TLC-Silica gel 60 H supplied by Merck and argentation liquid chromatography (Houx et al., 1974). DMPU was purchased from Fluka AB. Immediately before use, it was distilled over CaH_2 at reduced pressure and kept over 4 Å molecular sieves under an argon atmosphere.

(*Z*)-[14,14,14-$^2H_3$]12-Tetradecenoic acid (**1**) ([14-D_3]*Z*12–14 : Acid) (Figure 1) was prepared from 1-(2-tetrahydropyranyloxy)-dodecyne (6.0 g, 21 mmol) (**3**) (Smith and Beumel, 1974; Rossi et al., 1980) *n*-butyl lithium (11 ml, 2.09

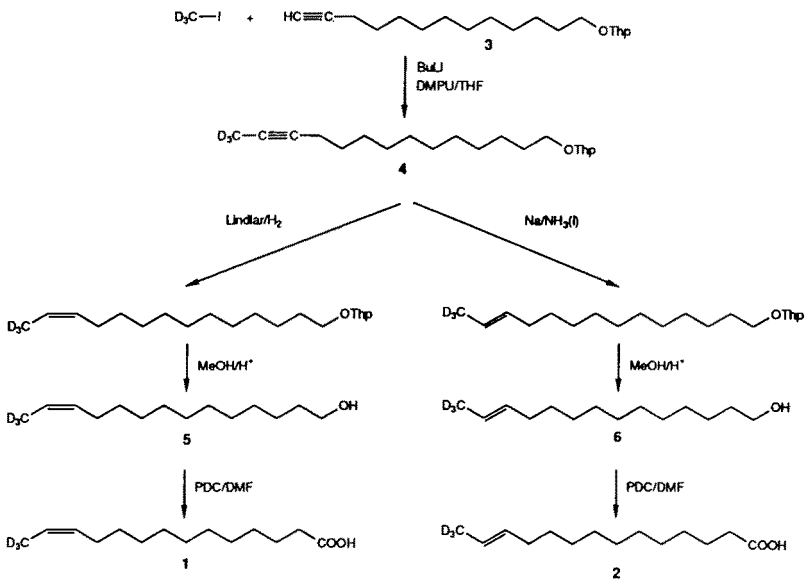

FIG. 1. Scheme for the synthesis of (*Z*)- and (*E*)-[14,14,14-$^2H_3$]12-tetradecenoic acid.

M in hexane) in dry THF (21 ml) and [$^2H_3$]methyl iodide (4.1 g, 34 mmol) in DMPU (36 ml) according to a method previously described for similar systems (Bengtsson and Liljefors, 1988) affording 5.6 g (88%) of the product (**4**) (Figure 1) after flash chromatography. Reduction with Lindlar catalyst (Leznoff et al., 1977; Wong et al., 1984) gave the *Z* monoene, which was converted to the corresponding alcohol (**5**) by treatment with *p*-toluenesulfonic acid in methanol. The fatty alcohol (**5**) was oxidized by the same method used in the synthesis of Δ14:Acid and purified with liquid chromatography.

The final product (**1**) was obtained in 60% overall yield. *m/z* 229 (M^+, 11%), 211(31), 169(17), 137(13), 124(20), 110(31), 97(49), 83(60), 69(100), 58(77), 55(97), 41(51). High-resolution mass spectra: $[M]^+_{calc}$ = 229.2121, $[M]^+_{obs}$ = 229.2114. ^1H NMR (300 MHz); δ 1.27–1.35 (m, 14H, CH_2CH_2), 1.58–1.65 (m, 2H, CH_2—C—COOH), 1.99–2.05 (m, 2H, CH_2—C=C), 2.35 (t, 2H, CH_2—COOH), 5.36–5.41 (m, 2H, CH=CH). Capillary GC analyses showed that the purity of (*Z*) [14,14,14-$^2H_3$]12-tetradecenol ([14-D_3]*Z*12-14:OH) was 97.4%, and no *E* isomer was detected (the limit of detection was 0.1%). The purity of [14-D_3]*Z*12-14:Acid was 97.4%, with no corresponding alcohol detected.

(*E*)-[14,14,14-$^2H_3$]12-Tetradecenoic acid (**2**) ([14-D_3]*E*12-14:Acid) was prepared as described above for the corresponding *Z* isomer (**1**), except that the

reduction of the triple bond was instead performed with sodium in liquid ammonia (Warthen and Jacobson, 1973) to give the desired *E* monoene. *m/z* 229 (M^+, 11%), 211(27), 193(4), 169(15), 138(12), 123(19), 110(31), 97(46), 83(57), 69(88), 58(90), 55(100), 43(42), 41(59). High-resolution mass spectra: $[M]^+_{calc}$ = 229.2121, $[M]^+_{obs}$ = 229.2115. ^1H NMR (300 MHz); δ 1.23–1.28 (m, 14H, CH_2CH_2), 1.60–1.65 (m, 2H, CH_2—C—COOH), 1.92–1.98 (m, 2H, CH_2—C=), 2.32 (t, 2H, CH_2—COOH), 5.39–5.42 (m, 2H, CH=CH). Capillary GC analyses showed that the purity of (*E*)-[14,14,14-$^2H_3$]12-tetradecenol ([14-D_3]*E*12-14:OH) was 94.0%, and the corresponding *Z* isomer was 0.9%. The purity of [14-D_3]*E*12-14:Acid was 95.7%, and no corresponding alcohol was detected.

Insect Source, Application of Fatty Alcohol or Fatty Acid to Pheromone Glands. Insects were reared as previously described (Zhao et al., 1990). Pupae were sexed and then kept under a 16:8 hr light–dark cycle. The application procedure was as follows, unless otherwise specified: 5–8 hr after dark, 24 to 48 hr old female moths were used for topical application (Bjostad and Roelofs, 1981; Zhao et al., 1990) of a tested compound. (*E*)-11-Tetradecenol (*E*11-14:OH) and (*E*)-11-tetradecenoic acid (*E*11-14:Acid) were chosen as metabolic standards for studying substrate specificity of the acetyltransferase and the reductase, respectively. The glands were exposed by gently squeezing the female abdomen. To each pheromone gland we applied 0.05 μl dimethyl sulfoxide (DMSO) containing 500 ng of a mixture of a standard and the compound to be tested in an approximate 1:1 ratio. About 15 min after application, the pheromone glands (5 glands/batch for the acetyltransferase study and 10 glands/batch for the reductase study) were extracted with hexane containing 6 ng of pentadecyl acetate as an internal standard for about 1 hr.

Chain length specificity of the reductase was investigated in two separate experiments. In the first experiment, a mixture of 13:Acid, [14-D_3]14:Acid, and [15-D_3]15:Acid was applied to glands of 3–9 females. Conversion rates in each batch (replicate) were calculated relative to that of [14-D_3]14:Acid. In the second experiment, a mixture of 13:Acid and [16-D_3]16:Acid was applied to glands of 5–10 females.

Gas Chromatography and Combined Gas Chromatography–Mass Spectrometry. Gas chromatographic (GC) analyses were performed on a Pye Unicam 204 GC equipped with a splitless capillary injector, a flame ionization detector, and an HP 3394 integrator. The linear velocity of the carrier gas (hydrogen) was 50 cm/sec and the purge valve was opened 0.25 min after injection. The following columns were used for the separation of various positional and geometric isomers of tetradecenyl acetates in the extracts: (A) 25 m × 0.22 mm ID BP-20 (Pye Unicam), temperature program: 1 min at 80°C and then 3°/min to 200°C; (B) 25 m × 0.22 mm ID BP-5 (SGE), temperature program: 1 min at 80°C and then 4°/min to 200°C; (C) 50 m × 0.22 mm ID BP-20 (SGE), temperature program: 1 min at 80°C and then 2°/min to 200°C; and (D) 51 m

× 0.22 mm ID CPSIL 88 (Chrompack), temperature program: 1 min at 80°C and then 2°/min to 200°C.

Gas chromatographic–mass spectrometric analyses (GC-MS) were performed using an Hewlett-Packard 5970B GC-MS system (electron impact, 70 eV) equipped with a 59970B computer system and interfaced with an Hewlett-Packard model 5890 GC. The diagnostic ions *m/z* 194.20 and *m/z* 197.20 were selected in an acquisition program to monitor unlabeled and D_3-labeled tetradecenyl acetates, respectively. Other acetates were also monitored at ions corresponding to [M-60].

Relative Conversion Factors. To define substrate specificity, a relative conversion factor was calculated for each compound tested. The relative conversion factor (RCF) for a specific compound was calculated as:

$$RCF = (\text{Test:OAc}/E11\text{–}14\text{:OAc}) \times (\text{Met stand/test compound})$$

Test:OAc/*E*11–14:OAc is the ratio between the acetate generated from the test compound and *E*11–14:OAc generated from the metabolic standard in gland extracts after incubation as determined by GC or GC-MS analyses. Met stand/test compound is the GC-determined ratio between the amounts of the compound to be tested and the metabolic standard in the solution that was applied to the gland (this ratio was always close to 1 but varied slightly between mixtures, which made this correction necessary).

Synthetic samples of the naturally occurring pheromone precursors, (*E*)- and (*Z*)-12-tetradecenol (*E*12- and *Z*12–14:OH), were initially used to determine the relative conversion factors for these isomers. The amount of *E*12- or *Z*12–14:OAc from the corresponding applied precursor was calculated by subtraction of the average amount of natural pheromone in a control group (no acids applied). The amount of tetradecanyl acetate (14:OAc) produced from applied 14:OH was calculated in a similar way (a normal ratio between native 14:OAc and one of the pheromone components was determined in control groups); thus, the relative conversion factor of 14:OH was calculated. The deuterated precursors [14-D_3]*E*12- and [14-D_3]*Z*12–14:OH were synthesized in the course of the study, and the relative conversion factors of *E* and *Z*12–14:OH were confirmed by the application of these compounds.

The relative conversion factors of (*E*)- and (*Z*)-12-tetradecenoic acid (*E*12- and *Z*12–14:Acid) were also determined with both unlabeled and labeled acids ([14-D_3]*E*- and [14-D_3]*Z*12–14:Acid, compounds **2** and **1** and Figure 1), using the same approach as in the acetyltransferase study.

RESULTS

Dosage for Topical Application. In an initial experiment, 100 ng of (*Z*)-11-tetradecenoic acid (*Z*11–14:Acid) was applied to the pheromone glands. One

batch of 10 female glands was incubated for 15 min, and another one was incubated for 30 min. Gas chromatographic analyses showed that the average recovered amount of Z11-14:OAc was significantly larger after 15 min of incubation than after an incubation time of 30 min (3.03 and 1.16 ng, respectively; t test, $P \leq 0.05$, $N = 5$). Thus, 15 min of incubation was used in all of the following experiments. Glands incubated with larger amounts of Z11-14:Acid produced slightly more Z11-14:OAc. It was evident from this experiment that the amount of the product may vary considerably between replicates (Figure 2). We subsequently used a dosage of 250 ng of a tested fatty acid or a tested fatty alcohol throughout the study.

Acetyltransferase Specificity. In the study of the acetyltransferase specificity, each of the tetradecenols tested, as well as the saturated 14:OH, was converted to the corresponding acetate with similar relative conversion factors (Figure 3) with one exception. The exception was (Z)-7-tetradecenol (Z7-14:OH), for which the smallest relative conversion factor (0.56) was determined. The relative conversion factors for the other fatty alcohols were in the range of 0.72 to 1.01. For each pair of geometric isomers the E isomer was normally converted at a higher rate than the Z isomer. A typical mass chromatogram showed that [14-D_3]E12-14:OH and E11-14:OH were converted to the corresponding acetates in approximately equal amounts (Figure 4A). Very similar relative conversion factors of E- and Z12-14:OH were obtained from both unlabeled and labeled precursors (Figure 3).

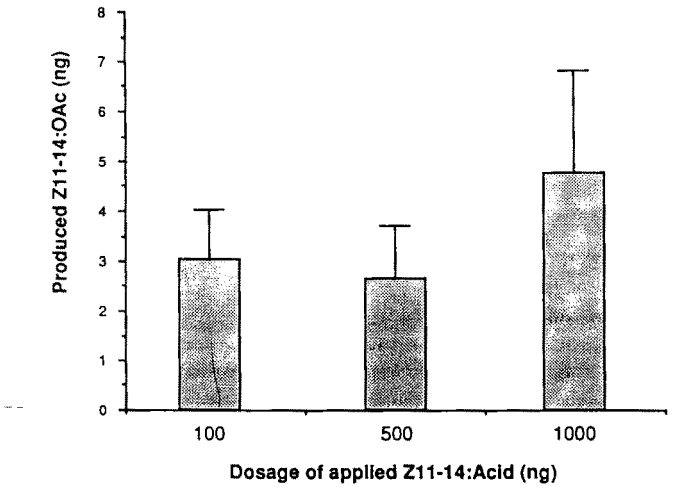

FIG. 2. Titer of Z11-14:OAc in pheromone glands of *O. furnacalis* as determined by GC analysis after topical application of different amounts of Z11-14:Acid and 15 min of incubation ($N = 5$, each batch consisted of 10 female glands).

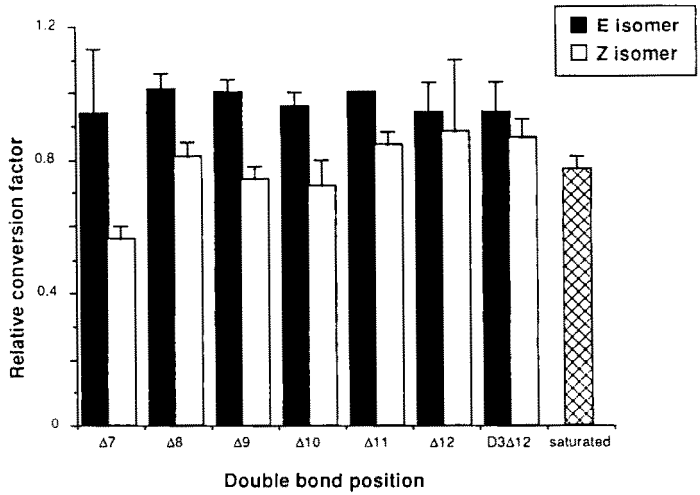

FIG. 3. Substrate preference of the acetyltransferase in *O. furnacalis* for 14-carbon alcohols. All conversion factors are normalized to that of *E*11–14:OH, which thus becomes 1.0 ± 0.0 by definition. The relative conversion factors of Δ7, Δ11, Δ12, and saturated 14:OH were determined by GC analyses of gland extracts from five females ($N = 6$). The relative conversion factors of Δ8, Δ9, Δ10, and [14-D_3]Δ12–14:OH (D3Δ12) were determined by GC-MS analyses of individual females ($N = 4$). Vertical bars indicate standard error of the mean.

Reductase Specificity. In the study of the reductase specifity, most of the tetradecenoic acids varying in double bond position (from 7 to 13) and geometry of the double bond, as well as saturated [14-D_3]14:Acid, were converted to the corresponding acetates, but with very different conversion factors (Figure 5).

The relative conversion factors of the *E* isomers of the tested Δ14:Acids were larger than those of the corresponding *Z* isomers, except for Δ11–14:Acid, in which the relative conversion factor of the *Z* isomer is much larger than that of the *E* isomer (Figure 5). The smallest conversion factor was found for the (*Z*)-7- and (*Z*)-8-tetradecenoic acids, from which the corresponding acetates could not be detected by GC upon incubation with pheromone glands. A typical mass chromatogram showed that [14-D_3]*E*12–14:Acid and *E*11–14:Acid were converted to the corresponding acetates at different rates (Figure 4B). The relative conversion factor for [14-D_3]*E*12–14:Acid was 2.6 ± 0.2, while the factor for [14-D_3]*Z*12–14:Acid was 1.4 ± 0.1. Thus, the relative conversion factor for the *E* isomer pheromone precursor was almost two times larger than that of the *Z* isomer. This relation was also found for unlabeled pheromone precursors (Figure 5).

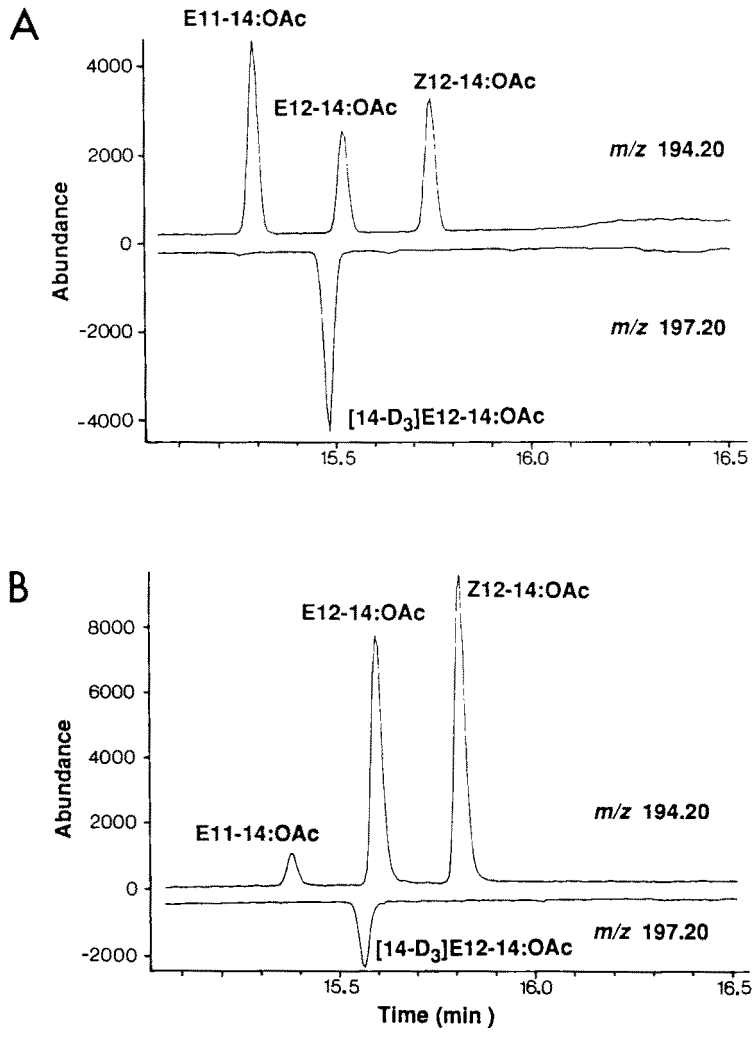

FIG. 4. Mass chromatograms from analyses of the pheromone gland extracts of *O. furnacalis* showing labeled and native pheromone components after application of labeled pheromone precursors. (A) The acetates produced from the extract of a gland after application of [14-D_3]E12-14:OH and *E*11-14:OH. (B) The acetates produced from the extract of two glands after application of [14-D_3]*E*12-14:Acid and *E*11-14:Acid.

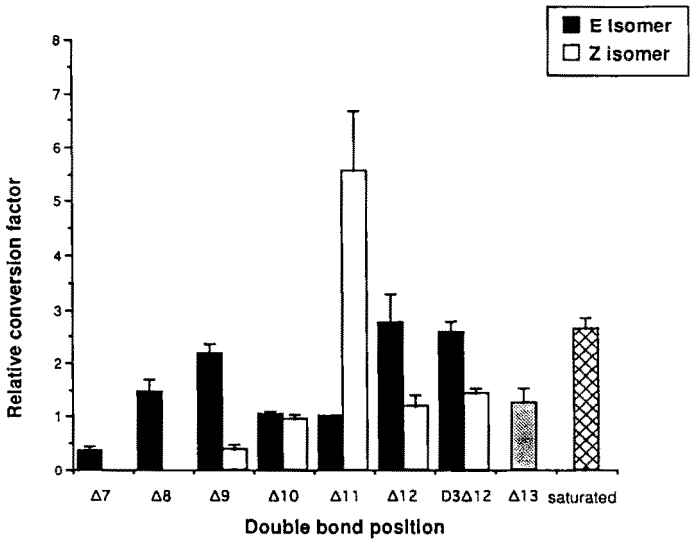

FIG. 5. Substrate preference of the fatty acid reductase in *O. furnacalis* for 14-carbon acids. All conversion factors are normalized to that of *E*11-14:Acid, which thus becomes 1.0 ± 0.0 by definition. The relative conversion factors of [14-D_3]Δ12-14:Acid (D3Δ12) were determined by GC-MS analyses of gland extracts from two females (N = 6). The relative conversion factors of other fatty acids including [14-D_3]14:Acid (saturated) were determined by GC analyses of pooled gland extracts from 10 females (N = 6). The relative conversion factors of *Z*7- and *Z*8-14:Acid were below the limit of detection. Vertical bars indicate standard error of the mean.

Conversion of 13:Acid to the corresponding acetate was less than 60% of that obtained with [14-D_3]14:Acid (Table 1). For the longer homolog, [15-D_3]15:Acid, conversion to acetate was less than 5% of that observed with the 14-carbon substrate, and with [16-D_3]16:Acid the production of acetate was below the limit of detection.

Production of Specific Ratios. *E/Z* ratios of the pheromone precursors and components obtained by GC-MS analyses of methanolized and acetylated gland extracts were compiled from two earlier investigations (Zhao and Wang, 1990; Zhao et al., 1990). It is apparent that an approximate 50:50 ratio of *E*12- and *Z*12-14:OAc is produced by the reductase and acetyltransferase from a very different ratio of *E*12- and *Z*12-14:Acyl found in the pheromone gland (15:85 and 24:76, in the two investigations, respectively). Furthermore, the ratio of *E*12- and *Z*12-14:Acyl was produced from another ratio of (*E*)- and (*Z*)-14-

TABLE 1. CONVERSION OF TOPICALLY APPLIED SATURATED FATTY ACIDS TO ACETATES IN PHERMONE GLANDS OF *O. furnacalis*

Substrate	Relative conversion	*N*
13 : Acid	56[a]	6
[14-D_3]14 : Acid	100[b]	6
[15-D_3]15 : Acid	< 5[c]	6
[16-D_3]16 : Acid	0[d]	4

[a] Range of observed values was 47.0–60.7.
[b] Conversion rates were calculated relative to that of [14-D_3]14 : Acid, which thus always became 100 by definition.
[c] Observed values were below the limit of quantification, but were always less than 5% of [14-D_3]14 : OAc.
[d] [16-D_3]16 : OAc was below the limit of detection in all experiments.

hexadecenoate (*E*14- and *Z*14–16 : Acyl, ca. 75 : 25 in the two studies) by a β-oxidase for chain shortening (Figure 6). When a 13 : 87 ratio of [14-D_3]*E*- and [14-D_3]*Z*12–14 : Acid (the ratio is similar to that found in the gland) was applied to the glands, an average ratio 28 : 72 ± 8.5 of [14-D_3]*E*- and [14-D_3]*Z*12 : OAc was obtained from the gland extracts ($N = 6$). The results implied that an approximate 50 : 50 ratio of *E*12- and *Z*12–14 : OAc cannot be produced by the reductase from the ratio of *E*12- and *Z*12–14 : Acyl found in the gland (Figures 5 and 6).

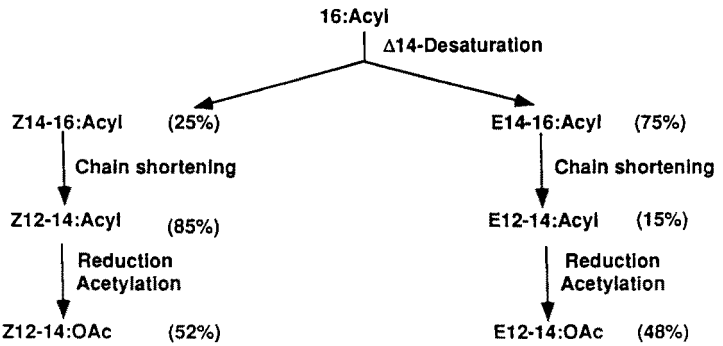

FIG. 6. Biosynthetic pathways for the production of pheromone components in *O. furnacalis* (after Zhao et al., 1990) with data added on the isomeric composition at each level.

DISCUSSION

The production of specific ratios between pheromone components in moths may be controlled by the selectivity of several postulated biosynthetic reactions. In the current study we have demonstrated a high chain-length specificity for the conversion of exogenously applied fatty acids to corresponding acetates in *O. furnacalis*. A highly selective conversion of positional and geometric isomers of tetradecenoic acid to the respective acetates was also shown. In contrast, the postulated final step in the pheromone biosynthesis, the acetylation of alcohols, is essentially nonselective with respect to the geometry and position of the double bond in the tetradecenol substrates. Our interpretation of these results is that the specificity of one or several reaction steps involved in the reduction of fatty acid precursors to alcohols is responsible for the production of a specific ratio between the pheromone components *E*12- and *Z*12-14:OAc.

Ideally it should be possible to study pheromone biosynthesis in individual insects to minimize the need for insect material and labeled precursors and to allow investigations of the biosynthetic basis for individual variation in pheromone composition. In the present study, we made some efforts to optimize the protocol for topical application and in vivo studies of the metabolism of pheromone precursors. We found that in *O. furnacalis*, variation of the dosage of the applied fatty acid between 100 and 1000 ng had no significant influence on the amount of product formed. This result is similar to what was found in *A. velutinana* for the application of tetradecanoic acid. When Bjostad and Roelofs (1986) increased the amount of saturated precursor from 100 to 4000 ng, the production of labeled (*E*)- and (*Z*)-11-tetradecenoate as well as labeled pheromone components increased only slightly. We subsequently used a standard dosage of 250 ng of both acid and alcohol precursors throughout our studies. Obviously, only a small percentage of the topically applied precursor is converted into pheromone components, and this fraction was even lower after 30 than after 15 min of incubation. The 15-min incubation time used in our studies of the acetyltransferase and the reductase in *O. furnacalis* was much shorter than that reported for the study of the actylation of alcohols in *Chrysodeixis chalcites* (Esper) (Dunkelblum et al., 1989) and *Hydraecia micacea* (Esper) (Teal and Tumlinson, 1987), but similar to what was used in the study of acetylation in *Mamestra brassicae* (L.) (Bestmann et al., 1987). In *M. brassicae*, the acetate could be found 5 min after the corresponding alcohol was applied to the pheromone gland. We believe that metabolism of precursors is generally very fast and 15 min of incorporation should normally be sufficient for in vivo studies of moth pheromone production. The decrease in titer of the products after longer periods of incubation could be due to release of pheromone by calling females or to recycling of labeled products, possible explanations that were not further investigated.

The calculation of a relative conversion factor in the present study is similar to the approach previously used by Dunkelblum et al. (1989). *E*11-14:OH and *E*11-14:Acid were chosen as metabolic standards for the acetyltransferase and the reductase study, respectively. These compounds are not naturally present in the gland but they are readily metabolized. The high variation between replicates in the formation of product, whether due to the performance of the insects or to the procedures used, makes the use of a metabolic standard important for every quantitative study of pheromone biosynthesis.

The results from the acetyltransferase study demonstrated low selectivity for tetradecenols with different position and geometry of the double bond. Low substrate specificity of the acetyltransferase was also observed in *H. micacea* (Teal and Tumlinson, 1987), *M. brassicae* (Bestmann et al., 1987), and *C. chalcites* (Dunkelblum et al., 1989). In all these noctuid species, in vivo experiments demonstrated that the acetylation was not specific with respect to carbon chain length, degree of unsaturation, or geometry of double bonds. In vitro experiments showed that 1.5–2.0 times more *Z* isomer of Δ11-14:OH was converted to the corresponding acetate by the acetyltransferase in *A. velutinana*, and similar results were reported for three other species of Tortricidae (Jurenka and Roelofs, 1989). However, in the same study no significant substrate selectivity with respect to *E*11- and *Z*11-14:OH was found in the *E*, *Z*, and hybrid strains of *O. nubilalis*, similar to what we report for *O. furnacalis*. We therefore conclude that the observed differences in substrate specificity among species are not due to the use of different techniques, but rather reflect real differences in insect biochemistry.

In contrast to the low selectivity of the acetyltransferase, high selectivity of the reductase system with respect to chain length and to double bond position and geometry was demonstrated by the experiments with different acid precursors. Because the acetyltransferase has low specificity for the series of corresponding tetradecenols as demonstrated above, the differences in relative conversion factors of the tested fatty acids should be due to high specificity of the reductase or other enzymes involved in the reduction of acyl precursors. To date little is known about the actual pathways for reduction of acids to aldehydes and alcohols in insects (Morse and Meighen, 1987). The fatty acid reductase elucidated in luminescent bacteria is part of a multienzyme complex (500 kDa), the so-called fatty acid reductase complex (for a review, see Meighen, 1993). In moth pheromone biosynthesis, the fatty acid reductase should generally be coupled to an aldehyde reductase, as fatty alcohols and not aldehydes are the normal product of the reduction (Morse and Meighen, 1987). Thus any one or several of the reaction steps taking place in this reductase complex could be responsible for the observed selectivity, In experiments with the European corn borer, *O. nubilalis*, we actually found that reduction of labeled aldehydes, postulated transient intermediates in sex pheromone biosynthesis, showed almost

the same selectivity as the overall conversion of free fatty acids to pheromone components, suggesting that the postulated aldehyde reductase alone may account for the selectivity (Zhu et al., 1995).

Moths do not normally make pheromones from exogenously applied precursors and the fatty acid precursors occur as acyl derivatives rather than free acids in the pheromone glands. Thus the observed selective conversion of precursors to acetates could theoretically be due to differences in uptake between different compounds, selective transport between cell compartments, or selective hydrolysis. However, the current study clearly demonstrates that hexadecanoic acid is not converted to the corresponding acetate 16:OAc, although earlier experiments with *O. furnacalis* (Zhao, et al. 1990) showed that topically applied hexadecanoic acid is readily desaturated, chain-shortened, and finally incorporated into the pheromone components. Thus we find it very unlikely that differences in uptake account for the pattern observed in the current study and favor an explanation involving the selectivity of the reductase complex or enzymes operating in close connection with this. The final proof of this hypothesis awaits the isolation and characterization of the different enzymes involved.

As mentioned above, hexadecanoic acid was not at all converted to the corresponding acetate. Neither was Z7–14:Acid, which is especially interesting as native (*Z*)-7-tetradecenoate is present in gland extracts at a titer comparable to that of (*E*)-12-tetradecenoate, whereas neither (*Z*)-7-tetradecenol nor Z7–14:OAc is (Zhao and Wang, 1990).

The reductase system had a preference for the *E* isomer of most of the Δ14:Acids tested in the present study. The exception from this pattern was Z11–14:Acid, which had the largest relative conversion factor among all the fatty acids tested. The efficient reduction of a fatty acid that does not naturally occur in *O. furnacalis* was surprising to us, but it may indicate a close relationship between this species and the *Z* strain of *O. nubilalis* or another corn borer species in which Z11–14:OAc is a major pheromone component. The productive interaction with Z11–14:Acid may be an evolutionary "memory-effect," an ability that is still there just because it has not been selected against.

The difference in *E/Z* ratios between the pheromone components and precursors can not be entirely accounted for by the twofold higher relative conversion factor for *E*12–14:Acid compared to the *Z* isomer. In *A. velutinana*, it was suggested that the fatty acyl precursors for reduction and acetylation are selected from a fresh supply of phospholipid acyl groups, whereas the unused portion is incorporated into triacylglycerols (Bjostad et al., 1987). More recently, it was proposed that phospholipids are not directly involved in pheromone biosynthesis, but that the biosynthetic enzymes interact with CoA derivatives. Once the intermediates are incorporated into a lipid class, they are no longer available for conversion to a pheromone component (Jurenka and Roelofs, 1993; Russell Jurenka, personal communication). Similarily, one may hypothesize that in

O. furnacalis, the pheromone is biosynthesized from a pool of fatty acids in which the *E/Z* ratio of Δ12–14 : Acyl is different from that found in total lipid extracts of the gland. Unfortunately, it seems as if pheromone biosynthesis in the gland proceeds so fast that the *E/Z* isomeric ratio of Δ12–14 : Acyl from the "fresh pool" can not be determined by in vivo experiments. The titer of deuterium-labeled pheromone was high 10 min after the application of deuterium-labeled palmitic acid to the glands. In *O. furnacalis*, the *E/Z* ratio of Δ12–14 : Acyl available for pheromone production is not only influenced by the geometric specificity of the desaturase, but also by the selectivity of the β-oxidase responsible for chain shortening from a Δ14–16 : Acyl (Figure 6). Therefore, in *O. furnacalis*, the specific *E/Z* ratio of the pheromone is influenced in concert by at least three different enzyme systems in the pheromone biosynthesis.

FOLIAR OXIDATIVE STRESS AND INSECT HERBIVORY: PRIMARY COMPOUNDS, SECONDARY METABOLITES, AND REACTIVE OXYGEN SPECIES AS COMPONENTS OF INDUCED RESISTANCE

J.L. BI and G.W. FELTON*

Department of Entomology
University of Arkansas

(Received October 18, 1994; accepted May 30, 1995)

Abstract—Oxidative responses of plants to pathogens and other environmental stresses have received considerable recent attention. We propose that an oxidative response also occurs following attack by herbivores. Our data strongly indicate a shift in the oxidative status of soybean following herbivory by the insect *Helicoverpa zea*. Herbivory caused significant increases in lipid peroxidation and ·OH radical formation. The activity of several oxidative enzymes including lipoxygenases, peroxidase, diamine oxidase, ascorbate oxidase, and NADH oxidase I increased after herbivory on soybean. The enhanced production of phenolic compounds is indicated by an increase in the activity of phenylalanine ammonia lyase in wounded tissues. On the other hand, the level of soybean foliar antioxidants such as ascorbic acid, total carotenoids, nonprotein thiols, and catalase decreased significantly following herbivory. These results implicate primary compounds (e.g., ascorbic acid, proteins), secondary metabolites (e.g., phenolics), and reactive oxygen species (e.g., hydroxyl radical, hydrogen peroxide) as multiple components of induced resistance. The oxidative changes in the host plant correspond with increased oxidative damage in the midgut of insects feeding on previously wounded plants. Decreases in nonprotein thiols and reduced ascorbic acid occurred in midgut epithelial tissue from insects feeding on wounded plants compared to the insects on control plants. In contrast, midgut hydroperoxides and dehydroascorbic acid concentrations were greater in insects on wounded plants compared to their counterparts on control plants. We conclude that oxidative responses in soybean may have both positive and negative effects upon the host plant: a decrease in herbivory and an increase in oxidative damage to the plant. The salient benefit to the plant, in terms of insect resistance, is the relative balance between these opposing effects.

Key Words—Oxidative stress; induced resistance, reactive oxygen species, soybean, midgut, ascorbic acid, *Helicoverpa zea*, lipoxygenase, peroxides.

INTRODUCTION

The role of oxidative stress in plant–pathogen interactions has received considerable attention during the last decade (Sutherland, 1991; Mehdy, 1994). It is now recognized that one of the most rapid responses in the plant cell following invasion by pathogens is an oxidative burst of reactive oxygen species (Doke, 1983; Apostol et al., 1989; Paxton and Groth, 1994; Mehdy, 1994). Reactive oxygen species include hydrogen peroxide (H_2O_2), hydroxyl radical ($\cdot OH$), and superoxide radical (O_2^-). Bursts of reactive oxygen species in plant tissues occur in response to viruses (Doke and Ohashi, 1988), bacteria (Adam et al., 1989; Devlin and Gustine, 1992), fungi (Doke, 1983; Montalbini, 1991; Davis et al., 1993), and nematodes (Zacheo and Bleve-Zacheo, 1988). These oxygen intermediates, particularly $\cdot OH$, are highly reactive and detrimental to living cells due to their ability to induce lipid peroxidation and DNA and protein oxidation (Fridovich, 1978; Halliwell and Gutteridge, 1985; Imlay et al., 1988). Furthermore, H_2O_2 may be an important signal for eliciting several plant defensive responses associated with systemic acquired resistance (Apostol et al., 1989; Chen et al., 1993).

The oxidative plant responses to attack by arthropod herbivores are comparatively unknown (Hildebrand et al., 1986a,b; Felton et al., 1994a,b). Spider mite damage on soybean foliage increased lipid peroxidation, lipoxygenase (LOX), and peroxidase (POX), but did not affect the levels of the antioxidant enzymes catalase (CAT) and superoxide dismutase (Hildebrand et al., 1986b). Foliar levels of antioxidant carotenoids declined with increasing mite populations (Hildebrand et al., 1986a). Phloem-feeding by aphids increased the levels of the antioxidant enzyme glutathione reductase in wheat and barley (Argandona, 1994), induced lipid peroxidation in alfalfa foliar tissues (Dillwith et al., 1991), and increased O_2^- formation in excised lucerne foliage (Jiang and Miles, 1993). Feeding damage to soybean by the phloem-feeding, three-cornered alfalfa hopper increased the activities of LOX, POX, polyphenol oxidase (PPO), and ascorbate oxidase (AOX) (Felton et al., 1994a).

Our laboratory has been examining the oxidative plant response to foliar feeding herbivores (Felton et al., 1994a,b). Herbivory by the corn earworm *Helicoverpa zea* (Lepidoptera: Noctuidae) on soybean increased LOX activity and lipid peroxidation (Bi et al., 1994; Felton et al., 1994b). Oxidative damage to foliar protein from wounded plants was indicated by a loss of free thiols (Bi et al., 1994). Felton et al. (1994a) reported that herbivory by the bean leaf beetle *Ceratoma trifurcata* also caused increases in LOX levels but did not affect POX or PPO in soybean.

The effects of herbivory on other reactive oxygen species, antioxidants, and many oxidative enzymes (e.g., NADH oxidase, diamine oxidases, etc.) have not been demonstrated. We initiated this study to gain a more complete understanding of the oxidative status of the host plant following foliar feeding. The system chosen for this study includes soybean and *H. zea*, a major pest in the mid-Atlantic region of the southeastern United States (Smith and Brim, 1979; Fitt, 1989). Our specific objectives were to: (1) assess the impact of herbivory on the oxidative status of soybean, and (2) assess the impact of induced responses in soybean on insect growth and on the oxidative status of the insect midgut.

METHODS AND MATERIALS

Plants and Insects. Eggs of *H. zea* were obtained from the University of Arkansas Insect Rearing Facility. Larvae were maintained on a wheat germ-based artificial diet until used in the experiment (Chippendale, 1970).

Soybean seeds (cv. Forrest or Hutcheson) were soaked in water for 6 hr and then incubated at 28°C for 24 hr. Preliminary experiments indicated that both cultivars showed similar oxidative responses to herbivory. Germinated seeds were sown in 430-ml polystyrene foam cups filled with soil mixture (Redi Earth Peat-Lite Mix) in the greenhouse. Plants were used in experiments at the V3 stage unless otherwise noted (Fehr et al., 1971). The cups were arranged in a completely randomized experimental design. Plants were watered every two days. Fertilizer (N/P/K = 20:20:20) was used weekly. Conditions were as follows: (1) 14-hr photophase, using high-pressure sodium light (1000 W) and (2) day temperature, 33 ± 2°C and night temperature, 20 ± 2°C.

Induction of Oxidative Responses. To determine if feeding by *H. zea* larva causes oxidative responses, soybean plants were grown in the greenhouse, treated with insects, and assayed for antioxidants and oxidants. A single fourth-instar *H. zea* was placed on each of five plants, and plants were placed individually in screen cages to prevent larval escape. Five control plants were placed in cages without larvae. After three days, fully expanded leaflets were excised from the uppermost node and assayed for enzymes and antioxidants as described below. Leaflets from the treated plants contained both damaged and undamaged leaflets. Preliminary results indicated that no significant differences existed between these leaflets in the variables assayed. A period of three days was initially chosen to investigate the oxidative changes because maximal systemically induced resistance to insects occurred within this period (Bi et al., 1994; Felton et al., 1994a). Percent defoliation was from ca. 20% by visual estimation using calibrated standards (Kogan and Kuhlman, 1982). The soybean cultivar Forrest was used for LOX, PPO, and nonprotein thiol determinations, whereas Hutcheson was

used for POX, AOX, ascorbate peroxidase (APX), ascorbic acid (ASC), dehydroascorbic acid (DHA), CAT, diamine oxidase (DAO), NADH oxidase I, carotenoids, lipid peroxidation, and ·OH assays. Assays were replicated three times, and the data were analyzed by one-way completely randomized ANOVA and mean differences were determined by LSD at $P = 0.05$.

Time Course for Induction of Oxidative Enzymes. To determine the time course of oxidative changes following feeding by *H. zea*, V4-stage soybean plants (cv. Hutcheson) were grown in the greenhouse, treated with insects, and assayed as described above. The levels of LOX (pH 5.5), POX, and AOX were determined after 24, 48, 72, and 96 hr of feeding by larvae. Six plants per treatment were used for each time period.

Plant Enzyme Assays. To assay for foliar enzymes, 1 g of foliage was homogenized in 10 ml 0.1 M ice-cold K Pi buffer, pH 7.0, containing 1% PVP and 0.5 mM EDTA. The homogenate was centrifuged at −2°C for 20 min at 10,000*g*, and the supernatant was used immediately as the enzyme source for the assays described below. A SLM-AMINCO 3000 diode array spectrophotometer with rate analysis software was used for all assays.

To assay for LOX, 0.25 mM linoleic acid was used as a substrate, and the rate of change in A_{234} was measured (Grayburn et al., 1991). The reaction mixture contained 50 μl of enzyme homogenate and 1 ml of substrate. LOX activity was assayed at pH 5.5, 7.0 (0.1 M K Pi), and 8.5 (0.1 M Na borate) to account for the activities of several isozymes. An extinction coefficient of 27 mM^{-1} cm^{-1} was used.

To assay for POX activity, guaiacol was used as the hydrogen donor according to the procedure of Ridge and Osborne (1970). Fifty microliters of enzyme solution was mixed with 1.0 ml of substrate containing 1 mM H_2O_2 and 2 mM guaiacol in 0.1 M K Pi, pH 7.0. POX activity was estimated from the increase in A_{470}.

To determine PPO activity, the procedure of Kahn and Miller (1987) was followed. Twenty-five microliters of enzyme solution was mixed with 200 μl of 20 mM Tiron (4,5-dihydroxy-1,3-benzenedisulfonic acid disodium salt) in 0.1 M K Pi buffer, pH 7.0, and PPO activity was estimated from A_{420}.

NADH oxidase I activity was measured as a decrease in A_{340} due to the loss of NADH (Brightman et al., 1991). The reaction mixture contained 100 μl enzyme extract in 2.9 ml 20 mM Tris Mes, pH 7.0, containing 1 mM KCN and 300 μM NADH. An extinction coefficient of 6.22 mM^{-1} cm^{-1} was used.

DAO activity was measured with 10 mM putrescine (diaminobutane) in 0.1 M K Pi, pH 7.0 (Federico et al., 1985). The reaction was initiated with 1 ml enzyme extract in 3 ml of substrate. After incubation at 37°C for 10 min, the reaction was stopped by adding 0.5 ml of 10% (w/v) TCA followed by 0.05 ml (10 mg/ml) *o*-aminobenzaldehyde in 95% ethanol. The absorbance of the Δ^1-pyrroline complex was measured at A_{430} after removal of protein by centrif-

ugation at 3000*g* for 20 min. An extinction coefficient of 1.86 mM^{-1} cm^{-1} was used (Federico et al., 1985).

AOX activity was measured according to the procedures of Felton and Summers (1993). The reaction mixture contained 100 μl enzyme homogenate, 1 ml of 0.1 M K Pi buffer (pH 7.0) with 0.15 mM ASC, 0.5 mM EDTA, and 0.002% metaphosphoric acid. The decrease in A_{265} of ASC was monitored, and an extinction coefficient of 14.7 mM^{-1} cm^{-1} was used.

APX activity was measured following Mittler and Zilinskas (1991) with the addition of 1 mM ASC to the extraction buffer. The reaction mixture contained 0.50 mM ASC, 50 mM K Pi buffer, pH 7.0, 0.1 mM H_2O_2, and 50 μl enzyme homogenate in a 1.5-ml total volume. Corrections were made for ASC disappearance due to nonenzymatic oxidation and H_2O_2-independent oxidation. An extinction coefficient of 2.8 mM^{-1} cm^{-1} for A_{290} was used.

CAT activity was monitored by following the loss of H_2O_2 at 240 nm (Aebi, 1984). The substrate was 0.059 M H_2O_2 in 0.05 M K Pi buffer, pH 7.0, containing 1 mM EDTA. The reaction was initiated by adding 100 μl enzyme homogenate to 2 ml of substrate, and enzyme activity was determined from the linear portion of the rate curve (A_{450} to A_{400}).

To assay for phenylalanine ammonia lyase (PAL) activity, the enzyme extract was prepared following Degousee et al. (1994). Briefly, 1 g fresh weight of soybean foliage was homogenized in 10 ml Na borate buffer, pH 8.8, containing 2.5% PVP and 15 mM 2-mercaptoethanol and then centrifuged at 20,000*g* for 15 min. The reaction mixture contained 100 μl supernatant from the enzyme extract and 1 ml 20 mM L-Phe. Reaction mixture was incubated for 1 hr at 40°C, and the change in A_{290} was measured against a blank without substrate (Degousee et al., 1994). An extinction coefficient of 10 mM^{-1} cm^{-1} was used.

Chemical Antioxidants. Carotenoid analysis followed the procedure of Hildebrand et al. (1986a). One gram of fresh foliage from each plant was lyophilized and then pulverized in a mortar and pestle. The pulverized sample was extracted with 8 ml of petroleum ether containing 0.45 mM butylated hydroxytoluene. The resulting mixture was incubated for 15 min at 30°C in a water bath, vortexed, and centrifuged at 2000*g* for 30 min. The A_{450} of the supernatant was measured, and an $E^{1\%}$ (Extinction coefficient of 1% concentration) value of 25,000 was used for carotenoid content.

The concentrations of foliar ASC and DHA were determined by a spectrophotometric assay (Law et al., 1983). Total ASC (ASC + DHA) was measured after reduction of DHA by DTT. Reduced ASC was estimated in the absence of DTT. DHA was estimated from the difference of total ASC and reduced ASC. Five hundred milligrams of foliage was homogenized in 5 ml of 5% metaphosphoric acid and centrifuged at 10,000*g* for 20 min. The reaction mixture for total ASC contained 0.02 ml of tissue aliquot, 0.05 ml of 150 mM Na Pi (pH 7.4) containing 5 mM EDTA, and 0.01 ml of 10 mM DTT. After 10

min at room temperature, 0.01 ml of 5 mM *N*-ethylmaleimide was added to remove DTT. Color was developed with 0.04 ml of 10% TCA, 0.04 ml of 44% orthophosphoric acid, 0.04 ml of 4% α,α'-dipyridyl in 70% ethanol, and 0.02 ml of 3% $FeCl_3$. The color development was processed at 25°C for 3 hr, and the A_{525} was read. The assay for reduced ASC omitted the DTT and *N*-ethylmaleimide, using 0.02 ml water as a replacement. L-ASC was used as a standard.

To assay for nonprotein thiols, 500 mg foliage was homogenized in 5 ml 5% metaphosphoric acid and centrifuged at 10,000*g* for 20 min. The color was developed by adding 0.1 ml of supernatant to 2.5 ml of 2.5 mM 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) in 0.2 M K Pi buffer, pH 8.0 (Anderson and Wetlaufer, 1975). The A_{412} was recorded and concentrations determined from a standard curve for glutathione.

Plant Hydroxyl Radical Formation, Lipid Peroxidation, and Total Foliar Peroxides. To assay for ·OH formation in soybean, DMSO was used as a specific detector for ·OH formation in vivo (Babbs et al., 1989; Popham and Novacky, 1991). DMSO may also react with the potent oxidant peroxynitrite (Crow et al., 1994). The wounded DMSO treatment contained five greenhouse-grown plants treated with one larva per plant and watered with 0.5% DMSO. The control DMSO treatment contained five plants that were treated identically except that no larvae were placed on the plants. The remaining 10 control plants contained five plants with larvae and five without. Twelve hours prior to infesting plants with larvae, the DMSO-treated plants were watered to saturation with 0.5% DMSO and control plants were watered with tap water. Larvae were placed on treatment plants for 24 hr. The watering procedure was repeated three times during the experiment. Foliage was then excised from the two uppermost nodes (2 g/plant), quickly frozen with dry ice, and then ground with a mortar and pestle. The resulting slurry was extracted with distilled water and centrifuged to remove solid materials (Babbs et al., 1989). Removal of interfering chemicals and the color reaction with fast blue BB dye was as described (Babbs et al., 1989). The A_{420} of the methane sulfinic acid product was read, and concentrations were calculated based upon a standard curve. The A_{420} of the appropriate water-treated controls was subtracted from the DMSO treatments. Nonspecific absorbance in the water treatments was 28% of the DMSO treatments.

Lipid peroxidation was assayed using the thiobarbituric acid assay (Dhindsa and Matowe, 1981). One gram of fresh foliage was homogenized in 5 ml H_2O, and 5 ml of 5 mM thiobarbituric acid in 20% TCA was added. The mixture was heated to 95°C for 30 min and then quickly cooled in an ice-bath. The cold mixture was centrifuged at 10,000*g* for 20 min, and the A_{532} and A_{600} were recorded. The nonspecific A_{600} was subtracted from the A_{532}. Thiobarbituric-reactive substances were expressed as malondialdehyde equivalents using the extinction coefficient of 155 mM^{-1} cm^{-1}.

Total hydroperoxides (ROOH) were measured following Jiang et al. (1992). The method is based on the hydroperoxide-mediated oxidation of Fe^{2+} to Fe^{3+} under acidic condition. The Fe^{3+} forms a Fe^{3+}–xylenol orange complex measured at 560 nm. The extinction coefficients for lipid hydroperoxides and H_2O_2 are very similar in this assay (Jiang et al., 1991). Foliar samples were homogenized in the same buffer used for preparation of enzyme extract, but with the addition of 2.5% TCA and 1 mM BHT. After centrifugation of the homogenate, 100 μl of the sample was incubated with a 900-μl reaction mixture containing 100 μM xylenol orange, 250 μM Fe^{2+}, 25 mM H_2SO_4, and 4 mM BHT in 90% (v/v) methanol. After a 30-min incubation, the A_{560} was recorded and concentrations of hydroperoxides were calculated based on a standard curve with H_2O_2.

Effect of Induced Responses on Oxidative Status of Insect Midgut. To determine the effect of induced responses in soybean plants on larval growth and the oxidative status of the midgut epithelium, V6-stage soybean plants (cv. Hutcheson) were grown in cages in the field (Felton et al., 1994a). Three third-instar *H. zea* were placed on each treatment plant for three days. After this time period, the third instars were removed from plants and discarded. Five plants from each treatment were assayed for POX, LOX (pH 5.5), and LOX (pH 7.0). Newly molted fifth instars were then placed on each remaining control and treatment plant. Initial weights of these larvae were not significantly different ($P = 0.514$). Mean weight of larvae placed on the treatment plants was 125.7 $\pm$ 6.5 mg, and mean weight of larvae on control plants was 121.5 $\pm$ 5.0 mg. A total of 30 larvae per treatment was tested.

After three days, larvae were removed from each plant and weighted. The midgut epithelium was removed, weighed, and homogenized (Summers and Felton, 1994). Midgut tissue was pooled with three larvae per replicate providing a total of 10 replicates per treatment. ASC and ROOH were assayed using the assays described above and modified following Summers and Felton (1994). Nonprotein thiols were determined with DTNB in absolute methanol (Hu, 1994). Because of the movement of larvae between plants in their respective cages, the relative growth rate (milligrams per day/per milligram of larva) was calculated using the mean initial weights rather than individual larval weights (Felton et al., 1994a).

RESULTS

Foliar Oxidative Response to Herbivory. Larval *H. zea* feeding on soybean increased the activities of several foliar oxidative enzymes. LOX activities increased by 2.5-fold when measured at pH 5.5 ($P < 0.001$), 2.81-fold at pH 7.0 ($P < 0.001$), and 3.34-fold at pH 8.5 ($P < 0.001$) compared with the control foliage (Table 1). The feeding also significantly increased the activities of several other foliar oxidases (Table 1) such as POX by 1.6-fold ($P = 0.006$),

TABLE 1. EFFECT OF HERBIVORY ON FOLIAR ENZYME ACTIVITIES IN SOYBEAN

Enzyme	Control	Wounded	LSD (0.05)
AOX

DAO by 1.57-fold ($P < 0.001$), AOX by 2.14-fold ($P = 0.006$), and NADH oxidase I by 1.56-fold ($P = 0.026$) (Table 1). PAL activity was increased 2.35-fold ($P = 0.001$) by herbivory, but PPO was not significantly affected ($P = 0.06$) (Table 1). The level of the antioxidant enzyme CAT decreased 36% ($P = 0.03$) in damaged foliage compared to control foliage; however, another antioxidant enzyme, APX, increased 1.5-fold ($P = 0.002$) following herbivory (Table 1).

Feeding by *H. zea* in soybean also resulted in significant changes in foliar antioxidants as indicated by a 26% loss of ASC ($P = 0.003$) and 104% higher DHA ($P = 0.02$) level compared to controls (Table 2). The ratio of ASC to DHA was reduced from 11.68 to 3.62 reflecting the significant change in redox status. Herbivory resulted in a greater than 33% decrease in carotenoid concentration ($P < 0.001$) and 8% loss of nonprotein thiols ($P < 0.001$) in comparison with those in control foliage (Table 2).

TABLE 2. EFFECT OF HERBIVORY ON FOLIAR ANTIOXIDANTS IN SOYBEAN

Antioxidant	Control	Wounded	LSD (0.05)
Total ASC			
(μg/g fresh weight)	621.5 ($\pm$50.1)[a]	462.8 ($\pm$40.5)	70.6
Reduced ASC			
(μg/g fresh weight)	572.5 ($\pm$50.2)	362.6 ($\pm$41.0)	71.6
DHA			
(μ/g fresh weight)	49.0 ($\pm$11.6)	100.2 ($\pm$39.5)	42.4

Nonprotein thiols			
(ng/g fresh weight)	279 ($\pm$5.8)	257 ($\pm$4.8)	7.7

[a] Numbers in parentheses are standard deviations.

Folivory by *H. zea* caused an increase in ·OH flux by 3.87-fold (P = 0.038) in wounded soybean foliage compared to the undamaged control treatment (Table 3). Lipid peroxidation increased in wounded tissue as indicated by a 17% increase in malondialdehyde equivalents (P = 0.009) (Table 3). Total hydroperoxide levels were increased by 2.26-fold (P = 0.002) in the wounded tissue compared to the control treatment (Table 3).

Time Course for Induction of Oxidative Enzymes. Herbivory caused significant increases in LOX after 24 hr of feeding, which continued throughout the sampling period ($P < 0.05$; Figure 1). Maximal increase occurred at 72 hr for LOX and for POX, but the POX increase was significant ($P < 0.05$) only

TABLE 3. EFFECT OF HERBIVORY ON FOLIAR LIPID PEROXIDATION, TOTAL HYDROPEROXIDES, AND HYDROXYL RADICAL (·OH) LEVELS IN SOYBEAN

Oxidant	Control	Wounded	LSD (0.05)

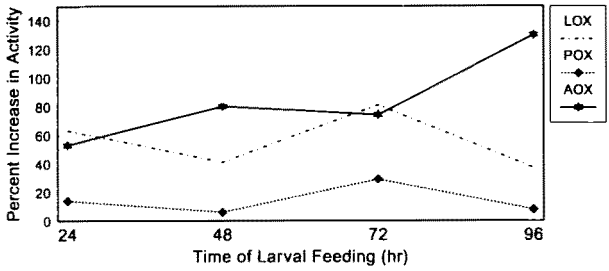

FIG. 1. Effect of length of herbivory on oxidative enzymes in soybean foliage. AOX = ascorbate oxidase; LOX = lipoxygenase measured at pH 5.5; and POX = peroxidase.

at 72 hr of herbivory. AOX was significantly increased throughout all time periods ($P < 0.05$) and was maximal after 96 hr of larval feeding.

Effect of Induced Responses on Oxidative Status of Insect Midgut. The oxidative shift in soybean plants caused by insect feeding was indicated by a 2.09-fold increase in LOX (pH 5.5), a 1.44-fold increase in LOX (pH 7.0), and a 1.42-fold increase in POX (Table 4). The ingestion of previously wounded plant tissue by larvae affected relative growth rate and the oxidative status of the midgut. The relative growth rate of larvae feeding on the wounded plants was reduced by more than 62% compared to larvae on control plants ($P < 0.001$; Table 4). Evidence that oxidative damage occurred in larvae ingesting wounded tissue was indicated by the fact that total ASC was decreased by ca. 15% ($P = 0.002$), reduced ASC was decreased by more than 20% ($P < 0.001$), and the oxidized form of ASC, DHA, was increased by 2.25-fold ($P = 0.005$). Accordingly, the ratio of midgut ASC to DHA decreased from 26.50 in larvae on control plants to 9.33 in larvae feeding on wounded plants. The levels of nonprotein thiols were significantly decreased in the wounded treatment by 48% ($P < 0.001$). Total hydroperoxides, an indicator of oxidative stress, were more than 66% higher in larvae feeding on the wounded plants compared to larvae on control plants ($P = 0.035$).

DISCUSSION

Plant chemical defense against insects is largely ascribed to plant secondary metabolites (Rosenthal and Berenbaum, 1991) and to a lesser extent primary metabolites such as amino acids, water, vitamins, etc. (Slansky, 1990). Our data indicate that the induced responses to herbivory in soybean entail a three-fold, integrated response (Figure 2) that includes: (1) enhanced secondary metabolite production (e.g., phenylalanine ammonia lyase; Liu et al., 1992;

Table 1); (2) a loss in the quantity and/or quality of essential nutrients and antioxidants (e.g., protein, Bi et al., 1994; ascorbic acid, Table 2); and (3) the production of reactive oxygen species (e.g., hydroxyl radical, Table 3; hydrogen peroxide, superoxide radical). However, at present it is not known if these oxidative responses are the direct result of herbivory or the result of microbes entering open wounds caused by insect feeding. Nonetheless, we suggest that the net impact upon the herbivore involves both nutritional and oxidative stress (Figure 2).

The role of reactive oxygen species has been largely overlooked as a component of plant defense (Norris and Liu, 1992; Ahmad, 1992; Appel, 1993; Norris, 1994) for several reasons. First, there are no clearly defined pathologies or diseases associated with oxidative stress in insects as have been defined for mammals and humans (e.g., amytrophic lateral sclerosis, atherosclerosis, etc.; Felton, 1995). Second, because many consider oxidative stress to be a chronic phenomenon in animals, some scientists have assumed that insects are too short-

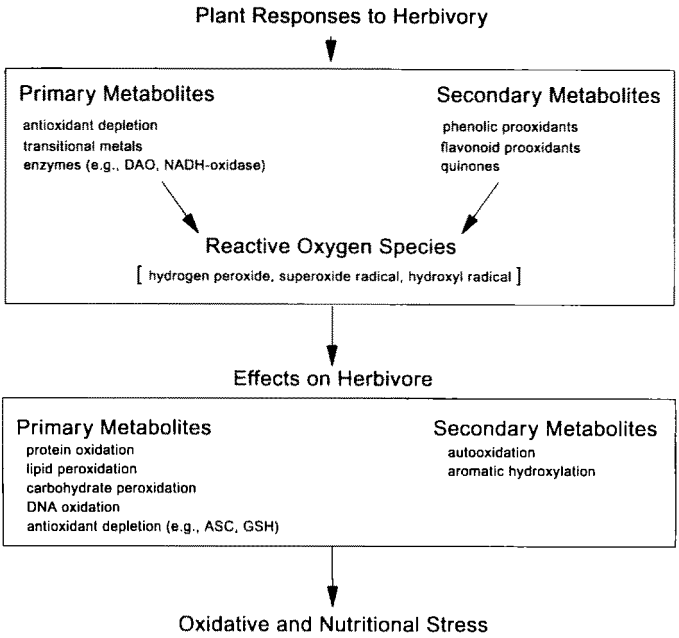

FIG. 2. Threefold response of soybean foliage to insect herbivory. Numerous interactions may take place among the metabolites produced in response to herbivory. For example, phenolic prooxidants may produce reactive oxygen species or may bind to proteins. Alternatively, phenolics may be reduced by primary metabolites (e.g., ascorbate, cysteine) or be oxidized by enzymes requiring reactive oxygen species such as hydrogen peroxide.

lived to be affected by oxidative stress. However, it has been recently shown that even short-lived insects such as *Drosophila melanogaster* can greatly benefit by additional antioxidant protection (Orr and Sohal, 1994). Third, the methodologies for measuring reactive oxygen species (e.g., ESR spectroscopy and spin traps) have been relatively difficult and expensive. Furthermore, these methodologies have been difficult or impossible to deploy for many *in situ* or *in planta* determinations. Fourth, because of the highly transitory behavior of reactive oxygen species, it is essentially impossible to use artificial diets to bioassay their effect directly. Thus, chemical fractionation of plant tissues to isolate and identify potential sources of chemical resistance may fail to account for not only the activities of plant enzymes (e.g., polyphenol oxidase; Felton et al., 1989; peroxidase, Liu et al., 1993), but also for potential contribution of reactive oxygen species. The problems in causally linking insect herbivore performance with oxidative stress are difficult but not insurmountable. Decades of intensive

research in the biomedical field have encountered similar difficulties, but the use of selective inhibitors of antioxidant systems and the ability to genetically modify the expression of antioxidant systems has contributed to rapid progress in recent years.

Several lines of evidence suggest that oxidative stress may be an important factor in insect biology and a potential mechanism of plant resistance to insects. First, insect life-span and fitness can be increased by elevated levels of chemical antioxidants, as well as the overexpression of antioxidant enzymes in transgenic insects (Orr and Sohal, 1994; Felton and Summers, 1995).

Second, selective modification of the antioxidant status of insects has demonstrated the detrimental effects of dietary prooxidants. For instance, specific inhibition of antioxidant enzymes (e.g., superoxide dismutase) decreases insect performance on certain host plants or artificial diets rich in prooxidants (Pritsos et al., 1991; Ahmad, 1992). Elevated levels of dietary chemical antioxidants such as vitamin E, carotenoids, and ascorbate decrease the toxicity of prooxidant compounds (Aucoin et al., 1990; Summers and Felton, 1994).

Third, insects feeding on previously wounded foliage show evidence of oxidative damage in the midgut (Table 4). The toxicological effect of the oxidative stress in the midgut is unknown, but disruptions in absorption, transport, and membrane-bound enzymes may be likely (Yu, 1994). The oxidative change in foliage may alter the nutritional quality of foliage to herbivores as well. The loss of nutrients such as ASC, free fatty acids (e.g., linoleic acid), and carotenoids that occur in damaged foliage may disrupt normal growth and development of insects (Dadd, 1973). Bi et al. (1994) also showed that prior herbivory reduced the nutritional quality of foliar protein to *H. zea*.

Fourth, herbivory causes increases in reactive oxygen species, namely, ·OH (Table 3) in soybean foliage. The ·OH radical is the most reactive known and can attack and damage virtually any molecule found in living cells (Halliwell, 1991). ·OH reacting with lipids, proteins, or DNA can initiate chain reactions that involve lipid peroxidation, protein oxidation and fragmentation, and substantial alteration of DNA (Halliwell, 1991). Several enzymatic systems may contribute to elevated ·OH levels. The ·OH may be formed from H_2O_2 during metal-catalyzed reactions (Halliwell, 1991). Increases in H_2O_2 may arise from several biochemical pathways in different cellular compartments. Our results (Tables 1 and 4) indicate that H_2O_2 may arise from several enzymes that produce reactive oxygen species as primary or secondary products including NADH oxidase, DAO, POX, and LOX (Kanofsky and Axelrod, 1986; Chamulitrat et al., 1991; Sutherland, 1991; Vianello and Macri, 1991; Liu et al., 1993). Alternatively, H_2O_2 accumulation could result from the decreased levels of several scavenging agents such as CAT, ASC, or thiols (Tables 1, 2, and 4). However, the H_2O_2-scavenging enzyme APX increased following herbivory (Table 1). We have not differentiated the chloroplastic vs. cytosolic APX isozymes, and thus

do not know the relative importance of differences in H_2O_2 synthesis and degradation between different cellular compartments. Herbivory caused a decline in CAT levels, which have also been implicated in plant–pathogen interactions (Chen et al., 1993). The inhibition of CAT was due to induction of salicylic acid, a potent CAT inhibitor (Chen et al., 1993). Presumably levels of H_2O_2 increase following CAT inhibition and then act as an elicitor of plant defenses (Chen et al., 1993). It is unknown if the decrease in CAT following herbivory is due to enhanced salicylic acid biosynthesis.

Fifth, increases in oxidative enzymes and other oxidative changes in soybean may serve in several manners to enhance insect resistance (Liu et al., 1993; Felton et al., 1994a,b). Increased production of H_2O_2 by DAO (Federico and Angelini, 1986, 1988; Angelini and Federico, 1989; Angelini et al., 1990) may provide substrate for POXs. NADH oxidase occurs in the plasma membrane of plant cells and oxidizes NADH or NADPH to form O_2^- that then dismutates to H_2O_2 (Doke et al., 1991; Brightman et al., 1991). POXs are important in cell wall strengthening, including lignification (Goldberg et al., 1985; Lagrimini et al., 1987), suberization (Espelie and Kolattukudy, 1985; Espelie et al., 1986), and cross-linking of hydroxyproline-rich cell wall protein (Fry, 1986). These cross-linking processes may ultimately decrease the digestibility of plant tissues for herbivores. PAL provides phenolic precursors for these reactions (Goldberg et al., 1985). Moreover, oxidative products of enzymes (e.g., phenolic prooxidants, quinones, lipid hydroperoxides, aldehydes) can impose considerable toxicological assault upon herbivores (Duffey and Felton, 1991; Appel, 1993; Summers and Felton, 1994; Barbehenn and Martin, 1994). Increases in PAL activity (Table 1) may lead to increased levels of phenolic prooxidants such as caffeic acids that are toxic to larvae (Summers and Felton, 1994). The volatile aldehyde products of LOX are repellent to certain insect herbivores including bean bugs *Riptortus clavatus*, strawberry leafy beetles *Galerucella vittaticollis*, and false melon beetles *Atrachya menetriesi* (Mohri et al., 1990). Moreover, the induction of LOXs may be important in defense signal transduction because LOXs are involved in the initial phases of jasmonic acid biosynthesis (Ueda and Kato, 1980; Vick and Zimmerman, 1987; Enyedi et al., 1992). The jasmonates induce the synthesis of several plant defensive proteins or chemicals, including proteinase inhibitors, chalcone synthase, proline-rich cell wall proteins, PAL, and alkaloids (Creelman et al., 1992; Enyedi et al., 1992; Hamberg and Gardner, 1992).

Oxidative responses in plants may have both positive and negative effects upon the host plant: a decrease in herbivory but an increase in oxidative damage to the plant. Oxidative stress is an important factor in plant responses to several environmental stresses including chilling temperatures (Prasad et al., 1994; Gupta et al., 1993), phytopathogens (Devlin and Gustine, 1992; Aver'yanov et al., 1993), NaCl injury (Gossett et al., 1994), and environmental pollutants (Badiani

et al., 1993; Guzy and Heath, 1993). Our data provide more substantive evidence that plant responses to herbivory also include changes in the oxidative status of foliage. Consequently, herbivory may predispose the plant to damage by other environmental stresses that impose oxidative stress to the plant. Conversely, the oxidative changes may be a component of plant defense against herbivores and other pests. The salient benefit to the plant, in terms of insect resistance, may represent the relative balance between these opposing effects.

In summary, we propose that at least five potential functions for oxidative stress in plant–herbivore interactions exist including: (1) direct oxidative injury to the herbivore (Appel, 1993; Felton et al., 1994b; Summers and Felton, 1994); (2) indirect injury to the herbivore through oxidative damage to dietary nutrients and antioxidants (Felton et al., 1989, 1992; Bi et al., 1994; Barbehenn and Martin, 1994); (3) obstruction of access to plant protein and nutrients via rapidly induced oxidative cross-linkage of cell wall proteins (Bradley et al., 1992); (4) formation of volatile compounds that are repellent to herbivores (Mohri, 1990); and (5) signal transduction for elicitation of plant defenses (Apostol et al., 1989; Norris and Liu, 1992; Creelman et al., 1992; Farmer et al., 1992; Chen et al., 1993; Norris, 1994). Thus, induced resistance in certain soybean cultivars may be composed of a threefold, integrated response involving primary metabolites, secondary metabolites, and reactive oxygen species (Figure 2). Further research is needed to determine if these results are generalizable to other plant cultivars and species.

Acknowledgments—The authors wish to thank Drs. K.S. Johnson, E.M. Lamb, and L.C. Purcell for critical review of an earlier version of the manuscript. This paper is published with the approval of the Director of the Arkansas Agricultural Experiment Station as manuscript #94100. This research was supported by USDA/NRICG (93-37302-9571), USDA/CSRS (92-34195-7162), and the American Soybean Association (FY92-119).

A FLAVONOID GLUCOSIDE, PHELLAMURIN, REGULATES DIFFERENTIAL OVIPOSITION ON A RUTACEOUS PLANT, *Phellodendron amurense*, BY TWO SYMPATRIC SWALLOWTAIL BUTTERFLIES, *Papilio protenor* AND *P. xuthus*: THE FRONT LINE OF A COEVOLUTIONARY ARMS RACE?

KEIICHI HONDA* and NANAO HAYASHI

(Received December 1, 1994; accepted June 1, 1995)

Abstract—We studied the chemical basis for the differential acceptance of a rutaceous plant, *Phellodendron amurense*, by ovipositing females of two sympatric *Papilio* butterflies, *P. protenor* and *P. xuthus*, that have a very similar host range. *P. amurense*, on which larvae of both species perform well, was rejected by *P. protenor* females but was marginally accepted by *P. xuthus*, even though water-soluble fraction of this plant elicited significant ovipositional responses from the two species. A prenylated dihydroflavonol glucoside, 3,5,7,4′-tetrahydroxy-8-(3-methylbut-2-enyl)flavanone-7-*O*-β-glucoside (phellamurin), was identified as a dominant active substance that deters oviposition. *P. protenor* responded highly sensitively to phellamurin, whereas *P. xuthus* was less susceptible and was affected conspicuously only at higher concentrations than that found in living plants, thereby accounting for their differential responses to *P. amurense*. In *P. protenor*, the deterrent effect of phellamurin was considered to outweigh the activity of coexisting stimulant(s) at the concentrations actually present in the foliage, resulting in avoidance of this plant. The phellamurin content in the foliage amounted to as much as 1.8% of the fresh weight, which is far higher than the average levels of flavonoids present in other major host plants of *Papilio*. The dose-response experiments demonstrated that unacceptability of *P. amurense* for *P. protenor* was attributable largely to such a high concentration of phellamurin. These results appear to provide information on possible coevolutionary interactions between herbivores and plants and also on the potential for shifts in host affiliation.

Key Words—Oviposition deterrent, *Phellodendron amurense*, Rutaceae, phellamurin, dihydroflavonol glucoside, papilionid butterfly, *Papilio protenor*, *Papilio xuthus*.

INTRODUCTION

Two Rutaceae-feeding oligophagous papilionid butterflies, *Papilio protenor* and *P. xuthus*, occur sympatrically in most localities in Japan and are pests of various cultivated *Citrus* plants, their major host plants in nature. Occasionally, and in certain cases frequently, they utilize some rutaceous plants in other genera, e.g., *Zanthoxylum*, *Poncirus*, *Fortunella*, in the field. Several rutaceous mountainous plants, *Orixa japonica*, *Fagara ailanthoides*, *Skimmia japonica*, and *Phellodendron amurense*, are also potential hosts, but although the larvae sometimes feed on *F. ailanthoides* and *S. japonica*, *O. japonica* is not accepted. Thus the host range of *P. protenor* and *P. xuthus* is almost overlapping. The acceptability of *P. amurense* for ovipositing females differs, however, between the two species. *P. protenor* females never lay eggs on *P. amurense* in nature nor under experimental conditions, whereas the plant is barely acceptable for *P. xuthus* females. However, the plant can be found infested by *P. xuthus* in the field. Previous work (Honda and Hayashi, 1995) has demonstrated that despite the presence of oviposition stimulant(s) in *P. amurense*, coexisting oviposition deterrent(s) severely inhibit *P. protenor* from ovipositing.

It is widely accepted that host utilization of herbivorous insects is mediated to a large extent by plant secondary metabolites serving as stimulants or deterrents (e.g., Dethier, 1982; Miller and Strickler, 1984). Studies on the chemical cues implicated for host recognition by papilionid butterflies have exclusively concentrated on oviposition stimulants, which are perceived by foretarsal chemoreceptors upon contact with leaf surface (Ohsugi et al., 1985, 1991; Honda, 1986, 1990; Nishida et al., 1987; Nishida and Fukami, 1989; Feeny et al., 1988; Papaj et al., 1992; Sachdev-Gupta et al., 1993a; Nishida, 1994) or by antennal chemoreceptors (Feeny et al., 1989; Baur et al., 1993). However, information on phytochemicals responsible for deterring oviposition by papilionids is quite insufficient. To our knowledge only one publication (Nishida et al., 1990) has dealt with the identification of an oviposition deterrent. A flavonol glycoside (a xylosyl derivative of rutin) was isolated from *O. japonica* and claimed to be one of the deterrents of *P. xuthus*. Thus, it is essential to study further the behaviorally or physiologically active substances involved in plant–herbivore associations in order to clarify the evolutionary processes of host specificity.

This paper addresses the isolation and identification of a flavonoid oviposition deterrent involved with the differential acceptance of *P. amurense* by the two *Papilio* butterflies.

METHODS AND MATERIALS

Insects. Adults of *P. protenor* and *P. xuthus* used for the behavioral bioassays were 3- to 10-day-old gravid females derived from laboratory stock cultures. These originated from a natural population principally infesting cultivated *Citrus* plants in Kanagawa Prefecture. The larvae were reared at 25°C under a 16-hr light–8-hr dark regime on fresh leaves of *Citrus unshiu*. Females were fed daily with 15% aqueous sucrose solution.

Extraction and Fractionation of Plant Materials. Young foliage of *P. amurense* (820 g) collected in early summer in Kanagawa Prefecture was extracted with methanol (3 liters) at room temperature for one month. The methanolic extract was concentrated in vacuo below 50°C, and an aliquot of the whole concentrate, after being dispersed in water, was extracted successively with chloroform and isobutanol to give three fractions (two organic and one aqueous fraction). The chloroform and isobutanol fractions were evaporated to dryness, and each residue was dissolved in acetone and in methanol, respectively. On the other hand, the water-soluble fraction, once lyophilized, was stored in 50% aqueous methanol.

Bioassay for Ovipositional Response. To evaluate stimulatory or deterrent activity of test samples, behavioral bioassays were carried out by a method given in a previous paper (Honda, 1986) employing artificial green plastic leaves as ovipositional substrates. Before testing, females were screened daily to assess their responsiveness, and only those that showed positive responses to *Citrus* foliage and negative responses to water alone (control) were chosen. The rate of response was defined as the mean response rate of the individual females, represented by the equation 1:

$$\text{Rate of response} = \frac{\Sigma R_i}{N} \tag{1}$$

$$R_i = \frac{\Sigma S_j}{n} \tag{2}$$

where N is the total number of females tested, and R_i denotes the response rate of an individual, which in turn was calculated by expression (2). S_j and n are the scores for a single trial of a given female and the number of trials, respectively. Trials were replicated five to seven times. S_j was scored as 1.0 for actual egg-laying or an equivalent behavior, 0.5 for half-curling the abdomen with continuous drumming, and 0.0 for drumming only with no positive response. For all trials, merely alighting on ovipositional substrates without drumming was not included.

Instrumentation for Structural Elucidation. ^{13}C NMR (CMR) spectra were measured at 100 MHz in acetone-d_6 on a Jeol JNM-A400 FT-NMR spectrometer

with tetramethylsilane as the internal standard. Chemical shifts were represented by δ unit. Multiplicities of signals determined by DEPT are abbreviated as follows: singlet (s), doublet (d), triplet (t), quartet (q).

FAB-mass spectra (FAB-MS) were recorded with a Jeol JMS-DX 303 mass spectrometer using a mixture of NaI and glycerine as a matrix.

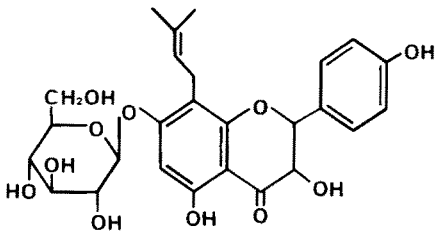
RESULTS

Previous work (Honda and Hayashi, 1995) and preliminary experiments revealed that the aqueous fraction derived from a methanolic extract of *P. amurense* strongly evoked positive responses from ovipositing females of both *P. protenor* and *P. xuthus*, suggesting the presence of oviposition stimulant(s), and hence, the potential acceptability of this plant for both species. By contrast, the isobutanol fraction, in which the key substance(s) regulating differential oviposition was found to be localized, exerted conspicuous deterrent activity that is potent for *P. protenor* and moderate for *P. xuthus* (Honda and Hayashi, 1995). Thus, the isobutanol fraction was chemically examined in this study.

The isobutanol solution, when evaporated to dryness, gave pale brown crystals, which, after recrystallization from acetone–water, afforded pale yellow needles (compound **1**). Since compound **1** was found to singly suppress the stimulatory activity of the aqueous fraction, structural elucidation of compound **1** was undertaken. Compound **1** (mp: 199–201°C) was presumed to be a flavonoid because its aqueous methanolic solution gave a reddish purple coloration when treated with Mg-HCl. Spectral evidence of FAB-MS: $[M+Na]^+$ at *m/z* 541, combined with elemental analysis: found, C, 60.26; H, 5.80, definitely determined the molecular formula of the compound to be $C_{26}H_{30}O_{11}$ (calcd., C, 60.23; H, 5.83). In addition, the CMR spectrum, δ(ppm): 17.9(q), 22.3(t), 25.9(q), 62.5(t), 71.2(d), 73.4(d), 74.6(d), 77.9(d), 78.0(d), 84.3(d), 96.5(d), 101.5(d), 102.8(s), 110.5(s), 115.9(d, 2C), 123.6(d), 129.2(s), 130.2(d, 2C), 131.4(s), 158.8(s), 160.1(s), 162.7(s), 164.7(s) and 199.4(s), shows the presence of a glucosyl and a prenyl moiety and also the lack of methoxyl groups in the molecule. From all these data, compound **1** was concluded to be a C-prenyl derivative of 5,7,4′-trihydroxydihydroflavonol. Another CMR measurement without proton decoupling was attempted to determine the position (C-6 or C-8) of the prenyl substituent by observing long-range ^{13}C–^{1}H coupling between C-6 (C-8) and a hydroxyl proton attached to C-5 (C-5-O**H**). The resonance at 110.5 ppm, assigned to a prenylated carbon, showed a simple singlet, while the signal of unsubstituted carbon at 96.5 ppm was a double doublet (J = 164.2, 7.7 Hz) coupled both with a directly attached proton and with C-5-O**H**, implying that C-6 is not substituted and that the prenyl group, therefore, is attached to C-8 (Shirataki et al., 1985). This was further corroborated by the fact that the

multiplicity of C-6 resonance apparently changed to doublet by the addition of D_2O, although the line width was somewhat broadened. This phenomenon can reasonably be explained by the small value of J_{CD} that is theoretically known to be 1/6.51 of that of J_{CH}. Consequently, compound **1** was concluded to be 3,5,7,4′-tetrahydroxy-8-(3-methylbut-2-enyl)flavanone-7-*O*-glucoside, which is identical with phellamurin (Figure 1), reported by Sakai and Hasegawa (1974). The stereochemistry of the anomeric carbon of the glucosyl group, appearing at 101.6 ppm, was concluded to be in the β-configuration, following chemical shift values of β-glucosylated flavonoids (Harborne, 1982).

The deterrent effect of phellamurin on oviposition by the two *Papilio* species was investigated in combination with the aqueous fraction that induces positive ovipositional response. The results are shown in Table 1. Phellamurin exerted remarkable deterrence in oviposition by *P. protenor* at concentrations higher than 0.1%, and at doses over 0.25% oviposition was completely inhibited. In contrast, *P. xuthus* was less influenced by this compound, and considerable reduction of positive response occurred only at 0.5% (and at higher doses, probably). Such differences in responsiveness appear to reflect clearly the acceptability of *P. amurense* for each species. In fact, the response rates of *P. protenor* and *P. xuthus* to 0.3% phellamurin sample are congruent with those to the foliage of *P. amurense* (0 and 0.73, respectively) (Honda and Hayashi, 1995). Upon composition analysis, water-soluble substances contained in the foliage of the plant amounted to ca. 3.7% of the fresh weight, and the relative quantities of isobutanol-soluble substances and phellamurin were approximately 2.0% and 1.8%, respectively. Since the quantity of phellamurin in the foliage was estimated at about one half that of the hydrosoluble substances, a mixed solution composed of 0.25% phellamurin and 0.5% aqueous fraction is regarded as equivalent to an extract from the foliage. Accordingly, avoidance of *P. amurense*



PHELLAMURIN

by *P. protenor* seems to be well explained solely by the quantitative balance of phellamurin and stimulant(s) in the plant. In *P. xuthus* as well, phellamurin is likely to play a dominant role in assessing the suitability of the plant by females, although there still remains the possibility of involvement of other deterrents. In addition, females of *P. protenor* from a Hiroshima (ca. 650 km distant from Kanagawa Prefecture as the crow flies) population also rejected *P. amurense*, while *P. xuthus* females inhabiting the same locality accepted it. Therefore, the geographical differences in their responsiveness to the plant seem to be negligible, at least in Japan.

DISCUSSION

Quantitative relationships between the oviposition deterrent (phellamurin) and stimulant(s) (water-soluble substance) present in *P. amurense* make it possible to account for rejection of this plant by *P. protenor*, in which positive activity of co-occurring stimulant(s) is entirely masked by potent deterring action of phellamurin. On the other hand, *P. xuthus*, which is less susceptible to this compound, is permitted to accept this plant marginally. In other words, *P. xuthus* is narrowly adapted for *P. amurense*, whereas *P. protenor* is not at all at present. Our previous work (Honda and Hayashi, 1995) has revealed that the total content of flavonoids in *P. amurense* (ca. 2%) is approximately two to four times as high as those present in *C. unshiu*, *F. ailanthoides*, and *O. japonica*, which are the major host plants of *Papilio* butterflies in Japan, and that phellamurin comprises 90% of the total flavonoids. Such an extraordinary level of a single compound suggests the possibility that phellamurin might function as a defensive

chemical of the plant, which has possibly been elaborated through a coevolutionary arms race with herbivores. The present results permit the conclusion that if phellamurin content in *P. amurense* were less than ca. 0.7% (an intermediate value among flavonoid levels of other major host plants), even *P. protenor* might be able to colonize this plant. Furthermore, *P. xuthus* as well as *P. protenor* might be expelled from the plant if the phellamurin content were to exceed ca. 3.6%, unless they overcome the chemical constraint. Larval preadaptation for *P. amurense* (Honda and Hayashi, 1995) and the occurrence of oviposition-stimulatory substance(s) and profuse accumulation of phellamurin in this plant, when taken altogether, suggest the feasibility of ancient or future colonization on this plant by *P. protenor*. These facts, therefore, also seem to provide some information on possible coevolutionary interaction, whether pairwise or diffuse, between plants and herbivores and also on host shifts.

In Pieridae, certain cardiac glycosides from *Erysimum cheiranthoides*, a plant accepted by *Pieris napi* but not by *P. rapae*, have been shown to exert deterrent effects in varying degrees on egg-laying by both species (Sachdev-Gupta et al., 1990; Huang et al., 1993). Not only females but also larvae of *P. rapae* refuse the plant. Cardenolides have been reported to be responsible for deterring oviposition and larval feeding (Sachdev-Gupta et al., 1990, 1993b). However, in *P. protenor* and *P. xuthus*, females' adaptability for *P. amurense* is not correlated with larval fitness for the plant. The dissection of larval performance and oviposition preference has also been documented for other *Papilio* species (e.g., Wiklund, 1975; Thompson et al., 1990; Thompson and Pellmyr, 1991). Such differential adaptation of "mother and child" to a given plant would be a powerful driving force to facilitate shift to a novel host.

For all three *Papilio* butterflies (*P. xuthus*, *P. protenor*, and *P. polyxenes*) for which oviposition stimulants have so far been elucidated, flavonoids or their derivatives are known as common (distinct compounds being involved) active substances implicated for stimulating oviposition (Ohsugi et al., 1985; Honda, 1986; Feeny et al., 1988). In contrast, the present work and a previous report (Nishida et al., 1990) have substantiated that flavonoids do not always serve as stimulants, but act as deterrents in some cases. How can we provide a reasonable and convincing explanation for the dual bioactivities of flavonoids to *Papilio* species? Flavonoids, which are ubiquitous in the plant kingdom and are generally postulated to be defensive substances produced by plants, are highly likely to have originally displayed a deterrent effect on egg-laying by *Papilio* butterflies. Behavioral adaptation to and speciation onto a particular plant would have given rise to the change of sensorial responsiveness to specific phytochemicals (e.g., flavonoids), hence, the eventual conversion of the unacceptable into the acceptable. *P. xuthus* appears to be overcoming the chemical barrier of phellamurin, which is considerably different from *Citrus* flavonoids in chemical structure.

It is intriguing that *P. amurense* is a primary host of *Papilio maackii* and is also utilized frequently by *P. bianor* as a secondary host (Endo and Nihira, 1990). In this context, our findings are helpful to understanding the chemical basis for host selection and host shifts in *Papilio* species. Further investigation is being undertaken on the action of phellamurin on ovipositing females of other *Papilio* species that are successfully adapted for *P. amurense*.

(Received January 10, 1995; accepted June 1, 1995)

Abstract—A feeding deterrent against larvae of a papilionid butterfly, *Luehdorfia puziloi* (Parnassiinae), a specialist on *Asiasarum* plants (Aristolochiaceae), was isolated from another aristolochiaceous plant, *Heterotropa aspera*. Antifeedant activity was exhibited by the *n*-hexane-soluble fraction that proved to contain at least two active components. One of the deterrents was identified as a neolignan compound, asatone. The concentration of asatone in *H. aspera* was estimated at approximately 225 ppm, and larval feeding of *L. puziloi* was significantly deterred at concentrations over 90 ppm. By contrast, asatone was not detectable (< 1 ppm, if any) in its host plant, *Asiasarum sieboldii*.

Key Words—Feeding deterrent, *Luehdorfia puziloi*, *L. japonica*, Papilionidae, Parnassiinae, Zerynthiini, neolignoid, asatone, *Heterotropa aspera*, *Asiasarum sieboldii*, Aristolochiaceae.

INTRODUCTION

Two papilionid butterflies, *Luehdorfia puziloi* and *L. japonica* (subfamily Parnassiinae, tribe Zerynthiini), share a unique univoltine life history (Hidaka et al., 1971; Tabuchi, 1974) and are regarded as sibling species. In Japan *L. puziloi* inhabits the central to northern districts, while *L. japonica* occurs in the central to southwestern districts of the main island (*Honshû*). Their geographical distribution is distinctly partitioned off along the boundary known as the "Luehdorfia Line," although several patches of common habitat spread around this

*To whom correspondence should be addressed.

line (Tabuchi, 1974). Another distinctive characteristic between the two species is manifested by the difference in host plants. *L. japonica* feeds on a large variety of *Heterotropa* plants (Aristolochiaceae, tribe Sarumeae) in the field and is also able to perform well on other aristolochiaceous plants such as *Asiasarum* or *Asarum* (Sarumeae). In contrast, *L. puziloi* is restricted to *Asiasarum* plants. It never deposits eggs on and usually fails to complete larval development on most plants of other genera even under experimental conditions.

Numerous investigations of the mechanism of host selection by herbivorous insects indicate that phytochemical information perceived by contact with plants ultimately serves as a primary determinant of host selection and that a qualitative and quantitative balance of stimulants and deterrents finally governs acceptance or rejection of plants by herbivores (e.g., Dethier, 1982; Miller and Strickler, 1984; Renwick and Chew, 1994).

In Papilionidae, an array of oviposition stimulants (Ohsugi et al., 1985, 1991; Honda, 1986, 1990; Nishida et al., 1987; Nishida and Fukami, 1989; Feeny et al., 1988; Papaj et al., 1992; Sachdev-Gupta et al., 1993a; Baur et al., 1993; Nishida, 1994) and oviposition deterrents (Nishida et al., 1990; Honda and Hayashi, 1995b) has come to light during the last decade. Chemical bases for differential acceptance of some rutaceous plants by ovipositing *Papilio* females have also been examined (Honda and Hayashi, 1995a). However, the chemistry of larval discrimination between host and nonhost plants is little known.

We report here on the isolation and identification of an antifeedant to *L. puziloi* larvae from *H. aspera*, which is one of the host plants accepted by western populations of *L. japonica*.

METHODS AND MATERIALS

Insects. Eggs of *L. puziloi inexpecta* (a subspecies inhabiting *Honshû*), usually deposited in a cluster on the underside of the foliage of *A. sieboldii*, were collected in Nagano Prefecture or obtained from females of stock cultures maintained in our laboratory. Larvae were reared on fresh leaves of *A. sieboldii* at 17°C under a 16-hr light–8-hr dark regime.

Extraction and Fractionation of Bioactive Substances. Young foliage of *H. aspera* (650 g) collected in the spring in Osaka and Hiroshima Prefectures was extracted with *n*-hexane (2 liters) at room temperature for a month. The *n*-hexane extract was concentrated in vacuo below 50°C. An aliquot (100 mg) of the residue was subjected to flash column chromatography (FCC) with silica gel (Whatman, LPS-1, 13-24 μm), and eluted stepwise with *n*-hexane (50 ml, fraction 1), benzene (80 ml, fraction 2), chloroform (200 ml, fraction 3), methanol (90 ml, fraction 4), and methanol (250 ml, fraction 5). Subsequent fractionation of an active fraction (114 mg) was carried out by reversed-phase FCC on ODS-

silica gel (Whatman, LRP-2, 37–53 μm), using 95% aq. methanol (120 ml, fraction 41), methanol (220 ml, fraction 42), and acetone (210 ml, fraction 43), successively. Isolation and purification of active substances were achieved by preparative TLC [2-mm-thick silica gel plate (Merck Art. 5745); chloroform–acetone (25 : 1) or chloroform] and finally by HPLC. Fresh leaves of *A. sieboldii* collected in Nagano Prefecture were also extracted with *n*-hexane, and a sample for chemical analysis was prepared by an analogous chromatographic procedure. Concentrations of test samples were expressed as weight/volume percent.

Bioassay for Feeding Deterrence. Deterrent activities of test samples were evaluated by binary-choice assays with young leaves of *A. sieboldii.* As the foliage of this plant is very thin and can be severely damaged by physical treatment, intact foliage was used without cutting. A pair of leaves of similar size (ca. 20 ± 10cm^2) were laid at the bottom of a cylindrical assay chamber (19 cm diameter × 7 cm high) that was lined with wet paper towels. One leaf was soaked in a given concentration of a test sample in dichloromethane for a split second and air-dried. The other leaf (control) was similarly treated with dichloromethane alone. Since the two leaves were often not of the same size, the larger one was designated as the control. Twenty fourth- or fifth-instar larvae, which had been starved beforehand for 6 hr, were placed near or on the sample-treated leaf and were allowed to feed freely. After the control leaf had been thoroughly consumed (usually 30 min later), the remaining area of the treated leaf was measured. Feeding deterrence was indexed (DI) by the following formula: $DI = A_R/A_0 \times 100$ (%), where A_R represents the remaining area of treated leaf, and A_0, its original area. Bioassays were replicated four times for each sample.

Instrumentation for Chemical Analyses and Structural Elucidation. HPLC analyses were carried out using a Jasco 880-PU liquid chromatograph equipped with a ODS column (Merck, LiChrospher 100 RP-18, 5 μm). Samples were eluted with acetonitrile and water (70 : 30) at a flow rate of 1 ml/min. The column eluate was monitored at 275 nm.

^{13}C NMR (CMR) spectra were measured at 100 MHz in $CDCl_3$ on a Jeol JNM-A400 FT-NMR spectrometer with tetramethylsilane as the internal standard. Chemical shifts were given as δ units. Multiplicities of signals determined by DEPT are abbreviated as follows: singlet (s), doublet (d), triplet (t), and quartet (q).

EI-mass spectra (70 eV) were recorded with a Jeol JMS-DX 303 mass spectrometer.

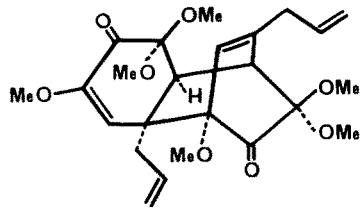
RESULTS

Larvae of *L. puziloi*, when given a choice of the foliage of *A. sieboldii* and *H. aspera*, fed on the former only and were reluctant to ingest the latter even when

starved. This behavior was strongly suggestive of the presence of some feeding deterrent(s) in *H. aspera*. In preliminary experiments, a methanolic extract of *H. aspera*, that was found to exhibit potent deterrent activity when applied to the foliage of *A. sieboldii*, was evaporated and partitioned with chloroform–water. Deterrence was obtained only with the chloroform fraction, which, after removal of the solvent, was extracted with *n*-hexane. Since apolar substances soluble in *n*-hexane exerted conspicuous deterrent activity, *n*-hexane was used thereafter instead of methanol to extract active substances from living plants.

n-Hexane extract (100 mg) of *H. aspera* was subjected to normal-phase FCC with silica gel, yielding fractions 1–5. Bioassays with these fractions at a concentration of 0.1% revealed that only fraction 4 (23 mg) was active with a DI of 69. Thus, fraction 4 (114 mg) was further fractionated on ODS-silica gel into three fractions (fractions 41–43). Among these, fraction 41 (80 mg) exhibited deterrent activity as high as DI 86 at 0.1%. This fraction, when analyzed by TLC with silica gel and developing with chloroform–acetone (25 : 1), gave five spots: A (R_f = 0.80), B (R_f = 0.69), C (R_f = 0.34), D (R_f = 0.24), E (R_f = 0.18). Since fraction B appeared to be still contaminated with minor components, it was further separated by TLC with chloroform to afford a major (B-II, R_f = 0.18) and two minor (B-I, R_f = 0.38; and B-III, R_f = 0.11) components. Individual fractions, obtained by preparative TLC in a similar manner, were assayed (0.1%) for feeding deterrence except for B-I, which was presumed to be an artifact. Comparison of DIs (0.1%) of A (21), C (11), D (34), E (61), B-II (70), and B-III (6) clearly indicated that the principal compounds responsible for feeding deterrence reside in fractions E and B-II. However, fraction E, was not pursued further in this study, because it was found to be accompanied by a large quantity of ubiquitous aliphatic acids. Final purification of fraction B-II was achieved by reversed-phase HPLC. A peak appearing at R_t = 8.2 min was collected to yield compound **1**.

Compound **1** (mp 100–102°C), upon MS measurement, gave M^+ at *m/z* 448 (rel. int., 1%) and diagnostic fragment ions at *m/z* 416(13), 384(16), 343(17), 224(67), 193(27), 181(37), 165(37), 105(100). The CMR spectrum of **1**, δ(ppm): 39.0(t), 41.3(t), 43.9(d), 44.5(d), 49.1(q), 49.8(s), 50.1(q), 50.2(q), 50.4(q), 54.8(q), 55.6(q), 92.1(s), 93.3(s), 98.7(s), 116.7(d), 116.9(t), 118.2(t), 121.8(d), 133.5(d), 135.3(d), 145.0(s), 150.6(s), 188.7(s) and 201.4(s), suggested the presence of at least 24 carbon atoms. It was evident that this compound has two carbonyl and six methoxyl moieties in its molecule. Moreover, resonances observed from 116.7 ppm to 150.6 ppm were suggestive of eight olefinic carbons, two of which are assignable to terminal methylenes. This spectral information suggested a possible molecular formula of **1** as $C_{24}H_{32}O_8$ and fits with the chemical structure of a neolignoid named asatone (Yamamura and Terada, 1975). Comparison of the spectral data with those of an authentic sample isolated from *Asarum asperum* (=*H. aspera*) (Hayashi et al., 1976) corroborated the identity of compound **1** as asatone (Figure 1).



ASATONE

FIG. 1. Chemical structure of a feeding deterrent against *Luehdorfia puziloi* larvae identified from *Heterotropa aspera*.

A dose–response relationship of antifeedant activity of asatone against *L. puziloi* larvae was examined by the same method of bioassay. Fresh leaves of *A. sieboldii* were impregnated with known concentrations of asatone in dichloromethane and air-dried. The amount of asatone adhering to the foliage, expressed as parts per million to the fresh weight of the foliage, was estimated on the basis of the volume of the solution applied, and the average of 10 replicates was obtained. The results are shown in Figure 2. DIs at 36, 90, 180, and 360 ppm were 4.3, 56, 73, and 91, respectively. Thus, larval feeding was significantly deterred at a concentration of 90 ppm or higher.

Quantitative determination of asatone in *H. aspera* and *A. sieboldii* by HPLC analyses revealed that the average content of asatone in *H. aspera* amounted to 225 ppm of the fresh weight, whereas asatone was not detected from *A. sieboldii* (detection limit, 1 ppm).

DISCUSSION

L. puziloi is a specialist, relying only on *Asiasarum* plants for larval growth. The fact that the two sibling species, *L. puziloi* and *L. japonica*, utilize distinct plant genera even in common habitats has long been the center of interest for entomologists and amateurs from the viewpoint of phylogeny or cladogenesis. On the one hand, many publications have dealt with essential oil constituents of *Heterotropa* and related genera in terms of chemotaxonomy (e.g., Endo and Nagasawa, 1974; Hayashi et al., 1984, 1990). In this context, earlier work has reported on feeding attractants for *L. japonica* larvae, in which three phenylpropanoid components, safrole, methyleugenol, and elemicin, were listed as active compounds (Takaishi et al., 1969). Very recently, a flavonoid oviposition stimulant for *L. japonica* was identified from *H. aspera* (Nishida, 1994).

In *L. puziloi*, however, nothing is known to date about the phytochemicals mediating differential acceptance of actual and potential host plants. A neolignoid, asatone, which proved to be a potent antifeedant to *L. puziloi* larvae,

seems to be specific to some, but not all, species of *Heterotropa* (Yamamura et al., 1976; Hayashi et al., 1976). This compound is, therefore, highly likely to be one of the key substances that regulate host selection by *L. puziloi*. Several neolignans have been shown to have growth-inhibitory or toxic action on some insects (e.g., Nitao et al., 1991; Gonzalez-Coloma et al., 1994).

Differential responses of papilionid larvae to plant metabolites have also been demonstrated in studies on *glaucus* members of *Papilio* butterflies. Sesquiterpene lactones in *Liriodendron tulipifera* are suspected to be responsible for larval avoidance or toxicity of *P. canadensis* (formerly *P. glaucus canadensis*) (Lindroth et al., 1986), and phenolic glycosides, such as tremulacin in *Populus tremuloides*, are toxic to larvae of *P. glaucus* (formerly *P. glaucus glaucus*) (Scriber et al., 1989). A few neolignan compounds (magnolol and/or a certain allyl-substituted biphenyl ether) contained in *Magnolia virginiana* were found to be toxic to Lauraceae-feeding *P. palamedes* and *P. troilus* larvae and significantly reduced the survival of their neonates (Nitao et al., 1992). In addition, recent investigations on a pierid butterfly, *Pieris rapae*, have documented that larval feeding on *Erysimum cheiranthoides* or *Iberis amara* was notably deterred by cardenolides or cucurbitacins (Sachdev-Gupta et al., 1993b,c).

The content of asatone in *H. aspera*, combined with the results given in Figure 2, leads to the conclusion that about 75% of the total deterrent activity of *H. aspera* against *L. puziloi* larvae may be attributed to asatone. Unidentified constituents present in fraction E would account for the remainder of the activity. The implication of these or other substances for both larval feeding and female oviposition is currently under investigation.

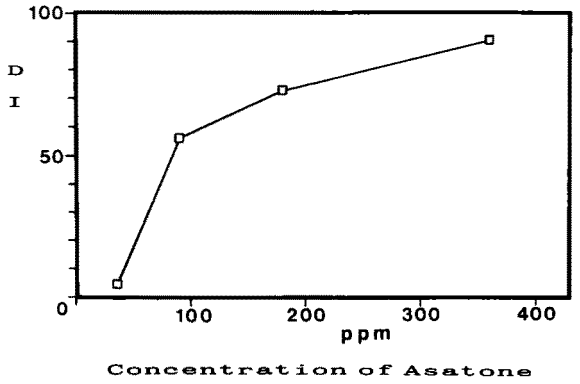


FIG. 2. Deterrent effect of asatone on feeding by *Luehdorfia puziloi* larvae. DI denotes deterrent index (see text).

Acknowledgments—We thank Satoshi Ishii and Takayoshi Matsumura for eggs of *L. puziloi*.

(Received October 31, 1994; accepted June 6, 1995)

Abstract—Male coconut rhinoceros beetles, *Oryctes rhinoceros* (L.), produce three sex-specific compounds, ethyl 4-methyloctanoate, ethyl 4-methylheptanoate, and 4-methyloctanoic acid, the first of which is an aggregation pheromone. Synthesis of these compounds involving conjugate addition of organocuprates to ethyl acrylate is reported. In field trapping experiments, (4*S*)-ethyl 4-methyloctanoate and the racemic mixture were equally attractive and 10 times more effective in attracting beetles than ethyl chrysanthemumate, a previously recommended attractant. Ethyl 4-methylheptanoate was as attractive as ethyl chrysanthemumate and more attractive than 4-methyloctanoic acid, but further studies are required before it can be classed as an aggregation pheromone. Compared to ethyl 4-methyloctanoate alone, combinations of the three male-produced compounds did not increase attraction, whereas addition of freshly rotting oil palm fruit bunches to pheromone-baited traps significantly enhanced attraction. With increasing dose, captures of *O. rhinoceros* increased, but doses of 6, 9, and 18 mg/day were competitive with 30 mg/day lures. Newly designed vane traps were more effective in capturing beetles than were barrier or pitfall traps. Results of this study indicate that there is potential for using ethyl 4-methyloctanoate in operational programs to control *O. rhinoceros* in oil palm plantations.

Key Words—Coleoptera, Scarabaeidae, *Oryctes rhinoceros*, coconut rhinoceros beetle, aggregation pheromone, pheromone chirality, ethyl 4-methyloctanoate, ethyl 4-methylheptanoate, 4-methyloctanoic acid.

INTRODUCTION

The coconut rhinoceros beetle, *Oryctes rhinoceros* (L.) (Coleoptera: Scarabaeidae), is one of the most important pests of coconut and oil palms in South and Southeast Asia (Ho and Toh, 1982; Zelazny and Alfiler, 1986). Adult rhinoceros beetles burrow into the growing point of palms and feed on unopened fronds, causing damage to inflorescences and reduction in photosynthetic area, which decreases or delays fruit production (Zelazny, 1979; Liau and Ahmad, 1991, 1993). Prolonged attacks can kill mature palms by defoliation and young palms if the growing point is destroyed. The wounds produced by the beetle provide entry points for lethal diseases and the palm weevils, *Rhynchophorus ferrugineus* Olivier and *R. vulneratus* Panzer (Bedford, 1980; Jacob and Bhumannavar, 1991).

O. rhinoceros breeds in decaying organic matter, such as felled rotting palms, and usually becomes a major problem in newly planted or replanted oil palm plantations. Covering the trunks with a rapidly growing ground cover (Wood, 1968) and/or shredding and burning of the felled trunks are common practices to minimize the build up of *O. rhinoceros* populations (Liau and Ahmad, 1991). Although effective, shredding and burning is very expensive and has been banned in some parts of Southeast Asia (Tajudin et al., 1993) to lower air pollution in this region of 4.5 million hectares of oil palm.

Treatment of breeding sites, such as stumps, with insecticidal drenches and routine application of granular insecticides (e.g., carbofuran) to the leaf axils of young oil palms are recommended (Ho and Toh, 1982). These techniques are currently considered economic (Liau and Ahmad, 1991) but are not very effective and present environmental and health risks. Manual removal of beetles from palms and larvae from decomposing trunks is costly and labor-intensive (Ho and Toh, 1982).

Limited success in managing *O. rhinoceros* populations has been achieved through introduction of the baculovirus, *Rhabdionvirus oryctes* Hüger (Bedford, 1986). Introduction of the baculovirus to the Philippines reduced *O. rhinoceros* populations to 10–20% of prerelease levels, but even low-level populations of *O. rhinoceros* can cause great damage (Zelazny and Alfiler, 1987, 1991). The baculovirus remains effective only if it infects new larval hosts or is repeatedly introduced, and the potential exists for *O. rhinoceros* to develop resistance to the baculovirus after prolonged exposure (Zelazny and Alfiler, 1991). Several compounds, including ethyl chrysanthemumate (EC, rhinolure) have been recommended as lures for trapping *O. rhinoceros* (Barber et al., 1971; Maddison

et al., 1973; Vander Meer et al., 1979), but they are only moderately attractive (Vander Meer et al., 1979; Young, 1986).

O. rhinoceros adults are gregarious. More than one beetle may attack a given palm at the same time while a neighboring tree is unattacked (Gressit, 1953). Aggregation of adults in decaying palm trunks to mate and the occurrence of both single and multiple pairs of adults in the same breeding site (Zelazny and Alfiler, 1991) suggest that *O. rhinoceros* is attracted to host kairomones and employs either an aggregation or sex pheromone or both. Sex pheromones have been identified in several scarabaeids: *Costelytra zealandica* White (Henzell and Lowe, 1970), *Popillia japonica* Newman (Tumlinson et al., 1977), *Kheper Lamarcki* MacLeay (Burger et al., 1983), *Anomala rufocuprea* Motschulsky (Tamaki et al., 1985), *A. cuprea* Hope (Leal, 1991; Leal et al., 1993a), *A. daimiana* Harold (Leal et al., 1993b), *A. schonfeldti* Ohaus (Hasegawa et al., 1993), *Blitopertha orientalis* (Leal, 1993), *A. octiescostata* Burmeister (Leal et al., 1994a), *A. albopilosa sakishimana* Nomura (Leal et al., 1994b), *Holotrichia parallela* Motschulsky (Leal et al., 1993c), *Exomala orientalis* Waterhouse (Leal et al., 1994c), and *A. orientalis* Waterhouse (Zhang et al., 1994). An aggregation pheromone, ethyl 4-methyloctanoate, has recently been reported for *Oryctes monoceros* Olivier (Gries et al., 1994a).

The candidate pheromones revealed for *O. rhinoceros* are 4-methyl alkanoic acids and esters (Figure 1). Because the methyl branch of these compounds is remote from the functional group, syntheses had to be developed that allowed introduction of chirality at remote locations. The candidate pheromones were synthesized through conjugate addition of organocuprates to ethyl acrylate, which provided a shorter route to racemic 4-alkyl substituted ethyl esters than previously reported. Use of readily available enantiomers of citronellol allowed synthesis of both chiral isomers of ethyl 4-methyloctanoate.

We report the structural elucidation, synthesis, and field testing of a male-produced aggregation pheromone and two other male-specific compounds that have the potential to be used in mass trapping of *O. rhinoceros* populations.

METHODS AND MATERIALS

Volatile Analysis and Bioassays

Larvae, pupae, or adults of *O. rhinoceros* were collected at Parungkuda, West Java, Indonesia. Fourteen female and 16 male adults were separately aerated for one week in modified Nalgene desiccators (#5311-0250) containing sugarcane (Oehlschlager et al., 1988, 1992). A water-driven, charcoal-filtered air stream (2 liters/min) was maintained through the chambers and volatiles were captured on Porapak Q held in a glass column (14 cm length × 13 mm OD). In a second series of aerations, 10 female and 10 male adults were aerated

separately. Volatiles were eluted from the Porapak Q with 175 ml of pentane, and the eluant was concentrated by distillation of solvent through a 30-cm Dufton column. The concentration of volatiles was adjusted so that 1 μl equaled 0.6 beetle hours of production.

Porapak Q-captured volatiles from both males and females were analyzed by gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975) (Hewlett Packard 5890A), utilizing a custom-built amplifier with a passive low-pass filter and a cutoff frequency of 10 kHz, and by GC analyses (Hewlett Packard 5830A) and GC–mass spectrometry (GC-MS) (Hewlett Packard 5985B), employing either a fused silica (30 m × 0.25 mm ID) or glass (30 m × 0.5 mm ID) column coated with SP-1000 (Supelco, Mississauga, Ontario).

Bioassays were conducted with a white Plexiglas Y-shaped olfactometer (stem 5 × 5 × 20 cm, arms 5 × 5 × 15 cm) with a clear lid. Test compounds were added with a syringe to filter paper inside a glass cartridge placed in each arm of the olfactometer. Compressed air at 200 ml/min carried the volatiles through each arm towards beetles released singly into the stem of the olfactometer 10 cm from the Y junction. A baffle prevented mixing of the two stimuli in the Y junction. Beetles with intact antennae and walking ability were held 2–3 hr in separate containers without food prior to testing. Prior to each test, the paper lining on the olfactometer floor was replaced, and beetle and position of stimuli were randomly selected. A beetle that did not move forward within 5 min of introduction was classed as a nonresponder, whereas complete entrance of a beetle into one of the arms was recorded as a response. In two experiments, 10 μl of distillate from males (experiment 1) or females (experiment 2) were tested against 10 μl of hexane. In order to determine behavioral activity of two synthetic male-produced compounds, a 612-ng dose of ethyl 4-methyloctanoate, **1**, and ethyl 4-methylheptanoate, **3**, in a 100:2 ratio was tested against 10 μl of hexane (experiment 3).

Instruments and General Synthetic Procedures

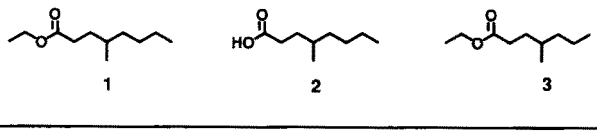
Nuclear magnetic resonance (NMR) spectroscopy was conducted on a Bruker AMX-400 spectrometer at 400.13 and 100.62 MHz for ^{1}H and ^{13}C NMR spectra, respectively. ^{1}H chemical shifts are reported relative to TMS, and ^{13}C chemical shifts are referenced to $CDCl_3$. Gas chromatographic analyses were performed on Hewlett-Packard 5880A and 5890 instruments equipped with a flame ionization detector and a fused silica, DB-1 coated column (15 m × 0.25 mm ID; 0.25 mm film) (J & W Scientific, Folsom, California). Elemental analyses were performed using a Carbo Erba model-1106 Elemental Analyzer. Diethyl ether (Et_2O) and tetrahydrofuran (THF) were freshly distilled from sodium-benzophenone-ketyl, and dichloromethane (CH_2Cl_2) was freshly distilled from CaH_2. Unless otherwise indicated, chemicals obtained from com-

mercial sources were used without further purification. All moisture- and air-sensitive reactions were conducted under argon. Column chromatography refers to flash chromatography using Silica Gel 60 (230–400 mesh, E Merck, Darmstadt, Germany) (Still et al., 1978). Thin-layer chromatography (TLC) was conducted on aluminum-backed plates precoated with Merck Silica Gel 60F-254 as the adsorbent, and visualized by treatment with an acidic solution of 1% $Ce(SO_4)_2$ and 1.5% molybdic acid followed by gentle heating.

Syntheses

(±)-Ethyl 4-methyloctanoate ***(1).*** Compound **1** (97% pure) (Figure 1) was synthesized as previously described (Gries et al., 1994a) or by ethyl ester formation from commercially available 4-methyloctanoic acid, **2** (CTC Organics, Atlanta, Georgia).

(±)-Ethyl 4-methylheptanoate ***(3).*** This compound was prepared by the conjugate addition of 2-pentyl magnesium cuprate to ethyl acrylate (Gries et al., 1994a). Compound **3** (Figure 1) was obtained as a colorless liquid (40% yield, 95% pure). ^{1}H NMR ($CDCl_3$, ppm): 0.88 (6H, m); 1.10 (1H, m); 1.27 (3H, t, J = 8 Hz); 1.30 (2H, m); 1.40 (3H, m); 1.66 (1H, m); 2.30 (2H, m); 4.10



Scheme 1

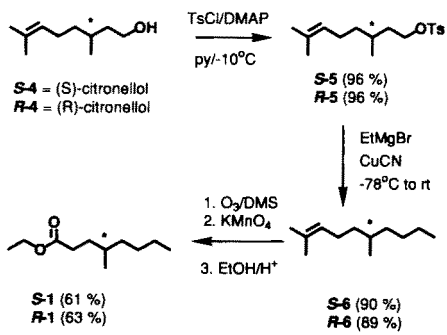


FIG. 1. Compounds **1–3** and scheme for synthesis of (4*S*)- and (4*R*)-ethyl 4-methyloctanoate.

(2H, q, J = 8 Hz); ^{13}C NMR ($CDCl_3$, ppm): 174.16, 60.11, 36.97, 32.17 (2C), 31.95, 31.16, 19.99, 19.23, 14.23. Cl-MS m/z (relative intensity): 172 (M^+, 3), 127 (M^+-OEt, 30), 101 (M^+-CO_2Et, 100).

(3S)-3,7-Dimethyl-6-octenyltosylate ***(S-5).*** Enantiomer ***S*-5** (Figure 1, scheme 1) was prepared according to the procedure of Mori and Harashima (1993b) using (*S*)-citronellol, ***S*-4** (97.5% ee, Aldrich Chemical Co., Milwaukee, Wisconsin). Purification by column chromatography (9:1, pentane/Et_2O as eluant) yielded 5.70 g of ***S*-5,** (96% yield, 98% pure) as a pale yellow oil; ^{1}H NMR ($CDCl_3$, ppm): 0.80 (3 H, d, J = 8.8 Hz); 1.10 (1H, m); 1.20 (1H, m); 1.40 (1H, m); 1.50 (1H, m); 1.52 (1H, m); 1.56 (3H, s); 1.70 (3H, s); 1.90 (2H, m); 2.45 (3H, s), 4.02 (2H, m); 5.0 (1H, t, J = 8.8 Hz); 7.32 (2H, d, J = 8.8 Hz); 7.80 (2H, d, J = 8.8 Hz); ^{13}C NMR ($CDCl_3$, ppm): 144.60, 133.41, 131.44, 129.79, 127.88, 124.34, 69.05, 36.72, 35.69, 28.93, 25.66, 25.27, 21.60, 19.06, 17.60; Cl-MS m/z (relative intensity): 310 (M^+, 2), 138 (M^+-OSO_2-C_6H_4-CH_3, 50). ***R*-5** [from (*R*)-citronellol; 96% ee]: 5.61 g, 96% yield (98% pure).

(6R)-2,6-Dimethyl-2-decene ***(R-6).*** This intermediate compound was prepared according to the procedure of Fouquet and Schlosser (1974). CuCN (Aldrich Chemical Co.) was used as received. Column chromatography (pentane) afforded 2.42 g (89% yield, 97% pure) of ***R*-6** as a colorless liquid. ^{1}H NMR ($CDCl_3$, ppm): 0.88 (3H, d, J = 7.3 Hz); 0.90 (3H, t, J = 7.3 Hz); 1.10 (2H, m); 1.30 (7H, m); 1.60 (3H, s); 1.70 (3H, s); 1.90 (2H, m); 5.1 (1H, t, J = 8 Hz); ^{13}C NMR ($CDCl_3$, ppm): 130.83, 125.16, 37.19, 36.68, 32.46, 29.29, 25.62 (2C), 23.01, 19.60, 17.55, 14.05. Cl-MS m/z (relative intensity): 168 (M^+, 40); IR (neat): 2926, 1673, 1458, 1377, 1122, 1094, 984, 826 cm^{-1}. Anal. calcd. for $C_{12}H_{24}$: C, 85.63; H, 14.37. Found: C, 85.69; H, 14.30. ***S*-6:** 2.39 g, 90% yield (98% pure). Anal. calcd. for $C_{12}H_{24}$: C, 85.63, H; 14.37. Found: C, 85.78; H, 14.57.

(4R)-Methyloctanal ***(R-7).*** Compound ***R*-7** was prepared according to the procedure of Mori and Harashima (1993a). Column chromatography (8:2, pentane/Et_2O as eluant, TLC R_f = 0.55) afforded ***R*-7** (1.68 g, 87% yield, 96% pure) as a colorless liquid. ^{1}H NMR ($CDCl_3$, ppm): 0.90 (6H, m); 1.12 (1H, m); 1.30 (5H, m); 1.40 (2H, m); 1.64 (1H, m); 2.64 (2H, m); 9.75 (1H, s); ^{13}C NMR ($CDCl_3$, ppm): 202.87, 41.70, 36.36, 32.38, 29.16, 28.93, 22.91, 19.35, 14.05; Cl-MS m/z (relative intensity): 143 (M^+ + 1, 100); IR (neat): 2927, 2715, 1727, 1465, 1379, 1263, 1133, 1012, 896, 849, 729 cm^{-1}. Anal. calcd. for $C_9H_{18}O$: C, 75.00; H, 12.76. Found: C, 75.09; H, 12.48. ***S*-7:** 1.65 g, 85% yield (98% pure). Anal. calcd. for $C_9H_{18}O$: C, 75.00; H, 12.76. Found: C, 74.98; H, 12.66.

(4R)-4-Methyloctanoic acid ***(R-2).*** This compound was prepared by the oxidation of ***R*-7** (yield 1.78 g) according to the procedure of Furniss et al.

(1989). Compound ***R*-2** was used for the next step without further purification. ^{1}H NMR ($CDCl_3$, ppm): 0.90 (6H, m); 1.12 (1H, m); 1.14 (5H, m); 1.60 (2H, m); 1.80 (1H, m); 2.35 (2H, m), 11.30 (1H, br. s). ***S*-2:** 1.45 g.

(4R)-Ethyl-4-methyloctanoate **(*R*-1).** Enantiomer ***R*-2** was esterified using the Fisher method (Furniss et al., 1989). Column chromatography (9:1, pentane/Et_2O as eluant) gave 1.34 g of ***R*-1** (61% yield based on ***R*-7**, 98% pure). $[\alpha]_D^{20} = -1.67°$ (c = 1.345, $CHCl_3$); ^{1}H NMR ($CDCl_3$, ppm): 0.88 (3H, d, J = 8 Hz); 0.90 (3H, t, J = 8 Hz); 1.10 (1H, m); 1.24 (3H, t, J = 8 Hz); 1.30 (5H, m); 1.40 (2H, m); 1.66 (1H, m); 2.30 (2H, m); 4.10 (2H, q, J = 8 Hz); ^{13}C NMR ($CDCl_3$, ppm): 174.12, 60.14, 36.36, 34.42, 32.21, 31.97, 29.17, 22.94, 19.31, 14.25, 14.06; IR (neat): 2958, 2884, 1737, 1461, 1373, 1261, 1173, 1108, 1032, 932, 855, 779, 732 cm^{-1}. Chiral Determination

Enantiomeric excess of (*R*)- and (*S*)-citronellol was determined through GC analysis (DB-1) as the amides of D-(+)-α-phenylethylamine (Sigma, St. Louis, Missouri) of the corresponding citronellic acids (Sonnet and Gazzillo, 1990).

Analysis of ***S*-1** and ***R*-1** by GC on a fused silica, Cyclodex-B-coated column (30 m × 0.25 mm ID, J & W Scientific) failed to resolve the enantiomers. ^{1}H NMR spectra in the presence of tris[3-(heptanofluoropropylhydroxymethylene)-(−)-camphorato]europium(III) [Eu(hfc)$_3$] in CS_2 (1:1 or 1:2 ratio, ester: shift reagent) (McCreary et al., 1974; Valentine et al., 1976) or the chiral solvating agent (*R*)-2,2,2-trifluoro-1-(9-anthryl)ethanol in CCl_4 (1:1 or 1:2 ratio, ester: anthrylethanol) (Pirkle et al., 1977; Pirkle and Sikkenga, 1977) failed to display diastereoisomeric complexes at different chemical shifts.

Field Experiments

Experiments were conducted in 1- or 2-year-old oil palm plantings at three P.T.P.P. London Sumatra Indonesia estates in North Sumatra, Indonesia. Specific locations are given either in Figures 5–10 below or in the text, if data are not presented in figures. All experiments were set up as randomized complete blocks with intertrap and interblock distances of at least 27 and 54 m, respectively. Traps were checked daily and captured beetles removed.

All compounds, except ***S*-1** and ***R*-1,** were released from heat-sealed, polymer membrane bag devices (Chem Tica International, Costa Rica) at constant rates. Release rates for each compound were determined by placing 10 sealed

devices containing 1 ml of neat compound in a thermostated chamber (25 ± 1°C, 60% relative humidity), allowing 48 hr equilibration, and then weighing (±0.1 mg) each device every two to three days for two weeks (devices releasing 30 mg/day) or four to five weeks (devices releasing <30 mg/day). Variability of release rates between devices was <±5% and over the measurement period was <±10%. Compound **1** was released at 0.9, 3, 6, 9, and 30 mg/day; **2** at 3 and 15 mg/day; **3** at 1 and 30 mg/day; and EC at 15 mg/day. Combinations of devices were used to achieve some release rates. ***S*-1** and ***R*-1** were released at 0.3 mg/day (at 25°C) from 1-mm-ID glass capillary tubes cut 1 cm above the meniscus and placed in capped 400-μl plastic centrifuge tubes with two 3-mm holes 1 cm below the top.

Behavioral Activity of Ethyl 4-methyloctanoate

A three-treatment, 10-replicate experiment (experiment 4) determined activity of the candidate pheromone, **1**. Black pitfall traps (Figure 2) were buried in the ground 1–1.5 m from palms and baited with either decomposing oil palm tissue (1–2 kg of leaf bases or empty fruit bunches), **1** (released at 30 mg per day), or both. Oil palm tissue or a cloth placed in traps baited with **1** only, was treated with 0.3% active ingredient solution of Basudin 60 EC (diazinon, Ciba-

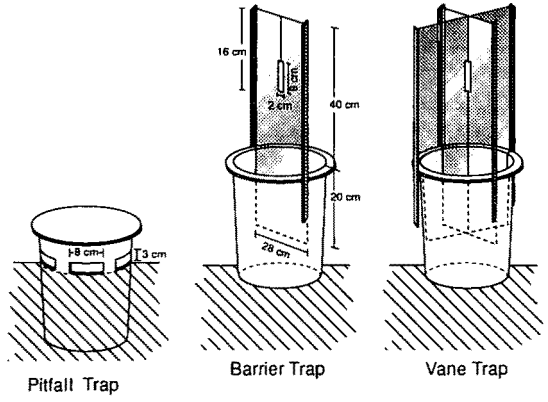

FIG. 2. Trap designs used for capturing *O. rhinoceros*. Pitfall trap: 19-liter black bucket buried in ground to allow beetles to enter through slots below rim; pheromone lure suspended within bucket from plywood lid. Barrier and vane traps: 20-liter white bucket with one or two unpainted sheet metal vanes extending 20 cm into bucket to prevent beetles from flying out; wooden slats on edge of vanes for reinforcement; lures suspended within slot to allow volatile dissemination in all directions.

Geigy). Beetles were captured because of contact with the insecticide-treated substrate or inability to exit the traps.

Trap Design Experiments

A three-treatment, 10-replicate experiment (experiment 5) compared trapping efficacies of pitfall to barrier and vane traps (Figure 2). In experiment 6 ($N = 9$), four types of vane traps were compared: unpainted (standard) vane traps (Figure 2), vane traps fitted with an internal funnel (15 cm opening) to prevent beetle escape, traps with matte black-painted vanes, and traps with both funnels and black-painted vanes (Dolok Estate, February 26–March 11, 1994). In both experiments 5 and 6, traps were baited with lures releasing **1** at 30 mg/day. No insecticide or organic matter was used in any of the traps.

Dose–Response of Ethyl 4-methyloctanoate

In a four-treatment, 18-replicate experiment (experiment 7) with standard vane traps at 36 m intervals, **1** was released at 0, 0.3, 3, or 30 mg/day. In experiment 8 ($N = 15$), standard vane traps were baited with **1** released at 0, 3, 6, 9, or 30 mg/day. In experiment 9 ($N = 12$), standard vane traps were baited with **1** released at 0, 6, 9, 18, or 30 mg/day. To minimize interference between treatments in experiments 8 and 9, intertrap and interblock distances were increased to 54 and ≥ 63 m, respectively.

Chiral Isomers of Ethyl 4-methyloctanoate

A four-treatment, 10-replicate experiment (experiment 10) tested attraction of beetles to racemic **1**, ***S*-1**, ***R*-1**, or a blank control in standard vane traps. ***S***- or ***R*-1** were released at ~ 2 mg/day from eight capillary tubes and racemic **1** was released at ~ 4 mg/day from 16 capillary tubes.

Other Candidate Pheromones and Attractants

Attraction of beetles to three male-produced compounds, **1**, **2**, **3**, and to (±)-ethyl chrysanthemumate (EC, 95% pure, mixture of *cis* and *trans*, Aldrich Chemical Co.) was compared in experiment 11 ($N = 10$). All compounds were released at 30 mg/day. Experiment 12 ($N = 9$) compared attraction of beetles to **1** alone (30 mg/day) and in combination with **3** at ratios of 100:1, 100:10, and 100:100 (Rambong Sialang Estate, April 13–21, 1994). Experiment 13 ($N = 10$) compared attraction of beetles to **1** alone (10 mg/day) or in approximate natural ratios with either or both of **2** (30 mg/day) and **3** (0.1 mg/day) (Rambong Sialang Estate, June 9–17, 1994).

Pheromone–Host Material Interactions

The attraction of beetles to **1** (9 mg/day) alone, freshly milled empty fruit bunches (1/3 to 1/2 bunch per trap), or to both was examined in a three-treatment, 12-replicate experiment (experiment 14).

Statistical Analyses

The proportions of beetles responding to each stimulus in laboratory bioassays were compared by using the normal approximation to the binomial test, and differences between responses of female and male beetles were compared with χ^2 tests (Zar, 1984).

In all field experiments, no significant differences were found in the responses of male and female beetles and so catches were pooled by sex for analysis. Data were transformed by log $(x + 1)$ if they were not normally distributed and were subjected to analysis of variance (general linear modeling) (Minitab, 1989). If replicates were run at different times or locations, data were analyzed for time × treatment or location × treatment interactions. Following ANOVA, multiple pair comparisons were made using Bonferroni t tests. If homoscedasticity was not achieved by transformation, data were analyzed by χ^2 tests (Zar, 1984).

RESULTS

GC and GC-EAD analyses of Porapak Q-trapped volatiles obtained from aerations of either *O. rhinoceros* males or females revealed two abundant male-specific components (Figure 3), of which the early eluting volatile elicited antennal responses by male and female antennae (Figure 4). Retention and mass spectrometric characteristics of these two compounds were identical to ethyl 4-methyloctanoate, **1**, and 4-methyloctanoic acid, **2**. A second EAD-active compound (not visible in Figure 4) had a Kovats retention index (RI = 1379) suggestive of ethyl 4-methylheptanoate, **3**. GC-MS in both electron impact and chemical ionization modes of beetle-produced and authentic **3** confirmed this structural assignment.

In laboratory bioassays (experiments 1 and 2), male-produced volatiles were equally attractive to walking male and female *O. rhinoceros*, but female-produced volatiles were attractive only to males (Table 1). Behavioral activity of synthetic **1** plus **3** was demonstrated in experiment 3 (Table 2) and justified field testing of synthetic candidate pheromones. In field experiments, **1** at 30 mg/day alone or in combination with decomposing palm tissue attracted more beetles than palm tissue alone (Figure 5; experiment 4).

Both vane and barrier traps were superior to the pitfall trap (Figure 2), with

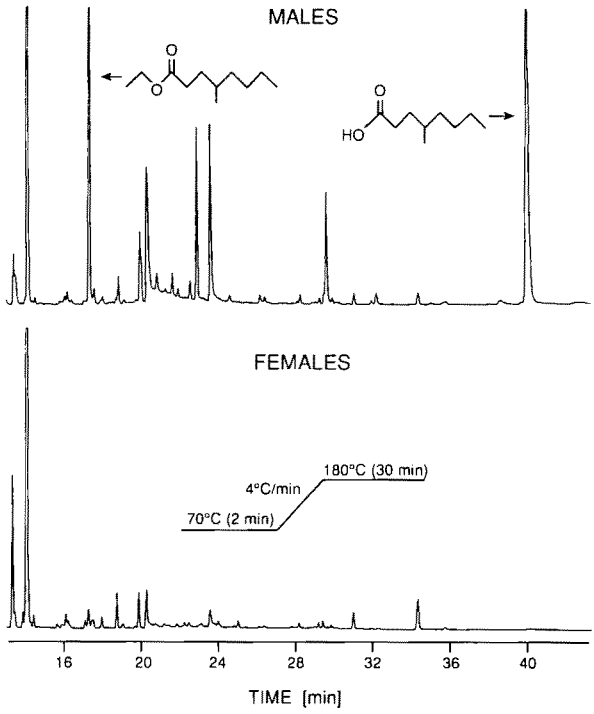

FIG. 3. Gas chromatograms of volatiles from 10 male and 10 female *O. rhinoceros* maintained in aeration chambers for one week with provision of sugarcane as food source. Chromatography: Hewlett Packard 5830A gas chromatograph (GC) equipped with a glass capillary column (30 m × 0.5 mm ID) coated with SP-1000.

vane traps capturing about three times more beetles than pitfall traps (Figure 6; experiment 5). Addition of a funnel to the vane trap and painting vanes black did not alter trap efficacy (experiment 6; ANOVA, $F = 1.19$, $df = 3$, $P = 0.341$).

Catches of *O. rhinoceros* increased with increasing release rates of the pheromone (Figure 7; experiments 7–9). A significant location × dose interaction was observed in experiment 7 ($F = 18.39$, $df = 1$, $P < 0.001$), which arose from the 3 mg/day lure being more attractive relative to the 30 mg/day lure at Rambong Sialang than at Dolok (mean catches in 3 mg/day traps were 64% and 32% of those in 30 mg/day traps, respectively). This result along with the prohibitive cost of 30 mg/day lures, prompted us to examine release rates between 3 and 30 mg/day. In experiments 8 and 9, lures releasing **1** at 6, 9, and 18 mg/day were competitive with 30 mg/day lures (Figure 7).

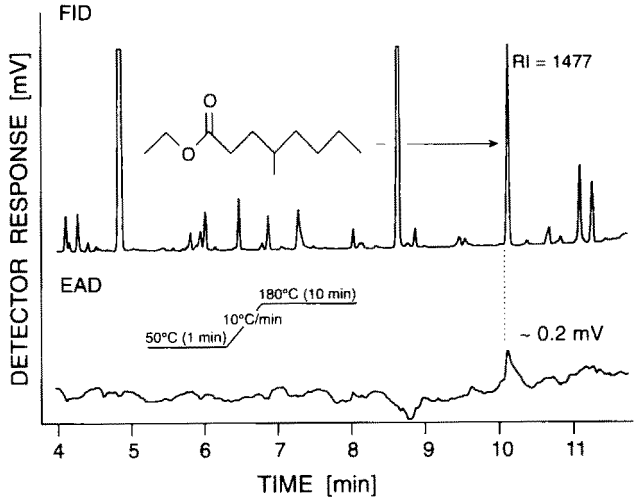

FIG. 4. FID and EAD responses to volatiles obtained from male *O. rhinoceros*. The antennal recording was carried out with an antenna of a female beetle. Chromatography: Hewlett Packard (HP) 5890A gas chromatograph (GC) equipped with a fused silica column (30 m × 0.25 mm ID) coated with SP-1000.

Racemic **1** and ***S*-1** were superior to ***R*-1** in attracting beetles (Figure 8; experiment 10). Racemic **1** was significantly more attractive than **2, 3,** or EC (Figure 9; experiment 11); **3** was significantly more attractive than **2,** but both compounds did not differ in attraction from EC. Traps baited with **1** alone or with **3** in different ratios were equally attractive (experiment 12; ANOVA, $F = 0.49$, $df = 3$, $P = 0.693$), as were traps baited with **1** alone, **1** plus **2,** or **1** plus **2** and **3** (experiment 13; ANOVA, $F = 2.28$, $df = 3$, $P = 0.105$).

Freshly milled oil palm fruit bunches alone were unattractive to rhinoceros beetles, but in combination with **1** they significantly enhanced pheromonal activity (Figure 10; experiment 14).

DISCUSSION

Methyl-branch-substituted pheromones are very common (Mori, 1992). There are several synthetic methods described for the synthesis of 4-methyl alkanoic acids and esters. Compounds **1** and **3** were prepared by Cason et al. (1944) by reaction of ethyl levulinate or levulinic acid with the corresponding Grignard reagent to produce a γ,γ-dialkylbutyrolactone. Treatment of the lactone with $SOCl_2$/ethanol/HCl followed by hydrogenation produced the respec-

TABLE 1. RESPONSES OF MALE AND FEMALE *Oryctes rhinoceros* TESTED INDIVIDUALLY TO PENTANE EXTRACT OF MALE- AND FEMALE-PRODUCED VOLATILES (10 μl = 5.6 BEETLE HOURS) VERSUS 10 μl OF HEXANE CONTROL IN Y-SHAPED OLFACTOMETER

Experiment	Sex	n	Number of responders to stimuli[a]		P^b
			Extract	Control	
1. Female extract *versus* hexane control	Male	20	9	2	0.006
	Female	20	5	8	0.393
2. Male extract *versus* hexane control	Male	15	12	1	0.0001
	Female	17	13	3	0.0014

[a] Responses to female extract in experiment 1 differ between males and females, $\chi^2 = 4.608$, $df = 1$, $P = 0.032$. Responses to male extract in experiment 2 are not significantly different between males and females, $\chi^2 = 0.738$, $df = 1$, $P = 0.39$.

tive 4-methyl esters in overall yields of 50–60%. Vasi and Desai (1973) prepared 4-methylheptanoic acid from 2-methylbutyric acid using Arndt-Eistert synthesis. Mrowca (1981) reported the synthesis of carboxylic acids or esters by catalytic carboxylation or alcoxycarbonylation of unsaturated hydrocarbons (**2** was obtained in 86% yield). More recently, Sonnet and Baillargeon (1989) synthe-

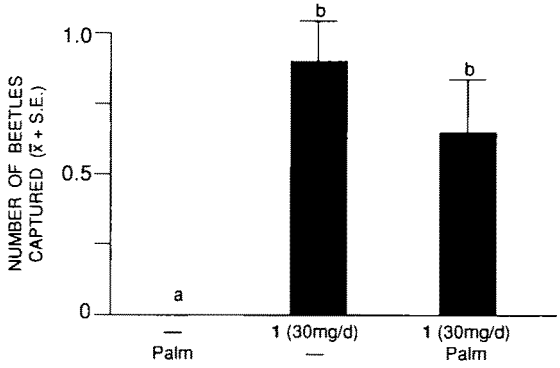

FIG. 5. Attraction of *O. rhinoceros* to ethyl 4-methyloctanoate, **1** (released at 30 mg/day), decaying oil palm tissue, or both together, in pitfall traps at Bah Lias and Rambong Sialang Estates, North Sumatra, Indonesia (October 14–22 and 16–23, 1993, respectively) (experiment 4). Data pooled as no locational differences were found ($\chi^2 = 2.2305$, $df = 1$, $P > 0.10$). Treatment differences for pooled data, $\chi^2 = 13.036$, $df = 2$, $P < 0.01$. Bars with the same letter are not significantly different, pairwise χ^2 tests, $P < 0.05$.

