Abstract—Two hermit crabs, *Dardanus venosus* (Milne-Edwards) and *Pagurus pollicaris* Say, have evolved mutualistic symbiotic relationships with sea anemones, *Calliactis tricolor* (Le Sueur). Anemones live on gastropod shells occupied by the crabs. Both partners are thought to participate in the transfer of the anemone to the crab's shell. However, neither species invariably exhibits transfer behavior when in contact with the other symbiont. Factors influencing transfer activity of *C. tricolor* were studied. Anemone attachment is stimulated by disturbance and is time dependent. Anemones attached to shells more frequently immediately after the anemone was disturbed. Assays testing surface texture and surface composition showed that attachment activity of the sea anemone is dependent upon the organic matrix of the shell and is enhanced by texture. Attachment by anemones to shells with organic matrix removed is reduced, but is stimulated by adsorption of complex odor mixtures. Anemones respond to odor mixtures that signal food to crabs and to odor mixtures that stimulate shell investigation and shell switching in crabs. Thus, *C. tricolor* participates in shell transfer activity after disturbance. Behavior of the anemone is cued by texture and chemicals, including chemical mixtures that cause hermit crabs to change shells.

Key Words—Anemones, *Calliactis tricolor*, chemical mediation, coevolution, *Dardanus venosus*, hermit crabs, *Pagurus pollicaris*, symbiosis.

INTRODUCTION

Communication and recognition are important factors in initiating and maintaining symbiotic associations. Information flow between symbionts can involve chemical, physical, and visual cues (for review, see Davenport, 1966; Ache, 1974). We chose the symbioses between hermit crabs and sea anemones to study information flow that mediates behavior. The hermit crabs *Pagurus pollicaris* and *Dardanus venosus* have the anemone *Calliactis tricolor* as a symbiont. *P. pollicaris* usually hosts no more than one or two anemones (Brooks and Mariscal, 1986). *Dardanus venosus* are often found with numerous *C. tricolor* attached to their gastropod shells (Brooks, 1991a). The relationship between crabs and anemones is mutualistic; both partners deter some of the other partner's predators (Ross, 1971; Brooks, 1988, 1989; Brooks and Gwaltney, 1993).

How crabs and anemones initiate their symbiosis in the field is unknown. Laboratory studies show that crabs can locate anemones from a distance using chemical cues (Brooks, 1991b). In the laboratory, *D. venosus* regularly transfer anemones to their shells from other shells or surfaces (Ross, 1960, 1970, 1979; Ross and Sutton, 1961; Cutress and Ross, 1969; Cutress et al., 1970; Brooks and Mariscal, 1986; Brooks, 1988, 1989). To transfer an anemone, the crab pokes the column of the anemone with its dactyls, which triggers the release of the pedal disc from the substrate. The crab then manipulates the anemone onto its shell where the anemone reattaches to this new surface.

Transferring of *C. tricolor* from shell to shell requires active participation by the anemone (Cutress and Ross, 1969; Cutress et al., 1970; Brooks, 1991a). First, *C. tricolor* clings to the shell with its tentacles, then, in a slow-motion somersaulting action (flipping), it attaches its pedal disc. Early studies indicated that tentacle adhesion and subsequent somersaulting by *C. tricolor* and the European species *C. parasitica* are responses to factors associated with molluscan shells (Ross and Sutton, 1961; Cutress and Ross, 1969; Ross, 1967).

In the present study, we examine factors influencing attachment of *C. tricolor*. Assays were developed to determine the effect of temporal, textural, and chemical factors on anemone attachment behavior. We show anemone attachment is directly related to time since disturbance. Additionally chemical mixtures that signal food and shells stimulate anemone attachment.

METHODS AND MATERIALS

Two species of anemones, *C. tricolor* and *Aiptasia pallida* Verrill, were used in studies of unassisted attachment. *C. tricolor* were removed from the shells of *Dardanus venosus* collected off-shore near Beaufort, North Carolina. *A. pallida*, nonsymbiotic and locally common anemones on rocks and pilings, were collected from flow-through seawater tables at the laboratory. Anemones

were maintained in monospecies groups in 25-liter aquaria at 23–26°C in the laboratory. Light cycles were uncontrolled, and anemones were fed *Artemia* spp. nauplii daily. In addition to *D. venosus*, the hermit crabs *Clibanarius vittatus* (Bosc) and *Pagurus pollicaris*, clam shells (of *Mercenaria mercenaria*), and the gastropods *Polinices duplicatus* were collected from the immediate vicinity of the Duke University Marine Laboratory and used in experiments. Shrimp (*Penaeus* sp.) used in the study were purchased frozen from local sources.

We disturbed anemones by dislodging them and observed their subsequent behavior. We determined the frequency of anemone reattachment to different objects after dislodgement. During the assays, anemones were kept in 12-liter plastic buckets containing 2 liters of filtered seawater. After each trial, the buckets were rinsed and filled with fresh seawater.

Time Assay. To simulate *D. venosus* disturbance of *C. tricolor*, 10 anemones in each of six buckets were dislodged from the bucket surface. A nonsymbiotic intertidal hermit crab, *Clibanarius vittatus*, was placed in each bucket with the anemones. In the first experiment, all buckets received a crab immediately (0 time); in the next experiment, anemones were disturbed and crabs added after 15 min. The process was continued to include additions at 45, 90, and 180 min and at 48 hr. Because *D. venosus* actively gather anemones, *C. vittatus* was used so that just the effects of crab movement on anemone attachment could be studied. The number of anemones that attached to the crab's shell after 3 min for each of the time regimes was scored as positive transfer behavior. *A. pallida* was used for controls in this attachment assay.

Object Assay. The specificity of anemone transferring behavior was investigated by presenting each of 60 *C. tricolor* 17 objects of various textures and composition (Table 1 below). The objects, one at a time per anemone, were placed in the assay buckets 15 min after the anemones were detached from the bucket surface. The response was scored as a positive if, after 3 min, the anemone remained attached when the object was moved.

Surface Treatments. Different techniques were used to prepare each surface. *Mercenaria mercenaria* (Linnaeus) shells used in texture and chemical adsorption studies were first baked at 500°C for 4 hr to remove native organic material. To obtain surfaces with *D. venosus* odor, bare clam shells were soaked for 45 min in water from a 10-liter aquarium containing five live *D. venosus*. All other objects were soaked in filtered seawater for 45 min. To prepare a coating of *Balanus amphitrite* Darwin odor on glass slides, slides were placed for 15 min in an 8-liter aquarium containing 100 *B. amphitrite*. Bovine serum albumin (BSA, Sigma Chemical, St. Louis, Missouri, #A4378) was applied to baked shells at a concentration of 0.5 mg/ml (10^{-5} M). Treated shells were dried in an oven overnight at 70°C to create a coating.

Responses to Complex Odors. We hypothesized that it would be adaptive if anemones responded to the same complex odor mixtures that signaled shell

searching and switching by their symbiotic hermit crabs. This would ensure the anemone gets on the new shell. Thus, we chose complex odors that are known to signal food (shrimp extract) (Rittschof, personal observation) and available shells (snail extract) (Rittschof, 1980; Rittschof et al., 1992) to many hermit crabs. Because these odors had not been previously tested in either *D. venosus* or *C. tricolor*, we tested the odor mixtures on both species of symbiotic hermit crabs and the anemone. The two complex mixtures tested were extracts from the snail *Polinices duplicatus* and the shrimp *Penaeus* sp. Both extracts were generated by thawing approximately 3 g of frozen flesh in 5 ml seawater for approximately 30 min before use (Rittschof et al., 1992).

Snail and shrimp extracts were applied separately to baked shells and dried overnight at 70°C. *C. tricolor* attachment behavior was recorded as previously outlined in the Object Assay section.

Snail and shrimp extracts were tested separately on *P. pollicaris* and *D. venosus* in modified bucket assays (Rittschof et al., 1992) to determine if these crabs were also responsive. In the modified assays, approximately 30 hermit crabs were allowed to adjust for several days to confinement in a 70-cm × 120-cm fiberglass tank filled to a depth of 10 cm with running ambient seawater. To perform an assay, the water flow was turned off and after 30 min 200 ml of seawater was added directly to the group of quiescent crabs. The number of crabs investigating other shells in a 2-min interval was recorded. Next, 200 ml of odor solution was added, and the number of crabs investigating other shells was recorded.

Previously, Katz and Rittschof (1992) showed that reducing the size of the shell (by clipping) occupied by *Clibanarius vittatus* will increase its rate of shell investigative behavior. Preliminary observations in our study showed that *D. venosus* was very responsive to snail extract, but the response of *P. pollicaris* was less dramatic (although still higher than control conditions). Thus, *P. pollicaris* was tested twice, once in unmodified shells and next in shells that were reduced approximately one fifth in size by clipping with wire cutters. After clipping, these crabs were tested the next day to determine whether their activity level increased.

Statistical analysis tested frequencies using contingency analysis (Sokal and Rohlf, 1981) and the proportions test (Walpole, 1974) when appropriate.

RESULTS

Time Assay. None of the *A. pallida* attached to shells of *C. vittatus*. The frequency with which *C. tricolor* transferred to the new surface was highest immediately after disturbance. At 0 min after removal from the bucket bottom, 48% of *C. tricolor* attached to the shell of *Clibanarius* as the crab moved around

the assay bucket. This transfer behavior onto shells occupied by *C. vittatus* decreased with time after disturbance, with a significant decrease to 10% after 90 min (Figure 1). After 180 min and 48 hr, the transferring was negligible. By then, most anemones were firmly attached to the bucket and remained there.

Object Assays. Responses to surface features were measured by recording the frequency of reattachment to new surfaces. Results are summarized in Table 1. Anemone transferring behavior was tested with *M. mercenaria* shells with a proteinaceous organic matrix and with the matrix removed by combustion of the shell at 500°C for 6–10 hr. Transferring was markedly reduced onto shells with the organic matrix removed ($Z > 2.33$, $P < 0.01$ compared to shells with a matrix). Transferring onto baked shells was significantly ($Z > 1.65$, $P < 0.05$) greater than onto smooth glass and unlike transferring tests with calcium carbonate (limestone), slate, and rough (sintered) glass, in which no anemones transferred. Odor of living, intact *D. venosus* and *Balanus amphitrite*, bovine serum albumin, and calcium carbonate did not stimulate transferring.

Responses to Complex Odors. Extracts of *Polinices duplicatus* (Figure 2)

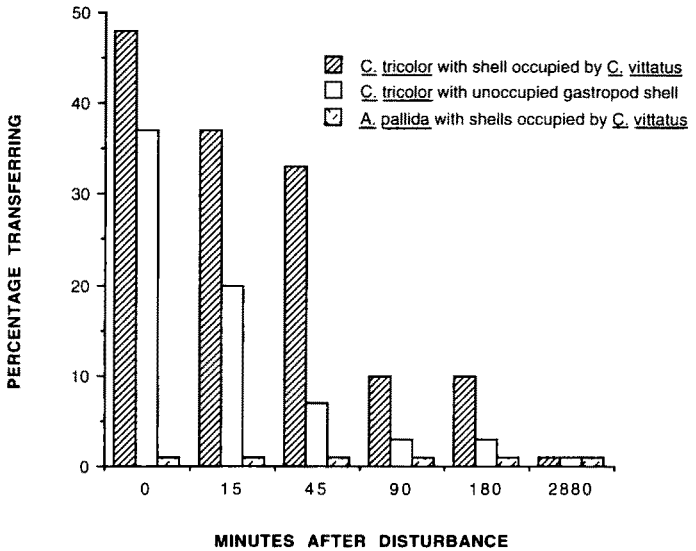

FIG. 1. Attachment of disturbed anemones to gastropod shells. Sixty anemones for each time interval and data test were disturbed. Total anemones tested = 1080. Immediately after disturbance, either empty shells or shells occupied by *C. vittatus*, a hermit crab that does not participate in shell transferring behavior, were added. Anemones that transferred within 3 min were recorded. The procedure was repeated at each time interval noted. With empty shells, one shell was provided to each anemone. With occupied shells, one shell was provided for each 10 anemones.

TABLE 1. RESPONSE OF 60 ISOLATED *Calliactis tricolor* TO SELECTED OBJECTS

Object	Response (%)	Significance[a] vs. slide	Significance[a] vs. shell
Clibanarius vittatus occupied shell	48	<0.01	NS
Glass slide	0		<0.01
Mercenaria shell	42	<0.01	
Baked *Mercenaria* shell	10	<0.05	<0.01
Baked *Mercenaria* shell + *Dardanus* odor	4	NS	<0.01
Baked *Mercenaria* shell + *Polinices* odor	48	<0.01	NS
Baked *Mercenaria* shell + shrimp odor	48	<0.01	NS

and *Penaeus* sp. shrimp stimulated transferring in *C. tricolor* (Table 1). Modified bucket assays were used to test shell investigation behavior of *P. pollicaris* and *D. venosus* in response to *Polinices duplicatus* odor. Responses of hermit crabs to seawater addition were compared to responses to *P. duplicatus* odor. *P. pollicaris* were tested in unmodified shells and after shells were reduced approximately one fifth in size by clipping. *D. venosus* were tested in unmodified shells. *P. pollicaris* showed increases in shell investigation behavior and a doubling of responses when shells were reduced in size (Figure 3A). *D. venosus* also dramatically increased shell investigation activity in response to *P. duplicatus* odor (Figure 3B). Although feeding movements and activity increased, crabs did not increase shell investigation activity in response to shrimp odor ($Z < 1.0$, $P > 0.05$).

DISCUSSION

Attachment by Calliactis tricolor. Results from the present study support the conclusions by Cutress and Ross (1969) that chemical cues stimulate *C. tricolor* to transfer to gastropod shells. *Aiptasia pallida*, a nonsymbiotic species,

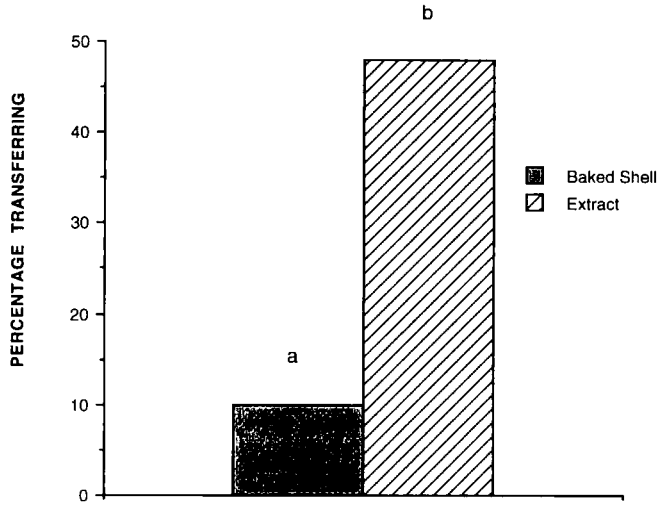

FIG. 2. Attachment of anemones to baked shells and to baked shells soaked in *Polinices duplicatus* odor mixture. *Mercenaria mercenaria* shells with organic matrix removed by baking at 500°C for 6–12 hr were soaked in seawater on *P. duplicatus* extract for 30 min and dried at 70°C overnight. Sixty anemones were tested in each condition. A Z test showed significantly ($P < 0.01$) more anemones attached to shells with the snail extract. Letters over the bars group them into significant subsets.

failed to respond to mollusk shells. This suggests that attachment behavior mediated by textural and chemical cues from mollusk shells is not a general actinian response. Cuing is not to hermit crab odor but to chemical components of shells. The shell components are organic rather than inorganic. We reach this conclusion because baking at 500°C destroys organic cues without substantially altering inorganic composition.

Hermit crabs prod and stroke the columns of *C. tricolor* until the anemone is detached from its surface. This behavior by the crab stimulates anemone transfer and has been simulated to induce anemone detachment (Cutress and Ross, 1969). Reattachment of anemones is highest immediately after disturbance and decreases with time after disturbance until, after 3 and 48 hr, anemones attached to shells at an extremely low frequency. Thus, without disturbance, anemones are unlikely to attach to a new surface. Upon disturbance, the availability of a shell substrate in the vicinity of the anemone is central to transferring behavior. Shells occupied by *C. vittatus* hermit crabs that do not participate in anemone transferring behavior were rapidly colonized by detached anemones. Observation showed the crab occupant ensured, through its movement, that

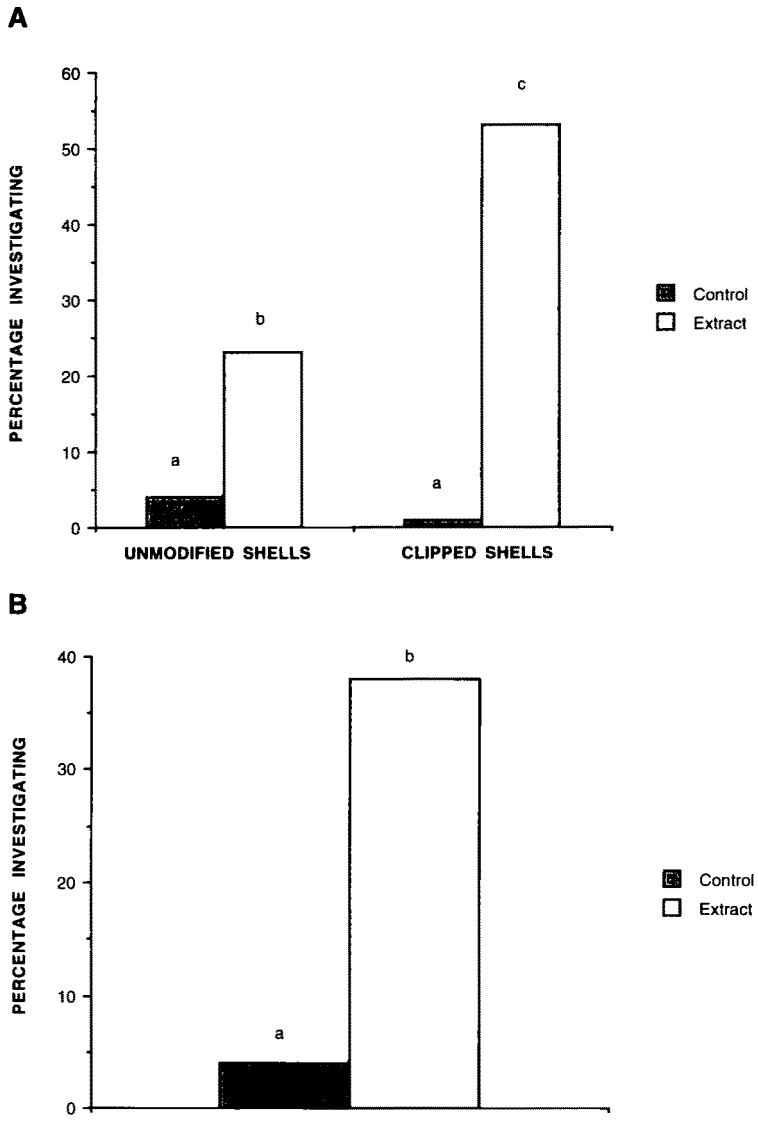

FIG. 3. Chemically stimulated shell investigation by hermit crabs symbiotic with *Calliactis tricolor*. (A) Responses of *P. pollicaris* to seawater control and *Polinices duplicatus* odor. Crabs were first tested in the shells in which they were collected. Next shells were reduced one fifth in size by clipping and the animals retested the next day. Different letters over the bars indicate where Z tests showed groups were different at $P < 0.05$. (B) Responses of *D. venosus* to seawater control and *Polinices duplicatus* odor. Crabs were tested without modifying shells. Letters over the bars group them into significant subsets.

anemones would contact the shell. Symbiotic hermit crabs use disturbance to accumulate anemones.

These experiments provide evidence about the nature of chemicals stimulating anemone attachment. In addition to responding to the organic shell matrix, we found that *C. tricolor* responds to the cue mixture that stimulates shell investigation and switching in hermit crabs. However, shrimp extract, a complex mixture that does not stimulate crabs to switch shells, stimulates anemone attachment. Thus, anemones probably use different cues in the mixture that signal hermit crabs to the availability of a new shell and stimulate shell switching. Natural sources of shell cues (Rittschof et al., 1990) typically are complex mixtures, and each partner could be responding to a different component in the mixture. The organic material in mollusk shells may emit a specific cue that resembles that in extracts (see Kratt and Rittschof, 1991) or the response may be a totally separate chemical cue. Thus, the potential exists for three or more chemical cues to guide anemone attachment.

Both species of symbiotic hermit crabs respond to gastropod extract by shell investigation behavior, as does the nonsymbiotic crab *C. vittatus* (Rittschof et al., 1992). At least for *P. pollicaris*, making shells smaller increases shell investigation activity. Shell investigation activity in response to volatile odors has been reported in terrestrial crabs (Small and Thacker, 1994). Thus, all major groups of hermit crabs display this response.

Although surface texture alone does not seem to be of great importance to anemone transfer, the combination of surface and chemical cues enhances *C. tricolor* attachment. The low or zero percentage of *C. tricolor* transferring to glass surfaces is not surprising if a chemical cue is needed to stimulate anemone attachment. It is likely that the tentacles of *C. tricolor* adhere more readily to rougher surfaces than to the smooth surface of the glass slide (see Mariscal, 1972).

We envision the following scenario in nature: (1) a gastropod is killed and gives off odors; (2) crabs carrying anemones are attracted to the predation site by odors from the flesh of gastropods (Rittschof, 1980) and switch into new shells; (3) anemones on the unoccupied shell are located by a crab; (4) anemones are disturbed by crabs and, with the aid of surface-associated chemical cues and texture attach to occupied shells.

Although symbiotic crabs initiate the transfer of *C. tricolor* by disturbance, it is the anemone's behavior that completes the transfer. Crabs can remove anemones from rocks or shells, but it is the anemone that finalizes the attachment. With the proper organic cue and a rough surface, disturbed anemones will readily attach to any surface.

Transferring Patterns in Related Species. Anemones, including swimming sea anemones of the genera *Actinostola* and *Stomphia*, respond to mollusk shells (Ross, 1965; Ross and Sutton, 1967). There are also two other common species

of *Calliactis* that are associated with hermit crabs in different regions of the world: *C. parasitica* and *C. polypus*.

Apparently, these three *Calliactis* species represent a continuum of behavioral responses towards shells. *C. parasitica* has the strongest responses to mollusk shells (Ross, 1960, 1967; Ross and Sutton, 1961). In fact, in some associations, the hermit crab has very little to do with anemone transfers (Ross, 1960). At the other extreme is *C. polypus*, which relies almost exclusively on the hermit crab's behavior during transfers (Ross, 1970, 1975). *C. tricolor* behavior is somewhere between *C. parasitica* and *C. polypus*, with a distinct response to shells but normally requiring disturbance by the hermit crab for initiation of transfers.

The differences in responses by the three anemones may reflect differences in evolutionary status of their respective associations with hermit crabs. Ross (1983) has argued that the most likely scenario for the development of these associations initially involved anemones living on live snails, which is true of several extant species (Hand, 1975; Ross and Kikuchi, 1976). For these anemones, a strong response to a molluscan shell factor would be a requisite, because the snail would not participate in the transfer. *C. parasitica* shows characteristics of this early stage. Because of its strong shell response, Ross (1960) points out that *C. parasitica* responds readily to shells of live snails in the laboratory, but it is rarely found on snails in the field. The scarcity of *C. parasitica* and other symbiotic anemones living on live snails could be explained by the development and subsequent prevalence of anemone-gathering hermit crabs, which could easily take anemones from these snails. Indeed, *D. venosus* individuals can be characterized as anemone hogs. They will gather up anemones in rapid succession until no room remains on the shell (Brooks, 1991a).

The scenario above suggests that participants in *C. tricolor*–hermit crab associations might be likely to coevolve similar responses to cues that signal shell switching because both organisms are active in the transfer to new shells. This could explain why both *D. venosus* and *C. tricolor* respond to *Polinices* odor. By the same reasoning, crab and anemone symbionts with unequal roles in anemone transfers might be less likely to respond to the same chemical cues.

Finally, associations involving *C. polypus* may represent the most evolutionarily advanced associations, with a further relative loss of response to shells by the anemone and a greater dependence on the crabs for transfer.

Concomitant with these different strategies, one would expect physiological differences between anemone species (and crabs) to account for their behavioral differences. Comparative studies of symbiotic anemones and crabs, as well as further efforts to identify the specific chemical nature of shell factors, would provide clues regarding the validity of Ross' hypothesis on the evolution of hermit crab–anemone symbioses.

Acknowledgments—The authors thank G.C., E.H., M.M.C., A.O., M.C.L., and J.R. for their thoughtful contributions and J. Gutierrez for assistance in doing experiments. Funding and opportunities were provided by Susan Palmer through the COSEN program funded by the Pew Charitable Trusts. Funding was also provided by the NSF. FAU provided sabbatical leave for W.R.B. The authors would especially like to thank R. Forward, M. Salmon, and Tony the fisherman for making the project possible.

(Received April 25, 1994; accepted September 15, 1994)

Abstract—Short-chain unsaturated chiral methyl carbinols are identified as a new class of lepidopteran pheromone components. The natural female-produced pheromone of the banded apple pigmy *Stigmella malella* (= *Nepticula malella*) (Stainton) (Lepidoptera: Nepticulidae) was identified to be a mixture of (*S*)-(*E*)-6,8-nonadien-2-ol and (*S*)-(*Z*)-6,8-nonadien-2-ol. For monitoring traps, a 10:3 *E*:*Z* blend at 100–1000 μg is recommended. It is suggested that pheromones with similar structures may be specific to Nepticulidae and other related microlepidopteran families.

Key Words—*Stigmella malella*, *Stigmella crataegella*, *Trifurcula (Glaucolepis) melanoptera*, Lepidoptera, Nepticulidae, sex pheromone, (*S*)-(*E*)-6,8-nonadien-2-ol, (*S*)-(*Z*)-6,8-nonadien-2-ol, (*R*)-(*E*)-6,8-nonadien-2-ol, (*R*)-(*Z*)-6,8-nonadien-2-ol.

INTRODUCTION

The vast majority of lepidopterous pheromone components were identified from species of only a handful of families such as Tortricidae, Noctuidae, Pyralidae, Gelechiidae, etc., where mono- or diunsaturated aliphatic primary alcohols,

*To whom correspondence should be addressed.

acetates, or aldehydes are most abundant (Arn et al., 1992). Another group of pheromone components is represented by polyunsaturated hydrocarbons and oxygenated derivatives found predominantly in Geometridae, Arctiidae, and some noctuid subfamilies (Arn et al., 1992). The study of species belonging to taxonomic groups clearly distinct from and more primitive than the above families can still offer many surprises with respect to pheromone structures, as evidenced by scattered examples from the microlepidopteran families of Lyonetiidae (Sato et al., 1985, Francke et al., 1988), and more recently, of Bucculatricidae (Hall et al., 1992).

In the course of our studies on leafminers, our interest was strongly evoked by the banded apple pigmy *Stigmella malella* (= *Nepticula malella*) (Stainton) (Lepidoptera: Nepticulidae), which caused severe defoliation in apple orchards in the eastern part of Hungary in the late 1980s (Balázs, 1993). The family Nepticulidae includes some of the smallest moth species known, with a wingspan of only about 2–12 mm. The large suborder Ditrysia comprises more than 95% of the lepidopteran species, while the Nepticulidae belong to the lower Heteroneura and form the suborder Monotrysia, together with the superfamily Incurvaroidea and some smaller groups. In Europe only the families Micropterygidae, Eriocraniidae, and Hepialidae are placed lower in the phylogenetic tree of Lepidoptera (van Niekukerken, 1986). Apart from the life history of the larvae, most feeding as leafminers, some as miners in stems or bark, and a few gallmakers, an interesting aspect of this family is the presence of a unique antennal sensillum type, the sensillum vesiculocladum, unknown outside this family (van Nieukerken and Dop, 1987). This sensillum almost certainly plays an important role in pheromone detection. Knowledge of pheromones of the more primitive lepidopteran families is important for better understanding the evolution of pheromones within Lepidoptera and may add important phylogenetic information.

S. malella is known to be present all over Europe (Johansson and Nielsen, 1990) and is counted among the most important leafminer pests in France, Italy, Switzerland, Great Britain, and the Ukraine (Réal, 1966, Balázs, 1993). In Hungary, it has several flight periods (generations) per year (Molnárné, 1981), and the detection of the rise of the moth population, which could easily be accomplished by the use of pheromone-baited traps, could be very advantageous in timing control measures. In the present paper we describe the identification of a novel type of Lepidopteran sex pheromone structure from *S. malella*.

METHODS AND MATERIALS

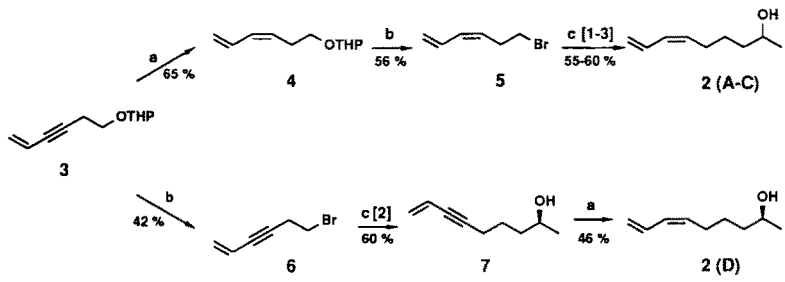
Insects. Insects were collected as pupae from the soil of heavily infested apple orchards near Sárospatak (Borsod-Abaúj county, Hungary). Pupae were held in outdoor conditions, and the emerging adults were collected each day.

Females and males were held in separate glass containers (2 liters) and were supplied with water on cotton wool.

For extraction of the female-produced pheromone several methods were tried. Intact bodies of 2- to 3-day-old female moths collected between 8:00 and 9:00 AM were extracted in a minimal amount of pentane (Merck pro Analysi) for 15 min. Headspace collections were carried out according to described methods (Francke et al., 1987). In the present experiments, which were run for several days, the collections were started on 1-day-old females.

Chemical Analysis. Preliminary gas chromatographic analyses of crude natural extracts were performed on 30-m × 0.25-mm-ID FFAP- or DB5-fused silica columns under various conditions. Structure elucidation of target compounds was carried out by combined gas chromatography–mass spectroscopy (GC-MS) under the same conditions as described earlier (Hansson et al., 1990). Mass spectra and gas chromatographic retention times (coinjection) of synthetic samples served as references. Microreactions such as hydrogenation and ozonolysis were conducted according to known methods (Huwyler, 1973; Beroza, 1975). Enantiomeric separation of chiral compounds was achieved by gas chromatography using a 1:2 mixture of octakis-(6-*O*-methyl-2,3-di-*O*-pentyl)-γ-cyclodextrin and OV-1701 as the stationary phase and hydrogen (4 ml/min) as the carrier gas. Separation conditions were as follows: 30-m × 0.2-mm-ID fused silica column, kept for 24 min at 90°C then programmed to 110°C at a rate of 2°C/min. Separation of geometrical isomers was carried out on a 20-m × 0.2-mm-ID fused silica column coated with a 1:1 mixture of hexakis-(2-methyl-3,6-di-*O*-pentyl)-α-cyclodextrin and OV-1701; hydrogen (4 ml/min) served as the carrier gas. The column was operated 9 min at 60°C then programmed to 120°C at a rate of 2°C/min. Synthesis of the cyclodextrins as well as preparation of our tailor-made columns have been described in detail (König et al., 1992, Pietruszka et al., 1992). Separation conditions were carefully optimized. Assignment of absolute configurations of naturally occurring compounds and determination of proportions of geometrical isomers was performed using synthetic optically active, geometrically defined reference compounds.

Synthesis. Syntheses of samples used for structure confirmation and bioassays are outlined in Figures 1 and 2. Purification of synthetic products was carried out by column chromatography using 10% $AgNO_3$ on Silicagel 60 (Merck 240-400 mesh) and a 5:1 mixture of ether–pentane as the mobile phase. Purities of samples used for bioassays are shown in Table 1. NMR spectra (400.1 MHz for ^1H and 100.6 for ^{13}C) of synthetic samples were run on a Bruker AMX 400; $\delta TMS = 0$; $\delta CDCl_3 = 7.26$ (bs = broad singlet, d = doublet, dd = doublet of a doublet, dddd = doublet of a doublet of a doublet of a doublet, bdd = broad doublet of a doublet, bt = broad triplet, dt = doublet of a triplet, ddt = doublet of a doublet of a triplet, bq = broad quartet, dq doublet of a quartet, hex = hexet, m = multiplet. Attribution of ^{13}C signals was made according to



a: Zn (Cu) / EtOH; b: Ph_3PBr_2 / CH_2Cl_2; c: Mg, rac-methyloxirane [c1] or (2*S*)-methyloxirane [c2] or (2*R*)-methyloxirane [c3]

FIG. 1. Syntheses of samples A–D. Nonoptimized yields are shown; for enantiomeric, geometric, and chemical purity of samples, see Table 1.

DEPT spectroscopy (CH_3 and CH = +, CH_2 = −). Assignment of protons and carbon atoms are based on COSY experiments.

The syntheses of the first samples of (*Z*)-6,8-nonadien-2-ol are outlined in Figure 1. The key compound (**3**) was obtained by coupling protected 3-butyn-1-ol to vinyl bromide according to Andreini et al. (1987). Reduction of the triple bond by a Zn/Cu pair (Aerssens and Brandsma, 1984) and transformation of the protected (*Z*)-3,5-hexadien-2-ol (**4**) into the corresponding bromide (**5**) (Wijnberg et al., 1981), followed by Grignard reaction (Baker et al., 1991) with epoxypropane (Merck) completed the synthesis of the racemic sample A. Following the same route, but using optically active epoxypropane (Merck) (Johnston and Slessor, 1979), we synthetized sample B showing the *S* configuration and sample C showing the *R* configuration (for enantiomerical, geometrical, and chemical purity of samples see Table 1).

Starting from (**3**) in an analogous synthesis for the *S* enantiomer, we carried out the reduction of the en–yne system at a later stage. The alcohol (**3**) was transformed into the corresponding bromide (**6**), which was chain elongated with (2*S*)-epoxypropane to yield (**7**). Reduction with activated zinc (Aerssens and Brandsma, 1984) completed the synthesis of sample D.

Our first synthesis of (*S*)-(*E*)-6,8-nonadien-2-ol is shown in Figure 2. Reaction of (2*S*)-epoxypropane (**8**), prepared according to Ghirardelli (1973), with allyl magnesium chloride followed by protection of the alcohol moiety of the obtained (*S*)-5-hexen-2-ol, furnished (**10**). Chain shortening of (**10**) by ozonolysis and reductive work up yielded the monoprotected diol (**11**), which was converted into the corresponding bromide (**12**). This compound was coupled to propargyl alcohol (Brandsma, 1988), followed by Birch reduction (Campbell and Eby, 1941) to form the *trans*-configured allylic alcohol (**14**). Oxidation

to the 8-TBDMS-derivative of either (*S*)-(*E*)-3-nonen-1,8-diol (17) or to that of (*S*)-(*Z*)-3-nonen-1,8-diol (**19**). Transformation of these alcohols to the corresponding bromides, (**18**) and (**20**), followed by elimination (Dehmlow and Lissel, 1979) established the terminal conjugated double bond systems yielding pure (*S*)-(**1**) (sample F) and pure (*S*)-(**2**) (sample G). Sample F showed a rotation value of $\alpha_D^{22} = +10.4$ (C = 1.8 CH_2Cl_2), while sample G showed $\alpha_D^{22} = +9.2$ (C = 2.2 CH_2Cl_2).

The set of NMR data for compound 1, (2*S*)-(*E*)-6,8-nonadien-2-ol was registered as follows: ^{1}H NMR: 6.31 (dt, 1H, $J_{8,9} = 17.2$ Hz, $J_{8,7} = J_{8,9} = 10.4$ Hz, H-8); 6.06 (bdd, 1H, $J_{7,6} = 15.0$ Hz, H-7); 5.70 (dt, 1H, $J_{6,5} = 7.2$ Hz, H-6); 5.09 (dd, 1H, $J_{9,9'} = 1.6$ Hz, H-9); 4.97 (dd, 1H, H-9′); 3.80 (hex, 1H, $J_{2,1} = J_{2,3} = 6.1$ Hz, H-2); 2.11 (bq, 2H, $J_{5,6} = J_{5,4} = 7.2$ Hz, H-5); 1.39–1.56 (m, 4H, H-3, H-4); 1.30 (bs, 1H, OH); 1.19 (d, 3H, H-1). ^{13}C-NMR: 137.23 (+, C8); 124.94 (+, C6); 131.28 (+, C7); 114.90 (−, C9); 68.03 (+, C2); 38.80 (−, C3); 32.45 (−, C5); 25.33 (−, C4); 23.55 (+, C1).

The set of NMR data for compound **2**, (2*S*)-(*Z*)-6,8-nonadien-2-ol was registered as follows: ^{1}H NMR: 6.62 (dddd, 1H, $J_{8,9} = 16.8$ Hz, $J_{8,7} = 11.0$ Hz, $J_{8,9'} = 10.4$ Hz, $J_{8,6} = 1.2$ Hz, H-8); 6.00 (bt, 1H, $J_{7,6} = J_{7,8} = 11.0$ Hz, H-7); 5.44 (ddt, 1H, $J_{6,5} = 7.6$ Hz, H-6); 5.18 (dd, 1H, $J_{9,9'} = 2.0$ Hz, H-9); 5.08 (bdd, 1H, H-9′); 3.79 (hex, 1H, $J_{2,1} = J_{2,3} = 6.1$ Hz, H-2); 2.21 (dq, 2H, $J_{5,6} = J_{5,4} = 7.6$ Hz, $J_{5,7} = 1.4$ Hz, H-5); 1.36–1.54 (m, 5H, H-3, H-4, OH); 1.18 (d, 3H, H-1). ^{13}C NMR − 132.40 (+, C6); 132.19 (+, C8); 129.50 (+, C7); 116.97 (−, C9); 67.94 (+. C2); 38.76 (−, C3); 27.59 (−, C5); 25.70 (−, C4); 23.50 (+, C1).

Trapping Tests. Dispensers for the trapping tests were prepared by using 1 × 0.5-cm pieces of rubber tubing (Taurus, Budapest, Hungary; No. MSZ

9691/6; extracted three times in boiling ethanol for 10 min, then three times in methylene chloride overnight, prior to usage). For making up the baits, the required amounts of compounds were administered to the surface of the dispensers in hexane (Merck, pro Analysi) solutions. Prepared dispensers were stored at −65°C until use.

For female-baited traps, 1-day-old unmated female *S. malella* were placed in 2 × 2 × 4-cm plastic screen cages, and the cages were suspended into traps the same way as the dispensers with synthetic compounds. The females in the cage were supplied with water in a 2-ml glass vial plugged by cottonwool.

Field tests were conducted at several apple orchards in Hungary. Traps similar in shape and size to those described by Arn et al. (1979), but made from polyethylene sheets, were used. Traps were suspended from the branches of orchard trees at a height of 1.5 m. Traps containing different baits were set up in rectangular blocks. The distance between traps within a block was 4–5 m. The distance between blocks ranged between 100 and 1000 m. Traps were moved one position forward within a block at each occasion when the traps were checked. At the same time, captured males were recorded and sticky inserts changed to new ones. Capture data were transformed to log $(x + 1)$, and differences between means were tested for significance by ANOVA followed by Duncan's new multiple range test (DNMRT).

Identification of males of species captured was confirmed by checking the genitalia of some trapped specimens belonging to groups, provisionally sorted on the basis of external characters. Samples of the species and genitalia slides are deposited in the collection of the National Museum of Natural History (Leiden, The Netherlands).

RESULTS AND DISCUSSION

Adult *S. malella* mated readily from the second day on after emergence, in the morning hours (7:00–11:00 AM). Surprisingly, there was no indication of calling behavior on the part of the females prior to mating (Tóth, unpublished).

Gas chromatographic investigations of extracts separately obtained from 2-day-old females or males as well as from headspace collections showed the constant presence of a female-specific compound (Figure 3), which was estimated to range in the upper nanogram level per individual. The mass spectrum of the substance (Figure 4A) showed a molecular mass at *m/z* 140, intense signals at *m/z* 79 and *m/z* 80, and a characteristic fragment at *m/z* 45. Microhydrogenation yielded a mixture of nonan-2-ol and some nonan-2-one, the mass spectra of which were known (McLafferty and Stauffer, 1989). Ozonolysis yielded 2-methyl-3,4-dihydro-2H-pyrane (Figure 4B), the mass spectrum of

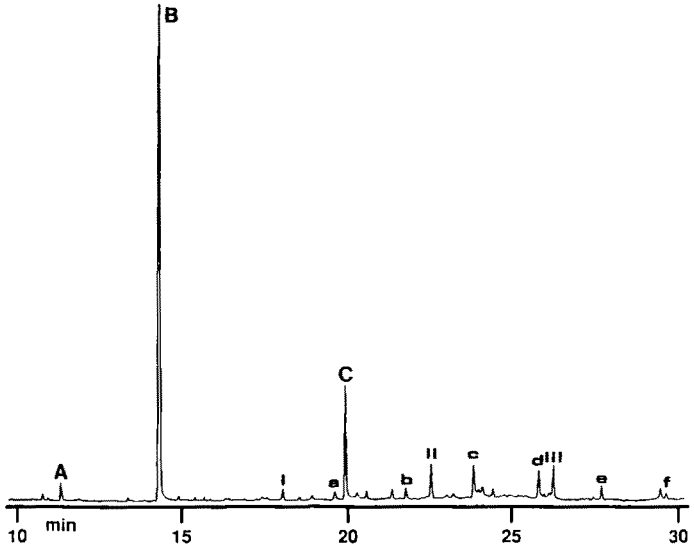

FIG. 3. Gas chromatogram of a pentane extract from 2-day-old female *S. malella*. A = (Z)-6-nonen-2-ol: female specific, not consistently present; B = 6,8-nonadien-2-ol: female specific, consistently present; C = unknown; female specific, not consistently present; I, II, III = alkenes C_{19}, C_{21}, C_{23}: not sex specific; a–f = straight chain carboxylic acids: C_7–C_{12}, not sex specific.

which was known to us from earlier work (Hübener, 1988). The results of our microreactions indicated the structure of an unbranched doubly unsaturated methyl-carbinol, showing at least one double bond at position 6. Among the possible structures of 6,8-nonadien-2-ol, the allenic 6,7-nonadien-2-ol, and 6-nonyn-2-ol, we regarded the conjugated dienol as the most likely one, and we therefore decided to synthesize the corresponding *E* and *Z* isomers (see Figures 1 and 2).

Mass spectra and gas chromatographic retention times of synthetic samples obtained according to Figure 1 and run on FFAP and DB5 columns were identical with the corresponding data of the natural product. Although it became obvious that on the columns used the *E/Z* isomers (and of course the enantiomers) could not be distinguished, we carried out preliminary field trapping tests with samples A, B, and C (see Tables 2 and 3).

On the test site with very high population density, 10 times higher numbers of male *S. malella* were attracted into traps baited with sample B (*S* enantiomers) at both doses tested, as compared to sample C (*R* enantiomers) (Table 2; Sárospatak). The capture by sample B did not differ significantly from the capture in traps baited with three unmated female *S. malella* (Table 2).

At the site with low population level, the only traps that caught males were baited with sample B (*S* enantiomers) (Table 2; Julianna major). There was no significant difference between the doses of 1000 or 100 μg on any of the sites. These results suggested the *S* enantiomer to be the active compound. However,

at this point of our investigations it was not clear whether the natural product was a pure enantiomer or a mixture. The addition of *R* enantiomers of 6,8-nonadien-2-ol (sample C) to the *S* enantiomers (sample B) dramatically reduced catches (Table 3). This corresponded well with the inactivity of the racemic sample A (Table 3) and also suggested the natural product to have the *S* configuration.

Gas chromatographic separation of the enantiomers of nonan-2-ol could be achieved on the γ-cyclodextrin phase under the conditions mentioned above. The obtained retention value of $\alpha = 1.04$ [$R_t(R) \div R_t(S)$] represented a difference of retention times of about 1 min during a running time of 25 min. A hydrogenated sample of the natural product coeluted with (*S*)-nonan-2-ol and showed no traces of the *R* enantiomer. Under these conditions, the four stereoisomers of 6,8-nonadien-2-ol could only be partially resolved, producing three peaks. The *E/Z* isomers showing *S* configuration furnished one peak at $R_t = 33.4$ min only, while the *R* enantiomers were well resolved with (*R*)-(*E*)-6,8-nonadien-2-ol eluting at $R_t = 33.8$ min and the *Z* isomer appearing at $R_t = 34.1$ min. Again, the natural product coeluted with the *S* enantiomers. Our synthetic samples B–D showed enantiomeric purities of 95% ee (see Table 1), while samples E and F were of higher purity. Consequently, as a result of our analyses and field tests, the structure of the target compound was established to be (*S*)-6,8-nonadien-2-ol.

With respect to the configuration of the double bond in position 6, we were puzzled by the fact that in further trapping tests (Table 4) sample B [1 : 1 *E/Z* mixture of enantiomerically pure (*S*)-6,8-nonadien-2-ol; Table 1] caught better

TABLE 4. CAPTURES OF MALE *S. malella* IN TRAPS BAITED WITH DIFFERENT *E/Z* MIXTURES OF (*S*)-6,8-NONADIEN-2-OL (SAMPLES B, D, AND *E*)[a]

1:1 *E/Z* (sample B)	6:94 *E/Z* (sample D)	93:7 *E/Z* (sample E)	Test 1	Test 2
	100		2.6 b	not tested
		100	not tested	5.9 b
100			15.5 a	13.6 a

[a]Test 1: August 12–21, 1991; test 2: August 8–19, 1992; inspected twice weekly; five traps of each treatment were used. Means followed by same letter within one column are not significantly different, $P > 0.05$.

than sample D [(*S*)-(*Z*)-6,8-nonadien-2-ol containing 6% of the *E* isomer; Table 1] or sample E [(*S*)-(*E*)-6,8-nonadien-2-ol containing 7% of the *Z* isomer; Table 1]. We, therefore, had to establish unequivocally the geometry of the crucial double bond in the natural product and the isomeric purities of our samples. For the separation of the geometrical isomers, we successfully used a mixture of OV-1701 and a derivative of α-cyclodextrin, which, however, left the corresponding enantiomers unresolved. Under the conditions mentioned above, the obtained retention values were $\alpha = 1.02$ [$R_t(E) \div R_t(Z)$]. A careful reinvestigation with respect to the *E/Z* ratio revealed insufficient purities in some of our samples (Table 1). We found that during the syntheses of samples A–C (Figure 1) isomerization of the double bond system had occurred and that even after extensive chromatographic purification only ca. 1:1 mixture of the geometrical isomers of 6,8-nonadien-2-ol had been obtained. Samples D and E contained 6–7% of the corresponding *E* or *Z* isomer, respectively. Samples F and G proved to be highly pure, containing only traces of the geometrical isomer. Analyses of natural pheromone samples showed *E/Z* ratios of 10:1 to 10:3.

On the basis of these results, we established the natural pheromone to be a mixture of pure *S* enantiomers of 6,8-nonadien-2-ol in an *E/Z* ratio of 10:1 to 10:3 and continued our bioassays using the samples F and G. When these were tested in different ratios, maximal catches were recorded in traps baited with the 10:3 *E/Z* ratio, followed by the 10:1 and 1:1 blends (Figure 5). (*S*)-(*E*)-6,8-Nonadien-2-ol on its own captured some males, while (*S*)-(*Z*)-6,8-nonadien-2-ol yielded no catches.

In a test with different doses of the optimal 10:3 blend of (*S*)-(*E*)-6,8-nonadien-2-ol and (*S*)-(*Z*)-6,8-nonadien-2-ol, catches increased in parallel with doses, the higher doses catching significantly higher numbers as compared to

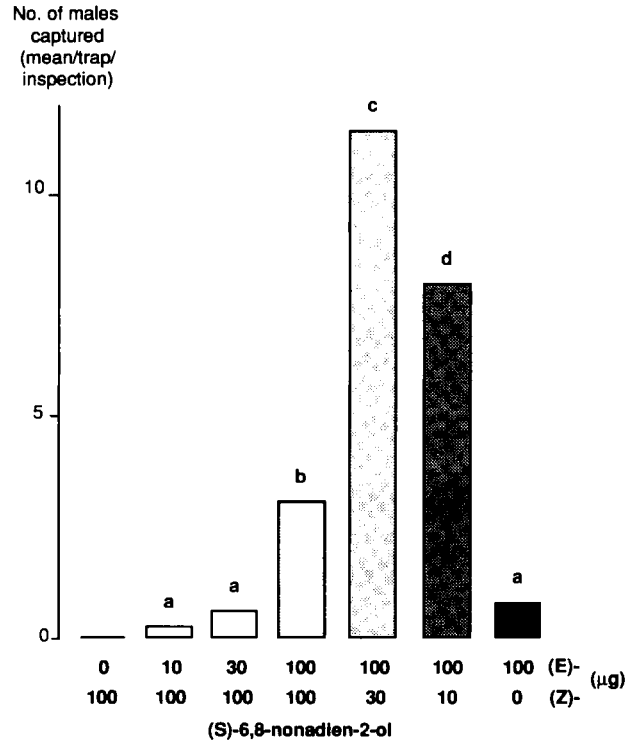

FIG. 5. Captures of male *S. malella* in traps baited with (*S*)-(*Z*)-6,8-nonadien-2-ol and (*S*)-(*E*)-6,8-nonadien-2-ol and their mixtures in different ratios. Julianna major, Budapest, June 10–16, 1993, inspected every second day; 10 traps of each bait variation were used. Columns with same letter are not significantly different by DNMRT, $P > 0.05$.

lower ones (Table 5). Best activity was recorded at the 1000-μg level, the highest dose tested.

Results of the field tests corroborate results of the analyses of extracts and demonstrate that the main pheromone components of *S. malella* are (*S*)-(*E*)-6,8-nonadien-2-ol and (*S*)-(*Z*)-6,8-nonadien-2-ol. For monitoring traps, a 10:3 *E*/*Z* blend at 100–1000 μg can be recommended. Synthetic samples used for the preparation of monitoring baits should be cross-checked for the presence of the *R* enantiomer, as it may interfere with the activity of the sample.

In season-long monitoring trials, the only species other than *S. malella* captured by a 1:1 mixture of *E*/*Z* isomers showing *S* configuration (sample B), was *Stigmella crataegella* (Klimesch) (Lepidoptera: Nepticulidae), on sites with *Crataegus* bushes (Table 6). It is interesting to note that in these tests large

numbers of a recently described species, *Trifurcula (Glaucolepis) melanoptera* (van Nieukerken and Puplesis, 1991) of the same family were attracted to the mixture of the *R* enantiomers (sample C) (Table 6).

The identification of a secondary alcohol is novel in moth pheromone chemistry. Pheromone components with similar structures may be specific to Nepticulidae and other related microlepidopteran families. In screening tests with compounds similar in structure to the pheromone components of *S. malella*, several Nepticulidae spp. and some Eriocraniidae spp. were captured (Tóth et al., to be published in detail elsewhere).

(Received April 25, 1994; accepted September 29, 1994)

Abstract—Extracts from different body parts of adult female *Eriocrania cicatricella* (Zett.) were tested for electrophysiological activity on conspecific male antennae. Extracts from the Vth abdominal segment, containing a pair of exocrine glands, elicited the largest electroantennographic response when compared to extracts of other body parts. Female extracts were analyzed by gas chromatography with simultaneous flame ionization and electroantennographic detection (EAD). The EAD active peaks were identified as (*Z*)-4-hepten-2-one, (2*R*)-heptane-2-ol, and (2*R*)-(*Z*)-4-hepten-2-ol by coinjection on a gas chromatography and by comparison of mass spectra with those of synthetic standards. In field tests, a blend of these three pheromone components was highly attractive to conspecific males, and a subtractive assay confirmed that the unsaturated alcohol is the major pheromone component, whereas no definite behavioral activity could be assigned to the ketone or the saturated alcohol. A bait containing the two alcohols with *S*-configuration was attractive to male *E. sparrmannella* (Bosc), whereas no males of *E. cicatricella* were found in these traps. The sex pheromone compounds in *E. cicatricella* are

INTRODUCTION

Although sex pheromone communication systems in moths are generally well investigated, there is still a lack of data on the pheromones of the first evolutionary lineages of the order Lepidoptera. Absence of sex pheromones has been suggested for *Micropterix calthella* (L.) (Pirngruber, 1944). However, male attraction by synthetic lures and by conspecific females was reported for three eriocraniid species (Kozlov, 1985, 1988; Wagner and Rosovsky, 1991). The only examination of a nonditrysian species reported so far, *Lampronia capitella* (Clerck) (Prodoxidae), suggested that it may have the same type of sex pheromone as most of the ditrysian lepidopterans (Löfstedt, 1991).

Within the Trichoptera, the sister group of Lepidoptera, sex pheromone components are short-chain alcohols and ketones, which are different from the olefinic compounds that are widely used in Lepidoptera. Based on the accumulated data on the pheromones identified in Lepidoptera (Arn et al., 1992) and some previous studies on pheromone production in Trichoptera, independent evolution of sex pheromones of Trichoptera and Lepidoptera has been hypothesized (Löfstedt, 1991). An investigation of archaic Lepidoptera is needed to state whether the chemical structure of lepidopteran pheromone components (which generally include products of Δ11-desaturation of long-chain fatty acid precursors) has evolved within the Lepidoptera or whether it should be considered a synapomorphy[5] of the whole order.

Trichoptera differ from ditrysian Lepidoptera not only in the structure of the sex pheromones, but also in the location of the pheromone-producing glands, which are situated in the Vth abdominal segment (Nielsen, 1980). Similar glands have been described in some archaic Lepidoptera (for a list of taxa possessing these glands, see Davis, 1975), whereas most females of ditrysian moths possess specialized pheromone glands at the ovipositor (Percy-Cunningham and MacDonald, 1987). The function of the abdominal glands in the primitive Lepidoptera is still unclear, although it has been repeatedly hypothesized that they release some kind of pheromone (Razowski, 1975; Kristensen,

[5]Synapomorphy: a homologous character shared by two or more taxa and inferred to have been present in the nearest common ancestor but not in earlier ancestors nor in taxa outside this group.

1984a). Bioassay and chemical elucidation of components produced by abdominal glands is necessary to prove this hypothesis.

Since the presence of sex pheromone communication has already been demonstrated in Eriocraniidae (Kozlov, 1985, 1988; Wagner and Rosovsky, 1991), this family was chosen as a target group for a detailed investigation of pheromone communication in archaic Lepidoptera. Our aims in the present study were: (1) to associate the pheromone production with some morphological structures of the female's body, (2) to identify the sex pheromone components produced by female *Eriocrania cicatricella*, and (3) to contribute to an understanding of the evolutionary trend in location of pheromone-producing glands and pheromone composition in the Trichoptera and primitive Lepidoptera.

METHODS AND MATERIALS

Insects. Eriocranic cicatricella Zett. were collected from a young birch forest on May 1–6, 1992 (Turku, Finland) and on April 21–30, 1993 (Lund, Sweden). Adults were sexed immediately after capture, kept in plastic vials containing moist filter paper, and transported to the laboratory in Lund for electrophysiological tests and chemical analyses.

Preparation of extracts. Extracts of the whole abdomen, the Vth abdominal segment, and the ovipositor from adult females and the whole abdomen from adult males of *E. cicatricella* were used in electroantennogram (EAG) experiments. Extracts from the presumed pheromone gland located at the Vth abdominal segment of females were used for gas chromatography with electroantennographic detection (GC-EAD). The insects were anesthesized by cooling them to −20°C, and they were then dissected by use of different scalpels for different body parts to avoid contamination. The dissected segments were extracted for at least 30 min in pointed tubes containing 50 μl dichloromethane or hexane. These extracts were subsequently used for both electrophysiological tests and chemical identification.

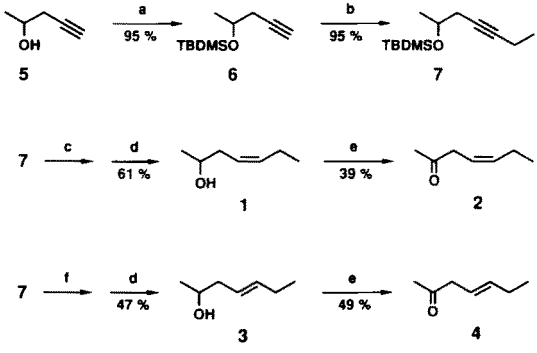
Electrophysiological and Chemical Analysis. To examine male antennal sensitivity to different body extracts of females, the tip of the male antenna of *E. cicatricella* was cut off and the antenna was mounted between two pipet electrodes containing Beadle-Ephrussi Ringer, and grounded via an Ag–AgCl wire. The tip electrode was connected to a high-impedance DC amplifier with automatic baseline drift compensation. One female equivalent of the different body extracts, deposited in the tip of a Pasteur pipet, was used as the odor source. One milliliter of air was puffed through the pipet and injected into the airstream flowing over the antenna (0.5 m/sec). The two different solvents used for the extraction, dichloromethane and hexane, were also tested for male EAG responses.

A Hewlett Packard 5830 GC equipped with a DB-wax column (30 m × 0.25 mm ID, J & W Scientific, Folsom, California) and an effluent split allowed simultaneous flame ionization (FID) and electroantennographic detection (EAD) of the separated pheromone components. Hydrogen was used as carrier gas, and the effluent split ratio was approximately 1:1. Samples were injected splitless. The injector temperature was 250°C and the split valve was opened 1 min after injection. The column temperature was maintained at 40°C for 3 min following the injection and then linearly increased to 230°C at a rate of 5°C/min. The outlet for the EAD was placed in a purified airstream flowing over the antennal preparation at a speed of 0.5 m/sec. Five microliters of extracts containing 5–10 female equivalents were injected into the column for the analysis. The equivalent chain lengths of active pheromone compounds relative to a homologous series of straight-chain acetates (7–22:OAc) were established.

Gas chromatographic–mass spectrometric analyses of GC-EAD active compounds were performed by using a fused-silica capillary (50 m × 0.32 mm ID) coated with FFAP, programmed from 60 to 220°C at a rate of 5°C/min. Mass spectra were recorded with a double focusing instrument VG 70-250 SE at 70 eV. Microhydrogenation was carried out according to Huwyler (1973). Enantiomeric separation was achieved by using a fused silica capillary (25 m × 0.32 mm ID) coated with a mixture of 6-*O*-methyl-2,3-di-*O*-pentyl-γ-cyclodextrin and OV-1701 (1:4) operated under the following conditions: 12 min at 60°C, then programmed to 120°C at a rate of 3°C/min. NMR spectra (400.1 MHz for ^{1}H and 100.6 for ^{13}C) of synthetic samples were run on a Bruker AMX 400; δ TMS = 0, δ $CDCl_3$ = 7.26 (s = singlet, bs = broad singlet, d = doublet, t = triplet, qu = quintet); attribution of ^{13}C signals was made according to DEPT spectroscopy (CH_3 and CH = +; CH_2 = −; quart C = 0).

Field Tests. Field-trapping was conducted in a young birch forest close to Lund (Sweden) and at a similar site in Turku (Finland). Synthetic blends were prepared in hexane. Red rubber septa (Arthur H. Thomas Co. Catalog No. 1780-J07) were used as dispensers, and the traps used were Lund II sticky traps (Anderbrant et al., 1989). All traps were hung on the branches of young birch trees 1–2 m above ground. Within a replicate (N = 5), each trap was set at least 5 m apart. The traps were checked every day, and trap positions within a series were randomized to minimize the effects of habitat heterogenities. Subtractive assays were first carried out in Lund, April 23–27, 1993, to determine the attractiveness to males of blends containing compounds isolated from the female pheromone gland extracts. The second set of field trapping tests was designed the same way and carried out in Turku, May 3–8, 1993. These experiments included a dose response test and an examination of the *R* and *S*-enantiomers of two alcohols.

Chemical Synthesis. The synthesis of the compounds used in the field tests is shown in Scheme 1 and is described as follows.



SCHEME 1. Syntheses of 4-hepten-2-ols (**1**) and (**3**) and 4-hepten-2-ones (**2**) and (**4**).

rac.-2-(t-Butyldimethylsiloxy)-4-heptyne **(7).** To a stirred suspension of 0.6 g (26 mmol) lithium amide in 30 ml liquid ammonia, 1.0 g (5.04 mmol) 3-(*t*-butyl-dimethylsiloxy)-1-pentyne **(6),** synthesized by alkynylation of methyloxirane according to Jacobson *et al.* (1982), followed by protection of the produced 4-pentyn-2-ol **(5),** was added during 15 min. Subsequently, 7.2 g (66 mmol) of ethylbromide was added, and the mixture was warmed to 0°C. After the addition of 50 ml ether and 20 ml saturated aqueous (aq.) ammonium chloride, the organic layer was separated, and the aqueous phase was extracted twice with 50 ml of ether. The combined organic solutions were dried over anhydrous magnesium sulfate and concentrated. The crude product (yield 1.05 g = 92%) was used for the next step without further purification.

rac.(Z)-4-Hepten-2-ol **(1).** According to the general procedure for the production of P-2 nickel (Brown and Ahuja, 1973), 260 mg (1.02 mmol) nickel acetate tetrahydrate dissolved in 10 ml of ethanol was reduced with 1.02 ml of a 1 M solution of sodium borohydride in ethanol. After hydrogen production ceased, 137 μl (2.04 mmol) ethylene diamine was added. To the black suspension 1.05 g (4.64 mmol) of **(7)** dissolved in 1 ml of ethanol was added. The stirred mixture was hydrogenated under standard conditions (1m H_2, room temperature). The mixture was filtered through a pad of celite, the solvent was evaporated, and then 10 ml of water and 10 ml ether were added. The organic layer was separated, the aqueous layer was extracted twice with 10 ml of ether, and the ethereal extracts were dried over anhydrous $MgSO_4$. The solvent was evaporated and the crude product was dissolved in 15 ml of acetonitrile and stirred with 10 drops of 40% aq. hydrogen fluoride. After 1 hr, the mixture was poured onto brine and extracted twice with 20 ml of ether. The filtered organic

layer was washed with sodium bicarbonate, dried over magnesium sulfate, and concentrated. The residue was chromatographed on silica Merck 60/240–400 mesh impregnated with 10% $AgNO_3$ using a 2:1 mixture of pentane and diethylether, which, upon TLC, had been previously known to give an R_f value of 0.25, yielding 490 mg (61%) of **(1)**.

^{1}H NMR (400.1 MHz, $CDCl_3$, attribution of carbon atoms according to COSY experiment): δ = 5.57 (dtt, $J_{5,4}$ = 10.8 Hz, $J_{5,6}$ = 7.2 Hz, $J_{5,3}$ = 1.5 Hz, 1H, H-5), 5.32–5.41 (m, 1H, H-4), 2.77–3.82 (m, 1H, H-2), 2.14–2.29 (m, 2H, H-3), 2.08 (dqu, $J_{6,5}$ = $J_{6,7}$ = 7.4 Hz, 2H, H-6), 1.55 (bs, 1H, OH), 1.21 (d, $J_{1,2}$ = 6.2 Hz, 3H, H-1), 0.97 (t, 3H, H-7). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 135.12 (+, C 5), 124.46 (+, C 4), 67.70 (+, C 2), 37.04 (−, C 3), 22.71 (+, C 1), 20.70 (−, C 6), 14.25 (+, C 7).

rac.(E)-4-Hepten-2-ol **(3)**. To a solution of 1.9 g (8.4 mmol) of **(7)** in a mixture of 50 ml liquid ammonia and 20 ml tetrahydrofuran 0.6 g (25 mmol) sodium was added in small portions at −40°C. The dark blue solution was stirred for 1 h and subsequently warmed to room temperature. After the addition of 50 ml ether and 50 ml saturated aq. ammonium chloride, the organic layer was separated and the aqueous phase was extracted twice with 20 ml of ether. The combined organic solution was washed with 20 ml of water, dried with magnesium sulfate, and concentrated in vacuo. The crude product was diluted with 20 ml of acetonitrile. After the addition of 15 drops of 40% aq. hydrogen fluoride, the product was stirred for 1 hr, and worked up. The final purification was carried out by column chromatography (Merck 60 impregnated with 10% $AgNO_3$ using a 5:2 mixture of pentane and diethylether, which, upon TLC, had been previously known to give an R_f value of 0.22), yielding 460 mg (47%) of **(3)**.

^{1}H NMR (400, 1 MHz, $CDCl_3$): δ = 5.59 (dtt, $J_{5,4}$ = 15.2 Hz, $J_{5,6}$ = 6.4 Hz, $J_{5,3}$ = 1.3 Hz, 1H, H-5), 5.36–5.45 (m, 1H, H-4), 3.74–3.81 (m, 1H, H-2), 2.16–2.23 (m, 1H, H-3), 2.00–2.13 (m, 3H, H-3, H-6), 1.65 (bs, 1H, OH), 1.18 (d, $J_{1,2}$ = 6.1 Hz, 3H, H-1), 0.99(t, $J_{7,6}$ = 7.5 Hz, 3H, H-7). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 136.24 (+, C5), 124.82 (+, C4), 67.23 (+, C 2), 42.54 (−, C 3), 25.68 (−, C 6), 22.65 (+, C 1), 13.82 (+, C 7).

(Z)-4-Hepten-2-one **(2)**. To a solution of 0.4 g (3.6 mmol) of **(1)** in 20 ml dichloromethane, 1.4 g (3.6 mmol) pyridine dichromate and 1.4 g pulverized molsieve 4 Å (Herscovici et al., 1982) was added and vigorously stirred for 4 hr. The mixture was filtered through 10 g of silica (Merck 60), which was subsequently washed with 80 ml of ether. The organic solution was concentrated and chromatographed on silica (Merck 60 impregnated with 10% $AgNO_3$ using a 10:1 mixture of pentane and diethylether, which, upon TLC, had been previously known to give an R_f value of 0.25), yielding 150 mg (39%) of **(2)**.

^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 5.61 (dtt, $J_{5,4}$ = 10.7 Hz, $J_{5,6}$ = 7.1 Hz, $J_{5,3}$ = 1.5 Hz, 1H, H-5), 5.51 (dtt, $J_{4,3}$ = 7.1 Hz, $J_{4,6}$ = 1.4 Hz, 1H,

H-4), 3.17 (bd, 2H, H-3), 2.16 (s, 3H, H-1), 2.05 (qu, $J_{6,7}$ = 7.6 Hz, 2H, H-6), 0.99 (t, 3H, H-7). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 207.55 (o, C 2), 136.86 (+, C 5), 120.83 (+, C 4), 47.67 (−, C 3), 29.32 (+, C 1), 25.63 (−, C 6), 13.52 (+, C 7).

(E)-4-Hepten-2-one **(4).** The procedure was essentially the same as for the synthesis of **(2).** Purification was carried out by column chromatography on Merck 60 using a 8:1 mixture of pentane and diethylether as the eluent. The same yield was obtained as with (*Z*)-4-Hepten-2-one.

^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 5.47–5.63 (m, 2H, H-4), 3.11 (bd, $J_{3,4}$ = 6.8 Hz, 2H, H-3), 2.14 (s, 3H, H-1), 2.02–2.10 (m, 2H, H-6), 0.99 (t, $J_{7,6}$ = 7.4 Hz, 3H, H-7). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 207.55 (o, C 2), 136.86 (+, C 5), 120.83 (+, C 4), 47.67 (−, C 3), 29.32 (+, C 1), 25.63 (−, C 6), 13.52 (+, C 7).

(2R)-(Z)-4-Hepten-2-ol **(1a).** Using (2*R*)-methyloxirane (Merck) in the synthesis of **(5),** the procedure was essentially the same as for the synthesis of **(1):** $[\alpha]_D^{22}$ = −4.9 (c = 2.2 CH_2Cl_2). The optical purity was 98% ee (enantiomeric excess) as determined by chiral gas chromatography.

(2S)-(Z)-4-Hepten-2-ol **(1b).** Using (2*S*)-methyloxirane in the synthesis of **(5),** the procedure was essentially the same as for the synthesis of 1: $[\alpha]_D^{22}$ = +4.8 (c = 1.8 CH_2Cl_2). The optical purity was 96% ee as determined by chiral gas chromatography.

Heptan-2-ol. While racemic 2-heptanol was commercially available (Merck), optically active products were synthesized from optically active methyloxirane by Grignard reaction (Gaylord and Becker, 1951).

RESULTS

Courtship Behavior. Eriocrania cicatricella is a day-flying insect. Males have an unusual type of search behavior. Starting from a height of 0.5–1.5 m, they fly slowly upwards, along a wave-form trajectory, up to 2–3 m height; then they fly downwards quickly. This cycle is usually repeated two to five times. Virgin females do not demonstrate any special pose when "calling." Males flew around the female (which usually was sitting on the thin branch of a birch), then landed 10–15 cm away from the female and ran to her displaying a typical wing-fanning behavior. If the population density was high, up to five males "dancing" around a female were observed. The moths took position with their heads in opposite directions 1–2 sec after copulation. During the first 20–40 sec, the male had his wings raised, then he folded them slowly. If more than one male was attracted, the other males tried to copulate with the pair during 1–2 min, and then flew away. Copulation usually took 10–30 min. Copulating pairs were most frequently observed from 14:00–19:00 hr, when the air temperature usually reached the daily maximum.

EAGs of Different Body Parts. Male EAG response to the extract from the Vth abdominal segment of female *E. cicatricella* was as high as to the extract of the whole abdomen (Figure 1), indicating that the gland contained in this segment produced the active compounds. The extract from female ovipositor elicited a low response compared to extracts from the rest of the abdomen. There were no significant male EAG responses to the two solvents, dichloromethane and hexane, used for the female extraction. The reaction of female antennae to the extracts of the abdomen of both sexes was also tested, but no responses were observed. Thus, we found no EAG evidence for a male-produced pheromone in this species.