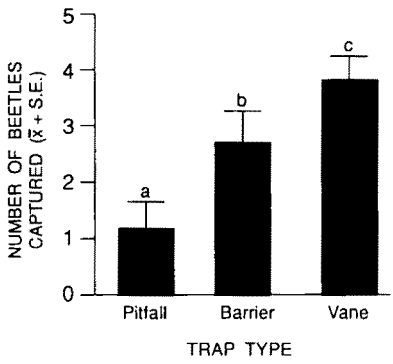

FIG. 6. Efficacy of three insecticide-free trap types for capturing *O. rhinoceros* (February 2–10, 1994), tested at Rambong Sialang Estate (experiment 5). All traps baited with **1** released at 30 mg/day. ANOVA, $F = 6.58$, $df = 2$, $P = 0.007$. Bars with the same letter are not significantly different, Bonferroni t test, $P < 0.05$.

sized 4-methyloctanoic acid, **2**, in 53% overall yield by methylation of the *N*-*t*-butylimine derivative of hexanal by condensation with malonic acid and hydrogenation.

In our study, both **1** and **3** were prepared by conjugate addition of organocuprates to ethyl acrylate (Corey and Boaz, 1985; Matsuzawa et al., 1989; Perlmutter, 1992; Gries et al., 1994a), a shorter synthetic procedure than in earlier reports. The required cuprates were prepared by adding 10 mol% CuCN to a solution of the corresponding Grignard reagent at −40°C. Subsequent addition of trimethylchlorosilane, HMPA, and ethyl acrylate (2:2:1 ratio) in THF or Et_2O produced **1** or **3** in 40–55% yield. Use of CuBr·DMS increased the yield of the conjugate addition by 10–15%. No further attempts to optimize the reaction yields were made because **1** can also be prepared by the esterification of commercially available **2** (CTC Organics, Atlanta, Georgia).

Syntheses of ***R*-2** and ***S*-2**, in high optical purity (95.4%) have been reported by Sonnet and Gazzillo (1990). Accordingly, alkylation of hexanoic acid produced 2-methylhexanoic acid, which was reacted with (*R*)- or (*S*)-α-phenylamine to give diastereoisomeric amides that were separated by crystallization. The optically pure amides were *N*-hydroxylated and reduced to the corresponding 2-methylhexanols, which were oxidized and converted to the methyl 4-methyl-2-octanoates via a Wittig reaction with carbomethoxymethylene triphenylphosphorane. Hydrogenation and saponification afforded ***R*-2** and ***S*-2** in ~10% overall yield (eight steps).

We envisioned a more efficient route using a highly enantiomerically enriched citronellol (Hanessian et al., 1990; Ho, 1992). The citronellane skel-

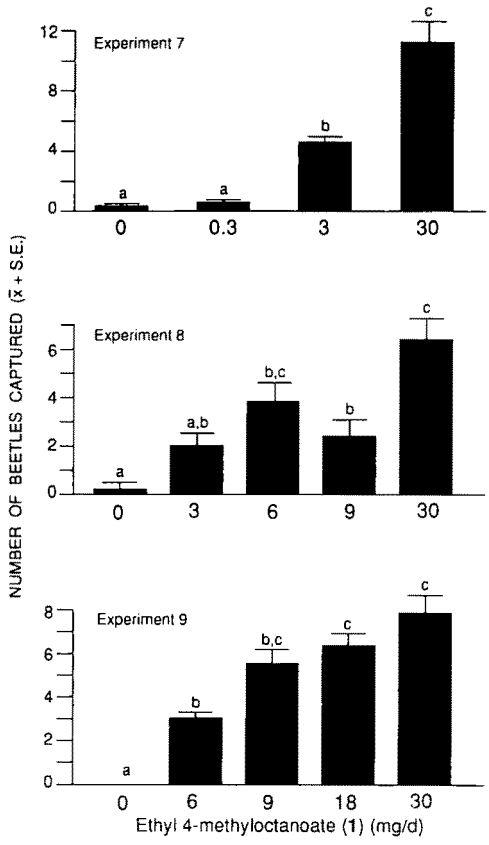

FIG. 7. Attraction of *O. rhinoceros* to **1** released at various rates from standard vane traps. Experiment 7, February 12–26 and February 21–March 4, 1994, Dolok and Rambong Sialang Estates, respectively; ANOVA, $F = 44.89$, $df = 3$, $P < 0.001$. Experiment 8, March 11–17, 1994, Dolok; ANOVA log $(x + 1)$ transformed data, $F = 12.13$, $df = 4$, $P < 0.001$. Experiment 9, May 24–June 8, 1994, Dolok; ANOVA $\log_{10}(x + 1)$ transformed data, $F = 49.84$, $df = 4$, $P < 0.001$. Bars with the same letter are not significantly different, Bonferroni t test, $P < 0.05$. Untransformed means presented.

eton is commonly used in the synthesis of natural products (e.g., Mori et al., 1991; Stork and Nakamura, 1983; Ho, 1992; Mori and Harashima, 1993a,b; Weinges et al., 1993; Mori and Murata, 1994; Paquette et al., 1995). Modifications at both termini of the citronellane skeleton can be performed without perturbing the chiral center (Ho, 1992). The synthesis of ***S*-1** and ***R*-1** (Figure 1, scheme 1) commenced with tosylation of (*R*)- or (*S*)-citronellol. Chain exten-

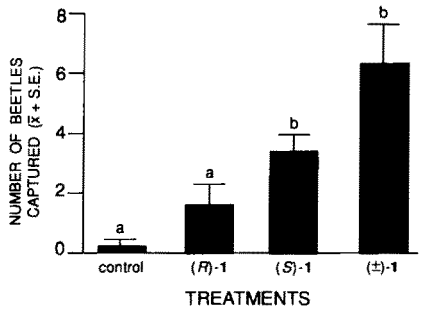

FIG. 8. Attraction of *O. rhinoceros* to standard vane traps containing stereoisomers of **1** at Rambong Sialang Estate (May 23–June 8, 1994) (experiment 10). ANOVA log (x + 1) transformed data, $F = 24.04$, $df = 3$, $P < 0.001$. Bars with the same letter are not significantly different, Bonferroni t test, $P < 0.05$. Untransformed means presented.

sion *via* cuprate displacement of the tosylate, **5** (Fouquet and Schlosser, 1974), produced the corresponding 2,6-dimethyl-2-decenes, **6**, in high yield. Ozonolysis followed by permanganate oxidation and esterification afforded ***S*-1** and ***R*-1** in yields of 45–47% over five steps. Attempts to determine the optical purity of **6**, **7**, ***S*-1**, or ***R*-1** by gas chromatography using a Cyclodex B column and NMR techniques were unsuccessful. Since the above procedures have significant precedent in the literature and involve transformations remote from the stereogenic carbon, we assumed that the chiral purity of ***S*-1** and ***R*-1** was identical to that of citronellol.

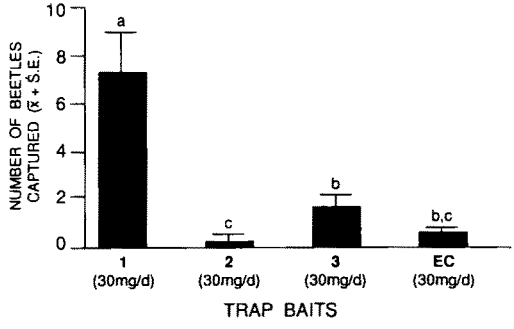

FIG. 9. Attraction of *O. rhinoceros* to **1**, **2**, **3**, and EC in standard vane traps at Rambong Sialang Estate (March 30–April 7, 1994) (experiment 11). ANOVA, log (x + 1) transformed data, $F = 35.77$, $df = 3$, $P < 0.001$. Bars with the same letter are not significantly different, Bonferroni t test, $P < 0.05$. Untransformed means presented.

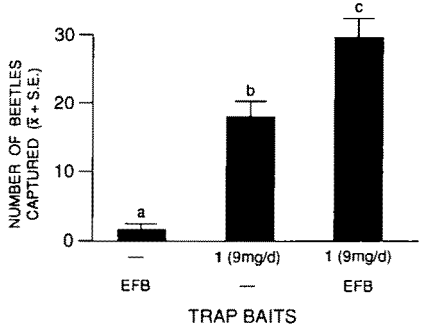

FIG. 10. Attraction of *O. rhinoceros* to standard vane traps containing **1** (released at 9 mg/day), freshly milled empty fruit bunches (EFB), or both together at Rambong Sialang and Dolok Estates (April 26–May 11 and May 3–18, 1994, respectively) (experiment 14). ANOVA, $F = 46.60$, $df = 2$, $P < 0.001$. Bars with the same letter are not significantly different, Bonferroni t test, $P < 0.05$.

Semiochemical communication in *O. rhinoceros* appears to involve both a male-produced aggregation pheromone and a female-produced sex pheromone (Table 1). Because aggregation pheromones have greater potential than sex pheromones for controlling *Oryctes* populations through mass trapping, research was focused on the identification of aggregation pheromones. Compound **1** was confirmed in field experiments as the major male-produced aggregation pheromone of *O. rhinoceros* (Figures 5 and 9). The same compound is a male-produced aggregation pheromone in the African rhinoceros beetle, *O. monoceros* (Gries et al., 1994a). Other geographically or temporally isolated scarabaeid beetles also utilize identical sex pheromones (Leal et al., 1993a,b).

Oryctes spp. respond to vertical silhouettes (Bedford, 1980). Above-ground light traps with vanes are effective in capturing *O. elegans* in the Arabian peninsula. Superior efficiency of vane and barrier traps for capturing *O. rhinoceros* (Figure 6) may mostly be attributed to the vertical silhouettes that are lacking in the pitfall trap. Because response to the vertical silhouette could not be enhanced further by use of nonreflective black vanes and the use of funnels did not improve retention of captured beetles in traps, insecticide-free, unpainted vane traps were adopted as the standard trap for *O. rhinoceros*.

As in *A. octiescostata* (Leal et al., 1994a), increase of pheromone release rate resulted in increasing numbers of captured beetles. Because traps baited with **1** released at 6, 9, 18, or 30 mg/day were similarly attractive, a release rate of 9 mg/day was adopted for operational trapping trials.

In the Japanese beetle, pheromonal attraction is strongly inhibited by the presence of the nonnatural enantiomer of its sex pheromone, (*R*,*Z*)-5-

(1-decenyl)dihydro-2(3H)-furanone (Tumlinson et al., 1977). We therefore investigated the response of *O. rhinoceros* to chiral isomers of **1.** Racemic and ***S*-1** were similarly attractive to *O. rhinoceros* (Figure 8), indicating that ***S*-1** is a naturally produced isomer and ***R*-1** is not repellent. Behavioral activity of ***R*-1** and enhanced attraction of *O. rhinoceros* to racemic **1** rather than ***S*-1** may indicate that both isomers are produced naturally. Accessible racemic **1** can be used operationally.

Synergism between aggregation pheromones and host compounds has recently been demonstrated for *A. octiescostata* (Leal et al., 1994d), and palm weevils, *Rhynchophorus* spp. (Oehlschlager et al., 1992; Gries et al., 1994b; Hallett et al., 1993; Giblin-Davis et al., 1994). Synergistic oil palm volatiles are apparently produced early in the decomposition (fermentation) process because freshly milled fruit bunches but not decomposed palm tissue enhanced pheromone attraction. Investigations are underway to identify palm kairomones and to determine the potential of mass-trapping *O. rhinoceros* in oil palm plantations.

AN EVALUATION OF REPELLENTS TO SUPPRESS BROWSING BY POSSUMS

A.D. WOOLHOUSE[1,*] and D.R. MORGAN[2]

[1]*Industrial Research Limited*
P.O. Box 31.310, Lower Hutt, New Zealand

[2]*Landcare Research Limited*
P.O. Box 31.011, Christchurch, New Zealand

(Received December 16, 1994; accepted June 6, 1995)

Abstract—The efficacy in feeding suppression trials with possums (*Trichosorus vulpecula* Kerr) of six synthetic odorous chemicals uniquely associated with various of the Mustelidae species and of the red fox (*Vulpes vulpes*) has been evaluated with respect to several proprietary repellents. The predator odors, two proprietary repellents, and two other repellent formulations (olive oil in petroleum jelly and a synthetic fermented egg odor cocktail) were applied as 5% w/v solutions in paraffin to the foliage of *Pinus radiata* seedlings and the extent of browse compared with that on seedlings treated with Treepel, an effective egg-based repellent already available commercially. All four of the mustelid predator odors [(∓)-2-*n*-propylthietane, (∓)-3-*n*-propyl-1,2-dithiolane, 2,2-dimethylthietane, and 3,3-dimethyl-1,2-dithiolane] and the volatile compound from fox urine (Δ^3-isopentenyl methyl sulfide) were shown to be more or at least equally effective compared to Treepel. This was true also of one commercial repellent Gori, which contained bitrex and the synthetic fermented egg formulation. The most effective compounds will be evaluated when administered with adhesives and surfactants in the further development of possum repellents with longer field lives.

Key Words—Herbivore repellents, carnivore odors, possum, *Trichosorus vulpecula*, predator-prey interactions.

INTRODUCTION

The damage to both native forests, exotic forest plantations, and agricultural and horicultural crops (Cowan, 1990) that is occurring in New Zealand as a

*To whom correspondence should be addressed.

0098-0331/95/1000-1571$07.50/0 © 1995 Plenum Publishing Corporation

result of the introduced Australian brush-tail possum (*Trichosorus vulpecula* Kerr) has created a demand for more effective control measures. Control is further mandated as this animal is also the major vector in the transmission of bovine TB to cattle. Poisoning with sodium monofluoroacetate (1080) or cyanide and trapping are presently effective strategies for the control of possums in uninhabited areas. However, the use of toxins and traps may be inappropriate in situations where people, livestock, or pets are present. There is therefore a demand for alternative strategies of control with nonlethal methods.

We have had a longheld interest in evaluating possum gland secretions as potential sources of compounds (pheromones) that might function uniquely as attractants to possums (Woolhouse et al., 1994) and in evaluating biological fluids (and compounds derived from them) from both sympatric and allopatric carnivorous predators as repellents to possums. The potential for control by repellency, based upon predator avoidance by herbivores, has been demonstrated for a number of herbivorous mammals in recent years (Sullivan et al., 1990a,b; Abbott et al., 1990; Robinson, 1990; Swihart et al., 1991; Pfister et al., 1990; Weldon et al., 1993; Boag and Mltokiewicz, 1994; Epple et al., 1993; for a review of earlier literature see Müller-Schwarze, 1990). Sulfurous metabolites from meat digestion have been suggested as the common factor in predator secretions that elicit aversive behavior among herbivores (Nolte et al., 1994b). Another sulfur-rich formulation, based on egg powder, was effective as a repellent against rabbits (*Oryctolagus cuniculus*) and hares (*Lepus europaeus*) for up to two months (Crozier, 1991) and deterred possums from eating apples in a pen study (Eason and Hickling, 1992).

With the exception of the work reported largely by Sullivan et al. (1990a,b and earlier work), virtually all of the other studies have been carried out with biological fluids (or extracts of them). We have therefore attempted to extend these various findings to the point where active ingredients may be practically applied in wildlife management. We report the results of pen trials on the repellency towards possums of six synthetic mammalian kairomonal compounds uniquely associated with a number of carnivorous mammals and compare these findings to those from other herbivore repellent formulations including three commercial repellents.

METHODS AND MATERIALS

Synthesis. We synthesized six odorous predator compounds (Figure 1) in amounts of 20–50 g, formulated them for field use as 5% w/v solutions in medicinal-grade paraffin oil (to produce a slow release of odor), and dispersed them in the form of a spray, as described by Robinson (1990), for example, in his studies with a synthetic predator odor.

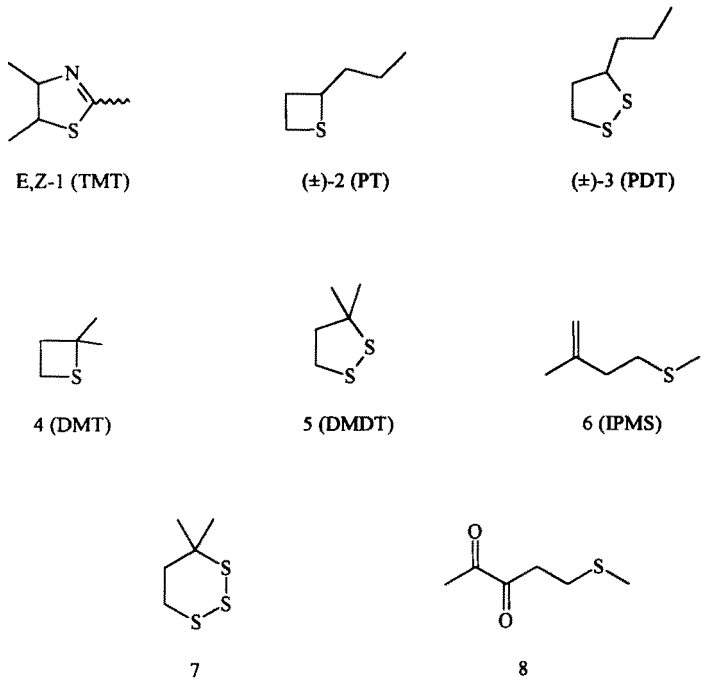

FIG 1. Chemical structures of the compounds referred to in the text.

(*E*,*Z*)-4,5-Dihydro-2,4,5-trimethyl-Δ^3-thiazoline (TMT-1 in Figure 1) is an odorous component of fox (*Vulpes vulpes*) feces that induces fear responses in rats (Vernet-Maury et al., 1984). This compound was synthesized as a mixture of *E* and *Z* isomers by the one-pot condensation of 2-mercaptobutan-2-one (Hromatka and Haberl, 1954) with acetaldimine (prepared in situ from acetaldehyde and ammonia) as outlined by Dubs and Pesaro (1974).

(±)-2-*n*-Propyltheitane (PT-2 in Figure 1) is a volatile compound identified as a major component of the anal sac secretion of the stoat (*Mustela erminea*) (Crump, 1980a) and ferret (*M. putorius* forma *furo*) (Crump, 1980b) that has been shown in field trials to suppress feeding by a number of pest herbivores (see, for example, Sullivan et al., 1988). This compound was synthesized from 3-*n*-propylthiete 1,1-dioxide by the method described by Woolhouse et al. (1993).

(±)-3-*n*-Propyl-1,2-dithiolane (PDT-3 in Figure 1) is also a volatile compound identified as a component of the anal sac secretion of the stoat and of the ferret (Crump, 1980b). It has likewise been shown to field trials to suppress feeding by a number of pest herbivores (Sullivan et al., 1988). This compound

was prepared by the phase transfer-mediated cyclization of (±)-1,3-dibromohexane with disulfide anion, which was based upon the method originally described by Eliel et al. (1975). The dithiolane was obtained pure as a mobile yellow liquid. However, to minimize an apparently slow polymerization, the compound was stored as a 10–20% solution in hexanes.

2,2-Dimethylthietane (DMT-4 in Figure 1) is a highly volatile major component of the anal sac secretion of the mink (*M. vison*) and polecat (*M. putorius*) (Schildknecht et al., 1976). This compound was synthesized by the intramolecular alkali-induced cyclization of 1-chloro-3-mercapto-3-methylbutane as described by Mayer (1974).

3,3-Dimethyl-1,2-dithiolane (DMDT-5 in Figure 1) is a compound found in the feces of the red fox (*Vulpes vulpes*) (Vernet-Maury et al., 1984) and the anal sac secretion of the mink and is obtained as an unstable readily polymerizing oil (Schildknecht et al., 1976). This compound was synthesized by the method of Eliel et al. (1975) but purified to a level of approximately 60% (GC) only with considerable loss of product. GC-MS analysis (Hewlett-Packard MSD, 25-m HP Ultra 2 capillary column operated in the split mode; 100° to 200°C at 10°/min) revealed the presence ($\leq$20%) of a species we believe to be the cyclic trisulfide, 4,4-dimethyl-1,2,3-trithian (**7** in Figure 1), although this has not been authenticated by synthesis.

Δ^3-Isopentenyl methyl sulfide (IPMS-6 in Figure 1) is a urinary constituent of the red fox (*Vulpes vulpes*) (Jorgenson et al., 1978) that has been shown to be effective either alone or in combination with other chemicals in reducing feeding damage by voles (*Microtus montanus, M. pennsylvanicus*) pocket gophers (*Thomomys talpoides*), and red squirrels (*Tamiasciurus hudsonicus*) (see Sullivan et al., 1988, for example). This compound was prepared by methanethiolysis of Δ^3-isopentenyl tosylate by a published method (Wilson et al., 1978) but using DMF rather than HMPA as solvent.

Our attempts to prepare 5-thiomethylpentan-2,3-dione (**8** in Figure 1) by either of the two methods outlined by Wheeler et al. (1975), and not since published in detail, were unsuccessful. This compound, which would represent an unusual member of the carnivore odor arsenal, has been isolated from the anal scent gland of the striped hyena (*Hyaena hyaena*).

The proprietary repellent formulations we tested were Treepel (Aorangi Forestry Services, Waimate), which contains a mixture of egg powder and adhesive (Crozier, 1991); Ro-pel, which contains the bitter compound denatonium saccharide (DS) (Nolte et al., 1994a); and Gori, which contains the bitter compound denatonium benzoate (DB). Two other compounded formulations were tested. These were: (1) a form of synthetic fermented egg (SFE) concocted by mixing the eight predominant odor components used by Bullard et al. (1978) and modified to minimize phytotoxicity before being administered, as a 5%

w/v solution in paraffin oil, and as a 1:1 mixture of petroleum jelly, and (2) olive oil in petroleum jelly (PJO), which we have already shown (unpublished observations) to be highly repellent to rabbits, possibly as a result of the presence of plant defense compounds.

Trial Design. The compounds and preparations were tested in pen trials by spraying them at a rate of 5 ml/seedling directly onto the foliage of *Pinus radiata* seedlings. These were of a uniform size ($\leq$45 cm) to permit a ready assessment of the extent of browse. Three adjacent pens (each 30 $\times$ 5 m) with open gates between them to permit free access were used in all trials. Three groups of six possums were used in rotation to minimize the likelihood of any of them becoming desensitized towards repellents. The animals used a sheltered area with next boxes at one end of each pen during the daytime and were provided with supplementary feed pellets and apples, as well as grass and clover growing in the pens, and a continuous supply of fresh water.

In each of the trials, a row of seedlings was planted in each of the outer pens, one to be treated and one to function as a control, no seedlings were planted in the center pen so that treated and control groups were separated. This arrangement was designed to simulate a field application of repellents to groups of seedlings, where each treated seedling reinforces the effect of the group. At the commencement of the trials, 25 seedlings were planted in each row but in later trials only 15 were planted as they were by this stage approximately 60 cm in height. These measures ensured that feeding pressure on foliage was maintained at a similar level that was deliberately greater than expected in the wild to ensure a rapid aquisition of results. In the first and last trials, untreated seedlings were planted in both end pens to determine whether or not possums demonstrated a preference for feeding in either pen. In the second trial, the repellent action of Treepel was evaluated and confirmed (Table 1) to be repellent to possums. Consequently, this was then used as a positive control in all other trials.

The height of each seedling was measured directly after planting, and the proportion of each seedling left unbrowsed was assessed daily until only about 10% seedling foliage remained in one of the pens. The duration of each trial was about 7–10 days. Trials were started only during fine weather, and rainfall was measured on a daily basis before assessing seedlings. The percentage of each seedling left unbrowsed each day was plotted as a function of time. The mean area under the curve (AUC) for treatments was divided by the mean AUC for controls as a combined measure of treatment effectiveness and durability in relation to Treepel. Values in excess of unity therefore indicate that treatments are more effective than Treepel. The mean AUC's for treatments and controls were also compared by ANOVA to test for significant differences in effectiveness.

TABLE 1. TRIAL DETAILS AND EFFECTIVENESS OF REPELLENTS RELATIVE TO CONTROL

Compounds tested		Mean AUC treatment/mean AUC control	P

RESULTS AND DISCUSSION

The extent of browsing upon untreated seedlings in each of the two end pens in the trials at the beginning and at the end of the study did not differ significantly (Table 1). Since both test and control compounds applied to seedlings in both pens in most trials proved to be repellent, there was evidently no strong inducement for possums to develop any preference for feeding location.

Three of the predator odor compounds were more effective repellents than Treepel, the most effective being the DMDT, which still remained its activity at the end of the trial when the control seedlings had been almost completely eaten (Figure 2a). Moreover, rain on three days during the trial caused no apparent loss in the repellency of this preparation. Both PT and IPMS were also shown to be more repellent to possums than the control but seedlings treated with PDT and DMT were browsed upon to the same extent as the control-treated plants. The TMT was significantly less repellent than Treepel (Table 1).

These variations in repellent effectiveness over the duration of the trial are unlikely to be solely due to differences in odor strength or volatility: there is no obvious correlation between boiling point, for example, and the apparent order of effectiveness of these predator odors. Treatment effects might, in fact, be

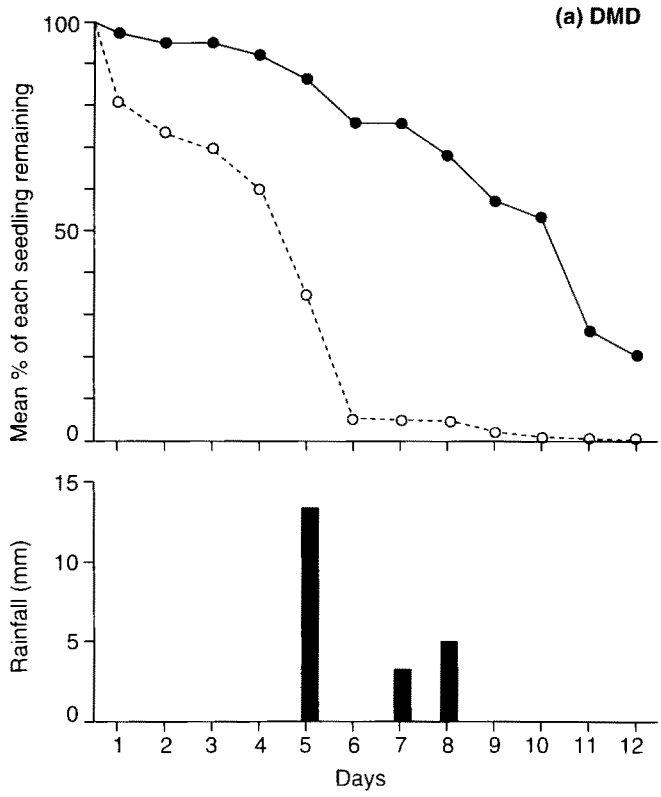

FIG 2. Effectiveness of four repellent compounds (bold line) compared to Treepel (broken line) and daily rainfall.

more dependent upon the sympatric or allopatric nature of the evolution of predator and prey, the duration of the association, and the ability of the prey to learn to avoid predator odors (Swihart et al., 1991). Possums in Australia (where they are endemic) did not evolve sympatrically with foxes and mustelids, but only came into contact with these predators after the predators were introduced by Europeans. Although possums in New Zealand could have learned to avoid mustelids, with which they have been associated for some 200 years, by odor detection, such a response to foxes could not have been learned. This might explain why TMT was the least effective repellent odor in these trials. While there are a few reported instances at an experimental level in which predator odors have no apparent effect upon certain herbivorous prey species (Stoddart, 1976; Gorman, 1984), there is wide support (present study included) for the

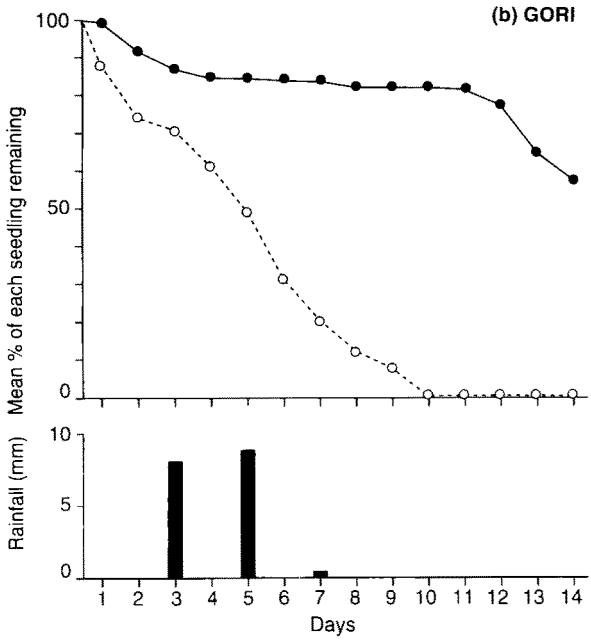

FIG. 2. Continued

suggestion that herbivore avoidance of carnivore odor(s) is inate and generalized rather than being a conditioned response to a specific predator (Stoddart 1982a,b; Dickman and Doncaster, 1984; Gorman, 1984; Robinson, 1990; Kavaliers, 1990; Weldon et al., 1993; Boag and Mlotkiewicz, 1994).

The mechanism of this avoidance behavior is most probably by recognition of the odor of sulfurous by-products of meat digestion. For example, when such sulfurous compounds were removed from coyote urine, it was far less aversive to mountain beaver than whole urine (Nolte et al., 1994b). However, the identity of the active sulfur-containing compounds in coyote urine has not yet been determined. C-S lyase enzymes are known that catalyze fragmentations of naturally occurring *S*-substituted cysteines to produce thiols, and therefrom sulfides and higher ogligosulfides. The apparently unique role of L-cysteine as the only biosynthetic means of introducing sulfur into organic molecules has been noted by Kjaer (1977).

The fate of ingested proteinaceous sulfur is apparently diverse. Whereas mustelid (sloat, ferret, mink) 'odor' compounds (e.g., DMT, DMDT, PT, PDT) or their respective precursors are apprently uniquely present as components of

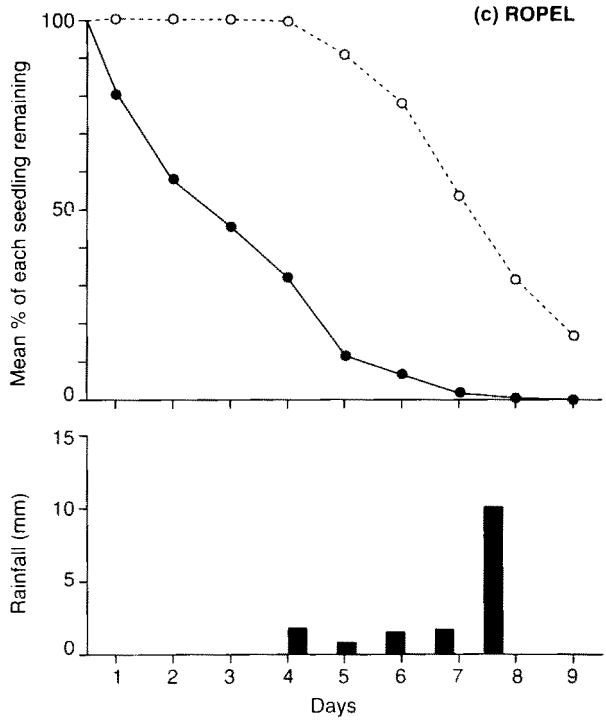

FIG. 2. Continued

anal sac secretions, TMT and IPMS are uniquely associated, the former with fox feces and the latter with fox urine. The many organosulfur compounds associated with skunk (*Mephitis mephitis*) also are apparently uniquely associated with anal sac secretions (Andersen et al., 1982). Similarly, the sulfur-containing aminoacid L-felinine [*S*-(1,1-dimethyl-3-hydroxypropyl)cysteine] is uniquely present as a component of the urine of felids (Datta and Harris, 1953), and 5-thiomethylpentan-2,3-dione is a component of the urine of hyena (*Hyaena hyaena*) (Wheeler et al., 1975). Moreover, L-felinine is believed (but not proven) to be the precursor to a number of interesting sulfur-containing compounds in cat urine (*Felis domesticus*) (Joulain and Laurent, 1989) and in bobcat urine (*Lynx rufus*) (Mattina et al., 1991).

Of the two proprietary repellents evaluated, Gori was more effective than Treepel, whereas Ro-pel was less effective (Table 1, Figures 2b and c). Like DMDT, Gori remained effective after the control-treated seedlings had been eaten, despite rain on two days. Ro-pel was ineffective with possums. Treated

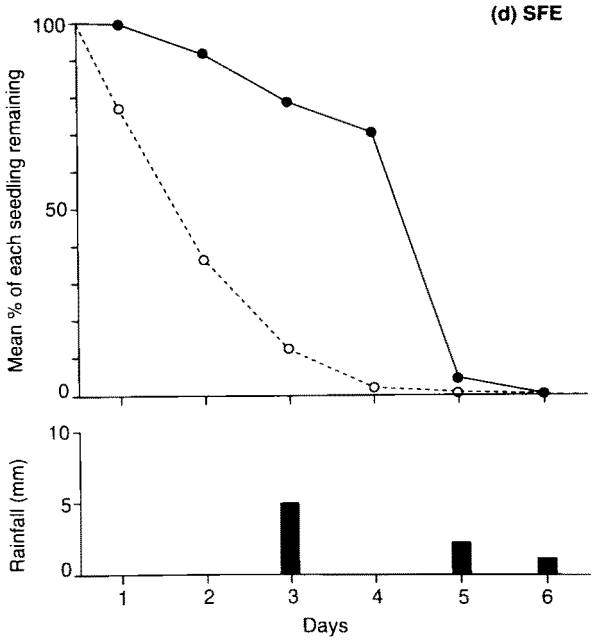

FIG. 2 Continued

seedlings were browsed immediately, while the treated controls were unbrowsed for four days. Both Gori and Ro-pel contain bittering agents. That present in Gori (DB) is much more effective in this formulation than the DS present in Ro-pel. Bitrex is known to be some 50 times more bitter than alkaloids such as brucine and strychnine, which occur naturally in plants and protect them from browsing animals (Payne, 1988). However, herbivores vary in their responses to bittering agents. Guinea pigs (*Cavia porcellus*), for example, are indifferent to DB and DS, and some rodents avoid DS, while others demonstrate a preference for it (Nolte et al., 1994a). While herbivore responses to plant defensive compounds may have developed partly as a result of evolutionary selection (Lindroth, 1988), the lack of uniformity of response to bitter compounds compared with their more generalized response towards sulfurous predator odors suggest that more diverse biochemical pathways have developed in plant chemical defense. Thus, as pointed out by Nolte et al., (1994b), it is unlikely that broadly effective herbivore repellents will be developed using bitter compounds.

Of the other compound tested, SFE was more effective as a repellent than Treepel (Figure 2d), but PJO was much less effective than the control. While the notion is yet untested, the effectiveness of SFE is probably attributable to

the odor profile produced by the four (major) constituents, three unsaturated fatty acids and trimethylamine, which are all found in anal sac secretions of canids (Bullard et al., 1978). The initial activity attributable to PJO might be vitiated by the rapid rancidification typical of triacylglycerides that contain high levels of unsaturated fatty acids.

The use of fear- or avoidance-inducing odors as repellents to minimize seedling predation by herbivores, in general, and possums, in particular, is an important strategy for consideration in any integrated program of pest control. This study has identified several carnivore-derived chemicals that could be further developed as possum repellents. Combinations of these compounds may prove to be even more effective, if, for example, they were used in conjunction with a bittering agent. For example, DB (which is repellent to possums) could be used to reinforce the signal presented by the repellent odor of a compound such as DMDT or that produced with an SFE chemical "cocktail." There is the very real possibility also that, in the wild, the mustelid odors might prove to be even more effective in reducing damage by actually attracting additional predators to the area (Sullivan et al., 1988). Our research will now focus upon the formulation of such combinations with adhesives and surfactants with the express purpose of evaluating habituation effects and of extending the field life of repellent applications to perfect an overall cost-effective means of delivery.

Acknowledgments—This study was funded by the Foundation for Research, Science, and Technology in New Zealand. We wish to acknowledge the assistance of W. Townsend for providing assistance in possum husbandry and pretrialing, and of C. Frampton for statistical advice. A.D.W. acknowledges the forebearance of his colleagues within Industrial Research Limited during the synthesis component of this research effort.

(Received March 16, 1995; accepted June 8, 1995)

Abstract—Insect antifeedant and growth-regulating activities of 22 limonoids (both natural and their derivatives) against *Spodoptera litura* were studied to understand the structure-related bioactivities of the limonoids. The C-seco limonoids (azadirachtins A, B, D, H, and I) were the most effective compounds as a group, while the intact limonoids (cedrelone and its derivatives) were the least effective. The cyclohexenone A ring and the α-hydroxy enone group in the B ring appear to be important for antifeedant activity. The presence of a cyclohexenone or 1,2-epoxide in the A ring coupled with an α-hydroxy enone in the B ring correlated well with growth regulatory activity. An acetoxy at C-7 instead of α-hydroxy enone and perhaps the carbonyl at C-16 increase growth regulatory activity. Absence of 14–15 epoxide may not drastically reduce antifeedant activity and growth regulatory activity.

Key Words—Antifeedants, growth regulation, limonoids.

INTRODUCTION

The species of Meliaceae, a family of both herbaceous and arborescent forms, elaborate limonoids (tetranortriterpenoids) of diverse structural types. Over 300 limonoids have been isolated to date (Champagne et al., 1992). These compounds, which are bitter tasting, have attracted much attention due to bioactivities observed in over 70 of them. While it is presumed that limonoids function

*To whom correspondence should be addressed.

0098-0331/95/1000-1585$07.50/0 © 1995 Plenum Publishing Corporation

primarily as insect antifeedants, some interfere with insect development and ecdysis. Azadirachtin, a C-seco limonoid, and some of its derivatives possess both antifeedant and insect growth-regulating activities. Azadirachtin at different concentrations, either in pure form or as an active ingredient in mixtures, is active against over 200 insect species (Saxena, 1989). The only group other than the C-seco limonoids known to possess insect growth-regulating (IGR) activity is the intact apo-euphol limonoids, with a 14–15 epoxide and a cyclohexenone (3-oxo-1-ene) A ring, as in cedrelone and anthothecol.

Although these structural features have been assumed to impart IGR activities, simpler compounds, such as nimocinolide and isonimocinolide, which lack the 14–15 epoxide, also have IGR activities (Naqvi, 1987). Studies, however, are restricted only to a few related series of compounds (Blaney et al., 1990), and comparative data on the bioactivities of different limonoids also are limited (e.g., Klocke, 1987). Indeed, the understanding of quantitative structure-related bioactivities in limonoids suffers due to differences in bioassay methods and the choice of insect and larval instars used with different compounds. These limitations indicate the need for a more thorough examination of limonoids, both for antifeedant and for IGR activities.

Cedrelone, an intact apo-euphol type limonoid, isolated from *Cedrela toona* (=*Toona ciliata*) was shown to have IGR activities against some Lepidoptera (Kubo and Klocke, 1986). When administrated orally, topically, or via injection, cedrelone induced mortality, larval growth inhibition, and molt inhibition in *Peridroma saucia* and *Mamestra configurata* but failed to show any appreciable antifeedant activity (Koul and Isman, 1992). As cedrelone can be isolated in large quantity, we made certain synthetic modifications in its structure and tested the compounds against the tobacco cutworm *Spodoptera litura*, in order to understand its structure-related antifeedant and IGR activities. Azadiradione and epoxy-azadiradione (two intact limonoids from *Azadirachta indica*); ocotillone, dymalol, and shoreic acid (protolimonoids from *Dysoxylum malabaricum*); piscidinol C (a protolimonoid from *Walsura piscida* with a 7-membered lactol acetate instead of a furan ring); azadirachtins A, B, D, H, and I (C-seco limonoids from *A. indica*); and limonin (an A-seco limonoid from *Citrus* sp.) were also studied for comparison. The results of this study are presented here.

METHODS AND MATHERIALS

Compounds. Cedrelone was isolated from the powdered wood of *Cedrela toona* by repeated hexane extractions. After concentration in vacuo in a rotary evaporator, cedrelone crystallized. The crystals were captured by filtration, and cedrelone was repeatedly recrystallized from benzene (Hodges et al., 1963). The purity of the sample was confirmed by analytical HPLC (Shimadzu LC 10 AD, Shimpack RP-18 column, 25 cm × 4.6 mm, with 60:40 methyl alcohol–

water (MeOH : H_2O) as eluent, 1 ml/min flow, 215 nm as the detection wavelength). From cedrelone, cedrelone methyl ether, cedrelone acetate, cedrelone epoxide, cedrelone epoxide methyl ether, cedrelone epoxide acetate, dihydrocedrelone, dihydrocedrelone acetate, isocedrelonic acid, and methyl isocedrelonate were prepared (Gopinath et al., 1961; Hodges et al., 1963). The purity of these compounds was checked by analytical TLC on precoated silica plates (Merck) using 20% ethyl acetate (EtOAc) in hexane as the eluent. Azadirachtins A, B, D, H, and I (Govindachari et al., 1991), azadiradione, and epoxy-azadiradione were isolated from neem seed kernel extract by preparative HPLC (Govindachari et al., 1992). Dymalol, shoreic acid and ocotillone were isolated from the leaves of *Dysoxylum malabaricum* (Govindachari et al., 1994a). Piscidinol-C was isolated from the leaves of *Walsura piscida* (Purushothaman et al., 1985; Govindachari et al., 1995). The structures of the compounds used in this study are shown in Figure 1.

Insects. The test insect, *Spodoptera litura*, was reared in the laboratory on *Ricinus communis* (castor) leaves at 25 ± 2°C.

Antifeedant Studies. A dual-choice bioassay was performed for antifeedant tests. Circular discs (180 cm^2) were cut from the leaves of *Ricinus communis*, with the median vein as the marker between the two equal halves. One milliliter of the test compound in acetone (at 50, 10, 5, and 1 μg concentrations/cm^2 area of leaf) was spread using a fine pipet on the right half (90 cm^2 treated). The left half served as the untreated control. In one treatment, 1 ml of acetone alone was spread on the right half, leaving the left half untreated. The latter served to show the solvent effect. For each compound and concentration, five replicates were used. After air drying, each leaf disc was placed inside separate Petri dishes, and five freshly molted third instars (from the same egg batch, approximately similar in weight and size) were placed at the center of the leaf. The Petri dishes were then closed and kept undisturbed. After 24 hr, the insects were removed and the unfed area of both halves of the leaf was measured using a ΔT area measurement meter. The raw data were subjected to analysis of variance and Neuman-Keul means were derived. Using the Neuman-Keul means, percentage of antifeedant activity was calculated using the formula

$$\text{Antifeedant activity (\%)} = 100 - \frac{\text{area fed in treated}}{\text{area fed in untreated control}} \times 100$$

where treated is treated with compound in 1 ml of acetone or treated with 1 ml of acetone only.

Using the Neuman-Keul means, the percentage feeding index (PFI) was also calculated (cf., Luco et al., 1994) using the formula

$$\text{PFI} = \frac{\text{area fed in treated}}{\text{area fed in treated} + \text{area fed in solvent control}} \times 100$$

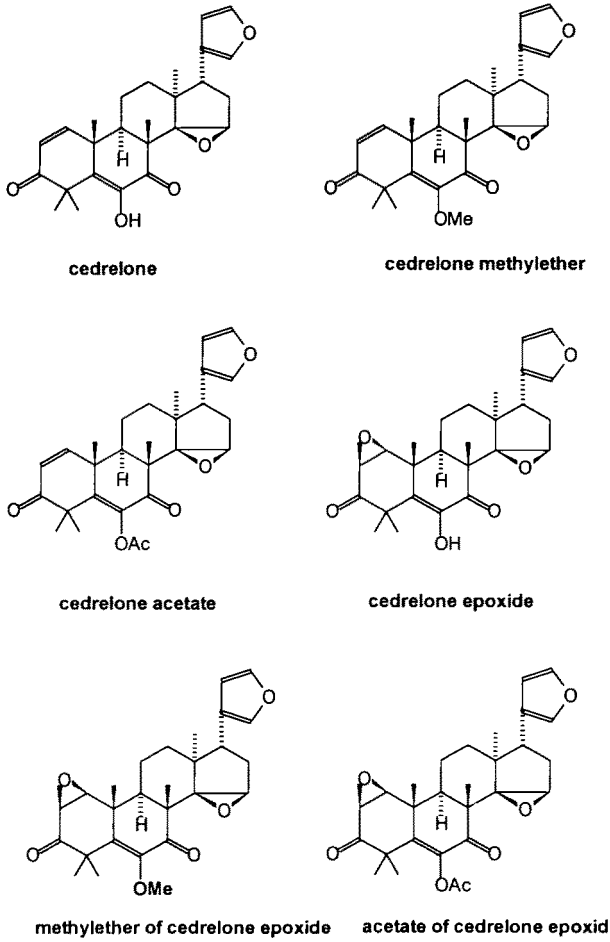

FIG. 1. Limonoids used in the study.

where treated is treated with compound in 1 ml of acetone, and solvent control is treated with 1 ml of acetone only

Insect Growth Regulation Studies (IGR). For insect growth regulatory (IGR) activity, leaf discs (180 cm^2) were spread with 2 ml of the test compound in acetone to give 10 $\mu g/cm^2$ leaf for cedrelone and its derivatives; 1 $\mu g/cm^2$ for azadiradione, epoxy-azadiradione, limonin, piscidinol-C, dymalol, shoreic acid, and ocotillone; and 0.5 $\mu g/cm^2$ for azadirachtins. The differences in concentrations for different compounds were designed to take into account variation in

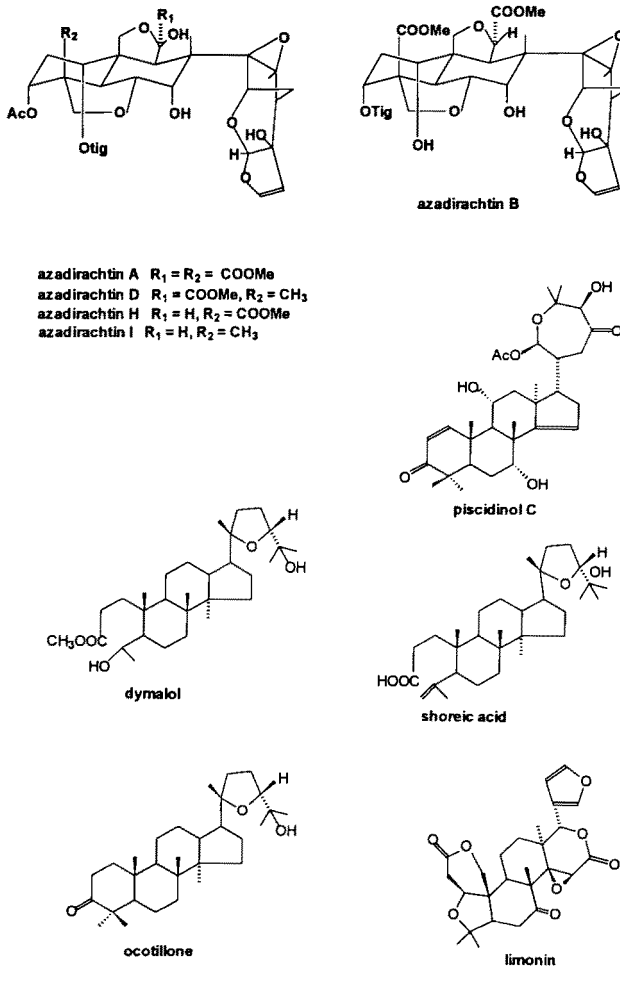

FIG. 1. Continued

the antifeedant activities of the compounds. The leaves were then air dried and placed in separate Petri dishes. Five replicates were maintained for each compound. Five freshly emerged third instars were introduced into the Petri dish and allowed to feed until they molted into the fourth instar. Fourth instars then were provided with normal diet (*R. communis* leaves) until the end of the experiment. Duration of instars, mortality of larvae and/or pupae, and pupal weight were recorded.

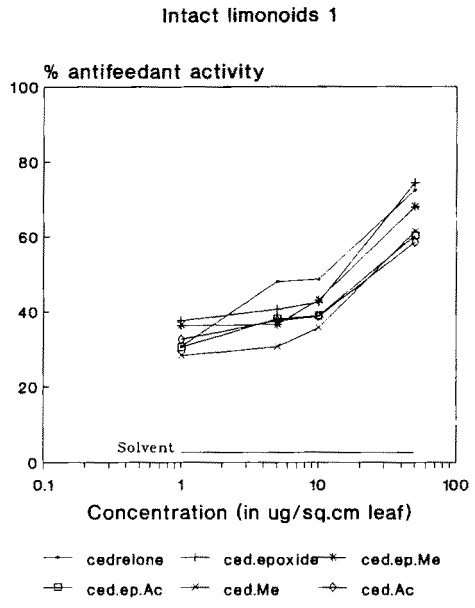
RESULTS AND DISCUSSION

Antifeedant Activity. Cedrelone and its derivatives showed appreciable antifeedant activity only at a concentration of 50 $\mu g/cm^2$ of leaf. The degree of antifeedant activity was concentration dependent. Among this group, cedrelone showed maximum antifeedant activity (Figure 2). Comparing the compounds at the highest concentration tested (50 $\mu g/cm^2$), a clear-cut trend could be observed. Compounds in which the 6-OH group is replaced with -OMe or -OAc groups,



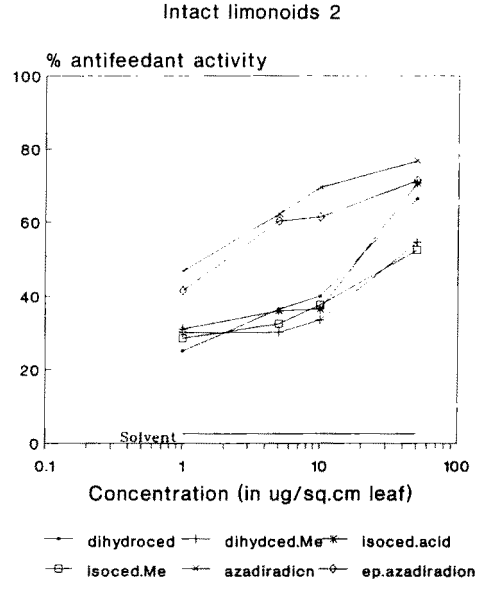


FIG. 2. Percent antifeedant activity of limonoids. Solvent line in graph indicates % antifeedant activity of acetone.

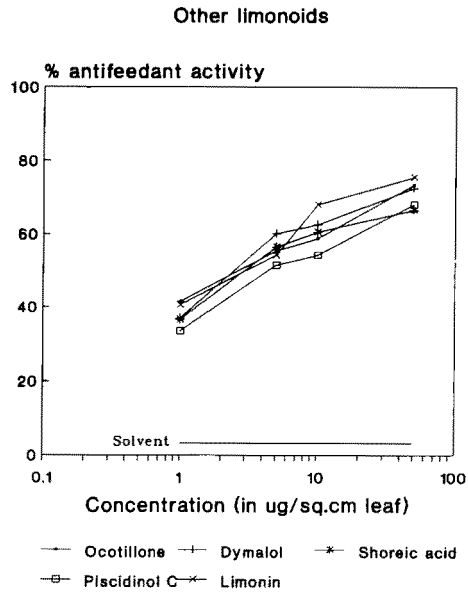

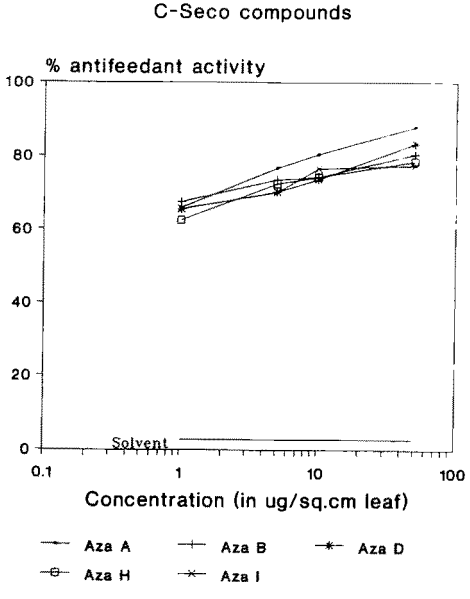

FIG. 2. Continued

irrespective of modifications in the A ring, reduced the antifeedant activity considerably. Presumably this indicated a hydrophilic binding/reactivity site in this part of the molecule. With α-hydroxy enone in ring B intact, introduction of an epoxide at C-1–C-2 position or removal of the C-1–C-2 double bond (e.g., dihydrocedrelone) reduced antifeedant activity. This suggested that the cyclohexenone (3-oxo-1-ene) A ring was important for imparting antifeedant activity.

A comparison of the antifeedant activities of cedrelone and its derivatives with both azadiradione and epoxy-azadiradione was meaningful as all have a cyclohexenone A ring. Both azadiradione and epoxy-azadiradione showed higher antifeedant activity compared to cedrelone and its derivatives, even at 5 $\mu g/cm^2$ area (cedrelone showed comparable antifeedant activity only at 50 $\mu g/cm^2$ area). Differences between azadiradione and epoxy azadiradione antifeedant activity are not statistically significant. Structural comparison between these two compounds indicated that the presence or absence of the C-14–C-15 epoxide may not drastically change the antifeedant activity. The experiment also reaffirmed the point that the presence of the cyclohexenone A ring (a common feature in all these intact limonoids tested) with a C-6 hydroxy group in the B ring was a requirement for antifeedant activity. Modifications of the B ring seem to affect antifeedant activity very much, as exemplified by isocedrelonic acid and its methyl ester.

Ocotillone, dymalol, and shoreic acid showed excellent PFI (percentage feeding index) values comparable to azadiradione, epoxyazadiradione, and limonin (Table 1). Protolimonoids like meliantriol and melianone are known to possess good antifeedant activities (Lavie et al., 1967) as does limonin, an A-seco limonoid (Liu et al., 1990).

Azadirachtins (C-seco compounds) are highly modified structurally and it may be incorrect to compare them with the other compounds tested. Indeed, the azadirachtins stand out as the most effective antifeedants. The PFI values (Table 1) even at 1 $\mu g/cm^2$ were very low, indicating high antifeedant activity. As shown earlier (Govindachari et al., 1994b), a trend towards decreasing antifeedant activity was noticed with the five compounds tested, the order being azadirachtin A > azadirachtin B > azadirachtin D > azadirachtin H > azadirachtin I.

Growth Regulation. The concentrations of each compound used for IGR testing had to be fixed based on its antifeedant activity ranking. The percentage antifeedant activity of each compound at different concentrations was plotted, and the concentration at which less than 50% antifeedant activity was detected was chosen for further testing. Based on this information, the compounds tested were grouped into three categories. Category 1 consisted of cedrelone and its derivatives, where less than 50% antifeedant activity was noticed at concentrations of 10 $\mu g/cm^2$ of leaf. Category 2 consisted of azadiradione, epoxyazadiradione, dymalol, ocotillone, shoreic acid, limonin, and piscidinol-C, where

TABLE 1. PERCENTAGE FEEDING INDEX (PFI) OF *Spodoptera litura* FED ON DIFFERENT LIMONOIDS[a]

Ocotillone	44.5(6.4)	43.2(5.0)	30.8(12.4)	27.5(5.4)
Dymalol	44.4(3.7)	40.5(6.5)	27.5(7.1)	24.9(7.4)
Shorcic acid	48.2(5.4)	44.2(8.2)	25.4(8.4)	24.5(5.6)
Cedrelone	51.5(2.9)	50.5(7.8)	44.9(7.3)	24.2(6.2)
Cedrelone methylether	56.0(6.6)	49.5(8.0)	51.5(5.1)	42.8(4.5)
Cedrelone acetate	55.0(7.5)	54.8(4.4)	43.0(6.8)	38.5(8.2)
Cedrelone epoxide	43.5(5.0)	40.8(12.6)	41.5(8.5)	35.5(6.9)
Cedrelone epoxide-meth.ether	54.0(9.5)	48.4(12.0)	47.6(6.8)	37.1(5.9)
Cedrelone epoxide-acetate	53.2(9.0)	47.6(3.4)	40.8(5.4)	40.9(7.5)
Dihydrocedrelone	50.5(6.3)	42.9(4.5)	29.5(9.8)	32.3(6.8)
Dihydrocedrelone methylether	56.5(10.6)	55.5(5.0)	43.5(4.2)	35.5(8.2)
Isocedrelonic acid	57.4(7.3)	53.5(12.0)	40.2(6.0)	33.6(5.8)
Methylisocedrelonate	54.8(5.0)	47.5(7.5)	41.5(9.0)	25.9(9.3)
Azadiradione	42.5(9.5)	39.0(7.2)	25.9(6.3)	23.0(5.5)
Epoxyazadiradion	48.5(7.8)	38.6(10.5)	35.2(4.2)	27.0(7.3)
Piscidinol C	52.5(12.6)	48.5(6.5)	38.4(8.9)	37.6(7.0)
Limonin	44.6(4.6)	40.3(7.1)	30.9(4.5)	25.2(6.5)
Azadirachtin A	27.5(4.0)	17.9(6.6)	16.5(7.8)	11.5(4.8)
Azadirachtin B	26.7(1.7)	25.0(9.2)	21.6(3.9)	18.0(8.5)
Azadirachtin D	28.9(3.2)	29.5(3.6)	19.0(6.8)	20.9(4.5)
Azadirachtin H	30.5(3.0)	33.4(2.8)	24.4(5.5)	24.0(7.6)
Azadirachtin I	32.2(6.4)	35.6(4.5)	25.0(4.0)	23.5(6.5)

[a]Concentrations per square centimeter of *Ricinus communis* leaf area; data indicate mean of five replicates, each replicate had five individuals of the same age; values in parentheses indicate standard deviation.

less than 50% antifeedant activity was noted at concentrations 1 $\mu g/cm^2$ of leaf. Category 3 consisted of azadirachtins A, B, and D, where more than 50% antifeedant activity was evident even at 1 $\mu g/cm^2$ of leaf. Based on these results, concentrations to be used for growth regulation studies were fixed at 10 $\mu g/cm^2$ leaf area for category 1 compounds, 1 $\mu g/cm^2$ for category 2, and 0.5 $\mu g/cm^2$ for the azadirachtins.

Larval duration during development, as an indication of growth regulation, was studied by feeding third instars with treated food until they molted. In the case of cedrelone and its derivatives, comparison of data indicated that differences were marked only in the fifth instar. The compounds that were effective in extending the fifth instar were cedrelone, cedrelone epoxide, and cedrelone epoxide methyl ether (Table 2). The same compounds also brought about significant reductions in pupal weight and higher pupal mortality (Table 5). This

[c] Data collected using 0.5 μg/cm^2.

indicated that these were the most effective compounds in category 1. Interestingly, this correlates very well with the earlier deduction that cyclohexenone or 1,2-epoxide in ring A coupled with an α-hydroxy enone in ring B is of importance for growth regulation. A comparison to azadiradione and epoxyazadiradione, although at 1/10th the concentration, indicated that an acetoxy at C-7 instead of a α-hydroxy enone and, perhaps, the carbonyl at C-16 increases growth regulatory activity considerably, indicating the possible active sites. Comparison between azadiradione and epoxyazadiradione indicated again that a C-14–C-15 epoxide may not drastically affect growth regulatory activity in the intact limonoids. This may explain the IGR activities of nimocinolide and

isonimocinolide (Naqvi, 1987), which have a cyclohexenone A ring with OH at C-6 and an acetoxy group at C-7, but lack the C-14–C-15 epoxide. In category 2, azadiradione and epoxy azadiradione showed remarkable growth regulatory activity by significantly increasing the duration of the feeding stages (third, fourth and fifth instars), decreasing pupal weights considerably and inducing pupal mortality (Table 3, Table 5). While azadiradione has been shown not to possess IGR activity against some Lepidoptera (Kubo and Klocke, 1986), in our experiments it showed good IGR activity at 1/10th the concentration of cedrelone. Limonin also showed growth regulatory activity similar to azadiradione and epoxy-azadiradione.

As in the case of cedrelone and its derivatives, the dammaranes as well as piscidinol C also caused pronounced increased duration only of the fifth instar (Table 3). These compounds also allowed comparatively higher pupal weights and reduced mortality, (Table 5) indicating clearly that protolimonoids and piscidinol C are good antifeedants but are not effective growth regulators.

The azadirachtins as a group were the most effective insect growth regulatory compounds, with all five azadirachtins inducing significantly increased duration in the third, fourth, and fifth instars and decreasing pupal weights (indicating reduced fitness) even at a concentration of 0.5 $\mu g/cm^2$ (Table 4, Table 5).

Among the compounds tested, the only other compounds that can be compared to azadirachtins were azadiradione and epoxyazadiradione, which had both higher antifeedant activity and growth regulatory activity; but only at twice the concentrations of azadirachtins.

CHEMICAL AND EXPERIENTIAL BASIS FOR REJECTION OF *Tropaeolum majus* BY *Pieris rapae* LARVAE

XIN PEI HUANG and J.A.A. RENWICK*

Boyce Thompson Institute at Cornell University
Tower Road, Ithaca, New York 14853

(Received March 23, 1995; accepted June 9, 1995)

Abstract—Rejection of nasturtium, *Tropaeolum majus*, by cabbage-reared larvae of *Pieris rapae* has been explained by the presence of feeding deterrents in the nastrutium foliage. Sensitivity to the deterrents develops as neonate larvae feed on cabbage. The most prominent deterrent compound, which is present in nasturtium at a concentration of 40 mg/100 g fresh leaves, was identified as chlorogenic acid. When neonate larvae were fed on a cabbage leaf treated with high concentrations of deterrent-containing extracts of nasturtium foliage, they remained insensitive to the deterrents, so they accepted nasturtium when transferred as second instars. When neonate larvae were reared on a cabbage leaf treated with 0.1 mg chlorogenic acid, ca. 35% of the second instars accepted nasturtium. Similar dietary exposure of neonates to the subunits of chlorogenic acid, caffeic acid and quinic, acid resulted in much less or no effect on the rejection behavior of second instars. The results suggest that the combined effects of specific chemical constituents of nasturtium can explain the rejection of this plant by larvae of *P. rapae*, but if larvae are continuously exposed to these compounds immediately after hatching, they apparently become habituated to the feeding deterrents. The lack of activity of the subunits of chlorogenic acid suggests that specific structural features are necessary for a dietary constituent to cause such habituation or suppression of sensitivity development.

Key Words—*Pieris rapae*, Lepidoptera, Pieridae, *Tropaeolum majus*, nasturtium, feeding deterrent, chlorogenic acid, habituation.

INTRODUCTION

Responses of insects to plant constituents are believed to be influenced to a large extent by previous experience. Larvae of some lepidopterans are thought to be "imprinted" on the plant on which they emerge from the eggs, resulting in a preference for that early food source (reviewed by Szentesi and Jermy, 1989). The importance of behavior of newly hatched insects when they encounter a plant has therefore been emphasized (Chapman and Bernays, 1989). This behavior may be crucial for survival of the species when a butterfly or moth oviposits on a novel plant. For example, *Pieris* butterflies lay eggs and their larvae feed only on plants that contain glucosinolates, but not all such plants will support larval development (Chew, 1980). However, if an ovipositing female selects a plant that is generally unsuitable for her progeny, the capability of hatching larvae to survive, through habituation or resistance to feeding deterrents or antibiotics in the plant, may enable them to exploit alternative resources.

Recent studies have shown that cabbage-reared larvae of the white cabbage butterfly, *Pieris rapae* L. refused to feed on nasturtium (*Tropaeolum majus* L.), even though ovipositing butterflies readily accepted the plant and hatching larvae fed and developed normally on it (Renwick and Huang, 1995). Induction of food preference (Szentesi and Jermy, 1989) has been ruled out as a possible mechanism for this rejection behavior, since reverse transfer (from nasturtium to cabbage) resulted in normal feeding. Instead, this appears to be a unique phenomenon of diet-based sensory development or suppression. Chemical fractions from solvent extracts of nasturtium foliage showed strong feeding deterrent activity for cabbage-reared larvae. However, nasturtium-reared larvae were only slightly deterred, and larvae reared on a wheat-germ diet were completely unaffected by these deterrents (Renwick and Huang, 1995). This would suggest that cabbage contains some factor that causes feeding larvae to become sensitive to the deterrents. An alternative explanation is that neonate larvae feeding on nasturtium or the diet become habituated to potentially deterrent compounds. A study addressing questions about the mechanisms controlling acceptance or rejection of nasturtium by the larvae would help us to understand the factors involved in host selection by phytophagous insects.

A previous study showed that *Pieris brassicae* selected cabbage leaves over nasturtium leaves for egg-laying, although the nasturtium contained a slightly higher concentration of glucosinolates (Rothschild, 1987). Recently, nasturtium has been found to contain both oviposition stimulants and deterrents, and a balance between positive and negative chemical input is important in selection of this plant by *P. rapae* and *P. napi oleracea* (Huang and Renwick, 1993). The maor stimulant was identified as glucotropaeolin (Sachdev-Gupta et al., 1992), and a combination of several compounds appeared to be responsible for the deterrent activity (Huang and Renwick, unpubl.). Gupta and Maleyvar (1983)

found that *P. brassicae* larvae consumed significantly less tissue of nasturtium than of *Brassica oleracea* var. *gongylodes*. The growth rates and pupal weights of *P. brassicae* were lowest on nasturtium when compared with Brussels sprouts, Swedish turnip, and rape, but larval development rate and adult longevity of the parasitoid, *Cotesia glomerata*, were greatest for wasps from *P. brassicae* reared on nasturtium (Karowe and Schoonhoven, 1992). The phenolic content of leaves from nasturtium and three other host plant species was correlated with the extent of damage by a leaf miner, *Liriomyza brassicae* (Ipe and Sadaruddin, 1984). Although Ma (1972) observed that *P. brassicae* reared on *Brassicae oleracea* refuse to feed on nasturtium, no further work on the mechanism of rejection was performed. The present study was designed to isolate and identify the feeding deterrents to *P. rapae* larvae in nasturtium and to explain the mechanism for diet-dependent differences in sensitivity of larvae to the deterrents.

METHODS AND MATERIALS

Plants and Insects. Cabbage (*Brassica oleracea* L. var. Golden Acre, 4–6 weeks old) and nasturtium (3–4 weeks old) plants for food, extraction, or bioassays were grown in an air-conditioned greenhouse maintained at ca. 25°C, with supplemental light provided by 400-W multivapor high-intensity discharge lamps. *P. rapae* larvae for feeding deterrent assays were obtained from colonies started from field-collected insects each summer and maintained in the laboratory at ca. 22°C under fluorescent lights providing a photoperiod of 16:8 hr light–dark. Larvae were reared on cabbage plants. Naive neonate larvae were obtained by allowing butterflies to oviposit on a strip of Parafilm (Webb and Shelton, 1988).

Extraction and Fractionation of Plant Materials. Fresh nasturtium foliage was extracted in boiling ethanol for 5 min, cooled, homogenized, and filtered. The ethanolic extract was evaporated to dryness under reduced pressure and lipids were removed with *n*-hexane. The defatted residue was dissolved in water and the aqueous extract partitioned three times with 1-butanol. The hexane extract, the butanol extract, and the postbutanol water extract were concentrated under reduced pressure at ca. 50°C and stored in the refrigerator until used.

The deterrent materials in the butanol extract were subjected to preliminary separation by flash column chromatography using 45 × 2-cm reversed-phase columns packed with 30 g 55- to 105-μm preparative C_{18} silica (Millipore Corporation, Milford, Massachusettes 01757). About 100 gram leaf equivalents (GLE) of extract was loaded onto each column. Five fractions (90 ml each) were collected by sequentially eluting the column with 90 ml each of water and 10%, 20%, 50%, and 100% acetonitrile in water. These fractions were tested for deterrent activity.

Thin-Layer Chromatography. Two thin-layer chromatography systems (TLC) were used to compare the isolated compound with a standard: (A) 5 × 10-cm, 0.25-mm-thick, Whatman K6 silica gel plates, with ethyl acetate–methanol–acetic acid–water (4:1:1:0.5) as the solvent system; and (B) 10 × 10-cm, 0.1-mm-thick, Merck cellulose plates, with 10% acetic acid or water as the solvent system. Plates were examined under long- and shortwave UV light.

HPLC. System 1 was Supelcosil LC-ABZ column (25 × 1 cm), gradient program 0% CH_3CN in 25 mM KH_2PO_4 at 0 min, 10% at 10 min, 30% at 50 min, and 100% at 55 min, 3 ml/min. System 2 was Varian MicroPack MCH-10 semipreparative reversed-phase C_{18} column (50 × 0.8 cm), gradient program 0% CH_3CN in H_2O from 0 to 5 min, and 100% from 10 to 20 min, 3.3 ml/min. System 3 was Phenomenex Bondex10 C_{18} column (30 × 0.78 cm), gradient program 0% CH_3CN in H_2O at 0 min, 20% at 10 min, 25% at 25 min, and 100% at 30 min, 1 ml/min. System 4 was the same column as system 2, gradient program 0% MeOH in 1% acetic acid at 0 min, 15% at 10 min, 30% at 40 min, 50% at 60 min, and 100% at 65 min, 3.3 ml/min. The eluate was monitored at 254 nm for all the HPLC systems.

Bioassays. Feeding deterrent assays were performed as described by Sachdev-Gupta et al. (1993) with some modifications. Twenty microliters of solutions of the test extracts, fractions, or compounds were applied in MeOH, except for the hexane extract, which was applied in ethyl ether, with a Rainin battery-operated motorized pipet onto each side of a cabbage leaf disc (340 mm^2) made with a No. 14 cork borer. For each disc (both sides) 0.01, 0.03 or 0.1 gram leaf equivalents (GLE) of extract or fraction from nasturtium were used. The isolated or standard compounds were used at a dose of 10 ng/mm^2 for each side (6.8 μg/disc). Control discs were treated with the solvent alone. The tests were conducted in ice cream cups (250 ml), each containing a paraffin wax layer at the bottom, which was covered with a moist filter paper. Two discs treated with the same sample and two control discs were alternatively arranged in each cup and supported on No. 3 insect pins. In no-choice tests, either four treated or control discs were placed in each cup. Four early fourth-instar larvae were introduced in the center of the cup, and the cup was covered with a perforated plastic lid. The cups were then placed in a translucent polystyrene box with moist paper towels at the bottom. The covered box was kept in an incubator maintained at 28°C. After 6 hr, the disc areas were measured using a LiCor-3100 area meter. The area consumed was obtained by subtracting the remaining portion of each eaten disc from the average measurement of all discs that showed no sign of feeding.

Nasturtium acceptance assays as described by Renwick and Huang (1995) were employed to determine whether nasturtium constitutents are responsible for the lack of sensitivity of neonate larvae to the deterrents. Test extracts from nasturtium or known compounds were applied to cabbage foliage by spraying

in MeOH solution. Control leaves were sprayed with MeOH alone. Neonate larvae hatching on Parafilm were transferred to the cabbage leaves using a small camel-hair brush. They were allowed to feed until early second instar and were then tested for their acceptance or rejection of nasturtium. The tests were carried out using individual leaves in 250-ml ice cream cups. The leaf petiole was inserted through a hole punched in the bottom of the cup into a beaker of water. One test larva was placed on each leaf, and the cup was covered with a plastic lid. Observations were made after 24 and 48 hr to record whether or not feeding had occurred.

Design and Analysis. For feeding deterrent assays, a replicate consisted of one cup with four larvae, and 6–25 replications were performed for each bioassay. Deterent activities were compared by calculating a feeding deterrent index (FDI) based on the area consumed of treated and control leaf discs: FDI = 100 [(control − treated)/(control + treated)]. The proportion of disc area consumed, treated ÷ (treated + control), was calculated, and the data were subjected to arcsine square root transformation. Differences between treatments and controls were analyzed using a one-sample *t* test on the transformed data, under the null hypothesis that equal feeding occurred on treated and control discs. A Waller-Duncan *K* ratio *t* test on the transformed data was used to assess significance of differences among treatments.

Identification. The deterrent isolated from nasturtium was identified by comparing its retention time on HPLC, R_f on TLC, and its UV, ^{13}C, and ^{1}H NMR spectra with those of an authentic sample. UV spectra were obtained with a Perkin-Elmer Lambda 5 in MeOH. ^{1}H NMR (500 MHz) and ^{13}C NMR (100 MHz) spectra in MeOH-d_4 were recorded on a Varian Unity-500 and a Varian VXR-400s, respectively. The chemical shifts were indirectly referenced to tetramethylsilane by using the solvent as an internal reference.

RESULTS

The hexane extract showed no feeding deterrent activity on cabbage-reared fourth instar larvae in a choice bioassay at a dose of 0.01 GLE per cabbage leaf disc (FDI = 8.5; between treatment and control $P > 0.05$). The postbutanol water extract was slightly deterrent at a higher dose of 0.1 GLE/disc (FDI = 29.1; $P < 0.05$). However, the butanol extract was highly deterrent at 0.01 GLE/disc (FDI = 97.8, $P < 0.01$), in the choice bioassay (Renwick and Huang, 1995). This extract deterred larval feeding even in a no-choice feeding bioassay (Figure 1). Six hours after the larvae were introduced into the bioassay cups, little feeding had occurred on the disc treated with 0.1 GLE, and the treatment of 0.01 GLE/disc significantly reduced larval feeding when compared with the control. After 24 hr, only ca. 9% of the leaf discs treated with the extract at

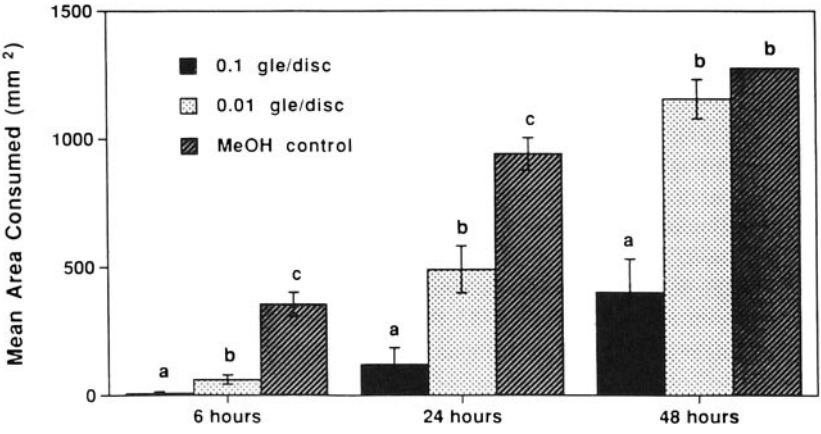

FIG. 1. Feeding by fourth-instar *P. rapae* larvae on cabbage leaf discs treated with the BuOH extract of nasturtium foliage in no-choice assays. Both sides of a leaf disc (340 mm^2) were treated with 0.1 or 0.01 GLE of the extract. Control discs were treated with the solvent (MeOH) alone. Replicated six times. A replication consisted of three bioassay cups, each with four test or control leaf discs and four larvae. Means ($\pm$SE) with the same letters in each time period are not significantly different according to a Waller-Duncan K-ratio t test ($K = 100$).

0.1 GLE/disc was consumed, but ca. 75% of the control discs had been eaten. A significant difference was also found between consumption of control and treated discs at a lower dose (0.01 GLE/disc) (Figure 1). After 48 hr, about one third of the larvae on discs treated with the higher dose (0.1 GLE/disc) were dying due to starvation, and those larvae that did feed were much smaller compared to the control larvae. While there were some leaf fragments remaining from the discs treated with the lower dose of the extract, no control discs were found, and the larvae in control cups were moving rapidly in an apparent search for food. This indicated that all the control discs had been consumed a considerable time before the final measurements were made (48 hr). Therefore, although no statistically significant difference was detected between the control and the treatment with 0.01 GLE/disc, based on the final measurements (Figure 1), control larvae probably would have consumed much more if food had been available. Because the BuOH extract had the most potent deterrent effect, subsequent work was concentrated on this extract.

When the BuOH extract was fractionated into five fractions by open-column chromatography, fractions I, II, and V were not active as feeding deterrents at a dose of 0.03 GLE/disc (Figure 2; between treatment and control, $P > 0.05$ in each case). Fractions III and IV were almost equally deterrent to the larvae,

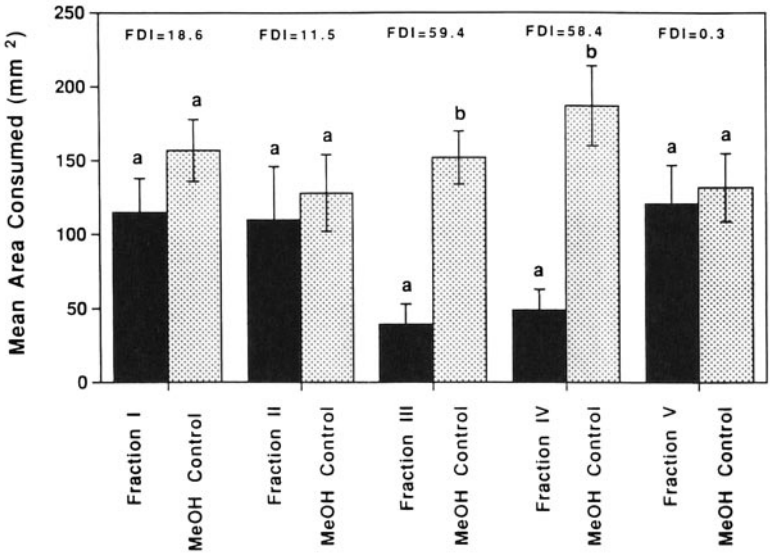

FIG. 2. Feeding by fourth-instar *P. rapae* larvae on cabbage leaf discs treated with five open-column fractions of the BuOH extract of nasturtium foliage in choice assays. Both sides of a leaf disc (340 mm^2) were treated with 0.03 GLE of a fraction. Control discs were treated with the solvent (MeOH) alone. Replications: 7 for fractions I and II, 25 for fraction III, 14 for fraction IV, and 10 for fraction V. A replication consisted of one bioassay cup with two test and two control leaf discs and four larvae. Means ($\pm$SE) with the same letters in each series are not significantly different according to a one-sample *t* test ($P < 0.05$), under the null hypothesis that feeding occurred evenly on control and treated discs.

giving FDIs of 59.4 ($P < 0.01$) and 58.4 ($P < 0.01$), respectively (Figure 2). The open-column fraction IV was subjected to repeated HPLC separation, and bioassays of the resulting fractions showed that several compounds were responsible for the deterrence. The deterrents in this fraction are not related to compounds detected in III and are under further investigation. However, one prominent component of fraction III, which was absent in IV, appeared to account for most of the activity of this fraction, and the present study focused on the identification of this major deterrent.

Fraction III was separated by HPLC system 1, and three fractions, (III-I, III-II, and III-III) were collected, evaporated under reduced pressure, redissolved in water, and desalted using HPLC system 2. When tested at 0.03 GLE/disc, no deterrent activity was detected in fractions III-I (FDI = -3.9, $P > 0.05$) and III-III (FDI = 5.0, $P > 0.05$) (Figure 3). Only HPLC fraction III-II, which

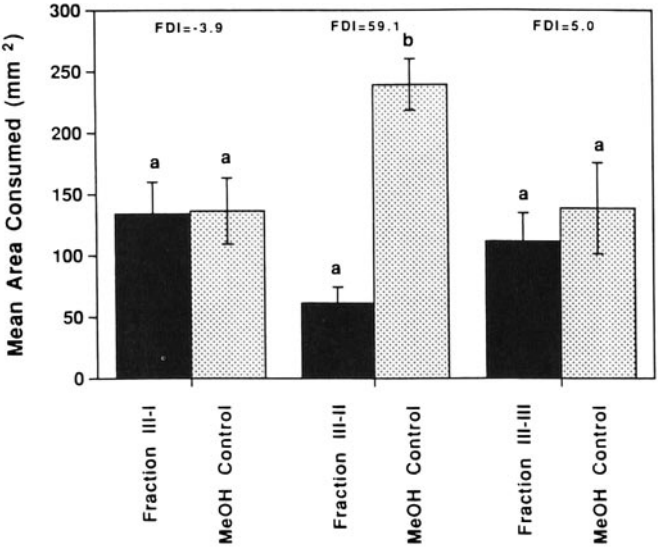

FIG. 3. Feeding by fourth-instar *P. rapae* larvae on cabbage leaf discs treated with three HPLC fractions from open-column fraction III of the BuOH extract in choice assays. Both sides of a leaf disc (340 mm^2) were treated with 0.03 GLE of a HPLC fraction. Control discs were treated with the solvent (MeOH) alone. Replications: 8 for fractions III-I and III-III, and 25 for fraction III-II. A replication consisted of one bioassay cup with two test and two control leaf discs and four larvae. Means ($\pm$SE) with the same letters in each series are not significantly different according to a one-sample *t* test ($P < 0.05$), under the null hypothesis that feeding occurred evenly on control and treated discs.

contained one prominent compound, was significantly deterrent to the larvae (FDI = 59.1, $P < 0.01$). The major compound in this fraction was purified using HPLC system 3 and named compound **1**. About 40 mg of compound **1** was obtained from a sample of 100 g fresh nasturtium foliage.

The UV spectrum of compound **1** matched that of chlorogenic acid, and preliminary HPLC further suggested that the isolated material could be chlorogenic acid. Additional diagnostic work was conducted to compare the properties of the isolated material with those of the commerically available compound.

The retention times on HPLC were identical for compound **1** and an authentic sample of chlorogenic acid (Sigma Chemical Co.) when systems 1 (21.5 min), 3 (22.0 min), and 4 (37.5 min) were employed. Compound **1** and chlorogenic acid showed the same properties on TLC in systems A (R_f = 0.58) and B (R_f = 0.61 in 10% acetic acid and 0.97 in H_2O). On TLC plates developed

in solvent system A, both compound **1** and chlorogenic acid appeared under UV light as a gray spot on a purple background. They were blue (UV) and bright turquoise (UV + NH_3) on plates using system B. Furthermore, compound **1** and chlorogenic acid gave the same UV absorption pattern: λ_{max} (MeOH) nm 244, 299 (s), 328. These results are consistent with those reported by Feeny et al. (1988) when chlorogenic acid was identified from carrot foliage as an oviposition stimulant for the black swallowtail butterfly. When compound **1** and chlorogenic acid were tested for feeding deterrent activity, they were active at a dose of 10 ng/mm^2 (Figure 4). A sample of compound **1** was isolated and purified with HPLC system 4 for NMR analyses. For comparison, chlorogenic acid was also passed through the same HPLC system and analyzed under the same NMR conditions. The two samples showed identical ^1H and ^{13}C NMR

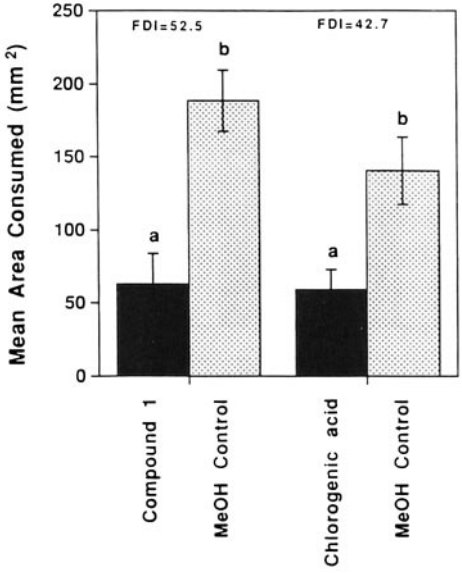

FIG. 4. Feeding by fourth-instar *P. rapae* larvae on cabbage leaf discs treated with chlorogenic acid and compound **1** isolated from open-column fraction III of the BuOH extract of nasturtium foliage in choice assays. Both sides of a leaf disc (340 mm^2) were treated with 10 ng/mm^2 of a sample. Control discs were treated with the solvent (MeOH) alone. Replicated 25 times. A replication consisted of one bioassay cup with two test and two control leaf discs and four larvae. Means ($\pm$SE) with the same letters in each series are not significantly different according to a one-sample *t* test ($P < 0.05$), under the null hypothesis that feeding occurred evenly on control and treated discs.

profiles. These combined data confirmed the identity of compound **1** as chlorogenic acid.

Figure 5 summarizes the results of nasturtium acceptance assays after exposure of the larvae to the BuOH and the post-BuOH water extracts from nasturtium. Neonate larvae were allowed to feed on cabbage leaves treated with one extract or with a combination of both until they reached early second instar. At 24 and 48 hr after they were transferred to nasturtium leaves, observations were made to record whether or not feeding had occurred. After 48 hr, those larvae that accepted nasturtium usually continued to feed, whereas those that refused were dead or dying. Because most feeding started within 24 hr after transfer and the records made at 24 and 48 hr were similar, only those data from the

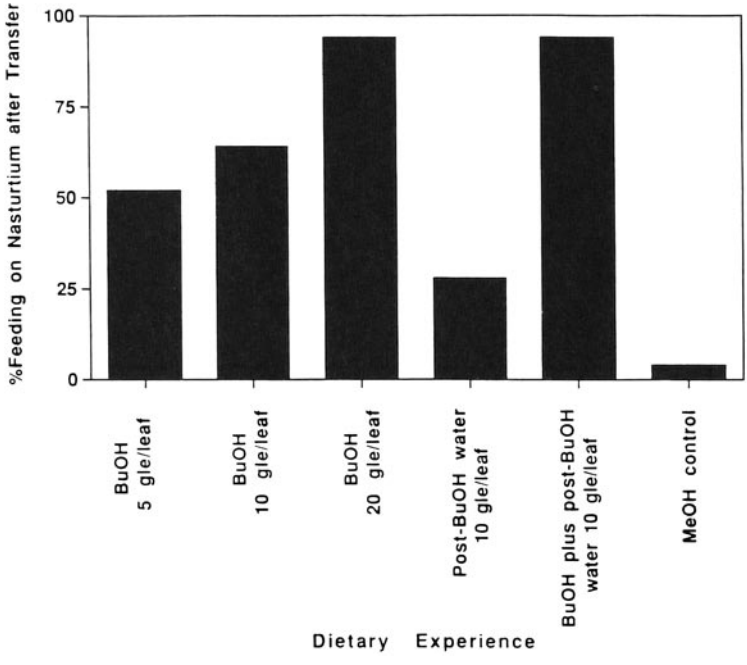

FIG. 5. Feeding by second-instar *P. rapae* larvae on nasturtium. Neonate larvae were reared on cabbage leaves (ca. 120 cm^2) treated with 5, 10, or 20 GLE of the BuOH or the post-BuOH water extracts of nasturtium foliage. Control larvae were reared on cabbage leaves treated with the solvent (MeOH) alone. Individual early second-instar larvae were transferred to nasturtium leaves. Percentage of larvae feeding on nasturtium is shown based on observations made at 48 hr after transfer. Fifty larvae were tested for each treatment.

second observation are presented here. Only two of 50 control larvae fed on nasturtium (Figure 5), but more than 50% of the larvae reared on cabbage leaves treated with the BuOH extract of nasturtium at a dose of 5 GLE/leaf or higher accepted it. The post-BuOH water extract was also active in causing larvae to feed on nasturtium, but the activity was much weaker when compared with the BuOH extract. When the BuOH extract was used at 20 GLE/leaf, almost all larvae accepted nasturtium. Similar results were obtained when a cabbage leaf was treated with a combination of 10 GLE each of the BuOH and the post-BuOH water extracts. The results clearly show that chemical constituents of nasturtium deter cabbage-reared *P. rapae* larvae, but if neonate larvae are exposed to these and/or other compounds, they become habituated to the feeding deterrents.

This idea of habituation is further supported by similar assays using pure chlorogenic acid. When neonate larvae were reared on a cabbage leaf treated with 0.1 mg chlorogenic acid, ca. 35% of the second-instar larvae accepted nasturtium (Figure 6). The percentage of larvae feeding on nasturtium was similar at 1 mg/leaf, but increased when a dose of 10 mg/leaf was used. The two subunits of chlorogenic acid, quinic acid and caffeic acid, were tested under the same conditions. Only four of 100 larvae reared on cabbage leaves treated with quinic acid at a dose of 1 mg/leaf fed on nasturtium. This response was similar to that of the control larvae reared on cabbage leaves treated with the solvent alone (Figure 5). Caffeic acid, however, had some effect, but was less active than chlorogenic acid in causing habituation (Figure 6). Thus, the complete structure of chlorogenic acid appears to be necessary for habituation of *P. rapae* larvae to the feeding deterrents in nasturtium.

DISCUSSION

When *P. rapae* larvae were transferred from cabbage to nasturtium, they refused to feed and eventually starved to death (Renwick and Huang, 1995). The present study shows that nasturtium foliage contains more than one feeding deterrent to cabbage-reared *P. rapae* larvae. In a no-choice situation, the larvae were significantly deterred from feeding on cabbage discs treated with the BuOH extract from nasturtium for at least 48 hr (Figure 1). The results indicate that during this period the larvae do not become habituated to these deterrents. A similar lack of habituation was noted by Jermy et al. (1987) for larvae of a polyphagous strain of *Mamestra brassicae* that was offered nonhost plants that contained a complex of stimuli including deterrents. Nevertheless, habituation has been found to occur in cases of other phytophagous insects (Szentesi and Bernays, 1984). Direct observations of behavior of individual caterpillars of *Pseudaletia unipuncta* revealed that nicotine was deterrent the first time it was

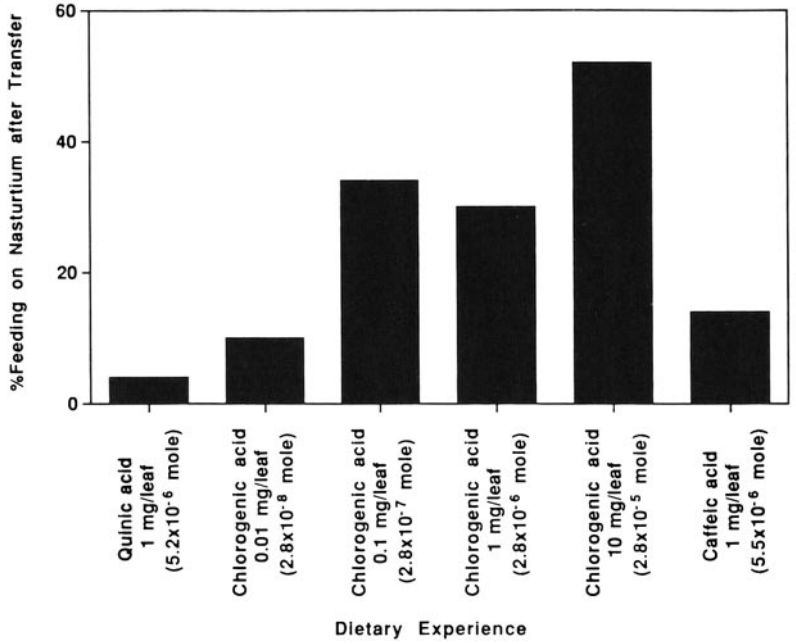

FIG. 6. Feeding by second-instar *P. rapae* larvae on nasturtium. Neonate larvae were reared on cabbage leaves (ca. 120 cm^2) treated with 0.01, 0.1, 1, or 10 mg of quinic acid, chlorogenic acid, or caffeic acid. Control larvae were reared on cabbage leaves treated with the solvent (MeOH) alone. Individual early second-instar larvae were transferred to nasturtium leaves. Percentage of larvae feeding on nasturtium is shown based on observations made at 48 hr after transfer. Fifty larvae were tested for chlorogenic acid at 0.01 mg/leaf, and 100 for all the others.

encountered but not in a 6-hr preference assay (Usher et al., 1988). The results indicated that habituation had developed during this time.

Unlike cabbage-reared larvae, *P. rapae* neonates fed and grew normally on nasturtium (Renwick and Huang, 1995). This could mean that cabbage contains an inducer that triggers sensitivity of larvae to the nasturtium deterrents or that neonates become habituated as they feed on nasturtium constituents. When neonate larvae were reared on a cabbage leaf treated with the deterrent-containing fractions from nasturtium foliage, they remained insensitive to the deterrents, so that they accepted nasturtium when transferred as second instars (Figure 5). It is therefore concluded that the chemical constituents from nasturtium are responsible for the insensitivity of larvae to the deterrents, and the assumption that cabbage contains an inducer is ruled out as a mechanism. The results also

suggest that neonate *P. rapae* can, but larger larvae from cabbage or other host plants (Renwick and Huang, 1995) cannot, become habituated to the nasturtium deterrents. The unique capability of newly hatched *P. rapae* larvae is therefore important for this insect to utilize a marginally acceptable host plant such as nasturtium. Assays using larvae from cabbage leaves treated with the identified feeding deterrent, chlorogenic acid, showed similar feeding as a result of habituation (Figure 6). This implies that the nasturtium constituents responsible for habituation may be those compounds that act as feeding deterrents.

The potential value of feeding deterrents in pest management programs has long been recognized (Bernays, 1983). However, possible habituation of insects to feeding deterrents is a major concern that could limit the practical application of such natural compounds for insect pest control. For example, acceptance of diets containing deterrents has been shown to increase after repeated contact with the active material (Schoonhoven, 1982). When switched from one host plant to another, some larvae initially refused or lowered their consumption rate of the new food (Hanson, 1976), but in no-choice situations they usually accepted the new host after a period of temporary starvation (Grabstein and Scriber, 1982; Scriber, 1982). Here we have been able to show an extreme case of habituation, in which *P. rapae* larvae reared on cabbage leaves treated with nasturtium constituents become habituated to the feeding deterrents and feed on nasturtium, which was otherwise refused.

Chlorogenic acid is found in many higher plants, and its antibacterial, antimutagenic, antitumor, antiviral, and antioxidant activities have been previously reported (reviewed by Harborne and Baxter, 1993). The role this compound plays in insect–plant relationships is of great interest to entomologists and ecologists and intensive investigations have been made on its antibiotic, feeding, or oviposition-deterring or -stimulating effects on phytophagous insects. In a study of chemosensory responses of *P. rapae* larvae using electrophysiological methods, van Loon (1990) found that among five phenolic acids tested, chlorogenic and protocatechuic acids were the strongest stimuli affecting lateral and medial maxillary sensilla styloconica. This chemosensory activity is reflected in the present study where chlorogenic acid is identified as a constituent of nasturtium responsible for deterring feeding by *P. rapae* larvae. Similar results were obtained by Otter (1992), who pointed out that there was a cell sensitive to chlorogenic acid in the medial styloconic sensilla of *Chilo partellus* larvae and that the presence of this cell may account for the positive correlation between total phenol content and resistance of sorghum cultivars to this borer.

Previous studies have shown that chlorogenic acid may play a defensive role that affects host-plant selection by certain phytophagous insects. For example, feeding by *P. brassicae* larvae was deterred by chlorogenic acid (van Loon, 1990). The rejection of *Salix integra*, *S. chaenomeloides*, and *S. koriyanagi* by the leaf beetle, *Lochmaeae capreae cribrata*, was due to the high levels of

chlorogenic acid in these plants, whereas another beetle species, *Plagiodera versicorola distincta*, which accepted these plants, was not deterred by this phenolic compound (Matsuda and Senbo, 1986). de Boer and Hanson (1987) reported a concentration-dependent effect of chlorogenic acid on feeding by *Manduca sexta* larvae. However, despite a strong deterrent effect at high concentrations, it was slightly stimulatory at its natural concentration (1 mM). The authors therefore concluded that chlorogenic acid did not play an important role in food selection by the tobacco hornworm.

The effects of chlorogenic acid on oviposition behavior vary with insect species. This is one of the compounds in carrot foliage responsible for stimulating oviposition by the black swallowtail butterfly (Feeny et al., 1988). Honda (1990) found that chlorogenic acid acted as an excellent synergist for a mixture of compounds that stimulated *Papilio protenor* to oviposit on *Citrus* host plants. On the other hand, ovipositing *P. rapae* was deterred by chlorogenic acid at a 1000 ppm level, based on a bioassay using white paper discs (Traynier, 1987). In a related study using a cabbage plant as the oviposition substrate (Huang and Renwick, unpublished results), however, we found that the chlorogenic acid-containing fraction from HPLC of nasturtium extract had little effect on oviposition. Activity was associated with other components of nasturtium extract separated by open-column chromatography. No oviposition deterrent activity was detected when an authentic sample of chlorogenic acid was tested at 1.6 mg/plant under the same conditions. The inconsistency between Traynier's results and ours might be due to differences in concentration of the compound as well as differences in the oviposition substrate.

Felton et al. (1989) found that chlorogenic acid ingested from tomato (*Lycopersicon esculantum*) foliage and fruit by *Heliothis zea* larvae was oxidized to chlorogenoquinone by polyphenol oxidase in the insect gut. The relative growth rate of the larvae was negatively correlated with polyphenol oxidase activity. This was explained by the fact that the resulting chlorogenoquinone is a highly active electrophilic molecule that binds covalently to amino acids and proteins, thus reducing the digestibility of nutrients from the plant. Antibiotic resistance involving chlorogenic acid was reported for centipedegrass (*Eremochloa ophiuroides*) to *Spodoptera frugiperda* (Wiseman et al., 1990), popcorn (*Zea mays*) to *Helicoverpa zea* (Wiseman et al., 1992), and a wild groundnut (*Arachis paraguariensis*) to *Spodoptera litura* (Stevenson et al., 1993). The growth rate of *Spodoptera exigua* larvae declined when they were fed with dietary proteins treated with chlorogenic acid and polyphenol oxidase (Felton et al., 1992a). The pH status in the digestive system of an insect may have an effect on the binding of chlorogenic acid to proteins (Felton et al., 1992b). When *Bacillus thuringiensis* subsp. *Kurstaki* was incubated with chlorogenic acid and polyphenol oxidase, the bacterium became more toxic to *Heliothis zea* larvae. This suggested the compatibility of hostplant resistance and biological control (Lud-

lum et al., 1991). However, Felton et al. (1987) observed possible incompatibility of this chemically based resistance with viral control of the same insect. Chlorogenic acid significantly inhibited the infectivity of nuclear polyhedrosis viruses on *H. zea*, and the ingestion of this phytochemical significantly prolonged the survival time of virus-infected larvae.

Chlorogenic acid has no deleterious effect on some insects such as *Spodoptera eridania* (Lindroth and Peterson, 1988). Furthermore, a positive correlation was found between the concentrations of chlorogenic acid in different cultivars of carrot and the susceptibility of these plants to carrot fly larval damage (Cole, 1985). Midgut catalase in several lepidopterous pests of tomato plants including *Helicoverpa zea*, *S. exigua*, *Manduca sexta*, and *Heliothis virescens*, in addition to removing toxic hydrogen peroxide, may reduce the oxidation of plant phenolics mediated by plant peroxidases (Felton and Duffey, 1991). Although chlorogenic acid in nasturtium acted as a feeding deterrent to *P. rapae* larvae, it apparently has no significantly harmful impact on this insect. Survivorship, growth rates, and pupal weights were similar for nasturtium-reared and cabbage-reared larvae (Huang and Renwick, unpublished results).

Acknowledgments—We thank Kathy Jo Champion for technical assistance. We are indebted to Drs. Meena Haribal and Kusum Sachdev-Gupta for assistance in identification of the deterrent. This research was funded in part by NSF grant BSR-9107322, and USDA grant 91-37302-6198.

(Received November 18, 1994; accepted June 12, 1995)

Abstract—4-Methyl-5-nonanol is a male-produced aggregation pheromone of the Asian palm weevil, *Rhynchophorus bilineatus* (Montr.). The pheromone was identified by coupled gas chromatographic-electroantennographic detection (GC-EAD) and coupled GC-mass spectrometric (MS) analyses of male- and female-produced volatiles. Analyses by GC-EAD and GC-MS of weevil-produced and stereoselectively synthesized isomers of 4-methyl-5-nonanol on a Cyclodex B column, which separated isomers with baseline resolution, revealed that only (4*S*,5*S*)-4-methyl-5-nonanol is EAD active and produced by the males. In field experiments in Papua New Guinea, (4*S*,5*S*)-4-methyl-5-nonanol and a racemic mixture of disatereoisomers of it enhanced attraction of male and female weevils to sugarcane-baited traps. (4*S*,5*S*)-4-Methyl-5-nonanol is also an aggregation pheromone of two other Asian palm weevils, *R. ferrugineus* (Oliv.) and *R. vulneratus* (Panz.). The stereoisomeric mixture of 4-methyl-5-nonanol is currently used to manage populations of *R. bilineatus* in Papua New Guinea.

Key Words—Coleoptera, Curculionidae, *Rhynchophorus bilineatus*, aggregation pheromone, pheromone chirality, (4*S*,5*S*)-4-methyl-5-nonanol, coconut palm.

INTRODUCTION

In Papua New Guinea the palm weevil *Rhynchophorus bilineatus* (Montr.) causes mortality of coconut palms used as shade trees in cocoa plantations. While the weevil may directly attack the palms, they are frequently attracted to and ovipost in feeding tunnels of the New Guinea rhinoceros beetle, *Scopanes australis* (Boisd.). Feeding by weevil larvae often destroys the terminal bud, contributing to the death of the palm (Wattanapongsiri, 1966).

Male-produced aggregation pheromones have been reported for most economically important species of palm weevils (Rochat et al., 1991, 1993a,b; Oehlschlager et al., 1992a; Gries et al., 1993; Hallett et al., 1993a,b; Zagatti et al., 1993; Weissling et al., 1994). This paper reports the structural elucidation, stereochemistry, antennal response to, and behavioral activity of a male-produced aggregation pheromone for *R. bilineatus*.

METHODS AND MATERIALS

Laboratory Analysis. Male and female *R. bilineatus* of mixed age and sex were collected in cocoa plantations with interspersed coconut palms near Rabaul, East New Britain Province, Papua New Guinea. Collections were made in modified 19-liter plastic buckets containing 10–20 pieces of cut sugarcane (10–15 cm). Because weevils may mate within a few days of emergence (Wattanapongsiri, 1966) prior to and after capture in the buckets, it is likely that mainly mated weevils were used in aeration experiments. Twenty-five male and 20 female *R. bilineatus* were aerated separately for 6 to 7 days in a modified Nalgene desiccator containing 0- to 4-day-old sectioned apples. A water aspirator was used to draw charcoal-filtered air through the chamber and insect- and sugarcane-produced volatiles were trapped on Porapak Q. Volatiles were eluted from Porapak Q with pentane, concentrated by distillation (Oehlschlager et al., 1988), and subjected to gas chromatographic analysis (Figure 1). Gas chromatographic–electroantennographic detection (GC-EAD, Figure 2) (Hewlett Packard 5890A) (Arn et al. 1975) and GC-mass spectrometry (MS) (Hewlett Packard 5985B) in both electron impact (EI) and chemical ionization (CI) mode, employing a 30-m × 0.25-mm-ID fused silica column coated with SP-1000 (Supelco Inc., Belafonte, Pennsylvania), revealed 4-methyl-5-nonanol as an antennally active male-produced volatile. For GC-EAD recordings, a weevil antenna was removed from the rostrum and suspended between two glass capillary electrodes with the antennal base inserted into one and the olfactory club impaled by the other electrode. GC-MS-EI in selected ion monitoring mode (SIM) of natural and synthetic chiral isomers of 4-methyl-5-nonanol were further conducted on a fused silica Cyclodex-B-coated column (30 m × 0.25 mm ID, J & W Sci-

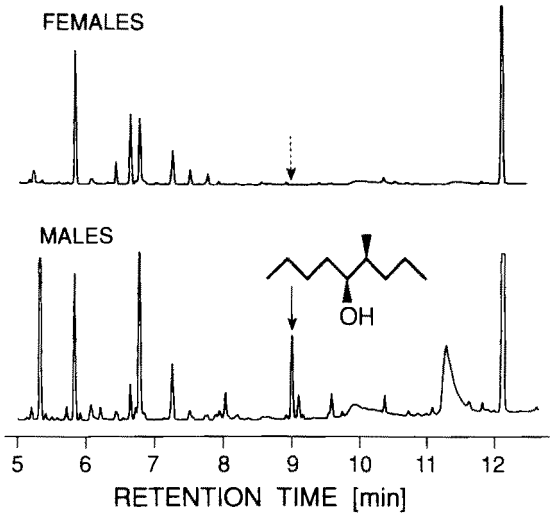

FIG. 1. Gas chromatograms of volatiles obtained from female and male *R. bilineatus* feeding on apples. Chromatography: SP-1000 fused silica column; temperature program: 1 min at 50°C, 10°C/min to 180°C.

entific, Folsom, California; isothermal 100°C) to deduce which stereoisomer was weevil-produced (Figure 3). For GC-MS-EI-SIM, a full-scan mass spectrum of synthetic 4-methyl-5-nonanol, [(±)-**1**], was obtained to select diagnostic ions [*m/z* = 69, (M^+-C_5H_{11}) 87 and (M^+-C_4H_9) 101]. Synthetic (±)-**1**, hexane, and concentrated weevil-produced compound were then injected in split mode and analyzed by scanning for the diagnostic ions. GC-EAD of synthetic chiral isomers of 4-methyl-5-nonanol was also conducted on this column to determine which stereoisomer was antennally active (Figure 4).

Synthesis. Synthetic (±)-**1** was prepared by slow addition of freshly distilled 2-methyl-1-pentanal in ether to butyl lithium in hexane cooled in an ice-water bath. After the usual work-up distillation of the crude product under reduced pressure yielded 67% of (±)-**1** in >95% purity (1.5:1 *syn*:*anti*). The *syn* and *anti* diastereoisomers of (±)-**1** separated on an SP-1000 column. In analogy to previous work (Perez et al., 1994a), *R. bilineatus*-produced **1** was hypothesized to be the *syn* diastereoisomer, which was confirmed by stereoselective synthesis of all isomers of (±)-**1**. Preparation of (4*R*,5*R*)-**1** (97% ee) and (4*S*,5*S*)-**1** (98% ee) was according to methodology previously reported (Perez, et al. 1994a) for the preparation of chiral isomers of 3-methyl-4-octanol and 5-methyl-4-octanol. Details of the preparation of (4*R*,5*R*)-**1** and (4*S*,5*S*)-**1** is described in another paper (Perez et al. 1994b).

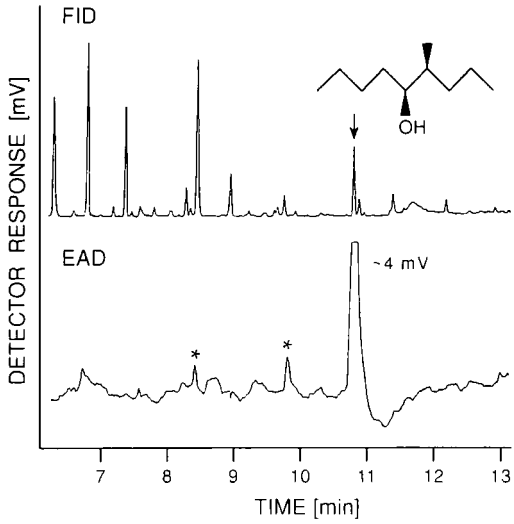

FIG. 2. Flame-ionization (FID) and electroantennographic detector (EAD: female *R. bilineatus* antenna) responses to volatiles obtained from male *R. bilineatus* feeding on apples (*apple-derived components). FID trace: 0.8 weevil hours of an extract containing 4200 weevil hours of volatile production. Column as in Figure 1.

Field Experiments. Field experiments were conducted in coconut-shaded cocoa plantations near Kervera and Vunabang, Papua New Guinea. Modified white 19-liter plastic bucket traps were attached to palms at chest height in randomized blocks with traps at 27-m intervals and blocks 80 m apart (Oehlschlager et al., 1993b). Detergent-laced (0.3%) water (2–3 cm) in the bottom of each trap retained captured weevils. A wire mesh above the water held halved sugarcane stalks. Every three to four days sugarcane was changed and weevils counted.

The first three-treatment experiment tested the attractiveness of (±)-**1** (3 mg/day), sugarcane stalk, and both combined (Figure 5). The second treatment experiment tested attraction of male and female weevils to sugarcane stalk alone and the same combined with (±)-**1** (0.3 mg/day, Figure 6). The third four-treatment experiment tested sugarcane alone and in combination with (±)-**1** released at 0.3, 3.0, or 30 mg/day (Figure 7). The fourth four-treatment experiment tested sugarcane alone and in combination with (±)-**1** (0.4 mg/day), 4*S*,5*S*-**1**, or 4*R*,5*R*-**1** (each stereoisomer released at 0.1 mg/day, Figure 8). Release rates were determined by weight loss of release devices maintained at 25°C. For the low release rate, (±)-**1** was evaporated from three glass capillary tubes (1 mm ID), cut 1 cm above the liquid meniscus and each placed inside

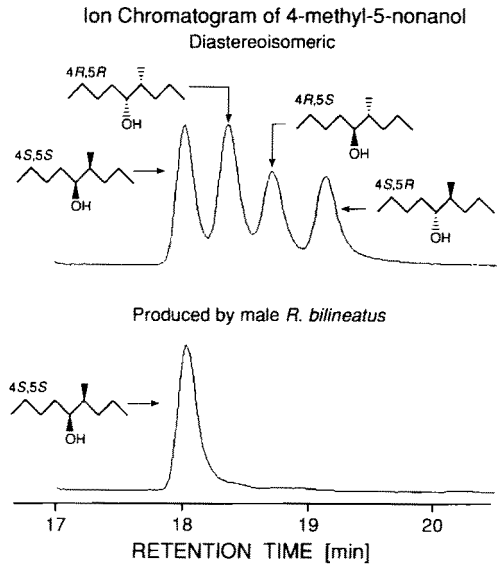

FIG. 3. Selected ion m/z = 69, 87, and 101 chromatogram (Hewlett Packard 5985B GC-MS) of stereoisomeric and weevil-produced **1**. m/z was the parent ion of the full scan EI mass spectrum of $(M^{+}\text{-}C_4H_9)$ 101 or $(M^{+}\text{-}C_5H_{11})$ 87. Analysis on a Cyclodex B column, isothermal 100°C, linear flow velocity of carrier gas 35 cm/sec, split injection and injector temperature 220°C.

capped 300-μl plastic centrifuge tubes with two 2-mm holes near the top. For the medium and high release rates, (±)-**1** was evaporated from 1 or 10 dispensers (heat-sealed plastic bags providing constant release rates under isothermal conditions; ChemTica Internacional, S. A., Apdo. 159-2150, San Jose, Costa Rica).

Statistical Analysis. Assumptions of data normality and homogeneity of variance were tested by graphical assessment of log (variance) versus log (mean), and Bartlett's test, respectively (SAS, 1990). Data were transformed by $(X + 0.5)^{0.5}$ to eliminate heteroscedasicity (Zar, 1984) and were subjected to ANOVA using PROC GLM (SAS) with means compared by Bonferroni's t-test (SAS, 1990).

RESULTS AND DISCUSSION

Analyses of volatiles from males and females revealed several male specific compounds (Figure 1). GC-EAD revealed only one male-specific compound that elicited strong antennal response from male and female weevils (Figure 2).

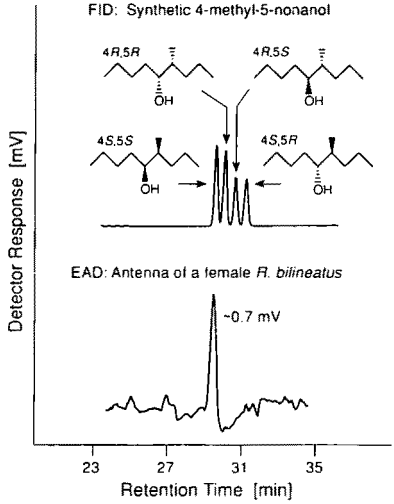

FIG. 4. Flame-ionization (FID) and electroantennographic detector (EAD: female *R. bilineatus* antenna) responses to isomers of 4-methyl-5-nonanol. Column as in Figure 3.

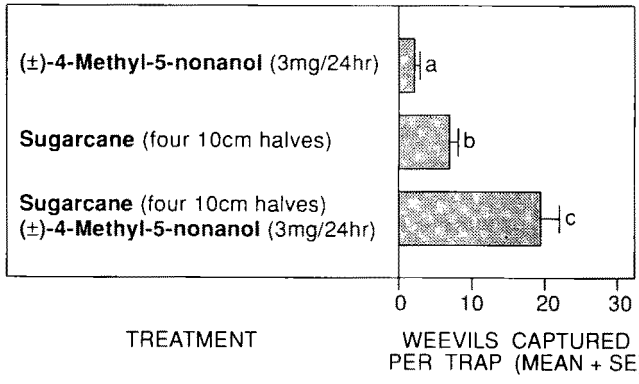

FIG. 5. Mean (+ standard error) captures of *R. bilineatus* in bucket traps baited with sugarcane, (±)-**1**, or both. Experiment ($N = 10$) was conducted in Kervera plantation, November 2–December 4, 1992. Data transformed to approximate homogeneity are presented untransformed. ANOVA, $F = 29.18$; $df = 2,15$; $P < 0.001$. Means followed by the same letter are not significantly different (Bonferonni's t test, $P < 0.05$).

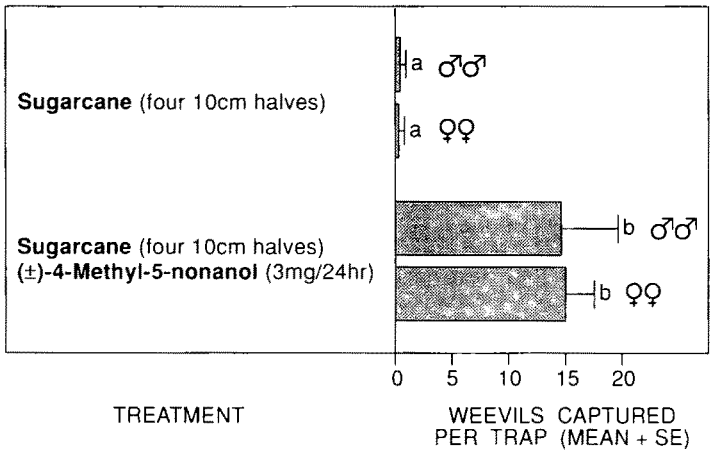

FIG. 6. Mean (+ standard errors) captures of *R. bilineatus* in bucket traps baited with sugarcane or (±)-**1**. Experiment ($N = 4$) was conducted in Vunabang plantation, May 4–14, 1994. Analysis determined there was not a date effect. ANOVA on pooled trap catches for each date, for males $F = 8.84$; $df = 1,6$; $P < 0.02$; for females $F = 35.84$; $df = 1,6$; $P < 0.001$. Means followed by the same letter are not significantly different (Bonferonni's t test, $P < 0.05$).

Mass spectral and retention characteristics of the EAD-active compound were consistent with 4-methyl-5-nonanol [(±)-**1**], the recently identified aggregation pheromone of *R. ferrugineus* and *R. vulneratus* (Hallett et al., 1993a,b; Perez et al., 1993). This nonanol is also a male-specific volatile produced by *R. palmarum* (Hallett et al., 1993a). Analysis by GC-MS of synthetic chiral isomers of **1** and of **1** produced by male *R. bilineatus* on a Cyclodex B column revealed that 4*S*,5*S*-**1** was produced by male *R. bilineatus* (Figure 3). Analysis of synthetic chiral isomers of **1** by GC-EAD revealed that only 4*S*,5*S*-**1** was antennally active (Figure 4).

The first field experiment revealed that (±)-**1** or sugarcane alone was not very attractive, but in combination they caught many weevils (Figure 5). Equal attraction of males and females to traps containing (±)-**1** and sugarcane demonstrated that **1** constitutes an aggregation pheromone (Figure 6). Synergistic attraction of *R. bilineatus* to traps containing both aggregation pheromone and food is consistent with findings in five other species of the Rhynchophorinae (Chinchilla and Oehlschlager, 1992, Oehlschlager et al., 1992a, 1993a,b; Gries et al., 1993, 1994; Hallett et al., 1993a,b; Perez et al., 1993; Weissling et al., 1994).

A third experiment tested sugarcane alone and in combination with (±)-**1**

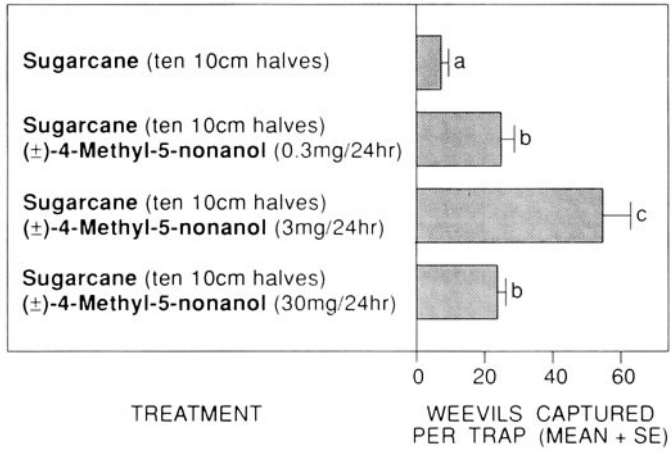

FIG. 7. Mean (+ standard mean error) captures of *R. bilineatus* in bucket traps baited with sugarcane alone or combined with (±)-**1** at three release rates. Experiment (N = 15) conducted at Vanabang plantation, November 25, 1992–January 5, 1993. Data transformed to approximate homogeneity are presented untransformed. ANOVA, $F = 24.67$; $df = 12,67$; $P < 0.0001$. Means followed by the same letter are not significantly different (Bonferonni's t test, $P < 0.05$).

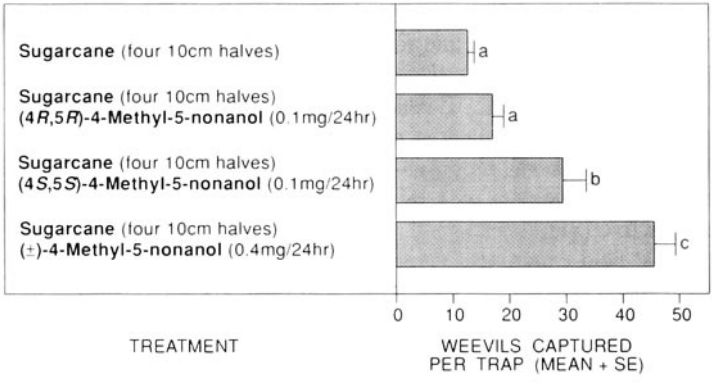

FIG. 8. Mean (+ standard error) captures of *R. bilineatus* in bucket traps baited with sugarcane alone or in combination with (±)-**1**, (4*S*,5*S*)-**1**, or (4*R*,5*R*)-**1**. Experiment (N = 10) at Vimy plantation, January 21–February 22, 1994. Analysis determined there was not a date effect. ANOVA on pooled trap captures for each date gave $F = 22.22$; $df = 3,36$; $P < 0.0005$. Means followed by the same letter are not significantly different (Bonferonni's t test, $P < 0.05$).

released at 0.3, 3.0, or 30 mg/day. Attraction was optimal to those traps from which 3 mg/day of (±)-**1** was released (Figure 7). *R. palmarum* responds equally well to the same three release rates of its pheromone when combined with food, but without food the beetles prefer a 30 mg/day dose (Oehlschlager et al., 1992a, 1993b). In the presence of palm tissue, *R. ferrugineus* is more strongly attracted to traps from which 3 mg/day rather than 0.3 mg/day of (±)-**1** are released (Hallett et al., 1993a,b).

In further field experiments (±)-**1** or 4*S*,5*S*-**1** but not 4*R*,5*R*-**1** enhanced attraction to sugarcane baited traps (Figure 8). The better attractiveness of (±)-**1** than 4*S*,5*S*-**1** is not understood because only the latter is detected in male volatiles (Figure 3) and elicits antennal responses (Figure 4). Interestingly, 4*S*,5*S*-**1** is an aggregation pheromone of *R. ferrugineus* and *R. vulneratus* (Mori, 1993b; Perez et al., 1993). The same stereoisomer of **1** is also produced by male *R. palmarum* (Perez et al., 1993). In Central America, (±)-**1** alone does not enhance attraction of *R. palmarum* to taps containing sugarcane (A.C. Oehlschlager et al., unpublished data).

Production of and antennal response to only one stereoisomer of the aggregation pheromone in *R. bilineatus*, *R. ferrugineus*, and *R. vulneratus* (Perez et al., 1993) is consistent with findings in other Rhynchophorinae. *R. phoenicis* and *R. cruentatus* produce and respond only to (3*S*,4*S*)-3-methyl-4-octanol (Mori et al., 1993a; Perez et al., 1993, 1994a) and (4*S*,5*S*)-5-methyl-4-octanol, respectively (Perez et al., 1994a). Similarly, *R. palmarum* produces and responds to (4*S*,2*E*)-5-methylhepten-4-ol with the antipode being inactive (Oehlschlager et al., 1992a).

The occurrence of 4*S*,5*S*-**1** in the American and three Asian palm weevils supports the hypothesis that the American palm weevil speciated from Asian weevils. This would be consistent with the prevailing theory that palm trees evolved in Southeast Asia, spread through Africa and eventually arrived in the Americas (Harries, 1991). The production of and response solely to 4*S*,5*S*-**1** by *R. ferrugineus*, *R. vulneratus*, and *R. bilineatus* suggest that other mechanisms contribute to reproductive isolation of these weevils. Geographic isolation may allow *R. bilineatus* to use 4*S*,5*S*-**1** as its major pheromone without competition from *R. ferrugineus* or *R. vulneratus*. Sympatric *R. ferrugineus* and *R. vulneratus* are cross-attracted, and males produce the same unique volatiles, suggesting similar communication systems (Hallett et al., 1993a,b). This has raised doubts as to their being separate species (Hallett et al., 1993a,b). Pheromone communication in *R. ferrugineus* and *R. vulneratus* may be different than that of *R. bilineatus* due to the ketone corresponding to **1** that is produced by both the former species (Hallett et al., 1993a) but not by male *R. bilineatus*. The ketone is EAD active in both producing species (Hallett et al., 1993a).

Traps containing (±)-**1**, sugarcane, and detergent-laced water are presently used in Papua New Guinea for management of *R. bilineatus* (R.N.B. Prior and

S. Laup, personal communication). Pheromone-based trapping over one year has proven effective in reducing populations of *R. palmarum* by >80% in commercial oil palm and is used operationally in Central and South America to manage red ring disease vectored by this insect (Oehlschlager et al., 1992b, Chinchilla et al., 1993).

Acknowledgments—We thank the Natural Sciences and Engineering Research Council of Canada for support of this research through an Operating and Infrastructure Grant to A.C.O. and the University of Costa Rica for a fellowship to A.L.P. We also thank R.S. McDonald of SFU for statistical analysis and G. Owen for mass spectrometry.

Book Review

Bioregulators for Crop Protection and Pest Control. Paul A. Hedin (ed.). ACS Symposium Series 557. Developed from a symposium sponsored by the Division of Agrochemicals at the 205th National Meeting of the American Chemical Society, Denver, CO, March 28–April 2, 1993. Washington, D.C.: American Chemical Society, 1994. Hardback $59.95. 221 pages. ISBN 0-9412-2918-X.

Bioregulators as described in the preface to this symposium proceeding include natural and synthetic compounds that are used to regulate any aspect of plant growth and development (excluding those used for killing weeds). The first chapter by L.G. Nickell, "Plant Growth Regulators in Agriculture and Horticulture," provides an introduction to the symposium. He lists the following potential uses for bioregulators; (1) alteration of chemical composition, (2) regulation of dormancy, (3) stimulation of rooting, (4) control of plant or organ size, (5) control of flowering, (6) control of fruit drop, (7) control of fruit set and development, (8) influence of mineral uptake, (9) alteration of maturation, (10) increase resistance to pests or environmental stresses, and (11) prevention of postharvest spoilage.

Following the introductory chapter, the book is divided into three sections. The first section, "Current Applications of Plant Growth Regulators," contains four chapters that give examples of current bioregulator use in agriculture. Chapter two, "New Chemical Approaches for Control of Biennial Bearing of Apples" by M.W. Williams, addresses applied aspects of the use of several chemical thinning agents to prevent excessive fruit set and the subsequent depletion of photosynthate that greatly reduces apple productivity the following year.

In chapter three "Bioregulator-Induced Changes in The Composition of Sugarcane," B.L. Legendre et al. discuss the use of the herbicide glyphosate to improve the sucrose content and other properties of sugarcane.

Chapter four, by P.D. Greeny et al., "Use of Gibberellic Acid to Reduce Citrus Fruit Susceptibility to Fruit Fly," examines the use of gibberellin to prevent senescence of the peel which confers resistance to fruitfly in citrus fruit. This treatment also reduces susceptibility to fruit rot organisms and enhances fruit appearance.

Chapter five, "Bioregulator-Induced Effects on the Allelochemicals and Agronomic Traits of Cotton" by P.A. Hedin and J.C. McCarty, Jr., examines the effect of bioregulators on cotton growth patterns and allelochemical and phytoalexin production. A large number of inorganic and organic substances are

0098-0331/95/1000-1631$07.50/0 © 1995 Plenum Publishing Corporation

known to induce the production of defense compounds, and the authors propose that there is potential for using exogenous application of bioregulators to increase pest resistance.

The second section entitled, "Natural Products as Emerging Bioregulators of Crop Protection and Production" contains seven chapters. Chapters in this section are of particular interest to those in chemical ecology inasmuch as they are good examples of commercial applications for this area of research. In chapter six by A. Stierle et al., "Endophytic Fungi of Pacific Yew (*Taxus brevifolia*) as a Source of Taxol, Taxanes and Other Pharmaceuticals," the authors report on the isolation of a fungus associated with the roots of Pacific yew that produces the chemotherapeutic drug taxol, related taxanes, and other antibiotic compounds. They give a detailed description of the chromatographic, radioisotope, and immunoassay techniques use to confirm the ability of the fungus to synthesize taxol.

In chapter seven, "Effects of Neem and Azadirachtin on Aphids and their Natural Enemies," D.T. Lowery and M.B. Isman review their evaluations of the natural compounds from the seed oil of *Azadirachta indica* for selectively controlling aphids.

Chapter eight by P.J. Rice and J.R. Coats, "Structural Requirements for Monoterpenoid Activity against Insects," examines the effect of variations in structure on the topical, fumigant, and ovicidal activity of these compounds against the house fly. Relatively minor differences in basic carbon skeleton, type of functional group, degree of saturation, volatility, and type of derivatization all affect the activity of these compounds. The chapter illustrates the benefit of understanding structure-activity relationships in developing pesticides and bioregulators.

Chapter nine by R.F. Severson et al., "Characterization of Natural Pesticide from *Nicotiana gossei*," describes the isolation and identification of the components of sugar esters in an insectidal extact of the aphid and whitefly resistant species. The relatively high activity of these compounds indicates their potential as biorational insecticides.

Chapter 10 by M.E. Snook et al., "New Flavone C-Glycosides from Corn *Zea mays* for the Control of Corn Earworm (*Heliocoverpa zea*)," describes isolation and characterization of insecticidal compounds other than maysin from silks of earworm resistant corn genotypes.

Chapter 11 "Inhibition of Phytotoxin (Viridiol) Biosynthesis in the Biocontrol Agent *Glyocladium virens*" by R.D. Stipanovic and C.R. Howell, examines the use of cytochrome P-450 inhibiting fungicides to prevent the synthesis of phytotoxins that limit the usefullness of *G. virens* in controlling seedling diseases.

The final chapter in this section, entitled "After Discovery: the Issues of Supply Strategies in the Development of Natural Products," by J.D. McChesney

discusses the problems and advantages encountered in the commercialization of secondary plant compounds for pharmaceuticals and agrochemicals.

The last section, "Mechanisms of Interactions of Natural Bioregulators and Their Hosts," contains four chapters. Chapter 13, "Development of Economical Population Control of Codling Moth (*Cydia pomonella*) by Disrupting Communication with Semiochemicals," by L.M. McDonough examines the feasibility of using semiochemicals to disrupt mating and control insect population. Among the difficulties encountered with this approach were the lack of an adequate control release device and the rapid decomposition of the pheromone.

Chapter 14, "Metabolites of *Pseudomonas corrugata* that Elicit Plant Defense Reactions," by D.L. Gustine et al. provides another example of bioregulator-induced pest resistance in plants. Two peptides from the bacterial pathogen of tomato induced hypersensitive resistance response in nonhost plant species.

Chapter 15, "Mechanisms of *Heliothis virescens* Resistance to Exogenous Ecdysteroids," by M. Zhang and I. Kubo discusses the multiple mechanisms of resistance of tobacoo budworm to these plant defense compounds. Their studies indicate that low gut permeability, occurrence of a unique pathway for metabolism in the gut, and a high rate of metabolite excretion contribute to resistance.

The last chapter, "Characterization of Auxin Transport Proteins Using Phytotropins" by S. Brun et al., provides a good example of the value of inhibitors for elucidating biological mechanisms of action.

As is typical for the ACS Symposium Series, most chapters are compilations of the authors' research. Each chapter is independent and related to other chapters only in their relevance to the symposium topic. This limits the book's usefulness as a text. Due to the limited number of tropics presented at the symposium, this book cannot be considered a comprehensive review of bioregulator use in agriculture. Several important uses of bioregulators were not discussed. However, the authors are experts in their fields, and most chapters will be excellent resources for those interested in their specific topics. Although the chapters vary considerably in content and style, they are generally well written.

(Received July 3, 1994; accepted June 18, 1995)

Abstract—The behavioral response of honeybees (*Apis mellifera* L.) and bumblebees (*Bombus terrestris* L.) to the flower volatiles 2-ethyl-1-hexanol and myrcene isolated in situ from white clover (*Trifolium repens* L.) and oil seed rape (*Brassica napus oleifera*), respectively, were investigated on a rotating arena with 12 visually identical, but differently scented, feeding stations. When locating a feeding station, neutral in both shape and color, foragers used scent as orientation cue. Introduction of 2-ethyl-1-hexanol to the honeybee hives induced significantly more visits to sites containing this compound. In contrast, introduction of myrcene to the hives did not influence the foraging choices of honeybees significantly. No effect of hive scent composition on the choices made by bumblebees could be detected. "Experienced" bumble bees, i.e., bees with more than five visits to the feeding stations, tended to visit a particular position on the arena without discriminating between the two volatiles. In contrast, honeybees showed no positioning behavior on the arena, using primarily odoriferous stimuli. The observed influences of addition of scents to the hives are discussed in relation to the general knowledge on foraging behavior of social bees and the emission of volatiles from leaves and flowers.

Key Words—*Bombus terrestris*, bumblebee, *Apis mellifera*, honeybee, floral scent, hive scent, foraging choices, foraging behavior, positioning, scent orientation.

INTRODUCTION

Foraging honeybees (*Apis mellifera* L.) are influenced in their choice of flower by the scents previously experienced in the colony. The scents may originate from the food stores (Wenner et al., 1969), from the cuticula of dancing bees, and from the food samples passed on from the dancing bee to attending bees (Frisch, 1950). This knowledge has been used in early attempts to direct honeybee foragers to certain crops in order to avoid the common phenomenon that the foragers choose a crop other than the one intended. Colonies have been fed inside the hive with sugar solution containing flowers of the crop (Glushkov, 1958; Stapel, 1962; Frisch, 1965), or the bees have been fed outside the hive with a sugar solution either surrounded by flowers from the crop, or they were forced to crawl through flowers of the crop in order to reach the sugar solution (Frisch, 1950). The efficiency of these methods was reported to be highly variable (Frisch, 1965; Free, 1970a), and a more thorough knowledge of the mechanisms influencing the foraging choices based on odoriferous stimuli at the hive is evidently required.

A series of investigations have underlined the influence of the hive scent composition on the foraging behavior of honeybees; Ribbands (1954) demonstrated that foragers, trained to visit feeding stations with a particular scent at a particular time of the day, could be activated to search for it at other times by introducing the scent to the hive air. Free (1969) reported that although the food store scents influenced the foraging choices of honeybees, artificial scent added to the top of the frames showed no detectable effects on the foraging behavior. Further, it has been demonstrated that honeybees exposed to a certain scent, e.g., geraniol, during the first eight days after emergence generally show an increased affinity for this compound (Pham-Delègue et al., 1990a). Similarly, the "inexperienced" solitary bee *Colletes julgidus longiplumosus* has a preference for the species of pollen they received during the larval stage (Dobson, 1987). Finally, in a field study parallel to the present one, we found that application of a defined concentration of natural or artificial white clover (*Trifolium repens* L.) flower fragrance to honeybee hives increased the proportion of foragers returning with white clover pollen (Terkildsen et al., unpublished data). The majority of these studies indicates a potential for influencing the foraging choices of honeybees by changing the composition of scent in the colonies. The influence of hive scent on the foraging behavior of bumblebees (*Bombus* spp.) has received little attention in the literature. Studies by Free (1970b) suggested that hive scent originating from the pollen stores influenced the floral choices made by bumblebee foragers (*Bombus lucorum* L.).

In the present study we make an attempt to interfere in the odoriferous signaling in the hive described above by adding a single floral component to the hives in relatively high concentration in order to influence the foragers to choose

feeding stations scented with the same floral component rather than differently scented stations.

METHODS AND MATERIALS

Insect Material. Two honeybee (*Apis mellifera* L.) colonies (Y and Z) each comprising 1000–1500 workers and a mated queen (supplied by the Danish Institute of Plant and Soil Science, Laboratory of Bee Keeping, Roskilde) were kept in small hives (234 × 175 × 57 mm). All foragers were removed from the colony, leaving only workers with no foraging experience and the queen. Three bumblebee (*Bombus terrestris* L.) colonies (A, B, and C) each with 50–100 workers and a queen (supplied by Koppert B. V., Berkel en Rodenrijs, The Netherlands) were kept in polystyrene boxes (270 × 190 × 160 mm). The bumblebee workers had been raised in captivity and had no foraging experience. Hives of both species were maintained in an incubator at 28°C. Every second day all colonies were fed with a mixture of pollen pellets, originating from a wide range of plant species. The pollen had been collected in pollen traps mounted on honeybee hives and stored at −18°C. All colonies were fed from the same batch of pollen throughout the experiment. When the level of stored sugar in the colonies was evaluated as being deficient, the colonies were offered a sugar solution (80% invert sugar) in a feeder placed on a table 3 m from the hive entrance.

The Arena. The design of the arena was based on that developed by Waller et al. (1973). It consisted of a round grey PVC disc placed on a wooden base (1.25 m diam.) with 12 feeding stations along the rim (Figure 1). At each feeding station a landing disc, with a central hole (6 mm diam.), was located above a

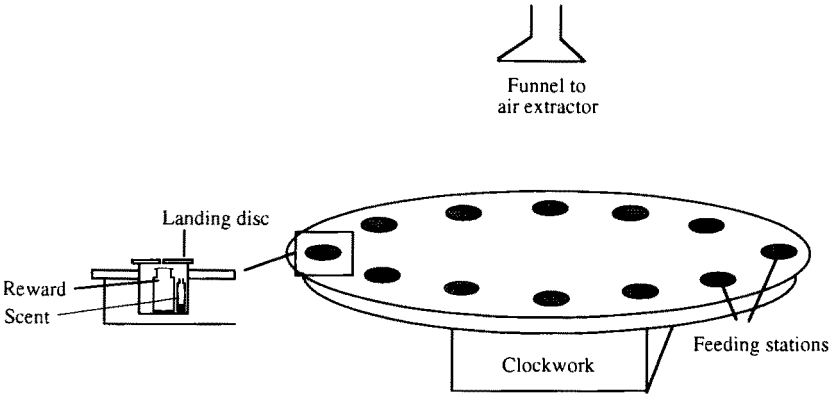

FIG. 1. The rotating arena and a cross section of a feeding station.

100-ml polycarbonate beaker (id: 50 mm ID, 50 mm high). A glass vial (11 ml; 45 mm high, 13 mm ID) containing the reward (80% invert sugar or water) and a 2-ml screw-top glass vial (5 mm ID) (Hewlett Packard) containing the scent were placed inside the beaker (Figure 1). In order to facilitate scent orientation, every second feeding station was unscented and contained water, whereas stations between the water stations contained a sugar reward and were scented alternately with myrcene and 2-ethyl-1-hexanol (Figure 1). The arena was rotated by a clockwork mechanism (12 rotations per hr) to ensure a random location of each feeding station.

Experimental Design. Honeybee colony Y was exposed to three treatments, i.e., initially without scent added to the hive (control), then with myrcene, and finally with 2-ethyl-1-hexanol added to the hive. Colony Z was exposed to the same three treatments, but with a reversed order of scent treatment (control, 2-ethyl-1-hexanol, and finally myrcene). Bumblebee colonies are suitable for participation in the experiments during the relative short interval from the developmental stage with 20–30 workers until the emergence of new males and queens. Consequently, each colony could only be subjected to two treatments as described below. Colony A was initially tested with 2-ethyl-1-hexanol in the hive and subsequently with myrcene. Colony B was tested without addition of scent to the hive, then with 2-ethyl-1-hexanol, and colony C without addition of scent to the hive, followed by conditions with myrcene added. The myrcene and 2-ethyl-1-hexanol vials (0.2 ml scent added, 95–99% purity in each of three 2-ml vials) were placed inside the hives of both species in a netted beaker at least 24 hr prior to test start. Each scent component remained inside the hive for five to seven days, i.e., until a sufficient number of visits at the arena had been recorded.

Each bee participated in one treatment only. Each bumblebee colony participated in the experiments for about one month, i.e., from the stage with 20–30 workers and until the emergence of males and new queens. The honeybee colonies were used for approximately one month. Between nine and 15 bees from each colony were used in each treatment. Colonies were tested in sequence in the period June–November. Visits at the arena were recorded daily between 10 AM and 3 PM. Recordings of bees at the arena took place in a netted flying cage (4 × 12 × 2 m) placed inside a thermoregulated greenhouse (20–25°C) under natural light conditions. Bees were allowed to fly in the cage for a few days prior to participation in the experiments.

Individual bees were marked during first landing at a feeding station in order to be able to follow the foraging pattern of each forager. Honeybees were marked on the abdomen and/or the legs or thorax with combinations of colors (Ceramic Colour, Pepeo, France), whereas bumblebees were marked on the legs only. A visit was regarded as successful if the bee managed to take up sugar solution (or water) at the feeding station.

The relative position of each landing on the arena was noted together with

the scent of the feeding station (i.e., myrcene, 2-ethyl-1-hexanol or water, positions 1–12 (in Figure 2). At most, three bees were permitted to land on the arena at the same time. Each bee was allowed a maximum of eight visits a day. Surplus bees approaching the arena were captured and kept in matchboxes until the recordings of the day were completed. Between two and 10 bees participated each test day, depending on the activity level of the colony. If a bee visited the arena less than five times on its first test day, succeeding visits the following day were included. The arena was removed from the cage after the daily recordings. The hive entrance was closed at the end of the day, and any bees still flying in the cage were transferred to the hive.

Bees of both species normally started to investigate the arena soon after it had been transferred to the cage, landing on the feeding stations within the first 2 hr. However, on some occasions bees hovered above the feeding stations and seemed unwilling to land on the arena. In order to enhance landing, free-flying workers were captured and placed either in the middle of the arena with a sugar droplet or on a separate unscented feeding station containing sugar water. Landing discs were replaced after each bee visit, and all materials were cleaned with an aroma-free detergent (Extran), demineralized water, and ethanol (70%) in order to remove any odor contamination. Handling of all test material was performed with vinyl gloves. To prevent the accumulation of volatiles from the scented feeding stations in the greenhouse air, a vacuum cleaner (Nilfisk GA71, flow 20–25 liters/sec, tube ID: 31 mm, length 1 : 12 m) positioned outside the greenhouse was connected to a funnel [12 cm ID, positioned 65 cm above the center of the arena (Figure 1)].

Scent Sampling. Concentrations of volatiles in the air within the hive and above individual feeding stations were monitored by collecting air samples for 30 min every third day. Samples of the hive air were collected by placing a glass column (4 mm ID, 180 mm long) with 100 mg Porapak Q 50–80 mesh (Waters Inc., Milford, Massachusetts) inserted between two desiloxanized glass-wool plugs in a hole drilled in the side of the hive. Air samples above feeding stations were collected by positioning the Porapak column 5 cm above the landing disc. A vacuum pump carried a constant flow of air (300–600 ml/min) through the columns; flow rates were controlled by a flowmeter. Gas chromatographic quantification of myrcene and 2-ethyl-1-hexanol was performed as described previously (Jakobsen and Olsen, 1994).

Statistics. Visits were statistically grouped into three categories: (1) the first visit made by a bee to the arena ("inexperienced" bees); (2) the first five visits to the arena ("learning" bees); and (3) visits following the initial five visits ("experienced" bees). Only the initial five visits of each bee were used in the statistical analysis on influences of addition of scent to the hives. Visits extending the first five were used to describe the long-term foraging pattern of the individual bee.

The distribution of visits to nonscented, myrcene-scented, and 2-ethyl-1-

hexanol-scented feeding stations was observed for the foragers of each colony prior to introduction of myrcene or 2-ethyl-1-hexanol to the hives. These tests served as controls in the statistical analysis. Visits to a nonscented visiting station were only observed for a minor group of bees that collected water repeatedly from these stations. Therefore they were excluded from the statistics on differences among scented feeding stations.

The null hypothesis that the proportions of foragers choosing feeding stations scented with myrcene and 2-ethyl-1-hexanol, respectively, is the same under conditions with and without scent added to the hive was tested in a 2 × 2 contingency table using the χ^2 distribution. This test was also used in the comparisons of the distribution of visits on the arena during the "learning" phase and the "experienced" phase. Probability values for possible preferences for one of the two scents under control conditions were calculated using common methods under the binomial distribution.

RESULTS

The mean concentrations of volatiles measured directly above the feeding stations were 114 ± 58 ng/liter of air for myrcene and 42 ± 8 ng/liter for 2-ethyl-1-hexanol. Concentrations of the scents in the hives were 21120 ± 1891 ng/liter and 1920 ± 267 ng/liter, respectively. Bees of both species visited only one feeding station per foraging trip and spent 2–3 min taking up the sugar solution.

Honeybees. The two tested scents were equally attractive to honeybees (*Apis mellifera* L.) prior to any addition of scent to the hives (Table 1). After introduction of 2-ethyl-1-hexanol to the hives, a significantly higher proportion of the visits were to feeding stations scented with this compound (70.9%) than under conditions without addition of scent to the hives (43.3%, Table 1). These comparisons were performed using the initial five visits made by each bee. Similarly, high proportions of visits were recorded at stations scented with 2-ethyl-1-hexanol during conditions with this compound added to the hives when only the first visit of each bee was used in the comparisons (Table 1). Introduction of myrcene to the hives did not induce more visits to sites with this compound compared to conditions without addition of scent to the hives (Table 1). A strong correlation was noted between the first and subsequent scent choices on the arena, i.e., honeybees visiting myrcene on the first trip chose myrcene in 66% of the following visits, and bees choosing 2-ethyl-1-hexanol on their first encounter landed on this scent in 69% of the following visits.

An analysis of the visiting pattern for 13 honeybees each visiting the arena approximateiy 25 times showed no preference for visiting feeding stations positioned within a particular area of the test arena (Figure 2A). Eight of the expe-

TABLE 1. EFFECT OF SCENT ADDITION TO HONEYBEE HIVES[a]

[a] The heading "Initial five visits to arena" refers to the initial five visits made by the bees of each hive participating in a given treatment. These visits are cumulative, whereas only the very first visit made by each bee to the arena is analyzed under the heading "first visit to arena."

[b] Probability under the null hypothesis that the two scents are equally attractive to the bees. Binomial test.

[c] Probability values comparing the distribution of visits prior to addition of scent to the hive with those observed with scent added to the hive. Data were analyzed in a 2 × 2 contingency table.

NS: nonsignificant at the 0.05% level, $*P < 0.05$, $**P < 0.01$, $***P < 0.001$.

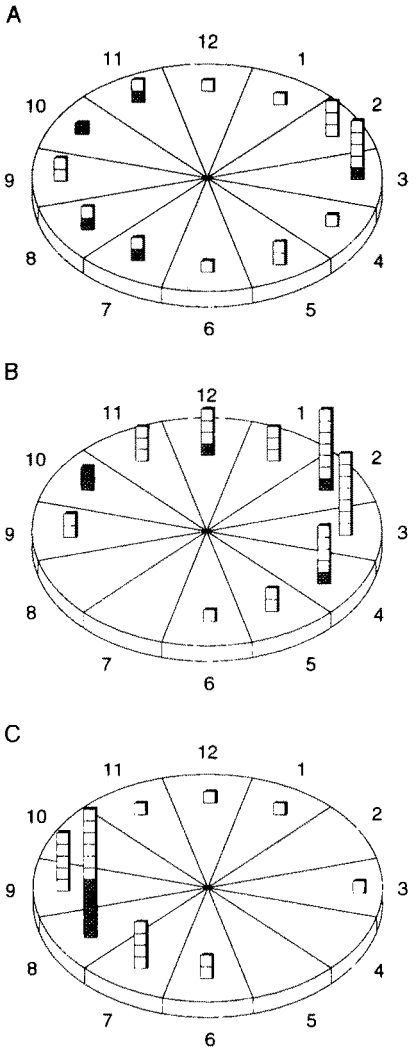

FIG. 2A–C. The three major foraging patterns described by honeybees and bumblebees on the arena. Each cube on the arena represents one visit to a feeding station at the position indicated by numbers along the periphery (e.g., 3 = north, 6 = east, 9 = south, 12 = west). ▨ = first five visits, □ = subsequent visits. (A) A honeybee visiting feeding stations with the same scent every time. The visits are evenly distributed to the 12 different positions on the arena. This pattern was displayed by 92% of the honeybees. (B) Visiting pattern of a bumblebee that did not orient in relation to a particular position during the first five visits, but showed a preference for the 2 and 3 o'clock region during

rienced bees oriented towards a particular scent (although not necessarily the same as the one in the hive) while the remaining five visited both odors equally without showing preference for any of them. A few honeybee foragers collected water repeatedly from the unscented feeding stations.

Bumblebees. Myrcene and 2-ethyl-1-hexanol were equally attractive to bumblebees (*Bombus terrestris* L.) at the arena prior to addition of scent to the hives (Table 2). Addition of 2-ethyl-1-hexanol to the hives did not induce significantly more visits to feeding stations scented with this compound (47.4% before and 57.6% after addition of scent, Table 2). Similarly, introduction of myrcene had no detectable influence on preferences during either the first or subsequent visits to the arena (Table 2). The bumblebees showed a significant constancy towards one of the two components in the first five visits to the arena ($P < 0.001$, Figures 2B and C). This strong correlation between the scent chosen on the first visit and during subsequent visits to the arena was not influenced by addition of scent to the hive ($P > 0.05$). After the first five visits, approximately 75% of all foragers became indifferent to scent type. Furthermore, 91% of these ended up visiting solely a particular position, regardless of the scent emitted from the station (Figure 2B and C). The bumblebees visited primarily sites with odor and sugar water. Some foragers, however, collected water repeatedly and carried it back to the hive (3.4% of all visits, $N = 1008$).

DISCUSSION

The observed similar attractiveness of myrcene and 2-ethyl-1-hexanol to both honeybees and bumble bees on the test arena prior to addition of scent to the hives suggested that a comparison of these two compounds would be appropriate in a test for effects of scent introduction to the hives. The subsequent significant increase in the proportion of honeybees choosing sites scented with 2-ethyl-1-hexanol after introduction of this volatile to the hive air demonstrates that the foraging choices of honeybees can be influenced by introducing odoriferous stimuli to the hive. This conclusion is supported by recent studies showing that introduction of white clover scent to honeybee hives under field conditions incited colonies to collect significantly more white clover pollen than control hives (Terkildsen et al., unpublished data). The added scents were either a mixture of synthetic volatiles or detached white clover flower heads. Two

subsequent visits. This pattern type was displayed by 36% of all the bumblebees. The bee visited only beakers with myrcene during the first eight visits but became gradually indifferent to scent type over time. (C) Bumblebee orienting almost exclusively toward the 8 o'clock region. Pattern displayed by 39% of the bumblebees. This bee was indifferent to scent type from the beginning.

TABLE 2. EFFECTS OF SCENT ADDITION TO BUMBLEBEE HIVES[a]

[a]The heading "Initial five visits to arena" refers to the initial five visits made by the bees of each hive participating in a given treatment. These visits are cumulative, whereas only the very first visit made by each bee to the arena is analyzed under the heading "First visit to arena."

[b]Probability under the null hypothesis that the two scents are equally attractive to the bees. Binomial test.

[c]*P* value comparing the distribution of visits prior to addition of scent to the hive with those observed with scent added to the hive. Data were analyzed in a contingency table.

NS: non-significant, $*P < 0.05$, $**P < 0.01$, $***P < 0.001$.

possible causes for the lack of response to myrcene application to the hives may be suggested: (1) The concentration of myrcene in the hive was too high (it was approximately 10 times higher than for 2-ethyl-1-hexanol). (2) The information of myrcene in the hive air may not be used by foraging bees in the same way as 2-ethyl-1-hexanol. Menzel (1985) suggested that certain odors are more attractive due to a "prepared search image," i.e., a genetically programmed preference for some orientation cues. Two major observations support this second hypothesis: (1) The scent emitted from the whole plant may be used when locating the plant from a distance, whereas the floral fragrance is used as an orientation cue on close range (Beker et al., 1989). Consequently, volatiles effective in guiding bees to the flower should be emitted from the flowers only (Pellmyr and Thien, 1986). Besides being among the most common floral volatiles (Knudsen et al., 1993), myrcene is also a constituent of green leaves (Jakobsen et al., 1994). It may therefore not be suitable as an orientation cue for pollinators attempting to locate the flower. Previous investigations support the assumption that some of the volatiles comprising the floral fragrance are "excluded," i.e., are not necessarily used as an orientation cue by the bees when identifying the flower of a particular species; Pham-Delègue et al. (1990b, 1991) demonstrated that only a limited fraction of the floral fragrance is needed for the recognition of the total volatile blend in the flower. The compound effective in influencing the foraging choices of honeybees in the present study, 2-ethyl-1-hexanol, has only been detected in the floral headspace of *Theobroma* (Erickson et al., 1987) and *Trifolium repens* L. To our knowledge 2-ethyl-1-hexanol has not been identified in the emissions from leaves. (2) In *Brassica napus* myrcene is emitted from both leaves and flowers, but, in contrast to some of the other floral volatiles, it is emitted in a nonrhythmic manner (Jakobsen et al., 1994). This may be yet another indication that this compound is of secondary importance in the attraction of pollinators to the *Brassica napus* flower. The rhythmic emission of floral volatiles in species with a diurnal or nocturnal maximum of emission has been demonstrated to coincide with the period of activity of the major pollinators (Matile and Altenburger, 1988; Loughrin et al., 1990, 1991; Jakobsen and Olsen, 1994; Hansted et al., 1994; Jakobsen et al., 1994). This correlation suggests that the rhythmically emitted compounds are significant in the attraction of pollinators to the flower. In *T. repens* 2-ethyl-1-hexanol is emitted in a rhythmic manner with a diurnal maximum of emission (Jakobsen and Olsen, 1994), and *T. repens* is pollinated almost entirely by honeybees.

The influence of added scents on the honeybee foraging behavior observed in the present study is in accordance with Ribbands (1954), who reported that honeybees conditioned to visit a feeder scented with either methyl benzoate or benzyl acetate at a particular time of day could be activated to visit the feeder at other times by introducing the feeder scent to the hive air. In contrast, Free (1969) observed that benzyl acetate or methyl heptanone distributed in solution

to the top of the frames of honeybee hives failed to influence the behavior of foragers. However, no information on the concentration levels of the added scents in the hive air was given in any of the investigations. The theories mentioned above on "prepared search images," etc., are not applicable in the experiment by Ribbands (1954) or Free (1969) because the bees in those studies had been conditioned to the scents prior to participation in the hive scent experiments.

The observed lack of response of bumblebees to the added hive scents is in contrast to suggestions by Free (1970b), who compared foraging patterns of bumblebee colonies (*Bombus lucorum* L.) under natural conditions and suggested that hive scents originating from the pollen stores may influence the floral choices made by the bumblebee foragers. The lack of response to hive scents observed in the present study may be partly explained by the positioning behavior discussed below.

The observed strong positive correlation between the scent first encountered at the test arena together with a reward and the scent chosen during subsequent visits is consistent with general theories on associative learning (Menzel, 1993). Changes in foraging behavior through associative learning during the series of visits to the arena showed clearly different patterns for bumblebees and honeybees: After a few visits to the arena, bumblebees associated the reward with a certain position on the arena in most cases, whereas honeybees associated the reward with a particular scent. The observed positioning of bumblebee foragers, in contrast to that of honeybees, may be compared to the foraging strategies of the two species under natural conditions. Honeybees have developed a dance language for recruitment of foragers in order to exploit extensive food sources efficiently (Frisch, 1965, 1974; Michelsen et al., 1987). The message of the dance, however, only communicates the approximate direction and distance to the food source. At the approximate location, several potential sources, i.e., plant species, may be present in the area. The foragers may locate the source by associating the floral scent diffusing from the dancing bee and from the nectar passed on from the dancer with the scents encountered in the area. Consequently, the honeybee forager primarily uses odoriferous orientation only after arriving in the general area of the food source. If the flower odor is used for orientation, then little accurate positioning in relation to the area is required. The significance of a particular odoriferous composition may be reflected in the fact that honeybees normally visit only one flower species per foraging trip. In contrast, bumblebees, which have no known dance language, often follow the same route during trips on successive days, visiting several different species each day (Free, 1970b), and they are not "linked" to a particular scent as are honeybees. This strategy indeed requires some positioning behavior when flying between small patches, i.e., the exact position of the plant is of importance to the bumblebee's strategy. The hypothesis that the foraging choices of bumblebees are based on

the position and scent of the plant rather than the scent stimuli received in the hive is in accordance with studies by Pham et al. (1983). Their study showed that experiences of the individual bee during foraging appears to dominate when it selects among potential food sources, in spite of the communication via indirect trophallaxis among the individuals in the colony. These differences in foraging strategy may be reflected in the positioning behavior observed in bumblebees, which contrast with the odoriferous orientation at the arena observed in honeybees.

Water collection by bumblebees has not been reported previously to our knowledge. These foragers appear to use the odoriferous stimuli of the beakers containing sugar differently from the sugar-collecting bees, i.e., water-collecting foragers avoided scented beakers, thereby locating beakers with water only. The association between hive scent composition and increased preference of honeybees for food sources emitting the same scent is clearly not a simple one. Further investigations on the effects of scents comprising more than one compound, together with tests involving several levels of scent concentrations, are required in order to understand more fully the association between the accumulated floral scents in the hive and the choices made by foraging bees.

Acknowledgments—We thank Kerstin Henriksen for technical assistance, the Laboratory of Bee Keeping, Danish Institute of Plant Science, for supplying the honeybee colonies and net cages, and Koppert B.V., The Netherlands, for supplying the bumblebee colonies. We appreciate financial support provided by The Danish Agricultural and Veterinary Research Council (grant 13-4580-1).

(Received January 31, 1995; accepted July 8, 1995)

Abstract—The response of the *Ceutorhynchus assimilis* antenna to volatiles in air entrainment-derived extracts of oilseed rape, *Brassica napus*, was studied using coupled gas chromatography (GC)–electroantennography (EAG) and coupled GC-single cell recording (SCR). By means of these techniques and coupled gas chromatography-mass spectrometry (GC-MS), 25 active compounds were identified, including isoprenoids and compounds derived from fatty acids and amino acids. Some of the latter, the isothiocyanates and goitrin, and probably indole and benzyl cyanide, are catabolites of glucosinolates. The electrophysiological activity of the identified compounds was confirmed by EAG using a physiologically discriminating dose, and by SCR studies. The importance of the combined use of the EAG and SCR techniques was demonstrated, since specific olfactory cells were located for five compounds that did not elicit significant EAG responses. The majority of the olfactory cells from which single cell recordings were obtained showed very high specificity, and in numerous recordings there were consistent pairings of specific cell types.

Key Words—*Ceutorhynchus assimilis*, cabbage seed weevil, Coleoptera, Curculionidae, *Brassica napus*, oilseed rape, volatiles, isothiocyanates, EAG, SCR, GC-EAG, GC-SCR.

INTRODUCTION

Over the last 20 years, the area grown to oilseed rape, *Brassica napus* (Brassicaceae = Cruciferae), in the United Kingdom has increased approximately 100-fold to a recorded area of 376,700 ha in 1993, i.e., 8% of the total arable crop area. Similar increases have occurred in other temperate European countries (Anon., 1994). One of the more important bud and inflorescence pests of oilseed rape is the cabbage seed weevil, *Ceutorhynchus assimilis* (Payk.) (Curculionidae). The eggs are deposited singly in developing pods and larval feeding on the seeds reduces crop yield in heavy infestations. In addition, punctures in pods made by *C. assimilis* during feeding and egg-laying are used for oviposition by another pest, the pod midge, *Dasineura brassicae* (Cecidomyidae) (Alford et al., 1991).

Host location in phytophagous insects is mediated by a combination of visual and olfactory cues (Visser, 1986). *C. assimilis* is attracted to *B. napus* volatiles (Görnitz, 1953; Free and Williams, 1978; Evans and Allen-Williams, 1989; Bartlet et al., 1993), and a number of the components involved, particularly the isothiocyanates (NCS), volatile catabolites of the glucosinolates that are characteristic of the Brassicaceae, have been identified and their antennal perception studied using both electroantennograph (EAG) (Kozlowski, 1984; Evans and Allen-Williams, 1992) and single cell recording (SCR) techniques (Blight et al., 1989, 1992). Although excellent field-trapping results have been obtained with synthetic isothiocyanates (Blight et al., 1992; Smart et al., 1993), the complex mixture of volatiles emitted by current varieties of *B. napus* contains a preponderance of secondary metabolites not derived from glucosinolates (Tollsten and Bergström, 1988; Blight et al., 1992; Evans and Allen-Williams, 1992) and many of these may also influence orientation of *C. assimilis* to the host plant.

We now report a detailed study in which electrophysiological techniques directly coupled to high-resolution capillary column gas chromatography (GC) were used to identify *B. napus* volatiles that interact with the seed weevil antenna. The activities of these volatiles, and some related compounds were then examined using both the EAG and SCR techniques.

METHODS AND MATERIALS

Plant Volatiles. Volatiles were collected from flowering shoots of *B. napus* using a dynamic headspace (air-entrainment) technique described previously (Blight, 1990). Cut flowering stems, bearing a few leaves, of the single low *B. napus* cv. Willi were contained in water in conical flasks placed in a glass culture vessel (20 liters). Volatiles were drawn from the vessel, using purified

air, onto a tube of the adsorbent Porapak Q (4 g). At the conclusion of each air entrainment, which lasted 7–10 days, the volatiles were eluted from the Porapak with pentane and the extract was concentrated by fractional distillation of the solvent using a column of glass helices. After final concentration under nitrogen, the extracts (100–500 μl) were stored at $-20°C$ in microvials for immediate use or sealed in glass ampoules.

Insects. C. assimilis were collected from crops of flowering *B. napus* and sexed, under carbon dioxide, according to Bonnemaison (1957). The sexes were maintained separately on flowering racemes of glasshouse-grown *B. napus* (cv. Topas) contained in jars of water that were enclosed in polyester mesh bags. The cultures were kept in a controlled environment cabinet at 15°C:9°C, 16L:8D.

Chemicals. Pentane and hexane (both HPLC grade, Fisons) were purified as in Blight (1990). Most chemicals were obtained from commercial sources (Aldrich Chemical Co. Ltd., Fluka Chemie AG, Lancaster Synthesis Ltd., Bedoukian Research Inc.), but (*E,E*)-α-farnesene was extracted from apple skins with ether (Murray, 1969) and purified by elution from Florisil. 3-Butenyl and 4-pentenyl NCS and all the cyanides (Table 3 below) except 2-phenylethyl cyanide (purchased from Aldrich) were synthesized in the laboratory by standard methods (Dawson et al., 1993). α-Terpinolene was a gift from Professor F. Camps, University of Barcelona. Most substances were of purity $\geq 98\%$, except for 4-pentenyl NCS, linalool, and benzthiazole (each 97%), allyl NCS (94%), and phenylacetaldehyde (90+%). α-Terpinene and myrcene were ca. 85% pure. Standard solutions (10^{-5} to 10^{-10}g/10 μl) of all compounds were prepared in purified hexane for electrophysiological studies.

Gas Chromatography (GC). Air entrainment volatiles were separated on a 50 m × 0.32 mm ID methyl silicone bonded-phase fused silica capillary column (HP-1) fitted in a Hewlett Packard 5880A gas chromatograph equipped with a split/splitless injector and a flame ionization detector (FID). The carrier gas was hydrogen and the oven temperature was maintained at 40°C for 5 min and then programmed at 5°/min to 150°C, then at 10°/min to 250°C.

Gas Chromatography–Mass Spectrometry (GC-MS). A capillary column (50 m × 0.32 mm ID HP-1) fitted in a Hewlett Packard 5890 GC was directly coupled to the MS and integrated data system (70-250 VG Analytical). Ionization was by electron impact at 70 eV, 230°C. The GC was maintained at 30°C for 5 min and then programmed at 5°/min to 180°C. Tentative identifications made by GC-MS were confirmed by comparison of the mass spectral data with those of authentic samples and by peak enhancement when coinjected with authentic compounds using GC, as above (Pickett, 1990).

Electrophysiology: EAG. Recordings from whole antennae were made using Ag–AgCl glass electrodes filled with saline solution (composition as in Maddrell, 1969, but without the glucose). Antennae were excised and suspended

between the two electrodes. The signals generated by the antenna were passed through a high-impedance amplifier (Syntech UN-03b) and displayed on an oscilloscope. The output from the oscilloscope was monitored on a chart recorder. EAG responses were normalized with respect to the response elicited by 10^{-6} g of (Z)-3-hexen-1-ol presented after every sixth stimulation. Compounds were tested against five individual antennae and results were analyzed using Student's *t* test.

Electrophysiology: SCR. Recordings from individual olfactory cells on the antenna were made with tungsten microelectrodes (Boeckh, 1962). The indifferent electrode was placed in the antennal scape, and the recording electrode was brought into contact with the surface of the antenna until impulses were recorded. Signals were amplified (Syntech UN-03b), displayed on an oscilloscope, and stored on magnetic tape. Permanent copies of the action potentials generated by the olfactory cells were obtained by standard methods (Wadhams et al., 1982). Impulse frequency was determined as the number of impulses elicited during the first 1 sec after stimulation. Compounds were presented twice to each preparation at intervals of 2–10 min, the exact interval being determined by the concentration of the previous stimulus.

Stimulus Delivery. For both the EAG and SCR techniques, the stimulus (1 sec duration) was delivered into a purified airstream (1 liter/min) flowing continuously over the preparation. The delivery system, which employed a filter paper in a disposable Pasteur pipet cartridge, has been described previously (Wadhams et al., 1982). Samples (10 μl) of the standard solutions of test compounds were applied to filter paper strips, and the solvent was allowed to evaporate (30 sec) before the paper strip was placed in the cartridge. The control stimulus was hexane (10 μl). Fresh cartridges were prepared immediately prior to each stimulation.

GC-EAG and GC-SCR. The GC-EAG and GC-SCR systems, in which the antennal preparation is directly coupled to the capillary column of the gas chromatograph, have been described previously (Wadhams, 1990). Separation of the air entrainment samples was achieved on an AI 93 gas chromatograph equipped with a cold on-column injector and a FID. The carrier gas was hydrogen and the column (50 m × 0.32 mm ID HP-1) was maintained at 40°C for 1 min and then programmed at 5°/min to 100°C and then at 10°/min to 250°C. Simultaneous records of the FID and antennal responses were obtained by detecting with a level discriminator and plotting by means of a voltage/frequency convertor.

RESULTS

On GC analysis, volatiles from intact flowering shoots of *B. napus* were shown to comprise highly complex mixtures (Figure 1), as expected from pre-

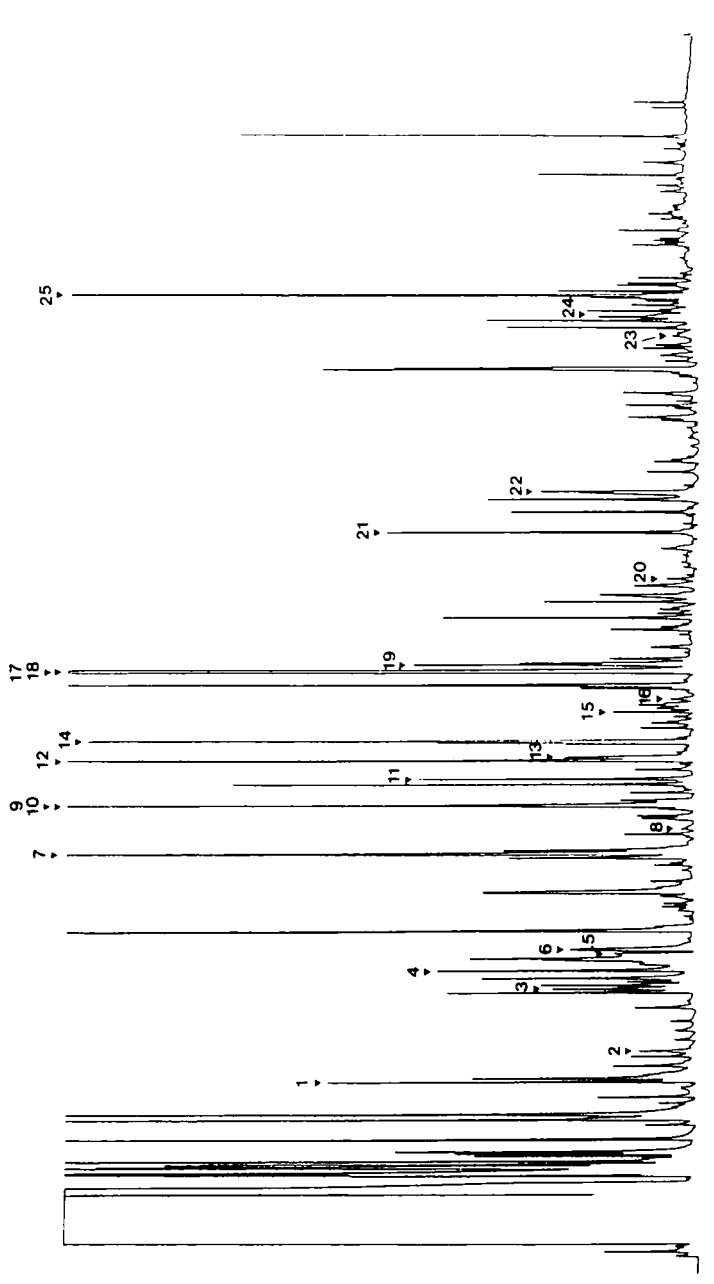

FIG. 1. Gas chromatogram of an extract of volatiles from *Brassica napus* cv. Willi. Numbered peaks (see Table 1) showed electrophysiological activity.

vious studies (Tollsten and Bergström, 1988; Evans and Allen-Williams, 1992). Biologically active compounds in these samples were located using coupled GC-electrophysiological techniques, initially GC-EAG and then GC-SCR (Tables 1 and 2). A typical GC-SCR trace is shown in Figure 2.

The electrophysiological activity of the identified compounds was confirmed by EAG recordings at the 10^{-6} g level, using authentic samples. Most of the active compounds (Tables 1 and 2) were ubiquitous plant volatiles such

TABLE 2. *Ceutorhynchus assimilis*: COMPOUNDS FOR WHICH SPECIFIC OLFACTORY CELLS HAVE BEEN LOCATED

Compound	Cells (*N*)
Isothiocyanates[a] (3-butenyl, 4-pentenyl, 2-phenylethyl)	60
1-Octen-3-ol	29
Methyl salicylate[a]	25
2-Phenylethanol[b]	13
Oxygenated monoterpenes (verbenone, verbenol)	9
1,8-Cineole[b]	8
(±)-Linalool	7
(*Z*)-3-Hexenyl acetate[c]	7
(*Z*)-3-Hexen-1-ol[c]	4
Benzyl alcohol	2
(*E*)-2-Hexenal	1
Sabinene	1

[a,b,c] Compounds followed by the same letter are detected by cells frequently occurring in pairs.

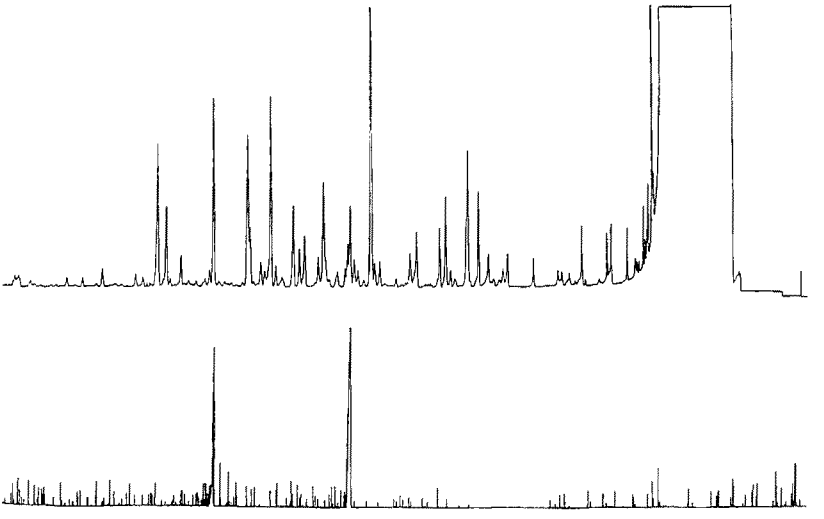

FIG. 2. Coupled gas chromatography–single cell recording (GC-SCR) from *Ceutorhynchus assimilis*. Upper trace: GC of volatiles from insect-damaged *Brassica napus* cv. Willi; lower trace: SCR showing response to 3-butenyl and 4-pentenyl isothiocyanates (small spikes are spontaneous cell activity).

as isoprenoids and compounds derived from fatty acids and amino acids. The isothiocyanates and goitrin, and probably the other nitrogen-containing compounds, indole and benzyl cyanide, are catabolites of glucosinolates derived originally from amino acids. Four of the compounds, 3-butenyl and 4-pentenyl

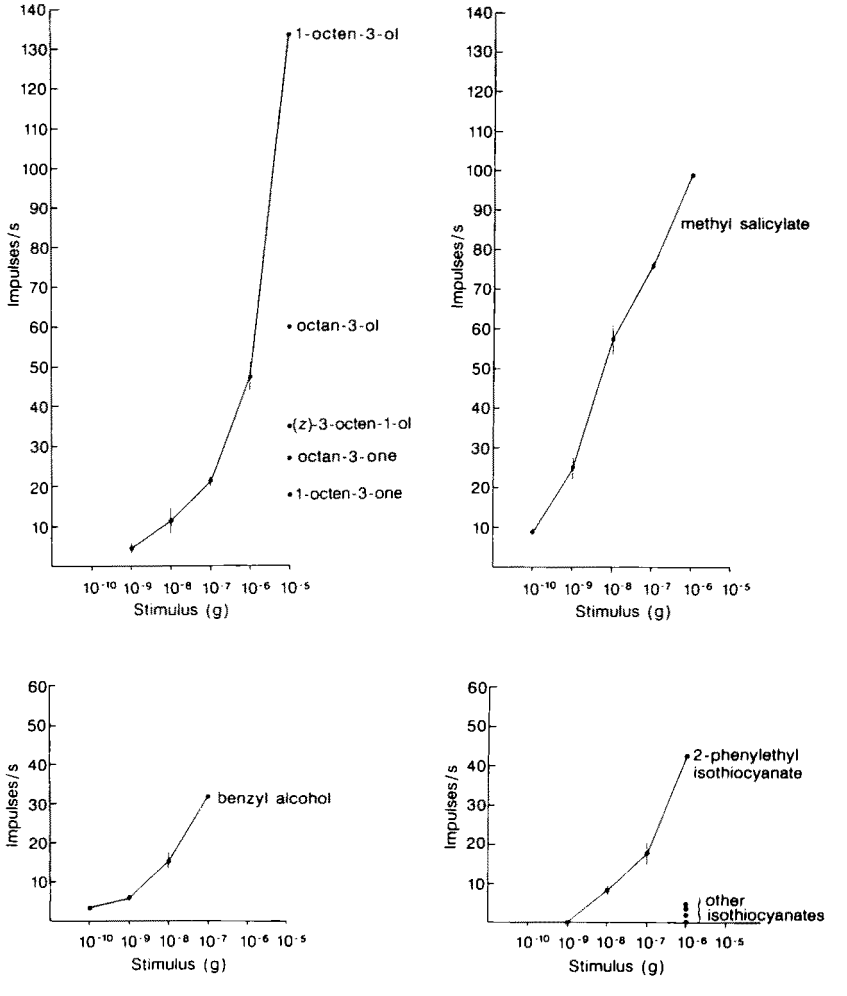

FIG. 3. Dose-response of *Ceutorhynchus assimilis* olfactory cells to *Brassica napus* volatiles. (Other isothiocyanates = allyl, butyl, pentyl, propyl, 3-butenyl, 4-pentenyl). Each point is the mean of two stimulations (bars = SE).

NCS, 1,8-cineole and (*Z*)-3-hexenyl acetate, did not elicit significant EAG responses, but nevertheless, specific olfactory cells were located for them using the SCR technique (Table 2, Figures 2 and 3).

Some additional compounds, including the known *B. napus* volatiles 2-aminobenzaldehyde, β-ionone, myrcene, dimethyldisulfide and dimethyltrisulfide, and six cyanides, which are glucosinolate catabolites found in macerated tissues of *Brassica* spp. (Tollsten and Bergström, 1988), were tested against females but elicited no EAG activity at physiologically discriminating levels (Table 3) and did not stimulate specific olfactory cells in these studies.

A total of 166 responding cells were recorded from the antenna of *C. assimilis*, most of which showed considerable specificity in their response pro-

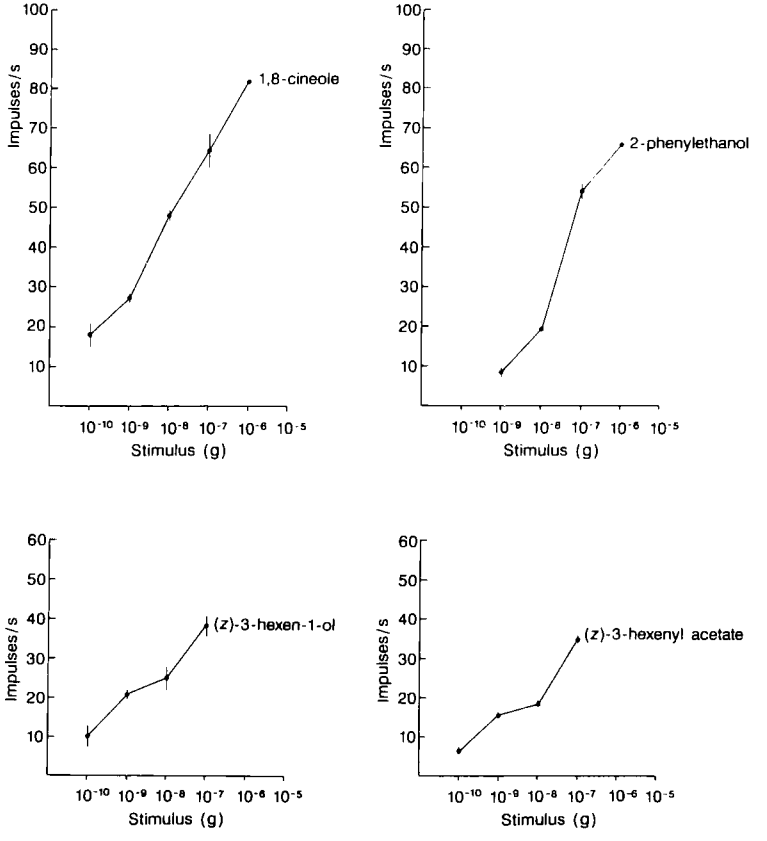

FIG. 3. Continued.

Cyanides	2-propenyl cyanide
	4-pentenyl cyanide
	2-hydroxy-3-butenyl cyanide
	4-methylthiobutyl cyanide
	3-butenyl cyanide
	2-phenylethyl cyanide
Sulfides	dimethyldisulfide
	dimethyltrisulfide

files. Typical dose-response data and the numbers of the various cell types are shown in Figure 3 and Table 2, respectively. Approximately one third of the cells from which recordings were made responded specifically to 3-butenyl, 4-pentenyl and/or 2-phenylethyl NCS.

In a number of instances, recordings showed consistent pairings of certain cell types (Table 2, Figure 4). In most cases, the amplitudes of the two cells could be discriminated and the relative amplitudes of these cell pairs remained consistent between recordings. Thus, four of the seven recordings containing cells responding specifically and at low stimulus concentrations to (*Z*)-3-hexenyl acetate were associated with cells responding to (*Z*)-3-hexen-1-ol. In this instance, the large amplitude cell responded to the acetate while the smaller amplitude cell responded to the alcohol. Similar cell pairings were found with specific cells for methyl salicylate (small amplitude)/isothiocyanates (large amplitude) and for 1,8-cineole (large amplitude)/2-phenylethanol (small amplitude) (Figure 4).

DISCUSSION

The biologically active components of a mixture of *B. napus* volatiles, at concentrations appropriate to those encountered by insects in the field, have been identified by coupled GC–electrophysiology and subsequent GC-MS. However, coupled GC-EAG alone did not prove exhaustive in locating all the activity

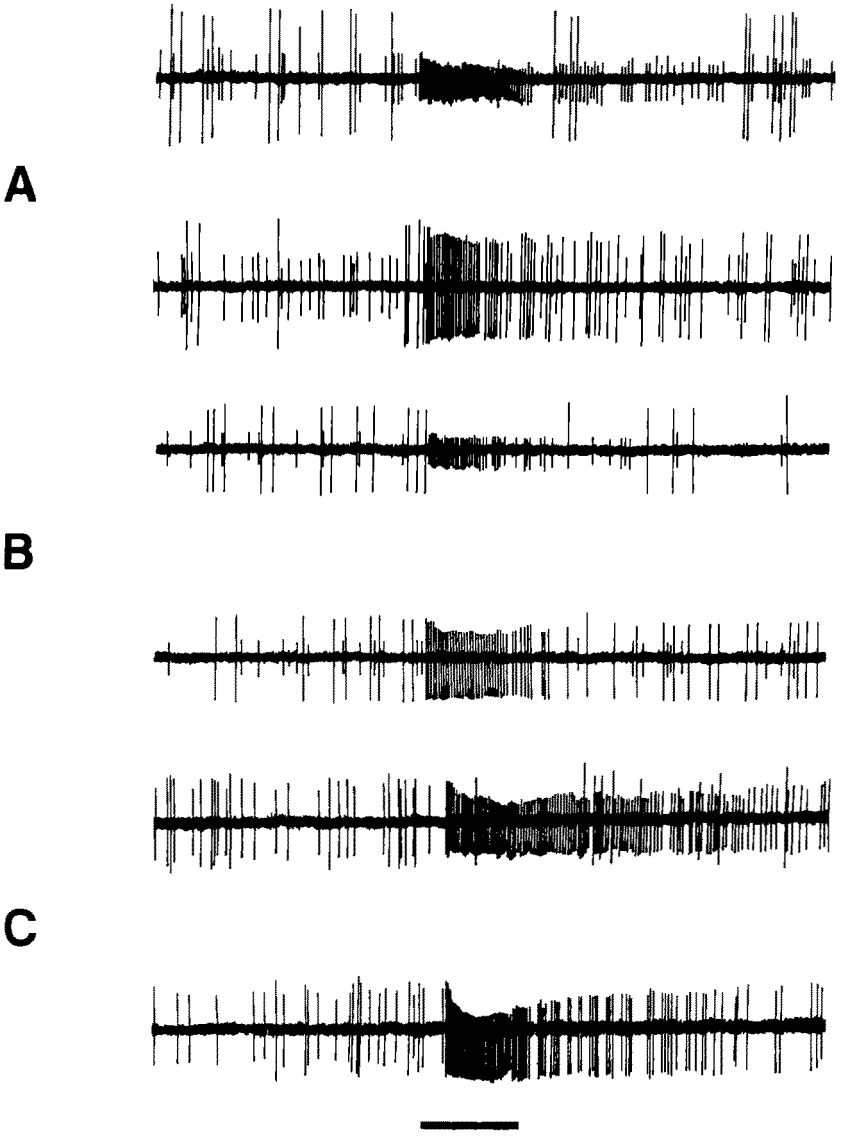

FIG. 4. Cell pairings occurring on *Ceutorhynchus assimilis* antenna: response to *Brassica napus* volatiles applied at 10^{-7} g. (A) Upper trace, methyl salicylate; lower trace, 2-phenylethyl isothiocyanate. (B) Upper trace, (*Z*)-3-hexen-1-ol; lower trace, (*Z*)-3-hexenyl acetate. (C) Upper trace, 2-phenylethanol; lower trace, 1,8-cineole. Bar = 1 sec stimulation.

in the samples in that some components, e.g., (*Z*)-3-hexenyl acetate and 1,8-cineole, elicited only weak EAG responses but showed significant SCR activity. This illustrates the importance of the combined use of these techniques.

The biological activity of the compounds identified from coupled GC–electrophysiology was confirmed initially by EAG at the 10^{-6} g level, which was used as a physiologically discriminating dose reflecting the situation occurring naturally. Previous studies using the same delivery system have shown that, at this level, stimulus concentrations at the antenna for compounds with molecular weights ranging from 120 to 200 are of the order of 10^{11} to 10^{12} molecules/ml of air (Wadhams et al., 1982). Such stimulus concentrations are close to the maximum level of volatiles produced from many crop plants.

Of the 25 electrophysiologically active compounds identified during this study, benzyl alcohol, methyl salicylate, 2-methoxyphenol (guaiacol), and 1-octen-3-ol have not been reported previously among volatiles from *Brassica* spp. Differences in the volatile profiles observed by different authors are undoubtedly due, in part, to variations between cultivars, but are also due to differences in sampling methods. Indeed, use of a coupled thermal desorption–GC-MS technique gave an entirely different profile of volatiles (Robertson et al., 1993), and (*E*,*E*)-α-farnesene, which was found as a major component in this and other studies (Tollsten and Bergström, 1988; Blight et al., 1992; Evans and Allen-Williams, 1992; Jakobsen et al., 1994), was not detected, probably because of its thermal instability.

Differences were observed in the EAG response given by males and females for a number of compounds (Table 1), suggesting a sexual dimorphism that is not apparent from the antennal morphology (Isidoro and Solinas, 1992). In the majority of cases, males showed an enhanced response compared to females and appeared to be more sensitive to the green leaf aldehydes hexanal and (*E*)-2-hexenal. Females were relatively more sensitive to (*E*,*E*)-α-farnesene. This is a dominant component of *B. napus* flower volatiles, and further studies are required to determine the behavioral significance of the differential response. It is interesting to note that (*E*,*E*)-α-farnesene is also one of the key compounds mediating mixture recognition of *B. napus* flower volatiles by foraging honeybees (Pham-Delègue et al., 1992).

A more detailed study on the perception of the electrophysiologically active compounds in *B. napus* air-entrainment samples was carried out using SCR techniques. From coupled GC-SCR analysis, where the antenna is stimulated with a wide range of compounds, and from dose–response data, it is evident that the majority of the olfactory cells have very high compound or functional group specificity, e.g., for the 1-octen-3-ol and 2-phenylethyl NCS cell types (see Figure 3A). Only in the case of cells responding to the oxygenated monoterpenes such as verbenol and verbenone is there any evidence for a gen-

eralist receptor system. These compounds have not been detected among *B. napus* volatiles but occur among volatiles from *B. nigra* (Tollsten and Bergström, 1988). However, the possible generalist nature of this receptor may simply reflect our inability in this study to identify the appropriate key compound for these cells.

Two types of olfactory sensilla are present on the antenna of *C. assimilis* (Isidoro and Solinas, 1992). The more numerous peglike sensilla basiconica are innervated by two sensory neurons, while the hairlike sensilla basiconica are singly innervated. The density of olfactory sensilla on the antenna precludes recording from predetermined olfactory structures with tungsten electrodes. However, the occurrence of numerous recordings showing consistent pairings of specific cell types indicates that these cell pairs are associated with the same peglike basiconic sensillum. The presence of paired receptor systems suggests that specific ratios of these compounds are important in the chemical ecology of this insect.

In general, there was a good correlation between the EAG amplitudes obtained and the proportion of cells responding to the active compounds, although cells responding to (*E*,*E*)-α-farnesene have not yet been found. Only weak EAG responses were obtained with the alkenyl isothiocyanates, but 2-phenylethyl NCS elicited significant EAG responses from both male and female *C. assimilis* antennae (Table 1). Significant EAG responses to alkenyl isothiocyanates have been obtained in previous studies but only at unnaturally high stimulus concentrations (Kozlowski, 1984; Evans and Allen-Williams, 1992). Our SCR studies have shown that perception of isothiocyanates by *C. assimilis* is mediated by both specialist and generalist isothiocyanate cell types, which constitute by far the greatest proportion of receptors on the antenna (Blight et al., 1989). None of these cells responded strongly at natural stimulus concentrations to allyl NCS.

Attraction of *C. assimilis* to mixtures of isothiocyanates has been demonstrated in a linear track olfactometer (Bartlet et al., 1993) and in the field (Blight et al., 1992) and suggests that these compounds play a key role in host-plant recognition by this insect. The behavioral function of 2-phenylethyl NCS requires further investigation, since *C. assimilis* did not respond to this substance when presented alone in the olfactometer, although responses were obtained to both 3-butenyl and 4-pentenyl NCS (Bartlet et al., 1993). However, the presence of cells that respond specifically to 2-phenylethyl NCS (see Figure 3A) does suggest that the compound is involved in insect–plant interactions.

Until relatively recently, agricultural ecosystems incorporating brassicaceous plants comprised a variety of species including *B. oleracea* (cabbage, cauliflower), *B. rapa* (= *campestris*) (turnip rape), *B. nigra* (black mustard), and *Sinapis alba* (white mustard). *B. napus* (swede rape), which originated from crosses between *B. rapa* and *B. oleracea* (U.N., 1935), was at first a relatively

minor component of such ecosystems. The chemical compositions of these species, particularly the glucosinolate content, differ from those of contemporary cultivars of *B. napus* (Fenwick et al., 1983; Heaney and Fenwick, 1987) and, as a result, the volatiles originally influencing host-plant recognition by pests would have been different from those now produced by *B. napus*. Thus, as populations of *C. assimilis* in the U.K. adapted to the large relative area of oilseed rape, the detection of 3-butenyl, 4-pentenyl, and 2-phenylethyl NCS by specific olfactory cells would have become of paramount importance. However, modern double low cultivars of *B. napus* have a lower glucosinolate content and produce only trace amounts of isothiocyanates. The large number of other electrophysiologically active components in the volatiles of present-day *B. napus* suggests that, in the future, these may become more important than glucosinolate catabolites as signals for orientation to the host plant.

ISOLATION, PURIFICATION, AND CHARACTERIZATION OF NEW *Daphnia*-TOXIC COMPOUND FROM AXENIC *Microcystis flos-aquae* STRAIN PCC7806

DIRK JUNGMANN[1]

Max-Planck-Institute of Limnology
August-Thienemann-Str. 2
24306 Ploen, Germany

(Received January 24, 1995; accepted July 7, 1995)

Abstract—A new compound, that is toxic to *Daphnia*, called the *Daphnia*-toxic compound (DTC), was isolated and purified from water extracts of *Microcystis* PCC7806. An established *Daphnia*-bioassay was used as a detection system for the DTC in purified fractions. Temperature and pH stability were used to separate DTC from unstable compounds by changing the pH while the temperature was kept at 90°C. This was followed by ultracentrifugation at 100,000*g*. A molecular cutoff filtration technique was used to separate compounds with a molecular weight >100,000 Da and to reduce the volume of the fraction that was >500 Da. Evaporation in a vacuum led to a fraction that had a suitable volume for further characterization procedures. DTC was resistant to degradation by two bacteria that were isolated from a laboratory culture. DTC was not inactivated by incubation with protease K or pronase E. A strong anion-exchange resin at the stationary phase of the FPLC equipment was used to purify and concentrate the DTC. The molecular weight determined by gel filtration was between 1.0 and 3.1 kDa. A UV spectrum from this purified fraction exhibited absorption maxima at 220, 260, and 360 nm. The ecological and analytical relevance of the DTC is compared with microcystins.

Key Words—*Daphnia*, *Microcystis*, DTC, chemical interaction, toxicity.

INTRODUCTION

Freshwater cyanobacteria are known to produce different toxins, as described in detail by Carmichael (1992). Toxic blooms are commonly associated with the cyanobacterium *Microcystis* spp., which produces cyclic hepatotoxic heptapeptides named microcystins (cyanoginosins). There is no apparent evolutionary adaptive value for cyanobacteria to produce compounds toxic to land animals, but the relevance of secondary metabolites of *Microcystis* to their interaction with aquatic organisms has been investigated. Lampert (1981a,b, 1982) examined the interactions between *Microcystis* and *Daphnia* and found that *Microcystis* was toxic to *Daphnia* and inhibited the filtering rate. Jungmann et al. (1991) separated the compounds responsible for these interactions and found that toxicity to *Daphnia* and filtering inhibition are caused by chemically different compounds. DeMott et al. (1991), who investigated toxic effects of purified microcystin-LR and extracts from *Microcystis* PCC7820 to copepods and daphnids, found significant effects at high concentrations. Jungmann (1992), however, found a fraction from *Microcystis* PCC7806 water extracts that was more active than two known microcystins. Reinikainen et al. (1993) concluded that microcystin concentrations in their experiments were low and the reason for toxicity of *Microcystis* PCC7820 was to be found in other compounds. Jungmann and Benndorf (1994) investigated a *Daphnia*-toxic compound (abbreviated DTC) isolated from the natural and laboratory samples of *Microcystis*.

In this paper I report evidence that acute toxicity of *Microcystis* to *Daphnia* is caused by a compound other than microcystin. This work was conducted to characterize DTC, which is a new compound or compounds with biological activity isolated from *Microcystis* PCC7806. It is toxic to daphnids and is a possible source of interference in bioassays established for microcystin detection. Ecologists should take these results into considerations of *Microcystis*–*Daphnia* interactions and biomanipulation (Shapiro et al., 1975) in nutrient-rich lakes.

METHODS AND MATERIALS

Origin and Cultivation of Organisms. Axenic *Microcystis* PCC7806 was originally supplied by R. Rippka, Pasteur Culture Collection (Paris) and tested for sterility by plating on DEV-agar (Merck No. 11471). Culture conditions and harvesting procedure were described earlier (Jungmann, 1992). *Daphnia pulicaria* was cultured in filtered lake water (0.45 μm, Schleicher & Schuell) taken from the Schöhsee (Lampert, 1982) as previously described by Jungmann et al. (1991). *Microcystis* PCC7806 produces considerable amounts of microcystin-LR and 3-desmethylmicrocystin-LR (Jungmann, 1992; Martin et al., 1990).

Detection of DTC by Daphnia *Bioassay.* Toxicities of different *Microcystis* cell extract fractions were tested against *Daphnia* in 2-ml Eppendorf tubes (polyethylene) filled with 2 ml filtered lake water and a 4-day-old daphnid. The procedure for detection of DTC by *Daphnia* bioassay (a two-day survivorship test) was described in detail by Jungmann and Benndorf (1994). Statistically significant differences between fractions were calculated with two-by-two-tables based on χ^2 test with 51 individuals for each treatment ($P < 0.05$). Animals incubated without food or extract (starved animals) were used as controls. The *Microcystis* extract is expressed as dry weight of lyophilized cell material in a tested volume (milligrams per milliliter).

Extraction Procedure. Lyophilized *Microcystis* was suspended in double-deionized water (−18 MΩ/cm conductivity) to give a concentration of 10 mg/ml at room temperature and sonicated for 15 min. During extraction, the pH was adjusted to pH 10 with 0.1 N NaOH, and the suspension was stirred over night (12 ± 1 hr). The procedure was terminated after readjusting the pH to 10 followed by centrifugation (25,000*g*, 4°C, 30 min, Sorval RC-5B). The pH of the resulting supernatant was lowered to 4 with 0.1 N HCl, the extract was stirred for 15 min, and centrifuged at 100,000*g* (30 min, 4°C, Centrikon T-1075, Kontron). The supernatant contained the toxin (Jungmann and Benndorf, 1994) and was used for further purification steps.

Influence of Temperature on DTC Activity. The supernatant from ultracentrifugation was placed in polyethylene tubes and stored at −18°C up to 10 days. The activity of the DTC was tested after thawing at room temperature. Toxicity to *Daphnia* was determined at a concentration corresponding to 347 μg lyophilized *Microcystis* cell material per milliliter of water. It was necessary to suspend this in 1 ml water to get a DTC concentration in the extract toxic to daphnids. This corresponded to the earlier calculated LC_{50} for extracts from *Microcystis* PCC7806 (Jungmann and Benndorf, 1994). After heating the supernatant for 15 min to 50, 70, and 90°C as well as autoclaving (20 min, 0.21 MPa), toxicity was determined with the *Daphnia* bioassay. The autoclaving procedure was also conducted with double-deionized water to test whether the procedure by itself had any effect on sample toxicity.

Purification of DTC. In further experiments the extraction procedure was modified to incorporate the following steps: (1) extraction at pH 10 overnight (12 hr), (2) centrifugation at 25,000*g*, (3) adjustment of the pH of the supernatant to 4 and heating for 15 min to 90°C, and (4) ultracentrifugation at 100,000*g*. The resulting supernatant from ultracentrifugation was passed through a 100,000-Da ultrafilter membrane (Amicon Diaflo YM-100, 0 62 mm) using a membrane-ultrafilter cell (Amicon series 8000, Witten, Germany). The filter was activated by passing through 50 ml double-deionized water with slight pressure (nitrogen, 0.03 MPa). The sample was passed through by pressure

(nitrogen, 0.05 MPa) with stirring. The fraction > 100,000 Da was resuspended stepwise from the membrane filter (50 mM CH_3COONH_4) until the original volume was reached. The filtered fraction (< 100,000 Da, adjusted to pH 7 with 0.1 M NaOH) and the resuspended fraction (> 100,000 Da) were tested for toxicity to *Daphnia* at a concentration of 347 μg/ml. The next purification step was carried out with same equipment and conditions but using a 500-Da ultrafilter membrane (YC-05, 0 62 mm). The fraction > 500 Da was stepwise resuspended (50 mM CH_3COONH_4 adjusted to pH 7 with 0.1 M NaOH) in 50% of the original volume. Toxicity of the fraction < 500 Da was tested at 347 μg/ml and the > 500-Da fraction at 174 μg/ml.

The volume of the fraction > 500 Da was reduced in vacuum in a glass flask to 10% of the original volume. The glass flask was then stepwise washed with double-deionized water equal to 10% of the original volume and both fractions were pooled. The reduction of the original volume was thus 80%, and *Daphnia* toxicity was tested with 50 μg/ml. This partially purified fraction was stored in polyethylene caps at −18°C until it was used, but not longer than 15 days.

Stability of DTC to Bacterial Attack. Microbiological decomposition of DTC was tested with bacteria isolated by filtration (0.8 μm, cellulose acetate, Nalgene) from the nonaxenic *Microcystis* strain NRC-1 (Gorham, 1964). The two isolated bacteria were characterized with the bioassay of api 20 E (Bio Merieux SA, Marcy l'Etoil, France). One bacterium was identified as a gram negative, motile, staff-shaped organism without spores belonging to the genus *Pseudomonas*. The genus of the second bacterium was not identified, but it was cocci-shaped, gram positive, nonmovable, and without spores.

An unsterile sample of the fraction stored at −18°C was thawed at room temperature and tested immediately and again after 48 hr for toxicity to *Daphnia*. The effect of sterile filtration with 0.2-μm mesh size (Gelman Sciences) was tested with double-deionized water as a control. Then 500 μl of the bacteria-containing culture filtrate was incubated for three days in 50 ml CPS medium (Taylor, 1940; modified by Collins and Willoughly, 1962). A 1-ml sample of partially purified extract was thawed, 200 μl of glucose stock solution (0.5 g/liter) added, and it was incubated with 500 μl of the pregrown bacteria and a sterile filtered medium from a pregrown bacterial culture. The growth of the bacteria in the samples was tested by plating on 4% CPS–agar before testing for toxicity.

Stability of DTC to Proteolytic Enzymes. To test for the presence of peptide bonds, the DTC partially purified sample was incubated with two proteases. A stock solution of pronase E (Merck, Darmstadt, Germany) was made in 40 mM KH_2PO_4/K_2HPO_4, pH 7, 2 mM $CaCl_2$ buffer with an enzyme concentration of 1 μg/μl. A stock solution of protease K (Merck) was made in 50 mM Tris HCl

buffer, pH 8, with a concentration of 1 μg/μl. Pronase E (300 μl) or protease K (300 μl) and 200 μl $CaCl_2$ (200 mM) were added to a 1-ml partially purified sample of DTC and incubated in a temperature-controlled waterbath for 6 hr at 30 ± 2°C. Samples treated with pronase E or protease K were tested for toxicity to *Daphnia* at a concentration of 100 μg/ml. The control was buffer solution with and without enzymes.

Purification with Anion-Exchange Resin. The partially purified extract was concentrated and purified using a strong anion-exchange resin (Mono Q HR 5/5, Pharmacia, Germany) and FPLC equipment (two P500 pumps, LCC 500 controller, 2-ml sample loop, UV M 280 nm detector, fraction collector Frac-100, Rec 482 recorder, Pharmacia). The mobile phase was a gradient of A: 50 mM NH_4CH_3COO, pH 8 (adjusted with 0.1 M NaOH); and B: 75 mM CH_3COOH, 225 mM NaCl. The flow was 1 ml/min and the controller program was as follows: Solvent composition: 0–8 min 100% A; 9–12 min the proportion of B rose from 0 to 100%; 9–45 min 100% B. Sample: From 0 to 8 min, 2-ml samples were loaded twice. Six fractions were collected at 2-min intervals between 8 and 20 min, leading to the 2-ml sample amount. After 45 min the separation procedure was terminated and the column was equilibrated to 100% A. The pH of all collected fractions was monitored by pH indication paper (Macherey & Nagel). If the pH was below 5, NaOH (0.1 M) was added until the pH was between 5 and 6. All sample fractions were tested for DTC activity with a concentration of 200 μg/ml in the *Daphnia* bioassay.

Determination of Molecular Weight of DTC. The above-described FPLC equipment was used to estimate the molecular weight of the DTC. However, the stationary phase was a HiLoad 16/60 column filled with Sephacryl S-100 HR resin (Pharmacia, Germany). The mobile phase was a 100 mM NH_4CH_3COO buffer with a flow of 1 ml/min. The column was calibrated with a kit from Pharmacia containing blue dextran 2000, chymotrypsin A (25 kDa), ovalbumin (43 kDa), and albumin (67 kDa). The total volume of the column was determined with acetone and the K_{av} values were calculated with the equation:

$$K_{av} = V_e - V_0/V_t - V_0$$

in which K_{av} is the distribution coefficient; V_e the elution volume of the collected fraction, V_0 the dead volume of the gel; and V_t the total volume of the gel. The fraction sampler collected 10-ml fractions.

Wavelength Spectra of Fraction Containing DTC. The UV-visible absorption spectrum of DTC in the *Daphnia*-toxic fraction F7 from gel filtration was determined by a UV-VIS photometer (Uvikon 930, Kontron) between 200 and 700 nm using 1-cm quartz cuvettes.

Protein Determination. The protein concentration in fractions was deter-

mined by the Bio-Rad Protein Assay (Bio-Rad, Muenchen). The concentration of dye complex was measured with a photometer (Uvikon 930, Kontron) at 595 nm wavelength in quartz cuvettes. Albumin (Pharmacia) was used as standard. All chemicals were of analytical grade from Merck unless otherwise noted.

RESULTS

Treatment of water extracts with temperatures ranging from −18°C to 121°C did not affect the toxicity of DTC to *Daphnia* (Figure 1). After centrifugation, the toxic supernatant was passed through two different membrane ultrafilters. The supernatant from the ultracentrifugation was the positive toxicity control for the following procedures. The fraction with a molecular weight < 100,000 Da showed significant toxicity (Figure 2), and its toxicity was significantly higher than the toxicity of the fraction with a molecular weight > 100,000 Da.

The fraction < 500 Da showed no toxicity, whereas the fraction with a molecular weight > 500 Da was toxic. Thus, DTC appears to have a molecular weight between 500 and 100,000 Da.

The DTC was resistant to degradation by two isolated bacteria during a 48-hr test (Figure 3). Sterile filtration had no detectable influence on DTC activity.

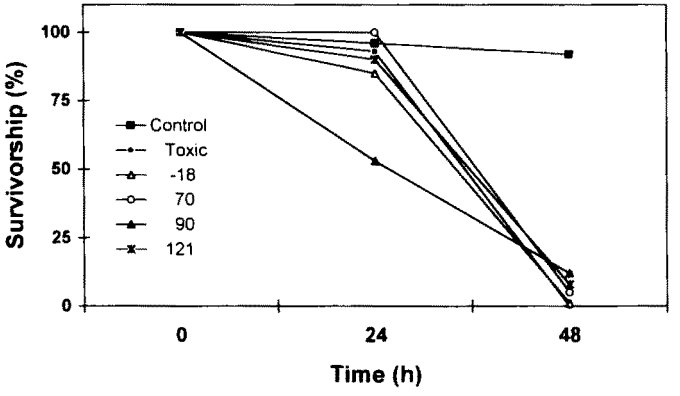

FIG. 1. Survivorship of *D. pulicaria* during incubation with different temperature treated fractions of partially purified *Microcystis* PCC7806 extracts. Control: starved animals; Toxic: positive control (the toxin in fraction of the previous purification step); −18: sample frozen for 10 days at −18°C; 70, 90: fractions heated for 15 min; 121: autoclaved sample; $P < 0.05$.

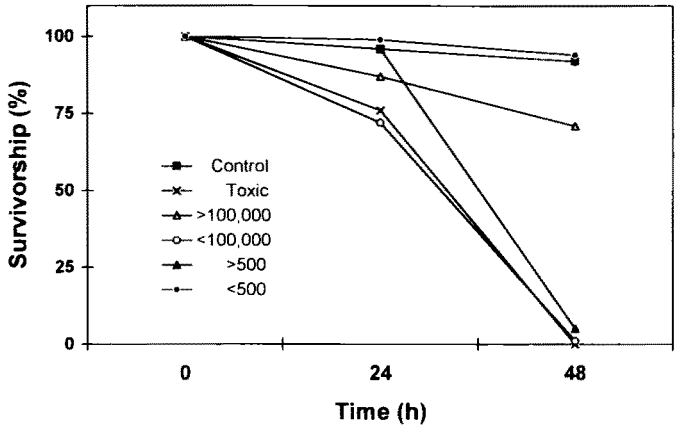

FIG. 2. Survivorship of *D. pulicaria* during incubation with fractions obtained by membrane ultrafiltration of partially purified *Microcystis* PCC7806 extract. Control: starved animals; Toxic: positive control (the toxin in fraction of the previous purification step); fractions of molecular-dependent membrane ultrafiltration are given in Daltons; $P < 0.05$.

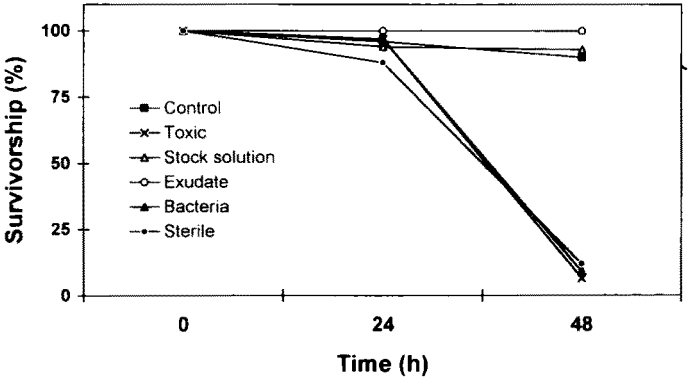

FIG. 3. Survivorship of *D. pulicaria* during incubation with different fractions from bacterial degradation experiments of partially purified *Microcystis* PCC7806 extract. Control: starved animals; Toxic: positive control (the toxin in fraction of the previous purification step); Exudate: exudates from cultured bacteria; Bacteria: fraction after bacterial degradation; Sterile: sterile filtered sample; $N = 51$, $P < 0.05$.

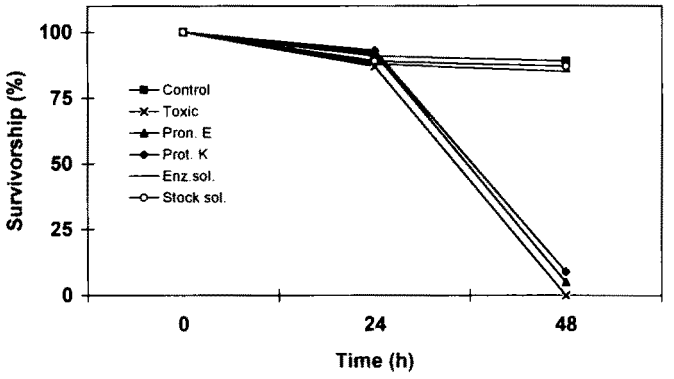

FIG. 4. Survivorship of *D. pulicaria* during incubation with samples exposed to enzymatic degradation of partially purified *Microcystis* PCC7806 extract. Control: starved animals; Toxic: positive control (the toxin in previous fraction); Pron E: pronase E; Prot. K: protease K; Enz.sol.: enzymes without toxin containing sample; Stock sol: stock solutions; $N = 51$; $P < 0.05$.

Figure 4 shows the results of experiments with two nonspecific proteases. The stock solutions as well as the two enzymes had no toxic effect on daphnids or on their survival rates. The activity of DTC was not influenced by an incubation for 6 hr with each protease.

Table 1 shows the toxicity to *Daphnia* of different fractions after separation by an anion-exchange resin. No toxicity was found in fractions sampled from 0 to 8 ml and 20 to 45 ml (data not shown). The 12 to 14-ml fraction (Table 1) was the only sample that had toxic action, and it was used for further purification.

Gel filtration of the toxic fraction indicates a molecular weight between 1.0 and 3.2 kDa for the toxic substance (F7, Table 2). Toxicity of all other fractions was not different from the control except fraction F1, which showed a molecular

weight between 67 and 100 kDa. The 67 to 100-kDa fraction was less toxic in the assay than the fraction with molecular weight (1.0–3.2 kDa). Table 2 shows the survival of *Daphnia* after incubation with each of seven fractions from gel filtration. Protein concentrations in the fractions were between 6.4 and 17.9 μg/ml. In comparison with the protein concentration of crude pH 10 extract (396.2 μg/ml), the purified fractions contained 1.6–4.5% of the originally extracted proteins. Figure 5, a wavelength scan of fraction 7, shows three absorbance maxima at 200, 260, and 340 nm, respectively.

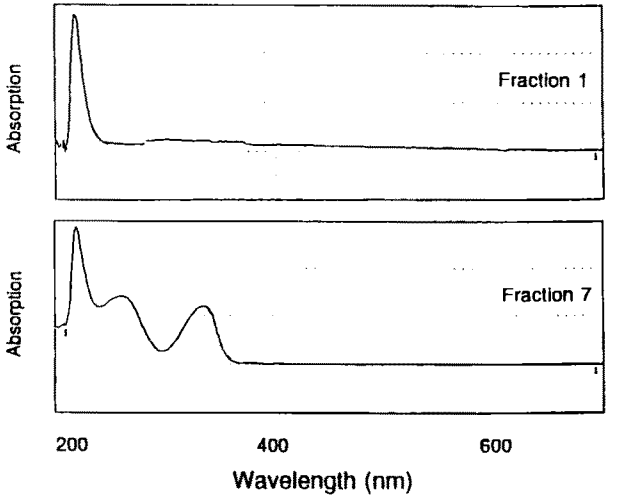

FIG. 5. Wavelength spectrum of the fraction resulting from gel filtration of the partially purified water extract. Spectrum was taken from fraction 7, which contains the DTC. Absorbance maxima were found at 220, 260, and 340 nm.

DISCUSSION

The toxic compound(s) in the extract from *Mycrocystis* described herein is probably not a micocystin, since known microcystins from *Microcystis* spp. are not responsible for acute toxicity to *Daphnia* (Jungmann, 1992; Reinikainen et al., 1993; Jungmann and Benndorf, 1994). Weckesser and Martin (1990) found that microcystins were stable at 160°C, and Martin et al. (1993) examined cyanopeptolins, which are stable at 100°C. These temperature stabilities are comparable with that found for DTC. Temperature stability of the *Microcystis* toxin was used to advantage in purification of the extract by heating it to 90°C and then separating precipitated heat-sensitive compounds by centrifugation. Crude extract or purified fractions of DTC were stable when stored at −18°C. These results are in contrast to those from Peñaloza et al. (1991), who extracted and purified a compound from natural *Microcystis* samples that was toxic to *Daphnia magna* but was inactivated by boiling for 5 min. Possible explanations for these contradictory results could be that *Microcystis* can synthesize a variety of different toxins or that field-collected samples might contain other contaminants that are toxic to zooplankton.

Fractionation by molecular cutoff filtration separated large compounds, reduced the original volume by 50%, and gave an indication of the range of molecular weight for the DTC. Bacteria and fungi typically degrade complex compounds in lake ecosystems (Odum, 1983), but DTC was resistant to degradation by two bacteria tested. Investigations with bacteria or fungi from natural sources with *Microcystis* may reveal organisms with degradation activity. Kiviranta et al. (1991) found that microcystin-LR persisted for two to three months in cultures enriched with water and bacteria from a Finnish river, but Watanabe et al. (1992) observed the decomposition of microcystin-LR and microcystin-YR within two months after being released into a nonaxenic culture medium. Jones and Orr (1994) observed decomposition of microcystin-LR within one day and concluded that fauna and chemical composition of the environment were major influences on the decomposition process.

DTC was resistant to hydrolysis by pronase E and protease K, both of which cut peptide bonds unspecifically. This may mean the absence of peptide bonds in DTC or the presence of some unusual amino acid composition of DTC. Separation by strong anion-exchange resin was successful for the purification and concentration of DTC and indicates toxic compounds with a negative charge. Molecular cutoff filtration showed that DTC has a molecular weight between 500 and 100,000 Da. Two fractions from gel filtration showed activity in the *Daphnia* bioassay. Fraction 7 was more toxic to *Daphnia* than fraction 1 ($P > 0.05$). This leads to the conclusion that fraction 7 contains the DTC. However, it is not clear whether another *Daphnia*-toxic compound is responsible for the minor toxicity in fraction 1 or whether this is a result of the technique used.

The DTC in fraction 7 has a molecular weight between 1 and 3.2 kDa. This molecular weight is close to the molecular weight of microcystins (Carmichael, 1992). However, other results (Jungmann, 1992; Jungmann and Benndorf, 1994; Reinikainen et al., 1993) showed that toxicity of *Microcystis* to *Daphnia* is independent of microcystins. The molecular weight of the compound toxic to *Daphnia* isolated by Peñaloza et al. (1991) is similar to the DTC in fraction 7. However, the compound isolated by Peñaloza et al. (1991) was not stable at high temperatures, in contrast to DTC in this report.

Determination of absorbance maxima of fraction 7 (Table 2) suggests a method that may be useful for detecting and measuring DTC in future work. It is not clear at present, however, if the toxic principle(s) show these maxima or if that absorption might be due to other compounds in the fraction.

Acknowledgments—I thank W.R. DeMott and an anonymous reviewer for critical comments on the manuscript. N. Zehrbach and I. Grüneberg provided linguistic improvements and D. Fraude provided excellent technical assistance.

QUADRUPOLE STORAGE MASS SPECTROMETRY OF MONO- AND DIMETHYLALKANES

ROBERT E. DOOLITTLE,* ADRON T. PROVEAUX, HANS T. ALBORN, and ROBERT R. HEATH

Insect Attractants, Behavior, and Basic Biology Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Gainesville, Florida 32604

(Received January 15, 1995; accepted July 6, 1995)

Abstract—Monomethyl and dimethylalkanes with one, two, three, four, five, and seven methylene groups separating the methyl branches were synthesized and analyzed by magnetic sector and quadrupole storage (ion trap) mass spectrometry. The spectra produced by the magnetic sector instrument were in good agreement with previously reported data, whereas the ion trap spectrometer produced ions resulting from cleavages adjacent to the branching points, markedly different than those from the magnetic sector instrument. Fragmentation patterns show that the ion trap mass spectrometer can be used to characterize branched alkanes in nanogram and subnanogram quantities.

Key Words—insect hydrocarbons, monomethyl alkanes, dimethylalkanes, mass spectra ion trap, magnetic sector.

INTRODUCTION

The determination of the structure of methyl-branched alkanes in nanogram amounts or less is important in investigations designed to elucidate the chemistry of interactions of insects with other insects and their environment, and especially when the cuticular waxes of individual insects are analyzed for chemotaxonomic purposes (Jackson and Blomquist, 1976; Lockey, 1978, 1980; Jacob, 1979). Hydrocarbons found on the cuticle of insects can serve as chemical messengers

(Blomquist and Dillwith, 1985); they also can protect insects from desiccation (Hadley, 1994; Lockey, 1976). 13-Methylhentriacontane, found in the corn earworm *Helicoverpa zea* (Boddie), triggers a short-range host-seeking response in *Microplitis croceipes* (Cresson), which is a parasitic wasp (Jones et al., 1971). Dimethyl-substituted alkanes have been identified in cuticular extracts of gypsy moth, *Lymantria dispar* (L.) pupae that elicit host recognition and oviposition behavior by the parasitoid *Brachymeria intermedia* (Nees) (Alborn et al., in press).

During the course of identification of hydrocarbons from insects, we recorded their mass spectra on a quadrupole storage (ion trap) mass spectrometer. Since this methodology generally displays enhanced sensitivity and thus a lower detection limit than conventional quadrupole spectrometers (and the instruments are of significantly lower cost) (March and Hughes, 1989), it is being applied widely in the identification of nanogram and smaller quantities of biologically active chemicals from biological and environmental sources. Fragment ions in the electron impact mass spectra of monomethyl-branched alkanes from conventional magnetic sector instruments that are characteristic and diagnostic for the position of the branching point were observed by Biemann (1962) and Spiteller (1966). Fragmentation of the molecular ion occurs on either side of the branch with charge retention on the substituted carbon atom producing a stable carbocation ($C_nH_{2n+1}^+$) or rearrangement and cleavage resulting in the production of a $C_nH_{2n}^+$ ion that is prominent and sometimes more intense than the $C_nH_{2n+1}^+$ ion. This phenomenon was initially observed by Biemann and Spiteller and subsequently thoroughly investigated in a definitive study of dimethyl-branched alkanes by McCarthy et al. (1968) with subsequent publications by Nelson et al. (1972) and Pomonis et al. (1978, 1980), in which this type of cleavage was demonstrated and documented.

Simultaneously, the parent ions produce ions of even mass ($C_nH_{2n}^+$) that do not contain the other branch. These ions will generally be dominant when they contain seven to nine carbon atoms (McCarthy et al., 1968) and when the mass ratio of the neutral particle (NP) produced concomitantly with these fragment ions (FI) is high (NP/FI > 1) (Nelson et al., 1972). When the fragment ions contain more than nine carbon atoms, the ratio of the even to odd ion intensities decreases in magnitude unless there is a coincidental increase in the mass of the neutral particle. The fragment ions containing the remaining branch do not exhibit a marked doublet of odd and even peaks, but the abundance of these ions can be significant (Pomonis et al., 1980; Nelson and Sukkestad, 1970, 1975). Since the mass spectrometry of methyl-branched alkanes using a quadrupole storage (ion trap) spectrometer has not been reported, we present here spectra from a variety of mono- and dimethylbranched alkanes and compare their spectra with those obtained from a magnetic sector instrument.

METHODS AND MATERIALS

Mass Spectrometry. The magnetic sector mass spectrometer built by Gunnar Stenhagen at the Department of Chemical Ecology, Göteborg Universitet, Göteborg, Sweden, is a large-radius (300-mm) magnetic sector (90°) instrument built for high-sensitivity GC-MS work, and it consisted of equipment from several manufacturers. The high-vacuum system and the analyzer were constructed in Göteborg. The ion source housing was evacuated by a diffusion pump (Edwards Diffstak 160-700) and was largely isolated from the analyzer vacuum system by the ion source exit slit. The analyzer was evacuated with a second diffusion pump (Edwards EO4) and the detector with a turbomolecular pump (Pfeiffer 250). The forevacuum system consisted of two independent forevacuum pumps (Edwards 112). The first pump backed the ion source diffusion pump. The second forevacuum backed the analyzer and the detector. The ion source temperature was 200°C and was operated at 70 eV ionizing energy. Samples were introduced via a direct inlet probe as dilute solutions (2–4 ng/μl) in hexane, which was evaporated by the forepump.

The quadrupole storage mass spectrometer (ion trap) was a Finnigan MAT ITS 40 Magnum operated at 70 eV ionizing energy in the electron impact mode. The spectrometer was interfaced to a Varian 3400 gas chromatograph equipped with either a 30-m × 0.25-mm (J&W Scientific, Inc.) nondeactivated fused silica capillary tube or a 30-m × 0.25-mm DB-5ms (J&W Scientific, Inc.) fused silica capillary column with a 0.1-μm film thickness. Both the column and tube were operated at a linear flow velocity of 18 cm/sec, and the samples were introduced as solutions (2–4 ng/μl, injections) in hexane directly on column via an SPI injector. The SPI injector is an on-column septum programmable injector that is programmed from 60°C to 300°C at 150°C/min during a column programmed run. The column was programmed during an analytical run as follows: the temperature was held at 60° for 1 min and then programmed at 20°C/min to a maximum temperature of 285°C. The source temperature and acquisition (ACQ) tuning parameters were varied in order to study the effect of these parameters on the ion abundances for 13-methylhentriacontane (entry B, Table 1).

Syntheses. The hydrocarbons (designated as entry A, B, C, etc., in Tables 1–5 and Figures 5–7 below) were synthesized by a variety of methods depending upon their structure. The monomethylalkanes A, B, and C were prepared by a Wittig olefination procedure involving the preparation of a 1-methylalkyltriphenylphosphonium salt followed by reaction with the appropriate aldehyde as described by Sonnet (1976), with subsequent reduction of the olefinic product to the requisite hydrocarbon.

The hydrocarbon with one methylene group between the methyl branches, 11,13-dimethyltritriacontane (D), was prepared from α-methyldodecanoic acid

[a] Data are *m/z* abundances as percentage of base peak which was *m/z* 57 for each spectrometer.
[b] *X* and *Y* are the number of carbon atoms on either side of the methyl branch.

via reduction to the alcohol, oxidation to the aldehyde, and Wittig condensation with 1-methyldocosyltriphenylphosphonium bromide followed by reduction of the olefin. 11,14-Dimethyltetratriacontane (E) was prepared via the reaction of the same phosphonium salt as for D with 3-methyltridecanal prepared from 4-hydroxy-2-butanone by conversion to the tetrahydropyranyl (THP) ether, condensation with decyltriphenylphosphonium bromide, hydrogenation and cleavage of the THP ether, and oxidation of the resultant alcohol to the requisite aldehyde. 15,18-Dimethyltritriacontane (F) was prepared from 19-methyl-16-tritriacontanone via methylenation with methylene triphenylphosphorane followed by hydrogenation. The hydrocarbons with three methylene groups between the methyl branches (G–P) were prepared from 5-hydroxy-2-pentanone THP and the appropriate 1-methylalkyltriphenylphosphonium salts according to Sonnet (1976). The remaining dimethylalkanes (Q–U) were prepared from thiophene by procedures and modifications of procedures developed by Pomonis et al. (1989).

RESULTS AND DISCUSSION

Inspection of the mass spectra in Tables 1 and 2 shows clearly the differences in the ion trap and magnetic sector instruments in regard to the production of diagnostic ions from cleavages at branching points. In addition, the ion trap produces even lower abundances of molecular ions than the magnetic sector instrument. The ion trap does not, at least in the present work, appear to have an advantage of enhanced sensitivity over the magnetic sector instrument for the detection of very small amounts of hydrocarbons. The reference peak for the calculation of relative abundances is m/z 57 for all spectra in both spectrometers.

When the spectra were recorded using the standard "normal" values for the source temperature and acquisition (ACQ) parameters [source temperature $\approx$ 200°C (ACQ) segment tune parameters (SC) = 100, and radio frequency time factor (RF) = 125], very low abundances were observed for all ions. Since a study had been ongoing in our laboratory delineating the effects of these parameters on the abundances of ions produced from other types of organic molecules, and since Phinney (1993) had reported the effect of source temperature on ion abundance, these parameters were varied for 13-methylhentriacontane and the results recorded.

It is clear from the data in Figures 1 and 2 that the source temperature and ACQ tuning parameters have marked effects on the abundances of ions produced from hydrocarbons in the ion trap. We studied the effect of variation of the source temperature on the intensities of ion b-1 (m/z 280) and h-3 (m/z 166) for 13-methylhentriacontane (B), and the data are presented in Figure 1. We studied the effect of changing the acquisition (ACQ) tuning parameters on the intensities

[a] Data are *m/z* abundances as percentage of base peak which was *m/z* 57 each spectrometer.
[b] *N* is equal to the number of methylene groups ($-CH_2-$) between the methyl branches.
[c] *X* and *Y* are the number of carbon atoms on either side of the methyl branches.

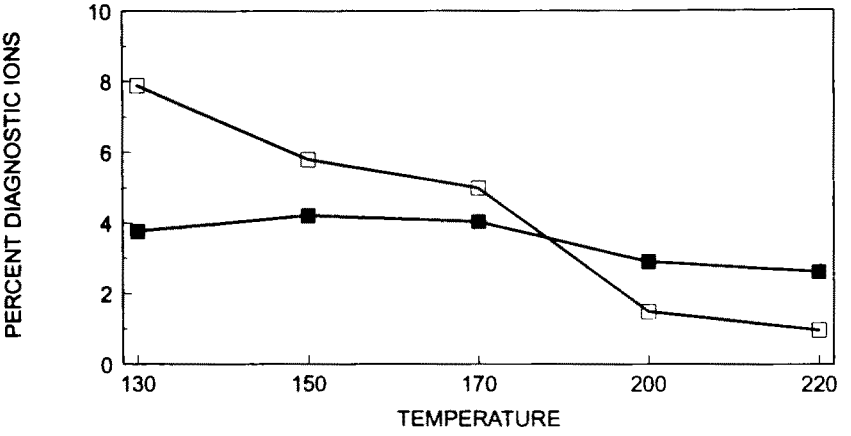

FIG. 1. Diagnostic ions *m/z* 166 (h-3; - ■ -) and 280 (b-1; - □ -) vs. ion source temperature for 13-methylhentriacontane (entry B).

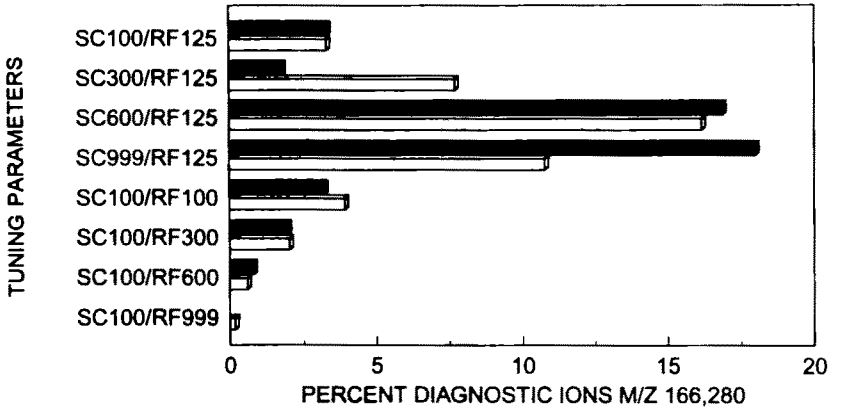

FIG. 2. Acquisition tuning parameters (segment tune parameters, SC; radio frequency tune factor, RF) vs. diagnostic ions at *m/z* 166 (h-3; ■) and 280 (b-1; □) for 13-methylhentriacontane (entry B). SC represents the ionization time determined by the automatic gain control prescan pulse. The values of 100–999 are arbitrary values on a scale and do not represent 100% through 999%. RF is the radio frequency level number given as a percent of the RF voltage (storage voltage) applied to the ring electrode.

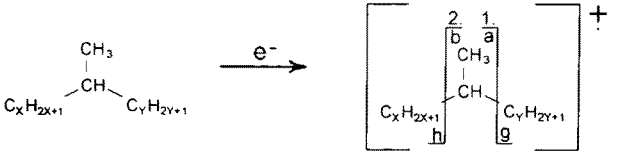
of these same two ions, and the data are presented in Figure 2. The (ACQ) SC values are on an arbitrary scale that represents the segment ionization pulse lengths as a percent of the calculated ionization pulse time determined by the automatic gain control prescan pulse. By changing this value, we were able to increase the lengths of the ionization pulse times in three of the four segments of the mass scale. The four segments are 10–99, 100–249, 250–449, and 450–650 amu. We increased the ionization time for the three highest atomic mass unit segments and did so uniformly for all three segments, although the capability of using a different ionization time for each amu segment is available.

RF represents the radio frequency level number as a percent for the RF applied to the ring electrode. This RF voltage is used to focus the ions in the center of the ion trap, and thus, it is referred to as the storage voltage. It creates the field that temporarily stores ions until they are made unstable by changing the voltage and are ejected from the trap into the electron multiplier for detection. The fixed RF voltage sets a cutoff of mass, and ions below this value are ejected from the trap prior to ionization. This has the effect of limiting the ionization of residual ions and increases sample ion concentration, which increases spectral sensitivity.

The data presented in Figures 1 and 2 show clearly that the source temperature and ionization pulse time SC parameters have the greatest influences on the abundances of the ions from hydrocarbons. The RF variation had very little effect on ion abundances.

The monomethylalkanes exhibited a markedly different fragmentation pattern than the dimethylalkanes in the two spectrometers, producing the ions listed in Figure 3. The results from the magnetic sector instrument were in good agreement with those reported (McCarthy et al., 1968; Nelson and Sukkestad, 1970), with monomethyl-branched compounds cleaving at the branches with production of pairs of peaks representing ions a and b from cleavages 1 and 2.



Cleavage	Produced Ions
1.	a, a-1, a-2, a-3, g, g-1, g-2, g-3
2.	b, b-1, b-2, b-3, h, h-1, h-2, h-3

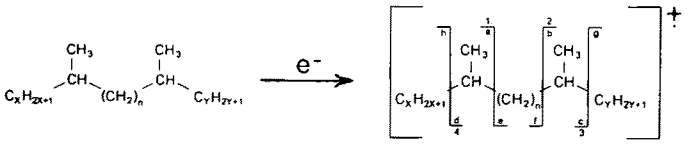
FIG. 3. Characteristic ions produced by fragmentation of monomethylalkanes.

respectively. The ratio of the substituted even-fragment-ion intensity (a-1 or b-1) to the intensity of the fragment ions a or b is greater than 1, i.e., the even ion dominates in the pair. The ion abundances for three monomethyl compounds, 9-methylheptacosane, 13-methylhentriacontane, and 16-methylhexatriacontane, are presented in Table 1.

The same compounds produced markedly different spectra in the ion trap (Table 1). The abundances of ions in which the charge was retained on the unsubstituted carbon atom (ions g and h of Figure 3) were clearly evident in these spectra, and ions with one, two, or even three fewer hydrogen atoms, i.e., g-1, g-2, g-3 and h-1, h-2, h-3, were significant, especially in the case of 13-methylhentriacontane (entry B, Table 1).

The abundances of the ions produced from the dimethyl-branched alkanes (Figure 4) in the magnetic sector and the ion trap instruments are listed in Table 2. Examination of the data shows that there are dramatic differences between the spectra produced by the two spectrometers. The abundances for the magnetic sector instrument are in agreement with published reports (McCarthy et al., 1968; Nelson and Sukkestad, 1970). The fragment ions containing a substituted carbon gave high abundances (ions a, b, c, and d). The molecular ions produced significant amounts (sometimes dominant) of even ions only when no second branch was present (ions a and b from cleavages 1 and 2). Since ions e, f, g, and h were usually produced in low abundances they were not included in Table 2. An exception to this is 11,16-dimethylhexatriacontane (Q) containing four methylene groups between the branches. It produced ions e and f (from cleavages 1 and 2) at *m/z* 365 and 225 in significant abundances. This special case has been reported (Pomonis et al., 1978), and these ions are clearly present in the spectrum of Q (Figure 5, magnetic sector).

Examination of the abundances produced by the dimethyl-branched alkanes in the ion trap reveals that, analogous to the magnetic sector instrument, only ions a, b, c, and d were prominent. As with the monomethyl compounds,



Cleavage	Produced Ions
1.	a, a-1, a-2, a-3
2.	b, b-1, b-2, b-3
3.	c, c-1, c-2, c-3
4.	d, d-1, d-2, d-3

FIG. 4. Characteristic ions produced by fragmentation of dimethylalkanes.

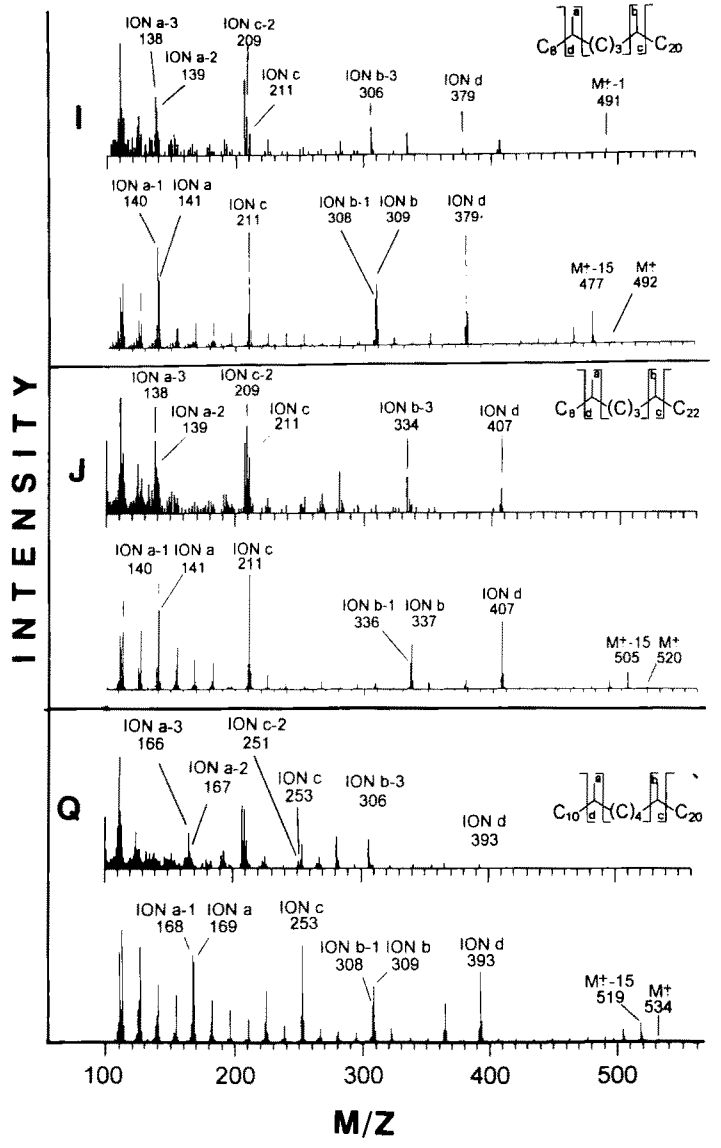


FIG. 5. Ion trap (top) and magnetic sector (bottom) mass spectra pairs of 9,13-dimethyltritriacontane (I), 9,13-dimethylpentatriacontane (J), and 11,16-dimethylhexatriacontane (Q). Abundances are relative to *m/z* 57.

production of ions with one, two, or three fewer hydrogen atoms was highly significant, with ions a-3 and b-3 predominant. Production of ions c-3 and d-3 was minor. 11,16-Dimethylhexatriacontane (Q) gave quite different results with the ion trap; ions at *m/z* 365 and 225 could not be seen in the ion trap spectrum (Figure 5). Conditions, i.e., source temperature and ACQ parameters, that gave optimum results for the monomethyl-branched alkanes were found to give the optimum results for the dimethyl-branched alkanes as well (low source temperature and SC 600, RF 125).

The ratios of the even to odd ion abundances for all the hydrocarbons in the magnetic sector instrument are presented in Table 3. These data are in general agreement (with two exceptions) with results reported earlier (McCarthy et al., 1968). The monomethyl-branched alkanes produce an a-1/a intensity ratio larger than 1.0 when the neutral particle (NP) to fragment ion (FI) ratio (NP/FIa as expressed in carbon numbers) is relatively large and less than 1 when the neutral particle to fragment ion (NP/FIb ratio) is relatively small. The data of Table 3 for the dimethyl-branched alkanes are at variance with these observations in the two entries F and K that have ratios of the NP to FIb of 0.82 and 0.56, respectively. Ratios of b-1/b for F and K are 1.29 and 1.25, respectively. Entry P has a NP/FIb ratio of 0.55 (approximately equal to entry K) and a ratio of 0.67 for b-1/b. We do not have an explanation for these discrepancies.

Our data confirm observations (McCarthy et al., 1968) that the ions containing the second branch (c and d) do not produce an even-to-odd ion ratio larger than 1.0 for any values of FI size or NP value. The data in Table 3 confirm the conclusions reached by Pomonis (1978), i.e., that when the number of methylene groups between the methyl branches is 0 or 1, it is difficult to predict the ratio of the intensities of the even and odd ion types (i.e., entry D had a ratio of a-1/a greater than 1). The data in Table 3 also confirm the observation that when the number of intervening methylene groups is two or greater, the even-to-odd ion ratios for ions a and a-1 (the smaller unbranched ions) will be greater than 1.

The eight even ion/odd ion ratios, a-1/a, a-1/a-2, a-3/a, a-3/a-2, b-1/b, b-1/b-2, b-3/b, and b-3/b-2, that can be produced for the substituted unbranched fragment ions a and b were calculated from the ion trap data and are presented in Tables 4 and 5, respectively. In general, ratios were fairly consistent within each group of hydrocarbons (either mono- or dimethyl-branched) with the ratios of a-1/a-2 and b-1/b-2 being the most consistent. The monomethylalkanes produced ratios greater than 1 and the dimethylalkanes gave ratios less than 1. The a-3/a and b-3/b ratios were consistent for the dimethylalkanes, with the a-3/a-2 and b-3/b-2 ratios consistently larger than 1, except for G, R, and U where the *m/z* values were low. The ion trap and magnetic sector spectra for 13-methylhentriacontane (B) and for each value of the number of methylene units separating the methyl branches are presented in Figures 5–7. The background

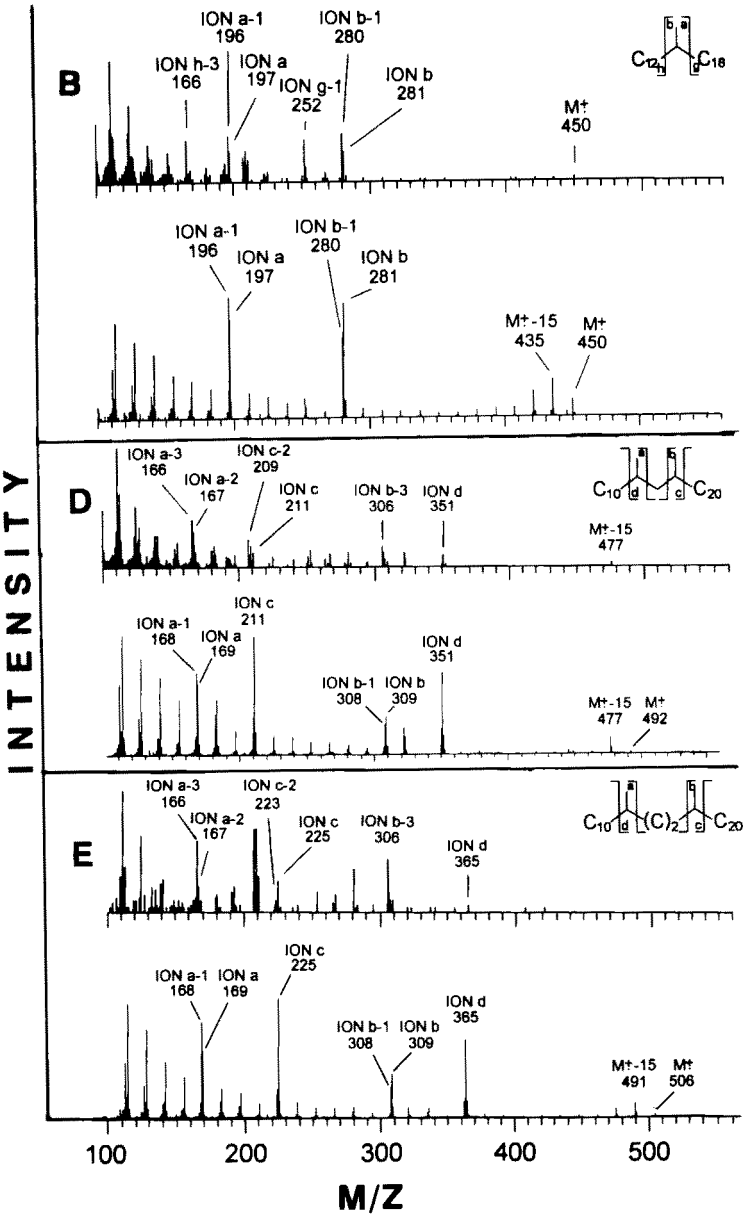

FIG. 6. Ion trap (top) and magnetic sector (bottom) mass spectra pairs of 13-methylhentriacontane (B), 11,13-dimethyltritriacontane (D), and 11,14-dimethyltetratriacontane (E). Abundances are relative to *m/z* 57.

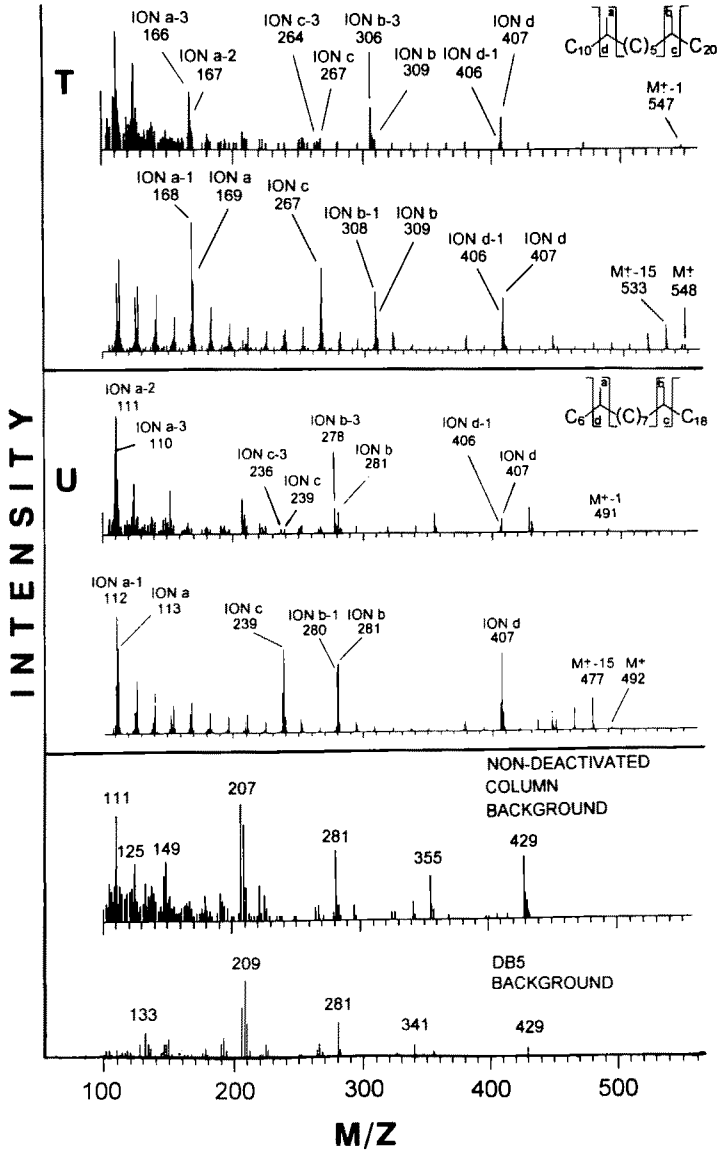

FIG. 7. Ion trap (top) and magnetic sector (bottom) mass spectra pairs of 11,17-dimethylheptatriacontane (T), 7,15-dimethyltritriacontane (U), and background magnetic sector mass spectra from non-deactivated and DB-5 columns. Abundances are relative to m/z 57.

spectra for the deactivated capillary tube and the DB-5ms column are included for comparison purposes. Analysis of the spectra recorded from the varying amounts of 11,16-dimethylhexatriacontane showed that the ratios of ion abundances, such as a-1/a-3, etc., were not dependent upon the amount of sample introduced into the ion trap spectrometer.

CONCLUSIONS

The mass spectra produced by the magnetic sector instrument from the series of hydrocarbons studied are consistent with those reported in the literature. The data collected from the quadrupole storage spectrometer (ion trap) clearly demonstrate that it can be used to identify mono- and dimethyl-branched alkanes in nanogram quantities, providing conditions in the spectrometer are adjusted for this application. The atomic mass unit segments did not vary in size from their standard values, and the highest three segments were subjected to the same ionization pulse length. Since these are two more parameters that can be changed once the *m/z* values for ions resulting from cleavages at branching points are known or suspected for a hydrocarbon, changes in these parameters might result in higher abundances for diagnostic ions. We would encourage other researchers interested in this area to pursue such investigations. At present, we do not know why the changes in the source temperature and ACQ parameters affected diagnostic ion abundances, but the subject is under investigation. It is also important to be aware that the *m/z* values and distribution of fragment ions in the ion trap will differ markedly from the patterns produced by magnetic sector instruments. Scientists attempting to use the ion trap for the identification of branched hydrocarbons will also have to be aware that molecular ion intensities will be weak and sensitivities not as good as is normally found for other structural types of organic molecules. The spectra presented in Figures 5–7 illustrate clearly the differences to be expected when the spectra of monomethyl- and dimethylalkanes from magnetic sector and ion trap spectrometers are compared. These data can aid scientists in the identification of branched-chain hydrocarbons using ion trap spectrometers.

Acknowledgments—We acknowledge J. George Pomonis of ARS, USDA, Fargo, North Dakota, for the generous gift of 19-methyl-16-tritriacontanone, and Gunnar Stenhagen of the Department of Organic Chemistry, Göteborg Universitet, Göteborg, Sweden, for recording the magnetic sector spectra.

HOST-SPECIFIC RECOGNITION KAIROMONE FOR THE PARASITOID *Microplitis croceipes* (CRESSON)

H.T. ALBORN,[1,2] W.J. LEWIS,[3] and J.H. TUMLINSON[1,*]

(Received January 13, 1995; accepted July 6, 1995)

Abstract—A water-extractable host recognition kairomone in frass of corn earworm, *Helicoverpa zea* Boddie (Lepidoptera: Noctuidae), host larvae stimulates antennation by females of the parasitoid *Microplitis croceipes* Cresson (Braconidae: Hymenoptera). In addition, when the wasps contact water extracts of host frass they will subsequently fly in a flight tunnel to odor associated with the extract. Contact with water extracts of cowpea leaves or with water extracts of frass from larvae of nonhost beet armyworm, fall armyworm, or cabbage looper that were fed cowpea leaves does not stimulate antennation; nor do wasps fly to associated odors after contact with these substances. However, contact with the water extract of host frass in association with hexane extract of cowpea-fed nonhost frass will induce the wasps to subsequently fly to the hexane extract of the nonhost frass when it is used as an odor source in a flight tunnel. Thus the host-specific kairomone by which *M. croceipes* recognizes the frass of its host is extractable with water. This substance plays a crucial role in the foraging behavior of this parasitoid by allowing it to recognize host frass and to learn to search for odors originating from plants on which the host is feeding.

Key Words—Associative learning, recognition kairomone, host specific, *Microplitis croceipes*, corn earworm, *Helicoverpa zea*.

INTRODUCTION

The oligophagous wasp *Microplitis croceipes* (Cresson) attacks only *Heliothis* and *Helicoverpa* larvae (Lewis, 1970), which are polyphagous and severe pests on several important crops such as corn and cotton. *M. croceipes* is considered a candidate for biological control of these pest insects (Lewis, 1970), but its use on a practical basis is limited because of a lack of a reliable method for employing it as a control agent. In an effort to develop more effective methods of biological control of insect pests with natural enemies, we have been studying the foraging behavior of insect parasitoids. Artificially reared parasitoids must be able to locate and to recognize their host insects in the field. We must also be able to retain native or released parasitoids in a target crop and keep them searching for hosts.

Semiochemicals associated with the host or the host habitat play a major role in location and recognition of hosts by many parasitoids (Vinson, 1976, 1984; Turlings et al., 1990, 1992). However, it has been shown that females of *M. croceipes*, as well as the closely related *M. demolitor* (Wilkinson), reared in the laboratory on host larvae fed artificial diet do not respond to host-related cues released by a natural plant–host complex, unless first given a brief encounter with plant-fed hosts or their products (e.g., frass) (Drost et al., 1986; Hérard et al., 1988; Eller et al., 1988). An actual encounter with a host larva is not necessary. After experiencing host frass only, or a combination of water and hexane extracts of the frass, female *M. croceipes* wasps flew in a wind tunnel as often to a volatile source consisting of hexane extract of the frass as to the frass itself. However, after experiencing only hexane extract of frass, the wasps showed a very low flight response, which was not significantly different from the response by inexperienced wasps (Lewis and Tumlinson, 1988). Response after experiencing only water extracts of frass was also very low. The conclusion was that host frass contained recognition kairomones. When the kairomones are perceived by female wasps in conjunction with host-related volatiles, such as those released from host frass hexane extract, the likelihood of subsequent upwind anemotactic flight and eventual location of a source releasing the same volatiles is increased. Although antennation of host frass and the subsequent encounter with recognition kairomones will initiate host searching behavior in mated female wasps, this is not simple innate behavior. Lewis and Tumlinson (1988) showed that female wasps also are able to learn to recognize, and subsequently to fly to, novel volatiles, such as vanilla, presented in combination with the host frass. Thus, associative learning is a very important part of the host recognition process.

While antennating host frass on a plant, a naive female wasp (without a

previous experience) will be able to associate volatiles released by the frass as well as volatiles released by the damaged plant. Eller et al. (1992) showed that host frass is an important emitter of volatile attractants. More recently, it has been shown that, at least for long distance attraction, volatiles emitted by the damaged host plant are more important (McCall et al., 1993). If given several experiences with host insects feeding on one plant species and nonhost insects feeding on another plant species, the wasps preferentially respond to volatiles being released by damaged plants of the species on which the host insects were feeding (McCall et al., 1993). Again, an encounter with host larvae does not seem to be necessary for this association. However, if the wasps are given an experience with nonhost frass, no association will be made, and the wasps will not respond to any volatile cues. When *M. croceipes* females were experienced on host frass, they flew almost as well to a hexane extract of nonhost frass (*Trichoplusia ni* Hübner) as to host frass hexane extract, but showed no flight response to either of the hexane extracts after experience on nonhost frass (Lewis et al., 1991).

All these results point to very host-specific recognition kairomones present in host frass or possibly the presence of deterring components in frass from nonhost insect larvae. In either case, the antennation of frass and the subsequent association of host-related cues seems to be an extremely important part of the foraging strategy of *M. croceipes* wasps.

Jones et al. (1971) showed that *Helicoverpa* (*Heliothis*) *zea* (Boddie) frass contained hydrocarbons that were attractive to *M. croceipes* females at close range and induced extensive antennation by the females. The most active component of these hydrocarbons was 13-methylhentriacontane. Lewis et al. (1991) showed that addition of this component to hexane and water extracts of host frass on which wasps were experienced resulted in an increased flight response in the wind tunnel to host frass hexane extract. The question then arose as to whether there might not be other factors like 13-methylhentriacontane present in the hexane extract of host frass that serve as important recognition kairomones, in addition to the factor present in the water extract. The possibility also existed that the water-soluble component might be present in nonhost frass, and the lack of response by female wasps after experiencing nonhost frass might be because some hexane-soluble component of host frass is not present in nonhost frass. To answer these questions we decided to investigate the host specificity of water/hexane-soluble kairomones by preparing the same type of extracts of frass from the host—corn earworm, CEW (*Helicoverpa zea*)—and from three nonhosts—cabbage looper, CL (*Trichoplusia ni*); beet armyworm, BAW (*Spodoptera exigua* Hübner); and fall armyworm, FAW (*Spodoptera frugiperda* J.E. Smith); and to bioassay these in different combinations. To test the possibility

that the recognition kairomone might be of plant origin, we also bioassayed water extracts of the host plant, prepared in the same way as the frass extract, in combination with host frass hexane extract.

METHODS AND MATERIALS

Plants and Insects

Pink-eye purple hull cowpeas, *Vigna unguniculata*, were grown in a green house in trays (35 × 50 cm) with 50 seedlings per tray. Peat moss-based potting soil was used with no additional fertilizer. Fully developed young leaves from 7- to 14-day-old plants were used for rearing of larvae and for leaf extraction.

Larvae of all moth species reared for three to four days after hatching on a pinto bean-based artificial diet prepared according to the method of King and Leppla (1984) were transferred to fresh leaves in polystyrene trays with individual compartments. Frass produced the first 24 hr after the transfer contained artificial diet and was discarded. After that the larvae were daily transferred to new trays with fresh cut leaves and the frass collected.

M. croceipes parasitoids were reared on *H. zea* larvae according to the procedures of Lewis and Burton (1970). The wasps were held in 30 × 30 × 20-cm cages at 26°C, 70% relative humidity, under a 14 L : 10D-hr photoperiod. Males were removed two days after emergence and 2- to 4-day-old females were used in all experiments.

Extraction of Frass

Frass produced in the trays by larvae feeding on leaves was collected, taking care not to acquire bits of leaves, weighed, and stored at −60°C in glass vials with Teflon-lined screw caps. Collection continued until the larvae were about 10 days old. For each species of larvae, all frass collected was pooled and extracted with hexane (B&J GC[2], Burdick and Jackson, Muskegon, Michigan) and water (B&J HPLC grade). The frass was first extracted with hexane overnight at 4°C while being continuously stirred (2 ml hexane/g frass). The hexane was decanted and the frass extracted for another 24 hr with an equal amount of new hexane. Both extracts were combined and the concentration adjusted to 2 mg frass equivalents per 10 μl by adding hexane. The extract was stored at −60°C until used in bioassays. To prevent interference with the subsequent water extraction, the hexane still left in the frass was eliminated by placing it under vacuum (200 mm Hg) for approximately 1 hr. The frass was then extracted overnight with water at 4°C while being continuously stirred (2 ml water/g frass). The thick slurry was centrifuged at 4000*g* for 30 min, and

the supernatant was decanted and saved. The water extraction was repeated a second time, and both water extracts were combined and the concentration adjusted to 2 mg frass equivalents/10 μl by adding more water. The water extract was then filtered through a 0.45-μm HV-type membrane filter (Millipore, Bedford Massachusetts) followed by sterile filtering through a 0.22-μm GV-type sterile filter (Millipore) directly into sterile glass containers, which immediately were capped and stored at −60°C.

When used in the experiments below, the extracts were thawed and the water extracts diluted with HPLC grade water to a concentration of 1.25 mg frass equivalents/10 μl. The hexane extracts were diluted with GC[2] hexane to 1 mg frass equivalents/10 μl.

Leaf Extraction

Young, fully developed leaves taken from 14-day-old cowpea plants were ground in a mortar and extracted with water in the same way as the frass (2 ml/g leaf material). The final concentration of the water extract was adjusted in the same way as above for storing and bioassaying.

Learning Experience

Prior to use in bioassays, female wasps were conditioned by giving them a contact experience with a combination of the water extract and the hexane extract to be used as a volatile source in the flight tunnel. Water extract (5 mg frass equivalents in 40 μl) was pipetted onto Whatman No. 40 filter paper in a Petri dish. After the filter paper absorbed the water, 10 μl (1 mg frass equivalents) of the hexane extract was added on top of the water extract and the hexane allowed to evaporate for a few minutes. Then, one wasp at a time was placed on the filter paper with the extracts, and her antennae were gently pushed toward the surface with tweezers. The wasp was allowed to remain on the filter paper for 60 sec, and the duration of antennation after initial contact was recorded. Within a minute following this experience, the wasp was released in the flight tunnel. Normally six to nine female wasps could be conditioned and tested with each Petri dish application during a 30-min time period.

Flight Tunnel Bioassays

All behavioral bioassays were conducted as described by Lewis et al. (1991) in the flight tunnel described by Drost et al. (1986). Wasps were bioassayed 3 hr daily starting 2 hr into the photophase (9–12 AM). Flight responses were tested at 26–28°C, with a wind speed of 56 cm/sec and a light intensity of 2500 lux. The hexane extract to be used as an attractant source (30 μl at a concen-

tration of 1 mg frass equivalents/10 μl) was pipetted onto a triangular (9.5 × 9.5 × 6.5 cm) piece of Whatman No. 1 filter paper suspended from the tip of a disposable pipet placed in an inverted position at the center of the upwind end of the flight tunnel. The females were released from a 4-dram shell vial 80 cm downwind and directly in line with the odorant source. They were allowed to walk to the rim of the vial and their behaviors were observed and recorded for a maximum of 5 min after the vial had been placed in the flight tunnel. Females either dispersed (i.e., flew to the sides, top, or bottom of the tunnel) or responded with anemotactic flight. A positive response consisted of a complete flight resulting in landing on the target source.

Experiment 1. The wasps were experienced with water extract of either *H. zea* frass, host plant (cowpea) leaves, or HPLC-grade water in combination with hexane extract of *H. zea* frass. Hexane extract of *H. zea* frass was used as the attractant in the wind tunnel.

Experiment 2. Wasps were given an experience with water and hexane extracts of frass from each of the four insect species used: the nonhost BAW, FAW, and CL insects and the host CEW insect. In each case the hexane extract used in the experience was also used as the attractant source in the wind tunnel.

Experiment 3. Wasps were experienced with water extract of CEW frass in combination with hexane extract from CEW, BAW, FAW, or CL. The same hexane extract that was used in conditioning a female was also used as the attractant source when she was released in the flight tunnel.

Experiment 4. Wasps were experienced with hexane extract from CEW frass combined in separate trials with water extract from each of the four insect species. Hexane extract of CEW frass was also used as the attractant source in the wind tunnel.

RESULTS AND DISCUSSION

Experiment 1. All 36 wasps experienced to hexane extract of CEW frass in combination with CEW frass water extract subsequently flew to the hexane extract in the wind tunnel (Figure 1). Only one of 36 wasps flew after experiencing the host frass hexane extract together with host plant water extract. No wasps flew in the wind tunnel after experiencing the host frass hexane extract and a water control. These results, in agreement with previous reports (Lewis and Tumlinson, 1988; Lewis et al., 1991), indicate that a water-extractable component of host frass is required, in combination with components of the hexane extract of the same frass, to condition the wasps to subsequently fly to the odor of the hexane extract. Since hexane extract of CEW frass should contain the antennation activator 13-methylhentriacontane (Jones et al., 1971), these results also indicate that this compound alone is not sufficient to evoke associ-

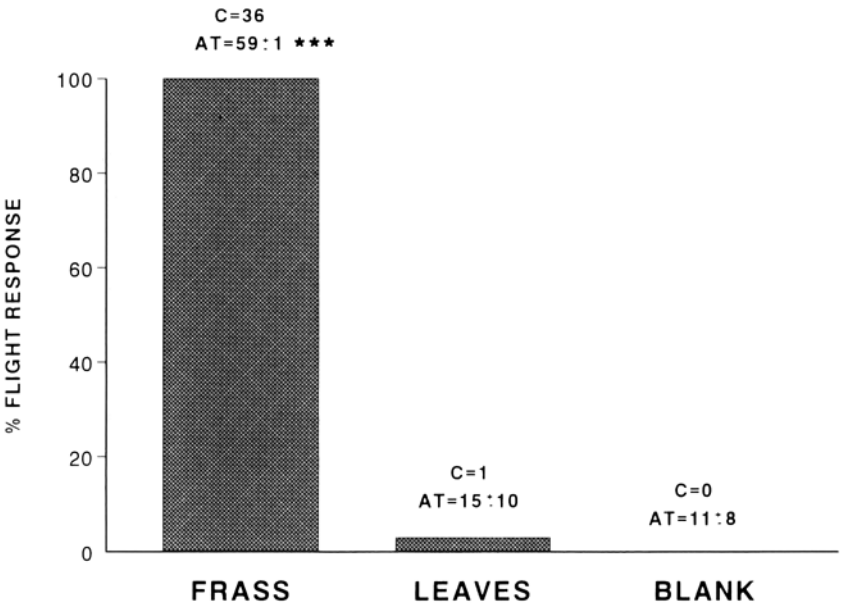

FIG. 1. Percent of female wasps flying to CEW frass hexane extract odorant source in a flight tunnel after an antennation experience with: FRASS—frass water and hexane extracts; LEAVES—cowpea water extract and frass hexane extract; and BLANK—water only and frass hexane extract. A total of 36 wasps were tested with each treatment and C is the number of insects making a complete flight to the target in the wind tunnel. AT is the mean antennation time $\pm$ SD per wasp for each treatment during the 60 sec of preflight experience. ***indicates a significantly higher antennation time (least significant difference test at $P < 0.005$)

ative learning. Furthermore, the results of this experiment indicate that the water-extractable kairomone is not a plant constituent that passes through the insect gut unchanged and acts in combination with larval components (like 13-methylhentriacontane) and plant volatiles (present in the frass hexane extract) to induce the wasps to respond to the odor of the hexane extract.

Experiment 2. No wasps flew to hexane extracts of frass from nonhosts after experiencing the hexane extract in combination with the water extract of frass from the same species. Of 21 wasps tested, 16 flew to the hexane extract of host frass after experiencing it together with host frass water extract (Figure 2). Thus, *M. croceipes* female wasps have a very strong preference for host insect larval frass, and they are capable of distinguishing hosts from nonhosts

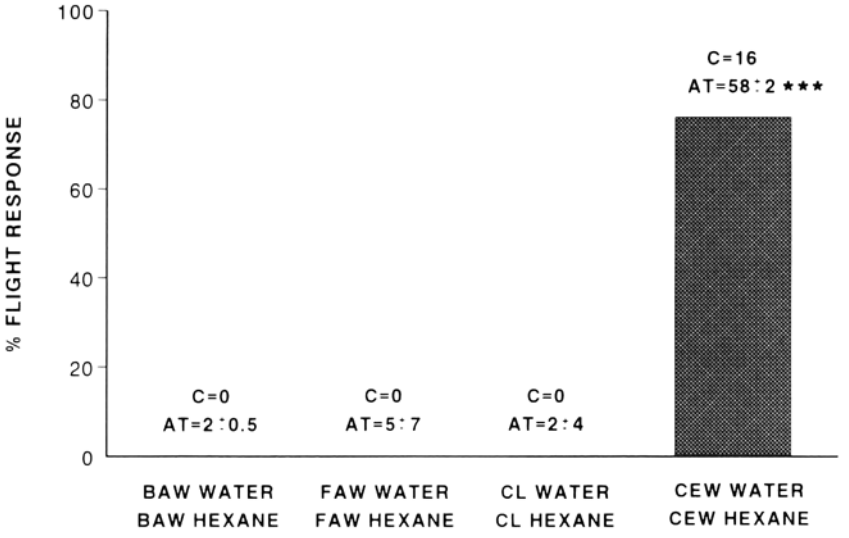

FIG. 2. Percent of female wasps flying to hexane extract of frass of BAW, FAW, CL, or CEW as an odorant source in the flight tunnel after an antennation experience with hexane and water extracts of frass from each insect species. A total of 21 wasps were used/treatment, and C is the number of insects making complete flights in the wind tunnel. AT is the mean antennation time ± SD per wasp for each treatment during the 60 sec of preflight experiment. ***indicates a significantly higher antennation time (least significant difference test at $P < 0.005$)

based on kairomones present in the frass. These results confirm and extend those of Lewis et al. (1991).

Experiment 3. The results of experiments 1 and 2 do not eliminate the possibility that kairomones crucial to learning in *M. croceipes* are present not only in the water extract but also in hexane extract of CEW frass. However, in experiment 3 all treatments showed activity, indicating that the important and host-specific factor responsible for associative learning of various odor sources is located in the water extract only (Figure 3). Despite that, the response to the CEW–CEW combination was significantly higher (least significant difference test at $P < 0.05$) than to any of the other treatments. This suggests that some important, but not crucial, factor is present in host frass hexane extract. Alternatively, a deterring component could be present in hexane extract of nonhost insect frass.

Experiment 4. When water extract of frass from each species was combined with hexane extract from CEW, the wasps responded in the wind tunnel to the

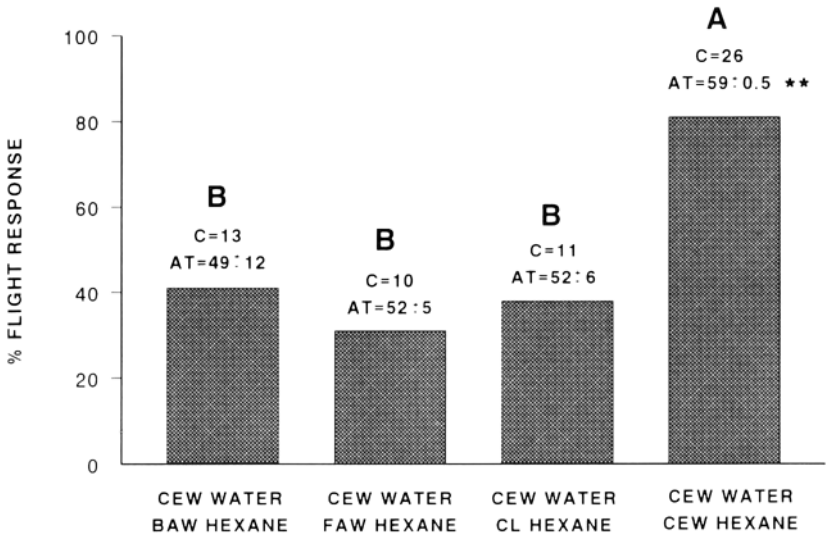

FIG. 3. Percent female wasps flying to hexane extract of frass of BAW, FAW, CL, or CEW as an odorant source in the flight tunnel after experiencing the same hexane extract in combination with CEW water extract. Four replications of eight wasps were used per treatment, and bars with different letters indicate significant difference using a least significant difference test ($P < 0.05$). C is the total number of the 32 insects per treatment that made a complete flight in the wind tunnel. AT is the mean antennation time ± SD per wasp for each treatment during the 60 sec of preflight experience. **indicates a significantly higher antennation time (least significant difference test at $P < 0.01$).

CEW hexane extract only when experienced with the CEW–CEW combination (Figure 4). If the water-soluble kairomone had also been present in frass from another species, but with the activity covered by a deterring factor present in the hexane extract of nonhosts, other treatments should have shown some activity. If the water-soluble kairomone also is present in the water extract from nonhost frass, but must be perceived in combination with 13-methylhentriacontane, then again other treatments should have shown activity.

Antennation Time. In experiment 1 (Figure 1) all treatments contained CEW frass hexane extract and thus the same amount of 13-methylhentriacontane. Despite that, the mean antennation times were very different (least significant difference test at $P < 0.01$). Most of the wasps given the host CEW–CEW combination of extracts antennated continuously for the entire minute, while wasps that experienced the plant water extract or water blank, in combination with CEW frass hexane extract, gave up antennation after a few seconds.

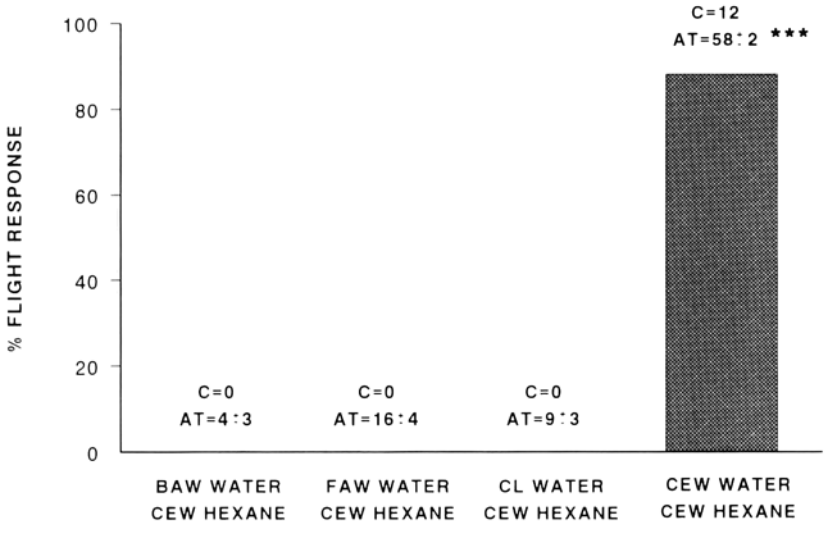

FIG. 4. Percent of female wasps flying to CEW frass hexane extract after experiencing CEW frass hexane extract in combination with BAW, FAW, CL, or CEW frass water extract. A total of 14 insects were used per treatment, and C is the number of insects making complete flights in the wind tunnel. AT is the mean antennation time ± SD per wasp for each treatment during the 60 sec of preflight experience. ***indicates a significantly higher antennation time (least significant difference test at $P < 0.005$).

In experiment 2, again, only wasps that experienced the host frass water + hexane extract combination showed sustained antennation (Figure 2). The same results were also obtained in experiment 4 (Figure 4). However, in experiment 3, in which all treatments contained CEW frass water extract, the difference in antennation time was less prominent. Although the wasps experiencing the CEW water and hexane combination antennated the target significantly longer than wasps given other combinations (least significant difference test at $P < 0.05$), all wasps antennated for 40 sec or more (Figure 3). Thus, the presence of 13-methylhentriacontane in frass (or a frass extract) is not enough to induce sustained antennation. The water-soluble recognition kairomone must also be present.

The antennation of host frass is an important component of the foraging strategy of *M. croceipes* wasps. When female wasps encounter and antennate host insect frass, they learn to associate volatile components or odors of the frass with the presence of a host recognition signal and will be attracted to these odors subsequently (Lewis and Tumlinson, 1988). Furthermore, contact with host frass appears to have a priming function (Eller et al., 1992) and is sufficient

to evoke host-searching behavior in these wasps even if a host larvae is not encountered. Manifestly, the wasps must be able to distinguish host frass from nonhost frass, as earlier results have indicated (Drost et al., 1986; Hérard et al., 1988; Eller et al., 1988). From the results of this investigation we can conclude that the crucial host recognition kairomone for *M. croceipes* females is present only in water extract of host frass. 13-Methylhentriacontane plays an important role as an antennation activator, and its importance has already been well documented (Jones et al., 1971; Lewis et al., 1991). However, this component is not host specific and occurs in frass from other lepidopteran larvae (Jones et al., 1971). Therefore, it could hardly function as a host-specific recognition kairomone. The results in experiment 3, where a significantly higher percentage of the wasps flew to the CEW frass hexane extract than to the nonhost frass hexane extract, might be explained by lower or less optimal concentrations of this and similar antennation-activating hydrocarbons in the nonhost frass hexane extract, but the kairomone present in CEW water extract was strong enough to induce a good flight response in all treatments.

This investigation has also eliminated the plant as a direct source for the host recognition kairomone. The origin of a precursor to the recognition kairomone might still be the host plant, but in that case only *Heliothis* and *Helicoverpa* larvae make this component into a reliable host-recognition kairomone for the parasitoid *Microplitis croceipes*.

(Received January 3, 1995; accepted June 7, 1995)

Abstract—The secretion of the tegumental glands of the fifth and sixth gastral sternites of *P. dominulus* and of its social parasite *P. sulcifer* was analyzed by gas chromatography–mass spectrometry. Seven long-chain carboxylic acids have been identified; hexadecanoic, octadecadienoic and octadecenoic acids are the major components of the gland secretion of *P. dominulus* and octadecenoic acid the main compounds of *P. sulcifer* sternal gland secretion. The same carboxylic acids have been found on the nest pedicel.

Key Words—Vespidae, Polistinae, *Polistes*, sternal glands, long-chain carboxylic acids.