GC-EAD of Female Extracts and Chemical Identification. Analysis of the extract from female Vth abdominal segment of *E. cicatricella* indicated that three compounds elicited strong responses from a conspecific male antenna (Figure 2). On a DB-wax column, the equivalent chain lengths of three pheromone candidates were 1236, 1310, and 1330, respectively. The mass spectra of these three GC-EAD active compounds suggested two methylcarbinols (*m/z* 45) and a methyl ketone (*m/z* 43), each having seven carbon atoms. According to its fragmentation pattern, one of them (II) could easily be identified as heptan-2-ol (McLafferty and Stauffer, 1989). A minor component (I) showed a mass spectrum almost identical to (*E*)-4-hepten-2-one (McLafferty and Stauffer, 1989). The mass spectrum of the main component (III) is shown in Figure 3. Upon microhydrogenation (Huwyler, 1973), the compound was converted to heptan-2-ol, proving the natural product to be an unbranched hepten-2-ol. Provided that this unsaturated methylcarbinol and the above mentioned methylketone, 4-hepten-2-one, are biogenetically related, the main component would most probably

show the double bond in position 4. Gas chromatographic investigations showed that the geometrical isomers of both 4-hepten-2-one and 4-hepten-2-ol could be very well separated on a FFAP-fused silica column under the conditions mentioned above. For the ketone, a separation value of $\alpha = 1.04$ [$R_t(Z)/R_t(E)$] was found, while the alcohol showed $\alpha = 1.10$ [$R_t(Z)/R_t(E)$]. Synthetic reference samples of (*Z*)-4-hepten-2-one and (*Z*)-4-hepten-2-ol coeluted with the natural products and showed the identical mass spectra. The absolute configuration of the natural alcohols could be determined by chiral gas chromatography on a cyclodextrin derivative. As shown with synthetic samples, the two racemates were well separated under the conditions mentioned above (Figure 4). The results revealed that this species produced pure enantiomers that coeluted with (2*R*)-(*Z*)-4-hepten-2-ol and (2*R*)-heptan-2-ol. The EAD active compounds in the extracts could thus be identified as (2*R*)-(*Z*)-4-hepten-2-ol, (2*R*)-heptan-2-ol, and (*Z*)-4-hepten-2-one in a ratio of 110:20:1, and an average female contained approximately 126 ng of (2*R*)-(*Z*)-4-hepten-2-ol, 23 ng of (2*R*)-heptan-2-ol and 1.1 ng of (*Z*)-4-hepten-2-one.

Field Tests. A synthetic mixture of these three compounds identified from *E. cicatricella* trapped large numbers of conspecific males in a field experiment (Table 1). Subtraction of either (*Z*)-4-hepten-2-one or (2*R*)-heptan-2-ol from the mixture did not significantly reduce attractiveness of the synthetic lure. Subtraction of (2*R*)-(*Z*)-4-hepten-2-ol caused complete loss of the attractivity. The importance of the enantiomeric composition of the two alcohols was elucidated

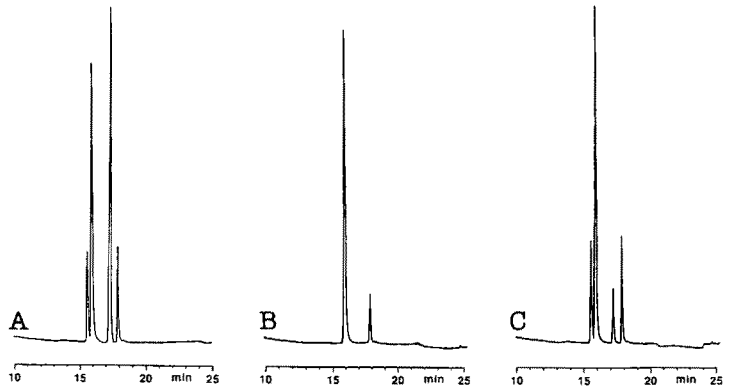

FIG. 4. Determination of the absolute configuration of the female sex pheromone components of *Eriocrania cicatricella* through chiral gas chromatography. Mixture of racemic (*Z*)-4-hepten-2-ol spiked with (2*R*)-(*Z*)-4-hepten-2-ol (first pair of peaks) and racemic 2-heptanol spiked with (2*S*)-heptanol (second pair of peaks) (A), natural gland extract (B), and mixture of racemic (*Z*)-4-hepten-2-ol, racemic 2-heptanol and natural gland extract (C).

in a field test in Turku, Finland (Table 2), which showed that the traps with baits containing the (*R*)-enantiomer of the major component, (*Z*)-4-hepten-2-ol, caught the highest number of males of *E. cicatricella*. Neither (2*R*)- nor (2*S*)-heptan-2-ol showed any effect on male attractivity. (2*S*)-(*Z*)-4-hepten-2-ol seemed to act as an inhibitor on the attraction of male *E. cicatricella*, but a large number of male *E. sparrmannella* (Bosc) were caught in the traps by the bait with this compound. When the dose of baits containing the two alcohols in (*R*)-configuration was decreased to half, the number of moths attracted to the

traps was significantly reduced (Table 2). A mixture of the two alcohols with (*R*)–configuration and this mixture plus (*Z*)-4-hepten-2-one were also tested in different doses. The highest dose of the three-component mixture was the most attractive. The attraction of males to the highest dose of the two-component mixture was not different from that of the medium dose of the three-component or the highest dose of the three-component mixture (Table 3).

DISCUSSION

Little is known about sex pheromones in archaic lepidopteran groups. The present investigation of the pheromone of *E. cicatricella* demonstrates that this primitive lineage of Lepidoptera (suborder Eriocraniina = Dacnonypha) is more similar to Trichoptera than to the well-investigated ditrysian lepidopterans, when it comes to pheromone communication. *E. cicatricella* produces short-chain ketones and alcohols as pheromone components, which are related to compounds earlier identified from Trichoptera; heptan-2-ol is a female-produced pheromone component in *Rhyacophila fasciata* (Mclachlan), and (*Z*)-6-nonen-2-one was identified in sternal gland extracts from male *Hydropsyche angustipennis* (Curtis) (Löfstedt et al., 1994). Our findings agree with the hypothesis of Wagner and Rosovsky (1991), which states that the presence of female-produced sex pheromones should be considered a synapomorphy of Trichoptera and Lepidoptera.

The pheromone components identified from *E. cicatricella*, (*Z*)-4-hepten-2-one, (2*R*)-(*Z*)-4-hepten-2-ol, and (2*R*)-heptan-2-ol are chemically very similar and most likely have a common biosynthetic origin. Within Lepidoptera, such

chemical structures have not been reported as pheromone components in any ditrysian family, but in the monotrysian family Nepticulidae similar chemical structures have been found (Tóth et al., 1995). Thus, the typical "lepidopteran" composition of sex pheromones has evolved within the order Lepidoptera. If we look at the phylogenetic tree of the order (Kristensen, 1984b), we can suppose that this event might be attributed a synapomorphy within nonditrysian Heteroneura, since one of the first lineages of the last taxa includes incurvarioid moths, which probably possess the "typical" lepidopteran pheromone (Löfstedt, 1991).

The site of pheromone synthesis and release may prove to be of special phylogenetic significance. A pair of glands opening on the Vth abdominal segment are considered an autapomorphy[6] of Amphiesmenoptera (Trichoptera + Lepidoptera), but these glands have been reduced independently in many lineages in both orders (Kristensen, 1984b). The ultrastructure of these glands (Kristensen, 1984a) is rather uniform within archaic Lepidoptera; the walls of the reservoirs are covered with secretory cells that belong to "type 3" according to the scheme by Noirot and Quennedy (1974). In most species in the family Eriocraniidae, the Vth abdominal segment is variously modified in association with the presence of the glands. The glands usually occur in both sexes (Davis, 1978), but in the genus *Eriocrania* we observed that the glands occur in the females only. In Trichoptera, female sex pheromones evidently are released from the Vth sternite (Wood and Resh, 1984; Löfstedt et al., 1994). The EAG test of different body parts showed that in Eriocraniidae, the pheromone production is associated with Vth abdominal segments. We were unable to isolate the gland specifically for EAG examination, but since no other secretory structures are known from this segment, we believe this is enough to associate the identified pheromones with the Vth abdominal glands. More advanced Lepidoptera, as summarized by Davis (1975), do not possess glands of the type mentioned above, and pheromone production, if present, is provided by other morphological structures. A large variety of pheromone-producing glands has been described, but generally females of ditrysian moths possess pheromone glands in the intersegmental region between abdominal segments VIII and XI (see references in Percy-Cunningham and McDonald, 1987).

Our field trapping experiments indicate that there is no significant reduction in the male attraction when (*Z*)-4-hepten-2-one or (2*R*)-heptan-2-ol was subtracted from the 3-component pheromone bait (Table 1). The chiral alcohols identified in *E. cicatricella* are pure (*R*)-enantiomers and (2*R*)-(*Z*)-4-hepten-2-ol is very attractive to conspecific males. When testing the attractivity of both (*R*)- and (*S*)-enantiomeric forms of these pheromone components in the field, we found that the *S* antipodes of the alcohols caught almost no *E. cicatricella*,

[6] Autapomorphy: The derived character state found in only one of two sister groups.

but large numbers of *E. sparrmannella*. Enantiomeric composition of the chiral components may contribute to the species specificity of this kind of pheromone. Geometrid moths have earlier been reported to use different combinations of chiral epoxides in their pheromone communication systems (Szöcs et al., 1993). Eriocranniidae provide another example within Lepidoptera of species where pheromone specificity is based on the chirality of the sex pheromone components.

Thus, both chemical and morphological data on the sex pheromone in this primitive moth, *E. cicatricella*, demonstrate the great similarities between the chemical communication system of the basic lineages of Trichoptera and Lepidoptera. This similarity can be explained by the common origin of these sister groups and therefore should be considered as a symplesiomorphy.[7] Sex pheromones used by most ditrysian species in Lepidoptera are derived from palmitic acid acted upon by various combinations of desaturases, β-oxidases, reductases, and acetyltransferases. The $\Delta 11$ desaturase seems to account for the largest number of unsaturated pheromone components, although several unusual desaturases such as $\Delta 10$, $\Delta 9$, and $\Delta 14$ are also involved in some species (see references in Löfstedt, 1991). Studies of pheromone biosynthesis in *E. cicatricella* will allow a comparison of biosynthetic routes to pheromones employed by primitive and more advanced lepidoptera.

COMPARISON OF THREE METHODS FOR QUANTIFYING BROWN ALGAL POLYPHENOLIC COMPOUNDS

KATHRYN L. VAN ALSTYNE

Department of Biology
Kenyon College
Gambier, Ohio 43022

(Received June 10, 1994; accepted September 20, 1994)

Abstract—Three methods of quantifying total phenolic compounds in marine brown algae were compared for their ability to measure accurately known concentrations of phloroglucinol in the presence of a protein, bovine serum albumin (BSA). These methods were: (1) a Folin-Ciocalteu assay for compounds dissolved in 80% methanol, (2) a Folin-Ciocalteu assay for compounds dissolved in 75% methanol–25% trichloroacetic acid, and (3) an assay in which polyvinylpolypyrrolidone (PVPP) was used to remove phenolic compounds in order to quantify nonphenolic, Folin-Ciocalteu-reactive materials. The Folin-Ciocalteu assay used with compounds dissolved in 80% methanol was the method that produced the most consistent results. It was also the assay in which the presence of proteins interfered least with the measurements of phloroglucinol and the assay that was easiest to conduct. The presence of TCA decreased the pH of the extracting solution and increased the amounts of proteins in solution. These proteins later interfered with the Folin-Ciocalteu reaction. TCA effectively bound proteins when protein concentrations were low but not when protein concentrations were high. The amount of phloroglucinol removed by PVPP varied widely and was dependent on phloroglucinol concentration, making this an unreliable method for quantifying phenolic concentrations. The Folin-Ciocalteu assay will measure some nonphenolic substances when brown algae are extracted in 80% methanol; however, in *Fucus gardneri*, nonphenolic substances were at most 5% of the material quantified by the assay.

Key Words—Brown alga, polyphenolics, phenols, *Fucus gardneri*.

INTRODUCTION

Marine brown algae (Division Phaeophyta) frequently contain large quantities (up to 20% dry wt, K. Van Alstyne, unpublished data) of phenolic compounds

0098-0331/95/0100-0045$07.50/0 © 1995 Plenum Publishing Corporation

(phlorotannins). These compounds are polymers of phloroglucinol (Ragan and Glombitza, 1986) and are structurally different from the hydrolyzable and condensed tannins of terrestrial plants. Phlorotannins have been hypothesized to serve a variety of functions in phaeophytes including deterring grazers from feeding on the algae (Geiselman, 1980; Geiselman and McConnell, 1981; Anderson and Velimirov, 1982; Steinberg, 1985, 1988; Van Alstyne and Paul, 1990), preventing bacterial infections (Conover and Sieburth, 1964; Sieburth, 1968), and serving as allelopathic agents (Conover and Sieburth, 1966; McLachlan and Craigie, 1966; Fletcher, 1975).

Two groups of methods are commonly used to quantify concentrations of tannins and phenolic compounds (Mole and Waterman, 1987; Bernays et al., 1989; Hagerman and Butler, 1989, 1991). The first group, chemical assays (*sensu* Hagerman and Butler, 1989), include redox assays, metal binding assays, and assays based on specific chemical reactivity (Hagerman and Butler, 1989). The second group, protein-binding assays, are used to determine the tanning ability of phenolic compounds (Mole and Waterman, 1987). The binding of proteins is one of the putative modes of action of phenolic compounds. Plant phenolic compounds that are ingested by an herbivore could potentially bind to plant proteins and herbivore digestive proteins, reducing the assimilation efficiency of the herbivore (Boettcher and Targett, 1993). Therefore, assays that measure protein binding may have biological relevance.

The Folin-Denis assay is one of the most common chemical assays used for ecological research (Folin and Denis, 1912). This assay is one of several that quantifies concentrations of easily oxidized compounds, such as phenols, by color changes accompanying a redox reaction (Hagerman and Butler, 1989). To conduct the assay, known quantities of algal tissue are extracted in aqueous methanol. The extracts are diluted and reacted with a phosphotungsten–polymolybdic acid that reacts with hydroxylated aromatic compounds. In alkaline solutions, the reagents produce a blue color that can be quantified spectrophotometrically. The Folin-Ciocalteu reagent (Folin and Ciocalteu, 1927) provides an improvement over the Folin-Denis reagent with the addition of lithium sulfate to the reagent. The lithium salts reduce the amounts of precipitate that can form when high concentrations of reagent are used to increase the assay's reactivity. Both the Folin-Denis and Folin-Ciocalteu assays have been widely used by marine chemical ecologists to quantify concentrations of brown algal phlorotannins (e.g., Boettcher and Targett, 1993; Carlson and Carlson, 1984; Pfister, 1992; Ragan and Glombitza, 1986; Steinberg, 1984, 1985, 1986, 1989; Steinberg and van Altena, 1992; Targett et al., 1992; Van Alstyne, 1988, 1989; Van Alstyne and Paul, 1990).

The Folin-Denis and Folin-Ciocalteu assays share a common problem; both reagents react with many oxidizable compounds. In brown algae, the most abundant reactive compounds are phenols; however, brown algae may also contain

other reactive compounds, such as tyrosine, tryptophan, and ascorbic acid. To address this problem, Hatch et al. (1993) proposed extracting organisms in an acetone–trichloroacetic acid (TCA) solution. TCA, like other strong acids, precipitates proteins. Hence, it should eliminate the tyrosine and tryptophan residues from solution, reducing the nonphenolic, reactive compounds quantified in the Folin-Denis and Folin-Ciocalteu assays.

Even if all proteins are eliminated from the extracts, there will still be some nonphenolic substances measured by the Folin-Denis and Folin-Ciocalteu assays. One means of alleviating this interference is to remove selectively phenolic compounds with polyvinylpolypyrrolidone (PVPP) (e.g., Yates and Peckol, 1993). Phenolic compounds bind to nonsoluble PVPP under acidic conditions and can then be removed from solution by filtering or centrifuging. The remaining oxidizable species are then quantified with a Folin-Ciocalteu or Folin-Denis assay and subtracted from the results of the assay prior to the addition of PVPP. However, if all the phenolics are not removed by the PVPP, phenolic concentrations are underestimated. The binding efficiency of PVPP for brown algal phlorotannins has not been explored.

The purpose of this study is to examine the efficiencies of these three methods for quantifying phenolic compounds in the presence and absence of a protein, bovine serum albumin (BSA), and known concentrations of phloroglucinol. In the first part of this study, the Folin-Ciocalteu assay was used to quantify the interference of proteins dissolved in 80% aqueous methanol or in 75% methanol–25% TCA. A second set of assays was used to examine the effectiveness of PVPP in removing phenolic compounds from the solutions. The final part of this study addressed the question of whether these three methods for extracting phenolics and preparing extracts yielded significantly different results when used to measure concentrations of phenolics in a marine brown alga, *Fucus gardneri*.

METHODS AND MATERIALS

Measurements of Known Concentrations of Phenols and Proteins. In the first set of assays, known mixtures of phloroglucinol (Sigma P-3502) and bovine serum albumin (BSA Sigma A-6918) were used to examine the effects of proteins on the Folin-Ciocalteu assay when compounds were dissolved in 80% methanol or 75% methanol–25% TCA. Sixteen solutions were made by dissolving various amounts of phloroglucinol (0–0.17%) and BSA (0–1.10%) in 10 ml of 80% aqueous methanol. A second set of 16 solutions was made by adding the same amounts of phloroglucinol and BSA to 75% methanol–25% TCA. The methanol–TCA solution was prepared by dissolving 100 g of TCA in 100 ml of distilled water. The TCA solution was then added to 300 ml of methanol.

The amounts of phloroglucinol that were used were chosen to be equivalent to the amounts of brown algal phenolics that would be present in an extract of a 1-g brown algal sample (dry–wet mass ratio of 0.25) containing 0%, 2%, 5%, or 10% phenolic compounds by dry weight. The BSA concentrations used were chosen to be equivalent to the amount of nitrogen that would be present in algal samples containing either 0%, 2%, 4%, or 10% nitrogen. Steinberg (1985) reported that nitrogen concentrations of 13 brown algal species from California ranged from 1.02% to 2.87% dry mass. Hence, the maximum amount of nitrogen in these assays will exceed the maximum nitrogen concentration measured by Steinberg (1985) by a factor of three.

The 32 solutions were filtered through Whatman No. 1 filters to remove precipitated compounds. Large amounts of precipitates formed in the 80% methanol solutions containing BSA, but no preceipitates were seen in the methanol–TCA solutions. An aliquot (0.050 ml) from each filtrate was added to 1.00 ml of distilled water and 1.00 ml of 40% Folin-Ciocalteu reagent. The flasks were stirred to mix the solutions thoroughly. Five minutes later the solutions were made alkaline with the addition of 1.00 ml of 2 N Na_2CO_3. The flasks were heated in a 50°C water bath for 30 min. The absorbance of the solutions was then measured at 765 nm after removal from the bath.

In the second series of experiments, the sixteen 10-ml aqueous methanol solutions from the previous experiments were acidified with 0.10 ml of concentrated hydrochloric acid to bring the pH to ~1. The sixteen 10 ml methanol–TCA solutions were already at pH 1.3 so it was not necessary to acidify them further. One gram of PVPP (Sigma P-6755) was added to each of the 32 solutions. This amount of PVPP, equivalent to 100 g/liter, is far more than is generally used to remove phenolic compounds from solutions. The slurry was vigorously mixed and allowed to react overnight in darkness at 4°C. The next morning, the slurries were mixed again and approximately 1 ml of each slurry was spun down in a microcentrifuge. Folin-Ciocalteu assays were then performed on the liquid fractions.

Simple linear regressions (MINITAB, Release 9) were used to obtain regression equations of phloroglucinol concentrations (x) and absorbance at 765 nm (y). The slopes and elevations (y intercepts) of regression equations for different concentrations of BSA were compared with analysis of covariance (Zar, 1984).

Measurements of Phenolic Compounds in Fucus gardneri. *Fucus gardneri* were collected from an exposed ($N = 7$) and a protected ($N = 10$) site at Fogarty Creek Point, Oregon. Approximately 0.3 g of blade and midrib tissue from each alga was weighed and extracted in 15 ml of 80% aqueous methanol. Another blade and midrib sample from each individual of approximately the same size was weighed and extracted in 15 ml of 75% methanol–25% TCA solution. A third sample from each individual was weighed and placed in a 60°C drying

oven for 48 hr to obtain a dry-to-wet mass ratio. The algal samples in 80% methanol and 75% methanol–25% TCA were extracted overnight in darkness at 4°C. A Folin-Ciocalteu assay was used to measure the concentrations of phlorotannins in the solution prior to homogenization. The samples were then homogenized with a Virtishear Tempest I.Q. homogenizer. After filtration, Folin-Ciocalteu assays were used to quantify phenolic concentrations in the extracts.

PVPP was used to remove phenolic compounds from the mixture to attempt to quantify the concentrations of nonphenolic, Folin-Ciocalteu-reactant materials. The 80% methanol extracts were acidified with 0.15 ml HCl and 1.5 g of PVPP was then added to each of the 15-ml aqueous methanol and methanol–TCA extracts. After reacting overnight in the darkness at 4°C, the slurries were stirred. A 1-ml sample was removed from each, spun in a microcentrifuge, and assayed again with a Folin-Ciocalteu assay. The amount of nonphenolic, Folin-Ciocalteu-reactant materials was determined by subtracting the concentrations of reactive materials after the addition of PVPP from the concentrations prior to the addition of PVPP.

Paired *t* tests (MINITAB, Release 9) were used to compare: (1) phenolic concentrations of algae prior to and after homogenization, and (2) algae extracted in 80% methanol and algae extracted in 75% methanol, 25% TCA. Correlation coefficients (MINITAB, Release 9) were calculated to determine if quantities of nonphenolic, Folin-Ciocalteu-reactive compounds were correlated with concentrations of phenolic compounds.

RESULTS

The addition of bovine serum albumin (BSA) did not affect the outcome of the Folin-Ciocalteu assays that were used to measure known concentrations of phloroglucinol when 80% methanol was used as a solvent (Figure 1A). When BSA was added to 80% methanol, a substantial portion of the protein precipitated from solution and was removed by filtering before the assays were conducted. Absorbance at 765 nm was tightly and positively correlated (Figure 1) with phloroglucinol concentration but was unaffected by the addition of BSA.

PVPP was not effective at removing all of the phloroglucinol from the acidified 80% methanol solutions (Figure 1B). The amount of phloroglucinol remaining in solution was significantly correlated with the initial phloroglucinol concentration (regression $r^2 = 0.988$; $P = 0.006$). The addition of BSA to the solution significantly decreased the amount of phloroglucinol remaining in solution (Figure 1B). This decrease may have occurred because phloroglucinol was more effectively absorbed by PVPP in the presence of BSA. Alternatively, some of the phloroglucinol may have complexed with the BSA and precipitated from solution in the presence of PVPP. The amount of phloroglucinol remaining in the solution was independent of BSA concentration (Figure 1B).

Measurements of phloroglucinol in 25% TCA–75% methanol yielded a tight correlation between the measured absorbance and the concentration of phloroglucinol in the solution in the absence of BSA (Figure 2A). The addition of BSA had little effect on the regression at concentrations comparable to those seen in most brown algae (2–4% N). However, at high protein concentrations (equivalent to 10% N), proteins affected the absorbance of phenols, causing an increase in the slope of the regression line. BSA also affected the uptake of phloroglucinol by PVPP in 25% TCA–75% methanol (Figure 2B). The addition of BSA to the methanol–TCA solutions appeared to have decreased the absorption of phloroglucinol by PVPP. In contrast, when BSA was added to the aqueous methanol solutions, phloroglucinol absorption appeared to increase (Figure 1B).

Both 80% methanol and 25% TCA–75% methanol work equally well as solvents for extracting *Fucus* for Folin-Ciocalteu analyses. There were no significant differences in the phenolic levels of algae extracted in 80% methanol versus 25% TCA–75% methanol (Table 1: paired t test: $P = 0.48$). However, it is important that the samples be ground prior to running the analysis. Grinding samples increased the mean measured phenolic concentrations by 54% to 210% (Table 1; paired t test: $P < 0.001$).

In *Fucus gardneri*, nonphenolic substances make up at most ~3–5% of

FIG 1. (A) The results of Folin-Ciocalteu assays of known mixtures of phloroglucinol and bovine serum albumin (BSA) dissolved in 80% methanol prior to the addition of PVPP. The four lines shown in each graph represent the best fit lines for phloroglucinol concentrations versus absorbance ($N = 3$) for each of the four BSA concentrations used. Vertical lines represent ±1 SE. The regression equations for the lines are: 0% BSA absorbance = 16.7 * [phloroglucinol] + 0.10 ($r^2 = 0.997$, $P < 0.001$), 0.22% BSA absorbance = 16.3 * [phloroglucinol] + 0.10 ($r^2 = 0.997$, $P < 0.001$), 0.44% BSA absorbance = 16.7 * [phloroglucinol] + 0.08 ($r^2 = 0.993$, $P < 0.001$), and 1.1% BSA absorbance = 16.7 * [phloroglucinol] + 0.08 ($r^2 = 0.996$, $P < 0.001$). The slopes and elevations of the regressions are not significantly different (ANCOVA: slope $F = 0.146$, $P > 0.5$, elevation $F = 0.557$, $P > 0.5$). (B) The results of Folin-Ciocalteu assays of known mixtures of phloroglucinol and bovine serum albumin (BSA) dissolved in 80% methanol after the addition of PVPP. The four lines shown in each graph represent the best fit lines for phloroglucinol concentrations versus absorbance ($N = 3$) for each of the four BSA concentrations used. Vertical lines represent ±1SE. The regression equations for the lines are: 0% BSA absorbance = 1.172 * [phloroglucinol] + 0.010 ($r^2 = 0.973$, $P < 0.001$), 0.22% BSA absorbance = 0.816 * [phloroglucinol] + 0.015, ($r^2 = 0.972$, $P < 0.001$), 0.44% BSA absorbance = 0.841 * [phloroglucinol] + 0.011 ($r^2 = 0.951$, $P < 0.001$), and 1.1% BSA absorbance = 0.733 * [phloroglucinol] + 0.012 ($r^2 = 0.917$, $P < 0.001$). The slopes of the regressions are significantly different (ANCOVA: $F = 12.67$, $P < 0.001$). However there are no significant differences among the elevations of the regression lines (ANCOVA: $F = 0.412$, > 0.5).

the compounds measured by the Folin-Ciocalteu analysis (Table 2). It should be noted that these values are likely to be overestimates of the nonphenolic materials since PVPP does not remove 100% of the phenolics present in either solvent (Figures 1B and 2B). In *Fucus gardneri*, the amounts of nonphenolic materials quantified by the Folin-Ciocalteu analysis were not significantly correlated with the concentrations of phenolic compounds (80% methanol: $r = -0.242$, $P > 0.05$; 75% methanol, 25% TCA: $r = 0.038$, $P > 0.05$).

DISCUSSION

None of the three methods used for quantifying brown algal phenolic compounds were without problems. Extracting plants in 80% methanol results in some nonphenolic, Folin-Ciocalteu-reactive substances being included in the measurement of total phenolic compounds. However, it is unlikely that amino acid residues from proteins will be a substantial portion of these compounds because proteins are generally insoluble in high concentrations of organic solvents (Bollag and Edelstein, 1991). Extracting algae in 75% methanol–25% TCA does not improve the precision or accuracy of the Folin-Ciocalteu results

FIG. 2. (A) The results of Folin-Ciocalteu assays of known mixtures of phloroglucinol and bovine serum albumin (BSA) dissolved in 75% methanol–25% TCA prior to the addition of PVPP. The four lines shown in each graph represent the best fit lines for phloroglucinol concentrations versus absorbance ($N = 3$) for each of the four BSA concentrations used. Vertical lines represent ± 1 SE. The regression equations for the lines are: 0% BSA absorbance = 14.7 * [phloroglucinol] + 0.15 ($r^2 = 0.988$, $P = 0.006$), 0.22% BSA absorbance = 15.1 * [phloroglucinol] + 0.15 ($r^2 = 0.990$, $P = 0.005$), 0.44% BSA absorbance = 15.3 * [phloroglucinol] + 0.20 ($r^2 = 0.989$, $P = 0.006$), and 1.1% BSA absorbance = 14.8 * [phloroglucinol] + 0.39 ($r^2 = 0.987$, $P = 0.004$). The slopes of the regressions are not significantly different (ANCOVA: $F = 0.122$, $P > 0.5$). However, there are significant differences among the elevations of the regression lines (ANCOVA: $F = 10.20$, $P < 0.0005$). (B) The results of Folin-Ciocalteu assays of known mixtures of phloroglucinol and bovine serum albumin (BSA) dissolved in 75% methanol–25% TCA after the addition of PVPP. The four lines shown in each graph represent the best fit lines for phloroglucinol concentrations versus absorbance ($N = 3$) for each of the four BSA concentrations used. Vertical lines represent ± 1 SE. The regression equations for the lines are: 0% BSA absorbance = 0.052 * [phloroglucinol] − 0.008 ($r^2 = 0.995$, $P < 0.001$), 0.22% BSA absorbance = 0.050 * [phloroglucinol] + 0.057 ($r^2 = 0.999$, $P < 0.001$), 0.44% BSA absorbance = 0.046 * [phloroglucinol] + 0.095 ($r^2 = 0.998$, $P < 0.001$), and 1.1% BSA absorbance = 0.036 * [phloroglucinol] + 0.173 ($r^2 = 0.916$, $P < 0.001$). Both the slopes (ANCOVA: $F = 3.14$, $P < 0.05$) and elevations (ANCOVA: $F = 46.23$, $P < 0.001$) of the regression lines for the different levels of BSA are significantly different from one another.

[a]Two pieces of blade and midrib tissue from each of 17 individual *Fucus gardneri* were extracted. The first piece was extracted in 80% methanol–distilled water. The second piece was extracted in 75% methanol–25% TCA. The amounts of nonphenolic material were measured with a Folin-Ciocalteu assay after phenolic compounds were removed from the extracts with PVPP.

at low protein concentrations, and at high protein concentrations may make the assays less accurate. In my experiments, proteins stayed in solution in the methanol–TCA solutions, but readily precipitated out of the aqueous methanol solutions. The presence of high concentrations of proteins in the methanol–TCA solutions later interefered with the Folin-Ciocalteu analysis. Therefore, the use of aqueous methanol as a solvent is preferred over a methanol-TCA mixture.

The concentrations of nonphenolic materials measured with the Folin-Ciocalteu method appear to be a small fraction of the actual phenolic concentrations (Table 2). At least 95–97% of the Folin-Ciocalteu-reactive compounds were phenolic compounds in *Fucus gardneri*. The percentage of phenolic compounds removed by PVPP from *F. gardneri* was larger than the percentage removed from phloroglucinol–BSA mixtures. PVPP may have a greater affinity for complex phlorotannins, such as the polyphenols found in brown algae, than for low-molecular-weight compounds, such as phloroglucinol.

The small concentrations of nonphenolic materials in *Fucus gardneri* were well below the differences in phenolic levels that have been described to occur in brown algae over a variety of spatial and temporal scales (Geiselman, 1980; Steinberg, 1984; Johnson and Mann, 1986; Ilvessalo and Tuomi, 1987; Van Alstyne, 1988, 1989; Tugwell and Branch, 1989). Yates and Peckol (1993) measured concentrations of Folin-Denis-reactive compounds before and after the addition of PVPP in 70% aqueous methanol extracts of *Fucus vesiculosus* from MA. They report that concentrations of nonphenolic, Folin-Denis-reactive

compounds were about 70% of the concentrations of phenolics removed by PVPP. This is substantially higher than the 3–5% concentrations of nonphenolic, Folin-Ciocalteu-reactive compounds reported in *Fucus gardneri* in this study. These differences could be due to species-specific differences in oxidizable, nonphenolic compounds, but they are more likely due to the incomplete binding of phenolics to PVPP, resulting in an underestimate of phenolic concentrations. In my study, there was a high degree of variation in the amounts of phloroglucinol removed by PVPP, suggesting that this method is not able to give consistent results and should be avoided.

Several other methods are routinely used to quantify phenolic compounds and their activity in terrestrial plants. The Prussian blue assay (Price and Butler, 1987) is a chemical assay for quantifying total phenolic compounds that has been used by terrestrial chemical ecologists, but not by marine chemical ecologists. Several protein binding assays (Mole and Waterman, 1987) are also routinely used, although their relevance in marine systems is, at this point, unknown. Brown algal polyphenolic compounds do complex with proteins (Tugwell and Branch, 1992); however, there is currently little evidence to support or refute protein binding as the primary functional role of brown algal polyphenolic compounds.

Measurements of total phenolic levels with chemical methods such as the Folin-Denis or Folin-Ciocalteu assays appear to provide ecologically relevant information about defensive abilities of algal tissue. Measurements of total phenolic compounds with chemical assays have provided strong negative correlations between phenolic levels and herbivore food preferences (Steinberg, 1984, 1985; Johnson and Mann, 1986; Van Alstyne, 1988, 1989; Van Alstyne and Paul, 1990), even though the biological effects of brown algal phenolics are often dependent on their molecular size (Geiselman and McConnell, 1981; Boettcher and Targett, 1993). The data from this study provide some guidelines for the use of the Folin-Denis and Folin-Ciocalteu chemical assays for quantifying levels of brown algal phenolic compounds.

Acknowledgments—I would like to thank C. Blanchette for providing the *Fucus* samples from Oregon. The insightful comments of two anonymous reveiwers greatly improved the quality of the manuscript.

PRODUCTION OF PHEROMONE BY HAIRPENCIL GLANDS OF MALES OBTAINED FROM INTERSPECIFIC HYBRIDIZATION BETWEEN *Heliothis virescens* AND *H. subflexa* (LEPIDOPTERA: NOCTUIDAE)

PETER E.A. TEAL,* and ANDREA OOSTENDORP

Insect Attractants Behavior and Basic Biology Research Laboratory, USDA PO Box 14565, Gainesville, Florida, 32604

(Received May 16, 1994; accepted September 29, 1994)

Abstract—Pheromone produced by the hairpencil glands of interspecific hybrid- and backcross-generation males from crosses between *Heliothis virescens* (F.) with *H. subflexa* (Gn.) was studied. Males of reciprocal F_1 hybrids, all of which had hairpencil glands morphologically similar to those of *H. virescens*, produced neither the same pheromone blend nor amounts of pheromone that were produced by males of *H. virescens*. Instead, these hybrid males produced pheromone that was quantitatively and qualitatively similar to that produced by *H. subflexa*. Hairpencil gland extracts from males obtained from backcrossing F_1 females of either cross to males of *H. subflexa* were the same as those of *H. subflexa*. However, extracts from backcross males of crosses between F_1 females and *H. virescens* were variable. Some extracts from these backcross males were like those of *H. virescens* while others were either like *H. subflexa* or were intermediate between those of the parent species. These results showed that the production of pheromone by the hairpencil glands of hybrid and backcross males is under the dominant regulation of autosomal genes of the *H. subflexa* genome.

Key Words—Hairpencils, sex pheromone, *Heliothis*, autosomes, sex chromosomes.

INTRODUCTION

Heliothis virescens (F.) and *H. subflexa* (Gn.) are closely related species of noctuid moths that can be induced to hybridize in no-choice laboratory condi-

*To whom correspondence should be addressed.

tions (Laster, 1972; Proshold and LaChance, 1974). However, the two species are reproductively isolated, and there is no evidence for interspecific hybridization in nature. Reproductive isolation between the two species is maintained by both pre- and postmating mechanisms. The principal means by which species integrity and reproductive isolation are maintained is through the use of highly specific blends of female produced pheromones (Tingle et al., 1978; Heath et al., 1991). These pheromones attract males from varying distances and are the first step in the mating ritual. However, the success of mating depends also upon female acceptance of courting males.

Among many moth species, acceptance of males by females is mediated chemically by pheromones released from male hairpencil glands during courtship (Birch and Hefetz, 1987). Males of *H. virescens* partially expose genital hairpencil glands just prior to landing near a female that is releasing pheromone and fully expose these structures just prior to copulation (Teal et al., 1981). Exposure of the hairpencils results in a sudden release of a blend of pheromone components in which hexadecan-1-ol and hexadecan-1-ol acetate are present in greatest amounts (Teal and Tumlinson, 1989). Studies have indicated that effective hairpencil exposure is important for reproductive success (Teal et al., 1981; Teal and Tumlinson, 1989). Similarly, males of *H. subflexa* expose the genital segments prior to attempting to copulate with conspecifics (Cibrian-Tovar and Mitchell, 1991).

Recent studies have shown that inheritance of the hairpencil glands by interspecific hybrid and backcross males is controlled by a dominant gene(s) on the male sex chromosome (Z chromosome) of *H. virescens* (Teal and Oostendorp, 1993). Thus, all hybrid and any backcross males that obtain one of the two Z chromosomes from *H. virescens* have the same type of hairpencil glands as males of *H. virescens* because males of Lepidoptera are homogametic and have two sex chromosomes (denoted ZZ). Given that the hairpencil pheromone is sex specific and that the structure of the hairpencil glands was regulated by the chromosomes, we were interested in knowing if the production of pheromone by these male glands was regulated by sex-linked inheritance or autosomal genes as reported for pheromone production by females of these hybrids (Klun et al. 1982). The following reports the results of studies in which the amounts and ratios of hairpencil pheromone present in extracts from hybrid and backcross males were compared to those present in extracts from males of the parent species.

METHODS AND MATERIALS

Insect Cultures. Both *H. virescens* and *H. subflexa* parent stocks were obtained as pupae from colonies maintained at our laboratory. The founding colonies of both species were begun from larvae collected in fields in Alachua

County, Florida, in 1986. Interspecific hybridizations were conducted by combining five males of one species with five females of the other species in 500-ml cardboard cartons with screen tops. Three cartons were set up each time a cross was conducted. Cartons were inspected daily for the presence of larvae. Approximately equal numbers of larvae from each of the three cartons were reared individually as described by Teal and Oostendorp (1993). All insects were held in environmental chambers having a reversed 14:10 (light–dark) photoperiod at 26°C and 55% relative humidity. Four separate crossing experiments, conducted at different times, were undertaken for each interspecific cross. Female hybrids from each rearing were backcrossed to males of the parent species in a similar manner. Thus, all experiments were replicated four times and hybrid and backcross insects from each crossing experiment were the progeny of at least three matings between different parents. After adult emergence, males were aged for two to four days prior to use. No males from hybrid or backcross lines could be used for crossing experiments because of sterility (Laster, 1972; Proshold and LaChance, 1974; Karpenko and Proshold, 1977).

Hairpencil Gland Excision and Extraction of Pheromone. Studies on the pheromone produced by males of hybrid and backcross insects were conducted using insects sampled during the fifth to sixth hours of the second to fourth scotophase after adult emergence. This time period corresponded to the peak periods of pheromone production by females of *H. virescens* and *H. subflexa* (Heath et al., 1991; Teal et al., 1993).

Tissue used to obtain extracts included the terminal abdominal segments, which are normally retracted into the abdomen. These segments, bearing the hairpencil glands, were exposed by application of pressure to the anterior abdominal segments. The exposed genital segments were then excised and placed into 60 μl of hexane containing 20 ng each of octadecane and nonadecane, internal standards used for quantitation and calculation of relative retention indices. After ca. 10 min, the solvent was removed and stored in a clean microvial at −60°C until analysis. Prior to chemical analysis, the volume of the extracts was reduced to ca. 5 μl under a stream of nitrogen.

Chemical and Data Analysis. Routine chemical analyses were conducted by capillary gas chromatography (GC) using Hewlett Packard 5890 GCs equipped with split/splitless injectors and flame ionization detectors. Capillary columns used for analysis included both apolar phase (SPB1) and polar phase (Supelcowax 10) columns. The fused silica columns were 30 m × 0.25 mm ID and had a film thickness of 0.25 μm. Conditions of chromatography were as follows: initial oven temperature 60°C, oven temperature increased after 2 min at 30°/min, final temperature 200°C. Helium was used as the carrier gas at a linear flow velocity of 18 cm/sec. Individual extracts were injected in the splitless mode with the injector being purged after 0.5 min. Data were acquired with a Nelson 3000 data acquisition system and analyzed by using Nelson 2600 soft-

ware. Quantitative data on the two principal components of the pheromone of *H. virescens*, hexadecan-1-ol (16:OH) and hexadecan-1-ol acetate (16:Ac), were transferred to Lotus 1-2-3 spreadsheets and ratios were calculated. Statistical analyses were performed on these data using NCSS statistical software. For the purposes of this study, we considered the ratio of components in extracts obtained from hybrid and backcross males to be like *H. virescens* if the ratio of 16:AC to 16:OH was 3.5:1 or greater or to be like *H. subflexa* if the ratio was 1:1 or less. Extracts containing more than a total of 125 ng of pheromone were considered to be like *H. virescens* and those containing less than 10 ng were considered to be like *H. subflexa*. All other values were considered to be intermediate between the two species.

Mass spectral analyses were used to confirm the identities of compounds present in extracts obtained from hairpencil glands of the parent species and in samples selected at random from hybrid and backcross insects. A Nermag R1010 MS operated in the chemical ionization mode (methane reagent gas) and interfaced to a Hewlett Packard 5790 GC was used. The SPB1 column used for GC-MS studies was operated as described above.

RESULTS AND DISCUSSION

Parent Species. Extracts of the hairpencil glands from individual males of *H. virescens* analyzed during the present study showed that 16:Ac and 16:OH were the principal components of the pheromone, confirming previous findings (Teal and Tumlinson, 1989). The mean amount of 16:Ac was 286.1 ng (SE = 24.84, N = 15, max = 430.5 ng, min = 128.4 ng) and for 16:OH was 70.4 ng (SE = 8.89, N = 15, max = 127.64 ng, min = 17.5 ng, mean ratio Ac:OH = 4:1). These values were also in agreement with those of earlier work (Teal and Tumlinson, 1989).

Analysis of extracts of the terminal abdominal segments of males of *H. subflexa* did not reveal the presence of any compounds that were unique to this species. Minute amounts of 16:OH (mean = 1.36 ng, SE = 0.36) were found in 18 of the 50 extracts analyzed by GC. Data supporting the presence of 16:OH was obtained from GC-MS analysis of an extract of 15 glands on the basis of retention time and selected ion monitoring using major ions determined from analysis of synthetic 16:OH (m/z 242 = M, 241 = M-1 (parent ion), 225 = (M+1)-18, 224 = M-18). Only six of the 50 samples contained detectable amounts of 16:Ac (mean = 0.39 ng, SE = 0.28) and the presence of the acetate could not be confirmed by GC-MS. The maximum amount of 16:AC plus 16:OH found in an individual extract was 7.3 ng (3.1 ng 16:Ac plus 4.2 ng 16:OH).

F_1 Hybrids. Extracts of the hairpencil glands from both of the hybrid lines

contained small amounts of pheromone. The mean amounts of 16:Ac and 16:OH for *H. subflexa* female × *H. virescens* male (S line) males were 0.8 ng (SE = 0.13, N = 125), and 3.17 ng (SE = 0.29, N = 125) and for *H. virescens* female × *H. subflexa* male (V line) males were 1.01 ng (SE = 0.20, N = 102) and 3.76 ng (SE = 0.35, N = 102), respectively (Figure 1). Neither the mean total amounts of 16:OH plus 16:Ac nor the mean amounts of the individual compounds present in extracts from either hybrid line were greater than that of *H. subflexa* (Fisher's LSD, P = 0.05). Similarly, the mean ratios of 16:OH to 16:Ac for the hybrid groups were the same as that of *H. subflexa*. Although four extracts from V line males and six extracts from S line males contained more 16:Ac than 16:OH, the ratios from these individual extracts were not different from the highest ratio of 16:Ac to 16:OH (3.1 to 4.2, 16:Ac to 16:OH) found in an individual extract from *H. subflexa* (χ^2, P = 0.05).

These data indicate that both the blend and amounts of 16:Ac and 16:OH present in hairpencil glands were the same as that present in extracts of *H. subflexa*. Therefore, although the presence and structure of the hairpencil glands are regulated by dominant genes on the Z chromosome of *H. virescens* (Teal and Oostendorp, 1993), the male sex chromosome (Z chromosome) of this species does not exert a dominant effect on pheromone production. Although the data implied that regulation of both the amount and ratio of pheromone components produced by hybrids is controlled by dominant genes in the *H. subflexa* genome, we could not determine if the genes were sex linked or auto-

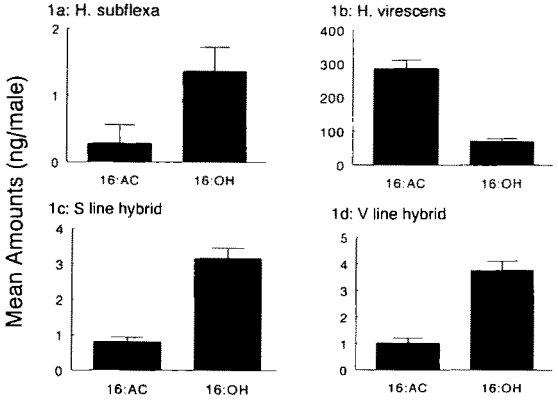

FIG. 1. Comparison of mean amounts (±SE) and ratios of 16:Ac and 16:OH present in extracts obtained from hairpencil glands of males of S line F_1 (N = 125) and V line F_1 hybrids (N = 102) with those found in extracts from males of *H. virescens* and *H. subflexa*.

somal because males of Lepidoptera are homogametic and the hybrid males obtained a Z chromosome from each of the parent species (Table 1).

Backcross 1 Generations. Extracts of males obtained from backcrossing hybrid V line F_1 females to *H. subflexa* (V line female × *H. subflexa* male = VA line) or S line F_1 females to *H. subflexa* (S line female × *H. subflexa* male = SD line) contained the same amounts and ratios of 16:OH and 16:Ac as those obtained from *H. subflexa* males (Figure 2, Table 1). These results were expected because the chromosomal make up of both hybrid lines was either the same as that of the F_1 males or males of *H. subflexa* (Table 1). Although these results confirmed that production of 16:OH and 16:Ac was regulated by dominant genes in the *H. subflexa* genome, they did not indicate if the genes were sex linked.

Extracts obtained from males of backcrosses between V line females and *H. virescens* males (VB line) contained variable amounts of 16:Ac and 16:OH (N = 75) (Figure 2, Table 1). Only six of the extracts contained combined amounts of the two compounds that were greater than 100 ng. These males were considered to be able to produce as much pheromone as males of *H. virescens*. Seven of the extracts contained amounts equivalent to those from *H. subflexa*.

TABLE 1. EFFECT OF HYBRIDIZATION AND BACKCROSSING ON RATIO AND TOTAL AMOUNT OF PHEROMONE IN EXTRACTS OF HAIRPENCIL GLANDS OF MALES[a]

Insect line	Male sex chromosomes[b]	Phenotypes if sex linked, *H. subflexa* dominant	Observed phenotypes for total amount	Observed phenotypes for ratio of 16:Ac and 16:OH
Parent, *H. virescens*	ZvZv	all V type	all V type	all V type
Parent, *H. subflexa*	ZsZs	all S type	all S type	all S type
S line hybrid	ZvZs	all S type	125 S type	125 S type
V line hybrid	ZvZs	all S type	102 S type	102 S type
BC1 SC line	ZvZv	all V type	17 V type[c]	12 V type[c]
			39 I type	34 I type
			6 S type	16 S type
BC1 SD line	ZvZs	all S type	35 S type	35 S type
BC1 VA line	ZsZs	all S type	30 S type	30 S type
BC1 VB line	ZvZs	all S type	6 V type[c]	13 V type[c]
			62 I type	36 I type
			7 S type	26 S type

[a]Phenotype designations are: V = *H. virescens* type, S = *H. subflexa* type, I = intermediate between parental types.

[b]Zv = *H. virescens* Z chromosome, Zs = *H. subflexa* Z chromosome.

[c]There is a difference in these cells between the observed frequency and the frequency expected if the trait were linked to the Z sex chromosome.

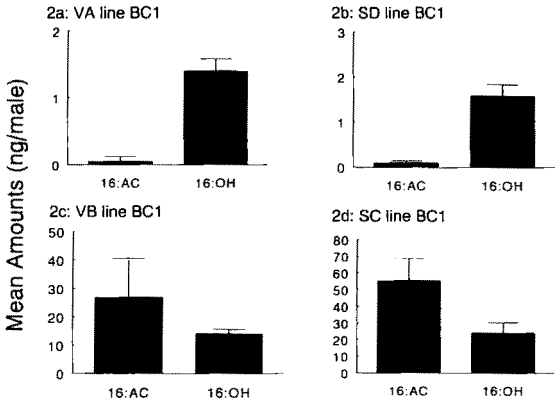

FIG. 2. Mean amounts (±SE) and ratios of 16:Ac and 16:OH present in extracts obtained from hairpencil glands of VA line (N = 30), SD line (N = 35), VB line (N = 75), and SC line (N = 62) backcross 1 generation males.

The remaining 62 extracts contained amounts of these two components that were intermediate between those of *H. subflexa* and *H. virescens*.

Thirteen of the extracts from VB line males contained a 16:Ac to 16:OH ratio similar to that of *H. virescens* (i.e., 4:1) and of these, five contained total amounts greater than 100 ng, while the remaining eight had intermediate amounts of pheromone. Twenty-six extracts contained the same ratio of 16:Ac to 16:OH that was found in *H. subflexa*. The remaining 36 extracts contained ratios of 16:Ac to 16:OH that were intermediate between those of the parent species.

The data obtained from VB line backcross males indicated that genes responsible for the regulation of production of both amounts of 16:Ac and 16:OH and ratios of these compounds were not sex linked. The V line hybrid females obtained their Z chromosome from *H. subflexa*. Thus, backcrossing these females to *H. virescens* males resulted in male progeny that obtained one Z chromosome from *H. virescens* and the other from *H. subflexa* (Table 1). These backcross males had the same sex chromosome makeup as V line hybrid males. If the genes were sex linked, then all of the VB line males should have produced the same amount and ratio of 16:Ac to 16:OH that was produced by males of V line hybrids and *H. subflexa*. However, a significant number of extracts had amounts and ratios of 16:Ac and 16:OH that were intermediate between those of the parent species and others were like *H. virescens*.

Backcrossing S line hybrid females to *H. virescens* (SC line) resulted in males (N = 62) that produced both 16:Ac and 16:OH. However, both the amounts and ratios of the two compounds were variable (Figure 2, Table 1). Seventeen of the extracts contained combined amounts of 16:Ac and 16:OH

equivalent to that of *H. virescens*. Six extracts contained amounts as low as those present in *H. subflexa* extracts, and the remaining 39 contained intermediate amounts of pheromone.

Extracts of 12 SC line males contained the same ratio of 16:Ac to 16:OH as was present in males of *H. virescens* and, of these, seven had as much pheromone as *H. virescens* (Table 1). Another group of 16 extracts contained a ratio of 16:Ac to 16:OH that was like *H. subflexa*. The remaining 34 were intermediate between the two parental ratios.

If the genes regulating the ratio and amount of pheromone were sex linked, then all SC line males should have been identical to *H. virescens* because SC line males obtained both of their Z chromosomes from *H. virescens* (Table 1). However, as occurred with extracts from VB line males, a large number of extracts contained intermediate amounts and ratios of the two components. Additionally other extracts were the same as extracts from males of *H. subflexa*. Therefore, the regulation of both the ratio and amounts of 16:Ac and 16:OH produced by the hairpencil glands of interspecific hybrid and backcross males is controlled by autosomal genes. Additionally, the data from analyses of extracts of both the VB and SC line backcross males show that more than one gene is responsible for regulation of each trait. If single genes were responsible for regulating either trait, then 50% of the populations of males from backcrossing females of either hybrid line to *H. virescens* should have been like this species and the other half should have been like *H. subflexa*. However, approximately 50% of the males from both VB and SC backcross lines were intermediate for both traits (Table 1).

These results, coupled with those from other studies on the regulation of the pheromone-mediated biology of interspecific hybrids between *H. virescens* and *H. subflexa*, indicate that different aspects of the communication system are regulated in different ways. For example, studies on the sex pheromones produced by female hybrids from crosses between *H. subflexa* females and *H. virescens* males showed that these females produced the same blend of pheromone components as do females of *H. virescens* (Klun et al., 1982). This indicates that the regulation of pheromone production by females of this hybrid line appears to be under the dominant regulation of the *H. virescens* genome (Klun et al., 1982). Similarly, both the presence and structure of the male *H. virescens*-type hairpencil glands are dominantly regulated by the *H. virescens* genome (Teal and Oostendorp, 1993). However, in this case, the genes reside on the Z sex chromosome, whereas genes controlling production of the female pheromone are autosomal. The results of this study show that the production of the male hairpencil pheromone in hybrids is under the dominant regulation of autosomal genes of *H. subflexa*. These results, in conjunction with previously published work on *Heliothis*, demonstrate that control of the pheromone communication system in *Heliothis* moths is regulated by a complex genetic system

and support the hypothesis that genes controlling different aspects of the system are not closely linked and are inherited independently in Lepidoptera (Lofstedt et al., 1989).

(Received July 18, 1994; accepted September 27, 1994)

Abstract—*tert*-Butyl 4- (and 5-) chloro-*trans*-2-methylcyclohexane-1-carboxylate (TML), a mixture of four major *trans* and four minor *cis* isomers, is used as an attractant for detecting and monitoring the male Mediterranean fruit fly (medfly), *Ceratitis capitata* (Wiedemann). The eight isomers (racemic mixtures) were isolated by HPLC, and their relative attractiveness in the field was determined. A quantitative structure–activity relationship (QSAR) was proposed that related a molecular measurement ($Å^3$) of the TML structure to male medfly captures. More recently, the *trans*-TML enantiomers were synthesized in sufficient quantities for field testing. This paper reports the computer-aided molecular modeling, via Chem-X, of the *trans*-TML enantiomers and the staggered and superimposed fitting with the most attractive isomer, (1*S*,2*S*,4*R*)-TML-C, to determine common volumes and surface areas from Van der Waals (VdW) maps. Observations of structure–activity relationships (SAR) are reported for the staggered fittings.

Key Words—Insecta, *Ceratitus capitata*, medfly, trimedlure, enantiomer, attractant, lure, SAR, VdW, Chem-X.

INTRODUCTION

tert-Butyl 4- (and 5-) chloro-*trans*-2-methylcyclohexane-1-carboxylate (TML), is a synthetic mixture of 90–95% of four *trans* isomers (Beroza et al., 1961; McGovern et al., 1986). Each of these isomers exists as two enantiomers (Sonnet et al., 1984; Doolittle et al., 1991); the racemic isomers are designated A, B1, B2, and C (McGovern and Beroza, 1966). TML is used as an attractant for detecting and monitoring the male medfly, *Ceratitis capitata* (Wiedemann), which is a worldwide pest of fruits, nuts, and vegetables (Hagen et al., 1981; Jackson and Lee, 1985).

The stereochemical structural assignments of each of the *trans* (McGovern and Beroza, 1966) and *cis* racemic isomers (McGovern et al., 1986) and the GLC separation of these eight racemic isomers (Leonhardt et al., 1982; Warthen and McGovern, 1966; Beroza and Sarmiento, 1964) paved the way for their semipreparative HPLC separation (Warthen and McGovern, 1988) in sufficient quantities to determine relative medfly attractiveness (McGovern et al., 1990) in the field. The biological data permitted the postulation of a structure/medfly-attractiveness relationship via computer molecular modeling that related a molecular measurement ($Å^3$) to medfly catch (Warthen et al., 1993):

$$\text{Medfly catch} = (\text{molecular volume/molecular surface area}) \times (\cos abcd + 0.895)^2 \times \{[(t\underline{C}H_3\text{-}6C) + (Cl\text{-}2\underline{C}H_3)/2] - 5.221\}^2$$

Essentially, this equation states that optimal medfly catch of the eight-isomer racemic TML series is determined by an optimal ratio of molecular volume to surface area, but the molecular surface area is modulated by an optimal torsion angle (*abcd*) and an optimal average of two interatomic distances. The index or independent variable in terms of the molecular measurement determines the dependent variable of medfly catch; a linear best-fit line results ($R^2 = 0.939$, $N = 8$, $P < 0.01$).

It has been known for some time that the most attractive of the eight racemic TML isomers was *trans*-TML-C (McGovern et al., 1966, 1987), or more specifically the (1*S*,2*S*,4*R*)-TML-C enantiomer (Sonnet et al., 1984). The recent report by Doolittle et al. (1991), involving the stereospecific chiral synthesis of the eight *trans*-TML enantiomers, made possible the determination of the relative field attractiveness of these substances. It has also afforded an opportunity to study the SAR of the *trans*-TML enantiomers in light of our previous work (Warthen et al., 1993) with TML racemic isomers.

Therefore, this paper reports an examination of the eight *trans*-TML enantiomers via computer molecular modeling so as to relate structural characteristics to medfly attractiveness.

METHODS AND MATERIALS

Lowest energy conformations of *trans*-TML enantiomers were determined using molecular mechanics (Burkert and Allinger, 1982; Clark, 1985; Warthen et al., 1993) with modified force-field parameters (including Gasteiger charges) of the computer program Chem-X (January 1991 VAX version, Chemical Design Ltd, Oxford, England).

The mirror images of the lower-energy molecular mechanics (MM) minimized *trans*-TML enantiomers (Warthen et al., 1993) were constructed via the Crystal Symmetry mode in Chem-X. All enantiomers were then compared to (1*S*,2*S*,4*R*)-TML-C, which was the most attractive TML enantiomer for medflies. Comparison of each *trans*-TML enantiomer with (1*S*,2*S*,4R)-TML-C was accomplished in a staggered and a superimposed fitting so that carbon 1 of the cyclohexane ring was directly below the carbon 1 of (1*S*,2*S*,4*R*)-TML-C or superimposed with carbon 1 of (1*S*,2*S*,4*R*)-TML-C, respectively.

The staggered fit was achieved by placing ring carbons of the isomer directly above or below the ring carbons of (1*S*,2*S*,4*R*)-TML-C so that the substituted axial groups would be parallel (Figure 1). Dummy planes with accompanying dummy atoms (P1 and P2) were placed in both enantiomers utilizing carbons 6, 2, and 4 in (1*S*,2*S*,4*R*)-TML-C and carbons 3, 5, and 1 in (1*R*,2*R*,4*S*)-TML-C. A view was then set through P1 and carbon 4 for (1*S*,2*S*,4*R*)-TML-C; and a view was set through P2 and carbon 1 for (1*R*,2*R*,4*S*)-TML-C.

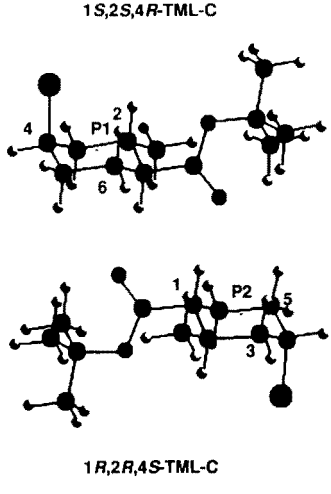

FIG. 1. Calculated lowest energy MM minimized (1*S*,2*S*,4*R*)-TML-C and (1*R*,2*R*,4*S*)-TML-C with dummy atoms P1 and P2.

Another view was set through carbons 6 and 2 for (1*S*,2*S*,4*R*)-TML-C; and a view was set through carbons 3 and 5 for (1*R*,2*R*,4*S*)-TML-C. (1*R*,2*R*,4*S*)-TML-C was then rotated about the *y* axis 180°. In this manner, the dummy planes were oriented perpendicular to the *y* axis and parallel to the *x* axis. A rigid fit between the two enantiomers was then performed by specifying connection between P1 and P2 (Figure 2). The superimposed dummy atoms were then deleted. The remaining six enantiomers were each fitted to (1*S*,2*S*,4*R*)-TML-C in a similar fashion.

The superimposed fitting was implemented by specifying carbons 5, 3, and 4 of (1*S*,2*S*,4*R*)-TML-C and carbons 3, 5, and 4 of (1*R*,2*R*,4*S*)-TML-C (Figure 3) and performing a rigid fit (Figure 4). The remaining six enantiomers were each fitted to (1*S*,2*S*,4*R*)-TML-C in a similar fashion.

A Gasteiger charge was then placed upon the staggered, fitted pair (Figure 2). After a contour density of 3 contours/Å was selected, a Van der Waals (VdW) map was constructed for (1*S*,2*S*,4*R*)-TML-C as map 1; then, a similar map was drawn for (1*R*,2*R*,4*S*)-TML-C as map 2. The two maps were combined after setting the logical cutoff at 0.95 with a Chem-X ".AND. A MAP" selection to create map 3 (Figure 5). After redrawing maps 1 and 2, the volumes and surface areas were displayed and recorded (Table 1). A similar procedure was used to construct the VdW maps of the superimposed fitted pair of the same enantiomers. Similar maps were constructed for the remaining six staggered and six superimposed, fitting pairs of the other enantiomers and (1*S*,2*S*,4*R*)-TML-C.

Simple linear equations were used to fit the data points from the scatter plots via the linear least-squares method (sum of the square of the errors was minimized) to determine the best fit. These were performed on medfly catch

(Doolittle et al., 1991) vs six observations consisting of common volume, common surface area, and common volume/common surface area ratio for the staggered and superimposed fittings with (1*S*,2*S*,4*R*)-TML-C (Table 1).

RESULTS AND DISCUSSION

The previous work (Warthen et al., 1993) on the medfly quantitative structure–activity relationship (QSAR) of the eight racemic TML isomers revealed that the molecular volume of each isomer was extremely important to the relative medfly attractancy of the eight isomers. This total molecular volume was modulated by the surface area, a torsion angle, and an average of two interatomic distances in order to relate it to medfly catch (Warthen et al., 1993). Since the *trans*-TML enantiomers were synthesized and their medfly field attractancy was determined (Doolittle et al., 1991), a more specific measure of molecular volume characteristic for each enantiomer was permissible, namely, that volume of each enantiomer that was common to the most active enantiomer, (1*S*,2*S*,4*R*)-TML-C, when compared in a specific type of fitting. That fitting was determined by considering the stereochemistry of the most active enantiomer, (1*S*,2*S*,4*R*)-TML-C, which was used as a standard for optimal stereochemistry, atomic, and electrostatic potential for attractancy.

The importance of the stereochemical position of the equatorial 1-*t*-butyl

carboxy, the equatorial 2-methyl, and the axial 4-chloro of (1*S*,2*S*,4*R*)-TML-C for attractancy is obvious. When the orientation of the calculated lowest energy MM minimized (1*S*,2*S*,4*R*)-TML-C is viewed as in Figure 1, then the upper face of the molecule would have to approach a medfly antennal receptor in order

to optimize the stereochemical fit of these three groups. The chlorine atom and the majority of the *t*-butyl carboxy are above the plane of the cyclohexane ring, and the methyl group is accessible for binding in the equatorial position.

Since the *t*-butyl carboxy group is the bulkiest, we compared each *trans*-TML enantiomer with the standard in a staggered (Figure 2) and a superimposed fitting (Figure 4), so that carbon 1 of the cyclohexane ring was directly below the carbon 1 of (1*S*,2*S*,4*R*)-TML-C or superimposed with carbon 1 of (1*S*,2*S*,4*R*)-TML-C, respectively. The staggered fitting was chosen as a comparison to the superimposed fitting, but also so that the puckered cyclohexane rings would be in the same plane with their axial groups parallel to one another.

Those volumes, surface areas, and volume–surface area ratios common to (1*S*,2*S*,4*R*)-TML-C from the staggered and superimposed fittings of the *trans*-TML enantiomers are reported in Table 1. Simple linear regression (Kilpatrick, 1987; Freund and Walpole, 1980; Hayslett, 1968) for seven data points of the six observations revealed regression lines for Δ volume ($R^2 = 0.693$, $N = 7$, $P < 0.05$), Δ surface area ($R^2 = 0.710$), and Δ volume/Δ surface area ($R^2 = 0.567$) from staggered fittings and $R^2 < 0.02$ for the same three observations from superimposed fittings. It is obvious that the staggered fitting produces the better regression lines. The regression lines obtained from Δ volume and Δ surface area from staggered fittings are each more important than the regression line from Δ volume/Δ surface area with its lower R^2. A factor that may be involved is that the common surface area is actually a measurement of the surface of map 3 and not "available" surface area as related to attractancy.

Simple linear regression of the log weighted mean male medfly catch versus Δ volume or Δ surface area from staggered fittings (Figure 6) revealed $R^2 = 0.815$ or $R^2 = 0.840$, respectively. The log scale of the male medfly catch was more linear with Δ volume or Δ surface area than the numerical male medfly catch scale. Thus, the sensitivity of the male medfly catch to small changes in Δ volume or Δ surface area at a molecular level was even more significant than with a numerical scale.

The best information on the attractancy of any one isomer comes from the most active isomer. Attractancy of less active isomers reinforces the structural basis of this activity and determines what structurally hinders attractiveness. Comparing the attractiveness of the isomers makes it possible to see the direct effects of Δ volume and Δ surface area from staggered fittings with (1*S*,2*S*,4*R*)-TML-C without modulating with angles and distances. The logical input of these descriptors based on chemistry (Warthen et al., 1993) was used to determine the independent variable for the *x* axis (Figure 6), resulting in a type of principal components analysis. Therefore, since stepwise multiple regression (Topliss and Edwards, 1979; Dunn et al., 1984) was not specifically used, it was not possible (Hansch, 1991) to evaluate the probability for the chance correlations. We believe that each of the observed R^2 (Figure 6), without the

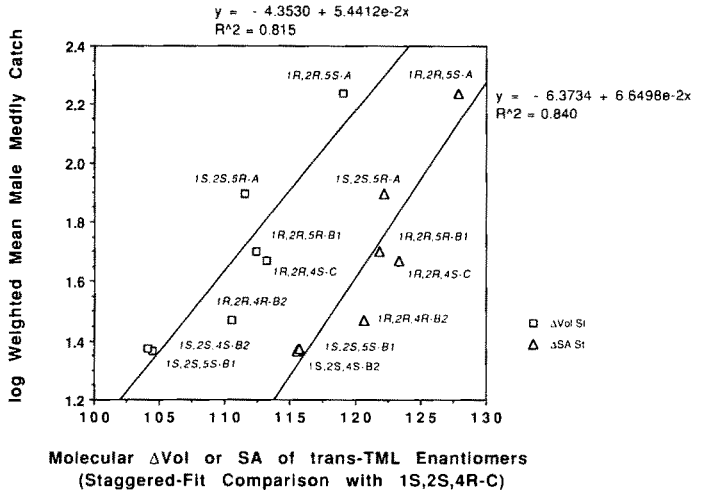

FIG. 6. Simple linear regression of log weighted mean male medfly catch versus common molecular volume ($Å^3$) or surface area ($Å^2$) of calculated lowest energy MM minimized *trans*-TML enantiomers determined by staggered-fit comparison with calculated lowest energy MM minimized (1*S*,2*S*,4*R*)-TML-C.

angle and distance modulators (Warthen et al., 1993), only substantiates the observed relationship between male medfly catch and Δ volume or Δ surface area, rather than indicating chance correlations. The Δ volume and Δ surface area are not proposed as absolute keys to activity, but they are variables that reflect the atoms, the charge on the atoms, the torsion angles, the interatomic distances, the stereochemical nature, etc., in that volume or on that surface.

CONCLUSIONS

Chirality is a factor in SAR that is usually addressed by comparing related isomers of a series by superimposed fitting. However, in the case of the *trans*-TML enantiomers, it was necessary to compare them via staggered fitting of the cyclohexane carbons with the carbon 1 being directly above and below one another to show the SAR. Computer-aided molecular modeling, via Chem-X, of *trans*-TML enantiomers with staggered fitting with (1*S*,2*S*,4*R*)-TML-C and determination of common volumes from VdW maps and subsequent simple linear regression of data resulted in the observation that Δ volume and Δ surface area were directly proportional to the log of the medfly catch if one related the statistical significance of the catches to these molecular measurements. There was a sharp decrease in medfly attactiveness when the Δ volume of a *trans*

enantiomer is $<64\%$. Small changes in the optimal Δ volume or Δ surface area had a much greater effect when male medfly catch was high than when male medfly catch was low (non-optimal Δ volume or Δ surface area). The chirality of (1*S*,2*S*,4*R*)-TML-C was important for optimal activity in this series of enantiomers, but it does not explain why there is activity with the other enantiomers. It is proposed that changes in Δ volume or Δ surface area among the enantiomers are the basis for the differences in their biological activity.

This work and previous research (Warthen et al., 1993), it is hoped, are establishing the groundwork for the use of computer molecular modeling in explaining SAR of agricultural compounds that exhibit behavioral responses, similar to the well-established work that has been done in the pharmaceutical industry. The goal of this tool in agriculture is to be predictive in the design of behavioral substances. Future molecular modeling is planned for possible further elaboration of the TML medfly SAR when *cis*-TML enantiomers are synthesized and field attractancy data become available. Other on-going research is being carried out on other behavioral substances also.

Abstract—Studies were conducted to evaluate biomass production, tissue phytotoxicity, and allelochemical content of rye (*Secale cereale* L.) shoots grown in three fertility regimes (low, medium or high) in the greenhouse. Wheeler rye or a polyculture of rye and hairy vetch (*Vicia villosa* Roth) grown with high fertility produced the greatest biomass (78.7 and 82.7 g), with the lowest root-to-shoot ratio (0.22 and 0.43) produced in the high-fertility treatments. The polyculture treatment grown with low fertility had a greater proportion of hairy vetch (18%) than when grown with high fertility (6%). Rye shoot residue phototoxicity was affected by fertility regime. Radicle elongation of cress (*Lepidium sativum* L.) and barnyardgrass [*Enchinochloa crus-galli* (L.) Beauv.] was inhibited by rye shoot residues in a modified Parker bioassay. Rye shoot residue grown with low fertility was less inhibitory to cress radicle elongation than rye residue from the medium- or high-fertility regimes. Extracts of dried rye shoots grown with high fertility were less inhibitory than extracts from other fertility regimes. The concentrations of ether extracts of rye causing 50% inhibition (I_{50}) of cress radicle elongation were between 125 and 276 μg/ml for greenhouse-grown and 60 and 138 μg/ml for the field-grown rye shoots. The major phytotoxic compounds in the rye shoot extracts were identified as DIBOA and BOA. The concentration of DIBOA in the greenhouse-grown rye shoots ranged between 128 and 423 μg/g while BOA concentration ranged between 2.5 and 31 μg/g. DIBOA and BOA levels were lowest in rye shoots grown with high fertility. Correlations between rye shoot biomass,

INTRODUCTION

Rye (*Secale cereale* L.) is a winter-hardy, erect, herbaceous plant that grows well on marginal soils (Bushuk, 1976; Nuttonson, 1958). It is a long-day plant capable of developing an extensive root system that reduces erosion and nutrient loss (Nuttonson, 1958). In the Midwestern United States, rye is widely grown as a cereal, interseeded with legumes in winter pastures, or as a green manure crop (Amador and Gliessman, 1990).