INTRODUCTION

In the independently founding polistine wasps (*Polistes*, *Mischocyttarus*, *Belonogaster*, *Parapolybia*, and many species of *Ropalidia*) the nest, consisting of a single comb of cells, is suspended from the substrate by a narrow pedicel or by a small number of pedicels (Jeanne, 1975; Wenzel, 1991). As the pedicel constitutes the only access to the nest for invertebrate pedestrian predators (among which ants have been shown to exert the highest predation pressure), this struc-

ture is advantageous for defending the immature brood contained in the nest. The effectiveness of the pedicel in the nest defense is increased by the wasps' application of a repellent substance by rubbing the pedicel with the abdomen (Jeanne, 1970; Marino Piccioli and Pardi, 1970; Corn, 1972; Hermann and Dirks, 1974; Turillazzi and Ugolini, 1979; Post and Jeanne, 1981; Kojima, 1983a,b; Raposo Filho, 1989; Keeping, 1990).

Gland cells situated on the gastral sternites, especially those on the anterior part of the two last sternites (see Downing, 1991; Jeanne, 1995), have been indicated as the source of the repellent substances. Nevertheless, some authors have hypothesized that the sternal glands have a role in the chemical communication of dominance between nestmates (West-Eberhard, 1982; Downing and Jeanne, 1983), and that the fifth and sixth gastral sternite glands may differ in their function (Post and Jeanne, 1980).

In the three species of obligate and permanent social parasites among *Polistes* (*P. sulcifer*, *P. semenowi*, *P. atrimandibularis*), females invade nests of other *Polistes* species and rely on the host workers for rearing their brood (Weyrauch, 1937). Soon after the invasion of the nest, the parasite intensively strokes the nest comb with the abdomen, often near the cell opening. Some hours after the invasion this behavior is no longer performed (Turillazzi et al., 1990; Cervo et al., 1990). Indeed, during their cohabitation with the host, parasites rub the pedicel only rarely (Cervo, 1990). It has been hypothesized that the sternal glands of these social parasites may produce pheromones that control the host colony (Turillazzi et al., 1990; Borgioli and Delfino, 1994).

Despite speculation about the role of the sternal glands, chemical analyses have been carried out only on the sixth gastral sternite glands of two new world species of *Polistes*, namely *P. fuscatus* (Post et al., 1984) and *P. annularis* (Espelie and Hermann, 1990). Methyl hexadecanoate has been identified in the secretion of the first species, while hexadecanoic and octadecenoic acids have been found in the second one.

The aim of this work has been the analysis of the fifth and sixth gastral sternite gland secretions of foundresses and workers of the European species *P. dominulus*. We also analyzed the fifth and sixth gastral sternite gland secretions of *P. sulcifer*, one of the social parasites of *P. dominulus*; we wanted to determine if the sternal glands of this parasite produce a secretion similar to that of the host species.

METHODS AND MATERIALS

Polistes dominulus nests and foundresses were collected near Florence, Italy, during the month of May before the emergence of the first workers (number of nests = 4; number of foundresses = 2.5 ± 0.58 (mean ± SD), number

of cells = 33.7 ± 2.63, number of pupae = 7 ± 3.56) and again during the month of June, when some workers had already emerged (number of nest = 2; number of cells = 48.5 ± 4.95). *P. sulcifer* females ($N = 3$) that had invaded the nests of *P. dominulus* some days earlier were collected at the beginning of summer on the pre-Alps near Verona in northern Italy. Once in the laboratory, nests and animals were frozen and maintained at −20°C. All samples were chemically analyzed at the Chemistry Department of Keele University.

The sternal glands were separated from cuticle under a binocular microscope using thin forceps and placed in glass capillaries (2 × 20 mm) sealed at one end (Morgan and Wadhams, 1972; Morgan, 1990). The samples prepared are reported in Table 1.

As preliminary gas chromatography–mass spectrometry analysis of sternal glands had shown traces of carboxylic acids in the samples (but not the presence of methyl esters), acids were derivatizated to methyl esters to make them more suitable for gas chromatography. An ethereal solution of diazomethane (Arndt, 1943) (20 μl) was inserted into each capillary with a microliter syringe. After the solution made good contact with the tissue, the excess was evaporated with a stream of nitrogen and the capillary resealed in a small flame.

The analyses were carried out by combined gas chromatography–mass spectrometry (GC-MS) on a Hewlett Packard 5890 gas chromatograph connected to a 5970 Mass Selective Detector. The GC-MS unit was controlled by a HP59970C ChemStation. The gas chromatograph was equipped with a fused silica capillary column (12 m × 0.2 mm), coated with a 0.33-μm-thick film of immobilized dimethylsiloxane. Helium was used as carrier gas. The mass spectrometer was set to scan m/z from 30 to 500.

TABLE 1. SAMPLES ANALYSED[a]

Number of capillaries	Content of each capillary
5	Sixth sternal glands of one foundress of *P. dominulus*
3	Fifth sternal glands of one foundress of *P. dominulus*
1	Sixth sternal glands of three workers of *P. dominulus*
2	Sixth sternal glands of one female of *P. sulcifer*
2	Fifth sternal glands of one female of *P. sulcifer*

2	3 mg of pedicel material from one preemergence nest (two different nests were used)

[a]Each capillary represents one analysis.

A sealed capillary tube was placed in the injection area of the gas chromatograph (Morgan and Wadhams, 1972; Morgan, 1990), which was heated to 220°C, and the capillary crushed after 2 min, at which time chromatography commenced. The initial oven temperature of 100°C was increased by 7°C/min to 290°C. Substances were identified by their mass spectra and retention times compared with standard samples of the same esters.

The amount of each methyl ester was calculated by comparing the area of its peak with that given by a known amount of methyl octanoate. As two of the methyl esters (methyl octadecadienoate and methyl octadecenoate) elute in one peak (see below), we used the proportion between the area given by two diagnostic ions (*m/z* 294 and *m/z* 296, respectively) for calculating the amounts of these compounds. For samples containing the sixth sternal glands of *P. dominulus* foundresses, using this method, it was possible to estimate the amount of the two esters in only three of the five samples.

RESULTS

Polistes dominulus. The following carboxylic acids were identified (as their methyl esters) in the fifth and sixth sternite glands of the foundresses and in the sixth sternal glands of workers: dodecanoic (lauric), tetradecanoic (myristic), hexadecenoic (palmitoleic), hexadecanoic (palmitic), octadecadienoic (linoleic), octadecenoic (oleic), and octadecanoic (stearic) acids. Methyl octadecadienoate and methyl octadecenoate eluted as one peak (Figure 1A). The average total quantity of carboxylic acids found in *P. dominulus* foundress fifth and sixth sternal glands were 1.9 ± 1.9 μg and 5.3 ± 3.7 μg, respectively, while an average of 6.6 μg was found in the sixth sternal glands of the workers. In many samples, methyl dodecanoate and methyl tetradecanoate were only present in traces; sometimes also traces of an unidentified hydroxymethyl ester were found. As esters were not found in nonderivatizated samples, we are certain that these methyl esters indicate the presence in the tissues of the corresponding carboxylic acids.

The amounts of the seven acids found in the fifth and sixth sternal glands of *P. dominulus* foundresses and in the sixth sternal glands of workers are reported in Table 2. Octadecenoic acid was the main component extracted and identified for all three groups of samples. Octadecadienoic and hexadecanoic acids were present in similar percentages in the sixth sternite glands of workers and foundresses, while the quantity of octadecadienoic acid was higher than that of hexadecanoic acid in the fifth sternal glands of the foundresses.

The same acids have been found on the nest carton. The total amount of carboxylic acids found on 3 mg of pedicel material is on average 5.5 μg, while an average of 2.0 μg was present in the same amount of nest bottom material.

P. sulcifer. Four acids found in *P. dominulus* were present in the sternal glands of *P. sulcifer* (Figure 1B). The average quantity of carboxylic acids found in the sixth sternite glands was 1.5 ± 1.2 μg while only 157 ± 79.2 ng was found on average in the glands of the fifth sternite. Table 2 shows the average quantity per female and the average percentage of each acid in the fifth and sixth sternal glands.

DISCUSSION

Our work confirms that, as already found by Espelie and Hermann (1990) in *P. annularis*, the sternal glands of *P. dominulus* secrete carboxylic acids. In *P. dominulus* we found five acids in addition to those identified by Espelie and Hermann (1990).

The presence of the same carboxylic acids in the sixth and fifth sternite glands of *P. dominulus* foundresses indicate that, as suggested (Hermann and Dirks, 1974; Turillazzi, 1979), both glands may have the same function. The sixth sternite glands of *P. dominulus* workers contain the same carboxylic acids. Four of the same carboxylic acids are also present in the sixth and fifth sternite glands of the social parasite *P. sulcifer*. It seems likely that the function of the fifth and sixth sternite gland is similar for both foundress and workers of *P. dominulus* and for females of the social parasite *P. sulcifer*. It does not seem that in the parasite *P. sulcifer* the sternal glands have assumed a different function with respect to nonparasite species.

It is noteworthy that these acids are commonly found in the lipids of insects and higher animals, but the proportion of unsaturated acids (hexadecenoic, octadecadienoic, and octadecenoic) is much higher than in other animal lipids (Gunstone et al., 1986). Approximately 70% of the acids in the fifth sternal glands of *P. dominulus* foundresses are unsaturated, while 77% of the acids in the sixth sternal glands of foundresses and 64% from workers are unsaturated. While there is less total secretion in the glands of *P. sulcifer*, they are 88% unsaturated in the fifth sternal glands and 80% unsaturated in the sixth sternal glands.

The higher amount of carboxylic acids in the pedicel with respect to the comb material indicates that more of the carboxylic acids produced by the sternal glands are applied to the pedicel than to the comb. It must be stressed that the pedicel is enlarged by the wasps during nest growth and in our analyses we probably measured acids in the internal layers of the pedicel as well as on its surface. Bioassays are needed in order to determine if the carboxylic acids have a repellent effect against ants. Unlike our results and those by Espelie and Hermann (1990), Post and coworkers (1984) found methyl esters in the sternal glands of *P. fuscatus* females; the reasons for this difference are unclear, and it would be interesting to repeat the analyses of the glandular secretion of this

[a]For the sixth and fifth sternite glands of *P. dominulus* foundresses, average quantity per individual, average of the percentages and standard deviation of the percentages of each carboxylic acids are given. For the workers, for which only one sample containing the sixth sternite glands of three individuals has been analyzed, the average quantity per workers and the percentage of each acids are given. For the sixth and fifth sternite glands of *P. sulcifer*, average quantity per female and average of the percentages are given for the carboxylic acids.

[b]Only in three samples of the sixth sternite glands was it possible to calculate the quantity of oleic and linoleic acids on the basis of the diagnostic ions (see materials and methods.)

species by means of GC-MS. The production of ant repellents seems to be a common feature of all independently founding Polistinae (Kojima, 1992), and although the sternal gland secretions have been implicated in ant repellency, the chemical nature of the secretion from the sternal glands has been investigated only in the genus *Polistes*. Indeed, nothing is known about the chemistry of the secretion of these glands in the swarm founding Polistinae, where they are thought to be involved in the production of trail pheromones used during swarming (Jeanne et al., 1983). In the subfamily Vespinae, the function of the sternal glands is uncertain (Landolt and Akre, 1979) and only recently Martin (1992) has shown that the fifth and sixth gastral sternite glands of two species of *Vespa* secrete ant repellent substances. Future comparative studies await further data on the chemical nature of the secretion of these glands.

Acknowledgments—We wish to thank L. Cruz Lopez, R.R. do Nascimento, and N.J. Oldham for help and advice given during the laboratory work and R. Cervo for her comments on the manuscript. The study was supported with funds from the Ministero della Pubblica Istruzione (60%).

ALLOCATION OF PEDERIN DURING LIFETIME OF *Paederus* ROVE BEETLES (COLEOPTERA: STAPHYLINIDAE): EVIDENCE FOR POLYMORPHISM OF HEMOLYMPH TOXIN

RUPERT L.L. KELLNER* and KONRAD DETTNER

(Received December 27, 1994; accepted June 19, 1995)

Abstract—Pederin, a hemolymph toxin found in the rove beetle genus *Paederus*, is quantified in individual specimens of *P. fuscipes* and *P. riparius*. Whereas males always contain only small quantities of the toxin (0.1–1.5 μg), females are not so restricted (0.2–20.5 μg) and in most cases possess roughly 10-fold that in males. There are, however, females containing as little pederin as the males, and so two clearly separate groups of females can be discerned. These two groups hint at two types of females defined by the eggs they lay. About 85% of the females, i.e., those containing much of the substance, transfer pederin into every egg and thus are denoted (+)-females. The remaining 15%, the (−)-females, contain at best small amounts of the toxin, which is transferred in minute quantities into the first eggs while the subsequent ones lack pederin. With respect to the pederin content of their eggs, there is no overlap between these two types of females. If fed with pederin, (−)-females can transfer it into the eggs like (+)-females. After hatching the larvae store pederin when present. Larvae are not able to biosynthesize the toxin on their own, but storage of that received in the egg is very efficient, and the difference between larvae with and without pederin is preserved until imaginal eclosion. In (+)-females, pederin increases, probably reflecting a biosynthetic capacity, but in males and presumptive (−)-females the amount of pederin never exceeds the quantity transferred by parental (+)-females. Consequently, males and (−)-females probably are unable to biosynthesize pederin. This polymorphism of females may have a genetic basis. Individuals of all stages nevertheless sequester pederin if it is supplied with the diet.

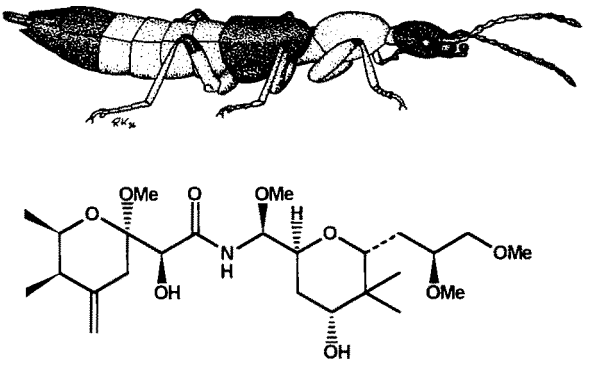
INTRODUCTION

Rove beetles of the genus *Paederus* are notorious for having a toxin that causes lesions on human skin. This kind of dermatitis was first described by Vorderman (1901), who noted its similarity to the blistering caused by cantharidin that was already known from *Lytta vesicatoria* and other meloids. Although Netolitzky (1919), by isolating crystals and carefully observing the formation of the blisters, discovered the difference between cantharidin and the toxin of *Paederus*, this distinction was not unanimously accepted until Pavan and Bo (1953), working with *P. fuscipes* again obtained and examined crystals of the substance that they named pederin. Subsequently, the molecular structure of this new compound (Figure 1) was elucidated by Italian and Japanese groups (Cardani et al., 1965b; Matsumoto et al., 1968). Among the trace constituents of *P. fuscipes* extracts, two analogs of pederin were described and named pseudopederin (Quilico et al., 1961) and pederone (Cardani et al., 1967), respectively. Apart from toxic peptides, these amides still are the most complex toxins found in beetles (Dettner, 1993).

Pederin has been chemically identified in only six different species but most of the *Paederus* studied so far have the same vesicant properties (Frank and Kanamitsu, 1987), indicating a wider distribution of the amide in this genus. The toxin is dispersed throughout the body of adults and is located in the



Pederin

FIG. 1. Female of *Paederus riparius* (length about 8 mm) and formula of pederin, a toxin contained in the hemolymph of the beetle.

hemolymph (Pawlowsky and Stein, 1927; Ito, 1934; Pavan, 1963). Since *Paederus* beetles do not reflexly bleed as meloids do, they have to be injured in order to release the amide contained in their hemolymph (Pavan and Valcurone Dazzini, 1971). Pederin is highly toxic to various eukaryotic cells, in which it blocks protein synthesis (Pavan, 1975). If injected intraperitoneally, comparatively small quantities of pederin suffice for killing mammals such as mice (LD_{50} = 0.14 mg/kg, Pavan and Valcurone Dazzini, 1971). Because of its cytotoxicity, pederin is regarded as a defensive compound (Blum, 1981).

Little is known about the pederin content of individuals because in former investigations pederin was evaluated after extracting a great number of specimens: Since 1 kg of *P. fuscipes* yields 0.25 g pederin (Quilico et al., 1961), one individual beetle weighing 4 mg might be expected to contain 1 μg of pederin (Pavan, 1963). Cardani et al. (1965a) stressed finding considerable variation of the pederin content of individual specimens by biological tests, but gave no details of this variation other than a broad outline. Pavan (1975) reported that adults of *P. fuscipes* contain 1 μg pederin, with females having up to 10 times that amount. Eggs, larvae, and pupae of *P. fuscipes* are known to contain the toxin, but there is no information on pederin content of these stages, and they were only tested for their ability to produce the dermatitis (Kurosa, 1958; Pavan, 1975).

Assessing the severity of dermatitis apparently has been the only method to quantify the pederin content of individuals. Research by Théodoridès (1950) has shown, however, that this method is not really reliable, as he had to postulate immunization in order to explain failure of skin reactions. Therefore, a chemical method had to be found to determine trace amounts of pederin present in single individuals. After developing a procedure that took advantage of the known properties of pederin (e.g., Pavan and Bo, 1953), we present quantitative data here for the first time concerning the amount of pederin present in adults and all developmental stages. These data enable a preliminary answer to the question as to which stadium might synthesize this unusual compound.

METHODS AND MATERIALS

Beetles. Adult *Paederus fuscipes* Curtis 1826 and *P. riparius* (Linné 1758) were collected from several sites in northeastern Bavaria, Germany. In order to obtain eggs, pairs of beetles were kept in plastic boxes (10 × 10 × 5.5 cm) containing a layer of plaster, some flowerpot fragments, and a small dish with moistened cotton. They were fed flightless *Drosophila melanogaster* and honey–water. The cages were placed in a climate chamber at 20°C with 15 hr of photophase, where females laid one to five eggs per day for a period of several weeks. Daily or every other day the eggs were isolated and kept singly in small

Petri dishes (3.5 cm diameter) on moist absorbent paper. The two larval stages (L1 and L2) were fed twice a day with frozen *Drosophila* flies until they pupated under the absorbent paper. Newly emerged adults were transferred to large Petri dishes (9 cm diameter) and fed *ad libitum* with living *Drosophila* flies. Breeding trials with these laboratory-reared adults were not successful because females only rarely laid eggs. Samples of adults and all developmental stages were preserved at −25 or −40°C for pederin analysis.

Extraction. Each specimen was ground in a small volume of water (eggs and L1 in 10 μl; L2, pupae, and adults in 30 μl demineralized H_2O). Extraction of the suspension proceeded with 100 μl ethyl acetate and was repeated three times. All three extracts were combined and the solvent removed in a centrifugal evaporator (Jouan RC 10-10). The following cleanup procedure was necessary only for extracts from L2, pupae, and adults: The dry sample was again dissolved in 50 μl water and extracted once with 100 μl hexane in order to eliminate most of the accumulated lipids, whereas pederin is left in the watery phase. This was dried in the centrifugal evaporator and, like the unmodified extracts from eggs and L1, it could then be analyzed.

High-Performance Thin-Layer Chromatography (HPTLC). Extracts of single specimens as well as known amounts of authentic pederin (from D. Ghiringhelli) were dissolved in 10 μl ethyl acetate and applied to the starting line on HPTLC plates (0.2 mm silica gel 60 on glass plates, 10 × 10 cm, Merck). The plates were developed in ethyl acetate in a vapor-saturated tank (Cardani et al., 1966). After evaporation of the solvent, they were stained in a dipping solution of anisaldehyde (4-methoxybenzaldehyde) and sulfuric acid in acetic acid (1 : 2 : 100 v/v/v) and heated for 2 min on a hot-plate (Desaga Thermoplate) at 90°C (Jork et al., 1989). Pederin ≥0.05 μg gives lilac spots at R_f = 0.22 after this procedure. This method is suited for detecting the analogs of pederin, pseudopederin and pederone, but they were not found in the extracts of either species. This study therefore treats only pederin, which certainly is the main if not the only toxic compound of *Paederus*. Images of fluorescent screen light transmitted through the plates were analyzed with a computer program (BASys 1D, Biotec-Fischer GmbH, Reiskirchen). Pederin spot intensities were transformed into peak areas, which then could be compared quantitatively within one plate. Known amounts of authentic pederin on several lanes of every plate were used to calculate a regression line in order to estimate the unknown amounts of samples on the plate. The amounts of pederin applied to calibration lanes were chosen to represent the expected range of samples. In most cases 0.5, 1.0, and 1.5 μg pederin were used to determine the regression line, but other combinations, such as 0.5, 1.0, and 2.0 μg or more than three standards, were also used. As the regression of spot intensity on pederin amount was linear only up to about 2 μg pederin, extracts with suspected higher amounts of pederin were

analyzed in diluted portions. Thus, in the first instance 1/10 of the extract (in 10 μl ethyl acetate as above, i.e., a 10^{-1} dilution) was applied to a silica plate and, if the resulting measurement still exceeded 2 μg, 1/20 of the original sample (i.e., a $5 \cdot 10^{-2}$ dilution) was used in a second determination. If little pederin was found in the first measurement, 9/10 of the original sample could be applied in the second trial to quantify the small amount of pederin. Repeated quantifications of the same samples on different plates show that, as a rule, the error due to the method is about 0.1 μg, but much better results with two identical decimal places were also obtained. Using this method, it was, for the first time, possible to quantify chemically the amount of pederin present in individual specimens of *Paederus*.

Feeding with Pederin. Selected specimens were given access to conspecific eggs, whose pederin load was known according to other eggs laid by the same female. The number of eggs eaten was counted and, as the egg content was always ingested completely, the amount of pederin received could be summed.

Data Analysis. Statistical tests were chosen according to the requirements described by Sachs (1984). They were performed using the statistical software packages CSS (StatSoft Inc., Tulsa, Oklahoma; Release 2.1) and SPSS (SPSS Inc., Chicago, Illinois; Version 3.1). One-way ANOVA was applied to pederin data of the eggs of 26 *P. riparius* females that transferred pederin to their offspring (treated as groups) in order to reveal variation between females. To adjust the different amounts of pederin that distinct females transfer into their eggs, the differences between the actual value and the mean amount of pederin transferred by the respective *P. riparius* female were calculated individually for eggs, L1, L2, pupae, and young adults and analyzed using the H test of Kruskal and Wallis. In case of nonlinear correlation, the curve fitting option of SigmaPlot (Jandel Scientific, Corte Madera, California; Version 5.0) was applied.

RESULTS

Pederin in Adults. Pederin could be identified in extracts of single specimens of *Paederus fuscipes*, the species from which Pavan and Bo (1953) had first extracted and named the toxin. Pederin was also found in *P. riparius*, whose vesicant action had not been analyzed chemically. All adults, which were preserved just after collection from the field, had at least small amounts (0.1 μg) of the amide, but the sexes differ greatly in the maximum amount determined. Males had only 1.2 (*P. fuscipes*) to 1.5 μg pederin (*P. riparius*), whereas females had up to 20.5 and 16.8 μg, respectively. In both species, females thus have significantly more pederin than males (Table 1, Kolmogorov-Smirnov two-sample test: *P. fuscipes:* $D = 1.00$, $P < 0.001$; *P. riparius:* $D = 0.85$, $P <$

0.001). Within sexes there are no discernible differences between the two species (Kolmogorov-Smirnov test not significant, $\alpha = 0.05$), although *P. riparius* is about 1.36 times the weight of *P. fuscipes*.

Remarkably, the amount of pederin detected in *P. riparius* females is not evenly distributed within the range measured (0.2–16.8 μg). Most of the females ($N = 28$) had more than 6.6 μg pederin, and the others ($N = 5$) had less than 1.2 μg with only one female in between (4.5 μg pederin, cf. Figure 3a below, open bars). The females do not belong to a uniform population, but can be subdivided into a smaller group (about 15% of the females) with little pederin, like the males, and a larger group (the remaining 85%) containing much more of the amide. These two groups are not linked to a seasonal rising and falling of the pederin content of females but coexist throughout the year. The few females with little pederin cause the overall mean of *P. riparius* females (Table 1) to be somewhat biased. Within the smaller number of *P. fuscipes* analyzed after collecting in spring, there was no female with little pederin, with all containing at least 9.5 μg of the amide.

Pederin Transferred into Eggs. The eggs of *P. riparius* ($N = 212$) are composed of two clearly defined groups (Figure 2), namely eggs with 0.4–2.1 μg pederin ($N = 172$) and others almost devoid of pederin ($N = 40$). As the female from which the eggs were derived is known in every case, these two groups evidently are not related to the time of laying (early or late), the volume or age of the eggs, or the number of eggs laid per female. The females studied can, however, be classified into two different types, here denoted (+)-females and (−)-females according to their ability to endow all their eggs with pederin or not (Figure 3b). In (−)-females, only the first few eggs laid may contain fairly small amounts of pederin (<0.1 μg). These two types of females proven by the eggs they lay are equally found in *P. fuscipes*. Quantitatively analyzed eggs of (+)-females lie in the range of 0.7–1.8 μg pederin, $N = 13$. As the distinction is very clear-cut (Figure 2), it is sufficient to analyze one egg laid by a female in order to classify her type. According to these determinations three of 15 *P. fuscipes* females (20%) and four of 37 *P. riparius* females (11%) that laid eggs in the laboratory belonged to the (−)-female group. These per-

TABLE 1. PEDERIN CONTENT OF ADULTS OF TWO *Paederus* SPECIES

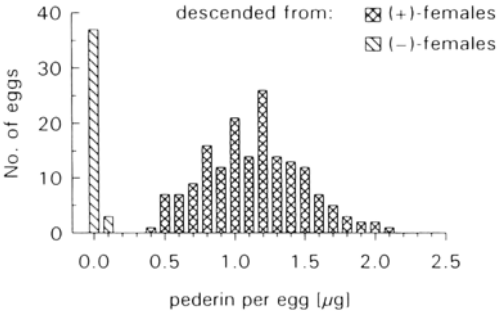

FIG. 2. Amount of pederin in the eggs of *Paederus riparius* laid by two types of females.

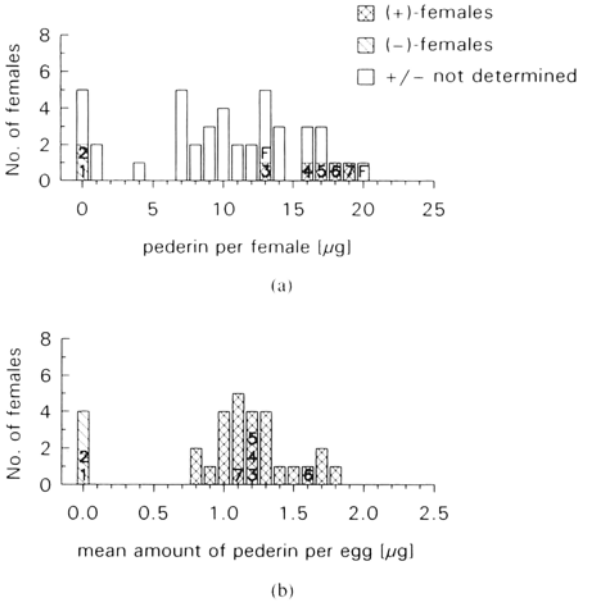

FIG. 3. Pederin content of *Paederus riparius* females and their eggs. (a) Whole bodies of females collected from the field were analyzed immediately ($N = 34$) or after an egg-laying period in the laboratory ($N = 9$). Two females failed to lay eggs (F); females 1–7 laid eggs. (b) Females were assigned to the two types, (+)-females and (−)-females, by the amount of pederin they transferred to their eggs. All females from which at least four eggs were analyzed are considered. Numbers refer to individual females in a, b and Table 2.

TABLE 2. PEDERIN CONTENT OF SELECTED *Paederus* FEMALES AFTER THEY CEASED LAYING EGGS AND AMOUNT OF PEDERIN TRANSFERRED INTO THEIR EGGS

Species	Female			Pederin per egg	
	No.	Type	μg	*N*	μg ± SE
P. riparius	1	(−)	0.0	10	0.00 ± 0.000
	2	(−)	0.0	16	0.04 ± 0.026
	3	(+)	12.7	7	1.16 ± 0.078
	4	(+)	16.2	7	1.17 ± 0.097
	5	(+)	16.9	8	1.16 ± 0.033
	6	(+)	18.1	7	1.56 ± 0.104
	7	(+)	18.8	13	1.13 ± 0.087
P. fuscipes	8	(−)	0.0	1	0.00 ± nd
	9	(+)	16.0	5	1.02 ± 0.038

centages correspond quite well to the ratio of the two groups of *P. riparius* females found from whole-body extracts. (+)-Females of both species contained a lot of pederin after they had ceased laying eggs (*P. fuscipes*: $\bar{X} \pm SE = 13.7 \pm 1.33$ μg, $N = 6$; *P. riparius*: $\bar{X} \pm SE = 16.5 \pm 1.06$ μg, $N = 5$), whereas (−)-females did not (Table 2). Consequently, those *P. riparius* females that had elevated amounts of pederin in their bodies but were not kept to lay eggs presumably were (+)-females (Figure 3a).

In order to determine whether a shortage of pederin in (−)-females may be the cause for eggs being laid without the amide, a (−)-female of *P. riparius* that had already laid 34 eggs was fed 10 eggs with pederin (about 11 μg) descended from a conspecific (+)-female (female 7 in Table 2). The next two eggs from this (−)-female, which were obtained on consecutive days three days after the pederin feeding, contained appreciable amounts of pederin, 0.7–0.8 μg each (Figure 4). This level equals that of (+)-females that transfer only limited quantities of pederin into their eggs. The amount of pederin transferred by the (−)-female dwindled until depletion of the resource (Figure 4). After her last egg (egg 61) the (−)-female had no pederin left in her body, and approximately 3.3 μg had been transferred into the eggs. Another (−)-female *P. fuscipes* that did not lay eggs after being fed with pederin contained about half of the pederin ingested five months later.

Pederin during Development of Offspring. The amount of pederin found in L1 matches that of the eggs and nearly nothing is left in the eggshell (only a trace in 200 eggshells of *P. riparius*). The same is true for L2 and exuviae. Furthermore, the descendants of the two types of females can be discerned in all developmental stages (Figure 5). Larvae, pupae, and young adults thus con-

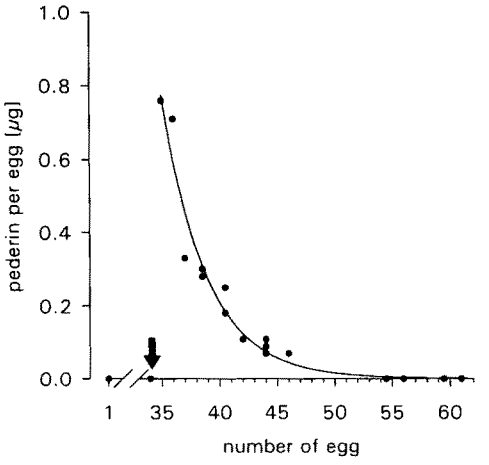

FIG. 4. Fluctuation of the amount of pederin transferred by a (−)-female of *Paederus riparius* to her eggs after feeding once with pederin (arrow). The curve shown [$P(x) = 1.005e^{-0.261x}$, x = (egg number −34)] is derived from the equation of a first-order process.

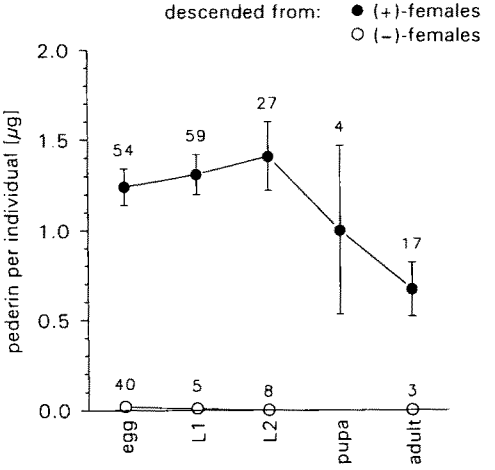

FIG. 5. Pederin in descendants of (+)-females and (−)-females of *Paederus riparius* [$\bar{X}$ with 95% confidence interval, which is too small to be visible in the offspring of (−)-females; N above] in all developmental stages and young adults (at most 1 week old). To reduce the excessive number of eggs analyzed of (+)-females, these are represented only when the developing larva was not yet visible through the chorion.

tain pederin if they are descended from (+)-females. In contrast, the offspring of (−)-females have no pederin and clearly cannot compensate for this deficiency by *de novo* biosynthesis. The possibility exists that larvae descended from (+)-females might synthesize pederin on their own, which would be obscured because (+)-females (*P. riparius* only) endow their eggs with significantly different amounts of pederin (ANOVA: $F = 6.81$, $df = 25, 145$, $P < 0.0001$). Analysis of the data with the H test, however, did not reveal any differences among eggs, L1, and L2 ($H = 4.36$, $df = 2$, $P = 0.113$), while significant differences arise if pupae and young adults are considered as well ($H = 38.71$, $df = 4$, $P < 0.0001$). The larvae do not increase their pederin content, whereas the decrease in pupae and adults (Figure 5) is confirmed.

Pederin in Maturing Adults. Shortly after eclosion most adults have less pederin than originally received with the egg. In all males and some of the females of *P. fuscipes* and *P. riparius*, the quantity of pederin does not increase over time. Only in some females is pederin accumulated, reaching 19.4 μg in *P. fuscipes* and 15.5 μg in *P. riparius* (Figure 6). These quantities are close to those of females collected from the field. After living 8.5 months, a female of *P. riparius* laid eggs that contained 1.38 ± 0.120 μg pederin per egg ($\bar{X}$ ± SE, $N = 5$) and was thus a (+)-female. With respect to the offspring of (+)-females only, the next generation of females is split into (+)-females that accumulate

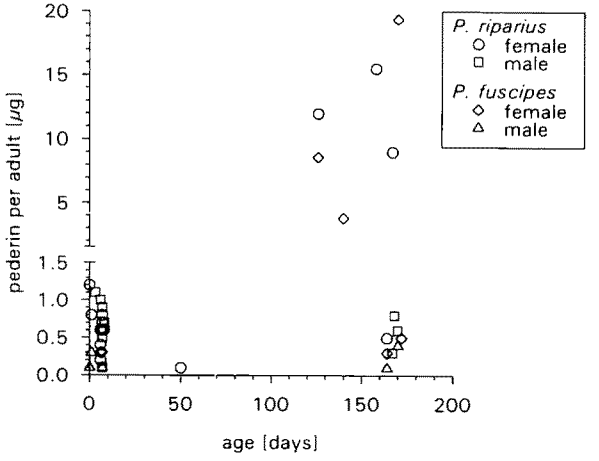

FIG. 6. The amount of pederin in *Paederus fuscipes* and *P. riparius* after imaginal eclosion. All specimens are descended from (+)-females and had not reproduced prior to analysis.

pederin and transfer it into their eggs and presumptive (−)-females that obviously are not able to biosynthesize that substance (Figure 6). Females analyzed after more than 100 days (*P. fuscipes*: $N = 5$, *P. riparius*: $N = 4$) are each descended from different (+)-females. Unfortunately, we did not obtain enough females descended from (−)-female to keep them several months in order to quantify their pederin content at an advanced age.

Pederin Ingested. If specimens are allowed to feed on conspecifics containing pederin, adults as well as larvae sequester the amide. Storage of the toxin is accomplished very efficiently, so that the amount of pederin found in (−)-females that do not lay eggs and in males is still elevated considerably several months after the feeding. The intake of adults collected from the field cannot be analyzed quantitatively, however, because the pederin content at the starting point of the feeding is not known well enough. In feeding trials conducted during rearing of *P. riparius* the pederin content of larvae, pupae, and adults was greatly increased, depending on the amount of pederin ingested during the larval stages (Figure 7). Freshly hatched males and females thus can have an amount of pederin that matches that of older (+)-females. The slope of the regression line in Figure 7 shows that on average 60% of the maternal and ingested amount of pederin could be recovered after up to two molts.

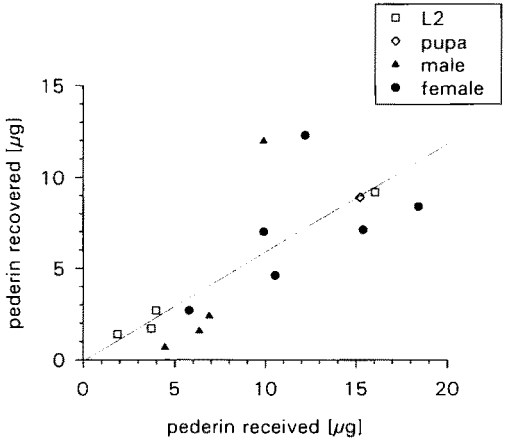

FIG. 7. Total pederin recovered from various stadia of *Paederus riparius* (adults at most 1 week old) that were fed with pederin (usually as L2) during larval development (regression line: $y = -0.08 + 0.60x$). The quantity received is the sum of maternally transferred and ingested pederin.

DISCUSSION

Using the microanalytical technique developed in the course of this study, it was possible for the first time to quantify the amount of pederin present in individual specimens of *Paederus*. Data obtained by this method are only partly identical with those summarized by Pavan (1975). Males of both *P. fuscipes* and *P. riparius* possess relatively little pederin, as expected, but females containing as much as 15–20 μg pederin are not exceptional. At least 85% of the females have much more of the amide than males, and a higher pederin content of females is the rule rather than an exception. More important, however, is the finding that females can be classified into (+)-females and (−)-females. This differentiation is suggested by their pederin content, but only becomes clear if the pederin content of the eggs laid is considered. The two types of females might be confused if only adults were studied. This kind of entanglement may be the reason for the vague descriptions in the literature.

Offspring of (+)-females and (−)-females are different with regard to their pederin content throughout all developmental stages. When individuals are kept apart so that they cannot prey on each other, no accumulation of the amide could be determined in larvae and pupae descended from both types of females, or in males descended from (+)-females. Although biosynthetic capabilities for pederin might be obscured by unknown losses balancing the gain, it would be quite astonishing that larval growth is not reflected in an increase of the actual amount of pederin, whether retarded or not, if larvae were able to produce the amide. Pupae are about 18 times heavier than eggs, and growth is accompanied with a marked dilution of pederin that is not compensated. Larvae are able to sequester pederin if it is contained in the diet. (+)-Females are the source of pederin present in the offspring. This is corroborated by some females reared in the laboratory that were able to increase their pederin content well before laying eggs. They clearly biosynthesized the substance on their own. They were analyzed four to five months after eclosion, but the first eggs were obtained four months later, indicating that the increase of pederin is not linked to egg production. Biosynthesis must occur during the egg-laying period, however, because most females lay 50 eggs but do not contain the amount of pederin needed for all of it at the same time. (+)-Females are not depleted of pederin in course of laying eggs; (−)-females, however, are not able to synthesize the substance and thus cannot produce eggs with pederin. Small amounts transferred into their first eggs may be derived from a maternal donation or from conspecifics eaten in the field. Likewise, transfer from the gut to the ovaries is not hindered if they have access to extraneous sources of pederin during the egg laying period. Only then are (−)-females able to lay eggs with appreciable amounts of pederin, so that the distinction between (+)- and (−)-females is disrupted temporarily.

The amount of pederin in whole-body extracts of females collected from the field might not be related in every case to the two types of females. On the one hand, females with little pederin include (−)-females and also young (+)-females that have not accumulated much of the toxin. In this study this effect was minimized by collecting most of the females analyzed during spring, when there are no young females because the adults hibernate (Horion, 1965). Females containing much pederin might include (−)-females that had eaten conspecifics with pederin and had not lost the pederin through egg-laying. Cannibalism probably is not common in the field, and the pederin content of females appropriately gives evidence of a pederin polymorphism with regard to the two types of females.

The polymorphism of females might be explained by genetic differences between (+)-females and (−)-females. The biosynthesis of pederin is not known in detail but is classified rudimentarily as a kind of polyketide synthesis (Cardani et al., 1973). If part of the population is heterozygous with regard to the genes necessary for synthesis of pederin, these may recombine to give homozygous specimens without the genes in question. The presumptive (−)-females that are descended from (+)-females but do not accumulate pederin during several months of adulthood suggest this possibility. Polymorphism for cyanogenesis in *Trifolium repens*, for example, is known to be controlled by two genes (Jones, 1972), and plants with and without the ability to release hydrogen cyanide (HCN) coexist within the same field (Dirzo and Harper, 1982).

The capability for synthesizing pederin is apparently confined to the (+)-females of *Paederus*. Cantharidin, the toxin that was formerly confounded with pederin, is synthesized by female as well as male and larval oedemerid beetles (Holz et al., 1994), whereas in meloid beetles only the larvae and males produce the substance. Meloid females get cantharidin from their mates and then transfer it into their eggs (Sierra et al., 1976; Carrel et al., 1993). The biosynthesis of a defensive chemical may occur in all stages or in only some of them, and the substance may be transferred intraspecifically. Offspring without pederin, however, may not be as fit for life as those with the toxin because all adults collected from the field had some pederin. Pederin may deter significant arthropod predators from larvae containing the toxin (Kellner and Dettner, unpublished data). For adults pederin may not be as necessary as for the soft-bodied offspring. Males do not synthesize the toxin and eat conspecifics only rarely because their pederin content was always low. The pederin content of young adults of both sexes was clearly lower than that of the larvae. Adults thus might reduce their amount of pederin either by decomposition or by discharge.

Acknowledgments—We thank Professors D. Ghiringhelli (Milan) and P. Kocieński (Southampton) for their generous donations of small samples of authentic pederin and pseudopederin.

We also thank Professor E. Beck (Bayreuth) for allowing to use BASys 1D at his department and two anonymous reviewers for their comments on a previous version of the manuscript. This study was supported by a grant from BASF AG (Ludwigshafen) and funds of a Graduiertenkolleg at the University of Bayreuth.

Abstract—Jasmonic acid (JA) has potent activity in enhancing cotyledon toughness and stimulating the biosynthesis of 3-indolymethyl glucosinolate in seedlings of canola, *Brassica napus* L. Structure–activity relationships among cyclopentane analogs of JA revealed that maximum activity in both systems was achieved when an acetyl side chain (or a methylated acetyl side chain) occurred at the C-1 ring position, an *n*-pentenyl side chain at the C-2 ring position, and a keto group at the C-3 ring position. Although coronatine and coronafacic acid both possess a cyclopentane ring with a keto group at the C-3 position, only coronatine was active in *B. napus* seedlings. Coronatine, a chlorosis-inducing toxin essential to the infectivity of pathovars of *Pseudomonas syringae*, acted as a complete molecular mimic of JA and had the same stimulatory effect on specific indole glucosinolates in *Brassica* species, thereby casting doubt on the hypothesis that indole glucosinolates serve in bacterial pathogen defense. Similarities and differences for structural requirements for activity among several diverse physiological systems affected by jasmonates likely reflect species-, tissue-, and developmental-specific differences.

Key Words—Jasmonate, *Brassica napus*, canola, toughness, glucosinolate, structure–activity, analogue, defense.

INTRODUCTION

Wounding or feeding by flea beetles, *Phyllotreta cruciferae* Goeze, induces many striking changes in the physicochemical properties of the seedlings of canola, *Brassica napus* L. (Bodnaryk, 1992, 1994; Bodnaryk and Rymerson, 1994). Some of the changes, such as increased cotyledon toughness, may serve to defend the seedling against subsequent insect attacks. Other effects of wounding, such as the stimulation of indole glucosinolate biosynthesis, may be involved in defense against invading pathogens, a hypothesis that has not been adequately tested (see review by Bennett and Wallsgrove, 1994).

Jasmonates mimic many of the effects of wounding and insect feeding in *B. napus* seedlings (Bodnaryk, 1994; Bodnaryk and Rymerson, 1994) and may act as natural mediators of signal transduction during wounding and pathogen infection (Farmer and Ryan, 1990, 1992; Farmer et al., 1992; Gundlach et al., 1992; Enyedi et al., 1992; Creelman et al., 1992; Albrecht et al., 1993). Structural features of jasmonates that are required for biological activity are of interest because the various actions of jasmonates may be mediated by specific receptor(s). Chemical moieties of jasmonates important in the induction of expression of plant defense genes have been determined for protease inhibitor genes in potato (Ishikawa et al., 1994) and tomato (Feys et al., 1994). In this research, we have used various cyclopentane compounds related to jasmonic acid to investigate structure–activity relationships for two induced responses in seedlings of *B. napus*, namely the stimulation of indole glucosinolate biosynthesis (Bodnaryk, 1994) and the enhancement of cotyledon toughness (Bodnaryk and Rymerson, 1994).

METHODS AND MATERIALS

Plants. Seed of the canolas *B. napus* cv. Legend and *B. rapa* cv. Parkland and the mustards *B. juncea* cv. Cutlass and *Sinapis alba* cv. Gisilba was obtained from commerical suppliers. The seeds were planted in a mixture of sunshine potting mix, Vermiculite, and Perlite (2 : 1 : 1) in 175-ml styrofoam coffee cups with a 0.5-cm hole punched in the bottom and subirrigated with Hoagland's nutrient medium. Seedlings received 240 μmol/sec/m^2 of photosynthetically active radiation from wide-spectrum fluorescent tubes in a plant growth room maintained at 20 $\pm$ 1°C, 60–70% relative humidity, and 18L : 6D photoperiod. Experiments used 6-day-old seedlings randomly assigned to control and treatment groups, which were analysed 24hr after-treatment.

Treatment of Seedlings. The jasmonates and cyclopentane analogs in Figure 1 were first dissolved in methanol and then diluted 50-fold with 0.01% Triton X-100 to a final concentration of 0.5 mM. Cotyledons were treated topically

with a single dose of 5 μl applied to the periphery of the upper surface of a cotyledon. Controls received 5 μl of the methanol–0.01% Triton X-100 solvent alone.

Extraction and Quantitation of Glucosinolates. Cotyledons (2 g per replicate; four to six replicates) were cut from seedlings and extracted in boiling 80% methanol. Glucosinolates in partially purified extracts were bound to a column of DEAE-Sephadex A-25, desulfated with arysulfatase (Sigma), and eluted from the column for separation by HPLC on a 250-mm LiChrosphere 100 RP-18 (10 μm) column (Merck) with monitoring at 227 nm. Glucosinolates were quantified by comparison of peak areas with an internal standard of *o*-nitrophenyl-β-D-galactopyranoside (Sigma) (Bodnaryk and Palaniswamy, 1990; Bodnaryk, 1992).

Toughness. Relative cotyledon toughness in treated and untreated seedlings was expressed as the weight in grams needed to drive a polished stainless steel rod 3 mm in diameter through the larger of the two cotyledons, as measured in a block punchameter (Bodnaryk and Rymerson, 1994). A minimum of 15 seedlings were used for each treatment.

Chemicals. Allyl glucosinolate was from Sigma. Other glucosinolates (*p*-hydroxybenzyl, 3-indolylmethyl, 4-hydroxy-3-indolymethyl) were isolated from natural sources (Hanley et al., 1983). Coronatine and coronafacic acid were a gift from Robin Mitchell, The Horticulture and Food Research Institute of New Zealand, Auckland, New Zealand. The remaining jasmonates and cyclopentanes were as described by Ishikawa et al. (1994).

RESULTS AND DISCUSSION

Jasmonic acid (Figure 1) enhanced cotyledon toughness and stimulated the biosynthesis of 3-indolylmethyl glucosinolate in cotyledons of *B. napus* (Table 1). The acetyl side chain at the C-1 position of the cyclopentane ring of jasmonic acid seems essential for activity since its elimination in 2-[(*Z*)-2-pentenyl]-2-cyclopentene-1-one (Figure 1) abolished activity in both assays (Table 1). The acetyl side chain, however, can be methylated (methyl jasmonate, Figure 1) without any significant loss of activity (Table 1). The double bond in the *n*-pentenyl group at the C-2 position of the cyclopentane ring of jasmonic acid is important for activity, since its elimination in dihydrojasmonic acid and methyl

TABLE 1. EFFECT OF TREATING SEEDINGS OF CANOLA, *Brassica napus*, WITH JASMONIC ACID AND VARIOUS CYCLOPENTANE ANALOGS ON COTYLEDON TOUGHNESS AND 3-INDOLYLMETHYL GLUCOSINOLATE CONCENTRATION

Treatment	Cotyledon response	
	Toughness g (N = 15)	3-indolylmethyl glucosinolate (nmol/g wet wt)
Untreated	72.4 ± 4.8a[a]	200 ± 15a
Solvent only	70.9 ± 5.4a	187 ± 12a
Jasmonic acid	95.6 ± 9.7b	1304 ± 350b
Methyl jasmonic acid	92.1 ± 10.0b	1378 ± 309b
Dihydrojasmonic acid	80.7 ± 9.2c	389 ± 13c
Methyl dihydrojasmonic acid	78.8 ± 9.4c	434 ± 38c
Cucurbic acid	85.9 ± 9.0c	437 ± 34c
Methyl cucurbic acid	74.8 ± 6.5a	468 ± 19c
Methyl tuberonic acid	78.9 ± 6.3c	378 ± 93c
2-[(Z)-2-pentenyl]-2-cyclopentene-1-one	71.5 ± 6.6a	159 ± 35a
Coronafacic acid	75.9 ± 11.5a	332 ± 82c
Coronatine	90.4 ± 8.1b	1447 ± 293b

[a]Values are means ± SD obtained 24 hr after treatment. Means in the same column followed by the same letter do not differ (ANOVA, Student-Newman-Keuls test, $P < 0.05$).

dihydrojasmonic acid significantly reduced activities in both assays. Lengthening the *n*-pentenyl group with a hydroxy group in methyl tuberonic acid also significantly reduced activity in both assays. The keto group at the C-3 position of the cyclopentane ring was important for activity, since its replacement by a hydroxy group in cucurbic acid and methyl cucurbic acid significantly reduced activities in both assays. Coronatine, which has some structural resemblance to jasmonic acid in that both have a cyclopentane ring with a keto group at C-3, was as potent as jasmonic acid in both assays. Coronafacic acid, which lacks the conjugated amino acid of coronatine, had greatly reduced activity in stimulating 3-indolylmethyl glucosinolate biosynthesis and no activity in enhancing cotyledon toughness.

Coronatine acted as a molecular mimic of jasmonic acid and had the same effect on specific glucosinolates in the canola and mustard species (Table 2). Like jasmonic acid, coronatine stimulated the accumulation of 3-indolylmethyl glucosinolate, but not 4-hydroxy-3-indolylmethyl glucosinolate in *B. napus*; both stimulated the accumulation of 4-hydroxy-3-indolylmethyl glucosinolate, but not 3-indolylmethyl glucosinolate in *B. rapa*. Coronatine and JA stimulated the accumulation of 4-hydroxy-3-indolylmethyl glucosinolate and 3-indolylmethyl glucosinolate in *B. juncea*, and neither had any effect on the aromatic

glucosinolate, sinalbin, in *S. alba*. Unlike jasmonic acid, which had no effect on the aliphatic glucosinolate sinigrin in *B. juncea*, coronatine had a relatively weak stimulatory effect (1.6×) on sinigrin (Table 2). Although coronatine appeared to act more powerfully than jasmonic acid on the indole glucosinolates (Table 2), our jasmonic acid was an unidentified mixture of isomers (only one of which is known to be active) and quantitative comparisons therefore are tenuous.

Similarities and differences exist for structural requirements for activity among several physiological systems affected by jasmonates (Yamane et al., 1980; Sembdner and Parthier, 1993; Ishikawa et al., 1994) and may reflect species-, tissue-, and developmental-specific differences. Similar requirements for chemical groups at the C-1, C-2, and C-3 positions of the cyclopentane ring of jasmonic acid were observed for enhancing cotyledon toughness and stimulating biosynthesis of 3-indolylmethyl glucosinolate in *B. napus* and for inducing the expression of proteinase inhibitor genes of potato (Ishikawa et al., 1994). Maximal activity in both systems was achieved when an acetyl side chain (or a methylated acetyl side chain) occurred at the C-1 ring position, an *n*-pentenyl side chain at the C-2 ring position, and a keto group at the C-3 ring position. Although coronatine and coronafacic acid both possess a cyclopentane ring with a keto group at the C-3 position, only coronatine is active in enhancing cotyledon toughness and stimulating biosynthesis of 3-indolylmethyl glucosinolate in *B. napus*, in stimulating hypertrophy of potato tuber tissue (Shiraishi et al., 1979), and causing chlorosis of bean leaves (Mitchell and Young, 1978). On the other hand, both coronatine and coronafacic acid are active in inducing systemic proteinase inhibitor activity in tomato, in stimulating anthocyanin and protein accumulation, and in inhibiting root growth in the cruciferous weed *Arabidopsis thaliana* (Feys et al., 1994).

The function of indole glucosinolates in seedlings and young plants in *Brassica* species is not well understood. Indole glucosinolate biosynthesis in the cotyledons of *B. napus* is nutritionally and developmentally controlled (Bodnaryk and Palaniswamy, 1990) and is strongly stimulated by flea beetle feeding, wounding, or jasmonates (Bodnaryk, 1992, 1994). However, indole glucosinolates have no antiinsect properties (Larsen et al., 1985; Weber et al., 1986; Bodnaryk and Palaniswamy, 1990; Birch et al., 1992), and it has been suggested that indole glucosinolates (Butcher et al., 1974; Rausch et al., 1983; Koritsas et al., 1989; Schnug and Ceynowa, 1990; Doughty et al., 1991; Stobbs et al., 1991; Spak et al., 1993a) and indole phytoalexins (Conn et al., 1988; Dahiya and Rimmer, 1988; Rouxel et al., 1990, 1991; Jejelowo et al., 1991; Browne et al., 1991; Tsuji et al., 1992) may participate in pathogen defense. It is difficult to reconcile participation of indole glucosinolates in pathogen defense with our finding that coronatine, a chlorosis-inducing toxin essential to the infectivity of pathovars of *Pseudomonas syringae* (Ichihara et al., 1977; Mitchell and Young,

1978; Mitchell et al., 1983; Bender et al., 1987; Greulich et al., 1993; Feys et al., 1994; Weiler et al., 1994), stimulates the biosynthesis of indole glucosinolates. Recent studies also cast doubt on the hypothesis that glucosinolates, at least in *B. napus*, participate in viral (Spak et al., 1993b) or bacterial pathogen defenses (Rawlinson et al., 1989; Mithen and Magrath, 1992; Nashaat and Rawlinson, 1994). The partial and complete mimics of jasmonic acid described here may be of use in probing and redefining indole glucosinolate function in crucifers.

Acknowledgments—We thank Lubomyr Kudryk for excellent technical assistance and Dr. Robin Mitchell for providing coronatine and coronafacic acid.

(Received December 6, 1994; accepted June 16, 1995)

Abstract—North American beavers (*Castor canadensis*) mark their territories with castoreum, the strong-smelling paste in their castor sacs. In their own territories, beavers respond with scent marking to experimental scent marks that consist of strange castoreum (or selected components). In part, the unique odor of castoreum is due to large amounts of phenolic compounds and neutral compounds. Purified neutral compounds were analyzed by GC, GC-MS, and NMR; identities of the neutral compounds were confirmed by comparing the properties of authentic compounds with those of the isolated compounds. We identified 13 neutral compounds that had not been reported before for castoreum. Most of these are oxygen-containing monoterpenes. Of the nine neutral compounds reported by Lederer (1949), only three are confirmed in our analysis; the other six neutral compounds are either absent or are not volatile enough to be detected by our methods. Eight compounds—6-methyl-1-heptanol, 4,6-dimethyl-1-heptanol, isopinocamphone, pinocamphone, two linalool oxides, and their acetates—were synthesized for structure identification and bioassays.

Key Words—beaver, *Castor canadensis*, castoreum, neutral compounds, monoterpenes, co-injection, fractionation, identification, synthesis, territory marking.

INTRODUCTION

Castoreum is a strong-smelling brown paste contained in the paired castor sacs of both the Old and New World beaver (*Castor fiber* and *Castor canadensis*,

*To whom correspondence should be addressed.

0098-0331/95/1100-1745$07.50/0 1995 Plenum Publishing Corporation

respectively). Distinguished from the castor sacs are a pair of anal glands, termed "oil sacs" by trappers. Castoreum consists of phenolic, neutral, basic, and acidic components.

As a result of several field studies in recent years, the biological role of castoreum in the social life of beaver is now better understood (Hodgdon, 1978; Bollinger, 1980; Müller-Schwarze and Heckman, 1980; Svendsen, 1980; Houlihan, 1989; Schulte et al., 1994). Beaver deposit castoreum and anal gland secretion on mud piles that they build at the banks of their ponds. The scent marks applied to these "scent mounds" are territorial signals (Houlihan, 1989). Furthermore, unoccupied beaver habitat is less likely to be colonized if it is scented with artificial scent mounds (Welsh and Müller-Schwarze, 1989).

Castoreum has been bioassayed in behavioral experiments several times. Resident beaver respond to experimental scent mounds by approaching, going on land, sniffing the mound, pawing it, and often marking the sample (Hodgdon, 1978; Bollinger, 1980; Müller-Schwarze and Heckman, 1980; Svendsen, 1980). Castoreum fractions also elicit these behavioral activities (Müller-Schwarze et al., 1986; Svendsen and Huntsman, 1988), but less so with progressive fractionation. The activity disappears completely well before the level of single compounds is reached (Müller-Schwarze et al., 1986).

Because bioassays of fractions led to a level of fractionation with no demonstrable biological activity, single compounds known to be constituents of castoreum and their mixtures were tested in subsequent experiments (Houlihan, 1989; Müller-Schwarze and Houlihan, 1990; Schulte et al., 1994). Several compounds were active, albeit at a very low level. The activity of mixtures was intermediate between castoreum and single compounds (Müller-Schwarze and Houlihan, 1990; Müller-Schwarz, 1992, Schulte et al., 1994).

This chemical study was prompted by these and other ongoing behavior investigations. It is imperative to know the composition of castoreum from the specific study populations and to bioassay any compounds hitherto unknown for castoreum.

The composition of castoreum has been investigated several times. Walbaum and Rosenthal (1927) first identified some phenolic and neutral compounds from castoreum; the neutral compounds were acetophenone, borneol, and benzyl alcohol. Later, Stevens (1943) separated some neutral red oil from dried beaver castors called American musk, but he did not report any further isolation work. Lederer (1946, 1949) identified nine neutral compounds from castoreum: benzyl alcohol, cholesterol, β-cholestanol, mannitol, *cis*-5-hydroxytetrahydroionol, borneol, acetophenone, 4-methoxyacetophenone, and cholesteryl oleate. Valenta et al. (1960) isolated *cis*-cyclohexane-1,2-diol from beaver castoreum. Maurer and Ohloff (1976) isolated nitrogen containing compounds from castoreum. Newly found phenolic components were reported in Tang et al. (1993).

The anal gland contains chemically very different compounds. Many C_{15}–C_{22} carboxylic acids and their waxy esters from the anal gland secretion were characterized by Grønneberg (1978) and Grønneberg and Lie (1984) using thin layer chromatography (TLC), gas chromatography (GC), and mass spectroscopy (MS). No further work concerning neutral compounds has been reported since.

We have reinvestigated the neutral compounds extracted from male castoreum. The compounds were isolated by packed column GC fractionation and analyzed by capillary GC, gas chromatography–mass spectrometry (GC-MS), capillary GC coinjection, nuclear magnetic resonance (NMR) spectrometry and by comparing the spectra of the unknown components with those of synthesized compounds. We identified 16 neutral compounds, 13 of which had not been known from castoreum.

METHODS AND MATERIALS

Chemicals. The solvents used for extraction and for flash column chromatography were reagent grade. Solvents used for capillary GC were HPLC grade. Anhydrous tetrahydrofuran (THF) was dried over 4 Å molecular sieves. Ethylene oxide was purchased from Eastman company, dried over sodium, and distilled before use. Linalool was purchased from Kodak. All other reagents were purchased from Aldrich Chemical Company.

Instrumentation. Analytical capillary GC was performed on a Varian 3700 gas chromatograph equipped with a splitless injector, fused silica column, and a flame ionization detector (FID). Standard capillary GC conditions for all identification work used the following temperature program: 40°C (3 min), 3°C/min, 210°C (30 min). Carrier and makeup gas for capillary GC work was nitrogen. Capillary GC analyses were carried out on one of two columns: (A) DB-1, 30 m × 0.25 mm; (b), FFAP column, 50 m × 0.25 mm.

Capillary GC coinjection was conducted by taking 0.5 ml of a fraction (5–10 ng/μl) and adding 1 μg of a standard to it; 2 μl of this mixture were injected onto the capillary GC. The unknown compounds were coinjected with the same standards on one or two capillary GC columns (one polar and one nonpolar), except for nojigiko alcohol and junenol because they are not commercially available and their syntheses are beyond the scope of this investigation.

Semipreparative-scale packed-column GC fractionations were performed on a Varian 2700 aerograph instrument. All GC fractions were collected in glass capillary tubes (3 mm × 30 cm) using a Brownlee-Silverstein thermal gradient collector (Brownlee and Silverstein, 1968). The purity of the isolated fractions was checked by capillary GC on column A. The pure fractions were then char-

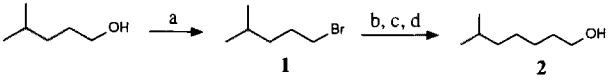
acterized by GC-MS and NMR. The following packed columns were used to purify the crude extract: column C, OV-101 (5%) on Chromasorb W, 3 m × 10 mm OD; column D, Carbowax 20 M (4%) on Chromasorb G, 6 m × 6 mm, temperature program: 100°C (0 min), 4°C/min, 230°C (5 min).

Mass spectra were obtained using a Finnigan 4500 automated gas chromatograph/EI-CI mass spectrometer system (GC-MS). All spectra were obtained at 70 eV. Proton NMR (^{1}H NMR) spectra were obtained using a Bruker AMX-300 (300 MHz). All spectra were run in $CDCl^3$ using the residual $CHCl_3$ protons as an internal reference. Carbon nuclear magnetic spectra (^{13}C NMR) were obtained using the Bruker AMX-300 instrument at 75.5 MHz in $CDCl_3$. All chemical shifts are given in ppm relative to tetramethylsilane.

Isolation and Identification. Sixteen frozen male castor sacs (970 g) were blended in a Waring Laboratory Blender for 2 min in methylene chloride (500 ml). The homogenate was filtered through a large Büchner funnel, and the solvent was removed by fractional distillation through a Vigreux column (17.5 cm) to prevent loss of the low boiling point fraction. The castoreum was treated with dilute sulfuric acid (200 ml of 2 N) and extracted with ether (3 × 200 ml) to isolate the neutral, acidic, and phenolic materials. The ether extract was washed with saturated sodium bicarbonate (3 × 130 ml) to remove the acidic compounds. The ether solution was then treated with enough sodium hydroxide to bring the pH to 12 (ca. 200 ml of 20%) in order to remove phenolic materials. The remaining ether solution was washed completely with brine, dried over anhydrous sodium sulfate, filtered, and the solvent removed by fractional distillation.

Synthetic Work: All compounds that were identified and not commercially available were synthesized except for nojigiko alcohol and junenol. Enough material was made not only to confirm our identification, but also for field bioassays with beaver.

6-Methyl-1-heptanol (2). 4-Methyl-1-pentanol (5.11 g, 50 mmol) and pyridine (0.5 g, 6 mmol) were dissolved in methylene chloride (8 ml), and freshly distilled phosphorus tribromide (13.5 g, 50 mmol) in methylene chloride (8 ml) was added dropwise over 30 min with stirring at −20°C under a nitrogen atmosphere (Scheme 1). After the addition was completed, the mixture was stirred for another hour at 0°C. The reaction mixture was treated with water



1 2

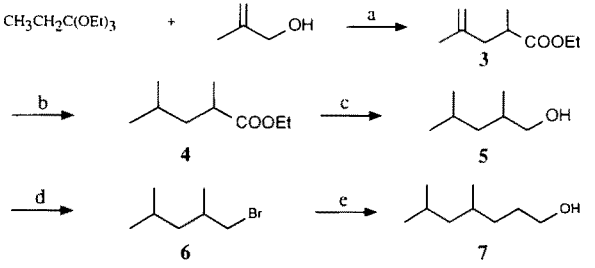
(a) PBr_3-pyridine, 1.5 hours, -20-0°C; (b) Mg, THF;
(c) ethylene oxide, -20°C; (d) HCl-H_2O.

SCHEME 1.

(5 ml), saturated sodium bicarbonate and brine, and dried over anhydrous sodium sulfate. The crude 1-bromo-4-methylpentane was purified by distillation (70.0–71.5°C/53 mm Hg) to yield **1** 2.30 g (28%).

Active magnesium powder (322 mg, 13.2 mmol) was placed in anhydrous THF (8 ml), and 1-bromo-4-methylpentane (2.20 g, 13.3 mmol) in anhydrous THF (16 ml) was slowly added. The reaction mixture was stirred for 4 hr at room temperature under nitrogen. Anhydrous cuprous iodide (250 mg, 1.3 mmol) was added after cooling to −10°C. Ethylene oxide (3 g, 68 mmol) was added through a tube with its end about 10 mm above the surface of the liquid (Dreger, 1941); the temperature was maintained at −20°C overnight. Water (3 ml) was added to the mixture, and the mixture was filtered through a Büchner funnel. The residue was rinsed with hexane (4 × 5 ml), and the combined organic phase was washed with dilute hydrochloric acid (3 N) and brine and dried over anhydrous sodium sulfate. The crude alcohol was purified by distillation (152–159°C) to yield 1.64 g (95%) of (2) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 3.67–3.63 (t, 2H, CH_2OH), 2.61 (s, 1H, OH), 1.58–1.48 (m, 3H, CH, CH_2), 1.38–1.29 (m, 4H, CH_2CH_2), 1.27–1.13 (m, 2H, CH_2), 0.86 (d, 6H, $CHMe_2$). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 63.0, 38.9, 32.7, 27.9, 27.1, 25.9, 22.6.

4,6-Dimethylheptanol (7). Unsaturated ester (**3**) was prepared by Claisen rearrangement (Johnson et al., 1970) (Scheme 2). 2-Methyl-2-propen-1-ol



(a) CH_3CH_2COOH, heat; (b) H_2, Pd-C; (c) $LiAlH_4$;
(d) TsCl; LiBr-acetone; (e) Mg, THF; ethylene oxide, -20°C.

SCHEME 2.

(5.95g, 83 mmol) was added to six equivalents ethyl orthopropionate containing a few drops of propionic acid. The ethanol produced in the reaction was continuously removed by fractional distillation. The crude ester was purified by distillation to yield 12.0 g (93%) of compound **3**. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 4.68 (d, 2H, $=CH_2$), 4.08 (q, 2H, OCH_2CH_3), 2.69–2.30 (m, 2H,

CH_2), 2.01 (q, 1H, CH), 1.67 (s, 3H, CH_3), 1.21 (t, 3H, OCH_2CH_3), 1.11 (d, 3H, CH_3). Catalytic hydrogenation (Augustine, 1965) of compound **3** in absolute ethanol over Pd-C at room temperature yielded 11.3 g (86%) of 2,4-dimethylvalerate **4**. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 4.08 (q, 2H, OCH_2CH_3), 2.49 (q, 2H, CH_2), 1.64–1.51 (m, 2H, 2CH), 1.21 (t, 3H, OCH_2CH_3), 1.17 (d, 3H, CH_3), 0.88 (d, 3H, CH_3), 0.87 (d, 3H, CH_3). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 177.2, 60.0, 43.1, 37.7, 25.8, 22.3, 17.7, 14.3. The saturated ester **4** was added to 0.6 equivalent $LiAlH_4$ suspended in dry ether (Moffett, 1963). After stirring for 2 hr at room temperature, the mixture was quenched with H_2O–15% NaOH–H_2O. The precipitate was filtered and rinsed with ether. The combined organic solution was washed with brine and dried over anhydrous sodium sulfate. After removal of the solvent, the crude product was distilled to yield 7.37 g (89%) of 2,4-dimethyl-1-pentanol. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 3.51–3.44 (m, 2H, OCH_2), 1.74 (bs, 1H, OH), 1.75–1.56 (m, 1H, CH), 1.23–1.13 (m, 1H, CH), 1.04–0.95 (m, 2H, CH_2), 0.88 (d, 3H, CH_3), 0.87 (d, 6H, $2CH_3$). ^{13}C NMR (75.5 MHz, $CDCL_3$): δ (ppm) 68.6, 42.3, 33.5, 25.4, 23.9, 22.1, 17.0.

The alcohol (**5**) (7.37 g, 63 mmol) was added to 1.3 equivalent toluenesufonyl chloride in CH_2Cl_2 and pyridine at 0°C (Marvel and Sekera, 1955). The mixture was kept in a refrigerator overnight. The crystals were filtered and rinsed with hexane. The combined organic phase was washed with cold water, 2 N HCl, saturated $NaHCO_3$, and brine and dried over anhydrous sodium sulfate. After removal of solvent, the tosylate was added to three equivalents of LiBr in acetone and stirred overnight at room temperature (Wilt et al., 1970). After removal of the solvent, the syrup was extracted with hexane, and the organic phase was washed with water and brine, and dried over anhydrous sodium sulfate. After removal of the solvent, the crude product was purified by distillation to yield 10.1 g (94%), of 1-bromo-2,4-dimethylpentane (**6**) as a colorless liquid. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 3.41–3.24 (m, 2H, $BrCH_2$), 1.96–1.78 (m, 1H, CH), 1.73–1.54 (m, 1H, CH), 1.33–1.22 (m, 1H, CH_2), 1.15–1.01 (m, 1H, CH_2), 0.97 (d, 3H, CH_3), 0.88 (d, 3H, CH_3), 0.87 (d, 3H, CH_3). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 44.3, 41.8, 32.9, 25.2, 23.0, 22.3, 18.8.

Active magnesium powder (312 mg, 12.8 mmol) was placed into anhydrous THF (7 ml), and 1-bromo-2,4-dimethylpentane (2.01 g, 11.2 mmol) in anhydrous THF (14 ml) was slowly added to it. The reaction mixture was stirred for 4 hr at room temperature under nitrogen. The solution was cooled to −10°C and anhydrous cuprous iodide (200 mg, 1.2 mmol) was added. Ethylene oxide (0.57 g, 13.3 mmol) was added through a tube whose end was about 10 mm above the surface of the liquid; the temperature was maintained at −20°C overnight. Water (3 ml) was added to the mixture, and the solution was filtered through a Büchner funnel. The residue was rinsed with hexane (4 × 5 ml), and

the combined organic phase was washed with dilute hydrochloric acid (3 N) and brine and dried over anhydrous sodium sulfate. The crude alcohol was purified by distillation (146–150°C) to yield 1.25 g (87%) of **7** as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 3.63 (t, 2H, CH_2OH), 1.69–1.42 (m, 4H, 2CH, CH_2), 1.39–1.27 (m, 2H, CH_2), 1.20–1.07 (m, 2H, CH_2), 1.06–0.89 (s, 1H, OH), 0.89–0.83 (sextet, 9H, $3CH_3$). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 63.5, 46.7, 33.3, 30.3, 30.2, 25.3, 23.4, 22.3, 19.7.

Isopinocamphone (8). Pyridinium chlorochromate (18 g, 84 mmol was dissolved in methylene chloride (100 ml), and (1*S*, 2*S*, 3*S*, 5*R*)-(+)-isopinocampheol (4.63 g, 30 mmol) in methylene chloride (15 ml) was added at room temperature (Corey and Suggs, 1975). After the addition was completed, the reaction mixture was stirred for 2 hr and diluted with anhydrous ether (60 ml).

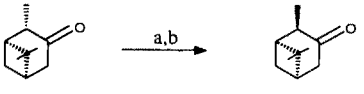
(a) PCC-CH_2Cl_2

SCHEME 3.

The solution was decanted, and the black residue was washed twice with ether. The combined organic solution was filtered through a short column packed with Florisil. The solvent was removed by rotary evaporator. The residual oil was purified by distillation (59.5–60.5°C/1.75 mm Hg) to yield 2.98 g (65%) of **8** as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 2.56–2.46 (m, 2H, CHC=O, CH_2C=O), 2.37–2.28 (m, 2H, 2CH), 2.05–1.86 (m, CH_2), 1.19 (s, 3H, CH_3), 1.08 (d, 3H, CH_3), 0.76 (s, 3H, CH_3). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 214, 51.2, 45.0, 44.8, 39.0, 34.4, 27.5, 21.8, 16.7.

Pinocamphone (9). Sodium (0.20 g, 8.7 mmol) was dissolved in absolute ethanol (5 ml), and the solution was cooled to 0°C; isopinocamphone (**8**) (1 g, 6.5 mmol) was then added quickly (Scheme 4). The reaction mixture was stirred overnight and neutralized with dilute hydrochloric acid (3 N). The crude product



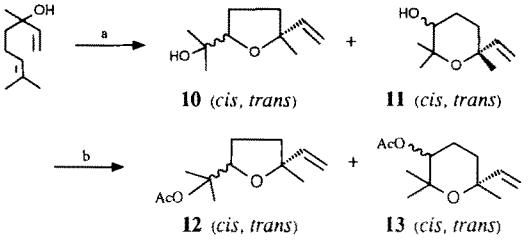
8 **9**

(a) NaOEt-EtOH; (b) H_2O-HCl

SCHEME 4.

(**9**) and starting material (**8**) were taken up in ether, and the organic phase was washed with brine and dried over anhydrous sodium sulfate. Evaporation of the solvent followed by separation by flash chromatography (hexane–EtOAc, 10:1) yielded 0.39 g (40%) of **9** as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 2.63–2.57 (m, 2H, $CH_2C{=}O$), 2.45–2.29 (m, 3H, $CH_2C{=}O$, CH), 2.10–1.84 (m, 2H, CH_2), 1.28 (s, 3H, CH_3, H-9), 1.05 (d, 3H, CH_3, H-10), 0.84 (s, 3H, CH_3, H-9), ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 216, 51.2, 46.3, 44.3, 39.3, 38.8, 29.5, 26.4, 20.0, 15.5.

*Oxides of linalool (**10** and **11**) and their acetates (**12** and **13**).* Our synthesis (Scheme 5) was based on that of Klein et al. (1964) for the oxidation of linalool.



(a) MCPBA-CH_2Cl_2; (b) CH_3COCl-DMAP-pyridine-CH_2Cl_2.

SCHEME 5.

m-Chloroperbenzoic acid (MCPBA, 4.3 g, 25 mmol) was dissolved in CH_2Cl_2 (30 ml) and cooled to 0°C; linalool (3.1 g, 20 mmol) was added dropwise over 30 min with stirring at 0°C. After the addition was completed, the mixture was stirred for 5 hr at 0°C, then stirred overnight at room temperature. The mixture was filtered through a Büchner funnel, and the filtrate was treated with aqueous NaOH (10%, 3 × 10 ml), washed with brine (3 × 10 ml), and dried over anhydrous sodium sulfate. Evaporation of the solvent followed by flash chromatography (hexane–EtOAc, 10:1) yielded 1.61 g (47%) of **10** and 0.36 g (11%) of **11**. Separation of isomers of **10** by packed column gas chromatography (column D) yielded *cis*- and *trans*-isomers of linalool oxide. *trans*-Linalool oxide: ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 5.87–5.76 (four d, 1H, =CH), 5.16–5.09 (d t, 1H, $=CH_2$), 4.95–4.90 (d t, 1H, $=CH_2$), 3.76–3.70 (t, 1H, CHOH), 2.27 (s, 1H, OH), 1.88–1.61 (m, 4H, CH_2), 1.25 (s, 3H, CH_3), 1.16 (s, 3H, CH_3), 1.07 (s, 3H, CH_3). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 143.7, 112.0, 86.1, 83.0, 72.0, 37.7, 27.0, 26.3, 25.8, 24.1. *cis*-Linalool oxide: ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 5.99–5.89 (q, 1H, =CH), 5.19–5.12 (d d, 1H, $=CH_2$), 5.01–4.95 (d d, 1H, $=CH_2$), 3.83 (t, 1H, CHOH), 2.10 (s, 1H, OH), 1.92–1.71 (m, 4H, CH_2), 1.28 (s, 3H, CH_3), 1.20 (s, 3H,

CH_3), 1.10 (s, 3H, CH_3). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ (ppm) 144.9, 112.0, 85.6, 82.8, 71.9, 37.7, 27.3, 26.4, 25.9, 24.2. Mixture **11** was not separated but was directly converted to its acetate.

Freshly distilled acetyl chloride (117.8 mg, 1.50 mmol) was added to pyridine (240 mg, 3 mmol) and 4-dimethylaminopyridine (DMAP, 5 mg, 0.04 mmol) in 1.5 ml CH_2Cl_2. The solution was cooled to −20°C and oxide **10** or **11** (120 mg, 0.71 mmol in 0.5 ml CH_2Cl_2) was added. The reaction mixture was kept at 0°C for 3 hr and at room temperature overnight. The mixture was cooled to −20°C, the supernatant decanted, and the precipitate washed with 0.5 ml CH_2Cl_2. The combined organic phases were treated with water (1 ml), hydrochloric acid (3 N 2 × 0.5 ml), and brine (2 × 0.5 ml) and dried over anhydrous sodium sulfate. The crude ester was purified by gas chromatography (packed column D) to yield 80 mg (53%) of acetate **12** and **13**. ^1H NMR of **12**: δ (ppm) 4.11-4.03 [q, 1H, −O−CH−C(Me)$_2$−OAc]. ^1H NMR of **13**: δ (ppm) 4.62-4.57 [q, 1H, −O−C(Me)$_2$−CHOAc].

RESULTS

Our reinvestigation of the neutral compounds in beaver castoreum led us to identify the 16 neutral compounds listed in Tables 1 and 2. Of these 16 compounds, only three had previously been reported as constituents of castoreum. Table 1 lists the characterization methods and structures of the oxygen-containing monoterpenes. Of these nine monoterpenes, only borneol was previously known as a constituent of castoreum (Walbaum and Rosenthal, 1927). Table 2 lists the characterization methods and structures of other neutral compounds. Among these seven compounds, acetophenone and benzyl alcohol had been reported as constituents of castoreum before (Walbaum and Rosenthal, 1927; Lederer, 1946, 1949). The remaining five—two aromatic compounds, two branched aliphatic alcohols, and a sesquiterpene—were found in castoreum for the first time.

Table 3 gives the average amounts (in milligrams) of the various neutral compounds found in one beaver castor sacs (gland), termed one gland equivalent (GE). The quantity refers to the amount of each individual neutral compound per castor gland. The determination of GE is as follows: The most abundant neutral compound, borneol, was isolated and weighed directly. The gland equivalents of the remaining neutral compounds were obtained by comparing the GC peak areas of each compound to that of borneol.

Of the nine neutral compounds reported by Lederer as being constituents of castoreum, only three were found in this study: benzyl alcohol, acetophenone, and borneol. The other six neutral compounds reported by Lederer, but not found in our neutral fractions are cholesterol, β-cholestanol, mannitol, choles-

terol oleate, *cis*-5-hydroxytetrahydronol, and 4-methoxyacetophenone. Except for 4-methoxyacetophenone, these compounds may not be volatile enough to be detected by our methods. The other possibility is that Lederer appears to have used a different species of beaver (*Castor fiber*), but his papers are not clear on this point.

Eight compounds—6-methyl-1-heptanol, 4,6-dimethyl-1-heptanol, iso-

TABLE 3. AVERAGE AMOUNTS OF NEUTRAL COMPOUNDS FOUND IN ONE BEAVER CASTOR SAC

Name	Gland equivalent (mg)
Acetophenone	0.18

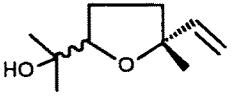
Borneol	16.9

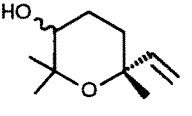
pinocamphone, pinocamphone, and two linalool oxides and their acetates—were synthesized as described under Methods and Materials.

DISCUSSION

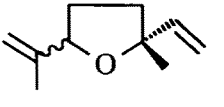
Many of the neutral castoreum constituents occur in plants or in excretions of mammals. Linalool oxides have been isolated from *Cryptocaria aschersoniana* oil of southern Brazil (Naves et al., 1963). Even though they have been used as flavor and perfume agents for some time, the first definite structure was not established until 1963 (Felix et al., 1963). They first oxidized (±)-linalool with monoperoxyphthalic acid yielding two pairs of diastereometric oxides, $C_{10}H_{18}O_2$ (**9**: *cis*, *trans* and **10**: *cis*, *trans*).



9 (*cis*, *trans*)



10 (*cis*, *trans*)



13 (*cis*, *trans*)

Furans **9** are the major products. The structures of **9** (*cis*, *trans*) were deduced by conversion of **9** to its benzoate, which was pyrolyzed at 180–220°C to give a mixture of two doubly unsaturated ethers (**13**). IR analysis showed the presence of a vinyl group and a methylene double bond; ^{1}H NMR analysis gives a multiplet at δ (ppm) 4.2–4.3, which is a proton in the environment of C=C−CH−O. Therefore, Felix et al. named these tetrahydrofuran derivatives "linalool oxide," which was accepted by the *Handbook of Terpenoids* (Dev et al., 1982) and many others. However, there are some differences in the ^{1}H NMR data of our isolated compounds with those reported by Felix et al. This may be due to different instruments or solvent effects. Pure **9** (*cis*, *trans*) and **10** (*cis*, *trans*) are not commercially available. To determine whether our isolated compounds are furan-type or pyran-type compounds, a modified method was employed to convert linalool into its oxides, which were separated into two mixtures, **9** and **10**, by flash chromatography. These two mixtures, **9** and **10**, were converted to acetates **11** and **12**, respectively. Comparing the ^{1}H NMR data of the alcohols and their esters, the peak at δ (ppm) 3.83–3.78 (t) in alcohol **9** shifts to δ (ppm) 4.10–4.03 (q) in ester **11**, while the peak at δ (ppm) 3.44–3.38 (t) in alcohol **10** shifts to δ (ppm) 4.62–4.54 (q) in ester **12**. The former small difference is caused by a field effect of the OAc group; the latter big difference is caused by a scalar effect of the OAc group (Duddeck and Dietrich, 1989). In summary, this experiment gives another proof that **9** (*cis*, *trans*) are tetrahydrofuran derivatives, and **10** (*cis*, *trans*) are tetrahydropyran derivatives.

A further separation of **9** (*cis*, *trans*) on column D gave pure *cis*- and *trans*-linalool oxides, whose ^{1}H NMR data and ^{13}C NMR data coincide with our isolated compounds. In the *cis*-isomer, the proton attached to the C=C was deshielded by the *cis*-OH group and its chemical shift is further downfield than that of the *trans*-isomer.

Isopinocamphone is a major constituent of the essential oil from the mint, *Mentha aquatica* L. found in southern Europe (Shimizu et al., 1966). The compound was prepared from isopinocampheol by oxidation with CrO_3 (Zweifel and Brown, 1964). In our method, we employed the more effective reagent pyridium chlorochromate. The chemical shifts of three characterizing methyl groups (C_8, C_9, and C_{10}) (Erskin and Knight, 1960) are in good agreement with our isolated and synthetic samples.

(−)-Pinocamphone can constitute up to 45% of the oil of *Hyssopus officinialis* L. (Guenther, 1949). Pinocamphone was synthesized from α-pinene by treatment with perphthalic acid and acidic alumina (Nigam and Levi, 1968). The epimerization of isopinocamphone to pinocamphone was employed in our work (Zweifel and Brown, 1964). The equilibrium favors pinocamphone. The reported ^{1}H NMR spectrum (Erskin and Knight, 1960) is identical with our isolated and synthetic compounds.

trans-Pinocarveol has been found in Spanish eucalyptus, *E. globulus* (Schmidt, 1944). The ^{1}H NMR spectrum of the synthetic compound (Jashi et al., 1968; Heikman et al., 1968) is the same as that from our isolated fraction.

Nojigiku alcohol and its acetate are major components of the essential oil of *Chrysanthemum japonense* (Uchio, 1977). The ^{1}H NMR spectrum (Uchio, 1977) is identical with our isolated fraction, and the ^{13}C NMR data (Darby et al., 1978) agree with our sample.

Verbenone (**14**) occurs in small amounts in *Verbena* and various other species (Kerschbaum, 1900). The ^{1}H NMR spectrum of synthetic verbenone (Bates and Thalacker, 1988) is identical with that of our isolated sample.

Both (+)- and (−)-myrtenol have been isolated from the essential oil of *Cyperus africalatus* L. in West Africa by vacuum fractionation (Couchman et al., 1964). The ^{1}H NMR of myrtenol (Heikman et al., 1968) is nearly the same as that from our isolated fraction. The only difference is that the peak of CH_2OH is reported at 3.89 ppm (a mutiplet in Heikman's paper), and in our spectrum it is at 3.98 ppm, doublet (J = 1.7 Hz). This split is caused by long-range olefinic proton coupling.

No natural source of the two branched alcohols was found in the literature. The first synthesis of 6-methyl-1-heptanol was reported by Levene and Allen (1916). They treated 4-methylpentyl iodide with malonic ester and reduced the resulting ester with Na-EtOH to give the above alcohol. This method requires more steps than ours. The ^{1}H NMR and ^{13}C NMR data of the synthesized 6-methyl-1-heptanol agree with authetic data (Sadtlar, 1980, 1981). The synthesis of 4,6-dimethyl-1-heptanol has also been reported (S. Julia, et al., 1961, M. Julia, et al., 1966). In Julia's work (1961), the starting material, 1,1-diethoxy-1-cyclopropylethane, was converted to 1,3-dimethyl 1-cyclopropyl-1-butanol in six steps. The homoallylic rearrangement was accomplished by treatment of the alcohol with HBr. The resulting unsaturated bromide was converted to 4,6-dimethyl-1-heptanol by catalytic hydrogenation. In our work, the starting material, 2,4-dimethylpentyl bromide, was prepared from triethyl orthopropionate and 2-methylallyl alcohol via Claisen rearrangement and three subsequent steps. Our synthetic route is short and the yield is good.

Junenol is an eudesmane class sesquiterpene. A dextrorotatory alcohol, junenol was first isolated from the essential oil of juniper berries (Herout et al., 1954). The first total synthesis of (±)-junenol was completed by Schwarz et al. (1972). From our isolated fraction, we acquired ^{1}H NMR, ^{13}C NMR, HETCOR, and HH COSY (Duddeck and Dietrich, 1989). From the NMR data, the structure of our isolated compound was deduced as junenol. The ^{1}H NMR of the isolated compound [(300 MHz, CDC_3): δ (ppm) 4.96 (d, 1H), 4.66 (d, 1H), 3.65 (t, 1H), 2.35–1.25 (m, 14H), 0.96 (d, 3H), 0.87 (s, 3H), 0.73 (s, 3H)] agrees with Schwartz's data (Schwartz et al., 1972). The ^{13}C NMR data are not

available in the literature. The ^{13}C NMR (75.7 MHz, $CDCl_3$) of our sample: δ (ppm) 148.3, 106.3, 67.2, 58.3, 49.8, 41.9, 40.4, 37.9, 37.6, 26.8, 24.0, 21.1, 18.4, 17.5, 16.1.

A number of the described compounds are known as detoxification products in the urine of various herbivores and also of carnivores. For instance, in rabbits *trans*-pinocarveol is derived from β-pinene and myrtenol is a metabolite of α-pinene. In rabbits and brushtail possums, verbenol is formed from α-pinene. Acetophenone occurs in the urine of dogs and cats that have been fed cinnamic acid. Benzyl alcohol is excreted by dogs and cats that had been given benzyl acetate. In rabbits, borneol is a metabolite of camphor. Benzaldehyde was found in rat hepatocytes as a metabolite of benzylamine. These numerous studies are summarized by Scheline (1991). The beaver appears to sequester metabolites of secondary plant compounds in its castor sac.

Our purpose for identifying the neutral constituents from beaver castoreum was to determine what role these and other compounds, such as phenolics and basics from beaver scent marks, play in chemical communication. Beaver possibly use at least some of the neutral compounds for intraspecific communication via their scent marks. Several studies have compared beaver responses to whole castoreum and to its components. The neutral fraction released responses from beaver in experiments by Svendsen and Huntsman (1988). While some of the phenolic castoreum constituents have been shown to elicit responses from beaver (Müller-Schwarze and Houlihan, 1991, Schulte et al., 1994), only one neutral compound, borneol, has been bioassayed individually so far (Schulte et al., 1994). A mixture of 12 neutrals reported here released slight to moderate responses from beaver. The 12 tested neutral compounds were borneol, benzaldehyde, benzyl alcohol, 6-methyl-1-heptanol, *cis*- and *trans*-linalool oxide, 4,6-dimethylheptane-1-ol, *trans*-pinocarveol, isopinocamphone, verbenone, (1*R*)-myrtenol, and 3,4-dimethoxyacetophenone. A fivefold higher concentration of the same mixture rendered it more active. Finally, a mixture of these 12 neutrals and 14 phenolics proved to be almost as active as whole castoreum (Schulte et al., 1994). The beaver appear to recycle catabolites and detoxification products by storing them in their castor sacs for scent marking when needed. This added benefit may offset the cost of detoxification.

Having identified a series of neutral compounds, we can now analyze individual scent mounds and castoreum from specific individuals on a routine basis. The chemical identifications reported here have opened the door for selecting and manipulating specific compounds in castoreum. In our experiments, borneol released scent-marking responses (Schulte et al. 1994). Castoreum composition profiles may be indicative of individuals, sex, age, colony membership, diet, population, or species. Knowledge of the precise pattern of compounds will permit analysis of genotypic and environmental influences on castoreum composition.

Acknowledgments—The authors wish to thank Mr. D. Kiemle for his assistance in performing the GC-MS and NMR analyses. This research has been supported by National Science Foundation grant BNS 88-19982.

(Received March 27, 1995; accepted July 7, 1995)

Abstract—The major component of the male-produced aggregation pheromone of *Carpophilus dimidiatus* (F.) is (3*E*, 5*E*, 7*E*, 9*E*)-6,8-diethyl-4-methyl-3,5,7,9-dodecatetraene. It attracts beetles of both sexes in the field and is synergized by odors from fermenting bread dough; mean trap catches for the tetraene alone, tetraene plus dough, dough alone, and control were 24.5, 48.3, 0.02, and 0.00, respectively. In the laboratory, individual males produced 0.58 μg ± 0.35 μg (SD) of the tetraene per day, but males in groups of 10–50 produced <2% as much per beetle. A second male-specific compound, (3*E*, 5*E*, 7*E*, 9*E*)-5,7-diethyl-9-methyl-3,5,7,9-tridecatetraene, was also identified from *C. dimidiatus* and is about 5% as abundant as the major pheromone component. *Carpophilus* flight activity was monitored for one year in South Carolina corn fields with the pheromones for *C. dimidiatus*, *C. freemani* Dobson, *C. mutilatus* Erichson, *C. hemipterus* (L.), *C. lugubris* Murray, and *C. obsoletus* Erichson, all in combination with bread dough. The first four of these species accounted for 18, 70, 5.7, and 0.03%, respectively, of the total *Carpophilus* trapped, but no *C. lugubris* or *C. obsoletus* were captured. Captures of *C. freemani* were as high as 11,400/trap/week. Species specificity

for the first four pheromones was high, except that a synthetic impurity in the *C. dimidiatus* pheromone was somewhat attractive to *C. freemani* and *C. mutilatus*. Three other species captured, *C. antiquus* Melsheimer, *C. marginellus* Motschulsky, and *C. humeralis* (F.), accounted for 0.005, 5.0, and 1.3% of the total catch, respectively. *C. antiquus* was attracted primarily to the pheromone of *C. dimidiatus*, but *C. marginellus* and *C. humeralis* responded to most of the test pheromones. There were two major periods of *Carpophilus* flight activity: February through June and September through November.

Key Words—*Carpophilus* spp., *C. dimidiatus*, Coleoptera, Nitidulidae, pheromone, hydrocarbon, tetraene, trap, corn.

INTRODUCTION

The corn sap beetle, *Carpophilus dimidiatus* (F.), is a small (2 to 3-mm) dark brown nitidulid that occurs in tropical, subtropical, and warmer temperate regions throughout the world. In the United States it ranges north to North Carolina and northern California (Connell, 1991). It attacks a wide variety of agricultural commodities such as corn, peanuts, cacao, and various spices, either in storage or in the field (Connell, 1975). In the early literature, the name *C. dimidiatus* was often applied to all five members of a complex of very similar, sibling species occurring in North America. Dobson (1954, 1956) and Connell (1991) provided keys and descriptions that allowed *C. freemani* Dobson, *C. mutilatus* Erichson, *C. fumatus* Boheman, and *C. pilosellus* Motschulsky to be distinguished from *C. dimidiatus*. *C. dimidiatus*. Two of the sibling species, *C. freemani* and *C. mutilatus*, are very common in corn fields in South Carolina.

A goal of our project has been to understand pheromone chemistry and biology in nitidulid beetles so that synthetic pheromones can become tools for monitoring beetle populations and for preventing beetle-related damage (e.g., direct feeding injury or transmission of harmful microorganisms). Male-produced aggregation pheromones have been reported previously for a number of species, including *C. freemani* and *C. mutilatus* (Bartelt et al., 1990b, 1993a), but *C. dimidiatus* was unstudied in this way. We report here the identification of a male-produced pheromone from *C. dimidiatus* and verification of its activity under field conditions. We also present baseline information about the responses of *C. dimidiatus* and other *Carpophilus* species to various *Carpophilus* pheromones in South Carolina cornfields throughout the year.

METHODS AND MATERIALS

Pheromone Identification for C. dimidiatus. A culture of beetles was started from individuals captured 17 km southeast of Bamberg, Bamberg County, South Carolina. The beetles were reared on a wheat-germ and brewer's yeast diet as

described previously for *C. antiquus* Melsheimer (Bartelt et al., 1993b; Dowd and Weber, 1991).

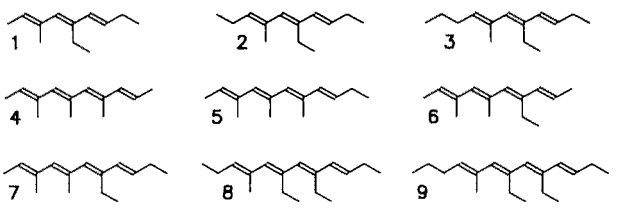
Bartelt et al. (1990a) described the system for collecting volatiles from feeding beetles. Beetle-produced and diet volatiles were collected on filters of Super-Q porous polymer (Alltech Associates, Deerfield, Illinois) and were eluted from the filters every one to three days with hexane. Initial collections were from groups of about 10 males or females on the artificial diet. Later collections were made from groups of 50 males or females and from individual males. Beetles were placed in volatile collectors within one week of emergence. All were in the volatile collectors for at least two weeks; one individual male was monitored for 3.5 months. Nonadecane (2.5 μg) was added to each collection as an internal standard for quantitation by GC.

Male- and female-derived collections were compared by capillary gas chromatography (DB-1 column, 15-m length, 1-μm film thickness, 0.25-mm ID; temperature programmed from 50°C to 250°C at 10°C/min), and GC retention indices relative to *n*-alkanes were calculated for sex-specific compounds. (Any sex-specific compounds would be considered as likely pheromone components.) The Hewlett Packard 5890 gas chromatograph was equipped with splitless injector, flame ionization detector, and Hewlett Packard 3396A integrator. Electron impact mass spectra were obtained for the detected sex-specific compounds on a Hewlett-Packard 5970 Mass Selective Detector with capillary GC inlet.

When it became evident that *C. dimidiatus* followed the pattern existing in other *Carpophilus* species (i.e., that the only detectable sex-specific compounds were hydrocarbons emitted by males), the male-derived hydrocarbons were analyzed further for any related, minor components because multiple component pheromones occur in other *Carpophilus species*. The 58 volatile collections from individual males were combined, and the constituents were separated by polarity on silica gel (Bartelt et al., 1990a). The hexane (hydrocarbon) fraction from this sample was examined in detail by GC and mass spectrometry for compounds analogous to the major, male-specific hydrocarbon.

Synthetic Compounds. The synthetic hydrocarbons used in this study are shown in Figure 1: (2*E*, 4*E*, 6*E*)-5-ethyl-3-methyl-2,4,6-nonatriene (**1**), (3*E*, 5*E*, 7*E*)-6-ethyl-4-methyl-3,5,7-decatriene (**2**), (3*E*, 5*E*, 7*E*)-5-ethyl-7-methyl-3,5,7-undecatriene (**3**), (2*E*, 4*E*, 6*E*, 8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene (**4**), (2*E*, 4*E*, 6*E*, 8*E*)-3,5,7-trimethyl-2,4,6,8-undecatetraene (**5**), (2*E*, 4*E*, 6*E*, 8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-decatetraene (**6**), (2*E*, 4*E*, 6*E*, 8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-undecatetraene (**7**), (3*E*, 5*E*, 7*E*, 9*E*)-6,8-diethyl-4-methyl-3,5,7,9-dodecatetraene (**8**), and (3*E*, 5*E*, 7*E*, 9*E*)-5,7-diethyl-9-methyl-3,5,7,9-tridecatetraene (**9**). Compounds **1**–**8** were synthesized previously and were available for the present study (Bartelt et al., 1990b,c, 1993b).

Compound **9** was prepared and purified in the same way as **8** (Bartelt et al., 1993b) except that (*E*)-2-methyl-2-hexenal, an intermediate in the synthesis of **3** (Bartelt et al., 1993a), was used as the starting material instead of (*E*)-2-



SEPTUM TYPE	COMPOUND

OBS					100			

FIG. 1. Structures of compounds involved in this study and assigned structure numbers (top). Composition of pheromone baits for six *Carpophilus* species (bottom). The abbreviations DIM, FRE, MUT, HEM, LUG, and OBS refer to septa for *C. dimidiatus*, *C. freemani*, *C. mutilatus*, *C. hemipterus*, *C. lugubris*, and *C. obsoletus*, respectively. Compositions are relative, by weight, with the most abundant (or only) component given as 100. For DIM, total weight of pheromone was 1.2 mg/septum; for all other baits, the total was 500 μg/septum. Compound **9** was not used in field baits. Asterisk: compound **2** in the DIM bait was an artifact of synthesis and was not intentionally added.

methyl-2-pentenal. The mass spectrum of **9** is given in Figure 2, and the following NMR proton spectrum was obtained (400 MHz, Bruker ARX-400 spectrometer, deuterobenzene solvent): δ 0.94, 3H, t, J = 7.4; δ 1.02, 3H, t, J = 7.4; δ 1.12, 3H, t, J = 7.5; δ 1.22, 3H, t, J = 7.5; δ 1.40, 2H, sext, J = 7.3; δ 1.79, 3H, br s; δ 2.05–2.15, 4H, apparent distorted sext (actually δ 2.08, 2H, q, J = 7.4; and δ 2.11, 2H, quin, J = 7.4); δ 2.42, 2H, q, J = 7.5; δ 2.60, 2H, q, J = 7.5; δ 5.58, 1H, br t, J = 7.3; δ 5.76, 1H, dt, J = 15.7, 6.6; δ 5.95, 1H, br s; δ 6.11, 1H, br s; δ 6.13, 1H, d, J = 15.7 (half obscured by δ 6.11 signal). Proton assignments are given in Figure 2 and are consistent with previously analyzed all-*E* tetraenes and trienes having partial structures in common with **9** (Bartelt et al., 1990b, 1992, 1993b). The identification and synthesis of compound **9** were not completed in time for field testing.

Baits for Field Tests. The compositions of the six pheromone types are presented in Figure 1 (Bartelt et al., 1990b, 1991, 1992, 1993a; Petroski et al.,

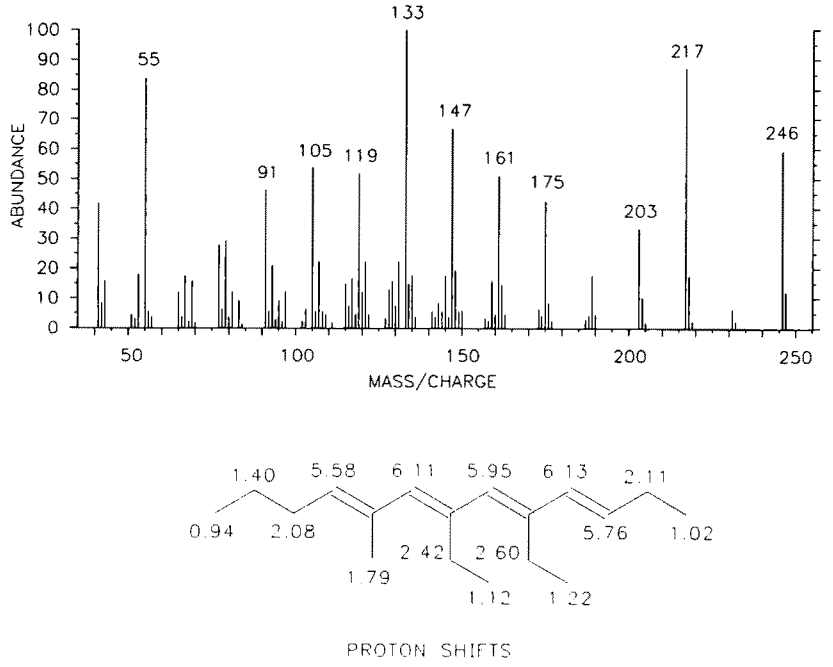

FIG. 2. Mass spectrum and assigned NMR proton shifts for tetraene **9.** Shifts are in parts per million from tetramethylsilane.

1994). Proportions were chosen so that emissions from septa would be as similar in composition as possible to those from beetles. For all species except *C. dimidiatus*, a total of 500 μg of all-*E* isomers was used per trap bait. The pheromone for *C. dimidiatus* was used at the rate of 1.2 mg/bait; this higher value was as in an earlier study (Bartelt et al., 1993b) and was chosen to compensate for the relatively low volatility of **8.** Each trap bait was prepared by adding the synthetic pheromone in 10 μl hexane, followed by 300 μl methylene chloride, to a rubber septum. After the chemicals had soaked in, the septa were stored in tightly closed bottles in a freezer until used.

The *C. dimidiatus* pheromone was intended to include only compound **8,** but compound **2** was also present due to an incomplete Wittig-Horner reaction during synthesis (Bartelt et al., 1993b). Compound **2** was removed from a sample of this synthetic mixture by reverse-phase HPLC (Serva Biochemicals 5-cm × 25-cm C_{18} column, 5-μm particle size, distributed by Crescent Chemical Co., Hauppauge, New York); the solvent was acetonitrile, and effluent was monitored with a refractive-index detector. Injection size was 100 mg; com-

pound **2** eluted 580–670 ml after injection, and compound **8** at 780–950 ml. The HPLC fractions were diluted with water and extracted with hexane to recover the hydrocarbons. Additional septa were prepared with the purified **8.**

Otherwise, technical grade synthetic components were used for all field baits (60–90%). Except for **2** as a contaminant of synthetic **8,** none of the synthetic compounds contained detectable levels of any other component shown in Figure 1. The impurities were almost exclusively *Z* isomers unavoidably produced during synthesis and could not be removed on the scale required for field baits. Bartelt et al. (1992) found that *Z* isomers of the major component of the *C. hemipterus* (L.) pheromone were inert or slightly attractive but not repellent.

Field Bioassays. The field experiments were conducted at two sites in South Carolina. The first (33°11′ north latitude, 80°55′ west longitude) was 17 km southeast of Bamberg, in Bamberg County, and the other (30°23′ north latitude, 81°18′ west longitude) was at Blackville, in Barnwell County. The traps (wind-oriented funnel traps; Dowd et al., 1992) were always placed at the edges of corn fields at the interface with native vegetation. The traps were attached to tree branches and suspended about 1.5 m above the ground. The experimental design was a randomized block. Traps within a block were separated by ca. 10 m. Each week, captured beetles were removed from the traps, fermenting whole-wheat bread dough (usually present as a coattractant) was replaced, and the traps were rerandomized within the blocks. Pheromone septa were replaced every two weeks. Trap catches were frozen to kill any remaining live beetles and were sent to NCAUR at Peoria for separation and counting by species (and in experiment 1, by sex). Species were identified primarily by using the characteristics described by Okumura and Savage (1974) and Connell (1991). Species identifications were confirmed by the USDA Systematic Entomology Laboratory at Beltsville, Maryland. The field bioassays consisted of three experiments.

Experiment 1 tested for the activity of the putative pheromone of *C. dimidiatus*, both with and without a food-related coattractant. The four treatments were synthetic *C. dimidiatus* pheromone (with impurity **2** present, Figure 1), the pheromone in combination with fermenting whole-wheat bread dough (15 ml/trap), bread dough alone, and unbaited controls. The trap design prevented incoming beetles from contacting any trap baits; the two components of combination baits (septum and dough) were physically separated from each other. The treatments were arranged in six blocks, four at the Bamberg County site and two at the Barnwell County site. The study ran for six weeks, from March 18 to April 29, 1993.

Experiment 2 was a year-long survey for *Carpophilus* flight activity at the study sites (May 5, 1993, to May 4, 1994). There were seven treatments; six were the synthetic pheromones for *C. dimidiatus* (with impurity **2**), *C. freemani*,

C. mutilatus, *C. hemipterus*, *C. lugubris* Murray, and *C. obsoletus* Erichson (Figure 1), each combined with bread dough, and the seventh treatment was the bread-dough control. The study was arranged in three blocks, two in Bamberg County and one in Barnwell County.

Experiment 3 explored the previously observed cross attraction of *C. freemani* and *C. mutilatus* to the pheromone of *C. dimidiatus* (with impurity **2**) and of *C. freemani* to the pheromone of *C. mutilatus*. The experiment was established by adding three additional treatments to all three blocks of experiment 2 during a 10-week period (October 13–December 22, 1993). These treatments were: compound **8** (1.2 mg) from which impurity **2** had been chromatographically removed plus dough; compound **2** (500 μg) plus dough; and compound **3** (500 μg) plus dough. Catches for these treatments were to be compared with those for four treatments of experiment 2: the pheromones for *C. dimidiatus* (containing **8** and impurity **2**), *C. freemani*, and *C. mutilatus* plus dough and the dough control.

For all field experiments, trap catches were transformed to the log $(x + 1)$ scale to stabilize variance and subjected to analysis of variance. Separation of means was by the least significant difference (LSD) method, and the probability level was 0.05.

Weather and Corn Phenology. The daily maximum and minimum temperatures and daily precipitation amounts at Bamberg during the field studies were obtained from the National Oceanic and Atmospheric Administration. The town of Bamberg is located about halfway between the two field sites. The times of certain events and stages for the corn crop were recorded: planting, silking, milk stage, dough stage, and harvest.

RESULTS

Pheromone of C. dimidiatus. Volatile collections from males on artificial diet consistently contained a compound (GC retention index = 1620) that was always lacking in collections from females on diet. The compound eluted from silica gel with hexane, indicating it had the polarity of a hydrocarbon. The compound was identical to synthetic compound **8** by both GC retention and mass spectrum. Compound **8** was previously identified as the aggregation pheromone of *C. antiquus* (Bartelt et al., 1993b).

The amount of compound **8** emitted from *C. dimidiatus* depended greatly on the number of males present in the collection flask. Individual males emitted a mean of 0.58 μg/day (±0.35 SD, $N = 58$ observations), but the mean was only 0.012 μg/male/day (±0.014 SD, $N = 8$) in collections from groups of 10–13 males and only 0.0011 μg/male/day (±0.0009 SD, $N = 15$) in collections from 50 males. Regardless of beetle density, emission began within two to five

days of placing the beetles into the volatile collectors. One individual was monitored for 3.5 months, and compound **8** was still being produced (0.5 μg/day) when the study was terminated.

Whenever tetraene **8** was prominent in the gas chromatogram of a volatile collection, a second male-specific peak was also observed (retention index = 1725; peak area 4.9% as large as that for **8** in the combined volatile collections from individuals). By mass spectrometry, the molecular weight was 246, which was consistent with an 18-carbon tetraene. Study of retention indices of various hydrocarbon analogs (Bartelt et al., 1990b, 1992) suggested that the new compound had structure **9**. Compound **9** was synthesized and was identical to the beetle-derived compound both in mass spectrum and GC retention.

Experiment 1. Synthetic pheromone for *C. dimidiatus* was highly attractive to this species in the field (Table 1). The activity of the pheromone was increased about two-fold by the presence of fermenting bread dough, but dough by itself was not attractive. The unbaited control caught no *C. dimidiatus*. Overall, 21,681 *C. dimidiatus* were captured.

Five other species responded and were significantly more attracted to the combination of *C. dimidiatus* pheromone plus dough than to dough by itself or to the unbaited control (Table 1). For *C. antiquus*, the combination and pheromone alone were equally attractive, but for *C. freemani*, *C. mutilatus*, *C. marginellus* Motschulsky, and *C. humeralis* (F.), synergism was evident, and the combination was clearly more attractive than the pheromone alone. Overall

TABLE 1. FIELD RESPONSES TO SYNTHETIC PHEROMONE FOR *C. dimidiatus* WITH AND WITHOUT COATTRACTANT, MARCH 18 TO APRIL 29, 1993

Species	Mean trap catch (N = 36)[a]				Percent females (%)[c]
	Pheromone + dough[b]	Pheromone	Dough	Control	
C. dimidiatus	48.3 a	24.5 b	0.02 c	0.00 c	69
C. antiquus	0.39 a	0.40 a	0.00 b	0.00 b	51
C. freemani	47.9 a	8.00 b	0.08 c	0.00 c	64
C. mutilatus	10.1 a	0.47 b	0.33 bc	0.00 c	73
C. marginellus	2.39 a	0.96 b	0.04 c	0.02 c	46
C. humeralis	0.15 a	0.02 ab	0.00 b	0.00 b	38

[a] In each row, means not accompanied by the same letter are significantly different (LSD, 0.05 level). Means were calculated in the analysis scale [log(x + 1)] but were converted back to the numerical scale for presentation.

[b] Synthetic pheromone for *C. dimidiatus* is shown in Figure 1 (DIM) and contains impurity **2**; dough is fermenting whole-wheat bread dough.

[c] Percentages are based on totals over all treatments.

totals for the latter five species were 59, 4764, 966, 383, and 13, respectively. Both sexes of all species were trapped.

Experiment 2. The overall effectiveness of the six synthetic pheromones is summarized in Figure 3. *C. dimidiatus*, *C. freemani*, *C. mutilatus*, and *C. hemipterus* responded significantly better to their pheromones (plus bread dough) than to the dough controls. The overall trap totals for these species during the one-year study were 41,500; 164,000; 13,300; and 75, respectively. The final two species for which pheromones were put out, *C. lugubris* and *C. obsoletus*, were not detected.

As in the first experiment, *C. antiquus* was also captured; nine of the 11 specimens were in traps baited with the *C. dimidiatus* pheromone, and the *C. lugubris* and *C. obsoletus* pheromones each caught one. In addition, *C. marginellus* and *C. humeralis*, for which pheromones are not yet known, were caught consistently (Figure 3); their overall totals were 11,700 and 2960, respectively. *C. marginellus* responded best to the *C. lugubris* and *C. freemani* pheromones, but only for the *C. mutilatus* pheromone was the response not significantly higher than the dough control. *C. humeralis* responded significantly to all six pheromones, but these responses were relatively moderate (in the range of only two to five times higher than the control).

Various degrees of cross-attraction occurred for *C. dimidiatus*, *C. freemani*, *C. mutilatus*, and *C. hemipterus* and their pheromones (Figure 3). Cross-attraction was least for *C. dimidiatus*, and the mean trap catch to an interspecific bait never exceeded 5% of that to its own pheromone. For *C. freemani*, cross-attraction to the *C. dimidiatus* and *C. mutilatus* pheromones was about 22% of the response to its own pheromone, but cross-attraction to the other pheromones was only 4–5%. For *C. mutilatus*, cross-attraction was greatest to the pheromone of *C. dimidiatus* (17% of the response to the pheromone of *C. mutilatus*). *C. hemipterus* was not significantly cross-attracted to the pheromones of the other three species but responded clearly to those of *C. lugubris* and *C. obsoletus*. The small numbers of *C. hemipterus* captured during the study made it difficult to assess relative attractiveness of baits.

Responses to Pheromones over Time. Trap catches for all six species were relatively high during autumn (September through November) and, for all species except *C. humeralis*, again during late winter and spring (late February through mid-June) (Figure 4). Few beetles were captured during the coldest part of winter (mid-December to mid-February) or during summer, when the corn crop was developing and ripening. Data for temperature, rainfall, and corn phenology are included in Figure 4 for reference. Harvest times for the Bamberg and Barnwell County fields (plots 1 and 2, respectively, Figure 4) differed by six weeks, but other events and stages for the two fields were synchronized to within a week.

Experiment 3. The synthetic pheromone for *C. dimidiatus*, which contained

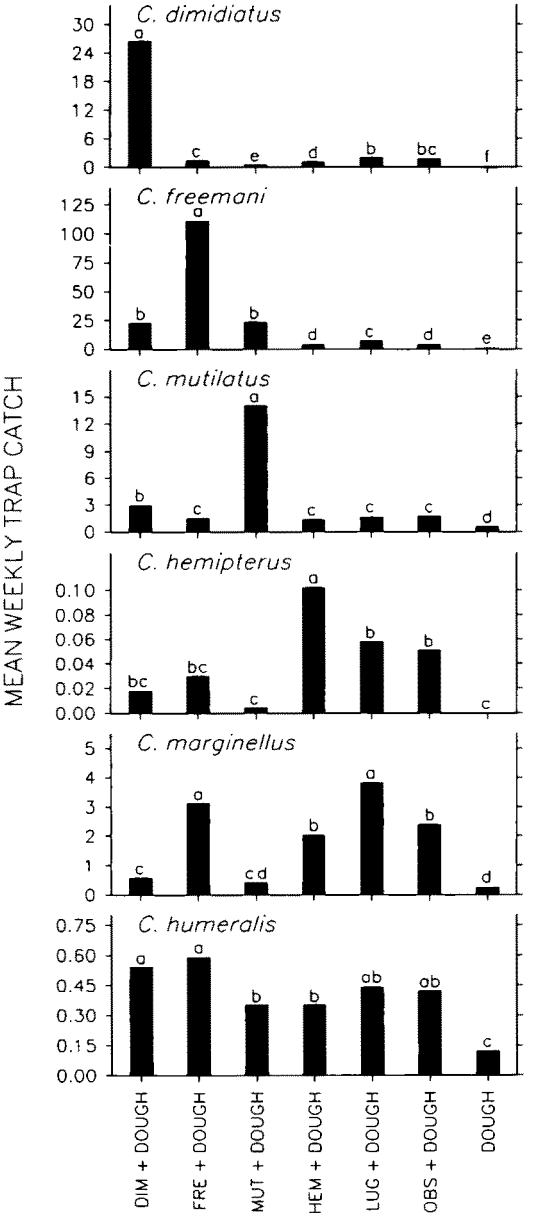

FIG. 3. Mean weekly captures for six *Carpophilus* species by traps baited with synthetic pheromones plus fermenting dough (N = 156). The study period was May 5, 1993, to May 4, 1994. Within each panel, means accompanied by the same letter were not significantly different (LSD, 0.05 level).

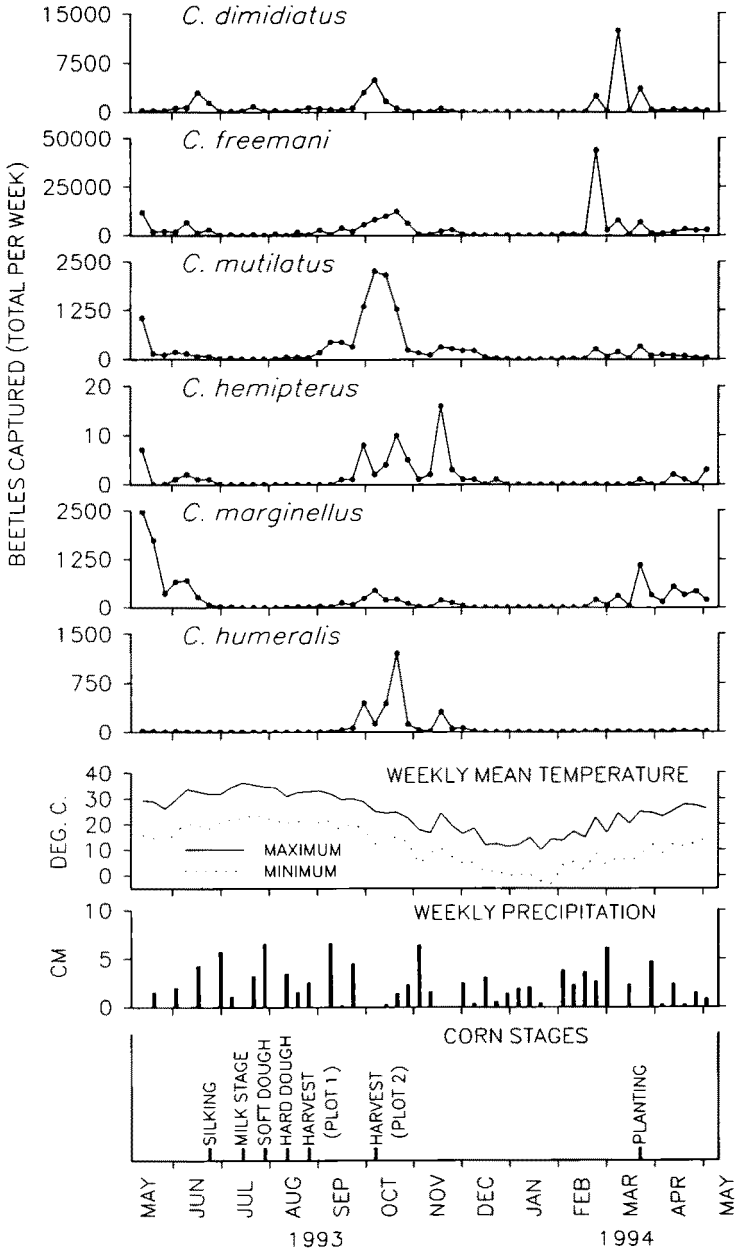

FIG. 4. Weekly trap catches for six *Carpophilus* species, totaled over all treatments, and data for temperature, precipitation, and corn phenology.

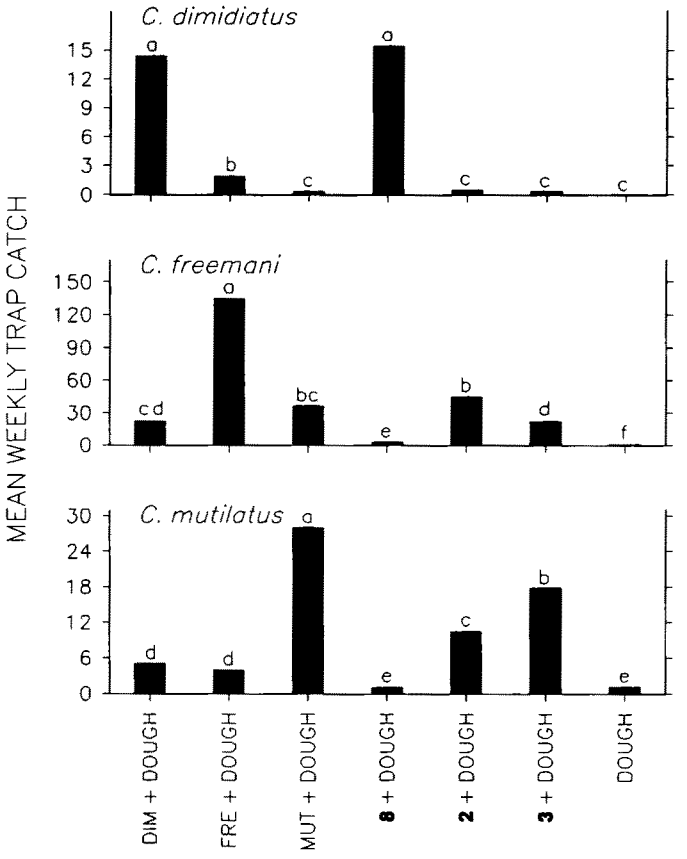

FIG. 5 Field responses of the three most abundant *Carpophilus* species to their synthetic pheromones and to various single components ($N = 30$). Study period was October 13 to December 22, 1994. Within each panel, means accompanied by the same letter were not significantly different (LSD, 0.05 level).

compound **8** and impurity **2**, and chromatographically purified compound **8** were equivalent for attracting *C. dimidiatus* in the field (Figure 5). However, responses of *C. freemani* and *C. mutilatus* to the *C. dimidiatus* pheromone decreased markedly when impurity **2** was removed. Correspondingly, compound **2** was active by itself for both *C. freemani* and for *C. mutilatus* but not for *C. dimidiatus*. *C. mutilatus* responded clearly to the separate components of its pheromone (**2** and **3**), but the standard synthetic blend, which contains both components, was most attractive. For *C. freemani*, compound **3** was less active

than **2** but still attracted significantly more beetles than the control. Neither **2** nor **3** was added to the synthetic bait for *C. freemani*; see Discussion.

DISCUSSION

Pheromone of C. dimidiatus. The major pheromone component of *C. dimidiatus* is concluded to be (3*E*, 5*E*, 7*E*, 9*E*)-6,8-diethyl-4-methyl-3,5,7,9-dodecatetraene (compound **8**). The same compound was previously identified as the pheromone of *C. antiquus* (Bartelt et al. 1993b). The compound by itself was highly attractive in the field, but trap catches nearly doubled when fermenting whole-wheat bread dough was added to the trap as a coattractant; the dough was not attractive by itself. It is typical for *Carpophilus* pheromones to be synergized by volatiles from a food source such as fermenting dough or fruit (Bartelt et al., 1994; Blumberg et al., 1993). The major volatiles from fermenting bread dough were reported by Lin and Phelan (1991).

A second male-specific compound, (3*E*, 5*E*, 7*E*, 9*E*)-5,7-dimethyl-9-methyl-3,5,7,9-tridecatetraene (**9**), is about 5% as abundant as **8** in male-derived volatiles and may serve as an additional pheromone component. Compound **9** is a novel structure. Synthetic material was not available before the field trials ended, and its activity remains unmeasured.

The pheromone emission rate per male decreased greatly as the number of males in the pheromone collector increased. A similar reduction was reported for *C. davidsoni* Dobson (Bartelt and James, 1994) and *C. obsoletus* (Petroski et al., 1994). In nature, such a reduction would help to limit the size of forming aggregations; otherwise, the largest aggregations would be most attractive to flying beetles and would continue to grow still larger. The mechanism controlling emission rate is unstudied.

Relationships among C. dimidiatus, C. freemani, *and* C. mutilatus. *C. dimidiatus* and its two sibling species, *C. freemani* and *C. mutilatus*, were the nitidulids captured in greatest numbers, and each demonstrated a great deal of specificity for its own pheromone. The differences in pheromone chemistry must contribute to their successful coexistence in the same habitat. The significant cross-attraction of *C. freemani* and *C. mutilatus* to the synthetic *C. dimidiatus* pheromone noted in experiments 1 and 2 was primarily an artifact of synthesis; when compound **2**, which *C. dimidiatus* does not make, was removed from the *C. dimidiatus* pheromone for experiment 3, captures of *C. freemani* and *C. mutilatus* were reduced essentially to control levels.

That *C. mutilatus* would respond to **2** was expected because its aggregation pheromone contains **2** (Bartelt et al., 1993a); however, compound **2** was less attractive than an equal weight of compound **3**, the major pheromone component of *C. mutilatus*, and both compounds alone were less attractive than an equal

weight of the appropriate mixture of compounds **2** and **3** (Figure 5). A greater response of *C. mutilatus* to a mixture than to individual components was not noted in earlier wind-tunnel tests (Bartelt et al., 1993a).

Compound **2** is also a minor component of the pheromone of *C. freemani* (Bartelt et al., 1990b). It did not enhance the attractiveness of the main component **1**, in earlier wind-tunnel tests (Bartelt et al., 1990b); therefore, **2** has been left out of the "standard" field bait. Compound **3** also occurs to a very minor extent in emissions from *C. freemani*. It was not active in initial wind-tunnel tests (Bartelt et al., 1990b), but it was slightly active in the field (Figure 5). The modest attraction of *C. freemani* to the baits for *C. mutilatus* apparently has a biological basis, but the *C. mutilatus* baits are still far less attractive than the baits prepared specifically for *C. freemani* (containing **1** and **7**). The present results also suggest that an even more potent bait for *C. freemani* could be developed if more of the known minor components were included.

Other Relationships among Species. *C. dimidiatus* and *C. antiquus* share the same pheromone chemistry (except for possible minor components), but conflicts in chemical communication for these species appear to be avoided primarily by geographic separation. *C. antiquus* has a more northern distribution than *C. dimidiatus* (Connell, 1991; Bartelt, et al., 1993b and references therein). South Carolina may represent a transition zone, south of which only *C. dimidiatus* would be found.

C. dimidiatus did not exhibit the obvious cross-attraction to the *C. lugubris* pheromone that was previously demonstrated for *C. antiquus* (Bartelt et al., 1993b; Williams et al., 1995). In the midwestern United States, *C. antiquus* appears to use the *C. lugubris* pheromone as a kairomone, locating suitable host sites (e.g., corn ears) previously colonized by *C. lugubris*. There was no indication that *C. dimidiatus* exploits another species in this way.

The absence of *C. lugubris* in this study was surprising because it is common in the eastern states, being the most abundant *Carpophilus* species in Delaware and having been reported in the eastern states from New Jersey south to South Carolina (Connell, 1956). The species occurs widely in North, Central, and South America (Williams et al., 1983).

C. hemipterus was caught in very low numbers, but cross-attraction to the pheromones of *C. lugubris* and *C. obsoletus* was especially clear. This is not surprising because these pheromones contain one or both of compounds **5** and **7**, which are active minor components in the *C. hemipterus* pheromone (Bartelt et al., 1992). *C. marginellus*, for which a pheromone is not yet known, also responded very clearly to all baits that contained tetraenes **5** or **7**, or both.

C. humeralis, for which a pheromone is also unknown, responded significantly to all of the pheromones, whether they were tetraenes or trienes. While a preference for a small subset of the synthetic compounds was evident for *C. marginellus*, such was not the case for *C. humeralis*.

Flight Activity Throughout the Year. Most of the beetles were captured during periods when food resources were scarce. As the weather warmed in late winter, adults dispersed from their overwintering sites and probably emerged from pupation in the soil as well (Connell, 1956). Moderate flight activity (and presumably, reproduction at various ephemeral feeding sites) continued through the spring until the developing corn crop, probably the richest nitidulid food source in the area, had reached the silking stage and become infestable. Examination of developing ears revealed that the beetles were present in the corn and that reproduction was occurring, but the traps detected little further flight activity until the corn was ready to harvest. The autumn flight probably represented adults reemerging from the dried corn crop as well as their progeny that had developed on the corn and were maturing.

The species were generally similar in their trap-catch trends over time except for *C. humeralis*, which was captured commonly only during September–November (Figure 4). It is unknown whether the population of this species was large only in autumn (e.g., from immigration) or if the responsiveness to the traps changed during the year.

Most trap catches occurred when the daily maximum temperature was in the range of 20–30°C (Figure 4). Other factors besides temperature, such as condition of food supply, must be involved in regulating overall flight activity, but it does appear that rising temperatures after relatively cool periods are able to trigger and synchronize beetle flights. The final trap catch in February and the second and fourth catches in March were relatively large, and this heavy flight activity was correlated with weekly mean maximum temperatures that were 5–8°C higher than for the prior or intervening weeks (Figure 4). A similar peak, apparently related to temperature, occurred for the third trap check of November. There was no obvious correlation between flight activity and rainfall.

The 1993 growing season was poor for South Carolina corn farmers. Despite frequent rains from June to harvest, precipitation for April and May was spotty and below normal, resulting in stunted corn plants and low yields. It is unknown whether nitidulid flight patterns would be different in more normal years.

Comparison with Other Field Studies. The responses to the *Carpophilus* pheromones observed in this study were generally very similar to those in Australia (James et al., 1993), Israel (Blumberg et al., 1993), Ohio (Williams et al., 1995), and California (Bartelt et al., 1994), to the extent that the same pheromones were tested and that the responding species were present in meaningful numbers. The pheromones have become useful tools for revealing the *Carpophilus* fauna and monitoring its seasonal activity in a variety of habitats.

Nitidulids and Aflatoxin. Although the feeding damage caused by nitidulids in field corn is of little concern, nitidulids have been implicated as vectors of *Aspergillus flavus* Link: Fr., the fungus that produces aflatoxin (Lussenhop and Wicklow, 1990; Wicklow, 1991). Aflatoxin has been a recurrent problem in

corn, particularly in the southeastern United States. The nitidulid pheromones would be useful in the study of beetle-mediated movement of *A. flavus* inoculum. Furthermore, it was recently suggested that feral beetles could be manipulated to disseminate biocompetitive microrganisms into corn that would suppress *A. flavus* development (Vega et al., 1995). The concept depends on pheromone-baited autoinoculators. Now that pheromones are known for the major indigenous *Carpophilus* species in the Southeast, the utility of this approach for reducing aflatoxin levels in this region can be explored.

Acknowledgments—The assistance of several scientists at NCAUR is gratefully acknowledged: Dr. Richard O. Adlof guided the preparative scale HPLC separation of compounds **8** and **2**, Dr. David Weisleder kindly ran the NMR spectrum of compound **9**, and Ronald D. Plattner helped to obtain the mass spectra. Richard V. Byrd and B. Ray Flaherty assisted in the field work in South Carolina. The cooperation of Joe J. Bates and Richard and Howard Rentz in providing field sites is gratefully acknowledged. Dr. James Pakaluk of the USDA ARS Systematic Entomology Laboratory confirmed the beetle identifications; specimens were deposited in the collection of the U.S. National Museum, Washington, D.C.

(Received March 23, 1995; accepted July 8, 1995)

Abstract—Iridoid glycosides, terpene-derived compounds found in many plant families, protect the plant against generalist and nonadapted specialist insect herbivores, fungi, and bacteria. Antirrhinoside, a common iridoid glycoside in the tribe Antirrhineae (Scrophulariaceae), was rapidly labeled when mature leaves of *Asarina scandens* were exposed to $^{14}CO_2$. Antirrhinoside was translocated in the phloem along with sucrose. Radiolabeled antirrhinoside appeared in the petiole of the labeled leaf within 20 min of the beginning of the labeling period. Antirrhinoside was also found in phloem sap obtained by the EDTA method.

Key Words—Antirrhinoside, *Asarina scandens*, iridoid glycoside, phloem, Scrophulariaceae, translocation.

INTRODUCTION

Plants synthesize a wide array of compounds to protect them against herbivores and pathogens. If any of the components of the chemical defense system are translocated, the plant gains a potential defense against phloem-feeding organisms and also gains the ability to coordinate the synthesis and use of protective resources in various organs. Note, for example, the systemic nature of signals in acquired resistance to virus, bacteria, and fungi (Ryals et al., 1994) and to insects (Narvaez-Vasquez et al., 1994).

An ideal candidate class of phloem-mobile defensive chemicals is the group of terpene-derived compounds known as iridoid glycosides (Bowers, 1991). There are almost 600 known iridoid glycosides in at least 57 families of plants (Bowers, 1991). Some of these compounds, which can comprise almost one quarter of the dry weight of certain leaves (Bowers, 1991; Boros et al., 1991), are among the most bitter substances known and are effective in protecting many plant species against generalist and nonadapted specialist insect herbivores. They may also inhibit seed germination and seedling growth (Adam et al., 1979) and act as toxins to both fungi (van der Sluis et al., 1983) and microbes (Kubo et al., 1985). Many insects sequester iridoid glycosides that they obtain from plants in order to defend themselves against potential predators (Bowers, 1991; Bowers and Farley, 1990).

Iridoid glycosides are synthesized via the mevalonic acid pathway (Inouye and Uesato, 1986). Many are potentially phloem-mobile because they are of low molecular weight, water soluble, and nonreducing, as are other phloem-mobile substances. We report here that antirrhinoside, a common iridoid glycoside found throughout the tribe Antirrhineae in the family Scrophulariaceae (Kooiman, 1970) and sequestered by aposematic moth larvae (Boros et al., 1991) is translocated in *Asarina scandens*.

METHODS AND MATERIALS

Plant Material. Seeds of *Asarina scandens* (Cav.) Penn. were obtained from Thompson and Morgan (Jackson, New Jersey). Plants were grown in a greenhouse in artificial soil (Metro-Mix 350; E.C. Geiger, Harleyville, Pennsylvania) and used for experimentation when approximately 3 months old (Turgeon et al., 1993). Daylight in the greenhouse was extended to 16 h with fluorescent lamps.

Analytical Methods. Mature leaf blade tissue was frozen and ground in liquid N_2 and extracted at 50°C in methanol–chloroform–water (12:5:3, v/v/v) (Haissig and Dickson, 1979). Water was then added to obtain biphasic partitioning of the extract (3 parts water per 5 parts extract). Following centrifugation (2,000*g*, 10 min), the separated aqueous phase was passed through ion-exchange membranes [Bio-Rex AG50W cation membrane (H^+ form) and AG1 anion membrane (carbonate form)] (Bio-Rad, Richmond, California) (Turgeon and Gowan, 1992), filtered through a 0.22-μm nylon spin filter, and separated by HPLC using a Waters (Milford, Massachusetts) model 510 pump, a Waters SugarPak 1 column held at 90°C, and a Waters model 410 differential refractometer. Water was used as the mobile phase. A large peak migrating at 10.5 min was isolated by pooling three 0.5-min fractions and dried down at 70°C under a stream of N_2 gas. When rechromatographed by the same methods, 96% of the pooled material ran as a single peak.

Two-dimensional TLC on plant extracts and purified compounds was performed using silica gel GHL plates (Analtech, Newark, Delaware), pretreated by dipping in a solution of 0.03 M boric acid in 60% ethanol (v/v), and activated at 95–110°C for 1 h. The first development was in chloroform–acetic acid–water (6:7:1, v/v/v) and the second in isopropanol–water (5:1, v/v).

NMR spectroscopy of the purified material was performed in a 5-mm tube in D_2O on a Varian VXR-400S with acetone as internal reference. The ^{13}C spectrum was obtained in the proton-decoupled mode. Carbon-13 chemical shifts were corrected to 61.55 ppm for C-6 of the glucosyl residue.

Radiolabeling Methods. Plants were brought into a laboratory fumehood illuminated by a water-filtered incandescent 1000-W metal-halide lamp providing approximately 400 μmol photons/m^2/sec (photosynthetically active radiation) at plant level. Approximately 1 hr later a mature leaf blade was enclosed in a plastic bag and $^{14}CO_2$ (1.5 MBq), generated in the barrel of a syringe by addition of excess 80% lactic acid to [^{14}C]Na_2CO_3 (6.6×10^5 MBq/mmol), was injected into the bag without delay. The petiole of the labeled leaf was covered with aluminum foil to prevent accidental photosynthetic incorporation of leaked gas. After a 5-min exposure to $^{14}CO_2$, the bag was removed and, following a chase period in room atmosphere, the leaf blade and petiole were quickly removed and separately plunged into liquid N_2. Tissue was extracted and analyzed by TLC as described above. Radiolabeled spots were detected with X-ray film, scraped from the plate, and quantified by scintillation counting.