Rye and its residues reduce weed and crop growth by modifying the microenvironment and releasing allelochemicals (Putnam et al., 1983; Rice, 1984). Rye produces a dense canopy, which is more competitive than weeds for light, moisture, and nutrients. In addition, rye residues on the soil surface reduce weed germination and growth by shading, lowering soil temperatures, moderating diurnal temperature fluctuations, and acting as a physical barrier (Barnes and Putnam, 1986; Putnam et al., 1983; Rice, 1984; Vidal et al., 1994). Rye and its residues can release allelochemicals that accumulate near the soil surface inhibiting seed germination and seedling growth (Barnes and Putnam, 1983; Barnes et al., 1987).

Environmental factors influence allelochemical production in higher plants and also related biological activity (Putnam, 1988; Rice, 1984; Tukey, 1969). For example, increased air temperatures enhanced allelochemical concentration and consequent inhibition of plant growth (Putnam and Tang, 1986; Rizvi and Rizvi, 1992). Stowe and Osborne (1980) reported reduced plant growth and increased allelochemical concentrations due to limited nutrient availability. Fast-growing plants in fertile environments contained lower allelochemical concentrations than slow growing species in areas of limited ferility. Besides affecting allelochemical concentration, allelopathy was enhanced in soils of low fertility (Stowe and Osborne, 1980).

The phytotoxicity of rye and its residues has been attributed to cyclic hydroxamic acids, phenylacetic acid, 4-phenylbutryic acid, and a complex of benzoic and cinnamic acids (Barnes and Putnam, 1986; Einhellig and Leather, 1988; Putnam and Tang, 1986; Rizvi and Rizvi, 1992; Shilling et al., 1985). Two benzoxazinones, 2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA) and its decomposition product, 2(3H)-benzoxazolinone (BOA), have been identified in extracts of rye shoots and their allelopathic activity characterized using cress

radicle elongation (*Lepidium sativum* L.) as a bioassay (Barnes and Putnam, 1987; Barnes, et al., 1987; Gagliardo and Chilton, 1992; Nair et al., 1990). DIBOA and BOA were more toxic to seedling growth than were other allelochemicals from rye residues (Barnes et al., 1987). In intact plant tissues, DIBOA exists as a glycoside (Hofman and Hofmanova, 1971). β-Glycosidases released upon injury to the plants rapidly hydrolyze the glycoside to release DIBOA, which decomposes in water to form BOA. Additional allelochemicals may arise by microbial transformation of compounds from rye residues. Nair et al. (1990) isolated and characterized a compound [2,2'-oxo-1,1'-azobenzene (AZOB)] produced by microorganisms in the presence of rye residues. AZOB was more toxic to curly cress and barnyardgrass than either DIBOA or BOA. Although allelochemicals have been identified, their significance and role in the inhibition of weed growth by rye residues still remain unclear.

Rye was seeded alone or interseeded with hairy vetch (*Vicia villosa* Roth) in field and greenhouse experiments in an effort to determine how fertility influences allelopathy. We hypothesized that allelochemicals from rye residues are partially responsible for reductions in weed growth observed in previous studies with monocultures and polycultures (Masiunas, et al., 1994; Mwaja, 1994). Our objectives in these experiments were to: (1) determine the effect of low-, medium-, or high-fertility regimes on biomass production and rye allelopathic activity; and (2) isolate, identify, and quantify the allelochemicals in rye shoots grown under selected fertility regimes.

METHODS AND MATERIALS

Rye and Hairy Vetch Biomass Production. A greenhouse experiment was conducted to investigate factors that influenced biomass production of winter rye and hairy vetch. The cropping systems evaluated were: (1) a monoculture of rye, (2) a monoculture of hairy vetch, and (3) a polyculture of rye and hairy vetch. Wheeler rye and hairy vetch were seeded into sterilized silica quartz sand in 38-liter plastic containers at rates equivalent to 112 and 34 kg/ha, respectively, for monoculture treatments and similar rates for polyculture treatments. Prior to planting, the silica sand was prewashed first with deionized water and then with twice the volume of the appropriate nutrient solution (Osborne and Wellington, 1981).

Eight days after seeding (two days after germination), three fertility regimes were initiated. The nutrient solutions utilized were dilutions of Hoagland and Arnon (1950) solution, which contained either: (1) low fertility, 5 mM NO_3^-, 0.5 mM P, and 3 mM K; (2) medium ferility, 10 mM NO_3^-, 1 mM P, and 6 mM K; or (3) high ferility, 20 mM NO_3^-, 2 mM P, and 12 mM K. All nitrogen was in the form of nitrate. Other nutrients, including S, Ca, Mg, and micro-

nutrients (i.e., Fe, Cl, Mn) were added in similar proportions as N, P, and K. The pots were fertilized every other day with 250 ml (from 8 to 37 days) or 500 ml (from 38 to 74 days) of the nutrient solutions, and watered daily with deionized water to prevent wilting. Once a week, an excess of deionized water (approximately 1 liter) was applied to flush salts from the sand cultures.

After 75 days, when rye was 45–50 cm tall, the experiment was terminated. Rye and hairy vetch shoots were harvested separately. Roots were washed with running water to remove any adhering sand. Shoot and root biomass was determined after drying at 45°C for seven days. Dried shoots were retained for bioassay and extraction of allelochemicals. The experiment was arranged as a randomized complete block with four replications and was repeated once.

Winter Rye Shoot Bioassay. Experiments were designed to determine the influence of rye fertility regime on rye residue phytotoxicity. Hairy vetch tissue was not evaluated in these bioassays or for allelochemical content because it represented a small (<20%) portion of the polyculture biomass, and its residues are not generally considered to be allelopathic or weed suppressive (White et al., 1989). A modified Parker bioassay was used to measure the allelopathic potential of rye shoots (Parker, 1966; Weston et al., 1989). Flanagan silt loam soil was sifted through a 3- × 3-mm^2 mesh screen and combined with fine quartz sand (1 : 1 v/v). The soil–sand mixture was dried at 45°C for seven days and 100 g was placed in 95- × 95-mm^2 plastic Petri dishes. Next, either 0.5 or 1.0 g of chopped, dried rye from each fertility regime or paper toweling cut into 1.5- × 1.5-cm^2 pieces (control) was placed on the soil. Another 50 g of soil was spread over the chopped residue or toweling. A sheet of filter paper (Whatman No. 1) was placed on the soil surface. A 35-ml aliquot of distilled water was then added to each dish.

Ten seeds each of cress (*Lepidium sativum* L. cv. Extra Fine Curled) and barnyardgrass [*Enchinochloa crus-galli* (L.) Beau.] were placed in two parallel rows (approximately 3.5 cm apart) on the surface of the filter paper. The Petri dishes were taped shut and randomly arranged by treatment in a 28 ± 2°C germination chamber in the dark. The plates were maintained in a vertical position to encourage downward root growth of seedlings. Radicle length was measured after 72 hr. The experiment was arranged as a completely randomized design with four replications and was repeated once. Cress and barnyardgrass indicators were analyzed separately.

Rye Extract Bioassay. This study evaluated the activity and quantity of phytoinhibitors present in extracts of rye shoot residues grown under selected fertility regimes (low, medium, or high fertility). Dried rye shoot residues from each treatment were ground separately in a Wiley mill (mesh screen size of 1 mm). Powdered material was stored in tightly closed glass containers until used for extraction of phytoinhibitors. For each treatment, 40 g of powdered shoot residue were placed in 720 ml distilled water and shaken at 4°C on an orbital

shaker at 200 rpm. The aqueous rye extracts were filtered through four layers of cheesecloth and centrifuged at 9500*g* for 15 min. After centrifugation, extracts were filtered under vacuum using a series of filter papers (Whatman Nos. 4, 1, and 42). The filtered extracts were maintained at 4°C.

Filtered extracts were sequentially partitioned six times each with 150 ml of hexane and 150 ml of ethyl ether. The extracts were rotary evaporated at 35°C to dryness. Dried extracts were weighed and dissolved in the appropriate amount of chloroform to develop a dose–response curve for bioassaying. Six concentrations (666, 333, 166, 83, 42, and 21 μg/ml) of each treatment extract were formulated, and 0.5 ml solution was added to individual glass Petri dishes lined with Whatman No. 1 filter paper. Chloroform was evaporated completely from the dishes and 1.5 ml distilled water was added. Controls consisted of dishes to which 0.5 ml chloroform was added, allowed to evaporate, and followed by addition of 1.5 ml distilled water. Twenty cress seeds were then placed on each moistened filter paper. Dishes were closed, sealed with parafilm, and placed in the dark at 26 ± 2°C. Radicle length was measured after 72 hr of incubation. Treatments were arranged in a completely randomized design with three replications. Sixty seeds were used per treatment, and results were expressed as a percentage of the untreated controls.

Identification and Quantification of Allelochemicals. Major phytotoxic components present in ether extracts of rye shoots were examined using thin-layer chromatography (TLC) and reverse-phase high-pressure liquid chromatography (HPLC). For TLC characterization, 50 μl of the ether extracts of each rye shoot treatment were loaded onto a silica K_6F plate (Whatman). The plates were developed using a mobile phase of 5 : 1 chloroform–methanol (v/v). TLC plates were sprayed with a mixture of 5% vanillin–H_2SO_4, and compounds were visualized under UV (254 nm). The two major components were identified by comparing their migration on TLC plates with that of pure standards of DIBOA and BOA (Barnes et al., 1987). BOA was provided by Dr. M. Nair (Department of Horticulture, Michigan State University) and DIBOA was purified by the laboratory of L. Weston from corn seedlings using the methodology of Nair et al. (1990). The two components and DIBOA and BOA standards had identical R_f values, exhibited fluorescence under UV (254 nm) and absorption maxima in methanol above 254 nm (Chou and Patrick, 1976; Nair et al., 1990). Bands at R_f = 0.44–0.50 and R_f = 0.51–0.57 were identified as DIBOA and BOA, respectively (Nair et al., 1990).

For HPLC characterization, each sample extract was partially purified by eluting through an octadecyl (C_{18}) Sep-Pack (Baker bond, 40 μm APD, 60 Å) with approximately 2 ml of methanol, and then twice filtering through a disposable nylon 66 filter (25 mm syringe filter, 0.2 μm). Samples were rotary evaporated to dryness and redissolved in chloroform at a 1 mg/ml concentration. Twenty microliters of each sample was injected into a HPLC equipped with a

C_{18} column (Water's Nova Pak, Water's, Millpore, Milford, Massachusetts) (3.9 × 150 cm^2). Absorbance at 254 nm was measured with an UV detector (Water's Lambda model 481). The mobile phase consisted of 75% acidified water, adjusted to pH 3.0 with addition of acetic acid and 25% acetonitrile at a flow rate of 1 ml/min. Identities of unknown compounds were confirmed by coelution with standards of DIBOA and BOA. The concentrations of the two benzoxazinones in each sample extract were estimated using standard concentration curves generated for DIBOA and BOA (integration of peak area). All samples were injected twice and results were averaged.

Data from the greenhouse biomass experiment and the laboratory bioassays were subjected to analysis of variance using the general linear model procedure of SAS (SAS Institute, Cary, North Carolina). When effects were significant, means were separated using Fisher's protected least significant difference test (LSD, 0.05). The relationships between rye shoot extract concentration and cress radicle elongation were analyzed using linear regression after logarithmic transformation (base 10). Correlation analysis between rye shoot biomass production, extract concentration, bioassay results, and allelochemical content was performed using SAS.

RESULTS AND DISCUSSION

Rye and Hairy Vetch Biomass Production. Rye and hairy vetch biomass production was affected by both fertility regime and cover crop production system (polyculture vs. monoculture). Shoot biomass of rye grown in monoculture and in polyculture with hairy vetch was significantly increased under high fertility by up to 15% in comparison to low-fertility treatments (Table 1). Hairy vetch biomass was significantly less than rye biomass in all treatments. In general, root dry weight in the three cover crop systems (rye monoculture, rye–vetch polyculture, and hairy vetch monoculture) was highest in the medium-fertility regime. This is similar to the results obtained by Osborne and Whittington (1981), who reported maximum dry weights of *Agrostis* species with 10 mM NO_3^- with a similar sand culture. In our experiments, root dry weights were lower in the hairy vetch monoculture than in either the rye monoculture or rye–vetch polyculture. Root biomass of the hairy vetch monoculture was not affected by fertility (Table 1). However, the root biomass of the rye–vetch polyculture was significantly greater under medium fertility in comparison to the low fertility regime.

Fertility regime and cover crop system also interacted to affect the root-to-shoot ratio. The root-to-shoot ratio ranged from 0.22 for the hairy vetch monoculture under high fertility to 0.63 for the rye monoculture under moderate fertility. Rye root biomass was generally only 50% of the corresponding shoot

biomass (Table 1). This was also observed by Barnes and Putnam (1986) and Nuttonson (1958) in rye field and greenhouse studies.

Increasing the fertility regime reduced the proportion of hairy vetch in the rye–hairy vetch polyculture from 18% of the total shoot biomass in low fertility to 6% in high fertility. This decrease may have occurred because higher fertility levels favored greater rye shoot growth. Since rye grows and tillers at a rapid rate, it may quickly utilize nutrients and water, making these resources less available to hairy vetch. However, the levels of nitrogen and other elements such as P, K, Ca, Mg, and Mn were not significantly influenced by fertility regime or cropping system (data not shown). Since the amounts of nutrients, water, and light provided were closely controlled in this study, it is possible that differences observed in biomass production and root-to-shoot ratios between monoculture or polyculture cropping systems were due to plant–plant interactions. For example, rye plants may exude from living roots allelochemicals that inhibit hairy vetch growth (Barnes and Putnam, 1983; Perez and Ormeno-Nunez, 1993).

(ECHCG) was reduced in the presence of moistened rye residues (Table 2). In all treatments, 1 g of rye residue was more inhibitory to radicle elongation than 0.5 g of residue. In the presence of 1.0 g of rye residue, cress seeds imbibed water, darkened in color; and subsequent radicle elongation was inhibited. Injury symptoms were similar to those observed by Barnes and Putnam (1983) and Chou and Patrick (1976) when lettuce seeds were germinated in the presence of rye residues.

The cover crop system (polyculture versus monoculture) and fertility regime affected cress and barnyardgrass radicle growth in the presence of 0.5 g of rye shoot residue, but there were no treatment differences at 1.0-g residue rates. At 1.0-g residue rates all treatments were quite inhibitory. Cress radicle length ranged from 51 to 81% of the control with 0.5 g residue, and the monoculture did not differ from the polyculture. The effect of rye residue treatments was dependent upon the indicator species evaluated. Rye residues grown under moderate- or high-fertility regimes were more inhibitory to cress radicle elongation than residues grown under low-fertility regimes. At 0.5 g residue, barnyardgrass radicle growth ranged from 63 to 128% and from 34 to 58% of the control when exposed to rye residues from the monoculture and polyculture, respectively (Table 2). Rye produced in a polyculture was more inhibitory to radicle elongation than rye produced in a monoculture. Residues of fall-seeded, field-grown rye were equally toxic in comparison to greenhouse-grown rye. However, toxicity of spring-seeded, field-grown rye differed from fall-seeded rye. Spring-seeded, field-grown rye was more inhibitory to cress radicle growth, while fall-seeded rye was more inhibitory to barnyardgrass growth. Barnes and Putnam (1983) also observed greater phytotoxicity to curly cress from spring-seeded versus fall-seeded, field-grown rye. The inhibition of cress and barnyardgrass radicle elongation indicates that small germinating seeds are vulnerable to chemicals released from rye residues, but cultural practices used to produce the rye cover crop residues may influence tissue toxicity. It is possible that practices used to produce residues could be manipulated to better manage weeds in no-till cropping systems.

Rye Extract Bioassay. The recovery of crude ether extracts of dried rye shoots differed between fertility regimes. For example, rye produced at moderate to high fertility levels in monoculture yielded two to five times more extract than rye produced at low fertility levels (Table 3). Rye produced at moderate fertility in the polyculture yielded almost two times more extract than did rye at low fertility.

The toxicity of the crude ether extracts of rye shoots was influenced by cropping system and fertility regimes in which the rye was grown (Table 4). Ether extracts of rye shoots grown in a polyculture with hairy vetch were generally less inhibitory than those treatments grown in monoculture. Regression analysis indicated that for the rye monoculture, cress radicle elongation was

linearly related to extract concentration. In rye monoculture, extracts of rye shoots grown under low fertilty (I_{50} = 60 μg/ml) were more toxic than those grown at higher fertility (I_{50} = 120 μg/ml). In polyculture treatments, there was a quadratic effect of extract concentration on radicle elongation. Fertility treatments had little effect on toxicity of rye shoot extracts grown in polyculture.

Extracts from stressed plants tend to be more inhibitory to cress radicle elongation than those from plants not under stress (Barnes and Putnam, 1986; Barnes et al., 1987; Rice, 1984). The monocultures of rye grown in the low-fertility regimes may be more stressed than the polyculture treatments of rye grown with hairy vetch. The quadratic equations for the polycultures suggest that there may be a critical concentration below which the allelochemicals are tolerated (Barnes and Putnam, 1983). The range of concentrations we found to be inhibitory to cress radicle elongation (Table 5) were similar to the range reported to be inhibitory by Barnes et al. (1987).

Identification and Quantification of Allelochemicals. Phytotoxic compounds were isolated from extracts of winter rye shoots. The HPLC and TLC data (Table 5) indicated that DIBOA and BOA were the major substituents of ether extracts of rye shoots. In all rye treatments, DIBOA was the major component present in the filtered ether extracts (69–86%), with considerably less BOA present (0.6–5.8%). Following separation by TLC, a strong inhibitory

activity was associated with two zones having R_f = 0.44–0.48 and 0.51–0.54 (data not presented). These compounds cochromatographed with DIBOA and BOA standards, suggesting that the extracts contained the two benzoxazinones. Furthermore, similar color development, fluorescence in UV radiation, and UV absorption maximum were observed for the unknowns and standards on TLC plates. IN HPLC analysis, each of the unknown samples contained two predominant constituents that coeluted with DIBOA and BOA, respectively, at 2.08 and 3.11 min. In addition, the extracts from the unknown samples showed two other minor constituents that eluted at approximately 2.50 and 2.80 min. These constituents were most likely 2,4-dihydroxy-7-methoxy-1,4-benzoxazinone (DIMBOA) and 2-*O*-glucosyl-1,4-benzoxazin-3-one (GDIBOA), compounds which are structurally related to DIBOA and BOA (Hofman and Hofmanova, 1971; Nair et al., 1990).

Ether extracts of rye shoot tissues varied in their concentrations of DIBOA and BOA. BOA concentrations ranged from 2.5 to 31.3 μg/g (Table 3). DIBOA concentrations ranged from 138 to 532 μg/g, with the greatest quantity detected in spring-seeded, field-grown rye. This is not surprising, since plant tissues grown under high light intensity generally produce greater levels of extractable allelochemicals (Rice, 1984). Our results differed from the findings of Barnes and Putnam (1987), who reported greater quantities of DIBOA in greenhouse-

[a]Crop systems were: Monoculture, winter rye in a monoculture; and Polyculture, winter rye in a rye and hairy vetch polyculture.

[b]Fertility regimes were: low, medium, and high nutrient levels applied in Hoagland's solution.

[c]HPLC parameters: the mobile phase was based on the Weston et al. (1989) method; 75% acidified water, 25% acetonitrile; adjusted to pH 3.0 with addition of acetic acid; Min is the peak retention time in minutes, and percent is component compound present in the filtered ether extracts of rye shoots detected at the peak retention time.

[d]Cress bioassay: I_{50} values represent the point at which 50% inhibition of cress radicle growth occurred. A dose-response curve was calculated on the basis of 60 seeds at six concentrations of the ether extract. The I_{50} values were estimated using the regression equations shown in Table 4.

[e]*, NS significant at 5% and not significant, respectively.

[f]Spring- and fall-planted rye harvested after 75 and 240 days of growth, respectively.

[g]The identity of the benzoxazinones was based on comparison with the values obtained in DIBOA and BOA standards in our laboratory analyses and values reported by Barnes et al. (1987).

grown rye shoots as compared to field-grown rye shoots. Fall-planted, field-grown rye shoot extracts contained lower levels of DIBOA and higher levels of BOA then extracts from spring-planted, field-grown rye. Fall-seeded rye was also more inhibitory to barnyardgrass than were other treatments, such as spring-seeded rye. Rye grown in the high-fertility regime had lower levels of DIBOA and BOA than rye grown in moderate or low fertility. Fertility regime and cropping systems effects on DIBOA and BOA are not unexpected. Two major differences between greenhouse-grown and field-grown (spring- or fall-planted)

rye are the age of tissue at harvest and the environmental conditions encountered during growth. Tissue age influences biosynthesis of secondary plant products, and plants growing in unfavorable conditions produce more secondary metabolites than those growing in favorable environments (Barnes and Putnam, 1987; Bushuk, 1976; Putnam et al., 1983; Rice, 1984). Plant age can be managed in the field by timing the rye kill, potentially maximizing DIBOA and BOA concentration and increasing field-grown rye's weed-suppressing ability.

In our study, ether extracts of rye shoots contained primarily DIBOA. The estimated concentrations of DIBOA and BOA in shoot tissues ranged between 2.28 and 18.94 kg/ha for DIBOA and 0.001 and 1.90 kg/ha for BOA (data not presented). These estimates agree with the 13.5 kg/ha of DIBOA and BOA reported by Barnes and Putnam (1987) and Barnes et al., (1986). Based on our field studies (Masiunas et al., 1994; Mwaja, 1994), rye residues and their allelochemicals can effectively control redroot pigweed (*Amaranthus retroflexus*) for four to eight weeks, depending on weather conditions.

Biomass production, extract concentrations, bioassay results, and allelochemical content were correlated (Table 6). As shoot dry matter accumulation increased, crude ether extract ($r = -0.73$), DIBOA concentration ($r = -0.81$) decreased while BOA concentration ($r = 0.62$) increased. A modified Parker bioassay examining toxicity of rye shoot residues gave low correlations with DIBOA and BOA concentrations in ether extracts of rye shoot residues. This suggests that the field soil bioassay using cress as a seedling indicator is limited in its ability to predict allelochemical concentration. Barnyardgrass radicle growth had a correlation coefficient of -0.53 for DIBOA but only -0.18 for BOA. These results are in agreement with those of Barnes and Putnam (1987) and Barnes et al. (1986, 1987), showing DIBOA as most active to monocots and BOA as more active to dicots. The concentration of DIBOA and BOA in ether extracts was most strongly correlated with the results obtained from the crude ether extract bioassay using 333 μg/g. Simple extraction of rye residues followed by bioassay may be a relatively quick and accurate method to estimate DIBOA and BOA concentrations in allelopathic residues.

In conclusion, although high-fertility regimes may produce large amounts of rye biomass, the allelochemical content and biological activity of these residues may not be increased. The negative correlation of rye shoot dry weight with filtered extract content or DIBOA concentration (Table 6) suggests that cultural practices (i.e., fertility) that increased growth of winter cover crops may not optimize phytotoxicity of residues or allelochemical content. Our bioassays implicated chemical interference by rye residues with suppression of seedling growth. We also observed strong weed suppressive activity by rye residues in field experiments. DIBOA and BOA concentrations may be associated with weed suppressive activity of rye residues in the field. Hence, an integral approach

TABLE 6. MATRIX OF CORRELATION COEFFICIENTS BETWEEN BIOMASS PRODUCTION, EXTRACT CONCENTRATIONS, BIOASSAY RESULTS, AND ALLELOCHEMICAL CONTENT

Variable[a]	Shoot dry wt	Extract Conc.		Soil bioassay		Extract bioassay conc. (μg/ml)		Conc. (μg/g)

(Received May 10, 1994; Accepted September 21, 1994)

Abstract—The *Np* mutant of pea (*Pisum sativum* L.) is characterized by two physiological responses: growth of callus under pea weevil (*Bruchus pisorum* L., Coleoptera: Bruchidae) oviposition on pods, and formation of neoplastic callus on pods of indoor-grown plants. Although these two responses are conditioned by *Np*, they are anatomically and physiologically distinguishable, based on sites of origin, distribution pattern, and sensitivity to plant hormones. Further characterization of the response to extracts of pea weevil showed that response of excised pods, measured by callus formation, was log-linear, and treatment with as little as 10^{-4} weevil equivalents produced a detectable response. Mated and unmated females contained similar amounts of callus-inducing compound(s), and immature females contained significantly less of the compound(s). Female vetch bruchids (*Bruchus brachialis* F., Coleoptera: Bruchidae), a related species, contained callus-inducing compound(s), but usually less than pea weevils on a per weevil basis. Males of both species contained less than 10% of the activity of the mature females. Extracts of female black vine weevils, a nonbruchid species, did not stimulate callus formation. Based on partitioning and TLC analysis, the biologically active constituent(s) was stable and nonpolar. Thus, the *Np* allele probably conditions sensitivity to a nonpolar component of pea weevil oviposition as a mechanism of resistance to the weevil.

INTRODUCTION

Expression of the dominant gene *Np* (neoplastic pod) in pea (*Pisum sativum* L.) is characterized by neoplastic growth, or "pustular outgrowths" of callus, on pods of greenhouse-grown plants (Nuttall and Lyall, 1964). Absence of ultraviolet light permits full development of this *Np* phenotype, where neoplasms form over the entire pod, often preventing normal seed development (Snoad and Matthews, 1969). Snoad and Matthews (1969) reported that subsidiary cells associated with stomata on pods, but not on leaves and stems, were the site of neoplasm formation. Seed removal reduced the occurrence of neoplasms, and the seed effect was replaced by GA_3 and auxins (Jones and Burgess, 1977).

Following a report by Vilkova et al. (cited in Berdnikov et al., 1992) that oviposition by pea weevil (*Bruchus pisorum* L., Coleoptera: Bruchidae), a major insect pest of pea (Clement, 1992), resulted in cell growth under the egg, Berdnikov et al. (1992) showed that aqueous extracts of pea weevil stimulated callus on pods of *Np* but not on *np* genotypes. They proposed that this response comprised a form of resistance to pea weevil, as callus dies and falls from the pod, with the weevil egg. More often, however, larvae hatched and burrowed into the pod before the callus died; thus, the resistance provided by *Np* appeared to be weak. Hardie (1990, 1993) also observed callus formation in response to pea weevil oviposition, although he proposed that the callus retarded entry of the weevil larvae into the pod, thereby reducing infestation of the seed.

These separate lines of investigation have converged on the involvement of *Np* in control of cell division, a question of fundamental importance to biology. In this case, a stimulus from the weevil is associated with a specific plant gene that also mediates a response to plant hormones. This interaction of pea weevil with a single genetic locus to elicit growth in a specific plant organ may yield new insights into regulation of cell division. The purpose of this study was to: (1) initiate characterization of the extractable weevil factor, and (2) explore physiological and anatomical responses of pea tissue to weevil extracts.

METHODS AND MATERIALS

Plant Material. Pea plants (*Pisum sativum* L.) were grown in a greenhouse as described previously (Proebsting et al., 1992). Two lines, C887-332 (*Np/Np*) and I_3 (*np/np*), a selection from cv. Alaska (both lines derived from material provided by the late Dr. G.A. Marx, New York Agricultural Experiment Station, Geneva, New York), were used for all studies. To prevent neo-

plasm formation, potted plants were transferred outdoors at the onset of flowering. Unless otherwise noted, pods selected for bioassay were one half to fully expanded in length.

Insects. Adult pea weevils (*Bruchus pisorum* L., Coleoptera: Bruchidae) were obtained from infested pea seed harvested the previous season from experimental plots in eastern Washington and stored at 4°C. Sufficient seed to yield the desired number of weevils was placed in a screen-covered container at 25°C. As the insects emerged from the seed, their sex was determined (Pesho and van Houten, 1982), and the females were placed individually in plastic Petri dishes containing a moist dental wick. The weevils were provided with fresh pea flowers two or three times per week to supply fresh pollen required for sexual maturation (Pesho and van Houten, 1982). Weevils were assumed to be sexually mature upon deposition of a few eggs on the Petri dish or pea flower. Maturation typically occurred 10–20 days after exposure to pollen.

Sexually mature vetch bruchids (*Bruchus brachialis* F., Coleoptera: Bruchidae) were field-collected from wild vetch plants (*Vicia villosa* Roth.) growing near Pullman, Washington. The sex of these insects was determined (Pinckney, 1937), and they were extracted as described below. Sexually mature black vine weevils (*Otiorhynchus sulcatus* F., Coleoptera: Curculionidae), a parthenogenetic species, were provided by Dr. C.H. Shanks, Jr. (Washington State University, Vancouver) from a colony maintained on strawberry plants.

Insect Extraction. Whole insects were homogenized either in water or in chloroform–methanol (2 : 1 v/v) (100 μl per insect) using a glass tissue homogenizer. After brief centrifugation, the supernatant was removed and used for bioassay. Organic extracts were partioned 3× against equal volumes of water and each fraction, unpartitioned chloroform–methanol, nonpolar, and polar, was dried in vacuo and reconstituted with 100 μl water per weevil.

Female weevils secrete an egg-covering fluid at oviposition that also is used to attach eggs to pea pods and is referred to as "accompanying fluid" (Annis and O'Keefe, 1984). Extracts were prepared from pea weevil eggs and the accompanying fluid by pressing the underside of the terminal segments of the abdomen of sexually mature female weevils to cause extrusion of the copulatory and ovipository organs and provide access to the eggs and accompanying fluid. Eggs were transferred to a microcentrifuge tube using a glass capillary tube drawn to a fine, sealed tip. The eggs were homogenized in water (100 μl per weevil) using a plastic pestle fitted to the microcentrifuge tube. After centrifugation, the supernatant was transferred to a fresh tube and used for bioassay.

The accompanying fluid was taken up in finely drawn glass capillaries. The capillaries containing the extract were placed in microcentrifuge tubes and broken with a plastic pestle. The fluid was extracted into water (chloroform, if using thin-layer chromatography), centrifuged, and the supernatant transferred to a fresh microcentrifuge tube.

Bioassay. Pods at mid- to late-flat pod phase (Meicenheimer and Muehlbauer, 1982) were split along the suture and the seeds removed. The half pods were placed with their inner side on moist filter paper in plastic Petri dishes (100 mm diameter). One-microliter droplets of test solutions were placed along the middle of the pods. Droplet order was random, except for TLC fractions. In some cases, the pod surface was marked adjacent to the droplet to indicate site of application. The droplets were air-dried, the dishes covered, and placed in an incubator [23 ± 2°C, continuous light, fluorescent tubes (Philips F36T12/CW/HO, 30–40 μmol photons/m^2/sec).

After one week in the growth chamber, callus that formed at the sites of application was removed and weighed. All bioassays were comprised of six half pods (treated as blocks), and the data analyzed by analysis of variance. In some cases, means were compared using Tukey's studentized range test. All bioassays were carried out at least two times with qualitatively similar results.

Thin-Layer Chromatography. Five weevil equivalents (WEq) of a chloroform extract of eggs and accompanying fluid were spotted and dried on reversed-phase TLC plates (Whatman $KC_{18}F$) and developed in ethanol–water (80:20 v/v) to 10 cm beyond the origin. Fractions 1 cm^2 were eluted from the adsorbent with chloroform–methanol (1:1 v/v). The 10 fractions were dried in vacuo and redissolved in water.

Microscopy. Light microscopy was conducted using material fixed in 4% formaldehyde in 0.1 M phosphate buffer, pH 7.3, dehydrated in an ethanol series, and embedded in paraffin. Sections 10 μm thick were deparaffinized and stained with hematoxylin and eosin. Specimens for scanning electron microscopy were fixed in 2.5% (v/v) glutaraldehyde in 0.1 M phosphate buffer, pH 7.3, dehydrated, and critical point dried before coating with gold–palladium (60:40) and examined using an Amray 1000A scanning electron microscope operated at 30 keV.

RESULTS AND DISCUSSION

Response of Np *to Weevil.* Callus developed under pea weevil eggs laid on *Np* pods (Figure 1A and B). These micrographs also show early development of neoplasms associated with stomata, as reported previously (Snoad and Matthews, 1969). Unlike the neoplasms, the response to weevil was not restricted to stomata (Figure 1B and C). Both oviposition and application of weevil extract stimulated callus formation throughout the site of contact.

Aqueous extracts prepared from sexually mature female pea weevils also induced callus development when applied to intact pods of *Np*. Callus growth was preceded by discoloration (browning) of the pod surface at the site of application within 3–6 hr after application of active extracts. This effect is

evident in Figure 1D, where the application site is clearly delineated by darkened epidermis. Darkening did not appear in response to inactive extracts from other insects, inactive chromatographic fractions of female pea weevils, or organic solvents. Browning was not gene-specific, however, appearing in *np* lines in response to active extracts. We considered this discoloration to be a rapid, but preliminary, index of biological activity.

Swelling at the site of extract application appeared within two days and expanded on subsequent days (Figure 1E and F). By day 7, a disordered mass of callus, still largely bounded by the epidermis, was evident (Figure 1G). These figures clearly show involvement of exocarp and mesocarp cells (Esau, 1977), rather than stomata, in response to weevil components, thereby distinguishing the weevil-generated response from the autogenous, neoplastic response. Cell growth on the inner surface of the pod was also apparent by day 2 (Figure 1D–G). This growth occurred on both *np* and *Np* pods, and was not stimulated by weevil extracts.

Response of the pod to pea weevil oviposition and extracts: (1) occurred both outdoors and in the greenhouse, (2) occurred on seeded and deseeded pods, and (3) was restricted to the site of contact with either weevil eggs or extract. In contrast, neoplasms were formed almost exclusively under low UV light in the greenhouse, and covered the entire pod, often preventing normal seed development. Limited neoplastic development was observed occasionally on shaded pods within the canopy of plants grown outdoors.

Neoplasm formation on *Np* reportedly occurs exclusively on pods (Snoad and Matthews, 1969). We routinely observed small neoplasms on stems and petioles of indoor-grown plants, and occasionally on field-grown plants of line C887-332. However, pea weevil extracts did not stimulate callus development on immature or mature stems, petioles, or leaves, whereas pods responded to extract at any time prior to senescence (data not shown). Pea weevil oviposition and extracts did not stimulate callus formation on *np* tissues. Thus, *Np* conditions an organ-specific response to pea weevil and to autogenous factors that stimulate neoplasm formation. Although these events depend on *Np*, they appear to be physiologically and anatomically distinguishable.

Bioassay. We observed a log-linear dose–response of *Np* half pods to weevil extract. Application of as little as 10^{-4} WE reliably produced a measurable response in the excised pods (Figure 2). In one experiment, visually detectable callus formed on two of six pods treated with 10^{-5} WE. The amount of callus varied from pod to pod, but the qualitative response to weevil extract was always very distinct. Browning of the epidermis occurred within a few hours of application, and callus development could be visually distinguished within two or three days.

Berdnikov et al. (1992) emphasized the importance of using pea lines with weak expression of *Np* in order to distinguish neoplasms from weevil-induced

callus. We found only occasional neoplasm formation on excised, expanding, half pods from outdoor-grown plants. Furthermore, weevil-induced callus appeared compact and light-brown, whereas neoplasms were pustular in texture and nearly white in color. As a result of these characteristics, this simple bioassay was rapid and sensitive.

Sources of Callus-Inducing Activity. Female pea weevils and vetch bruchids, a closely related species, were the best source of callus-inducing compound (Figure 3A), whereas female black vine weevils, a distantly related coleopteran, contained no callus-inducing compound. Mated and unmated females contained roughly similar amounts of callus-inducing compound, whereas immature females contained significantly less compound (Figure 3B). Based on dose–response studies, mature females of both species contained at least 10-fold more activity than males (Figure 3C), and, in the case of pea weevil, than immature females (Figure 3B). Pea weevil eggs and the accompanying fluid both stimulated callus formation (Figure 3D). We could not distinguish whether the activity in the egg fraction was actually in the small amount of fluid adhering to the eggs.

Gibberellic acid (GA_3) and naphthaleneacetic acid (NAA) were inactive in the half-pod bioassay over the concentration range of 10^{-6}–10^{-2} M and within the seven-day assay period (data not shown). Benzylaminopurine occasionally, but not reproducibly, stimulated a small amount of callus. In contrast, GA_3 and NAA were reported to stimulate neoplasms on deseeded pods still attached to the plant, and on *Np* pods in sterile culture on medium containing MS salts plus GA_3, IBA, or IAA (Jones and Burgess, 1977). We reproduced both these responses, but found them to be variable and relatively weak compared to the response to pea weevil.

FIG. 1. Micrographs showing response of *Np* pods to pea weevil oviposition (A, B) and to application of 1 μl (2×10^{-2} WE) pea weevil extract on *Np* pods (C–G). Bar = 200 μm in all cases. (A) Effects of pea weevil oviposition (e, egg and a, egg adhesive) after two days. Slight swelling under the oviposition is apparent. Nascent neoplasms associated with stomata are also evident (arrow). (B) SEM with oviposition removed (a, egg adhesive) from pod and showing swelling (arrowheads) at site four days after oviposition. Neoplasm is indicated by arrow. (C) SEM of pod three days after treatment with pea weevil extract. Swelling is evident at site of application (arrowheads) and nascent neoplasms are evident (examples marked by arrows). (D–G) Light micrographs of pod cross sections. Arrowheads mark boundaries of extract application. (D) One day after application of pea weevil extract, discoloration of epidermis and swelling of exocarp cells are evident. (E–F) Progressive swelling of exocarp and mesocarp under application site is detectable two and four days after application of pea weevil extract. (G) Seven days after application, substantial, irregular callus development has broken through the discolored epidermis, but appears to be still largely bounded by the epidermis.

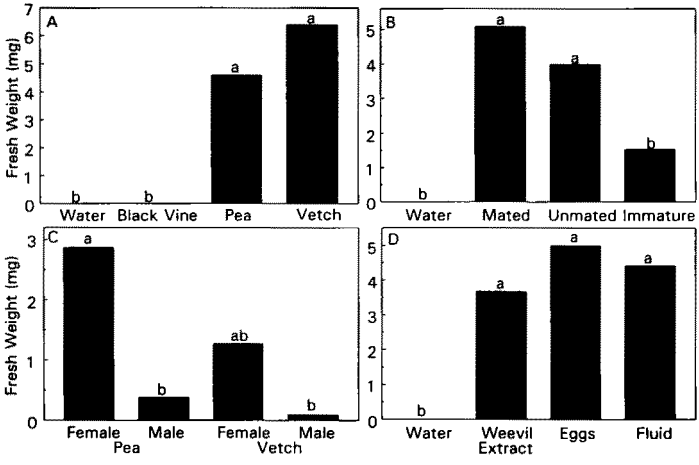

FIG. 3. Callus formation by *Np* pods in response to insect extracts. (A) extracts of pea, vetch, and black vine weevils. (B) extracts of mated, unmated, and immature pea weevils. (C) extracts of female and male pea and vetch weevils. (D) extracts of whole weevils, eggs and accompanying fluid. Response measured by weighing callus produced at site of application seven days after application. Letters over bars represent mean separation by Tukey's studentized range test at $P < 0.05$.

Characterization. Callus-inducing compound was extractable by both water and chloroform–methanol. When chloroform–methanol extracts were partitioned against water, however, the biological activity remained in the nonpolar fraction (data not shown). Reversed-phase, thin-layer chromatography of partitioned extracts resulted in recovery of activity from R_f 0.2 to 0.3 (data not shown). Retention of biological activity through these procedures indicated that the active constituent(s) were sufficiently stable to be purified by routine methods.

Np was originally characterized as an abnormal, and rather curious, growth response to seeds and plant hormones in specific environmental conditions. The tumor-like growths were described as neoplasms, defined as a new growth of tissue serving no physiological function. Neoplasm formation similar to that in *Pisum sativum* was described in pea subspecies (Snoad and Matthews, 1969; Hardie, 1990) and on two sweet pea (*Lathyrus*) species (Snoad and Matthews, 1969; Annis and O'Keefe, 1984; Hardie, 1993). Callus or gall formation in response to pea weevil oviposition was also reported on *L. tingitanus* and *L. sativus* and was proposed to play a role in resistance to weevil (Annis and O'Keefe, 1984). However, the relationship of weevil oviposition and *Np* in *Pisum* was only reported recently (Berdnikov et al., 1992).

Callus, or gall, formation is a common defensive response to insect herbivory that, ironically, usually results in high-quality food and shelter for the insect. An extensive variety of galls are formed by plants in response to insects. The most elaborate are referred to as prosoplasmic galls, which involve specific, patterned development and have not been mimicked experimentally (Rohfritsch, 1992). Kataplasmic galls, on the other hand, are less organized, consisting largely of calluslike growth such as that formed by *Np* peas. Chemical, rather than mechanical, stimuli initiate these galls. Characterization of insect extracts has resulted in identification of several amino acids, IAA, and putative IAA cofactors, a steroid, and a variety of unidentified factors associated with insect secretions and gall formation (reviewed by Hori, 1992). The *Np*–pea weevil relationship in pea is the first reported gene-specific interaction governing insect-induced growths on plants.

Our observations of the anatomy and morphology of the *Np* response to weevil differed from those described for the neoplastic response (Dodds and Matthews, 1966; Snoad and Matthews, 1969). Neoplasms formed a thick layer of cells covering virtually the entire pod, were eliminated by UV light, and appeared lighter in color and more pustular than weevil-induced callus. GA_3 and auxins could stimulate neoplasm formation over the entire pod, mimicking the stimulus provided by seeds. In contrast, pea weevil oviposition or application of pea weevil extracts caused callus formation only at the site of application and callus did not grow beyond this site. Perhaps more importantly, the response to weevil involves exocarp and mesocarp tissues and is not restricted to the stomatal apparatus, as neoplasms were reported to be (Snoad and Matthews, 1969).

It appeared, superficially, that the seed- and weevil-induced responses of *Np* pods were somewhat different manifestations of the same cellular response. Thus, based on earlier work (Berdnikov et al., 1992), as well as ours, cell proliferation on pods of *Np* now appears to have a function. We think the *Np* allele of pea regulates expression of a plant resistance trait (callus formation), albeit only after attack by an insect (pea weevil) that has a highly specific relationship with pea. The degree of weevil resistance conferred by *Np* has yet to be determined, however. The seed and hormone responses previously observed under low UV light conditions are believed to be related, but secondary.

(Received July 18, 1994; accepted October 14, 1994)

Abstract—A flavonoid decomposition product that is present in peanut (*Arachis hypogaea*) shells, 5,7-dihydroxychromone (DHC), was found to inhibit the radial growth of cultures of the soil pathogenic fungi *Rhizoctonia solani* and *Sclerotium rolfsii* with I_{50} (the concentrations of DHC required to inhibit growth 50%) values of 18 and 26 μM, respectively. Radicle elongation of velvetleaf, corn, peanut, and wheat was inhibited by DHC with I_{50} values of 30, 50, 65 and 200 μM, respectively. DHC had no effect on the growth of *Bradyrhizobium* sp. at 10 μM in medium containing low (1.0 g/liter) mannitol as the carbon source, although the related flavones luteolin and chrysin each promoted bacterial growth at 10 μM 48 hr after inoculation. When tested in high (10.0 g/liter) mannitol medium, DHC initially inhibited growth of *Bradyrhizobium* sp., but 120 hr after inoculation the growth of all treatments were similar. These results suggest a role for DHC released from peanut shells in suppressing pathogenic fungal infection and competing plant growth but not for *Bradyrhizobium* growth promotion.

Key Words—Peanut, *Arachis hypogaea*, *Rhizoctonia solani*, *Sclerotium rolfsii*, *Bradyrhizobium*, 5,7-dihydroxychromone, chrysin, luteolin, flavonoids, allelopathy, growth inhibition.

INTRODUCTION

Flavonoids are a diverse class of compounds with over 1000 different flavonoids reported in higher plants (Harborne, 1982). Their physiological roles are varied,

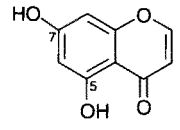
[1] Mention of firms or products does not imply endorsement by the U.S. Department of Agriculture over other firms or products not mentioned.

0098-0331/95/0200-0107$07.50/0 © 1995 Plenum Publishing Corporation

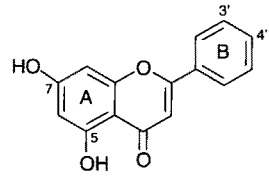
ranging from plant pigments to defensive substances and pollination attractants (Harborne, 1982). Flavones are a subgroup of flavonoids containing a ketone oxygen at the 4 position of the central ring. Certain flavones have been shown to function in the induction of nodulation genes in legumes (Hartwig et al., 1990; Maxwell et al., 1989; Peters and Long, 1988); in the growth promotion of *Rhizobia* bacteria (Hartwig et al., 1990); in the inhibition of growth of plants and fungi (Paszkowski and Kremer, 1988; Rivera-Vargas et al., 1993; Weston et al., 1987); in the stimulation of vesicular–arbuscular mycorrhizal fungi (Poulin et al., 1993); and as phytoalexins (Sharon et al., 1992).

The flavone decomposition product 5,7-dihydroxychromone (DHC; Figure 1) has been found at relatively high (0.02% by weight) levels in peanut shells (Pendse et al., 1973). DHC has been reported to inhibit velvetleaf (*Abutilon theophrasti*) seed germination (Spencer and Tjarks, 1985) and depress aflatoxin production by *Aspergillus parasiticus* (DeLucca et al., 1987). The high levels of DHC in the shells suggest a role for it in the chemical ecology of the soil environment surrounding the shells, as the shells generally remain under the surface of the soil for several months before the seeds break dormancy and are able to germinate. Because peanut shells are the primary structures encountered by soil microorganisms and competing plant seeds during the time period that the dormant seeds are in the soil, compounds present in the shells would likely have the greatest effect on these rhizosphere organisms. DHC may thus confer a competitive advantage to the peanut seeds by preventing soil pathogenic fungi from entering the shells and attacking the seeds prior to germination while also inhibiting the germination and growth of neighboring seeds.

The 5,7-dihydroxy substitution pattern may be critical for biological activity, as Lane et al. (1987) found that eight of nine isoflavonoids isolated from



DHC



3' = 4' = H; Chrysin

3' = 4' = OH; Luteolin

FIG. 1. Chemical structures of DHC, chrysin, and luteolin.

Lupinus angustifolius that had insect deterrent activity and antifungal activity contained a 5,7-dihydroxychromone moiety. The 5,7-dihydroxychromone group may also be critical for the attraction and growth promotion of *Bradyrhizobium* sp. associated with nitrogen fixation in peanut. Flavonoids released by alfalfa (*Medicago sativa*), which promoted nodulation (*nod*) gene expression and the growth of *Rhizobium meliloti*, contained this functional group (Hartwig et al., 1991). Lynn and Chang (1990) hypothesized that flavonoids released by plants could be catabolized by symbiotic *Rhizobia* species by removal of the B ring, thus becoming simple benzoquinones. They observed a similar phenomenon existing in the parasitic plant *Striga*, which converts the flavanone hesperitin to a benzoquinone. However, 5,7-dihydroxysubstituted flavones such as chrysin and luteolin (Figure 1), which have been shown to promote the growth of several *Rhizobium* species, would be converted to DHC rather than benzoquinones by removal of the B ring.

The purpose of this study was to examine the effects of DHC on the growth of *Bradyrhizobium* sp., two soil pathogenic fungi of peanut (*R. solani* and *S. rolfsii*), and several plant species in order to explore possible roles of DHC in regulating the soil microenvironment surrounding peanut shells.

METHODS AND MATERIALS

Synthesis of 5,7-Dihydroxychromone. DHC used in experiments was prepared by chemical synthesis by the method of Spencer (1991), and confirmed to be identical with DHC obtained from the extraction of peanut shells by the method of Spencer and Tjarks (1985). Synthesized rather than extracted DHC was used because of the difficulty in extracting sufficient amounts of naturally occurring DHC for experiments. The structure of naturally occurring and synthetic DHC was confirmed by gas chromatography–mass spectrometry (GC-MS) and nuclear magnetic resonance (NMR) spectroscopy.

Bradyrhizobium Bioassays. A bacterial culture of *Bradyrhizobium* sp. (NRRL #B-14192) symbiotic with peanut was obtained from the culture collection at the USDA, ARS, National Center for Agricultural Utilization Research, Peoria, Illinois. Bacteria were maintained on a solid maintenance medium and transferred to a minimal liquid medium for experiments. Both the maintenance and minimal media were slight modifications of those of Hartwig et al. (1991) and contained the following constituents (milligrams per liter): KH_2PO_4 (300); K_2HPO_4 (300); $MgSO_4 \cdot 7H_2O$ (100); $CaCl_2 \cdot 2H_2O$ (5); H_3BO_3 (15); $ZnSO_4 \cdot 7H_2O$ (2); $CuSO_4 \cdot 5H_2O$ (1); $MnCl_2 \cdot 4H_2O$ (0.5); $Na_2MoO_4 \cdot 2H_2O$ (0.1); $FeCl_3 \cdot 6H_2O$ (0.1); biotin (1); thiamine HCl (1); and calcium pantothenate (1). The solid maintenance medium additionally contained 2.5 g/liter yeast extract and 15 g/liter agar. The liquid minimal medium contained 2.5 g/liter NH_4NO_3

and lacked the yeast extract and agar. In both cases, the carbon source was mannitol, at either 1.0 or 10.0 g/liter. Growth experiments were conducted with 6 ml of minimal medium in 50 ml sidearm culture flasks kept at 28°C. Growth of the bacteria was monitored spectrophotometrically by absorbance at 600 nm (A_{600}). DHC, chrysin, and luteolin were added to autoclaved medium by diluting 60 μl of filter-sterilized methanol stock solutions into the medium after cooling to approximately 70°C, which prevented chemical degradation of the flavonoids. Sixty microliters of methanol without compounds was added to controls, and the open flasks were allowed to cool to room temperature in a laminar flow hood. Cells in early log growth phase were added to the medium to give A_{600} values between 0.050 and 0.060, corresponding to approximately 10^7 viable cells/ml for *Bradyrhizobium*. Experiments were conducted three times with three replicate flasks per treatment.

Fungal Bioassays. Cultures of *R. solani* and *S. rolfsii* isolated from and pathogenic on peanut were obtained from Dr. T. Brenneman, University of Georgia. Both fungi were maintained on, and experiments conducted with, ATCC medium 343 (Jong and Gantt, 1987), pH adjusted to 5.8. Appropriate amounts of stock solutions of DHC in methanol were added to cooled ATCC 343 medium in 9.0-cm plastic Petri dishes. Experiments were initiated by placing 7-mm plugs taken from the growing margins of week-old cultures mycelial side down on the appropriate medium. Radial growth of the cultures was measured by taking average values calculated from several points taken from the edge of the inoculum disk to the growing margin of each plate when the fastest-growing culture reached the edge of the culture plates. Treatments were reported as percentages of the untreated control. Each experiment consisted of 10 plates per treatment per fungus and was repeated. I_{50} values (the concentrations of DHC required to give 50% radial growth inhibition) were calculated from the graphed results.

Seedling Radicle Elongation Bioassay. Peanut (cv. Red Tennessee), corn (cv. DeKalb IL 645-786), wheat (cv. Cardinal), and velvetleaf (purchased from Valley Seed Service, Fresno, California) seed were surface disinfected with 10% Clorox for 15 min, after which they were rinsed with and then soaked in sterile distilled water for 2 hr. Seeds were wrapped in sterile paper towels saturated with water and incubated overnight in darkness at 25°C. DHC stock solutions in methanol were added to autoclaved water agar (0.6% w/v) at ~70°C (controls contained only methanol) and placed in 9.0-cm-square plastic Petri dishes. Five germinated seedlings were removed from the wet paper towels and placed on the agar in the Petri dishes, and the dishes were incubated in darkness at 25°C on 45° slants. The growth of the radicles was measured after 48 hr, and I_{50} values were calculated from the graphed results.

RESULTS AND DISCUSSION

Effect of DHC and Flavonoids on Bradyrhizobium Growth. Bradyrhizobium sp. growth was initially inhibited by 10 μM DHC when the bacteria were grown in the low (1.0 g/liter) mannitol medium (Figure 2A) but not in the high (10.0 g/liter) mannitol medium (Figure 2B). Chrysin and luteolin in both mannitol concentrations promoted bacterial growth after 48 hr (and after 96 hr in the high mannitol medium), but by 120 hr there were no significant differences between treatments. These results differ from those of Hartwig et al. (1991), who found that in 1.0 g/liter mannitol medium *R. meliloti* growth was promoted to a greater extent by the addition of flavonoids than with 10.0 g/liter mannitol medium. Perhaps with this *Bradyrhizobium* species DHC inhibited sugar utilization and hence produced the slower growth at the lower mannitol level. The lack of promotion of growth by DHC for *Bradyrhizobium* cultures compared to chrysin and luteolin is not surprising, as DHC has only been reported in peanut shells

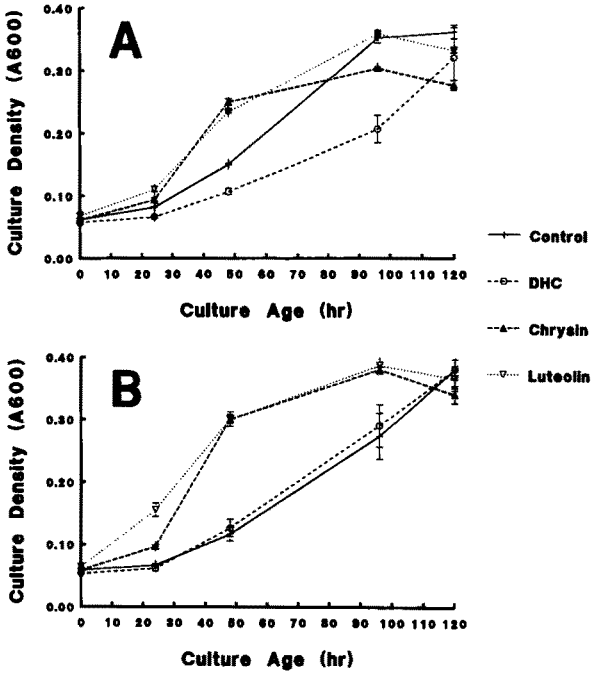


FIG. 2. *Bradyrhizobium* sp. growth with (A) 1.0 g/liter mannitol as the carbon source or (B) 10.0 g/liter mannitol. Vertical bars represent ± 1 SE.

and not in seeds or seed coats. Other growth-promoting flavonoids have been found in seed and seed coats of other legume species as well as closely related flavonoids such as 5,7-dimethoxyisoflavone (Daigle et al., 1985; Turner et al., 1975) and dihydroquercetin (Pratt and Miller, 1984).

Fungal Bioassays. DHC mildly suppressed both *R. solani* and *S. rolfsii* cultures at 5 and 10 μM concentrations and was fungicidal at 100 μM (Figure 3). I_{50} values for *R. solani* and *S. rolfsii*, calculated from the graphed results, were 18 and 26 μM, respectively. This fairly high toxicity towards both species is surprising when compared to the data of DeLucca et al. (1987), who found no significant decrease in the dry weights of mycelial mats of *Aspergillus parasiticus* after 14 days incubation on medium containing 61 μM DHC. However, these authors found that aflatoxin production was markedly decreased by DHC, to a greater extent than either luteolin or the related flavonoid eriodictyol, which are also found in peanut shells. Perhaps *A. parasiticus*, which is also a post-harvest pathogen, has a much higher tolerance to DHC than do either *R. solani* and *S. rolfsii*, which primarily attack the underground structures of the peanut plant prior to harvest. The reported I_{50} for the phytoalexin 2-(4-hydroxyphenoxy)-5,7-dihydroxychromone, found in *Cassia obtusifolia* leaves infected with *Alternaria cassiae*, was 300 μM, over 10 times the levels required to inhibit *R. solani* and *S. rolfsii* (Sharon et al., 1992). However, in this case the authors noted that levels of up to 3 mM were detected in infected leaves, so that sufficiently inhibitory concentrations were reached *in vivo*. The total amount of DHC reported in peanut shells by Pendse et al. (1973) of 0.02% and in the present study (0.023% w/w; data not shown) would correspond to roughly 1 mM based upon average fresh weights of the extracted shells. Although the long-term stability of DHC in the soil is not known, it is moderately water soluble, so that localized concentrations of DHC much higher that the I_{50}s found in these experiments could occur in the rhizosphere surrounding peanut shells.

Seedling Bioassays. DHC affected the elongation of seedling radicles in all

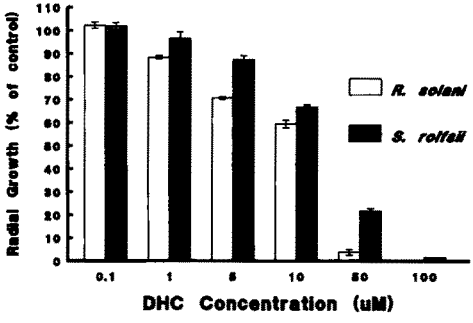

FIG. 3. Inhibition of fungal growth by DHC. Bars represent ± 1 SE.

species tested (Figure 4). Velvetleaf was the most sensitive species tested, with an I_{50} value of 30 μM, while wheat was the most tolerant, with an I_{50} of 200 μM. Corn and peanut had similar I_{50} values of 50 and 65 μM. Somewhat surprisingly, peanut radicle elongation was inhibited to a greater degree at 10^{-4} M DHC than wheat, even though wheat was the only species tested that was completely inhibited by 10^{-3} M DHC. Because DHC is present naturally in peanut, it would be expected that it would be fairly tolerant to the compound. Some aspect of lipid metabolism would appear to be a possible active site for toxicity to DHC, as peanut, corn, and velvetleaf are species that rely primarily on lipid metabolism during germination while wheat utilizes stored carbohydrate.

This study demonstrates that DHC possesses activity against certain soil fungal and plant species at concentrations lower than have been found in intact peanut shells. Because the main role of the peanut shell is to protect the seeds during development and dormancy under the soil, some antifungal activity by DHC, especially against soil pathogens, was expected. Siqueira et al. (1991) reported that flavonoids related chemically to DHC had a significant impact on plant-soil organism relationships. However, depending on the particular organism, similar concentrations of other 5,7-dihydroxysubstituted flavonoids have been shown to be either inhibitory or stimulatory. Quercetin and myricetin at 10 μM promoted hyphal growth of the mycorrhizal fungus *Gigaspora margarita*, while apigenin inhibited growth and luteolin had no effect (Poulin et al., 1993). This concentration of quercetin and luteolin slowed the growth of the alfalfa pathogens *Pythium irregulare* and *P. ultimum* (Hartwig et al., 1991).

The present data, coupled with related studies, furnish strong evidence for implicating DHC and other flavonoids in the regulation of rhizosphere ecology. From a more practical standpoint, the relatively high toxicity of DHC towards soil pathogens in our tests and in related research indicate that breeding for

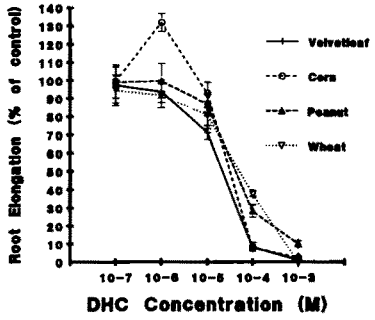

FIG. 4. Inhibition of seedling radicle elongation by DHC after 48 hr treatment. Vertical bars represent ± 1 SE.

increased DHC levels in peanut shells may be desirable for increased disease resistance and the reduction of mycotoxins during storage.

EXTRACTION OF PHENOLIC COMPOUNDS FROM FRESH LEAVES: A COMPARISON OF METHODS

SYLVIA D. TORTI,* M. DENISE DEARING, and THOMAS A. KURSAR

201 South Biology
University of Utah
Salt Lake City, Utah 84112

(Received June 10, 1994; accepted October 17, 1994)

Abstract—The conventional sonicator/shaker bath method for phenolic extraction was compared with a less traditional one using a homogenizer. The homogenizer proved to be both more efficient and consistent in extracting phenolics from tender, as well as tough, leaves. We propose that adoption of the homogenizer technique will increase phenolic yield and efficiency.

Key Words—Extraction, phenolics, homogenizer, *Ouratea lucens*, *Acomastylis rossii*, tannin, sonicator.

INTRODUCTION

Phenolics are carbon-based compounds present in many plants. They are of general interest because of their wide-ranging ecological effects from the organism to ecosystem level (Appel, 1993). They are perhaps most noted for their ability to bind to proteins in vitro, forming soluble and insoluble complexes (Goldstein and Swain, 1965; Feeny, 1976; Hagerman and Butler, 1980; McManus et al., 1981; Hagerman and Klucher, 1986; Hagerman and Robbins, 1987). These phenolic–protein interactions are thought to be, in part, responsible for the putative function of phenolics as plant defense compounds (Feeny, 1976; Rhoades and Cates, 1976; Coley, 1983; Mole and Waterman, 1987).

To explore any of the several hypotheses in which phenolics play a prominent role, e.g., plant defense theory, phenolic quantification is often necessary. Numerous researchers have investigated various phenolic assays (Peri and Pom-

pei, 1971; Hagerman and Butler, 1980, 1989; Mole and Waterman, 1987; Wisdom et al., 1987; Mole et al., 1989), appropriate standards (Hagerman and Butler, 1989) and extraction solvents (Hagerman, 1988). To our knowledge, no studies have systematically investigated the extraction technique itself.

Conventional methods typically involve reducing the plant material into smaller particles using liquid nitrogen and a mortar and pestle. The pulverized plant material is then extracted in a solvent, and the extraction is enhanced by using a sonicator or shaker bath. This step is repeated several times (Hagerman, 1988; Hagerman and Butler, 1989). Our extraction method differs from the conventional method in the use of a homogenizer to facilitate the release of phenolics instead of several sonicator/shaker bath extractions. We propose that the homogenizer method is superior to that of the sonicator/shaker bath technique in both accuracy and efficiency of extraction. Moreover, we predict that this difference will be most pronounced in plants with tough, fibrous leaves, as the thicker cell walls should further hinder extraction by conventional methods.

METHODS AND MATERIALS

We chose two species of plants that differ in leaf toughness: *Acomastylis* (*Geum* Ser.) *rossii* (R.Br.) Greene (Rosaceae), a temperate alpine plant with relatively tender leaves, and *Ouratea lucens* Engl. (Ochnaceae), a tropical species with tough leaves. Toughness was estimated from the amount of mass required to force a 5-mm-diameter rod through leaf material and is correlated with fiber content (Coley, 1983). Toughness was measured directly on *O. lucens*, and is 500 g (Kursar, unpublished data). It was impossible to directly measure toughness on *A. rossii* leaves because they are highly dissected. However, we calculated *A. rossii*'s toughness from its acid detergent fiber (ADF) content (Dearing, unpublished data), using an equation obtained by Coley (1983), who regressed toughness on ADF content for 46 species. Her equation is $y = 11.95x + 77.5$, where y is toughness in grams and x is percent ADF content ($r^2 = 0.32$, $P < 0.01$). The estimated toughness of *A. rossii* is 220 g, which is representative of a very nontough species.

A. rossii leaves were harvested in August 1993 and kept at −70°C until the day of the experiment. *O. lucens* was freshly harvested from the University of Utah greenhouse and immediately put on Dry Ice.

General Leaf Preparation. Major veins were removed with a razor and the leaf fragments were cut into small pieces. The leaf fragments were further ground under liquid nitrogen using a mortar and pestle. Grinding in liquid nitrogen was necessary for both techniques. A subsample was weighed, dried at 50°C, and reweighed to obtain the dry weight/wet weight ratio.

Extraction. Samples of ground leaves were simultaneously subjected to both extraction techniques three separate times (trials 1–3). Wet weight samples of powdered leaves, approximating 0.1 g dry weight, were extracted first with 25 ml of 85% MeOH (extract A). Each sample was extracted three successive times with 10 ml 85% MeOH (extracts B, C, and D).

Phenolics were extracted by using either a Di Sontegrator (Ultrasonic Industries Inc.) sonicating bath followed by shaking in a standard shaker bath, or a Brinkmann Homogenizer Polytron 10/35, equipped with a PTA 10 TS generator with saw teeth (Brinkmann Instruments, Inc.). For the conventional extraction, test tubes with ground leaves and solvent were placed in a sonicator at 4°C. Tubes were removed after 30 min and centrifuged at 16,000*g* for 15 min at 4°C. The supernatant volume was measured, and 1 ml was saved for phenolic analysis (extract A). The pellet was resuspended in 10 ml solvent, vortexed and placed in a shaker bath at 4°C at high speed for 30 min. The sample was centrifuged as described above, the supernatant was measured, and again 1 ml was saved (extract B). This was repeated two more times, for a total of four extracts (A–D). Extracts were stored in a freezer (−5°C) in the dark until the phenolics analyses were conducted.

The plant material was extracted by using the homogenizer for 60 sec at maximum speed. Homogenization for 60 sec slightly warms but does not greatly raise the temperature of the solvent. The test tubes were then centrifuged at 16,000*g* for 15 min at 4°C, after which the supernatant was removed, measured, and 1 ml was saved for phenolic assaying (extract A). For the subsequent extracts (B–D), the pellet was resuspended by vortexing with 10 ml of 85% MeOH. The samples were centrifuged between extractions as described above.

To determine whether the homogenization extraction procedure was exhaustive, we passed samples through a French press (Aminco, SLM Instruments Inc.). Because the plant material must be ground extremely fine for use in the French press, more than that which is possible with a mortar and pestle, we first extracted the plant material by homogenization as described above. After the four extractions, the pellet was then resuspended in 15 ml of 85% MeOH and passed once through the French press at 21 MPa. This machine imparts a force of 21 MPa on sample material, which causes the rupture of all cells (Milner et al., 1950). The French press extracts were then analyzed for phenolics.

Phenolics Assay. Extracts were assayed within one week of extraction. Sonicator/shaker bath and homogenizer samples that had been extracted on the same day were assayed at the same time. Extracts A–D were assayed individually for total phenolics using the Folin-Ciocalteu method (Singleton and Rossi, 1965). The amount for each extract was combined (A + B + C + D) for an absolute quantity of phenolics/sample. Tannic acid was used as the standard (Sigma lot #1764 KCNT).

RESULTS

The homogenizer extracted significantly more phenolics for all extracts combined (A–D) than did the sonicator/shaker bath method. This difference was consistent for both plant species tested (Randomized complete block, blocking on trial: *A. rossii*, method F = 94.91, $P < 0.0001$, $df = 1, 20$; block F = 14.43, $P < 0.0001$, $df = 2, 20$; *O. lucens*, method $F = 30.53$, $P < 0.0001$, $df = 1, 20$; block $F = 8.61$; $P < 0.002$, $df = 2, 20$; Figure 1). The sonicator/shaker bath technique extracted only three quarters of the total amount of phenolics extracted by the homogenizer (*A. rossii*, 74.6% ± 5.2 and *O. lucens*, 68.0% ± 9.0, Figure 2). In addition, for both species we found three to four times less variability among samples using the homogenizer technique (Table 1).

Results from the analysis for absolute phenolic quantity in samples extracted after using the French press show zero phenolics for one sample of *A. rossii*, negligible phenolics for the other sample (0.06% of total), and no remaining phenolics for the two *O. lucens* samples. Hence, we are confident that the higher yields extracted using the homogenizer represent virtually all extractible plant phenolics detectable by the Folin-Ciocalteu assay.

Interfraction Comparison: Extracts A–D. The percent of the total extracted per extraction (A–D) for the two methods was compared. Because the homogenizer extracted all phenolics, this amount is used as the denominator for the sonicator extracts. We found that for both species, the homogenizer removed significantly more phenolics in the first extraction than did the sonicator and that this difference diminished, and even reversed, in successive extractions (Figure 2). The homogenizer extracted virtually all phenolics with only one extraction, while even with four extractions, the sonicator had not always extracted a comparable amount of phenolics. In the initial extraction of *A. rossii* leaves, the homogenizer extracted 93.8% of the total extractible phenolics, whereas the sonicator/shaker bath extracted only 38.7% (Figure 2). The difference in the extraction efficiency of the two techniques was similar in *O. lucens*; the homogenizer extracted 99.2% of the total phenolics in the initial extract and then negligible amounts in subsequent extractions. The sonicator/shaker bath extracted only 45.5% of the total in the initial extract. In both species, the homogenizer pellet additionally released only small amounts of phenolics in subsequent extractions (B–D), while the sonicator/shaker bath consistently yielded more phenolics in these extracts (Figure 2).

DISCUSSION

Our results show that the homogenizer technique extracts totally more phenolics, with less variability, than the sonicator/shaker bath technique. Moreover, extraction time for the same number of samples (up to eight) with four extrac-

	A. rossii (tender leaves)	*O. lucens* (tough leaves)
Homogenizer	1.9 (0.9)	6.7 (4.1)
Sonicator	9.2 (3.5)	20.4 (8.4)

[a] Average coefficient of variation for three trials plus one standard error.

tions per sample is much shorter using the homogenizer technique: 1 hr 10 min for the homogenizer vs. 3 hr for the sonicator/shaker bath. The number of extractions for the homogenizer technique can be reduced further to two extractions, with no decline in accuracy, as the third and fourth extractions are superfluous, yielding negligible phenolics. Thus, total extraction time using the homogenizer requires approximately 40 min, which represents a considerable time savings over the 3-hr sonicator/shaker bath technique.

Those familiar with the sonication method may initially conclude that the homogenizer is less efficient for large numbers of samples than the sonicator. It is important to note that the number of samples that can be processed using the sonication method is not infinite. The sonication method may be limited by either the sonicator or centrifuge size. Furthermore, even if neither the sonicator nor the centrifuge is restricting, measuring the supernatant after centrifugation can become tedious with sample sizes greater than 20. We suggest grinding be done in subsamples as numerous as the centrifuge will allow and that other subsamples are ground while the first set of subsamples are spinning in the centrifuge. Thus, large sample sizes, i.e., 20, can be managed using the homogenizer with little increase in total time.

The dramatic differences between the two techniques can be partly attributed to the different modes of action of the machines used in the extractions. Several compounding factors contribute to the variability and inefficiency of a sonicating bath. First, ultrasonic waves are effective at emulsifying lipids and are typically employed to break up the lipid membrane surrounding bacteria and animal cells. However, the lipid membrane of a plant cell is encased within a rigid, fibrous cell wall that is probably more resilient to ultrasonic waves. Thus, sonication effectiveness is likely to be dependent on the extent of cell wall damage during mortar and pestle grinding. Moreover, the ultrasonic waves in a sonicating bath are typically not focused or uniform; thus, some samples may receive more sonication than others. In practice, sonicating probes, not baths, are employed to disrupt cells, as probes better focus the sound waves within the sample, while sonicating baths are typically used for cleaning surfaces. Given these considerations, the appropriateness of the sonicating bath for the purpose

of rupturing plant cells is questionable. Cork and Krockenberger (1991) found no difference in extraction yield when a shaker bath was substituted for a sonicator. In addition to these technical drawbacks, the long extraction period (3 hr) may further reduce yield due to phenolic oxidation during the extraction itself.

The superiority of the homogenizer is partially due to its efficacy in breaking down cell walls. The joint action of the partial vacuum created by the homogenizer and the tearing by the saw tooth generator serve to break the cell walls of plant leaves in a way in which a sonicating bath cannot. This difference is obvious in the appearance of the ground leaves. The initial extractions prepared in the homogenizer are bright green in color, while first extractions from the sonicator are much lighter green.

Contrary to our prediction, there was no major difference in extraction efficiency with respect to leaf toughness. The sonicator/shaker bath extracted approximately 75% of all phenolics, regardless of leaf toughness. The homogenizer consistently extracted all detectable phenolics in both tender and tough leaves. Furthermore, the pattern of extraction was similar with both fresh and frozen leaves.

CONCLUSION

We propose that the efficiency and accuracy of phenolic extraction can be enhanced by the utilization of the homogenizer method. The adoption of this device may be beneficial for extractions of other types of phenolics as well and should facilitate investigations in the area of plant defense.

Abstract—Leaves of two highly aromatic plants, *Artemisia tridentata* (Nutt.) and *Monarda fistulosa* L., prepared according to a patented process, inhibited oviposition by the Mexican bean weevil, *Zabrotes subfasciatus* (Boheman), in beans at concentrations less than 1% w/w. Both plant species were less effective against the rice weevil, *Sitophilus oryzae* L., in wheat, with only *M. fistulosa* exhibiting any concentration-dependent activity. The maximal control achieved against this species was less than 50% at 3% w/w. Two less aromatic plant species, *Balsamorhiza sagittata* (Pursh.) Nutt. and *Geranium viscosissimum* Fisch. and Mey., caused only low levels of inhibition against both insect species. Volatiles probably caused the response to *A. tridentata* and *M. fistulosa*, while the asymptotic concentration dependence for the less volatile plant material was likely caused by behavioral factors related to the physical presence of foreign particulate matter in the foodstuff. Chemical analysis indicated that most of the volatile components from the dried leaf

INTRODUCTION

Many plant species are known to contain phytochemicals that may protect them against herbivory, and farmers have historically used such plants to protect stored foodstuffs from insects. Aromatic plants, those yielding a pungent odor from essential oils after crushing, are noted for insecticidal activity (e.g., Duke, 1990). For example, the wild mint species *Ocimum canum* Sims has been used as a protectant for stored beans in Rwanda (Dunkel et al., 1986) and for groundnuts in the Congo (Delobel and Malonga, 1987). The volatile terpene alcohol linalool is predominant in *O. canum* leaves and acts as a potent insecticide against several species of stored-product insects (Shaaya et al., 1991; Weaver et al., 1991, 1994). Crude plant materials used as protectants against pest insects are usually locally available aromatic plants, and their use has a long history. Insecticidal activity of plants that lack a history of such use has been little tested.

Here we examine the possibility that Rocky Mountain aromatic plants might protect against two species of stored-product insects. We tested four plant species that were relatively free of damage by insect herbivores, but for which there was no prior knowledge about their protectant activity. Two highly aromatic species, wild bergamot, *Monarda fistulosa* L. (Lamiaceae), and big mountain sagebrush, *Artemisia tridentata* (Nutt.) (Compositae), and two less aromatic species, arrowleaf balsamroot, *Balsamorhiza sagittata* (Pursh.) Nutt. (Compositae), and sticky geranium, *Geranium viscosissimum* Fisch. and Mey. (Geraniaceae), were investigated. Specific objectives were: (1) to determine if an admixture of powdered material, prepared according to a patented process, from these species could protect stored beans and wheat from infestation by two species of stored-product beetles, and (2) to determine chemical composition of volatiles extracted from these plant species.

METHODS AND MATERIALS

Plant Material. Material was collected from plants growing in a foothill *Artemisia tridentata–Festuca idahoensis* community (Mueggler and Stewart, 1980) on June 27, 1991. All four species were collected at an altitude of 1550 m on a southwestern facing slope in T2S, R4SW, approximately 8 km northeast

of Bozeman, Montana, USA. Representative leaves were harvested in a random pattern from most individuals in the stand (dozens to hundreds of individual plants). The materials collected included petioles, but main stems were removed. Samples were dried <3 hr after harvest, at 52°C for 72 hr. Intact leaves were then stored under dry N_2 at −20°C in sealed glass containers until use. Voucher specimens were deposited in the Montana State University Herbarium on July 10, 1991 as: *Balsamorhiza sagittata*, voucher F. Dunkel #2, *Artemisia tridentata*, voucher F. Dunkel #3; *Monarda fistulosa*, Voucher F. Dunkel #4; and *Geranium viscosissimum*, Voucher F. Dunkel #5.

Insect Culture. Protectant material was tested against two insect species, a cosmopolitan pest of stored beans, *Zabrotes subfasciatus* (Coleoptera: Bruchidae) (*Boheman*) and a severe cosmopolitan pest of stored grains, *Sitophilus oryzae* L. (Coleoptera: Curculionidae). Both species develop within the seed kernel. *Z. subfasciatus* is short-lived and nonfeeding in the adult stage. Eggs are firmly attached to the bean surface and the larva bores directly into the bean from within the egg. *S. oryzae* is long-lived and feeds as an adult. Females chew a small hole in the host grain, deposit a single egg, and seal the hole with a mucilaginous plug. *Z. subfasciatus* was reared on a diet of dried pinto beans, and *S. oryzae* was reared on a diet of soft white wheat. Cultures were maintained in 0.95-liter jars containing 0.6 liters of commodity and held in 27 ± 1°C incubators maintained at 65 ± 5% relative humidity with a 12L:12D photoperiod. *Z. subfasciatus* cultures were inoculated with approximately 300 adult bruchids, and *S. oryzae* cultures were inoculated with approximately 100 adult weevils. Cultures were discarded after the emergence of two subsequent generations. Both species had been maintained in the laboratory for many years.

Bioassay. Leaves were prepared according to a patented process (Dunkel et al., 1994). This material was added to the commodity to yield concentrations of 0.1, 0.2, 0.3, 1.0, and 3.0% w/w. For *Z. subfasciatus*, the processed leaf material was mixed with 20 g of pinto beans (equilibrium moisture content 14.4%) in a washed 10-dram plastic shell vial, while for *S. oryzae*, the material was added to 1 g of equilibrated soft white wheat (moisture content 12.9%) in a similar vial. There were 10 replicates of each dosage and 12 of the control for *Z. subfasciatus*, while there were eight replicates of each dosage and the control for *S. oryzae*. Five males and five females were added to each vial. The *Z. subfasciatus* were zero to one day after adult emergence and the *S. oryzae* were four to nine days after adult emergence. Incubation conditions were similar to those for culture maintenance. Hatched and unhatched eggs of *Z. subfasciatus* were counted at 25 days and live and dead progeny adults were counted at 55 days. For *S. oryzae*, adults were removed at seven days, and the immature insect cohorts were incubated for a further seven days and then frozen. Wheat kernels were soaked in 70% ethanol (w/w in distilled H_2O) for 2 hr and then immersed in 15 mg/ml malachite green in absolute ethanol for 15 min. This

selectively stained the egg plugs, facilitating dissection of the wheat to determine egg viability. The adult *S. oryzae* were sexed according to the Halstead (1963) method. Postmortem sexing was superior to live determination and thus resulted in elimination of some replicates. The high densities of pests used in our experiments resulted in suboptimal reproduction. The staining and counting methods were limiting, which is reflected in the experimental design. Therefore, low level treatment effects may have been obscured if density-stressed females oviposited in available resources, even when marginally suitable.

Statistical Analyses. Data from the experiments were fitted to three equations of biological relevance. These were: (1) the logistic dose–response transition equation, $y = a + \{b/[1 + (x/c)^d]\}$ with a and b being constants for this data set, (2) an asymptotic equation, $y = a + b/x$, and (3) a linear equation $y = a + b(\ln x)$. For these experiments $x = \log_{10}$ (concentration) + 0.02. Analyses were performed with PROC NLIN or PROC REG (SAS Institute, 1988). Tests for a significant effect of plant species within asymptotic data sets for a particular insect (with the common control data deleted) were conducted with PROC GLM (SAS Institute, 1988), and evaluations of a significant concentration effect on the same data sets were conducted using PROC REG (SAS Institute, 1988).

The data collected from these experiments follow a "many y for each x" pattern. Thus, it is difficult to determine how well the regression equation describes the data with its innate variability. This is an important and measurable component of the percentage variation explained (r^2) and can be used to calculate the maximum r^2 possible, that is, the greatest amount of the total variation that can be explained by any model given the inherent variation, or pure error, in the data. The equation used is Max r^2 possible = $(SS_{\text{corrected total}} - SS_{\text{pure error}})/SS_{\text{corrected total}}$ (Draper and Smith, 1981). This equation has been suggested for the percentage variation explained for linear equations, for which it is exact, but it also provides useful descriptive information for the approximate percentage variation explained for nonlinear equations (Bates and Watts, 1988). The models were subjected to lack-of-fit tests ($\alpha = 0.1$) prior to evaluation of the significance of the regressions themselves (Draper and Smith, 1981; Bates and Watts, 1988).

Extraction and Analysis of Plant Volatiles. Five grams of the processed material from each plant were extracted separately in 50 ml of 1:4 isopropanol:hexane (both HPLC grade) and 1.33 mg of *n*-decane was added as an internal standard. The crude extracts were subjected to a purification procedure using flash column chromatography on a 1.9-cm-diameter × 10-cm column packed with TLC grade MgO using 125 ml of the extraction solvent. Samples were then concentrated under cool N_2 to approximately 3 ml and then were subjected to a second flash chromatography procedure on a 1.0-cm-diameter × 12-cm column packed with TLC grade MgO using 50 ml of the extraction solvent.

The samples were evaporated under cool N_2 to near dryness and then resolvated in 1.5 ml of HPLC-grade hexane.

Extracts were subjected to gas chromatographic (GC) analyses on two separate instruments. Initial inspection of the extracts and ultimate quantification of volatiles were done on a Hewlett Packard 5890 GC equipped with a flame ionization detector (FID). The column used was a 30-m × 0.252-mm-ID DB-1 with 0.25-μm film thickness (J & W Scientific, Folsom, California); He flow was 1 cm/sec. The injector was set at 225°C, the detector at 280°C, and the column oven programmed at 60°C for 30 sec, then increased to 270°C at 10°C/min, and held at 270°C for 20 min. The injector purge was operated in split mode throughout. Output went to a Hewlett Packard 3392A integrator recorder, and quantities of detected compounds were calculated by comparison of the area under the decane peak with areas under sample peaks. GC–mass spectrometric (GC-MS) analyses were made using a Shimadzu GC-14A coupled to a Finnigan model 800 series Ion Trap Detector with an ionizing voltage of 70 eV. The injector oven was set at 230°C and the heated transfer line to the MS was set at 265°C. The column used was also a 30-m × 0.252-mm DB-1 with 0.25-μm film thickness, temperature programmed at 40°C for 30 sec, then 20°C/min to 60°C, held for 1 min, then increased to 280°C at 10°C/min, and held at 280°C for 20 min. Injection was made with the splitter closed initially, but then opened at 30 sec. The MS was operated in the full-scan mode, ranging from 35 to 350 amu at 1 scan/sec. Tentative identifications were made by matching background-subtracted sample spectra with those in the National Bureau of Standards mass spectral library and with those in the terpene library of Adams (1989) using the Finnigan ITDS software. Confirmation of library matches was made when possible by matching retention time and spectra of authentic samples.

RESULTS

The bioactivity of the powdered material from all four plants varied against the two stored-product pests. *Z. subfasciatus* was more susceptible to the more aromatic plant species than *S. oryzae*. Both *M. fistulosa* and *A. tridentata* completely prevented reproduction of *Z. subfasciatus* at higher concentrations (Figures 1–3), with no oviposition occurring above 1.0% w/w. The activity of *M. fistulosa* was much higher, with 80% inhibition of oviposition occurring at the lowest concentration tested (0.1% w/w). The concentration-dependent activity of both more aromatic plant species was similar within each plant for all three biological variables, although the decrease in beans exploited (Figure 1) was lower at low doses than the decrease in eggs hatched (Figure 2) or the decrease in progeny adult emergence (Figure 3). In contrast, both *B. sagittata* and *G. viscosissimum* caused clear asymptotic inhibition of biological productivity, with

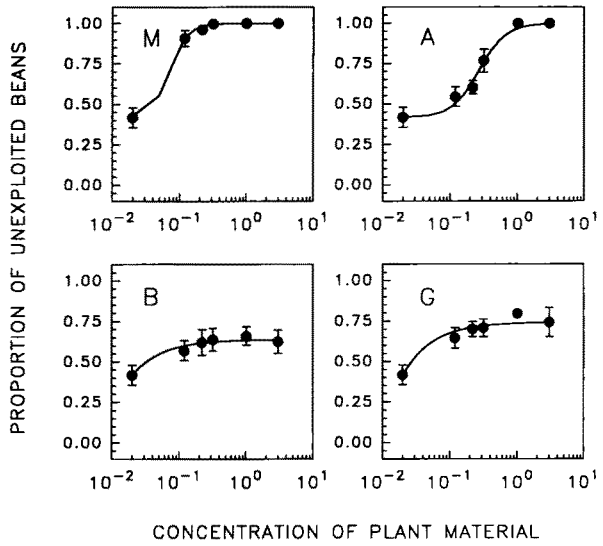

FIG. 1. Mean proportion (±SE) of beans unexploited by *Z. subfasciatus* as influenced by increasing concentration of plant material. Plant species: M, *Monarda fistulosa*; A, *Artemisia tridentata*; B, *Balsamorhiza sagittata*; G, *Geranium viscosissimum*. Concentration units are % (w/w) + 0.02. Regression equations: M, proportion unexploited = $a + b/1 + (\text{concentration}/c)^d$, $a = 0.42$, $b = 0.58$, $c = 0.07$, $d = -3.19$, lack-of-fit $F = 0.39$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.93$, percentage of maximum attainable $r^2 = 100\%$; A, proportion unexploited = $a + b/1 + (\text{concentration}/c)^d$, $a = 0.42$, $b = 0.58$, $c = 0.27$, $d = -2.19$, lack-of-fit $F = 1.65$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.88$, percentage of maximum attainable $r^2 = 99\%$; B, proportion unexploited = $a + b/(\text{concentration})$, $a = 0.64$, $b = -0.0045$, lack-of-fit $F = 0.42$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.39$, percentage of maximum attainable $r^2 = 95\%$; G, proportion unexploited = $a + b/\text{concentration}$, $a = 0.74$, $b = -0.0067$, lack-of-fit $F = 1.59$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.62$, percentage of maximum attainable $r^2 = 94\%$.

very limited concentration dependence at doses greater than the control (Figures 1–3). Deletion of the control data gave no significant slope for *B. sagittata* (proportion of unexploited beans: $F = 0.24$, $df = 1, 48$, $P = 0.63$; hatched eggs per female: $F = 2.26$, $df = 1, 48$, $P = 0.14$; progeny adults per female: $F = 0.37$, $df = 1, 48$, $P = 0.55$) or *G. viscosissimum* (proportion of unexploited beans: $F = 3.07$, $df = 1, 48$, $P = 0.09$; hatched eggs per female: $F = 2.50$, $df = 1, 48$, $P = 0.12$; progeny adults per female: $F = 1.04$, $df = 1, 30$, $P = 0.32$), but there was a significant effect of species when comparing the data for the two plants without the common control (proportion of unexploited beans: $F = 21.00$, $df = 1, 99$, $P < 0.001$; hatched eggs per female: $F = 8.77$, $df =$

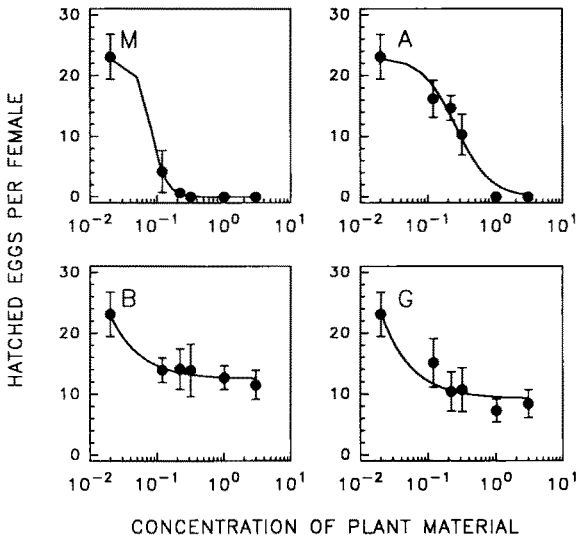

FIG. 2. Mean number (±SE) of hatched eggs per female *Z. subfasciatus* as influenced by increasing concentration of plant material. Plant species and concentration units as indicated in Figure 1. Regression equations: M, hatched eggs per female = $a + b/1 + (\text{concentration}/c)^d$, $a = 0.0$, $b = 23.10$, $c = 0.08$, $d = -3.74$, lack-of-fit $F = 0.012$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.87$, percentage of maximum attainable $r^2 = 100\%$; A, hatched eggs per female = $a + b/1 + (\text{concentration}/c)^d$, $a = 0.00$, $b = 23.10$, $c = 0.27$, $d = -1.71$, lack-of-fit $F = 1.63$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.80$, percentage of maximum attainable $r^2 = 98\%$; B, hatched eggs per female = $a + b/\text{concentration}$), $a = 12.53$, $b = 0.21$, lack-of-fit $F = 0.21$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.40$, percentage of maximum attainable $r^2 = 98\%$; G, hatched eggs per female = $a + b/\text{concentration}$, $a = 9.28$, $b = 0.29$, lack-of-fit $F = 1.76$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.51$, percentage of maximum attainable $r^2 = 92\%$.

1, 99, $P = 0.004$; progeny adults per female: $F = 3.96$, $df = 1, 30$, $P = 0.05$), indicating that the asymptotes are different for the two species.

M. fistulosa was the only plant species that caused concentration-dependent inhibition of oviposition by *S. oryzae* (Figures 5 and 6), although the proportion of grains exploited was asymptotic (Figure 4). In contrast, only asymptotic patterns were evident for the other three plant species. Deletion of the control data gave no significant slope for the remaining data for *A. tridentata* (proportion of unexploited grains: $F = 0.00$, $df = 1, 31$, $P = 1.00$; eggs laid per female: $F = 0.63$, $df = 1, 31$, $P = 0.43$; hatched eggs per female: $F = 0.87$, $df = 1, 31$, $P = 0.36$), for *B. sagittata* (proportion of unexploited grains: $F = 1.60$, $df = 1, 30$, $P = 0.22$; eggs laid per female: $F = 0.03$, $df = 1, 30$, $P = 0.86$;

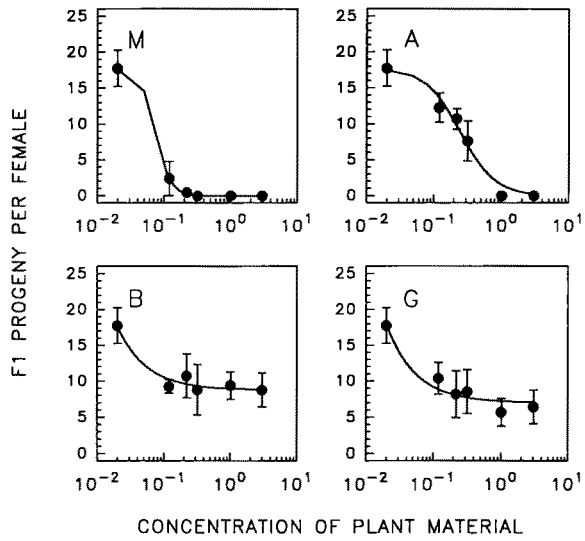

FIG. 3. Mean number (±SE) of progeny adults per female *Z. subfasciatus* as influenced by increasing concentration of plant material. Plant species and concentration units as indicated in Figure 1. Regression equations: M, progeny adults per female = $a + b/1 + (\text{concentration}/c)d$, $a = 0.00$, $b = 17.75$, $c = 0.07$, $d = -3.85$, lack-of-fit $F = 0.023$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.89$, percentage of maximum attainable $r^2 = 100\%$; A, progeny adults per female = $a + b/1 + (\text{concentration}/c)^d$, $a = 0.00$, $b = 17.75$, $c = 0.25$, $d = -1.67$, lack-of-fit $F = 1.53$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.82$, percentage of maximum attainable $r^2 = 98\%$; B, progeny adults per female = $a + b/\text{concentration})$, $a = 8.79$, $b = 0.18$, lack-of-fit $F = 0.42$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.42$, percentage of maximum attainable $r^2 = 98\%$; G, progeny adults per female = $a + b/\text{concentration}$, $a = 7.03$, $b = 0.22$, lack-of-fit $F = 0.87$, $df = 4, 56$, $P > 0.05$, $r^2 = 0.50$, percentage of maximum attainable $r^2 = 94\%$.

hatched eggs per female: $F = 0.65$, $df = 1, 30$, $P = 0.43$), or for *G. viscosissimum* (proportion of unexploited grains: $F = 2.90$, $df = 1, 27$, $P = 0.10$; eggs laid per female: $F = 0.89$, $df = 1, 27$, $P = 0.35$; hatched eggs per female: $F = 1.04$, $df = 1, 27$, $P = 0.32$), but there was a significant effect of species when comparing the data for the three plants without the common control (proportion of unexploited grains: $F = 7.63$, $df = 2, 88$, $P < 0.001$; eggs per female: $F = 21.29$, $df = 2, 88$, $P < 0.001$; hatched eggs per female: $F = 18.18$, $df = 2, 88$, $P < 0.001$), indicating that the asymptotes were different for at least two of the three species.

In general, the predetermined equations showed no significant lack of fit, although certain of the data patterns were quite variable, particularly for *S.*

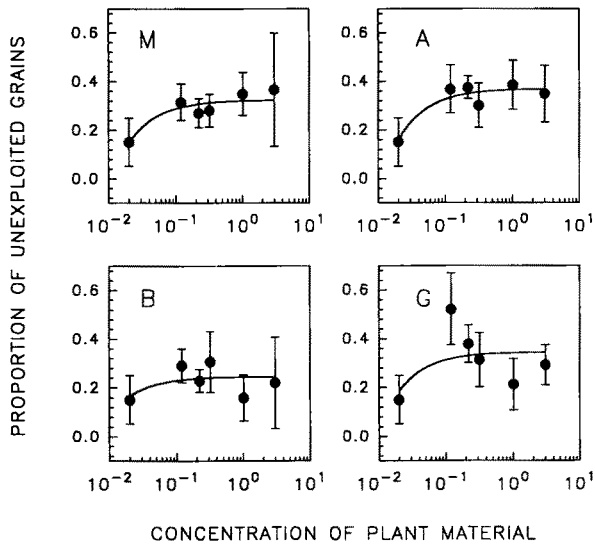

FIG. 4. Mean proportion (±SE) of grains unexploited by *S. oryzae* as influenced by increasing concentration of plant material. Plant species and concentration units as indicated in Figure 1. Regression equations: M, proportion unexploited = $a + b$(ln concentration), $a = 0.32$, $b = -0.0035$, lack-of-fit $F = 0.70$, $df = 4, 30$, $P > 0.05$, $r^2 = 0.24$, percentage of maximum attainable $r^2 = 80\%$; A, proportion unexploited = $a + b$/concentration, $a = 0.37$, $b = -0.0042$, lack-of-fit $F = 0.72$, $df = 4, 32$, $P > 0.05$, $r^2 = 0.25$, percentage of maximum attainable $r^2 = 78\%$; B, proportion unexploited = $a + b$/concentration), $a = 0.25$, $b = -0.0016$, lack-of-fit $F = 2.70$, $df = 4, 31$, $P = 0.05$, $r^2 = 0.05$, percentage of maximum attainable $r^2 = 30\%$; G, proportion unexploited = $a + b$/concentration, $a = 0.34$, $b = -0.0032$, lack-of-fit $F = 5.53$, $df = 4, 28$, $P < 0.005$, $r^2 = 0.11$, percentage of maximum attainable $r^2 = 22\%$.

oryzae. The only exception was the proportion of unexploited grains for *G. viscosissimum* with *S. oryzae*, in which there was a significant lack of fit (Figure 4). A systematic trend for the lower three doses is apparent when viewing the data residuals, but subsequent curve-fitting trials yielded no better fitting, biologically plausible equation. The same trend was not apparent for egg numbers (Figure 5) or hatch (Figure 6), so the equation was retained despite the poor fit, and the data for the lower doses can be treated as logically explainable anomalies (see Discussion).

Total ion current chromatograms of plant extracts are given in Figure 7, and identities and quantities of compounds are given in Table 1. *A. tridentata* contained the largest number of extractable volatiles, primarily terpenoids, with camphor and cineole being most abundant (Figure 7 and Table 1). *M. fistulosa*

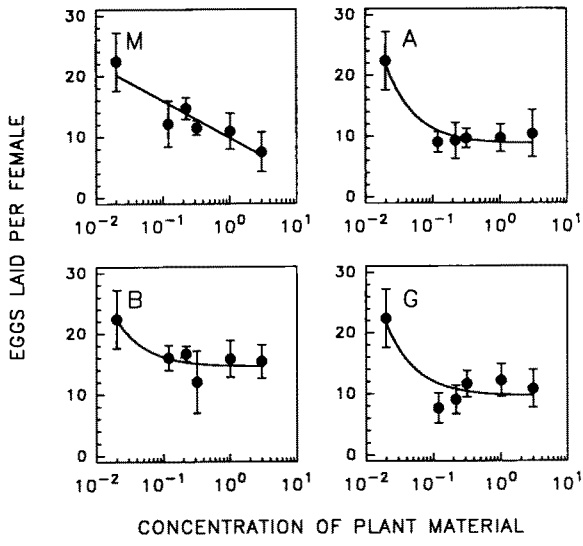

FIG. 5. Mean number (±SE) of eggs laid per female *S. oryzae* as influenced by increasing concentration of plant material. Plant species and concentration units as indicated in Figure 1. Regression equations: M, eggs laid per female = $a + b$(ln concentration), $a = 9.83$, $b = -2.64$, lack-of-fit $F = 1.63$, $df = 4, 30$, $P < 0.05$, $r^2 = 0.44$, percentage of maximum attainable $r^2 = 82\%$; A, eggs laid per female = $a + b$/concentration, $a = 8.73$, $b = 0.26$, lack-of-fit $F = 0.94$, $df = 4, 32$, $P > 0.05$, $r^2 = 0.60$, percentage of maximum attainable $r^2 = 94\%$; B, eggs laid per female = $a + b$/concentration), $a = 14.57$, $b = 0.16$, lack-of-fit $F = 1.06$, $df = 4, 31$, $P > 0.05$, $r^2 = 0.25$, percentage of maximum attainable $r^2 = 74\%$; G, eggs laid per female = $a + b$/concentration, $a = 9.64$, $b = 0.24$, lack-of-fit $F = 0.07$, $df = 4, 28$, $P > 0.05$, $r^2 = 0.52$, percentage of maximum attainable $r^2 = 79\%$.

also contained a substantial number of volatile compounds, with carvacrol being most abundant (Figure 7 and Table 1). The amount of carvacrol extracted from *M. fistulosa* is nearly three times greater than that for the next most abundant compound extracted, camphor from *A. tridentata*. Both *B. sagittata* and *G. viscosissimum* contained limited quantities of volatile material, with germacrene from *B. sagittata* being the only identified compound present in greater than 1 mg/g quantities (Figure 7 and Table 1).

DISCUSSION

The addition of small amounts of plant material from any of the test plant species inhibited the size of the resulting insect population. For the two less aromatic species, no concentration-dependent effects were seen for either pest

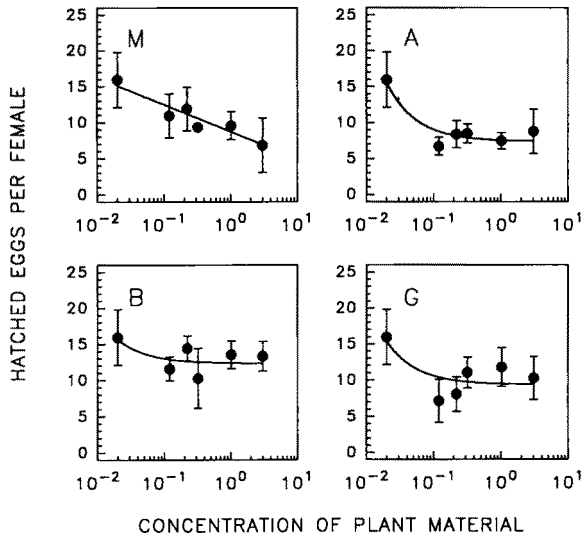

FIG. 6. Mean number (±SE) of hatched eggs per female *S. oryzae* as influenced by increasing concentration of plant material. Plant species and concentration units as indicated in Figure 1. Regression equations: M, hatched eggs per female = $a + b$(ln concentration), $a = 8.78$, $b = 1.63$, lack-of-fit $F = 0.67$, $df = 4, 30$, $P > 0.05$, $r^2 = 0.34$, percentage of maximum attainable $r^2 = 85\%$; A, hatched eggs per female = $a + b$/concentration, $a = 7.42$, $b = 0.17$, lack-of-fit $F = 1.58$, $df = 4, 32$, $P > 0.05$, $r^2 = 0.49$, percentage of maximum attainable $r^2 = 85\%$; B, hatched eggs per female = $a + b$/concentration), $a = 12.34$, $b = 0.067$, lack-of-fit $F = 1.68$, $df = 4, 31$, $P > 0.05$, $r^2 = 0.09$, percentage of maximum attainable $r^2 = 36\%$; G, hatched eggs per female = $a + b$/concentration, $a = 9.38$, $b = 0.12$, lack-of-fit $F = 2.54$, $df = 4, 28$, $P > 0.05$, $r^2 = 0.24$, percentage of maximum attainable $r^2 = 55\%$.

species. Rather, at the low concentrations used, some threshold was exceeded. This may be due to irritation of the insects when moving through the fine plant preparation. The threshold is especially evident in the data for the proportion of unexploited grains for *G. viscosissimum* against *S. oryzae* (Figure 4), in which the avoidance of grains in contact with any plant material seems to be a plausible explanation for the greater activity occurring for the lower doses (resulting in a significant lack of fit for the asymptotic equation). Very simply, the less material present, the greater the probability that more grains will be untreated during the mixing procedure. This seems probable because the resulting fecundity and fertility data show no such effect, i.e., the same proportion of eggs hatched in fewer grains, which is likely a physical/behavioral phenomenon influenced by clumped oviposition in grains that were free of plant preparation. This effect

[a] Peak letters and retention times correspond to those in Figure 7.

[b] Identity of peaks determined in the following ways: C = confirmed by comparison with retention time and spectrum of authentic material; L = identity assigned based on match of sample spectrum to library spectrum; S = type of compound determined by direct interpretation of spectrum and retention information.

[c] Quantity per gram of dried plant material estimated by quantitative GC/FID on a DB-1 column with 1.33 mg decane as an internal standard in each sample.

was noted against *Z. subfasciatus* with the leaves of another plant species that did not contain many highly volatile compounds (Weaver et al., 1992).

The very significant activity of the two aromatic plant species against *Z. subfasciatus* suggests that highly volatile terpenoid compounds can be liberated from the site of biosynthesis, the glandular hairs (Heinrich et al., 1983; Duke, 1990), by powdering according to a patented process. This is a very simple insecticidal preparation for bruchid control, and control can be achieved at dramatically low doses of unconcentrated, unpurified material. However, these preparations are not candidates as broad-spectrum insecticides, as was evidenced by the low level of control against *S. oryzae* even by the carvacrol-rich *M. fistulosa*. This insect was found to be quite resistant to fumigation with volatile natural products by Shaaya et al. (1991). This indicates that careful screening of such simple natural product preparations is required to ensure that they have significant toxicity to the target species.

There is an enormous volume of literature on the insecticidal and repellent activity of terpenoids. The three most abundant compounds we identified, camphor, carvacrol, and 1,8-cineole, all have been evaluated by Shaaya et al. (1991) as fumigants against stored-product insects. The commercial insecticide toxaphene, which structurally is polychlorinated camphor, was marketed for use against several pests until its use was restricted (Duke, 1990). Extensive reviews of the terpenoid chemistry of *Artemisia* spp. have been written by Duke (1990) and Duke et al. (1988). Essential oil characterization has been conducted for *M. fistulosa* (Simon and Beliveau, 1986) and the site of oil biosynthesis elucidated (Heinrich et al., 1983). The flavonoids of *B. sagittata* (Bohm et al., 1989) have been studied, as have the sesquiterpene lactones (Bohlmann et al., 1985).

We believe that volatile plant preparations have significant potential as insecticides against short-lived stored-product pests. The volatile component exerts its controlling effect as it dissipates, thus reducing harmful residue in the foodstuff. Chemical characterization of the major components of the preparation are desirable to preclude the possibility of harmful residues, either volatile or nonvolatile. If a reliable source of plant material is established and used in stored commodities, the dry plant powder remaining after dissipation of volatiles can be removed mechanically. Such preparations may be very practical in low technology surroundings, particularly in subsistence agriculture.

Here, we have demonstrated that plant species that are aromatic and free of insect damage will likely protect stored foodstuffs. Such observations may have been the basis for the origination of some insect control practices in primitive times. However, every new material needs to be evaluated to ensure the safety and palatability of the end product to consumers.

Acknowledgments—The authors wish to acknowledge the fine technical assistance of Mark Cheek, Geoff Fitzgerald, Kraig Hollingworth, Shawn Lantis, Jennifer Pahaham, David Richards, Coby Schultz, and Sharlene Sing. Joel Phillips provided preliminary chromatographic information. Brenda Allwardt developed portions of the egg plug staining technique, and Jeremy Hampton

assisted in the collection of plant material. Thanks are expressed for the comments provided by Larry Zettler, James Baker, and Megha Parajulee, who read an earlier draft of the manuscript. Financial support was provided by the Montana Agricultural Experiment Station (No. 157, F. Dunkel) and the NSF Science Teaching Institute of the Rockies (F. Dunkel, J. Hampton). (Received May 21, 1994; accepted September 10, 1994)

Abstract—Female white pine cone beetles, *Conophthorus coniperda*, attacking second-year cones of eastern white pine, *Pinus strobus* L., produced a sex-specific pheromone that attracted conspecific males in laboratory bioassays and to field traps. Beetle response was enhanced by host monoterpenes. The female-produced compound was identified in volatiles collected on Porapak Q and in hindgut extracts as (+)-*trans*-pityol, (2*R*,5*S*)-(+)-2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran. Males and females produced and released the (*E*)-(−)-spiroacetal, (5*S*,7*S*)-(−)-7-methyl-1,6-dioxaspiro-[4.5]decane, which was not an attractant for either sex, but acted as a repellent

for males. Porapak Q-trapped volatiles from both sexes contained (+)-*trans*-pinocarveol and (−)-myrtenol. In addition, hindgut extracts of females contained *trans*-verbenol, while males had pinocarvone and verbenone. Work in Georgia and Canada confirmed that the same isomers of pityol and spiroacetal are present in two distinct and widely separated populations of *C. coniperda*.

Key Words—*Conophthorus coniperda*, white pine cone beetle, Scolytidae, pheromone, pityol, 2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran, (*E*)-7-methyl-1,6-dioxaspiro[4.5]decane, spiroacetal, chiral analysis, walking bioassay, traps.

INTRODUCTION

The white pine cone beetle (WPCB), *Conophthorus coniperda* (Schwarz) (Coleoptera: Scolytidae), occurs throughout the range of eastern white pine, *Pinus strobus* L., and is rarely found on other hosts (Wood, 1982). It is the most serious insect pest of eastern white pine cones in natural stands (Godwin and Odell, 1965; Hedlin et al., 1980) and seed orchards (DeBarr et al., 1982).

Semiochemicals are commonly used by scolytids for locating suitable hosts or mates (Borden, 1985). However, little is known about the responses of *Conophthorus* spp. to either pheromones or odors released by cones. Beetle-infested cones and their monoterpenes attracted male and female ponderosa pine cone beetles, *C. ponderosae* Hopkins, in laboratory bioassays (Kinzer et al., 1972; Kinzer and Reeves, 1976). However, Mattson et al. (1984) and Mattson and Strauss (1986) rejected the hypothesis of cone-directed alightment by the red pine cone beetle (RPCB), *C. resinosae* Hopkins, in response to cone-produced volatiles.

Recently, we reported evidence for a female-produced sex pheromone that attracts WPCB and RPCB males to their cone galleries (de Groot et al., 1991). Herein we describe the isolation and identification of both female- and male-produced compounds from airborne collections and hindguts of WPCB. Laboratory bioassays and field trapping were used to determine beetle response to host- and beetle-produced volatiles and to compounds identified as pheromone candidates. Volatiles from beetles and beetle-infested cones were analyzed independently in the United States and Canada to identify pheromone candidates. Analyses in Canada were also aimed at clarifying taxonomic relationships for three sympatric *Conophthorus* species (de Groot, 1992).

METHODS AND MATERIALS

Collection and Maintenance of Beetles. Eastern white pine cones containing overwintering WPCB were collected in February 1989 at the USDA Forest Service's Beech Creek seed orchard near Murphy, North Carolina. They were

kept in the dark at 5°C and 50–70% relative humidity until late March. Beetles were allowed to emerge naturally from the cones under a 16L:8D photoperiod at 29°C and 70% relative humidity. They were sexed by examining the seventh and eighth abdominal tergites (Herdy, 1959) and held in darkness on moistened filter paper in Petri dishes at 4–5°C and 70% relative humidity.

WPCB were also collected during September and October 1988, near Chalk River, Ontario, and handled as described by de Groot et al. (1991). Materials and methods used in Canada are described in detail in Pierce et al. (1995).

Collection of Beetle and Host Volatiles. Fresh second-year cones (20–30 mm long) were picked from eastern white pines at Beech Creek, North Carolina; their petioles were sealed with melted paraffin, and they were stored at 5°C. Emerged WPCB were placed individually with one cone in a 10-ml plastic cup. To stimulate beetle attack, a basal cone scale was removed. Cones that were not successfully attacked within 2 hr were discarded. For cones with paired beetles, a male was added 24 hr after the female. After attacks were initiated, cones with beetles were placed in a small desiccator jar (600 ml; 10 cm ID). Charcoal-filtered air was introduced into the bottom of the desiccators and drawn over the attacked cones. Volatiles were collected on Porapak Q (Supelco, Inc. Bellefonte, Pennsylvania) columns (ID 50 mm × 5 mm; 300 mg; 80–100 mesh) (Birgersson and Bergström, 1988; Dobson, 1991; Gries et al., 1988). In control aeration, undamaged cones were used to measure the turpentine background, while cones with a small hole (2 mm ID) drilled at the base were used to simulate beetle attack. Volatiles were collected for 24 hr at a flow rate of 500 ml/min. The Porapak Q columns were rinsed with 3 ml of redistilled diethyl ether (Baker p.a.) and the extracts were concentrated in 0.5-ml tip-vials prior to analysis.

To accumulate sufficient material for chiral analysis, several groups of ca. 100 single females attacking new cones were aerated for 24 hr, starting 24–48 hr after attack. The aeration extracts were combined and concentrated in a tip-vial to $< 100\ \mu l$. The concentrated extract was put on a short Sep-Pac (Millipore Corp., Bedford, Massachusetts) column filled with Florisil (Fisher Scientific Co., Pittsburgh, Pennsylvania) (8 mm × 20 mm ID; 500 mg), and eluted with 3 ml pentane (redistilled) + 2 × 1.5 ml pentane + 2 × 1 ml diethyl ether + 0.5 ml ether (Figure 1). The last 0.5-ml ether fraction contained material sufficiently pure for chiral analysis.

Extracts of Beetle Hindguts. After the aerations, WPCB remaining in cones were excised and stored on Dry Ice. To analyze their volatiles, they were thawed, and pentane extracts were made of hindguts. Wings, elytra, and legs were removed from the degutted beetles, and a second pentane extract was made of the carcass. During dissection, the sex of the beetles was verified by the median lobe (de Groot, 1992) or spermatheca.

Synthetic Compounds. Syntheses of the racemate and the (5*S*,7*S*)-enantiomer of 7-methyl-1,6-dioxaspiro[4.5]decane followed the method of Jacboson

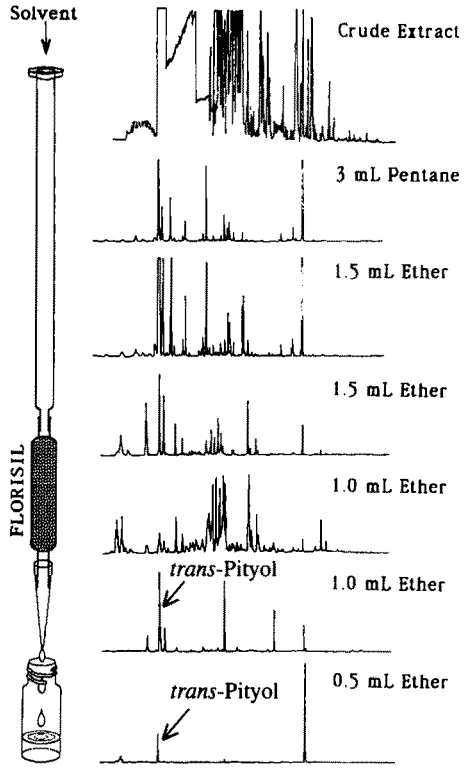

Fig. 1. Isolation of *trans*-pityol in Porapak Q-trapped volatiles from *C. coniperda* females in *P. strobus* cones.

et al. (1982). The enantiomers of 2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran (*trans*-pityol) were provided by K. Mori (for synthesis see Mori and Puapoomchareon, 1987). The (±)-*trans* and (+)-*trans*-pityol used in field bioassays were made by H.D. Pierce, Jr. (Pierce et al., 1995). The enantiomers of *trans*-pinocarveol were prepared from the enantiomers of β-pinene (Aldrich) according to Joshi (1968) by W. Francke; pinocarvone was obtained by oxidation of *trans*-pinocarveol. All other terpenes were commercially available (Aldrich, Milwaukee, Wisconsin).

Chemical Analyses. Porapak Q-trapped volatiles and hindgut extracts were analyzed on a Hewlett-Packard 5890-5970 coupled gas chromatograph and mass spectrometer (GC-MS). Each extract contained an internal standard of 250 ng heptyl acetate (C_7Ac) (Birgersson et al., 1984). The limit of reliable quantification was ca. 0.5 ng/beetle, and the limit of identification was <0.05 ng using

the extracted ion current profile (EICP). The fused silica capillary columns used were HP-1 (Hewlett-Packard Corp., Avondale, Pennsylvania) (25 m × 0.20 mm ID; 0.3 μm film thickness; temperature program: 50°C for 5 min then 8°/min to 200°C for 10 min) and HP-FFAP (Hewlett-Packard) (50 m × 0.20 mm; 0.3 μm film thickness; temperature program: 50°C for 5 min then 10°C/min to 200°C for 10 min). In both columns the flow rate of the helium carrier gas was 25 cm/sec.

The absolute configuration of the spiroacetal in pentane extracts of male hindguts was determined on a glass capillary (40 m × 0.25 mm ID) coated with hexakis-per-*O*-hexyl-α-cyclodextrin (Tengö et al., 1990), programmed at 2°C/min from 50 to 100°C. The same column at 60°C was used to separate the enantiomers of trifluoroacetylated *trans*-pityol from aerations, while underivatized *trans*-pityol was resolved on octakis-(3-*O*-acetyl-2,6-di-*O*-pentyl)-γ-cyclodextrin at 80°C (Grégoire et al., 1992). Trifluoroacetates of monoterpene alcohols were separated on a glass capillary column (40 m × 0.25 mm ID) coated with heptakis-(3-*O*-methyl-2,6-di-*O*-pentyl)-β-cyclodextrin (König et al., 1989). Volatiles produced by *C. coniperda* collected in Chalk River, Ontario, were analyzed as described by Pierce et al. (1995).

Laboratory Bioassays of Beetle- and Host-Produced Volatiles and Candidate Pheromones. Responses by male and female WPCB to beetle- and host-produced volatiles were measured in laboratory bioassays (Payne et al., 1976; de Groot et al., 1991) at Athens, Georgia, during April 1989 and 1990, coinciding with emergence of feral WPCB at the Beech Creek seed orchard. For the bioassays, volatile concentrations were expressed as cone-minutes (CM) or beetle-minutes (BM) where 1 CM or BM is the quantity of volatiles collected during 1 min of aeration (Birgersson et al., 1995). Groups of five beetles of the same sex were exposed to diluted diethyl ether formulations containing 1 CM or BM/μl equivalents dispensed from a 10-μl syringe at 1 μl/min for 10 min. Beetles were placed onto the center of an 18.5-cm-diam. filter paper arena; positive responders were those that walked up the airstream to within 1 cm of the syringe tip. A minimum of 15 replications per sex were run per treatment in bioassay 1. Fewer replications were run for bioassays 2 and 3 because of low populations of feral beetles.

Bioassay 1 tested the responses of WPCB to: (1) control (air only); (2) diethyl ether; (3) diethyl ether extracts containing 10 CM of Porapak Q-captured volatiles from aerations of wounded uninfested cones; (4–6) diethyl ether extracts containing 10 BM of Porapak Q-captured volatiles, respectively, from males, females, or pairs of beetles feeding in cones; and (7 and 8) (*E*)-(±)-spiroacetal alone or in combination with volatiles from cones in 10 BM equivalents.

Bioassays 2 and 3 compared responses to candidate pheromones. Volatiles from aerations or synthetic chemicals were formulated in redistilled diethyl ether in 10 BM or 10 CM equivalents (Birgersson et al., 1995). In bioassay 2 the

effects of combining various beetle and host-produced compounds were compared in nine treatments (Table 1). In bioassay 3, the effects of excluding single components from four- or five-component mixtures were determined in 11 treatments (Table 1).

Field Experiments. Experiments 1–3 and 5 were conducted in the Beech Creek seed orchard and experiment 4 was in a natural white pine forest in Pancake Bay Provincial Park, 80 km north of Sault Ste. Marie, Ontario. Experiments 1 and 2 compared beetle catches in traps baited with: (1) *P. strobus*

[a] Pit[1] = (±)-*trans*-pityol; Pit[2] = (+)-*trans*-pityol; tP = (+)-*trans*-pinocarveol; Mt = (−)-myrtenol; CV = volatiles from aerations of cones; MT = synthetic monoterpene hydrocarbons (mixture of α-pinene, β-pinene, myrcene, limonene 1:1:1:1; Aldrich); BorAc = bornyl acetate (Aldrich); Spiroacetal = (*E*)-(±)-7-methyl-1,6-dioxaspiro[4.5]-decane; CT = control (air only); FV = volatiles from aerations of cones infested with females.

cones that were artificially wounded; (2 and 3) cones infested with male or female WPCB (de Groot et al., 1991); (4 and 6) Porapak Q-trapped volatiles from wounded cones or cones infested with male or female beetles; or (7 and 8) (*E*)-(±)-spiroacetal alone or in combination with cone volatiles. Experiments 3 and 4 compared catches for (±)-*trans*-pityol, (+)-*trans*-pityol, and WP cone oils alone or in combinations. The volatile oil of *P. strobus* cones (WP cone oil) was prepared as described in Pierce et al. (1995) and dispensed from 2-ml polypropylene Eppendorf tubes (Brinkman Instruments, Rexdall, Ontario). No baits were placed in "unbaited" traps in Experiments 3 and 4. Experiment 5 compared catches to (±)-*trans*-pityol and α-pinene with and without (*E*)-(±)-spiroacetal.

Plexiglas barrier traps (de Groot et al., 1991) were used in experiment 1, 12-unit multiple-funnel traps (Lindgren, 1983) were used in experiment 2, and yellow Japanese beetle trap tops (Trécé Inc., Salinas, California) fitted with plastic Mason jar bottoms containing 25 ml of propylene glycol were used in experiments 3–5. Traps were hung ca. 10–15 m high in the upper third of the tree crown, one trap per tree, and were spaced 12–30 m apart. For experiments 1–3 and 5, treatment locations were randomized at weekly intervals. For all experiments, beetles were removed from the traps weekly and the traps were rebaited. Captured beetles were preserved in 70% alcohol, identified, counted, and the sex determined.

Screw-cap glass vials (2 ml) served as releasers for volatiles in experiments 1, 2, and 5. Cotton wicks pulled through 5-cm lengths of 1.6-mm-ID Teflon tubing were inserted through holes drilled in the plastic caps. For experiment 1, a wire was used to suspend a vial in the center of a 10-cm hole cut in the Plexiglas vanes of each barrier trap. For experiment 2, a spring clip was used to attach a vial to one of the plastic rods between funnels 6 and 7 on the multiple-funnel traps. For experiment 5, the vial was clipped to one of the vanes of the Japanese beetle trap. Each vial contained volatiles formulated at a final volume of 2 ml of *n*-octane (Aldrich) and released at a rate of 2 ml/week at 25 ± 2°C in the laboratory. Volatiles collected on Porapak Q were eluted with redistilled diethyl ether and formulated in *n*-octane to release 20 cone equivalents (CE), female equivalents (FE), or male equivalents (ME), where 1 CE, FE, or ME is the quantity of volatiles collected during aerations of one cone or beetle-infested cone for 1 hr (Birgersson et al., 1995). Capillary tubes (1.04 mm ID) were used to dispense 3 μl neat pityol or spiroacetal in experiments 3 and 4. The release rate was 4.2 mg of pityol/week at 24°C in the laboratory.

Data Analyses. Percent response data from the bioassays were analyzed by the GLM procedure and count data from the field experiments (except experiment 5) were analyzed using the RANK and GLM procedures (SAS Institute, 1987). A completely randomized, factorial design was used for the pedestrian bioassays. Factor one, with two levels, was gender of the beetles bioassayed

for olfactory response. Factor two was mixtures of volatiles offered, with levels referred to as treatments. The treatments differed for each bioassay experiment and were various combinations of host-, female-, and male-produced volatiles. Within each experiment these treatments had a structure planned to provide tests of specific hypotheses, so all possible pairwise comparisons of treatments was not a goal. Within each experiment, treatment and gender main effects, and treatment–gender interaction were tested at a 95% confidence level ($\alpha = 0.05$). In order to maintain this experiment-wise (α_E) confidence level and perform a group of planned, nonorthogonal contrasts of treatment–gender interaction effects using multiple t tests, Šidák's inequality was used to set a comparison-wise (α_C) confidence level used to declare significance of any specific comparison (Šidák, 1967; Games, 1977; Jones, 1984). Šidák's inequality relates α_E and α_C as $\alpha_C \leq 1 - (1 - \alpha_E)^{1/n}$, which sets an upper bound on the comparisonwise α_C for n, possibly dependent, comparisons that should be used to declare significance of any single comparison in a group and still maintain the experimentwise probability of a type-I error. In the five field experiments, traps were deployed in a randomized block design. Two response variables were analyzed separately. One response was the number of males caught in baited traps, the other was the number of females caught. In these experiments, planned treatment contrasts were made using t tests with significance levels controlled with Šidák's inequality.

RESULTS

Volatiles from Attacked Cones. All *P. strobus* cones with or without *C. coniperda* released large amounts of host terpenes (Figure 2A). Attacked cones released the four major monoterpene hydrocarbons α-pinene, β-pinene, myrcene, and limonene (Mirov, 1961) and the oxygenated monoterpene bornyl acetate.

Both female and male beetles released (+)-*trans*-pinocarveol and (−)-myrtenol (Figure 2B and C). Volatiles from feeding males contained a beetle-produced peak (Figure 2C) with a mass spectrum dominated by two large fragments, m/z 84 and 87, and a molecular ion at m/z 156. The compound was identified as 7-methyl-1,6-dioxaspiro[4.5]decane by comparison of the mass spectral data to that reported by Francke et al. (1979b). This spiroacetal has been named MDOS by Kohnle et al. (1992) and conophthorin by de Groot (1992), after the genus. Analysis of Porapak Q-trapped volatiles from females feeding in second-year cones in Canada also revealed presence of the (*E*)-spiroacetal (96% ee) (Figure 3). After the female-specific compound pityol had been found in the hindgut extracts (see following), a reexamination of the Porapak Q-trapped volatiles using an extracted ion current profile (EICP) (Garland

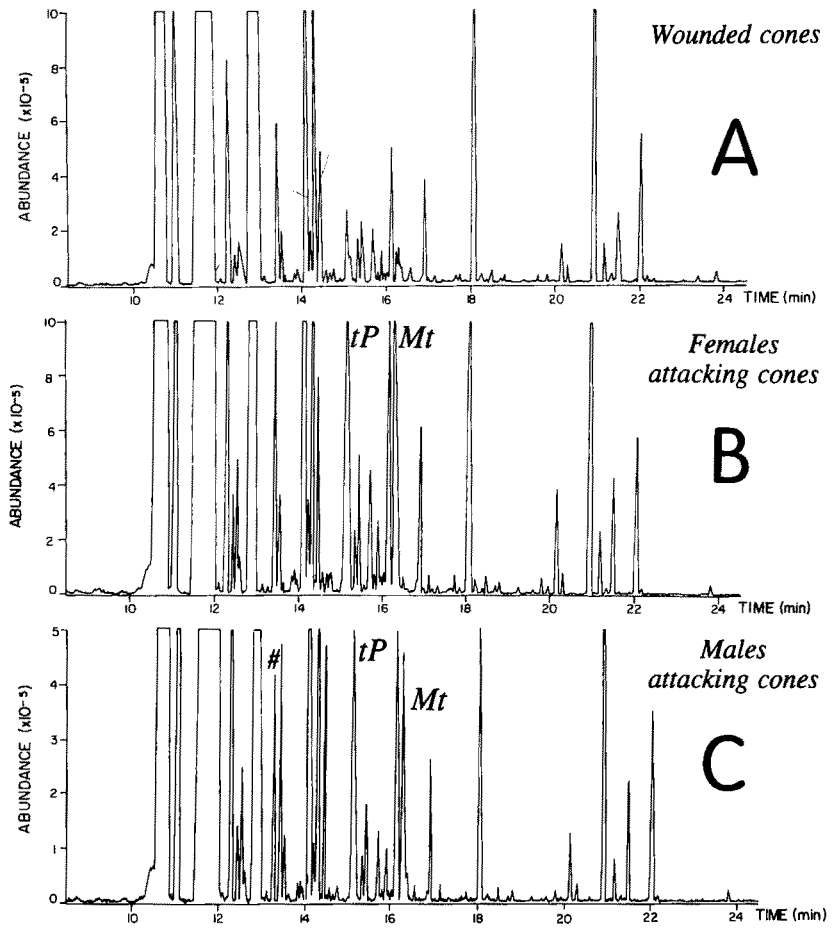

Fig. 2. Chromatograms from GC-MS analyses of Porapak Q-collected volatiles of *C. coniperda* attacking *P. strobus* cones in Georgia; fused silica column coated with HP-1. (A) Wounded cones, (B) single females in cones, (C) single males in cones. tP = *trans*-pinocarveol, Mt = myrtenol, # = spiroacetal.

and Powell, 1981) of *m/z* 59 revealed that it coeluted with, and was totally hidden by β-pinene in all aerations of female-infested cones (Figure 2B).

Analyses of Hindgut Extracts. In addition to the compounds identified in the aerations, analyses of hindguts showed that females produced *trans*-verbenol (Figure 4A) and males produced pinocarvone and verbenone (Figure 4B). Females also produced a female-specific compound (Figure 4A), with a mass

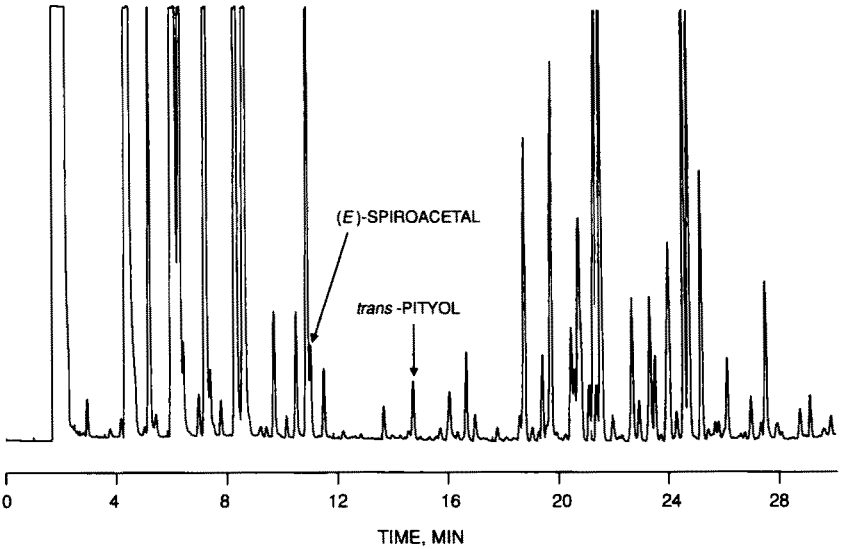

Fig. 3. Chromatogram of Porapak Q-collected volatiles of female *C. coniperda* attacking *P. strobus* cones in Ontario; glass capillary column coated with SP-1000 (30 m × 0.5 mm ID).

spectrum having a base peak of *m/z* 59 and a molecular ion at *m/z* 144, indicating a tertiary alcohol with the formula of either $C_8H_{16}O_2$ or $C_9H_{20}O$. The compound was identified as 2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran, first described as a pheromone of a *Pityophthorus* spp. and named pityol by Francke et al. (1987). Chiral analysis revealed the female-specific pityol to be the 2*R*,5*S*-isomer, and 1% of a *cis* isomer was also present. The same isomer of pityol was also present in the Porapak Q-captured volatiles of feeding *C. coniperda* from Canada (Figure 3).

The chromatogram for hindguts from males was dominated by a large peak of a spiroacetal. A smaller peak, with almost the same mass spectrum, eluted $1\frac{1}{2}$ min later (Figure 4B). Chiral analysis determined that the major peak was (5*S*,7*S*)-7-methyl-1,6-dioxaspiro[4.5]decane, and the minor peak, the 5*R*,7*S*-isomer. Traces of other spiroacetals were detected, but not identified. Pityol was never detected in any male hindgut sample. No additional host- or beetle-produced compounds were found in pentane extracts of degutted beetles, besides those identified in hindgut extracts or aerations. Pentane extracts of both female and male *C. coniperda* from Canada also contained both *E* and *Z* isomers of the spiroacetal (Figure 5).

Laboratory Bioassays. WPCB adults showed strong responses to Porapak

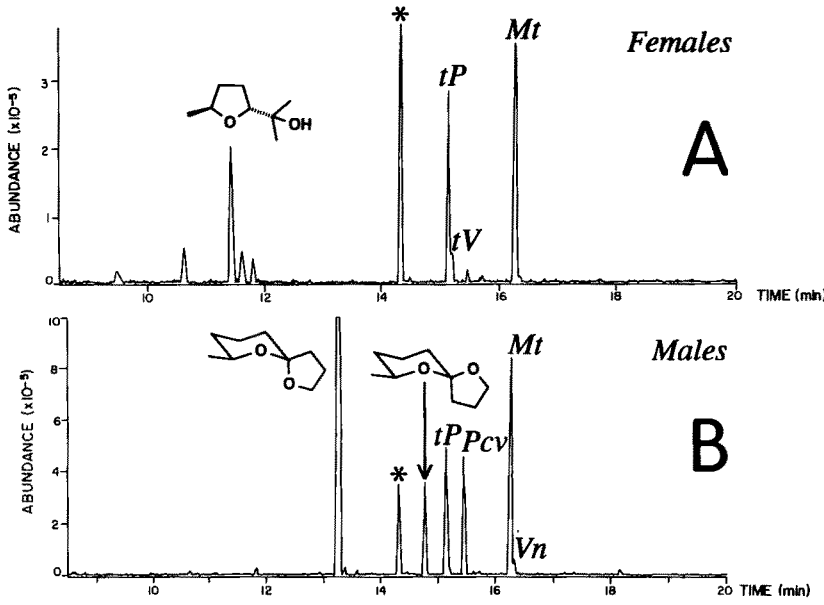

Fig. 4. Chromatograms from GC-MS analyses of volatiles of hindguts of *C. coniperda* attacking *P. strobus* cones in Georgia; fused silica column coated with HP-1. (A) Pityol from seventeen single females in cones 40 hr, (B) spiroacetal from 15 single males in cones 40 hr. tP = *trans*-pinocarveol; tV = *trans*-verbenol; Mt = myrtenol; Vn = verbenone; Pcv = pinocarvone; * 250 ng C_7Ac.

Q-trapped volatiles from infested cones in the walking bioassay (Figure 6, Table 2). Males responded more often than females. Significant response differences occurred among treatments ($F = 67.1$; $df = 7, 377$; $P = 0.0001$), between sexes ($F = 7.96$; $df = 1, 377$; $P = 0.0001$), and for the treatment-by-sex interaction ($F = 24.75$; $df = 7, 337$; $P = 0.0001$).

Only 4% of the beetles responded positively to air alone (Figure 6); adding ether to the airstream did not significantly increase the response (Table 2). However, both sexes responded significantly to Porapak Q-trapped volatiles containing host- and/or beetle-produced compounds, and males responded positively to cone volatiles. Significantly more beetles of both sexes responded to volatiles from males in cones than to cones alone. Over 90% of the test males responded to volatiles from cones with females, but females did not respond to this stimulus better than to cones alone. Females, but not males, responded significantly more to volatiles from cones containing pairs of beetles than to volatiles from cones containing either sex. Neither sex showed a significantly greater response to a combination of cone volatiles and spiroacetal than to cone

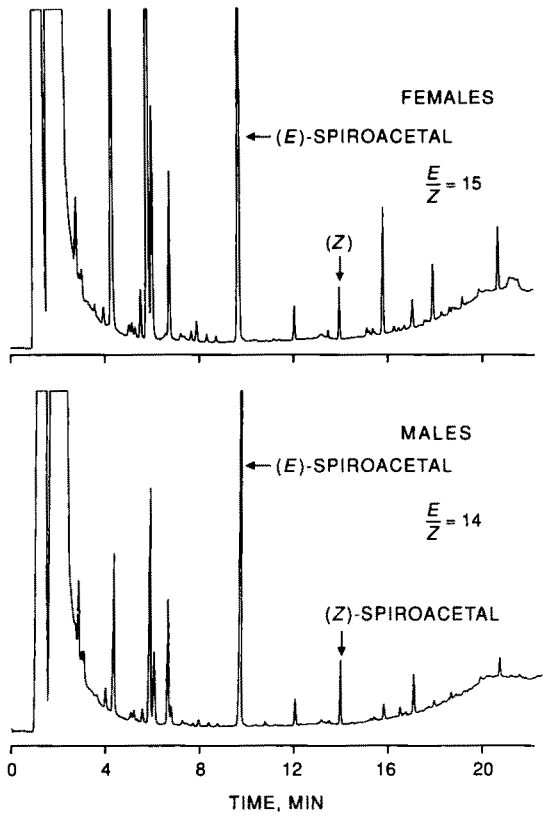

Fig. 5. Chromatograms of volatiles in pentane extracts of *C. coniperda*, excised from *P. strobus* cones in Ontario; glass capillary column coated with SP-1000.

volatiles or the spiroacetal alone. However, male response to a mixture of spiroacetal and cones volatiles was significantly less than their response to volatiles from male-infested cones.

Synthetic beetle and host-produced compounds also elicited strong positive responses by WPCB (Tables 3 and 4). Again, males responded more frequently than females. Responses differed significantly among treatments (bioassay 2: $F = 31.8$; $df = 8, 117$; $P = 0.0001$; bioassay 3: $F = 6.21$; $df = 10, 77$; $P = 0.001$) and between sexes ($F = 11.5$; $df = 1, 117$; $P = 0.0001$; bioassay 3: $F = 48.4$; $df = 1, 77$; $P = 0.0001$). Treatment-by-sex interactions were also significant (bioassay 2: $F = 5.46$; $df = 1, 117$; $P = 0.0001$; bioassay 3: $F = 2.96$; $df = 9, 77$; $P = 0.0045$).

Beetle responses to pityol alone or in combination with two other female-

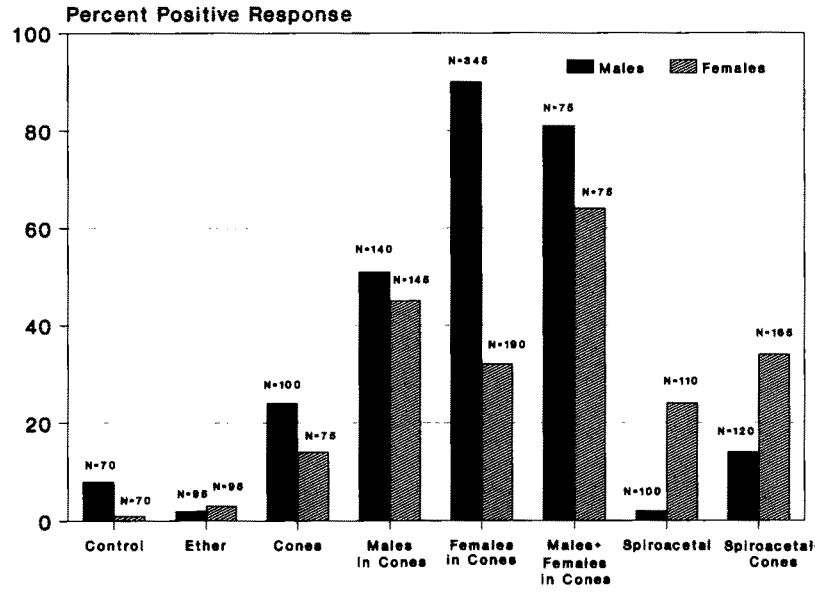

Fig. 6. Responses by female and male *C. coniperda* to volatiles in laboratory bioassay 1.

produced compounds, *trans*-pinocarveol and myrtenol, ranged from 18 to 33% (Table 3). Comparisons for the (±)-*trans*-pityol vs. control; (+)-*trans*-pityol vs. (±)-*trans*-pityol; and the (+)-*trans*-pityol, *trans*-pinocarveol, and myrtenol mixture vs. (+)-*trans*-pityol were not significant for either sex. Male response to (*E*)-(±)-spiroacetal plus the three-component mixture, was only 8%, while 33% responded to the mixture alone, but the differences were not significant for either sex.

Combining volatiles from cones with the three female compounds significantly increased male response to 91%, but did not increase female response (Table 3). Male response to a mixture of four host monoterpenes and the three female compounds was equal to their response to cone volatiles plus the three female compounds or Porapak Q-trapped volatiles from female-infested cones. In contrast, the female response of 82% to volatiles from females in cones was significantly greater than their 23% response to the three female compounds and monoterpenes.

Female responses were not significantly different for any component deletion from the complex mixtures of beetle- and host-produced compounds (Table 4). Male response was 91% for mixture 1 containing the three female-produced compounds plus cone volatiles and 81% for mixture 2 containing the three

[b]$P \leq 0.0028$ is required for an experiment-wise error rate of $\alpha = 0.05$ (Šidák, 1967; Games, 1977) for each of the 18 comparisons.

female-produced compounds plus monoterpenes and bornyl acetate. These responses were significantly greater than to pityol alone. However, when pityol was removed from either mixture 1 or mixture 2, male response was significantly decreased to only 20%. Substituting bornyl acetate for the four monoterpene hydrocarbons significantly reduced male response.

Field Experiments. Catches of females in traps baited with beetle-infested cones or Porapak Q-trapped volatiles of infested cones were no greater than to uninfested cones, but significantly more males were attracted to female-infested cones than to uninfested cones or male-infested cones (Table 5, experiment 1). However, in experiment 2, more beetles of both sexes were both attracted to Porapak Q-trapped volatiles from female-infested cones than to volatiles from male-infested cones. The (*E*)-(±)-spiroacetal was not an attractant for either sex.

Females were not attracted to pityol in experiment 3, but in experiment 4 significantly more females were caught in traps baited with (±)-*trans*-pityol

spiroacetal to baits containing (±)-*trans*-pityol and α-pinene significantly reduced the trap catch of males but not females in experiment 5 (Table 7).

DISCUSSION

Identification of Pityol and Spiroacetal. The discovery of (+)-*trans*-pityol (1% *cis*) in female WPCB (Figure 7) constitutes the first record of occurrence in this genus. Pityol was first identified in, and named after, the European

TABLE 7. MEAN NUMBERS OF *C. coniperda* CAPTURED IN TRAPS BAITED WITH (±)-*trans*-PITYOL AND α-PINENE, AND (±)-*trans*-PITYOL, α-PINENE, AND (*E*)-(±)-SPIROACETAL AT BEECH CREEK SEED ORCHARD, NORTH CAROLINA

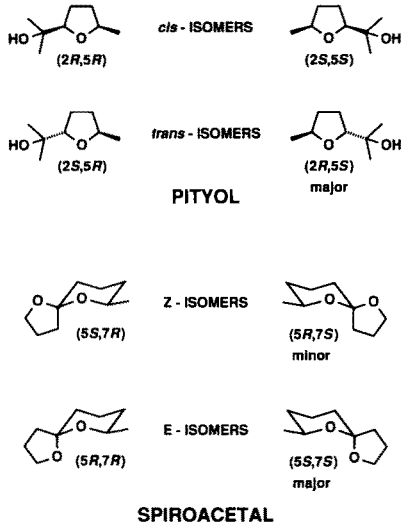

Fig. 7. Stereoisomers of *Conophthorus* pheromones.

species, *Pityophthorus pityographus*, which also contained grandisol (Francke et al., 1987). Klimetzek et al. (1989) isolated *cis*-pityol from the elm bark beetle, *Pteleobius vittatus*, which also produced 3-methyl-3-buten-2-ol and *cis*-vittatol (*cis*-3-hydroxy-2,2,6-trimethyltetrahydropyran). In field tests, the combination of three compounds was far superior to any single compound or two-component mixture. The occurrence of pityol in *Conophthorus* in North America, and

Pityophthorus in Europe supports the hypothesis that these are closely related genera (Wood, 1982).

The spiroacetal produced by WPCB (Figure 7) was previously identified in abdominal glands of social wasps (Francke et al., 1979a). It also occurs in males of *Leperisinus varius* (F.) and in frass of the fir beetle, *Cryphalus piceae*, where it acts as a strong inhibitor of aggregation for these two bark beetle species (Kohnle et al., 1992).