Phloem Exudate. Ten leaves were cut at the base of the petiole, in the middle of the day, and immediately recut under water. The leaves were then placed in a single group in a small tube so that the petiole bases were immersed in 0.2 ml of a solution of 20 mM EDTA in 20 mM PIPES buffer (pH 6.8). The leaves were then placed, in their tube, in a humid chamber in complete darkness at room temperature. The EDTA solution was entirely removed for analysis and replaced every hour for 4 hr. The solutions were purified by ion-exchange chromatography and the neutral fraction analyzed by HPLC as described above.

RESULTS

Identification of Antirrhinoside. In extracts of *A. scandens* leaf blade tissue we detected an HPLC peak that eluted at 10.5 min from the SugarPak column, while sucrose eluted at 7.8 min. There was considerably more of this material (9.5 mg/g fresh weight) than sucrose (1.4 mg/g fresh weight) or any other component of the neutral fraction. This substance was present in all five species of the Antirrhineae that we previously studied (Turgeon et al., 1993). It co-chromatographed with several monosaccharide standards on the SugarPak column but tested negatively as a reducing compound with Benedict's solution or 2,2′-bicinchoninate (Sturgeon, 1990). On TLC plates it produced an intense

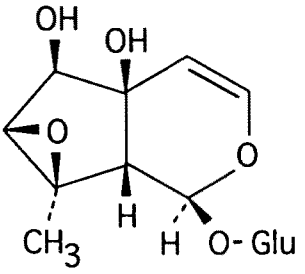

FIG. 1. Structure of antirrhinoside.

dark brown to black color with Seliwanoff's reagent (Zweig and Sherma, 1972) or vanillin-H_2SO_4 reagent (Touchstone and Dobbins, 1983) and a blue fluorescence with *p*-anisidine phosphate reagent (Kooiman, 1970). Glucose was produced upon hydrolysis with 2 N trifluoroacetic acid (room temperature for 2 hr).

The compound was identified as antirrhinoside (Figure 1) by ^1H and ^{13}C NMR. Chemical shifts and coupling constrants for protons of the aglycone and the anomeric carbon (H1′) of the glucosyl unit agreed closely with reported values for antirrhinoside (Scarpati et al., 1968). Carbon-13 NMR data confirmed the identity of antirrhinoside. The chemical shifts for all carbons in the aglycone and glucosyl unit were in close agreement with published values (Bianco et al., 1981).

Translocation Experiments. Antirrhinoside in the lamina became labeled, although not as quickly as sucrose, following exposure of the leaf to $^{14}CO_2$ (Figure 2). With increasing time the amount of labeled antirrhinoside increased in both absolute terms and in proportion to sucrose so that within an hour the label in antirrhinoside was approximately one quarter that of sucrose. To determine if antirrhinoside is translocated, the petioles of the same leaves were extracted. Radiolabeled sucrose and antirrhinoside were first found in the petioles in measurable quantities 20 min after exposure of the leaves to $^{14}CO_2$, and the amount of these radiolabeled compounds increased rapidly over the next 40 min (Figure 2). The proportion of labeled antirrhinoside in the petiole increased in the same way that it did in the lamina.

It is important to note that radioactive antirrhinoside was already present in the translocate when label was first detected in the petiole. This rules out the possibility that labeled antirrhinoside is synthesized in the petiole from transported sucrose, rather than being translocated to the petiole from the leaf blade. At any given time point, the ratio of labeled antirrhinoside to labeled sucrose was lower in the petiole than in the leaf blade. This lag in the labeling pattern

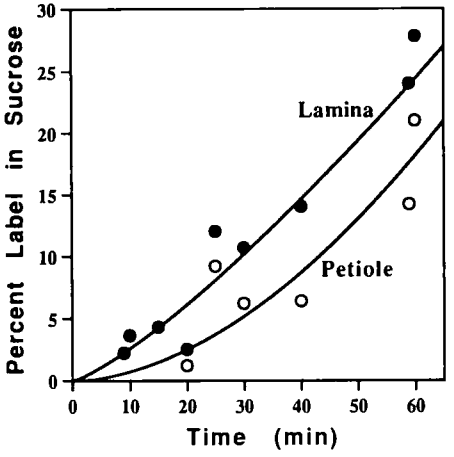

FIG. 2. Labeling of antirrhinoside in the lamina and petiole of *Asarina scandens* leaves following exposure of the leaf blade to $^{14}CO_2$. The amount of label in antirrhinoside is expressed in a percentage of that in sucrose.

of the compound in the petiole in comparison to the blade is to be expected, since the composition of translocate entering the petiole is a reflection of the labeling pattern in the mesophyll cells at an earlier point in time.

While labeling experiments demonstrated that antirrhinoside is transported, the experiments did not reveal the concentration of this compound in the phloem sap. Samples of sap, obtained by the EDTA method (King and Zeevart, 1974), were composed mainly of sucrose with smaller amounts of raffinose and stachyose, as previously shown (Turgeon et al., 1993), and also contained antirrhinoside (Figure 3), as well as monosaccharide. The amount of antirrhinoside was approximately 7% that of sucrose. If it is assumed that the concentration of sucrose in the phloem is in the range of 1 M (Winter et al., 1992), the concentration of antirrhinoside would be approximately 70 mM.

DISCUSSION

The data reported here indicate that antirrhinoside is translocated from source leaves to other parts of the plant in the phloem of *Asarina scandens*. Very little work appears to have been done on the transport of iridoid glycosides. Aucubin is transferred from *Penstemon teucrioides* to the parasitic plant *Castilleja integra* (Stermitz et al., 1993) but the route of transport has not been determined. An aphid, *Acyrthosiphon nipponicus*, sequesters paederoside, an

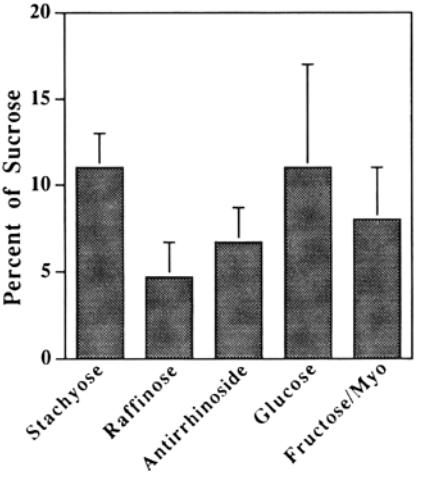

FIG. 3. Sugars in the phloem sap obtained from leaves of *Asarina scandens* by the EDTA method and measured by HPLC. The amount of each compound is expressed as a percentage of the amount of sucrose in the sap. Fructose and myoinositol coeluted. Bars = SE (N = 4).

iridoid glycoside that protects it from ladybird beetles (Nishida and Fukami, 1989); since aphids are known to feed in sieve elements, it is reasonable to conclude that this iridoid is also phloem mobile. Considered together the results indicate that phloem transport of iridoid glycosides may be a common occurrence.

The labeling of antirrhinoside after exposure of the leaf to $^{14}CO_2$ follows a complex pattern, increasing in the leaf blade and lamina over time in proportion to sucrose. While there is more antirrhinoside than sucrose in the leaf blade, there appears to be a higher proportion of sucrose in the transport system, as determined by the EDTA exudation method. These data are consistent with the occurrence of two pools of antirrhinoside in the leaf blade, a large nonmobile pool, presumably in the vacuoles, and a high-specific-activity transport pool that is the source of antirrhinoside in the phloem. It should be noted, however, that the EDTA procedure on which these conclusions are partially based provides only a rough estimate of phloem sap composition (Girousse et al., 1991). While it is clear from our labeling experiments that antirrhinoside is transported, the data we report here on the composition of the phloem sap should be considered tentative until they are confirmed by other methods, such as collection of sap from aphid stylets.

On the basis of the information at hand it is difficult to know whether the

amount of antirrhinoside in the phloem would be high enough to deter phloem-feeding organisms such as aphids. First, we have been unable to determine the concentration of transported antirrhinoside with complete confidence, as discussed above. Second, deterrence tests are usually conducted with dry diets, so it is not possible to compare those results with our own. However, the fact that antirrhinoside is present in the phloem in easily detectable quantities indicates that such deterrence may be possible. Furthermore, if imported antirrhinoside is stored in sink tissues, it will accumulate to high levels over time; thus the transported compound could be an important factor in protecting growing regions of the plant from herbivores.

ROLE OF VOLATILE INFOCHEMICALS EMITTED BY FECES OF LARVAE IN HOST-SEARCHING BEHAVIOR OF PARASITOID *Cotesia rubecula* (HYMENOPTERA: BRACONIDAE): A BEHAVIORAL AND CHEMICAL STUDY

NICKY G. AGELOPOULOS,[1] MARCEL DICKE,[1,*] and MAARTEN A. POSTHUMUS[2]

[1]*Department of Entomology, Wageningen Agricultural University P.O. Box 8031, NL-6700 EH Wageningen, The Netherlands*

[2]*Department of Organic Chemistry, Wageningen Agricultural University Dreijenplein 8, NL-6703 HB Wageningen, The Netherlands*

(Received March 13, 1995; accepted July 13, 1995)

Abstract—The role of volatile infochemicals emitted by feces of larvae in the host-searching behavior of the parasitoid *Cotesia rubecula* was evaluated during single- and dual-choice tests inside a wind tunnel. The following treatments were tested: feces produced by second and fourth instars of *Pieris rapae* (preferred host), second instars of *P. brassicae* (inferior host), second instars of *P. napi* (nonhost), and wet feces of second instars of *P. rapae*. During a single-choice situation females of *C. rubecula* oriented to all types of feces tested. When a preference was to be made, *C. rubecula* preferred feces of second instars of *P. rapae* over that of fourth, feces of *P. rapae* over that of *P. brassicae*, feces of *P. napi* over that of *P. brassicae*, and wet over normal host feces. No preference was exhibited between feces of second instars of *P. napi* and that of second instars of *P. rapae*. The relative importance of infochemicals from host feces versus plant damage caused by host larvae to the searching behavior of *C. rubecula* was also evaluated. Plant damage was more important to the searching females than host feces when feces were present in specific concentrations in relation to damage. The volatiles released by normal and wet feces of second instars of *P. rapae*, wet feces of fourth instars of *P. rapae*, and normal and wet feces of *P. brassicae* were collected and identified. Overall, 85 chemical compounds were recorded belonging to the following chemical groups: alcohols, ketones, aldehydes, esters, isothio-

cyanates, sulfides, nitriles, furanoids, terpenoids and pyridines. The blend of chemicals emitted by feces of different instars of *P. rapae* and different species of *Pieris* exhibited an instar and species specificity in both quantity and quality. Wetting of normal feces increased the amount of volatile chemicals released, and it was also responsible for the appearance of new compounds. The role of feces of larvae in the host-seeking behavior of *C. rubecula* is discussed.

Key Words—Volatile infochemicals, kairomone, host feces, parasitoid, *Cotesia rubecula*, host-searching behavior, *Brassica oleracea gemmifera*, *Pieris rapae*, *Pieris brassicae*, *Pieris napi*, Lepidoptera.

INTRODUCTION

During their search for hosts, parasitoids attacking larvae of Lepidoptera are known to utilize volatile chemicals emitted by plants infested by their hosts. Some of the chemicals emitted by host-infested plants may be released by the plant itself and others may originate from activities related to the biology of larvae, e.g., feces, silk, etc. (for an overview see Vinson, 1976, 1984; Vet and Dicke, 1992). Some of the volatiles emitted by the host plant are produced independently of the presence of larvae, and others may appear only during or after feeding of larvae has occurred (Whitman and Eller, 1990; Turlings et al., 1990, 1991, Turlings and Tumlinson, 1992; Agelopoulos and Keller, 1994c; Blaakmeer et al., 1994; Mattiacci et al., 1994; Potting et al. 1995, Takabayashi et al., 1995). Plant compounds induced by larval feeding are extensively used by female parasitoids during location of host-infested plants (Loke et al., 1983; Nadel and van Alphen, 1987; Steinberg et al., 1993; Turlings et al., 1990; Agelopoulos and Keller, 1994b; Geervliet et al., 1994, Takabayashi et al., 1995). Volatiles emitted by feces of larvae may also be involved in orientation to host-infested plants since many species of parasitoids are known to be attracted to feces of their host larvae (Lecomte and Thibout, 1986, 1993; Eller et al., 1988a,b; Elzen et al., 1987; Ding et al., 1989; Ramachandran et al., 1991; Turlings et al., 1991; Cortesero et al., 1993; Steinberg et al., 1993; Agelopoulos and Keller, 1994a; Geervliet et al., 1994). The aim of this study was to investigate the role of host feces in orientation to host-infested plants by the parasitoid *Cotesia rubecula*.

Cotesia rubecula Marshall (Hymenoptera: Braconidae) is a larval endoparasitoid of *Pieris rapae*. *Pieris rapae* is the preferred host of *C. rubecula*, and all host stages can be attacked. Other host species have also been reported (Shenefelt, 1972). For example, it is known that females of a Dutch population of *C. rubecula* develop most successfully in *P. rapae* although they do oviposit and develop less successfully in *Pieris brassicae* as well (Geervliet and Brodeur, 1992). Although the parasitoid accepts *Pieris napi* as a host, the parasitoid cannot successfully develop in this species (Geervliet and Brodeur, 1992). Dur-

ing their search for hosts, females of *C. rubecula* are known to be attracted from a distance to host-infested plants (Nealis, 1986, 1990; Keller, 1990), and their searching behavior is influenced by experience (Kaiser and Cardé, 1992; Geervliet et al., 1993). Detailed studies on the role and identity of plant volatiles involved in long-distance orientation to host-infested plants have been conducted for two different populations of *C. rubecula*: an Australian population (Agelopoulos and Keller, 1994a–c) and a Dutch one (Geervliet et al., 1993, 1994, 1995; Blaakmeer et al., 1994). For both populations the same holds true: females of *C. rubecula* rely mainly on plant volatiles related to damage to locate host-infested plants. They are able to distinguish from a distance between plants damaged by larvae of Lepidoptera and those damaged by mechanical means, but they are not able to discriminate between host plants damaged by larvae of different species of Lepidoptera. However, in a more complex situation where plants infested by *P. rapae* are simultaneously present with plants infested by *P. brassicae*, females of *C. rubecula* preferably land on plants infested by *P. rapae* (Wiskerke and Vet, 1994). Since the blends of volatiles released by cabbage plants damaged by different Lepidoptera is not species specific (Blaakmeer et al. 1994), the question still remains as to which component of the plant-herbivore complex provides species-specific information to the searching females. Studies on other sources of volatiles related to infestation that may be involved in orientation to host-infested plants have revealed that females of *C. rubecula* are not attracted to host larvae (Kaiser and Cardé, 1992; Agelopoulos and Keller, 1994a), but they are attracted to feces of the host (Agelopoulos and Keller, 1994a; Geervliet et al., 1994). In the chemical study by Agelopoulos and Keller (1994c), there is evidence of species specificity related to volatiles emitted by feces of larvae, but the question still remains as to whether feces are the component that provides species-specific information to the searching females.

In this study we explored further the role of feces in attracting *C. rubecula* to its host. By conducting single- and dual-choice tests and by using feces of different host instars and feces of three closely related species of *Pieris*, we tested whether the information released by feces and utilized by *C. rubecula* was: (1) host-instar specific, (2) species specific, (3) dose dependent, and (4) affected by feces moisture. The relative importance of volatiles released by feces, compared to those released by plant damage was also evaluated. Finally, we sought to identify the volatiles released by feces of different instars of *P. rapae*, feces of *P. rapae* with different moisture levels, and feces of *P. brassicae*.

METHODS AND MATERIALS

Plants and Insects. Brussels sprouts plants, *Brassica oleracea gemmifera* cv. Titurel, were grown under greenhouse conditions (20–30°C, 50–80% rel-

ative humidity, 16L:8D). *Pieris rapae* and *P. brassicae* (Lepidoptera: Pieridae) were reared on Brussels sprouts plants inside a climate-controlled room (20–22°C, 50–70% relative humidity, 16L:8D), and *P. napi* was reared on Brussels sprouts plants under greenhouse conditions (20–30°C, 50–80% relative humidity, 16L:8D). The parasitoid *C. rubecula* was reared on *P. rapae* at 20–22°C, 50–70% relative humidity, 16L:D8. Upon emergence, mated females of *C. rubecula* were released into a gauze cage with honey and water. Two- to 3-day-old "experienced" females were used for the bioassays. Experience of females was obtained by introducing inside the cage a leaf of Brussels sprouts bearing feeding damage and feces of the host. The leaf remained there for 22 hr and was removed 4 hr prior to testing.

Bioassays. All tests were performed inside a wind tunnel under the following conditions: 25°C, 45–60% relative humidity, and wind speed 50 cm/sec (description of wind tunnel by Geervliet et al., 1994). One female, held in a vial that was placed in vertical position, was introduced into the wind tunnel 1 m away from the stimulus. The observation started when the plug of cotton wool restricting the insect inside the vial was removed. A maximum of six tries was given to insects that failed during earlier attempts. "Attraction to stimulus" was defined as a complete flight of the insect inside the odor plume and successful location (landing) of the stimulus. Insects that flew half way to the stimulus were given a second try. To reduce the effect of day-to-day variation in response, the same test was conducted on at least three different days in different weeks. Feces were collected by placing Petri dishes under infested leaves for a period of 24 hr (25°C, 50–60% relative humidity).

Single-Choice Tests. The response of females of *C. rubecula* to a single stimulus was observed for the following: feces of second instars of *P. rapae*, feces of fourth instars of *P. rapae*, feces of second instars of *P. brassicae*, and feces of second instars of *P. napi*. For each bioassay, 65 mg of feces was used and placed on a flat surface at the upwind end of the wind tunnel. Five, 10, and 20 mg of feces of late second instars of *P. rapae* were used to record dose-dependent responses. The three different doses were tested on the same day.

Dual-Choice Tests. The landing preference of *C. rubecula* was tested for the following: (1) feces of late second instars of *P. rapae* vs. feces of early fourth instars of *P. rapae* (second vs. fourth *P. rapae*), (2) feces of late second instars of *P. rapae* vs. wet feces of late second instars of *P. rapae* (second *P. rapae* vs. wet second *P. rapae*), (3) feces of late second instars of *P. rapae* vs. feces of late second instars of *P. brassicae* (*P. rapae* vs. *P. brassicae*), (4) feces of late second instars of *P. rapae* vs. feces of late second instars of *P. napi* (*P. rapae* vs. *P. napi*), and (5) feces of late second instars of *P. brassicae* vs. feces of late second instars of *P. napi* (*P. brassicae* vs. *P. napi*). "Wet" feces is defined as feces wetted prior to testing with three drops of water. "Normal" feces is rather dry. In each case, 65 mg of feces was used.

The two stimuli were placed on separate flat surfaces located 5 cm apart and 1 m away from the release point of insects. To avoid bias caused by the left or right position of stimuli inside the wind tunnel, the stimuli were alternated after every fifth observation. To evaluate the relative significance of feces over plant damage in leading *C. rubecula* to its host, the following were tested: (1) a leaf carrying feeding damage of 10 instars of *P. rapae* vs. a leaf carrying feeding damage of 10 instars of *P. rapae* plus 10 mg of feces of *P. rapae* (D_{10} vs. $D_{10}F_{10mg}$), (2) a leaf carrying feeding damage of 10 instars of *P. rapae* vs. a leaf carrying feeding damage of 10 instars of *P. rapae* plus 65 mg of feces of *P. rapae* (D_{10} vs. $D_{10}F_{65mg}$), (3) a leaf carrying feeding damage caused by 20 instars of *P. rapae* vs. a leaf carrying feeding damage of 10 instars of *P. rapae* plus 65 mg of feces of *P. rapae* (D_{20} vs. $D_{10}F_{65mg}$). For all tests, damage and feces were produced by late second instars of *P. rapae*. Damage on the leaves was produced over a period of 24 hr. Prior to testing, larvae and larval by-products were removed. In the cases where leaf and feces were used together, the feces were located on a flat surface next to the leaf. To avoid bias caused by left or right position of stimuli inside the wind tunnel, the stimuli were alternated after every fifth observation. Production of feces by second and fourth instars of *P. rapae* was accomplished by placing 20 late second instars and 20 early fourth instars of *P. rapae* individually on single leaves held in vials with water where they were left to feed for 24 hr. The feces produced by each larva were collected and weighed.

Statistics. The chi-square test for goodness-of-fit was used to determine preference for one of the stimuli tested during dual choice situation (distribution of expected values 50:50).

Collection of Volatiles from Larval Feces and Chemical Analysis. Feces used for identification of volatile components were collected by placing Petri dishes under infested leaves for a period of 24 hr (25°C, 50–60% relative humidity). Volatiles from feces were collected by placing feces in a glass flask (50 ml), which was closed with a glass top having a ground glass connection and an inlet and outlet glass tube. Purified air was passed through the inlet tube with an air flow of 90 ml/min. Volatile chemicals emitted by feces were transported with the aid of airflow to the outlet tube, where they were trapped on 90 mg of Tenax-TA. The Tenax-TA was placed inside a glass tube connected immediately to the outlet tube (Dicke et al., 1990). Thermodesorption was the method used to release the volatiles trapped on Tenax-TA (description of method by Dicke et al., 1990). The samples were analyzed by using a gas chromatograph–mass spectrometer (Finnigan MAT 95). The GC column used was Supelcowax 10 (60 m × 0.25 mm ID; 0.25-μm film thickness), and the temperature conditions were 3 min at 40°C, increased by 3°C/min to 140°C, and after that increased by 6°C/min to 270°C. The mass spectrometer was operated in the 70-eV electron impact ionization mode. Control samples (clean air) were also

analyzed to ascertain which chemicals were specific to feces. Identification of compounds was based on the commercial spectra libraries NIST and WILEY and on our own collection of spectra of natural compounds. Volatiles released by 250 mg of feces produced by late second instars of *P. rapae* (samples named as normal) were collected for a period of 2.5 hr. At the end of that collection period, the same feces were wetted with nine drops of distilled water and volatiles were collected for a further 2.5 hr (samples named as wet). The same procedure was followed for 250 mg of feces produced by late second instars of *P. brassicae*. Volatiles were also collected from 250 mg of feces produced by early fourth instars of *P. rapae*. The samples for that particular treatment were all wetted with nine drops of distilled water. Three samples were collected for each treatment.

RESULTS

Bioassays. During a single-choice situation, females of *C. rubecula* oriented to and landed on all types of feces tested irrespective of instar or species that had produced them (Table 1). *C. rubecula* was able to locate the source of volatiles even when very small amounts (e.g., 5 mg of feces) of host feces were used (Table 2). A higher degree of attraction was observed for 20 mg of feces over that of 5 and 10 mg. However, the attraction of females to the different doses tested was not significantly different (contingency table, $P = 0.07$). *C. rubecula* preferred feces of *P. rapae* over that of *P. brassicae*, but it did not show preference for feces of *P. rapae* when tested against that of *P. napi*. Feces of *P. napi* were also preferred over that of *P. brassicae* (Table 3). Preference was also exhibited for feces of second instars over feces of fourth instars of *P. rapae* (Table 3). The preference of females for leaves damaged by the host over leaves damaged by the host that also carried feces of the host depended on the amount of feces present on the leaves (Table 4). When leaves carrying

TABLE 2. DOSE-RELATED RESPONSES OF FEMALES OF *C. rubecula* TO FECES OF SECOND INSTARS OF *P. rapae* ($N = 30$)

Amount of feces (mg)	Attraction	No attraction
20	25 (83%)	5
10	19 (63%)	11
5	17 (56%)	13

damage caused by 10 second instars of *P. rapae* were tested against leaves carrying the same amount of damage plus 10 mg of feces of *P. rapae*, the females did not show preference for any of the two stimuli. When the 10 mg of feces was replaced with 65 mg, the females showed a preference for the latter. Leaves bearing damage caused by 20 second instars of *P. rapae* were preferred over leaves carrying feeding damage of 10 second instars of the host plus 65 mg of host feces.

A 10-fold increase in production of feces was observed from second (0.62 ± 0.03 m/larva/24 h, mean ± SEM) to fourth instars of *P. rapae* (5.87 ± 0.17 m/larva/24 h).

"D_{10}, D_{20} = plant damage caused by 10 and 20 second instars of *P. rapae* respectively, *F* = feces, D + F = damage and feces together, NS = not significantly different, *significantly different $P \leq 0.05$).

Chemical Analysis. Overall, 85 volatile chemical compounds were identified from the various treatments tested belonging to the following chemical groups: alcohols, ketones, aldehydes, esters, isothiocyanates, sulfides, nitriles, furanoids, terpenoids, and pyridines (Table 5). The blends of volatiles released by feces of larvae of different species of *Pieris*, different instars of *P. rapae*, and by feces affected by moisture are different in both quantity and quality (Table 5; Figure 1). The average amount of the identified compounds is represented in Table 5 by units of peak area. Depending on the chemical nature of the compound, one unit of peak area is equal to 0.3–0.5 ng. Wet feces of second instars of *P. rapae* and *P. brassicae* emitted the highest amounts of volatiles (total peak area, Table 5). Wet feces of fourth instars of *P. rapae* emitted much less and normal feces of second instars of *P. rapae* and *P. brassicae* emitted the lowest amount of chemicals.

Most of the compounds detected were present in all treatments tested, but some compounds or classes of compounds were present in one treatment only (Table 6). For example, nitriles were solely, and pyridines mainly, present in feces of fourth instars of *P. rapae*. Feces of *P. brassicae* emitted more aldehydes, alcohols, and ketones in comparison with that of *P. rapae*, and feces of second instars of *P. rapae* exhibited the least qualitative specificity but showed a quantitative specificity for a number of compounds. For example, compounds such as 2-methyl-1-propanol, 1-penten-3-ol, 1-penten-3-one, 3-methylbutanal, pentanal, and β-cyclocitral appeared in high concentration in that treatment (Table 5, Figure 2).

Total peak area (mean ± SE)		62 ± 9	2633 ± 917	746 ± 483	64 ± 56	2515 ± 1949

"The number after each compound represents the average peak area (±SE) in samples of the same treatment. Depending on the chemical nature of compounds, one unit of peak area is approximately equal to 0.3–0.5 ng [N = number of samples analysed in each treatment; + = presence of compound in one sample; ++ = present in 2 samples; +++ = present in all 3 samples; * = presence of compound in the volatile blend released by Brussels sprouts infested by *P. brassicae* (Mattiacci et al., 1994), *isomer* = the identity of the geometric isomer of the compound is unknown].

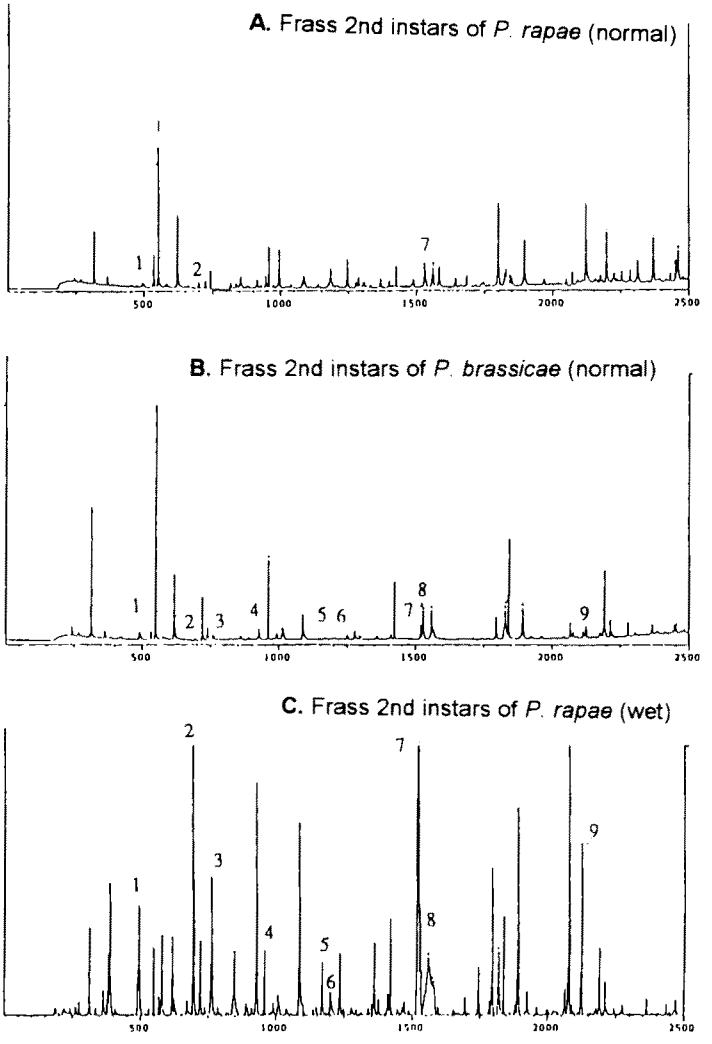

FIG. 1. Chromatograms of volatiles emitted by feces of second instars of *P. rapae* [(A) normal, (C) wet], second instars of *P. brassicae* [(B) normal, (D) wet], and fourth instars of *P. rapae* [(E) wet]. Each chromatogram represents only one of the three samples analysed in each treatment. 1 = 2-pentanone, 2 = dimethyl disulfide, 3 = 2-methyl propanol, 4 = 1-penten-3-ol, 5 = 1-pentanol, 6 = methylthioacetaldehyde, 7 = dimethyl trisulfide, 8 = (*Z*)-3-hexen-1-ol, 9 = β-cyclocitral.

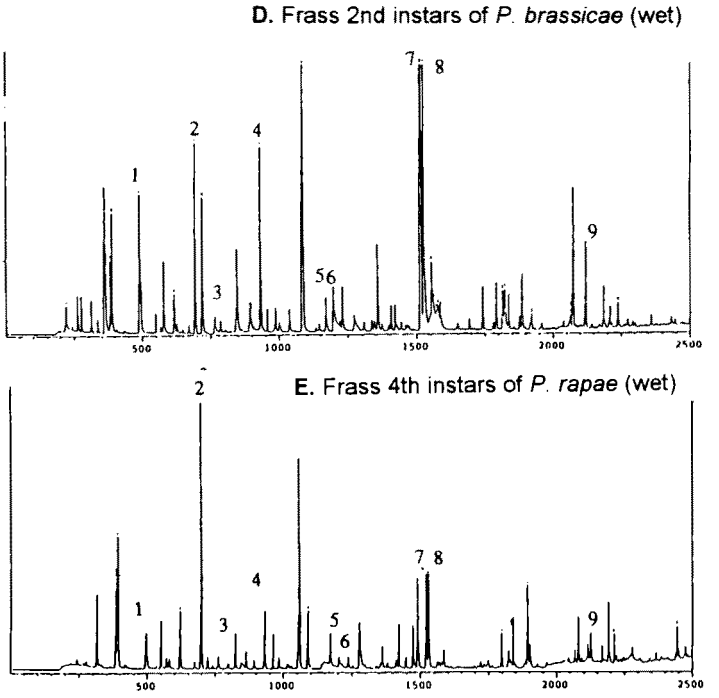

FIG. 1. Continued.

Wetting of samples not only increased the amount of compounds already present in normal samples but was also responsible for the appearance of new compounds. At present, it is not known if the appearance of new compounds is strictly related to reactions initiated by the presence of water or if those compounds were also present in normal feces but in undetectable amounts. The detection limit of the GC-MS used is approximately 0.1 ng.

Variation in the presence and concentration of some compounds between samples of the same treatment was recorded. Figure 3 shows the spectra of the unidentified compounds, unknown 1 and unknown 2.

DISCUSSION

Feces of Larvae and Their Influence on Host-Searching Behavior of Parasitoids. The host-seeking behavior of some parasitoid species is known to be influenced by feces of larvae from a distance (Lecomte and Thibout, 1986, 1993; Eller et al., 1988a,b; Elzen et al., 1987; Ding et al., 1989; Ramachandran

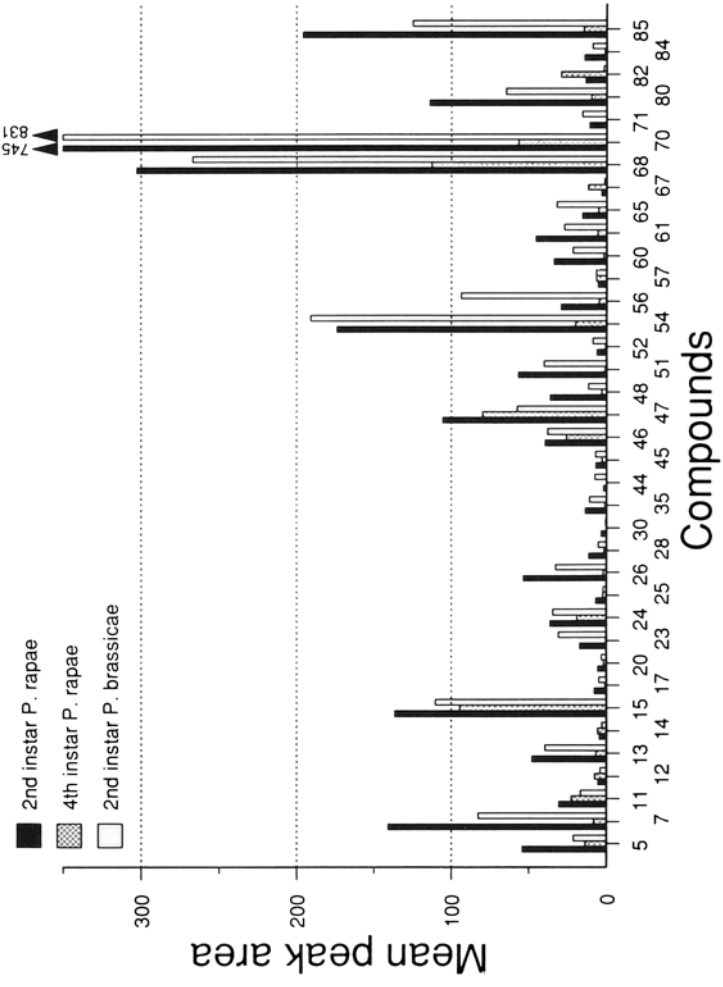

FIG. 2. Relative concentration (mean peak area) of compounds common in the treatments: second instar *P. rapae* (wet feces of second instars of *P. rapae*), fourth instar *P. rapae* (wet feces of fourth instars of *P. rapae*), second instar *P. brassicae* (wet feces of second instars of *P. brassicae*). Compound numbers are the same as in Table 5.

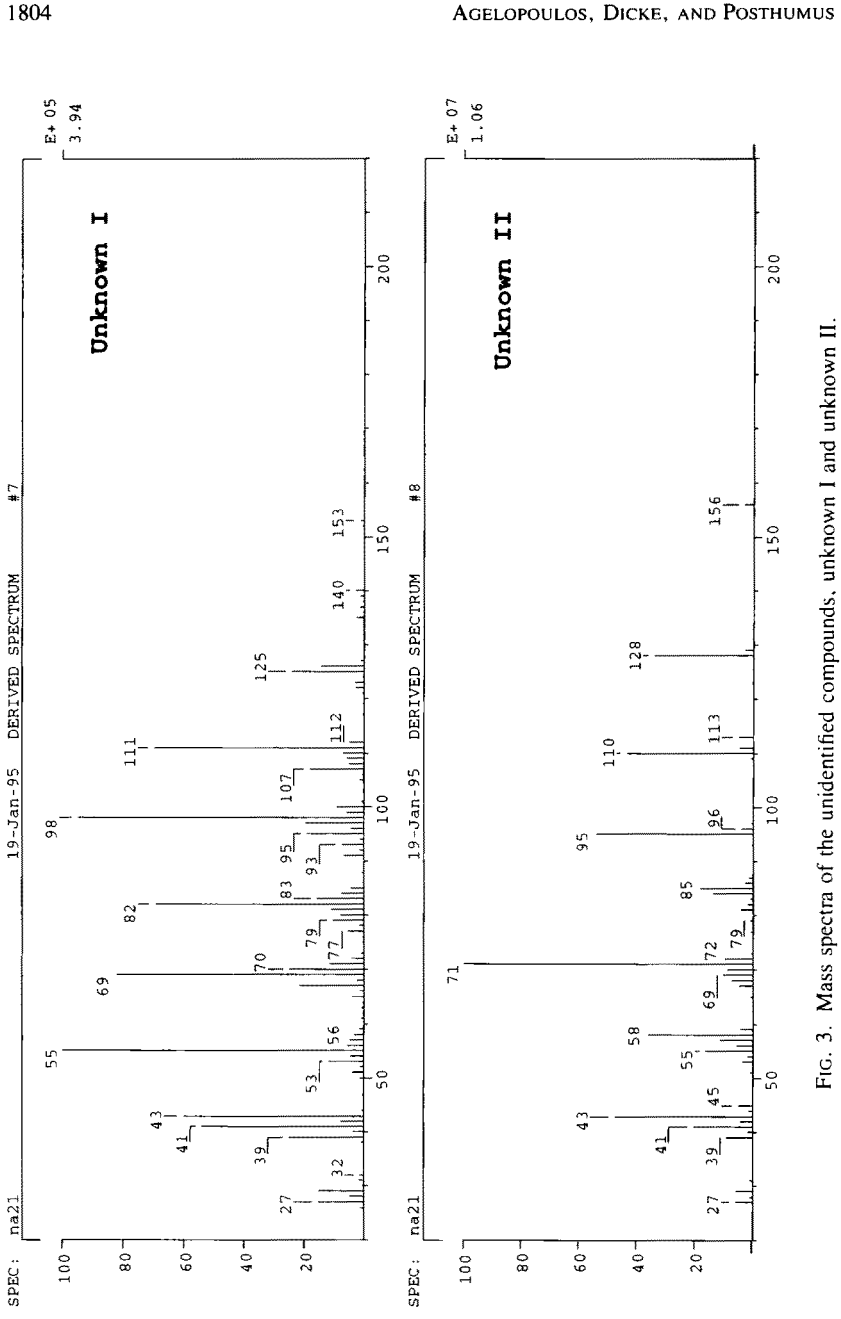

FIG. 3. Mass spectra of the unidentified compounds, unknown I and unknown II.

TABLE 6. COMPOUNDS PRESENT ONLY IN ONE OF THE FOLLOWING CLASSES: FECES OF SECOND INSTARS OF *P. rapae* (WET OR NORMAL), FECES OF FOURTH INSTARS OF *P. rapae*, AND FECES OF SECOND INSTARS OF *P. brassicae* (WET OR NORMAL)

Second instars of *P. rapae*	Fourth instars of *P. rapae*	Second instars of *P. brassicae*

		2-Ethylfuran (wet)[a]

[a] Presence of compound in the volatile blend released by Brussels sprouts plants infested by *P. brassicae* (Mattiacci et al., 1994).

et al., 1991; Turlings et al., 1991; Cortesero et al., 1993; Steinberg et al., 1993; Agelopoulos and Keller, 1994a; Geervliet et al., 1994) and upon contact (Lewis and Jones, 1971; Sato, 1979; Nordlund and Sauls, 1981; van Leerdam et al., 1985; Nordlund and Lewis, 1985; Ding et al., 1989; Fukushima et al., 1989; Takabayashi and Takahashi, 1989; Mattiacci and Dicke, 1995). Factors related to production of feces, such as species of larvae (Lewis and Jones, 1971; Thibout et al., 1993; Agelopoulos and Keller, 1994a; present study), species of plant that larvae feed on (Nordlund and Sauls, 1981; Ramachandran et al., 1991), developmental stage of larvae (Mattiacci and Dicke, 1995; present study), and moisture content of feces (Sato 1979; van Leerdam et al., 1985; present study) are known to influence the behavior of female parasitoids from a distance and upon contact.

The variation in percentage of attraction of females during the various tests conducted here is not uncommon for the population of *C. rubecula* kept in our laboratory. Females of that population exhibit an average attraction of 50% to host-infested plants, varying from 20% to 95%, depending on the day of testing (Geervliet et al., 1994, 1995; N.G. Agelopoulos personal observations). Variation in attraction to host-infested plants has also been observed for a Dutch population of *C. glomerata* (Steinberg et al., 1993). The reason behind the observed variation in the responses of *C. rubecula* is not known, although

decreasing barometric pressure has been shown to be one of the factors affecting the response of females of *C. glomerata* (Steinberg et al., 1993). Because of the day-to-day variation in percentage of wasps that fly upwind to the odor source, the data for the different odor sources in Table 1 (different experimental days per treatment) cannot be compared to draw conclusions on the relative attraction towards different feces. This can only be done with the data in Table 3.

Plant Origin of Chemicals in Feces. Indications of the plant origin of chemicals present in feces of larvae have been abundant in studies related to behavior of parasitoids. The differential responses of parasitoids to feces produced after feeding of host larvae on different plants (van Leerdam et al., 1985), the nonattraction of parasitoids to feces produced after feeding of larvae on artificial diet (Nordlund and Lewis, 1985; Ding et al., 1989; Ramachandran et al., 1991), and the attraction of parasitoids to feces of nonhost larvae feeding on hostplants (Lewis and Jones, 1971; Thibout et al., 1993; Agelopoulos and Keller, 1994a) are indicative of the involvement of the plant in the chemical composition of feces. Identification of volatiles released by feces of different species of larvae has revealed the plant origin of those compounds (Auger et al., 1989; Ramachandran et al., 1991; Agelopoulos and Keller, 1994c). Our chemical study further supports the plant origin of compounds emitted by feces, since most of the volatiles emitted by feces of *P. rapae* and *P. brassicae* have previously been reported in cruciferous plants (Bailey et al., 1961; Buttery et al., 1976; Wallbank and Wheatley, 1976; Cole, 1976, 1980a,b; Tollsten and Bergström, 1988; Evans and Allen-Williams, 1992; Blaakmeer et al., 1994; Mattiacci et al., 1994). The presence of some of the volatiles emitted by feces may be related to breakdown processes of plant material after digestion by larvae and the presence of others may be the end product of processes related to microorganisms inhabiting the feces (Thibout et al., 1993).

Agelopoulos and Keller (1994c) identified volatiles from "normal" frass of *P. rapae* larvae on a *capitata* variety of cabbage and recorded eight compounds, five of which are also recorded here. One of these five compounds is identified here as methylthioacetaldehyde on the basis of mass spectrum and chromatographic behavior and has the same mass spectrum as the compound labeled as methyl propyl sulfide by Agelopoulos and Keller (1994c). The spectrum has small, but significant differences from that of methyl propyl sulfide. Our analyses show that moistening of the feces greatly increases the amount of chemicals recorded.

Specificity Related to Volatiles Emitted by Feces of Different Species and Instars of Larvae. The chemical profile emitted by feces of *P. rapae* and *P. brassicae* produced after feeding of larvae on Brussels sprouts plants is species specific in both quantity and quality. Species specificity related to the blend of chemicals released by feces of larvae has also been observed for

P. rapae and *Plutella xylostella* (Lepidoptera: Yponomeutidae) (Agelopoulos and Keller, 1994c). An instar specificity, in both quality and quantity, is also exhibited in the blend of chemicals emitted by feces of second and fourth instars of *P. rapae*. The quantitative differences consist of a higher emission of chemicals in feces of second instars than of fourth instars. This may be due to higher evaporation from the feces of second instars. Pellets of feces of second instars are much smaller than those of fourth instars, and consequently the number of pellets in 250 mg of feces of second instars is greater than that in the same amount of feces of fourth instars; this increases the surface area of evaporation in feces of second instars. If higher evaporation causes the greater emission of chemicals from feces of second instars, the quantitative differences between the two will be eliminated as the amount of feces of fourth instars increases. This is possible since fourth instars produce 10 times more feces than second instars. The species and instar specificity reported in feces may be due to different digestion processes of larvae and to different microorganisms inhabiting the feces of larvae.

Effects of Volatiles Released by Feces of Larvae in Host-Searching Behavior of C. rubecula. Females of *C. rubecula* are attracted to both infested plants and feces of larvae. Many volatiles emitted by feces of *P. rapae* and *P. brassicae* are also present in the blend of chemicals emitted by Brussels sprouts plants infested by either of the two species of larvae (Blaakmeer et al., 1994; Mattiacci et al., 1994). Nevertheless, some groups of chemicals appear only in one of the two infested plants or feces. For example, esters are a predominant group of chemicals related to plant damage caused by larvae and are hardly represented in feces. The same holds true for terpenoids, which are mainly emitted by infested or uninfested Brussels sprouts plants. On the other hand, pyridines are only present in feces and are totally absent in the volatiles released by plants. The question arises as to whether the chemicals utilized by *C. rubecula* to orient to feces are chemicals common to both infested plants and feces or a combination of common and specific chemicals.

The results of our bioassays showed that during landing leaves carrying large amounts of plant damage were preferred over those carrying less damage and small amounts of feces. Although landing manifests the final preference of females, it does not convey information about the different sources of information employed from a distance or while flying before landing. Specific chemicals in feces may be utilized from a distance in discriminating between plants infested by different species of *Pieris* or instars of the host. Upon landing, plant chemicals related to plant damage may be more important, because plant damage relates to the position of the larvae while feces rarely do. Fecal pellets rarely are present on the leaf of production; in most cases they fall, contaminating the lower parts of the plant and the surrounding ground. The position of feces on or around the plant can be influenced by factors such as the orientation and

structure of leaves and plant, hygienic behavior of the larvae (Usher, 1984), factors shaking the plant (wind, storms, passing animals), the size of fecal pellet (larger pellets tend to roll more easily than smaller ones), and evaporation. When fecal pellets are produced, they are more sticky than when dry.

C. rubecula also favored wet over normal feces of its host. Moisture is one of the factors increasing the release of volatile compounds from feces, and high humidity related to climatic or microclimatic conditions (e.g., dense foliage), morning dew, or rain may increase the volatile emission of feces in favor of the parasitoid.

Although at present we have a good knowledge of the identity of volatiles that may be involved in orientation to host-infested plants, much more work has to be done to understand which of those chemicals are the most reliable indicators of host presence and to understand how females of *C. rubecula* cope with the great variability associated with the chemical information available in every moment of their search for hosts.

Acknowledgments—We would like to thank the Wageningen Agricultural University for providing financial support for this project. Particular thanks go to André Gidding, Leo Koopman, Herman Dijkman, and Jacqueline Geervliet for their invaluable help in culturing the insects, and the various people involved in growing the plants used for this project.

(Received February 28, 1995; accepted July 13, 1995)

Abstract—Two compounds were isolated and identified from abdominal tips of the female tussock moth, *Euproctis taiwana* (Shiraki), by a combination of gas chromatography–electroantennographic detection, coupled gas chromatography–mass spectrometric analysis, microreaction, and synthesis. These compounds were (*Z*)-16-methyl-9-heptadecenyl isobutyrate (74.8%) and 16-methylheptadecyl isobutyrate (25.2%). Their total amount was determined to be ca. 29.8 ng/female. Field bioassays showed that (*Z*)-16-methyl-9-heptadecenyl isobutyrate is a sex attractant for the male moths. These chemical compounds had not previously been found as the sex pheromone components in the genus *Euproctis*.

Key Words—Tussock moth, *Euproctis taiwana*, sex attractant pheromone, (*Z*)-16-methyl-9-heptadecenyl isobutyrate, 16-methylheptadecyl isobutyrate.

INTRODUCTION

The tussock moth, *Euproctis taiwana* (Shiraki), distributed in the Okinawan region of Japan and Taiwan, is polyphagous and a serious pest of a variety of crops. These include guava, mango (Azuma, 1968), rose (Wang, 1982a), gladiolus (Wang, 1982b), loquat (Miyatake et al., 1990), kidney beans, tea, cabbage, and corn. Furthermore, *Euproctis* larvae are covered with bristles that can lead to severe dermatitis when they contact human skin (Ogata, 1958; Su, 1981).

In the genus *Euproctis*, sex pheromones have been identified for *E. chrysorrhoea* (Leonhardt et al., 1991), *E. psudoconspersa* (Wakamura et al., 1994), *E. similis similis* (Yasuda et al., 1994), and *E. similis xanthocampa* (Tan et al., 1984), but no common component has been found in the sex pheromones of these species of *Euproctis*.

This paper describes the isolation and identification of the female sex attractant pheromone of *E. taiwana*.

METHODS AND MATERIALS

Insects. In May 1993, *Euproctis taiwana* larvae were collected from fields of cabbage and kidney beans, Naha City, Okinawa Prefecture, Japan. The larvae were reared on an artificial diet at 25°C under a 16L:8D photoperiod.

Preparation of Pheromone Extracts. Abdominal tips were excised from 2-day-old virgin females 1 hr into photophase and extracted with hexane for 30 min at room temperature. The extracts were filtered through a piece of absorbent cotton, accumulated, and stored below −30°C until used.

Column Chromatography. For separation of the extracts, column chromatography on Florisil was carried out (Carroll, 1961). Components were successively eluted with hexane and 5%, 10%, and 50% ether in hexane.

For separation of geometric isomers, column chromatography on silica gel impregnated with silver nitrate ($AgNO_3$: 16.7%) ($AgNO_3$–SiO_2 chromatography) was used. Components were successively eluted with hexane and 1%, 2%, 3%, 4%, 5%, 7%, and 10% ether in hexane.

Gas Chromatograph–Electroantennographic Detector (GC-EAD). The fractions from Florisil chromatography were analyzed by a GC-EAD system (Struble and Arn, 1984). Gas chromatography was performed with a Hewlett-Packard HP 5890 Series II gas chromatograph with a DB-WAX column (polyethylene glycol 20M, 30 m × 0.25 mm ID × 0.25-μm film thickness) and a flame ionization detector (FID) and electroantennographic detector (EAD). FID and EAD responses were simultaneously recorded. The column temperature was set at 50°C for 1 min, programmed at 20°C/min to 150°C, and then programmed at 5°C/min to 220°C and held for 10 min. Helium was the carrier gas.

Gas Chromatograph–Mass Spectrometer (GC-MS). GC-MS analyses were conducted with a JEOL JMS-SX102A mass spectrometer combined with a Hewlett-Packard HP 5890 Series II gas chromatograph using the following columns: DB-1 (100% dimethyl polysiloxane, 30 m × 0.25 mm ID × 0.25-μm film thickness), HP-5 (5% diphenyl–95% dimethyl polysiloxane, 30 m × 0.25 mm ID × 0.33-μm film thickness), DB-WAX and DB-23 (50% cyanopropyl polysiloxane, 30 m × 0.25 mm ID × 0.25-μm film thickness). The column temperature conditions were the same as those in the GC-EAD system. Helium was

the carrier gas. High-resolution mass spectra (HRMS) were obtained by the same system.

Chemical Reactions. The monounsaturated components were hydrogenated with diimide to determine the acid moieties (Yamaoka et al., 1976). The diimide reduction products were analyzed by the GC-MS system. Esters of 1-octadecanol were used as authentic standards.

Microozonolysis was used to determine the double-bond positions of alcohol moieties (Beroza and Bierl, 1967). Oxygen with ozone was blown into a hexane solution of the sample below −50°C for 1 min, and it was then immediately injected into the GC-MS system.

Naturally occurring esters were hydrolyzed in 1% KOH in ethanol at 50°C for 22 hr. After evaporation of the solvent, the residue was extracted with hexane and poured on a silica gel column. Compounds were successively eluted with hexane and 5%, 10%, 25%, and 50% ether in hexane. A part of the 25%-ether-in-hexane fraction, which contained alcohols, was concentrated and chlorinated with methanesulfonyl chloride and dimethylformamide at 65°C for 16 hr (Evans et al., 1968). The reaction mixture was then placed directly onto a silica gel column, and the chloride derivatives were eluted with hexane and then injected into the GC-MS system with the DB-WAX column.

Synthesis. 8-Methyl-1-nonyne was synthesized from 1-bromo-3-methylbutane and 2-propyn-1-ol following the methodology of Naoshima et al. (1990). (*Z*)-16-Methyl-9-heptadecen-1-ol (16Me-Z9-17:OH) was synthesized from 8-methyl-1-nonyne and 8-bromo-1-octanol following the methodology of Hendry et al. (1975). 16-Methyl-1-heptadecanol (16Me-17:OH) was prepared from methyl 16-methylheptadecanoate by reduction with lithium aluminum hydride. Corresponding esters were obtained from 16Me-Z9-17:OH and 16Me-17:OH reacted with acid anhydride. (*Z*)-16-Methyl-9-heptadecenyl isobutyrate (16Me-Z9-17:iBu) was purified by $AgNO_3$–SiO_2 chromatography.

Field Bioassay. Field tests were conducted at the Okinawa Prefectural Agricultural Experiment Station, Naha City, using sticky traps (SE trap, Sankei Chem. Co.). Traps were placed 0.5–1.5 m above ground at intervals greater than 5 m. Hexane solutions of test samples were impregnated into a piece of filter paper (2 × 5 cm, Advantec No. 2) and placed into the trap. The reference trap was baited with three 3-day-old virgin females. Trap data ($x + 0.5$) were subjected to square-root transformation before analysis of variance, and Tukey's test was used for comparing means where the variance analysis (general linear models procedure) indicated a significant F value (SAS Institute, 1988).

RESULTS

The accumulated extract of 262 virgin females was fractionated with the Florisil column. Each fraction was checked by the GC-EAD analysis at 1 female equivalent. The 5%-ether-in-hexane fraction showed two EAD-active peaks

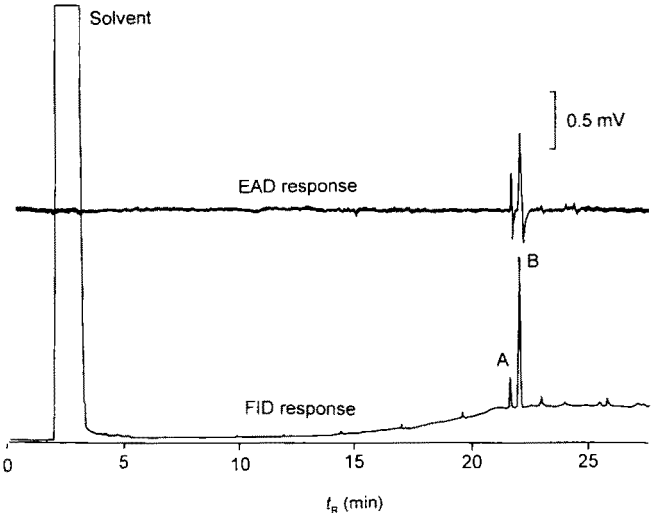

FIG. 1. GC-EAD profile of female gland extract of *Euproctis taiwana*. One female equivalent of 5% ether-in-hexane fraction from Florisil column was injected. GC: DB-WAX, operated at 50°C for 2 min, programmed at 20°C/min to 150°C, and then programmed at 5°C/min to 220°C, where it was kept for 10 min.

(Figure 1, peaks A and B). The ratio of the areas of these two compounds was 1:3, and the total amount was estimated to be ca. 29.8 ng/female by GC analysis. GC-MS analysis with the DB-WAX column of the 5% fraction led to an estimate that compound A was an isomer of an 18-carbon saturated alcohol ester of a 4-carbon carboxylic acid, which showed the following characteristic fragment ions: *m/z* 89 ($C_3H_7CO_2$ + 2H, base peak), 252 (M−88, 29%) and 340(M^+, 32%) (HRMS found: 340.3338, calcd. for $C_{22}H_{44}O_2$: 340.3341). Compound B was also estimated to be an isomer of an 18-carbon monounsaturated alcohol ester of a 4-carbon carboxylic acid, which showed the following characteristic fragment ions: *m/z* 82 (base peak), 89 ($C_3H_7CO_2$ + 2H, 44%), 250 (M−88, 58%) and 338 (M^+, 2%) (HRMS found: 338.3126, calcd. for $C_{22}H_{42}O_2$: 338.3185).

The 5% fraction was further chromatographed by $AgNO_3$–SiO_2 chromatography to confirm the degree of unsaturation of the components. Compound A was eluted in 2%-ether-in-hexane fraction and compound B was eluted in the 4%-, 5%-, and 7%-ether-in-hexane fractions.

One peak was detected in the products of diimide reduction of compound B, the 5% fraction of $AgNO_3$–SiO_2 chromatography, by GC-MS analysis with the DB-WAX column. This compound was shown to be identical to compound

A by cochromatography with the 2% fraction from $AgNO_3$-SiO_2 chromatography and by GC-MS analysis. Furthermore, the product of diimide reduction of compound B showed a clear EAD response.

The retention time of compound A on DB-1 column was, however, lower than on those of authentic esters possessing a straight chain of the corresponding number of carbon atoms in the alcohol moiety. This indicated that the compound had alkyl branch(es) in the alcohol moiety. The alkyl chloride derived from the ester in the 2% fraction from $AgNO_3$-SiO_2 chromatography after hydrolysis and subsequent chlorination was analyzed with the HP-5 column. One peak was observed at 16.83 min. The mass spectrum of this compound showed a molecular ion at *m/z* 288 (15%) and an M+2 ion at *m/z* 290 (5%), which indicated that this compound contained 18 carbon atoms and one chlorine atom, that is, it was derived from the alcohol moiety of compound A. Diagnostic fragment ions were observed at *m/z* 245 (M−43, 74%) and 273 (M−15, 34%), which were accompanied by the isotopic ions at *m/z* 247 (23%) and 275 (11%), respectively. This suggested the presence of one methyl branch at the position 16 of the 17-carbon chain. This was confirmed by GC-MS analysis of authentic 1-chloro-16-methylheptadecane. The mass spectrum and retention time of compound A were identical to those of synthetic 16-methylheptadecyl isobutyrate (16Me-17:iBu) in subsequent GC-MS analysis, but did not fit with those of synthetic 16-methylheptadecyl *n*-butyrate. Compound A was, therefore, identified as 16Me-17:iBu.

GC-MS analysis with the DB-WAX column of reductive ozonolysis products of the 5% fraction from $AgNO_3$-SiO_2 chromatography showed two major compounds: a 9-carbon aldehyde and 8-formyloctyl isobutyrate. These indicated the double bond at carbon 9 in the 18-carbon alcohol moiety of compound B. Furthermore, the alkyl chlorides derived from the products of diimide reduction of compound B showed properties identical to those of compound A by GC-MS analysis. Compound B was estimated to be 16-methyl-9-heptadecenyl isobutyrate on the basis of these microreactions.

The synthetic compounds were analyzed by GC-MS with the DB-23 column. The retention time of compound B fit well with synthetic (8)-16-methyl-9-heptadecenyl isobutyrate (16Me-Z9-17:iBu), and (*E*)-16-methyl-9-heptadecenyl isobutyrate did not fit with compound B. The mass spectrum of synthetic 16Me-Z9-17:iBu was identical to that of compound B. Therefore, compound B was identified as 16Me-Z9-17:iBu.

The mixture of the two synthetic esters at the natural ratio was analyzed by the GC-EAD. This showed two clear EAD responses to the synthetic mixture, which were similar to those occurring when the 5% fraction from Florisil chromatography was injected.

Field tests were conducted to determine the activity of synthetic 16Me-Z9-17:iBu (Table 1). More *E. taiwana* males were caught with 16Me-Z9-17:iBu

TABLE 1. TRAP CATCHES OF MALE *Euproctis taiwana* WITH (Z)-16-METHYL-9-HEPTADECENYL ISOBUTYRATE (16ME-Z9-17:IBU) (OCTOBER 18–20, 1994, NAHA)[a]

16Me-Z9-17:iBu (μg/filter paper)	No. of males caught/trap/night (mean ± SE)[b]

alone than with three 3-day-old females, but the difference was not statistically significant. The male catch increased when the dose was increased from 30 μg to 100 μg. These results suggest that this is the optimum dose level for male attraction.

Field tests were also conducted to determine the activity of synthetic 16Me-17:iBu, 16Me-Z9-17:iBu, or their blends (Table 2). From June 22 to July 4, males were caught with three 3-day-old females and also with 300 μg of 16Me-Z9-17:iBu alone. No significant increase or decrease was observed when 10, 100, or 200 μg of 16Me-17:iBu was added to 300 μg of 16Me-Z9-17:iBu. From October 20 to 22, no males were caught with 100 μg of 16Me-17:iBu alone, although many males were caught with 300 μg of 16Me-Z9-17:iBu alone or a blend of 300 μg of 16Me-Z9-17:iBu and 100 μg of 16Me-17:iBu.

DISCUSSION

Two compounds were identified as possible sex pheromone components in *Euproctis taiwana*. The major component was characterized as 16Me-Z9-17:iBu and the minor one as 16Me-17:iBu. These two components have not previously been reported as natural products. Field bioassays showed that 16Me-Z9-17:iBu is essential to attract male *E. taiwana* moths. Synergistic effects on male attraction by 16Me-17:iBu were not apparent in the field tests (Table 2), although 16Me-17:iBu was EAG-active. Further studies are necessary to check the behavioral activity of the minor components and to develop an effective synthetic

lure for monitoring field populations and/or use as a tool in integrated pest management strategy.

In the genus *Euproctis*, sex pheromones have already been identified for three species and one subspecies (Table 3). As volatile sex pheromones, these chemical compounds have relatively high molecular weights. The alcohol moieties of the esters identified from *Euproctis* include 16-, 17-, 18- or 22-carbon alcohols that includes saturated or unsaturated and straight or methyl-branched chains. The acid moieties of the esters are derived from 4- or 5-carbon organic acids.

In many closely related species of Lepidoptera, the sex pheromones include one or more common components (Arn et al., 1992). For example, 2-methylheptadecane is one of the sex pheromone components in the genus *Holomelina* (Arctiidae) and (*Z,E*)-9,12-tetradecadienyl acetate has been identified as a common component of sex pheromones in many species of the genus *Spodoptera* (Noctuidae). However, no such common compound has been found in the genus *Euproctis*.

(Received March 17, 1995; accepted July 9, 1995)

Abstract—We have identified five compounds from the headspace of calling male Mediterranean fruit flies (medfly), *Ceratitis capitata* (Wiedemann), and three compounds from the headspace of ripe mango (*Mangifera indica* L). using coupled gas chromatographic-electroantennographic (GC-EAG) recordings, coupled gas chromatographic-mass spectrometric (GC-MS) analysis, and electroantennographic (EAG) assays of standards. The male-produced volatiles eliciting responses from female antennae were ethyl-(*E*)-3-octenoate, geranyl acetate, (*E,E*)-α-farnesene, linalool, and indole. An EAG dose-response test of linalool enantiomers and indole with female medfly antennae showed relatively strong EAG activities, but no significant difference between (*R*)-(−)-linalool and (*S*)-(+)-linalool. The three mango volatiles were identified as (1*S*)-(−)-β-pinene, ethyl octanoate, and β-caryophyllene. In addition, a strong antennal response was recorded from a contaminant, α-copaene, present in a commercial sample of β-caryophyllene. The EAG response amplitudes from both male and female antennae to the above three mango volatiles were significantly greater than to a hexanol control. For both male and female medfly antennae, the greatest EAG responses were elicited by β-caryophyllene followed by ethyl octanoate. The mean EAG responses of female antennae to β-caryophyllene and (1*S*)-(−)-β-pinene were significantly greater than those of male antennae.

Key Words—Diptera, Tephritidae, Mediterranean fruit fly, *Ceratitis capitata*, pheromone, attractants, mango volatiles, *Mangifera indica*, headspace analysis, gas chromatography-electroantennography.

INTRODUCTION

The medfly, *Ceratitis capitata* (Wiedemann) (Diptera: Tephritidae), is a notorious pest because of its broad host range, attacking over 250 different types of fruit and vegetables, and its importance to international quarantine (Hagen et al., 1981). The most widely used lure in trapping programs for medfly detection is trimedlure, a synthetic compound primarily attractive to male medflies (Beroza et al., 1961). The lack of an effective female attractant has prompted several studies to examine the male sex pheromone and host odors as lures for attracting female flies. Several researchers have reported on the isolation, identification, or attractancy of male-produced volatiles from calling male medflies, resulting in a total of 56 identified compounds (R.R. Baker et al., 1985; P.S. Baker et al., 1990; Jang et al., 1989, 1994; Heath et al., 1991; Landolt et al., 1992a; Flath et al., 1993). The focus of these studies has been mainly on the attractiveness of the most abundant male odor components. A three-component blend was shown to have limited attraction for medfly females in wind-tunnel bioassays and in field tests (Heath et al., 1991; Landolt et al., 1992a). Recently, Jang et al. (1994) reported on the attractiveness of a five-component blend in wind-tunnel experiments, including the three components tested by Heath et al. (1991) and Landolt et al. (1992a); they found that this blend was still less attractive than the natural male pheromone. These results indicate that improvements in the synthetic male pheromone blend may be possible. Analysis of volatile compounds with coupled gas chromatographic–electroantennographic (GC-EAG) assays may help eliminate compounds with no biological activity and suggest compounds for behavioral studies. Furthermore, host odor volatile analysis by GC-EAG assay could identify compounds that, in combination with male pheromone, may further enhance female attraction to male pheromone, as was shown with the papaya fruit fly, *Toxotrypana curvicauda* Gerstaecker (Landolt et al., 1992b).

By using GC-EAG and EAG recordings, we have examined the peripheral olfactory selectivity of female medflies to volatile compounds from males and from ripe mango in order to identify potentially attractive novel compounds. Volatiles of mango were analyzed because this fruit is a preferred host of several fruit fly species and the identity of many volatiles of intact mango have been determined (Engel and Tressl, 1983; MacLeod and Pieris, 1984; MacLeod and Snyder, 1985; Bartley and Schwede, 1987; Bartley, 1988; MacLeod et al., 1988). Our study represents the first use of the GC-EAG technique with medfly

and allowed us to pinpoint compounds present in trace amounts that may have gone undetected by using GC analysis and EAG recordings as separate techniques.

METHODS AND MATERIALS

Insects. Pupae were obtained from a medfly rearing facility operated by USDA-APHIS in Petapa, Guatemala. Upon arrival at the UCR Insect Quarantine Facility, the dyed (Day Glo Yellow) male and female pupae were placed in separate cages and held under natural light conditions. Adults flies used for the EAG and GC-EAG studies were fed honey and tested 3–30 days after emergence.

Collection of Male-Produced Volatiles. Extracts of volatiles produced by aeration of calling males were provided by R.R. Heath at the Insect Attractants, Behavior, and Basic Biology Research Laboratory, USDA-ARS, Gainesville, Florida, who used collection procedures previously described (Heath et al., 1991). Volatiles were collected from wild male medflies 5–10 days old in groups of 8–12 flies for 2-hr periods throughout the photophase. The males had access to a yeast hydrolysate food source, which was replaced with sugar water 24 hr prior to the collection of the volatiles. The male-produced volatiles were collected in glass tubes (4 cm long × 4 mm ID) containing 25 mg of Super-Q (Alltech Assoc. Inc., Deerfield, Illinois) placed between two stainless steel frits. The Super-Q traps were eluted with 200 μl of methylene chloride. Each sample was concentrated to ca. 50 μl under nitrogen prior to GC-EAG analysis.

Collection of Mango Fruit Volatiles. Ripe mangos (cv. Tommy Atkins) were obtained from a local supermarket and washed with water before being analyzed. A piece of mango peel with pulp attached (ca. 0.5 × 0.5 × 0.5 cm) was placed in a 25-ml fritted sparger, which was connected to a Tekmar 2000 purge and trap concentrator (Tekmar, Cincinnati, Ohio). The conditions for collecting volatiles on a Tenax trap were as follows: 5 min purge at room temperature (He, 20 ml/min), 5 min dry purge, and 4 min desorb at 180°C. The Tekmar 2000 was directly interfaced to the GC-EAG setup.

Chemical Analyses. One-microliter aliquots of the collected male-produced volatile extract were injected in splitless mode onto 30-m × 0.25-mm-ID fused silica capillary gas chromatographic columns, coated either with DB-5 or DB-1 (J & W Scientific, Folsom, California) or Ultra-2 (Hewlett-Packard Company, Palo Alto, California; equivalent to DB-5) for analyses by GC-EAG and GC–mass spectrometry (GC-MS). Column conditions were as follows: He carrier gas flow of 1.5 ml/min, injector temperature 200°C, oven temperature program 1 min delay on inlet purge, 2 min at 40°C, then 20°C/min to 220°C.

Mango volatiles were analyzed by interfacing the GC-EAG and GC-MS

with the Tekmar 2000 purge and trap collector, using the same columns with the following column conditions: He carrier gas flow of 1.5 ml/min, injector temperature 200°C, oven temperature program, 4 min at 0°C, 4 min at 40°C, 25°C/min to 220°C (GC-EAG); and injector temperature 250°C, oven temperature program, 4 min at 0°C, 10°C/min to 250°C (GC-MS).

GC-MS analyses were performed using a Hewlett-Packard 5890 gas chromatograph with a direct interface to a Hewlett-Packard 5970 mass selective detector (electron impact, 70 eV).

Electroantennogram Responses. Simultaneous GC-EAG and EAG analyses were performed as described by Baker et al. (1991) using a Varian model 3740 GC (Varian Associates, Sugarland, Texas). EAG recordings were made by placing a saline-filled (Beadle-Ephrussi Ringer) glass electrode in the back of an excised medfly head. The recording electrode was inserted into the tip of one of the antennae. To examine antennal sensitivity to the identified "minor" male-produced volatiles and to mango odor, EAGs, not coupled to GC, were recorded for a series of commercial or synthetic compounds. Serial dilutions of the tested compounds were made in redistilled HPLC-grade hexane such that the tested compounds were applied to filter-paper strips (0.5 × 3.0 cm, Whatman No. 1) in 10 μl of solvent. The filter-paper strips were placed inside Pasteur pipets (15 cm long). Control puffs of blank (filter paper plus solvent) and air (empty pipet) controls showed relatively low EAG activities, which were difficult to distinguish from the background activity. For this reason and to compensate for possible deterioration of the preparation, each 2-ml puff of test compound was preceded by a standard control compound, hexanol (10-μg dose). EAG amplitudes were standardized according to the responses to hexanol by dividing the amplitude of the EAG generated from the test compounds by that of hexanol. Within a particular series of test compounds, presentation of the test compounds was randomized. EAG data were subjected to ANOVA and mean responses were compared using a t test.

Chemicals. Racemic linalool, ethyl octanoate, indole, geranyl acetate, and (1*S*)-(−)-β-pinene were obtained from Aldrich Chemical Company (Milwaukee, Wisconsin) and were >98% pure (label information and GC analysis). (*R*)-(−)-Linalool and β-caryophyllene were purchased from K & K Laboratories (Cleveland, Ohio). The β-caryophyllene sample contained 1% α-copaene based on GC-MS comparisons with authentic samples of α-copaene isolated from cubeb oil (Millar et al., 1986) and 10% α-humulene based on GC-MS comparisons with commercially available material (Fluka Chemical Company, Ronkonkoma, New York). (*S*)-(+)-Linalool was synthesized according to Landolt et al. (1994) and ethyl-(*E*)-3-octenoate was prepared as described by Heath et al. (1991). (*E*,*E*)-α-Farnesene was obtained from R.R. Heath, USDA, Gainesville, Florida.

RESULTS

Analysis of Volatiles Collected from Calling Males. A total of 30 combined GC-EAG analyses of the volatiles collected from calling male medflies by aeration was obtained using 30 different female medfly antennae. Only those GC peaks that consistently revealed EAG activity were targeted for further analysis. The combined GC-EAG analysis consistently revealed five GC peaks on both DB-1 and DB-5 columns with corresponding EAG activity with female medfly antennae (Figure 1, compounds I, II, III, IV, and V). The retention times on both columns and GC-MS spectra of compounds I–V corresponded precisely to those of five compounds known to be produced by male medfly: linalool, ethyl-(*E*)-3-octenoate, indole, geranyl acetate, and (*E*,*E*)-α-farnesene, respectively. Moreover, combined GC-EAG recordings on both DB-1 and DB-5 columns demonstrated that linalool, ethyl-(*E*)-3-octenoate, indole, geranyl acetate, and (*E*,*E*)-α-farnesene had retention times identical to compound I–V, respectively, from the collected male volatiles and were EAG active.

Standardized EAG dose responses revealed that 100 ng and higher dosages of indole and (*S*)-(+)-linalool, and 1 μg and higher dosages of (*R*)-(−)-linalool elicited stronger EAG responses in female antennae than hexanol (Figure 2). Indole (10 μg) generated responses 2.1 times (±0.4 SD) as great as those elicited by hexanol, (*S*)-(+)-linalool (10 μg) 1.5 times (±0.5 SD) as great, and (*R*)-(−)-linalool (10 μg) 1.4 times as great (±0.4 SD). The 10-μg dosages of indole generated significantly stronger responses than either (*R*)-(−)-linalool or (*S*)-(+)-linalool ($t = 2.61$, $P < 0.05$, $t = 2.15$, $P < 0.05$, respectively), and the 100-ng dosage of indole generated significantly stronger responses than (*R*)-(−)-linalool ($t = 5.12$, $P < 0.05$). However, there were no significant differences in the EAG responses to (*R*)-(−)-linalool and (*S*)-(+)-linalool for the dosages tested. The mean EAG response of female medfly antennae to hexanol was 0.4 mV (±0.5 SD, $N = 9$).

Analysis of Mango Volatiles. Analyses of trapped mango volatiles by coupled GC-EAG on both DB-1 and DB-5 columns revealed three compounds that consistently elicited strong antennal responses from female medflies (Figure 3). These compounds were identified as β-pinene, ethyl octanoate, and β-caryophyllene, respectively, by comparison of GC-MS retention times and mass spectra with those of authentic compounds. Moreover, combined GC-EAG recordings of (1*S*)-(−)-β-pinene, ethyl octanoate, and β-caryophyllene on the same two capillary columns demonstrated that these retention times were identical to compounds VI, VII, and VIII, respectively, from the collected mango volatiles and that all three compounds were EAG active (Figure 4). Closer examination of the GC-EAG responses obtained with a mixture of commercially available compounds identified from mango revealed an additional minor peak with EAG

activity labeled with a question mark in Figure 4. Mass spectral and retention time analyses of the β-caryophyllene sample revealed the presence of β-caryophyllene, α-copaene, and α-humulene. The identities of the latter two compounds were confirmed by comparison of retention times and mass spectra with authentic standards. Combined GC-EAG analysis of β-caryophyllene consistently revealed that α-copaene elicited strong EAG responses in addition to the

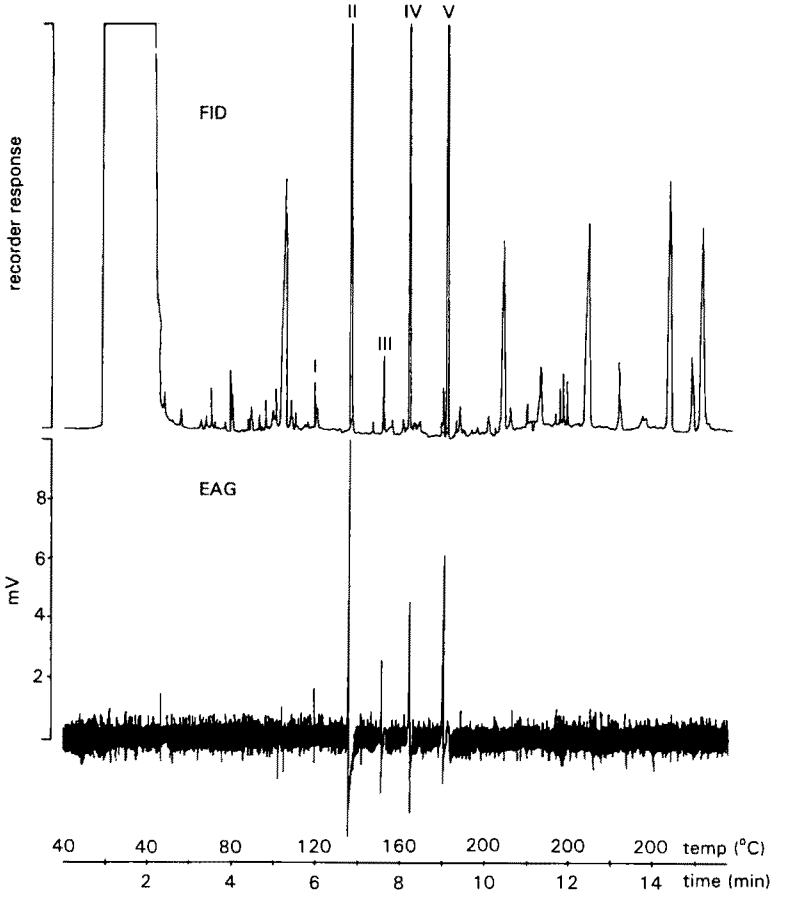

FIG. 1. Reconstructed simultaneously recorded gas chromatogram [flame ionization detector (FID)] of trapped volatiles of calling male medflies (top) and electroantennogram (EAG) of a female medfly antenna (bottom). EAG active compounds are labeled I, II, III, IV, and V (see text for details).

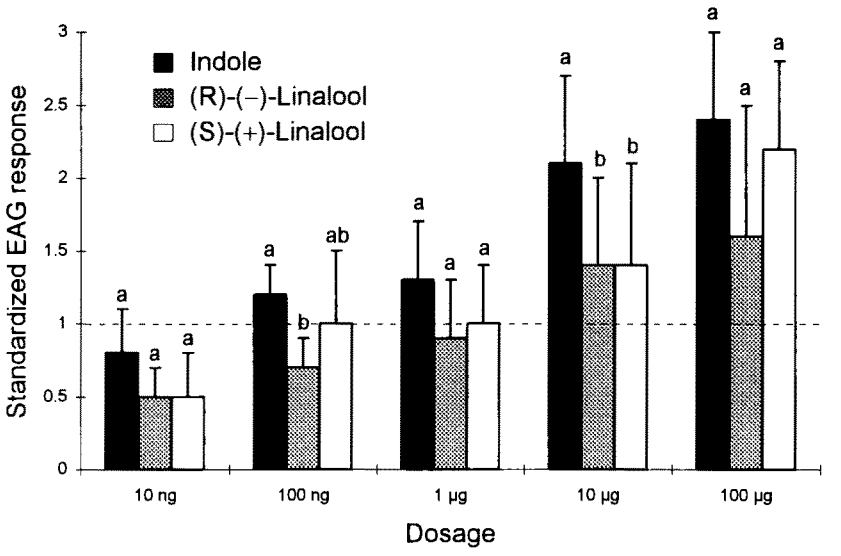

FIG. 2. EAG dose responses of female medfly antennae to selected known volatile compounds released by calling males. Stimuli were commercial or synthetic standards. Standard deviations of mean responses are presented as error bars. Dotted line indicates the mean response to the hexanol standard (10 μg). Dosage means with the same letter are not significantly different by Student's t test at $P < 0.05$ ($N = 9$).

EAG activity of β-caryophyllene, while α-humulene showed no activity on female antennae (Figure 5). No α-copaene was detected in the trapped mango volatiles. The following compounds were also identified by retention time and mass spectral matches with standards, but showed no GC-EAG activity: 1-butanol, ethyl propanoate, 3-methyl butanol, ethyl butanoate, ethyl-(*E*)-2-butenoate, α-pinene, *o*-cymene, myrcene, ocimene, *p*-cymene, limonene, terpinolene, and α-humulene.

Standardized EAG response measurements with 100-ng dosages of (1*S*)-(−)-β-pinene, ethyl octanoate, and β-caryophyllene showed greater EAG responses elicited by ethyl octanoate and β-caryophyllene than by hexanol for both male and female antennae (Figure 6). Average responses to (1*S*)-(−)-β-pinene, ethyl octanoate, and β-caryophyllene of female antennae were 0.78 $\pm$ 0.04 SD, 1.88 $\pm$ 0.25 SD, and 4.68 $\pm$ 0.70 SD, respectively, while average responses from male antennae were 0.41 $\pm$ 0.08 SD, 1.90 $\pm$ 0.28 SD, and 3.84 $\pm$ 0.42 SD, respectively. The mean EAG responses of female medflies to β-caryophyllene and (1*S*)-(−)-β-pinene were significantly greater than those of male flies ($t = 3.27$, $P < 0.01$, $t = 12.86$, $P < 0.01$, respectively). The

presence of a 1% α-copaene contamination in the 100-ng dosage of β-caryophyllene would have elicited at most a 40% increase in the EAG response to that of β-caryophyllene alone (see Figure 5). The mean EAG responses of female and male medfly antennae for hexanol were 0.3 mV ($\pm$0.3 SD, $N = 9$) and 0.3 mV ($\pm$0.2 SD, $N = 11$), respectively.

DISCUSSION

The goal of this research was to provide some focus regarding the many compounds that have been identified from volatile emissions of calling male

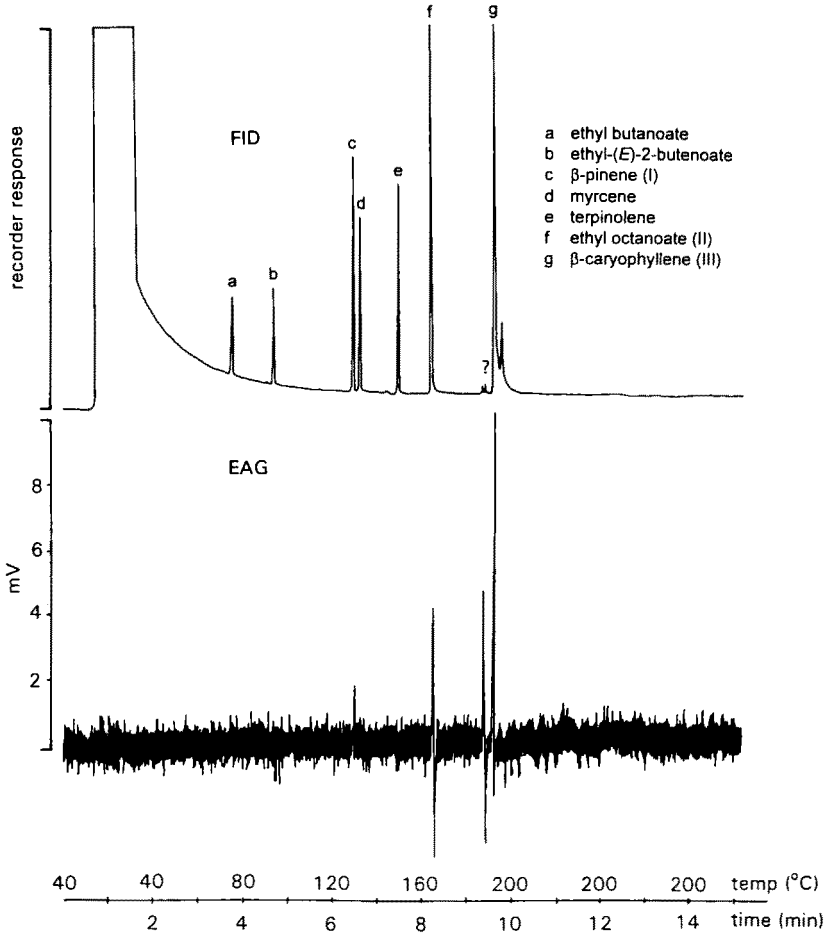

FIG. 4. Reconstructed simultaneously recorded gas chromatogram [flame ionization detector (FID)] of a mixture of commercial and synthetic compounds identified from ripe mango (top) and electroantennogram (EAG) of a female medfly antenna (bottom). EAG active compounds are labeled VI, VII, VIII, and ? (see text for details).

medflies and from host fruits. In particular, we wanted to see if some heretofore overlooked minor or trace compounds in these volatile emissions might stand out with regard to EAG amplitude and indicate that behavioral testing should be performed with those compounds added to the blend if such testing had not previously been done.

The coupled GC-EAG provides a real-time plot of the sequential responses

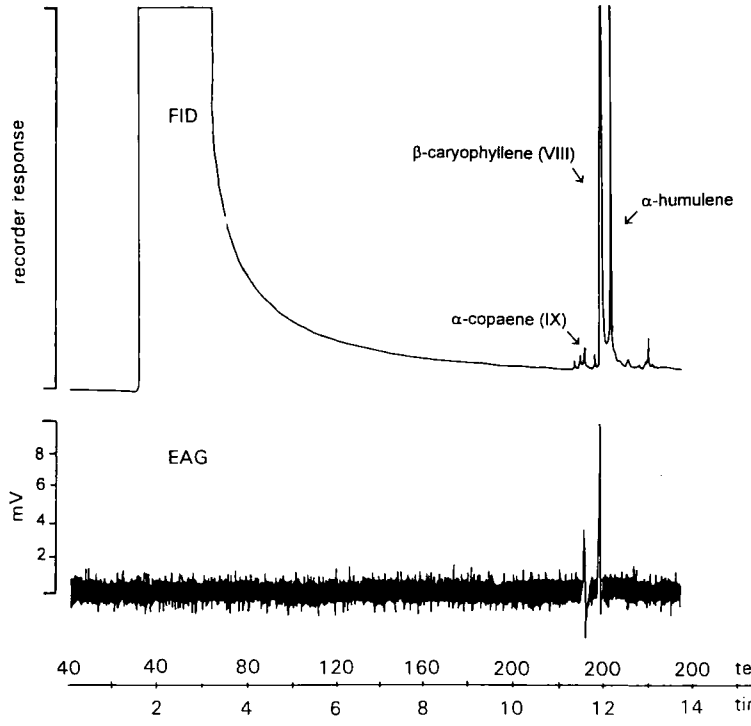

FIG. 5. Reconstructed simultaneously recorded gas chromatogram [flame ionization detector (FID)] of a mixture of α-copaene, β-caryophyllene, and α-humulene (top) and electroantennogram (EAG) of a female medfly antenna (bottom). EAG active compounds are labeled VIII and IX (see text for details).

of a single antenna to every compound in a natural extract. Thus, a single run provides comparative antennal response data for each compound and unequivocally highlights the compounds in the extract to which the antennae are most sensitive. Furthermore, possible problems of being misled by strong responses to trace contaminants in a synthetic sample that is puffed over the antenna are eliminated because the sample is separated into its component compounds, which are then passed over the antenna one at a time as they elute off the GC column. This technique requires that the preparations stay extremely stable over the course of the GC run in order to avoid spurious peaks from occurring and confounding the analysis. We were able to achieve this stability and sensitivity for our medfly preparations. This study, to the best of our knowledge, represents the first-ever medfly GC-EAGs.

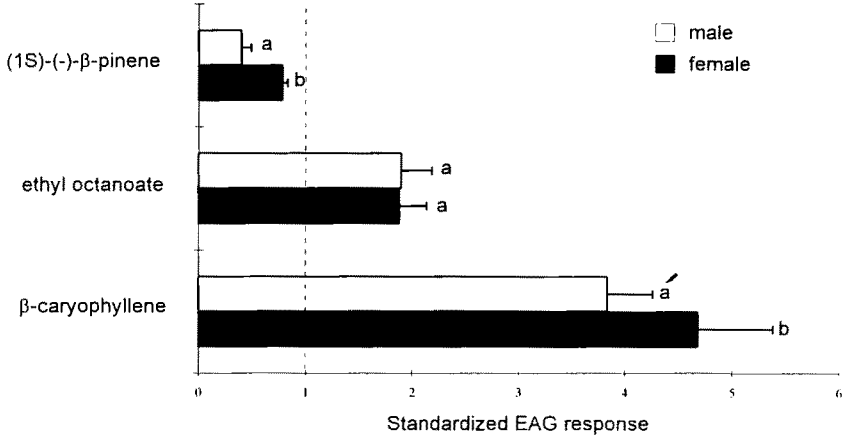

FIG. 6. EAG responses of male and female medfly antennae to commercial or synthetic compounds (100 ng) identified from ripe mango. Standard deviations of mean responses are presented as error bars. Dotted line indicates the mean response to the hexanol standard (10 μg). Male and female response means from the same compound with the same letter are not significantly different by Student's t test at $P < 0.05$ ($N = 10$).

Our approach of combined GC-EAG analyses demonstrated that female medfly antennae selectively responded to only five of the many compounds that were present in the headspace of calling male medflies. We identified these compounds as ethyl-(*E*)-3-octenoate, geranyl acetate, (*E*,*E*)-α-farnesene, linalool, and indole by GC-MS analyses. All five compounds had been previously identified (Baker et al., 1985; Jang et al., 1989; Heath et al., 1991; Flath et al., 1993). Ethyl-(*E*)-3-octenoate, geranyl acetate, and (*E*,*E*)-α-farnesene represent three of the five most abundant male odor components (Jang et al., 1989; Heath et al., 1991; Flath et al., 1993), and linalool and indole have been previously quantified as "intermediate" and "trace" components, respectively, based on reconstructed gas chromatograms (Figure 1 and Jang et al., 1989; Flath et al., 1993). Jang et al. (1989), working with medflies from Hawaii, isolated and identified 56 compounds from the odor of calling males and, by using EAGs, ranked the response to linalool in the top half of all the compounds tested, whereas the response to indole was ranked as one of the two lowest responses recorded. In contrast, our EAG dose–response tests showed indole equaling or exceeding the responses elicited by either (*R*)-(−)-linalool or (*S*)-(+)-linalool. However, due to differences in methodology, no accurate comparison can be made between our results and those of Jang et al. (1989).

Several studies have reported on the field attractancy of female medfly to the identified compounds, individually or as mixtures, with the exception of

indole. Recently, Jang et al. (1994) reported on flight behavior of females in a wind tunnel to a synthetic blend of ethyl-(*E*)-3-octenoate, geranyl acetate, (*E*,*E*)-α-farnesene, ethyl acetate, and 1-pyrroline, as well as to the odor of calling males, and they found that the natural male pheromone was still the most active blend for female attraction. Indole and linalool were not included in these tests. Initial laboratory assay results showed a significant increase in attraction of a previously tested three-component sex pheromone blend when indole was added (R.R. Heath, personal communication).

Our results with mango volatiles have revealed potential new attractants. Of the previously reported 54 volatile compounds identified from mango (Bartley, 1988), we identified 16 compounds in the headspace of mango pieces. Only three compounds consistently evoked responses in combined GC-EAG analyses with female antennae. Our GC-MS analyses identified the compounds as β-pinene, ethyl octanoate, and β-caryophyllene. In addition, the results from our studies showed that the known attractant, α-copaene, a contaminant in our commercial sample of β-caryophyllene, was strongly EAG active, as might be expected from its behavioral activity (Flath et al., 1994a,b). β-Caryophyllene has been reported as a medfly attractant (Beroza and Green, 1963), but Warthen and McInnis (1989) were unable to reproduce these results and suggested that the β-caryophyllene samples tested were attractive because of the presence of α-copaene as an impurity. This conclusion possibly should be reexamined in light of our results showing highly selective GC-EAG responses to both α-copaene and β-caryophyllene by female antennae. The behavioral activity of ethyl octanoate either alone or as part of a blend has not been tested. Jang et al. (1989) did not find ethyl octanoate in medfly emissions, but they did test it as an analog of ethyl-(*E*)-3-octenoate and ranked it as giving an intermediate EAG response on both male and female medfly antennae. Ethyl octanoate does function as one component of a four-component host-fruit blend that attracts male and female Mexican fruit flies, *Anastrepha ludens* Loew (Robacker et al., 1992). Its structure is similar to that of the medfly sex phermone component, ethyl-(*E*)-3-octenoate.

ROLES OF CUTICULAR HYDROCARBONS IN INTRA- AND INTERSPECIFIC RECOGNITION BEHAVIOR OF TWO RHINOTERMITIDAE SPECIES

SHOZO TAKAHASHI* and AHDIN GASSA

Pesticide Research Institute, Faculty of Agriculture
Kyoto University, Kyoto 606, Japan

(Received February 15, 1995; accepted July 13, 1995)

Abstract—Soldiers of two termite species, *Reticulitermes speratus* and *Coptotermes formosanus*, showed aggressive behavior toward workers of other species. Soldiers always exhibited aggressive behavior to a conspecific worker treated with heterospecific cuticular hydrocarbons. A bioassay using live workers to test contact chemical cues was developed.

Key Words—Specific recognition, aggressive behavior, contact chemical cues, Rhinotermitidae, cuticular hydrocarbons.

INTRODUCTION

Cuticular hydrocarbons in a number of social insects have been analyzed in recent years to determine their chemotaxonomic, physiological, and semiochemical roles (Howard, 1993). Termites show a species-specific profile of hydrocarbons from the cuticle, although the composition seems to differ among families (Haverty et al., 1990). In Rhinotermitidae, each sympatric species has a qualitatively unique hydrocarbon composition. The hydrocarbons function as critical ecological cues, and there are populational and seasonal differences within species (Bagnères et al., 1991; Su and Haverty, 1991). It was postulated that the hydrocarbons from the North American termites *Reticulitermes flavipes* (Kollar) and *Zootermopsis anguisticollis* (Hagen) were being used as species- and caste-

recognition cues. A role for cuticular hydrocarbons as species-recognition cues was reported (Howard et al., 1982b) for termites in which aggressive behavior was shown towards a critical-point-dried (CPD) specimen treated with heterospecific hydrocarbons. Application of cuticular hydrocarbon mixtures to CPD specimens elicited the same behavioral response as that directed towards live heterospecifics, but the biting response occurred at relatively low frequency due to the lack of movement by the specimens. Various behavioral tests were made with living or dead individuals to clarify the role of cuticular hydrocarbons in interspecific recognition of two species of termites, *Reticulitermes* (*lucifugus*) *grassei* and *R.* (*l.*) *banyulensis*. These termites show a high degree of aggressiveness towards each other, and dead (CPD) termite lures covered with an extract of nonpolar lipids from *R.* (*l.*) *grassei* provoked the strongest aggression in *R.* (*l.*) *banyulensis* workers (Bagnères et al., 1991). Agonistic behavior was observed in an arena test when groups of *C. formosanus* from the same colony or a different colony were paired (Su and Haverty, 1991). Among six colonies each from Florida and Hawaii, that were tested, three Florida colonies were not attacked aggressively by any other colony. Thirteen of 36 pairings of colonies from Hawaii resulted in aggressive responses. Comparison of cuticular hydrocarbon patterns of the colonies showed no apparent relation between cuticular hydrocarbon composition and agonistic behavior in the *C. formosanus* populations (Su and Haverty, 1991).

Coptotermes formosanus Shiraki inhabits the Pacific coastal area of the eastern and western parts of Honshu, Shikoku, and southern Japan. *Reticulitermes speratus* (Kolbe) is widely distributed all over Japan except for the northeastern part of Hokkaido. In a small arena test, 100% of the soldiers tested showed biting behavior toward a heterospecific worker. The soldiers never attacked freeze-killed heterospecific workers in this test, which suggested the need to use live workers when testing the role of cuticular hydrocarbons in species recognition (Gassa and Takahashi, 1995). When a soldier encountered a conspecific worker coated with powdered material or liquid paraffin, it recognized the worker not as a conspecific, but as a different species and attacked it with open mandibles, biting the worker to death (Gassa et al., 1994). Coating of the worker body surface with foreign hydrocarbons apparently imbued them with a kairomonal activity that elicited biting from conspecific soldiers (Gassa et al., 1994). In order to understand more clearly this interspecific aggression, behavioral assays with live termites coated with the cuticular wax from workers of the two species were conducted. In this paper we report a bioassay method confirming that cuticular hydrocarbons have a major function in intra- and interspecific recognition in termites. This bioassay seems applicable to many termite species as an aid in identifying nest and caste recognition cues.

METHODS AND MATERIALS

Insects. Workers and soldiers of *C. formosanus* were obtained from a stock culture in the insectory of the Wood Research Institute, Kyoto University, Uji. The colony of *R. speratus* was collected from the Botanical Garden of the Faculty of Science, Kyoto University, Kyoto. Groups of both species were maintained in a plastic container in 25 ± 2°C in the Pesticide Research Institute laboratory.

Extraction of Cuticular Wax. Fifty workers (or soldiers) of each termite species were immobilized by cooling and placed in a filter funnel plugged with a piece of cotton. The insects were washed with hexane three times, and the hexane solution was concentrated in vacuo after drying over anhydrous sodium sulfate. The extract was then placed on a silica gel column and hydrocarbons were eluted with hexane.

Preparation of Cuticular Wax Test Mixtures. To solvent evaporated and dried cuticular hydrocarbons from the 50 workers was added 50 μl of 2% aqueous Triton X-100 solution, and the mixture was warmed (at about 40°C) and shaken in an ultrasonic cleaner (Branson B-92) for 30 min to give an opaque liquid.

Observation of Termite Behavior. Observations were made at 25 ± 2°C, and humidity was not adjusted. A soldier and a worker of the same species were released into a Petri dish (30 mm diameter, 12 mm high) with a filter paper. Combinations of a solider and a worker from the two species, *C. formosanus* and *R. speratus*, were then made for behavioral observations.

One worker equivalent of the cuticular hydrocarbons (as a suspension or as a solution in 2% Triton X-100) was topically applied to the dorsal surface of a worker resting on a cooled Petri dish, and the dish and worker were then kept at room temperature for 15 min. After drying, each treated worker was transferred to an observation Petri dish (arena), and a conspecific soldier or a soldier of the other species was introduced. Antennal contact, opening of the mandibles, and biting by the soldier during a 1-hr test period were recorded. The survival time of the treated worker was noted. All behaviors were recorded on video tape.

Analysis of Cuticular Wax Extract. The cuticular hydrocarbons were analyzed by gas–liquid chromatography (GLC) with a Shimadzu GC-14A gas chromatograph with a 15-m × 0.2-mm-ID HP-1 column. All GC analyses were done with temperature programming from 120°C to 320°C at 8°C/min, with a 2-min initial hold period. Helium was the carrier gas with a head pressure of 1.0 kg/cm^2. Retention times were compared to those of *n*-alkane standards.

Gas chromatograph–mass spectroscopy (GC-MS) analyses were performed on a Shimadzu GC-14A operated in splitless mode, with an injection temperature

of 300°C, a 25-m × 0.28-mm DB-1 capillary column, temperature programmed from 200°C to 300°C at 5°C/min. A Shimadzu QP-1000EX mass spectrometer was used with an ion source temperature of 250°C and interface temperature of 300°C for EI-MS (70 eV). CI-MS was obtained using isobutane.

RESULTS

A conspecific soldier and worker in the arena showed antennal scissors movement several times at their first encounter. *C. formosanus* workers and soldiers in the arena survived without food or water about 24.7 hr and 32.2 hr, respectively (Table 1). When a soldier and a heterospecific worker were placed in the arena, the soldier quickly made antennal contact with the worker and simultaneously opened its mandibles. Soldiers of both species killed heterospecific workers within a short time after mandible opening and biting (Table 1). When a soldier was placed in the arena with both a conspecific and a heterospecific worker, the soldier selectively killed only the heterospecific worker. However, no soldier ever demonstrated aggressive behavior toward a freeze-killed worker, whether conspecific or heterospecific. These findings confirmed that a bioassay to test chemical cues for species recognition behavior by soldiers must be conducted with live workers.

Soldiers showed a strong aggressive response to conspecific workers treated with one worker equivalent of heterospecific hydrocarbons prepared from the cuticular wax of 50 workers suspended in Triton X-100 (Tables 2 and 3). Soldiers showed only antennal scissors movements toward heterospecific workers treated with a suspension of hydrocarbons from the soldier's conspecific work-

ers. In the latter case, the soldiers only rarely displayed mandible opening or biting (Table 4).

Hydrocarbons in cuticular wax extracts from workers of the two species were clearly different in composition. *R. speratus* hydrocarbons had carbon numbers from 23 to 26 (Table 5), whereas those from *C. formosanus* showed 25–31 carbons (Table 6). Comparison of the hydrocarbon composition of the Japanese *C. formosanus* colony with colonies from the United States showed

slight differences in composition but similarities in the large amount of mixed, internal methyl-branched heptacosanes (Haverty et al., 1990).

DISCUSSION

A bioassay for intra- and interspecies recognition behavior by termite soldiers has been needed for many years by researchers involved in the chemical

ecology of social insects (Howard, 1993). The effect of moving of surrogate insects was shown in defense behavior of *Nasutitermes exitiosus* (Hill) soldiers. The device consisted of a small ferromagnetic bar that was placed on the floor of the arena on a magnetic stirrer. The soldiers approached the moving bar and sprayed a defensive substance but not the bar ceased twirling (Beaton et al., 1973; Eisner et al., 1976). Dead termites or various inert dummies treated with hydrocarbons have never elicited a response behavior in soldiers (Howard, 1993). Critical-point-dried (CPD) termites only infrequently elicited the biting response in soldiers (Howard et al., 1982b). Our test with live termite workers covered with heterospecific hydrocarbons elicited aggressive behavior in the conspecific soldiers 100% of the time, and the aggressive action strongly affected the survival time of the workers. Soldiers showed no aggressive behavior toward a heterospecific worker covered with added conspecific hydrocarbons of the soldier. Apparently, recognition of the conspecific hydrocarbons on the worker prevented such behavior. A similiar situation has been found in semiochemical studies on inquilines of termites. Many inquilines possess a cuticular hydrocarbon profile qualitatively identical to that of its host termites. The similarity to its termite host in composition of cuticular hydrocarbons seems to be a factor for success of the inquiline in living in close association with its host (Howard et al., 1980; 1982a).

Ethological studies on the role of chemical cues, called "chemical ethology" by Takahashi (1993), has been aided greatly by advances in chemical technology and in the discovery, identification, and synthesis of many semiochemicals. Bioassays, even if inherently limited, are absolutely critical in studies in semiochemical cues in all animals. Limited behavioral tests, however, have made it more difficult to understand the role of cuticular wax in species recognition of termites. Recent bioassays with dead, critical-point-dried specimens, and the use of dummies treated with heterospecific hydrocarbons to elicit aggression failed to show the level of agression elicited by live alien termites. Termite soldiers aggressively respond to moving objects similar to them in size but chemically or physically different in body composition (Gassa et al., 1994). Bioassays using live termites designed to determine the role of cuticular hydrocarbons indicate the success of this approach, and similar bioassays will likely be utilized in many chemical perception tests of social insects.

Acknowledgments—We thank Dr. T. Yoshimura, Wood Research Institute, Kyoto University, for supplying the *C. formosanus* colony. Our sincere thanks go to Dr. H. Okamoto, United Graduate School of Agricultural Sciences, Ehime University, for his suggestions and discussions throughout our experiments.

EVALUATION OF ORGANIC INFUSIONS AND SYNTHETIC COMPOUNDS MEDIATING OVIPOSITION IN *Aedes albopictus* AND *Aedes aegypti* (Diptera: Culicidae)

SANDRA A. ALLAN* and DANIEL L. KLINE

United States Department of Agriculture
Agriculture Research Service

(Received March 17, 1995; accepted July 10, 1995)

Abstract—Oviposition responses of gravid *Aedes albopictus* and *Ae. aegypti* were evaluated to natural organic infusions (hay infusion, larval rearing water, and field-collected larval water) as well as compounds isolated from hay infusion (3-methylindole, 4-methylphenol, 4-ethylphenol, indole, and phenol) known to elicit oviposition in *Culex* mosquitoes. In laboratory bioassays, significant oviposition responses were obtained from *Ae. albopictus*, but not from *Ae. aegypti*, to dilutions of hay infusion and field water. Oviposition responses of both species were moderate to the synthetic compounds tested in the laboratory (0.01–100 μg/liter). Only 3-methylindole (0.1 μg/liter) and 4-ethylphenol (1.0 μg/liter) elicited significantly more oviposition by *Ae. albopictus* than did well water. Of the synthetic compounds tested with *Ae. aegypti*, only phenol (1.0 μg/liter) and 4-ethylphenol (0.1 μg/liter) elicited significantly more oviposition than did well water. Significant repellency or oviposition deterrence for both species occurred in response to at least one high concentration of most of the compounds tested. In field cage evaluations, oviposition responses by *Ae. albopictus* were strongest to larval water and field water, moderate to hay infusion and 3-methylindole (100 μg/liter), and low to well water. A mixture of five synthetic compounds mimicking hay infusion was no more effective than 3-methylindole alone. For *Ae. aegypti*, oviposition responses were greatest to larval water and least to 3-methylindole. In an olfactometer, gravid females of both species oriented more to field water than to well water and only *Ae. albopictus* oriented more to larval water or hay infusion than well water. In general, gravid *Ae. albopictus* responded more strongly to oviposition stimuli than did *Ae. aegypti*.

INTRODUCTION

The selection of oviposition sites by many mosquito species is greatly influenced by chemical stimuli (Bentley and Day, 1989). Chemical factors mediating oviposition may result from the previous presence of larvae or pupae (reviewed in Bentley and Day, 1989) or from eggs, which in several *Culex* species contain an apical droplet of pheromone (Laurence and Pickett, 1985; Starratt and Osgood, 1973). In addition, water from natural breeding sites such as ponds (Gjullin et al., 1965) or infusions of organic material (such as hay or grass infusions) are attractive to gravid female mosquitoes (Ritchie, 1984; Millar et al., 1992). Different chemical cues may elicit oviposition behaviours beginning with the initial orientation towards a potential oviposition site and culminating in the deposition of eggs.

A wide range of mosquito species, including *Aedes albopictus* (Hein, 1976; Holck et al., 1988), *Ae. aegypti* (Gjullin et al., 1965; Chadee, 1993), *Ae. triseriatus* (Holck et al., 1988), *Culex nigripalpus* (Ritchie, 1984), *Cx. pipiens* (Madder et al., 1980; Reiter, 1986), *Cx. quinquefasciatus* (Gjullen et al., 1965; Reisen and Meyer, 1990; Millar et al., 1992), *Cx. restuans* (Madder et al., 1980; Reiter, 1986), and *Cx. tarsalis* (Reisen and Meyer, 1990) have been reported to be attracted to hay and grass infusions for oviposition. For this reason, infusions have been used to enhance collections in CDC light traps (Reiter et al., 1991), gravid female traps (Reisen and Meyer, 1990; Reiter, 1983), and ovitraps (Holck et al., 1988; Kitron et al., 1989).

Recently Millar et al. (1992) isolated and identified five compounds (3-methylindole, 4-methylphenol, 4-ethylphenol, phenol, and indole) from fermented Bermuda grass infusions that strongly stimulated oviposition by *Cx. quinquefasciatus*, both individually and in a blend of similar concentrations as isolated from the grass infusion. The five-compound blend and 3-methylindole alone were equally attractive to ovipositing *Cx. quinquefasciatus* in laboratory bioassays. In addition, 3-methylindole also mediated oviposition of *Cx. tarsalis* and *Cx. stigmatosoma* under field conditions (Beehler et al., 1994). It is not known if these compounds have similar effects on the oviposition behavior of other mosquito species known to be attracted to grass or hay infusions.

The objectives of our study were to: (1) evaluate oviposition responses of *Ae. albopictus* and *Ae. aegypti* to various organic infusions and solutions; and (2) to evaluate the effect of the recently identified components from Bermuda hay infusion (Millar et al., 1992) on their oviposition.

METHODS AND MATERIALS

Aedes albopictus and *Ae. aegypti* were reared and maintained at 27 ± 2°C, 70–80% relative humidity, and a 16L:8D-hr photoperiod. Larvae were reared by conventional methods using standardized density and nutrition (1000 immatures/3 liters of water and fed on a 1:1 mixture of liver powder and brewer's yeast). Female mosquitoes were blood-fed four to five days after emergence on defibrinated beef blood (*Ae. aegypti*) or chicks (*Ae. albopictus*). Blood-fed mosquitoes were held four to five days at 30 ± 1°C under fluorescent lighting with a 14L:10D photoperiod including 1 hr of simulated dawn and dusk period (provided by a 15-W incandescent bulb). A 10% sucrose solution was provided continuously to mosquitoes prior to bioassays.

Laboratory Bioassays. Bioassay cages were cylindrical cardboard containers (25.4 cm high × 24.7 cm diam.) with clear plastic lids. A 2-cm-diam. plugged access hole in the side of the container allowed introduction of mosquitoes into the cage. Disposable 70-ml plastic cups were painted black and filled with either 60 ml of well water (nonchlorinated water used to rear mosquitoes as controls) or the treatment preparations. One control and one treatment cup were placed in each bioassay cage ca. 6 cm apart, and a strip of seed germination paper (2 × 5 cm) (Steinley et al., 1991) was placed against the inside of each cup. A single gravid female was added to each cage at least 1 hr prior to the scotophase and mosquitoes were removed after 22 hr. Bioassays were conducted using individual females to reduce the potential influence of previously laid eggs on oviposition site preference (Chadee et al., 1990). Assays were run overnight in an environmental chamber at 30 ± 1°C with 14L:10D photoperiod with 1 hr of simulated dawn and dusk. They were scored by counting the numbers of eggs on the germination paper from the control and treatment cups.

Organic infusions used for bioassays included hay infusion (prepared after Reiter, 1986), larval rearing water, and water collected from a field site known to contain populations of *Ae. albopictus*. Preparation of the hay infusion involved adding 450 g Bermuda grass hay, 5 g brewer's yeast, and 20 g lactalbumin hydrolysate to 75 liters of well water, held at ambient temperatures (25–30°C) for 12 days. Two preparations of infusion were made and each was frozen in ca. 2-liter aliquots until needed. Hay infusion was diluted with well water as needed to produce dilutions of 10%, 25%, 50%, and 100% for testing in bioassays. Larval rearing water that had contained immature mosquitoes was obtained from the mosquito colony and stored at 10°C for a maximum of two days prior to use. Field-collected water originated from a natural oviposition site (an open container with oak leaves) that contained a continuous population of immature *Ae. albopictus*. Water was collected directly from the source prior to bioassays.

Field water was diluted with well water to produce dilutions of 5%, 25%, 75%, and 100% for testing in bioassays.

Synthetic compounds previously identified as components of hay infusion (3-methylindole, indole, phenol, 4-methylphenol, 4-ethylphenol) (Sigma Chemical Co.) (Millar et al., 1992) were prepared in hexane and added to well water in 10 μl of solvent. Concentrations of test compounds ranged from 0.01 to 100 μg/liter, and reflected concentrations typical of hay infusions (Millar et al., 1992). Control cups were treated with 10 μl hexane. All treatments consisted of 20–30 replicates.

Oviposition activity was expressed using the oviposition activity index (OAI) of Kramer and Mulla (1979), which is calculated as follows:

$$OAI = (N_t - N_c)/(N_t + N_c)$$

where N_t = number of eggs deposited in treatment cups and N_c = the total number of eggs deposited in control cups. Responses using this system range from 1 (attraction) to −1 (repellency) with zero denoting no preference. In this context, attraction refers to the deposition of eggs as the end result of a complex sequence of behaviors including orientation towards the source and stimulation to oviposit. These behaviors were not differentiated under the current bioassay conditions and only the endpoint of the pre- and oviposition behaviors (i.e., oviposition) was used to determine attraction or repellency. Treatment means were subjected to ANOVA to determine if significant differences were present ($P < 0.05$). Mean numbers of eggs laid under each treatment were compared by chi-square analysis to the number of eggs. Statistical comparisons were made by chi-square analysis between the mean numbers of eggs deposited in treatment cups (that were paired with well water control cups) compared to the expected number of eggs if oviposition was random between the treatment and control.

Field Bioassays. Bioassays were conducted in a screened field cage (ca. 5 × 5 × 5 m). Large potted plants were placed along the perimeter and in the center of the cage to provide resting sites for mosquitoes. Black glass oviposition jars (500 ml), each with 400 ml of water or solution and a strip of seed germination paper (4.5 × 9.6 cm) fastened with a paper clip to the inside upper edge of the jar, were used to evaluate oviposition responses. Jars were spaced evenly around the interior of the cage about 0.5 m from the cage wall. Each day, one jar containing each treatment was randomly assigned to one of five positions (experiment 1) or four positions (experiment 2) in the cage and treatments rotated in position from one day to the next to avoid positional bias. Each day, 50 gravid females were released from a central point in the cage in mid-afternoon. Treatments placed in the cage in mid-afternoon and oviposition strips with eggs were collected 24 hr later. Temperature and climatic conditions were

noted for each day. The numbers of eggs present on seed germination paper from each day were counted to determine oviposition responses.

Two experiments were conducted for each species. For experiment 1, treatments consisted of well water (nonchlorinated), a 25% solution of hay infusion, 3-methylindole (100 μg/liter), larval rearing water, and field water. Immediately before the test, hay infusion and 3-methylindole solutions were prepared in well water and field water and larval rearing water were obtained. Aliquots of thawed hay infusion and rearing water were kept at 10°C for up to two days. Treatments were repeated for 15 days (replicates).

For experiment 2, treatments consisted of 25% hay infusion, 3-methylindole (100 μg/liter), well water, and a mixture of synthetic compounds combined in concentrations similar to those found in hay infusion as described by Millar et al. (1992). This mixture consisted of phenol (0.27 mg/liter), 4-methylphenol (1.99 mg/liter), 4-ethylphenol (0.07 mg/liter), indole (0.01 mg/liter), and 3-methylindole (0.25 ng/liter). Synthetic compounds and mixtures were added to jars 10–15 min prior to placement in the field cage. Treatments were repeated for 10 days (replicates).

For each day, the percentage of eggs deposited in response to each treatment was determined. Means for each treatment were transformed to arcsine values and subjected to ANOVA ($P < 0.05$) to determine if significant differences were present in each experiment. Differences between means were determined using Tukey's studentized t test ($P < 0.05$). Data are presented as untransformed means.

Olfactometer Bioassays. To determine if organic infusions elicited an upwind orientation response, gravid *Ae. albopictus* and *Ae. aegypti* were tested in a dual-port olfactometer similar to that described by Schreck et al. (1967), but consisting of three stacked chambers (35 cm high × 90 cm long × 48 cm wide). Only one chamber at a time was used for assays. Outside air was conditioned prior to entry through the choice ports, the mosquito trap, and the olfactometer by passing through a series of charcoal filters and then heated and humidified. Conditions in the olfactometers were 27°C, 80% relative humidity with an air flow of 1 liter/sec. One hour before initiation of tests (ca. 14:00 hr EST), females were aspirated into the olfactometer chamber and allowed to acclimate. For each of the 10 replicates, 50 gravid females were used. Treatments were placed into two test ports upwind of the traps and olfactometer chamber. For each olfactometer test, one port contained well water and the other contained a test solution. Treatments (field water, larval water, and 50% hay infusion) were presented in glass Petri dishes that were cleaned and handled with gloves to minimize contamination and were alternated between ports from one day to the next. After 24 hr, the relative numbers caught in the treatment and control traps upwind of each port were compared. Treatments were added to each port and tests initiated at 15:00 hr EST.

Means were transformed to arcsine values and differences between means of treatments and controls determined by ANOVA ($P < 0.05$). Data are presented as untransformed means.

RESULTS

Oviposition responses of *Ae. albopictus* females differed significantly across the range of concentrations of hay infusion (ANOVA; $F = 6.58$; $df = 3,76$; $P < 0.001$) and field water tested (ANOVA; $F = 3.94$; $df = 3,76$; $P < 0.01$) (Figure 1). Only the 25% dilution of hay infusion elicited significantly more oviposition than expected (if oviposition was random between the paired treatments and well water controls) (chi square, $P < 0.001$). In response to 10% and 100% hay infusion, significantly lower levels of oviposition occurred (chi square, $P < 0.001$). Oviposition responses were strongly in response to solutions of 25% field water and 75% field water (chi square, $P < 0.001$). Oviposition responses to 100% field water were significantly lower than expected (chi square, $P < 0.001$).

Oviposition responses of *Ae. aegypti* did not differ across the same range of concentrations of hay infusion (ANOVA; $F = 0.94$; $df = 3,76$; $P = 0.42$) or field water (ANOVA, $F = 0.54$; $df = 3,76$; $P = 0.65$) (Figure 1). In general, OAI values for hay infusion were negative with significantly lower oviposition than expected in response to a 25% solution of hay infusion (chi square, $P < 0.001$). OAI values were moderately positive in response to field water with significantly greater oviposition than expected with solutions of 75% and 100% field water (chi square, $P < 0.001$).

Responses of gravid female *Ae. albopictus* to the synthetic compounds tested were moderate. Oviposition responses differed significantly across the range of concentrations of 3-methylindole (ANOVA; $F = 2.48$; $df = 4,145$; $P < 0.05$) and phenol (ANOVA; $F = 2.45$; $df = 4,95$; $P < 0.05$) but not indole (ANOVA; $F = 0.83$; $df = 4,95$; $P = 0.50$), 4-ethylphenol (ANOVA, $F = 0.55$, $df = 4,145$; $P = 0.69$) and 4-methylphenol (ANOVA; $F = 0.64$; $df = 4, 95$; $P = 0.63$) (Figure 2). Of the treatments with positive OAI values, only one concentration of 4-methylphenol (0.01 μg/liter) (chi square, $P < 0.001$) and 3-methylindole (0.1 μg/liter) (chi-square, $P < 0.05$) elicited significantly more oviposition than expected. Significantly fewer eggs were deposited in treatment cups than expected for 10 μg/liter (chi square, $P < 0.05$) and 100 μg/liter (chi square, $P < 0.001$) of 3-methylindole, 0.01 μg/liter (chi square, $P < 0.001$) and 100 μg/liter (chi square, $P < 0.001$) of phenol, 0.01 μg/liter (chi square, $P < 0.001$) of 4-ethylphenol and 100 μg/liter (chi square, $P < 0.001$) of indole.

Oviposition responses to synthetic compounds by *Ae. aegypti* females were

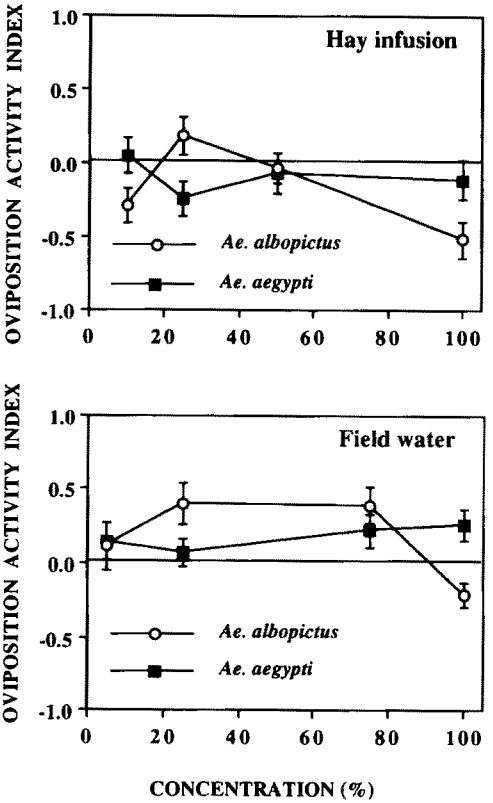

FIG. 1. Oviposition responses of gravid *Ae. albopictus* and *Ae. aegypti* to organic infusions in a laboratory bioassay. Data are presented as means (±SE) of oviposition activity indices (OAI) from 20 replicates. Positive OAI values indicated attractiveness and negative values repellency. *Significantly different at $P < 0.05$; **Significantly different at $P < 0.001$.

also moderate and only increased significantly across the range of concentrations of 4-ethylphenol (ANOVA; $F = 3.82$; df = 4,95; $P < 0.01$) and phenol (ANOVA; $F = 6.68$; df = 4,95; $P < 0.001$) but not 3-methylindole (ANOVA, $F = 0.943$; df = 4,95; $P = 0.44$), indole (ANOVA, $F = 1.19$, df = 2,57; $P = 0.31$), or 4-methylphenol (ANOVA; $F = 0.59$; df = 4,95; $P = 0.27$) (Figure 2). Of the treatments with positive OAI values, only 1.0 μg/liter of phenol and 0.1 μg/liter of 4-ethylphenol were significantly attractive (chi square, $P < 0.001$). Significantly lower oviposition than expected was noted for 3-methylindole (0.1 μg/liter) (chi square, $P < 0.001$), phenol (0.01 μg/liter, 100 μg/liter)

(chi square, $P < 0.001$), 4-ethyl phenol (0.01 μg/liter, 100 μg/liter) (chi square, $P < 0.001$), and 4-methyl phenol (0.01 μg/liter, 1.0 μg/liter) (chi square, $P < 0.001$).

In field cages, ovipositional responses by gravid *Ae. albopictus* differed significantly between well water, hay infusion, 3-methylindole (100 μg/liter), larval water, and field water (ANOVA; $F = 9.23$; $df = 4,45$, $P < 0.001$) (Table 1). In comparison to well water, significantly more eggs were deposited in response to hay infusion, 3-methylindole, larval water, and field water. Ovipositional responses to larval water were greater than to 3-methylindole but similar to hay infusion and field water. Ovipositional responses by gravid *Ae. aegypti* were also significantly different between treatments in experiment 1 (ANOVA; $F = 3.35$; $df = 4,45$; $P < 0.01$) (Table 1). Ovipositional responses to ovitraps with larval water were significantly greater than those with 3-meth-

FIG. 2. Oviposition responses of gravid *Ae. albopictus* and *Ae. aegypti* to concentrations of synthetic chemical compounds. Data are presented as means (±SE) of oviposition activity indices (OAI) from 20 to 30 replicates. Positive OAI values indicated attractiveness and negative values repellency. *Significantly different at $P < 0.05$; **Significantly different at $P < 0.001$.

TABLE 2. RESPONSES OF GRAVID *Ae. albopictus* AND *Ae. aegypti* FEMALES TO FIELD WATER, LARVAL WATER AND HAY INFUSION (50%) COMPARED TO WELL WATER IN DUAL-PORT OLFACTOMETER

	% responding[a]	
	Ae. albopictus	*Ae. aegypti*
Field water	83.9 ± 6.3**	63.8 ± 8.7*
Well water	17.0 ± 6.2	35.9 ± 8.6
Laval water	74.5 ± 6.6**	54.5 ± 5.9
Well water	18.2 ± 5.1	40.2 ± 6.4
Hay infusion	69.4 ± 8.7*	59.9 ± 5.5
Well water	30.5 ± 9.2	40.1 ± 5.5

[a]Mean ± SE of 10 replicates of 50 mosquitoes. Paired comparisons of means of well water and paired treatment significantly different by ANOVA and *F* statistics, $*P < 0.05$, $**P < 0.001$.

ylindole. No differences were present in ovipositional response between well water, hay infusion, larval water, and field water, or between well water, hay infusion, 3-methylindole, and field water.

Oviposition responses of *Ae. albopictus* in experiment 2 differed significantly between treatments (ANOVA; $F = 5.04$, $df = 3, 56$; $P < 0.01$) (Table 1). Ovipositional responses to well water, 3-methylindole, and the mixture of compounds were similar and significantly lower than to hay infusion. Ovipositional responses of *Ae. aegypti* also differed significantly between treatments (ANOVA, $F = 4.79$, $df = 3, 36$; $P < 0.05$). Ovipositional responses to well water and 3-methylindole were similar. Responses to hay infusion and the mixture of synthetic compounds were significantly greater than to well water, but not significantly different from 3-methylindole.

Significantly more gravid *Ae. albopictus* and *Ae. aegypti* were collected in the olfactometer port containing field water than in the one containing well water (Table 2). The preference for field water over well water appeared stronger for *Ae. albopictus* (4.9-fold increase) than for *Ae. aegypti* (1.8-fold increase). Significantly more gravid *Ae. albopictus* were collected in the ports with larval water and hay infusion than in the ports with well water. Gravid *Ae. aegypti*, however, were collected equally in olfactometer ports with well water and either of these solutions.

DISCUSSION

Organic infusions such as hay infusion, larval rearing water, and field water clearly elicited strong oviposition responses from gravid *Ae. albopictus*, whereas

oviposition by *Ae. aegypti* was moderate to larval rearing water and field water and low in response to hay infusion even over a wide range of concentrations. These results are in agreement with previous reports that gravid *Ae. albopictus* oviposit readily in grass or hay infusions (Gubler, 1971; Hein, 1976; Holck et al., 1988) and in water containing immatures (Gubler, 1971). Our data support previous reports of the low response of gravid *Ae. aegypti* to grass or hay infusions (Hazard et al., 1967; Holck et al., 1988; Chadee, 1993), and the lack of orientation of gravid *Ae. aegypti* to hay infusion in an olfactometer is consistent with previous reports (Hazard et al., 1967). In contrast, Reiter et al. (1991) reported enhanced oviposition by *Ae. aegypti* in ovitraps with hay infusion. Responses of both species to organic infusions were lower than those reported for *Cx. quinquefasciatus* (Millar et al. 1992), and this may reflect that these *Aedes* species characteristically deposit eggs from a single gonotrophic cycle in several sites and that both species readily oviposit in clean water (Gubler, 1971; Holck et al., 1988). Organic infusions such as those tested in our study consist of complex mixtures of compounds that vary over time. At least some of the oviposition attractants from such organic infusions are products of bacterial degradation (Hazard et al., 1967; Ikeshoji et al., 1979; Benzon and Apperson, 1988). Larval water and field water, both of which contained mosquito larvae, elicited more oviposition by both *Aedes* species than hay infusion, and the production of more volatiles by these infusions related to attraction of females and/or stimulation of oviposition could possibly be related to the presence of larvae.

Compounds isolated and identified from Bermuda grass infusions known to elicit oviposition from *Cx. quinquefasciatus* (Millar et al., 1992) clearly play a lesser role in mediation of oviposition for both *Ae. albopictus* and *Ae. aegypti*. In *Cx. quinquefasciatus*, a species generally associated with polluted water, oviposition responses to 3-methylindole were strong across the entire range of concentrations tested (0.01–100 μg/liter), with up to 3.5× more egg rafts deposited in treatment cups compared to control cups (Millar et al., 1992). In our study, oviposition responses of female *Ae. albopictus* were significantly greater than to well water at only one concentration of 3-methylindole (0.1 μg/liter) and one of 4-methylphenol (0.01 μg/liter). Gravid *Ae. aegypti* did not appear to differentiate between well water and 3-methylindole at any dose for selection of oviposition sites. Millar et al. (1992) also reported moderate oviposition responses by gravid *Cx. quinquefasciatus* to one concentration of 4-ethylphenol (10 μg/liter) and two concentrations of indole (10 and 100 μg/liter). However, the latter responses were possibly due to trace amounts of 3-methylindole present. In contrast, 3-methylindole did not increase oviposition by either *Ae. albopictus* or *Ae. aegypti*. *Ae. aegypti* also exhibited a moderate increase in oviposition to 4-ethylphenol and phenol, but only at one of the concentrations tested. Exposure of gravid females to several concentrations of the synthetic compounds and organic infusions clearly resulted in lower oviposition responses than to well

water controls. These decreased responses may reflect repellency at these concentrations. The presence of the compounds identified by Millar et al. (1992) in concentrations found in this study to elicit low oviposition responses may contribute to the apparent repellent/deterrent effects to these species. Results from the field cage and olfactometer studies clearly indicate that larval water and field water contain attractants and/or stimulants for gravid females of both *Aedes* species. More studies are needed to isolate and identify compounds from these sources and to evaluate the behavioral roles of these compounds.

Compounds of infusions that attract gravid *Ae. albopictus* and *Ae. aegypti* females to potential oviposition sites have considerable potential for both increasing the sensitivity for monitoring populations of these species and for the potential delivery of pathogens or pesticides into larval populations (Schlein and Pener, 1990; Itoh et al., 1994). Surveillance of *Ae. albopictus* and *Ae. aegypti* is difficult, as adults are not readily attracted to light traps (Service, 1977; Hawley, 1988) and larval sampling is time-consuming. Ovitraps are often used for population monitoring and surveillance (Chadee et al., 1988; McHugh and Hanny, 1990), and the use of oviposition attractants/stimulants to increase the sensitivity of these traps as well as gravid female traps (Reiter, 1983; Freier and Francy, 1991) has considerable potential. Of particular importance for this application are infusions or compounds that both elicit long-range orientation of gravid females to potential oviposition sites and stimulate oviposition once at the oviposition site. The use of infusions such as hay infusions in conjunction with ovitraps or gravid females traps may, however, bias trap collections towards *Ae. albopictus*, as our results indicated a greater attraction of *Ae. albopictus* than *Ae. aegypti* to hay infusion. This is currently being examined under field conditions.

(Received February 28, 1995; accepted July 12, 1995)

Abstract—Volatile chemicals from tryptic soy broth cultures of *Staphylococcus aureus* that attract sugar-fed, protein-hungry adult Mexican fruit flies were identified. Chemicals identified from the headspace above the filtrate of the bacterial cultures were ammonia, trimethylamine, isoamylamine, 2-methylbutylamine, 2,5-dimethylpyrazine, and acetic acid. Each chemical attracted flies. A mixture of the chemicals in the same concentrations as were found in the bacterial filtrate was 89% as effective in attracting flies as the bacterial filtrate in laboratory bioassays. Additional chemicals were identified from various concentrated or pH altered preparations made from the filtrate. Many of these chemicals also attracted flies. One of these chemicals, dimethylamine, was the most effective chemical identified. The use of solid-phase microextraction for volatile collection and of thick-film (5-μm) capillary GC columns was essential to the success of this work.

Key Words—Attractants, Mexican fruit fly, Diptera, Tephritidae, *Anastrepha ludens*, bacteria, amines, solid-phase microextraction.

INTRODUCTION

Associations of bacteria with fruit flies have been known for nearly a century (Petri, 1910) but remain little understood to this day. Popular views during the first half of this century were that bacteria and fruit flies engaged in obligate symbioses (Stammer, 1929; Hellmuth, 1956; Boush and Matsumura, 1967; Miyazaki et al., 1968). Later studies suggested that bacteria serve as a protein

source for fruit flies (Drew and Lloyd, 1989; Robacker and Moreno, 1995). Neither of these views is entirely satisfactory nor entirely disproven, and the possibility of other explanations must also be acknowledged. Whatever the explanation, associations of bacteria with fruit flies seem nearly ubiquitous. As examples, Stammer (1929) isolated bacteria from 37 species of fruit flies and Hellmuth (1956) from 43 species. Fitt and O'Brien (1985) isolated at least 20 species of bacteria from four *Dacus* species, and Martinez et al. (1994) isolated at least 11 species of bacteria from *A. ludens* alone.

Some understanding of the nature of fruit fly–bacteria associations has been gained by studies showing that bacteria or their metabolic products attract fruit flies in many cases. Several studies have shown that inoculation of protein baits with bacteria increased the attractiveness of the baits (Gow, 1954; Bateman and Morton, 1981; Drew and Fay, 1988). Others have shown that bacteria or their cultures alone, or combined with fruit volatiles, make good trap baits (MacCollom et al., 1992; 1994; Martinez et al., 1994) or attract fruit flies in laboratory bioassays (Jang and Nishijima, 1990; Robacker et al., 1991; MacCollom et al., 1992).

Papers in which attractants from bacterial preparations have been assessed generally reported little progress beyond identification and evaluation of ammonia (Gow, 1954; Drew and Fay, 1988). Most who have worked with bacterial attractants agree that additional chemicals probably are involved. Drew (1987) tested several components of bacterial odor and demonstrated that one of these, 2-butanone, was significantly more attractive to *Bactrocera tryoni* Froggatt than cuelure, the standard attractant for this fly. The attractiveness of this chemical was attributed to its structural similarity to cuelure rather than any bacteria–fruit fly relationship. Two other components, butanol and isopentanol, were not attractive.

Recent work by Robacker et al. (1993) showed that standard insect attractant volatile collection methods were unsuitable for collecting attractive compounds from a highly attractive bacterial fermentation. Specifically, volatile collections of bacterial odors on adsorbents typically used in insect attractant research such as Porapak Q, Tenax, and Super Q were not attractive to Mexican fruit flies. The work also demonstrated that the attractants were water soluble and could not be partitioned into organic solvents by solvent–solvent extraction. The conclusion of the work was that the most attractive chemicals probably were low-molecular-weight amines or other compounds containing ionizable nitrogen. It also appeared that some attractants did not have properties of amines and possibly were carboxylic acids or other water-soluble organic molecules. These findings may help explain the lack of progress in identification of bacteria-produced chemicals attractive to fruit flies since most reported studies used standard volatile collection methods.

The current reseach is a continuation of the work reported by Robacker et al. (1993) to identify the volatile chemicals produced by tryptic soy broth cultures of *Staphylococcus aureus* (strain RGM-1) originally isolated from the mouthparts of a laboratory-colony, adult Mexican fruit fly (Robacker et al., 1991). Solid-phase microextraction technology developed especially for analysis of trace organics in aqueous solution (Belardi and Pawliszyn, 1989; Zhang and Pawliszyn, 1993) was used to collect volatiles from the headspace above the filtrate of RGM-1 cultures and various concentrated or pH-altered preparations made from the filtrate. Trapped chemicals were identified and tested for attractiveness to Mexican fruit flies.

METHODS AND MATERIALS

Insects and Test Conditions. Flies used to test attractiveness of bacterial preparations and chemicals identified from the preparations were from a culture that had been maintained on laboratory diet for about 400 generations with no wild-fly introductions. Mixed-sex groups of 180–200 flies were kept in 473-ml cardboard cartons with screen tops until used in tests. Flies were tested when 5–12 days old. Flies were deprived of protein as adults but were fed sucrose and water up until the time of attractiveness testing. Recent tests have shown that protein-deprived flies are maximally attracted to bacterial odor when 5–7 days old and remain highly responsive through 15 days of age (Robacker and Garcia, 1993). All tests were conducted in the laboratory between 08:30 and 15:30 hr under a combination of fluorescent and natural light. Laboratory conditions were 22 ± 2°C, 50 ± 20% relative humidity, and photophase from 06:30 to 19:30 hr.

Bacterial Preparations. S. aureus strain RGM-1 (Robacker et al., 1991) was grown in tryptic soy broth (Difco Laboratories, Detroit, Michigan) in a shaker for 144 hr at 30°C. Bacterial culture was centrifuged at 10,000 rpm for 20 min and separated into pellet and supernatant. The pellet was discarded because previous experiments indicated that the pellet, which contained most of the bacterial cells, was less attractive than tryptic soy broth (Robacker et al., 1993). Supernatant was filtered through 0.45-μm type HA aqueous filters (Millipore Corporation, Bedford, Massachusetts) followed by 0.22-μm type GV aqueous/organic filters (Millipore). Filtration was conducted to remove remaining bacterial cells. Robacker et al. (1993) demonstrated that the attractants were dissolved in the filtrate.

RGM-1 filtrate was concentrated and otherwise manipulated to enhance collection and identification of volatiles. RGM-1 concentrate was prepared by lowering pH of filtrate to 4.0 with 10 N HCl and concentrating it 12-fold by

rotary evaporation (Rotavapor RE-111, Buchi-Brinkman Instruments, Inc., Westbury, New York). The evaporation was aided by heating the filtrate while pulling a vacuum on the system. RGM-1 salt was prepared as described previously (Robacker et al., 1993), with a few differences. Briefly, RGM-1 filtrate was put into a two-neck 500-ml flask and heated gently while steam was used to sweep the headspace from the flask into a water-cooled condenser. Steam was generated from vigorous boiling of Milli-Q (Millipore)-grade water in a second two-neck 500-ml flask. The procedure was carried out until 400 ml of steam distillate was collected per 100 ml of original RGM-1 filtrate. The pH of the steam distillate was lowered to 4.0 with HCl, and the water was removed by rotary evaporation as described for the RGM-1 concentrate. The resulting dry powder was termed RGM-1 salt.