The first spiroacetal identified as a bark beetle-produced compound was isolated from *Pityogenes chalcographus* (Francke et al., 1977). This compound, chalcogran (2-ethyl-1,6-dioxaspiro[4.4]nonane), is weakly active by itself and is strongly synergized by methyl 2(*E*),4(*Z*)-decadienoate (Byers et al., 1988). Several alkyl-1,6-dioxaspiro[4.5]decanes occur in the social wasps, *Paravespula vulgaris* L., *P. germanica* (F.), and *Dolichovespula saxonica* (F.), and in the ash bark beetle, *L. varius* (F.) (Francke et al., 1979a).

Stereochemistry of Pityol and Spiroacetal. Chiral analyses showed that the *trans*-pityol produced by female WPCB is (2*R*,5*S*)-(+) (Figure 7). Based upon results of our bioassays and field experiments, (+)-*trans*-pityol, synergized by host monoterpene hydrocarbons, is a pheromone for WPCB. Since pityol exists in four different isomers (Figure 7), and only one is produced by the WPCB, it is possible that the stereochemistry is also a key to species separation. In field tests, (+)-*trans*-pityol and racemic grandisol acted synergistically as an aggregation pheromone for *P. pityographus*, whereas a mixture of (−)-*trans*-pityol and grandisol was inactive (Francke et al., 1987). Alone, (+)-*trans*-pityol exhibited only slight attraction for *P. pityographus*. A racemic mixture of *cis*-pityol was active for *P. vittatus*, but *cis*-pityol baits with (−)-*cis*-vittatol attracted more beetles than those with (+)-*cis*-vittatol (Klimetzek et al., 1989).

Isomers of the spiroacetal identified from WPCB were of the 5*S*,7*S* and 5*R*,7*S* configurations in a proportion of ca. 15:1 (Figure 7). However, spiroacetal produced from 1,8-dihydroxynonan-4-one in hydrochloric acid was mostly the more stable *E* isomer ($E/Z \geq 100$). Under acidic conditions the spiroacetal may epimerize at the spirocenter. The 5*S*,7*S* isomer has the methyl group in an equatorial position and, due to the stabilizing anomeric effect, the second oxygen is attached axially at the spirocenter to the tetrahydropyran ring (Francke et al., 1981; Delongchamps et al., 1981). Thus, the natural mixture found in the WPCB is not in a thermodynamically stable equilibrium.

The instability of the bouquet opens the possibility that the "aging" (i.e., equilibration) of the proportion may function as a "built-in clock" providing information about the age of the signal. This effect is even more pronounced in the case of 2,8-dimethyl-1,7-dioxaspiro[5.5]undecane, which was identified from the cephalic secretion of the solitary bee *Andrena wilkella* (Bergström et al., 1982). The major component, the thermodynamically stable *E*,*E* isomer, has both methyl groups in equatorial positions and a diaxial coupling of the oxygens

at the spirocenter. It is accompanied by an *E,Z* product that also has two methyl groups in equatorial positions, but the oxygens at the spirocenter are in axial and equatorial positions. The ratio between these two compounds in the bees favors the thermodynamically less stable *E,Z* isomer. In *A. wilkella*, the more stable and highly attractive 2,8-dimethyl-1,7-dioxaspiro[5.5]undecane is of 2*S*, 6*R*,8*S* configuration (Tengö et al. 1990); only this enantiomer is recognized by the bees.

Alkyl-1,6-dioxaspiro[4.4]nonanes, such as chalcogran (Francke et al., 1977), are much more sensitive to acidic epimerization at the spirocenter than the two other systems. In *Pityogenes chalcographus*, only (2*S*,5*R*)-2-ethyl-1,6-dioxaspiro[4.4]nonane showed strong activity (Byers et al., 1989). In nature this isomer is accompanied by the behaviorally inactive 2*S*,5*S* diastereomer, in a ratio of about 3:2 (Schurig and Weber, 1984), which almost represents the thermodynamically stable equilibrium.

Beetle Response. The strong male WPCB response to volatiles emanating from cones with females (Figure 6) agrees with the responses reported for male *C. ponderosae* (Kinzer et al., 1972) and *C. resinosae* (de Groot, 1992). However, WPCB males also responded strongly to volatiles from cones infested with pairs of beetles. The strongest response by female WPCB was to volatiles from cones with pairs or male beetles, as was reported for *C. ponderosae* females Kinzer et al., (1972). Few beetles were caught in experiment 1, perhaps because WPCB populations were sparse and the Plexiglas barrier traps were inefficient (Table 5).

Pityol alone elicited only weak WPCB responses in laboratory bioassays (Table 3) and in field experiment 3 (Table 6), but attracted males in field experiment 4. Neither *trans*-pinocarveol nor myrtenol, two other female-produced volatiles, enhanced WPCB responses in the laboratory (Tables 3 and 4). Because male WPCB did not distinguish between (±)-*trans*-pityol and the (+)-*trans*-pityol isomer (Tables 3 and 4), the more easily synthesized, and therefore less expensive, racemic *trans*-pityol may suffice for applied uses in the field.

Host monoterpenes often synergize scolytid pheromones (Borden, 1985). Volatiles collected from cones or a mixture of the four major monoterpene hydrocarbons found in cones, dramatically increased male response to pityol (Tables 3 and 4). Mixtures containing both pityol and monoterpenes produced male responses of about 80%, which were equal to those for volatiles from female-infested cones (Tables 3 and 4). Removing the host volatiles or the monoterpenes greatly decreased male response.

Female WPCB showed weak responses to cone volatiles or monoterpenes (Tables 2–4). Their response was much greater to a mixture of pityol, (+)-*trans*-pinocarveol, and monoterpenes, but was not as strong as to volatiles from female-infested cones (Table 3). Apparently other beetle- or host-produced compounds were emanating from female-infested cones. Bornyl acetate, a host vol-

atile released in prodigious amounts from wounded cones, did not affect beetle response.

The spiroacetal, the major male-produced volatile, did not attract male or female WPCB beetles (Figure 6 and Table 6). However, adding the spiroacetal to the three-compound female-produced mixture reduced male response from 30% to 8%, which was the lowest male response to any bioassay treatment containing pityol (Tables 3 and 4). Had the spiroacetal been added to a mixture of pityol combined with host volatiles, the potential for demonstrating a reduction in male response by the spiroacetal would obviously have been much greater. In the field, the spiroacetal inhibited the attraction of males (Table 7); Pierce et al. (1995) obtained similar field results with *C. resinosae*.

CONCLUSIONS

Independent and parallel chemical analyses undertaken in Georgia and Canada clearly confirmed that pityol and the spiroacetal are present in *C. coniperda*. Furthermore, the compounds do not differ in their chirality between two distinct and widely separated populations. Both pityol and the spiroacetal are potentially useful as behavior-modifying chemicals in an integrated pest management system for WPCB in *P. strobus* seed orchards. Pityol is also an effective attractant for male *C. resinosae* (Pierce et al., 1995), and we propose that it be tested in traps for monitoring WPCB and RPCB populations, or perhaps for mass-trapping populations. The spiroacetal could also have practical application as an inhibitor of normal cone beetle behavior.

Acknowledgments—We thank Dr. Y.C. Berisford, T. McClure, C. Crowe, and M. Cody for their assistance in collecting the cones and beetles and in conducting the laboratory bioassays and field experiments. G. Beaver permitted us to work at the Beech Creek Seed orchard. Ray Souter and Stan Zarnoch provided helpful advice on the statistical analyses. We are especially indebted to Prof. K. Mori for the gift of the chiral pityols. We also thank B. Aelick and B. Zylstra for laboratory and field assistance, and the Ontario Ministry of Natural Resources for permission to conduct our field studies on Crown land. This research was supported in part by the Natural Sciences and Engineering Research Council of Canada.

(Received May 31, 1994; accepted October 31, 1994)

Abstract—Analyses of abdominal extracts and beetle-produced volatiles revealed that female *Conophthorus resinosae* and *C. banksianae* produced optically pure (*E*)-(+)-pityol [(2*R*,5*S*)-(+)-2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran]. In field tests, traps baited with (*E*)-(±)- or (*E*)-(+)-pityol captured only males. Addition of host oils to traps baited with pityol did not significantly enhance the capture of males. Males of these former sibling species produced the spiroacetal (5*S*,7*S*)-(−)-7-methyl-1,6-dioxaspiro[4.5]decane with high optical purity (96%). Addition of the racemate or the optical isomers of the spiroacetal to traps baited with (*E*)-(±)-pityol almost completely inhibited the capture of males. It is hypothesized that to ensure their reproductive success, males produce the spiroacetal to repel rival males. Species specificity in pityol and the spiroacetal was not found between *C. resinosae* and *C. banksianae*, thus supporting their synonymy.

Key Words—*Conophthorus resinosae*, *Conophthorus banksianae*, cone beetle, Scolytidae, sex pheromone, repellent, pityol, 2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran, spiroacetal, 7(*E*)-methyl-1,6-dioxaspiro[4.5]decane.

INTRODUCTION

Wood (1989) synonymized the morphologically identical sibling species *Conophthorus resinosae* Hopkins, red pine cone beetle, and *C. banksinae* McPherson, the jack pine tip beetle. Taxonomic studies of the karyotypes (de Groot and Ennis, 1990), allozymes (de Groot et al., 1992), cuticular hydrocarbons (Page et al., 1990), life-history traits (de Groot and Borden, 1991), male genitalia (de Groot, 1992), and host acceptance behaviors (de Groot and Borden, 1992) uphold the placement of *C. banksianae* as a junior synonym of *C. resinosae* (Wood, 1989). Another taxonomic character that can be used to distinguish species or host races is pheromone specificity in chemical communication. (Roelofs and Cardé, 1974; Cardé and Baker, 1984).

Evidence that the red pine beetle and the white pine cone beetle, *C. coniperda* (Schwarz), produce sex pheromones has been disclosed by de Groot et al. (1991). This study led us to explore chemical communication in *C. resinosae* and *C. banksianae* as part of a biosystematic study to determine the species validity of the latter (de Groot, 1992). Our objectives were to identify and compare the pheromones of *C. banksianae* and *C. resinosae* and to determine the response of the beetles to synthetic compounds in the field. For clarity, we retain the name *C. banksianae* in this paper to refer to populations of *C. resinosae* found on jack pine, *Pinus banksiana* Lamb.

METHODS AND MATERIALS

Collection and Maintenance of Beetles. Adult *C. banksianae* and *C. resinosae* were collected near Aubrey Falls and Thessalon, Ontario, respectively, during September and October of 1987 and 1988. Infested shoots of jack pine and cones of red pine, *P. resinosa* (Ait.), were placed in paper and burlap bags, respectively, and stored in darkness at 2°C and 70–87% relative humidity. Uninfested jack pine shoots and red pine branches bearing conelets were collected from Thessalon in October of each year. After about two to three days at 20–22°C, paper bags containing host infested with either *C. banksianae* or *C. resinosae* were gently warmed under a 60-W incandescent light bulb to induce beetle emergence. Beetles were sexed by examining the 7th and 8th abdominal tergites (Herdy, 1959) and held at 5°C on moist filter paper in Petri dishes until required. Beetles were assigned to species based on the species of the host tree from which they emerged and their feeding behavior (McPherson et al., 1970).

Collection of Beetle and Host Volatiles. Small branches (33) bearing conelets (1–6) of red pine were stripped of needles, cut 2–3 cm below the terminal bud, and equally distributed between two aeration chambers (Pierce et al., 1984). Male (304) and female (213) *C. resinosae* were introduced into separate chambers and allowed to attack host material. For the control, each conelet was

punctured three to four times with the tang of a small file before placement of branches into the aeration chamber. Humidified and charcoal-filtered air was drawn at 1.65 liters/min through the vertically oriented chambers and traps (ca. 200 mm × 14 mm OD) containing Porapak Q for one to five weeks. Volatiles were recovered by overnight extraction of the Porapak Q with pentane in a Soxhlet extractor. The pentane solution of the volatiles was concentrated (1–5 ml) either by distilling off the pentane through a Dufton column or by evaporation under a stream of helium.

For *C. banksianae*, volatiles were collected for two to seven days from separated males (60) and females (90) feeding on jack pine shoots (10 and 15, respectively) on analytical traps (6 mm OD) packed with a 30-mm length of Porapak Q. Volatiles were recovered by eluting the traps with 1 ml of anhydrous ether. Several collections with *C. resinosae* were also conducted in this manner.

Extraction and Analysis of Beetle Volatiles. After removal from host, beetles were placed in Dry Ice–cold pentane and crushed to a fine powder. After warming to room temperature, the supernatant was analyzed by gas chromatography (GC). Samples that were not immediately analyzed were stored in a freezer. For several samples of *C. banksianae*, the crude extract was placed on glass wool in the upper portion of an analytical Porapak Q trap. The volatiles were transferred from the glass wool to the Porapak Q with nitrogen (ca. 200 ml/min for 0.5 hr) and recovered by eluting the Porapak Q with pentane–ether (1 : 1, v/v). These samples were analyzed by GC for determination of chirality and enantiomeric enhancement (ee).

Isolation of Beetle Volatiles by Steam Distillation. A micro-steam distillation–continuous extraction apparatus (Godefroot et al., 1981) was used for the isolation of volatiles from the pentane extracts of crushed beetles. Pentane was used for extraction. The solutions of the volatiles were stored in the freezer until analyzed by GC.

Isolation of Volatile Oils by Steam Distillation. A simultaneous steam distillation–continuous extraction still head (Flath and Forrey, 1977) was used for the isolation of the volatile oils from macerated (Waring blender) cones, buds, or needles of red pine and shoots of jack pine. The steam distillation was conducted for 4 hr after boil-up, and pentane was used as the extracting solvent. The bulk of the pentane was removed under a steam of argon or nitrogen. Residual solvent was removed by brief vacuum pumping. The oils were stored in a freezer until use.

Instrumental Methods. Hewlett-Packard 5830, 5880, and 5890 gas chromatographs equipped with capillary inlet systems and flame-ionization detectors were used for analyses by GC. Glass columns (30 m × 0.5 mm ID) coated with SP-1000 or Carbowax 20 M (Supelco Canada Ltd., Oakville, Ontario) and a fused silica column (15 m × 0.25 mm ID) coated with DB-1 (J & W Scientific Inc., Folsom, California) were used. A fused silica column (25 m × 0.25 mm

ID) coated with Chirasil-Dex (8) (V. Schurig, University of Tübingen, Germany) was used for determination of chirality and ee. The injection port and detector temperatures were 260° and 270°C, respectively.

A Hewlett-Packard 5895B GC-MS-DS was employed for coupled gas chromatography–mass spectroscopy (GC-MS). Fused silica columns (0.32 mm ID) coated with DB-1 (30 m), DB-WAX (60 m), or SP-1000 (30 m) (J & W Scientific) were coupled directly into the ion source. The injection port, transfer line, and ion source were 260°, 250°, and 200°C, respectively. Helium was the carrier gas for GC and GC-MS.

A Varian 1200 gas chromatography equipped with 10:1 effluent splitter and thermal gradient collector (Brownlee and Silverstein, 1968) was used for micropreparative isolation of pheromones from the Porapak Q-trapped volatiles for chirality determinations. The column was a 3-m × 3.17-mm-OD stainless tube packed with a 10% SP-1000 on Supelcoport (100/120 mesh) (Supelco, Bellafonte, Pennsylvania).

Synthetic Pheromones. (*E*)-(±)-Pityol and (*E*)-(+) pityol were prepared from (±)-sulcatol and (*S*)-(+)-sulcatol (97% ee, Phero Tech, Inc., Delta, British Columbia) by the method of Mori and Paupoomchareon (1987). Distilled (*E*)-(±)-pityol (84%) containing ca. 2.3% of the *Z* isomer and 5% sulcatol was further purified by flash chromatography on silica gel with pentane–ether (4:1) as eluent to give (*E*)-(±)-pityol (98.3%), which contained 0.3% of the *Z* isomer and no sulcatol. The distilled (*E*)-(+)-pityol containing 3.1% of the *Z* isomer and no sulcatol was 86.6% chemically pure and 98.8% ee. The enantiomers and racemate of the spiroacetal 7(*E*)-methyl-1,6-dioxaspiro[4.5]decane were synthesized by procedures recently developed by Ramaswamy and Oehlschlager (1991). The racemic compound was 99.4% pure and contained 0.3% of the *Z* isomer. The (5*R*,7*R*)-(+) and (5*S*,7*S*)-(−) isomers were each ca. 93% chemically pure and contained 1.6 and 1.2% of the *Z* isomer, respectively. Both enantiomers were ca. 97% ee. Samples of 7(*E*)-(±)-methyl-1,6-dioxaspiro[4.5]decane and (±)-pityol (*E*/*Z*, 1:2) were gifts from W. Francke (University of Hamburg, Germany).

Field Experiments. These were conducted to determine the attractiveness of: (1) (±)-pityol and (+)-pityol alone or in combination with host oils (experiments 1 and 4), (2) three (*E*/*Z*) ratios of (±)-pityol with host oils (experiments 2 and 5), (3) (±)-pityol with the racemate of and with the (+) and (−) isomers of the spiroacetal (experiments 3 and 6), and (4) three ratios of (±)-pityol with racemic spiroacetal (experiment 7). Experiments for *C. banksianae* were located in a jack pine plantation in Hurlbert Township ca. 60 km northeast of Sault Ste. Marie, Ontario. A red pine plantation near Thessalon, Ontario, was used for the experiments with *C. resinosae*. Isozyme and karotype studies of *Conophthorus* from these two sites (de Groot et al., 1991; de Groot and Ennis, 1990) showed that *C. coniperda*, which is distinguishable by its morphology, karology,

isozymes, and cuticular hydrocarbons and appears not to use either red or jack pine as hosts (de Groot et al., 1991), was not present. Furthermore, ground surveys indicated that *C. coniperda* was not present within 20 km of these sites. As *C. banksianae* and *C. resinosae* could only be distinguished on the basis of adult size and host, we used these characters to identify the species caught at the sites.

Traps were made from yellow Japanese beetle trap tops (Trécé, Inc., Salinas, California) and Mason jar bottoms containing 50 ml of ethylene glycol. Pityol and the spiroacetal were released from glass capillary tubes (1 mm ID). Release rates from capillary tubes were calculated by determining volume loss at 24°C. Capillary tubes were placed inside 1.5-ml plastic centrifuge tubes in which four 1-mm holes were made to facilitate the release of volatiles. Host oils were released from plastic centrifuge tubes with two 0.5-mm holes. The tubes containing baits were taped to one vane of the trap. Control traps were unbaited. Experiments were laid out as complete randomized blocks, with traps hung in the upper third of the tree crown, one trap per tree, and spaced 15–20 m apart. Captured beetles were preserved in 70% ethanol and later identified and their sex determined. Voucher specimens from each experiment were kept and deposited in the collection of P. de Groot, Natural Resources Canada, Forest Pest Management Institute, Sault Ste. Marie, Ontario. Baits were replaced weekly and treatment locations rerandomized. The dates and number of replicates for each experiment are shown in Tables 1 and 2. Trap catch data were analyzed by the Kruskal-Wallis test with nonparametric multiple comparisons (BMDP program 3s, 1990 version).

RESULTS

Pheromone Identification. Analyses of the Porapak Q-trapped volatiles from female or male *C. banksianae* feeding on jack pine by GC established that beetles of each sex produced at least one unique compound (Figure 1). Sex-specific compounds were also present in pentane extracts of the feeding beetles (Figure 2). The mass spectrum of the female-produced compound exhibited a base peak at *m/z* 59, suggesting a tertiary alcohol, and prominent peaks at *m/z* 85, 102, and 129 but lacked a molecular ion peak. The spectrum of the unknown compound was similar to that of (*E*)-pityol, an aggregation pheromone produced by male *Pityophthorus pityographus* (Franke et al., 1987). Comparison of the mass spectrum and GC retention times of the unknown compound to those of authentic pityol (*E/Z*, 1:2) established that female *C. banksianae* had produced only the *E* isomer of pityol (Figure 3).

The mass spectra of the major and minor unknown compounds in the pentane extract of the males were identical and exhibited a molecular ion at

[a]Experiment 1, May 20–June 7, 1990, 10 traps/treatment; experiment 2, July 4–11, 1990, 10 traps/treatment; experiment 3, June 27–July 4, 1990, 7 traps/treatment. Release rates of (±)-pityol, (+)-pityol, (*E*)-(±)-, (+)-, and (−)-spiroacetal were 0.61, 0.59, 0.95, 1.00, and 0.93 mg/day, respectively, at 24°C in the laboratory.

[b]Means within an experiment followed by the same letter are not significantly different, Kruskal-Wallis test, $P > 0.05$.

m/*z* 156, but were completely different from those of *exo*- and *endo*-brevicomin (MW = 156). The mass spectra matched the partial spectrum reconstructed from data tabulated for 7(*E*)-methyl-1,6-dioxaspiro[4.5]decane (Francke et al., 1979a,b). The mass spectrum and GC retention time of the major male-produced unknown compound were identical to those observed for an authentic sample of this spiroacetal, which contained ca. 1% of the longer-eluting *Z* isomer. The structure of the minor male compound was assigned as the *Z* isomer because its mass spectrum and retention time in GC were, respectively, identical to and considerably longer than that of the *E* isomer (Franke et al., 1979b). The isomer ratio (*E*/*Z*) was 9.4 and 12.4 in two pentane extracts and 10.5 and 27.0 in two samples of Porapak Q-trapped volatiles.

Analyses of the Porapak Q-trapped volatiles (Figure 4) from feeding female and male *C. resinosae* by GC and comparison of the chromatograms to those of Figure 1 indicated that they had emitted the same major sex-specific compounds as had *C. banksianae*. Analysis of the female volatiles by GC-MS not

[c]*n*-Decane was used as a diluent.

only confirmed the identity of this compound as (*E*)-pityol but also revealed the presence of a small amount of (*Z*)-pityol. The ratio of the *E* and *Z* isomers was ca. 150:1. The identity of the male compound in a sample of volatiles isolated by steam distillation was confirmed by GC-MS. The ratio of the *E* and *Z* isomers in this sample was 49:1. In the Porapak Q-trapped volatiles the *E*/*Z* isomer ratio was variable and ranged from 19 to 39 ($N = 5$).

(*E*)-Pityol was not detected in pentane extracts of female *C. resinosae* (Figure 5). The chromatogram of the pentane extract of the males (Figure 5) was quite similar to that obtained from male *C. banksianae* (Figure 2), as was the ratio (9.4) of the *E* and *Z* isomers of the spiroacetal. Comparison of the

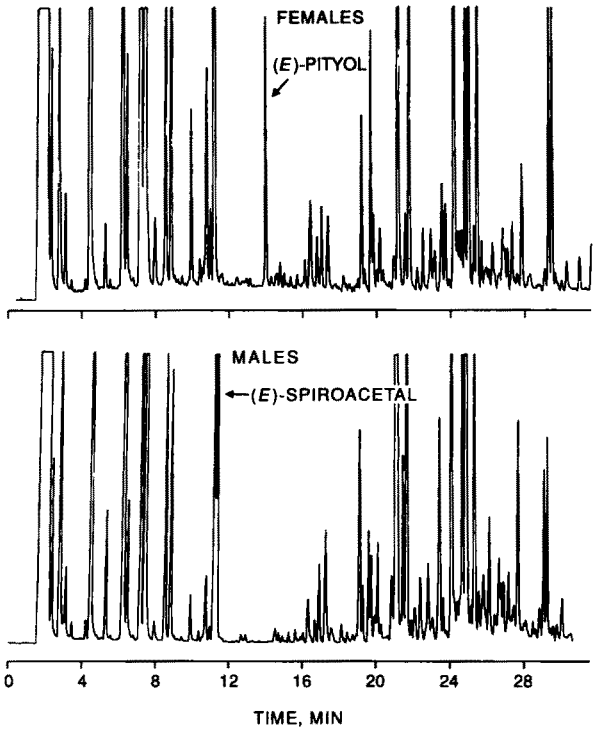

FIG. 1. Gas chromatograms of the Porapak Q-trapped volatiles from female and male *C. banksianae* feeding on jack pine.

chromatograms in Figure 5 indicated that no other sex-specific compound, which might not have been discernible in the complex mixture of Porapak Q-trapped volatiles, was present in these extracts.

Chirality. Analysis of the volatiles in the pentane extract of female *C. banksianae* (Figure 3) on a capillary column coated with Chirasil-Dex(8) revealed that the females had produced optically pure (*E*)-(+)-pityol (Figure 6), as had female *C. resinosae* (Figure 7). These determinations were made difficult by the presence in these samples of several compounds with retention times quite close to that of (*E*)-(−)-pityol. As the lower panels in Figures 6 and 7 show, a small amount of the (*E*)-(−) isomer could have been detected if it had been present in the volatiles. The absolute configuration of (*E*)-(+)-pityol is 2*R*,5*S* (Figure 3).

The *E* isomer of the spiroacetal from the males of the two species had the 5*S*,7*S* configuration and enantiomeric enhancements of ca. 96% as determined

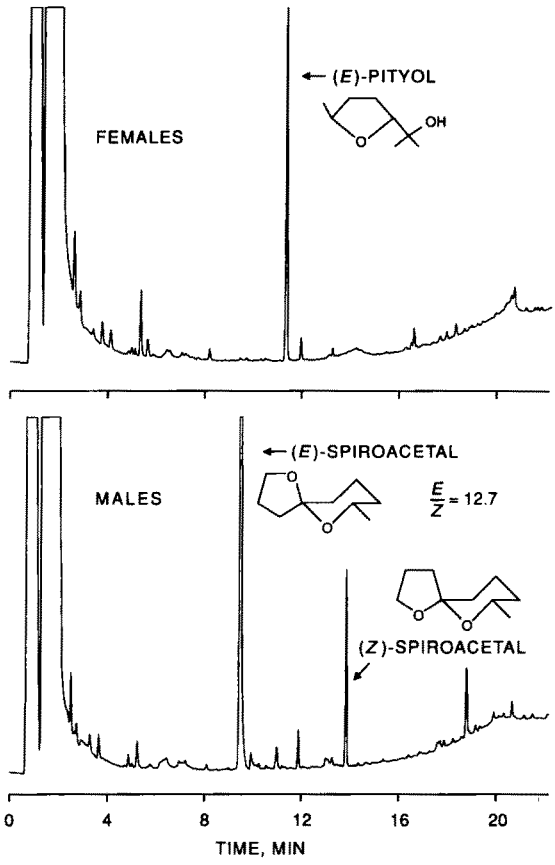

FIG. 2. Gas chromatograms of volatiles in pentane extracts of feeding female and male *C. banksianae* excised from jack pine.

by analyses on the Chirasil-Dex(8) column. Figure 8 shows the chromatogram of the spiroacetal isolated from the Porapak Q-trapped volatiles from feeding *C. resinosae* by micropreparative GC. Since the isomers were not completely resolved, it was fortunate the 5*R*,7*R* isomer eluted first.

Field Experiments. Males of both species responded to (+)- and (±)-pityol (experiments 1–7), except for *C. banksianae* males in experiment 2, where very low trap catches were obtained. No significant differences in trap catch between traps baited with (+)-pityol and (±)-pityol were obtained (experiments 1 and 4). The addition of the host oils to the traps did not appear to enhance male response significantly (experiments 1 and 4), and host oils by themselves were

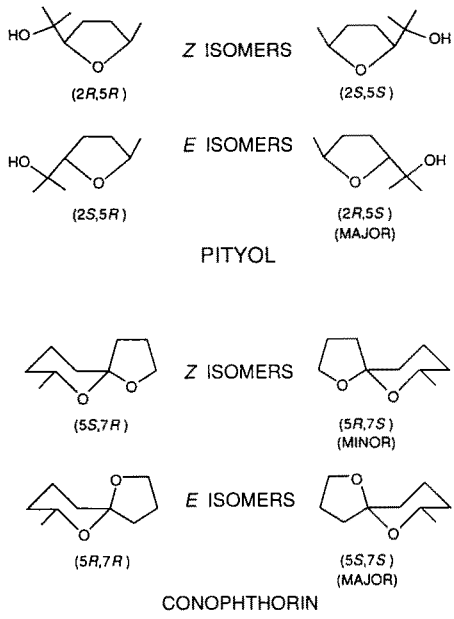

FIG. 3. Stereoisomers of *Conophthorus* pheromones.

unattractive. Male trap catches were not significantly different between the three *E*/*Z* ratios of (±)-pityol for *C. banksianae* and *C. resinosae* (experiments 2 and 5). The addition of (±)-, (+)-, or (−)-spiroacetal to (±)-pityol significantly inhibited the response of males (experiments 3 and 6), and traps baited with the combinations of pityol and the spiroacetal were as attractive as the unbaited traps. When (±)-pityol was released with (±)-spiroacetal (experiment 7) in ratios of 1 : 1, 5 : 1, or 10 : 1, the trap catches of male *C. resinosae* were significantly reduced in comparison to the traps baited with (±)-pityol alone. Neither female *C. banksianae* nor *C. resinosae* responded significantly to any stimulus (trap catches to most treatments were 0 and ranged from 0 to 3).

DISCUSSION

The discovery of (*E*)-(+)-pityol in female *C. resinosae*, *C. banksianae*, and *C. coniperda* (de Groot, 1992; Birgersson et al., 1995) confirms the finding that it is produced by females in this genus. Furthermore, the results clearly demonstrate that (*E*)-(+)-pityol is a sex pheromone that only attracts males. In the closely related genus, *Pityophthorus* (Bright, 1981; Wood 1982), (*E*)-(+)-

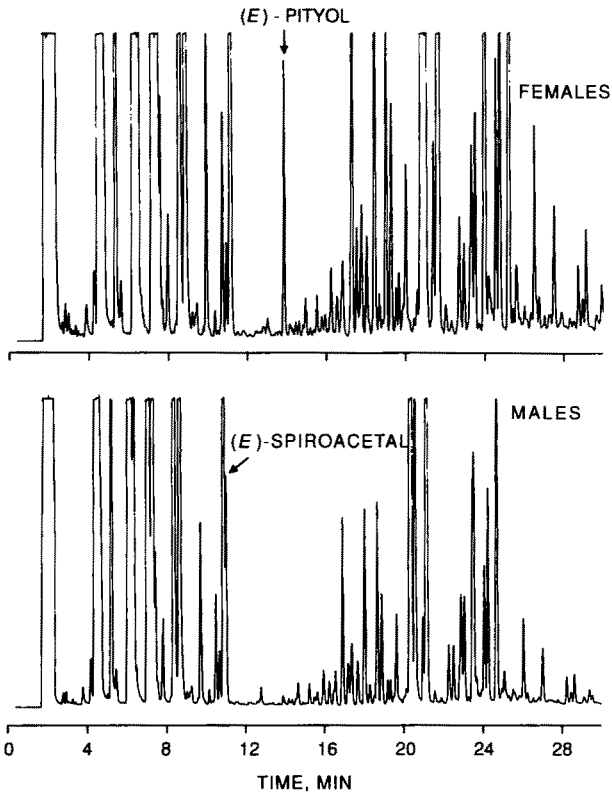

FIG. 4. Gas chromatograms of the Porapak Q-trapped volatiles from female and male *C. resinosae* feeding on red pine.

pityol is produced by male *P. pityographus* Ratz. and with racemic grandisol acts synergistically as an aggregation pheromone (Francke et al., 1987). Although the (+) isomer of (*E*)-pityol generally caught more male *Conophthorus* than the racemate, the differences were not significant, thus indicating that the antipode is benign and the racemate would be suitable in operational use.

The repellency of the spiroacetal to *Conophthorus* is consistent with the finding that its release with *exo-* or *endo*-brevicomin greatly reduced trap catches of both male and female ash bark beetles, *Leperisinus varius* (F.). It thus functions as an antiaggregation pheromone (Kohnle, 1985). Kohnle et al. (1992) found that the spiroacetal reduced the response of *L. varius* regardless of chirality, but only the naturally produced (5*S*,7*S*)-(−) enantiomer reduced the response of the fir bark beetle, *Cryphalus piceae* (Ratz.). The spiroacetal also

repelled worker wasps of several species (Francke et al., 1979b). We suggest that the spiroacetal produced by male *Conophthorus* spp. likely functions as a semiochemical message to warn rival males that they must contest the resident male for the female. Males may also physically protect females from intruders by remaining near the entrance hole between matings and during oviposition (de Groot and Borden, 1991).

Species specificity in (*E*)-pityol and spiroacetal production was not found between *C. banksianae* and *C. resinosae*. Females of both species had produced optically pure (*E*)-(+)-pityol, as had female *C. coniperda* (Birgersson et al., 1995). Similarly, in the males, there was no discernible trend with respect to

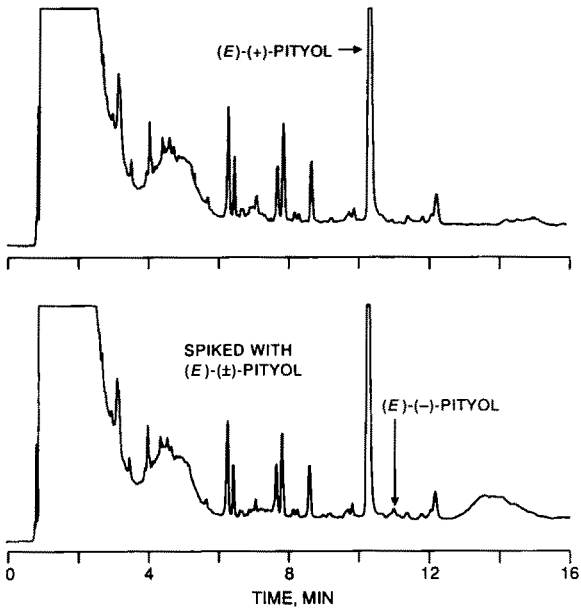

FIG. 6. Gas chromatograms of volatiles in pentane extracts of female *C. banksianae* excised from jack pine (top), and spiked with (*E*)-(±)-pityol (bottom).

species in the structural or optical isomerism of the spiroacetal. The lack of differences in these two pheromones further supports the synonymy of these two sibling species. The release of *E* isomer of the spiroacetal by virgin female *C. coniperda* (Birgersson et al. 1995), but not by female *C. banksianae* and *C. resinosae*, is consistent with other differences that separate the latter two species from *C. coniperda*. After mating, female *C. coniperda* cease production of pityol and continue production of the spiroacetal (Birgersson et al., unpublished results).

Host volatiles do not appear to enhance the attraction to pityol by *C. resinosae* and *C. banksianae*. It appears unlikely that host terpenes confer species specificity to semiochemical-based communication in *Conophthorus* for at least two reasons. First, terpene emissions from pine cones and foliage are highly variable both within and between trees, especially during the growing season (von Rudloff, 1975; Mattson and Strauss, 1986). It is doubtful that *Conophthorus* spp. can rely on such a variable message for highly specific information needed for consistent host finding (Mattson and Strauss 1986) or mate location. Second, *C. resinosae* is not monophagous, suggesting that it does not discriminate among different host "messages" or that differences are detected but are

not meaningful. In spite of the apparent vagueness of the chemical message produced by host odors, they may, nevertheless, play a role in host finding, particularly when coupled with gustatory cues and visual stimuli, such as tree silhouettes (Henson 1967) and cone color (Jenkins 1983).

Both pityol and the spiroacetal appear to have great potential in cone beetle pest management programs. As an attractant for males, pityol can be used to detect and monitor beetle populations in seed orchards. Pityol could also be used to disrupt mating or to trap out a sufficient number of males to reduce populations below an economic threshold. As a repellent, the spiroacetal could be used to deter males from finding females and thereby to disrupt mating. A combination of the pheromones could be used in a "push–pull" tactic (Borden, 1993), whereby the spiroacetal is released as a repellent within a seed orchard and pityol-baited traps are placed on the perimeter to trap out repelled males.

ETHYLENE EMISSION BY A DECIDUOUS TREE, *Tilia americana*, IN RESPONSE TO FEEDING BY INTRODUCED BASSWOOD THRIPS, *Thrips calcaratus*

L.K. RIESKE* and K.F. RAFFA

Department of Entomology
University of Wisconsin
Madison, Wisconsin 53706

(Received July 11, 1994; accepted November 1, 1994)

Abstract—Ethylene emission from excised and intact American basswood tissue was increased after seedlings were infested with the bud-feeding herbivore, *Thrips calcaratus*. Gas chromatographic analysis showed that thrips-infested tissue produced significantly more ethylene than mechanically damaged or control tissue. The possibility that thrips feeding enhances ethylene-mediated stress signals is discussed.

Key Words—Ethylene, thrips, *Thrips calcaratus*, *Tilia*, basswood, insects, induction, phytohormones, herbivory, plant-insect interactions.

INTRODUCTION

Ethylene is a volatile gaseous phytohormone that plays important regulatory roles in a number of physiological processes, including leaf senescence, leaf and bud abscission, radial growth, wood formation, leaf epinasty, seed germination, and fruit ripening (Pratt and Goeschl, 1969; Jackson and Osborne, 1970; Lipe and Morgan, 1973; Beyer et al., 1984; Little and Savidge, 1987; Abeles et al., 1992). Endogenous ethylene levels show diurnal, seasonal, and phenological periodicity (Rikin et al., 1984; Eklund, 1990, 1993; Ingemarsson et al., 1991; Abeles et al., 1992).

In addition to maintaining routine metabolic activities, ethylene can also regulate plant secondary chemistry. Both woody and herbaceous plants produce ethylene in response to a variety of biotic and abiotic stresses, including diseases

(Williamson, 1950; Hislop et al., 1973; Archer and Hislop, 1975), insects (Shain and Hillis, 1972; Wien and Roesingh, 1980; Grisham et al., 1987; Kappel et al., 1987; Martin et al., 1988; Burden et al., 1989; Kendall and Bjostad, 1990), drought (Apelbaum and Yang, 1981; but see Morgan et al., 1990; Narayana et al., 1991), flooding (Tang and Kozlowski, 1984; Yamamoto and Kozlowski, 1987), temperature extremes (Autio and Bramlage, 1986, Kondo and Takahashi, 1989), mechanical wounding (Yu and Yang, 1980), perturbations (Telewski, 1990), and synthetic chemicals (Kimmerer and Kozlowski, 1982; Corey et al., 1987).

American basswood, *Tilia americana* L. (Tiliaceae), is widely distributed across the northeastern United States and is an important component of subclimax forests in the Great Lakes region. The phytochemistry of this species has not been thoroughly studied, but related species are known to contain phytoalexic phenolic sesquiterpenes (Burden and Kemp, 1983).

The introduced basswood thrips, *Thrips calcaratus* Uzel (Thysanoptera: Thripidae), is an early-season defoliator of American basswood. Thrips outbreaks occur immediately following budbreak, with characteristic symptoms including bud or premature leaf abcisson, silvering of the leaf epidermal cells, thinned crowns, branch dieback, and reduction of radial growth (Raffa and Hall, 1989; Rieske et al., 1992).

Wien and Roesingh (1980) and Kendall and Bjostad (1990) showed that feeding by thrips can stimulate ethylene production in herbaceous plants. This response could be partially due to chemical interactions between thrips and host plants, rather than simple mechanical injury. Thrips feeding activity often involves injection of salivary secretions, which predigest plant material (Lewis, 1973). Insect salivary injections may trigger imbalances in phytohormones such as ethylene, and alter plant structure (Purtich and Petty, 1971).

Little research has been conducted on insect-induced ethylene emission by intact deciduous plants. Likewise, our understanding of host-plant chemical interactions associated with bud-feeding is particularly limited. The objectives of this study were to determine whether introduced basswood thrips induced ethylene emission by its deciduous host, *T. americana*, and to compare these emission patterns with those produced by mechanically damaged and uninjured hosts.

METHODS AND MATERIALS

Two-year old *T. americana* seedlings (McKay Nurseries, Waterloo, Wisconsin) with pruned root systems were transplanted into 25-cm-diam. plastic pots in soilless media (Fafard 3B, Carlin Sales, Milwaukee, Wisconsin). Seedlings were grown in a lightly shaded glasshouse under natural lighting and

watered as needed. When leaf expansion reached 5–25 mm, seedlings were fitted with gas collection chambers.

Basswood buds were collected in May 1994 from field sites in northern Wisconsin (Forest County) where there was a heavy infestation of *T. calcaratus*. In the laboratory, thrips were aspirated from the foliage for use in assays.

Ethylene Emission from Excised Tissue. Gas collection chambers consisting of inverted 54 ml (15 × 2.5 cm) glass tubes were fitted on to American basswood seedlings, which were then subjected to one of three treatments: thrips infestation, mechanical injury, and control. Insect-treatment seedlings were infested with 100 newly emerged, field-collected, adult *T. calcaratus*, with an additional 50 insects added 8 hr later. Mechanical damage consisted of puncturing each bud or leaf cluster two times with a group of five 000 sterile insect pins (area = 16 mm^2 per group; puncture depth = 1 mm), and an additional group of punctures to each bud or leaf cluster 8 hr later. Control tissue was untreated. There were five plants each of thrips-infested, mechanically damaged, and control plants, for a total of 15 plants.

Since the basswood buds were not fully opened, and *T. calcaratus* feeds within the opening bud, the actual area of thrips-damaged tissue was impossible to measure. However, the mechanical injury resulted in 48 mm^3 (16 mm^2 per group × 3 punctures × 1 mm deep) of damage per seedling. Modeling clay (VanAken International, El Monte, California) was used to seal the area around the stem and keep the gas collection chamber from contacting soil.

Seedlings were clipped at the base 24 hr following the initial damage, the clay was removed, and each collection chamber was fitted with a gas-tight septum. Headspace was analyzed for ethylene emission immediately and at each successive 8-hr interval, for a total of 96 hr.

Techniques for gas chromatographic analysis of head space were adapted from those of Shain and Hillis (1972). A 2-ml gas sample was withdrawn from each collection chanber using a 5-ml Hamilton Gastight syringe. Headspace samples were injected into a Shimadzu GC-9A gas chromatograph with a flame ionization detector fitted with a capillary Alumina column (30 m × 0.53 mm, J & W Scientific, Folsom, California). The gas chromatograph was operated isothermally at 35°C with an injection port temperature of 100°C; compressed air was used as the carrier gas at a flow rate of 30 ml/min. Samples were integrated with a Shimadzu Chromatopak C-R3A. External standards of 9.900 and 1.060 ppm were used for quantitation. Preliminary experiments demonstrated a highly reliable standard curve for ethylene analysis (peak area = 2400.91 * (ppm ethylene) + 45.000; $R^2 = 0.997$).

Following each sampling, the septum was removed and the collection chamber was flushed for 10–15 sec using a steady stream of ethylene-free air. Assays were maintained at 23°C under constant light for the duration of the experiment.

Buds, leaves, and petioles were dried (96 hr at 65°C) and weighed 120 hr following the initial damage. Ethylene emission was analyzed on a dry weight basis. Nondispersed thrips were counted in an attempt to correlate dispersal with feeding activity, so that the number of dispersed thrips present might be related to ethylene emission.

Ethylene Emission from Intact Plants. Glass globes (1160 ml, 16.5 × 8 cm) fitted with gas-tight septa were placed over American basswood seedlings and sealed with modeling clay as described above. Seedlings were infested with 400 adult *T. calcaratus* initially, followed by 200 additional thrips 8 hr later. Mechanical injury was applied as described above, with each bud or leaf cluster receiving two sets of five punctures, followed by one set of five punctures 8 hr later. There were six plants each of thrips-damaged, mechanically damaged, and control plants, for a total of 18 plants. Assays were maintained at 23°C under constant light for the duration of the experiment.

As described above, headspace samples were analyzed for ethylene emission 24 hr following the initial damage. Samples were taken at 8 hr intervals over 96 hr, with the exception of hour 80. Buds, leaves, and petioles were subsequently dried (96 hr at 65°C) and weighed, and ethylene emission was expressed on a dry-weight basis. Nondispersed thrips were counted in an attempt to correlate the number of dispersed thrips with ethylene emission.

Statistical Analyses. A repeated-measures analysis of variance using SuperANOVA (Abacus Concepts, 1989) was used for data analysis; Fisher's protected LSD was used for mean separations where appropriate.

RESULTS

The retention time for ethylene under the chromatographic conditions used was approximately 2.2 min. Figure 1 shows a typical chromatogram from an uninfested (Figure 1a) versus thrips-infested plant (Figure 1b).

Ethylene Emission from Excised Plants. Adult *T. calcaratus* remained very active on thrips-damaged excised tissue for up to 96 hr following infestation; some remained alive for the duration of the experiment. The first visible signs of thrips feeding were observed 24 hr after infestation.

Mean ethylene production from thrips-damaged tissue was 2.18 times higher than from mechanically damaged tissue, and 2.98 times higher than from control tissue (Figure 2). Ethylene emission from excised, mechanically injured leaves did not differ from controls (Figure 2).

The temporal pattern of ethylene emission from excised *T. americana* tissue over a 120-hr period is illustrated in Figure 3. Ethylene was detectable in all treatments 24 hr after initiation. All three treatments showed similar ethylene emission 8 hr following the initiation of measurements (32 hr following dam-

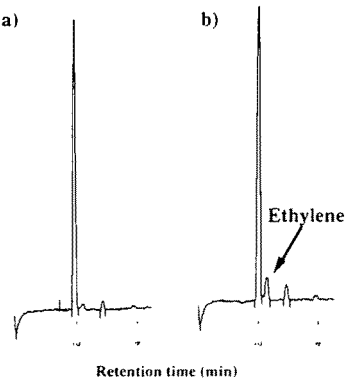

FIG. 1. Gas chromatograms comparing control (a) versus thrips-infested (b) seedlings.

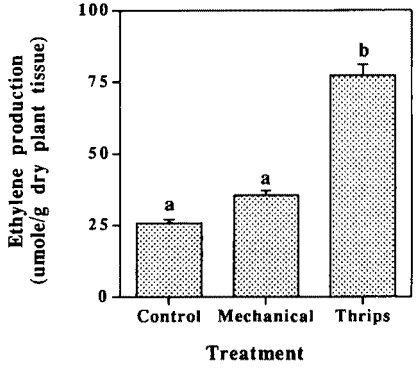

FIG. 2. Mean (± SE) ethylene production by control, mechanically damaged, and thrips-infested excised American basswood tissue. Means followed by the same letter are not significantly different, Fisher's protected LSDD: $F = 2.897$; $df = 2,12$; $P = 0.09$; $N = 5$.

age). However, ethylene production from thrips-infested tissue was greater than control tissue at all subsequent intervals (Figure 3). This increase became statistically significant ($P < 0.1$) at 72 hr, and continued to be significant for the duration of the experiment. Ethylene production from thrips-damaged tissue was also greater than mechanically damaged tissue 40 hr following damage. This difference was statistically significant ($P < 0.1$) at 72, 104, 112, and 120 hr. Although mechanically damaged tissue consistently emitted more ethylene than control tissue, there was no significant difference between mechanically damaged and control tissue at any time interval (Figure 3).

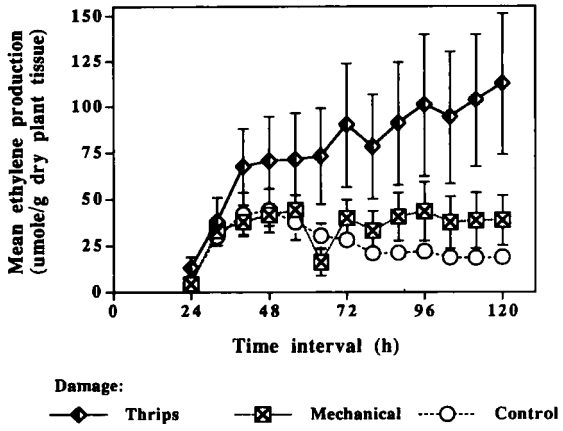

FIG. 3. Mean (± SE) temporal ethylene emission over 120 hr by excised American basswood tissue ($N = 5$). Thrips-infested tissue: $y = 0.801x + 19.587$, $R^2 = 0.833$, $P = 0.0001$; mechanically damaged tissue: $y = 0.170x + 22.272$, $R^2 = 0.211$, $P = 0.1143$; control tissue: $y = -0.122x + 34.652$, $R^2 = 0.124$, $P = 0.2390$.

There was no relationship between the number of thrips present and cumulative ethylene emission from thrips-infested excised plants ($R^2 = 0.021$, $P = 0.8155$).

Ethylene Emission from Intact Plants. Thrips remained active on intact seedlings for the duration of the experiment. The first signs of thrips damage were visible at 24 hr, with symptoms becoming severe by 40 hr.

Figure 4 shows mean ethylene emission from *T. americana* seedlings. Ethylene production from thrips-damaged tissue was 21.60 times higher than from mechanically damaged tissue, and 122.62 times higher than from control tissue (Figure 4). There was no significant difference in ethylene production between mechanically damaged and control plants.

Temporal patterns of mean ethylene production for all treatments are shown in Figure 5. Mean values were higher from thrips-infested than mechanically injured or control seedlings, but ethylene emission varied substantially among plants. Temporal differences between thrips-damaged and control plants appeared statistically significant ($P < 0.1$) beginning at 88 hr and continued to be different for the duration of the experiment (Figure 5). Temporal differences between thrips-damaged and mechanically damaged plants was statistically significant ($P < 0.1$) at 96 hr and remained different throughout. As with the excised tissue, there was no statistical difference between mechanically damaged and control tissue at any time interval (Figure 5).

Also consistent with the excised tissue, there was no relationship between

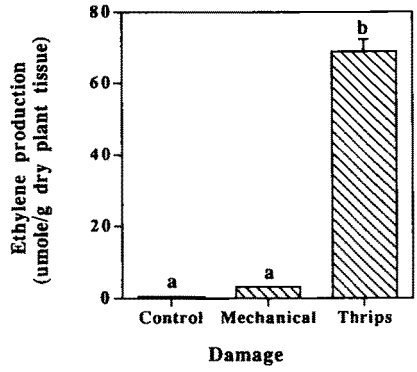

FIG. 4. Mean (± SE) ethylene production by control, mechanically damaged, and thrips-infested American basswood seedlings. Means followed by the same letter are not significantly different, Fisher's protected LSD: $F = 2.761$; $df = 2,15$; $p < 0.1$; $N = 6$.

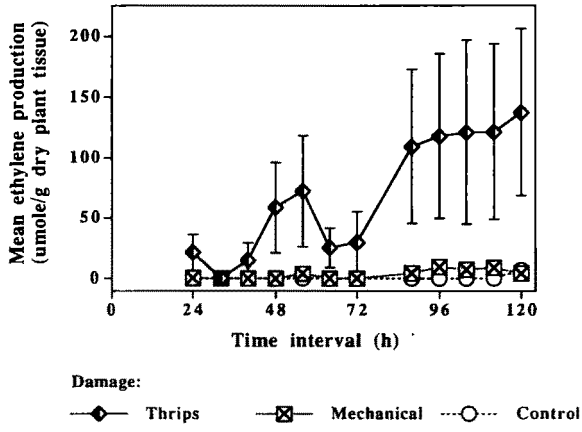

FIG. 5. Mean (± SE) temporal ethylene emission over 120 hr by intact American basswood seedlings ($N = 6$). Thrips-infested tissue: $y = 1.397x - 30.744$, $R^2 = 0.816$, $P = 0.0001$; mechanically damaged tissue: $y = 0.088x - 3.122$, $R^2 = 0.611$, $P = 0.0027$; control tissue: $y = 0.028x - 1.465$, $R^2 = 0.223$, $P = 0.1210$.

the number of thrips present and cumulative ethylene produced ($R^2 = 0.001$, $P = 0.4631$).

Intact infested plants showed a higher rate of increase in ethylene production than did excised, thrips-infested tissue. Moreover, intact plants showed temporal oscillations, whereas excised tissue showed a relatively steady rate of increase (Figures 3 and 5).

DISCUSSION

This is the first report of thrips-induced ethylene production by an intact deciduous perennial host. Feeding by *T. calcaratus* induced ethylene production in both excised and intact basswood plants relative to controls and at levels greater than that of mechanical damage alone. The patterns of ethylene emission among thrips-infested, mechanically damaged and control treatments were comparable between the two experiments (Figures 2–5). The high variability in ethylene emission is consistent with that found by other researchers using both excised tissue (Grisham et al., 1987; Martin et al., 1988) and intact plants (Kendall and Bjostad, 1990).

The duration of increased ethylene emission differed between insect-infested and mechanically injured tissue. Ethylene emission continued to increase in thrips-infested treatments in both experiments up to 120 hr following the initiation of damage (Figures 3 and 5). This contrasts with plant responses to mechanical wounding, which results in a peak rate of ethylene emission within 6 hr (Abeles et al., 1992). Whereas thrips feeding caused continuous injury over a 120-hr period with subsequent increases in ethylene emission, the mechanical injury was not continuous. Therefore, it is not surprising that thrips-induced ethylene emission was far greater than mechanically induced ethylene emission. In working with excised cotton infested with the cotton fleahopper, *Pseudatomoscelis seriatus* (Reuter), Grisham et al. (1987) found ethylene production peaked at 72 hr.

The lack of a correlation between the number of feeding thrips and ethylene emission from both excised and intact tissue was unexpected and suggests that adult thrips may be spending a considerable amount of time in nonfeeding activities. Since *T. calcaratus* is parthenogenetic (Raffa et al., 1992), the primary nonfeeding activity would not be mating, but would most likely be location of suitable oviposition sites.

The pattern of ethylene production by excised tissue shows none of the oscillations seen with intact tissue, suggesting that excision enhanced ethylene production. It is surprising that the overall level of ethylene measured from thrips-infested treatments was greater in the intact tissue, considering the greater than 20-fold increase in chamber volume and considering that wound ethylene caused by excising tissue is itself self-inducing (Abeles et al., 1992). However, the fourfold increase in the number of thrips released seems to have compensated for the increase in chamber volume. In contrast, ethylene emission from mechanically damaged and control treatments were considerably lower in intact than excised plants (Figures 2 and 4).

The low rate of ethylene emission in the mechanically damaged treatments is not inconsistent with that found in other studies (Kendall and Bjostad, 1990). Since ethylene production requires living cells (Abeles et al., 1992), ethylene

emission decreases as leaf necrosis proceeds. Kimmerer and Kozlowski (1982) showed ethylene emission by paper birch decreased when necrosis reached 80%. Although thrips feeding damage was not measured in this study, signs of necrosis were visible in both thrips-damaged and mechanically damaged treatments. The mechanical damage applied is equivalent to or exceeds the estimated 4.93 mm^3 of damage caused by daily feeding of *Thrips tabaci* Lindeman (Quartey, 1982). This suggests that the mechanical damage caused by thrips feeding is not solely responsible for the levels of ethylene emitted. In addition to mechanical wounding, insects can induce ethylene production by the introduction of microorganisms, the injection of hydrolytic salivary secretions, the release of elicitors, and inducing phytohormone imbalances (Abeles et al., 1992). The importance of insect-associated microbes in ethylene production has been shown in other systems (Shain and Hillis, 1972; Grisham et al., 1987). Martin et al. (1988) proposed that the role of the cotton fleahopper in ethylene-induced cotton bud abscission may be due, first, to physical wounding and salivary secretions, and secondly, to providing infection courts for opportunistic microorganisms. The pear thrips, *Taeniothrips inconsequens* (Uzel), which resembles *T. calcaratus* in life history and habits, has been associated with the opportunistic pathogenic fungus, *Discula campestris* (Pass.) von Arx, on sugar maple (Stanosz, 1993). Burden et al. (1989) found that the phytohormone indoleacetic acid and the ethylene precursor ACC (1-aminocycloproprane-1-carboxylic acid) were present in the cotton fleahopper; ethylene emission was enhanced not only by mechanical damage caused by feeding, but also by induced phytohormone changes.

Given the complexity of the roles of ethylene in primary and secondary plant metabolism, it seems reasonable that the mechanisms by which insect feeding increases ethylene evolution would be equally complex. More than likely, insect-induced increases in ethylene are due to a combination of these factors.

(Received August 22, 1994; accepted November 1, 1994)

Abstract—A method has been developed to convert disparlure (2-methyl-7,8-epoxyoctadecane) to the corresponding *N*-(α-methylbenzyl)aziridine with inversion of configuration at both the 7 and 8 positions. The diastereomeric aziridines can be separated on an efficient gas chromatography column, permitting determination of the enantiomeric constitution of the starting disparlure. As little as ca. 0.1% of the minor enantiomer can be detected.

Key Words—Disparlure, gypsy moth, enantiomer, diastereomer.

INTRODUCTION

Trapping of male gypsy moths (*Lymantria dispar*) with traps baited with synthetic (+)-disparlure [(7*R*, 8*S*)-2-methyl-7,8-epoxyoctadecane] has been used for monitoring populations for a number of years. During this time, differences in effectiveness have been noted among batches of the synthetic pheromone that could not be reconciled with differences in chemical purities as assessed by capillary gas chromatography. It has been reported on several occasions (Plimmer et al., 1977, Cardé et al., 1977, Miller et al., 1977, Odell et al., 1992) that the presence of the (−) enantiomer, even in small amounts, can reduce pheromone effectiveness. Since that time, a number of syntheses of disparlure enantiomers have been reported (Mori, 1992) and, because of its annual use in both control and experimental programs, it has become a commercial item. The optical rotation of pure disparlure is less than 1°, so measurement of rotation

is of little value for detecting small amounts of the opposite enantiomer. Since there have been no alternative means of assaying samples for the (−) enantiomer, quality control of purchased samples has been impossible except for trapping tests conducted during the short gypsy moth flying season. Accordingly, an analytical method for determining the enantiomeric composition of disparlure is needed.

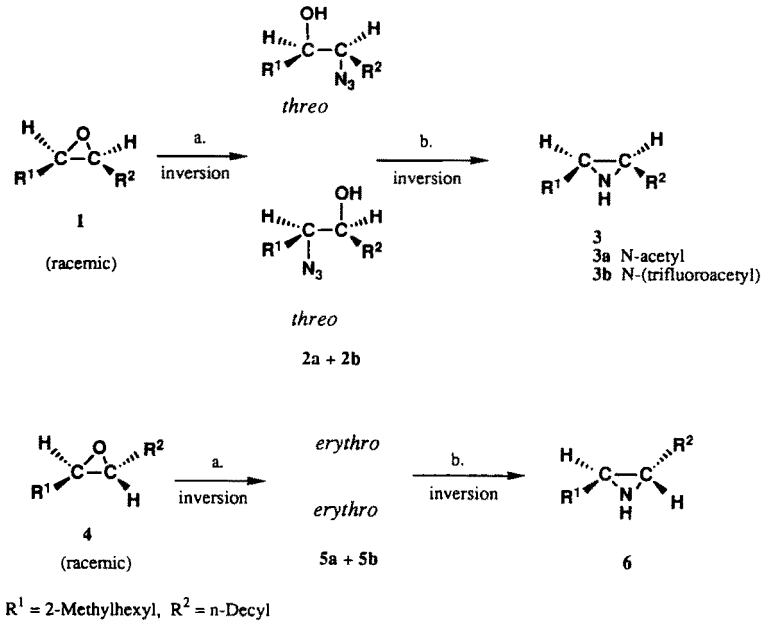
Although considerable progress has been made in HPLC and GLC separation of enantiomers on chiral stationary phases, attempts to apply these methods to disparlure have been discouraging. Undoubtedly, the major problem lies in the similarity of the two alkyl groups on the epoxide ring—each is a generally undistinguished aliphatic alkyl group whose properties in terms of polarity and conformation are very similar. Thus, there is little basis for preferential interaction with a chiral stationary phase. We describe here a stereospecific conversion of disparlure to diastereomeric aziridines and the configurational determination of the disparlure via gas chromatographic analysis of these products.

METHODS AND MATERIALS

Gas chromatography analyses were conducted in a Shimadzu model 14A instrument equipped with a flame ionization detector and a 60-m SPB 608 custom column obtained from Supelco Co. Neutral alumina (Woelm) was oven-dried for about four days at 135°C until constant weight was achieved. ^{1}H NMR spectra were obtained with a General Electric QE-300 NMR spectrometer on deuteriochloroform or deuteriobenzene solutions (significantly better resolution was realized with the α-methylbenzylaziridine spectra recorded with the latter solvent). Mass spectra were recorded on a Finnigan model 4510 GC-MS or a Finnigan Incos 50 GC-MS. Electron ionization spectra were collected at 70 eV and a source block temperature of 150°C. Mention of a proprietary product or company does not imply endorsement by the US Department of Agriculture.

threo-Azidoalcohols **2a** + **2b** *from Disparlure (Scheme 1).* A mixture of racemic disparlure (5.72 g), sodium azide (6.76 g), ammonium chloride (2.14 g), dimethylformamide (100 ml), and water (10 ml) was stirred and heated (bath temperature 122°C) for 4 hr. After cooling, the product was partitioned between water and ether–hexane (1 : 1 v/v), the organic phase was washed well with water, dried, concentrated, and flash chromatographed (5% ethyl acetate in hexanes) to provide 4.72 g of a mixture of **2a** and **2b** as a colorless oil.

Conversion of threo-Azidoalcohols **2a** + **2b** *to Racemic* cis *Aziridine* **3** *(Scheme 1).* A solution of **2a** + **2b** (1.00 g), and triphenylphosphine (0.90 g) in acetonitrile (18 ml) was heated at reflux for 2 hr, then was cooled and concentrated. The residue was extracted with pentane, the extract filtered and

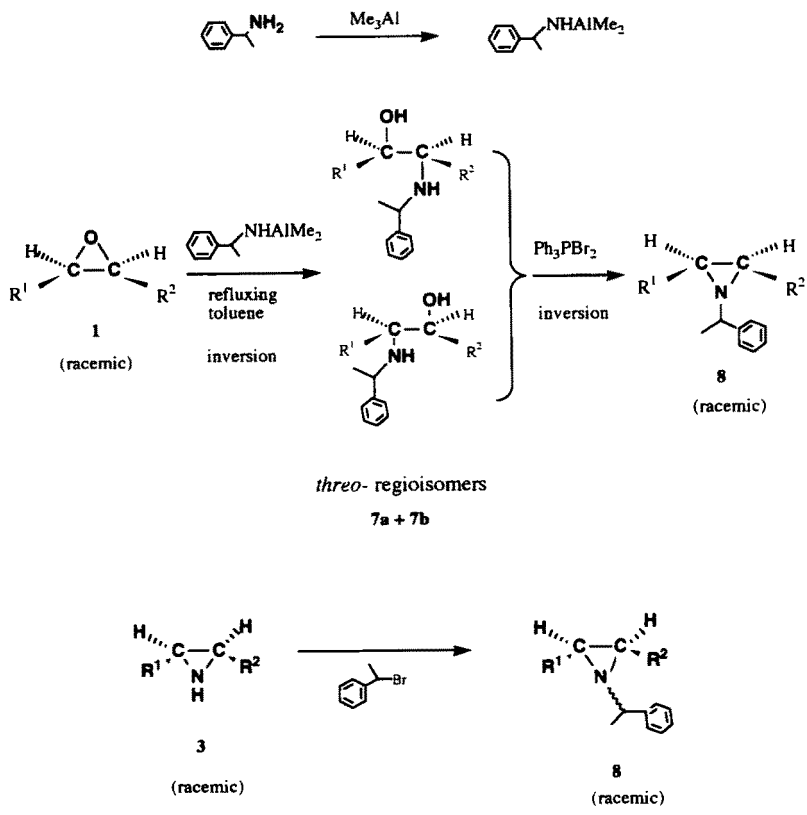


SCHEME 1.

concentrated, and the residue was again extracted with pentane. Flash chromatography (25% ethyl acetate in cyclohexane) gave 590 mg of **3** as a waxy solid. ^{1}H NMR ($CDCl_3$): 0.87 (d, J = 6.6, isopropyl methyl), 0.88 (m, terminal methyl), 1.32 (methylene), 1.52 (m, H-2), 1.98 (m, H-7 and H-8). Small portions of **3** were converted to the acetate **3a** and the trifluoroacetate **3b** with acetic anhydride and trifluoroacetic anhydride, respectively. ^{1}H NMR of **3a** ($CDCl_3$): 0.87 (d, J = 6.6, isopropyl methyl), 0.885 (m, terminal methyl), 1.56 (m, H-2), 2.41 (m, H-7 and H-8), 2.11 (s, acetate methyl). ^{1}H NMR of **3b** ($CDCl_3$): 0.877 (d, J = 6.6, isopropyl methyl), 0.882 (m, terminal methyl), 1.53 (m, H-2), 2.73 (m, H-7 and H-8).

erythro-Azidoalcohols **5a** *and* **5b** *and trans-Aziridine* **6** *(Scheme 1).* The above procedures were repeated starting with racemic *trans*-disparlure **4.** The *trans*-aziridine **6** was surprisingly polar and was eluted from a silica gel column with 75% ethyl acetate in hexanes to give **6** as a colorless oil.

*threo-(α-Methylbenzyl)amino Alcohols (***7a** *and* **7b***) from Disparlure (Scheme 2).* A solution of (−)-α-methylbenzylamine (1.05 g, 85 mmol) in



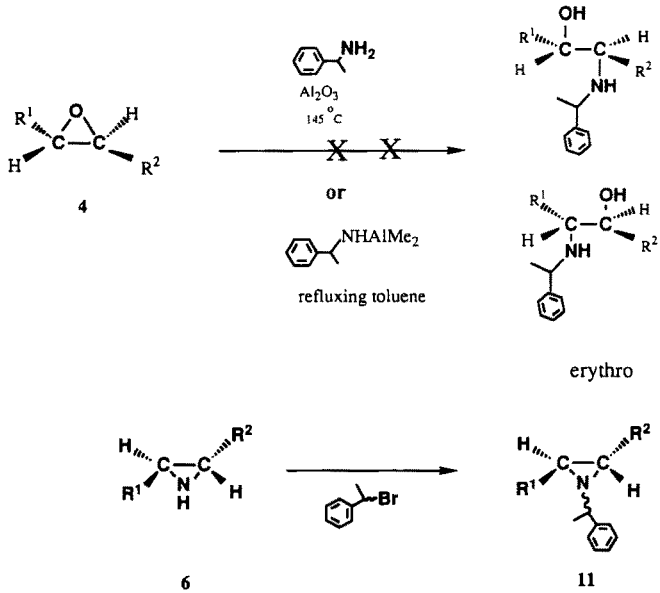
SCHEME 2.

toluene (10 ml) was added dropwise to a cold (ice bath), stirred solution of trimethylaluminum in toluene (5 ml, 2 M, 100 mmol). After the initial reaction had subsided, a solution of racemic disparlure (2.4 g, 85 mmol) in toluene (50 ml) was added and the solution was heated at reflux for 4 hr. After cooling, 6 N NaOH (8 ml) was added, the mixture was extracted with three portions of hexane, and the combined extracts were rinsed well with water, dried, concentrated, and flash chromatographed (20% then 30% ethyl acetate in cyclohexane) to give ca. 2.9 g of a mixture of **7a** and **7b.**

Conversion of threo-(α-Methylbenzyl)amino Alcohols **7a** *and* **7b** *to N-(α-Methylbenzyl)-cis-aziridines* **8** *(Scheme 2).* A solution of **7a** + **7b** (44 mg) in dichloromethane (125 μl) containing triethylamine (50 μl) was treated with meth-

anesulfonyl chloride (10 μl). After stirring overnight, the product was partitioned between aqueous sodium carbonate and pentane, then was flash chromatographed (2%, then 5% ethyl acetate in cyclohexane) to give 32 mg of racemic **8.** The same product was obtained upon treatment of **7a** and **7b** with triphenylphosphine dibromide. Mass spectrum of **8,** *m/e* (relative intensity, %): 385 (M^+, 1), 384, (2), 370 (1), 280 (100), 244 (12), 105 (57), 82 (12), 69 (34), 55 (35). Mass spectrum, chemical ionization, ammonia: *m/z* 386 ($M + H^+$, 100%). ^1H NMR (C_6D_6): **8** from racemic disparlure and (*S*)-(−)-α-methylbenzylamine: (C_{66}) 0.835 (d, $J = 6.6$), isopropyl methyl, 0.92 (m, terminal methyl), 1.30 (methylene), 1.41 (m, H-2), 1.43 (d, $J = 6.6$, α-methyl), 1.52 (m, H-7 and H-8), 2.30 (q, $J = 6.6$), 7.3 (m, phenyl), **8** from (+)-disparlure and (*S*)-(−)-α-methylbenzylamine (C_{66}) 0.84 (d, $J = 6.6$, isopropyl methyl), 0.92 (t, $J = 6.0$, terminal methyl), 1.30 (methylene), 1.38 (m, H-2), 1.43 (d, $J = 6.6$, α-methyl), 1.53 (m, H-7 and H-8), 2.31 (q, $J = 6.6$, α-H), 7.3 (m, phenyl).

N-α-Methylbenzyl-trans-aziridines **11a** *and* **11b** *(Scheme 3).* A solution of the *trans*-aziridine **6** (32 mg), diisopropylethylamine (25 μl), and 1-bromophenylethane (20 μl) in acetonitrile (300 μl) was heated at reflux for 2 hr, then was cooled and partitioned between 5% ethyl acetate in pentane and aqueous sodium carbonate. Flash chromatography of the product afforded a surprising degree of separation of pairs of diastereomers with one pair eluting with 5% ethyl acetate

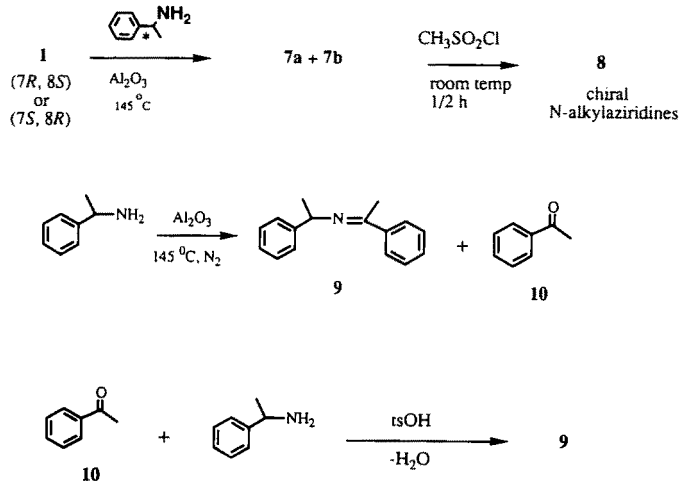


4 6 11

SCHEME 3.

in hexanes and the other with 10% ethyl acetate in hexanes. Gas chromatography of the crude mixture or of a reconstituted mixture showed both pairs of isomers to be later-eluting than the corresponding *cis*-*N*-(α-methylbenzyl)aziridines **8** from *cis*-disparlure. Mass spectrum of **11a** (earlier-eluting isomer from both silica gel and GC): *m/z* 385 (2), 384 (2), 286 (6), 281 (21), 280 (100), 105 (58), 69 (25), 55 (26); ^{1}H NMR (C_6D_6): 0.85 (d, J = 6.6, 3 H, isopropyl methyl), 0.90 (m, terminal methyl), 0.92 (d, J = 6.6, 3 H, isopropyl methyl), 1.29 (methylene), 1.46 (d, J = 6.6, α-methyl), 1.57 (m, H-7 and H-8), 3.10 (q, J = 6.6, α-H), 7.28 (m, phenyl). Mass spectrum of **11b:** 281 (22), 280 (100), 207 (6), 105 (50), 69 (26), 55 (23). ^{1}H NMR (C_6D_6): 0.84 (d, J = 6.6, 3H, isopropyl methyl), 0.92 (d, J = 6.6, 3H, isopropyl methyl), 0.925 (m, terminal methyl), 1.31 (methylene), 1.49 (d, J = 6.6, α-methyl, 3.16 (q, J = 6.6, α-H), 7.37 (m, phenyl).