Volatile Collections and Chemical Identifications. Chemicals in the headspace above RGM-1 filtrate, RGM-1 filtrate adjusted to pH 11 with aqueous NaOH, RGM-1 concentrate at pH 4 and also pH 11 after adjustment with NaOH, and RGM-1 salt partially dissolved in a few drops of saturated aqueous NaOH were collected and identified. Volatiles were collected by solid-phase microextraction (SPME) with a 100-μm polydimethylsiloxane-coated fiber (Supelco, Inc., Bellefonte, Pennsylvania). The fiber was inserted through a septum into the headspace above 1 ml of bacterial preparation in a 4-ml vial for 5 min to 24 hr. Sampling time varied inversely with the concentration of chemicals in the preparation.

Volatiles also were collected on ORBO 52 silica gel tubes (Supelco) connected to an outlet port in the volatile collection apparatus developed by Heath and Manukian (1992). One half milliliter of saturated NaOH was added to 0.5 ml of RGM-1 concentrate in a 4-ml glass vial to produce free amines. The vial was mounted inside the apparatus such that the inlet end of the silica tube was inside the lip of the vial. Air was pulled through the system for 17 hr at 0.5 liters/min. The silica gel was removed from the tube and extracted by sonication in a 4-ml glass vial with 0.5 ml of methanol for 0.5 hr followed by a rinse with a second 0.5 ml of methanol. The two methanol aliquots were combined and filtered through 0.45-μm type HV syringe filters (Millipore).

GC analyses were conducted on DB-1 and DB-5 fused-silica capillary columns (J & W Scientific, Folsom, California). The DB-1 column (60 m, 0.32 mm ID, 5 μm film) was used for most analyses because it appreciably retained but did not irreversibly adsorb nanogram-level quantities of ammonia and C_1 to C_5 aliphatic amines, providing baseline resolution of most of these compounds. The DB-5 column (30 m, 0.53 mm ID, 5 μm film) was used to separate a few amines that coeluted on the DB-1 column and to confirm identifications that were based on retention time matching to standards on the DB-1 column. Preliminary work with films of less than 5 μm demonstrated that the thick films (5 μm) were responsible both for the lack of irreversible adsorption and appreciable

retentions of the chemicals discussed above and also improved peak symmetry allowing for better resolution of components with similar retention times.

GC analyses were conducted with a Shimadzu GC-9A (Shimadzu Scientific Instruments, Inc. Columbia, Maryland) with flame ionization and flame thermionic (model FTD-9) detectors. The FTD was used to establish the presence of C—N bonds and thus confirm characterization of many of the bacteria volatiles as amines, to provide highly sensitive detection of trace quantities of several of the compounds and to calculate FID/FTD response ratios of unknowns for comparison with ratios of standards as another identification method.

Volatiles were thermally desorbed from the SPME fiber in the split/splitless injection port at 210°C. Splitless injection was conducted with the splitter closed 0.5 min. Analyses were at 100°C. ORBO 52 extracts were concentrated 10-fold under nitrogen assisted by low heating. Splitless injection was also used for 1 μl samples of the concentrated ORBO 52 extracts. Analyses of ORBO 52 extracts were conducted with an initial temperature at 100°C for 5 min then 4°C/min to 210°C. For all analyses, carrier gas was helium at a linear velocity of 20 cm/sec.

GC-MS analyses were conducted with a Finnigan MAT 4500 GC-MS data system (Finnigan MAT, San Jose, California) operated in the electron-impact ionization mode (emission current = −0.30 mA, electron energy = 70 eV, multiplier voltage = −1150 V). Mass spectral data were acquired over a mass range of 33–350 amu, using a 1-sec scan rate. Volatile injection was the same as described above except the injector temperature was 220°C and the SPME fiber was exposed in the injector for 2 sec. The column-oven temperature was programmed from 50 to 200°C at 4°/min. Carrier gas was helium at 28 cm/sec.

Cage-Top Bioassays. Various RGM-1 preparations and chemicals identified from the preparations were tested for attractiveness using cage-top bioassays. Tests of bacterial preparations were conducted because volatiles were identified from many of these preparations, and we wanted to compare attractiveness of preparations based on similarity of their volatiles.

Bioassays were conducted by placing four filter paper triangles (3 cm/side), two containing test samples and two containing appropriate controls, near the corners on the top of an insect cage (30 cm/side, aluminum-screened). The numbers of flies beneath each filter paper were counted once each minute for 10 min. The two papers containing test chemical were positioned diagonally from each other on two corners of the cage top, and the two papers containing controls were positioned diagonally from each other on the other two corners. The filter papers were raised 5 mm above the cage top using plastic rings to ensure that olfaction and not contact chemoreception was solely responsible for the response of the flies. One carton of 180–200 flies was used in each bioassay cage.

For bioassays of RGM-1 preparations, 10-μl test quantities were put on two papers and 10 μl of water were put on two papers as controls. The ORBO 52 collections were bioassayed similarly except methanol was used as the control. Ten replications were conducted for each RGM-1 preparation and for the ORBO 52 collection.

Chemicals identified from various RGM-1 preparations were obtained (Table 1) and dissolved in water or methanol for attractiveness testing. Chemicals dissolved in water were: dimethylamine HCl; trimethylamine HCl; ethylamine; propylamine; isopropylamine; isobutylamine; isoamylamine; 2-ethyl-5-methylpyrazine; and acetic acid. One drop of saturated NaOH was added to solutions of dimethylamine HCl and trimethylamine HCl to produce free amines.

TABLE 1. CHEMICAL NAMES, SOURCES, AND PURITIES OF CHEMICALS USED AS GC STANDARDS AND/OR TESTED IN CAGE-TOP BIOASSAYS

Chemical	Source[a]	Purity (%)[b]
Ammonium bicarbonate	Sigma	99

[c] Mixture with ammonium bicarbonate and ammonium carbamate.
[d] Approximately equal mixture with 2-ethyl-6-methylpryazine.

The other chemicals were dissolved in methanol. Four concentrations of each chemical were prepared and subsequently four quantities (10 ng, 100 ng, 1 μg, and 10 μg of most chemicals; 100 ng, 1 μg, 10 μg, 100 μg of amides) of each chemical were tested, each in 10 μl of solution. The control for each chemical was 10 μl of water or methanol for chemicals dissolved in water or methanol, respectively. Ten replications were conducted for each of the four concentrations of all of the chemicals, except trimethylamine and 2,5-dimethylpryazine for which 20 replications were conducted.

Chemicals identified from headspace above RGM-1 filtrate that were attractive to flies in cage-top bioassays were mixed together in aqueous solution in the same concentrations as were found in RGM-1 filtrate. Concentrations of the chemicals in RGM-1 filtrate were determined by comparing SPME collections in headspace above known concentrations of mixtures of standards, with SPME collections in RGM-1 headspace. The pH of the standards solution was adjusted to 7.9 with aqueous NaOH to equal the pH of unaltered RGM-1 filtrate. A trial-and-error approach was used in which standards were mixed together in a vial in various concentrations that were adjusted until FID peak heights on the DB-1 column matched those obtained from a vial containing RGM-1 filtrate. Concentrations in the final synthetic mixture that matched RGM-1 were: ammonium carbonate, 2.0 mg/ml; trimethylamine HCl, 4.0 μg/ml; isoamylamine, 1.6 μg/ml; 2-methylbutylamine, 0.3 μg/ml; 2,5-dimethylpyrazine, 5.0 μg/ml; and acetic acid, 250 μg/ml. Sources of chemicals used in the mixture are shown in Table 1. The final synthetic mixture was tested in cage-top bioassays using water as the control. Test quantities were 10 μl. Twenty-eight replications were conducted. Separate bioassays of RGM-1 filtrate ($N = 28$) were conducted concurrently using flies from the same cohort.

Statistical Analysis. Responses of flies to the various bacterial preparations were compared with each other in a randomized complete block experiment. This was done by subtracting total counts at solvent-blank papers from total counts at treatment papers to obtain differences that were then subjected to analysis of variance. Means were compared by Fisher's protected least significant difference method. Total counts of flies at filter papers containing test samples were compared to counts at solvent-blank papers by paired t tests in all experiments. Finally, responses of flies to the synthetic mixture of RGM-1 chemicals were compared with responses to RGM-1 filtrate by a t test of independent samples. Data for this test were differences between total counts at treatment and solvent-blank papers for each replication.

RESULTS AND DISCUSSION

All bacterial preparations were more attractive to flies than water in cage-top bioassays (Table 2). RGM-1 filtrate was the most attractive preparation.

TABLE 2. MEAN COUNTS OF *A. ludens* AT FILTER PAPERS CONTAINING WATER OR VARIOUS BACTERIAL PREPARATIONS USING CAGE-TOP BIOASSAYS

	Preparation[a]	Water
RGM-1 filtrate	141.7 a	14.3
RGM-1 filtrate pH 11	108.2 b	14.5
RGM-1 concentrate pH 4	29.9 c	18.5
RGM-1 concentrate pH 11	99.2 b	17.4
RGM-1 salt pH 11	113.5 b	17.1
ORBO 52 volatiles collection	36.4 c	20.1

[a] Mean responses to all bacterial preparations were significantly greater than responses to water by paired *t*-tests ($P < 0.05$); mean responses to bacterial preparations followed by the same letter were not significantly different from each other by LSD ($P < 0.05$).

Most of the results in Table 2 are similar to findings reported in Robacker et al. (1993). One preparation not tested by Robacker et al. (1993) was the ORBO 52 volatile collection. Here we show that at least some of the material responsible for attractiveness can be trapped on ORBO 52 silica gel tubes, although the attractiveness was low compared with that of RGM-1 filtrate. Robacker et al. (1993) reported that attractants evolving from concentrated RGM-1 filtrate could not be trapped on Porapak Q, Super Q, or Tenax GC.

Chemicals identified from headspace of RGM-1 filtrate at pH 7.9 (unaltered) are shown in Table 3. Calculated concentrations (mean ± SE; $N = 3$) in RGM-1 filtrate were: ammonia, 710 ± 41 μg/ml; trimethylamine, 2.5 ± 0.1 μg/ml; isoamylamine, 1.6 ± 0.7 μg/ml; 2-methylbutylamine, 0.3 ± 0.05 μg/ml; 2,5-dimethylpyrazine, 5.0 ± 0.1 μg/ml; and acetic acid, 250 ± 84 μg/ml.

All six chemicals found in the headspace above the RGM-1 filtrate attracted Mexican fruit flies. Data for trimethylamine, isoamylamine, 2-methylbutylamine, 2,5-dimethylpyrazine, and acetic acid are shown in Table 4. Ammonia was tested previously, and the data were reported in Robacker and Warfield (1993). Like most of the chemicals, ammonia was most attractive at the higher concentrations. Ammonia, isoamylamine, 2-methylbutylamine, and acetic acid appear to be nearly equally attractive according to ratios of counts at chemicals (10 μg test quantities) to counts at water. Trimethylamine and 2,5-dimethylpyrazine were much less attractive than the others. Trimethylamine was unusual in that it was attractive only at the lower concentrations.

The synthetic mixture of the chemicals found in RGM-1 filtrate was much more attractive than water but significantly less attractive than RGM-1 filtrate (Table 5). Nevertheless, the response to the synthetic mixture was 89% as high as the response to RGM-1 filtrate, indicating that the synthetic mixture was a fairly good match to the RGM-1 filtrate. Reasons for the slightly lower response

TABLE 3. CHEMICALS IDENTIFIED FROM VARIOUS BACTERIAL PREPARATIONS

	Chemicals Identified and Methods of Identification[a]
RGM-1 filtrate (pH not altered from 7.9)	ammonia, 2-methylbutylamine by DB-1 RT, FID/FTD ratios; trimethylamine, isoamylamine, 2,5-dimethylpyrazine, acetic acid by MS, DB-1 RT, FID/FTD ratios
RGM-1 filtrate (pH 11)	ammonia, trimethylamine, isoamylamine, 2-methylbutylamine by DB-1 RT, FTD detection; 2,5-dimethylpyrazine, 2-ethyl-5-methylpyrazine by MS
RGM-1 concentrate (pH 4)	acetic acid by MS
RGM-1 concentrate (pH 11)	ammonia, 2-methylbutylamine by DB-1 RT, FTD detection; trimethylamine, isoamylamine by MS, DB-1 RT, FTD detection; acetic acid, methyl disulfide by MS
RGM-1 salt (NaOH added)	ammonia, methylamine, dimethylamine, trimethylamine ethylamine, diethylamine, propylamine, isopropylamine, butylamine, isobutylamine, *sec*-butylamine, *tert*-butylamine, isoamylamine, 2-methylbutylamine by both DB-1 and DB-5 RT, FID/FTD ratios
ORBO 52	acetamide, propionamide, 2-methylpropionamide, 3-methylbutyramide by MS

[a] MS = mass spectrometry using DB-1 column; RT = retention time comparison with standards on DB-1 and/or DB-5 columns; FID/FTD ratios = comparison of response by flame ionization vs flame thermionic detectors

to the synthetic mixture are unknown. Possible reasons are: (1) one or more attractants in RGM-1 filtrate was not identified and consequently left out of the synthetic mixture; (2) contaminants in the synthetic mixture from the commercially obtained chemicals were repellent; and/or (3) concentrations of chemicals in the synthetic mixture were not identical to concentrations in RGM-1 filtrate.

The synthetic mixture did not have the same odor as RGM-1 filtrate, as judged by human olfaction. The Porapak Q and similar volatile collections tested in earlier work (Robacker et al., 1993) smelled very similar to RGM-1 filtrate. Nevertheless, the Porapak Q volatile collections did not attract Mexican fruit flies, whereas the synthetic mixture used in the present study was highly attractive.

Chemicals identified from RGM-1 filtrate adjusted to pH 11 were ammonia, trimethylamine, isoamylamine, 2-methylbutylamine, 2,5-dimethylpyrazine, and 2-ethyl-5-methylpyrazine (Table 3). Only acetic acid was identified from RGM-1 concentrate at pH 4. No other carboxylic acids were detected. Chemicals identified from RGM-1 concentrate adjusted to pH 11 were ammonia, trimethylamine, isoamylamine, 2-methylbutylamine, acetic acid, and methyl disulfide.

TABLE 5. MEAN COUNTS (±SE) OF *A. ludens* AT FILTER PAPERS CONTAINING SYNTHETIC MIXTURE OF CHEMICALS IDENTIFIED FROM RGM-1 HEADSPACE COMPARED WITH COUNTS AT PAPERS CONTAINING RGM-1 FILTRATE OR WATER USING CAGE-TOP BIOASSAYS

	Test preparation	Water
Synthetic mixture	135.9 ± 4.8[a]	20.5 ± 1.2
RGM-1 filtrate	152.9 ± 5.5	19.7 ± 1.2

[a] The mean response to the synthetic mixture was significantly greater than the response to water by a paired t test ($P < 0.01$), and significantly lower than the response to RGM-1 filtrate by a t test ($P < 0.05$)

Neither 2-ethyl-5-methylpyrazine nor methyl disulfide was attractive to flies (Table 4). 2-Ethyl-5-methylpyrazine was slightly repellent at the two highest test quantities. Methyl disulfide previously was identified from volatiles of the bacterium *Proteus* by Hayward et al. (1977), but it had not been tested as a fruit fly attractant.

Many additional chemicals were identified from the headspace above the RGM-1 salt partially dissolved in NaOH (Table 3). All of the chemicals were attractive to flies, mostly at the higher test quantities (Table 4). Dimethylamine was the most attractive chemical identified from any of the bacterial preparations according to ratios of counts at chemicals to counts at water. Attractiveness of methylamine was about equal to ammonia in experiments reported previously (Robacker and Warfield, 1993).

The only chemicals identified from ORBO 52 collections were acetamide, propionamide, 2-methylpropionamide, and 3-methylbutyramide (Table 3). Of the three that were tested, none attracted the flies (Table 6). These chemicals

[a] 3-Methylbutyramide also was identified from ORBO 52 collection, but was not available for testing. None of the chemicals were more attractive than blanks.

were tested at higher concentrations than the others because of their lower volatilities. Other chemicals that may have been present in the ORBO 52 extract and which may have accounted for its attractiveness (Table 2) probably were lost when it was concentrated for GC-MS analysis.

Not all of the chemicals in the various preparations were identified. The emphasis of the investigation was to identify chemicals that were water soluble and contained ionizable nitrogen, because chemical characterization studies had indicated that the chemicals most attractive to *A. ludens* fit this profile (Robacker et al., 1993). Most of the unidentified chemicals were minor components. However, some relatively large FID peaks present in the headspace of the RGM-1 salt were not identified because they were not detectable by FTD. One exception was a major unidentified peak in the headspace of the RGM-1 salt that produced a large FTD/FID ratio, indicating that it contained C-N. This peak had a retention time that matched that of 1,2-dimethypropylamine on the DB-1 column but not on the DB-5 column.

Another important point is that some of the chemicals identified in this study may have been artifacts of the harsh procedures used to concentrate the volatiles. The strong acids and bases used to manipulate pH may have catalyzed various hydrolyses and condensations involving water, alcohols, carboxylic acids, amines, etc., present in the original solution. Furthermore, headspace sweeping with steam was assisted with heating, and no attempt was made to remove oxygen from the system. Thus, numerous products not originally present in the RGM-1 filtrate may have formed. This probably occured the most in the RGM-1 salt, the product that was produced using the most rigorous treatment. Interestingly, all of the chemicals identified from RGM-1 salt headspace were attractive to the flies. Perhaps many of these same chemicals also form in natural fermentations where heat, water, and oxygen are also present.

The chemicals identified from the headspace of unaltered RGM-1 filtrate are considered natural products of bacterial metabolism of the tryptic soy broth. Therefore, only these chemicals were quantified and used to construct a synthetic mixture to mimic bacterial odor. The other bacterial preparations were not reproduced for attractiveness testing because they may have contained chemicals that were not present in the original culture. Quite possibly, many of the same chemicals identified in the various other preparations, including RGM-1 salt, may have been present in the RGM-1 filtrate but at concentrations too low to detect by our methods.

This is the first investigation to identify volatile chemicals produced by a bacterial culture attractive to an insect species, test the attractiveness of the chemicals to the insect, construct a mixture of the chemicals at the same concentrations as found in the bacterial preparation, and test the attractiveness of the mixture relative to the attractiveness of the bacterial preparation. As it has been shown that preparations made from bacterial fermentations can be highly

attractive to fruit flies in the field (Martinez et al., 1994), it is hoped that results of this work can contribute to development of better attractants for the Mexican fruit fly and perhaps other species of Tephritidae. However, it should be noted that the study was not entirely successful, as the synthetic mixture was only 89% as attractive as the bacterial filtrate.

(Received March 21, 1995; accepted July 13, 1995)

Abstract—Extracellular recordings show that the response to the sex pheromone component, (*Z*)-7-dodecenyl acetate (*Z*7-12:Ac) by the HS(a) antennal olfactory specialist neuron of the cabbage looper, *Trichoplusia ni* (Hübner), is synergized by two synthetic sex pheromone analogs and two components of the female sex pheromone. Complementary behavioral measures of upwind flight and copulatory responses to mixtures of *Z*7-12:Ac with the analogs and sex pheromone components in a wind tunnel produced behavioral evidence consistent with the neuron's electrophysiological responses. The phenomenon of receptor neuron synergism impacts several areas and provides a note of caution for common practices of identifying secondary sex pheromone components only from field traps and/or wind tunnel tests.

Key Words—Cabbage looper, electrophysiology, antenna, single cell responses, behavior.

INTRODUCTION

Chemical components of female moth sex signals are detected by olfactory receptor neurons housed within characteristic, often sexually dimorphic, sensilla located on the antenna. These receptor neurons are specialized to detect low, physiologically relevant, airborne concentrations of primarily one of the compounds that comprise the female signal. At elevated stimulus concentrations, however, even one of the most highly specialized neurons, the bombykol spe-

cialist of *Bombyx mori* (L.), will respond to other compounds (Priesner, 1969). This is typical also of the HS(a) specialist of the cabbage looper moth, *Trichoplusia ni* (Hübner), which detects the behaviorally most important component of its female chemical signal, (*Z*)-7-dodecenyl acetate (*Z*7–12:Ac) (Mayer, 1993). As a consequence of this type of stimulus-strength-dependent specificity, it seems reasonable that the admixture of a sex pheromone component with a less active compound would elicit an additive response if both compounds are present at concentrations exceeding their individual thresholds.

There are no reports of specialist neuron responses to mixtures of pheromone components or a particular component with other compounds at high stimulus intensities. At physiologically relevant airborne concentrations, Mayer (1993) showed that mixtures of pheromone components did not modify the response of the HS(a) specialist to *Z*7–12:Ac, but he did not assay these or other compounds at elevated stimulus intensities. What we examine in this report, inter alia, is whether or not a binary mixture stimulus, in which one of the components is *Z*7–12:Ac, will elicit a mixed response from the HS(a) specialist neuron.

This examination was prompted by our interest in the report of Burger et al. (1990) that 7-vinyldecyl acetate (7-VD) reduced trap captures of male false codling moths, *Cryptophlebia leucotreta* (Meyrick), when incorporated into an otherwise effective sex pheromone bait. Comparison of the structure (Figure 1) of one of the two false codling moth sex pheromone components, (*Z*)-8-dodecenyl acetate (*Z*8–12:Ac), with 7-VD shows that the length of the carbon chain between the double bond and the acetate function is the same in both molecules. In addition, the length of the carbon chain beyond the point of attachment of the double bond and the overall molecular size is the same. With these parameters in mind, we undertook the synthesis and behavioral and neurophysiological evaluation of molecules that would have a similar relationship to *Z*7–12:Ac and, therefore, might be expected to stimulate the HS(a) neuron. We chose 6-vinyldecyl acetate (6-VD, Figure 1) and 10-vinyltetradecyl acetate (10-VT, Figure 1) as candidates. In the case of 6-VD, the relationship to *Z*7–12:Ac is analogous to the relationship between 7-VD and *Z*8–12:Ac of the false codling moth. Indeed, one can make the reasonable claim that because the vinyl group has no stereochemical restrictions, 7-VD can be spatially compared with the other false codling moth sex pheromone component, (*E*)-8-dodecenyl acetate (*E*8–12:Ac), as well. Inclusion of 10-VT in the study enabled the evaluation of the combined effect on the HS(a) neuron of *Z*7–12:Ac and a molecule that had a longer carbon chain between the acetate function and the double bond than *Z*7–12:Ac but retained the same four-carbon chain on the other side of the double bond. We tested 6-VD and 10-VT alone and in binary mixtures with *Z*7–12:Ac and found that these mixtures synergized both the response of the HS(a) neuron and upwind flight responses in a wind tunnel.

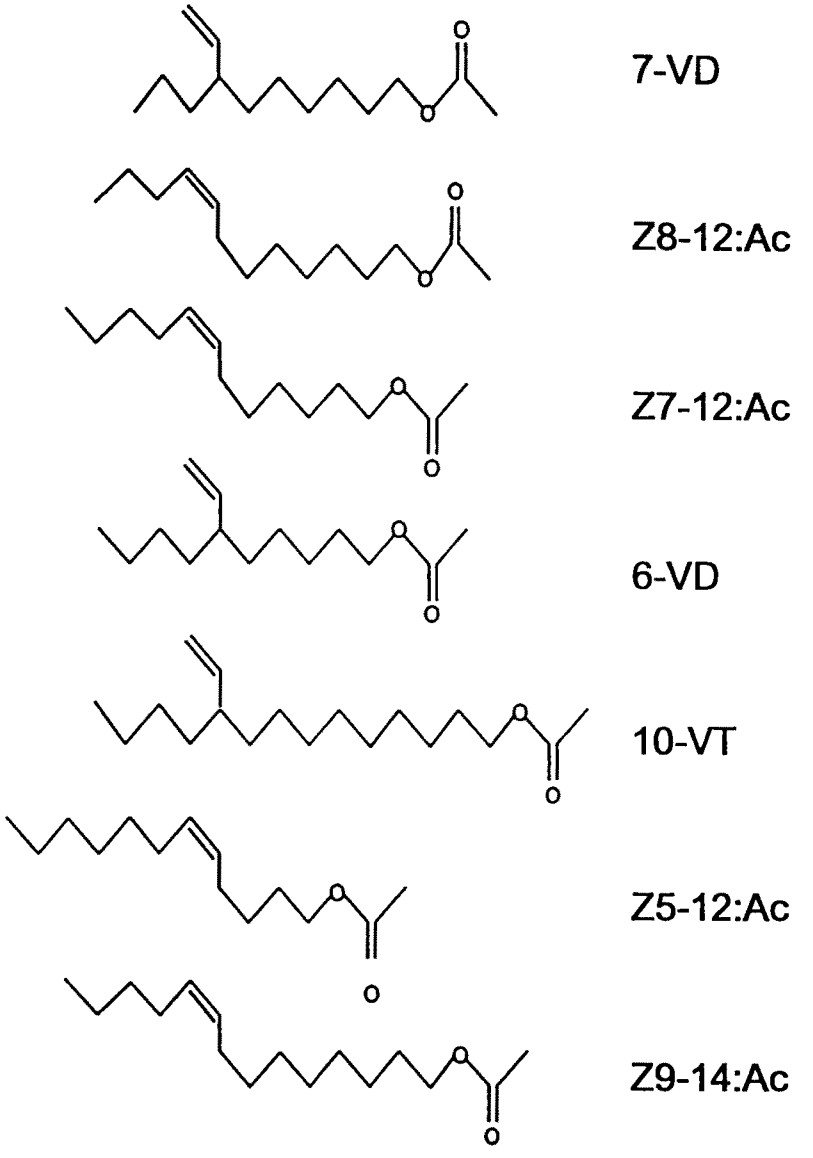

FIG. 1. Chemical structures of the compounds discussed in the text and/or used as odor stimuli in the electrophysiological and behavioral experiments: 7-vinyldecyl acetate, 7-VD; (Z)-8-dodecenyl acetate, Z8-12:Ac; (Z)-7-dodecenyl acetate, Z7-12:Ac; 6-vinyldecyl acetate, 6-VD; 10-vinyltetradecyl acetate, 10-VT; (Z)-5-dodecenyl acetate, Z5-12:Ac; and (Z)-9-tetradecenyl acetate, Z9-14:Ac.

Until now, however, synergism has not been observed in moth sex pheromone specialist neurons. Synergism, in the sense that we use it for these studies, is the resultant response of the specialist neuron to the cooperative action of two or more discrete chemicals that is greater than the sum of the responses to the individual compounds. From this juncture, we gave thought to the possibility that synergism might be the means by which female volatile emission components that lack specialists are able to influence behavior.

Two components that are considered to be part of the female sex signal were chosen for assay for the following reasons. One component, Z9–14 : Ac (Figure 1), has been shown to be detected by a specialist neuron (Mayer and Mankin, 1990), although its effect on behavior is marginal (Linn et al., 1984; Mayer and McLaughlin, 1991, 1993). The other component, Z5–12 : Ac (Figure 1), was chosen because no specialist yet has been observed for its detection, but some preliminary assays in our wind tunnel at high stimulus intensities showed that it elicited some upwind flight behavior. Both of the compounds were examined alone and mixed with Z7–12 : Ac. The mixtures synergized both the neural response and upwind flight responses in a wind tunnel. One component, Z5–12 : Ac, synergized the response at near physiological airborne concentration levels, but Z9–14 : Ac did not. The implications of these results are discussed with respect to pheromone component identification, the effect of synergism on some aspects of behavior, and briefly, the potential use of synergists in field applications.

METHODS AND MATERIALS

Insects. The moths were reared on a semisynthetic medium described in Guy et al. (1985). Males and females were separated during the pupal stage. After emergence, 40–60 males were maintained in 25 × 25 × 25-cm Plexiglas and fiberglass screen cages until assayed at 3–4 days of age. Two to four small plastic cups filled with a nutrient solution of 10% sugar-water on cotton were provided for each cage. The cages were maintained in cabinets at 25–27°C, 70–80% relative humidity on a 14 : 10 light-dark photoperiod.

Chemicals. 6-VD and 10-VT were synthesized at this laboratory and were 98% pure by capillary column gas chromatographic (GC) analysis. Details of their synthesis will be the subject of a future report. The (*Z*)-7-dodecen-1-ol acetate (Z7–12 : Ac) was a synthetic sample purified by HPLC and silicic acid column chromatographic procedures. It contained impurities totaling less than 0.1% of (*E*)-7-dodecen-1-ol acetate (*E*7–12 : Ac) or other compounds as determined by GC analysis. The sex pheromone components were analyzed by GC and were provided by R.R. Heath of this laboratory. Z5–12 : Ac was from Aldrich Chemical Co. (Milwaukee, Wisconsin) and was greater than 96% pure;

Z9–14:Ac was from Sigma Chemical Co. (St. Louis, Missouri) and was 96% pure. Based on GC comparisons with authentic standards, none of the compounds contained significant amounts of high boiling point inclusions that could affect the emission rate.

Electrophysiology. Action potentials were recorded from HS(a) specialists within sensilla by inserting electrolytically sharpened tungsten electrodes into the base of individual antennal sensilla (O'Connell, 1975; O'Connell et al., 1983; Grant et al., 1989). The spikes were amplified by a Grass P-16 AC-coupled preamplifier and digitized, sorted, counted, verified, and stored digitally (Mankin et al., 1987).

Pheromone Dispensers. All compounds and mixtures in both electrophysiological and behavioral assays were evaporated from calibrated glass dispensers (Mayer et al., 1987; Mayer, 1993). The dispensers were connected to two different glass devices that control the stimulus duration for the electrophysiological and behavioral assays. Chemical mixtures were released from the same dispenser. Slightly different airborne concentrations result from mixtures of 12- and 14-carbon acetates because there is about a 10-fold evaporation rate difference (Mayer, 1993).

The principles of the stimulus control device have been described by Grant et al. (1989) and Mayer (1993). The stimulus control device controls the stimulus and provides a constant 1200 ml/min of air to isolate the antenna from ambient laboratory air. A dosed dispenser is constantly purged with air at 200 ml/min. A bypass vacuum valve enables the stimulus to be injected countercurrently into the isolating airflow. Thus, a measured amount of pheromone from the dispenser is injected into the isolating airflow for a final airflow dilution of 1400 ml/min. The final airborne concentration can be calculated easily from the measured pheromone emission rate and the metered air flow.

Control of the stimulus for behavioral assays is by a glass Y tube modified from that of Mayer and McLaughlin (1993) as described below. The Y tube was fitted with a glass diverter port that was fused at a point after the junction of the two female ground-glass joints and a longer nozzle. The diverter port was attached to a valve-controlled vacuum. One treated and one untreated dispenser, both purged constantly with air at 200 ml/min were inserted into the joints. During periods when the stimulus was off, the stimulus-laden air from the constantly purging dispensers was vented into the vacuum line. Upon activation of the valve, the stimulus was diverted into the center of the wind tunnel. To end the assay, the valve to the vacuum was opened, and the stimulus was vented into the vacuum. The final airflow dilution of the stimulus in this system was 400 ml/min.

Wind Tunnel. Assays were conducted in a 183-cm-long, 60-cm-ID cylindrical Plexiglas tunnel. The input air was conditioned to 21–23°C, 50–70% relative humidity by an air handling unit (American Air Filter Inc., Louisville,

Kentucky) that brought in outside air, passed it through the laboratory's primary heating and cooling coils (96,000 BTU/hr and 129,000 BTU/hr capacity, respectively), filtered the conditioned air in turn through a 90% Varicel filter and then an Astrocel 95% filter (capacity 1500 cfm), and passed the conditioned air into the tunnel. The airspeed in the tunnel was maintained at 15–20 cm/sec. The air in the tunnel was exhausted through the roof of the building.

A white background with 37-mm-wide black strips 12 cm apart lay about 10 cm below the floor of the tunnel. Fiberglass sheeting diffused the light from an array of incandescent bulbs at the ceiling, controlled by a rheostat, to illuminate the tunnel uniformly. The light intensity at the center of the tunnel was maintained at 0.3 lux. The principle of this tunnel is the same as for other tunnels described by Baker and Linn (1984) and Miller and Roelofs (1978), except that it uses air drawn from the laboratory air supply. The plume produced from a dispenser loaded with tissue papers treated with NH_4OH and HCl was "turbulent" as defined by Mafra-Neto and Cardé (1994).

Behavior. For behavioral assays individual male moths were released from a holding cage centered downwind from the stimulus source. The behaviors observed were typical of moths flying upwind to a pheromone source and were characterized by a combination of opportunistic optomotor-chemoanemotaxis and/or a program of self-steered counterturning (Baker and Haynes, 1987). The final, most distinctive, and perhaps the most definitive of sex pheromone-stimulated intrinsic behaviors released by Z7–12:Ac are those just prior to and during copulation. Typically, this behavior occurs at the stimulus source and is characterized by ventrad abdominal thrusts, extrusion of claspers, and the eversion of both the lateral and terminal abdominal hairpencils.

Relationship of Deployed Stimulus Intensities to a Female. As discussed in Mayer (1993), it is necessary to reference the stimulus intensity to that of a female to both ensure the selectivity of the HS(a) specialist and maintain the environmental relevance of the stimulus. A female's instantaneous emission of Z7–12:Ac averages about 10 ng/min (Bjostad et al., 1980). More recent time-averaged measures support an average emission rate of about 4 ng/min (Haynes and Hunt, 1990; Hunt et al., 1990; Hunt and Haynes, 1990). On a logarithmic scale such a difference is within half an order of magnitude of our estimate. Each of the other components of the sex pheromone, (Z)-5-dodecenyl acetate (Z5–12:Ac), (Z)-7-tetradecenyl acetate (Z7–14:Ac), (Z)-9-tetradecenyl acetate (Z9–14:Ac), dodecenyl acetate (12:Ac), and Δ11-dodecenyl acetate (11–12:Ac), are considered to reflect their ratios to Z7–12:Ac as determined by Bjostad et al. (1984) from time-averaged collections of airborne volatiles: 0.0935, 0.0105, 0.0046, 0.0719, and 0.0278, respectively, although some differences may exist (Haynes and Hunt, 1990; Dunkelblum and Mazor, 1994).

Thus, if 10 ng/min of Z7–12:Ac were emitted into the dispenser used for the neurophysiological experiments, the airborne concentration at the antenna

of each of these components due to dilution by 1400 cm^3/min air (200 cm^3/min from the dispenser + 1200 cm^3/min from the stimulus delivery system) would average, as follows: Z7-12:Ac, 3.2×10^{-11} M; Z5-12:Ac, 2.9×10^{-12} M; Z7-14:Ac, 2.9×10^{-13} M; Z9-14:Ac, 1.3×10^{-13} M; 12:Ac, 2.3×10^{-12} M; and Δ11-12:Ac, 8.8×10^{-13} M. Correspondingly, the airborne concentration of each of these components at the nozzle of the dispenser in the wind-tunnel experiments due to dilution by 400 cm^3/min air (200 cm^3/min from one treated and one untreated dispenser) would be: Z7-12:Ac, 1.1×10^{-10} M; Z5-12:Ac, 1.0×10^{-11} M; Z7-14:Ac, 1.0×10^{-12} M; Z9-14:Ac, 4.5×10^{-13} M; 12:Ac, 7.9×10^{-12} M; and Δ11-12:Ac, 3.1×10^{-12} M. There may be further dilution by a factor of about 8 within the plume of the wind tunnel (Mayer and McLaughlin, 1991).

Estimation of Airborne Stimulus Concentration. Details of the estimation of the airborne stimulus concentration of the odorants deployed in these studies are in Mayer et al., (1987) and Mayer (1993). In essence, the estimate of the airborne concentration of the various compounds derives from gas chromatographic, radiometric, and electrophysiological measures of the emission rate of Z7-12:Ac from the same glass dispensers used in these assays (Mayer et al., 1987). From the established Z7-12:Ac emission rate and additional gas chromatographic measures of emission rates at high dispenser dosages, Mayer (1993) estimated the airborne concentration of the other cabbage looper sex pheromone components by extrapolation. The emission rate of 6-VD was assumed to be the same as that for 14-carbon compounds. There are no measures for the emission rate of an 18-carbon compound from the dispenser used here, and consequently the emission rate for 10-VT was judged to be about 10 times less than the emission rate measured of (*Z*)-11-hexadecenal (Mayer et al., 1987).

RESULTS

The single most behaviorally active sex pheromone component, Z7-12:Ac, elicits reliable responses from the HS(a) specialist at airborne concentrations at or lower than about 2×10^{-13} M (Table 1) (Mayer, 1993). Among the eight HS(a) specialists assayed, this concentration of Z7-12:Ac elicited an average of 8.7 ± 2.6 (SEM) action potentials (=spikes)/sec. Five other HS(a) specialists in the test series responded with an average of 40.7 ± 10.9 spikes/sec to 2.1×10^{-11} M Z7-12:Ac. The same eight neurons that were exposed to Z7-12:Ac alone also responded reliably to 6-VD alone at an airborne concentration of $\sim 1 \times 10^{-10}$ M (Table 1). They did not respond reliably to 10-VT alone at either level tested.

The response of the HS(a) specialists to admixtures of Z7-12:Ac with either 6-VD or 10-VT was greater than the sum of the responses elicited by

TABLE 1. RESPONSE OF HS(a) ANTENNAL SEX PHEROMONE SPECIALIST RECEPTOR NEURONS TO INDICATED STIMULI

Airborne synergen concentration (M)[a]	Average spikes/sec HS(a) neurons[a] with airborne Z7-12:Ac concentration (M)

[a] The emission rate and airborne stimulus concentration of 6-VD is estimated from the emission of Z11-16:Al because of their similarity in molecular weight; concentration of 10-VT stimulus is estimated as 10× less than the emission of Z11-16:Al (14).

[b] Number of neurons measured.

[c] Different letters within a column indicate means that differ from the response to an untreated dispenser or 1.9×10^{-13} M Z7-12:Ac alone at the $P < 0.01$ level of significance (Student's t test).

[d] Mixtures of the synergens with 2.1×10^{-11} M Z7-12:Ac were not measured because the resultant responses were overdriven spike trains characterized by significantly decremented spikes followed by an abnormally elevated spontaneous activity.

either of the two stimuli alone, thus fulfilling the definition of synergism (Table 1; Figure 2). Moreover, the response was proportional to the $\log_{10}$ M concentration of 6-VD added to constant levels of Z7-12:Ac. The four values for 6-VD mixtures fit the regression equation, log spikes/sec = 5.6 + 0.02 (log M) ($r^2 = 0.987$; SE = 0.204; $P < 0.004$).

The HS(a) specialist neurons also respond reliably to 1.6×10^{-10} M Z9-14:Ac and 2.0×10^{-10} M Z5-12:Ac alone (Figure 3). These stimulus intensities exceed the level emitted by females, and the response was expected (Mayer, 1993). These two pheromone components also synergized the response to 2.0×10^{-13} M Z7-12:Ac (Figure 3). The stimulus levels of these two compounds necessary to synergize the response to Z7-12:Ac exceed by two to four orders of magnitude the level emitted by females. Further work is necessary to demonstrate whether or not these compounds might synergize the response at physiological levels.

To ascertain both that the synergism observed in the receptor neurons is reflected in behavior and to measure how closely the proportion of sex phero-

mone-elicited behaviors reflect the responses of the HS(a) specialists, flight behaviors and copulatory responses were measured in a wind tunnel at nearly the same stimulus levels that were used in the electrophysiological measures (Table 2). The three concentrations of Z7–12 : Ac used all elicited submaximal upwind flight behaviors. In support of the electrophysiological measured synergism, the proportion of males flying upwind and copulating increased with increase in the amount of Z7–12 : Ac at constant levels of all four synergists. Additionally, the flight response also generally increased proportionally with the increase in amount of the four synergists at constant levels of Z7–12 : Ac.

DISCUSSION AND CONCLUSIONS

The data obtained by both electrophysiological and behavioral experiments are consistent with and support the conclusion that the HS(a) specialist response to Z7–12 : Ac is synergized by two synthetic pheromone analogs and at least two sex pheromone components. There are several facets to specialist synergism that impact such diverse areas as receptor interactions, behavior, and the identification and practical field use of sex pheromones that are significant and merit further comment.

Receptor Interactions. The receptor neuron's response begins when pheromone molecule(s) penetrate minute sensillar pores (Slifer et al., 1959; Schneider et al., 1964; Kaissling and Priesner, 1970) and bind to a carrier protein (Riddiford, 1970; Vogt and Riddiford, 1981; Steinbrecht et al., 1992; Laue et al., 1994) and/or inositol-1,4,5-triphosphate-coupled receptors in the dendritic membrane of the receptor neuron (Zufall and Hatt, 1991; Yoshii et al., 1992; Wegener et al., 1993; Stengl, 1994; and Schleicher et al., 1994). The stimulus-induced cascade of molecular events ultimately leads to action potentials that convey information directly to a macroglomerulus in the deutocerebral lobe of the brain (Boeckh et al., 1976; Hildebrand et al., 1980; Christensen et al., 1991). Based on what is now known about receptor interactions, we consider that synergism most likely reflects a simultaneous reaction of Z7–12 : Ac and the synergen with a receptor macromolecule. There appears to be a relative lack of specificity required of the synergen's structure in the *T. ni* receptor because the double bond can be located on a side chain.

Nevertheless, there is not a total lack of synergen specificity because some synergens elicit a greater response than others. This is demonstrated by the quantitative differences in responses elicited by mixtures of Z7–12 : Ac and 6-VD or 10-VT. While both of these synthetic analogs synergized the response, 10-VT elicits about the same response as 6-VD but at about 100 times lower airborne concentration (Table 1). Structurally, the 10-VT molecule has four more methylene groups between the double bond and the acetate group than the

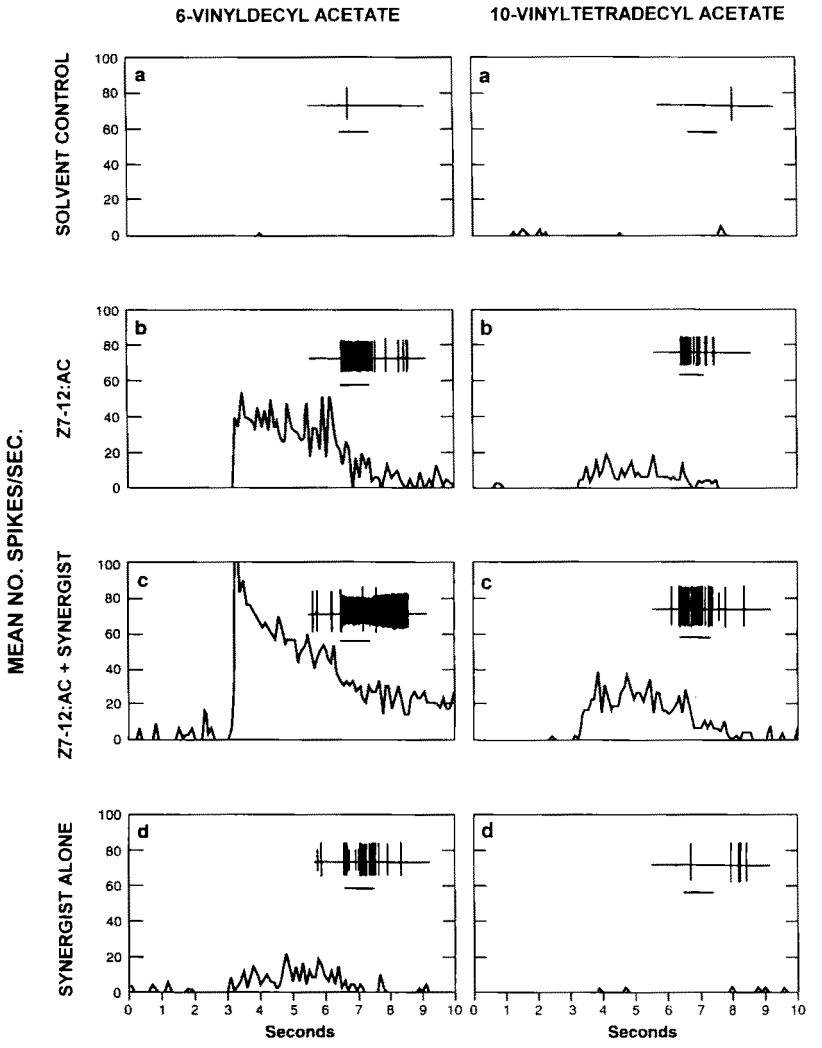

FIG. 2. Synergism of HS(a) specialists by 6-VD and 10-VT. Reading vertically, each of the four large panels shows the average of five consecutive stimuli of: (a) solvent control; (b) Z7-12:Ac alone; (c) admixture of Z7-12:Ac with 6-VD (left panel) or 10-VT (right panel); (d) 6-VD or 10-VT alone. The inset is a digitally reconstructed spike train from the recording that was nearest that of the average. The stimulus began at sec 3 and ended at sec 6, corresponding to the bar under the spike trains in the insets. The randomly occurring small spike in some of the recordings is the HS(b) neuron that responds to (Z)-7-dodecenol. The airborne concentration of Z7-12:Ac alone and mixed

6-VD molecule. We speculate that the increased chain length of 10-VT enables it to assume a greater number of active conformations that facilitate the synergistic molecular interaction at a hydrophilic receptor site (Kafka and Neuwirth, 1976; Bestmann and Vostrowsky, 1982; Jönsson et al., 1991, 1992).

Synergism and Behavior. The behavioral assays that corroborate the synergism of the electrophysiological responses to 6-VD and 10-VT were performed at airborne concentrations within the wind tunnel that were nearly the same as those of the electrophysiological assays (Table 2). The behavioral assays to corroborate Z5-12:Ac and Z9-14:Ac synergism were performed at airborne concentrations above that expected downwind of a female (see Methods and Materials and Table 2). While these two components may utilize other specialist or generalist neuron channels to transfer information to the brain, none yet have been observed at normally encountered stimulus levels. Clearly, however, the synergism of the HS(a) neurons is confirmed by the synergism of behavioral responses. Furthermore, because the moth behavior so reliably reflects primarily the response of HS(a) neurons, these data also support the contention that the cabbage looper's sex pheromone-elicited behavioral upwind flight sequence is predominantly a response to the single component, Z7-12:Ac (Mayer and McLaughlin, 1991, 1993). Consequently, the moth's behavior should increase or decrease as the response of HS(a) neurons increases or decreases as considered below.

Synergism—Behavioral Increase. Because the amount of behavioral response is proportional to the increased HS(a) neural response, significant and sometimes unwanted effects can result from synergized responses. Our results may have bearing upon the common practice of using field trap assays to decide which of several analytically determined compounds may constitute a conspecific sex pheromone signal. Assays of additional putative components at elevated dosages may result in greater amounts of behavior, but the increase might be due to synergism rather than the addition of an intrinsic component part of the sex signal. The likelihood of synergism would increase with increasing dosages similar to that shown in Table 2. Thus, electrophysiological assay methods may be necessary ultimately to conclude whether or not an additional compound constitutes a part of the conspecific sex signal.

Synergism—Behavoral Reduction. Elevated pheromone bait levels in field traps also may reduce trap captures through synergism. Trap captures or wind-tunnel responses typically increase with increasing dosages, reach an asymptote,

---

with 6-VD was 2.0×10^{-13} M; that of 6-VD was 1.6×10^{-10} M. Because of the enhanced response magnitude, the concentration of Z7-12:Ac was reduced to 1.8×10^{-14} M in mixtures with 10-VT; the 10-VT concentration was less than $\sim 6 \times 10^{-13}$ M.

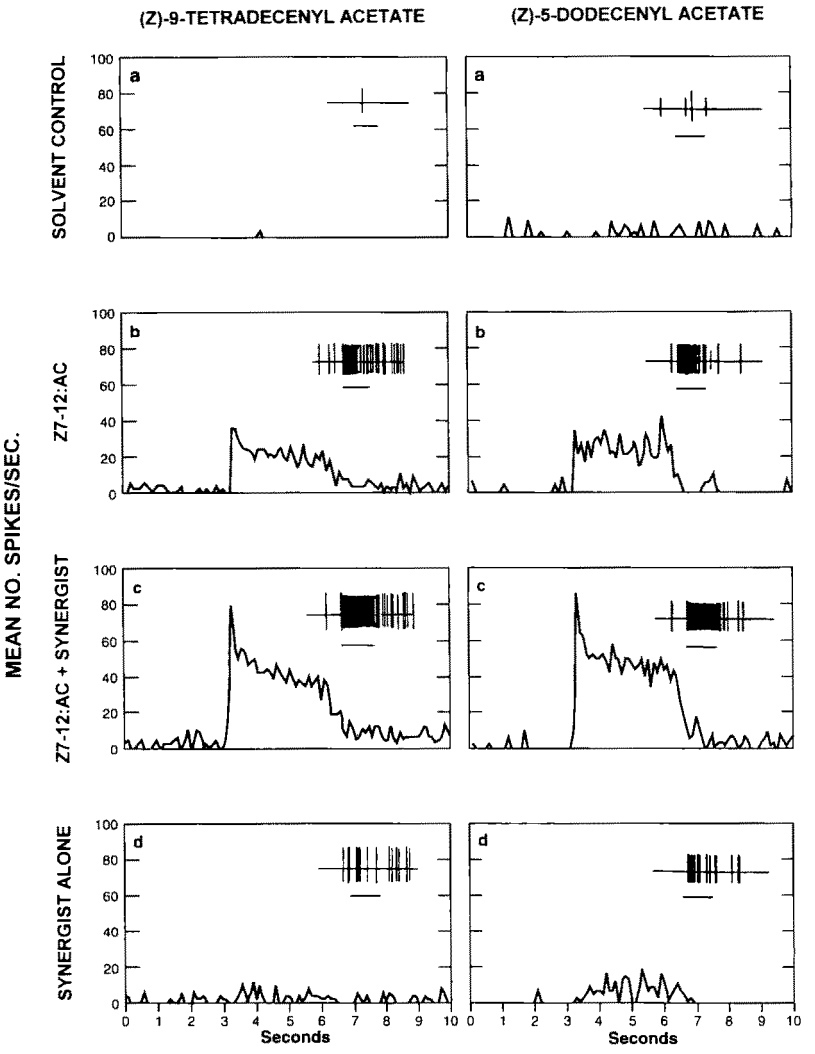

FIG. 3. Synergism of HS(a) specialists by Z9-14 : Ac and Z5-12 : Ac. Reading vertically, each of the four large panels is the average of five consecutive stimuli of: (a) solvent control; (b) Z7-12 : Ac alone; (c) admixture of Z7-12 : Ac with either Z9-14 : Ac (left panel) or Z5-12 : Ac (right panel); (d) Z9-14 : Ac or Z5-12 : Ac alone. The inset is a digitally reconstructed spike train from the recording that was nearest that of the average. The stimulus began at sec 3 and ended at sec 6, corresponding to the bar under the spike trains in the insets. The randomly occurring small spike in some of the recordings is the HS(b) neuron that responds to (Z)-7-dodecenol. The airborne concentration Z7-12 : Ac was 2.0×10^{-13} M, Z9-14 was 1.6×10^{-10} M, and Z5-12 : Ac was 2.0×10^{-10} M.

TABLE 2. PERCENTAGE OF MALE COPULATORY RESPONSES FOLLOWING UPWIND FLIGHTS ELICITED BY MIXTURES OF Z7-12:Ac AND TWO FEMALE SEX PHEROMONE COMPONENTS AND TWO SYNTHETIC ANALOGS IN WIND-TUNNEL ASSAYS

Airborne synergen concentration (M)[a]	Percentage attempted copulations with airborne Z7-12:Ac concentration (M)

[a] Under the assay conditions at the dispenser nozzle the airborne concentrations from a typical female should average: Z5-12:Ac, 1.0×10^{-11} M; Z9-14:Ac, 4.5×10^{-13} M (see text).

[b] The expected probability of copulation at the three airborne concentrations of Z7-12:Ac alone was based on logistic analysis of the flights of 525 moths (Proc Probit; logistic model, SAS Inc., Cary, North Carolina); 0.50 probability of copulation is expected at an average airborne concentration of 1.3×10^{-10} M. The airborne Z7-12:Ac concentration at the dispenser nozzle from a calling female emitting 10 ng/min under the same conditions in the wind tunnel would be 1.1×10^{-10} M.

[c] Numbers in parentheses are the number of males assayed.

[d] Average airborne emission concentration of 6-vinyldecyl acetate was computed using a previous calibration for (Z)-14-tetradecenyl acetate (see text). Dispenser dosages were 1, 3.16, and 10 μg.

[e] Airborne emission concentration was estimated as 10× less than the emission of equivalent dosages of (Z)-11-hexadecenal (see text). Dispenser dosages were 1, 3.16, and 10 μg.

[f] Not tested.

and diminish as the stimulus level is raised further (Mayer, 1973; Löfstedt et al., 1985; McDonough et al., 1993; Haniotakis and Pittara, 1994 among others). When a synergist is added to an already elevated pheromone stimulus level the combination could elicit a specialist receptor overdischarge of action potentials. In insects such overdischarges characteristically are observed at airborne concentration levels considerably above those found downwind from a female, usually exceed 100 spikes/sec, and display a decrementation of spike heights.

This overdischarge could lead either to neuronal adaptation, central habituation, and/or a perceptual change in the organoleptic signal quality.

There is a second alternative that might reduce the behavior of the false codling moth and other species such as the European corn borer, *Ostrinia nubilalis* (Hübner) (Kochansky et al., 1975) that encode ratios of two components. The European corn borer detects the pheromonal signal pair through two specialized receptor neuron lines (Hansson et al., 1987). If one of these specialized neuronal lines were to be synergized and the other not, the perceptual ratio of the two components would be different. Such modification of the perceptual ratio could modify or eliminate certain behaviors. It is not clear which of these, or perhaps other alternative mechanisms, apply to the false codling moth studies of Burger et al. (1990).

Synergism—Is Z5-12:Ac a Sex Pheromone Component? One or more components in the volatile secretion of the female could function as a part of the conspecific sexual signal by synergizing the response of the HS(a) specialists to Z7-12:Ac. Because all five acetates found in the volatile secretion of female cabbage loopers (Bjostad et al., 1984) [Z7-12:OH is found in Israel cabbage loopers (Dunkleblum and Mazor, 1994)] may synergize the HS(a) specialist at high airborne concentrations, it is crucial to assay at levels found downwind from the female. The component Z5-12:Ac alone was able to elicit a 0.32 probability of upwind flight and copulatory behavior, but only at 1.0×10^{-9} M, about 100× its concentration in the female's volatile secretion at about 1.0×10^{-11} M (Table 2). It was ineffective alone in eliciting upwind flight and copulation at 7.0×10^{-12} M. However, in mixtures with Z7-12:Ac it elicited greater than expected flight and copulatory behavior at two stimulus levels assayed than could be accounted for by Z7-12:Ac alone. By contrast, the other cabbage looper sex pheromone component, Z9-14:Ac, also synergized the HS(a) response and increased behavioral responses, but only at airborne concentrations about 1000× higher than would be found downwind of a female. We consider these data to support the hypothesis that Z5-12:Ac may function as a component of the sex signal by synergizing the HS(a) response to Z7-12:Ac, rather than by being detected by a specialist neuron ensemble.

Synergism—Practical Significance. Synergists could enhance the effectiveness of mating disruptants, reduce the amount of an expensive compound, and/or extend the life of labile compounds.

Acknowledgments—We thank D. Patrick and Ms. J.E. Sharp for their technical assistance and Ms. Sharp's suggestion to use higher proportions of the synergens. We also thank Ms. Valerie Malcolm for her assistance in preparing the figures. The samples of Z7-12:Ac, Z5-12:Ac, and Z9-14:Ac were kindly provided by Mr. R.R. Heath of this laboratory. We thank Drs. R.J. O'Connell, A.J. Grant, T.A. Christensen, and J.C. Dickens for their help in reviewing the contents of this report.

CYCLIC CHANGES IN VOLATILE CONSTITUENTS OF BOVINE VAGINAL SECRETIONS

WEIDONG MA, B.A. CLEMENT, and W.R. KLEMM*

Department of Veterinary Anatomy and Public Health
Texas A&M University
College Station, Texas 77843-4458

(Received February 7, 1995; accepted July 21, 1995)

Abstract—Headspace gas chromatography was used to examine the volatile components of bovine vaginal secretions in three consecutive estrous cycles from each of four cows. Results indicated that there was an interesting peak with a retention of 2.7 min. It showed a successive rise and fall zero to three days before estrus. Gas chromatographic evidence and mass spectral data confirmed that this peak was acetaldehyde. Another unidentified compound with a retention time of 27 min was found to be unique to proestrus. It occurred two to three days prior to estrus, but was absent at any other time of the cycle.

Key Words—Cow, vaginal secretions, estrus, pheromones, acetaldehyde, gas chromatography.

INTRODUCTION

In many vertebrate species the estrous female attracts the male and informs the male of its receptive state by means of chemical signals deriving from vaginal discharge (Albone, 1984). The amount and consistency of bovine vaginal secretions vary with different stages of estrous cycle (Cole, 1930; Hammond, 1972). Vaginal secretions generally become more abundant and flow out from the vulva at estrus. (We recognize that not all components of vaginal secretions originate in the vagina. Significant contributions come from cervical glands and vestibular glands). Under field conditions, bulls show overt behavioral responses such as sniffing, licking, and repeated flehmen in response to chemical cues from the

vulvar region and vaginal secretions (Hart et al., 1946; Jacobs et al., 1980; Hradecky et al., 1983; Klemm et al., 1987).

Behavioral studies have demonstrated that vaginal secretions from estrous cows contain estrous pheromones. Paleologou (1977) indicated that a volatile odor in the vaginal secretions of estrous cows was a source of sexual attraction for bulls. When placed in glass dishes and presented to a bull, vaginal secretions elicited sniffing, but no interest was shown in secretions from metestrous or diestrous cows. When vaginal secretions from estrous cows were rubbed on a dummy cow, bulls would mount the dummy, but did not mount a dummy smeared with secretions from diestrous cows. Dogs could even be trained to differentiate the smell of vaginal swabs between estrous and diestrous cows (Kiddy et al., 1978). The trained dogs were used to confirm that there was a distinctive odor in the urogenital tract of cows, which appeared a few days before estrus and disappeared or became less potent immediately after estrus (Kiddy and Mitchell, 1981). Estrus-related odors were apparently strongest in bovine vaginal secretions, but were also present in other body fluids such as milk and blood (Kiddy et al., 1984). Nishimura et al. (1991) reported that vaginal secretions from heifers at estrus stimulated sexual activity and mounting behaviors when the secretions were applied to the hindquarters of the donor heifer during diestrus.

All the evidence above suggests that vaginal secretions from estrous cows contain biochemical markers of proestrus or estrus. Clearly an understanding of the chemical nature of such reproductive signals employed by cows could have great scientific interest, and in some cases considerable economic importance. However, although the above references show that estrous pheromones from bovine vaginal secretions have been well-characterized biologically, chemical knowledge remains slight. Active compounds responsible for the sexual attraction have not been identified.

In a previous study in our laboratory, cow blood acetaldehyde was found to show a successive rise and fall just prior to estrus (Klemm et al., 1994). The present investigation had two purposes: (1) to examine whether acetaldehyde is present in bovine vaginal secretions and determine its variations with the stages of the estrous cycle; and (2) to monitor changes of other volatiles across the estrous cycle.

METHODS AND MATERIALS

Animals. Four Holstein dairy cows (308, 87086, 89124, and 88544) were used for this study. All animals were healthy and had normal estrous cycles. In order to synchronize estrous cycles, cows were given injections of $PGF_2\alpha$. After these treatments, cows were monitored for three natural estrous cycles.

Sample Collection. Vaginal secretions were collected with tampons. Before use, tampons were soaked with a chloroform–methanol solution (85 : 15) for 48 hr and followed with a diethyl ether soak for another 48 hr. The washed tampons were dried in air for 3 hr and then dried in the oven (100°C) for 1 hr. The cleaned tampons were stored in sealed containers until ready for use. Before collection, perineum and vulvar regions were washed with water and dried with paper towels. A tampon was gently inserted into the vagina by hand and left there for 30 min. Then the tampon was removed and placed into a screw-capped bottle (teflon-sealed). Samples were put on ice until they could be stored in a −20°C freezer. Samples were collected daily around the time of estrus (three to four days before and one to two days after estrus) and every three or four other days during diestrus. The stages of the estrous cycle were estimated by rectal palpation of ovarian structure and behavioral observations. Samples were collected from each cow for three consecutive estrous cycles.

Analytical Protocol. Prior to analysis, each sample was thawed at room temperature. Then the capped bottle containing the sample was preheated at 70°C in a water bath for 20 min. One milliliter of headspace was taken from the closed bottle with a hot (70°C) gas-tight syringe and injected immediately into the gas chromatograph (GC) Gas chromatography was carried out on a Hewlett-Packard model 5890 GC fitted with a cross-linked methyl silicone microbore capillary column (DB-1, nonpolar, 30 m × 0.5 mm × 0.53 μm film thickness, J&W Scientific, Folsom, California) and an FID. The oven temperature was kept at 30°C for 10 min and then programmed to 110°C at a flow rate of 4°C/min. The injector was set at 150°C and the detector at 200°C. Helium was used as the carrier gas at a rate of 4 ml/min. Compressed air and hydrogen were set at flow rates of 400 and 20 ml/min, respectively. Peak areas were calculated with the PC software "ChromPerfect" (Justice Innovations, Palo Alto, California).

Identification of Acetaldehyde. Acetaldehyde was initially identified by comparing the retention time of the sample with that of authentic acetaldehyde in solution and by its coelution with the putative acetaldehyde peak in the sample. To further confirm the identification, combined GC-MS was performed. Previous experiments in our laboratory showed that direct headspace samples were not appropriate for GC-MS analysis (Klemm et al., 1994). Because the headspace samples of body fluids contained much water, carbon dioxide, nitrogen and oxygen, mass spectral analysis could not unequivocally identify small molecules such as acetaldehyde. Furthermore, the GC-MS system can be easily overloaded and shut down by the large amounts of water and carbon dioxide. In the present study, organic solvent extraction was used to isolate volatiles for GC-MS analysis. Tampons were soaked with 100 ml ice-cold distilled water. Extracts were obtained by a simultaneous steam distillation and extraction method

(Maarse and Kepner, 1970) using diethyl ether (HPLC grade) as the organic solvent. GC-MS analysis was performed on a Hewlett-Packard model 5970C quadrupole mass spectrometer coupled to a Hewlett-Packard model 5890 GC with a microbore capillary column (Hewlett-Packard Inc., Avondale, Pennsylvania). The spectra were obtained by electron ionization at 70 eV. Identification of acetaldehyde was made by matching the mass spectrum with the library spectral data as well as with the data of authentic acetaldehyde.

RESULTS

A peak that eluted at about 2.7 min occurred in all samples across estrous cycles. This peak had the same retention time as that of authentic acetaldehyde (Figure 1). When samples were spiked with acetaldehyde, the peak coeluted with it, suggesting that this peak may represent acetaldehyde.

GC-MS analysis of the ether extract indicated that there was a peak that eluted at 2.7 min. The spectrum of this peak had significant ions at *m/e* 44, 43, 29, and 15. This is consistent with the spectrum expected for acetaldehyde. To further verify this identity, a comparison was made with an authentic sample of freshly distilled acetaldehyde dissolved in diethyl ether. It was found that the retention time and fragmentation pattern of the known acetaldehyde were identical to that of the 2.7-min peak.

Acetaldehyde levels changed with the stages of the estrous cycle. They showed an increase and decrease zero to three days prior to estrus (Figure 2). This result is similar to that obtained from bovine blood samples (Klemm et al., 1994). Figure 3 illustrates the relative changes of acetaldehyde for three consecutive cycles from each of four cows. In every cycle, there was a relative increase in acetaldehyde. The peak concentration occurred one to three days prior to the day of estrus.

Apart from acetaldehyde, seven other peaks were found in the early elution (0–8 min, Figure 4), but they changed intensities irregularly across the estrous cycles. These peaks seemed to have no close correlation with the estrous cycle. However, there was an interesting late-eluting component with a retention time of about 27 min (Figure 4). It was always present two to three days before estrus and disappeared suddenly thereafter. This peak had similar size in all cows at each cycle. Unfortunately, this peak was not clearly recognized in the profile of the ether extract, therefore we were not able to identify it at this time.

DISCUSSION

Acetaldehyde was found in bovine vaginal secretions. It showed a successive rise and fall in concentration just before estrus. This phenomenon coincides

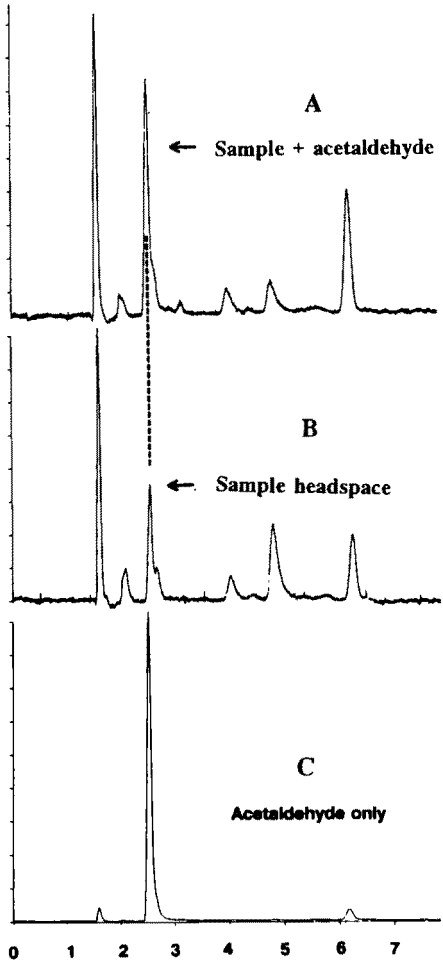

FIG. 1. Headspace gas chromatograms from vaginal secretions showing coelution of acetaldehyde standard at the same retention time as the 2.7 min peak. (A) Sample was spiked with authentic acetaldehyde. (B) Sample headspace. (C) Headspace from authentic acetaldehyde solution.

with the occurrence of estrus-related odors. We originally supposed that acetaldehyde might serve as a sex pheromone for attracting bulls during the estrous period. Acetaldehyde is highly volatile at room temperature and pressure. Pure acetaldehyde possesses a pungent irritating odor, but at dilute concentrations it gives a pleasant fruity aroma and is a necessary component for a balanced flavor in many dairy products (Vedamuthu, 1982). These characteristics could enable

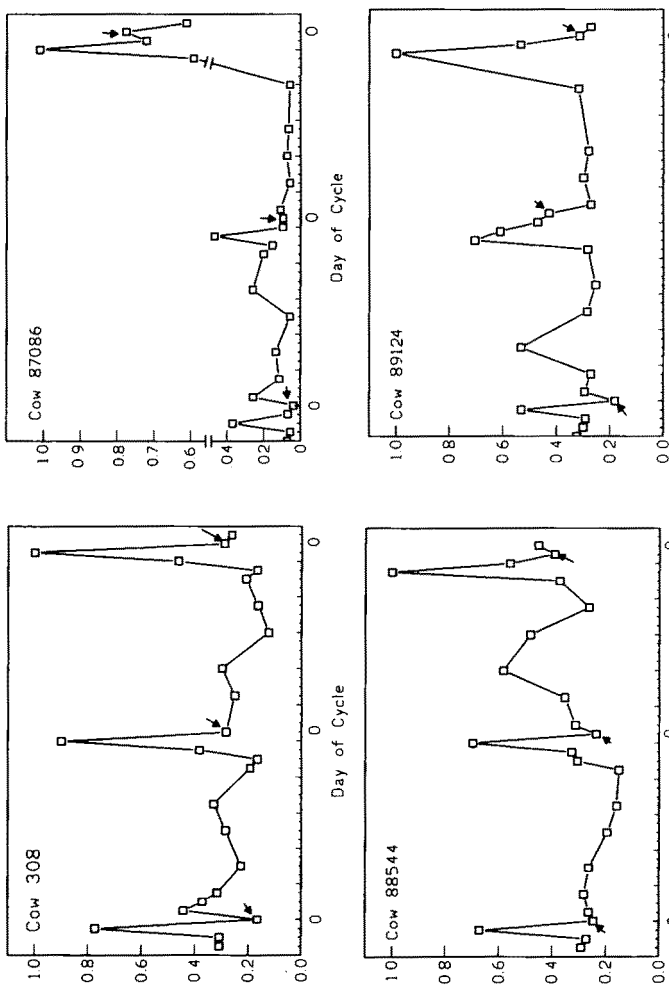

FIG. 3. Observations of acetaldehyde variations for three consecutive estrous cycles from each of four cows. The x axis indicates the day of cycle. Day 0 (arrows on the curve) was the day of heat. The y axis indicates the normalized data of peak area (detector response) of acetaldehyde.

acetaldehyde to be a pheromone. In fact, acetaldehyde was found to be a very powerful attractant for a parasitoid (Jones, 1981). However, in a bull bioassay study (Prescicce et al., 1993), acetaldehyde at a wide range of concentrations (1–100 ppm) failed to elicit appreciable responses in bulls. Although these behavioral tests were negative, we still cannot conclude that acetaldehyde is not an estrous pheromone. There are at least three possibilities:

1) Beauchamp et al. (1976) pointed out that mammalian chemical signals were likely to be coded in the patterns of compounds in a mixture rather than in individual components. A pheromonal action may derive from highly complex mixtures of chemicals in which synergistic or antagonistic effects could occur

among the components. Sometimes the behavioral response disappears completely when chemical mixtures are broken into individual components (Müller-Schwarze et al., 1986). Such a phenomenon was found in hamsters (O'Connell et al., 1978). Some compounds (aliphatic acids and alcohols) from estrous hamsters had no effects on either attraction or copulatory behavior when given alone but were effective when given in combination. Therefore, in bovine vaginal secretions, a mixture of compounds including acetaldehyde may be responsible for sexual attraction to bulls.

2) Behavioral responses often depend not only on chemical stimuli, but also on nonchemical cues. Many responses occur only in the proper physiological, social, and temporal contexts. For instance, receptors for some pheromones may be available only at a certain period of time. Only under these proper conditions is it possible to choose a significant compound for behavioral tests.

3) The taste of acetaldehyde could be a meaningful signal in bull courtship behavior, during which bulls lick the vulva and exhibit associated flehmen responses (Rivard and Klemm, 1992).

Whether acetaldehyde is a pheromone or not, it seems to be a good estrous marker. This finding may have real economic importance. In the modern dairy industry, cows are routinely bred by artificial insemination. Detection of estrus is necessary to obtain satisfactory conception rates. A basic problem facing producers, however, is the failure to detect estrus. In most dairy operations, detection of estrus is only about 50% effective (Williamson et al., 1972; Esslemont and Bryant, 1974). As a biochemical approach to this problem, it should be possible to use acetaldehyde as a marker to develop a biosensor system for estrus detection. For instance, one might be able to develop a chemically treated paper to monitor acetaldehyde change, whereby dairymen could test for estrus by simply dipping a strip of the paper into the body fluids. Acetaldehyde could be detected by other methods such as electric sensors. Additional work along these lines is being carried out in our laboratory in collaboration with a dairy cooperative.

The vagina is rich in blood vessels in the regions of lamina propria that underly the epithelium (Cormack, 1987). The lumen of the vagina receives a transudate of blood plasma through the intercellular channels of the epithelium. Since blood acetaldehyde in cows also showed a successive rise and fall three days before estrus (Klemm et al., 1994), acetaldehyde in the vaginal secretions may come directly from the bloodstream. The vagina also receives secretions from cervical glands and vestibular glands, although neither of these have been directly tested for acetaldehyde. Alternatively, acetaldehyde may be the result of vaginal microbial activity. Some microbial species can utilize and transform mammalian secretions and excretions, and in this process, mammalian chemical signals may be generated (Albone et al., 1977). Some studies indicate that certain bacteria (e.g., lactic acid bacteria) contain enzymes that can catalyze the

formation of acetaldehyde from a wide variety of substrates such as protein, glucose, amino acids, nucleic acids, and ethanol (Gonzalez et al., 1994). The accumulation of acetaldehyde in vaginal secretions before estrus may be caused by a high production rate that is regulated by the availability of substrates and the activities of enzymes, both of which are associated with the female's physiological state. Vaginal tissues, which are rich in glycogen (Albone, 1984), are very sensitive to circulating estrogen levels. As ovulation approaches, the high level of circulating estrogen stimulates the breakdown of glycogen and other materials into glucose, thus supplying microorganisms with increased nutrients. The increased glucose from the turnover of glycogen may be responsible for the high level of acetaldehyde at proestrus.

Some evidence indicated that estrogen was directly involved in the process of acetaldehyde formation. Birth control pills seem to elevate breath acetaldehyde levels (Jeavons and Zeiner, 1984). Alcohol dehydrogenase catalyzes the formation of acetaldehyde from ethanol. In some animals gene expression and activity of this enzyme can be induced by estrogen (Qulali et al., 1991; Qulali and Crab, 1992; Hiremath et al., 1992). If this is true for cows, the acetaldehyde increase before estrus may be regulated by the high circulating estrogen level before ovulation. Elevated acetaldehyde levels might also be caused by a deficiency or inhibition at estrus of aldehyde dehydrogenase, the enzyme that metabolizes acetaldehyde into acetate.

The 27-min peak is a potentially important compound. It was specific to proestrus and did not occur during the diestrus. Plans are under way to extract the vaginal secretions with an appropriate method so that the peak can be identified by GC-MS.

Acknowledgments—We thank Dr. G. Rivard for assistance in collecting vaginal secretion samples.

(Received March 23, 1995; accepted July 21, 1995)

Abstract—Many terrestrial Heteroptera have small, but functional, dorsal abdominal glands as adults. The chemistry, and associated intra- and interspecific behavior, for dorsal abdominal gland secretions from 10 species representing four genera of Pentatomidae was investigated. Eighteen volatile compounds were identified in species-specific blends from the dorsal abdominal gland secretions of *Euschistus*, *Acrosternum*, and *Eurydema* adults, including aliphatic, aromatic, and terpenoid constituents. Evidence from bioassays is presented that parasitic Tachinidae (Diptera) and Scelionidae (Hymenoptera) use these secretions as kairomones. A field experiment was performed to test the hypothesis that minor volatiles increase the specificity of the main pheromone component from Nearctic *Euschistus* species, methyl (2*E*,4*Z*)-decadienoate. However, significantly fewer individuals of *E. tristigmus* were captured in traps baited with the complete blend for this species than in traps baited with methyl (2*E*,4*Z*)-decadienoate alone. Thus, at the concentrations tested, these kinds of dorsal abdominal gland secretions may be epideictic, promoting spacing in the natural habitat.

Key Words—Parasitoid, Scelionidae, Tachinidae, *Nezara*, *Euschistus*, *Eurydema*, *Acrosternum*, *Trissolcus*, pheromone, kairomone.

INTRODUCTION

Methyl (2*E*,4*Z*)-decadienoate is the major male-specific volatile in several Nearctic *Euschistus* stink bugs (Aldrich et al., 1991a). In fact, traps baited with this fragrant, pear-like compound often simultaneously attract males, females, and nymphs of three species, and their tachinid fly parasitoids. Although a few minor components were identified from aerations of *Euschistus* males, field tests of lures including a minor component along with methyl (2*E*,4*Z*)-decadienoate did not alter attraction (e.g., decanoic acid for *E. tristigmus*; geranylacetone for *E. servus*) (Aldrich et al., 1991a). Therefore, it seemed that volatiles contributing to reproductive isolation of *Euschistus* species remained to be discovered.

An observation of the South American stink bug, *Acrosternum aseadum* (J.R.A., unpublished data), provided a clue to one possible source of biologically active, minor pheromone constituents in pentatomids. Dissection of a wild *A. aseadum* adult revealed two tachinid macroeggs underneath the bug's wings, with an egg perfectly positioned on each opening of the paired dorsal abdominal glands. Many terrestrial Heteroptera have small, but functional, dorsal abdominal glands as adults (Lucchi and Solinas, 1990; Pavis, 1987; Staddon, 1979). The chemistry of secretions from these adult glands is known for a few, mostly unrelated, species (Aldrich et al., 1978, 1990; Evans et al., 1990; Farine et al., 1992a,b; Staddon, 1990; Staddon et al., 1987). Behavioral roles for dorsal abdominal gland secretions are virtually unknown (Aldrich, 1995; Staddon, 1986). Female tachinids commonly use heteropteran pheromones as host-finding kairomones (Aldrich, 1988, 1995), so the apparent orientation of ovipositing tachinids toward the dorsal glands of *A. aseadum* suggested that secretion from these glands has a pheromonal role.

Here we report on our comparative investigations of the chemistry, and associated intra- and interspecific behavior, for dorsal abdominal gland secretions from 10 species representing four genera of Pentatomidae.

METHODS AND MATERIALS

Insects. Euschistus servus, *E. tristigmus*, and *E. politus* adults were caught in traps baited with methyl (2*E*,4*Z*)-decadienoate at the Beltsville Agricultural Research Center in 1989. *Acrosternum hilare* and *A. pennsylvanicum* were collected on the Research Center grounds in May and June, 1989 and 1990, from empress trees (Scrophulariaceae: *Paulownia tomentosa*), and bracken fern (Filicopsida: Dennstaedtiaceae: *Pteridium aquilinum*), respectively. A few individuals of *E. variolarius* were collected in the same area from woolly mullein, *Verbascum thapsus* (Scrophulariaceae), in August 1993. *Acrosternum aseadum* adults were collected on soybean in Brasília, Brazil, in August 1991. *Eurydema*

ventrale and *E. oleraceum* were found on various wild crucifers in and around Perugia and Colfiorito, Italy, July through August 1994. Experiments involving *Nezara viridula* (Pentatomidae) and its scelionid egg parasitoid, *Trissolcus basalis*, used the Italian strains of both these insects. *Nezara* was reared on sunflower seeds (*Helianthus annuus*), green beans (*Phaseolus vulgaris*), and water. *Trissolcus basalis* adults were maintained in glass tubes supplied daily with Safavi diet (Safavi, 1968). Host eggs were exposed to parasitoids for 24 hr, removed, and placed in another tube for incubation. Adult parasitoids emerged in 11–13 days (Mattiacci et al., 1993). *Nezara* and *Trissolcus* were maintained at 24 ± 1°C, 70 ± 5% relative humidity, and a 16L:8D photoperiod, and the other pentatomids were maintained under conditions similar to those for *N. viridula* for up to a month prior to dissection.

Chemical Analyses. Dorsal abdominal glands were excised from CO_2-anesthetized bugs submerged in tap water and extracted in ca. 200 μl of either hexane or CH_2Cl_2 (usually glands from 5–10 adults of each sex were pooled per sample). Samples were analyzed on DB-1 or DB-5 columns (0.25 μm film, 30 m × 0.25 mm ID) in a Varian 3500 GC with helium as carrier (50 cm/sec), a temperature program from 50°C for 2 min to 235°C at 15°/min, with a flame ionization detector. Data were recorded using the Varian GC Star Workstation software on a Gateway 2000 386/25 computer. Gas chromatogram (GC) traces presented in the figures begin at 2.5 min (at left) so as to exclude the solvent peak, and peaks were automatically normalized to the most abundant peak. Electron impact–mass spectra (EI-MS) were obtained using Hewlett Packard 5971 GC-MS instruments at 70 eV, with a HP-5 column (instrument in USA: 0.11 μm film; 25 m × 0.2 mm ID; instrument in Italy: 0.25 μm film; 30 m × 0.25 mm ID), programmed from 50°C for 2 min to 250°C at 15°/min. 4-Heptanol (Aldrich Chemical Co., Milwaukee, Wisconsin) was added to some *Euschistus* samples as an internal standard.

Identifications based on mass spectrometry were verified by comparison and coinjection with the following standards: hexanal, hexanoic acid, octanal, phenylacetaldehyde, acetophenone, nonanal, 2-phenylethanol, 1-nonanol, octanoic acid, decanal, citral (geranial + neral) (Aldrich Chemical Co.); (*E*)-2-hexenal, (*E*)-2-hexenol, 1-hexanol, (*E*)-2-hexenoic acid, (*E*)-2-octenal, (*E*)-2-decenal (Bedoukian Research Inc., Danbury, Connecticut). The preparation of 4-nonenal was accomplished using a three-step procedure based on dihydropyran, which was first stereoselectively converted to (*E*)-4-nonen-1-ol by reaction with butyllithium (Pattison and Dear, 1963). The alcohol was acetylated, and the (*E*)-4-nonenyl acetate was isomerized to a 67:33 ratio of *Z* and *E* isomers, respectively, using sequential bromochlorination–dehalogenation (Sonnet and Oliver, 1976). Finally, alkaline hydrolysis and pyridinium chlorochromate oxidation afforded the corresponding mixture of (*Z*)- and (*E*)-4-nonenal.

[b] Percentages are based on GC peak areas; compounds with * were combined for each *Euschistus* sp. for the pheromone field test.

Field Pheromone Test. Components marked with an asterisk in Table 1 (seven for each *Euschistus* sp. investigated) were combined proportionally using microliter volumes equal to the percent abundances of each compound multiplied by the density of the compound. The total volume of each species-specific blend was then combined with a volume of methyl (2*E*,4*Z*)-decadienoate (Bedoukian Research Inc.) equal to twice the total volume of dorsal abdominal gland components for each species, and this mixture was diluted 50% with heptane. One treatment consisted of only methyl (2*E*,4*Z*)-decadienoate diluted 50% with heptane. In the initial analysis of *E. tristigmus*, phenylacetaldehyde (8) and decanal (16) were not detected at concentrations as high as in later analyses; therefore, these components were not included in the synthetic blend used for the pheromone field test.

Traps were made of transparent cylindrical containers having either white or transparent lids (20.2 × 19.7 cm; Tri-State Molded Plastics, Inc., Dixon, Kentucky) by cutting two holes (9 cm diameter) in opposite sides, and covering each hole with an inwardly projecting screen funnel. The containers were turned upside-down, so that the normal top of the container became the trap bottom, small drainage holes were made in the bottom, and the bottoms were held in place by two elastic cords hooked into each screen funnel. Traps (alternating treatments) were hung from branches about 1.7 m from the ground, at least 50 m apart, bordering oak-dominated deciduous forest at the Beltsville Agricultural Research Center-East, Prince George's County, Maryland. Traps were monitored daily and rebaited every two to three days with 10 μl of pheromone solution from July 28 through September 15, 1992. Five traps were deployed per treatment, plus five unbaited control traps.

Egg Parasitoid Bioassays. Earlier research (Mattiacci et al., 1993) showed that *Trissolcus basalis* females could be induced to attempt oviposition in glass beads coated with extracts of host eggs. This bioassay was employed here to determine if the dorsal abdominal secretion of *Nezara viridula* influenced the acceptance of host eggs. *Trissolcus basalis* females used for bioassays were kept with males for 24 hr to allow mating, then placed singly in small vials with a drop of honey solution, and used for bioassays when they were 3–4 days old. *Nezara viridula* females were segregated from males when they were ≤1 day old and held for at least a week prior to dissection. Dorsal abdominal glands were removed from *N. viridula* females as described above with as small a piece of attached cuticle as possible, and taking care to not cause the bugs to emit metathoracic scent gland secretion. The glands from 20 virgin females were pooled per sample in 100 μl hexane. Samples were divided in half and, to one half, 1 μl of paraffin oil solution (50 μg/μl hexane; Aldrich Chemical Co.) was added. Control treatments consisted of hexane and 1 μg paraffin oil/μl hexane.

A flat-bottomed depression slide (15 mm diameter × 3 mm deep) covered with a glass cover slip served as the bioassay arena. The ends of the depression slide were cut off so that four arenas could be arranged in a compact square for video recording. Clean 1.0-mm-diameter glass beads (the size of host eggs) served as artificial eggs. The glass beads were coated with a control solution or an extract solution by rolling three beads in 10 μl of a solution in a small watch glass until the hexane evaporated. The three coated beads were held firm by pressing them onto a 1-cm^2 piece of parafilm (American National Can, Greenwich, Connecticut), and the beads on parafilm squares were placed in a bioassay arena. Wasps were released singly into an arena, and four arenas were run simultaneously, one for each treatment. The following behaviors were recorded: (1) walking (without contacting glass beads), (2) encounter (touching or walking over glass beads), (3) examination (antennation of glass beads), and (4) acceptance (attempting to oviposit in glass beads). Female wasps that did not contact

the glass beads within 5 min were excluded and, if acceptance did not occur after 7 min from the first encounter, the wasp was scored as rejecting the beads and the bioassays was terminated. Otherwise, bioassays were allowed to proceed for 10 min. Each set of beads was used to test three wasps and then replaced with freshly coated beads. Bioassays were conducted at room conditions (20–25°C, 55–65% relative humidity), with overhead fluorescent lighting and were recorded on video tape.

Data Analysis. Field data were analyzed by ANOVA (General Linear Models, SAS Institute, 1985) after square-root transformation, and reported values are back-transformed for easier interpretation. Laboratory bioassay data were scored using. "The Observer 2.0" video recorder software package (Noldus, 1991) and then analyzed by ANOVA.

RESULTS

Chemistry. Extracts from *Euschistus* spp. contained 208, 183, and 42 ng/adult of volatile compounds for *E. politus*, *E. tristigmus*, and *E. servus*, respectively, and the glands of *Acrosternum* and *Eurydema* adults appeared comparable in size. Eighteen volatile compounds were identified from the dorsal abdominal gland secretions of *Euschistus*, *Acrosternum*, and *Eurydema* adults, including aliphatic, aromatic, and terpenoid constituents (Table 1). The secretions of males and females were not obviously sexually dimorphic but, within each genus, the dorsal abdominal gland secretions were qualitatively and quantitatively species-specific (Figures 1–4).

Six-carbon compounds (1, 2, and 4) were most abundant among the three *Euschistus* spp. common in the study area, but these components were distinctively exhibited (Figure 1). Other components unique to a species further characterized these *Euschistus* secretions, such as 2-phenylethanol (13) for *E. politus*, and octanal (6) for *E. tristigmus*. Although only two males of *E. variolarius* were sampled (insufficient for EI-MS), the gas chromatogram of their dorsal gland extract indicates that the blend from this species is strikingly different from its closest relative, *E. servus* (Figure 2) (McPherson, 1982).

The Nearctic *Acrosternum* species produce similar dorsal abdominal gland secretions (Figure 3, top two traces); however, hexanal (1) is absent in the secretion of *A. pennsylvanicum*, whereas in *A. hilare* this compound is prominent in the secretion. In addition, the secretion of *A. hilare* appears to be more acidic than those of the other two *Acrosternum* spp. investigated. Secretion from *A. aseadum* is chemically novel, being dominated by (*Z*)-4-nonenal (11) (Figure 3, bottom trace).

Finally, the dorsal abdominal gland secretions of *Eurydema ventrale* and *E. oleraceum* are also species-specific, despite the coexistence of certain con-

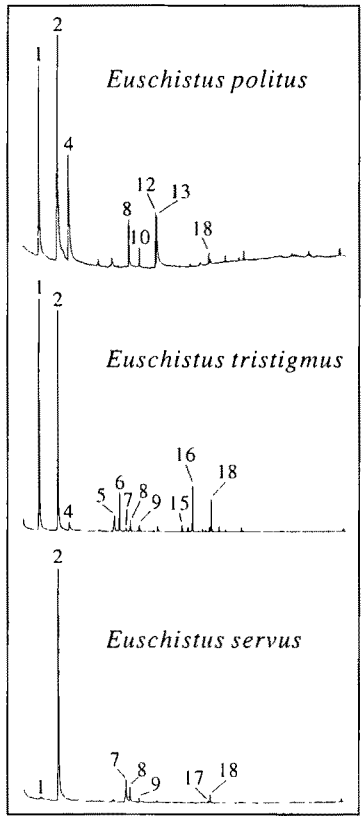

FIG. 1. Gas chromatograms of adult *Euschistus* species dorsal abdominal gland secretion (*E. politus*, 3 males and 7 females; *E. tristigmus*, 10 males and 10 females; *E. servus*, 7 males and 2 females). Numbers in this and other figures correspond to compounds listed in Table 1.

stituents (Figure 4). Substantial differences between these *Eurydema* secretions are the presence of hexanal (1) in *E. oleraceum*, and the occurrence of nonanol (14) in *E. ventrale*. Additionally, the unidentified, late-eluting component of the *E. ventrale* secretion (probably a sesquiterpene hydrocarbon based on EI-MS) was not detected in the secretion of *E. oleraceum*.

Phereomone Field Test. A total of 386 *E. tristigmus*, 33 *E. politus*, 15 *E. servus*, and 21 *Gymnosoma par* (Diptera: Tachinidae) were caught in pheromone-baited traps from July 28 through September 15, 1992. Only one male *E. tristigmus* was caught in unbaited control traps. For all three *Euschistus* spp.,

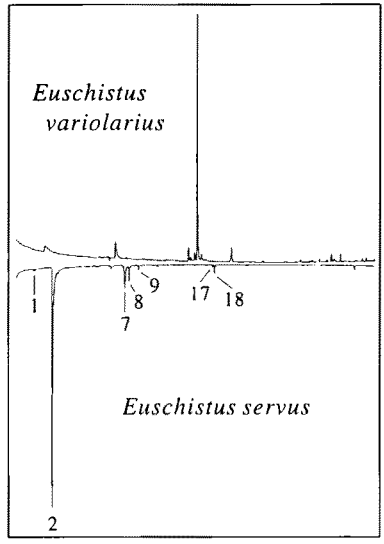

FIG. 2. Comparison of dorsal abdominal gland secretion of *Euschistus variolarius* (2 males) to that of *E. servus* (7 males and 2 males).

equivalent numbers of males, females, and second- to fifth-stage nymphs were captured. Only females of the tachinid parasitoid, *G. par*, were captured (Table 2).

The results of field attractancy are shown in Table 2; attraction to methyl (2*E*,4*Z*)-decadienoate alone (treatment E), and attraction to this ester combined with synthetic blends (treatments EP, ES, and ET) mimicking dorsal abdominal gland secretions of the three *Euschistus* spp. in the study area were tested. No treatment affect was detected for *E. politus*, *E. servus*, or *G. par*. However, significantly fewer adults and nymphs or *E. tristigmus* were caught in traps baited with its specific lure (ET) than in traps baited solely with methyl (2*E*,4*Z*)-decadienoate (E) or with the ES lure. Capture of *E. tristigmus* individuals was also lower in ET-baited traps than EP-baited traps, but this difference was not statistically significant ($P = 0.089$). Analysis of the data for *E. tristigmus* by sex and nymphal catch (Table 2) showed that all stages of *E. tristigmus* generally exhibited reduced attraction to ET-baited traps relative to traps baited with other treatments.

Tachinid Parasitism of Eurydema. A total of 27 wild *E. oleraceum* adults were carefully examined for the presence of tachinid eggs, including 17 females and 10 males. All the tachinid eggs observed were fastened onto the abdominal

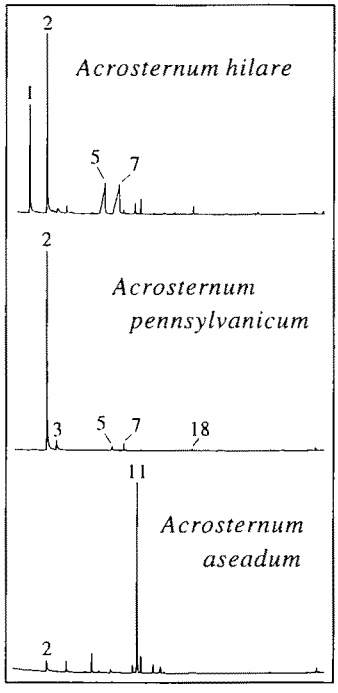

FIG 3. Gas chromatograms of adult *Acrosternum* species dorsal abdominal gland secretion (*A. hilare*, 14 males and 12 females; *A. pennsylvanicum*, 7 males and 11 females; *A. aseadum*, 1 male and 4 females).

tergum of the bugs near the openings of the dorsal abdominal glands underneath the wings; six females had one egg each, one male had three eggs, and one male had one egg. One female *E. ventrale* was observed to have a tachinid egg on her tergum near a dorsal abdominal gland ostiole. No tachinid eggs were observed anywhere else on the body for either *Eurydema* species.

Egg Parasitoid Bioassays. Trissolcus basalis females were significantly more likely to attempt oviposition in glass beads coated with extract of the dorsal abdominal glands from *N. viridula* females than in beads treated with solvent alone (Table 3). The addition of paraffin oil as a fixative for volatile compounds did not affect the behavior of *T. basalis* females. In addition to increasing acceptance of an artificial egg, the treatment of glass beads with dorsal abdominal gland extract also significantly increased the encounter time of the wasps toward beads ($F = 12.26$, 1 *df*, $P < 0.0001$).

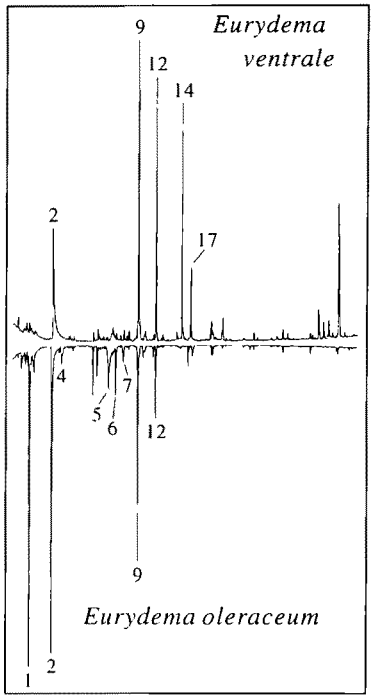

FIG. 4. Gas chromatograms of adult *Eurydema* species dorsal abdominal gland secretion (*E. ventrale*, 7 males; *E. oleraceum*, 8 males and 1 female).

DISCUSSION

In some stink bugs and assassin bugs, males release attractant pheromones from dorsal abdominal glands that are tremendously enlarged compared to those of females (Aldrich et al., 1991b; James et al., 1994a,b). However, in most heteropteran adults where these glands remain active, they are tiny and not noticeably sexually dimorphic (Pavis, 1987; Staddon, 1979). Curiously, the only other occurrence in insects of the most esoteric dorsal gland compound we identified, (Z)-4-nonenal from *Acrosternum aseadum*, is the presumed sex pheromone of an African scutellerid bug produced in the hypertrophied dorsal abdominal glands of males (Gough et al., 1986). In fact, all of the compounds now being reported have been found previously in Heteroptera (Aldrich, 1988), and most are known pheromone constituents of other insects (Mayer and McLaughlin, 1991). Nonetheless, the chemical analyses reported here, along with similar analyses for two *Elasmostethus* species (Acanthosomatidae) (Evans

et al., 1990), reveal that these pentatomoid secretions are normally species-specific.

Tachinid parasitoids of *A. aseadum* and *Eurydema* species seem to prefer to oviposit underneath the wings of hosts. Similarly, Eger (1981) found over 90% of the tachinid eggs on *Brochymena* spp. (Pentatomidae) hidden underneath the wings. This parasitoid behavior is circumstantial evidence that secretions from diminutive dorsal abdominal glands are exploited as kairomones. Alternative explanations for this type of oviposition are that the flies cannot stick their eggs to the powdery wax on *Brochymena* adults (Aldrich 1988; Leston, 1953) or that concealing eggs protects them from adverse environmental con-

ditions (Eger, 1981; Giangiuliani et al., 1991). There is even a report that (*E*)-2-hexenol from the dorsal abdominal glands of adults of one scutellerid species may be toxic to tachinid eggs (Hamilton et al., 1985). Nevertheless, in the past the ovipositional host sex preferences of tachinids foreshadowed discoveries of heteropteran pheromones (e.g., Todd and Lewis, 1976). Insectary workers in Brazil recognized (*Z*)-4-nonenal as the distinctive "colony odor" of *A. aseadum* (J.R.A. personal communication), and it seems plausible that tachinid flies are able to do the same.

Our demonstration that dorsal abdominal gland extract from *N. viridula* females elicits acceptance by *Trissolcus basalis* is added evidence that parasitoids use dorsal abdominal gland odors as kairomones. Earlier research on this egg parasitoid–host association showed that the female wasps orient at long range to the defensive secretion of *N. viridula* (Borges and Aldrich, 1994; Mattiacci et al., 1993) and, upon contact, they recognize host eggs by the glue used to fasten eggs to the substrate and to each other (Bin et al., 1993). Evidently, dorsal abdominal gland volatiles constitute intermediate-range kairomones in the hierarchy of cues leading to parasitism (Aldrich et al., 1984; Bin et al., 1988).

Scents from the small, nondimorphic dorsal abdominal glands of pentatomid bugs apparently betray their presence to parasitoids, raising the question: what is the true biological role for these secretions (Blum, 1974)? Field experiment results seem to refute the hypothesis that minor volatiles increase the specificity of methyl (2*E*,4*Z*)-decadienoate. The surprising discovery that fewer individuals of *E. tristigmus* were captured in traps baited with the lure more completely mimicking its own scent verifies that dorsal abdominal gland secretions play a pheromonal role, but the nature of this communication is more complicated than anticipated. At the concentrations tested, these kinds of dorsal abdominal gland secretions may be epideictic, promoting spacing in the natural habitat (Haynes and Birch, 1985), *Euschistus tristigmus* is the most abundant *Euschistus* species in the study area, and it could well be adaptive for individuals to avoid overpopulated host plants. Still, it is distinctly possible that secretions from the tiny dorsal abdominal glands of adult bugs both attract and repel conspecifics, depending on concentration. In ants, the most social of all insects, it is normal for the same exocrine compounds to recruit workers at low concentration, and elicit "fight or flight" at high concentration (Hölldobler and Wilson, 1990). Indeed, the only compound found in all of the heteropteran secretions examined in the present study, (*E*)-2-hexenal, performs just such a role in some ants (Blum et al., 1969).

Acknowledgments—We thank Drs. James Oliver and Ashot Krimean, ICEL, for synthetic chemistry support, and Drs. Thomas Henry and Norman Woodley, USDA-ARS, Systematic Entomology Laboratory, for species determinations. Special thanks go to Ms. Jung Lee for her diligent work in the field. Drs. Brian Staddon (University of Wales, Cardiff) and Andrea Lucchi (Entomologia Agraria, Pisa, Italy) provided helpful reviews of the manuscript, for which we are grateful. (Received March 17, 1995; accepted July 21, 1995)

Abstract—Structure–activity relationship (SAR) observations were made for the Z-type European corn borer moth pheromone, (Z)-11-tetradecen-1-ol acetate, and a series of analogs with fluorination in the alcohol portion of the molecule. The attractiveness of these analogs and the pheromone was compared to the electrostatic potential map of the molecular mechanics (MM) minimized lowest energy conformation for each compound. A critical range of electrostatic potential on the protons of the double-bond appears to be essential for optimal acceptor fit and attractiveness.

Key Words—Molecular modeling, SAR, Lepidoptera, Pyralidae, *Ostrinia nubilalis*, European corn borer moth, sex pheromone, attractant.

INTRODUCTION

The European corn borer (ECB), *Ostrinia nubilalis* (Hübner), is distributed over the greater part of Europe and parts of Asia. It has been present in North America since 1917 and is a major pest of corn (Metcalf and Flint, 1939).

The sex pheromone of the ECB moth was demonstrated by Sparks (1963) and confirmed by Klun (1968). It was subsequently identified as (Z)-11-tetradecen-1-ol acetate (1) (Figure 1, Table 1) (Klun and Brindley, 1970; Klun and Robinson, 1971). It was also discovered that there are two subpopulations of

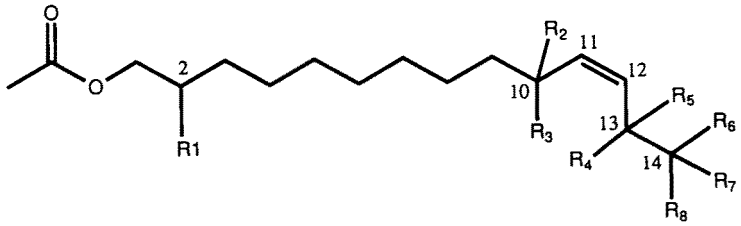

FIG. 1. European corn borer moth pheromone and fluoro analogs: (1) $R_1=R_2=R_3=R_4=R_5=R_6=R_7=R_8=H$, (*Z*)-11-tetradecen-1-ol acetate (*Z*-type pheromone); (5) $R_1=F$, $R_2=R_3=R_4=R_5=R_6=R_7=R_8=H$, (±)-(*Z*)-2-fluoro-11-tetradecen-1-ol acetate; (6) $R_8=F$, $R_1=R_2=R_3=R_4=R_5=R_6=R_7=H$, (*Z*)-14-fluoro-11-tetradecen-1-ol acetate; (7) $R_6=R_7=R_8=F$, $R_1=R_2=R_3=R_4=R_5=H$, (*Z*)-14,14,14-trifluoro-11-tetradecen-1-ol acetate; (8) $R_4=R_5=R_6=R_7=R_8=F$, $R_1=R_2=R_3=H$, (*Z*)-13,13,14,14,14-pentafluoro-11-tetradecen-1-ol acetate; (9) $R_2=R_3=F$, $R_1=R_4=R_5=R_6=R_7=R_8=H$, (*Z*)-10,10-difluoro-11-tetradecen-1-ol acetate; (10) $R_4=R_5=F$, $R_1=R_2=R_3=R_6=R_7=R_8=H$, (*Z*)-13,13-difluoro-11-tetradecen-1-ol acetate.

ECB, a *Z*-type and an *E*-type, that respond to a 97:3 ratio of (*Z*:*E*)- and a 3:97 ratio of (*Z*:*E*)-11-tetradecen-1-ol acetate, respectively (Klun et al., 1973; Cardé et al., 1975.; Klun and Cooperators, 1975; Klun and Junk, 1977; Klun and Maini, 1979).

Structure–activity relationships (SAR) for the ECB were first investigated by Klun and Robinson (1971) and then by Chapman et al. (1978a,b), the latter of whom found that (−)-(*S*)-9-(2-cyclopenten-1-yl)nonan-1-ol acetate (2) (Table 1) was as effective in eliciting precopulatory behavior as the natural sex pheromone (1) (refers to the *Z*-type subpopulation and hereafter in this paper); a chiral acceptor for the chiral pheromone was suggested. Further studies were carried out by Schwarz et al. (1989, 1990) to provide clues for spatial and functional group requirements for activity and to define a picture of the acceptor site. Flight-tunnel activity was induced only by those compounds that had a total chain length of 13–14 carbons and in which branching at carbon-13 was limited to one methyl group or extended as a cyclopropyl group. Two analogs were attractive: (*Z*)-13-methyl-11-tetradecen-1-ol acetate (3) and (*Z*)-12-cyclopropyl-11-dodecen-1-ol acetate (4) (Table 1).

More recently, Klun et al. (1994) investigated selectively fluorinated analogs of the sex pheromone (1) (Figure 1, Table 1) to study pheromone metabolism. Because the fluorine atom is only 10% larger than the hydrogen atom, substitution for hydrogen would not cause a significant molecular volume or surface area change (Wenqi et al., 1993), but would give valuable information

on electronic effects since fluorine is so electronegative. Pheromone analogs having monofluorination (5, 6) or trifluoro-substitution (7) mimicked the pheromone, while analogs with fluorine adjacent to the double-bond (8–10) were essentially inactive.

The general hypothesis for pheromone binding involves a three-pronged interaction of the pheromone with the acceptor: (1) by hydrogen bonding to and/or electrostatic interaction with the polar functional group, (2) electrostatic interaction with the double-bond, and (3) much weaker dispersion forces that are responsible for binding the terminal alkyl group (Liljefors et al., 1985). By altering electrostatic potentials at specific sites in a pheromone molecule using fluorine substitution, one can localize an electrostatic potential or change the charge intensity on adjacent atoms that interact with an oppositely charged area on an acceptor site.

Electrostatic potential is defined as the interaction energy between a point positive unit charge and the atoms of a structure; there are two contributions to the value of the electrostatic potential at any point: a nuclear contribution, and a contribution from the electrons within their molecular orbitals. Reasonable approximations can be found by using atom-based point charges, such as those provided by the Gasteiger method (Gasteiger and Marsili, 1980). For electrostatic potential maps, the minimum global, maximum global, and numerous maximum local positions (levels) can be located as "map extremes." This technique gives a number of key points in molecular space to simplify and aid in the identification of maximum and minimum electrostatic potential sites. A series of molecules that act at the same acceptor site may be expected to share common acceptor-interaction mechanisms. Positions of map extremes, which can reflect these acceptor interactions, could be a good basis on which to explain acceptor fit.

Since the electronegative fluorine-substitution in the ECB pheromone produces electrostatic changes, we explored these changes via computer molecular modeling to quantify their effects on activity. Thereby, we refined the ECB pheromone SAR model and thus learned more about the likely characteristics of its putative acceptor site.

METHODS AND MATERIALS

The ECB pheromone (1) (Figure 1, Table 1) and its fluoro analogs [5 (Oliver et al., 1994) and 6–10 (Klun et al., 1994)] were synthesized. Compounds 2–4 were also synthesized (Chapman et al., 1978a; Schwarz et al., 1989). The resulting acetates were tested in the field, and some were assayed using flight-tunnel techniques (Table 1).

The pheromone and its fluoro analogs were modeled via the computer

molecular modeling program, Chem-X (July 1993 VAX version, Chemical Design Ltd., Oxford, England). Lowest-energy conformations were determined using molecular mechanics (MM) (Burkert and Allinger, 1982; Clark, 1985) with modified force-field parameters and Gasteiger charges. Electrostatic potential maps with global and local electrostatic maxima and minima and three-dimensional (3D) Van der Waals surface maps were computed.

RESULTS AND DISCUSSION

Lowest-energy MM minimized conformations of the attractive compounds, (−)-(*S*)-9-(2-cyclopenten-1-yl)-9-nonan-1-ol acetate (2), (*Z*)-13-methyl-11-tetradecen-1-ol acetate (3), and (*Z*)-12-cyclopropyl-11-dodecen-1-ol acetate (4) (Table 1) have molecular volumes and surface area ranges of 219–240 $Å^3$ and 231–258 $Å^2$, respectively. The lowest energy MM minimized conformations of the ECB pheromone (1) and its attractive fluoro analogs (5–7) had similar ranges of 222–237 $Å^3$ and 235–251 $Å^2$ for molecular volume and molecular surface area, respectively. Fluorine substitution for hydrogen results in only a small increase in the molecular volume and surface area. However, molecular volume and surface area are important for activity since they represent steric bulk; previous work (Schwarz et al., 1990) showed that attractiveness to ECB males required a chain length of 13–14 carbons in which branching at carbon-13 was limited to one methyl group or was extended as a cyclopropyl group.

There appear to be ranges for attractive compounds (1, 5–7) of about 222–237 $Å^3$ and 235–251 $Å^2$ for molecular volume and surface area, respectively. However, the unattractive fluoro analogs (8–10) also had similar 232–246 $Å^3$ molecular volume and 242–257 $Å^2$ molecular surface area ranges. Therefore, molecular volume and surface area ranges in this series of compounds (1, 5–10) are not important SAR issues since they are so similar.

Thus, some other factor had to be considered. Since fluorine is very electronegative, the fluorinated ECB pheromone analogs (5–10) would be expected to have electron distributions different from the natural pheromone. Determination of dipole moments of the pheromone and its fluoro analogs via Chem-X molecular modeling revealed no correlations with activity because dipole is an average or overall electronic characteristic of the molecule. On the other hand, electrostatic potential maps for the pheromone (1) (Figure 2) and its fluoro analogs (5–10) revealed distinctive variations in potential on the surface of the molecules at numerous map extremes. Some sites in the molecules are strongly electronegative, whereas other sites are slightly or intensely electropositive; the patterns of these are likely important in the acceptor interaction because it is these patterns of local variability in electrostatic potential that interact with similar patterns of opposite electrostatic potentials on the acceptor.

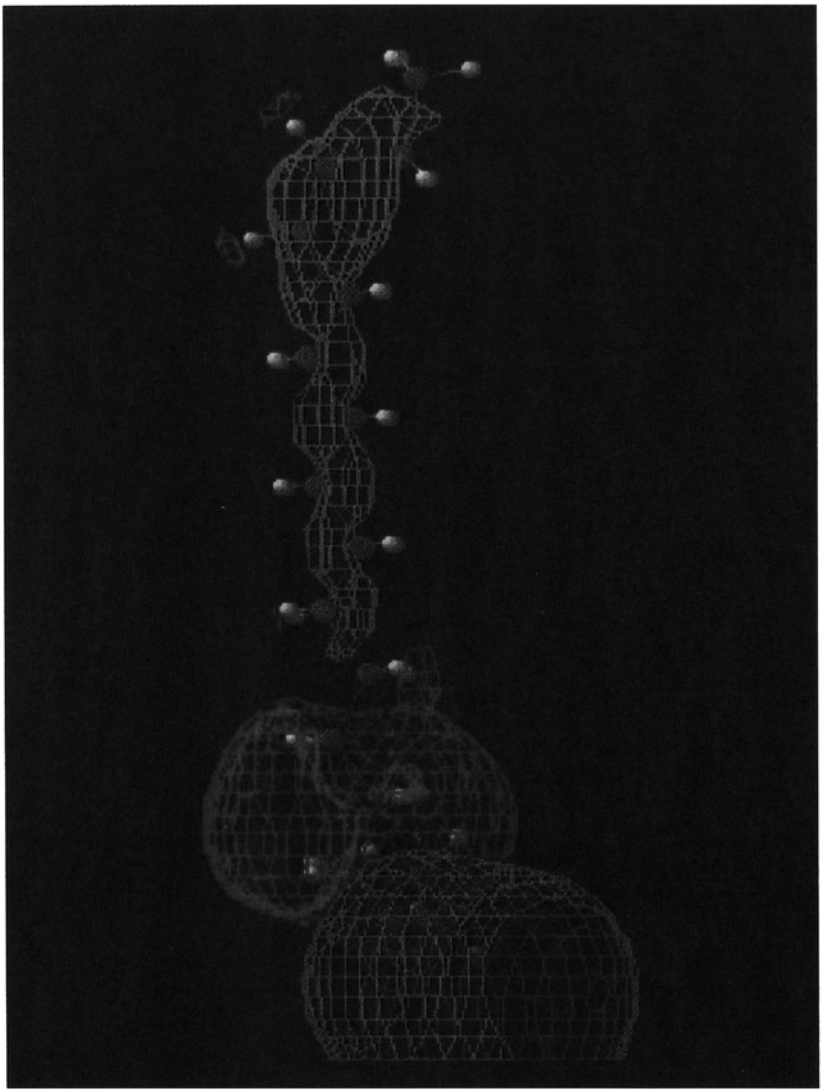

FIG. 2. Electrostatic potential 3D map of ECB pheromone (Z)-11-tetradecen-1-ol acetate (1). Standard contours: cyan < -10.0 kcal; red > 10.0 kcal; significance = 20; grid density = 2.5 contours/Å.

The global minima for 1, and 5–10 were between −78 and −83 kcal on the acetate end of the molecule. The global maxima were on the acetate end for 1 and 5 and on the terminal end of the chain for 6–10. However, 6–10 had the second or third local highest maxima (footnotes, Table 1) at the acetate end, comparable with 1 and 5. Considering this, there was a range of 41–61 kcal on the acetate end for compounds 1, and 5–10.

In contrast, the local maxima for the protons of the *Z*-double bond (1, 5–10) showed consistent differences between those analogs that exhibited attractiveness and those that did not. The electronegative withdrawing effects of the fluorine were particularly evident when fluorine was present on carbon atoms adjacent to the double-bond (8–10) (e.g., Figure 3, 10). The local range of electrostatic potential for the proton on carbon-11 of the ECB pheromone (1) and the attractive fluoro analogs (5–7) was 12–19 kcal at the sixth to eighth highest local maximum extreme; the local range for the proton on carbon-12 for the same substances was also 12–19 kcal but at the fifth to seventh highest local maximum extreme. Attractive (−)-(*S*)-9-(2-cyclopenten-1-yl)nonan-1-ol acetate (2), (*Z*)-13-methyl-11-tetradecen-1-ol acetate (3), and (*Z*)-12-cyclopropyl-11-dodecen-1-ol acetate (4) also had local maxima within the range of 12–19 kcal for protons on the double bond; they also had a global maxima range of 41–61 kcal and a global minima range of −78 to −83 kcal.

The inactive fluoro analogs (8–10) had electrostatic potentials of the double-bond hydrogens that were outside the range of 12–19 kcal. Visual examinations of the potential maps (8–10) (e.g., Figure 3, 10) showed great distortion of the partial positive charges around the double bond (in red) as compared to the pheromone (1) and the active fluoro analogs (5–7) (e.g., Figure 2, 1). This may characterize the basis for the inactivity of compounds 8–10.

The acceptor for the ECB pheromone (1) has chiral recognition, based upon the attractiveness of (−)-(*S*)-9-(2-cyclopenten-1-yl)nonan-1-ol acetate (2) as opposed to its much less active antipode (Chapman et al., 1978a). However, chirality was not investigated in this work.

Although the ECB pheromone contains 3% of the *E*-isomer, we did not address this component in our study, nor did we address the *E*-type pheromone/acceptor.

CONCLUSIONS

Three characteristics of 1–7 appear to be in common for ECB attractiveness. The first characteristic is demonstrated by the general ranges of 222–237 $Å^3$ molecular volume and 235–251 $Å^2$ molecular surface area that are reflected in the required chain length of 13–14 carbons in which branching at carbon-13 was limited to one methyl group or was extended as a cyclopropyl group (Schwarz

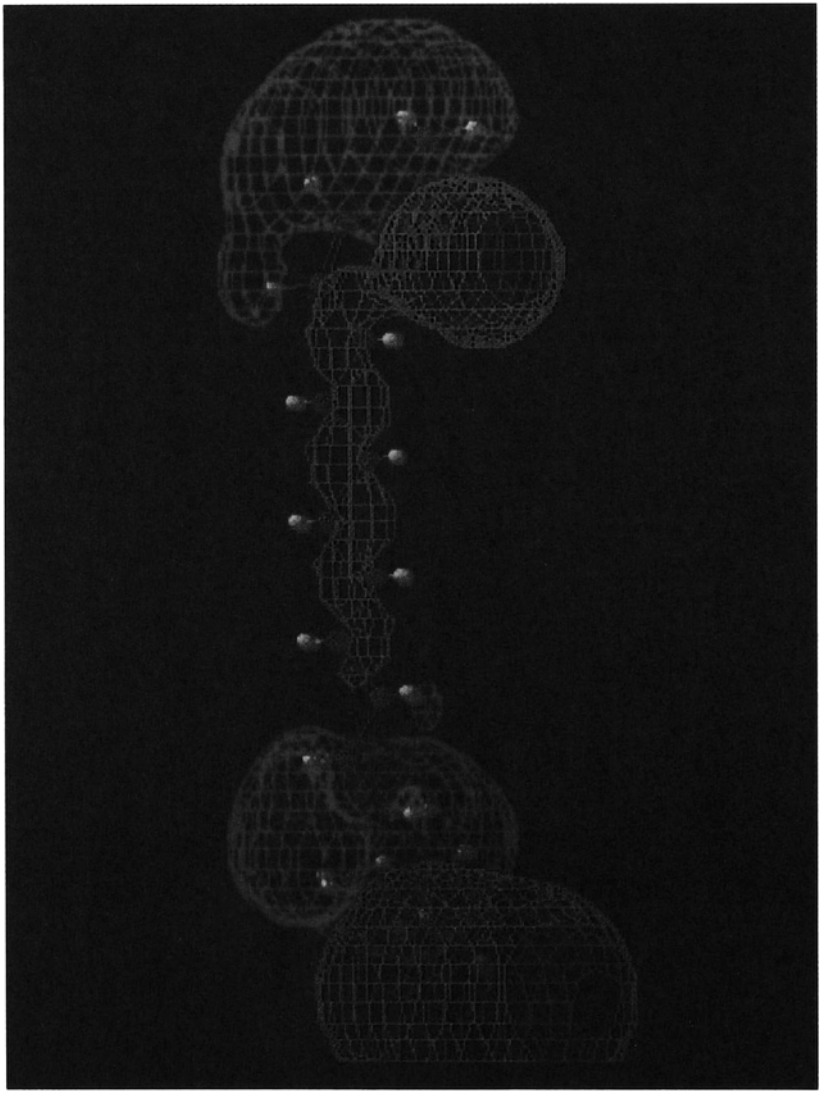

FIG. 3. Electrostatic potential 3D map of the nonattractive (Z)-13,13-difluoro-11-tetradecen-1-ol acetate (10). Standard contours: cyan < -10.0 kcal; red > 10.0 kcal; significance = 20; grid density = 2.5 contours/Å.

et al., 1989). However, these ranges are not distinguishing characteristics since the inactive fluoro compounds (8–10) also show these ranges.

The second characteristic is an electrostatic potential global minimum range of −78 to −83 kcal on the acetate end of the molecule and an electrostatic potential maximum range of 41–61 kcal (global or local) also on the acetate end. However, these also were not distinguishing characteristics since most of the inactive compounds (8–10) fell within these ranges.

The third characteristic is an electrostatic potential of 12–19 kcal for the proton on carbon-11 (sixth to eighth highest local maximum) and for the proton on carbon-12 (fifth to seventh highest local maximum). Greater values for the inactive fluoro compounds (8–10) than these ranges are consistent with absence of attractiveness. These ranges would be considered distinguishing characteristics for attractiveness.

These three characteristics are for the data set of attractive compounds (1–7) studied. These results and conclusions should be considered in the design of ECB pheromone mimics and analogs for metabolic studies. To maintain pheromonal activity, it appears essential to avoid the substitution of fluorine on carbons adjacent to the double-bond.

These characteristics can be related to the Liljefors et al. (1985) three-pronged pheromone/acceptor interaction model as follows: (1) the overall electrostatic interaction of pheromone–acceptor as reflected in the molecular volume and surface area characteristics that include some very weak potentials, (2) the electrostatic potential ranges of the functional groups for the above second characteristic, and (3) the very important distinguishing electrostatic potential range for the double-bond hydrogens.

Acknowledgments—We thank Dr. James Oliver for the sample of (±)-(*Z*)-2-fluoro-11-tetradecen-1-ol acetate and for comments and suggestions on the manuscript.

(Received March 17, 1995; accepted July 22, 1995)

Abstract—The presence of intraspecific variation in toxicity and its relationship with biological or ecological factors were studied in the sponge *Crambe crambe*. Within-specimen (periphery and central part), between-size (< 1000 mm^2 in area, between 1000 and 10,000 mm^2 and $> 10{,}000$ mm^2) and between-habitat (well-illuminated and dark communities) variations in toxicity were evaluated by the Microtox bioassay. Quantitative differences were detected that were not attributable to within-specimen variation but to size and habitat effects. Habitat comparisons showed that sponges in the shaded habitat were significantly more toxic than those of the well-illuminated community. Sponges of the smaller size classes displayed significantly less toxicity than the medium-sized specimens. Results are interpreted under the optimal defense theory and their ecological implications are considered.

Key Words—Chemical ecology, natural toxicity, spatial variation, defensive strategy, encrusting sponges.

INTRODUCTION

The field of chemical ecology in marine environments is rapidly expanding, building on the field of the chemistry of marine natural products. During the last few decades, numerous new compounds have been isolated from marine

*To whom correspondence should be addressed.

organisms (e.g., see reviews by Faulkner, 1984, 1986, 1991), many of them with interesting pharmacological properties (Fautin, 1988; Hall and Strichartz, 1990). Recently, there has been increased interest in understanding whether such properties have a significant role in ecological processes. In the better-known field of terrestrial chemical ecology, laboratory and field investigations have led to better understanding of the role that chemistry plays in plant growth and germination (Rice, 1984; Carral et al., 1988), patterning of vegetation (Rice, 1984; Stowe, 1979), or plant–herbivore relationships (Rhoades and Cates, 1976; Harborne 1988), to cite some examples.

Defense mechanisms analogous to those reported for terrestrial environments may be expected in their marine counterparts, benthic communities. Similar pressures may determine the evolution of toxic compounds causing inhibition of growth in plants (Rice, 1984) and sessile organisms (Sammarco et al., 1983 Sullivan et al., 1983; Porter and Target, 1988) or inhibition of seed germination (Rice, 1984; Carral et al., 1988) and settlement inhibition (Davis et al., 1991). These processes may function as a strategy for space acquisition and maintenance, influencing spatial patterning. If toxicity has been selected as a defensive mechanism, it must have been as a consequence of coevolution with competitors (in a wide sense). When the nature of such competitors is environmentally determined, one can expect a variation of toxicity in relation to ecological conditions. These patterns are well documented in terrestrial environments and, together with experimental work, have provided the basis for modeling the production of chemical defenses. Variation in defense investment has been reported, for example, as a function of plant size, intraplant distribution, resource availability, growth rate, stress, and herbivore pressure (Feeny, 1976; Rhoades and Cates, 1976; McKey et al., 1978; Coley et al., 1985; Fagerström et al., 1987; Basey and Jenkins, 1993).

Although similar patterns might be expected in benthic communities, there is a lack of information on naturally occurring toxicity as compared with terrestrial ecosystems. Few studies have specifically addressed toxicity variation in benthic communities, although it has been detected in numerous species (e.g., bryozoans: Harvell, 1986; algae: Moon and Martin, 1985; Hay et al., 1988; Paul and Van Alstyne, 1988; gorgonians: Pawlik et al., 1987; Harvell and Fenical, 1989; soft corals: Coll et al., 1982; Harvell et al., 1993; and sponges: Thompson et al., 1985). To our knowledge, the works by Thompson et al. (1987), Yates and Peckol (1993), Harvell et al. (1993), and Maida et al. (1993) are the only studies where intraspecific ecological variation in chemical defenses was specifically addressed. Thompson et al. (1987) demonstrated that the variability in diterpene composition of the sponge *Rhopaloeides odorabile* is caused by the environmental conditions under which the sponge lives rather than to genetic differences. Yates and Peckol (1993) detected higher polyphenolic levels in *Fucus vesiculosus* in a community with low nitrogen availability as

compared with a nitrogen-rich site. Harvell et al. (1993) found quantitative and qualitative differences in the toxic compounds of the gorgonian coral *Briareum asbestinum* associated with site and depth. Higher levels of compounds were detected in corals in deeper waters, where levels of predation and productivity rates were lower (but see Paul and Van Alstyne, 1988, for contrasting results in a seaweed species). Maida et al. (1993) detected significant differences in the relative production of three toxic substances in the soft coral *Sinularia flexibilis* as a function of size and habitat. A greater production of a molecule involved in spatial competition was reported for specimens from a highly diverse and competitive site.

The present study examined the naturally occurring toxicity of the poecilosclerid encrusting sponge *Crambe crambe* (Schmidt). There were several reasons for choosing this species. First, *C. crambe* shows an unusually wide range of distribution. It is present in numerous western Mediterranean communities (from 0 to 60 m in depth), where it is one of the most abundant sponge species. Second, this species is known to possess an array of highly active metabolites (Berlinck et al., 1990, 1992; Jares-Erijman et al., 1991) with diverse ecological roles, such as antifouling, antipredatory, or as a space competition mechanism (Becerro et al., 1994a; Becerro, 1994). Third, most of the biological functions of sponges are accomplished at the cellular level. No circulatory or coordination system has been found, resulting in a lower degree of integration at the individual level with respect to other Metazoa. Moreover, sponges present an unusual organization; they are formed by the iteration of canal systems, which are labile modular units much more variable in space and time than the typical, more stable, units such as leaves or polyps. Taken together, these facts raise interesting questions as to whether the production of chemical defenses is coordinated in the whole sponge or whether there may be intraindividual variation.

Toxicity assessment can be performed through a fine-scale quantification of the molecules responsible for it using either HPLC (Harvell et al., 1993) or ^{1}H NMR (Maida et al., 1993). A second approach is to quantify toxicity in itself through a sensitive and precise bioassay. This approach was adopted in this study due to the high number of active compounds present in *Crambe crambe*. Besides, synergistic effects may be easily overlooked if separate quantification of molecules is performed. Furthermore, if a nontoxic compound can act synergistically with a toxic one, the former will not be considered at all unless its connection with the toxic agent is known. Berenbaum and Neal (1985), for example, documented in plants the increased effectiveness of a deterrent metabolite due to the action of a nondeterrent, cooccurring compound. The substances presumably responsible for the activity of *C. crambe* belong to two families of compounds: crambines and crambescidines, each with several molecules whose interactions are not known and whose isolation, even partial, requires a very laborious process (Berlinck et al., 1990). Therefore, we thought

it more advisable, in order to interpret ecological roles, to quantify the general toxicity per sponge unit weight, rather than trying to quantify one or several of these compounds.

The purpose of this study was to analyze the toxicity of *C. crambe* in relation to size and environment. Morphological changes, as well as variations in investment in structural components and reproduction as a function of size and habitat, have already been reported in this species (Becerro et al., 1994b; Uriz et al., 1995). The sponge seemed to respond to shaded habitats, which were space-limited, macrozoobenthos-dominated assemblages, by increasing directional growth and strengthening physical structures with increasing area. In contrast, specimens from well-illuminated, algae-dominated habitats showed an increase in organic matter, but not in allocation to structural components, with increasing size. Uriz et al. (1995) interpreted these results as a consequence of the space competitors present in the space-limited community. Accordingly, a higher investment in chemical defense may also be expected, and this is the hypothesis set forth in this study. Specifically, an attempt was made to answer the following questions: (1) is there intraspecimen variation in the toxicity of *Crambe crambe*? (2) is there intraspecific variation? and if so, (3) is this variation size dependent? (4) is this variation habitat associated? and (5) is there any relationship between the two factors?

METHODS AND MATERIALS

Sampling. All the specimens used in this study were collected in the locality of Blanes (NE of Spain, western Mediterranean), April 1992. The site was a 2 to 3-m-wide, 40-m-long gorge with north- and south-facing walls. Therefore, environmental conditions (temperature, food availability, underwater currents) were comparable on both walls, except for the amount of incident light. The north- and south-facing walls correspond to a shaded and a well-illuminated habitat, respectively. Communities on such walls showed remarkable differences in species composition: a space-limited community mainly dominated by encrusting organisms was found on the shaded wall, whereas the well-illuminated habitat was dominated by algae, and patches of free substratum were easily observed (see Becerro et al., 1994b, for a general description of these communities). Three size categories were established, according to results of Becerro et al. (1994b) in each of the two contrasting communities: (1) < 1000 mm^2 in area, (2) 1000 to 10,000 mm^2, and (3) $> 10{,}000$ mm^2. Ten specimens for each category of size and habitat were randomly selected. Samples were collected as follows: one small piece (≈ 1 cm^2) was taken from the central part of the sponge and three smaller pieces (adding up to approximately 1 cm^2) were picked up from the periphery in an attempt to reduce the expected heterogeneity

along the sponge border. Separate sampling in the center and periphery was not possible in the smallest size class, and intraindividual variability was assessed only in specimens from the intermediate and largest size classes. The samples were individually placed in plastic bags and taken to the laboratory for chemical extraction of the toxic compounds.

Extraction Procedure. A moderate number of active compounds are known in *Crambe crambe:* up to four crambines (plus several homologs) and four crambescidins have been described (Berlinck et al., 1990, 1992; Jares-Erijman et al., 1991) (Figures 1 and 2), and the list may not be complete yet. These compounds consist of a long, nonpolar chain with a polar head, which confer to them a mixture of lipophilic and hydrophilic properties, making them amenable to solution with solvents of different polarity. Preliminary studies were conducted to determine a method for easy extraction of these families of compounds. These studies are explained in full in Becerro (1994) and can be summarized as follows: (1) after trying all possible sequences with solvents covering a large range of polarities (hexane, dichloromethane, and water), we found that a single extraction with dichloromethane (DCM) takes up all toxic compounds, and no toxicity was detected if the tissues were extracted afterwards with any of the other solvents; (2) subfractioning the DCM extract with silica-gel columns in a gradient from petroleum–ether, petroleum ether–ethyl ether (decreasing ratios), ethyl ether, chloroform–methanol (8:2) to methanol showed that the toxicity was due to compounds in the most polar extreme of the range of metabolites solubilized by the DCM; (3) toxicity tests on the DCM fraction alone

Crambescidin 816 $R_1 = R_2 =$ OH, n = 13
Crambescidin 830 $R_1 = R_2 =$ OH, n = 14
Crambescidin 844 $R_1 = R_2 =$ OH, n = 15
Crambescidin 800 $R_1 =$ H, $R_2 =$ OH, n = 13

FIG. 2. Schematic representation of the crambescidines (from Jares-Erijman et al. 1991).

showed the same effect as that found after pooling the fractions obtained by successive extractions with hexane, DCM, and water. Thus, no synergistic effect with molecules not extracted by DCM alone was expected.

Once in the laboratory, each sample was carefully cleaned of any foreign body (such as polychaete tubes, barnacles, etc.) under a stereomicroscope and ground. Ten milligrams dry weight of sponge were then extracted three successive times (5, 15, and 30 min) with 5 ml of DCM (Becerro, 1994). The three fractions were pooled, the solvent evaporated under reduced pressure, and the residue homogenized in an ultrasonic bath in 20 ml of distilled water. This led to a concentration of 500 ppm relative to the initial sponge dry weight.

Toxicity Analyses. Since we wanted a fine quantification of the general toxicity of the sponge, we sought a biological test that permitted accurate toxicity readings. On the other hand, the test had to be ecologically significant if the results were to be interpreted in terms of the ecological role of chemical defenses. Several such roles are possible (Coll, 1992), and it is not feasible to devise quantitatively accurate tests for all potential ecological functions of the bioactive substances or for all potential competitors or predators. Instead, we engaged in a number of tests with ecological meaning (antilarval, antibacterial, cytotoxic, and antipredator with sympatric species) and tested their correlations with an easy, accurate test (Becerro, 1994; Becerro et al., 1995). As a result, we adopted a standardized procedure, the Microtox bioassay (Ribo and Kaiser, 1987; Kaiser and Ribo, 1988) as a precise method for measuring toxicity changes. This method is based on measurements of bioluminescence in living cell suspensions of the deep-sea bacterium *Photobacterium phosphoreum*. This proved to be the best test in terms of repeatability and precision and, although of little ecological meaning per se (it is hard to envisage how this particular bacteria

could affect *Crambe crambe* in nature), it was well correlated (Becerro, 1994; Becerro et al., 1995) with the other ecologically significant assays ($r = 0.98$ with the paper diffusion test with sympatric bacteria, and $r = 0.97$ with the sea urchin assay) and was used here as a precise tool for measuring variations in toxicity.

Freeze-dried bacteria were reconstituted at 4°C. In the basic procedure, Microtox requires four concentrations and one control per sample. The initial toxic concentration tested was 225 ppm (relative to sponge dry weight), and a dilution factor of two was used for the three successive concentrations (see Becerro et al., 1995, for a full description of this procedure). Experiments were run for 5 min at a temperature of 15°C. The light produced by the bacteria was recorded before and after the experiments in gamma units (GU):

$$GU = (R_t * I_0/I_t) - 1$$

where R_t is the correction factor (light differences in the control), I_0 is the light at time 0, I_t is the light at time t. Finally, the concentration at which GU is equal to 1 (50% of light reduction or estimated median effective concentration, EC_{50}) was calculated by fitting the data in logarithmic scale to a linear regression. The toxicity units (TU) used in this study measure quantitative changes in the samples and were calculated as $100/EC_{50}$.

Further information on the toxic behavior of the compounds can be obtained through the study of the slope of the regression function mentioned above. Two samples may have similar EC_{50} values but different slopes, indicating qualitative differences in the compounds responsible for the toxicity or changes in the relative amounts of these compounds. Consequently, the slope of the regression lines was used as a variable to measure qualitative changes in the samples. Differences in the slope indicate differences in the relationship between concentration of toxic compounds and toxicity, i.e., the higher the slope, the more effective the toxins.

Numerical Methods. Within-sponge differences in toxicity (center–periphery) were studied by paired-sample t-test analyses (Zar, 1984). These tests were performed for medium and large specimens (the only ones from which separate samples from the center and periphery were taken). The inclusion of the smallest size class for analysis of size and habitat effects rendered the data heteroscedastic (F_{max} test; Bakus, 1990) so that a rank transformation (Potvin and Roff, 1993) was applied prior to further parametric tests. Two-way analyses of variance (ANOVA) were performed, using size classes (three levels) and habitat (two levels) as factors. The former is clearly a fixed factor, and the second must also be considered fixed as the two communities studied were not selected at random, but specifically chosen because they were a priori expected to differ (Bennington and Thayne, 1994). We therefore restrict the conclusions to these two types of wall, and we do not mean to use the results as an estimate of the general variation

among all possible habitats. Whenever we speak of a habitat effect, therefore, we refer exclusively to the two habitats considered. Both variables, TU and slope, were analyzed by the same methods. The analyses were performed using the Systat 5.0 package.

Unplanned pairwise comparisons were performed following the Ryan's Q method (Einot and Gabriel, 1975; Day and Quinn, 1989), a stepwise procedure similar to the more familiar Student-Newman-Keuls (SNK) test, but which differs from it in using a lower α level at each step except the first one. Day and Quinn (1989) compared the performance of several multiple comparison methods using Monte Carlo simulation, and found that the Ryan's Q procedure produced the best approximation between the probability of type I errors and the nominal α level. The overall α for each set of multiple comparisons was set at 0.05.

RESULTS AND DISCUSSION

Results of the within-sponge TU variation are shown in Table 1. No toxicity differences were detected between the center and periphery of the sponges by the paired-sample t-tests, either considering all samples together or analyzing separately each combination of size and habitat. The two readings per sponge were therefore averaged to give a single value for further analyses. Table 2 summarizes the outcome of the two-way ANOVA of TU using size class and habitat as factors, whose values are graphically represented in Figure 3. Both main factors proved significant, and the interaction was not. A higher overall toxicity did exist in the sponges from the sciaphilous environment. Unplanned comparisons between size classes (across habitats) showed that the sole significant pairwise comparison (Ryan's Q, $\alpha = 0.05$) was the one between small and medium-sized individuals (the latter featuring higher toxicity, Figure 4).

Error	11336.275	52	218.005		

The slope of the toxicity function also showed no within-sponge variation (Table 3) either analyzed by groups (habitat and size) or as a whole. Slope values for each habitat and size category are depicted in Figure 4. Two-way ANOVA of the slope values (Table 4) showed that neither the interaction term ($P = 0.604$) nor the main factors (habitat, $P = 0.691$; size, $P = 0.142$) had a significant effect.