Isolation and Identification of Imine **9** *(Scheme 4).* (*S*)-(−)-α-Methylbenzylamine (300 μl), anhydrous neutral alumina (3 g), and racemic disparlure (10 mg) were combined in a pressure tube and the tube was heated to 150°C for 16 hr. The tube was cooled and opened, and the contents were extracted with 5% ethyl acetate in pentane to give 330 mg of a pale yellow oil that was recombined with 1.1 g of alumina in an ampoule that was then sealed under nitrogen and heated an additional 2.5 hr at 150°C. The alumina was eluted with 10% ethyl acetate in cyclohexane, and the eluate was flash chromatographed on silica gel with the same solvent to give ca. 20 mg of **9** as a pale yellow oil,



SCHEME 4.

mass spectrum *m/z* 224 (34), 223 (70), 222 (44), 208 (42), 167 (21), 165 (18), 106 (44), 105 (100), 104 (72), 103 (60), 102 (17), 90 (12), 89 (21), 83 (20) 79 (59), 78 (52), 77 (60), 76 (20), 63 (15), 52 (15), 51 (48), 50 (19). ^{1}H NMR ($CDCl_3$) [These chemical shifts vary somewhat from those previously reported (Arjona et al., 1984)]: 1.48 (q, J = 6.6, $\underline{H}CMe$), 1.54 (d, J = 6.6, $C\underline{H}_3CH$), 2.27 (s, $C\underline{H}_3C{=}N$), 7.84 (m, phenyl). The same product could be prepared by refluxing equimolar portions of α-methylbenzylamine and acetophenone in toluene containing toluenesulfonic acid with azeotropic removal of water.

Analytical Procedure for Enantiomeric Evaluation of Disparlure Samples. About 30 mg of alumina (neutral, oven-dried to constant weight) was added to each of two 2-ml ampoules. Then to each is added a solution of disparlure in a volatile solvent (eg. hexane) such that ca. 100 μg disparlure is added. To one ampoule is added 3 μl of pure (−)-α-methylbenzylamine, and to the other is added 3 μl pure (+)-α-methylbenzylamine. A Firestone valve or gentle stream of nitrogen and gentle heat is used to replace simultaneously the air with nitrogen and to evaporate the solvent. The ampoules are sealed and heated at 145–150°C for 2.5 hr. The ampoules are cooled, opened, and to each is added 50 μl of a 10% solution of methanesulfonyl chloride in benzene. After allowing them to stand at room temperature 45–60 min, then 25–50 μl 2N sodium carbonate is added, and they are allowed to stand for 15 or more min. Then 1 ml of 5% ethyl acetate in pentane (in several successive portions) is used to transfer soluble products to (and through) a small column containing ca. 150–160 mg of silica gel. The eluate is concentrated with a stream of nitrogen just to dryness, and an appropriate solvent for gas chromatography is added (e.g., 25–50 μl cyclohexane). The results in Table 1 were obtained using this method with the GC injector operated in the split mode. Satisfactory results have been obtained on less than one tenth this scale using splitless GC injections.

RESULTS AND DISCUSSION

Conversion of enantiomers to diasteromers by the introduction of a second, defined chiral center is a common strategy for assessing the stereochemistry of an analyte (Skidmore, 1993). Diastereomers have different physical properties and are often separable on archiral GLC or HPLC columns. [For example, *cis*-disparlure (the 7*R*, 8*S* and 7*S*, 8*R* pair) is easily separated by GLC or even column chromatography from *trans*-disparlure (7*R*, 8*R* and 7*S*, 8*S*).] Alcohols, amines, acids, etc., with one asymmetric center are easily converted to diastereomeric esters, amides, carbamates, etc., with reagents that introduce a second chiral element. Disparlure, with two chemically similar alkyl groups and the epoxide as its only functionality, presents some limitations: although there are a number of stereospecific epoxide opening reactions, none of these can be

expected to be regiospecific in the disparlure case. Nonregioselective ring opening would lead to multiple products, complicating any subsequent separations and interpretations. Prestwich et al. (1989) described enantioselective enzymatic hydrolysis of disparlure and separation of the resulting diols on a chiral GLC column. In contrast, chemical hydrolysis, although presumably stereospecific, would result in virtual racemization because of nonselective attack of water at either of the two epoxide carbons.

An ideal derivative would be a single product that introduced the required additional chiral center while preserving the stereochemical information of each of the original chiral centers. The original configurations of these two carbons need not necessarily be retained, however; so processes that involved retention of configuration at each center, or inversion at each center, ought to serve equally well.

Conversion of epoxides to unsubstituted aziridines with two inversions of configuration are known, and a procedure based on that of Ittah et al. (1978) was applied to disparlure (Scheme 1). Reaction of disparlure (**1**) with sodium azide plus ammonium chloride in dimethylformamide at >90°C gave a pair of *threo*-azido alcohols **2a** + **2b,** which in turn were reacted with triphenylphosphine to provide the *cis*-aziridine **3** (inversion at each carbon). The *N*-acetyl (**3a**) and *N*-(trifluoroacetyl) (**3b**) derivatives were prepared, but neither pair of enantiomers could be separated on a Cyclodex B gas chromatography column. The unsubstituted aziridine could also be derivatized with Mosher's acid or with 1-(1-naphthyl)ethyl isocyanate; these diastereomeric derivatives ought to be amenable to analyses by HPLC, but the approach was not pursued because we simultaneously developed the procedure for gas chromatographic analysis of *N*-(α-methylbenzyl)aziridines described below.

Martinelli et al. (1990) described the reaction of a 1,2-disubstituted epoxide with α-methylbenzylamine and subsequent conversion of the resulting amino alcohol to the *N*-alkylaziridine upon treatment with triphenylphosphine dibromide or with diethyl azodicarboxylate. Disparlure, in the absence of acids, is remarkably resistant to nucleophilic ring opening and was recovered unchanged after attempting to react it with (+)-α-methylbenzylamine under the conditions (refluxing 1-butanol) described by Martinelli et al., as well as from a variety of more vigorous conditions. Slow ring opening occurred with α-methylbenzylamine and lithium perchlorate in acetonitrile [at 100°C in a sealed tube, less than 50% conversion was realized in 6 hr, in contrast to the room-temperature openings described by Chini et al. (1990)]. We eventually achieved the desired conversion by reacting the amine first with trimethylaluminum (Overman and Flippin, 1981) and then reacting the resulting reagent with disparlure in refluxing toluene (in contrast to the considerably milder conditions found satisfactory for the epoxides studied by the original authors). The resulting mixture (Scheme 2) of positionally isomeric *threo*-amino alcohols **7a** + **7b** could be converted to

the desired *N*-alkylaziridines **8** with either triphenylphosphine dibromide or with methanesulfonyl chloride in the presence of triethylamine. (The same products resulted from alkylation of the unsubstituted *cis*-aziridine **3** with 1-bromo-1-phenylethane).

The racemic *N*-α-methylbenzylaziridine thus prepared was examined on several GLC columns. Varying degrees of separation were observed, and a 60-m proprietary column was found that achieved essentially baseline separation in slightly over 35 min.

Seeking a more convenient alternative to the organometallic reagent, we found that disparlure could also be opened by α-methylbenzylamine on anhydrous neutral alumina (Posner and Rogers, 1977) (Scheme 4). Again the reaction was sluggish (excess amine, 2.5–3 hr at ca. 145°C in the absence of solvent in contrast to 1 hr at room temperature in ether for some examples cited in the original work). Furthermore, some amine oxidation invariably occurred, whether or not an inert atmosphere was used. The odor of acetophenone was always evident, and small amounts of acetophenone **10** could be detected by GLC as could larger amounts of the imine (**9**, Scheme 3) that would formally result from its condensation with α-methylbenzylamine (Arjona et al., 1984). However, these by-products did not interfere with the analyses, and furthermore, ring closure to the desired aziridine could be effected without isolation by simply treating the alumina-adsorbed products with methanesulfonyl chloride. Yields were variable, although not in a recognizably systematic way; from 100 to 200-μg reactions, after passing products through small silical gel columns, they tended to range from 10 to 25%.

As stated, stereospecific conversion of a *cis*-epoxide to a *cis*-aziridine requires an even number of (or zero) inversions of configuration. If one of the two reactions was imperfectly stereoselective, the result would not necessarily be analytically fatal, since the product from an odd number of inversions would be a *trans*-aziridine, which should have a different GLC retention time from either of the *cis*-diastereomers. To determine whether the corresponding *trans*-*N*-(α-methylbenzyl)aziridines would be distinguishable from the *cis*-isomers, we attempted to carry out the epoxide–aziridine conversion starting with *trans*-disparlure (**4**).

Whereas ring opening reactions of *cis*-disparlure with the amine had been difficult, useful ring openings of *trans*-disparlure with α-methylbenzylamine eluded us altogether. Neither the aminodialkylaluminum approach nor the alumina-catalyzed reaction was successful, and the *trans* epoxide was recovered unchanged from conditions that had satisfactorily opened the *cis* isomer as well as from increasingly vigorous conditions, to the point where extensive and undefined decomposition resulted. The difficulty was eventually circumvented, however, by opening *trans*-disparlure with azide as described above for *cis*-disparlure (Scheme 1). In contrast to the unsuccessful attempts with α-methylbenzylamine,

the reaction of *trans*-disparlure with NaN_3/NH_4Cl occurred much as it had for *cis*-disparlure, and the resulting *erythro* pair (positional isomers) of hydroxy azides **5a** and **5b** were converted to the *N*-unsubstituted *trans*-aziridine (**6**) with triphenylphosphine (Scheme 1). Aziridine **6** could be alkylated with 1-bromo-1-phenylethane to give the *trans*-*N*-alkylaziridines **11** (Scheme 4), giving a mixture of diastereomers. Both had GLC retention times longer than those of the corresponding *cis*-aziridines, so that their occurrence in a mixture would not interfere with the analyses. This proved to be a somewhat moot point inasmuch as they were essentially unobservable, their absence from reaction products from *cis*-disparlure testifying to the stereospecificity of each of the two steps in the epoxide–aziridine conversion.

Reliable stereospecificity was also indicated by the fact that one or more samples of each the (+)- and (−)-disparlure samples on hand consistently tested negative for detectable amounts of the opposite enantiomer, whereas many samples reproducibly tested positive for varying amounts of the unwanted enantiomer.

Enantiomeric purity of the starting α-methylbenzylamine was a necessity since any of the wrong enantiomer in the starting amine would give an aziridine product from (+)-disparlure indistinguishable from that formed from the correct amine and (−)-disparlure, i.e., a false positive. Accordingly, each amine (>99% as purchased) was rigorously purified by converting to the appropriate tartrate salt [(+)-amine and (−)-tartaric acid, (−)-amine and (+)-tartaric acid], recrystallizing at least two times from methanol, and regenerating and distilling the amine (Ault, 1973). None of the opposite enantiomer could be detected by conversion to amides with Mosher's acid and examination by gas chromatography.

All samples tested were reacted with both the (+)- and (−)-amines; thus in every case the product from the (−)-disparlure was observed as both the earlier- and later-eluting diastereomer. Consistent results between the two measurements provided confidence against random peaks inadvertently producing false positives, and, importantly, argue against the possibility of conclusions biased by diastereoselectivity. Inconsistent results from the two amines (in reality, very rarely experienced) would be a clear indication that the analyses required repetition. Although near-baseline separation had been achieved on dilute samples of racemic α-methylbenzylaziridines, somewhat larger samples were required when the minor enantiomer constituted only a fraction of a percent of the major enantiomer, and in these cases the minor GLC peak appeared as an incompletely resolved shoulder. It can be seen from Table 1 that in a majority of cases, the estimated value for (−)-disparlure obtained from the use of the (*R*)-(+)-α-methylbenzylamine (minor GLC peak later eluting) was slightly higher than that from the (*S*)-(−)-enantiomer (minor peak earlier eluting). This

is believed to be a reflection of the integration of incompletely resolved peaks as opposed to any diastereoselectivity in the chemical reactions.

A large number of samples, submitted over several years from a variety of sources as (+)-disparlure, were evaluated by the procedure described (Table 1). It is evident that the enantiomeric composition has varied widely, with some samples being nearly racemic and one actually containing more than 50% of the (−) enantiomer. Several of the samples, in contrast, contain virtually no detectable (−) enantiomer.

Some field tests, designed to examine more systematically the effects of known amounts of the (−) enantiomer, are being conducted by coworkers (B.A. Leonhardt, V. Mastro, among others), and for this purpose, along with that of testing our analytical method, some standard solutions were prepared by careful dilution (with racemic disparlure) of one of the (+)-disparlure samples in which none of the opposite enantiomer was detectable. Two of these dilutions [2.0% and 0.5% (−)-disparlure] were selected for analysis, and the results constitute entries 31 and 32, respectively, of Table 1. Acceptable results were obtained, and as discussed above, the values obtained from the product of (+)-α-methylbenzylamine were slightly higher than those from the (−)-amine. Accordingly, we conclude that the values recorded in column 2 of Table 1 represent reasonably accurate and reliable estimates of the enantiomeric compositions of the disparlure samples examined. Examinations of standard solutions also confirmed the detectability of concentrations of (−)-disparlure as low as 0.1%.

Acknowledgments—We thank D.J. Harrison and E.D. DeVilbiss for mass spectra, M. Schwarz for the organoaluminum reactions, S. Panicker for general assistance, and B.A. Leonhardt for suggesting the problem and for generous encouragement. Some of these results were presented at the 11th Annual Meeting of the International Society of Chemical Ecology, Syracuse, New York, June 4–8, 1994.

(Received August 11, 1994; accepted November 1, 1994).

Abstract—Previous analyses of the scent gland secretions of snakes have focused on the nonvolatile components. Gas chromatography–mass spectrometry of secretions from North American garter snakes (*Thamnophis butleri*, *T. couchi*, *T. elegans*, *T. melanogaster*, and *T. sirtalis*) indicated the following seven major volatile components: acetic, propanoic, 2-methylpropanoic, butanoic, and 3-methylbutanoic acids, trimethylamine, and 2-piperidone. Five or more of these compounds were observed in secretions of select boid, colubrid, pythonid, and viperid snakes, suggesting that they are widespread scent gland products. 3-Methylbutanal also was detected in some snake species.

Key Words—Garter snakes, *Thamnophis*, 2-piperidone, trimethylamine, short-chain carboxylic acids.

INTRODUCTION

The foul-smelling fluids discharged from the cloacal region of snakes are familiar to anyone who has handled an agitated specimen. Contributing to these odoriferous materials are the scent glands, two organs opening through separate ducts at the margin of the cloacal orifice (Whiting, 1969). Previous analyses of scent gland secretions have focused on the nonvolatile components. Both lipids (Oldak, 1976; Weldon et al., 1990, 1991, 1992; Simpson et al., 1993) and

*To whom correspondence should be addressed.

proteins (Weldon and Leto, 1995) have been reported. Studies on the volatile components of scent gland secretions are confined to an analysis of an ether extract of Drumeril's ground boa, *Acrantophis dumerili*, Boidae (Simpson et al., 1993). Short-chain carboxylic acids (C_3–C_5) and phenol, in addition to higher molecular weight compounds, were identified in this species' secretions.

We report here an analysis by gas chromatography–mass spectrometry (GC-MS) of the volatile components in the scent gland secretions of North American garter snakes (*Thamnophis* spp.). This is the first detailed identification of scent gland compounds from the Colubridae, the most speciose family of snakes. In addition, we provide preliminary results on the volatile secretions of select boid, colubrid, pythonid, and viperid snakes. Our results point to some compounds that likely are widespread scent gland products.

METHODS AND MATERIALS

Scent gland secretions were obtained from adult free-ranging and captive snakes. Free-ranging specimens of the western aquatic garter snake, *T. couchi* (one female), wandering garter snake, *T. elegans* (one female), and eastern garter snake, *T. sirtalis* (three females), were captured in Humboldt County, California; all individuals were released after samples were obtained. Captive secretion donors maintained in the Reptile Ethology Laboratory of the University of Tennessee, Knoxville, were *T. sirtalis* (four females, five males), captured in or born to females from Ottawa County, Ohio; the black-bellied garter snake, *T. melanogaster* (eight females, four males), captured in or born to females from Jalisco, Mexico; and Butler's garter snake, *T. butleri* (five females, three males), born to females captured in Wayne County, Michigan. Captive secretion donors from the Dallas Zoo, Texas, and the Houston Zoological Gardens, Texas, were *T. sirtalis* (one female, one male); *T. elegans* (one male); Dumeril's ground boa, *Acrantophis dumerili*, Boidae (one male); green anaconda, *Eunectes murinus*, Boidae (one female); common kingsnake, *Lampropeltis getula*, Colubridae (one male); ringed python, *Bothrochilus boa*, Pythonidae (one female); copperhead, *Agkistrodon contortrix*, Viperidae (one female); and speckled rattlesnake, *Crotalus mitchelli*, Viperidae (one female).

Scent gland secretions, expressed by gently pressing on the base of the tail, were collected in glass vials with Teflon-lined stoppers. Samples from free-ranging snakes from California were analyzed individually by GC-MS within 30 min. of collection. The pH of the secretions from these snakes was determined with pHydrion Paper (Micro Essential Laboratory, Brooklyn, New York) within a minute of collection. Samples from captive snakes were pooled by species and sex, placed on Dry Ice, shipped to California, and analyzed within a few hours of receipt. Approximately 1 μl of neat secretion was used for each GC-MS analysis.

GC-MS was done on a Hewlett-Packard gas chromatograph (model 5890) fitted with a mass selective detector (model 5970) using a 12-m cross-linked methyl silicone capillary column (HP-1). The gas chromatograph was programmed so the oven temperature was maintained at 40°C for 4 min., then increased to a final temperature of 250°C at a rate of 30°C/min and kept at this temperature for 4 min. For native secretions, mass spectral fragments below $m/z = 20$ were not recorded, and the mass spectrometer was turned on 0.1 min after injection of the sample so that all volatile components could be analyzed. For ether extracts, fragments below $m/z = 35$ were not recorded, and the mass spectrometer was turned on 2 min after injection of the sample. Compounds were identified by comparing their mass spectra and relative retention times of those of authentic standards (Aldrich Chemical Co., Milwaukee, Wisconsin).

To examine the possibility that trimethylamine was an artifact from the decomposition of nonvolatile trimethylammonium salts on the hot GC injector, 0.1 μl of 10% NaOH was added to the vial containing the secretions from *E. murinus*. The vial was immediately sealed with a rubber stopper. After 5 min, a 5-μl headspace sample was analyzed by GC-MS analysis using the same conditions as for native secretions.

To see if trimethylammonium salts of the short-chain carboxylic acids generate trimethylamine and the free carboxylic acids on injection into the GC-MS, a solution was prepared from 50 ml of water and 3 drops of each carboxylic acid. This was adjusted to pH 7 with an aqueous solution of trimethylamine and then analyzed by GC-MS using the same conditions as for the native secretions.

The presence of ammonia or low-molecular-weight amines was investigated by treating the secretions of *T. sirtalis* with 1 ml of 1.0 M NaOH and 1 drop of benzoyl chloride in 1 ml of ether. The ether solution was analyzed by GC-MS for benzamide and *N*-substituted benzamides.

To examine the possibility that 2-piperidone was an artifact from the dehydration of 5-aminopentanoic acid, 1.0 μl of a solution of 100 mg of 5-aminopentanoic acid (Aldrich Chemical Co.) in 50 ml was analyzed by GC-MS using the same conditions as for native secretions.

RESULTS AND DISCUSSION

GC-MS analysis of the neat scent gland secretions from samples of all *Thamnophis* species showed the same seven volatile compounds (in order of elution): trimethylamine, acetic acid, propanoic acid, 2-methylpropanoic acid, butanoic acid, 3-methylbutanoic acid, and 2-piperidone (Figure 1).The relative amounts of these compounds varied between samples, and no consistent variation was seen between sex or species. The electron impact-mass spectra of these compounds are as follows: trimethylamine—$m/z = 59(M^+, 42), 58(100), 44(11),$

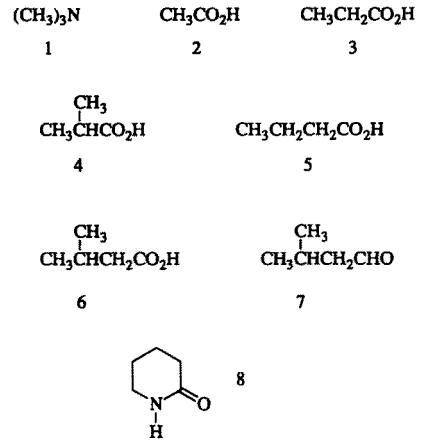

FIG. 1. Volatile components from the scent gland secretions of snakes: trimethylamine (1), acetic acid (2), propanoic acid (3), 2-methylpropanoic acid (4), butanoic acid (5), 3-methylbutanoic acid (6), 3-methylbutanal (7), and 2-piperidone (8).

43(18), 42(92), 41(25), 40(21), 30(50), 28(42), and 27(16), acetic acid—m/z = 61(1), 60(M^+, 48), 45(96), 43(100), 42(16), 41(6), 40(2), 31(7), 29(25), and 28(13), propanoic acid—m/z = 74(M^+, 16), 73(16), 57(9), 45(42), 44(11), 30(14), 29(65), 28(100), 27(68), and 26(35), 2-methylpropanoic acid—m/z = 73(20), 45(68), 44(28), 43(100), 42(21), 41(65), 39(44), 29(28), 28(81), and 27(100), butanoic acid—m/z = 73(39), 60(100), 45(38), 43(24), 42(50), 41(39), 39(32), 29(28), 28(62), and 27(56), 3-methylbutanoic acid—m/z = 87(20), 60(100), 45(68), 43(62), 42(42), 41(68), 39(68), 29(37), 28(24), and 27(62), and 2-piperidone—m/z = 99(M^+, 42), 71(30), 55(26), 44(24), 43(56), 42(74), 41(62), 39(32), 30(65), and 28(100).

The retention time of the amine and carboxylic acids varied between samples, a likely result of water in the secretions binding to the column and altering its polarity. To examine this possibility, we compared the retention times of pure acetic acid and an aqueous solution of it. Glacial acetic acid exhibited a retention time of 1.71 min. When 1 μl of a solution prepared from three drops of glacial acetic acid and 50 ml of distilled water was injected, acetic acid had a retention time of 5.16 min. The retention time of the other short-chain carboxylic acids and trimethylamine also increased when injected as aqueous solutions, but the relative order of elution remained constant. The retention time of 2-piperidone was 8.17 min for all runs.

The possibility that trimethylamine is an artifact from decomposition on the hot GC injector of trimethylammonium salts, a type of Hofmann degradation, was investigated. Trimethylamine was detected in the headspace over a

sample of secretions that was treated with a NaOH solution in a sealed container, indicating the compound is not an artifact.

The pH of the secretions from free-ranging garter snakes from Humboldt County was 7, indicating the trimethylamine and short-chain carboxylic acids exist in the ionized form. An aqueous solution of the short-chain carboxylic acids adjusted to pH 7 with trimethylamine was subjected to the same GC-MS analysis as native scent secretions. Free trimethylamine and carboxylic acids were observed; therefore, we surmise the heat of the injector or separation on the column lead to the generation of these species from trimethylammonium salts of the short-chain acids.

Low-molecular-weight amines or ammonia present with the trimethylamine might not be detectable on GC-MS analysis, so a sample of the secretions from *T. sirtalis* was treated with an ethereal solution of benzoyl chloride and an aqueous solution of sodium hydroxide (Shotten-Baumann reaction). GC-MS analysis of the resulting ether solution failed to show any benzamide or *N*-substituted benzamide derivatives; thus, these amines did not escape detection.

To examine the possibility that 2-piperidone was an artifact produced by the dehydration of 5-aminopentanoic acid, which is known to occur in some mammalian skin gland secretions (Albone *et al.*, 1976), an aqueous solution was analyzed by GC-MS, as was done with the native scent secretions. No cyclic lactam was observed; thus, 2-piperidone appears to be an actual component of the secretions.

A comparison of the scent gland secretions from other snakes demonstrates

TABLE 1. VOLATILE COMPONENTS FROM SCENT GLAND SECRETIONS OF SNAKES

	Compound[a]							
Family and species	1	2	3	4	5	6	7	8

Pythonidae								
Bothrochilus boa	ND	X	X	X	X	X	ND	ND
Viperidae								
Agkistrodon contortrix	ND	X	X	X	X	X	ND	X
Crotalus mitchelli	ND	X	X	X	X	X	X	X

[a]Trimethylamine (1), acetic acid (2), propanoic acid (3), 2-methylpropanoic acid (4), butanoic acid (5), 3-methylbutanoic acid (6), 3-methylbutanal (7), and 2-piperidone (8).
[b]ND = none detected.

some of the components found in *Thamnophis* (Table 1). All species were found to contain the same short-chain carboxylic acids. Trimethylamine was detected in *A. dumerili, E. murinus*, and *L. getula*, but not in the other snakes examined. 2-Piperidone was identified in the secretions from *A. dumerili, A. contortrix*, and *C. mitchelli*. *A. dumerili* and *C. mitchelli* secretions contained 3-methylbutanal, a compound not observed in the analysis of *Thamnophis* secretions. This compound had a retention time of 1.34 min and the mass spectrum m/z = 71(13), 58(25), 44(100), 43(50), 42(18), 41(71), 39(31), 29(50), 28(24), and 27(46).

Phenol and 2-methylbutanoic acid detected in a previous study of *A. dumerili* (Simpson *et al.*, 1993) were not seen on analysis of native secretions. Furthermore, the three suspected amines isolated by extraction and thin-layer chromatography of *A. dumerili* secretions were not seen in this study. Injection of neat samples of these secretions likely masks these minor components because of the high concentrations of the short-chain carboxylic acids.

The antipredator function generally attributed to scent gland secretions (e.g., Greene, 1987) needs to be examined. Trimethylammonium salts of short-chain carboxylic acids may themselves be effective defensive compounds. Furthermore, if the secretions are introduced into an alkaline environment, trimethylamine, a pungent gas with an ammonia-like odor, is released. If the secretions encounter an acidic environment, the short-chain carboxylic acid become volatile and more offensive. 2-Piperidone, the least volatile component we observed, while not itself strongly odoriferous, is bitter (tasted by W.F.W.).

Acknowledgments—G.M. Burghardt and D. Layne permitted access to garter snakes at the Reptile Ethology Laboratory, University of Tennessee, Knoxville, Tennessee, which was supported, in part, by grants from the Science Alliance at the University of Tennessee and NSF (BNS-9111387). D. Boyer, W. Card, C. Garret, A. Mitchell, J.B. Murphy, D. Roberts (Dallas Zoo), M. Chadwell, P. Freed, and K. Peterson (Houston Zoological Gardens) permitted access to zoo specimens. J. Welsh and W. Golden, Humboldt State University, helped in the collection of *Thamnophis* from California and A. Lind of the USDA, Redwood Sciences Laboratory, identified them. This study was supported by a Research and Creative Activity award from Humboldt State University to W.F.W. and from Texas A&M University to P.J.W.

(Received October 17, 1994; accepted November 1, 1994)

Abstract—Trichome exudate compounds isolated from leaves of *Nicotiana tabacum, N. glutinosa* (accessions 24 and 24a), and 21 other *Nicotiana* species were evaluated for biorational activity against *C. lagenarium*, the anthracnose pathogen of cucumber. Exudate compounds tested were the cembrane diterpenes α- and β-4,8,13-duvatriene-1,3-diols (DVT diols); the labdane diterpenes (13-*E*)-labda-13-ene-8α,15-diol (labdenediol) and (13-*R*)-labda-14-ene-8α,13-diol (sclareol); extracts from *N. gossei*; and various sugar ester isolates. In dose–response experiments test compounds were applied to a water agar surface that was then inoculated with a conidial suspension. Low levels of most test compounds reduced or completely inhibited germination of *C. lagenarium* conidia. IC_{50} values, concentrations (micrograms per square centimeter) at which conidium germination was reduced 50%, were 6.3 for DVT diols, 19.3 for sclareol, 1.0 for labdenediol, 2.8 for a mixture of sclareol and labdenediol, 1.2 for an *N. gossei* sucrose ester and 4.1 for the *N. gossei* crude extract. Higher levels of DVT diols and the sclareol–labdenediol mixture were required to reduce lesion size and number on inoculated cucumber leaves. At the highest concentration tested, 100 $\mu g/cm^2$, the DVT diols and sclareol–labdenediol mixtures protected cucumbers against lesion development by 93 and 98%, respectively. Sugar ester mixtures from 20 *Nicotiana* species and three different sugar ester fractions from *N. bideglovii* had in vitro antifungal activity at a concentration of 48 $\mu g/cm^2$. Sugar esters from nine of the species including *N. acuminata, N. attenuata, N. clevelandii, N. maritima, N. miersii, N. noctiflora, N. occidentalis, N. rustica*, and fractions 10, 12, and 13 from *N. bideglovii* completely inhibited *C. lagenarium* conidium from germinating. Sugar ester mixtures from only four species, *N. plumbaginifolia, N. bonar-*

iensis, *N. simulans*, and *N. palmerii*, had no significant effect on *C. lagenarium* conidium germination. These results suggest the potential of *Nicotiana* exudates as biorationals in reducing disease development.

Key Words—*Nicotiana*, *Colletotrichum lagenarium*, biorationals, trichome exudates, leaf surface chemistry, diterpenes, sugar esters.

INTRODUCTION

Secondary plant products derived from glandular trichome exudates have been implicated in host-plant resistance in certain genera of the Solanaceaous family including *Lycopersicon* and *Solanum* (Gentile and Stoner, 1968; Gibson, 1971). Trichome exudate compounds or crude leaf surface extracts from different *Nicotiana* species have also been shown to have activity against certain phytophagous insects and plant pathogens (Severson et al., 1985, 1991). Earlier, we reported that sporangium germination of *Peronospora tabacina* Adam, the blue mold pathogen of tobacco, was greatly inhibited following exposure to diterpenes and sucrose esters derived from the leaf surface of several *Nicotiana* species (Kennedy et al., 1992). The importance of these compounds as biorationals, natural products with pesticide activity, could increase greatly if they are found to be active against disease and insect pests of other plant species. Recently, foliar applications of sucrose esters, derived from the leaf surface of *N. gossei*, on field grown cotton showed similar or greater control of certain whitefly species than approved pesticides (R.F. Severson, unpublished observations, 1993). The objective of our research was to determine if compounds derived from *Nicotiana* have biorational activity against a fungal pathogen of an unrelated plant species. The following trichome exudate compounds were evaluated for activity against the cucumber pathogen *Colletotrichum lagenarium* (Pass) Ell & Halst.: a mixture of the cembrane diterpenes α- and β-duvatrienediols; two labdane diterpenes, sclareol and labdenediol; extracts from *N. gossei*; and sugar ester mixtures from 20 different *Nicotiana* species.

METHODS AND MATERIALS

Isolation and Purification of Leaf Surface Compounds. Cuticular components were extracted from *N. tabacum* cultivars NC 2326 and NFT, *N. glutinosa* (accessions 24 and 24a), and 24 other species grown in field plots at the Georgia Coastal Plain Experiment Station, Tifton, Georgia, and the Crops Research Laboratory, Oxford, North Carolina. Six to eight weeks after transplanting, tops cut from plants were extracted with methylene chloride (Baker Resianalyzed reagent grade) as previously described (Jackson et al., 1986; Severson et al., 1988). The α- and β-4,8,13,-duvatriene-1,3-diols (from NC 2326) were isolated

in 98 +% purity as described by Severson et al. (1988). *Nicotiana glutinosa* was the source of labdenediol, (13-*E*)-labda-13-ene-8α,15-diol and the sclareols, a mixture of (13-*R*)- and (13-*S*)-labda-14-ene-8α,13-diol (sclareol and episclareol). Labdenediol and sclareols were obtained in 98+% purity as described by Jackson et al. (1986).

Cuticular extracts from the *Nicotiana* species in Table 1 were taken to dryness on a rotoevaporator, and the residue was partitioned between hexane and 80% methanol–water (Severson et al., 1988). The methanol–water-soluble fraction (100–200 μg) containing the sugar esters was dissolved in 0.5 ml of 90% methanol–water, loaded into an injection loop, and chromatographed on a Bio-Sil C-18 (HL Silica, fully encapped; 40–63 μm; Bio-Rad Laboratories) preparative reverse-phase column (1.25 cm ID × 15 cm). The column was eluted with 225 ml 60% methanol–water, 90 ml 90% methanol–water, and 125 ml 100% methanol, and 5-ml fractions were collected. The solvent was removed on a Savant Speed Vac, and fractions with observable residue were derivatized and analyzed by capillary gas chromatography (Severson et al., 1984; Jackson et al., 1986). Fractions containing glucose and/or sucrose esters were combined to yield the sugar ester tested. The preparative chromatography cleanly separated the glucose and sucrose ester fractions in the *N. attenuata* sample, and they were combined separately.

Inoculum Preparation. Colletotrichum lagenarium (Pass) Ell. & Halst. race 1 was obtained from J. Kuć, Department of Plant Pathology, University of Kentucky. It was maintained on green bean agar at ±20–24°C in the dark (Goode, 1958). Conidial suspensions were prepared in sterile distilled H_2O from 7-day-old cultures and conidium concentrations were determined with a hemacytometer.

In vitro Bioassay. Efficacy of the test compounds and extracts was determined by assaying germination of *C. lagenarium* conidia on water agar covered uniformly with the test compounds. Sugar ester mixtures from 20 different *Nicotiana* species were tested at a concentration of 48 $\mu g/cm^2$. In separate experiments, DVTs, sclareol, labdenediol, a mixture of sclareol and labdenediol, a sucrose ester mixture from *N. gossei*, and a crude exudate mixture from *N. gossei* were tested at six concentrations ranging from 0.75 to 48 $\mu g/cm^2$. Desired concentrations were prepared by diluting portions of the stock solution with 100% acetone. Treatments were applied in 50-μl aliquots to the surface of 1.5% water agar in 35- × 10-mm Petri plates. A bent Pasteur glass pipet was used to evenly distribute the compound over the agar surface. Plates were set aside for the carrier solvent to evaporate before a 200-μl conidial suspension of *C. lagenarium* (1×10^5 sp/ml) was added to each plate. Plates were incubated overnight at 24°C in the dark. All treatments were replicated four times and contained two control treatments: (1) no compound or acetone was applied prior to the conidial suspension, and (2) application of 100% acetone, the carrier

solvent. Conidium germination was determined microscopically, and activity of each test compound was expressed as percent inhibition: [(% germination of control − % germination for each treatment)/% germination of control] × 100. Where appropriate, the log dose (concentration)–response relationship was linearized using probits, and inhibitory concentrations (IC_{50}) were estimated (SAS Institute Inc., 1985).

Plant Assay. Seeds of the anthracnose-susceptible cucumber cultivar SMR-58 were sown in 3 1/2-in. plastic pots containing a commercial medium. They were watered daily over the top until emergence of the first cotyledon and then were watered from the bottom of the pot for the duration of each experiment. A water soluble fertilizer, Peters 20:10:20 (N/P/K) was applied weekly. Plants were maintained in a greenhouse at 24–30°C under high-pressure sodium lights for a 14-hr photoperiod. Exudate compounds, α- + β-DVT-diols and mixture of sclareol and labdenediol, were evaluated in the greenhouse for controlling anthracnose disease development on the leaf surface of cucumbers. The DVT diols and the sclareol–labdenediol mixture were assayed in separate experiments. The first true leaves of 13-day-old cucumber plants were uniformly sprayed with different concentrations of the test compounds contained in 35% acetone (v/v) using an airbrush sprayer (Paashe Airbrush Co., Harwood Heights, Illinois) at 50 psi. Plants were returned to the greenhouse bench to dry overnight in absence of artificial light. Approximately 18 hr later, treated plants were inoculated following a procedure adapted by Kuć et al. (1975). Each treated leaf was inoculated with 30 10-μl drops of a conidial suspension of *C. lagenarium* (1×10^5 sp/ml). Thirty 10-μl drops of sterile water were placed on control plants. Plants were incubated in closed moist chambers for 24 hr in the greenhouse and then partially opened within the next 12 hr to establish air temperature equilibrium. Plants were returned to the greenhouse bench under high-pressure sodium lights and rated for symptom development one week after inoculation. Lesion number and necrotic area were determined for each leaf treatment. Treatments were replicated four times in each experiment and both experiments were done twice. Percent protection was calculated in a similar manner for each *in vivo* experiment: % protection = $[(C - T)/C] \times 100$ where C is the percent necrotic area for the acetone control treatments and T is the percent necrotic area for the various treatments.

RESULTS

Conidia germination rates for the control treatments were between 80 and 100% in all *in vitro* experiments (Table 1 and Figure 1). Acetone applied to the agar had no significant effect on conidium germination compared to the untreated agar plates. The acetone apparently evaporated completely and had no residual

[a]The germination rates for the conidia in the control treatments of water and acetone (the carrier solvent) were 94.8% and 93.5%, respectively.
[b]Denotes significant differences ($P < 0.05$) from the acetone control treatment according to a paired t test.

effect on the conidia. Thus, activities of the various chemicals were based on comparisons to the acetone control.

Sugar ester mixtures from 20 *Nicotiana* species and three different sugar ester fractions from *N. bideglovii* had *in vitro* antifungal activity at a concentration of 48 $\mu g/cm^2$. *C. lagenarium* conidia were completely inhibited from germinating when exposed to sugar esters from nine of the species, *N. acuminata*, *N. attenuata*, *N. clevelandii*, *N. maritima*, *N. miersii*, *N. noctiflora*, *N. occidentalis*, *N. rustica*, and fractions 10, 12, and 13 from *N. bideglovii*, when compared to the control treatments (Table 1). Conidia germination was reduced more than 25% when exposed to sugar esters derived from *N. nudicaulis*, *N. debneyi*, *N. langsdorffii*, *N. velutina*, *N. cavicola*, *N. pauciflora*, and *N. hesperis*. Sugar ester mixtures from only four species, *N. plumbaginifolia*, *N. bon-*

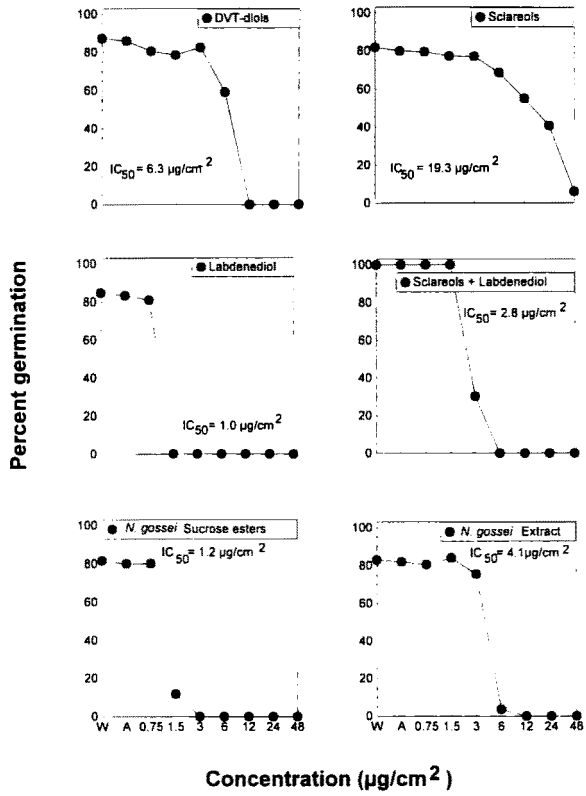

FIG. 1. Percent germination of *C. lagenarium* conidia in vitro after exposure to trichome exudates. Control treatments are represented by: W, no chemical or acetone; and A, acetone only.

ariensis, *N. simulans*, and *N. palmerii*, had no significant effect on *C. lagenarium* conidium germination.

Microscopic examination of conidia in all of the *in vitro* experiments revealed that for those conidia that did germinate, germ tube length and morphology was similar to that observed for conidia in the control treatments.

Inhibition of conidium germination was nearly complete when exposed to the highest concentrations of the six different test compounds for which dose responses were assessed (Figure 1). IC_{50} values, concentrations at which conidium germination was reduced 50%, were well under 5 $\mu g/cm^2$ for labdenediol, the sclareol–labdenediol mixture, *N. gossei* sucrose esters, and the *N. gossei* extract. IC_{50} values were 6.3 $\mu g/cm^2$ for the α- and β-DVT-diol mixture. The

most active compound tested was labdenediol with an IC_{50} value of 1 $\mu g/cm^2$ and the least active was sclareol with an IC_{50} value of 19.3 $\mu g/cm^2$. Figure 1 also reveals that for most of the tested compounds, germination inhibition was not linearly related to concentration. In fact, for labdenediol, DVTs, and the *N. gossei* compounds, a critical response to concentration was observed. This is best illustrated by the experiments with labdenediol in which conidium germination was little affected at 0.75 $\mu g/cm^2$ of labdenediol, but was greatly inhibited at the next higher chemical concentration of 1.5 $\mu g/cm^2$.

Mixtures of: (1) α- and β-DVT-diols and (2) sclareol and labdenediol were evaluated at different concentrations for control of anthracnose disease development on cucumber leaves. These two mixtures were chosen for the disease control experiments because both mixtures are abundant on *Nicotiana* leaf surfaces, DVT diols on most *N. tabacum* genotypes and on *N. glutinosa* accession 24a. Furthermore, abundant quantities of these mixtures were available for testing. Because cucumber leaves are very sensitive to chemical applications, we were initially concerned about using acetone as a carrier solvent for our exudates. However, when the concentration of acetone was reduced to 35%, no phytotoxicity was observed among the sprayed leaves in any of the treatments including the controls.

Preliminary experiments indicated that low concentrations of both mixtures were less effective in controlling anthracnose than they were in preventing *C. lagenarium* conidium germination in vitro. Therefore, higher concentration ranges were chosen for the disease control experiments.

There was significantly less disease as measured by lesion number and total necrotic area at the lowest concentration (40 $\mu g/cm^2$) of DVT diols. At a treatment concentration of 15 $\mu g/cm^2$, the sclareol–labdenediol mixture had significantly lower disease scores than the acetone control. At a concentration of 100 $\mu g/cm^2$, DVT diols and the sclareol–labdenediol mixture protected cucumbers against anthracnose disease development by 93 and 98%, respectively (Tables 2 and 3).

DISCUSSION

Controlling plant diseases in agricultural crops has traditionally been accomplished by using multidisciplinary approaches consisting of host-plant resistance, use of appropriate cultural practices including crop rotation and good sanitation, and the application of pesticides. However, some producer's options for disease control are becoming increasingly limited. This is due primarily to the lack of land available for crop rotation and the growing concern over the use of synthetic chemicals to control plant disease pests. The use of natural plant products, acting as applied pesticides or as factors in host-plant resistance,

is becoming increasingly desirable. One approach is to identify biorationals—naturally occurring products that have pesticide activity. Our hypothesis was that plant compounds that have already been classified as determinants of resistance in one host plant–pathogen relationship could possibly serve as biorationals against pathogens of other plant species.

Earlier investigations by our group and others (Kennedy et al., 1992, Menetrez et al., 1990) reported that trichome exudates produced on the leaf surface of some *N. tabacum* and *Nicotiana* species significantly reduced germination of *Peronospora tabacina* Adam, the obligate fungal pathogen responsible for the blue mold disease in tobacco. In our present study, we determined that many of these same compounds could be classified as biorationals effective against disease development of anthracnose in cucumbers.

The compounds were selected for our biological assays primarily because of their relative abundance on the leaf surface and their ease in isolation. The duvatriene diols (DVT) were relatively effective in inhibiting germination of *C. lagenarium* conidia in vitro and somewhat effective at higher concentrations in preventing disease development on the inoculated cucumber leaves. These compounds are of particular interest because they are present at high concentrations in the trichome exudate of many *Nicotiana* genotypes. Indeed, we estimate that

in certain genotypes, the DVTs could represent as much as 10% of the total leaf dry weight.

Sclareol and labdenediol are labdene diterpenes found primarily on the leaf surface of the *Nicotiana* species *glutinosa*. In *in vitro* experiments, we found sclareol to be the least active (IC_{50} value 19.3 $\mu g/cm^2$) and labdenediol to be the most active compound (IC_{50} value 1.0 $\mu g/cm^2$). The two compounds were mixed and concentrated as they naturally occur on the leaf surface in a 65:35 (sclareol–labdenediol) ratio. *C. lagenarium* conidium germination was completely inhibited when exposed to 6 $\mu g/cm^2$ of the mixture in vitro. Foliar applications of this mixture at 40 $\mu g/cm^2$ or greater protected the leaves of cucumbers from disease development by over 90% when compared to the control treatments.

Conidium germination was completely inhibited when exposed to concentrations of 3 $\mu g/cm^2$ and 12 $\mu g/cm^2$ of the *N. gossei* sucrose ester and extract, respectively. These compounds were included in our screen because they have been implicated as biorationals for control of some insects including whiteflies.

Only four of the sugar ester mixtures from the 20 different *Nicotiana* species did not significantly effect germination of *C. lagenarium* conidia. Sugar esters from nine of the species inhibited conidium germination completely. These sugar

esters vary with the type of acid substitution on the glucose or sucrose moieties (Severson et al., 1991) and are considered to be a very diverse class of compounds, having high potential for genetic manipulation. We screened a large number of sugar esters for biorational activity in hopes of correlating this activity with a particular acid substitution. Although we were unable to establish any relationship between biorational activity and any particular type of sugar ester, the positive results from the assays warrant further investigation.

Results of this study further demonstrate the potential of *Nicotiana* exudates as biorationals in reducing disease development. The effectiveness of these exudates in preventing or retarding disease progress under natural disease pressure needs to be investigated. Additional research is also necessary to estimate the overall value of these compounds as antifungal agents at the whole-plant level, including efforts to characterize these exudates for their biorational activity against a wide range of different plant pathogens and to determine appropriate application methodology. *Nicotiana* exudates are quantitatively and qualitatively different among genotypes and can be manipulated through breeding by the type and density of the trichome and by selection for specific compounds (Nielsen and Severson, 1990). New research should be initiated so that biorationals can efficiently and effectively be utilized as sources for developing additional alternatives to pest control that broaden opportunities for reducing fungicide use.

Acknowledgments—We thank E.M. Nuckles for technical advice and assistance, and J. Kuć for the *C. lagenarium* isolate and use of his humidity chambers for our experiments. This research was funded partially by a USDA Cooperative Agreement No. 58-6430-2-116. This paper (94-3-187) is published with the approval of the Director of the Kentucky Agricultural Experiment Station.

(Received May 24, 1994; accepted November 1, 1994)

Abstract—Three species of lichen-grazing snails, *Balea perversa*, *Chondrina clienta*, and *Helicigona lapicida*, all from the Swedish island of Öland, were found to sequester lichen compounds when feeding on the crustous lichen species *Aspicila calcarea*, *Caloplaca flavovirescens*, *Lecanora muralis*, *Physcia adscendens*, *Tephromela atra*, and *Xanthoria parietina*. The lichen compounds detected in the soft bodies of the snail species analyzed included the anthraquinone parietin, the depside atranorin, as well as a presumable degradation product of the latter. Other lichen compounds such as (+)-usnic acid or α-collatolic acid were not found in the soft bodies but were only detected in the feces, suggesting selective uptake of lichen compounds by the snails. In individuals of *C. clienta* initially fed on the lichen *X. parietina*, the amount of sequestered parietin decreased over time on a parietin-free diet but was still detectable in the soft bodies after 28 days. In the ovoviviparous land snail, *B. perversa*, sequestered parietin was transferred from the mother to the eggs in the reproductive tract.

Key Words—*Balea perversa*, *Chondrina clienta*, *Helicigona lapicida*, Gastropoda, Pulmonata, crustous lichens, lichen compounds, sequestration.

INTRODUCTION

Lichens comprise some 20,000 different taxa and show a worldwide distribution (Crittenden and Porter, 1991). In habitats with harsh environmental conditions (e.g., hot or cold deserts) that tend to suppress the growth of most higher plants, lichens can constitute dominant floral elements and may provide important nutritional resources for herbivores.

It was speculated some 100 years ago that the observed unpalatability of lichens to most potential herbivores is largely due to chemical defense relying on the accumulation of copious amounts of lichen compounds (Zukal, 1895; Stahl, 1904), whereas other authors, including for example Zopf (1896), denied a defensive function of lichen compounds. Recent years, however, have witnessed growing experimental evidence in favor of the chemical defense hypothesis (Slansky, 1979; Lawrey, 1986, 1989, 1991). For example, experiments with larvae of the vigorous polyphagous herbivore *Spodoptera littoralis* (Noctuidae) demonstrated pronounced acute toxicity and feeding deterrency for (−)- and (+)-usnic acid and for vulpinic acid at concentrations well below those found in lichen thalli (Emmerich et al., 1993). Other lichen compounds such as oxyphysodic acid, fumarprotocetraric acid, or calycin, which had no acute effects on survival, were found to retard larval growth and to cause developmental malformations of adults of *S. littoralis* originating from larvae that were reared on an artificial diet spiked with the respective lichen compounds at concentrations comparable to those found in lichen thalli (Giez et al., 1994).

The recent studies suggest that lichen compounds act as defense agents against generalist herbivores. However, there are numerous examples of specialized herbivores that feed solely on lichens. Important groups of oligophagous invertebrate lichen feeders include oribatid mites (Seyd and Seaward, 1984; Reutimann and Scheidegger, 1987), insects (especially Lepidoptera of the family Arctiidae) (Rambold, 1985), and terrestrial gastropods (Lawrey, 1986; Baur et al., 1992). How do these specialized lichen feeders cope with the toxic or unpalatable secondary compounds of their food source that effectively deter generalist herbivores (Emmerich et al., 1993; Giez et al., 1994)? Several strategies of dealing with potentially harmful compounds present in the food source have been elucidated in interactions of herbivores with higher plants. Specialized herbivores may, for example, overcome the defensive chemistry of their hosts by rapid excretion of harmful metabolites or by metabolic detoxification (Brattsten, 1986). Another strategy of dealing with harmful plant compounds frequently observed in specialized herbivores is sequestration of the respective compounds, as shown, for example, for arctiid moths that sequester pyrrolizidine alkaloids from host plants (Ehmke et al., 1990), for cardenolides that are sequestered by monarch butterflies (Malcolm, 1990), or for flavonoids sequestered by lycaenid butterflies (Wiesen et al., 1994). The sequestered plant compounds are often

used for the chemical defense of the herbivores (Ehmke et al., 1990; Malcolm, 1990).

As shown for the first time in the present study, specialized lichen-feeding snails (*Balea perversa*, *Chondrina clienta*, and *Helicigona lapicida*) are also capable of storing lichen compounds derived from their hosts. The ecological role of the sequestered lichen compounds in the snails, however, remains open. In addition to the comparative analysis of the sequestered lichen compounds, we present experimental evidence for the transfer of sequestered parietin from the mother to the offspring in the reproductive tract of the ovoviviparous snail *B. perversa*.

METHODS AND MATERIALS

Snail Species. Chondrina clienta (Westerlund) occurs in open limestone areas of central and southeastern Europe and in three isolated areas of Sweden (Kerney and Cameron, 1979). Its cylindroconical shell is dextral and in adults is 5.5–7 mm high (Baur, 1988). *Balea perversa* (L.) is characteristic of dry places among rocks and old stone walls, occurring occasionally on stems of trees. It is widespread in western Europe, and in Scandinavia it occurs mainly along the coast (Kerney and Cameron, 1979). Its narrowly conical shell is sinistral and in adults is 7–10 mm high. *Helicigona lapicida* (L.) is common in holes and crevices in rocky ground and in old woodland and hedgerows in western and central Europe. Fully grown snails have a flattened, sharply keeled shell measuring 12–20 mm in diameter. All three species are particularly well adapted to rocky habitats; they are very resistant to drought, with activity confined to periods of high air humidity, and their specialized radulae enable them to graze epi- and endolithic lichens from rock faces (Schmid 1929; Breure and Gittenberger, 1982).

In the limestone grassland Great Alvar on the Baltic island of Öland (Sweden), 108 species of calcicolous lichens have been recorded (Fröberg, 1989). On a limestone pavement in this grassland, 17 species of terrestrial gastropods have been found, four of them being potential lichen feeders (*Chondrina clienta*, *Balea perversa*, *Clausilia bidentata*, *Pupilla muscorum*) (Baur, 1987). Laboratory experiments demonstrated that individuals of *C. clienta* grazed on 18 of 27 lichen species offered, whereas *B. perversa* fed on all eight lichen species offered (Fröberg et al., 1993). Experiments also showed that these two snail species differed in their lichen preferences and that juveniles of both snail species exhibited differences in growth rate when fed on different lichen diets (Bauer et al., 1994). There is some experimental evidence that both intra- and interspecific competition for lichens occur between these snail species (Baur, 1988, 1990; Baur and Baur, 1990).

Lichen Compounds in Wild-Caught Snails. Specimens of the land snails *C. clienta*, *B. perversa*, and *H. lapicida* were collected at seven sites in the limestone grassland Great Alvar on Öland in August 1993: (1) in fissures of a vertical quarry wall, 1.8 m high, 1.5 km SSW of Vickleby church (*H. lapicida*), (2) a stone wall, 0.9 m high, made of flat pieces of limestone arranged in horizontal layers, 40 m S of site 1 (*C. clienta*, B. perversa); (3) in cracks of a limestone pavement (50 m × 40 m wide), 10 km E of Mörbylanga (*C. clienta*); (4) a stone wall adjacent to site 3, 1 m high, made of flat pieces of limestone (*B. perversa*); (5) in cracks of a limestone pavement (100 m × 120 m wide), 2.5 km N of Frösslunda (*C. clienta*); (6) on a pile of stones (4 m × 25 m wide, 1 m high), 1.5 km N of Frösslunda (*C. clienta*); and (7) a stone wall, 1 m high, separated by a 4-m-wide grass strip from the stone pile of site 6 (*B. perversa*).

To exclude any contamination by ingested lichen tissue, the snails collected were starved by keeping them active for four days on moist paper toweling. This time was found to be sufficient for the snails to empty their digestive tract of ingested lichen material as shown by light-microscopic inspection of dissected snails. HPLC was used to analyze sequestered lichen compounds in groups of four snails each.

Feeding Experiment. A controlling feeding experiment was designed to examine whether snails sequester particular lichen compounds. Six species of crustous lichens—*Aspicila calcarea* (L.) Mudd, *Caloplaca flavovirescens* (Wulfen) Dalla Torre & Sarnth., *Lecanora muralis* (Schreber) Rabenh., *Physcia adscendens* (Fr.) H. Olivier, *Tephromela atra* (Hudson) Hafellner, and *Xanthoria parietina* (L.) Th. Fr.—that occur in the snails natural habitats were collected in the surroundings of the Ecological Research Station of Uppsala University in Skogsby approximately 8 km N of site 1. Specimens of snails were collected at site 1 (*H. lapicida*) and site 2 (*C. clienta* and *B. perversa*; see above). Snails of all three species were fed a cyanobacteria diet during a conditioning period of six days. During this period, as well as in succeeding experiments, the snails were kept at room temperature (20–22°C) and under natural light conditions. Following a starvation period of eight days (as described above), four individuals of either *C. clienta*, *B. perversa*, or two individuals of *H. lapicida* were placed in a transparent plastic dish (6.5 cm diameter, 2 cm height) lined with paper toweling. A piece of lichen (approximately 3 cm in diameter) was placed on top. This set-up was repeated for each of the six lichen species. Snails of all three species are active only during periods of high air humidity, during which they graze lichens (Schmid, 1929; Neuckel, 1981). To stimulate periodic snail activity, the lichens and paper toweling were moistened and the dishes covered with an acetate film; after 12 h, the waterproof cover was exchanged for a paper towel to dry out the dishes. This procedure was carried out repeatedly at 48-hr intervals, resulting in a rhythm of alternating 12 hr activity and 36 hr resting.

After a feeding period of eight days, the snails were starved for four days (as described above), and the feces collected. Lichen samples, feces, and soft bodies of snails were analyzed for lichen compounds using HPLC.

HPLC Analysis. Lichens as well as feces were ground, extracted in a known aliquot of acetone, and directly subjected to HPLC analysis. Soft bodies of the snails were usually freeze-dried before extraction with known aliquots of acetone. The HPLC system was from Pharmacia (Sweden) and was equipped with a photodiode array detector (Waters). Samples were injected on a Nova-Pak C_{18} column (Waters) (150 × 3.9 mm, 4-μm pore size) and separated using a linear gradient from 100% A (10% MeOH, 90% H_2O adjusted to pH 2 with orthophosphoric acid) to 100% B (MeOH) in 40 min. Identification of lichen compounds was by comparison of retention times and by comparison of the on-line-recorded UV absorption spectra with those of commercially available lichen compounds (Roth) or with lichen compounds isolated and identified previously. Lichen compounds were quantified by the external standard method using commercially available lichen products (Roth).

Retention of Sequestered Parietin. Another laboratory experiment was conducted to examine whether sequestered parietin (**1** in Figure 1) is retained over a long period in snails feeding on a parietin-free diet. Specimens of *C. clienta* were collected from a vertical rock wall close to site 2 on August 8, 1993, and samples of *X. parietina* were collected in the surroundings of the Ecological Research Station. Twelve groups of snails, each consisting of 14 individuals, were kept on a *X. parietina* diet for 10 days. The snails were maintained as described in the feeding experiment (see above). After this period, the snails were randomly assigned to two treatments. Half of the snails were continuously kept on a *X. parietina* diet and the remaining snails were fed a parietin-free diet (free-living cyanobacteria growing on small pieces of limestone). Samples of snails were obtained from both treatments at the beginning of the experiment and after each of four successive periods of eight days. These snails were starved for four days to empty their digestive tract before they were analyzed for sequestered parietin using HPLC.

Sequestered Parietin in Newborn Snails. B. perversa is ovoviviparous, i.e., the young emerge from the egg in the reproductive tract of the mother (Baur, 1990). To examine whether sequestered parietin is passed to embryos in the reproductive tract of the mother, we analyzed neonate *B. perversa* with no feeding experience. Fifty adult *B. perversa* were collected at site 4 on August 8, 1993. The snails were kept in 10 groups each consisting of five individuals on a *X. parietina* diet for 10 days. Maintenance of snails was as described in the feeding experiment (see above). Following this conditioning period, the snails were repeatedly kept on moist paper toweling (no food available) for two days followed by a *X. parietina* diet for two days during a total period of 56 days. Snails born in the parietin-free environment ($N = 51$) were collected for

HPLC analysis of sequestered parietin. For each analysis, 8–12 neonate snails were used.

RESULTS

Lichen Compounds in Wild-Caught Snails. Table 1 summarizes the sequestered lichen compounds found in specimens of three snail species. HPLC analysis of the snails revealed the presence of the lichen compounds parietin (**1**, Figure 1), atranorin (**2**, Figure 1) and of the monomer (**3**, Figure 1)—the latter presumably originating by hydrolytic cleavage of atranorin—in *B. perversa* from two localities. Compounds **2** and **3** were also detected in specimens of *C. clienta* from two localities. Snails of the species *H. lapicida* were devoid of lichen compounds. However, specimens of the latter were only available from one natural habitat, whereas *B. perversa* and *C. clienta* could be collected at three localities each. Since the lichen compounds or their metabolites were detected in snails that were starved following collection to exclude contamination by ingested lichen tissue, a sequestration of lichen compounds must be assumed at least for *B. perversa* and *C. clienta*.

Feeding Experiment. Table 2 summarizes the lichen compounds found in six lichen species and in the soft bodies of *C. clienta*, *B. perversa*, and *H. lapicida* that had fed on the respective lichens. The feces of the three snail species usually resembled those of the corresponding lichen species with regard to the profiles of lichen compounds (e.g., Figures 2 and 3). Lichen products were also present in the soft bodies of the snails analyzed even though the total amounts (in micrograms per snail) of individual compounds showed considerable

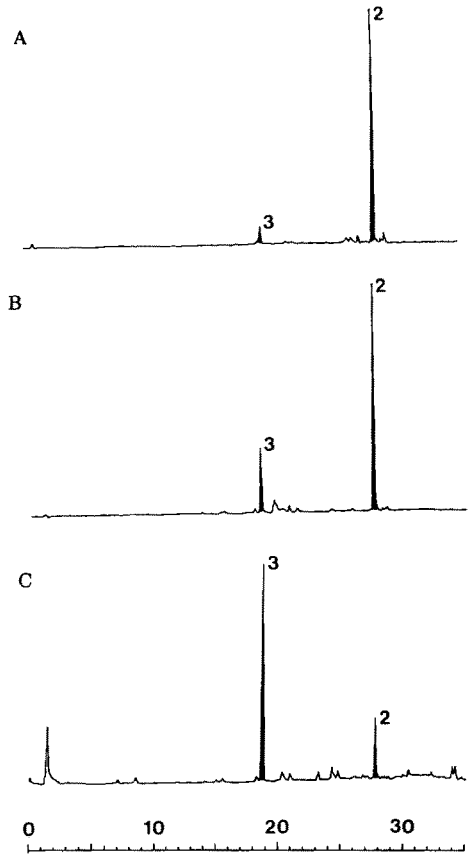

FIG. 2. Comparative HPLC analysis of soft bodies (C) and feces (B) of specimens of *Chondrina clienta* after feeding on thalli of *Physcia adscendens* (A). Specimens of *C. clienta* were treated as described in the feeding experiment. Numbers of compounds are as in Figure 1.

intra- and interspecific variation for the snail species studied. Relatively large amounts of lichen products were detected in specimens of *C. clienta* that fed on *P. adscendens* (Table 2). The major lichen compound detected in the snails was the monomer **3** (0.45 μg/snail), whereas its presumable precursor atranorin (**2**) (0.08 μg/snail) was dominant in both the thallus and feces (Figure 2), suggesting preferential sequestration of the monomer **3** by the snails vs. the depside atranorin (**2**). Similar results that suggest a preferential sequestration of the monomer (**3**) compared to its presumable precursor atranorin (**2**) were found in

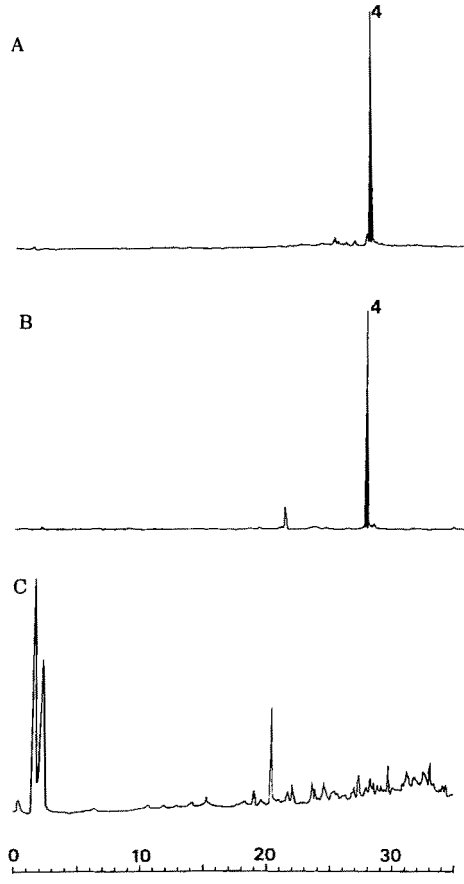

FIG. 3. Comparative HPLC analysis of soft bodies (C) and feces (B) of specimens of *Balea perversa* after feeding on thalli of *Lecanora muralis* (A). Specimens of *B. perversa* were treated as described in the feeding experiment. Numbers of compounds are as in Figure 1.

individuals of *B. perversa* and *H. lapicida* that fed on *P. adscendens*. The monomer (**3**) was the only detectable lichen compound in snails of both species (0.37 μg/snail for *H. lapicida* and 0.04 μg/snail for *B. perversa*), whereas the feces contained both atranorin (**2**) and the monomer (**3**) (data not shown). The anthraquinone parietin (**1**) was another lichen compound detected in specimens of *B. perversa* (0.02–0.13 μg/snail), *C. clienta* (trace–0.06 μg/snail), and *H. lapicida* (0.06–0.15 μg/snail) that fed on thalli of *C. flavovirescens* or *X. parietina*, which both contain parietin (Table 2). Other lichen compounds, however,

such as α-collatolic acid (**5**) (present in *T. atra*) or (+)-usnic acid (**4**) (present in *L. muralis*) were only found in the feces but were not detected in any soft body of the snails analyzed, as exemplified for *B. perversa* in Figure 3. These findings suggest a preferential sequestration of parietin (**1**), atranorin (**2**), and monomer (**3**) by the snails when compared to α-collatolic acid (**5**) or (+)-usnic acid (**4**).

Retention of Sequestered Parietin (1). Following an initial feeding period of 10 days on *X. parietina*, individuals of *C. clienta* were kept either on a parietin-free diet (cyanobacteria) or on a *X. parietina* diet for another 28 days. Subsamples of six snails were removed from both groups at intervals of eight days and analyzed for sequestered parietin (**1**) (Figure 1). The total amount of sequestered parietin (approximately 0.10–0.14 μg/snail) remained almost constant in the group of snails kept on a *X. parietina* diet during the whole experiment, whereas in the group that fed on cyanobacteria the amount of sequestered parietin decreased with time. However, even after being kept on a parietin-free diet for 28 days, the snails still contained traces of the sequestered anthraquinone (0.01 μg/snail compared to 0.10 μg/snail at the beginning of the experiment) (Figure 4).

Sequestered Parietin in Newborn Snails. Sequestered parietin (**1**) was passed on to newborn *B. perversa* that had no feeding experience on lichens. Adult *B. perversa* that were kept on a *X. parietina* diet for 10–66 days gave birth to young that contained parietin at amounts ranging from 2.8 to 3.9 ng/snail (equivalent to concentrations of 3.8–5.3 μg/g fresh wt).

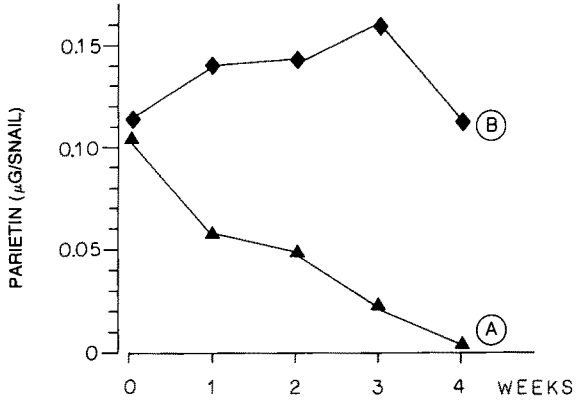

FIG. 4. Time-dependent decrease in the amount of sequestered parietin (**1**) in individuals of *Balea perversa* when fed a parietin-free diet (A). Snails of group B were constantly fed on *Xanthoria parietina*.

DISCUSSION

The present study provides, to our knowledge for the first time, evidence for a sequestration of lichen compounds by lichen-feeding terrestrial gastropods. The lichen compounds parietin (**1**), atranorin (**2**), or the presumable degradation product (**3**) were found (at least in trace amounts) in most of the soft bodies analyzed, whereas both (+)-usnic acid (**4**) as well as α-collatolic acid (**5**) were apparently discriminated by the snails (Table 2 and Figure 3).

Light-microscopic analysis of dissected snails indicated that a starvation period of four days (as used in the feeding experiments) was sufficient to empty the digestive tract of lichen material. The preferential uptake of parietin (**1**) or atranorin (**2**) vs. (+)-usnic acid (**4**), for example, seems not to be due to differences in lipophilicity, which may influence diffusion across membranes. When subjected to partitioning between H_2O and CH_2Cl_2 (the latter representing a lipophilic compartment) almost 100% of compounds **1–5** are recovered from the lipophilic phase (as measured by HPLC; data not shown), indicating that there are no significant differences between the compounds with regard to lipophilicity. Hence, there must be other, so far unknown reasons for the observed differences in sequestration of the various lichen compounds. The discrimination of (+)-usnic acid (**4**) by all of the snails studied (Table 2, Figure 3) is of special interest with respect to the established toxicity of this compound towards invertebrate herbivores. For example, when injected into last-instar larvae of the vigorous insect herbivore *Spodoptera littoralis* (Noctuidae), (+)-usnic acid (**4**) caused pronounced larval mortality (LD_{50} 70 mg/kg body wt), whereas both parietin (**1**) and atranorin (**2**) proved to be nontoxic to the larvae (Emmerich et al., 1993; Giez et al., 1994); α-Collatolic acid (**5**) has not been studied for toxicity towards invertebrates so far. It is possible that the toxicity of (+)-usnic acid (**4**) is not restricted to insects such as *S. littoralis* but extends to other invertebrate grazers including snails. Effective discrimination of usnic acid compared to the demonstrated sequestration of both parietin and atranorin may possibly enable snails to employ even potentially harmful lichens such as *L. muralis* as a food source without a risk of intoxication.