The sponge *Crambe crambe* showed, therefore, a remarkable between-specimen variation in toxicity. This variation was related to size and habitat. Both factors significantly influenced the extent of toxicity found, although no qualitative differences were detected (as evaluated by the slope of the toxicity function) in the extracts. On the other hand, within-specimen (center–periphery) variation was not observed, in contrast to reports on other benthic organisms (Paul and Van Alstyne, 1988; Wylie and Paul, 1989; Harvell and Fenical,

1989). It was suggested in these studies that such differences were related to the chance of being attacked by herbivores, since chemical defenses were greater in those parts that lacked morphological defenses and/or were at a greatest risk or herbivory. No predators are known for *C. crambe*, but a comparable pattern against competitors for space could be expected. Although the sponges investigated did not present these expected variations and seemed to respond as a whole, unpublished results by the authors show that intraspecimen variation can be found in other seasons, corresponding to periods in which competition with neighbors is more intense.

Although changes in toxic composition have been reported for this species, and Berlinck et al. (1992) pointed out that the relative proportion of active substances in *C. crambe* changed in their samples, we did not find "qualitative" differences in toxic behavior in our study (measured as the slope of the toxicity function), indirectly suggesting that the composition of the toxic compounds remains fairly constant among levels of the factors investigated. Harvell et al. (1993) reported quantitative and qualitative differences in the chemical defenses of gorgonian coral. They provided evidence that qualitative composition was fixed and depended on geographic zone, while levels (quantity) of defenses were environmentally modulated, which is in good agreement with the results obtained in our study.

Interpretation of the quantitative differences found for toxicity (TU values) is based on correlational evidence, but under the assumption that the production of chemical defense compounds is metabolically costly, investment in defensive substances must be optimized with respect to the organisms' needs and to the other terms of the energy budget. This is the basis of the optimal defense theory (Rhoades, 1979; Coley et al., 1985; Fagerström et al. 1987; Skogsmyr and Fagerström, 1992), and from this perspective some explanations can be proposed.

Between-habitat differences must be interpreted as a function of the parameters changing from one wall to another. Water temperature, amount of food, and most abiotic parameters can be recognized as being comparable on the two walls. Light incidence, on the other hand, is clearly different between them. As no photosynthetic symbionts were observed in the many sponges studied by electron microscopy (authors' unpublished results), a direct effect of light on this species is not likely. The biotic interactions, on the other hand, were clearly different since diverse communities developed in both sites studied, as a consequence of the different amount of light received. The space is saturated in the shaded habitat, whereas patches of bar substratum are frequently produced in the well-illuminated habitat. Moreover, slow-growing, surface-dependent invertebrates or calcareous, encrusting algae are the dominant forms in the dark habitat, while the photophilic community was dominated by erect, soft seaweeds whose abundance changed markedly with season. The higher turnover of the

patches of bare substratum in this last habitat should favor investment in rapid growth when the conditions are favorable rather than in skeletal or chemical defenses (Jackson, 1977; Russ, 1982).

In contrast, the latter mechanisms should prevail in the shaded, space-saturated habitat. This hypothesis is supported by the different growth shape (Becerro et al., 1994b) and resource allocation (Uriz et al., 1995) of *C. crambe* in these two habitats. As a whole, therefore, we interpret the higher toxicity in the shaded wall as a result of differential strategies of space competition. The evolution of chemical defense strategies in marine organisms responds to highly diverse pressures (Bakus et al., 1986; Davis et al. 1989; Wahl, 1989), and more experimental work is needed to confirm the underlying process determining the pattern observed in this study. In particular, predation or fouling pressures should be considered, although they do not seem relevant in this case, as no predators or foulers have been observed in several years of study of this species in different localities and habitats.

Between-size differences can also be interpreted as a function of differential needs at each size stage. Encounters with space competitors are clearly a function of size, so a higher production of toxic substances with size was expected in principle. On the other hand, changes in toxic production with size may be tied more to internal, physiological parameters than to external factors. Although size and age are largely decoupled in modular, indeterminate-growing organisms (Sebens, 1987; Turon and Becerro, 1992), it is nevertheless expected that small sponges invest more in somatic growth and space acquisition, leaving fewer resources available for chemical defense.

The general pattern of variation found for toxicity values in Figure 3 points to an increase in toxicity from small to medium-sized specimens in both habitats, while the values remained constant (photophilic sponges) or decreased (sciaphilous specimens) from medium-sized to larger forms. In fact, if we restrict our analysis to the sciaphilous sponges and perform a Ryan's Q test among the three size classes, we find that the medium-sized specimens are significantly more toxic than the other two size classes. The lower toxicity displayed by the smallest and largest sponges can be due to the fact that they devote energy preferentially to growth and reproduction, respectively (an increased investment in reproduction with size has been found in this species; Uriz et al., 1995). Moreover, a more favorable area–perimeter relationship in large sponges may result in a lower energetic demand for defense interactions along the border (Adler and Harvell, 1993).

The values for the slope featured largely the same general pattern as the toxicity values (Figures 3 and 4). However, their large standard errors prevented significant differences from showing up in the analyses (possibly a sample size larger than 10 specimens per size and habitat would have been necessary). In fact, a Spearman correlation coefficient between the mean values of TU and

slope per habitat and size showed that both were significantly correlated (r_s = 0.942, $N = 6$, $P < 0.001$).

In addition, *C. crambe* features highly effective toxins. The toxins are active at very small concentrations (Martin and Uriz, 1993; Becerro, 1994), and toxicity is rapidly enhanced by small increments in the toxin concentration, as indicated by the global values of the slope of the toxicity function (2.23 ± 0.05, mean ± SE). With such a slope, a 45% increase in toxin concentration would produce an approximately twofold toxicity increase. Both characteristics fit well with the hypothesis of a basal investment in toxic production and an ability for a precise regulation of the toxicity as a response to environmental pressures.

In conclusion, we did not find differences in toxicity between the center and the periphery of the sponges, although this study demonstrated that habitat and size exerted an influence in the levels of toxins encountered. The factors underlying the variation encountered in this study remain unclear, although the evidence suggests that space competition may be a key factor modulating toxin production. In this regard, Maida et al. (1993) also found higher levels of a molecule involved in spatial competition in specimens of the soft coral *Sinularia flexibilis* from a highly diverse and competitive site. The results of the present study also point to a chemically mediated interference competition, with higher toxicity in the sponges dwelling in the more space-saturated habitat. Whether this pattern of variation is followed by other chemically defended organisms is unknown. More research is needed to understand the processes modulating the production of chemical defenses and investment in biological parameters before an integrating perspective can be formulated.

Acknowledgments—This study is a part of a PhD dissertation supported by the Basque Government to M.A.B. The authors are indebted to G. Benito and the staff of the "Junta de Sanejament" of the Environment Department, Generalitat of Catalunya, for providing Microtox and laboratory facilities. The Spanish Marine Resources and Aquaculture Programme (project CICYT MAR91-0528) and Commission of the European Communities (project MAST-CT91-004) provided funds for this research. Thanks are due to Javier Lozano and to Jordi Galera for their help in the extraction process.

(Received March 20, 1995; accepted July 23, 1995)

Abstract—By means of gas chromatographic, mass spectrometric, and micropreparative methods *N,N*-dimethyluracil and actinidine were identified as two ethologically active compounds in the ponerine ant *Megaponera foetens*. The synthesized poison gland compound *N,N*-dimethyluracil released trail-following behavior, whereas actinidine, found in the pygidial gland, stimulated ants to leave the nest, possibly in an alarm reaction. Biological activity of the synthetic samples were confirmed by behavioral experiments and electroantennogram responses with worker antennae.

Key Words—*Megaponera foetens*, Formicidae, poison gland, pygidial gland, trail pheromone, recruitment pheromone, *N,N*-dimethyluracil, 1,3-dimethyl-2,4(1*H*,3*H*)-pyrimidinedione, actinidine, electroantennogram.

INTRODUCTION

Colonies of the African ponerine ant *Megaponera foetens* (Fab.) (Hymenoptera: Formicidae) conduct highly organized predatory raids on termites (Lèvieux, 1966). The organization of this group foraging behavior has been analyzed in great detail by Longhurst et al. (1978, 1979) and by Lepage (1981). According

to Longhurst et al. (1979), the major source of the trail pheromone involved in group raiding in *M. foetens* is the poison gland. Recently Hölldobler et al. (1994) discovered a second component of the chemical recruitment process that originates from the pygidial gland. The latter secretions have a more powerful recruitment effect, whereas poison gland secretions contain a much longer-lasting orientation cue.

In the present paper we report on the chemical identification of a trail pheromone compound from the poison gland and an alerting pheromone from the pygidial gland in *Megaponera foetens*.

METHODS AND MATERIALS

Ants. Nine colonies of *Megaponera foetens* were excavated in the Comoé National Park, Ivory Coast, and used for laboratory experiments in Würzburg and Erlangen, Germany. The ants were housed and maintained in laboratory nests similar to the procedures described in Hölldobler et al. (1994).

For the chemical analyses of the glandular secretions, poison glands or pygidial glands, respectively, were dissected under water after the ants had been killed by placing them for a few minutes in a freezer. In order to extract glandular secretions, 10 organs of a kind were kept in 100 μl solvent in a freezer for at least 24 hr. For solid injection, the dissected glands were inserted into small boron silicate tubes that were subsequently sealed.

Gas Chromatography. Gas chromatography was carried out on a Hewlett-Packard 5890 instrument fitted with a 25-m × 0.22-mm fused-silica capillary column coated with SE 30. The oven was held at 60°C for 4 min and programmed at 6°C/min to 260°C.

Micropreparative Gas Chromatography. Micropreparative gas chromatography was performed on a United Technologies Packard 438A instrument fitted with a 2-m × 4-mm glass column packed with SE 52. The effluent was split 99:1 (trap–FID) by an all-glass splitter. Gland extracts were injected and different fractions were trapped in metal U-tubes cooled in Dry Ice (Attygalle and Morgan, 1988). The material trapped was washed out with hexane and directly used for bioassays.

Gas Chromatography–Mass Spectrometry. The identification of the major components was achieved by GC-MS on a Finnigan MAT 90 instrument. A fused-silica capillary column (SE 52, 25 m × 0.22 mm) was directly coupled to the mass spectrometer (GC-MS). Helium was used as the carrier gas at a flow rate of 1 ml/min. The 70-eV EI spectra were recorded at a rate of 1 sec/scan. The samples were introduced by a solid injection method (Morgan and Wadhams, 1972).

Quantification. A solution of authentic *N,N*-dimethyluracil was used as an external standard for quantification.

Microreactions. For reduction with $LiAlH_4$ six poison glands extracted in 100 μl dry ether were treated with $LiAlH_4$. After the gas generation had stopped, water was added. Then the organic layer was separated and used for bioassays.

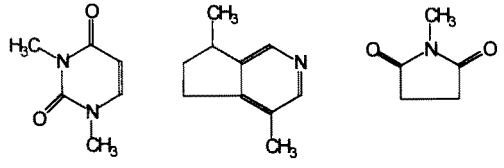
For catalytic hydrogenation, 200 μl of poison gland extract (dry in diethyl ether) was placed in a glass tube. A small portion of a blend of Pd (5%) and carbon powder was added, and the open tube was placed in a two-neck flask with an inlet tube. After the air inside the flask was removed, hydrogen was added until pressure was built up. The mixture was allowed to stand for 6 hr, then it was filtered and used directly for bioassays.

For silyl derivatization, 10 poison glands were extracted in 10 μl ether and mixed with 1 μl of *N*-methyl-*N*-trimethylsilyltrifluoracetamide (MSTFA). The solution was kept in a syringe for 10 min, and the mixture was freed from (MSTFA) by micropreparative GC and directly used for bioassay.

Synthesis. The synthesis of actinidine (**9,** Figure 1) was performed by a previously described method starting with citronellal (Fluka) via iridodial (Clark et al., 1959). In the last step, a 25% NH_3 solution was added to iridodial, which resulted in a stereoisomeric mixture of actinidine. Dimethyluracil (**1,** Figure 1) was obtained from uracil treated with methyl sulfate (Davidson and Baudisch, 1926). Authentic samples of *N*-methylsuccinimide (**4,** Figure 1), succinimide, and benzaldehyde were purchased from Aldrich.

Electroantennogram. Electrophysiological activity of the synthetic substances was investigated by a previously described electroantennogram method for Lepidoptera (Schneider, 1957), modified for smaller ant antennae (Kern and Bestmann, 1993). Briefly, the recording electrode was inserted into the distal segment of a worker antenna and the indifferent electrode was inserted into the head capsule near the antenna base after puncturing it with a sharpened tungsten needle. The test odorants, pipetted onto filter paper, in quantities ranging from 0.1 μl to 1 mg, were presented by a 1-sec air pulse led over the filter paper towards the antenna.

Bioassays. For bioassays, groups of approximately 300 workers were housed in shallow plaster nests that were covered by red glass plates (10 × 25 cm). Each nest was placed at one side of an arena (30 × 65 cm) so that the ants had direct access to the foraging area without having to cross a connecting



1 9 3

FIG. 1. *N,N*-dimethyluracil, (**9**) actinidine, and (**4**) *N*-methylsuccinimide.

bridge or to pass a plastic tube to get into the arena, as in Hölldobler and Wilson (1994, p. 216).

We tested the trail-following response of *M. foetens* workers to artificial trails drawn with the chemically identified substances. The trails were laid with a microsyringe along a 40-cm-long pencil line drawn on sheets of paper that were subsequently placed into the arena. As a control, a second trail was offered simultaneously using the pure solvent.

Both test and control trails started at the nest at the same point (0.5 cm diam.), but diverged at an angle of approximately 40°. All ants crossing a target line at the end of the artificial trails were counted. Each test started when the paper on which the trails were drawn was placed into the arena and lasted 1 min.

Additional details concerning the behavioral tests are given in the Results section.

RESULTS

As has been shown by Longhurst et al. (1979) and Hölldobler et al. (1994), poison gland secretions readily elicit trail-following behavior in *M. foetens*. For the first characterization of the trail pheromone we employed microreactions of the poison gland extracts.

Microreactions. The trail-following response of ants was tested with trails drawn with treated samples, and for comparison we also used untreated glandular extracts or pure solvent as control. A reduced activity was observed after reduction with $LiAlH_4$ and catalytic hydrogenation with Pd. This result points to a carbonyl group and at least one double bond in the pheromone structure. Other microreactions, such as silylation, did not affect trail following.

By micropreparative GC the poison gland extract was divided into different fractions, each of which was tested to determine whether or not it released a trail-following response in *M. foetens* workers. Only one fraction, with a retention time between 16 and 19 min was effective (Figure 2). The volatile poison gland components of this biologically active fraction were analyzed by GC-MS.

Similar microreactions with pygidial gland extracts were not possible, because the trail-following effect of these secretions vanished after a few minutes. We assume that in contrast to poison gland products, the biologically active components of the pygidial gland that release trail-following behavior are very volatile substances, which decompose during exposure to air or chemical reaction.

Mass Spectrometry. The chromatogram obtained from the contents of five *M. foetens* poison glands showed one major and at least five minor peaks (Figure 2). The major component **1** at a retention time of 18.25 min presented a mass

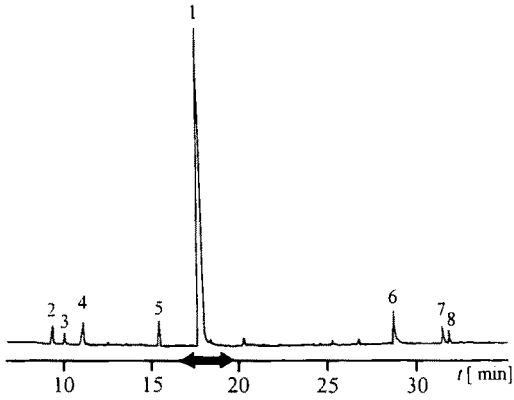


FIG. 2. A partial, reconstructed gas chromatogram obtained by solid sampling GC-MS analysis of poison gland volatiles from five *Megaponera foetens* workers: (1) *N,N*-dimethyluracil, (2) succinimide, (3) unknown, (4) *N*-methylsuccinimide, (5) indole, (6) hexadecanoic acid, (7) unknown, and (8) octadecanoic acid. The thick, double-headed arrow indicates the region corresponding to the GC effluent fraction that elicited trail-following behavior.

spectrum (Figure 3) that was congruent with that reported for *N,N*-dimethyluracil. A comparison of retention times between the natural product and synthetic *N,N*-dimethyluracil verified the structure.

The minor peaks in Figure 2 were identified as succinimide **2** m/z 99 (M^+, 100%), unknown compound **3,** *N*-methylsuccinimide **4** m/z 113 (M^+, 100%), indole **5** m/z 117 (M^+, 100%), hexadecanoic acid **6,** unknown compound **7,** and octadecanoic acid **8.**

GC-MS analysis of the contents of 15 pygidial glands of *M. foetens* demonstrated the presence of actinidine **9** (Figure 1) and benzaldehyde, as well as alkanes and alkenes. The mass spectrum of actinidine exhibited a molecular ion at m/z 147 (M^+, 65%), 132 (100), 117 (25), 103 (3), 91 (2), 77 (5), 65 (3), 51 (2), 38 (4) and matched with that of (+)-actinidine in the literature (Tomalski et al., 1987), and that of our synthetic product.

Electroantennogram. Preliminary EAG measurements with synthetic samples of the poison gland compounds *N*-methylsuccinimide, succinimide, hexadecanoic, and octadecanoic acid as well as the pygidial gland compound benzaldehyde showed no significant differences in comparison to a control stimulus with pure air. In contrast, *M. foetens* worker antennae responded significantly higher to both test compounds dimethyluracil **1** and actinidine **9** in comparison to a control of pure air (Figure 4). Among the test substances, actinidine elicited the highest electrophysiological responses of 1.5 mV at the given maximum

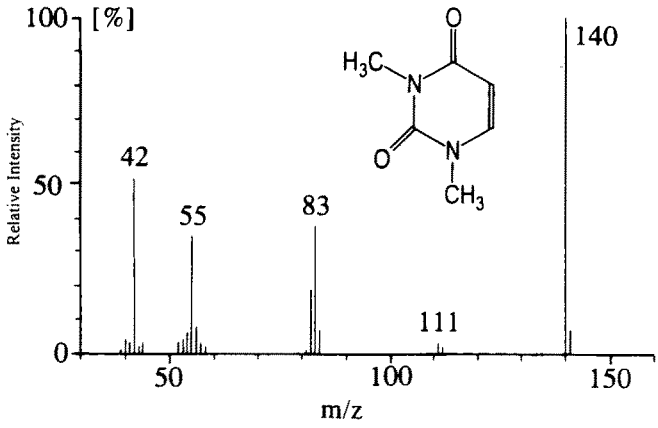

FIG. 3. Mass spectrum of *N,N*-dimethyluracil, **1**, 1,3-dimethyl-2,4(1*H*,3*H*)-pyrimidinedione.

dose of 1 mg applied to the filter paper source, whereas stimuli with dimethyluracil generated responses of 1 mV within the same concentration range.

Bioassays. The behavioral tests clearly demonstrated that dimethyluracil, which derives from the poison gland, represents a major chemical orienting

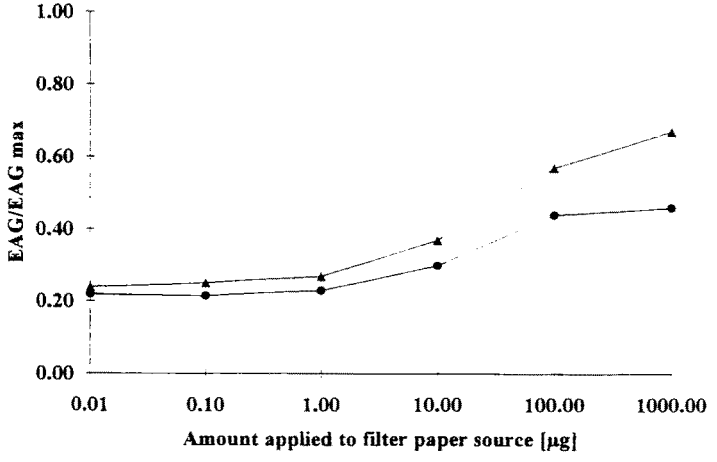

FIG. 4. Dose-response curves constructed from EAG measurements with *M. foetens* worker antennae. Responses from synthetic actinidine (closed triangles) and dimethyluracil (closed circles) are presented. Each point represents the mean of five replicates.

signal in *Megaponera* trails. One poison gland contains approximately 40 ng of dimethyluracil. This value, which was quantified from GC peak areas, showed, however, a significant variation from ant to ant. In a first series of tests, we applied 10 μl of a solution of 10 μg dimethyluracil per 1 ml hexane on a 40-cm-long trail. As a control we simultaneously offered trails drawn with 10 μl pure hexane. From a total of 12 tests, conducted with four different worker groups, 20.9 ± 7.7 ($X \pm$ SD) ants followed the dimethyluracil trail, and none followed the hexane trail. In this series we applied 100 ng dimethyluracil on each trail. In a second series we used only 1 ng of the trail pheromone (1 μl from 1 μg/ml solution) and still elicited a trail-following behavior, although the response was much weaker (7.3 ± 4.5).

Although the trail-following response to a higher concentration of the pheromone is obvious, it does not appear that dimethyluracil is also the main recruitment signal that elicits the mass exodus of workers during a group raid. We therefore focused on the pygidial gland contents, which have previously been shown to release a powerful recruitment response in *M. foetens* (Hölldobler et al., 1994). One of the pygidial gland compounds we identified is actinidine. Each gland contains approximately 10 ng of this substance. Artificial trails laid with 1 gland equivalents or 100 gland equivalents of actinidine did not elicit clear trail-following behavior. The ants run along the trails through short distances (approx. 1–4 cm), but never followed the whole 40-cm-long trail in a straightforward fashion, as they do along the dimethyluracil trails. It was obvious, however, that the ants increased their locomotory activities when actinidine was presented at the nest entrance, and the number of ants leaving the nest increased significantly in such situations.

This response was quantified in the following way: A hardwood applicator stick was dipped approximately 5 mm deep into the actinidine solution (1 mg/ml), the solvent allowed to evaporate 20 sec, and this contaminated tip of the applicator was inserted approximately 2 cm deep into the nest. Simultaneously, a second applicator, which had been dipped into the solvent hexane, was dried for 20 sec and inserted in the same way through another nest opening, 12 cm away from the first one. In subsequent tests the openings where the respective applicators were presented were alternated, and at least 15 min elapsed between each experiment. We then counted all ants leaving the nests through one or the other exit during 1-min intervals. In a total of 10 tests, 31.1 ± 18.2 ants left the nest at the actinidine exit and 11.6 ± 5.7 ants emerged at the control exit ($Z = 2.54$, $P = 0.011$; Mann-Whitney U test).

These results suggest that actinidine stimulates *Megaponera* workers to run out of the nest, possibly exhibiting alarm behavior. Next we investigated whether actinidine can enhance the trail-following response along dimethyluracil trails. We simultaneously presented trails drawn with 10 μl of the solution of 10 μg dimethyluracil/ml solvent plus 10 μl of the solution of 10 μg actinidine/ml

solvent and trails drawn with 10 μl of the dimethyl uracil solution alone. Unfortunately the results are inconclusive: In a total of eight tests, 14.2 $\pm$ 4.6 ants followed the combined trail, and 10.3 $\pm$ 3.4 ants followed the pure dimethyluracil trail. The difference ($Z = 1.94$, $P = 0.052$, Mann-Whitney U test) is not significant. Finally, we conducted tests with artificial trails drawn with pygidial gland extracts applying approximately 1 gland equivalent on each trail. We obtained the same results as previously reported to Hölldobler et al. (1994). In this case the ants readily responded by leaving the nest and following the trails along their entire length. This shows us that actinidine is not the effective recruitment and trail pheromone contained in the pygidial gland.

DISCUSSION

It has previously been demonstrated that group raiding in the termite-hunting ponerine *Megaponera foetens* is organized by complex chemical communication, involving at least two exocrine glands, the poison gland and the pygidial gland (Hölldobler et al., 1994). The current investigation focused on the chemical identification of pheromones involved in the release of trail-following and recruitment behavior. We were able to identify dimethyl uracil in the poison secretions and demonstrated that this substance serves as a trail pheromone. This is, to our knowledge, the first identification of a pyrimidine derivative in the secretions of an exocrine gland in ants, and it also comprises a hitherto unknown trail pheromone substance.

Although we were unable to identify the recruitment and trail pheromones that derive from the pygidial gland, we found actinidine in these glandular secretions. This alkaloid has been discovered previously in the pygidial gland of several genera of the subfamily Dolichoderinae, such as *Conomyrma* (Wheeler et al., 1977), *Monacis* (Blum and Wheeler, 1978), *Iridomyrmex* (Cavill et al., 1982, 1984), and *Tapinoma* (Tomalski et al., 1987), where it may function as a defensive secretion. It has not been previously found in species of the subfamily Ponerinae, where we now identified it in the pygidial gland secretion of *Megaponera foetens*. Actinidine elicits a repellent reaction in other ant species (see Tomalski et al., 1987), but in *Megaponera* it also stimulates workers to leave the nest, possibly in an alarm reaction. We failed, however, to demonstrate its involvement in recruitment and trail-following behavior. Recruitment and trail following can be released with untreated pygidial gland secretion.

Acknowledgments—We thank U. Braun for collecting *M. foetens* colonies, A. Laudahn for her assistance in culturing the ants, J. Heinze for statistical advice, two anonymous reviewers for helpful comments, and the Deutsche Forschungsgemeinschaft for the financial support.

(Received April 24, 1995; accepted July 23, 1995)

Abstract—The behavioral response of processionary males (*Thaumetopoea pityocampa*) to the natural pheromone (*Z*)-13-hexadecen-11-ynyl acetate (**1**) and structurally related analogs in a wind tunnel is presented. Stereomerically pure *Z*-**1** and a mixture with the *E* isomer in 80:20 ratio elicited similar attraction responses at 1 μg and higher. The activity was dose-dependent, being optimum at 1 μg with 90% and 80% of males contacting with the source in the presence of the *Z*-**1** and *Z*/*E*-**1**, respectively. 11-Hexadecynyl acetate (**2**) functioned as a pheromone mimic, being able to induce the complete mate-finding behavioral sequence, although its activity was much lower than that of the pheromone. (*Z*)-13-Hexadecen-11-ynyl alcohol (**3**) and, particularly, (*Z*)-13-hexadecen-11-ynal (**4**) were potent inhibitors of the upwind flight response in mixtures with *Z*-**1** in 99:1, 95:5, and 91:9 ratios. (*Z*)-1,1,1-Trifluoro-16-nonadecen-14-yn-2-one (**5**) also inhibited the response of males to pheromone, particularly in the source contact behavior. Comparison with activity displayed by analogs in field tests is also reported.

Key Words—Sex pheromone, processionary moth, *Thaumetopoea pityocampa*, Lepidoptera, Thaumetopoeidae, behavior, wind tunnel.

INTRODUCTION

The pine processionary moth *Thaumetopoea pityocampa* (Lepidoptera, Thaumetopoeidae) is one of the major defoliator pine pests in southern Europe and North Africa. Some other countries of Central Europe (Germany, Switzerland, Hungary, Bulgaria, Yugoslavia, etc.) may also suffer scattered attacks. The

moth is especially active against all species of pines growing below 1500 m altitudes but can also attack other conifers, such as cedars (Montoya and Hernández, 1991). Moreover, last-instar larvae may liberate microscopic urticating hairs, which can cause severe irritation to the skin and mucous membrane, often leading to strong allergic reactions in humans.

Only one compound has so far been found in the female sex pheromone gland and characterized as (*Z*)-13-hexadecen-11-ynyl acetate (Guerrero et al., 1981). This is the first and at present only structure with an enyne functionality as a constituent of the sex pheromone of a moth. Since its identification and synthesis (Camps et al., 1981a,b, 1983; Michelot et al., 1982), the compound has been found to display a remarkable attractant activity for males in the field (Cuevas et al., 1983; Einhorn et al., 1983).

Wind tunnels have been widely recognized as an effective technique to study orientation mechanisms of flying insects to their sex pheromone components (Cardé, 1984; Mafra-Neto and Cardé, 1994; Miller and Roelofs, 1978) as well as the inhibitory effect elicited by specific synthetic chemicals (Preiss and Priesner, 1988). Continuing our efforts directed towards development of inhibitors of the pheromone action both in the laboratory and in the field (Camps et al., 1988, 1990a,b; Parrilla and Guerrero, 1994), we now report on behavioral effects induced by the natural pheromone and a number of structurally related analogs (**2–5**, Figure 1) on processionary males in a wind tunnel. Although some of the compounds have been tested in the field (Cuevas et al., 1983; Camps et al., 1988), the activity elicited by these compounds at every stage of the mate-finding sequence has not been reported. Knowledge of the behavioral effects elicited by analogs as inhibitors, mimics, or synergists is important in order to gain better insight into their mode of action and, consequently, to develop new compounds with potential use in pest control (Albans et al., 1984; Camps et al., 1990a,b; Schwarz et al., 1990). In all cases the presence of the triple bond has been preserved since it was found by us to be crucial for bio-

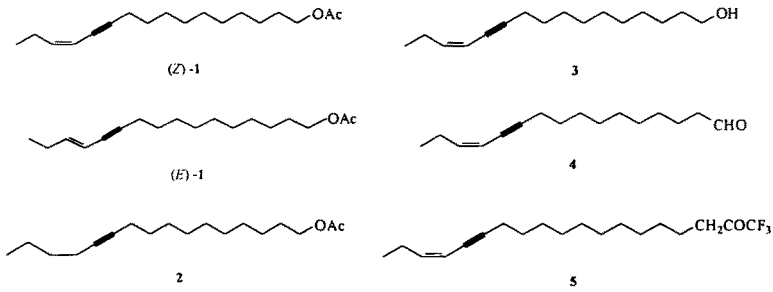

FIG. 1. Structure of the pheromone, *Z*-**1** and analogs tested.

logical activity. Trifluoromethyl ketones have been found to be strong inhibitors of esterases, particularly antennal esterases in insects (Prestwich, 1987; Durán et al., 1993), due to formation of hemiketals with a serine residue present at the active site of the enzyme (Linderman et al., 1988). In this regard, we have included trifluoromethyl ketone, **5**, which was assayed in two different types of experiments, i.e., in mixtures with the natural pheromone and after presaturation of the antennal receptors with vapors of the chemical.

METHODS AND MATERIALS

Chemicals. Alcohol **3** was prepared by stereospecific coupling of (*Z*)-1-bromo-1-butene with 2-(11-dodecynyloxy)tetrahydropyran catalyzed by tetrakis(triphenylphosphine)-palladium(0) as previously described (Michelot et al., 1982). The stereochemical purity was *Z:E* 98:2 on a SE-54 50 m × 0.32-mm-ID fused silica capillary column. Natural pheromone *Z*-**1** was obtained by acetylation of alcohol **3** under standard conditions (acetic anhydride/pyridine). Acetate **2** was prepared by alkylation of the corresponding acetylide with *n*-butyl bromide, and aldehyde **4** by oxidation of the corresponding alcohol **3** with pyridinium dichromate (Corey and Schmidt, 1979). Stereomeric mixture of *Z/E*-**1** 80:20 was obtained by reaction of the acetylide of 2-(11-dodecynyl-oxy)tetrahydropyran with 1,2-epoxybutane followed by tosylation of the resulting alcohol and dehydrotosylation (Camps et al., 1987). Trifluoromethyl ketone **5** was previously prepared in our laboratory (Parrilla et al., 1994). All the chemicals were purified by eluting them after column chromatography with hexane–ether or hexane–ethyl acetate mixtures and were homogeneous by TLC, NMR, and GC analyses.

Insects. Thaumetopoea pityocampa pupae were collected in an infested pine forest in Mora de Rubielos (Teruel) in the springs of 1992–1994, sexed, covered with a 3 to 6-cm layer of sawdust and sent to our department. They were kept in wooden boxes in a L16:8D reversed photoperiod at 23 ± 1°C and 55–65% humidity until emergence. Several toothpicks were placed standing in the sawdust to favor perching of males after emergence. In preliminary assays, we noted that reversal of the photoperiod to carry out the bioassays during working hours did not affect male behavior. Due to the short lifetime of the insects, and since young males responded better than the old ones in the wind tunnel, only insects 8–20 hr of age were used in the bioassays.

Wind Tunnel. The tests were carried out in a wind tunnel made of glass of dimensions 180 × 55 × 50 cm. The frame of the tunnel was made of aluminum with access gained by two sliding doors, each one covering one half of the tunnel. Air was pushed through by a centrifugal fan and pulled out of the building with the aid of an exhaust blower. The fan and blower worked simul-

taneously and their speed was carefully regulated by a potentiometer to avoid undesired turbulence in the moving air. The airstream was cleansed through a 2-cm-thick glass-wool bed and conducted through two nylon screens to smooth the air flow and get a laminar regime throughout the tunnel. A 58-W red fluorescent light located 16 cm above the tunnel provided the required illumination, which was dropped to 3–5 lux by covering the top of the tunnel with red cellophane paper. A white board containing irregular-shaped, dark brown spots was placed on the floor of the tunnel since stripped patterns may induce unexpected effects on the orientation of flying insects (David, 1982). The airspeed, measured at the center of the flight compartment, was 45 cm/sec. Two types of tests were conducted: one to study the behavioral effects induced by the test compounds alone and in combination with the natural pheromone, and one to study the inhibition response to the pheromone by presaturation of the antennal receptors with vapors of the trifluoromethyl ketone **5.**

Behavioral Effects Induced by Test Compounds 1–5. Newly emerged moths perched on the toothpicks were separated from the remaining pupae every day and placed into 31 × 12 × 21-cm plastic boxes containing a 2-cm layer of sawdust. The insects were allowed to acclimate to the tunnel conditions for 1 hr before they were tested 3–5 hr into the scotophase. The temperature of the experimental room was 22 ± 1°C and the relative humidity 60 ± 5%. The toothpicks supporting one to two males were carefully taken out, fixed on a polyurethane block, and placed into the tunnel on a stainless steel jack at 150 cm downwind from the source. The fan and blower were turned on and the males allowed to respond for 5 min. Moths were utilized only once and then discarded. The compounds were dissolved in nanograde hexane and the required volume to achieve the test doses (0–100 μg) was applied to a 1.5 × 1-cm cotton wick. The solvent was allowed to evaporate and the lure suspended 18 cm from the top and 40 cm from the closer screen of the tunnel. Solutions containing mixtures of *Z*-**1** and analogs in the specified ratios were prepared in hexane, and the required volume to have 1 μg of *Z*-**1** was taken. Solutions were prepared daily, just prior to the experiments, and the wicks discarded after use. Males were scored according to the following behaviors: wing fanning and taking flight (TF), arrival to the middle of the tunnel (65 cm, HW), close approach to the lure (ca. 10 cm, CA), and contact with the source (SC). Only those males arrested at the source for a minimum period of 5 sec were recorded as SC. The effect of a specific formulation was calculated as the percentage of males showing a particular behavior relative to the total number of insects released. Generally, 10–15 insects were assayed per day of experiment, with 20–30 males the total number of males considered for each treatment. Data obtained on different occasions corresponding to the same treatment were not significantly different, so they were combined for statistical analysis using a chi-square 2 × 2 test of independence (Sokal and Rohlf, 1969). Responses of insects of indi-

vidual compounds, i.e., *Z*-**1**, *Z*/*E*-**1** and -**2** were compared at specific doses, while responses to mixtures of **2**, **3**, **4**, and **5** with *Z*-**1** were compared with respect to specific behaviors. Bars in Figures 2–6 (below) bearing the same letter or lacking letters are not significantly different at $P < 0.05$.

Bioassays with Preexposure of Vapors of Ketone **5**. One-day-old individual insects were placed in a 12-cm-diameter Petri dish containing a 2 × 2-cm piece of filter paper on which 1 and 10 μg of trifluoromethyl ketone **5** in hexane had been absorbed. The solvent was evaporated before the assay. Care was taken to prevent the insects from directly contacting the compound. The moths were exposed to vapors of the chemical in the dark for 4 hr, then taken out, and, after 5 min of acclimation to the tunnel conditions, assayed for behavior. The same protocol was applied to control insects except that the filter paper was only treated with hexane.

RESULTS AND DISCUSSION

Male Responses to Natural Pheromone **1** *and Stereochemical Mixture* Z/E-*1*. Responses of males to the natural pheromone *Z*-**1** and the stereomeric mixture *Z*/*E*-**1** in 80:2 ratio were studied under different dosages (0.5–100 μg) in order to establish the role of the *E* isomer on the different behaviors of the sequence (Figure 2). A very high number of males (90–100%) responded to both lures at the early stages of the sequence (TF and HW), from which ca. 60–90% were able to establish contact with the source. The response of males displaying SC behavior was dose-dependent, being highest at a 1-μg dose of both compounds, with 90% of males landing at the source in presence of the *Z* isomer and 80% when the lure contained 20% of the *E* isomer. At a lower dose (0.5 μg), this mixture also evoked the complete set of behaviors, but with a lower number of males responding. Thus, in the presence of natural pheromone, the number of insects contacting the source was 70%, while this number decreased to 35% when the *E* isomer was also present in the lure. Diminution of responses was not significant, however ($P < 0.05$). In preliminary field tests carried out in 1983 on a very low population area, we had noted a significant decrease in catches when mixtures of *Z*/*E* were used (15.7, 6.8, and 8.9 males per trap attracted to *Z*-**1**, *Z*/*E*-**1** 97:3 and *Z*/*E*-**1** 90:10, respectively) (Cuevas et al., 1983). Our behavioral assays in the tunnel suggest, however, that the *E* isomer is behaviorally neutral when mixed with the natural pheromone. This assumption appears to be consistent with more recent ongoing trials in a heavier infested area (over 220 males per trap on average caught by the *Z* isomer), which showed a slight but nonsignificant decrease of males caught in lures treated with *Z*/*E* mixtures of different ratios relative to the catches with pure *Z*.

Male Response to Acetylene **2**. When acetylenic analog **2** was tested at

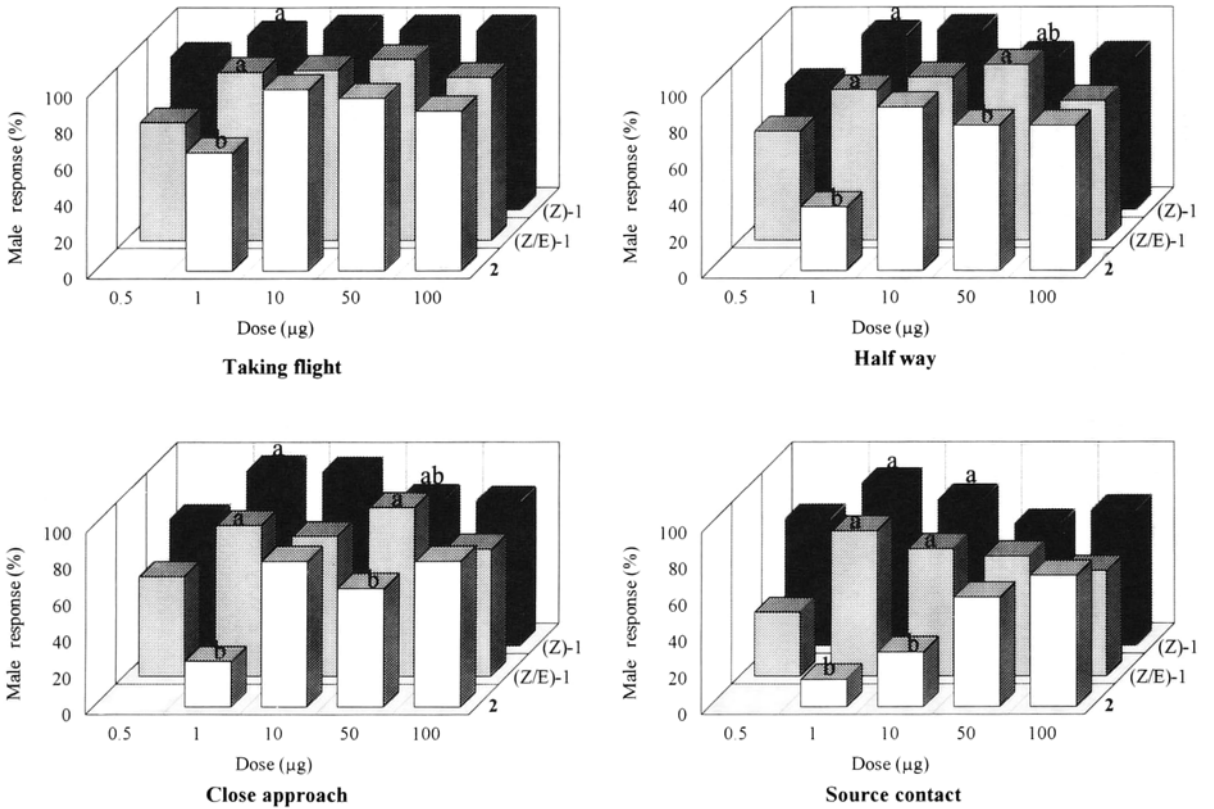

FIG. 2. Percentage of males responding to different dosages of natural pheromone *Z*-**1**, stereomeric mixture *Z*:*E*-**1** 80:2, and acetylene **2** in a wind tunnel. Bars containing different letters represent values significantly different using a chi-square 2 × 2 test of independence ($P < 0.05$). Bars with no letters represent values that are not statistically

different concentrations (1–100 μg) in comparison to the sex pheromone, moths successfully completed the mate finding sequence. However, high doses of the analog were required to elicit all behaviors, particularly SC (Figure 2). In general, a minimum dose of 10 μg evoked arriving to the proximity of the lure by 80% of the insects, although only 30% of males were arrested at the source. Higher doses (50–100 μg) were needed to elicit SC behavior by 60–72% of males (Figure 2). In order to test the effect of the analog **2** in the presence of the natural material, increasing amounts of the analog were added to 1 μg of the pheromone to obtain mixtures of **1** and **2** in 95:5 and 80:20 ratios. Unexpectedly, the results show a decrease in activity of the mixtures in comparison to that of the pheromone, particularly in the SC behavior. The numbers of males responding were, however, higher in both treatments than with acetylene **2** alone (Figure 3). From these results it can be inferred that acetylene **2** behaves as a pheromone mimic, being able to induce in males the complete mate-finding sequence, although its activity is much lower than that of the pheromone. This is in agreement with the results obtained in field tests where the number of catches using 1 mg of the analog were 65% relative to the number of males attracted to the pheromone (Camps et al., 1988), which is higher than we might expect from the behavioral data obtained in the wind tunnel. Similarly, in EAG bioassays, activity of the analog was 55–60% with regard to the pheromone (Gasol, 1988). The mimic character of the acetylene when tested alone, however, cannot explain the close-range and source-contact inhibition observed when the analog was mixed with the pheromone, and new studies at the electrophysiological level are needed to clarify this apparently contradictory point.

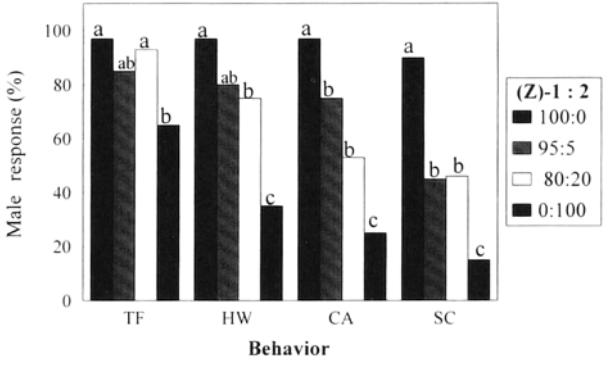

FIG. 3. Percentage of males responding to mixtures of natural pheromone *Z*-**1** and acetylene **2** in different ratios in a wind tunnel. Histograms with different letters are significantly different using a chi-square 2 × 2 test of independence ($P < 0.05$). TF, taking flight; HW, upwind flight and arrival to the middle of the tunnel; CA, close approach to the lure (ca. 10 cm); SC, source contact.

Male Responses to Alcohol 3 and Aldehyde 4. The effect of alcohol **3** was tested in **1** plus **3** mixtures in 99:1, 95:5, and 91:9 ratios. When the first two combinations containing 10 and 50 ng of **3** were tested, the number of males initiating upwind flight was very high (96–100%), but this number dropped to 70–80% in the HW and CA behaviors. However, almost all males that had successfully oriented completed the mate-finding sequence. When the analog was tested in the 91:9 mixture (100 ng of the analog), a strong inhibitory effect was noted in the first step of the sequence, i.e., TF, wherein only 30% of males responded. Moreover, although these males were able to sustain upwind flight to a point near the lure, none of them could land at the source (Figure 4). The notable drop in activity shown in this case, in comparison to that elicited when 50 ng of the analog was present, apparently suggests that the threshold inhibitory activity is somewhere between these two values. The inhibitory effect displayed by **3** is in agreement with the one elicited in field tests when mixed with the pheromone in 1:10, 1:1, and 10:1 ratios (Camps et al., 1988). A similar effect was found by Quartey and Coaker (1993) with (*Z*, *E*)-9,11-tetradecadienol, a third constituent of the sex pheromone of the tropical warehouse moth *Ephestia cautella*, which significantly inhibited attraction of males to conspecific females in wind tunnel. The alcohol also displayed a strong inhibitory effect in all behavioral steps when mixed with the corresponding dienic and monoenic acetates, the two main components of the pheromone. Schwarz et al. (1990) also reported the inhibitory activity of (*E*)- and (*Z*)-11-tetradecenol, the metabolic products of the sex pheromone of the *E* and *Z*-types of the European corn borer

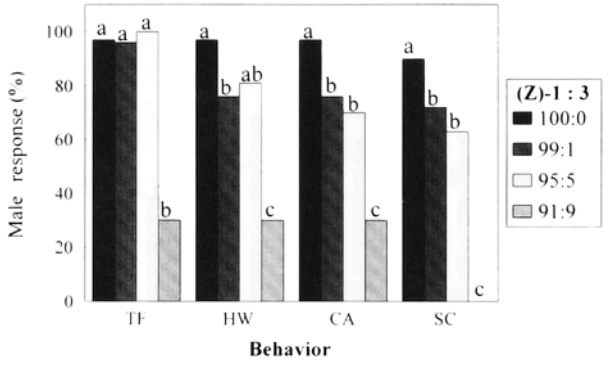

FIG. 4. Percentage of males responding to mixtures of natural pheromone *Z*-**1** and alcohol **3** in different ratios in a wind tunnel. Histograms with different letters are significantly different using a chi-square 2 × 2 test of independence ($P < 0.05$). TF, taking flight; HW, upwind flight and arrival to the middle of the tunnel; CA, close approach to the lure (ca. 10 cm); SC, source contact.

Ostrinia nubilalis, in the male upwind flight response when mixed with the natural pheromone in a very high ratio (3 μg of analog plus 100 ng of pheromone).

When aldehyde **4** was tested, the results were spectacular. The presence of 10 ng of the analog in 1 μg of pheromone was enough to evoke a complete inhibition of SC behavior, the number of males taking flight being only 25%. The effect induced was very similar to that elicited when used alone (Figure 5). This result was not surprising to us, however, since the analog had also behaved as a very potent inhibitor of the pheromone action in the field, lowering the number of catches by 90.4% in comparison with the pheromone, when mixed with the natural pheromone in a 1:10 ratio. This analog is the most potent inhibitor of the natural pheromone action in the laboratory and in the field ever found by us. Other saturated and unsaturated aldehydes have proven to be good inhibitors of the upwing flight response of the European corn borer males (Schwarz et al., 1990).

Male Response to Trifluoromethyl Ketone **5**. Trifluoromethyl ketones are potent inhibitors of a variety of serine esterases, including in some cases antennal esterases of insects (Prestwich, 1987; Durán et al., 1993), due to reaction with a serine residue at the active site of the enzyme. The inability to catabolize pheromone molecules may result in their accumulation at the receptor sites, which should disrupt the ability of the insect to perceive new incoming attractant molecules. Compound **5** is a structural analog of the sex pheromone and results from isosteric replacement of the acetate group by the trifluoroacetonyl moiety

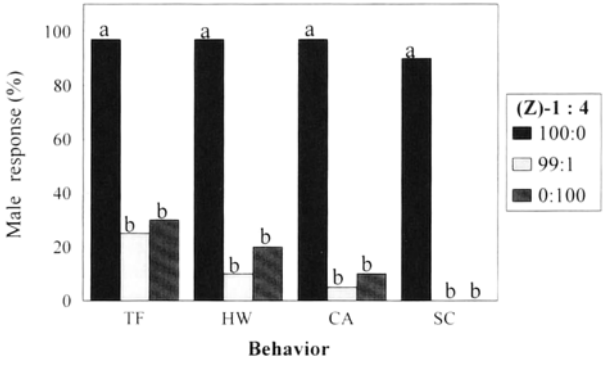

FIG. 5. Percentage of males responding to aldehyde **4** and mixture with the natural pheromone *Z*-**1** in 1:99 ratio relative to the pheromone in a wind tunnel. Histograms with different letters are significantly different using a chi-square 2 × 2 test of independence ($P < 0.05$). TF, taking flight; HW, upwind flight and arrival to the middle of the tunnel; CA, close approach to the lure (ca. 10 cm); SC, source contact.

CH_2COCF_3. The ketone was tested as an inhibitor of pheromone response in two ways: first, when coevaporated with the natural material and, second, after presaturation of the male antennal receptors with vapors of the chemical. When mixed with the pheromone in 5:95 ratio, the ketone showed no effect on TF and HW behaviors but significantly inhibited CA and SC behaviors (Figure 6A). This result contrasts with those found with 1,1,1-trifluoro-14-heptadecen-2-one,

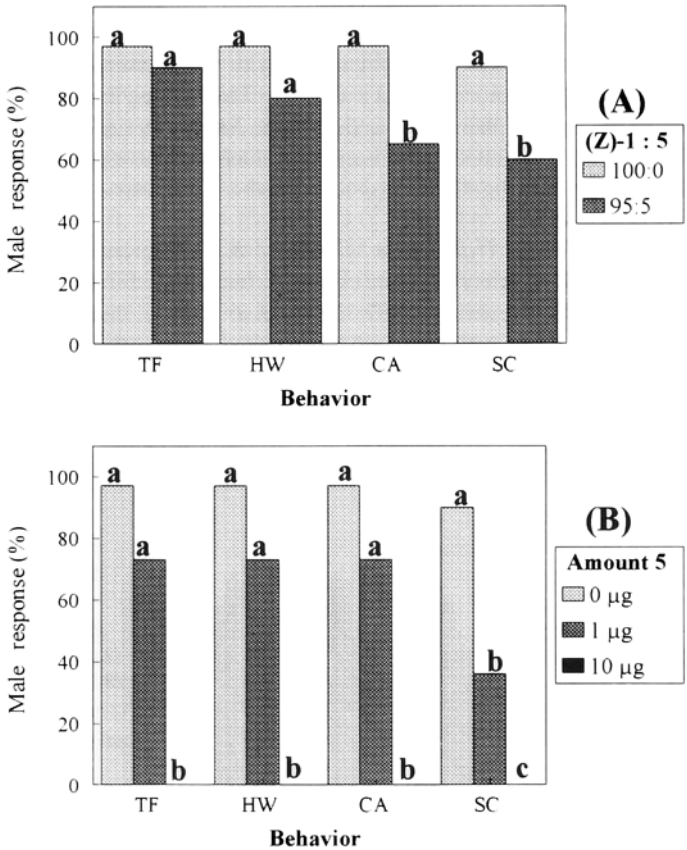

FIG. 6. (A) Percentage of males responding to a 95:5 mixture of the natural pheromone Z-**1** and trifluoromethyl ketone **5** relative to the pheromone. (B) Percentage of males responding to the natural pheromone Z-**1** after presaturation of the antennal receptors with vapors of 1 and 10 µg of **5**. Histograms with different letters are significantly different using a chi-square 2 × 2 test of independence ($P < 0.05$). TF, taking flight; HW, upwind flight and arrival to the middle of the tunnel; CA, close approach to the lure (ca. 10 cm); SC, source contact.

a pheromone analog of the European corn borer (Klun et al., 1991), which neither interfered with the normal behavioral response of males to the natural pheromone in a wind tunnel nor showed esterase inhibition. In the field also, compound **5** showed the same type of activity displayed in the wind tunnel, i.e., a disruptant effect of the pheromone action when mixed with the natural compound in 1:0, 1:1, and 1:10 ratios (Parrilla and Guerrero, 1994).

When male antennal receptors were exposed to vapors of 1 μg of the trifluoromethyl ketone, the insects were clearly impaired only in the SC behavior (only 36% of males landed at the source), although 73% were able to orient into the plume (HW and CA behaviors). Higher doses of the ketone (10 μg) completely inhibited all types of behavior considered (Figure 6B). The same type of experiment did not affect, however, the EAG response to the pheromone (Parrilla, 1994).

In summary, we have shown that the behavior of processionary males in the wind tunnel can be strongly influenced by structural analogs of the natural pheromone. Most of the compounds tested are potent inhibitors of the pheromone action, mainly aldehyde **4**, with the activity being more pronounced in the last stages of the mate-finding sequence, particularly in contact with the source. Our results correlate well with those obtained in the field and substantiate the usefulness of the wind tunnel to establish the behavioral responses of males to pheromones and analog.

Acknowledgments—Financial support from CICYT (PB 93-0158 and AGF 92-0178) and SEDEQ S.A., through CDTI 94/0329 and Ministry of Industry DGTI 583/94 contracts, is gratefully acknowledged. We also thank Kenogard, S.A. for a predoctoral fellowship to C.Q., J. Palencia (SEDEQ S.A.) for providing us with some chemicals, and Rodolfo Hernández (Centro de Protección Vegetal, Mora de Rubielos, Teruel) for field data and supply of insects.

(Received July 8, 1994; accepted July 24, 1995)

Abstract—Courtship in *Cardiochiles nigriceps* (Viereck) (Hymenoptera: Braconidae) involves male attraction to females and male antennation of females followed by mounting and copulation. Once the female is located, antennation and mounting of the female are mediated by the hydrocarbon fraction of female's Dufour's gland and cuticle. The identification of the cuticular hydrocarbons of males and females revealed a mixture of alkanes and alkenes, in addition to a series of alkadienes specific to females. These female-specific alkadienes reported from Braconidae are unusual among insect alkadienes in that the second double bond occurs in the middle of the molecule. Bioassays with three available alkadienes revealed that contact behaviors (antennation and mounting) are in part mediated by the (*Z*,*Z*)-7,13-heptacosadiene and at least one other alkadiene in combination with other hydrocarbons found in males and females.

Key Words—*Cardiochiles nigriceps*, parasitoid, Hymenoptera, Braconidae, pheromone, mating, courtship, hydrocarbon, cuticle, alkadienes.

INTRODUCTION

Cardiochiles nigriceps (Viereck) is one of the more important native parasitoids attacking *Heliothis virescens* (F.) the tobacco budworm (Grayson, 1944; Ridgway and Lingren, 1972). Although there may be ways to manipulate native parasitoid populations in agronomic settings (Greany et al., 1984), such efforts with *C. nigriceps* are presently limited to conservation (Cate, 1985). The inability to monitor adult populations hinders field research. Attempts to overcome this problem have included pheromone trapping (Lewis et al., 1971), but the limited information regarding the pheromones of *C. nigriceps* has hindered development of this approach.

Male reproductive behavior in parasitoids has been examined primarily with regard to the evolution of reproductive strategies (Hamilton, 1967, 1979; Van den Assem, 1986; Werren, 1983) and the evolution of courtship displays (Matthews, 1975; Van den Assem and Jackmann, 1982). However, answers to proximate questions (e.g., factors leading to courtship and the identification of the cues that elicit these reproductive behaviors) have lagged, despite a tremendous body of evidence indicating that a series of cues are involved (Eller et al., 1984; Swedenborg and Jones, 1992a,b; Van den Assem et al., 1980). The identification of a sex pheromone has been demonstrated in only four parasitoid species. The compounds identified are generally attractants and include neral and geranial in *Itoplectis conquisitor* Say (Robacker and Hendry, 1977), ethyl-(*Z*)-9-hexadecenoate in *Syndipnus rubiginosus* Walley (Eller et al., 1984), (*Z*)-4-tridecenal in *Macrocentrus grandii* Goidanich (Swedenborg and Jones, 1992b), and (*Z*)-9-hexadecenal in *Ascogaster reticulatus* Watanabe (Kainoh et al., 1991).

The pheromone (*Z*)-4-tridecenal, isolated from female *M. grandii*, is an air oxidation product from a series of (*Z*,*Z*)-9,13-alkadienes (Swedenborg and Jones, 1992b). In addition, Swedenborg et al. (1993) reported a third component of the sex pheromone blend used by *M. grandii*. Thus, the sex pheromones isolated from some parasitic Hymenoptera have been determined to consist of multiple compounds (Shu and Jones, 1993; Swedenborg and Jones, 1992a; Swedenborg et al., 1993).

The source of these pheromones is generally unknown although both the Dufour's gland (Weseloh, 1976; Vinson, 1978) and cells located at the base of the second valvifer (Tagawa, 1977) or base of the genital capsule (Field and Keller, 1994) have been suggested. Swedenborg et al. (1993) reported that the mandibular gland of *M. grandii* was the source of one of the pheromone blend components. This compound, (3*R*′,5*S*′,6*R*′)-3,5-diethyl-6-(methylethyl)-3,4,5,6-tetrahydropyran-2-one, is synergistic to the previously identified (*Z*)-4-tridecenal and its alkadiene precursors. The identification of several potential sources provides additional evidence that the sex pheromones of parasitoid hymenopterans consist of a complex of components.

Complex courtship behaviors often occur once the sexes have made contact (Matthews, 1975; Van den Assem et al., 1980) and are an important aspect of sex recognition. The role chemicals play toward the mediation of this process is poorly understood and appears to be as complex as the courtship display itself. Since courtship is the means by which species recognition occurs, knowlege of the entire suite of behavioral and chemical signals mediating this process can be useful when incorporated into taxonomic descriptions. This would be invaluable in those instances where cryptic species are suspected. The experiments described here pertain to those compounds that mediate the courtship behavior in *Cardiochiles nigriceps* Viereck, a braconid parasitoid of *Heliothis virescens* (F.).

METHODS AND MATERIALS

Insects. Host *Heliothis virescens* larvae were reared on Bio-serv Corn Earworm diet (Bio-serv, Inc., Frenchtown, New Jersey 08825) as discussed by Elzen et al. (1984) but modified by the addition of 10 ml of an aqueous solution of 46% propionic acid and 4% phosphoric acid to suppress the fungus *Aspergillus niger. Cardiochiles nigriceps* were reared on fourth-instar *H. virescens* by established methods (Vinson, 1973). Voucher specimens are deposited in the Insect Collection of the Department of Entomology, Texas A&M University.

Extraction and Fractionation of Dufour's Gland. Because female *C. nigriceps* are not receptive to courting males until 24 hr after emergence (Hirose et al., 1988), dissections were performed only on live females that had eclosed at least one day earlier. Females were dissected by anesthetizing them in an ice-water bath. The wasp was then placed (ventral-side up) in a Petri disk filled with Pringle's saline (Pringle, 1938) and the ovipositor gently withdrawn using watch-maker's forceps until the Dufour's gland was exposed. The gland was then cut loose and placed in a 1-ml conical vial filled with hexane (HPLC grade). Concentrations of glandular extracts ranged from 50–100 glands/500 μl solvent with the specific concentration of each extract recorded.

Crude extracts of the Dufour's gland were then separated by preparative gas chromatography (GC) on a Tracor 550 gas chromatograph equipped with a variable splitter to a flame ionization detector and to a Brownlee-Silverstein collection system. Separations were obtained on a 1.83-m × 4-mm-ID glass column packed with 3% Dexsil 410 on Chromosorb 750 (80–100 mesh). Nitrogen carrier gas flow rate was 60 ml/min and the temperature program was 150–350°C at 15°/min. Individual peaks were collected in 40-cm × 1-mm-ID capillary glass tubes cooled with liquid nitrogen. To destabilize aerosols, several fibers of dimethylchlorosilane-treated glass wool were inserted into each tube. Collected fractions were further purified by reinjecting them onto the same

column under isothermal conditions and again collecting individual peaks as above. The purified fractions were bioassayed and stored at −80°C for later study.

Extraction and Fractionation of Cuticular Lipids. For quantitation of cuticular hydrocarbons, sexually mature virgin male or virgin female *C. nigriceps* (24–120 hr old) were frozen and individually extracted with diethyl ether (0.5 ml/wasp) for 15 min (all diethyl ether was high purity grade from Burdick and Jackson and preserved with 2% ethanol). The wasp was removed and the diethyl ether was removed under nitrogen sweep. An internal standard of 1-eicosene (10 μg/wasp) was added in isooctane (10 μl/wasp) and 1 μl was analyzed by GC on a 30-m × 0.25-mm capillary column of Durabond DB-1, temperature programmed from 150 to 300°C at 5°C/min. Compounds were detected by flame ionization. Each peak was quantified relative to the internal standard.

Cuticular lipid extracts of large batches (50–100 wasps) of virgin female or virgin male *C. nigriceps* (24–120 hr old) were prepared by soaking freshly frozen adults (0.5 ml/wasp) in diethyl ether for 15 min and sonicating for 30 sec. Extracts were dehydrated by passing the supernatant through a Pasteur pipet plugged with dimethylchlorosilane-treated glass wool and filled with approximately 1 g anhydrous sodium sulfate. The eluant was concentrated at 55°C under a fractionating column to a volume of 5 ml and then concentrated to 1 ml by distillation with a spinning band column at 45°C. Finally, the extracts and distillates were stored at −80°C to be used later for bioassay or further separation.

Cuticular lipid extracts were fractionated on a 1-g Florisil (60–100 mesh) column and eluted with approximately 15 ml pentane followed by an equal amount of methylene chloride and finally methanol. The three fractions were concentrated by distillation using a fractionating column and spinning band column (as described above) with the temperature of the warm water bath adjusted so that it was 10° higher than the boiling point for each respective solvent fraction. The final volume for each fraction was reduced to 1 ml and stored at −80°C.

Hydrocarbon Fractionation and Identification. The cuticular hydrocarbons (pentane fraction from the Florisil column) were separated by degree of unsaturation on silica thin-layer chromatography plates impregnated with 10% $AgNO_3$. The plates were developed with 2% diethyl ether in hexane. Two centimeters of the sides of each plate were stained with iodine vapor to locate bands on the unstained portion of each plate. The bands and areas between were separately scraped from the plate, and the absorbed compounds were eluted with diethyl ether. Alternatively, the cuticular hydrocarbons were separated into alkane, alkene, and alkadiene fractions by high-pressure liquid chromatrography (HPLC). A Waters 4500 HPLC system with differential refractometer was used with a 25-cm × 4.6-mm-ID column of 5 μm Absorbosphere silica (Applied Science,

Deerfield, Illinois) coated in situ with $AgNO_3$ (Heath and Sonnet, 1980) and eluted with 25% toluene in hexane (v/v) at a flow rate of 1 ml/min to separate the hydrocarbons (Bartelt et al., 1986). Alkanes were collected within the first 3 min after injection (just after the void volume), alkenes were collected from 3 to 8 min, and alkadienes were collected from 8 to 15 min. Nothing was detected in the 15 to 32-min fractions at the end of the chromatogram.

The composition of each fraction was determined by GC analysis comparing retention to known standards using a Hewlett Packard 5890A gas chromatograph with a 30-m × 0.32-mm Durabond DB-5 capillary column temperature programmed from 200 to 300°C at 4°/min or GC-MS analysis with a 15-m × 0.25-mm Hewlett Packard HP-1 capillary column temperature programmed from 150 to 300°C at 5°/min and monitored by a HP 5971 mass selective detector.

Methoxymercuration–demercuration derivatives of the alkene and alkadiene fractions were prepared (Blomquist et al., 1980) and analyzed by GC-MS on a 30-m × 0.72-mm capillary column of DB-5 using a temperature program from 200 to 280°C at 2°/min and introduced into a Finnigan 4123 mass spectrometer operating at 70 eV. The positions of the double bonds in the alkene and alkadiene fractions were further verified by dimethyl disulfide derivatization and GC-MS analysis (Carlson et al., 1989).

The *E* or *Z* nature of the double bonds was determined by infrared (IR) absorption at 970 cm^{-1} for the *E* and at 740 cm^{-1} for the *Z* isomer. IR spectra were obtained with neat hydrocarbons (combined alkenes and alkadienes) between KBr plates in a Perkin-Elmer model 599 spectrophotometer.

Synthesis of Alkadienes. The alkadienes were prepared using the Wittig synthesis (Sonnet, 1974). Differences from Sonnet's procedure were: (1) the alkyltriphenylphosphonium salts were prepared from α,ω-dibromoalkanes, to allow for double bond formation on both ends; and (2) the equivalents of other reactants (butyllithium and aldehyde) were doubled correspondingly. For these asymmetrical alkadienes, equimolar amounts of the two appropriate aldehydes were added simultaneously. In these cases, two symmetrical alkadienes also formed, one shorter and one longer than the desired asymmetrical diene. Dimethylsulfoxide was used as a cosolvent to enhance the formation of *Z*-double bonds. The product mixture was passed through a column of silicic acid with hexane to elute the alkadienes and to remove polar by-products. Analysis of the synthetic alkadiene mixtures by GC relative to paraffin alkane standards and by GC-MS focusing on the molecular ion in each case showed that the expected carbon chain lengths were produced. The alkadienes, containing the *Z,Z*-isomer, *Z,E* and *E,Z*-iosmers, and traces of *E,E*-isomers (as well as several chain lengths, in the cases of asymmetrical dienes), were further purified by $AgNO_3$ HPLC (Bartelt et al., 1986). On $AgNO_3$ HPLC, the *E,E*-isomers eluted during the first 5 min of the HPLC analysis. The *E,Z* and *Z,E*-isomers along with greater than 34-carbon chain *Z,Z*-isomers eluted next in the 5- to 8-min fractions; *Z,Z*-iso-

mers in the 27- to 31-carbon range eluted in the 8- to 12-min fractions; and *Z,Z*-isomers in the 20- to 26-carbon range eluted in the 12- to 18-min fractions. Each HPLC fraction was analyzed by GC-MS and by dimethyl disulfide derivatization GC-MS as described above. (*Z,Z*)-7,13-Heptacosadiene, (*Z,Z*)-7,14-nonacosadiene, and (*Z,Z*)-7,15-hentricontadiene were 92%, 93%, and 99% pure, respectively.

Bioassays. To evaluate the role of the Dufour's and cuticular hydrocarbon fractions in the courtship behavior of male *C. nigriceps*, three types of bioassay were designed. The first bioassay, referred to as the close-range bioassay, was designed to examine the role chemicals play in the elicitation of the complete sequence of courtship behaviors exhibited by males. The behaviors examined ranged from close-range attraction of males (3–7 cm) toward females to the male's antennation of, orientation to, and mounting of the female upon contact (Vinson, 1978). The mounting of the female was typically followed by reorientation on the female's body and attempted copulation. Bioassays utilized freshly frozen (FF) females (controls) or FF males that served as models. Individuals of either sex that were selected to serve as models were $\geq$24 hr old. This age was selected because first-day adult *C. nigriceps* are not mature (Hirose et al., 1988) and dissections of Dufour's gland revealed that most glands were empty upon emergence, but were full by day 2 (Syvertsen and Vinson, personal observation). The close range bioassay was conducted by exposing a male to a FF female (positive control) or to an inert model (FF male) that was either treated with solvents (negative control) or with glandular or cuticular extracts of females. The latter was prepared with nonpolar (hexane) or weakly polar (diethyl ether) extract or fraction as described above. All extracts were adjusted so that a 10-μl aliquot contained 1 wasp equivalent (WE).

The close range bioassay consisted of attaching the model (FF male or FF female) to one end of a microscope slide with a nontoxic, odorless adhesive (Glue-Stic, Dennison Manuf. Co.) applied to the ventral thorax. A 10-μl aliquot of an extract (1 WE) was applied to a male model in such a way that the extract covered most of the exposed surface of the model. The slide was positioned on a flat surface so that an airstream could be directed over the model toward the opposite end of the slide. Air (purified and dehumidified by passing it through a cartridge filled with Drierite and activated charcoal) was adjusted to a flow rate of 0.5 ml/min via a flowmeter controlled with an on/off valve. Males were obtained from their cages by allowing them to walk onto a wooden applicator stick. The wasp was permitted to transfer from the stick to the downwind edge of the slide (Figure 1). When the male walked onto the slide, the airstream was turned on and the male's response was video-recorded. Each male was allowed 1.0 min to respond. If the response was positive and courtship was elicited, no maximum time limit was set and the behaviors were observed until the male dismounted and left the slide.

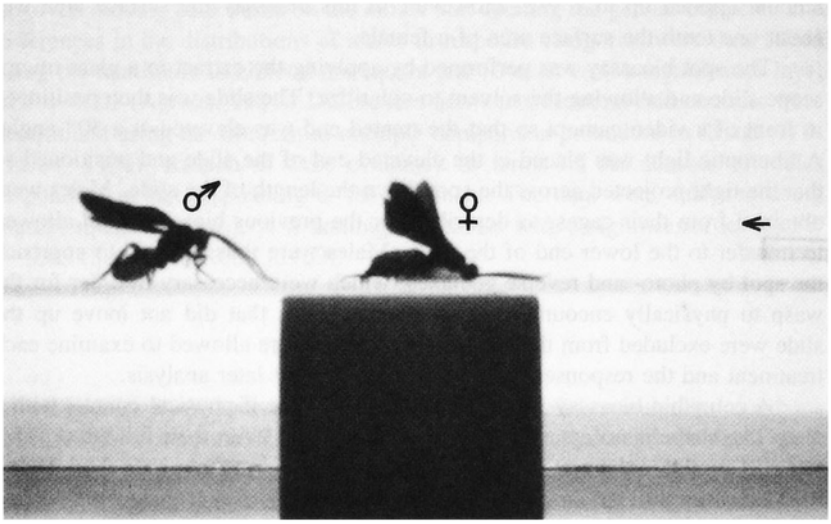

FIG. 1. Close-range bioassay: male *C. nigriceps* wing fanning and antennating the substrate in response to female sex pheromone.

A second bioassay, referred to as a spot bioassay, exposed males to a substrate treated with either compound extracted and fractionated from females or synthetic compounds. This bioassay was used because males often antennate the substrate where females have been resting and do so with a set of characteristic behaviors (Vinson, 1978). The bioassay is important in detecting behaviorally relevant nonvolatile or contact chemicals. High-purity hexane extracts of females were of two types: (1) Dufour's gland extracts, and (2) cuticular extracts. Each extract was bioassayed as a series of concentrations in order to determine the optimum dose–response for activity. The final concentrations of both the cuticular and glandular extracts were adjusted so that 10 μl equaled the dose being assayed, which ranged from 10 to 1×10^{-4} WE (Table 2 below). The glandular extracts were then fractionated by packed-column GC into groups based upon their carbon chain length (CL) and bioassayed similarly (Table 3 below). The cuticular extracts were not fractionated similarly, since the composition of the nonpolar or hydrocarbon fraction of this extract (purified with silicic acid) was identical to that of the Dufour's gland. Instead TLC and HPLC fractions separated on the basis of unsaturation were evaluated. The concentrations of all fractions were adjusted so that 10 μl equaled approximately 0.1 WE. This quantity was used since the dose–response experiments to both glandular and cuticular extracts indicated that the males' response increased with the

amount applied up to 1 WE. However, in this bioassay the surface area was about one tenth the surface area of a female.

The spot bioassay was performed by applying the extract to a glass microscope slide and allowing the solvent to volatilize. The slide was then positioned in front of a video camera so that the treated end was elevated at a 50° angle. A fiberoptic light was placed at the elevated end of the slide and positioned so that the light projected across the spot down the length of the slide. Males were obtained from their cages, as described for the previous bioassay, and allowed to transfer to the lower end of the slide. Males were thus inclined to approach the spot by photo- and reverse geotaxes, which were necessary in order for the wasp to physically encounter the treatment. Males that did not move up the slide were excluded from the test. Twenty males were allowed to examine each treatment and the responses were video recorded for later analysis.

A courtship bioassay was designed to determine if physical contact with a wasp like shape is necessary for these compounds to exert their full effect. This test was similar to the previous test with the modification that a model was used. This bioassay differed from the close-range bioassay in that males approached the model by photo- and reverse geotaxes rather than being attracted by an odor-laden airstream. Treatment models were frozen male *C. nigriceps* treated with select fractions found to be active in the spot bioassay and the female-specific hydrocarbons that were identified and synthesized. FF male models were held in place by an adhesive described for the close-range bioassay and treated with 10 μl of solvent containing approximately 1 WE of extract or fraction to be evaluated. Application of the compounds was via a Hamilton syringe and performed in such a way that most, if not all, of the body was treated. Untreated frozen females were used as positive controls.

Data Recording and Analyses. Bioassays were video recorded with RCA model 2000, RCA Video Equipment (New Holland Ave., Lancaster, Pennsylvania 17604) and replayed at a later time with the events logged on an IBM XT-286 PC equipped with The Observer, a software package for behavioral research (Noldus, 1991). Close-range bioassay behaviors (e.g., attraction to the model, wing fanning, antennating, mounting, orienting on the model, and copulating) were recorded as frequencies and only the highest-ranking behavior in the sequence was scored. For the spot bioassay, an antennation response was scored if, upon encountering the spot, the male stopped walking and the antennae were extended forward so that both were approximately parallel with respect to each other and repeated palpations across the spot occurred. Responses to the model in the courtship bioassay were recorded and analyzed as in the close-range bioassay, except that movement to the model was not considered and only males contacting the model were evaluated.

Analyses of the courtship bioassay behavioral frequencies were divided into three categories: antennation, mounting, and attempts at copulation that

involved moving backwards on the model and opening the genital claspers. The differences in the distributions of males in response categories were then tested using the maximum likelihood chi-square test (G test) with a significance level of $P = 0.05$ (Agresti, 1984). Differences between treatments and controls were determined using the Bonferroni multiple comparison procedure in Systat (Wilkinson, 1990). Responses were evaluated in terms of the number of males responding or not responding to the treatment. The data were analyzed using the chi-square test for $2 \times K$ contingency tables with a significance level of $P = 0.05$ (Sokal and Rohlf, 1969).

RESULTS AND DISCUSSION

Cuticular Hydrocarbons. Capillary GC resolved the cuticular hydrocarbons from female wasps into 25 peaks and the cuticular hydrocarbons from male wasps into 16 peaks (Table 1). Infrared absorption spectra indicated that the majority, if not all, of the double bonds were *Z* by strong absorption at 740 cm^{-1} and the absence of any absorption band at 970 cm^{-1}. Both $AgNO_3$-TLC and $AgNO_3$-HPLC resolved the cuticular hydrocarbons from females into alkane, alkene, and alkadiene fractions. However, the cuticular hydrocarbons from males yielded only alkane and alkene fractions. The alkane fractions from each sex were qualitatively similar, with some quantitative differences (Table 1). Quantitation of each of the alkene isomers was incomplete because of an unresolved mixture of isomers in some of the GC peaks. Mass spectra of the monomethoxy derivatives of the alkenes showed that the double bonds were located at position 7 (7-pentacosene, 7-heptacosene, and 7-nonacosene) or located at or near the center of the hydrocarbon chain (13- 11-, and 9-hexacosene; 12- and 13-heptacosene; 13-octacosene; 13- and 14-nonacosene; 13- and 15-triacontene; 13- and 15-hentriacontene; 13- and 15-tritriacontene; and 13- and 15-pentatriacontene). Alkenes with double bonds at or near the center of the hydrocarbon chain are rare in insect cuticular hydrocarbons.

The mass spectra of the methoxy derivatives of the alkadienes from females (Figure 2) showed that one of the double bonds was located near the middle of the chain (position 13, 14, or 15) and the other double bonds was at position 5, 6, or 7. The positions of the double bonds were established from the fragmentation of the monomethoxy derivatives in the mass spectrometer (Figure 2). For example, the 27:2 alkadiene had its double bonds in the 7,13- positions, and yielded monomethoxy derivatives with methoxy groups on positions 7, 8, 13, and 14, and all fragments corresponding to these isomers are present in the mass spectrum (Figure 2A). The 29:2 component has four isomers, and the methoxy derviatives and the expected ion fragments for the 5,14- isomer are highlighted in Figure 2B. In addition, the mass spectrum (Figure 2B) was inter-

7,13- and 7,15-Pentatriacontadiene	35:2		trace

[a] Carbon number: double bonds.
[b] Trace < 0.1 μg/wasp but > 0.05 μg/wasp.
[c] At least a 10-fold difference in quantity.
[d] Also 5,15- and 7,15-isomers.
[e] Also 6,15-, 6,16-, and 7,16-isomers.

preted as having arisen from isomers with double bonds in the 7,14-, 5,15-, and 7,15- positions. This was the only alkadiene with an isomer that had the first double bond at position 5. The mass spectrum from the monomethoxy derivative of 31:2 (Figure 2C) was interpreted in a similar manner, and the data show that the major isomer is the 7,15-alkadiene. On capillary columns the peaks

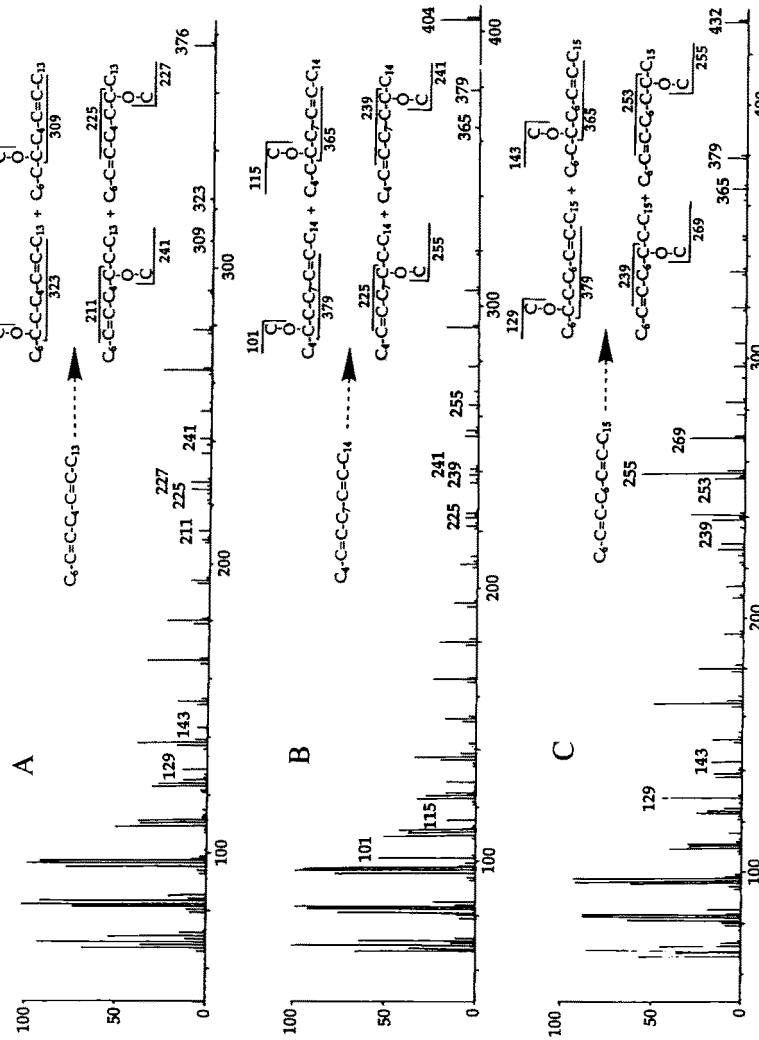

FIG. 2. Mass spectra of the monomethoxy derivatives of the 27:2 (A), 29:2 (B) and 31:2 (C) alkadienes from the cuticle of female *C. nigriceps*.

corresponding to methoxy derivatives with the methoxy group near the center of the chain were partially resolved from the methoxy derivatives with the methoxy group on positions 5, 6, or 7. The data presented in Figure 2 are the computer summed spectra across the cluster of peaks. The alkadienes, exclusively from female, have the first double bond predominantly at position 7 and the second double bond at or near the center of the hydrocarbon chain.

The alkadienes, therefore, have one double bond in the same location as the alkenes. Whether the same enzymes introduce double bonds in the biosynthesis of alkenes and alkadienes remains to be determined.

Comparison of Male and Female Cuticular Hydrocarbons. The most conspicuous difference between the composition of the cuticular hydrocarbons from males and females (Table 1) is the absence of di-unsaturated hydrocarbons (alkadienes) and the copious amount of 13-heptacosene in males. Females have greater quantities of 13- and 14-nonacosene and 13- and 15-hentriacontene than males. In addition, males also possess a slightly greater quantity of total cuticular hydrocarbons (101.2 μg/wasp) than do females (90.0 μg/wasp). Further, there were no significant differences in composition between extracts of the Dufour's gland and the hydrocarbon fraction of the cuticular extracts of females. Because the alkadienes were found to be specific to the female integument and Dufour's gland, and thus likely candidates for pheromonal activity, three of these hydrocarbons were synthesized and bioassayed.

Bioassays. Males isolated from females do not elicit any sexual response when placed with other males, while males exposed for just 1 min to females will elicit attraction, wing fanning, and even mounting by other males. These observations were confirmed in the short-range bioassay (Figure 3) where FF females attracted 63% ($N = 30$) of the males, all of which wing fanned and antennated and most mounted the female. Males were generally not attracted to FF males (Figure 3) and males contacting FF males just touched them and climbed on top, a behavior very different from a response to females. Female cuticle diethyl ether extracts applied to FF males attracted 57% of the males ($N = 30$), which also wing fanned and most antennated, mounted, and even attempted to copulate with the treated FF male. No difference in the response of males to FF females or diethyl ether cuticle female extracts applied to FF males was found ($G = 2.07$; 2 *df*; $P = 0.36$; NS).

However, neither the hexane extract of Dufour's gland ($G = 19$; 2 *df*; $P = 7.0 \times 10^{-5}$) nor the hydrocarbon fraction of the cuticle extract ($G = 33$; 2 *df*; $P = 8.3 \times 10^{-8}$) was as attractive to males (with less than 20% responding in both cases) as the female diethyl ether extract when applied to FF males in the short-range bioassay. These results show that the more volatile component of the sex pheromone blend is absent in the hydrocarbon extracts. However, both extracts did elicit antennation and mounting in a high proportion of males

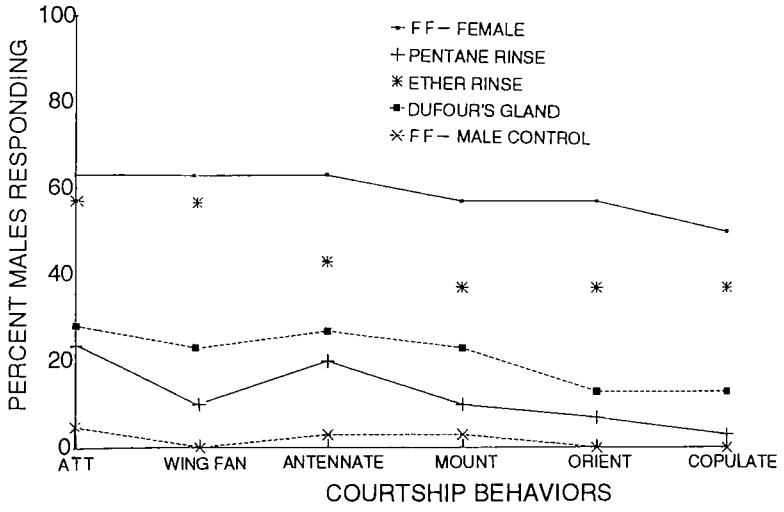

FIG. 3. Response of male *C. nigriceps* to a freshly frozen female (FF-female) or to freshly frozen males (FF-male) treated with solvent extracts of females. ATT = attraction to target (FF-female or FF-male) (N = 30).

that accidently contacted the treated males (Figure 3). No male response occurred to FF males treated with only hexane or diethyl ether (N = 10).

Since both Dufour's gland extract and the hydrocarbon fraction of the cuticle of females elicited sex-specific behaviors in males on contact, the spot and the courtship bioassay that depend on the subject males making contact with the test fractions were used. The remainder of this paper focuses on the contact sex pheromone activity.

Both the hydrocarbon fraction of the female cuticle extracts and Dufour's gland extract elicited wing fanning and antennating from males in the spot bioassay (Table 2), the latter confirming the results of Vinson (1978). However, 10 WE proved to be too strong, as males contacting the treated spot proceeded to preen their antennae rather than respond. The data did reveal that 1 WE elicited a good response. The response of males to GC peaks collected from the Dufour's gland extract (Table 3) indicated that only the odd-numbered hydrocarbon peaks (C_{25}, C_{27}, C_{29}, C_{31}, and C_{33}) had activity when compared to the even-numbered hydrocarbon peaks or the hexane extract of male cuticular hydrocarbons used as a control. Therefore, it appeared that no specific hydrocarbon chain length was responsible for the sex-specific male response, although the activity was confined to the GC peaks that are equivalent to the odd-numbered hydrocarbons.

TABLE 2. MALE RESPONSES TO DIFFERENT CONCENTRATIONS OF CRUDE EXTRACTS OF *Cardiochiles nigriceps* IN SPOT BIOASSAY ($N = 25$)

Concentration (WE)	Males wing fanning (N)	Males antennating (N)
Male cuticular diethyl ether extract		
1×10^{0}	0	0
Female cuticular hydrocarbon fraction		
10	17	20
1×10^{0}	23	24
1×10^{-1}	13	23
1×10^{-2}	4	22
1×10^{-3}	0	8
1×10^{-4}	0	0
Dufour's gland hexane extract		
10	5	11
1×10^{0}	12	24
1×10^{-1}	10	21
1×10^{-2}	6	20
1×10^{-3}	4	10
1×10^{-4}	0	0
Hexane	0	0
Ether	0	0

However, these GC peaks were broader than our standards, suggesting that these peaks consisted of a mixture of saturated and unsaturated hydrocarbons. Thin-layer chromatography confirmed the presence of alkanes, alkenes, and alkadienes. Spot bioassay of the alkanes give no response, while all males antennated the alkadiene spot ($N = 15$), but the duration of the response appeared to be shorter than the responses to the female cuticular hydrocarbon extract. Only 13% ($N = 15$) of the males responded to the alkenes with a brief antennation. The results suggest that some of the alkadienes may be responsible for the contact pheromone activity of the hydrocarbon fraction of females but that their activity may also be synergized by other components in the hydrocarbon fraction.

The identification and subsequent synthesis of three of the alkadienes allowed us to examine this possibility. The results of the spot bioassay of the three alkadienes (Table 4) indicated some male response (55%) to the (*Z*,*Z*)7,15-C_{31} alkadiene. However, the (*Z*,*Z*)7,13-C_{27} and (*Z*,*Z*)7,14-C_{29} did not elicit much activity in males. Since the latter two were inactive individually, we mixed

TABLE 3. MALE ANTENNATION RESPONSE USING SPOT BIOASSAY TO GC FRACTIONS OF DUFOUR'S GLAND OF *C. nigriceps* ($N = 20$)

GC fraction[a]	CL[b]	No. of males antennating	P[c]
1	C_{25}	0	NS
2	C_{25}	12	3.0×10^{-5}
3	C_{26}	2	NS
4	C_{27}	18	1.1×10^{-8}
5	C_{28}	0	NS
6	C_{29}	16	2.4×10^{-7}
7	C_{30}	—[d]	NC
8	C_{31}	16	2.4×10^{-7}
9	C_{32}	—[d]	NC
10	C_{33}	9	6.5×10^{-4}
Male cuticular extract	All	0	NC

[d] No GC peaks in fraction and not tested.

them with the inactive male hydrogen extract lacking any alkadienes. The results (Table 5) showed that the (Z,Z)7,13-C_{27} and the male hydrocarbon mixture were active (50% of the males responding), suggesting a synergistic component in the alkane-alkene mixture. However, the (Z,Z)7,14-C_{29} alkadiene was not synergized. Although the reason that the C_{29} alkadiene was not synergized by the male hydrocarbon blend that contains the C_{27} alkadiene is unknown, the unusually high C_{27} alkene in male hydrocarbons may be important. There are many possible combinations to be tested that await synthesis of the proper alkadienes and alkenes.

TABLE 4. MALE RESPONSE IN SPOT BIOASSAY TO THREE AVAILABLE SYNTHETIC ALKADIENES ($N = 20$)[a]

Treatment	No. males antennating	X^2	P
(Z,Z)7,13-C_{27}[a]	1	12	5.6×10^{-4}

(Z,Z)7,13-C_{27} + M[b]	10		
(Z,Z)7,14-C_{29}[c]	0	1.0	NS
(Z,Z)7,14-C_{29} + M[c]	1		

[a] All hydrocarbons were bioassayed at 0.1 female (or male) equivalents per test. M refers to male derived alkane and alkene mixture. Same letters indicate no significant difference between pairs of compounds within a molecular weight group ($P = 0.05$; Bonferroni multiple comparison procedure).

Although we obtained the characteristic sex specific response in males to the $C_{31:2}$ and a mixture of the $C_{29:2}$ with the male hydrocarbon mixture in the spot bioassay, we wanted to determine if the three available synthetic alkadienes would also elicit mounting or attempts to copulate if a female-like shape was involved. The three available alkadienes were applied to a FF male, which elicited intense antennation in 60% of the males (Table 6), but none of the males mounted the treated male (unlike what occurred when a Dufour's gland hexane extract was applied to FF males). The results suggest the alkadienes play a role in sexual behavior, while a parasitoid-like shape does not appear to play an important role. The results also suggest that (1) a specific combination of hydrocarbons is necessary to elicit mounting, (2) the presence of a large relative

TABLE 6. NUMBER OF MALES RESPONDING AS INDICATED IN COURTSHIP BIOASSAY TO TREATMENTS APPLIED TO MALE MODEL FOR FRESH FROZEN FEMALE ($N = 20$)

FF male and 3 synthetic (Z,Z) alkadienes	12	0	0

amount of the 12- and 13-heptacosene of males may inhibit this activity, or (3) yet other hydrocarbon components of the blend are necessary.

Regardless, the results of this study demonstrate differences in the hydrocarbon pattern of the cuticle of the two sexes. The results also show that the hydrocarbon composition of the cuticle of females and Dufour's gland are similar. Similar hydrocarbon patterns between cuticular extracts and Dufour's gland have been reported from bumble bees (Odham et al., 1994). The study also provides evidence that the sexual recognition of females by males is mediated by the hydrocarbon fraction of Dufour's gland and that the sex-specific alkadienes play a role in combination with some of the alkenes or alkanes present.

MODIFICATION OF RESPONSES BY *Campylomma verbasci* (HETEROPTERA: MIRIDAE) TO PHEROMONE BLENDS IN ATMOSPHERES PERMEATED WITH SYNTHETIC SEX PHEROMONE OR INDIVIDUAL COMPONENTS

(Received February 15, 1995; accepted July 24, 1995)

Abstract—Trapping experiments were conducted in orchards to test the hypothesis that exposure of the mullein bug, *Campylomma verbasci* (Meyer), to atmospheres permeated with its synthetic sex pheromone, a 94:6 blend of butyl butyrate (BB) and (*E*)-crotyl butyrate (CB), or BB or CB alone, would alter the pheromone responses of males toward off-ratio blends. Exposure to the natural 94:6 blend shifted the response preference away from the natural ratio to blends enriched in BB, including a 99:1 blend, which is normally significantly less attractive than the natural ratio. In an atmosphere permeated with CB, male mullein bugs were as responsive to blends containing 20, 33, and 43% CB, up to seven times the natural percentage, as they were to the 94:6 blend. In an atmosphere permeated with BB, responses to five blends ranging from 94:6 to 99:1 BB:CB were not significantly different, whereas in an untreated atmosphere blends of 98:2 and 99:1 were significantly less attractive than the 94:6 blend. Individual components appeared to disrupt pheromone communication primarily through the creation of a sensory imbalance and modified interpretation of pheromone blend ratios, whereas disruption by the complete pheromone blend apparently involves several mechanisms, including false-trail following and camouflage. Disruption of pheromone communication was most effective with the natural 94:6 sex pheromone blend.

Key Words—*Campylomma verbasci*, Miridae, mullein bug, sex pheromones, communication disruption, sensory imbalance, camouflage, resistance.

INTRODUCTION

Pheromones have been identified in very few heteropterans (Aldrich, 1988). The mullein bug, *Campylomma verbasci* (Meyer), is the only member of the family Miridae for which a pheromone has been identified (Smith et al., 1991). Female mullein bugs emit a sex pheromone composed of 94% butyl butyrate (BB) and 6% (*E*)-crotyl butyrate (CB), i.e., a 16:1 ratio of BB:CB. A synthetic pheromone blend containing 94% BB caught as many male mullein bugs as five caged virgin females (Smith et al., 1991), but blends containing 94–97% BB caught similar numbers of bugs (McBrien et al., 1994a). Outside this range of BB concentrations, catches fall off precipitously, and neither component is attractive alone (Smith et al., 1991; McBrien et al., 1994a).

Identification of the mullein bug sex pheromone has provided the opportunity (Smith et al., 1992) to develop pheromone-based management systems for this unpredictable and often serious pest of Red Delicious and Golden Delicious apples (Madsen and Proctor, 1985; Thistlewood et al., 1989). Disruption of pheromone communication using synthetic sex pheromones or individual components has been demonstrated in many lepidopteran species (Mitchell, 1981; Minks and Cardé, 1988; Jutsum and Gordon, 1989) and at least two coleopteran species (Huddelston et al., 1977; Mason and Jansson, 1991; Ridgway et al., 1990). Preliminary studies have demonstrated that pheromone communication in the mullein bug could be disrupted by atmospheric permeation of orchards with its complete two-component sex pheromone and suggested that false-trail following was a likely mechanism of disruption. However, as for other insects, the physiological and behavioral mechanisms of communication disruption in mullein bug are not well understood, but could include sensory adaptation at the peripheral level, central nervous system habituation, camouflage, or false-trail following (Bartell, 1982; Cardé, 1990).

Operationally, the exact mechanisms responsible for interruption of pheromone communication depend on the chemical composition of the disruptant and the release system employed (Minks and Cardé, 1988). When the disruptant consists of either an incomplete or unnatural blend of components, mechanisms quite different from those with a complete blend are possible (Minks and Cardé, 1988). An atmosphere treated with an off-ratio blend should provide the insect with a "sensory imbalance" (Hirano, 1979; Rothschild, 1981), in which the peripheral input from the component in excess lowers the sensitivity of receptors attuned to that component. Consequently, the natural ratio from a female would be interpreted as an unnatural ratio. Alternatively, unnatural peripheral input

could modify an insect's ability to interpret the natural ratio at a central neurological processing level. In either case the outcome is expected to be a diminished or abolished response to natural pheromone plumes.

Alteration of pheromone blend discrimination after preexposure to pheromone components has been demonstrated in several species, including oriental fruit moth, *Grapholitha molesta* (Busck) (Linn and Roelofs, 1981), pink bollworm, *Pectinophora gossypiella* (Saunders) (Flint and Merkle, 1983), and cabbage looper, *Trichoplusia ni* (Hübner) (Liu and Haynes, 1993). In addition, some lepidopteran species, like the codling moth, are more responsive to higher-release-rate pheromone sources in atmospheres treated with their sex pheromone than they are in nontreated atmospheres (Charmillot, 1990).

We investigated the general hypothesis that pheromone blend interpretation in the mullein bug would be altered by exposure to atmospheres treated with high concentrations of either or both of two individual sex pheromone components.

METHODS AND MATERIALS

General Methods. All experiments were conducted during September and October 1994 in the Okanagan and Similkameen Valleys of British Columbia. At this time of year most mullein bugs fly from herbaceous summer host plants into apple orchards (McBrien et al., 1994b), where they lay overwintering eggs in tree bark. Experimental apple orchards were planted predominantly with Red and Golden Delicious apple trees on semidwarf rootstocks at conventional tree and row spacings. All pheromone components and dispensers were supplied by Phero Tech Inc., Delta, British Columbia, Canada V4G 1E9. Butyl butyrate had at least 99.6% chemical purity and (*E*)-crotyl butyrate was at least 94% isomerically pure and 99.3% chemically pure (Phero Tech Inc., technical data).

Experiment 1: Response to Pheromone Blends in Crotyl Butyrate-Permeated Atmosphere. In this experiment we tested the specific hypothesis that mullein bugs would shift their pheromone responses from a preference for the natural blend of 94:6 BB:CB towards blends having a higher percentage of CB when exposed to an atmosphere treated with CB.

Two-hundred fifty low-density polyethylene Eppendorf centrifuge tubes, each containing 125 μl of CB (release rates described by McBrien et al., 1994a) were hung in the upper third of the canopy in the northeast sector of trees in each of five 0.25-ha plots (50 × 50 m), achieving a dispenser density of 1000/ha. Each crotyl butyrate-treated plot was paired with an identical nontreated control plot located 60 m up mean wind direction in the same orchard, and each pair was located in a different orchard. Five days later, five open-style wing traps (McBrien et al., 1994a) were suspended 1.5 m above ground in the

outer 0.5 m of foliage in trees in all treated and control plots. One trap was placed on the center tree of plots, and others were positioned on the diagonals 15 m from each plot corner. Traps within a plot were baited with one of five randomly assigned baits consisting of an Eppendorf tube containing 125 μl of BB:CB (v/v) in ratios of 94:6, 80:20, 67:33, 57:43, or 50:50. Baits were attached to the inner surface of each trap lid.

Trap catches were recorded daily for five days and summed. A three-factor analysis of variance (ANOVA) (binary bait, disruption treatment, orchard site) was used to test for differences in pheromone blend response as a function of disruption treatment. Mean trap catches for binary baits within each disruption treatment were compared using the Student-Neuman-Keuls' (SNK) multiple-range test (Zar, 1984). Distributions of trap catches with different pheromone blends in different disruption treatments were compared using χ^2 tests where appropriate. In this and all other experiments $\alpha = 0.05$.

Experiment 2: Response to Pheromone Blends in Butyl Butyrate-Permeated Atmosphere. Following the design of experiment 1, we tested the specific hypothesis that responses of mullein bugs would shift from a preference for the natural blend of 94:6 BB:CB towards blends containing a higher percentage of BB when they were exposed to atmospheres treated with BB.

Five different 0.25-ha experimental plots (50 × 50 m) were treated as above, with 250 Eppendorf tubes containing 125 μl of BB, and each was paired with an identical control plot. Five traps within a plot were baited as before, with one of five randomly assigned blends consisting of 94:6, 96:4, 97:3, 98:2 or 99:1 BB:CB, respectively. Trap catches were recorded daily, summed and data analyzed as in experiment 1.

Experiment 3: Response to Pheromone Blends in Atmosphere Permeated with Natural 94:6 Butyl Butyrate-Crotyl Butyrate Blend. We tested the specific hypothesis that in an atmosphere permeated with the natural 94:6 BB:CB pheromone blend, mullein bugs might shift their response from this natural blend towards marginally attractive off-ratio pheromone baits (McBrien et al., 1994a) having a higher than natural percentage of BB because they might be less well camouflaged by the 94:6 BB:CB disruptant blend than the natural binary bait.

In mid-August, 1000 polymer lures loaded with a 94:6 blend of BB:CB were hung as before in a 1-ha orchard plot (100 × 100 m). The load and emission rates of these dispensers are on file with Phero Tech, Inc. This plot was part of a study on pheromone-based management of mullein bugs in commercial orchards that was already in progress. Approximately one month after applying the disruption treatment, wing traps were baited with Eppendorf tubes containing 125 μl of one of five randomly assigned binary blends consisting of 94:6, 96:4, 97:3, 98:2, or 99:1 BB:CB. Each binary blend bait was replicated five times within the 1-ha plot by deploying traps in a 5 × 5 Latin square. Traps were at least 20 m from the border rows with 15 m between traps. Using an

identical experimental design, baited traps were deployed simultaneously in a nontreated 1-ha control plot located 2 km away.

Trap catches from the pheromone-treated and control plots were analyzed separately using an ANOVA appropriate for Latin squares (Cochran and Cox, 1957) followed by the SNK test. Because we were limited to one pheromone-treated site, we could not test for a binary bait × disruption treatment interaction using an ANOVA. A χ^2 test was used to compare the distributions of trap catches with binary baits in the treated and control plots.

Experiment 4: Response to High and Low-Release Rate Pheromone Sources in Atmosphere Permeated with Natural 94:6 Butyl Butyrate–Crotyl Butyrate Blend. We tested the final specific hypothesis that in an atmosphere permeated with this natural sex pheromone blend, mullein bugs would shift their response towards pheromone sources releasing the same blend as the disruptant but at a rate higher than the background. A 1-ha plot (100 × 100 m) was treated with a 94:6 blend of BB:CB by hanging 1000 polymer dispensers, our standard mating-disruption treatment, as 500 double-dispenser point sources. Six weeks later, two wing traps were hung 10-m apart and at least 20 m from the plot edge in each of five randomized blocks within the 1-ha plot. Blocks were separated by 20 m. Two baits, one new polymer disruption dispenser (high release rate) and one 6-week-old polymer disruption dispenser (low release rate) were randomly assigned to each pair of traps.

An identical design was used to compare attraction to low- and high-release-rate dispensers in a nontreated control plot located in an orchard at least 2 km from the pheromone-treated plot. The numbers of male mullein bugs captured in each trap were counted after 12 days. Mean trap catches were compared using ANOVA.

RESULTS

Experiment 1: Response to Pheromone Blends in Crotyl Butyrate-Permeated Atmosphere. There was a significant binary bait × disruption treatment interaction ($F_{4,12} = 14.47$, $P = 0.0002$), supporting the hypothesis that mullein bug's interpretation and response to pheromone blends is altered by atmospheric permeation with CB. In a nontreated atmosphere, mullein bugs were significantly more responsive to their natural 94:6 BB:CB pheromone blend than to all other blends tested (Table 1). When the percentage of CB was ≥33% of the blend, trap catches were similarly low.

In a CB-permeated atmosphere, however, response by mullein bugs to blends with percentages of CB ranging from 6- to 43% were not significantly different; only at 50% CB was the response significantly lower than that to a blend with 6% CB.

TABLE 1. COMPARISON OF RESPONSES BY MALE MULLEIN BUGS TO THEIR SYNTHETIC SEX PHEROMONE AND VARIOUS OFF-RATIO BLENDS OF BUTYL BUTYRATE (BB) AND (*E*)-CROTYL BUTYRATE (CB) IN NONTREATED AND CROTYL BUTYRATE-TREATED APPLE ORCHARDS

Binary blend BB:CB	Mean (± SE) number of males caught per trap[a]		Attraction ratio[b]
	Nontreated plots	Crotyl butyrate-treated plots	
94:6 (natural ratio)	130.3 ± 44.7a	68.3 ± 25.5a	0.5
80:20	40.3 ± 21.7b	72.8 ± 28.9a	1.8
67:33	10.8 ± 3.8c	41.5 ± 23.8a	3.8
57:43	6.3 ± 3.1c	32.0 ± 13.8ab	5.1
50:50	6.0 ± 3.2c	20.3 ± 13.3b	3.4

[a]Means ($N = 4$) within a column followed by the same letter are not significantly different (SNK test, $\alpha = 0.05$).

[b]Total catch in treated plots divided by total catch in control (nontreated) plots.

When catches were expressed as an attraction ratio (catch in treated plots/catch in control plots), all binary blends containing above normal percentages of CB were more attractive in a crotyl butyrate-treated orchard than the same blends in a nontreated orchard (Table 1). A bait containing 43% CB, seven times the natural percentage (Smith et al., 1991), was five times more attractive in the crotyl butyrate-treated plots than in the nontreated plots.

Experiment 2: Response to Pheromone Blends in Butyl Butyrate-Permeated Atmosphere. There was no significant interaction of binary bait × disruption treatment ($F_{4,12} = 1.05$, $P = 0.423$) when orchards were treated with BB. In the nontreated atmosphere response by male mullein bugs to blends containing 94–97% BB was not significantly different; at 98 or 99% BB response declined, with the 99:1 blend being least attractive (Table 2). In the butyl butyrate-treated plot there was no difference in trap catches with different baits. Although there was no binary bait × disruption treatment interaction, the frequency distributions of total catches with different binary baits in nontreated and BB-treated plots were significantly different ($\chi^2 = 39.5$, $df = 4$, $P < 0.0001$).

Experiment 3: Response to Pheromone Blends in Atmosphere Permeated with Natural 94:6 Butyl Butyrate–Crotyl Butyrate Blend. In a nontreated atmosphere, the responses of mullein bugs to baits containing percentages of BB higher than that found in the natural blend were similar in experiments 2 and 3, respectively (Tables 2 and 3). In an atmosphere permeated with the natural pheromone

TABLE 3. COMPARISON OF RESPONSES BY MALE MULLEIN BUGS TO THEIR SYNTHETIC SEX PHEROMONE AND VARIOUS OFF-RATIO BLENDS OF BUTYL BUTYRATE (BB) AND (*E*)-CROTYL BUTYRATE (CB) IN NONTREATED AND PHEROMONE-TREATED APPLE ORCHARDS

Binary blend BB:CB	Mean (± SE) number of males caught per trap[a]		Attraction ratio[b]
	Nontreated plot	Pheromone-treated plot (94:6 BB:CB)	
94:6 (natural ratio)	110.6 ± 15.9a	1.0 ± 0.5c	0.009
96:4	108.2 ± 14.2a	4.8 ± 2.0b	0.04
97:3	101.2 ± 18.9a	9.6 ± 2.6b	0.095
98:2	81.6 ± 13.4ab	20.4 ± 2.0a	0.25
99:1	63.4 ± 12.9b	19.8 ± 3.7a	0.312

[a]Means ($N = 5$) within a column followed by the same letter are not significantly different (SNK test, $\alpha = 0.05$).
[b]Total catch in treated plot divided by total catch in control (nontreated) plot.

blend, however, the response pattern was the inverse of that in a nontreated atmosphere (Table 3). The 99:1 bait caught 20 times more mullein bugs than did the natural 94:6 bait in an atmosphere treated with a 94:6 disruption blend. The frequency distributions (total trap catches) of responses to binary pheromone baits in nontreated and pheromone-treated plots were significantly different ($\chi^2 = 204.3$, $df = 4$, $P < 0.0001$).

Experiment 4: Response to High- and Low-Release Rate Pheromone Sources in Atmosphere Permeated with Natural 94:6 Butyl Butyrate–Crotyl Butyrate Blend. In the control plot, traps baited with low-release-rate baits of 94:6 BB:CB caught 88.4 ± 20.0 (mean ± SE) mullein bugs similar ($P > 0.05$) to the 100.6 ± 12.2 bugs caught in response to high-release-rate baits. While mean catches with these same baits were significantly lower ($P < 0.05$) in the pheromone-treated plot than in the control plot, mean catches with low (10.8 ± 5.3) and high (11.8 ± 5.7) release-rate baits were not significantly different ($P > 0.05$).

DISCUSSION

When trap catches in experiments 1–3 are expressed as a percentage of catch with the natural 94:6 blend in a nontreated plot, the patterns of pheromone response by male mullein bugs are clearly seen to be altered by exposure to the natural 94:6 blend of BB:CB or CB and BB released individually into the atmosphere (Figure 1). This is the first demonstration of such a phenomenon in the Heteroptera, indicating that similar responses found in the Lepidoptera (Linn and Roelofs, 1981; Flint and Merkle, 1983; Liu and Haynes, 1993) are not unique to that order.

Figure 1 illustrates that the natural pheromone blend is the most effective communication disruptant, causing 99% reduction in response to a 94:6 blend of BB:CB that mimics a female, compared with 48.4 and 35.6% reductions in response caused by CB and BB applied as individual components, respectively.

Shifts in pheromone blend response after exposing mullein bugs to single-component disruptants are probably best explained by the creation of a sensory imbalance (Hirano, 1979; Minks and Cardé, 1988) that leads either to adaptation of antennal receptors or a central nervous system change in the ability to interpret the ratio of pheromone components in a bait. If the sensitivity of receptors for BB and CB or central nervous system response to receptor inputs were lowered by exposure to these individual components (Minks and Cardé, 1988), then mullein bugs should respond to off-ratio blends in predictable ways. Lowering sensitivity to CB by exposure to a CB atmosphere is the same as increasing BB in the blend. Therefore, an 80:20 or 94:6 BB:CB blend in a CB background might be perceived or interpreted as similar to a 99:1 BB:CB blend in a non-

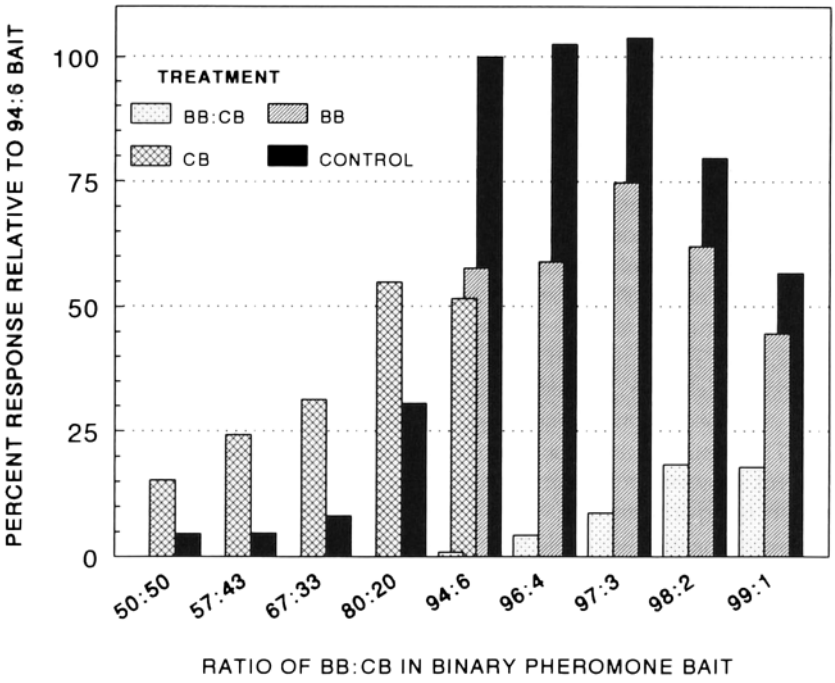

FIG. 1. Summary of relative responses (expressed as a percentage of the catch with the natural 94:6 ratio of BB:CB in nontreated control plots) of male mullein bugs in experiments 1–3 to various ratios of its synthetic pheromone blend in orchards permeated with CB, BB, or the natural 94:6 ratio of BB:CB compared with the pooled responses in nontreated, control orchards.

treated atmosphere and produce similar catches. Likewise, lowering sensitivity to BB by exposure to a BB disruptant is the same as increasing CB in the blend; consequently, a 94:6 blend in a BB background might be perceived as if it were a 90:10 or 80:20 blend in a nontreated atmosphere and produce similar catches. Each of these phenomena appears to occur in the mullein bug (Tables 1 and 2, Figure 1).

The more pronounced alteration of pheromone blend response with CB than with BB (Figure 1) could be caused in part by differential adaptation rates of receptors attuned to each component (Baker et al., 1989). Alternatively, there may be fewer CB receptors than BB receptors on the antennae of mullein bugs, or there may simply be less room for shifting response to BB because it repre-

sents most of the pheromone blend, and we never tested blends having >99% BB.

Unlike pink bollworm, in which a single pheromone component not only altered male response to pheromone blends, but disrupted communication and mating to a level comparable with that caused by the complete blend (Flint and Merkle, 1983, 1984), disruption of mating in mullein bug is probably best achieved with the complete pheromone blend, as the greatest levels of communication disruption were observed with this blend (Figure 1). Our study supports the threshold hypothesis erected by Roelofs (1978) and extended by Minks and Cardé (1988), that the complete pheromone blend should be the most effective disruptant at the lowest application rate. Moreover, it seems plausible that several, if not most, of the postulated mechanisms of communication disruption (Bartell, 1982; Cardé, 1990) may be working against mullein bugs when the natural pheromone blend is used as a disruptant.

The reason for this conclusion is that the complete blend is probably capable of invoking several disruption mechanisms simultaneously. The disruption dispensers in experiment 4 were highly attractive when they were new or six weeks old, indicating that they could have induced false-trail following over an extended period. Continued orientation to disruption dispensers could lead to a depletion of physical drive after an insect flies upwind several times and never mates. Such unrewarded and repeated responses could lead to habituation at a central neurological processing level (Kuenen and Baker, 1981) and, conceivably, to associative learning (Figueredo and Baker, 1992), wherein the male learns there is no female at the end of a synthetic plume and stops responding. Finally, there is evidence of a camouflaging effect. Traps releasing blends most similar to the disruption blend should be camouflaged more effectively than off-ratio blends. In support of this hypothesis, off-ratio blends remained detectable and attracted more mullein bugs than the natural blend (Table 3).

In contrast, the single-component disruptants are not attractive on their own in nontreated backgrounds (Smith et al., 1991; McBrien et al., 1994a) and could not elicit false-trail following. Mullein bugs would be unlikely to become fatigued from flying in response to these baits, and the likelihood of learned responses would be low. According to Minks and Cardé (1988) single components could conceivably camouflage the complete blend. However, if this mechanism were acting in the mullein bug system, a pure BB disruptant should camouflage a similar 99:1 BB:CB bait more effectively than a dissimilar 94:6 BB:CB bait. Based on trap catches, this did not appear to occur. In all likelihood the only mechanism operating in our single-component disruption plots was some form of sensory imbalance.

Modification of pheromone blend interpretation or response after exposure to disruptant components or blends raises some concern about the potential for

resistance to pheromone-based control systems. If the observed modifications of male response were accompanied by genetically based variation in ratios of female-produced pheromone components, resistance to pheromone-based mating disruption may develop quickly in isolated populations. However, the mullein bug is a highly mobile species that migrates between overwintering and summer host species (Thistlewood et al., 1989; McBrien et al., 1994b), allowing outbreeding in the absence of disruption that should counter selection pressure in disrupted orchards. In spite of these potential concerns, this study indicates that the natural 94:6 BB:CB pheromone blend would be the best candidate for commercialization as a mating disruptant for the mullein bug.

(Received April 14, 1995; accepted July 24, 1995)

Abstract—The sex pheromone of the South American potato tuber moth *Symmetrischema tangolias* (syn.: *Symmetrischema plaesiosema*) was identified as a 2:1 mixture of (*E*,*Z*)-3,7-tetradecadien-1-ol acetate and (*E*)-3-tetradecen-1-ol acetate by means of dual-column GC, EAG, GC-EAD, GC-MS, NMR, and wind-tunnel bioassays. (*Z*)-5-Tetradecen-1-ol acetate and (*Z*)-7-tetradecen-1-ol acetate were also identified in the pheromone gland extract. Male *S. tangolias* were able to detect these acetates (EAG), but their addition to the two-component sex pheromone did not improve attractiveness. Field trials in Cajamarca and Cusco, Peru, showed that traps baited with the synthetic sex pheromone were able to catch large numbers of male *S. tangolias*.

Key Words—*Symmetrischema tangolias*, *Symmetrischema plaesiosema*, Gelechiidae, moth sex pheromone, potatoes, identification, (*E*)-3-tetradecen-1-ol acetate, (*E*,*Z*)-3,7-tetradecadien-1-ol acetate.

INTRODUCTION

The potato tuber moth *Symmetrischema tangolias* (Gyen) (Hodges and Os, 1990; Povolny, 1967), formerly called *Symmetrischema plaesiosema* (Turner) (Sánchez et al., 1986), is a severe pest on potatoes in the field and in storehouses in Peru. *S. tangolias* was first reported in the Montaro Valley, Peru, in 1982

*To whom correspondence should be addressed.

(Alcázar et al., 1982), although this insect has also been reported in Australia (Osmelak, 1987) and, since 1993, in Bolivia (Alcázar, personal communication). Its main distribution areas are the higher regions of the Peruvian Andes (CIP, 1993). In the field the larvae bore into the stems of potato plants, which causes the plants to break and die. In storehouses the larvae mine into the potato tubers making them unsuitable for human consumption. Nevertheless, the infested tubers are still planted, which causes further spread of the pest. In Peru seed potatoes are generally stored in large storehouses of cooperatives where they are sometimes literally covered with pesticides. Amounts of malathion of 1.3 g/kg potatoes have been observed. In the Peruvian Andes small farmers keep the potatoes indoors or in small open storehouses. These potatoes are not treated with pesticides and are therefore an ideal food for *S. tangolias*. Crop losses can reach up to 100% (Alcázar, personal communication). Today *S. tangolias* is considered to be an even greater pest in Peru than *Phthorimaea operculella* (Zeller), which occurs in the same regions (Ewell et al., 1990). In 1976 Persoons et al. identified the sex pheromone of *P. operculella*, which now is efficient for pest control when applied in mass-trapping (Raman and Booth, 1983). We started the identification of the sex phermone of *S. tangolias* in order to develop a pest control strategy for this moth.

METHODS AND MATERIALS

Insects. The laboratory culture of *S. tangolias* was started with pupae that were collected in a storehouse for potatoes in Cajamarca, Peru, in November 1991. The moths were reared on potato tubers (cv. Bintje) under the following conditions: 22 ± 1°C at day and 17 ± 1°C at night, 65 ± 5% relative humidity, and a 12L:12D photoperiod. The potatoes were provided with small punched holes in which the females could lay their eggs. After four days the tubers, loaded with eggs, were relocated to transparent boxes with a 1-cm layer of clean sand. About 40 days later the pupae were collected, cleaned with a 3% hypochlorite solution and separated into males and females. Moths were fed on a 10% honey solution.

Pheromone Extracts. Pheromone glands from 3-day-old virgin females 7–10 hr into the scotophase were collected. Female moths had been observed to call in this time span. A little more than just the tip of the abdomen was cut off as reported in Attygalle et al. (1987) and kept in redistilled and degassed hexane. The extracts were stored under nitrogen at −20°C. Bioassays were carried out by offering a piece of filter paper (6 × 0.8 cm, Schleicher & Schuell 589[2]) loaded with 2FE (female equivalents) of extact to male moths. Bioactive fractions caused intensive "flutter" responses and attempts to copulate with the filter paper.

Electroantennograms (EAGs). Antennae from 3-day-old males were used for EAG measurements. The antenna was cut off at the base. About four segments of the tip were cut off to enable electrical contact with the recording electrodes. The tip and basal part were connected to glass electrodes filled with a 0.1 M KCl solution. All tetradecen-1-ol acetate isomers used (>99% purity), were obtained from the IPO-DLO pheromone bank (Voerman, 1988). Test cartridges were prepared by applying 100 μl of a 5 PPM solution of the acetate in hexane on a piece of filter paper (6 × 0.8 cm, Schleicher & Schuell 589^2). After evaporation of the solvent, the paper was put into a Pasteur pipet. A Pasteur pipet filled with a filter paper containing 25 μl of a 1% solution (v/v) of (Z)-3-hexen-1-ol acetate (Carl Roth, Karlsruhe, Germany) in paraffin oil (Merck, Uvasol) served as reference stimulus. Silver wires connected the electrodes to the recording instruments: Grass HIP16A input probe, Grass P16D DC-amplifier (rise time: 30 ms), Philips PM3302 oscilloscope, Krenz TRC 4010 transient-recorder and Estate PC AT386. For details on the recording and calculation of EAG data, see Visser and Piron (1995).

Coupled Gas Chromatography–Electroantennographic Detection (GC-EAD). GC-EAD measurements were carried out at Syntech Laboratories, Hilversum, The Netherlands. The GC was a Chrompack 9000 equipped with a split/splitless injection system. Injections were done in splitless mode only. The column was a J&W 12-m DB-5 (5% phenyl methyl polysiloxane), 0.20-mm ID and 0.33-μm film thickness. The sample was equally split between a flame ionization detector (FID) and the EAG detector. Conditions were: carrier gas, helium; inlet pressure, 150 kPA; temperature programming, 100°C (0 min hold) to 220°C (0 min hold) at 10°C/min; injector and detector temperature, 250°C. The EAG recorder, software, IDAC (Intelligent Data Acquisition Controller) interface board for the AT486 PC and other peripheral equipment were manufactured by Syntech Laboratories.

Dual-Column GC. Gas chromatographic analyses were performed on a Hewlett Packard (HP) 5890A equipped with a split/splitless injection system, a 1 : 1 inlet splitter, and two fused silica columns each equipped with an FID. The two columns were a J&W 60-m DB-1 (100% methyl polysiloxane), and a J&W 60-m DB-Wax (polyethylene glycol), both having 0.25-mm ID and 0.25-μm film thickness. Conditions were: carrier gas, hydrogen; inlet pressure, 20 psi; linear velocity, 35 cm/sec; temperature programming, 50°C (0 min hold) to 238°C (8 min hold) at 4°C/min; injector temperature 220°C; detector temperature 260°C. Retention Indices (RI) were calculated according to Kovats (1964); the real retention times instead of the adjusted retention times were used for RI calculations. The RI were calculated by comparing the retention times of the components of interest with those of the C_7–C_{23} alkanes. For the GC spiking experiments, a just-detectable amount of a reference compound was added to the gland extract. Both the extract and the extract combined with the reference

compound were examined by GC. Compounds were considered identified when on both columns the peaks of interest would rise by the same amount.

Preparative GC. Preparative GC was performed on an HP 5890 series II with an HP 7673 automatic sampler. The temperature controlled injection port (controller model 504) and trap unit (controller model 580) were obtained from Gerstel Mulheim, Germany. The column was a 60-m J&W DB-Wax, 0.53-mm ID and 1.0-μm film thickness. Conditions were: carrier gas, hydrogen; inlet pressure, 150 kPa; temperature programming, 150°C (1 min hold) to 230°C (1 min hold) at 5°C/min; injector temperature, 50°C (1 min hold) to 240°C (1 min hold) at 15°C/sec; detector temperature 260°C.

Dimethyl Disulfide (DMDS) Derivatization. Approximately 10 μl of freshly distilled DMDS and 5 μl of 5% iodine in diethylether were added to 20 FE of extract from which the solvent had been evaporated by a gentle stream of nitrogen. The mixture was heated for 16 hr at 60°C in a small airtight flask. The reaction was then stopped by addition of a drop of saturated $Na_2S_2O_3$ solution. The organic phase was separated and concentrated to approximately 10 μl by evaporating the solvent at 40°C in a nitrogen atmosphere (Vincenti et al., 1987; Schulz, 1987).

Coupled Gas Chromatography–Mass Spectrometry (GC-MS). GC-MS was performed on a Finnigan MAT 95 mass spectrometer (70 eV), coupled to a Varian GC equipped with a split/splitless injection system. Injections were done in splitless mode only. The column was a J&W 25-m DB-5 fused silica column, 0.25-mm ID and 0.25-μm film thickness. Conditions were: carrier gas, helium; temperature programming, 50°C (2 min hold) to 100°C (0 min hold) at 25°C/min and then to 280°C (8 min hold) at 4°C/min; injector and transfer-line temperature, 250°C.

NMR. NMR spectra were recorded on a Bruker AC-E 200 at 200 MHz in $CDCl_3$ (100.0% D, Janssen Chimica). Chemical shifts are reported in parts per million (δ) relative to TMS. As internal reference $CHCl_3$ (δ = 7.24) was used.

Synthesis. All chemicals used were of Pro Analyse (PA) quality. 3-Decyn-1-ol was purchased from ABCR Chemie, Karlsruhe, Germany. The *cis* reduction with the P-2 nickel catalyst in ethanol was carried out according to Brown and Ahuja (1973). More than 99% isomeric purity of the synthesized products was achieved through purification on a 200-cm × 0.8-cm Lewatit SP 1080/Ag^+ column (Voerman and Rothschild, 1977). Products were stored under nitrogen at −20°C with 0.1% 2,6-di-*tert*-butyl-4-methylphenol (BHT) as antioxidant (Goto et al., 1974).

Wind-Tunnel Bioassays. Male moths were given a dual-choice situation in the 3.0 (l) × 1.3 (w) × 0.8 (h) m flight section of a wind tunnel, which was entirely constructed from glass and stainless steel (Visser, unpublished data). Two black-painted delta traps (IPO-DLO, Wageningen, Netherlands) were placed at the same height 30 cm apart at the upwind side. Inside each trap a

horizontal strip of filter paper (6 × 0.8 cm, Schleicher & Schuell 589[2]) was suspended. These filter papers were supplied with 100 μl of a 1 ppm solution of a (mixture of) acetate(s) in double-distilled hexane. Conditions were: temperature 17 ± 1°C, 65 ± 5 relative humidity, 12 cm/sec wind speed, and ≤4 mW/m^2 red light. The tests started 2–3 hr into the scotophase with the release of 10–50 male moths at the downwind side. The males were left for 6 hr. The caught males were counted and subjected to the Wilcoxon matched-pairs, signed-rank test (Siegel, 1956). NS means $P > 0.05$ (two-tailed).

RESULTS AND DISCUSSION

Identification. From about 2000 virgin female moths the sex pheromone glands were collected and kept in 10 ml hexane. When exposed to male moths, 2-FE of this extract caused intensive "flutter" responses. The extract was concentrated to approximately 1.5 ml under a gentle stream of nitrogen and fractionated on a 6-ml Baker 10 SPE column packed with 500 mg, 45 μm, 60 Å silicagel. The column was successively eluted with 1.5-ml portions of 0, 2, 5, 10, 20, 50, and 100% of *tert*-butylmethylether in hexane. The column was sucked dry between each fraction. Only the 5% fraction generated a behavioral response. The EAG responses of this 5% fraction and the total extract were not significantly different. From GC-EAD measurements of this fraction, it was concluded that EAG-active peaks eluted during a short period of the entire GC run. The resolution of the GC-EAD equipment made it impossible to discriminate between the four peaks in the gas chromatogram of the active fraction on DB-1 (Figure 1). By comparison of the calculated RI on both the DB-1 and DB-Wax columns with those calculated for reference components from IPO pheromone bank (Voerman, 1988), it became obvious that peaks **2, 3,** and **4** were tetradecen-1-ol acetate isomers. The mass spectra of these peaks were in agreement with this. Peak **1** could be tentatively identified as a nonconjugated tetradecadien-1-ol acetate isomer because of its typical extra difference in RI on the DB-1 and DB-Wax columns. The mass spectrum of **1** (Figure 2) supported this hypothesis. Compounds **2, 3,** and **4** were identified, respectively, as (*Z*)-5-, (*Z*)-7-, and (*E*)-3-tetradecen-1-ol acetate by comparing the MS and the RI with those obtained from reference compounds. GC spiking experiments provided additional evidence (Figure 3). About 10 μg of the two main peaks, **1** and **4,** were isolated with preparative GC, which proved sufficient for NMR analysis. The NMR spectrum of **4** was identical to that of synthetic (*E*)-3-tetradecen-1-ol acetate. The NMR spectrum of **1** showed the same signal at 2.29 PPM as the NMR spectrum of (*E*)-3-tetradecen-1-ol acetate, which is characteristic for a double bond at the 3-position (Figure 4). Comparison of the olefinic part of the NMR spectrum of **1** with those of synthetic (*Z*)-3- and (*E*)-3-tetradecen-1-ol

acetate suggested that the double bond at the 3-position of **1** has the *trans* configuration. The extract was derivatized with DMDS to get information about the position of the second double bond. The mass spectrum of the DMDS-derivative of **1** is shown in Figure 5. The fragmentation pattern suggested **1** to be a 3,7-tetradecadien-1-ol acetate isomer. To determine the *cis/trans* configuration of the double bonds of **1**, all tetradecen-1-ol acetate isomers were tested with EAG (Figure 6). The difference in response between the (*E*)-7- and the (*Z*)-7- isomer suggested the (*E*,*Z*)-3,7- stereochemistry for **1**. This was proven

under formation of the diene rather than to couple with the lithium acetylide. More efficient routes for the synthesis of **1** are under investigation.

Behavioral Bioassays. Different mixtures of identified components were tested in the wind tunnel. Although the ratio of the four identified compounds in the gland extract was: (*E*,*Z*)-3,7-(*E*)-3-:(*Z*)-7-:(*Z*)-5 = 62:31:6:1, best results were obtained with a mixture containing two components, namely (*E*,*Z*)-3,7-tetradecadien-1-ol acetate and (*E*)-3-tetradecen-1-ol acetate. No significant difference in attractiveness could be determined between 2:1 and 1:1 mixtures of these two components. Addition of the two minor compounds (*Z*)-7-tetradecen-1-ol acetate and (*Z*)-5-tetradecen-1-ol acetate in the same ratio that had been found in the gland extract did not influence the attractiveness of the mixture. The addition of 10% of (*Z*)-5-tetradecen-1-ol acetate decreased the attractiveness of the mixture. The function of the (*Z*)-5- and (*Z*)-7-tetradecen-1-ol acetates, which were detected in the gland extracts, therefore remains unclear. It may be that the trap catches in the wind tunnel bioassays were not sensitive enough to reveal behavioral differences.

The 2:1 mixture of (*E*,*Z*)-3,7-tetradecadien-1-ol acetate and (*E*)-3-tetradecen-1-ol acetate was tested in potato fields and storehouses in Peru. Catches up to 120 and 450 individuals per night per trap for field and storehouse experiments, respectively, were achieved. The field catches emphasized the great attractiveness of the synthetic pheromone blend since no *S. tangolias* could be detected by us in an extensive search of the potato field and the surrounding areas. The catches in the storehouses dropped considerably after the first couple of days. Replacement of the traps by new ones did not improve the catches.

This means that traps indoors are able to diminish pest populations quite rapidly and may be efficient for pest control in storehouses through mass-trapping of pest insects. Large-scale field experiments will be carried out in Peru in the near future in order to determine the efficiency of the synthetic pheromone in the control of *S. tangolias*.

Acknowledgments—We would like to thank Mr. G. Romeijn (Plant Protection Service, Wageningen, The Netherlands) for the identification of *S. tangolias*; Dr. J.N.C. van der Pers of Syntech laboratories, Hilversum, The Netherlands, for the use of the GC-EAD equipment; Dr. M.A. Posthumus, Wageningen Agricultural University, The Netherlands, for running the GC-MS spectra; and Mr. A. van Veldhuizen, Wageningen Agricultural University, The Netherlands, for running the NMR spectra. The research for this publication was financed by the Netherlands' Minister for Development Co-operation.

Abstract—Codling moth females (*Cydia pomonella*, Lepidoptera: Tortricidae) (CM) usually lay single eggs and have a tendency to disperse. In a first experiment we observed that single females exposed to 20 apples distribute their eggs regularly among apples, suggesting a dispersive oviposition behavior. In a dual-choice situation, isolated females avoided oviposition on areas of cardboard treated with a methylene dichloride egg extract at the dose of ca. 1.0 egg equivalent/cm^2. A strong avoidance was obtained in response to a 20-fold dose, which was accompanied by a significant reduction of total oviposition. Seven major compounds found by GC analyses in the methylene dichloride extract of 2 to 3-day-old eggs were saturated or unsaturated C_{14}-C_{18} straight-chain fatty acids: myristic acid, palmitic acid, palmitoleic acid, stearic acid, oleic acid, linoleic acid, and linolenic acid. This was confirmed by GC-MS analysis of an extract made by ethyl ether. Smaller amounts of three methyl esters were also identified as methyl myristate, methyl palmitate, and methyl stearate. A blend of the seven fatty acids (FA) mimicked rather well the avoidance provoked by the extract, and this avoidance was confirmed by choice between treated and untreated fruits by single females. The treat-

ment of apples with the 7FA mixture induced an aggregative distribution of the eggs among apples. We also found that the amounts of fatty acids harvested in the extract depend on the egg age. Amounts of fatty acids increased until eggs were 4 days old and then decreased before hatching. In this paper we discuss the possible role of simple molecules, such as fatty acids and their esters, as semiochemicals indicative of juvenile tissues.

INTRODUCTION

Investigations on oviposition deterrents relative to the dispersion of progeny yield fascinating information on host-plant selection behaviors by phytophagous insects. Reproductive strategies involve factors that influence how progeny are distributed over space and time. In many cases perception by the female of information produced by eggs or larvae is of primary importance to adjust population level to the size of available resources. Assessment of oviposition sites and egg load by ovipositing females and avoidance of plants occupied by conspecifics have been reported in Lepidoptera [Urquhart, 1960 quoted in Chew and Robbins, 1984; MacLellan, 1962, Rothschild and Schoonhoven, 1977], and more generally in a wide variety of phytophagous insects (Prokopy, 1981; Messina and Renwick, 1985; Anderson, 1986; Roitberg and Prokopy, 1987). This behavior involves intraspecific chemical cues (Hurter et al., 1987; Imai et al., 1990) or both intra- and interspecific ones (Schoonhoven, 1990; Thiéry and Gabel, 1993; Blaakmer et al., 1994). In the latter category, simple chemicals (fatty acids and derivatives) deter oviposition in several lepidopteran species (Thiéry and Le Quéré, 1991; Thiéry et al., 1992; Gabel and Thiéry, 1994), which led us to propose that fatty acids and/or derivative esters exist on the eggs of several lepidopteran species and may allow interspecific recognition (Thiéry and Gabel, 1993).

The codling moth (CM), *Cydia pomonella* (Lepidoptera: Tortricidae), is an important pest of orchards, where it causes severe damage on apples and other fruits. Female CM normally deposit single eggs close to fruits (on bark or leaf) or directly on fruit. Eggs are always well distributed and more than one egg per single fruit or leaf occurs only occasionally (Geier, 1963; Wood, 1965; Jackson, 1979). As a possible result of that, more than one larva per apple is seldom found (Ferro and Harwood, 1973). Although Roitberg and Prokopy (1982) were unsuccessful in characterizing the occurrence of an oviposition deterring pheromone in CM, these reports motivated studies on egg dispersion in CM, with a dispersive oviposition behavior being hypothesized as the consquence of the moth perceiving fresh eggs (MacLellan, 1962). We

recently observed that CM females avoid ovipositing on apples treated with fatty acids and methyl esters isolated from *Lobesia botrana* at a dose of 72 egg equivalents per apple (Gabel and Thiéry, 1994).

The present study was intended to determine if simple chemicals acting as general oviposition deterrents occurred in CM eggs. The study had three objectives: (1) to quantify the distribution of eggs on apples under conditions of limited resource, (2) to verify the behavioral response of CM females to an extract of conspecific eggs, and (3) to determine the chemical constitution of this extract and the effect of egg age on its chemical constitution.

METHODS AND MATERIALS

Insects originated from a laboratory colony (strain: INRA Zoologie, Montfavet, France) reared for more than 20 generations on artificial diet (Guennelon et al, 1981) in climate chambers regulated with the following conditions: 16L : 8D photocycle regime (22 ± 0.5°C, 85 ± 5% relative humidity during photophase and 20 ± 0.5°C, 75 ± 5% relative humidity during scotophase). Behavioral observations were made with 2-day-old mated females. Mating was obtained by grouping 10 females and 10 males for two days in arenas with access to honey and water. Apples (cv. Golden Delicious) were harvested just before trials from an orchard free of pesticides, and those free of CM attacks and with horizontal diameter between 5 and 5.5 cm were used.