It is so far unknown whether the sequestered lichen substances are of ecological importance to the snails. However, it has been shown that anthraquinone derivatives such as chrysazin and chrysophanol, which are structurally closely related to parietin (**1**), are deterrent towards ants of the species *Myrmica sabuleti* (Hilker et al., 1992). Chrysazin and chrysophanol are used by various chrysomelid beetles for their chemical defense and have also been suggested to protect the eggs of the beetles (Hilker et al., 1992). Marine gastropods of the molluscan subclass Opisthobranchia (the so-called nudibranchs) are notorious for the sequestration of secondary products from dietary sources such as sponges, which in turn are utilized by the nudibranchs for their own chemical defense against

predators such as carnivorous fishes (Hay and Fenical, 1988; Rodgers and Paul 1991; Faulkner, 1992; Proksch, 1994). It is therefore possible that storage of lichen compounds may result in chemical protection of terrestrial snails from predators. In this context it is of interest to note that several species of birds on the island of Öland feed on empty shells of the snails under study but seem to avoid live specimens, suggesting deterrency that might be caused by sequestered lichen compounds (Baur et al., unpublished). Further studies on the ecological role of sequestered lichen compounds in terrestrial snails are underway.

Acknowledgments—We thank the staff at the Ecological Research Station of Uppsala University on Öland for their hospitality and Dr. L. Fröberg (Lund, Sweden) as well as Dr. B. Büdel and Prof. O.L. Lange (both Würzburg, Germany) for help in determining the lichen species. Financial support was received from the Deutsche Forschungsgemeinschaft as a project of the "Sonderforschungsbereich 251 der Universität Würzberg (to P.P.) and from the Swiss National Science Foundation (grant 31-33511.92 to B.B.), and the Treubel Foundation of the Freiwillige Akademische Gesellschaft, University of Basel (grant to B.B.).

(Received May 24, 1994; accepted November 1, 1994)

Abstract—In contrast to previous results from laboratory rats, when sexual dimorphism occurred, clitoral glands from wild female rats were heavier and accounted for a greater proportion of body mass than preputial glands from wild males. Gland length and weight increased with body weight, but gland weight as a proportion of body weight did not. Preputial and clitoral glands showed seasonal differences in size: at one site glands were smaller in December than in April. Maturity, estrus, and pregnancy had no significant effect on clitoral gland size, but immature males had proportionally smaller preputial glands than mature males, and the absolute gland weight, but not gland weight as a proportion of body weight, increased with testes weight. There were no differences between the sexes in lipid production, which increased with preputial or clitoral gland weight. An homologous series of aliphatic acids and their methyl and ethyl esters, plus squalene, cholesterol and lanosterol, was revealed by GC-MS study of the trimethyl silyl derivatized lipid extract. Males and females could be distinguished by principal component analysis of chromatogram peaks.

Key Words—*Rattus norvegicus*, preputial gland, clitoral gland, lipid production.

INTRODUCTION

In rats the specialized sebaceous preputial gland in the male, and the homologous clitoral gland in the female, are situated between the pubic skin and the abdom-

inal muscle. Essentially the same in males and females (Clevedon Brown and Williams, 1972), rat clitoral and preputial glands consist of two pear-shaped lobes connected via short ducts to the free margin of the male prepuce or female clitoris, where they exude their contents.

Albone (1984) stated that in laboratory rats preputial glands measure up to 20 mm in length and contribute 10–20 mg/100 g of body weight. Clevedon Brown and Williams (1972) described preputial glands as being better developed than clitoral glands, but it is not clear whether they referred to the relative sizes or to the chemical complexities of the two glands. Furthermore, there are no data for wild rats, to which laboratory studies (e.g., Clevedon Brown and Williams, 1972; Gawienowski et al., 1975, 1976, Orslak and Gawienowski, 1972; Stacewicz-Sapuntzakis and Gawienowski, 1977; Thody and Dijkstra, 1978) might not apply.

The preputial and clitoral glands are a rich source of lipids of varying complexity (Clevedon Brown and Williams, 1972; Albone, 1984) and are filled with sebaceous material attractive to the opposite sex (Clevedon Brown and Williams, 1972; Brown, 1985). Gawienowski et al. (1976) found that male Sprague-Dawley rats preferred the clitoral gland odors of estrus and sexually receptive females over the odors of anestrus females. Similarly, Thody and Dijkstra (1978) found that males were attracted to the odors of clitoral glands from estrus and proestrus females, but could not differentiate between the two. Males preferred whole-body odors of intact females over those of clitorectomized females. Preputial and clitoral glands also play an essential role in pup survival: dodecyl propionate, an active pheromonelike compound isolated from the preputial and clitoral glands of newborn pups, regulates anogenital licking, a vital maternal behavior (Brouette-Lahlou and Vernet-Maury, 1990). In addition, rats may be able to differentiate between pre- and postpubertal animals by using clitoral or preputial gland odors (Brown, 1985).

We aim to examine the morphology and chemistry of the clitoral and preputial glands in wild rats (*Rattus norvegicus*) by investigating sexual dimorphism in the production and chemical composition of sebaceous material and in gland size, measured as length, weight, and proportion of body weight. We also test for the effects of site, season, maturity, and sexual condition on gland size. Fatty acid metabolism is controlled by sex hormones (Smith et al., 1983), and therefore we would expect differences in the chemical composition of preputial and clitoral gland lipids. Thody and Dijkstra (1978) found no relationship between the size of clitoral glands and their ability to attract males, and so we predict that if female glands function only to attract males, clitoral gland size should not vary with reproductive state. Alternatively, if clitoral and preputial gland secretions have the potential to signal sex and reproductive condition, we might expect the glands to vary in size and/or chemical composition with both sex and hormone status. Testosterone has marked effects on preputial gland

weights (Ebling, 1977; Ebling et al., 1975), and we predict that rat preputial gland size will increase with testis size.

METHODS AND MATERIALS

Anatomical Studies. Using live- and kill-trapping and shooting, 100 male and 150 female wild brown rats, *Rattus norvegicus*, were collected from two Oxfordshire sites: Wytham Farm midden (O.S. grid reference SP 475098) and Tubney Manor Farm, (O.S. grid reference SP 447010). Rats from Wytham were collected during December and April, while rats from Tubney were collected during the end of July, throughout August and at the beginning of September. During April at Wytham, vaginal smears were taken from live-trapped females before they were culled, and estrus was determined by vaginal epithelial cell counts (Zarrow et al., 1964). Scores (1–5) for the abundance of leukocytes (L) and nucleated (N) and cornified (C) cells were used to determine an index of estrus (E) calculated using the formula $E = C/(C + N + L)$. Females were categorized as estrus if $E > 0.7$ or diestrus if $E < 0.3$; intermediate females were not used. Rat carcasses were kept at −20°C until postmortem examination. Culled rats were weighed with the gut removed; left and right preputial or clitoral glands were dissected out, and the mean gland length and weight was recorded for each individual rat. Left and right testes were also excised and a mean testes weight obtained for each male. Sexual maturity was determined by the presence of corpora lutea in females and cauda and caput epididymida in males. Pregnancy was determined by dissection.

Chemistry. Three female and seven male rats, culled from a laboratory colony, were used for chemical analyses. Lipids were extracted from preputial and clitoral glands using a Folch wash (Christie, 1982) prior to being analyzed by gas chromatography with either a FID or mass spectrometer. Preputial or clitoral glands were excised immediately postmortem and were placed in chloroform in clean glass bottles and stored at −20°C. Gland contents were squeezed into chloroform using a clean microspatula. The extract was then pipetted into a clean derivatizing tube and stored under nitrogen at −20°C until saponification and derivatization.

Lipid production was measured by weight of extracted lipid. Each sample was cleared of solvent under a stream of purified nitrogen, and the amount of lipid extracted was weighed before being resuspended in purified hexane. Saponification was accomplished by adding potassium hydroxide (100 μl, 1 M in 95% ethanol) and refluxing the mixture for 2 hr at 100°C. After cooling, hydrochloric acid (60 μl, 3 M) was added. Excess ethanol was removed under a stream of nitrogen, and water was removed by freeze drying. Trimethylsilyl (TMS) ethers were prepared when pyridine was added (50 μml) with *N*-methyl-*N*-trimethylsilyl-trifloroacetamide (100 μl) and the mixture heated for 45 min at 100°C.

A Carlo Erba chromatograph fitted with an OV-1 column (25 m × 0.22 mm ID bonded film) and an FID (air at 300 ml/min, H_2 at 30 ml/min) was used for gas liquid chromatography. The carrier gas was nitrogen at 3 ml/min. A split injection was used with a split ratio of 1 : 100. Chromatograms were recorded and integrated using a Hewlett Packard model 3390A integrator. Naphthalene (20 μg/ml) was used as an internal standard.

Peak identities were confirmed using library references and comparison with authentic compounds. Chromatograms for individual rats were matched by eye. Retention times of peaks from rat lipids were compared to those of a mixture of TMS and ethyl and methyl esters of saturated nC_6 to nC_{24} fatty acids.

Statistical Analysis. Three measures of preputial and clitoral gland size were used: weight (milligrams), proportion of body weight (milligrams per 100 g body weight), and length (millimeters). Gland sizes of rats were analyzed by three-factor analysis of variance, with three two-way interactions, for the effects of body weight, site, and either sex, maturity, pregnancy, estrus, or testes weight. Except when testing for effects of sex, data for males and females were analyzed separately, and except when testing for effects of maturity, only mature rats were used. Within sites, the effects of month, sex, and body weight were tested using three-factor analysis of variance with interactions. One way analysis of variance was used to test within months for sexual dimorphism, and within sexes for pairwise differences between months. Two-way analysis of variance with one interaction was used to test the effects of sex and gland weight on lipid production. Except when modeling factors affecting gland size as a proportion of body weight, models used log-transformed weights and lengths.

Chemical data were summarized using a principal component analysis (PCA) of peak proportions of total peak area for each specimen; glycerol esters were not included. Correlation of chemical peaks was obtained by least-squares regression. Statistical analysis was by SAS (1985).

RESULTS

Preputial and Clitoral Gland Size. Body weight had a significant effect on preputial and clitoral gland lengths (Table 1), with heavier animals having longer glands (Figure 1). Taking into account the effects of body weight, there was a significant difference between preputial and clitoral gland lengths (Table 1): overall females had a shorter mean gland length (143.73 ± 2.26 mm) than males (185.55 ± 3.81 mm). Gland length was also significantly affected by site (Table 1): mean gland length at Tubney was 146.5 ± 3.95 mm, while at Wytham it was 161.07 ± 3 mm. Within sites (Table 2), there remained a significant difference beween sexes ($F_{(1,114)} = 27.13$, $P < 0.0001$ for Wytham; $F_{(1,68)} = 41.7$, $P < 0.0001$ for Tubney). Once sex and body weight effects

TABLE 1. SUMMARY OF ANALYSIS OF VARIANCE FOR EFFECTS OF SEX, BODY, WEIGHT, AND SITE ON THREE MEASURES OF GLAND SIZE

Source of variation	df	MS	*F* value	*P* value
Log gland length				
Log body weight	1	4.512	238.12	<0.0001

were taken into account, there was no significant difference between July, August, and September samples at Tubney, but at Wytham mean gland lengths were significantly longer ($F_{(1,114)} = 15.73$, $P < 0.0001$) during April than during December (Table 3).

Glands were a constant proportion of body weight (Table 1), with heavier rats having heavier glands (Figure 1). Males had a heavier mean body weight (304.2 ± 9.7 g) than females (238.2 ± 7.2 g), and there was a significant effect of interaction between body weight and sex on gland weight as a proportion of body weight (Table 1). Both sex and site, and the interaction between sex and site, had a significant effect on proportional and absolute gland weight (Table 1). Taking account of body weight, at Wytham females had heavier glands ($F_{(1,119)} = 32.8$, $P < 0.0001$) than males, but at Tubney there was no difference between the sexes (Table 2). Similarly, at Tubney there were no differences between the sexes in gland weight as a proportion of body weight, but at Wytham

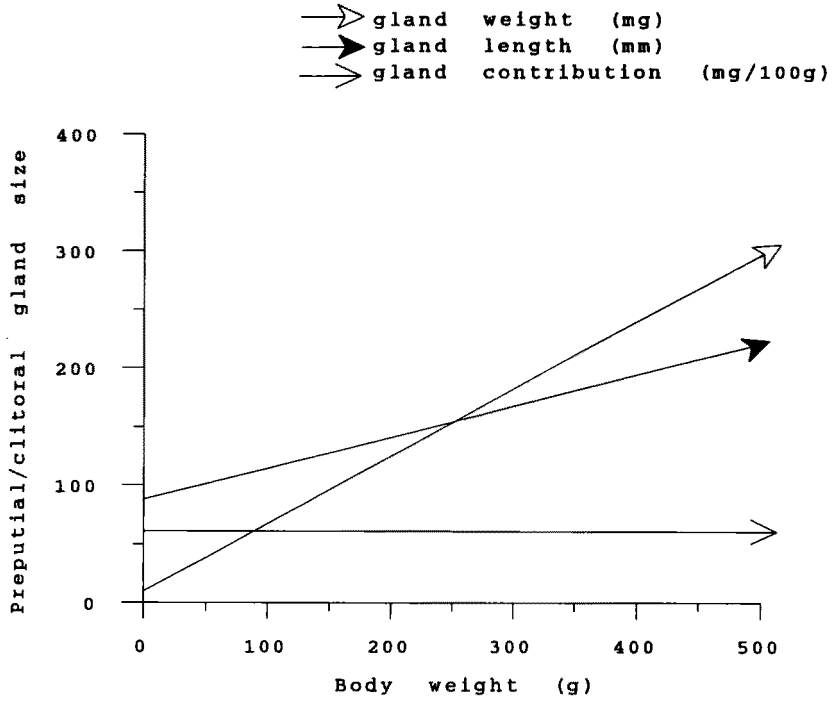

FIG. 1. Lines of best fit showing the relationship between adult rat clean body weight and preputial and clitoral gland size, measured as either gland weight or gland contribution to body weight, and gland length. Gland length and gland weight, but not gland contribution, were significantly affected by body weight (Table 1).

TABLE 2. VARIATION IN ADULT MALE PREPUTIAL AND FEMALE CLITORAL GLAND SIZE WITH SEX AND SITE[a]

			Mean (± SE) gland size		
Site	Sex	*N*	Weight (mg)	Weight (mg)/100 g, clean body weight	Length (mm)
Wytham	F	77	181.6 ± 11.3	66.0 ± 3.5	147.2 ± 2.9
	M	46	127.3 ± 12	38.5 ± 2.9	183.9 ± 4.6
Tubney	F	59	138.1 ± 11	66.9 ± 3.6	139.4 ± 3.5
	M	19	214.0 ± 30	82.8 ± 11	189.3 ± 7.1

[a] Differences between males and females and between Wytham and Tubney were significant for all three measures of gland size.

TABLE 3. THREE MEASURES OF ADULT MALE PREPUTIAL AND FEMALE CLITORAL GLAND SIZES FOR DECEMBER AND APRIL SAMPLES AT WYTHAM

Month	Sex	*N*	Mean (± SE) gland size		
			Weight (mg)	Weight (mg)/100 g clean body weight	Length (mm)
December	F	15	84.7 ± 19	32.6 ± 4.5	122.9 ± 9.6
	M	8	72.9 ± 11	22.0 ± 3.5	173.6 ± 15.2
April	F	62	205.1 ± 11	74.1 ± 3.6	151.9 ± 2.6
	M	38	138.8 ± 14	42.0 ± 3.2	185.9 ± 4.7

female glands were proportionally larger than male glands ($F_{(1,119)} = 34.1$, $P < 0.0001$). At Wytham there was a significant difference between male and female gland size as a proportion of body weight in April ($F_{(1,96)} = 37.9$, $P < 0.0001$), but not during December (Table 3).

Considering seasonal differences in gland weight as a proportion of body weight, month had no effect on gland size at Tubney, which is henceforth considered as a single August sample. For adult females, there was no significant difference in proportional gland weight between August and April, but in December glands were significantly lighter in proportion to body weight than in either April ($F_{(1,75)} = 30.1$, $P < 0.0001$) or August ($F_{(1,73)} = 20.7$, $P < 0.0001$). Adult male preputial gland weight, as a proportion of body weight, was significantly larger in August than in December ($F_{(1,25)} = 12.35$, $P = 0.002$) or April ($F_{(1,55)} = 20.55$, $P < 0.0001$), and again proportional gland weight in December was smaller than in April ($F_{1,44)} = 7.8$, $P = 0.008$).

Immature male rats had, on average, significantly shorter ($F_{(1,88)} = 5.91$, $P = 0.0171$) and lighter ($F_{(1,93)} = 6.09$, $P = 0.0154$) preputial glands than adults, and immature preputial glands were proportionally lighter than glands from mature males ($F_{(1,93)} = 6.28$, $P = 0.014$) (Table 4). For adult males, there was a significant effect of testes weight on preputial gland weight ($F_{(1,58)} = 4.42$, $P = 0.04$). However, testes weight had no significant effect on preputial gland length or preputial gland weight as a proportion of body weight. There was no significant relationship between testes weight and body weight.

When effects of site and body weight were taken into account, there was no significant effect of pregnancy, estrus, or maturity in adult female rats, for any measure of clitoral gland size.

Chemistry. Heavier preputial and clitoral glands produced significantly more lipid than lighter glands ($F_{(1,6)} = 20.6$, $P = 0.004$), but lipid production was not affected by sex or by an interaction between gland weight and sex.

TABLE 4. VARIATION IN THREE MEASURES OF MALE RAT PREPUCE GLAND SIZE WITH SITE AND MATURITY[a]

Month	Maturity	N	Mean (± SE) gland size		
			Weight (mg)	Weight (mg)/100 g clean body weight	Length (mm)
Wytham	Immature	19	45.3 ± 6.3	27.5 ± 2.7	130.2 ± 8.4
	Mature	46	127.3 ± 12	38.5 ± 2.9	183.9 ± 4.6
Tubney	Immature	16	55.7 ± 7.8	42.4 ± 4.5	130.5 ± 5.2
	Mature	19	214.0 ± 30	82.8 ± 11.1	189.3 ± 7.1

[a]Glands from mature males were significantly larger than glands from immature males.

A GC-MS study of the TMS derivatized lipid extract revealed an homologous series of aliphatic acids and their methyl and ethyl esters, plus squalene, cholesterol, and lanosterol. Chromatogram peaks were assigned as shown in Table 5, and chromatograms of TMS-derivatized samples are summarized in Table 6. Correlations between adjacent peaks (Table 7) suggest an even rate of lipid synthesis by the preputial and clitoral glands. Principal components analysis based on the correlation matrix revealed that the first four principal components account for 83% of the variation in the samples and provide a good summary of the data (Table 8). Between-sample variation was explained by a single factor in the first principal component. Peaks A–K share a similar positive loading on the first eigenvector and contrast with the negative loadings for peaks O, P, Q, and R. The interpretation of eigenvectors 2, 3, and 4 is not obvious.

A plot of the first and second principal components (Figure 2) grouped males and females separately along the first principal component axis. The single pregnant female separated from the two nonpregnant females along the first principal component axis, and the juvenile males separated from the adults along both the first and second principle component axes.

DISCUSSION

The compounds identified in our study support previous work with laboratory rats by a variety of authors (reviewed by Clevedon Brown and Williams, 1972; Albone, 1984) with the exception of Stacewicz-Sapuntzakis and Gawienowski (1977). Generally the compounds present in the greatest quantity were the $C_{18:1}$ methyl ester, $C_{18:1}$ ethyl ester, $C_{18:1}$ acid, $C_{18:0}$ acid, squalene, and cholesterol. In addition to the list presented in Table 5, GC-MS revealed a mixture of polyunsaturated methyl esters and glyceryl esters. The presence of

glyceryl esters indicates their incomplete hydrolysis at the saponification stage of sample preparation in the particular sample used for GC-MS. To what extent this affected the final analysis (glyceryl esters were not used in the statistical appraisal of the chromatograms) is difficult to determine because it is not known which acids occurred as glyceryl esters, in what proportions, or whether the glyceryl esters were mono-, di-, or triglycerides of mixed or homogeneous acids. However, it seems unlikely that the saponification failed unpredictably because PCA analysis did not reveal a random distribution, but distinguished between males and females.

In contrast to the established view that the preputial gland is better developed than the clitoral gland (Albone, 1984; Clevedon Brown and Williams, 1972; Brown, 1985), we found that in April at Wytham, where there was a significant difference between the sexes, female clitoral glands were heavier and accounted for a higher proportion of body weight than male preputial glands. Preputial glands, however, were consistently longer than clitoral glands. The

most obvious reason for our unusual results is that we worked with wild rats, whereas former results have been based on laboratory rats. Berdoy and Macdonald (1991) have reviewed instances where extrapolation from the laboratory to natural rat populations proved unjustified.

Seasonal effects on proportional gland weight were evident at Wytham: for both male and female rats, gland sizes were smaller during December than during April. However, it is impossible to say whether differences between the Tubney and Wytham samples were the results of seasonal or site effects. Although the only sample for which there was a significant difference between the sexes was April at Wytham, a reversal in the relative sizes of clitoral and preputial glands was the most marked difference between sites. Effects of site may be at least as important as effects of season: Stockley et al. (1994) found that seminal vesicle weights for male shrews (*Sorex araneus*), measured at the same time of year, differed significantly between sites. Differences between Wytham and Tubney rats might have arisen because of habitat differences. At

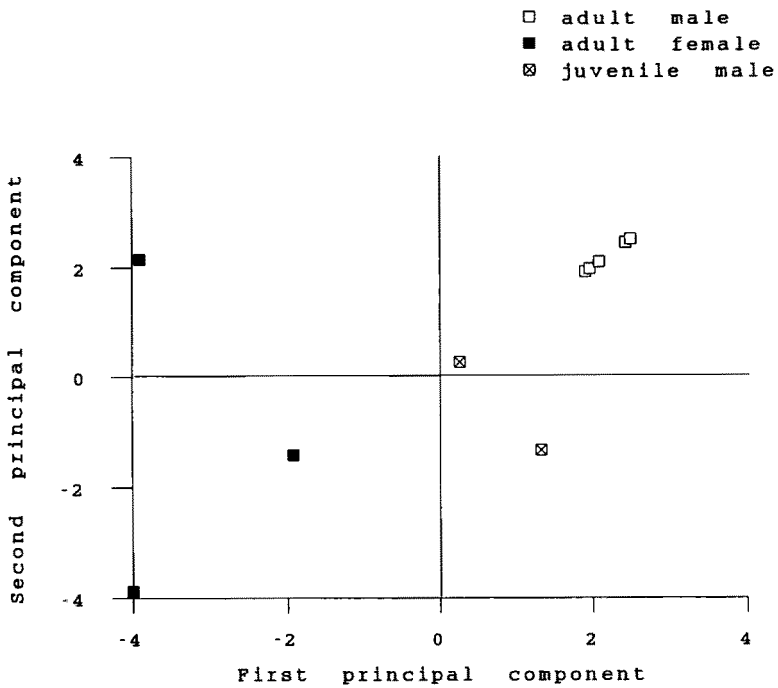

FIG. 2. Plot of first and second principal components, obtained by principal component analysis of a chromatograph peak correlation matrix using lipid produced from the clitoral glands of three females and the preputial glands of seven males. The female in the center of the plot was pregnant.

Wytham rats lived on an agricultural rubbish tip, while at Tubney rats lived in farm buildings and among grain silos (Fenn, 1989).

During December, when gland weight as a proportion of adult body weight was smallest, rats were not breeding (Fenn, 1989), suggesting that seasonal variation in gland size might be the result of seasonal fluctuations in hormones associated with breeding. Ebling (1977) noted that estrogen reduced the output of skin sebaceous glands and had a similar effect on the clitoral glands, as well as on lipogenesis in general. In our wild female rats, however, clitoral gland size did not fluctuate with the reproductive cycle, nor with pregnancy or maturity, although principal component analysis of chromatogram peaks separated a single pregnant female from two nonpregnant females. Females also showed less variation between samples than did males.

In contrast to estrogen, testosterone markedly increases preputial gland weights (Ebling, 1977; Ebling et al., 1975). Sexually mature male rats had larger preputial glands than immature male rats, and gland weight increased with testes weight, although proportional gland weight and gland length did not. The interpretation of these results remains obscure because there was no correlation between testes size and body weight. If the relationship between testes weight and preputial weight was not an artifact of correlation with body weight, testes weight appears to act on preputial glands by increasing lipid production rather than gland capacity.

Changes in gland size reflect changes in the amount of lipid available for secretion. Thus, a decline in gland size during the winter might be indicative of a reduced frequency of scent-marking, associated perhaps with a reduction in territoriality and breeding. Male preputial glands were affected by maturity and possibly by testes size and showed greater variation between seasons than female clitoral glands. Such variability might indicate that the male preputial gland has a greater range of functions than the clitoral gland and that males vary their use of preputial secretion in scent-marking depending on their status. The relatively consistent size of clitoral glands during the breeding season, and their reduction in size during the winter, is consistent with the hypothesis that the glands function only to attract males by signaling their sex, but do not rule out the possibility of chemical changes in gland secretions that might signal hormonal status. Indeed, chemical analysis of clitoral gland secretions suggested that this might be the case.

Acknowledgments—Helpful comments on an earlier draft were made by M. Berdoy and P. Stockley. M.G.P. Fenn assisted with fieldwork, and P. Johnson provided statistical help. The work was funded by an SERC studentship (SEN) and by the Nufield Foundation (D.W.M.).

Book Review

Chemical Ecology in Thrips–Host Plant Interactions. T.N. Ananthakrishnan and R. Gopichandran. New York: International Science Publisher, 1993. Hardback US$59.00, 125 pp. ISBN1-881570-23-1. (Originally published in India by Oxford & IBH Publishing Co. Pvt. Ltd, New Delhi.)

About 5000 species of thrips are known worldwide. Many species are flower dwellers or live on leaves, a few are predatory, and most feed on fungi. Some are serious economic pests of crops either by feeding on plants or by serving as vectors of plant disease. Considerable progress has been made in understanding the taxonomy and ecology of thrips. This book explores the lesser known biochemical aspects involved in thrips–host plant interactions. The premise is that knowledge of the chemical ecology of thrips–host plant interactions is vital to develop management strategies such as resistant plants for agriculturally important thrips pests.

The book is divided into eight chapters. The first chapter introduces the dimensions of chemical ecology of thrips–host plant interactions. An overview of the biochemical basis of host selection by thrips is presented, and the need to understand resistance mechanisms when developing resistant crops is emphasized. Chapter two generally explores the factors influencing utilization and survival of insects on plant resources, with specific emphasis and review of information on thrips. The chapter is divided into sections on behavioral and physiological aspects, the environment of plants, sensillar diversity in thrips, the role of primary and secondary compounds, and environmental stresses. Chapter three provides a discussion of thrips feeding mechanics and the responses of plant hosts to thrips injury. The biochemical profiles of host plants in relation to thrips infestation along with detailed examples are discussed in the fourth chapter. Chapter five describes the chemical ecology of anthophilous thrips, including the chemical basis of flower color and the chemical components of nectar and pollen. Other aspects of the coadaptation of thrips and flowering plants are discussed. The resistance mechanisms in thrips–host plant interactions, including induced resistance, static plant defense, and tolerance, are given in chapter six. Chapter seven describes the biochemical relationships between thrips galls and plant hosts. The last chapter outlines some commonly employed techniques used in quantitative assays in chemical ecology research.

The authors are experienced researchers in the chemical ecology of thrips. The senior author currently is the Director of the Entomology Research Institute,

Loyola College, Madris. This book on chemical ecology follows previous books by him on the bioecology and the reproductive biology of thrips. The coauthor is a senior research associate at the Entomology Research Institute who has worked in collaboration with the senior author on research projects.

Thrips are a diverse and biologically interesting group of insects. This book provides a much-needed review and discussion of published information relevant to thrips–host plant interactions. Entomologists interested in chemical ecology of insects in general or thrips specifically will find the book an information resource. Entomologists interested in determining economic injury levels for use in integrated pest management programs will find a good review of literature and discussion of plant response to thrips feeding. Another practical application of knowledge of chemical ecology of thrips–host plant interactions is development of resistant crops. The discussion in this book about expected sustainability of resistant crops developed utilizing different resistance mechanisms is especially relevant. The book is attractive, with numerous tables and figures of varying quality. In some cases it is difficult to determine the appropriate cited source for discussed information. Considering the purchase price, an entomologist should choose to purchase this book for their personal library based on interest in chemical ecology or management of thrips.

ANTIGNAWING FACTOR OF CRUDE OIL DERIVED FROM *Thujopsis dolabrata* S. et Z. var. *hondai* SAWDUST AGAINST MICE

YOUNG-JOON AHN,[1,*] SUNG-BAEK LEE,[1] TSUTOMU OKUBO,[2] and MUJO KIM[2]

[1]*Department of Agricultural Biology, College of Agriculture and Life Sciences, and Research Center for New Bio-Materials in Agriculture, Seoul National University, Suwon 441-744, Republic of Korea*

[2]*Central Research Institute, Taiyo Kagaku Co., Ltd., Yokkaichi, Mie 510, Japan*

(Received June 2, 1994; accepted September 15, 1994)

Abstract—The antignawing activity of the steam distillate of *Thujopsis dolabrata* S. et. Z. var. *hondai* sawdust against mice was evaluated using a wire-dipping method. This method is suitable for measuring repellent activities of chemicals and plant-derived materials. The steam distillate of the *Thujopsis* sawdust was shown to have potent antignawing activity. Three terpenoid compounds with antignawing activity were isolated from the steam distillate of the *Thujopsis* sawdust: thujopsene, carvacrol, and β-thujaplicine. Carvacrol exhibited the most potent repellent activity. As a naturally occurring repellent, carvacrol could be useful as new preventive agent against various kinds of damage caused by rodents.

Key Words—Rodent, mouse, repellent, antignawing activity, wire-dipping method, *Thujopsis dolabrata* S. et. Z. var. *hondai*, carvacrol, terpenoid.

INTRODUCTION

Rodents are cosmopolitan in their distribution and approximately 1800 species have been described. They cause great damage not only in agriculture, but also contribute significantly to the generation of serious problems for communication

*To whom correspondence should be addressed.

systems and structures. Control is primarily dependent upon continued or repeated applications of rodenticides. Although they have effectively controlled rodents, their extensive use for the past decades has led to the development of resistance to rodenticides (MacNicoll, 1986), persistence of residues, adverse effects on nontarget organisms, environmental problems, and human health hazards (Lund, 1983; Dubock, 1986). Increasing concern over adverse effects of the earlier types of rodenticides have brought about the need for the development of new types of selective alternatives for controlling rodents. Recently, much concern has been focused on plants as an alternative to the rodent control agents currently used, because plants are the richest source of bioactive organic chemicals (Harborne, 1988).

The most suitable alternative may be a rodent repellent, because for each rat killed with poison there are others in the area who survive. However, relatively little recent work has been carried out on repellents produced by plants compared to other aspects of rodent control. Although the rodent repellent cycloheximide from *Streptomyces griseus* is very effective, this compound irritates human skin very strongly (Budavari et al., 1989). During initial experiments for screening rodent repellents from plants, the tree *Thujopsis dolabrata* S. et. Z. var. *hondai*, the only Japanese *Thujopsis* species, was found to be resistant to rodent attacks. For example, a small pagoda (Nara, Japan) made from *T. dolabrata* is in a well-preserved state with no evidence of damage by various detrimental organisms such as rodents, insects, and microorganisms although it is almost 1200 years old (Kawaguchi et al., 1989). We have therefore examined the rodent repellent components of this tree as potential natural alternatives to toxic chemicals.

METHODS AND MATERIALS

Animals and Housing Conditions. Female SPF mice (Slc: ICR strain, 24–26 g) were purchased from SLC Co., Japan. Animals were allowed to acclimate to their new housing for two weeks prior to the test. They were approximately six weeks of age at the initiation of the study. They were randomly assigned to groups and housed, three per plastic cage, on aspen chip bedding (Soft Chip, Japan SLC Co., Ltd.) under conditions of controlled temperature (25 ± 1°C), 50–60% relative humidity, and a photoperiod of 12L:12D. Cages and food containers were changed every three days. Rodent Chow (MF, Oriental Yeast Industry, Co., Ltd.) and water were provided *ad libitum*.

Sample Preparation. The sawdust of *T. dolabrata* (Family Cupressaceae) was obtained from Aomori Forest Experimental Station, Aomori, Japan.

Isolation and Identification. The sawdust (42 kg) of *T. dolabrata* was subjected to steam distillation (Figure 1). Extraction of the distillate with ether

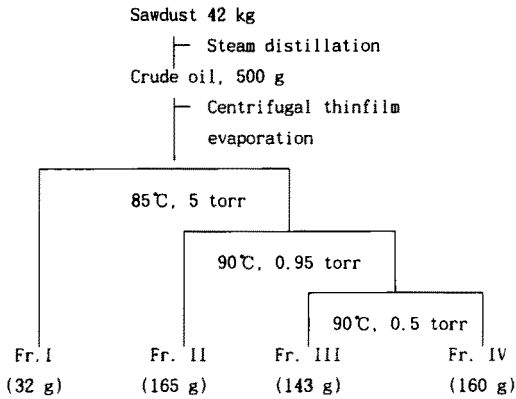

FIG. 1. Procedure of steam distillation of *Thujopsis dolabrata* S. et. Z. var. *hondai* sawdust and partition by centrifugal thin-film evaporation.

gave 500 g of a dark brown crude oil (1.2% yield). The crude oil was separated into fractions I (32 g), II (165 g), III (143 g), and IV (160 g), using a centrifugal thin-film evaporator for subsequent bioassay (Figure 1). Fraction I (1.18 g) was chromatographed on a silica gel column (Fuji-Davidson BW-350, 5 × 100 cm), and eluted with hexane–ethyl acetate (10:1). Column fractions were analyzed by TLC (chloroform–MeOH, 10:3), and the active fractions were combined.

Further separation of the biologically active components was carried out with HPLC (Hitachi 655A-11 LC). Develosil 60-5 (Nomura Chemical Co., Ltd) and Cosmosil $_5C_{18}$ column (Nacalai Tesque Co., Ltd.) were used with hexane–ethyl acetate (9:1) and acetonitrile–water (10:1), respectively. The detector wave length was 254 nm.

Structural determination of the active isolates was made by spectral analysis. ^1H and ^{13}C NMR spectra were recorded with a JEOL GSX-400 spectrometer (TMS as an internal standard) and chemical shifts were given in δ (ppm). UV spectra were obtained on a Shimadzu MPS-2000 spectrometer, IR spectra on a Shimadzu IR-460 spectrophotometer, and mass spectra on a JEOL JMS-DX 30 spectrometer.

Bioassay. Plastic-coated flexible electric cable was cut into 10-cm segments, and dipped in the 10% ethanol solution of the *Thujopsis*-derived materials for 3 min and allowed to dry. Control segments were prepared by dipping the cable in ethanol for 3 min. Ten segments treated with the test material, ten control segments and three female mice were placed in the same cage and the temperature was kept at 25 ± 1°C. All tests were conducted in triplicate. The mouse-induced damage state of the segments was observed two days after treat-

ment (DAT) for a rapid screening of active components. The responses to the *Thujopsis*-derived materials were compared with those to the controls.

The antignawing activities of the most active isolate during the 15-day test period were examined and compared with those of cycloheximide and two commercial terpenoids, thujone and thymol, which are known to have rodent repellent activity (Harding, 1985; Hansson, 1988). Tests were made in triplicate. The antignawing value (AV) of the test samples was calculated from the following formula. $AV = (0 \times n_1 + 1 \times n_2 + 2 \times n_3 + 3 \times n_4 + 4 \times n_5)/(n_1 + n_2 + n_3 + n_4 + n_5)$, where 0 = no damage in the wire segment; 1 = one damage spot in the segment; 2 = two damage spots in the segment; 3 = three to five damage spots in the segment; 4 = heavily damaged; and where n_1 to n_5 are the numbers of individuals showing grade 0 to 4 in each treatment.

Statistical Analysis. Data were subjected to ANOVA. Means were compared and separated by Tukey's studentized range test (SAS Institute, 1985).

RESULTS

During the initial experiments, we observed that the crude oil obtained by steam distillation of *T. dolabrata* sawdust possessed repellent activity on mice in the treated wire assay. The mice did not gnaw the treated wire segments, but gnawed heavily the control ones. Thus, this method is suitable for the measurement of repellent activity of compounds of synthetic or natural origin. Figure

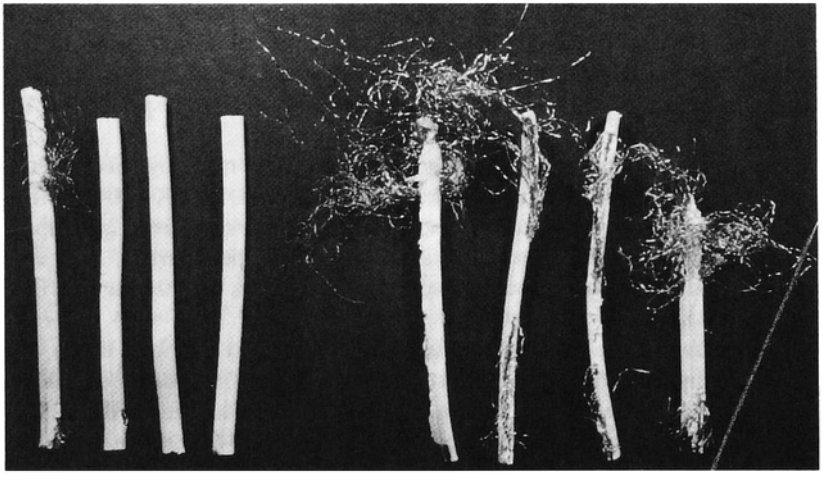

FIG. 2. A typical example of damage to wire after application of steam distillate derived from *T. dolabrata* sawdust (left) compared with control (right).

2 shows a typical example of the protective effect of the crude oil derived from the plant.

The fractions obtained from the crude steam distillate from the *Thujopsis* sawdust were assayed in the same manner. Ten percent ethanol solutions of fractions I and II showed strong (++) and weak (+) antignawing activity against mice. Purification of the biologically active compounds from fraction I (1.18 g) was done by silica gel column chromatography and HPLC, and 10% ethanol solutions of the isolates were bioassayed. Three isolates showed antignawing activity. Structural determination of the isolates was made by spectral techniques, and they were characterized as terpenoids: thujopsene (1530 mg), carvacrol (4 mg), and β-thujaplicine (10 mg) (Figure 3). For example, carvacrol was identified based on the following evidence: the molecular ion peak at *m/z* 150 (M^+) on the EI-MS (70 eV); IR (neat) ν_{max} cm^{-1}, 3375, 1616, 995; ^1H NMR ($CDCl_3$): δ 1.24 (6H, *d*, *J* = 8 Hz), 2.22 (3H, *s*), 2.83 (1H, *d*, *J* = 8 Hz), 6.66 (1H, *s*), 6.73 (1H, *d*, *J* = 8 Hz), 7.03 (1H, *d*, *J* = 8 Hz); ^{13}C NMR ($CDCl_3$); δ 15.3, 24.0, 33.7, 113.0, 118.8 *s*, 130.8, 148.4, 153.6. The structures of thujopsene and β-thujaplicine were identical with authentic samples by ^1H and ^{13}C NMR, MS, and IR.

The antignawing activities of 5% ethanol solutions of the three isolates were investigated. Carvacrol showed potent antignawing activity. Moderate activity was observed for thujopsene and β-thujaplicine.

The persistence of the repellent effects on mice, compared with that of the commonly used cycloheximide, was studied by assaying the damage to wire segments dipped in 5% ethanol solutions of the test materials over a 15-day period (Table 1). Untreated wire segments were heavily damaged during the test period. The antignawing value was 4.0 at six days after treatment. Carvacrol showed antignawing activity for a relatively short period (approximately six days), while cycloheximide provided protection for the full duration of the test.

DISCUSSION

Rodent control is most commonly dependent upon repeated application of rodenticides. However, these compounds have attendant problems (Meeham, 1984). In addition, rodents exhibit shyness behavior after exposure to toxic

chemicals (rat: Barnett et al., 1975; Prakash et al., 1975; and mouse: Rao and Prakash, 1980). Prakash (1976) reported that the shyness among rodents persists for 35 to 150 days. The adverse effects and shyness to poisons call for alternative control agents such as repellents rather than attempts to kill the rodents.

Certain plant-derived extracts have repellent properties against rodents (Harding, 1985; Hansson, 1988). In the present study, the steam distillate from *T. dolabrata* sawdust showed potent antignawing activity. Additionally, pharmacological investigations have shown that this plant was antimicrobial (Ito et al., 1980), hypocholesterolemic (Enomoto et al., 1977), and antitermitic effects (Nakashima and Shimizu, 1972; Ikeda et al., 1978).

Various compounds including phenolics, terpenoids, and alkaloids exist in plants and jointly or independently contribute to repellent activities (Hansson, 1988; Harborne, 1988). Many *Thujopsis* species are rich in terpenoids (Hasegawa and Hirose, 1982; Ohgaku et al., 1984; Yatagai et al., 1985). In our study, three terpenoids (carvacrol, thujopsene, and β-thujaplicine) with antignawing activity were isolated from the *Thujopsis* sawdust, and carvacrol was most potent. Harding (1985) also reported that thujone oil of *Artemsia absinthium* strongly repelled rodents.

The *Thujopsis* terpenoids were effective against mice only for a relatively short period of time, typically a few days. Carvacrol was the most effective, probably due to its high volatility in air. It has been also reported that the steam distillate of *Thujopsis* sawdust and its terpenoids carvacrol and β-thujaplicine have potent insecticidal and repellent activities against some stored-product and household insect pests (Lee, 1993) and termites (Ikeda et al., 1978; Chaboussou, 1978; Lee, 1993). These terpenoid compounds might be used as pest controls agent in limited spaces such as storage bins, greenhouses, or buildings, because of their high volatility, although the effects of these terpenoids on humans remain unknown. These results suggest that an appropriate carrier will be needed for slow release into the air. Harding (1985) recommended a suitable liquid or solid carrier such as lacquer, sodium silicate, or paraffin. A combination of thujone oil and lacquer (12:88), when used like a paint, has been reported to keep rodents away from the painted area for between three and five years (Harding, 1985).

Based upon our data and these earlier findings, carvacrol would be expected to protect against damage by rodents for a relatively long time if a carrier with slow-release properties could be selected or developed. Carvacrol has low toxicity (Worthing and Walker, 1987; Budavari et al., 1989) and causes no mutagenicity, when tested against four strains of *Salmonella typhimurium* (Lee, 1993). An average of 4000 tonnes of sawdust per year are produced as a by-product of the timber industry, because *T. dolabrata* is an important timber species in Japan (Kaburagi et al., 1969). Thus there is an adequate source of the crude oil available.

(Received June 21, 1994; accepted November 2, 1994)

Abstract—The female parasitic wasp *Cotesia kariyai* discriminated between the volatiles of corn leaves infested by younger host larvae *Pseudaletia separata* (first to fourth instar) and uninfested leaves in a Y-tube olfactometer; the wasps were attracted to the infested leaves. In contrast, when corn plants were infested by the later stages (fifth and sixth instar) of the armyworm, the wasps did not distinguish between infested corn leaves and uninfested corn leaves in the olfactometer. Mechanically damaged leaves were no more attractive than undamaged leaves, and host larvae or their feces were not attractive to the parasitoid. Through chemical analysis, the herbivore-induced plant volatiles were identified in the headspace of infested corn leaves. The herbivore-induced volatiles (HIVs) constituted a larger proportion of the headspace of corn leaves infested by early instar armyworms than of corn leaves infested by late instar armyworms. Application of third-instar larval regurgitant onto artificially damaged sites of leaves resulted in emission of parasitoid attractants from the leaf, whereas leaves treated with sixth-instar regurgitant did not. The function of this herbivore-stage related specificity of herbivore-induced synomones is discussed in a tritrophic context.

INTRODUCTION

Plants defend themselves against herbivores in various ways. These may comprise plant characteristics that affect herbivore performance directly or indirectly through natural enemies of the herbivores (Price et al., 1980; Price, 1981; Rhoades and Cates, 1976; Rhoades, 1985; Dicke and Sabelis, 1988a). These defense mechanisms may function constitutively (Rhoades and Cates, 1976; Price, 1981) or they may be induced by herbivory (Tallamy and Raupp, 1991; Dicke et al., 1990b; Dicke and Sabelis, 1988a; Takabayashi et al., 1994; Turlings et al., 1990).

In this study, we have investigated induced indirect defense of plants, involving the attraction of natural enemies to plants that are infested by herbivores. Plants that are infested by herbivores may emit so-called "herbivore-induced synomones" (Dicke and Sabelis, 1988b; Vet and Dicke, 1992). These are chemicals that are produced by the plant in response to damage done by specific herbivores. The chemicals are not emitted, or are only emitted in trace amounts, upon mechanical damage. Natural enemies of the herbivore use these chemicals in long-/short-range herbivore location (Dicke et al., 1990a,b; Sato, 1979; Turlings et al., 1990). Herbivore-induced synomones may be very specific stimuli: they may be specific for the herbivore species, the plant species, and/or the plant cultivar (Dicke et al., 1990b; Takabayashi and Dicke, 1993; Takabayashi et al., 1994; Turlings et al., 1993; Dicke, 1994). The value of this specificity has been discussed by Vet and Dicke (1992), who hypothesized that natural enemies of herbivores are faced with a reliability–detectability problem during foraging for their herbivore victims. Contact kairomones left by herbivores are the most reliable in indicating herbivore presence and identity, but they are difficult to detect from a distance (high reliability and low detectability). On the other hand, constitutively emitted plant volatile synomones are more detectable at a distance but less reliable in indicating herbivore presence and identity (low reliability and high detectability). Herbivore-induced synomones may combine the high detectability of plant volatiles with a high reliability in indicating herbivore presence. For plants, the specificity of the herbivore-induced synomones may be an important characteristic because it could ensure that the right natural enemy species is attracted.

Moreover, many parasitoid species are more specific and can attack only a limited range of host developmental stages within a species (Waage and Great-

head, 1986). If parasitized herbivores inflict less total damage to a plant than unparasitized herbivores, attraction of the natural enemies during an early phase of herbivore infestation would be beneficial. Yet, if quantities of herbivore-induced synomones are correlated to the extent of herbivory, the natural-enemy attracting stimuli would be expected to be most abundant during the later phase of herbivory. Thus, we were primarily interested in the question of whether the emission of herbivore-induced synomones is specific for the herbivore instars inflicting the damage. In this paper, we describe the effect of herbivore instars that damage plants on the attraction of natural enemies. This is done for a tritrophic system consisting of corn plants, the armyworm *Pseudaletia separata* Walker (Lepidoptera: Noctuidae) and the gregarious parasitic wasp *Cotesia* (= *Apanteles*) *kariyai* Watanabe (Hymenoptera: Braconidae).

Cotesia kariyai is one of the dominant parasitoid species of the common armyworm *P. separata* (Sato, 1988; Hirai, 1984). The wasps search for and attack host larvae actively during the day, while nocturnal host larvae hide in the ground or in the sheath of the host plant (Sato et al., 1983; Kanda, 1988). An intriguing question then is how the diurnal parasitoids find the nocturnal host larvae (Sato et al., 1983). It has been demonstrated that feces, feeding traces, and exuviae of the armyworm on an infested corn plant elicit strong behavioral responses in the parasitoid females upon contact with their antennae: the wasps are arrested and show area-restricted search patterns (Takabayashi et al., 1985; Takabayashi and Takahashi, 1989). This behavior increases the chances of finding a host that hides in the sheath of the infested corn plant or in the ground where host feces are scattered. The kairomones that mediate these behavioral responses were identified to be 2,5-dialkyltetrahydrofuran homologs that were present in host feces, feeding traces, and exuviae (Takabayashi and Takahashi, 1986a,b). Upon antennal contact with a *P. separata* larva, the wasp immediately inserts her ovipositor and lays a clutch of eggs.

The contact kairomones are highly reliable cues of host presence, but the question as to how the parasitoids locate the infested plants from a distance remains unanswered. *Cotesia kariyai* females are known to respond to volatiles from uninfested corn plants (Takabayashi et al., 1991a), but so far it is not known whether they are able to discriminate between uninfested plants and *P. separata*-infested plants. Other *Cotesia* species are known to distinguish uninfested plants from plants infested by their hosts on the basis of volatile infochemicals (Sato, 1979; Turlings et al., 1990; Kaiser and Cardé, 1992; Steinberg et al., 1992, 1993). Here we show that *C. kariyai* also has this ability. In addition we show that in *Cotesia kariyai* this discrimination on the basis of herbivore-induced synomones is affected by the stage of the herbivores infesting the plant.

METHODS AND MATERIALS

Insects

Pseudaletia separata has six larval instars. It takes about 15 days for the newly hatched larva to reach the pupal stage at 25°C, 17L:7D, and 50–70% relative humidity, and about three days at 25°C, 17L:7D for the adult female to initiate oviposition. The newly emerged adult female has a tendency to make a long-distance flight before the first oviposition. Females lay a cluster of ca. 100–300 eggs in one oviposition site.

Pseudaletia separata was introduced to the laboratory from a culture reared at the National Institute of Sericultural and Entomological Science in Tsukuba, Ibaraki, Japan in 1990. The insects were reared on corn leaves or artificial diet (INSECTA-LF: Nihon Nousan Kogyo, Ltd.) under conditions of 25 ± 3°C, 17L:7D, 50–70% relative humidity.

Cotesia kariyai is one of the dominant monophagous parasitoids of the common armyworm *Pseudaletia separata* in Japan (Hirai, 1984). The wasp is a gregarious endoparasitoid of second-instar to second-day sixth-instar larvae at 25°C, 17L:7D (Sato and Tanaka, 1984). The wasp cannot attack first-instar larva, probably because their small size hampers ovipositor insertion. When the wasp oviposits in a late sixth-instar host, the host pupates and the wasp offspring die.

Cotesia kariyai was introduced to the laboratory from a stock culture reared at the National Institute of Sericultural and Entomological Science in 1990. To maintain the wasp culture, fourth- or fifth-instar *P. separata* larvae were offered to female wasps for oviposition. It took about 10 days for the next generation of the wasp to egress at 25°C, 17L:7D. Egressed wasp larvae immediately made cocoons. The cluster of cocoons was collected and placed in a test tube (22 mm diam. × 200 mm long) with a small piece of paper towel moistened with 50% aqueous honey solution as food. Mating generally occurs right after emergence of the wasps. Adult wasps were stored in the dark at 10°C until used (not longer than five days). Naive *C. kariyai* were used in this study.

Corn (*Zea mays* L. vc. Royal Dent) was grown in a greenhouse (25 ± 5°C, 16L:8D). Seedlings of ca. 30–50 cm height were used for the experiments.

Bioassay

A Y-tube olfactometer was used to study the response of the wasps toward leaf volatiles (for details of the olfactometer setup, see Takabayashi et al., 1991b). The number of wasps that walked into the sample cage and the control cage was counted. Sign-tests determined whether the results differed significantly from a 50:50 distribution of the wasps (null hypothesis).

Olfactory Response of C. Kariyai *to Corn Leaf Volatiles*

The attraction of corn leaves infested by *P. separata* larva(e) of different developmental stages was tested. Infested leaves vs. uninfested leaves were compared in the Y-tube olfactometer.

Corn Plants Infested by Young Armyworms. Five intact corn plants (ca. 30 cm height) in a clear plastic cage (50 × 50 × 50 cm) were offered to five second-instar larvae in the climate room (25 ± 3°C, 17:7D, 50–70% relative humidity). Five days later, the armyworms were third instar. The host larvae and feces were then carefully removed from the plants with a brush.

Corn Plants Infested by Old Armyworms. Five intact corn plants (ca. 30 cm height) in a clear plastic cage (50 × 50 × 50 cm) were offered to five fourth-instar larvae in a climate room (25 ± 3°C, 17L:7D, 50–70% relative humidity). Five days later, the armyworms were fifth- to sixth-instar. The larvae and feces were then carefully removed from the infested plant with a brush.

Artificially Damaged Corn Leaves. Ten leaves of an uninfested corn plant (ca. 30 cm) were damaged slightly with sandpaper (ca. 30% of each leaf area) to imitate the young larva's infestation and with scissors (ca. 30% of each leaf area) to imitate the old larva's infestation. One hour later, the leaves were used for the bioassay.

Corn Plants Infested by Armyworms of Each Instar. Infested corn plants were further classified according to the instar of the armyworm that fed on them. Three corn plants were offered to armyworms of each instar during 2–6 hr, at 25 ± 3°C, 50–70% relative humidity. The number of armyworms offered and the infested area of each infested leaf are listed in Table 1.

Imitation of Caterpillar Damage on Corn Leaves. To imitate infestation by armyworm caterpillars, the corn leaf surface (ca. 30%) was damaged artificially with sand paper and then the regurgitant (5 larvae equivalent) of third-instar larvae or sixth-instar larvae was applied to the damaged part of the corn leaf.

TABLE 1. CORN LEAF SAMPLES USED FOR BIOASSAY AND CHEMICAL ANALYSIS

Infested by	Damaged leaf area (%)	Armyworms (*N*)	Bioassay[a]	Chemical analysis[a]
First instar	< 10	150	+	+
Second instar	< 10	100	+	+
Third instar	ca. 10	40	+	+
Fourth instar	ca. 40	10	+	−
Fifth instar	ca. 50	5	+	−
Sixth instar	ca. 50	3	+	+

[a] + = tested, − = not tested.

To collect the one equivalent regurgitant, the host was gently squeezed and the regurgitant was rapidly collected with 5-μl glass capillary tubes. Four leaves were treated. Six hours after treatment, the attraction of the treated leaves vs. undamaged leaves was compared in an olfactometer.

Chemical Analysis of Corn Leaf Volatiles

Infested corn leaves (as listed in Table 1), artificially damaged corn leaves, and uninfested corn leaves were used for chemical analysis. The headspace volatiles of each sample (50–100 g plant material in a 2-liter glass bottle) were collected on Tenax-TA for 30–60 min. The methods used to collect the volatiles of corn leaves were the same as previously reported (Takabayashi et al., 1991b).

The trapped headspace volatiles were subsequently analyzed with a gas chromatograph–mass spectrometer (GC-MS: VG MM7070F) of which the gas chromatograph was equipped with a thermal desorption cold trap injector (TCT, Chrompack). The GC conditions were: a Supelcowax 10 capillary column (60 m, 0.25 mm ID, 0.25-μm film thickness) and the oven temperature programmed from 40°C (4 min hold) to 100°C at a rate of 2°C/min, and then to 270°C at a rate of 6°C/min. The TCT conditions were: thermodesorption at 250°C during 10 min, while at the same time the cold trap was maintained at a temperature of −100°C. The analysis started by fast heating of the cold trap to 220°C. The mass spectrometer was working in the 70 eV electron impact (EI) ionization mode and scanning from 300 to 24 amu at a rate of 1 decade/sec.

The chemical structure of each compound was elucidated by comparison of the mass spectra with those of authentic chemical samples or by comparison with data in the mass spectra library of the Department of Organic Chemistry, Wageningen Agricultural University.

RESULTS

Effect of Armyworm Infestation on Response of Parasitoid to Corn Leaf Volatiles. Naive wasps preferred corn leaves infested by young larvae to uninfested leaves in the olfactometer (Figure 1). However, the wasps did not respond to larvae or their feces, isolated from corn leaves infested by young larvae when compared with clean air in the olfactometer (Figure 1).

The naive wasps did not prefer the odor of corn leaves infested by late-instar armyworms over that of uninfested leaves (Figure 1). The wasps also did not respond to isolated larvae or their feces when compared with clean air in the olfactometer (Figure 1).

The wasps showed no preference for leaves artificially damaged with sandpaper over undamaged leaves, or leaves artificially damaged with scissors over undamaged leaves (Figure 1).

Effect of Developmental Stage of Armyworm on Attractiveness of Infested Plant to Wasps. Corn leaves with ca. 10% (area) infestation by first-, second-, or third-instar host larvae attracted wasps more than uninfested leaves (Figure 2). Leaves with ca. 40% (area) infestation by fourth-instar larvae were also preferred by the wasp (Figure 2). However, when 50% of the area of corn leaves was infested by fifth- or sixth-instar larvae, they were not preferred by the wasp (Figure 2).

The six experiments in Figure 2 were also compared using the *G* test (Sokal and Rohlf, 1981). The attraction of leaves infested by first instars, second instars, third instars, and fourth instars were not significantly different. The attraction

of leaves infested by fifth instars and sixth instars was also not significantly different.

Mechanism of Production of Parasitoid Attractants. Leaves treated with third-instar regurgitant on a mechanical wound (five larvae equivalent per leaf) attracted wasps more than untreated leaves (Figure 3). In contrast, leaves treated with sixth-instar regurgitant (five larvae equivalent per leaf) did not attract wasps more than the untreated leaves (Figure 3). A 20-larvae equivalent of regurgitant of third- or sixth-instar larvae impregnated into a filter paper (2 × 2 cm) did not attract wasps (Figure 3).

Chemical Analysis. The main volatile compounds from uninfested corn leaves were hexanal, (*Z*)-3-hexenol, (*Z*)-3-hexenyl acetate, and limonene (Table 2). There were many compounds that were found in the volatiles of leaves infested by armyworms that were not detected or detected in only trace amounts in uninfested leaf volatiles (Table 3).

The herbivore-induced plant chemicals in the headspace of corn leaves infested by first- to second- and third-instar larvae were similar, and their combined amounts comprised ca. 70% of the total headspace volatiles emitted (Table 3). The major herbivore-induced compounds were terpenoids, indole, and oximes. (3*E*)-4,8-Dimethyl-1,3,7-nonatriene, (*E*)-α-bergamotene and (*E*)-β-farnesene were found as major compounds in the headspace of leaves infested by first to second instars and leaves infested by third instars. However, when corn leaves were infested by sixth-instar larvae, few compounds were found as herbivore-induced plant chemicals [indole, 3-hydroxy-2-butanone, (3*E*)-4,8-

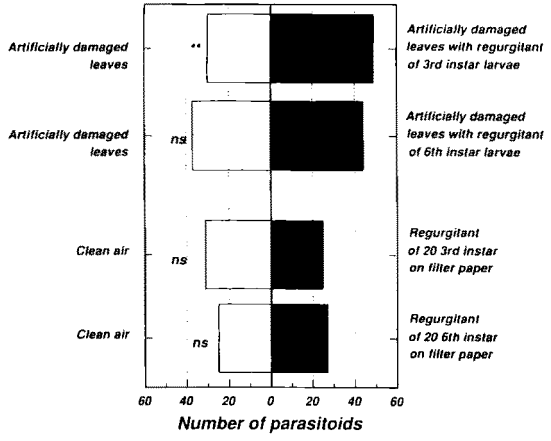

FIG. 3. Olfactory response of *Cotesia kariyai* to artificially damaged corn leaves treated with regurgitant of third-instar and sixth-instar armyworms. ** $0.01 > P > 0.001$; ns: not significantly different by sign test.

dimethyl-1,3,7-nonatriene and 2-methyl-1-propanol] and their total relative amount was only 15.2% (Table 3). The total peak area (arbitrary units) of sixth-instar armyworm-induced plant volatiles per gram leaf (77.3) was smaller than that of first-/second-instar, and third-instar armyworm-induced plant volatiles (846.2 and 928.8, respectively) (Table 3). Thus, there are qualitative and quantitative differences in the production of herbivore-induced plant volatiles depending on the developmental stage of the herbivores.

DISCUSSION

Cotesia kariyai is attracted by uninfested corn leaves, mediated by green leaf volatiles such as (*Z*)-3-hexenol (Takabayashi et al., 1991a). Artificially damaged leaves are not more attractive than undamaged corn leaves, while infochemicals from corn leaves infested by young armyworms were highly preferred compared to uninfested corn leaves. Neither the caterpillars themselves nor their feces are attractive to the parasitoids. The infochemicals that are emitted from host-infested leaves are not just the result of mechanical damage, but are specific for herbivore infestation. Similar phenomena are observed in other tritrophic systems (Turlings et al., 1990, 1991; Steinberg et al., 1992, 1993; Mattiacci et al., 1994). Moreover, the composition of the infochemicals emitted from armyworm-infested corn leaves is dependent on the herbivore developmental stage that feeds on the plant.

Damage by younger instars (first through third) attracts the parasitoids, while damage by older instars (fourth through sixth) does not. This difference was studied more precisely with corn leaves infested by each instar larvae separately. This revealed that corn plants infested by first-, second-, third-, or fourth-instar armyworms attract the wasp, whereas corn plants infested by fifth or sixth instars do not.

Chemical analysis supports our behavioral data. Corn leaves infested by younger instar larvae produce large amounts of herbivore-induced volatiles (70–80% of total volatile emission). However, corn leaves infested by sixth-instar larvae produce few herbivore-induced volatiles and their combined amount comprised only ca. 15% of the total volatile emission (Table 3). This may explain the attraction of leaves infested by young armyworms and the nonattraction of leaves infested by old armyworms.

Application of regurgitant of third-instar larvae onto artificially damaged leaves resulted in the attraction of parasitoids, whereas application of regurgitant of sixth instar leaves did not. It is likely that this effect was caused by buccal secretion or saliva of the host larvae, as has been found for other tritrophic systems (Sato, 1979; Turlings et al., 1990, 1991; Mattiacci et al., 1994). Furthermore, our data suggest that the buccal secretion or saliva of third instars and

those of sixth instar differ in composition and, thus, affect the plant differently with regard to the production of the wasp attractants.

Herbivore-induced synomone (HIS) production by plants for specific natural enemies of herbivores can be of two classes:

1. Unconditional HIS production. This occurs when the interaction mediated by HIS is unconditionally mutualistic, i.e., adaptive to both the plant and the natural enemy.

2. Conditional HIS production. This occurs when the interaction mediated by HIS is conditionally mutualistic in the following three ways. Type 1: Adaptive to the plant and conditionally adaptive to the natural enemy. In this case, the plant should be selected to produce HIS only when it is beneficial for the natural enemy to respond to HIS. Type 2: Adaptive to the natural enemy and conditionally adaptive to the plant. In this case, the plant should be selected to produce HIS only when it is beneficial to the plant. Type 3: Conditionally adaptive to both plant and natural enemy. In this case, plant should be selected to produce HIS only when it is beneficial to both the plant and the natural enemy.

In the case of the *C. kariyai*–armyworm–corn plant interaction, the HIS production is found to be conditional. Thus, the interaction between corn plants and *C. kariyai* is conditionally mutualistic. We examine this mutualistic interaction from the viewpoint of the plant and the wasp:

From the viewpoint for the plant, the wasps can successfully parasitize the larvae during the second to early sixth instar (Sato and Tanaka, 1984). It takes 10 days at 25°C for the parasitizing wasp larvae to develop and egress from the host. *Pseudaletia separata* larvae that are parasitized by *C. kariyai* at these stages do less damage to a plant than unparasitized larvae in this period, and this effect is more pronounced when parasitism takes place in younger host instars (Tanaka et al., 1992).

When a third-instar larva of *P. separata* is parasitized by *C. kariyai*, the total amount of food consumed by this larva until pupation is ca. 36% of the total food consumed by an unparasitized larva of the same developmental stage (Tanaka et al., 1992). Thus, attracting *C. kariyai* is adaptive for the infested corn plant.

When a fifth-instar larva is parasitized by *C. kariyai*, the total food consumed by this larva until pupation is reduced to ca. 63% of the food consumed by an unparasitized larvae of the same developmental stage. The parasitized fifth-instar larva, however, has already consumed food from the first up to the fifth instar developmental stage. Therefore, the total food consumed by a larva that is parasitized at the fifth instar is 76% of the total food consumed by an unparasitized larva of the same developmental stage until pupation (data from Tanaka et al., 1992). Thus, the reduction in feeding damage is much more pronounced when the larva is parasitized in the third instar. When early sixth-

instar larvae were parasitized by *C. kariyai*, the total food consumed by the larva is almost the same as that consumed by the unparasitized host (J. Takabayashi, unpublished data, 1992). Thus, for plants, it is advantageous to attract the parasitoids when the larvae are still small, as the benefit of attracting parasitoids decreases with time. The production of the wasp attractants is likely to have costs, in terms of energy or in terms of being more detectable to other herbivores, that are not affected by the wasps (Dicke and Sabelis, 1989). Therefore, it is adaptive for an infested plant to reduce the production of attractants with decreasing benefit due to herbivore development. This is probably one of the reasons why plants stop attracting wasps when the host is older than fifth instar.

From the viewpoint of *C. kariyai*, it is clearly adaptive for the wasps to find unparasitized hosts. There are three other dominant parasitoid species for *P. separata* larva in Japan: *Cotesia ruficrus*, *Microplitis mediator*, and *Campoletis chloridae* (Sato, 1988). *Cotesia kariyai* can successfully parasitize larvae during the second through the early sixth instar (Sato and Tanaka, 1984), but later-stage armyworms are more likely to be already parasitized by conspecific or heterospecific parasitoids. *Cotesia kariyai* cannot successfully produce offspring in an armyworm that has already been parasitized more than three days earlier by a conspecific wasp (J. Takabayashi, unpublished data). Under such a competitive situation, searching for young armyworms should be advantageous for the wasps. This may also select corn plants to produce HIS when inflicting armyworms are of a younger stage.

The above findings indicate that the interaction between corn plant and *C. kariyai* is type 3—conditionally adaptive to both the plant and the natural enemy. This study provides an example for illustrating a new scheme to evaluate plant–natural enemy interactions on the basis of HIS production. The experimental design developed in this paper is applicable to other tritrophic systems in evaluating the mutualistic interactions between plants and natural enemies of herbivores through HIS.

Acknowledgments—We thank Toshiharu Tanaka for his helpful discussion on the food consumption of the armyworm. We also thank Lisa Tsukamoto, Yoshibumi Sato, and Masahiko Higashi for the comments on the manuscript. (Received July 20, 1994; accepted November 28, 1994)

Abstract—A resin glycoside mixture isolated from *Ipomoea tricolor* inhibited radicle growth of *Echinochloa crusgalli*. The effect of the resin was tested on the activity of the plasma membrane H^+-ATPase from *E. crusgalli*. For this purpose, plasma membrane vesicles were purified by the method of aqueous two-phase partitioning. The resin glycoside inhibited by 30% the activity of the plasma membrane ATPase. The same result was obtained with the purified main component of the resin. This indicates that the plasma membrane ATPase can be one of the cellular targets of the resin. Hence it is possible that the mechanism of action of the resin involves an inhibition of the plasma membrane ATPase.

Key Words—*Ipomoea tricolor*, *Echinochloa crusgalli*, allelopathy, allelochemicals, resin glycoside, plasma membrane, plasma membrane H^+-ATPase.

INTRODUCTION

Plants produce and release to the environment secondary compounds that interact in different ways with plants, microorganisms, and animals. These interactions may result in the inhibition or stimulation of root or stem growth. These allelochemicals affect many cellular processes: ion uptake, protein synthesis, photosynthesis, activation or breakdown of hormones, respiration, cell division, energy metabolism, and enzymatic activity (Cameron and Julian, 1980; Mandava, 1985; Alam et al., 1987; Cruz et al., 1990; Wacker et al., 1990).

In a previous study, we isolated a resin glycoside from *Ipomoea tricolor* Cav. (Convolvulaceae) that inhibited radicle growth of *Amaranthus leucocarpus* (Amaranthaceae) and *Echinocloa crusgalli* (Gramineae) (Anaya et al., 1990). *Ipomoea tricolor* is used in Mexican traditional agriculture by peasants for weed control. Hence, we explored if the mechanism of action of the resin was related to inhibition of the H^+-ATPase of the plasma membrane. This possibility was considered since the resin has to interact first with the plasma membrane, and one of the most important proteins in this membrane is H^+-ATPase. This enzyme plays a central role in plant cell physiology, i.e., it gives rise to proton gradients that drive the transport of different molecules in and out of the cells. Furthermore, according to the "acid growth theory," the H^+-ATPase produces acidification of the apoplastic space; this increases the plasticity of the cell wall, allowing the cell enlargement. Such actions of ATPase may affect radicle growth (Altabella et al., 1990; Hager et al., 1991). The present experiments show that a resin glycoside from *Ipomoea tricolor* inhibits the activity of plasma membrane H^+-ATPase from *E. crusgalli*. This effect could be related to its overall action on radicle growth.

METHODS AND MATERIALS

Plant Material. Echinochloa crusgalli seeds were germinated at 30°C in the dark on wet filter paper. After three days of growth, the roots were dissected.

Resin Glycoside Mixture. The resin glycoside was isolated from *Ipomoea tricolor* Cav. (Convolvulaceae) by bioactivity-guided fractionation of an ethyl acetate extract (Anaya et al., 1990). Resin (20–200 μg) was dissolved in dimethylformamide; this yielded an approximate concentration of 130–1305 μM using the mol wt of tricolorin A.

Obtaining Tricolorin A. Tricolorin A is the major component from the resin glycoside (it was a kind gift from Dr. Pereda-Miranda). The structure of this compound is shown in Figure 1 (Pereda-Miranda et al., 1993). Tricolorin A dissolved in dimethylformamide was added to the ATP hydrolysis assay in a concentration range of 130–1305 μM.

Microsomal Fraction. The roots (5 g) were ground with a mortar and pestle with the addition of 30 ml of buffer I containing: 250 mM sucrose, 70 mM Tris HCl (pH 8.0), 10% glycerol, 1 mM Na_2ATP, 15 mM 2-mercaptoethanol, and 4 mM DTT (dithiothreitol). EDTA (ethylene diamine tetraacetic acid) 2 mM, 7 μg/ml chymostatin, 10 μg/ml TLCK [L-1-chloro-3-(4-tosylamido)7-amino-2-heptanone], 10 μg/ml TPCK [L-1-chloro-3-(4-tosylamido)-4-phenyl-2-butanone], and 1 mM PMSF (phenylmethylsulfonyl fluoride) were added as protease inhibitors. All steps were carried out at 4°C. The homogenate was filtered through four layers of cheesecloth and centrifuged for 10 min at 500*g*. The

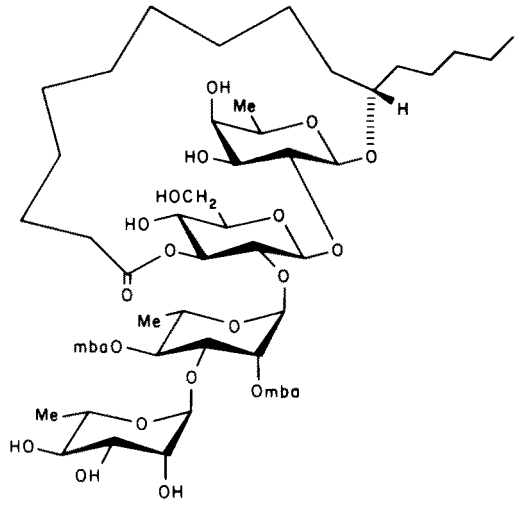

FIG. 1. Structure of tricolorin A, the main compound (85%) of the resin glycoside mixture (Pereda-Miranda et al., 1993).

supernatant was centrifuged at $13 \times 10^3 g$ for 10 min. The resulting supernatant was centrifuged for 1 hr at $80 \times 10^3 g$ to obtain the microsomal pellet.