Extraction and Analysis.

Two- to Three-Day-Old Egg Extracts. Females were forced to oviposit on clean glass slides for two consecutive nights. Eggs were then counted and glass slides with eggs were washed either in methylene dichloride (12,000 eggs) or in ethyl ether (4200 eggs). Moth scales were removed by passing the extracts through a Millipore filter (GW, 0.22 μm). The extract was then evaporated under nitrogen flow. An aliquot was devoted to GC analysis, and another aliquot devoted to bioassays was evaporated to dryness and then diluted according to the required concentration for application.

Effect of Egg Age. Age of eggs was studied by harvesting eggs during one night and extracting them with methylene dichloride as described above. We had four batches of 2000–2500 eggs each. One batch was immediately extracted (age < 12 hr), and the three others were kept in an incubator (climate conditions described above) for two, four, or six days before extraction.

Chemical Analysis. Analyses of the extracts were performed by gas chromatography (GC) with no prior treatment except filtration to remove scales as described above. GC, either coupled or not to a mass spectrometer (MS), was equipped with an HP Ultra 1 column (0.20 mm ID × 25 m) and a flame

ionization detector. The temperature program started at 60°C with 2 min isothermal and then linearly increased by 5°C/min to 240°C with 10 min isothermal at the end. Mass spectra were obtained with an HP 5971 A mass selective detector with positive 70 eV ionization. Spectra were compared to an MS data bank and spectra obtained from pure standards.

Bioassays

All bioassays were conducted in climatic chambers under conditions described above.

Bioassay 1: Distribution of Eggs on Untreated Apples. To check the distribution of eggs on apples, one female and two males were offered during a night 20 equidistant apples positioned in four rows of five apples on the floor of an arena designed to prevent oviposition anywhere else than on apples (60 × 40 cm, 30 cm high). Twenty replicates were performed.

Bioassay 2: Oviposition Responses to Extract and Synthetic Blend on Cardboard. Gravid females were isolated (no males) in an altuglass tube (6.5 cm ID, 13 cm long) and could only oviposit on a smooth cardboard providing treated areas (32 spots of 1.1 cm^2 each); the remaining area (109 cm^2) was untreated (Gabel and Thiéry, 1992). The extract was diluted for application with 6 parts acetone and 4 parts purified water (API). Treatments were made by applying on the cardboard 32 equidistant wells (ca. 1.1 cm diam.) and filling each with 5 μl of the solution of test (Gabel and Thiéry, 1992). After complete evaporation of the solvents, the cardboards were exposed to females. We determined the response either to API or to the following quantities of extract expressed in egg equivalents per spot: 1 egg eq. (A) and 20 egg eq. (B). Females were individually exposed the first night to a blank carboard, then on the second night to cardobard impregnated with treatment spots (API, extact, or synthetic blend), and on the third night to blank cardboard. The 3% of females that did not oviposit during the three consecutive nights were considered as unmated and then disregarded. The number of eggs deposited on treated areas (T) and untreated areas (UT) were counted, eggs in contact with boundaries being considered as T. We calculated for each female an avoidance index corrected to equivalent surface area (UT = 3T): Ai% = (UT − 3T)/(UT + 3T) × 100 (Gabel and Thiéry, 1992), which may vary from 100% (maximum avoidance) to −100% (maximum preference). An identical procedure was performed to verify the activity of a synthetic blend corresponding to seven identified fatty acids (7FA). Pure chemicals (GC standards, Sigma Ltd.) were dissolved in pure acetone (see Table 3 below for ratios) and the dose was adjusted in API to the higher dose of extract used (20 egg eq./spot).

Bioassay 3: Test of Synthetic Blend on Apples This bioassay was conducted in the same arenas as bioassy 1, with one female and two males per arena.

These experiments could not have be done with extracts of eggs because of the enormous number of eggs required. To prevent damaging effects of acetone on apple cuticles, we used a second solvent or application phase, AP2, consisting of 1 part acetone, 8.9 parts purified water, and 0.1 part wetting agents (Triton X-100, Prolabo). Apples were rapidly dipped into the treatment solution of 7FA (same proportions as in bioassay 2) dissolved in AP2. Oviposition assays were conducted either in dual-choice or no-choice situations. In the choice situation, females were exposed to two rows of five treated apples (7FA) alternating with two rows of apples treated with solvent only (AP2) (15 replicates). In the no-choice situation, all apples were dipped in the 7FA solution (18 replicates). The numbers of eggs on treated and control apples (C) were counted. We calculated in each experimental arena a simple avoidance index: $\text{Ai}\% = (C - T)/(C + T) \times 100$ (where T is the number of eggs on treated sites and C on control sites with C and T representing equal areas). This index is equivalent to that described above.

Statistics

Bioassays 1 and 3 (No-Choice Situation). Egg distribution on apples was analyzed using a nonparametric index of dispersion as described in Chessel (1978). The variable

$$D = \sum_{i=1}^{n} y_i^2,$$

where y_i is the number of eggs on apple i, describes the variability in the distribution of p eggs ($p = \Sigma_{i=1}^{n} y_i$) among n apples. D tends towards a maximum when eggs are concentrated on a single apple and towards a minimum when eggs are regularly dispersed. If the eggs are distributed randomly (null hypothesis), then the chance that a given egg is laid on apple i equals $1/n$. This hypothesis assumes that eggs are laid independently of each other and that apples have an equal chance of receiving an egg. Under this hypothesis, the mean (E) and the variance (V) of D equal:

$$\begin{cases} E(D) = \dfrac{p}{n}(n + p - 1) \\ V(D) = \dfrac{2p}{n^2}(p - 1)(n - 1) \end{cases}$$

For N replicates the following index of dispersion (Id) can be obtained:

$$Id = \frac{1}{\sqrt{N}} \sum_{i=1}^{N} \frac{D_i - E(D_i)}{\sqrt{V(D_i)}}$$

and the value of $Idc_i = [D_i - E(D_i)/\sqrt{V(D_i)}]$ represents the contribution of replicate i to Id. In practice, fitting the distribution of Id to a standard normal distribution is valid when $N \geq 15$.

At the level $\alpha = 0.05$, we may reject the null hypothesis when $Id > 1.96$ (aggregative distribution) or when $Id < -1.96$ (regular distribution).

Bioassays 2 and 3 (Choice Situation). Data are presented as mean numbers of eggs and mean Ai(s) per female. Nonparametric statistics were used: Mann-Whitney U test (M-W) for comparisons between experimental groups and Wilcoxon matched-pair signed-ranks test (WX) for comparisons within groups (oviposition during consecutive nights). Numbers of eggs laid on treated and untreated apples (bioassay 3) were compared by χ^2 analysis.

RESULTS AND DISCUSSION

Distribution of Eggs on Untreated Apples. Females laid a mean of 10.7 ± 4.7 eggs per arena. Among the 400 apples, 50% had no egg, 39% contained a single egg, and only 6% had more than one egg, with one apple carrying seven eggs. The global index of dispersion calculated from the 20 replicates ($Id = -1.54$) did not permit excluding a random distribution of eggs. However, 16 experimental arenas had a negative value of Id_{ci}, which indicates a tendency for egg dispersion. One female laid more eggs than the number of available apples and distributed the eggs in a completely different pattern than the 19 other females. This female constituted the most important contribution to $Id(5.83)$. After excluding this arena, $Id = -2.94$ allowed us to reject the hypothesis of a random distribution with $P < 0.003$. This regular distribution suggests a dispersive oviposition behavior which is consistent with previous analysis of egg dispersion in orchards, in which egg distribution among spurs, within spurs, and on leaves deviated from randomness (estimated as a Poisson distribution) (Jackson, 1979). In our experiment, the large number of apples bearing no or one egg suggest a dispersive oviposition behavior.

Oviposition on Cardboard Before and After Exposure to Treatment. The mean numbers of eggs laid per female are presented for the three consecutive nights of the experiment (Table 1). During the night before any exposure, the numbers of eggs were remarkably constant among experimental groups and varied from 36.2 ± 15.9 to 30.3 ± 15.1, which was very close to that observed in previous experiments (32.5 ± 15.1; Thiéry and Gabel, 1993). In all groups, this number regularly decreased by one third each night (difference between two consecutive nights: WX, $P < 0.001$). On night 3, values were similar between groups (from 9.4 ± 8.5 to 11.9 ± 4.7 eggs) no matter what the exposure on the second night was. As in other tortricids, mating stimulates egg production by CM; here females were exposed to mates prior to the observations and no

TABLE 1. EGGS (MEAN ± SD) LAID ON ARTIFICIAL SUBSTRATE BY *Cydia pomonella* FEMALES[a]

Treatments	Females (*N*)	Night 1, blank cardboard	Night 2, treated and untreated areas	Night 3, blank cardboard
Application solvent	22	33.2 ± 15.9a	21.7 ± 11.2b	10.1 ± 9.5c
Extract A	23	31.2 ± 12.5a	19.1 ± 8.8b	9.4 ± 8.5c
Extract B	15	36.2 ± 15.9a	15.6 ± 5.4c	10.2 ± 7.6c
7FA B	15	30.3 ± 15.1a	23.2 ± 9.9b	11.9 ± 4.7c

[a]During night 2, females had a choice between treated areas and an untreated area. Dose A = 1 egg eq./spot, dose B = 20 egg eq./spot. Seven fatty acids (FA) were tested at dose B. Different letters indicate statistical differences based upon Wilcoxon matched-pairs at $P < 0.001$ within lines and Mann-Whitney U test, $P < 0.04$ within columns.

additional mating occurred. The reduction in egg laying was thus considered as normal.

Response to Egg Extraction on Cardboard. The application phase (API) alone had no effect on the oviposition preference (Ai = −1 ± 24%) (Table 2), with a total of 120 eggs being laid on areas treated with API and 362 eggs on the untreated area. This is in aggreement with observations based on other solvents (pure methanol or methanol in water) (Thiéry and Gabel, 1993; Gabel and Thiéry, 1994). Females avoided ovipositing on the application spots of extracts, and this behavior was dose dependent (Table 2). Dose A (1 egg eq./spot) induced a slight avoidance: the 23 females laid a total of 66 eggs on treated

TABLE 2. OVIPOSITION PREFERENCES OF *Cydia pomonella* FEMALES BETWEEN AREAS OF CARDBOARD TREATED WITH DIFFERENT SUBSTANCES AND UNTREATED AREA[a]

Type of exposure and doses	*N*	Eggs per female (Mean ± SD)		Avoidance index (%, ± SD)
		Treated areas	Untreated area	
Control (API)	22	5.5 ± 2.9	16.5 ± 8.8	1 ± 24a
Extract A	23	2.9 ± 1.8	16.2 ± 7.3	34 ± 22b
Extract B	15	0.9 ± 0.8	14.6 ± 4.9	75 ± 23c
7FA B	15	1.5 ± 0.6	21.7 ± 9.4	66 ± 8c

[a]API was application solvent, egg extract dose A (1 egg eq./spot), egg extract dose B (20 egg eq./spot), and 7FA is a synthetic blend of seven fatty acids at dose B. Data are means ± SD of *N* observed females, different letters indicate statistical differences among avoidance indexes at $P < 0.001$, Mann-Whitney U test).

areas and 372 on the untreated area. The mean Ai (34 ± 22%) differs statistically from that observed in response to AP1 (M-W U test, $P < 0.0002$). At dose B (16 egg eq./spot), the 15 females laid 13 eggs on the treated areas and 219 on the untreated area. The mean Ai (75 ± 23%) differed from the previous dose (M-W U test, $P < 0.0005$) (Table 2). Six of the 15 females accounted for 68 eggs, and they laid no egg on treated areas. Females exposed to dose B of extract laid fewer eggs that females exposed to AP1 (15.6 ± 5.4 vs. 21.7 ± 11.2; MW, $P < 0.04$) (Table 1).

The avoidance of CM females to its egg extract is higher than that observed in the tortricid (*L. botrana*) exposed to its own extract (Ai = 50%; Gabel and Thiéry, 1992). In the present work, avoidance by *C. pomonella* was already evident at the dose of 1 egg eq./spot (32 egg eq./arena), whereas a weaker response by *L. botrana* required three times more egg equivalents.

Identification of Active Compounds. Seven major compounds were found in the GC analysis of 2 to 3-day-old eggs (Table 3). These molecules are C_{14} to C_{18} saturated or unsaturated straight-chain fatty acids. We found in the methylene dichloride extract myristic acid ($C_{14:0}$), plamitic acid ($C_{16:0}$), palmitoleic acid (Z9)($C_{16:1}$), stearic acid ($C_{18:0}$), oleic acid (Z9)($C_{18:1}$), linoleic acid (Z9,Z12)($C_{18:2}$), and linolenic acid (Z9,Z12,Z15)($C_{18:3}$) in the amounts shown in table 3. Slightly lower amounts of each of these seven fatty acids were found in the ethyl ether extract (except for $C_{14:0}$) (Table 3). Three methyl esters were detected in the ethyl ether extract. These were methyl myristate (Me $C_{14:0}$), methyl palmitate (Me $C_{16:0}$), and methyl stearate (Me $C_{18:0}$) (Table 3). Only the Me $C_{16:0}$) and the Me$C_{18:0}$ were detected in the methylene dichloride extract.

TABLE 3. FATTY ACIDS AND RELATED ESTERS EXTRACTED FROM 2 TO 3-DAY-OLD *Cydia pomonella* EGGS AS IDENTIFIED BY GC-MS ANALYSIS[a]

Compound		Methylene dichloride (ng/egg eq.)	Ethyl ether (ng/egg eq.)
Myristic acid	$C_{14:0}$	4.8	0.5
Palmitic acid	$C_{16:0}$	13.6	11.2
Palmitoleic acid	(Z9) $C_{16:1}$	2.7	1.8
Stearic acid	$C_{18:0}$	7.3	3.7
Oleic acid	(Z9) $C_{18:1}$	15.3	10
Linoleic acid	(Z9, Z12) $C_{18:2}$	16.6	11.7
Linolenic acid	(Z9, Z12, Z15) $C_{18:3}$	9.1	3.7
Methyl myristate	$MeC_{14:0}$	0	0.015
Methyl palmitate	$MeC_{16:0}$	0.024	0.67
Methyl stearate	$MeC_{18:0}$	0.01	0.02

[a] Amounts are expressed in ng per egg equivalent; numbers in parentheses are double bond positions.

Remarkably, we found the same kind of fatty acids as in *L. botrana*, the two major compounds [$C_{16:0}$ and $(Z9)C_{18:0}$] being identical to both species (Thiéry et al, 1992; Farkas, Gabel, and Thiéry, unpublished data), although we found them in higher amounts in CM. Methyl palmitate and stearate have also been identified as oviposition deterrents in *Ostrinia nubilalis* (Thiéry and Le Quéré, 1991).

Biological Activity of Synthetic Blend of Fatty Acids. We have verified the biological activity of a synthetic blend made according to the amounts of the seven fatty acids found in the 2 to 3-day-old egg extract. The exposure of 15 females to a dose of the seven fatty acids equal to 20 egg eq./spot evoked a mean Ai of 66 ± 8%, which was not statistically different from the extract at an identical dose (M-W U test) (Table 2). A total of 20 eggs were laid on treated areas and 326 on untreated ones. Females in total laid more eggs (23.2 ± 9.9) than when exposed to the extract applied at an identical egg equivalent dose (15.6 ± 5.4) (M-W U test, $P < 0.03$). The first value was similar to that observed in the control treatment (Table 1).

In previous work, CM females exposed to a synthetic blend of three acids [$C_{16:0}$, $C_{18:0}$ and $(Z9)$ $C_{18:1}$] and six esters [Me $C_{16:0}$, Me $(Z9)$ $C_{16:1}$, Me $C_{18:0}$, Me $(Z9)$ $C_{18:1}$, Me $(Z9,Z12)$ $C_{18:2}$, and Me $(Z9,Z12,Z15)$ $C_{18:3}$] significantly reduced their oviposition (Thiéry and Gabel, 1993), suggesting that esters of fatty acids could be candidates to explain such a reduction.

Responses of Females to Apples Treated with a Blend of Fatty Acids. Females exposed to 10 apples treated with the blend of fatty acids (7FA) and to 10 untreated apples laid more eggs (20.1 ± 11.4 eggs) than those exposed to 20 untreated apples or those exposed to 20 treated apples. They strongly avoided the treated apples. A total of 38 eggs were found on the treated apples and 323 on the untreated ones ($\chi^2 = 225$, 1 df, $P < 0.0001$), producing a mean Ai of 82 ± 12%. In eight of the 14 replicates, the Ai value was betweend 80% and 100%.

The 18 females exposed to uniform treatment aggregated their eggs among certain apples. Thirteen values of Id_{ci} were strongly positive, and after excluding one female that laid a single egg, the global index of dispersion ($Id = 15.56$) allowed us to reject the null hypothesis of a random distribution at $P < 0.0001$. The aggregation of eggs is probably due to a perturbation during oviposition bouts. It might also be the result of modification in locomotion patterns because of repulsion. Interpretation of the increased oviposition in the dual-choice situation is difficult. One possibility is that, because of restricted areas, the number of eggs laid is related to the time spend on apples. Short-range repulsion provoked by uniformly treated apples might have reduced the time invested in oviposition site selection, while in dual-choice assays females setting for longer periods on untreated apples would lay more eggs. In the present experiments, females laid almost 30% fewer eggs when exposed to apples than when exposed

to cardboard. One possibility is that preoviposition sequences are more complete and may last longer on apples than on artificial substrates. This needs, however, detailed quantification of flying, preoviposition and oviposition bouts.

Age-Related Composition in Fatty Acids. We focused on the variation in concentration of the seven fatty acids identified from the methylene dichloride egg extracts. Methylene dichloride was used to study this variation because it extracted a larger amount of the seven acids (Table 3). In each age class, plamitic, oleic, and linoleic acids were always the major compounds present and were present in almost equal proportions (Figure 1). The amount of all fatty acids increased until day 4 and then decreased just before hatching. The maximum increases was observed between 2-day-old and 4-day-old eggs, where it ranged from 80% ($C_{14:0}$) to 300% ($C_{18:0}$).

The mucus that coats the eggs contains free fatty acids and esters that contribute to retardation of dessication. Egg extraction certainly harvests large amounts of chemicals from the surface, but also extracts constituents from within the egg yolk. The exact proportion of both chemicals has not been determined. The permeability of the egg chorion might allow natural passage of chemicals to the surface and could to some extent allow relations between the external and internal constitutions. Anecdotally, the large increase in the amount of linoleic and linolenic acids is noteworthy since de novo synthesis of these fatty acids has been seldom reported in insects. We can not exclude these FA as being liberated from phospholipids or triglycerides stores. From an ecological point of view, the variation in amount of oviposition regulators released may represent dynamic information to CM because it is related to egg age. Probably because

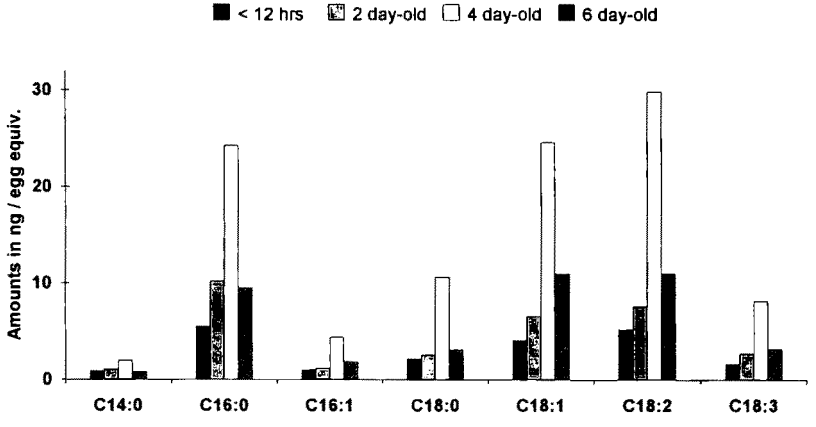

FIG. 1. Variation in the amount of fatty acids from methylene dichloride extracts of *Cydia pomonella* eggs of different ages.

of their simplicity and general occurrence, fatty acids and derivative esters have not drawn very much attention in insect communication. However, the literature provides interesting insights relative to their role as semiochemicals (Hwang et al., 1984; Rickli et al., 1992; Trouiller, 1993).

The present study is a first step towards demonstrating that chemical information produced by CM eggs regulates the oviposition site selection of conspecific females. This study has been conducted with CM reared for generations on artificial diet, and one might expect females from natural populations to be more egg dispersive than mass-reared ones. Such a comparison between natural and laboratory-reared populations has not yet been done.

We have identified free fatty acids in CM eggs whose amounts vary according to the egg developmental stage. This finding does not exclude that species-specific and more sophisticated chemicals may also influence egg dispersion. The results reported here reinforce the hypothesis that oviposition can be deterred by general chemical markers of juvenile tissue (eggs or larvae) (Thiéry and Gabel, 1993). Eggs of several moths (*O. nubilalis*, *L. botrana*, and CM) have characteristic odors very close to that of several fatty acids and esters of the fatty acids. The fact that C_{16} acids and esters released electroantennographic responses in *O. nubilalis* females (our unpublished data) suggests to us that long-chain fatty acids and related esters produce odors that might be involved in the perception of occupied oviposition substrates at a short range distance.

Acknowledgments—We are grateful to Dr. Serge Poitout and his colleagues (INRA, Montfavet, France) for supplying insects. We thank Drs. Wendell Roelofs (Cornell University, Geneva, New York), Henri Audemard (INRA Montfavet, France) and two anonymous reviewers for manuscript improvements.

Abstract—(3*S*,13*R*)-3,13-Dimethylheptadecane [(3*S*,13*R*)-3,13-dime-17Hy] is the major pheromone component of the western false hemlock looper (WFHL), *Nepytia freemani*. In comparative gas chromotographic-electroantennographic detection (GC-EAD) analyses of stereoselectively synthesized isomers, 1 pg of (3*S*,13*R*)-dime-17Hy elicited significantly stronger electrophysiological responses by male WFHL antennae than did 1 pg of separately injected (3*R*,13*R*)-, (3*R*,13*S*)- or (3*S*,13*S*)-3,13-dime-17Hy. In field experiments with individually tested stereoisomers, (3*S*,13*R*)-3,13-dime-17Hy was the only stereoisomer to attract males, but the four-stereoisomer blend was 3.6 times more attractive. Quaternary and all binary combinations of (3*S*,13*R*)-3,13-dime-17Hy with the other stereoisomers were equally attractive, suggesting that synergisytic behavioral activity in WFHL resided with either one of (3*R*,13*R*)-, (3*R*,13*S*)-, or (3*S*,13*S*)-3,13-dime-17Hy. Because optical isomers of (di)methylhydrocarbons do not separate on currently available columns, it remains unknown whether female WFHL also produce a four-stereoisomer pheromone blend. Substitutionality of pheromone stereoisomers without loss of behavioural activity has not previously been reported, but favorably compares with the concept of pheromone redundancy that was first suggested for the multiple pheromone component blend of the cabbage looper moth, *Trichoplusia ni*.

dimethylheptadecane, (3*R*,13*S*)-dimetylheptadecane, (3*S*,13*S*)-dimethylheptadecane.

INTRODUCTION

3,13-Dimethylheptadecane (3,13-dime-17Hy) has recently been reported as the major sex pheromone component of the western false hemlock looper (WFHL), *Nepytia freemani* (Gries et al., 1993b). In field experiments, a synthetic, stereoisomeric mixture of 3,13-dime-17Hy strongly attracted male WFHLs, but pheromone chirality has not yet been investigated. We report chiral synthesis of, and antennal responses and field attraction to, all four stereoisomers of 3,13-dime-17Hy.

METHODS AND MATERIALS

Experimental Insects and Laboratory Analyses

Natural WFHL populations were at very low levels in 1994 and did not warrant field collection of larvae to be reared to adults in the laboratory. To obtain wild males for electrophysiological recordings, pheromone-baited traps were suspended from mature Douglas-fir trees, *Pseudotsuga menziesii* (Mirb) Franco, 30 km west of Kamloops, British Columbia. Delta 2-liter milk cartons served as traps. Their inner 855 cm^2 surface was coated with adhesive Tangle-Trap (Tanglefoot Company, Grand Rapids, Michigan) to retain males approaching the pheromone (100 μg)-impregnated septum in the middle of the trap. After one night, captured males with intact antennae were carefully removed from the glue and individually placed in Petri dishes with moist filter paper. Fourteen of these males were used within 24 hr in coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses (Arn et al., 1975), employing a Hewlett Packard 5890A gas chromatograph equipped with a DB-210 coated, fused silica column (30 m × 0.25 mm ID; J&W Scientific, Folsom, California 95630). The antenna, with its tip clipped off, was carefully removed from a male's head and suspended between two glass capillary electrodes mounted on a portable micromanipulator. Electrical potentials generated by the antenna were amplified using a custom-built amplifier with a passive low-pass filter and a cutoff frequency of 10 kHz. Each antenna was subjected to 1 pg of all four separately injected stereoisomers of 3,13-dime-17Hy. One hundred picograms of 5-methylheptadecane, coinjected with each of the stereoisomers, served as an internal standard to monitor possible deterioration of antennal responses over the 30- to 40-min test period for each antenna.

Instruments and General Procedures

Nuclear magnetic resonance (NMR) spectroscopy was conducted on a Bruker AMX-400 spectrometer at 400.13 MHz. ^{1}H chemical shifts are reported in parts per million (ppm, δ) and relative to TMS (0.00 ppm). Infrared (IR) spectra were recorded as liquid films on a PE 1600 FTIR. Mass spectra were obtained on a Varian Saturn II Ion Trap GC-MS fitted with a DB-5 coated, fused silica column (30 m × 0.25 mm ID; J&W Scientific). Optical rotations were measured with a Rudolph Auto-Pol digital polarimeter. Elemental analyses were performed using a Carlo-Erba model 1106 Elemental Analyzer. GC analyses were carried out on an HP5880 fitted with a DB-1 coated, fused silica column (30 m × 0.25 mm ID, J&W Scientific). THF was freshly distilled from sodium-benzophenone ketyl. Recovered hexane–ether solvent mixtures were distilled from P_2O_5 via a Dufton fractionating column. Chemicals from commercial sources were used without further purification. All moisture- and air-sensitive reactions were conducted under argon. Column chromatography refers to flash chromatography using silica gel 60 (230–400 mesh E. Merck, Darmstadt, Germany) (Still et al., 1978). The usual reaction workup involved addition of aqueous NH_4Cl, extraction with recovered hexane/ether solvent mixtures, washing with water and then saturated brine, drying over anhydrous Na_2SO_4, and removal of solvent in vacuo by rotary evaporation.

Synthesis of 3,13-Dimethylheptadecane Stereoisomers

(S)-3-(2'-Furanyl)-2-methylpropyl methanesulfonate ***(4)*** *(Figure 1).* Compound **3,** synthesized as previously reported (Fuganti et al., 1988), was converted into mesylate **4** (Crossland and Servis, 1970). ^{1}H ($CDCl_3$); δ 7.35 (1H, d, J = 2 Hz), 6.30 (1H, t, J = 3 Hz), 6.08 (1H, d, J = 3 Hz), 4.1 (2H, m), 3.02 (3H, s), 2.75 (1H, dd, J = 12, 6 Hz), 2.66 (1H, dd, J = 12, 6 Hz), 2.27 (1H, m), 1.3 (3H, d, J = 7 Hz). GC-MS *m/z* (relative intensity): 218 (3), 122 (18), 107 (65), 81 (100), 53 (24). $[\alpha]_D$ = +6.6°, (c, 6.1, $CHCl_3$).

(2R)-1-(2'-Furanyl)-2-methylhexane ***(5)*** *(Figure 1).* A solution of Grignard reagent in THF [prepared from bromopropane (9.5 g, 80 mmol) and Mg (2.4 g, 100 mmol)] was cooled to −70°C. CuI (1.2 g, 6 mmol) was added, then **4** (9 g, 40 mmol). The reaction was allowed to warm to room temperature overnight, then worked up. The crude product was chromatographed on 300 g silica gel, yielding pure **5** (2.8 g, 40% yield). ^{1}H ($CDCl_3$); δ 7.30 (1H, d, J = 2 Hz), 6.26 (1H, t, J = 3 Hz), 5.95 (1H, d, J = 3 Hz), 2.62 (1H, dd, J = 12, 5 Hz), 2.43 (1H, dd, J = 12, 7 Hz), 1.8 (1H, m), 1.3 (5H, m), 1.15 (1H, m), 0.9 (6H, m); GC-MS *m/z* (relative intensity): 166 (4), 165 (18), 108 (11), 81 (100), 53 (20); $[\alpha]_D$ = +1.8% (c, 5.3, $CHCl_3$). Anal. calcd. for $C_{11}H_{18}O$: C, 79.52; H, 10.84, found: C, 79.24; H, 11.08.

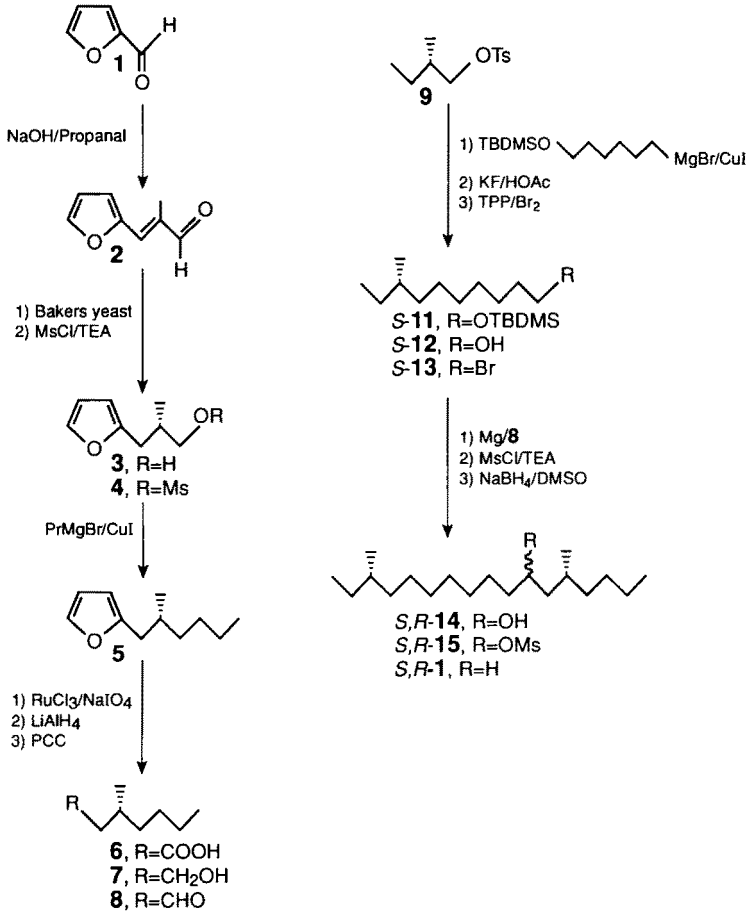

FIG. 1. Synthetic scheme for the synthesis of (3*S*,13*R*)-3,13-dimethylheptadecane.

(R)-3-Methylheptanoic acid ***(6)*** *(Figure 1).* Compound **5** (2.8 g, 17 mmol) was mixed with CCl_4 (65 ml), CH_3CN (65 ml), and H_2O (98 ml). To this was added 54 g of $NaIO_4$, followed by 0.34 g of $RuCl_3 \cdot 2H_2O$ (Carlsen et al., 1981). When, after several hours of stirring, the starting material was absent, the mixture was acidified, extracted with ether, and washed with water and then five times with 3 M NaOH. The basic solution was washed with ether, acidified, and extracted three times with ether. The combined organic phase was washed with water, brine, and then dried. Evaporation gave **6** (1.8 g, 70% yield). ^1H ($CDCl_3$); δ 10.4 (1H, bs), 2.40 (1H, dd, J = 12, 5 Hz), 2.15 (1H, dd, J =

12, 6 Hz), 1.95 (1H, m), 1.3 (6H, m), 0.95 (3H, d, J = 6 Hz), 0.86 (3H, t, J = 6 Hz). $[\alpha]_D$ = +3.6°, (c, 8.4, $CHCl_3$). Anal. calcd. for $C_8H_{16}O_2$: C, 66.67; H, 11.11, found: C, 66.56; H, 11.28.

(S)-2 Methylbutyl p-toluenesulfonate ***(9)*** *(Figure 1).* This compound was prepared from 2-methylbutanol {Aldrich, $[\alpha]_D$ = −5.8° (neat)} (5.1 g, 57 mmol) and tosyl chloride (12 g, 63 mmol) in pyridine at 0°C overnight. Careful addition of water followed by extraction and chromatography gave pure **9** (14 g, 100% yield). ^1H ($CDCl_3$); δ 7.80 (2H, d, J = 9 Hz), 7.35 (2H, d, J = 9 Hz), 3.86 (1H, dd, J = 11, 5 Hz), 3.82 (1H, dd, J = 11, 5 Hz), 2.46 (3H, s) 1.71 (1H, m), 1.38 (1H, m), 1.15 (1H, m), 0.90 (3H, d, J = 7 Hz), 0.85 (3H, t, J = 7 Hz), IR 1360, 1177, cm^{-1}. Anal. calcd. for $C_{12}H_{18}SO_3$: C, 59.50; H, 7.44, found: C, 59.35; H, 7.58. $[\alpha]_D$ = +4.1° (c, 3.7, $CHCl_3$), [Aldrich, +4.5° (neat)].

1-tert-Butyldimethylsilyloxy-6-bromohexane ***(10)*** *(Figure 1).* To 8.4 g (46 mmol) of 6-bromohexanol dissolved in 80 ml of DMF were added 7.6 g of tertbutyldimethylsilyl chloride followed by 7.1 g of imidazole (Corey and Venkataswarlu, 1972). The mixture was allowed to stand overnight. After workup, the product contained 3 parts chloride to 1 part bromide. Chromatography provided 10 g of mixed haloethers (~80% yield). GC-MS *m/z* (chloride) 124/122, 95/93, 83 (bromide) 168/166, 139/137, 83, ^1H ($CDCl_3$); δ 3.6 (2H, t) 3.52 (1.5H, t) 3.4 (0.5H, t) 1.8-1.3 (6H, m) 0.90 (9H, s) 0.05 (6H, s).

(S)-1-tert-Butyldimethylsilyloxy-8-methyldecane (S-11) (Figure 1). Ten grams of the above halide mixture were mixed with 2.2 g of 1,2-dibromoethane in 50 ml of dry ether and, under argon, were added to 2 g of Mg. Following an exothermic reaction, the mixture was refluxed for several hours until most of the starting materials had disappeared. Dry THF was added, the mixture cooled to −70°C, and copper(I) iodide (1 g) followed by **9** (8.5 g) were added. After stirring the mixture overnight at room temperature and the usual workup and chromatography, 5 g of the product were obtained, still containing 21% hexyl silyl ether from the directly quenched Grignard reagent. Extensive chromatography provided an analytical sample of **11.** ^1H ($CDCl_3$); δ 3.60 (2H, d, J = 6 Hz), 1.5 (2H, d, J = 6 Hz), 1.26 (12H, m), 1.10 (2H, m), 0.90 (9H, s), 0.85 (3H, t, J = 6 Hz), 0.81 (3H, d, J = 6 Hz), 0.0 (6H, s). GC-MS *m/z* (relative intensity): 286 (2), 270 (1), 228 (100), 97 (56), 83 (37), 75 (60). Anal. calcd. for $C_{17}H_{38}SiO$: C, 71.33; H, 13.28, found: C, 71.75; H, 13.10. $[\alpha]_D$ = +2.0° (c, 8.4, $CHCl_3$).

(S)-8-Methyldecanol (S-12) (Figure 1). The silyl ether mixture **11** was dissolved in a solution of HOAc (40 ml), THF (10 ml), H_2O (10 ml), and KF (2.5 g) and stirred overnight. The reaction was quenched with aq. NaOH and extracted. After chromatography, 1.4g of pure **12** was obtained (22% yield based on tosylate **9**). ^1H ($CDCl_3$); δ 3.64 (2H, t, J = 6 Hz), 1.56 (2H, pentet, J = 7 Hz), 1.3 (12H, m), 1.1 (2H, m), 0.85 (3H, t, J = 7 Hz), 0.83 (3H, d, J =

6 Hz). Anal. calcd. for $C_{11}H_{24}O$: C, 76.74; H, 13.95, found: C, 76.71; H, 13.84, $[\alpha]_D = +4.9°$ (c, 5.7, $CHCl_3$).

(S)-8-Methyl-1-bromodecane (S-13) (Figure 1). To a solution of **12** (1.4 g) and triphenylphosphine (2.7 g) in 20 ml of CH_2Cl_2 was added Br_2 (1.6 g) until the color of excess Br_2 persisted. The reaction was stopped by addition of MeOH, diluted with H_2O, extracted, and evaporated. The crude residue was triturated with hexane and the solution passed through 10 g of silica gel to remove triphenylphosphine oxide. Evaporation yielded 1.4 g of product, containing 6% bromohexane by GC. The mixture of bromides was dissolved in isooctane containing 11 g of activated 5Å molecular sieves (O'Connor et al., 1962). After a few hours of heating, the sieves were removed by filtration and washed with fresh solvent. Evaporation yielded pure **13** (1.3 g, 67% yield). ^1H ($CDCl_3$); δ 3.42 (2H, t, $J = 6$ Hz), 1.86 (2H, pentet, $J = 6$ Hz), 1.42 (2H, m), 1.25 (9H, m), 1.1 (2H, m), 0.88 (3H, t, $J = 7$ Hz), 0.85 (3H, d, $J = 6$ Hz)〉 Anal. calcd. for $C_{11}H_{23}Br$: C, 56.17; H, 9.79, found: C, 56.43; H, 9.78, $[\alpha]_D = +5.3°$ (c, 7.4, $CHCl_3$).

(R)-3-Methylheptanal 8 (Figure 1). To the acid **6** (1.8 g) dissolved in 50 ml of dry ether was added in portions 0.75 g of $LiAlH_4$. The mixture was refluxed overnight, quenched by dropwise addition of 2 ml of 5% NaOH, and stirred until the precipitate became granular. The solid was removed by filtration and washed well with dry ether, of which most was removed by careful evaporation. Crude **7** (0.7 g) was added to a stirred mixture of pyridinium chlorochromate (2.1 g) in 5 ml of CH_2Cl_2. After 1 hr the reaction was stopped by addition of ether and the mixture passed through 20 g of silica gel with ether until no more aldehyde eluted. Rotary evaporation at 25°C gave crude **8,** which was used immediately in the next step.

(3S,11R/S,13R)-3,13-Dimethyl-11-hydroxyheptadecane (SR-14) (Figure 1). A solution of 1,2-dibromoethane (0.19 g) and bromide *S*-**13** (1.3 g) in dry ether was added to Mg (0.25) and refluxed 1 hr before crude **8** was added to the cooled mixture. After 0.5 hr, acid workup and chromatography yielded 0.5 g of two diastereomers in equal amounts by GC. ^1H ($CDCl_3$); δ 3.68 (1H, bs), 1.60 (2H, bs), 1.40 (3H, m), 1.30 (18H, m), 1.1 (4H, m), 0.88 (6H, m), 0.83 (6H, m).

(3S,11 R/S, 13R)-3,13-Dimethyl-11-methanesulfonyloxyheptadecane (S,R-15) (Figure 1). To a cooled solution (0°C) of **14** (0.5 g) in CH_2Cl_2 (5 ml) containing 1 g of triethylamine was added dropwise 0.44 g of MsCl in 5 ml of CH_2Cl_2. The mixture was stirred 0.5 hr and then diluted with water. Extraction and evaporation yielded 0.7 g of crude **15**. ^1H ($CDCl_3$); δ 4.8 (1H, m), 3.0 (3H, s), 1.65 (2H, m), 1.6 (3H, m), 1.3 (18H, m), 1.1 (3H, m), 0.9-0.8 (12H, m).

(3S,13R)-3,13-Dimethylheptadecane (S,R-1) (Figure 1). Crude **15** was dissolved in DMSO (10 ml), mixed with $NaBH_4$ (0.19 g), and heated overnight to

100°C (Hutchins et al., 1978). The mixture was poured into water and extracted with hexane. Polar materials were removed by chromatography. The resulting product was treated with conc. H_2SO_4 and rechromatographed in sequence on silica gel and silica gel impregnated with 20% $AgNO_3$ to yield *SR*-**1** (0.13 g, >96% by GC. $[\alpha]_D = +3.8°$ (c, 3.0, $CHCl_3$).

Methyl (2R)-2-methyl-3-tert-butyldimethyl-silyloxypropionate (R-16) (Figure 2). A solution of hydroxy ester (4.6 g) {Sigma, $[\alpha]_D = -25.8°$ (C, 2.7, MeOH), lit. $[\alpha]_D = -26.1$ (Mori and Koseki, 1988)} in CH_2Cl_2 with triethylamine (8.5 ml) was mixed with tertbutyldimethylsilyl chloride (7.5 g) and dimethylaminopyridine (0.2 g) and allowed to stand overnight at 5°C. Usual workup and chromatography provided *R*-**16** (9.3 g, 100% yield). ^1H ($CDCl_3$); δ 3.75 (1H, m), 3.65 (3H, s), 3.62 (1H, m), 2.64 (1H, sextet, $J = 6$ Hz), 1.14 (3H,

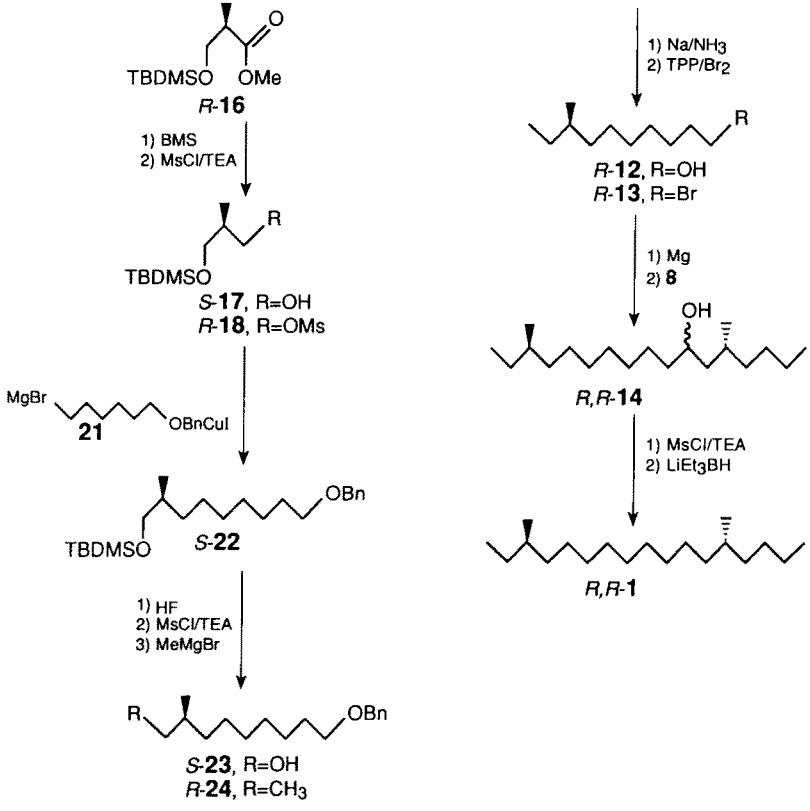

FIG. 2. Synthetic scheme for the synthesis of (3*R*,13*R*)-3,13-dimethylheptadecane.

d, J = 6 Hz), 0.86 (9H, s) 0.00 (6H, s). IR (neat), 1743, 1389, 1361, 1257, 1098 cm^{-1}. Anal. calcd. for $C_{11}H_{24}O_3Si$: C, 56.90; H, 10.34, found: C, 56.64; H, 10.29. $[\alpha]_D = -18.7°$ (c, 5.6, $CHCl_3$) [lit $-18.4°$, Mori and Koseki, 1988].

(2S)-2-Methyl-3-tert-butyldimethylsilyloxypropanol (S-17) (Figure 2). A solution of *R*-**16** (6.3 g) in dry THF (50 ml) was treated with 2.5 ml of a borane–methyl sulfide complex. The mixture was swept with argon to aid in removing methyl sulfide. After 24 hr, 10% $NaHCO_3$ was carefully added, followed by the usual workup. Chromatography gave *S*-**17** (5.0 g, 83% yield). IR (neat), 3357, 1090, 1041, 839 cm^{-1}, ^1H ($CDCl_3$); δ 3.72 (1 H, dd, J = 15, 6 Hz), 3.6 (2H, m), 3.53 (1H, dd, J = 15, 8 Hz), 2.9 (1H, bs), 1.95 (1H, m), 0.88 (9H, s), 0.82 (3H, d, J = 8 Hz), 0.05 (6H, s), $[\alpha]_D = -10.2°$ (c, 8.7, $CHCl_3$), lit $-10.8°$ (Mori and Koseki, 1988). Anal. calcd. for $C_{10}H_{24}O_2Si$: C, 58.82; H, 11.76, found: C, 58.95; H, 11.91.

(2S)-1-tert-Butyldimethylsilyloxy-2-methyl-9-benzyloxynonane-(S-22) (Figure 2). To an ice-bath-cooled solution of *S*-**17** (6 g, 30 mmol) and triethylamine (5 ml) in 50 ml of CCl_4 was added MsCl (4 g, 35 mmol) in 50 ml of CCl_4. After 0.5 hr, water was added and the mixture worked up as usual. Evaporation provided crude *R*-**18** (6.4 g, 76% yield). A Grignard solution was prepared from **21** (9.6 g, 35 mmol) (Tsuda et al., 1991) and Mg (1.2g, 50 mmol) in dry THF. The reaction was initiated by coaddition of 1,2-dibromoethane. After refluxing 30 min, the mixture was cooled to $-25°C$ and then CuI (0.9 g, 4.7 mmol) was added followed by crude *R*-**18** (6.4 g) in dry THF. The reaction was allowed to warm overnight and was quenched and worked up as usual to yield 19 g with 30% product by GC. Extensive chromatography provided an analytical sample of *S*-**22.** ^1H ($CDCl_3$); δ 7.32 (5H, s), 4.50 (2H, s), 3.45 (3H, m), 3.35 (1H, dd, J = 15, 7 Hz), 1.6 (2H, m), 1.4–1.2 (11H, m), 0.90 (9H, s), 0.85 (3H, d, J = 6 Hz), 0.0 (6H, s), $[\alpha]_D = -1.6°$ (c, 4, $CHCl_3$). Anal. calcd. for $C_{23}H_{42}O_2Si$: C, 73.02; H, 11.11, found: C, 72.88; H, 11.38.

(2S)-2-Methyl-9-benzyloxynonanol (S-23) (Figure 2). Crude *S*-**22** from the above reaction was dissolved in acetonitrile (95 ml) and 40% HF (5 ml) (Newton et al., 1979) and stirred until **22** had disappeared. The reaction was then diluted with water, extracted, and chromatographed to yield pure *S*-**23** (1.2 g, 22% yield from **18**). ^1H ($CDCl_3$); δ 7.3 (5H, s), 4.50 (2H, s), 3.45 (4H, m), 1.60 (2H, m), 1.4–1.2 (10H, m), 1.1 (1H, m), 0.89 (3H, d, J = 6 Hz), $[\alpha]_D = -5.1°$ (C, 5.7, $CHCl_3$). Anal. calcd. for $C_{17}H_{28}O$: C, 77.27, H, 10.61, found: C, 76.95, H, 10.65.

(8R)-8-Methyl-1-benzyloxynonane R-24 (Figure 2). To a solution (0°C) of **23** (4 g, 15 mmol) in CCl_4 (30 ml) mixed with triethylamine (8 ml) was added MsCl (2.5 g, 22 mmol) in 20 ml of CCl_4. The reaction was stirred 30 min and worked up to yield 4.6 g of product, which was evaporated twice from dry THF

to yield mesylate (4 g, 12 mmol). This was dissolved in dry THF and cooled to −70°C followed by addition of CuI (8 g, 4.5 mmol) and 3 M methyl magnesium bromide (10 ml). The mixture was allowed to warm up overnight. Usual workup and chromatography yielded *R*-**24** (2.6 g, 65% yield). ^{1}H ($CDCl_3$); δ 7.3 (5H, m), 4.52 (2H, s), 3.47 (2H, t J = 6 Hz) 1.61 (2H, pentet, J = 6 Hz), 1.3 (13H, m), 1.1 (2H, m), 0.89 (3H, d J = 6 Hz), 0.85 (3H, t, J = 6 Hz), $[\alpha]_D$ = −4.4° (c, 9.4, $CHCl_3$,). Anal. calcd. for $C_{18}H_{30}O$: C, 82.44; H, 11.45, found: C, 82.68; H, 11.05.

(8R)-8-Methyl-1-bromodecane R-13 (Figure 2). A solution of *R*-**24** (2.5 g, 10 mmol) in THF was added to 1 g of Na in liq. NH_3 (Reist et al., 1964). After 30 min, the (still) blue mixture was quenched with NH_4Cl, and ammonia allowed to evaporate. The mixture was extracted and chromatographed to yield *R*-**12** (1.5 g, 88% yield), with R_f and GC identical to that of *S*-**12** (Figure 1). $[\alpha]_D$ = −6.3° (c, 3.0, $CHCl_3$). Dibromotriphenylphosphorane was prepared by combining triphenylphosphine (4.5 g) and bromine (2.5 g) in 30 ml of CH_2Cl_2. To this was added 1.5 g of *R*-**12.** After 30 min, the usual workup and chromatography yielded *R*-**13** (2 g, 95% yield). ^{1}H ($CDCl_3$); δ 3.42 (2H, t, J = 6.0 Hz), 1.90 (2H, pentet, J = 7 Hz), 1.5–1.2 (13H, m), 1.1 (2H, m), 0.82 (6H, m), $[\alpha]_D$ = −5.7° (c, 6.1, $CHCl_3$). Anal. calcd. for $C_{11}H_{23}Br$: C, 56.17; H, 9.79, found: C, 55.89; H, 9.88.

(3R,13R)-3,13-Dimethylheptadecane (R,R-1) (Figure 2). To a Grignard solution prepared from *R*-**13** (0.7 g, 3 mmol) and Mg (0.2 g) in ether was added *R*-**8** (0.7 g). The usual workup and chromatography gave *RR*-**14** (0.4 g) as a diastereomeric mixture, which was converted to *RR*-**15.** The crude product was dissolved in THF and reduced with 5 ml of 1 M lithium triethylborohydride (Krishnamurthy and Brown, 1976). After 24 hr, the reaction was stopped with 6 ml of 5% NaOH, and 4 ml of 40% H_2O_2. The mixture was then extracted to yield 0.14 g of crude product containing 56% *RR*-**1** by GC. While treatment with alkaline $KMnO_4$ did not improve this purity, extensive chromatography on alumina and silica gel provided 30 mg of *RR*-**1** (75% pure by GC). Final purification of *RR*-**1** (>97%) was acheived by reverse-phase HPLC using acetonitrile on RP-18. $[\alpha]_D$ = −7° (c, 0.5, $CHCl_3$).

(3R)-3-Methyl-4-tert-butyldimethylsilyloxybutanonitrile (R-19) (Figure 3). Mesylate *S*-**18** was prepared as described above for *R*-**18.** ^{1}H ($CDCl_3$); δ 4.2 (2H, m), 3.64 (1H, dd, J = 15, 5 Hz), 3.55 (1H, dd, J = 15, 7 Hz), 3.02 (3H, s), 2.08 (1H, m), 1.00 (3H, d, J = 7 Hz), 0.90 (9H, s), 0.05 (6H, s). Crude *S*-**18** (4.1 g, 15 mmol) was dissolved in 40 ml of DMSO to which NaCN (2.6g, 53 mmol) was added. After stirring the mixture for two days, workup and chromatography gave *R*-**19** (3.0 g, 95% yield). IR (neat), 2248 cm^{-1}. ^{1}H ($CDCl_3$); δ 3.60 (1H, dd, J = 15, 5 Hz), 3.40 (1H, dd, J = 15, 7 Hz), 2.45 (1H, dd, J = 18, 5 Hz), 2.32 (1H, dd, J = 18, 6 Hz), 2.01 (1H, m), 1.04

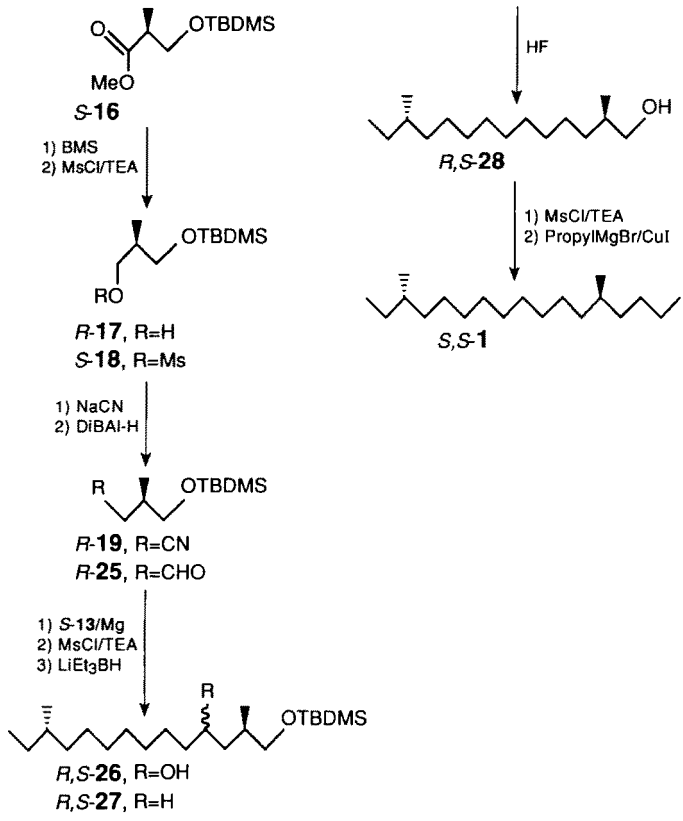

FIG. 3. Synthetic scheme for the synthesis of (3*S*,13*S*)-3,13-dimethylheptadecane.

(3H, d, J = 6 Hz), 0.88 (9H, s), 0.05 (6H, s), $[\alpha]_d$ = +16.8° (C, 4.0, $CHCl_3$). Anal. calcd. for $C_{11}H_{23}NOSi$: C, 61.97; H, 10.80; N, 6.57, found: C, 61.83; H, 11.00; N, 6.39.

(2R)-2-Methyl-3-tert-Butyldimethylsilyloxypropanal (R-25) (Figure 3). To a cooled (−70°C) solution of *R*-**19** (2.2 g, 10.3 mmol) in 50 ml of hexane was added dropwise 14 ml of 1 M diisobutylaluminum hydride in hexane. The mixture was kept cold 2 hr, 5 ml of water was added and the mixture stirred 1 hr at room temperature. Celite was added and the mixture filtered. The residue was washed several times with hexane–ether. After evaporation and chromatography, *R*-**25** (1.4 g, 54% yield) was obtained as a partial hydrate. ^1H ($CDCl_3$); δ 9.80 (1/2H, t, J = 2 Hz), 3.55 (1H, dd, J = 14, 5 Hz), 3.35 (1H, dd, J = 14, 7 Hz), 2.5 (1H, m), 2.2 (1H, m), 1.7 (1H, bs), 1.25 (1/2H, bs), 0.85 (3H,

d, J = 6 Hz), 0.80 (9H, s), 0.04 (6H, s), $[\alpha]_D$ = +6.7° (c, 6.0, $CHCl_3$). Anal. calcd. for 70% hydrate of $C_{11}H_{24}O2Si$: C, 58.43; H, 10.94, found: C, 58.43; H, 10.75.

(2R,12S)-2,12-Dimethyl-1-tert-Butyldimethylsilyloxytetradecane(R-27)(Figure 3). To 0.55 g (23 mmol) of Mg was added *S*-**13** (3.0 g, 13 mmol) in dry ether. After 1 hr reflux, the mixture was cooled and *R*-**25** (1.3 g, 6 mmol) was added. Workup and chromatography gave diastereomeric *R,S*-**26** (0.9 g), still containing 9% of **25.** This mixture was dissolved in 20 ml of CCl_4 containing 2 ml of triethylamine and reacted at 0°C with 0.5 g of MsCl to yield 1.1 g of crude mesylate. This was dissolved in 5 ml of THF and stirred overnight with 5 ml of 1 M lithium triethylborohydride. The reaction was stopped by addition of water, 5 ml of 5% NaOH, and 3 ml of 40% H_2O_2. The mixture was extracted three times; the organic layers were combined, washed with 5% NaOH and brine, dried, and evaporated. After chromatography with hexane, *R,S*-**27** (0.4 g) was obtained (0.4 g, 20% yield based on *R,S*-**25**). ^1H ($CDCl_3$); δ 3.43 (1H, dd, J = 12, 5 Hz), 3.31 (1H, dd, J = 12, 5 Hz), 1.55 (1H, m), 1.25 (18H, m), 1.1 (3H, m), 0.9 (9H, s), 0.85 (9H, m), 0.04 (6H, s), $[\alpha]_D$ = +5.1° (C, 5.7, $CHCl_3$), GC-MS, *m/z* (relative intensity) 355(1), 341(7), 299(77), 75(100). Anal. calcd. for $C_{22}H_{48}OSi$: C, 74.15; H, 13.48, found: C, 73.93; H, 13.70.

(2R,12S)-2,12-Dimethyl-tetradecanol (R,S-28) (Figure 3). Silyl ether *R,S*-**27** was stirred in 20 ml of acetonitrile and 1 ml of 40% HF. After 1 hr, **27** could no longer be detected. The reaction mixture was diluted with hexane–ether, washed, dried, and evaporated. Chromatography yielded *R,S*-**28** (0.3 g, 100% yield). ^1H ($CDCl_3$); δ 3.50 (1H, dd, J = 12, 5 Hz), 3.40 (1H, dd, J = 12, 5 Hz), 1.60 (1H, m), 1.36 (19H, m), 1.10 (3H, m), 0.90 (3H, d, J = 6 Hz), 0.84 (6H, m), $[\alpha]_D$ = +11.6° (c, 5.4, $CHCl_3$). Anal. calcd. for $C_{16}H_{34}O$: C, 79.34; H, 14.05, found: C, 79.09; H, 14.22.

(3S,13S)-3,13-Dimethylheptadecane (S,S-1) (Figure 3). To *R,S*-**28,** dissolved in 20 ml of CCl_4 and 1 ml of triethylamine, was added dropwise at 0°C 0.6 g of MsCl. After 0.5 hr, workup provided 0.7 g of crude mesylate. Grignard reagent prepared from bromopropane (0.75 g, 6 mmol) and Mg (0.24 g) was cooled to −70°C followed by addition of CuI (0.19 g) and subsequently crude mesylate. After stirring the mixture overnight under argon, the crude product was worked up, chromatographed on silica, and silica gel impregnated with 20% $AgNO_3$. The resulting 0.3 g of impure product was stirred several days with alkaline $KMnO_4$. The brown mixture was diluted with hexane, filtered, and evaporated to yield 0.14 g of *S,S*-**1,** which was purified (>98%) by HPLC on an RP-18 column with acetonitrile. $[\alpha]_D$ = +7° (c, 1.0, $CHCl_3$).

(2R,12R)-2,12-Dimethyl-1-tert-Butyldimethylsilyloxy tetradecane (R,R-27) (Figure 4). A Grignard solution, prepared from *R*-**13** (1.4 g, 6 mmol) and Mg (0.2 g) in dry ether, was added to *R*-**25** (1.4 g, 7 mmol). After workup and chromatography, diastereomeric *R,R*-**26** (0.5 g, 1.4 mmol, 20% yield) was

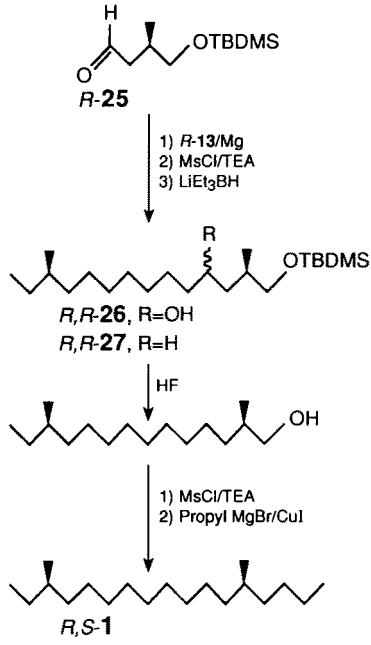

FIG. 4. Synthetic scheme for the synthesis of (3*R*,13*S*)-3,13-dimethylheptadecane.

obtained and treated with MsCl (0.4 g) in 20 ml of CCl_4 and 0.5 ml of triethylamine at 0°C to provide 0.6 g of crude mesylate. To this was added 6 ml of 1 M lithium triethylborohydride. After being stirred overnight, the reaction was worked up and chromatographed to yield *R,R*-**27** (0.22 g, 0.6 mmol, 89% pure) with 40% yield based on *R,R*-**26**). ^1H ($CDCl_3$); δ 3.44 (1H, dd, J = 12, 6 Hz), 3.33 (1H, dd, J = 12, 6 Hz), 1.53 (1H, m), 1.2 (18H, m), 1.05, m), 0.90 (9H, s), 0.85 (9H, m). Anal. calcd. for $C_{22}H_{48}OSi$: C, 74.16; H, 13.48, found: C, 75.07; H, 13.91.

(2R,12R)-2,12-Dimethyl-tetradecanol, R,R-28 (Figure 4). Silyl ether *R,R*-**27** was stirred in 15 ml of acetonitrile with 1 ml of 40% HF until *R,R*-**27** could no longer be detected. The mixture was neutralized, extracted, and chromatographed to give *R,R*-**28** (0.11g, 75% yield). ^1H ($CDCl_3$); δ 3.50 (1H, dd, J = 12, 6 Hz), 3.40 (1H, dd, J = 12, 6 Hz), 1.60 (1H, m), 1.25 (18H, m), 1.1 (3H, m), 0.90 (3H, d, J = 6 Hz), 0.84 (3H, t, J = 6 Hz), 0.81 (3H, d, J = 6 Hz), $[\alpha]_D$ = +2.0° (c, 3.6, $CHCl_3$,). Anal. calcd. for $C_{16}H_{34}O$: C, 79.34; H, 14.05, found: C, 79.55; H, 14.00.

(3R,13S) 3,13-Dimethylheptadecane (R,S-1) (Figure 4). Grignard reagent was prepared from Mg (0.24 g) and bromopropane (0.6 g) in THF, using 1,2-dibromoethane to initiate the reaction. After 2 hr of stirring, the mixture was cooled to −20°C and 0.1 g of CuI was added. Alcohol *R,R*-**28** (0.11 g) was converted to mesylate, of which 0.13 g was added to the above Grignard reagent and allowed to warm overnight. After the usual workup, the crude product was treated with $KMnO_4$ and chromatographed on silica and alumina to yield *R,S*-**1** (0.035 g, 85% pure). Final purification was achieved by HPLC using an RP-18 column with acetonitrile. $[\alpha]_D = -2°$ (c, 1.0, $CHCl_3$).

Field Experiments

Field experiments were conducted in widely spaced stands of mature Douglas fir 30–60 km west of Kamloops, British Columbia. All tests were set up in replicated, randomized complete blocks with traps and blocks 25–50 m apart. Unitraps (Phero Tech Inc., Delta, British Columbia) were suspended from trees 1.5–2 m above ground and baited with beige rubber septa (Sigma Chemical Co., St. Louis, Missouri) impregnated with test chemicals in HPLC-grade hexane. A dichlorvos cube (~1 cm^3) (Green Cross Co., Mississauga, Ontario) in each trap ensured rapid killing and retainment of captured moths. The first six-treatment, 10-replicate experiment tested (3*R*,13*S*)-, (3*R*,13*R*)-, (3*S*,13*S*)-, or (3*S*,12*R*)-3,13-dime-17Hy alone and in quaternary combination at 20 μg each. The second seven-treatment, eight-replicate experiment tested all stereoisomers at 20 μg each in quaternary and all binary combinations.

RESULTS

(3*S*,13*R*)-3,13-Dime-17Hy consistently elicited the strongest electrophysiological responses by male WFHL antennae, but all three other stereoisomers were also EAD-active (Figure 5). In field experiments, the four-stereoisomer blend attracted 3.6 times more males than did (3*S*,13*R*)-3,13-dime-17Hy by itself. None of the other three stereoisomers tested individually attracted any males (Figure 6). (3*S*,13*R*)-3,13-Dime-17Hy in binary combination with either (3*R*,13*R*), (3*S*,13*S*)-, or (3*R*,13*S*)-3,13-dime-17Hy was as attractive as the four-stereoisomer blend (Figure 7).

DISCUSSION

Chiral mono- and dimethylated hydrocarbon pheromone components have rarely been identified in the Lepidoptera (Roelofs and Cardé, 1971; Francke,

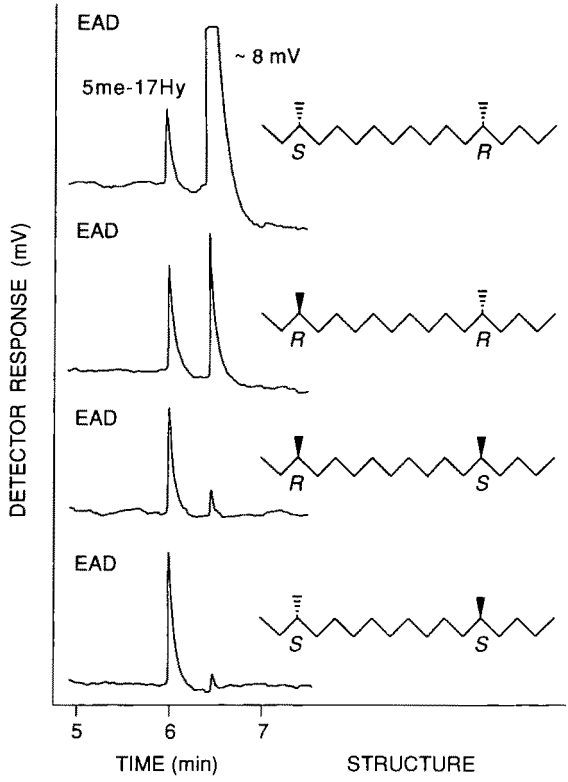

FIG. 5. Representative GC-EAD recordings of male *Nepytia freemani* antennae, responding to 100 pg of 5-methylheptadecane (internal standard, peak on the left) and to 1 pg of separately injected stereoisomers of 3,13-dimethylheptadecane (Hewlett Packard 5890A, DB-23 column, 1 min at 100°C, 10°C/min to 200°C).

1987; Francke et al., 1987, 1988; Riba et al., 1990; Gries et al., 1991a,b, 1993a,b, 1994). Of these methyl-branched hydrocarbons, only one of four possible stereoisomers or one of two enantiomers elicited strong antennal and/or behavioral responses, whereas antipodes were EAD-inactive and/or behaviorally benign. (5*S*,9*S*)-5,9-Dimethylheptadecane and (5*R*,11*S*)-5,11-dimethylheptadecane, e.g., were the only stereoisomers to attract males of, respectively, the mountain-ash bentwing, *Leucoptera scitella* (Zeller) (Tóth et al., 1989) and the hemlock looper, *Lambdina fiscellaria* (Li et al., 1993a). Similarly, (7*S*)-7-methylheptadecane and (2,5*S*)-2,5-dimethylheptadecane were synergistic pheromone components of the western hemlock looper, *Lambdina fiscelleria lugubrosa*

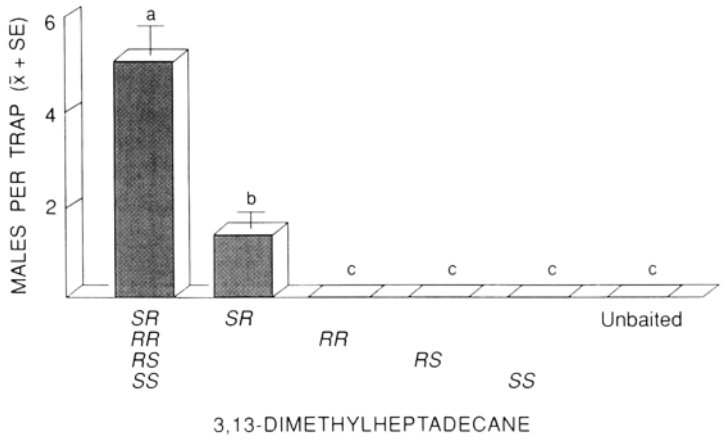

FIG. 6. Captures of *N. freemani* males in Unitraps baited with 20 μg of either (3*S*,13*R*)-, (3*R*,13*R*)-, (3*R*,13*S*)-, or (3*S*,13*S*)-3,13-dimethylheptadecane and all four compounds combined at 20 μg each. September 4–10, 1994; Walachin, British Columbia; $N = 10$. Bars with the same superscript letter are not significantly different [ANOVA on ranks (Friedman's test), followed by a comparison of means (Bonferroni test, $P < 0.05$)].

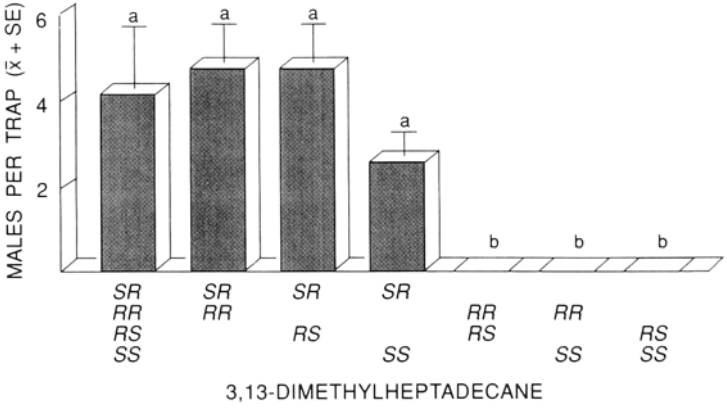

FIG. 7. Captures of *N. freemani* males in Unitraps baited with stereoisomers of 3,13-dimethylheptadecane at 20 μg each in quaternary and all binary combinations. September 11–24, 1994; Walachin, British Columbia; $N = 8$. Bars with the same superscript letter are not significantly different. [ANOVA on ranks (Friedman's Test), followed by comparison of means (Bonferroni test, $P < 0.05$)].

(Hulst), whereas their antipodes neither reduced nor enhanced attraction to the major pheromone component (Li et al., 1993b).

Chiral syntheses of pheromones have employed a great variety of different starting materials and synthetic routes (Li, 1993 and cited literature therein). Compared to classical chemical methods, microbe-mediated chiral syntheses (Fuganti et al., 1988; Fuganti, 1990; Li et al., 1993b) facilitate the preparation and enhance the chiral purity of synthetic starting material, intermediates and/or end products. Starting materials for syntheses of 3,13-dime-17Hy stereoisomers [(*S*)-2-methylbutanol (Aldrich Chemical Company, Milwaukee, Wisconsin); (*R*)-(−)-, (*S*)-(+)-3-hydroxy-2-methyl-propionic acid methyl ester (Sigma Chemical Company, Mississauga, Ontario); and (*S*)-3-(2′-furanyl)-2-methyl-propanol via furfural (Figure 1)] were invariably obtained through enantioselective, microbe-mediated chemical transformations. Acid **6** (Figure 1) and acids derived by oxidation of aldehydes *R*-**25** (Figure 3) and *S*-**25** were converted to their diastereomeric α-phenylethylamides with ee >97%, as determined by GC analyses. Because transformation of these three compounds and of 2-methyl-butanol to subsequent intermediates and end products could not conceivably reduce their chiral purities, enantiomeric excess of all four final stereoisomers should be equivalent to that directly determined for synthetic intermediates. (3*S*,13*R*)-3,13-Dime-17Hy, eliciting the strongest antennal response (Figure 5) and being the only stereoisomer by itself to attract males in the field (Figure 6), is the major sex pheromone component of the WFHL. Superior attraction of the quaternary blend (Figure 6), however, indicates that the presence of other optical isomers enhanced attraction of males. Equal attraction of (3*S*,13*R*)-3,13-dime-17Hy in quaternary and all binary combinations with other stereoisomers (Figure 7) suggests that optimal behavioral activity resides with the presence of only one (and either one) of (3*R*,13*R*)-, (3*R*,13*S*)-, or (3*S*,13*S*)-3,13-dime-17Hy.

Synergism between optical isomers of pheromones has rarely been discovered in the Insecta and was reported only for two moths. Enantiomers of (3*Z*,9*Z*)-*cis*-6,7-epoxy-eicosadiene synergistically attract males of the noctuid *Bleptina caradrinalis* (Guen.) (Millar et al., 1991), and a 1:9 mixture of (14*R*)- and (14*S*)-14-methyl-1-octadecene attracts more peach leafminer males, *Lyonetia clerkella* L., than the latter enantiomer alone (Sato et al., 1986).

Three optical isomers in WFHL similarly enhancing attraction to the major pheromone component is very unusual, but can not be attributed to stereoisomeric contamination of test chemicals. With chiral purities exceeding 97% ee, stereoisomeric contamination of all compounds was extremely low. Moreover, trace amounts of the major pheromone component, (3*S*,13*R*)-3,13-dime-17Hy, in each of individually tested (3*R*,13*R*)-, (3*R*,13*S*)-, or (3*S*,13*R*)-3,13-dime-17Hy, in each of individually tested (3*R*,13*R*)-, (3*R*,13*S*)-, or (3*S*,13*S*)-3,13-dime-17Hy failed to attract any males in the field, indicating that stereoisomer

contamination was unlikely to be responsible for synergistic behavioral activity of each of the three stereoisomers. Because optical isomers of (di)- methylated hydrocarbons do not separate on currently available chiral columns, it remains unknown whether female WFHL produce a pheromone blend of stereoisomers in which only one synergist is essential but can be substituted by either of two other isomers. Substitutionality of pheromone stereoisomers has not previously been reported but is another example of pheromone redundancy first suggested for the multiple pheromone component blend of the cabbage looper moth, *Trichoplusia ni* (Hübner) (Linn et al., 1984).

(Received February 28, 1995; accepted July 25, 1995)

Abstract—By using spectrophotometric analysis and isoelectric focusing electrophoresis (IEF), we found inhibition of acetylcholinesterase (AChE), general esterase activity (Est), and lipase activity in larvae of the Asian corn borer (ACB), *Ostrinia furnacalis* (Guenée), fed on cabbage dipped in DIMBOA (400 ppm). Amylase was not influenced, while activity of cytochrome P-450 monooxygenase and glutathlone *S*-transferase was increased. The results indicate that DIMBOA influences activity levels of some nervous system and detoxication enzymes and inactivates some hydrolysis enzymes.

Key Words—DIMBOA, 2,4-dihydroxy-7-methoxy-(2H)-1,4-benzoxazin-3(4H)-one, enzymes, Asian corn borer (ACB), *Ostrinia furnacalis* (Guenée), acetylcholinesterase, lipase, cytochrome P-450, isoelectric focusing electrophoresis (IEF).

INTRODUCTION

The Asian corn borer (ACB), *Ostrinia furnacalis* (Guenée), is a serious pest of corn, an important food crop in China. A key for ACB control and environmental protection is breeding of resistant corn hybrids. DIMBOA (2,4-dihydroxy-7-methoxy-(2H)-1,4-benzoxazin-3(4H)-one) is a biochemical agent in the resistance of corn to many insect pests (including ACB) and pathogens, and DIM-

BOA level in corn is considered to be the main index in resistance breeding. Several papers have been published recently on the effects of DIMBOA on insects (Cuevas et al., 1990; Houseman et al., 1992; Feng et al., 1992; Leszczynski and Dixon, 1992). We have conducted studies on the mechanism of action of DIMBOA on ACB, and in this paper we present results of biochemical analyses.

METHODS AND MATERIALS

Isolation and Identification of DIMBOA. Isolation of DIMBOA was by the methods of Tipton et al. (1967), Klun et al. (1967), and Woodward et al. (1978). The extracts were analyzed by UV, IR, and elemental analysis. Furthermore, DIMBOA was confirmed with an authentic standard sample.

Rearing and Treatment of Larvae. Leaves of cabbage (*Brassica oleracae* var. *capitata* L.) were cut into 1.6-cm-diameter round leaf discs and dipped for 1 sec into a DIMBOA solution (400 ppm, with acetone as solvent). Discs were dipped only in acetone as control for 1 sec. One leaf disc retained on its surface about 0.1 ml solution containing 0.04 mg DIMBOA. The solvent was allowed to volatilize completely at room temperature. One leaf disc and one third-instar, starved for 24 hr, were placed into a glass tube. At 24, 48, 72, and 96 hr after consuming the discs, the larvae were taken for tests. For some tests samples were taken only at certain time intervals. Larvae were starved after they ate the test discs. Larvae were reared under continous light at 25°C and 80–90% relative humidity.

Biochemical Analyses. Acetylcholinesterase (AChE), general esterase (Est), cytochrome P-450 monooxygenase, glutathione *S*-transferase, amylase, and lipase were determined spectrophotometrically after incubation with their substrates. Isoelectric focusing electrophoresis was completed for esterase. All analyses were repeated six times.

Acetylcholinesterase (AChE). The method of Ellman et al. (1961) was used for AChE analysis. Five heads were homogenized with 2 ml of ice-cold phosphate buffer (pH 7.4, 0.1 M). The tube was washed with 1 ml buffer, and the homogenate was centrifuged for 4 min at 1800*g*. One milliliter of the supernatant and 2 ml buffer were incubated in a water bath at 27°C for 5 min. Then 1 ml of a 1 : 1 mixture of acetylthiocholine iodide and 5,5′-dithio-2,2′-dinitrobenzoic acid (DTNB) was added and tubes were incubated for 25 min. Eserine was added to terminate the reaction, and absorbance of the solution was determined at 412 nm.

Esterase (Est). The modified method of Asperen (1962) was used for analysis of esterase activity. Thoraces, abdomens, and midguts of ACB larvae were isolated by dissection, homogenized, and centrifuged separately. One milliliter of supernatant and 5 ml 1-naphthol acetate (3×10^{-4} M) were incubated for

30 min, and 0.5 ml of a 2:5 (v/v) mixture of 1% fast blue B salt–5% sodium dodecyl sulfate (SDS) was added to develop color. The absorbance of solutions was determined at 600 nm after 30 min. Samples, including the whole body with contents, the whole body with the entire gut removed, the head, and hemolymph were subjected to electrophoresis with isoelectric focusing (IEF) (Righetti, 1983). The gel plate was 1 mm thick × 104 mm long × 87 mm wide. The pH gradients ranged from 3.0 to 9.5. Initially, voltage was 55 V and current was 10 mA; 3 hr later voltage and current were adjusted to 250 V and 7–8 mA. The experiment was completed in 4.5–5 hr at 4°C. General proteins were stained by addition of fast blue B RR′ salt in maleic acid–NaOH buffer (pH 6.0, 0.1 M). With 1-naphthol acetate as substrate, esterase activity was indicated by black bands. 2-Naphthol acetate as substrate produced red bands for esterase activity.

Cytochrome P-450 Monooxygenase. The analysis was conducted according to Hanson and Hodgson (1971). One single larva and five midguts of ACB were taken, respectively, with 0.4 ml 0.1 M Tris HCl buffer, pH 7.9, for homogenization. An additional milliliter of buffer used to wash the homogenization tube was added to bring the total volume to 1.4 ml. Tubes were centrifuged at 1800*g* for 15 min. The reaction volume consisted of 1 ml supernatant, 1.8 ml buffer, 20 μl *p*-nitroanisole (0.1 M), and 0.2 ml nicotinamide adenine dinucleotide phosphate in reduced form (NADPH) (1 mM). Tubes were incubated at 30°C for 30 min, and 0.2 ml NaOH (0.1 N) was added to terminate the reaction. The absorbance was determined at 400 nm after 15 min.

Glutathione S-Transferase. The homogenate preparation was similar to that for cytochrome P-450. The reaction consisted of 0.1 ml homogenate, 2.3 ml phosphate buffer (pH 6.5, 0.1 M), and 0.5 ml of glutathione in reduced form (GSH) (20 mM). The reaction tubes were incubated at 25°C for 2 min, then 0.1 ml of 2,4-dinitrochlorobenzene (CDNB) (30 mM) was added and the solution was incubated at 25°C for 3 min. Addition of 0.3 ml trichloroacetic acid terminated the reaction, after which the tubes were centrifuged at 1800*g* for 5 min. Absorbance was determined at 340 nm. Activity was expressed as moles per milligram protein per minute. The extinction coefficient was 9.6 mM^{-1} cm^{-1}.

Amylase. The analysis was conducted according to the method of Bennfeld (1951). The reaction mixture consisted of 1 ml homogenate, 1 ml phosphate buffer (pH 8.0, 0.02 M), and 2 ml of 1% amylase solution. Two milliliters of buffer were used as control. Tubes were incubated at 30°C for 20 min. NaOH (4 ml of 0.4 N) terminated the reaction. Finally 1 ml of 3,5-dinitrosalicylic acid was added, and the mixture was boiled at 100°C for 5 min. After cooling, the absorbance was determined at 520 nm.

Lipase. The method of Vogel et al. (1963) was used for analysis of lipase activity. Midguts were homogenized and centrifuged as above. Three milliliters

of an olive oil emulsion (0.17 mg/ml Tris HCl buffer) and 1 ml of enzymatic supernatant were mixed, and the absorbance was determined immediately at 420 nm. After incubating the mixture at 37°C for 20 min, the absorbance was determined again at 420 nm. Activity was expressed as moles of triglyceride per milligram protein per minute. The biuret method was used for protein determination (Alexander et al., 1985).

RESULTS AND DISCUSSION

Three categories of enzymes, i.e., nervous system enzymes, detoxifying enzymes, and hydrolytic enzymes that play important roles in biochemical or physiological reactions of ACB larvae were determined after DIMBOA was eaten. Twenty-four hours after consuming leaf discs containing DIMBOA, there was lower AChE activity, and 96 hr after treatment AChE activity in control larvae was two thirds higher than that in the treatment (Table 1). Esterase (Est) activity was higher in the thorax and in the abdomen of ACB larvae that ate DIMBOA than in the controls, but the midgut esterase activity was lower in DIMBOA fed larvae. Esterase activity in the midgut became slightly higher with time, which suggested that there may be some adjustment to the toxin (Table 2). The results from IEF showed that DIMBOA inhibited the activity of esterase (Figure 1). Because the total activity of esterases includes AChE activity when 1-naphthyl acetate is the substrate, lower activity of esterase in the head in Figure 1 may be due to lower activity of AChE. Activities of cytochrome P-450 monooxygenase, both in the whole body and in the entire gut, were higher than those of controls 48 hr after larvae consumed DIMBOA (Table 3). Glutathione *S*-transferase activity was elevated in the whole body with contents, the whole body with gut removed, and in the entire gut for larvae fed on DIMBOA (Table 4).

DIMBOA had little effect on amylase activity, and lipase activity was variable. Inhibition of amylase appeared 24 hr after DIMBOA treatment, but afterwards, enzyme activity was variable and was sometimes higher or lower than that of the control group (Table 5). Similarly, lipase activity was lower 24 hr after larvae fed on DIMBOA, but 48 hr later lipase activity suddenly became much higher than that of the control, and by 72 hr it was again lower than that of the controls (Table 6).

AChE is an important enzyme in normal functioning of the central nervous system in insects, and inhibition of its activity may have behavioral or physiological consequences. Reduction in the level of AChE may render ACB more easily preyed upon by its natural enemies. Electrophysiological experiments by Zhou et al. (1994) showed that DIMBOA can block nerve impulse conduction. The sensitivity of sensory organs may be altered by dietary DIMBOA, and ACB

may refuse to continue to feed. This may be one possible physiological explanation for the antifeedant property of DIMBOA.

Esterase, cytochrome P-450 monooxygenase, and glutathione *S*-transferase are three important detoxication enzyme systems in insects. DIMBOA inhibits the activity of Est, possibly allowing toxins to stay in the body for a longer time because of lower activity of detoxifying esterase enzymes. At the same time that some enzymes are inhibited by DIMBOA, others are stimulated, possibly leading to detoxication. Cytochrome P-450 monooxygenase and glutathione *S*-transferase are induced to higher levels in ACB larvae fed on DIMBOA, and they may reduce the toxicity of DIMBOA. Moreover, Campos et al. (1989) confirmed that the European corn borer excretes DIMBOA very quickly. Thus, detoxication and excretion of DIMBOA may help explain why ACB larvae successfully feed on corn containing this allelochemical.

DIMBOA adversely affects, to some extent, the activity of lipase in the midgut of ACB. This effect may cause lower digestive capability and loss of nutrients, both of which will influence growth and development of larvae.

We have conducted experiments on the effects of DIMBOA on selected enzyme systems in homogenates of tissues from Asian corn borer fed DIMBOA on leaf discs. Additional studies are needed to determine if degradation or decomposition of DIMBOA occurs in the midgut of ACB. The pH of the midgut in lepidopterous caterpillars is generally high, and it is possible for DIMBOA to decompose in a high pH environment. If DIMBOA is degraded in the midgut, both undegraded DIMBOA and its derivatives, or a combination of both, may have an influence on enzymes of the gut. Clearly, further biochemical and molecular biological analysis are needed to fully understand how DIMBOA affects enzymatic systems of insects.

Acknowledgments—The authors are grateful to Prof. H.M. Niemeyer, Universidad de Chile, Santiago, Chile, who kindly presented to us a standard DIMBOA sample and reprints. The research was supported by the Higher School Special Doctorship Grants of the National Educational Committee of China.

USE OF PAIRED AND SINGLE TRAPS TO ASSESS PERCEPTION AND DISCRIMINATION OF SEX PHEROMONE MIXTURES IN THE FIELD BY *Trichoplusia ni* (Hübner)

M.S. MAYER*, J.R. McLAUGHLIN, and E.R. MITCHELL

Insect Attractants, Behavior, and Basic Biology Research Laboratory, Agricultural Research Service, U.S. Department of Agriculture, Gainesville, Florida 32604
(Received July 18, 1994; accepted August 4, 1995)

Abstract—Paired wind-oriented traps (WORT) and single traps were deployed simultaneously in the same field to investigate whether or not inferences about the central nervous system processes of discrimination and perception can be made from differences in moth captures. The stimulus levels deployed were those that typically may be found downwind of a calling virgin female cabbage looper, *Trichoplusia ni* (Hübner), so that inferences are relevant to natural stimulus intensities. Captures of male cabbage loopers in the WORT traps paralleled prior laboratory measures of pheromone mixture discrimination. The pattern of captures by the two trapping systems probably reflects perceptive and discriminative processing differences in the central nervous system. Captures in traps baited with Z7-12 : Ac alone were equal to, or better than, captures in traps baited with three- and six-component mixtures that contained Z7-12 : Ac.

Key Words—Behavior, perception, discrimination, trap, sex pheromone.

INTRODUCTION

Traps baited with insect sex pheromones historically have been used in field surveys, in various communication experiments, and as a means of confirming laboratory-derived chemical identifications. In this report we examine captures in field traps that were baited with sex pheromone components to assess the central nervous system (CNS) processes of discrimination and perception. The

*To whom correspondence should be addressed.

results address questions about pheromone component redundancy and the usefulness of multicomponent information to male cabbage looper, *Trichoplusia ni* (Hübner), behavior in particular. Trap captures are usually only distantly and tacitly linked to studies of perception and discrimination by most investigators. These terms have never been clearly defined and tested in such a way that field captures can be applied successfully to studies of these processes.

The proximate question we examine is whether or not male cabbage looper moths discriminate differences between the single pheromone component, (Z)-7-dodecenyl acetate (Z7-12:Ac), and two mixtures containing Z7-12:Ac with other pheromone components. Previously, Mayer and McLaughlin (1993) found that male cabbage loopers discriminate the individual component, Z7-12:Ac, and different mixtures in the laboratory. For those laboratory assays, discrimination was defined as the difference in response to paired, simultaneously detectable stimuli (Mayer and McLaughlin, 1991, 1993). Stimulus perception is important in signal discrimination, but it is not measured in the same manner. In the laboratory, discrimination was intensity dependent but no pairing ever elicited an all-or-none response to one or the other pheromone component aroma. In addition to confirming the results that have been observed in the laboratory, we asked whether or not the imposition of the stringency of field trap assays would result in more or less clear evidence of mixture discrimination than the laboratory assays.

Discrimination in the field was assayed by use of paired wind-oriented traps (WORT) (Mitchell et al., 1988). The same mixtures that were used in the WORT traps also were used as baits in individual traps to examine whether or not it is appropriate to associate differences in captures between these traps with perception, another CNS process. The WORT system deploys paired traps that always are oriented into the wind. As a result, the plumes from each trap, in theory, are parallel and unmixed for at least a short distance downwind but mix at some further point downwind so that an insect flying upwind detects the plumes simultaneously. It is assumed that differences in captures between the two traps is the result of a difference discriminated between the two baits. These assays are the field analog of the laboratory-based wind-tunnel assays of discrimination (Mayer and McLaughlin, 1991, 1993).

If the WORT system can be used to investigate discrimination, then do single traps measure perception? If perception is defined as the innate recognition of an odor, captures at individual pheromone-baited traps are, indeed, measures of perception. A corollary of these definitions is that an insect can perceive disjoint stimuli, but can not discriminate between them unless it has a memory. Because the terms perception and discrimination are linked to neural processes within the CNS, other terms should be given to the mechanisms and response differences by which peripheral receptor neurons respond differently to different odors.

Central processes and linked flight behaviors are not only dependent on the quality of the stimulus but also on its quantity. For example, increasing pheromone stimulus intensities to levels much higher than that found downwind of a female results in diminished trap captures or behaviors (Linn et al., 1984; Mayer, 1973; Löfstedt et al., 1985: McDonough et al., 1993; Hainotakis and Pittara, 1994; among others). Furthermore, other as yet unknown behavioral effects may result from an insect encountering stimulus intensities that are marginally higher than would normally be encountered downwind of a female, but are not so high as to reduce responses. Consequently, we attempted to maintain the stimulus intensity in these studies to levels that normally may be found downwind of a female (Mayer, 1993).

Control of the stimulus intensity is particularly difficult in field studies, and for this reason two stimulus intensities received most of the scrutiny in these assays. One level was calculated to release 10 times higher than a female and one about three times higher because the low nighttime temperatures slowed the emission from the baited rubber septa, consequently lowering the pheromone release into the range of female emission. A third level was deployed to obtain dose–response data.

METHODS AND MATERIALS

Field Tests. The traps were set in the middle of the same cabbage field near Bunnell, Florida, from March 1 to April 26, 1993, and from March 11 to April 6, 1994. Two groups of assays were conducted in 1993; one in 1994. The traps were organized in four sectors along roadways in the field separated by a minimum of 60 m. Each sector comprised a block of three or four individual or WORT traps, each a minimum of 60 m apart. The positioning of the trap sectors reduced intrafield location variance but was expected to result in interactions between different plumes, particularly when the wind direction was 0 and 180° to the trap line. The position of the baits in each sector was randomized at the beginning of the tests and then rotated systematically each time the traps were serviced. The WORT trap baits in 1993 also were interchanged from left to right each time the traps were serviced, although this made no difference in the captures.

Traps. Bucket traps (International Pheromones Moth Traps, International Pheromone Systems, Merseyside, England) were used for the WORT system and for the single traps. Three Vaportape strips were placed in the bottom of each trap to kill the moths before they either escaped or beat their wings to a state where they could not easily be identified. Every Monday, Wednesday, and Friday, with some exceptions, the traps were serviced and each trap and bait rotated clockwise to the next position within the sector. The moths from each

trap were collected in plastic bags and counted later in the laboratory (1993) or field (1994).

WORT Traps. The WORT system was the same as that described by Mitchell et al. (1988). Briefly, the system consists of two traps suspended 1 m apart supported on a horizontal arm that is mounted on a vertical rotating bearing. A wind vane is attached to a long arm mounted at 90° to the trap support arm. The vane ensures that the arm from which the two traps hang is always oriented into the wind. The assumption is that the WORT system baits always provide two plumes originating 1 m apart. This constitutes a paired system comparable to the system deploying paired stimuli in laboratory wind tunnels (Mayer and McLaughlin, 1991, 1993).

Pheromones. The pheromones and the results of their GLC analyses were provided through the courtesy of R.R. Heath of this laboratory. The Z7-12:Ac, Z7-14:Ac, and 12:Ac were obtained from Aldrich Chemical Co. and were 98.5%, 96.4%, and 97.0% pure, respectively. The Δ11-12:Ac was from Nu Chek and was 99.1% pure; the Z9-14:Ac was from Shin Etsu Chemical Co. and was 89.8% pure, and the Z5-12:Ac was synthesized and HPLC purified to 99.5% purity by R.R. Heath.

Septum Dosing. In 1993 each compound was diluted separately in hexane and one, two, or four of the compounds were pipetted separately into the well of unextracted rubber septa (Wheaton #224100-202, 11-mm sleeve stopper). The 12-carbon acetates were dispensed from a separate septum than the 14-carbon acetates. After dosing, 50 μl of hexane was pipetted into the well to ensure penetration of the pheromone (McDonough and Butler, 1983). The septa were attached to the lid of the trap in such manner that they abutted to reduce the potential for separate plumes (Witzgall and Priesner, 1991). For the 1993 season, the septa were dosed to emit proportions of the 14-carbon acetates relative to Z7-12:Ac near those measured by Mayer (1993) from excised pheromone gland emissions. For the assays of 1994, the Z7-12:Ac and its two admixtures were formulated in one solution that was dispensed from a single septum releasing proportions that were the same as those determined by Bjostad *et al.*, (1984) (Table 1).

Quantitative Pheromone Formulation. Release rates can be used to compare results obtained with similar formulations. Unfortunately, however, it often is difficult or impossible to compare dissimilar formulations where air dilution factors may be so greatly different as those found in the field and in electrophysiological experiments conducted within the laboratory. For this reason, we modified the stimulus definition so that it can be more easily compared to natural pheromone levels in all these types of assays. Consequently, the rubber septum dosages were made relative to levels emitted by females. During the two years of assays, the mixtures differed by about one logarithm (Base 10) in the component ratios of the two 14-carbon acetates, Z7-14:Ac and Z9-14:Ac. This

TABLE 1. DOSAGES OF PHEROMONE COMPONENTS ON SEPTA[a]

Pheromone component	Septum dosage (μg) to emit 10 FE_{em}	Expected emission ratio	
		1993[b]	1994[c]
Z7-12:AC	3524.6	1.00	1.00
Z7-14:AC	249.9	0.0003	0.016
Z9-14:AC	113.6	0.0001	0.007
Z5-12:AC	331.3	0.0095	0.094
Δ11-12:AC	98.7	0.028	0.028
12:AC	253.8	0.073	0.072

[a]The emission rates were based on measurements by McDonough et al. (1989) for 25°C. For this report one female is assumed to emit Z7-12:Ac at a rate of 10 ng/min (Mayer 1993). Septum dosages for 0.3 FE_{em} the female emission level, and for 3 FE_{em} the above septum dosages must be divided by 31.6, 10.0, and 3.16, respectivly.

[b]Ratios of the 12-carbon acetates are within the range of those measured by Bjostad et al. (1984) from typical time-averaged emission-capture procedures; the ratios of the two 14-carbon acetates are within the range measured by Mayer (1993) by single-cell assay of excised sex pheromone glands.

[c]Ratios of all components are near those measured by Bjostad et al. (1984) from typical time-averaged emission-capture procedures. Small differences in ratios are due to small formulation deviations.

difference between the two formulations did not appear to noticeably affect the overall performance of the traps.

The average female emission rate of Z7-12:Ac was considered to be 10 ng/min (Mayer, 1993). The evaporation half-lives for emission from rubber septa at 25°C (McDonough et al., 1989) were used to calculate the initial septum dosage to begin releasing this quantity and the proper ratios of the other components (Table 1). The nighttime temperatures in the field during both 1993 and 1994 seldom, if ever, reached 25°C during the assays, so the emission levels during the time of moth flight activity probably never exceeded the calculated levels. The calculated stimulus levels shown in Figures 1 and 2 below are given as multiples of the logarithm of the female emission (FE_{em}) level. For example, 10 FE_{em} corresponds to a calculated airborne concentration 10× that of a single female emission; 3 FE_{em} and 0.3 FE_{em} correspond to 3.16× and 0.316× a female emission level, respectively. The upper end of this range was chosen because it is extremely unlikely that a female will ever emit considerably more than 10× the average.

Statistical Procedures. The number of nights between trap servicing varied, so the total number of moths captured during a particular interval first was divided by the number of nights in the trapping interval to obtain the number

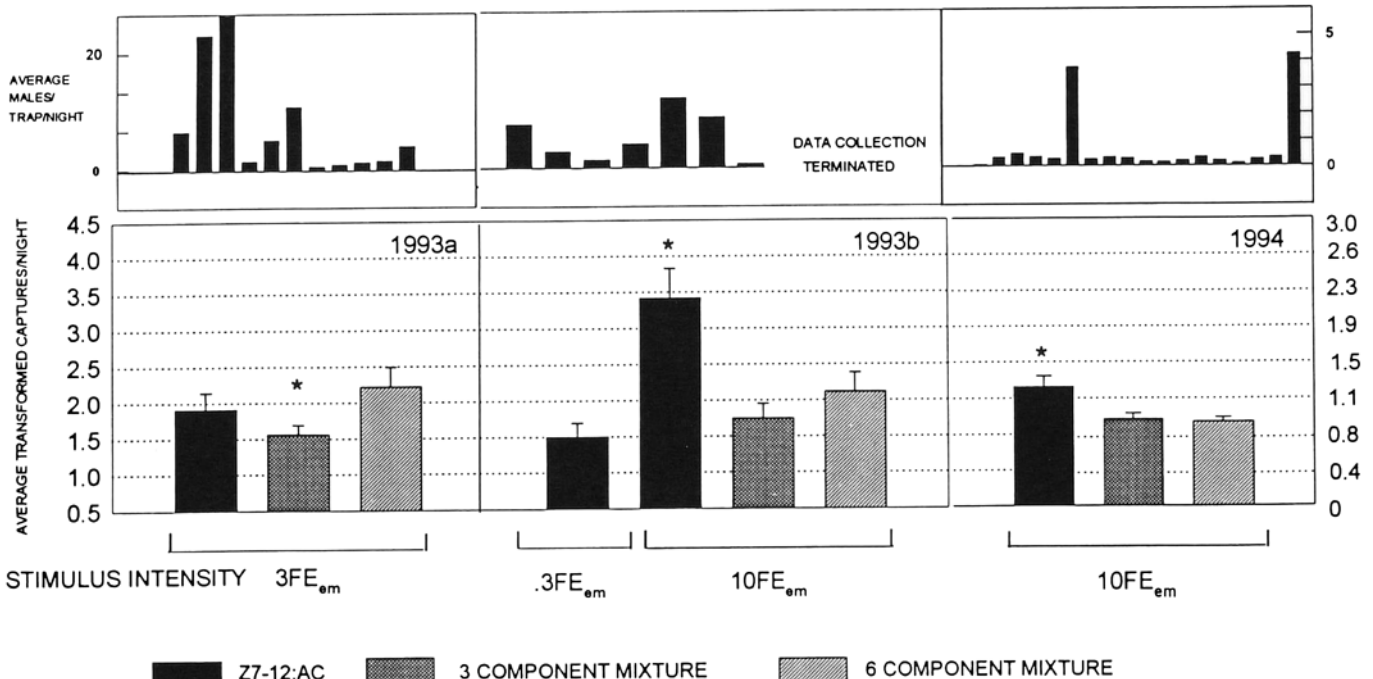

FIG. 1. Average transformed captures (error bars = SEM) of male cabbage loopers in single traps during two trapping periods. Pheromone stimulus levels are relative to the female emission. The three-component mixture comprised naturally occurring proportions of Z7–12 : Ac, Z7–14 : Ac, and Z9–14 : Ac; the six-component mixture comprised the latter three components and 12 : Ac, Z5–12 : Ac, and Δ11–12 : Ac. Asterisks mark trap capture means that were statistically different within the respective trapping period at the $P < 0.05$ level. Small graphs at top are the untransformed average number of males captured per night during each trapping interval by the individual traps.

captured per trap per night. A normalizing transformation ($\sqrt{x + 0.5}$) was applied before analyses across blocks, days, and replicates, using ANOVA (SAS, PROC GLM). Tests of means were by Scheffe's test. Differences between pairs of WORT traps were determined by paired difference t tests using both untransformed and transformed numbers of captures per trap per night and measuring the probability of the null hypothesis, H_0, that there was no difference between captures in the trap pairs (SAS Inst., Cary, North Carolina).

RESULTS

Single Traps. In 1993 single traps whose baits released three different levels of Z7–12 : Ac alone were deployed to demonstrate that different stimulus levels would capture different numbers of males (Figure 1). Individual traps baited with Z7–12 : Ac alone from 0.3 to 10 FE_{em} captured males in proportion to their nominal emission. In fact, single traps baited with 3 FE_{em} and WORT trap pairs (Figure 2) baited with 10 FE_{em} Z7–12 : Ac alone captured about as many males on average as any of the traps baited with the three- and six-component baits. During trapping period 2 (1993b, Figure 1), single traps and three of four WORT traps that were baited with Z7–12 : Ac alone captured more males than traps baited with three- and six-component mixtures. The six-component mixtures appeared to capture the most consistent average number of males per night across both trapping series. These differences in captures between Z7–12 : Ac alone and when admixed variously with five other components are not as large as those previously reported by Linn et al., (1988) and may reflect either considerable differences in emission rates between the baits or different field populations.

WORT Traps. The WORT traps were baited with septa that emitted Z7–12 : Ac alone or mixed with other pheromone components at levels that were the same as those in the individual traps (Figure 2). The control pairs that were baited with the same two stimulus levels of Z7–12 : Ac alone captured almost the same number of males in all three of the assay series. This result supports our hypothesis that the paired traps measure differences that we define as discrimination.

Discrimination of mixture differences appears to vary according to both the bait and the stimulus level. Males discriminated Z7–12 : Ac and the six-component mixture and a three- and a six-component mixture at 3 FE_{em} but not at 10 FE_{em}. At 10 FE_{em} males discriminated Z7–12 : Ac and the three-component mixture in 1993 but not in 1994 when the numbers captured were lower.

Two test mixtures link laboratory wind-tunnel assays and the field-trap assays. In both assays male cabbage loopers discriminated three-component and six-component mixtures where the distance between the sources was 30.5 cm

FIG. 2. Average transformed captures (error bars = SEM) of male cabbage loopers in paired WORT traps during two trapping periods. Pheromone stimulus levels are relative to the female emission. The three-component mixture was comprised of naturally occurring proportions of Z7–12:Ac, Z7–14:Ac, and Z9–14:Ac; the six-component mixture was comprised of the latter three compounds and 12:Ac, Z5–12:Ac, and Δ11–12:Ac. Probability of the null hypothesis, pH_0, accompanies the data for each trap pair. Small graphs at side are the untransformed average number of males captured per night during each trapping interval by the WORT traps.

and in the field where the sources were 1 m apart. In the field, however, the three- and six-component mixtures were discriminated at 3 FE_{em} but not at 10 FE_{em}. In the laboratory on the other hand, these two mixtures were discriminated at three stimulus levels.

Cross-Comparison between Trap Assay Results. Although remote, an argument could be made that different populations were sampled by the single traps vis à vis the paired traps and that the results are not comparable. Supportive evidence that the same field populations were assayed by each trap series is shown by the similarity in the average number of males captured in each trap per day in the small graphs of Figures 1 and 2.

DISCUSSION

Early in insect sex pheromone research, traps baited with sex pheromones were considered to measure the "attractiveness" of a stimulus. However, "attraction" was redefined by Kennedy (1977, 1978) as a portmanteau term for several upwind tracking behaviors. These complicated upwind tracking behaviors are being further redefined through the work of several investigators (Baker, 1986; Charlton et al., 1993; among others). However, little attention has been given to the CNS processes of perception and discrimination. Inferences about these two processes can be made from manipulation of information going into the brain and observation of what emerges in the form of behavior. Trap captures, however imprecise, reflect these two processes and can be a resource in such studies.

Laboratory-based assays of paired stimuli in a wind tunnel show that cabbage loopers discriminate different pheromone mixtures (Mayer and McLaughlin, 1991, 1993). The question examined here was whether the cabbage looper male discriminates different mixtures of pheromone components in the field. The WORT trap assays show in general that the males either are unable to discriminate or have difficulty in discriminating the single component, Z7–12 : Ac, from mixtures containing it and the other putative components of its female-originated sex signal.

While the paired traps measured discrimination, single traps measuring the process of perception show that males also fail to perceive a difference between the three assayed aromas. They fail to perceive a difference between three- and six-component mixtures at elevated stimulus levels based on the lack of significant differences in the average number of captures by the single traps. In fact, Z7–12 : Ac alone at 10× the female level captured more males than any of the mixtures. At the 3 FE_{em} stimulus level, with the exception of the three-component mixture, captures in traps baited with Z7–12 : Ac alone were no different than the six-component mixture. Based on the data, components of the female's

emission other than Z7-12:Ac appear not to alter significantly the perceptual quality of Z7-12:Ac.

In the introduction, we alluded to the importance of deploying stimulus levels that relate to the levels of sex pheromone that a male moth might encounter in nature immediately downwind from a calling female. Our reasoning is that a range of bait emission from low stimulus levels to naturally emitted levels typically results in a range from no captures to maximal captures. However, at unnaturally high stimulus levels, normally concentration-tuned antennal specialist receptor neurons lose their selectivity (Mayer, 1993) and adaptive effects may occur peripherally (Baker et al., 1988; Borroni and O'Connell, 1992), centrally, or both. Thus, from this report we see that the blurring of discrimination at the elevated stimulus level may result from the loss of antennal specialist selectivity at high airborne stimulus intensities, or it may be due to uncontrollable variables encountered in the field-trap assays, or both. Collaterally, at very high stimulus levels, a pheromone's ordinarily attractive quality may change to one of unattractiveness or even offensiveness (Mayer and McLaughlin, 1993; McDonough et al., 1983).

To summarize, the data support the hypothesis that male cabbage loopers discriminate pheromone mixtures, but none of the data support a hypothesis that a mixture comprising six components is a superior bait than Z7-12:Ac alone. Furthermore, perceptual differences between the mixtures and Z7-12:Ac also were not apparent. The data do not support a hypothesis that a mixture containing only the compounds that are detected by previously established antennal olfactory pheromone specialist neurons, Z7-12:Ac, Z7-14:Ac, and Z9-14:Ac, was any more effective than Z7-12:Ac alone. The question remaining is whether the compounds other than Z7-12:Ac really effect behavioral responses and if so, which?

Acknowledgments—We thank J.R. Rye, Jr., W.E. Copeland, and R.H. Guy for their assistance in conducting these assays. We thank Drs. Alan J. Grant, Juan D. Lopez, Jr., J.A. Coffelt, L.M., McDonough, and J.H. Tumlinson for their thoughtful comments during preparation of the manuscript.

CHEMICAL INVESTIGATION OF AGGREGATION BEHAVIOR OF *Triatoma* BUGS (HEMIPTERA: REDUVIIDAE)

LEOPOLDO CRUZ LÓPEZ[1] and E. DAVID MORGAN*

Department of Chemistry, Keele University
Keele, Staffordshire, England, ST5 5BG

(Received January 17, 1995; accepted August 9, 1995)

Abstract—Nymphs of *Triatoma infestans* and *Triatoma mazzottii* are weakly attracted to their feces and to extracts of feces in polar solvents, but not to nonpolar solvent extracts. The major volatile compounds identified in feces by solvent extraction and thermal desorption were *o*-aminoacetophenone, 4-methylquinazoline, and 2,4-dimethylquinazoline, but these showed no attractant activity at a range of concentrations. Choice tests with a moving current of air gave no positive reaction to feces, extracts, or pure compounds.

Key Words—Hemiptera, Reduviidae, *Triatoma*, aggregation, pheromone, feces, *o*-aminoacetophenone, quinazolines.

INTRODUCTION

The behavior of *Triatoma* bugs is of special importance because these blood-sucking insects are transmitters throughout Central and South America of the parasitic infection known as Chagas disease. It is estimated that there are 16–18 million people infected with this parasite, *Trypanosoma cruzi*, with a further 90 million at risk (WHO, 1991). Control of the disease relies heavily upon control of the vectors (Schofield, 1992), a group of about 12 species in the subfamily Triatominae (Hemiptera: Reduviidae). The most important of these generally is *Triatoma infestans*, although at the northern extremity of the disease range in southern Mexico, *T. mazottii* is thought to be a major vector (Rojas et al., 1989).

Pheromones of *Triatoma* species, if they exist, would offer a potential new approach to their control or dispersal. Adults and nymphs of the triatomines spend daylight hours aggregated in crevasses and in caves. It has therefore been suggested that they may produce aggregation pheromones. Early observations and experiments on the aggregation behavior of several species of *Triatoma* suggested that chemical substances contained in their feces were responsible (Velazquez, 1968; Baldwin et al., 1971; Schofield and Patterson, 1977; Neves and Paulini, 1982a; Ondarza et al., 1986). Recently, Cruz López et al. (1993) reported an interspecific aggregation behavior in five species of Triatominae induced by their feces. Aggregation of *Triatoma infestans* promoted by feces has been reinvestigated by Lorenzo Figueiras et al., (1994).

We have conducted a study on the response of larvae of *T. infestans* and *T. mazzottii* to their own feces and to chemical extracts of their feces in a search for an aggregation pheromone. Substances present in the feces have been identified by combined gas chromatography and mass spectrometry. Several substances have been identified but none induced aggregation behavior.

METHODS AND MATERIALS

Insects. Triatoma infestans and *T. mazottii* were reared in an incubator maintained at 28°C. The insects were fed with rabbit blood (Ryckman, 1952) and with heparinized human blood using an artificial feeder (Ramirez-Rovelo et al., 1990).

Still-Air Choice Test. The bioassays were carried out in a Petri dish (16 cm diam.), the bottom of which was lined with filter paper (Whatman No. 47). Two pieces of filter paper (2 × 2 cm) were placed on opposite sides of the dish. One of these papers was an untreated or pure solvent-treated control, and the other was exposed to the material being tested. The experiments were carried out in a darkened incubator at 26–28°C. First and second instars were placed in the center of the Petri dish using a glass tube (4 × 4 cm) open at both ends; after 10 min the insects were released, and after 1 hr the response was scored by counting the number of insects that had settled on the pieces of paper.

The response of insects was evaluated by using the aggregation index I (Cruz López et al., 1993) where:

$$I = \frac{A_1 - A_2}{N_t}$$

where A_1 is the number of insects aggregated on test filter paper, A_2 the number of insects aggregated on the control, and N_t the total number of insects used in each bioassay. The index value can range from +1 to −1; positive values

indicate aggregation, negative values indicate repulsion from the tested substance. Aggregate values were obtained from a number of experiments, usually 10 replicates.

Moving-Air Choice Test. Feces and extracts of fifth instars and adults of *T. mazottii* were also tested under moving air conditions. A Y tube made of glass was set up with the insects confined to the base of the Y. The tips of the branches were dipped into conical flasks, one of which contained pieces of paper impregnated with feces, extracts or pure compounds, the other branch was similarly arranged with control papers, either untreated or treated with pure solvent. Air was drawn into the system through charcoal filters, passed over the papers, into the Y tube, and the insects were released. After 60 min they were observed to see if they had moved upwind into the branches of the Y tube, and the numbers in each branch were counted.

Solvent Extraction. T. infestans feces were extracted with the hexane fraction of light petroleum, acetone, methanol, and water. After removing the solvent, the extracts were tested for aggregation response by placing 1 μl of the extract on the test filter paper. The activity of the feces after solvent extraction was also evaluated.

T. mazzottii feces were extracted with the hexane fraction, acetone, and ethanol, and tested similarly.

Thermal Desorption. Volatile compounds were thermally desorbed from filter papers by packing small strips of feces-impregnated paper into a glass capillary (15 × 15 mm), which was sealed at both ends and introduced directly into the heated zone of a gas chromatography inlet held at 200°C. The sample was heated for 2 min before crushing the capillary and beginning chromatography, as described by Morgan (1990).

Analysis. Gas chromatography–mass spectrometry (GC-MS) analysis was carried out in a HP-5890 gas chromatograph linked to a 5970B Mass Selective Detector and controlled by a HP5070C Chemstation. The column employed was a 12-m × 0.22-mm ID fused silica capillary column coated with BP1 immobilized dimethylsiloxane, equivalent to OV-101. The oven temperature was held at 30°C for 2 min and then increased to 280°C at 8°C/min; the injection port temperature was 200°C.

Synthetic Compounds. Syntheses of 4-methylquinazoline and 2,4-dimethylquinazoline were carried out by the method of Bergman et al. (1986), by treatment of 2-aminobenzonitrile with methylmagnesium iodide. The intermediate was treated *in situ* with ethyl formate to give 4-methylquinazoline ϸ 36–37°C (ethanol), M^+ 144 (100%), *m/z* 129 (25), 117 (18), 103 (25), 89 (8), 75 (27), 50 (20). Similar treatment of the intermediate with acetyl chloride gave 2,4-dimethylquinazoline, mp 72°C (hydrate from aqueous ethanol), M^+ 158 (100%), *m/z* 143 (60), 117 (42), 102 (12), 89 (10), 76 (20), 63 (10), 50 (15).

Other substances were purchased or available in the laboratory.

RESULTS

When first instars of *T. infestans* were given a choice between their own feces on filter paper or clean filter paper, they responded positively to their feces (Table 1). A significant response was also recorded with feces that had been extracted with hexane. On the other hand, the feces after treatment with acetone, methanol, or water elicited a weaker response. The hexane and acetone extracts were unattractive, unlike the methanol and aqueous extracts.

Similar results were obtained for the aggregation response of second instars of *T. mazzottii* (Table 2). The nymphs showed a variable aggregation response to fecal extracts. The hexane and acetone extracts elicited a weak response, and the feces treated with those solvents also showed some response. The ethanol extract elicited a weak aggregation response, while the feces extracted with ethanol were inactive.

The solvent extracts and heat-desorbed materials from feces were analysed by GC-MS. The solvent extracts and heat-desorbed material of both species showed a common pattern of three compounds, identified from their mass spectra as *o*-aminoacetophenone (I), the major substance, followed by 4-methylquinazoline (II) in lesser quantity, and still less of 2,4-dimethylquinazoline (III). Identification was confirmed in each case with authentic material. In addition,

all samples showed variable amounts of acetic acid and acetamide. Both extracts of *T. infestans* contained variable amounts of undecanal (Figure 1) and the methanol extract contained some 2-pyrrolidinone (IV) (Figures 2 and 4). In contrast, *T. mazzottii* feces contained variable amounts of isobutyramide and isovaleramide and an unsaturated hydrocarbon (Figure 3). The feces therefore contained common substances in a regular pattern and specific substances in very variable amounts. Extracts also contained phthalate ester plasticizers and carboxylic acids, which were also present in the paper on which feces were deposited.

All of the substances identified were used both singly and in blends in the aggregation test with nymphs but no compounds or mixtures showed any clear response with either species.

In tests carried out in Mexico on triatomids, including *T. mazzottii*, in a wind-tunnel similar to that used by Lorenzo Figueiras et al. (1994), some attraction towards feces was observed (Cruz López et al., 1993). In the present work, however, no preference was observed for feces, extracts or pure compounds, using fifth instars or adults in the Y-shaped moving-air test.

DISCUSSION

Aggregation pheromones have been reported in widely separated groups of insects, and many of them have been studied chemically (see, e.g., Otieno et

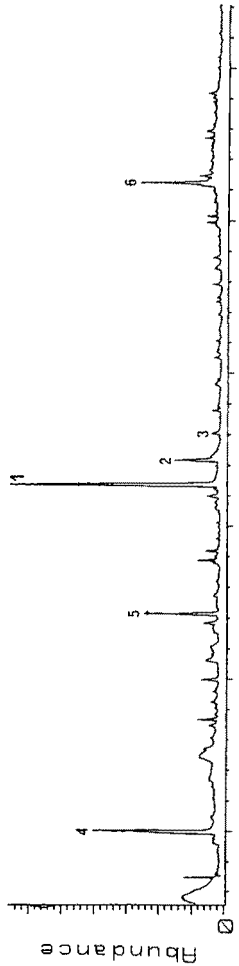

FIG. 1. Total ion gas chromatogram of the volatile products in the feces of *T. infestans*, obtained by thermal desorption. Numbered substances are: 1, *o*-aminoacetophenone; 2, 4-methylquinazoline; 3, 2,4-dimethylquinazoline; 4, acetic acid; 5, undecanal; 6, phthalate plasticizer contaminant.

al., 1985). The study of hemipteran pheromones has not proceeded at the rate of studies in other insect orders. Aldrich (1985) suggested that one possibility is that pheromones are not as prevalent in Hemiptera as in other insects. It may be that bugs have not yet attracted sufficient attention of researchers. In *triatomids* there are reports that the feces are the source of an aggregation pheromone. Cruz López et al., (1993) showed that fecal extracts made with polar solvents elicited a response in some *Triatoma* species.

The results obtained in this work support the evidence elsewhere that the feces of *T. infestans* and *T. mazzottii* do contain substances that promote aggregation, although the effect is weak. Aggregation indices (*I*) of 0.42 for *T. infestans* and 0.37 for *T. mazzottii* were recorded here. Cruz López et al. (1993) gave indices of 0.18 for *T. infestans* and 0.20 for *T. mazzottii*. The results of Lorenzo Figueiras et al. (1994), expressed in the same way, give an aggregation index of 0.5 for *T. infestans*. It is clear that polar solvents remove the aggregation effect from the feces and the solvent residue shows some positive effect, but in every case this was weak.

Analysis of the volatile substances on the paper, either by solvent extraction with methanol or direct thermal desorption, showed essentially the same mixture of compounds, regardless of the method or the species. *o*-Aminoacetophenone (I) was the major substance, followed by 4-methylquinozoline (II) and 2,4-dimethylquinazoline (III). These substances, when tested in the same way over a range of 0.1–100 ng, showed no consistently positive activity.

There is clear evidence that the insects are weakly attracted to feces. The substance or mixture responsible must be stable, since feces of both species are still effective after a few months of storage (unpublished observations). Any pheromone isolation attempt is strongly dependant upon a satisfactory bioassay. We are forced to conclude that the bioassay used here is not sufficiently close to natural conditions to give a good response or else that a complex interaction between substances is necessary.

The two quinazolines have not previously been reported in insects or their feces. *o*-Aminoacetophenone was identified in the mandibular glands of a primitive fungus-growing ant (Blum et al., 1981). It has also been reported as

repellent to birds (Mason et al., 1991) and to house mice (Nolte et al., 1993), but no other behavioural effects of these substances are recorded. It is possible that these compounds in feces may be repellent to predators of *triatomids*.

Acknowledgments—L.C.L. thanks CONACYT for the award of a studentship and CIES for a leave of absence to undertake this study. We thank Ann Pennell, University College of North Wales for helping to raise *T. infestans*, and Dr. Jorge Ricárdez from CIES for providing *T. mazzottii*.

(Received January 31, 1995; accepted August 9, 1995)

Abstract—A survey for the presence of sequestered lichen compounds in 103 wild-caught imagines representing eight different genera and 16 different species of the Arctiidae was conducted. Known lichen compounds were detected for the first time in 24 of the analyzed specimens (representing five different genera and 11 different species) based on their HPLC retention times and on their UV-absorption spectra. The anthraquinone parietin, the depside atranorin, as well as a hydrolytic cleavage product of the latter were among the lichen compounds most frequently detected in wild-caught imagines. The observed variation of sequestered lichen compounds in wild-caught imagines

with unknown feeding history may be due to several reasons. Lack of lichen compounds in imagines may have been caused, for example, by larvae feeding on lichens with no or only minute amounts of phenolic products. The age of the specimens analyzed may also influence the results obtained. Avoidance of lichen compounds by selective feeding on those parts of lichen thalli that have no or little lichen products may be another reason for the lack of lichen compounds in imagines. Preliminary feeding experiments conducted with larvae of *Eilema complana*, for example, indicated that the larvae fed exclusively on the algal layer and cortex of the lichen *Cladonia pyxidata*, whereas the medulla, which is rich in fumarprotocetraric acid, was avoided. As expected, imagines hatching from the larvae were free of this lichen compound. Any ecological role of the sequestered lichen compounds for the herbivores is unknown. It is possible, however, that sequestered lichen compounds may be utilized for the chemical defense of arctiid moths or against microbial pathogens.

Key Words—Arctiidae, Lepidoptera, lichens, lichen compounds, HPLC, sequestration, chemical defense.

INTRODUCTION

Lichens comprise some 20,000 different species and show a worldwide distribution, commonly growing on rocks and poorly developed soils such as those of arid lands and boreal-arctic regions, or as epiphytes on trees and shrubs (Crittenden and Porter, 1991). Especially in habitats that are poor in nutrients and characterized by extreme environmental conditions (such as hot or cold deserts), lichens may form the dominant floral elements and may thus provide important potential resources for herbivores. The large concentrations of mostly phenolic secondary compounds—the so-called lichen compounds—that are accumulated in copious amounts (sometimes exceeding 20% of the dry weight) by many lichens have long been suspected to protect these symbiotic organisms from generalist herbivores (Zukal, 1895; Stahl, 1904). Recent experiments with polyphagous larvae of the insect *Spodoptera littoralis* (Noctuidae) demonstrated pronounced acute toxicity and feeding deterrency for frequently occurring lichen compounds such as (+)- and (−)-usnic acid or vulpinic acid at concentrations comparable to or even below those found in many lichens (Emmerich et al., 1993). Other lichen compounds, such as oxyphysodic acid or fumarprotocetraric acid, had no effect on larval survival, but prolonged the larval period of *S. littoralis* and caused malformations of imagines when added to the larval diet (Giez et al., 1994).

In spite of the deterrent or even toxic effects of many lichen products toward generalist herbivores, there are examples of specialized lichen feeders, including oribatid mites (Seyd and Seaward, 1984; Reutimann and Scheidegger, 1987), terrestrial gastropods (Baur et al., 1992; Hesbacher et al., 1995) and Lepidop-

tera, for example, from the family Arctiidae (Rambold, 1985; Embacher, 1994; Trawöger, 1991). We are interested in the mechanisms that allow this kind of specialization and especially in the face of lichen compounds in these specialized lichen–insect associations. Recently, we have demonstrated for the first time that the lichen-feeding snails, *Balea perversa* and *Chondrina clienta*, sequester lichen compounds in their soft bodies (Hesbacher et al., 1995). In the present study we report for the first time on the occurrence of lichen compounds in wild-caught imagines of the Arctiidae that are known to feed on lichens in nature (Rambold, 1985; Embacher, 1994; Trawöger, 1991), as well as in insects that were raised in the laboratory on a known lichen diet.

METHODS AND MATERIALS

Wild-Caught Insects. Dates and localities for collection of wild-caught imagines in which lichen compounds could be identified are given in Table 2 below. Following air or freeze drying, all collected specimens were individually ground in a mortar and exhaustively extracted with acetone. The resulting extracts were subsequently reduced to a known volume and stored in a freezer until HPLC analysis.

Feeding Experiments with Eilema complana. Larvae of *Eilema complana* collected near Stallhof (Niederösterreich) were reared for the last five days of their larval period in the laboratory on the lichen *Cladonia pyxidata* (L.) Hoffm., containing fumarprotocetraric acid (**7**, Figure 1) as the major lichen compound. During these five days, larval feces were collected daily for HPLC analysis. The imagines emerged from the pupae after 12–14 days in darkness at 25°C. Feces, the lichen, and freeze-dried imagines were extracted in a known amount of acetone at room temperature (20–22°C). The extracts were stored in a freezer until HPLC analysis.

Localization of Fumarprotocetraric Acid (7) in the Lichen Cladonia pyxidata. Thallus pieces of the lichen *Cladonia pyxidata* (L) Hoffm. including basal squamules of the primary thallus as well as segments of podetia were soaked in H_2O followed by a treatment (10 min) with 1.8% HCl to dissolve oxalic acid present in the thallus. Air bubbles were removed from the thallus under vacuum. Subsequently, transversal sections (25 μm) were cut with a freezing microtome (Kryomat, Leitz; −25°C). The sections obtained were analyzed microscopically using polarized light.

HPLC Analysis. The HPLC system (Pharmacia) was equipped with a photodiode array detector (Waters). Samples were injected on a Nova-Pak C_{18} column (Waters) (150 × 3.9 mm, 4-μm pore size). Separation of the compounds took place by using a linear gradient from 100% A (10% MeOH, 90% H_2O adjusted to pH 2 with *o*-phosphoric acid) to 100% B (MeOH) in 40 min. Iden-

FIG. 1. Structures of lichen compounds: **1** (parietin), **2** (divaricatic acid), **3** (atranorin), **4** (presumably a degradation product of **3**), **5** [usnic acid, (+)- enantiomer), **6** (vulpinic acid), **7** (fumarprotocetraric acid).

tification of lichen compounds was by comparison of retention times and by comparison of the online-recorded UV absorption spectra with those of commercially available lichen substances (Roth) or with lichen compounds isolated and identified previously in our laboratory. Lichen compounds were quantified by the external standard method using commercially available lichen products (Roth).

RESULTS

Table 1 summarizes the data obtained in our survey for lichen compounds in 103 wild-caught imagines representing eight different genera and 16 different species of the Arctiidae. Lichen compounds **1–6** (Figure 1) were readily identified by HPLC based on their retention times and online UV absorption spectra as well as by comparison with authentic standards. The anthraquinone parietin (**1**), the depside atranorin (**3**), as well as the monomer (**4**), which presumably originates from atranorin by hydrolytic cleavage, were among the major lichen compounds detected in the insects (Table 2). Other lichen compounds that were sporadically found included usnic acid (**5**) [differentiation between (+)- or (−)-usnic acid was not possible due to the small amounts] as well as divaricatic acid (**2**). In addition to compounds **1–6,** several constituents were detected in the imagines that resembled lichen products (e.g., usnic or vulpinic acid) based on their characteristic UV absorption spectra but differed with regard to their retention times.

Considerable inter- as well as intraspecific variation with regard to the nature of the sequestered lichen compounds and to their amounts (micrograms per imago) was observed. Relatively large amounts of parietin (**1**) were found in one imago of *Atolmis rubricollis* (5.64 μg/imago), along with atranorin (**3**) (0.23 μg/imago), and the monomer (**4**) (0.09/μg/imago), whereas a second specimen of *A. rubricollis* yielded only parietin (**1**) (1.85 μg/imago). Five additional imagines of the same species were found to be devoid of any detectable lichen compounds (Table 1).

Analysis of 52 specimens from the genus *Eilema* showed also a high variability with regard to sequestered lichen compounds. Even though each of the six analyzed species of this genus was represented by one to several specimens in which lichen compounds could be unequivocally identified, a comparatively large number was devoid of detectable lichen products. For example, of 19 wild-caught imagines of *E. depressa* (syn. *E. deplana*), only five specimens were found to contain the lichen compounds parietin (**1**) (trace–5.43 μg/imago), divaricatic acid (**2**) (trace) as well as the monomer (**4**) and usnic acid (**5**) (both also in trace amounts), whereas the remaining 14 specimens were free of those

[a] Unknown lichen compounds resembled identified lichen products (e.g., divaricatic acid: **2**) by online UV spectra but differed from the latter by retention times.

lichen products (Table 1). However, 10 of 19 analyzed imagines contained unknown lichen products (metabolites?) that resembled identified lichen compounds based on their UV spectra, such as divaricatic acid (**2**), but differed from the latter with regard to retention times. The low concentrations of these unknown compounds and the limited number of specimens of *E. depressa* prevented isolation and identification of the unknowns.

Within the genus *Setina*, *S. aurita* ssp. *modesta*, *S. roscida*, and *S. irrorella* yielded specimens that contained trace amounts of the lichen products parietin (**1**), atranorin (**3**), the monomer (**4**), and an unknown vulpinic acid derivative, whereas none of the analyzed imagines from *S. cantabrica*, *S. flavicans*, and *S. roscida* ssp. *kuhlweini* contained detectable lichen compounds (Table 1).

Controlled feeding experiments were conducted with larvae of *Eilema complana*. Due to the small sample size (only two larvae were available), however, the experiments can only be regarded as preliminary in nature. Larvae of *E. complana* (second and third instars) were observed feeding on the lichen *Cladonia pyxidata*. When transfered from the natural habitat to the laboratory, the larvae were found to feed exclusively on the cortical and algal layers of the lichen thalli but avoided the medulla, as evidenced by the whitish appearence of the remaining parts of the thallus after the cortex and green algal layer had been completely removed by the larvae. Light microscopic analysis of transverse sections of the lichen thallus indicated that the lichen compound fumarprotocetraric acid (**7**) was confined exclusively to the medulla but appeared to be either lacking or negligible in the algal layer or in the cortex. Larval feces that were collected daily as well as the imagines that developed from the larvae were devoid of fumarprotocetraric acid (**7**) (Figure 2). Hence, the larvae avoided uptake of the lichen compound by selective feeding on those parts of the thalli that were essentially free of fumarprotocetraric acid (**7**).

DISCUSSION

Sequestration of secondary plant constituents such as alkaloids (Ehmke et al., 1990), flavonoids (Wiesen et al., 1994), or cardiac glycosides (Malcolm, 1990) by herbivorous insects has frequently been reported for interactions of herbivores with higher plants. Species of the Arctiidae, for example, are known to sequester pyrrolizidine alkaloids from plants of the Asteraceae, Fabaceae, or Boraginacae and to utilize these compounds either for their own chemical defense (Hartmann, 1991) or as precursors for pheromones (Boppré and Schneider, 1985). The present study provides, for the first time, evidence for sequestration of lichen compounds by lichen-feeding members of the Arctiidae. Of 103 specimens, 64 specimens were found to contain identified lichen compounds or metabolites resembling identified lichen products by their online UV spectra (Table 1). However, when comparing the number of species with sequestered lichen compounds to the number of species lacking detectable lichen compounds, the different sample sizes (number of analyzed specimens per species) of both groups have to be taken into account. Species of the Arctiidae that lacked identified lichen compounds, such as *Setina cantabrica* or *Setema cereola*, were represented by only one or two specimens compared, for example, to the 19 specimens of *E. depressa* and the 15 specimens for *E. complana* (including five and four specimens, respectively, that contained lichen products). Considering the pronounced intraspecific variation with regard to presence vs. absence of lichen compounds observed in this study, sequestration of lichen compounds may therefore be more widespread within lichen-feeding members of the Arctiidae than suggested by the results of Table 1.

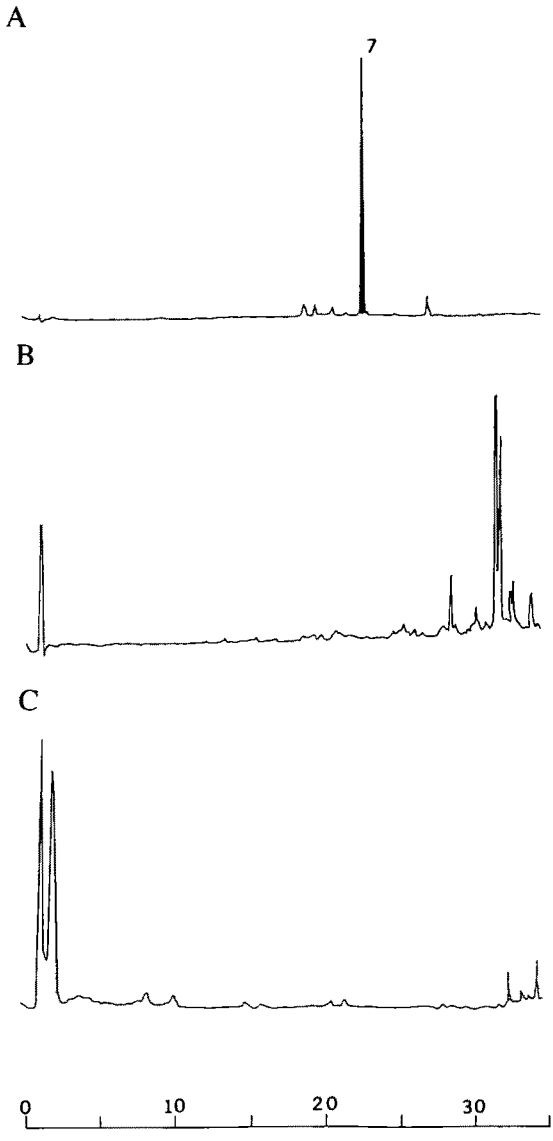

FIG. 2. (A) Detection of fumarprotocetraric acid, **7**, in medulla portion of thalli of *Cladonia pyxidata* not eaten by *Eilema complana* larvae; a lack of fumarprotocetraric acid in (B) larval feces and (C) adults of *Eilema complana* after feeding on cortical and algal layers of thalli of *Cladonia pyxidata*.

The observed variation of sequestered lichen compounds in wild-caught imagines may be due to several reasons. The data presented in Tables 1 and 2 are from insects with an unknown feeding history. Lack of lichen compounds in some imagines may, for example, have been caused by feeding on lichens with no or with only minute amounts of phenolic lichen compounds. Selective feeding on parts of thalli that are free of lichen compounds may be another reason for the observed variability. Preliminary feeding experiments with *E. complana* and the lichen *Cladonia pyxidata*, for example, indicate that the larvae feed only on the algal and cortical layers of the thallus, which are virtually free of phenolic compounds, but avoid the medulla, which contains the bulk of fumarprotocetraric acid (**7**). It is possible that similar feeding behavior that results in avoidance of lichen compounds deposited in the medulla regions of lichens may exist also in other species of the Arctiidae. The age of the specimens analyzed may also influence the results obtained. Phenolic lichen compounds are usually stable and are not expected to be chemically altered during storage. However, if sequestered lichen compounds are primarily accumulated in the scales (which is unknown so far), repeated handling of specimens, in addition to the natural wear and tear with age, could influence the results obtained. Nevertheless, this study demonstrates for the first time that sequestration of lichen compounds is variable, but widespread, in wild-caught arctiid moths.

It is not known yet if the lichen compounds sequestered by species of the Arctiidae or by lichen-feeding snails, which recently have been shown to sequester lichen compounds from their diet (Hesbacher et al., 1995), are of ecological importance to the herbivores. However, it has been demonstrated that anthraquinone derivatives, such as chrysazin or chrysophanol, which are structurally closely related to parietin, are deterrent toward ants like *Myrmica sabuleti* (Hilker et al., 1992). Anthraquinones are also known for their antimicrobial activities (Cudlin et al., 1976), and may be involved in chemical defense against microbial pathogens. It is therefore possible that storage of lichen compounds may result in chemical protection of insects or of snails from predators or from pathogens. Further studies on the roles of sequestered lichen compounds in invertebrate herbivores are underway.