Aqueous Two-Phase Partitioning. Purified plasma membranes were obtained by the method of aqueous dextran–polyethylene glycol two-phase partition (Larsson et al., 1987) with some modifications. The microsomal pellet from roots was resuspended in buffer II (330 mM sucrose, 5 mM potassium phosphate, pH 7.8, and 4 mM KCl) and brought to a final volume of 1 ml. This suspension was applied to an aqueous-phase partition system. Three tubes containing the aqueous-phase partition system were made as follows: tube 1 contained 2.7 g of a phase mixture consisting of 7% (w/w) dextran (50×10^4 mol wt), 7% (w/w) polyethylene glycol (3350 mol wt), 330 mM sucrose, 5 mM potassium phosphate, pH 7.8, and 5 mM KCl. Tubes 2 and 3 contained 15 g of the phase system identical in composition to tube 1. The microsomal suspension was layered onto the phase mixture in tube 1 (final weight of 3.6 g) and was mixed by inversion 20 times and centrifuged at $1500g$ for 5 min. The resulting upper phase (U_1) was transferred to tube 2, and the mixing and centrifugation were repeated to obtain the U_2 fraction. The procedure was repeated again for tube 3 (to obtain fraction U_3). To remove the polymers, the resulting upper layer (U_2 or U_3) was diluted at least twofold with buffer III (250 mM sucrose and 10 mM Tris HCl, pH 7.5) and centrifuged for 2 hr at $10 \times 10^4 g$. The resulting pellet was resuspended in buffer IV (250 mM sucrose, 5 mM Tris

HCl, pH 7.0, 10% glycerol, 1 mM DTT, and protease inhibitors) to give a final protein concentration of 1.9–2.6 mg/ml; this was stored at −70°C.

ATPase Assay. One microgram of protein from the microsomal fraction or the resuspended U_3 plasma membrane fraction was added to 150 μl of reaction medium consisting of 250 mM sucrose, 20 mM Tris HCl, pH 7.0, 10 mM ATP Tris, pH 7.0, 10 mM $MgCl_2$, and 7 μM CCCP (carbonyl cyanide *m*-chlorphenylhydrazone). When required, the following inhibitors were added as supplements: 2 mM NaN_3 to inhibit mitochondrial ATPase, 2 mM Na_2MoO_4 to inhibit acid phosphate, 150–250 μM Na_2VO_4 to inhibit plasma membrane ATPase, and 100 mM KNO_3 to inhibit tonoplast ATPase. The membranes were preincubated with the resin or the tricolorin A for 15 min when indicated. In preliminary experiments, the inhibitory effect of the resin was the same in the presence or absence of 0.05% Triton X-100; therefore all subsequent experiments were performed without the detergent. ATP hydrolysis was allowed to proceed at 37°C for 30 min; the reaction was stopped by addition of 24% SDS (sodium dodecyl sulfate). Phosphate release was determined by the method described in González-Romo et al. (1992). In each case four repetitions were tested. The results were processed by ANOVA Duncan's multiple-range test.

Protein Determination. Protein concentration was determined by the method of Peterson (1977) using BSA (bovine serum albumin) as standard.

RESULTS

Effect of Resin Glycoside on Radicle Growth of E. crusgalli. The effect of the resin glycoside on radicle growth of *Echinochloa crusgalli* at different times of growth is shown in Figure 2. The resin inhibited radicle growth, evaluated in terms of radicle length, by 82–89%. Fresh weight was inhibited by 78–97%.

Purification of Plasma Membranes. In order to explore the effect of the resin on the H^+-ATPase from the plasma membrane, we first measured the characteristics of the ATPase activity of the microsomal fraction. In this preparation there are four different components, as inferred from the inhibition of ATP hydrolysis by specific reagents (Table 1). The activity was inhibited 18% by vanadate, an inhibitor of plasma membrane ATPase; 33% by nitrate, an inhibitor of tonoplast ATPase; and 52% by a mixture of azide and molybdate, inhibitors of mitochondrial ATPase and acid phosphatase, respectively. Accordingly, plasma membrane vesicles from *E. crusgalli* radicles were purified by the method of aqueous-phase partitioning of Larsson et al. (1987). A polymer concentration of 7% dextran T-500 and 7% PEG-3350 yielded the purest preparation in the U_2 fraction: 76% of the activity was due to plasma membrane ATPase (sensitive to vanadate). Of the overall ATPase activity, 11% corresponded to mitochondrial ATPase plus acid phosphatase and 4% to tonoplast ATPase.

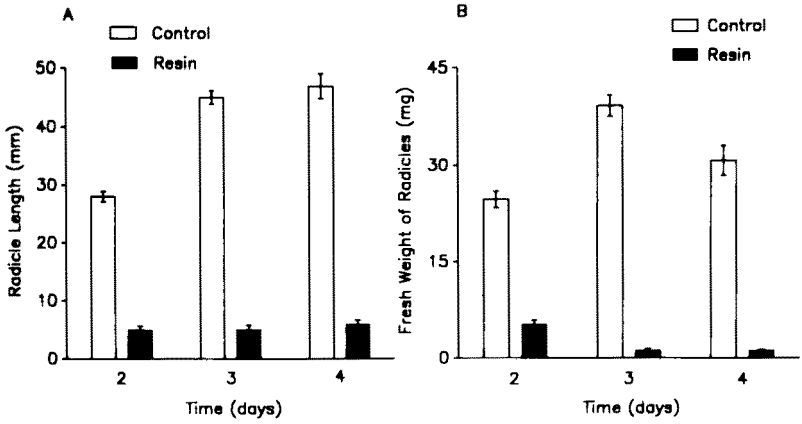

FIG. 2. Effect of the resin glycoside [65 μM (considering the mol wt of tricolorin A)] on the radicle growth of *E. crusgalli*. Resin was dissolved in methylene chloride. The radicle growth in the control was the same in the presence of methylene chloride or water. Resin was added at zero time and the measurements were done at the indicated times. Resin (261 μM)	506.5 ± 0.5 (90.0%)	358.8 ± 8.7 (83.0%)[a]	576.8 ± 0.6 (68.0)[a]

[a] $P < 0.05$, ANOVA.

In order to increase the degree of purity of plasma membrane vesicles, the U_2 fraction was repartitioned in a polymer concentration of 7% dextran and 7% PEG-3350 (Table 1). Of the total ATPase activity of the U_3 preparation, 88% correspond to that of the plasma membrane. The rest was due to ATP hydrolysis by mitochondria (10%) and an acid phosphatase. It is noted that no tonoplast ATPase activity was detected.

Effect of Resin on Purified Plasma Membrane Vesicles (U_3 Fraction). Table 1 shows the effect of the resin glycoside on the ATPase activity of vesicles at different levels of purification. In the U_3 fraction, which constitutes a highly purified membrane fraction of plasma membrane vesicles (about 90%), the resin glycoside inhibited ATP hydrolysis by about 30% as compared to inhibition of 10% in the microsomal fraction or 17% in the U_2. In consequence, inhibition of ATP hydrolysis in the U_3 fraction was due to an effect of the resin on the plasma membrane ATPase, since this is its major ATP hydrolytic component.

To determine whether the plasma membrane ATPase was the component affected by the resin glycoside, ATPase activity was measured in the U_3 fraction in a condition where ATP hydrolysis was solely due to the plasma membrane ATPase activity. This condition was attained by adding inhibitors of the mitochondrial ATPase and acid phosphatase. In this fraction, ATP hydrolysis was inhibited 30% by the resin glycoside (Table 2). This indicated that the resin inhibited the activity of the plasma membrane ATPase.

Effect of Resin Concentration on ATP Hydrolysis from Purified Plasma Membranes. The resin glycoside inhibited ATP hydrolysis in the U_3 fraction in a dose-dependent manner (Figure 3). Plasma membrane ATPase activity was reduced to the same extent by equivalent concentrations of tricolorin A, the

TABLE 2. EFFECT OF RESIN GLYCOSIDE ON ATP HYDROLYSIS OF FRACTION MEMBRANES FROM *E. crusgalli* RADICLES[a] IN PRESENCE OF SPECIFIC INHIBITORS

ATPase activity origin	ATPase activity (nmol Pi/min/mg protein)
Plasma membrane ATPase	965.9 ± 0.4
Plasma membrane ATPase + resin (261 μM)	673.7 ± 0.3[b]
Mitochondrial ATPase, acid phosphatase	132.6 ± 0.4
Mitochondrial ATPase, acid phosphatase + resin (261 μM)	154.0 ± 0.4[b]

[a] Total ATPase activity in plasma membrane vesicles was determined in the absence of any inhibitor and was 1077.3 nmol Pi/min/mg protein. Plasma membrane ATPase activity was measured as Pi released in a medium including NaN_3/Na_2MoO_4 (see Methods and Materials) with dimethylformamide (1.3%). Mitochondrial ATPase and acid phosphatase activity were determined in a similar way but in the presence of Na_3VO_4 (see Methods and Materials), with dimethylformamide (1.3%).
[b] $P < 0.05$, ANOVA.

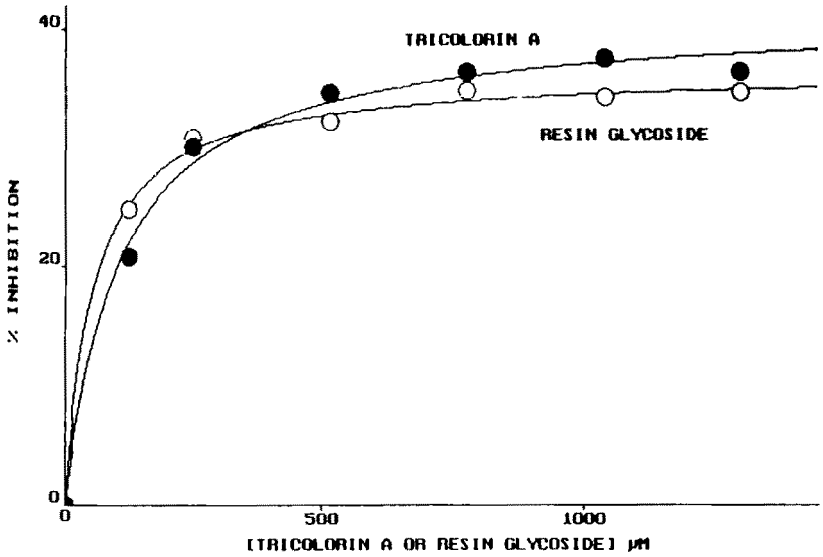

FIG. 3. Effect of the resin glycoside and tricolorin A on the ATPase activity of isolated plasma membranes vesicles of roots from *E. crusgalli*. The U_3 fraction (1 µg of protein) was preincubated with the resin glycoside (○) and tricolorin A (●) at the indicated concentrations during 15 min as described under Methods and Materials and ATP hydrolysis was measured as Pi release.

main component of the resin glycoside. These results indicate that the inhibitory effect displayed by the whole resin glycoside was caused by tricolorin A.

DISCUSSION

The plasma membrane vesicles from *Echinochloa crusgalli* roots prepared in this study by aqueous two-phase partitioning possess a high purity, similar to that obtained in other systems with this method (Buckhout and Hrubec, 1986; Larsson et al., 1987; Sandstrom et al., 1987). The activity of the ATPase of plasma membrane vesicles isolated by this method is similar to that reported by Sandstrom and Cleland (1989) on oat vesicles. The activity of these preparations is higher than those obtained with other methods of purification (DuPont et al., 1981; DeMichelis and Spanswick, 1986).

We have previously reported the effect of another phytotoxic compound, the monoterpene diacetyl-piquerol, on the plasma membrane ATPase activity (Cruz et al., 1990). This monoterpene inhibited radicle growth of *Ipomoea purpurea* (10–100%) in a concentration range of 10–1000 µM. This compound

also inhibited the H^+-ATPase activity in plasma membrane (67.2%) and tonoplast membrane (31.4%) of the microsomal fraction from the radicles of *Ipomoea purpurea* (Cruz et al., 1990). In this study, we obtained results that point out the importance of using membranes with a high degree of purity when effects of allelochemicals are characterized.

The inhibiting action of the resin could result from either a direct interaction of the resin with the enzyme or through its interaction with the immediate lipid environment of the protein, which has been reported to be important for its activity (Serrano et al., 1988; Brauer and Tu, 1989).

The resin glycoside at a concentration of 65 μM inhibits radicle growth by 87%. However, the inhibitory effect of the resin on the plasma membrane H^+-ATPase activity was 32% at 261 μM. This inhibition cannot be underestimated, since the expression of the activity of this enzyme is critical for cell elongation and nutrition, processes that are essential for root growth. The work of Hager et al. (1991) has shown that a decrease in the amount of the H^+-ATPase from plasma membrane is equivalent to a decrease in the elongation rate of maize coleoptiles. The difference in inhibition of radicle growth and H^+-ATPase suggests that besides the effect on ATPase activity, the resin could interfere with other cellular processes, producing an ultimate reduction in the radicle growth. This possibility is supported by the fact that within the cell, allelochemical compounds interfere with a vast number of processes (Cameron and Julian, 1980; Mandava, 1985; Alam et al., 1987, Cruz et al., 1990; Wacker et al., 1990). For instance, two allelochemicals, ferulic acid and vanillic acid, inhibit Ca^{2+} uptake, malate oxidation in mitochondria, and O_2 evolution in chloroplasts (Demos et al., 1975; Moreland and Novitzky, 1987). In the same case, coumarin inhibits Ca^{2+} uptake and respiratory activity in mitochondria and increases indoleacetic acid degradation (Zenk and Muller, 1963; Demos et al., 1975; Moreland and Novitzky, 1987). These data indicate that the toxicity of these kinds of compounds may involve not one, but several molecules present in the cell. However, there is not much information about the specific biological molecules that are affected in these processes.

[2]*Zoological Laboratory, Faculty of Agriculture Meijo University Tempaku-ku, Nagoya, 468, Japan*

(Received September 2, 1994; accepted November 28, 1994)

Abstract—(*Z,Z*)-6,9-Dienes with straight C_{18}–C_{23} chains were synthesized from linoleic acid, and a C_{17} chain was synthesized by hydrogenation of the corresponding 6,9-diyne prepared from propargyl alcohol. Oxidation of the homoconjugated dienes with *m*-chloroperoxybenzoic acid yielded a 1:1 mixture of two monoepoxides that could be separated by repeated medium-pressure liquid chromatography with a Lobar column. The chemical structure of each positional isomer was confirmed by analyses of the ozonolysis products, and the isomers showed characteristic ^{13}C signals in their NMR spectra and fragment ions in their EI mass spectra. In addition to the (*Z,Z,Z*)-3,6,9-trienes with straight C_{18}–C_{23} chains and their monoepoxides, field tests using single source lures incorporating one of the above seven dienes and 14 monoepoxymonoenes were carried out in a forest in Tokyo from 1992 to 1994. Consequently, attraction of six geometrid species and five noctuid species was observed for the first time.

Key Words—Sex pheromone, lepidopterous attractant, field test, monoepoxymonoene, monoepoxydiene, mass spectrum, Geometridae, Noctuidae.

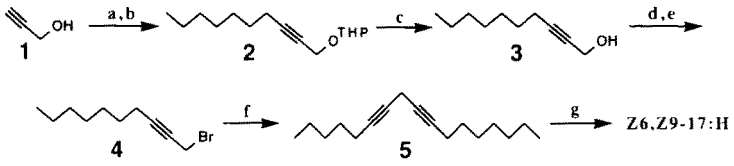
INTRODUCTION

(*Z*,*Z*,*Z*)-3,6,9-Triunsaturated hydrocarbons and their monoepoxides have been identified as sex pheromone components of female moths, mainly in the families Geometridae and Arctiidae (Arn et al., 1992). Furthermore, field screening tests in Canada, Europe, and Japan using synthetic compounds revealed that the trienes and monoepoxydienes attracted not only geometrid species but many noctuid species belonging to the subfamilies Catocalinae, Ophiderinae, Hyperminae, and Herminiinae (Arn et al., 1992; Ando et al., 1993). Recently Ohmasa et al. (1991) reported the major pheromone component of *Oraesia excavata* Butler (Noctuidae: Ophiderinae) to be (*Z*)-6-*cis*-9,10-epoxyheneicosene. Furthermore, the nonadecene analog was tentatively identified from the female gland of *Anacamptodes humaria* Guenée (Geometridae: Ennominae) by Millar et al. (1991). These results indicate that the monoepoxides of (*Z*,*Z*)-6,9-diunsaturated hydrocarbons constitute one group of the lepidopterous sex pheromones. This paper deals with the syntheses and chemical characterizations of monoepoxymonoenes and with their field attractancy as evaluated in a forest in Tokyo, in addition to the parent dienes, (*Z*,*Z*,*Z*)-3,6,9-trienes, and their monoepoxides.

METHODS AND MATERIALS

Synthesis of 6,9-Dienes. Homoconjugated dienes with straight C_{18}–C_{23} chains (Z6,Z9-18:H, Z6,Z9-19:H, and so on)[4] were synthesized starting from linoleic acid by the same method described for 3,6,9-trienes starting from linolenic acid (Ando et al., 1993). Z6,Z9-17:H was synthesized as shown in Scheme 1. After protecting the hydroxyl group, propargyl alcohol (**1**) was alkylated with 1-bromoheptane to yield THP ether of 2-decyn-1-ol (**2**). The THP

[4]Compounds are abbreviated as described in our previous paper (Ando et al., 1993) as follows: Z6,Z9-18:H is (6Z,9Z)-6,9-octadecadiene, epo6,Z9-17:H is (*Z*)-9-*cis*-6,7-epoxyheptadecene.



SCHEME 1. Synthetic route of (6Z,9Z)-6,9-heptadecadiene (Z6,Z9-17:H). a: 3,4-dihydro-2*H*-pyran/*p*-TsOH, b: *n*-BuLi/dry THF, and *n*-$C_7H_{15}Br$/HMPA, c: *p*-TsOH/EtOH, d: MsCl/Et_3N/CH_2Cl_2, e: LiBr/THF, f: *n*-$C_5H_{11}C{\equiv}CMgBr$/CuCl/dry THF, g: H_2/Pd-$BaSO_4$-quinoline/*n*-hexane.

protectional group was removed by acid, and the alcohol (**3**) was converted to 1-bromo-2-decyne (**4**) (37% yield from **1**) via the mesylate. The bromide (**4**) was coupled with hept-1-ynylmagnesium bromide, which was prepared with 1-heptyne and ethylmagnesium bromide, in the presence of copper chloride yielding 6,9-heptadecadiyne (**5**) (80% yield from **4**). Partial hydrogenation of the diyne (**5**) to Z6,Z9-17:H was achieved using Pd-$BaSO_4$ catalyst poisoned with quinoline (86% yield).

Synthesis and Separation of Monoepoxides of 6,9-Dienes. A mixture of epo6,Z9-17:H and Z6,epo9-17:H in a ratio of ca. 1:1 was obtained by oxidation of Z6,Z9-17:H with *m*-chloroperoxybenzoic acid (MCPBA). The two positional isomers were separated by a medium pressure liquid chromatographic system (MPLC), the components of which were a solvent pump (Yanaco L4000W liquid chromatograph), a Lobar column (Merck LiChroprep Si 60, 10 mm ID × 240 mm, 40–63 μm), and an RI detector (Shimadzu RID-2A). Although the mixture (50 mg) applied to the MPLC using 1.0% tetrahydrofuran (THF) in *n*-hexane as a solvent (flow rate: 2.0 ml/min) showed only one peak (R_t = 77.5 min), even in a recyclic mode (two times), the first half (fraction 1, 70.0–77.5 min) and the latter half (fraction 2, 77.5–83.0 min) of the eluent were recovered separately. By repeating this MPLC separation two more times, we obtained two fractionated compounds [8 mg of each with purity >95% by GC (i.e., TIC trace from GC-MS)], and their chemical structures were determined by ozonolysis experiments. Ozone was passed into the *n*-hexane (1 ml) solution of each compound (ca. 0.1 mg), cooled in a Dry Ice–acetone bath for 1 min, and an aliquot (1 μl) of the solution was injected into a capillary column of the GC-MS to analyze the aldehydes, which were produced from the ozonides by heat. Mixtures of two monoepoxides of other diunsaturated hydrocarbons (C_{18}–C_{23}) were prepared and separated into two fractions in the same manner. Their structures were determined also by the GC-MS analyses of ozonolysis products.

Synthesis of 3,6,9-Trienes and Their Monoepoxides. Trienes and their monoepoxides with C_{19}–C_{21} chains had been synthesized (Ando et al., 1993). Compounds with C_{22} and C_{23} chains were prepared by the same method, except for utilizing the bromo derivative of linolenic alcohol in a Grignard-type coupling reaction instead of a tosyl derivative (Fukumoto and Yamamoto, 1992). To yield Z3,Z6,Z9-18:H, the tosyl derivative was mixed with $LiAlH_4$ in dry THF and stirred for one night. The triene was also converted to the 1:1:1 mixture of monoepoxydienes by MCPBA oxidation. These positional isomers were separated more easily by the MPLC with the Lobar column than by the preparative TLC. With a solvent of 1.0% THF in *n*-hexane (flow rate: 2 ml/min), they were well separated from each other after one recycle (R_t = 62.3 min for epo3,Z6,Z9-18:H; 48.5 min for Z3,epo6,Z9-18:H; and 55.9 min for Z3,Z6,epo9-18:H). Monoepoxydienes with C_{22} and C_{23} chains were also separated by the MPLC purification.

Spectroscopy. The NMR spectrum of each compound in $CDCl_3$ was analyzed with a JEOL EX 270 Fourier transform spectrometer (270.2 MHz for ^1H and 67.9 MHz for ^{13}C) using TMS as an internal standard. Electron impact (EI) GC-MS was performed with a JEOL JMS-SX102A mass spectrometer containing a DB-1 capillary column (0.25 mm ID × 30 m, J&W Scientific). The ionization voltage of every measurement was 70 eV. The ion source temperature was 240°C, and the column temperature program was 40°C for 1 min, 50°C/min to 150°C, and finally 8°C/min to 300°C.

Field Evaluation. In the same manner reported previously (Ando et al., 1993), screening tests with seven 6,9-dienes (C_{17}–C_{23}), six 3,6,9-trienes (C_{18}–C_{23}), and their monoepoxides were carried out from August 1992 to July 1994 in a mixed forest area in the suburbs of Tokyo (Rolling Land Laboratory, Tokyo University of Agriculture and Technology, Hachioji-shi, Tokyo). Each chemical at 1 mg with purity >95% by GC was applied to a rubber septum, which was placed in a sticky-type trap (30 × 27-cm bottom plate with a roof, Takeda Chemical Ind., Ltd., Osaka, Japan). Two traps were used for each chemical.

RESULTS AND DISCUSSION

Characterization of Synthetic Compounds

Identification of Monoepoxides of 6,9-Dienes. Ozonolysis of the compound, which was collected as fraction 1 from the monoepoxides of Z6,Z9–17:H by a Lobar MPLC column, produced 3,4-epoxyundecanal with M^+ at *m/z* 184 (4%) and characteristic fragment ions at *m/z* 85 (95%), 127 (63%), 155 (12%), and 166 (19%), while *n*-hexanal, the counterpart of 3,4-epoxyundecanal, was not detected. This small aldehyde eluted from the GC column before starting the measurement of mass spectra. In contrast, ozonolysis of fraction 2 generated two aldehydes, 3,4-epoxynonanal with M^+ at *m/z* 156 (8%) and fragment ions at *m/z* 85 (84%), 99 (61%), 127 (22%), and 138 (18%); and *n*-octanal with M^+ at *m/z* 128 (1%) and fragment ions at *m/z* 99 (40%) and 110 (29%). These results showed that the compound in fraction 1 is Z6,epo9–17:H and that in fraction 2 is epo6,Z9–17:H. The chemical structures of monoepoxides with C_{18}–C_{23} chains were also determined by the same ozonolysis experiments, and it was revealed that 9,10-epoxides were recovered in fraction 1 and 6,7-epoxides in fraction 2.

It is difficult to distinguish between 6,7-epoxides and 9,10-epoxides by ^1H NMR measurements, since these compounds include a common functional group, an epoxy ring homoconjugated with C=C bond. In ^{13}C NMR, however, chemical shifts of some signals of 6,7-epoxides are different from those of the corresponding carbons of 9,10-epoxides, and the ^{13}C NMR spectrum of the crude

products of MCPBA oxidation represented some paired signals. Table 1 shows the ^{13}C NMR assignments (C-1 to C-12) for monoepoxymonoenes of the two types, which were accomplished by two-dimensional experiments and by referring to the ^{13}C NMR data of monoepoxydienes. In this table, carbons from position 4 to position 12 of the 6,7- and 9,10-epoxides are arranged conversely in order to compare the shift values of each carbon in the common structure represented with C-a to C-h (see the footnote of Table 1). Although the epoxy ring and olefinic carbons (C-c, C-d, C-f, and C-g) of the two positional isomers were at the same chemical shift values, each signal of the C-1, C-a, and C-b of the 6,7-epoxides appeared at a higher field than the corresponding signal of the 9,10-epoxides, and each signal of C-2, C-3, and C-h at a lower field. Particular differences of the shift values of C-3 and C-a are about 0.3 ppm; therefore the synthetic monoepoxide of 6,9-dienes can be identified based on the values of these ^{13}C signals.

MS Analyses of Monoepoxides of 6,9-Dienes. In EI-MS measurements, each monoepoxide of 6,9-dienes showed M^+ and $[M-18]^+$ ions with the relative intensities of ca. 5 and 10%, respectively. Reflecting the chemical structures, several abundant fragment ions are expected to be produced after the EI ionization as shown in Figure 1. While ions at *m/z* 71, 153 M-71, and M-153 are listed for both 6,7- and 9,10-epoxides in common, ions at *m/z* 99, 113, 127, M-127, M-114, and M-100 are nominated as characteristic fragments for the 6,7-epoxides and ions at *m/z* 97, 110, 124, M-125, M-111, and M-97 for the 9,10-epoxides. Their relative intensities, which were measured in this experiment, are listed in Table 2. Among them, ions at *m/z* 99, M-114, and M-100 are actually observed to be stronger in 6,7-epoxides, and ions at *m/z* 124, M-125, and M-111 in 9,10-epoxides than the other epoxides. 6,7-Epoxides showed smaller R_t than the corresponding 9,10-epoxides on a DB-1 capillary column (see Table 2). These two types of monoepoxymonoenes are distinguished from each other by using a capillary GC-MS system according to their chromatographic behavior and the above characteristic fragment ions.

Fragmentation at the epoxy ring produces ions at *m/z* 99 from 6,7-epoxides and at *m/z* 124 from 9,10-epoxides, including a moiety composed of C-1 to C-6 and C-1 to C-9, respectively, and ions at *m/z* M-100 from 6,7-epoxides and at *m/z* M-125 from 9,10-epoxides including a terminal carbon. Cleavage of the bond between the allylic carbon and the epoxy ring carbon produces ions at *m/z* M-114 from 6,7-epoxides and at *m/z* M-111 from 9,10-epoxides. When one pays attention to the three pairs of ions and divides the intensity of the latter ion by that of the former ion, namely [124]/[99], [M-125]/[M-100], and [M-111]/[M-114], the intensity ratios of 6,7-epoxides are less than or equal to 1.0, and those of 9,10-epoxides are larger than 1.0 as shown in Table 3. The main pheromonal component of *O. excavata* is Z6,epo9-21 : H, the chemical structure

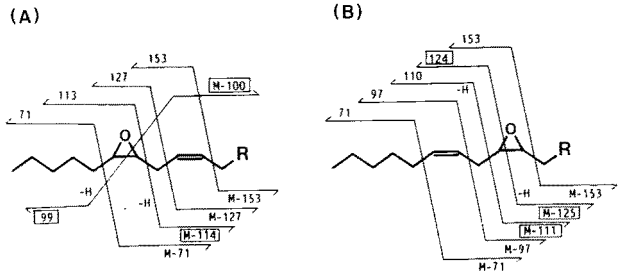

FIG. 1. Fragmentation proposed for 6,7-epoxides (A), and 9,10-epoxides (B) of 6,9-dienes with C_{17}–C_{23} chains after initial EI ionization at the epoxy oxygen and C=C bond. Diagnostic ions shown in squares were used in the calculation for Table 3. Molecular ions: C_{17} compounds (R = n-C_6H_{13}), m/z 252; C_{18} compounds (R = n-C_7H_{15}), m/z 266; C_{19} compounds (R = n-C_8H_{17}), m/z 280; C_{20} compounds (R = n-C_9H_{19}), m/z 294; C_{21} compounds (R = n-$C_{10}H_{21}$), m/z 308; C_{22} compounds (R = n-$C_{11}H_{23}$), m/z 322; C_{23} compounds (R = n-$C_{12}H_{25}$), m/z 336.

of which has been identified by ozonolysis and other experiments (Ohmasa et al., 1991). The values of the ratios calculated from the published mass spectrum of the natural pheromone are larger than 1.0 (see Table 3), indicating that it is a 9,10-epoxide. Because these three ratios reflect the position of the epoxy ring, the structure of monoepoxymonoenes of 6,9-dienes can be reliably estimated by examining the intensity ratios.

Characterization of Monoepoxides of 3,6,9-Trienes. The chromatographic behavior of the monoepoxydienes with C_{18}, C_{22}, and C_{23} chains on a normal-phase MPLC correspond to those of the C_{19}–C_{21} monoepoxydienes on a normal-phase TLC plate (Ando et al., 1993). NMR data of the compounds possessing the epoxy ring at the same position are almost the same except for the methylene signals of the long chains. The intensity of the methylene proton signals at ca. 1.3 ppm and the number of methylene carbon signals at ca. 29.5 ppm depends on the chain length. On EI-MS, fragmentation properties of the compounds previously synthesized (Ando et al., 1993) were also observed in the spectra measured for the new compounds as follows: ions at m/z M-29, M-72, and 79 for 3,4-epoxides; at m/z M-29, M-69, and 111 for 6,7-epoxides, and at m/z M-29, M-69, M-109, 108, and 79 for 9,10-epoxides. These results confirmed that these are diagnostic ions for identifying epoxydienes with C_{18}–C_{23} chains from a natural pheromone extract. By further examination of these spectra, it was revealed that other diagnostic ions, which were produced by fragmentation at the epoxy ring, were additionally characterized as follows: ions at m/z M-58 for 3,4-epoxides, at m/z 97 and M-83 for 6,7-epoxides, and at m/z 122 and M-123 for 9,10-epoxides.

[b] Spectrum was measured with a JEOL JMS-D300 mass spectrometer operated at 70 eV (Ohmasa et al., 1991).

Sex Attractants Discovered by Screening Tests

Field Evaluation from 1992 to 1994. By the field screening tests of 6,9-dienes, 3,6,9-trienes, and monoepoxydienes with C_{19}–C_{21} chains, sex attractants for 14 geometrid and four noctuid species had already been found in Japan (Ando et al., 1993). This time field evaluation mainly with their C_{18}, C_{22}, and C_{23} chain analogs and monoepoxymonoenes with chains from C_{17} to C_{23} showed attraction of male moths of another six geometrid and five noctuid species. Table 4 lists the scientific names of the new attracted insects, the abbreviated names of the attractants, the time of flight, and the total number of moths captured by dual traps. All of the six geometrid species belong to the subfamily Ennominae. Recently sex pheromones were investigated in geometrid moths closely related to three of these species. Two C_{17} components, epo3,*Z*6,*Z*9–17:H and *Z*3,*Z*6,*Z*9–17:H, have been identified as sex pheromone components from the pheromone gland of *Abraxas grossulariata* L., the 10:1 mixture of which attracted the male moths (Tóth et al., 1992), while the corresponding C_{18} epoxide epo3,*Z*6,*Z*9–18:H attracted *A. niphonibia* in our field test. Other sex pheromones, *Z*3,epo6,*Z*9–18:H and *Z*3,*Z*6,*Z*9–18:H, have been identified from the gland extract of *Ectropis obliqua* Prout (Yao et al., 1991) in China. The monoene derivative epo6,*Z*9–18:H more effectively attracted *E. excellens* than the

	Z3,epo6,Z9-22:H		14

[a] This species was attracted by epo3,Z6,Z9-20:H and Z3,epo6,Z9-19:H in our previous field tests (Ando et al., 1993).

monoepoxydiene in Japan. The mixture of two C_{19} pheromone components, Z3,epo6,Z9-19:H and Z3,Z6,Z9-19:H (10:3), attracted *Erannis defoliaria* Clerck (Hansson et al., 1990). In this test the C_{18} compound Z3,epo6,Z9-18:H caught males of *E. golda*. Sex pheromones and attractants have not been reported so far for any species in the same genera as the other three species, *Menophra senilis* Butler, *Rhynchobapta cervinaria bilineata* Leech, and *Synegia esther* Butler. In addition to these six species, *Colotois pennaria ussuriensis* Bang-Haas is also listed in this table, since Z3,epo6,Z9-20:H attracted this species more strongly in the winters of 1992 and 1993 than epo3,Z6,Z9-20:H and Z3,epo6,Z9-19:H, which had been announced to be its attractant in the field evaluation in 1991 (Ando et al., 1993).

Noctuid species attracted in this test are *Hypenomorpha calamina* Butler, *Neachrostia bipuncta* Sugi, *Pangrapta trimantesalis* Walker, *Rivula leucanioides* Walker, and *Adrapsa notigera* Butler. The first four species belong to

the subfamily Ophiderinae, and the last to Herminiinae. Although sex attractants of the species in the genus *Rivula* (*R. propinqualis*, *R. sericealis*, and *R. sasaphila*) are now known (Millar et al., 1990; Ando et al., 1993), no reports have been published concerning the pheromones and attractants of the moths in the other genera—*Hypenomorpha*, *Neachrostia*, *Pangrapta* and *Adrapsa*.

Structural Peculiarities of Discovered Sex Attractants. By field trials from 1991 to 1994, we finished the evaluation of 3,6,9-trienes with C_{18}–C_{23} chains, 6,9-dienes with C_{17}–C_{23} chains, and all of their monoepoxides. These systematic tests in Japan revealed the sex attractants for a total of 29 species. Although lepidopterous sex pheromones are usually composed of multiple components, not a few species were successfully attracted by single-source lures. The peculiarities of their chemical structures are summarized in Table 5. The number of the species attracted by the trienes and the monoepoxides (monoepoxydienes) is larger than that by the dienes and the monoepoxides (monoepoxymonoenes), and the epoxides attracted more species than the parent hydrocarbons. In particular, a considerable number of noctuid species were trapped by the lures baited with monoepoxydienes. By field evaluation of monoepoxymonoenes of C_{17}–C_{21} in Saskatoon (Canada), Millar et al. (1991) observed attraction of four geometrid species. Our test of the monoepoxymonoenes in Japan showed attrac-

C_{22}	0	0	0	0	0	0	0
C_{23}	0	0	0	0	1	1	2

tion of two other geometrid species and, interestingly, one noctuid species. While the number of the species attracted by monoepoxymonoenes is much smaller than those attracted by monoepoxydienes, these results indicate that the monoepoxymonoenes are also important pheromonal components of the geometrid and noctuid species.

Carbon lengths of the sex attractants discovered in Japan are mainly C_{18}–C_{21}. Since monoepoxydienes of C_{17} have not been tested, it cannot be concluded that the C_{17} compounds are novel for Japanese Lepidoptera. A biosynthetic pathway has been proposed for the hydrocarbons with a homoconjugated polyene system and their monoepoxides (Rule and Roelofs, 1989). Starting from the fatty acids with the polyene system, linoleic and linolenic acids, which commonly occur in insects, these compounds might be biosynthesized by a combination of chain elongation and reductive decarboxylation. When the chain elongation proceeds only with acetyl CoA, compounds with carbons of odd numbers are selectively produced. However, not a few hydrocarbons and epoxides with an even carbon chain are recognized as pheromone components (Arn et al., 1992). More than one third of the attractants found in our experiments have an even-number carbon chain. It is necessary to understand well the biosynthetic pathways of the geometrid and noctuid pheromones.

Our field tests utilized a racemic mixture of *cis*-epoxides. It is desirable to examine the attractancy of optically pure samples. Another valuable method to obtain further information about the geometrid and noctuid pheromones is the evaluation of multicomponent lures.

Acknowledgments—The authors are grateful to Prof. Y. Ambe of Rolling Land Laboratory (Tokyo University of Agriculture and Technology) for his assistance in the field screening tests.

(Received July 5, 1994; accepted November 29, 1994)

Abstract—A group of sensilla present on the maxillary galea of adult western corn rootworm, *Diabrotica virgifera virgifera* LeConte (Coleoptera: Chrysomelidae) beetles has been identified morphologically and physiologically to be involved in taste mediation. There are approximately 15 chemosensory hairs on each galea. Bilateral removal of these structures resulted in a significantly reduced consumption of a strongly phagostimulant triterpenoid, cucurbitacin B, and led to increased ingestion of a phagodeterrent alkaloid, strychnine. Electrophysiological responses obtained via tip-recording of galeal chemosensilla with submillimolar concentrations of host and nonhost plant compounds resulted in dose responses overlapping with the effective behavioral ranges. Cucurbitacin B was found to evoke chemosensory responses at levels as low as 0.1 μM. Since γ-aminobutyric acid (GABA) is an agonist, (−)-β-hydrastine and strychnine are antagonists, and cucurbitacin B has been proposed to act at a separate modulatory site of classical synaptic GABA and glycine receptor-channel complexes, results reported here raise the possibility that there are peripheral chemosensory receptor sites that may resemble, functionally and structurally, synaptic receptor sites in the central nervous system.

Key Words—Insect-plant interactions, chemoreception, feeding behavior, phagostimulant, deterrent, antifeedant, GABA, cucurbitacins.

INTRODUCTION

Western corn rootworm (*Diabrotica virgifera virgifera* LeConte) is a major pest of corn (*Zea mays* L., Gramineae) in the midwestern United States. Despite intensive insecticide applications, the geographical range of this species has been expanding eastward in recent decades. The annual costs of pesticide treatments and crop losses due to this insect amount to about one billion dollars in the United States. Most damage is done by the monophagous larvae, which attack the root system of young corn, leading to plant lodging. The polyphagous adult beetles feed on corn pollen, silk, tassels, and sometimes leaves, or flowers and foliage of alternative host plants, e.g., squash (Krysan and Miller, 1986; Metcalf and Metcalf, 1992, 1993). Although adults exert less damage on corn, this obligatory feeding leads to the production of about 500–1000 eggs per female that overwinter and constitute the next season's generation of rootworm larvae.

Despite the clear and long-standing agricultural pest status of *D. virgifera virgifera*, little is known about the physiological basis of its feeding, especially the sensory aspects of host-plant recognition. Cucurbitacins, a family of triterpenoids found in Cucurbitaceae, are the most powerful feeding stimulants established for this and closely related leaf beetles (Metcalf et al., 1980). On the other hand, compounds that reduce food intake in adult corn rootworms have only recently been discovered (Mullin et al., 1992, 1994). These findings contribute to other recent developments in antifeedant design and technology that have opened new opportunities for biological and chemical insect control, particularly as pest-specific formulations (Jermy, 1990; Frazier and Chyb, 1995).

We have previously shown that a number of sesquiterpenoid epoxides isolated from cultivated sunflower (*Helianthus annuus* L., Compositae), a marginal host plant for adults (Siegfried and Mullin, 1990), are able to reduce food intake by adult *D. virgifera virgifera* in a squash disk consumption bioassay (Mullin et al., 1992). In turn, isoquinoline alkaloids, commonly found in spring wildflowers of the northeastern United States (Papaveraceae, Fumariaceae, Ranunculaceae, and Berberidaceae) and thus temporally unavailable for consumption by adult rootworms, were potent antifeedants for *Diabrotica*. The antifeedant potency of selected terpenoids and alkaloids was high enough to counteract and overcome the phagostimulatory action of cucurbitacins present in the medium. Some of the deterrents identified to date are well-known antagonists of γ-aminobutyric acid (GABA) and glycine receptor-channel complexes in synaptic sites of the vertebrate central nervous system (CNS) (see for example Hall, 1992). GABA, glycine, and other agonists of these receptors are at least weakly phagostimulatory for *Diabrotica* (Mullin et al., 1994). These observations opened the possibility that a neurotransmitter receptor structurally related to one found in the insect CNS might be localized peripherally, within insect sensilla, and therefore be more susceptible to chemicals designed for insect control.

The aim of the present study is to identify and preliminarily characterize, morphologically and physiologically, sensory structures involved in taste mediation, specifically for phagostimulant and phagodeterrent detection, by adult beetles of *D. virgifera virgifera*. Knowledge of the mode of action of compounds affecting corn rootworm feeding behavior could potentially lead to the design of more effective and specific control agents and perhaps to a structural template for gustatory chemoreception in phytophagous insects.

METHODS AND MATERIALS

Insects. Pupae of a nondiapausing laboratory strain of western corn rootworm were obtained from a commercial colony (French Agric. Res., Lamberton, Minnesota) and kept in moist soil until adult emergence. Newly emerged beetles were placed in a separate container with access to water but were deprived of food prior to the electrophysiological recordings. For behavioral experiments, beetles were maintained on lettuce, winter squash, and an artificial pollen diet (Krysan and Miller, 1986) until their use in feeding bioassays.

Chemicals. GABA, (−)-β-hydrastine, and strychnine HCl were obtained from Sigma Chemical Co. (St. Louis, Missouri). Cucurbitacin B was isolated from squash, *Cucurbita maxima* Duchesne var. Blue Hubbard hypocotyls by a modified method of Metcalf et al. (1982). The residue remaining in the chloroform extract of the hypocotyl was partitioned between petroleum ether and methanol–water (9 : 1 v/v), and the aqueous methanol residue dissolved in ethyl acetate and purified using silica gel TLC. The UV-quenching band cochromatographing with cucurbitacin B was scraped and eluted with 2 : 1 $CHCl_3$–MeOH from a dry packed column.

Scanning Electron Microscopy. Excised heads or isolated maxillae of adult beetles were mounted on a stub by using silver paint, kept in a desiccator for 24 hr, and subsequently sputter-coated with particle gold. No cleaning or fixing was necessary to achieve the desired resolution. Preparations were viewed and photographed with a JEOL JSM 5400 scanning microscope at the Electron Microscope Facility of The Pennsylvania State University.

Galeal Ablation and Feeding Bioassays. Chilled beetles were placed in a plastic pipet tip from which only the head could protrude. Galeae on one (unilateral ablation) or both (bilateral ablation) sides were removed with a fine pair of forceps; control insects had no operation. After a two-day recovery period with food and overnight starvation, ablated beetles were given a choice between two different disks.

In one experiment, disks (177 mm^2) were punched out of squash blossoms and one beetle could choose between a solvent-treated and a 6.0-nmol strychnine-treated disk; consumption levels were evaluated at 5, 24, and 48 hr. In

the second experiment, two beetles could choose between two regenerated cellulose disks (30 mm^2, 0.45-μm pore size; Schleicher and Schuell, Keene, New Hampshire) stuck to insect pins 1–2 mm above the filter paper opposite one another. One disk contained only 10.7 nmol cucurbitacin B and the other disk contained the same amount of cucurbitacin B and 2.2 nmol strychnine. Beetles were removed 24 hr later, disks were air-dried, and the area of each disk measured with an image analyzer to the nearest 0.1 mm^2.

Electrophysiological Recordings. Responses of sensory hairs to phagostimulants and phagodeterrents were obtained by a standard tip-recording technique (Hodgson et al., 1955; Frazier and Hanson, 1986). Newly emerged adults were used in the experiments. This helped decrease the inherent variability of responses, and kept the signal-to-noise (S/N) ratio of electrophysiological recordings high as well, thus greatly facilitating subsequent data analysis. The insect's head was mounted on a glass capillary filled with 0.1 M KCl. Maxillae were gently pulled away from the head with a surgical thread lasso and immobilized by waxing the thread to the ventral surface of the prothoracic legs. Another glass capillary, pulled and sized to approximately 15 μm in external diameter, was filled with a solution of the test compound in 0.01 M KCl (which by itself evoked a low firing activity of 12.4 $\pm$ 2.1 spikes/sec, $N = 122$), and used as a stimulating/recording electrode. Its tip opening was just large enough to allow placing it over a single sensillum. Both microelectrodes were connected to a high-impedance, baseline-restoring preamplifier and a filter amplifier with a bandpass of 50–2000 Hz. Spike trains were viewed on a storage oscilloscope, monitored with a loudspeaker, and stored on an FM magnetic tape together with a voice commentary provided by the experimenter (Frazier and Hanson, 1986). Records were subsequently digitized at 10,000 Hz and analyzed with customized software for Macintosh computers, SpikeAnalysis 3.0 (Roessingh et al., 1992). For dose–response curves, stimuli were presented in the order of increasing concentrations and at least 2-min recovery periods between applications were allowed. At least 30 records were obtained, and the spike counts were averaged across trials within each concentration.

Functional differences among galeal sensilla were evaluated by comparing firing rates of different sensilla in response to a series of six concentrations of GABA or (−)-β-hydrastine. Hairs were numbered according to position from 1 (most medial) to 6 (most lateral). Often, because of the galeal orientation of a particular specimen, it was not possible to record from the most lateral hair (number 6); therefore, most of the data presented here do not include responses from this hair. Results were analyzed statistically using two-way analysis of variance.

RESULTS

Morphology. Adult *D. virgifera virgifera* have well-developed, paired maxillae that under natural conditions are located just below and behind the mandibles (Figure 1) and constitute crucial components of the insect's chewing

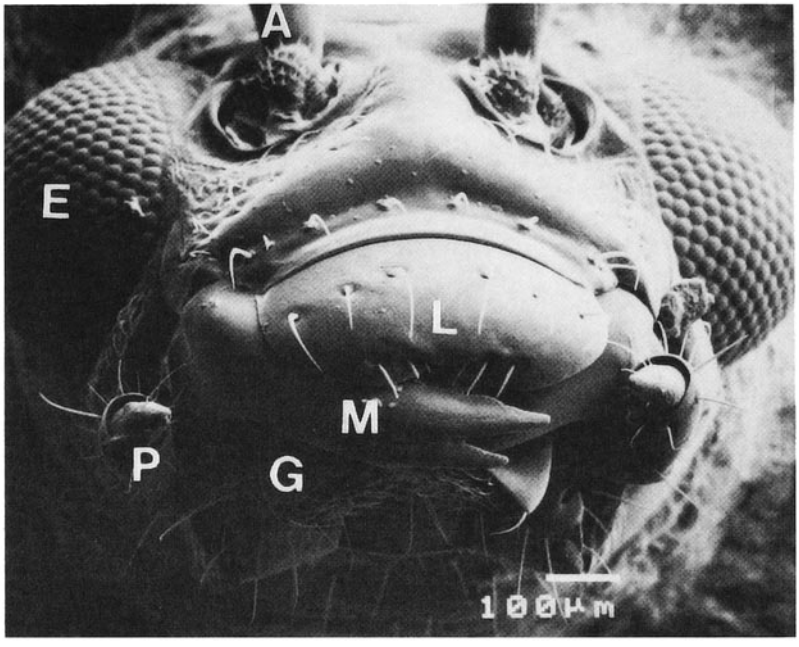

FIG. 1. Scanning electron micrograph showing a frontal view of the head of adult *D. virgifera virgifera*: antennae (A), compound eye (E), maxillary galea (G), labrum (L), mandible (M), maxillary palp (P).

apparatus. Each maxilla is composed of three structural elements: palp, galea, and lacinea (Figure 2).

The maxillary palps are the outermost parts of the maxillae. They are composed of four segments, with each segment having a complement of several long thin setae, variable in length. Based upon their morphology, at least some of these setae may have a mechanosensory function (Figure 2).

Located medially from the maxillary palp is the galea (Figure 2). It is roughly triangular in shape, measuring 50 μm at the base and widening to about 120 μm distally; and is approximately 250 μm long. The sensilla on the galea fall into two morphologically distinct groups: longer ($\sim$120 μm) and thinner ($\sim$3 μm) hairs localized on the perimeter of the galea, and shorter (see below), blunt-tipped hairs in the middle of the flattened surface. The latter are distributed in a relatively regular fashion along the medial–lateral axis of the galea surface, forming two rows of six to seven hairs each (Figure 3). Only these hairs are responsive to chemical stimulation. Neighboring taste sensilla, within and between the two rows, are separated by a distance of approximately 15–20 μm. From the medial to the lateral side of the galea, there is a noticeable decrease

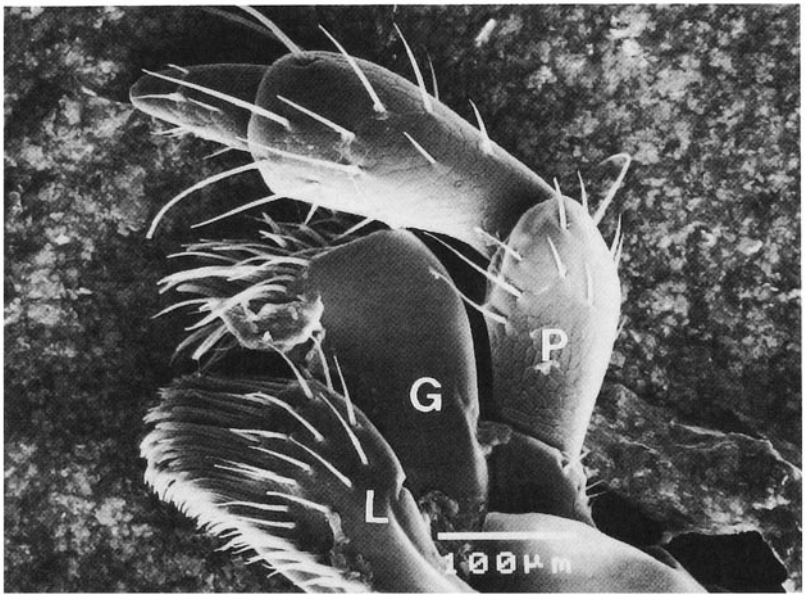

FIG. 2. Scanning electron micrograph of an isolated maxilla of adult *D. virgifera virgifera*, showing morphological details of maxillary palp (P), galea (G), and lacinea (L).

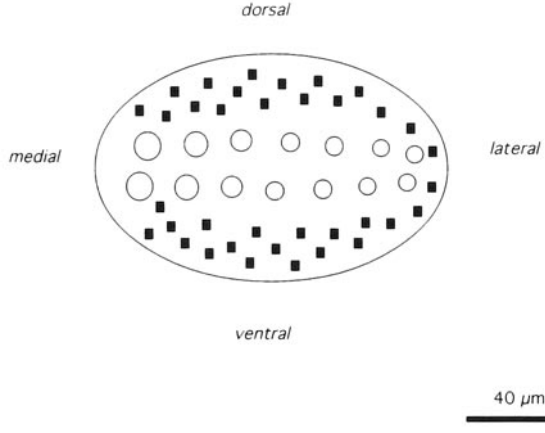

FIG. 3. Diagrammatic distribution of chemosensilla (open circles) and putative mechanosensilla (closed rectangles) on the galea of adult *D. virgifera virgifera* (reconstructed from a digitized video recording).

in length of chemosensilla from 70 μm to 30 μm, accompanied by a corresponding reduction in hair diameter. All chemosensilla are slightly curved along their length, with their tips pointing medially (Figure 4).

The lacinea, the most medial part of maxilla (Figure 2), is similar in shape and size to the galea, but equipped with a very dense cover of long (~100 μm) and relatively straight hairs on its proximal surface. The functional significance of these structures is unknown since individual hairs are not readily accessible for electrophysiological investigations. There are also several setae located along the sides of lacinea that may be involved in mechanoreception.

Although the major group of maxillary chemosensilla has been observed on the maxillary galea, it cannot be ruled out that there are other contact chemoreceptors present on the other parts of maxillae (e.g., lacinea), as well as associated with other body regions, including the other mouthparts. An important question, therefore, is whether the galeal chemosensilla are the ones responsible for food selection and host vs. nonhost discrimination in adult *D. virgifera virgifera*.

Galeal Ablation. In the deterrent-detection experiment (Figure 5A), bilaterally ablated beetles consumed significantly more of the strychnine-treated disks

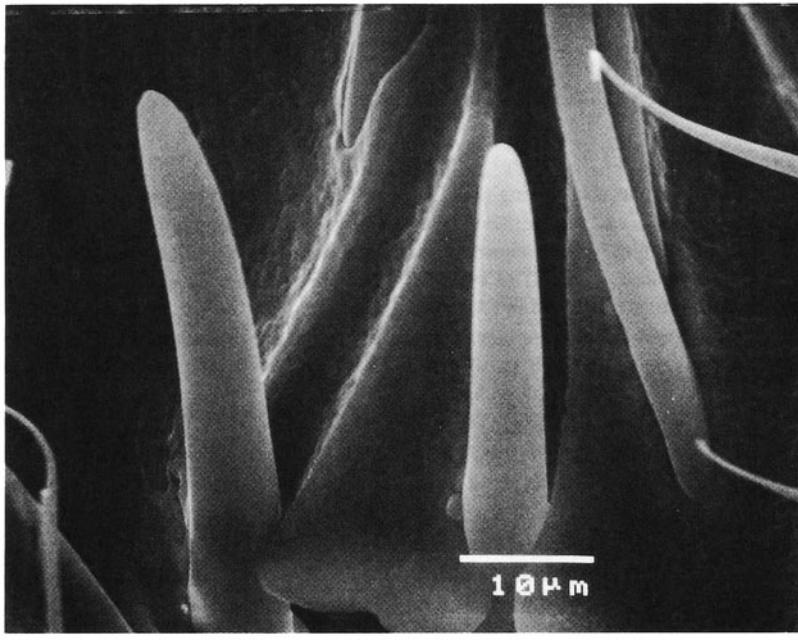

FIG. 4. Scanning electron micrograph of two of the galeal chemosensilla. The tips of two of the putative galeal mechanosensilla are visible to the right of chemosensilla.

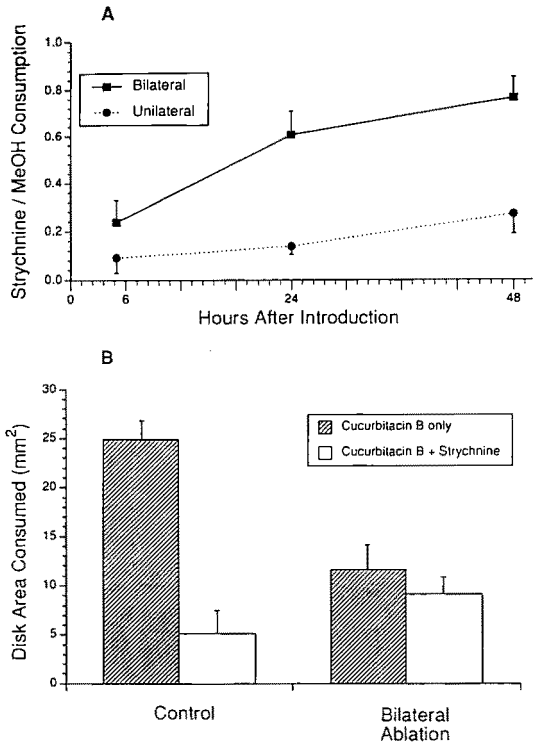

FIG. 5. Feeding by insects lacking maxillary galea: results of two bioassays using squash blossom disks (A), and regenerated cellulose disks (B). Consumption in A indicates beetle consumption of strychnine-treated disks relative to solvent-treated disks after 5, 24, and 48 hr (mean ± SEM) in bilaterally and unilaterally ablated beetles. (B) The amount of disk area consumed in 24 hr by beetles with both galeae intact (control) and both galeae ablated (bilateral ablation) when offered a choice between a cucurbitacin B-treated disk (Cucurbitacin B only) and a disk treated with both cucurbitacin B and strychnine (Cucurbitacin B + Strychnine).

than unilaterally ablated beetles at 24 and 48 hr (two-sample t-test, 24 hr: $P \leq 0.01$; 48 hr: $P < 0.001$) but not at 5 hr ($P > 0.05$). During the entire experiment, both sets of beetles fed more on solvent-treated disks than on strychnine-treated disks, as demonstrated by consumption ratios of less than 1.0. Strychnine was less deterrent to bilaterally ablated beetles than for unilaterally ablated beetles.

In the phagostimulant-detection experiment (Figure 5B), bilaterally ablated beetles consumed significantly less of the cucurbitacin B-treated disks than non-

ablated beetles ($P < 0.001$). Both sets of beetles consumed similar amounts of the cucurbitacin B plus strychnine-treated disks ($P > 0.05$). Galeal ablation affected consumption on both disks because a smaller percentage of total disk area was eaten by ablated beetles than by the controls. Nevertheless, beetles without galea could not discriminate between a disk treated with cucurbitacin B with or without strychnine.

Electrophysiology of Chemosensory Responses. Galeal chemosensilla of adult *D. virgifera virgifera* exhibited clear sensitivity to several compounds shown previously to enhance or reduce feeding. Although gustatory responses were usually unicellular, two-cell responses were also observed.

GABA stimulated a single cell (Figure 6A) over a concentration range of 1 μM to 10 mM. The dose–response curve within the lower limits of this range was relatively flat, and a substantial increase in the firing rate was observed above 100 μM (Figure 7A). It is worth noting here that responses to this compound were often quite variable, with the same concentration evoking different levels of firing activity in different insects. Spike trains were frequently characterized by a low S/N ratio, which made it difficult to separate spikes from background noise levels typical for electrophysiological recordings.

Cucurbitacin B (Figure 7B) evoked a vigorous response with a threshold

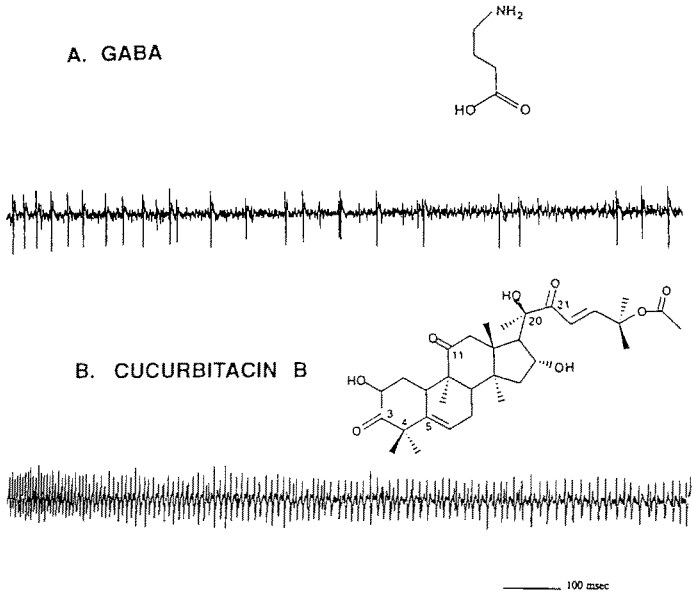

FIG. 6. Representative records of chemosensory responses of galeal sensilla to 10 μM concentrations of phagostimulants: GABA (A) and cucurbitacin B (B).

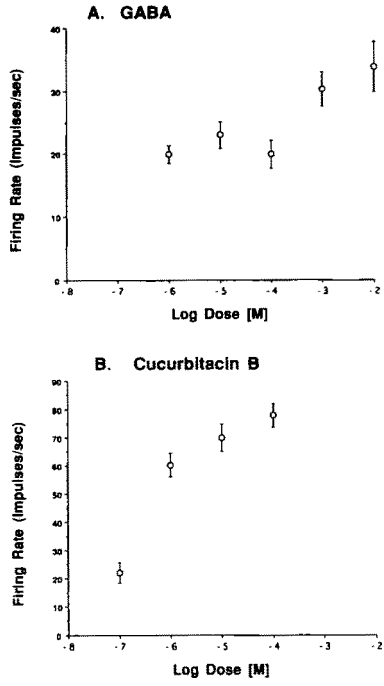

FIG. 7. Dose-response curves for phagostimulants: GABA (A), cucurbitacin B (B). Firing rates are expressed as the number of impulses within the first second of stimulation (means ± SEM, all data points based on ≥30 records).

at approximately 0.1 μM. Increasing the concentration to 100 μM activated a second cell. There was usually a response delay in the range of 10–20 msec followed by a period of rapid firing with very little sensory adaptation. Doses higher than 100 μM were not tested due to the limited solubility of cucurbitacin B in the reference solution (0.01 M KCl).

(−)-β-Hydrastine evokes responses from a single cell (Figure 8A), giving a sigmoid pattern of dose-response (Figure 9A). There were noticeable changes in the spike amplitude within the first 150–200 msec of the response, and little adaptation occurred within the first second of stimulation with this compound.

Strychnine stimulated a single cell with clear patterns of phasic and tonic components of responses (Figure 8B). Records from this compound were usually characterized by a high S/N ratio. A linear dose-response curve with saturation at 100 μM was found (Figure 9B). A further 10-fold increase in concentration did not significantly increase the intensity of response (one-way ANOVA, $P > 0.05$).

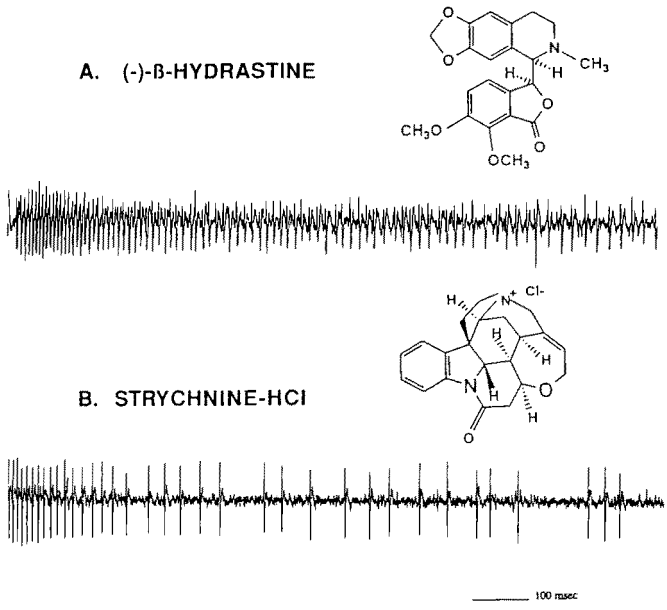

FIG. 8. Representative records of chemosensory responses of galeal sensilla to 10 μM concentrations of phagodeterrents: (−)-β-hydrastine (A) and strychnine HCl (B).

Functional Differences among Sensilla. No statistically significant differences in firing rate during the first second of stimulation were found among sensilla from the same galea when several individual hairs were tested with various doses of GABA or (−)-β-hydrastine (two-way ANOVA: $df = 4$, $F = 1.06$, $P = 0.38$ for GABA; $df = 5$, $F = 0.46$, $P = 0.81$ for (−)-β-hydrastine). Similarly, the interaction between the dose tested and the sensillum position along the medial–lateral axis of the maxillary galea was not statistically significant in either case ($df = 20$, $F = 0.35$, $P = 0.99$, and $df = 25$, $F = 1.02$, $P = 0.46$, respectively). Temporal patterns of observed responses were also similar (but were not quantified) regardless of the hair position.

DISCUSSION

Adults of western corn rootworm have a distinct population of galeal contact chemoreceptors exhibiting sensitivity to a number of compounds shown previously to evoke or deter feeding. Particularly novel is the potent electrophysiological response elicited by cucurbitacin B in the galeal chemosensilla of this *Diabrotica* species.

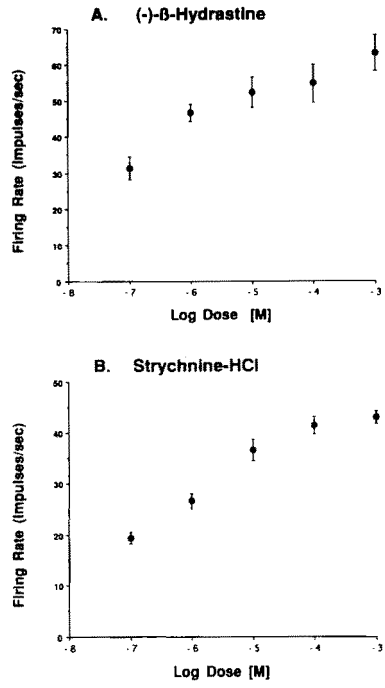

FIG. 9. Dose-response curves for phagodeterrents: (−)-β-hydrastine (A) and strychnine HCl (B). Firing rates are expressed as the number of impulses within the first second of stimulation (means ± SEM, all data points based on ≥30 records).

Mitchell and Harrison (1984) studied galeal chemosensilla of another chrysomelid, Colorado potato beetle, *Leptinotarsa decemlineata* (Say), and found a similar number of chemosensory sensilla they term apical pegs; the spatial distribution of these structures was reported by Sen and Mitchell (1987) as irregular, unlike the two-row formation observed here. Galeal sensilla in *L. decemlineata* were indistinguishable morphologically but, surprisingly, were functionally different. In particular, one of the hairs, dubbed the α-sensillum, was significantly more sensitive to stimulation with GABA (and L-alanine) than all other hairs; ultrastructurally, the α-sensilla had three, rather than four (like other galeal chemosensilla in this beetle) dendrites associated with its lumen. Our careful investigation of this possibility in *D. virgifera virgifera* provided no indication of sensitivity differences among galeal sensilla in this species. It appears, therefore, that the more polyphagous adult *D. virgifera virgifera* may have at its disposal a functionally uniform complement of gustatory hairs on the galea.

Ultrastructural studies of galeal sensilla of adult *D. virgifera virgifera* are underway.

D. virgifera virgifera feeds on nutrient-rich reproductive tissues of plants, including pollen. Although detailed chemical composition of these food sources has not been adequately determined, especially when compared with other plant tissues (e.g., leaves), high levels of amino acids and other nitrogenous compounds have been detected. Since GABA is one of the major components of pollen in some plant species, it raises the possibility that pollinivorous insects could possess gustatory receptors tuned to this and related compounds (Mullin et al., 1993, 1994). Clearly, as shown by our results, *Diabrotica* can perceive the presence of GABA in their diet and, as more recent preliminary data indicate, other short-chain neutral amino acids: glycine, alanine, β-alanine, and proline (Chyb and Hollister, unpublished data).

Cucurbitacin B was a potent stimulant of the chemosensory cells in our studies. It was effective at concentrations as low as 0.1 μM, the lowest of the tested doses, well below the thresholds for phagostimulation seen in any other insect species and for any other feeding stimulant where millimolar doses are usually required to evoke a chemosensory response. Clearly, the phagostimulant action of this compound was mediated by the galeal chemosensilla, as shown by the ablation study. A QSAR study correlating potential differences in efficacy of phagostimulation with discreet modifications in chemical structures of different cucurbitacins could provide much needed information on the binding site of the receptor involved in sensory transduction.

Bilateral ablation of galeae reduced but did not completely abolish the beetle's sensitivity to cucurbitacin B or to strychnine. That bilaterally ablated beetles fed on cucurbitacin B-treated disks and less on strychnine-treated disks in squash disk bioassay suggests that other mouthpart sensilla are involved in taste mediation. Metcalf et al. (1980) suggested that only maxillary palps are involved in cucurbitacin detection since adult *D. undecimpunctata* could not find cucurbitacin B spots on thin-layer plates after ablation of these structures. Branson and Ortman (1969) have shown that maxillectomy in *D. virgifera virgifera* larvae reduced sucrose sensitivity but did not affect deterrence to oat roots. This suggests that larval maxillae may mediate phagostimulant chemoreception, while other mouthparts are also probably involved in chemosensory response to deterrents.

D. virgifera virgifera responded to the phagostimulant cucurbitacin B and the phagodeterrent strychnine in a dose-dependent manner over a range of concentrations from 0.1 μM to 1 mM. This work presents the first electrophysiological records obtained with cucurbitacin and also the first description of chemosensory responses of any diabroticite. Mitchell and Harrison (1985) investigated the effects of some of the *Solanum* antifeedant glycoalkaloids, including solanine and tomatine, on galeal chemosensilla of the adult Colorado potato

beetle. None of these compounds stimulated a direct chemosensory response, but rather caused bursting in taste cells after a relatively long (on average 6–12 sec) period of latency. These changes in cell activity were attributed to membrane disruption resulting from chemical stress posed by applied chemicals and are qualitatively different from the results presented in this study. Several other alkaloids (e.g., bicuculline, quinine) and terpenoids (e.g., azadirachtin, picrotoxinin) have been observed to stimulate galeal chemosensilla in *D. virgifera virgifera* (Chyb, unpublished data).

Signaling the presence of nonhost chemicals could be accomplished through one or a combination of four basic mechanisms: stimulating a specialized deterrent cell, stimulating a general sensitivity cell, inhibiting a cell responding to phagostimulant, or evoking irregular activity of chemoreceptor cells, e.g., bursting (Schoonhoven, 1982). At present, we do not have a definitive answer as to which of these modes of deterrency coding is employed by adult *D. virgifera virgifera*. It is possible that one or more deterrent cells are present since strychnine and (−)-β-hydrastine seem to stimulate separate cells (e.g., they had different time courses of response, especially within the first 200 msec; there were changes in spike amplitude and shape visible in "hydrastine" but not "strychnine" spike trains). It is also possible that these and other deterrent compounds inhibit the activity of phagostimulant-detecting cells. We need to establish whether there is any overlap of sensitivity spectra for deterrent and stimulant-activated cells. It is also unclear how many functional chemoreceptor neurons are contained within each of the galeal sensilla. Spike extraction procedures combined with analysis of spike shapes have not, as yet, provided conclusive evidence. Results of such analysis also need to be correlated with histological and ultrastructural investigations.

There is a strong correlation (Figure 10) between the amount of feeding (Mullin et al., 1993, 1994; Mullin et al., unpublished data) and the sensory input from galeal chemosensilla presented here for cucurbitacin B, strychnine HCl, and (−)-β-hydrastine (correlation coefficient, $R = 0.92$, 0.88, and 0.95 for cucurbitacin B, strychnine, and (−)-β-hydrastine, respectively). The increase in firing rate due to the increase in phagostimulant (cucurbitacin B) concentration corresponds to the increase in feeding consumption, while the reverse is true for the two deterrent compounds (increased firing corresponds to reduction in feeding consumption). It is also worth noting that while the feeding response to cucurbitacin B is proportional to the chemosensory input over almost the whole range of firing rates, the deterrent activity of (−)-β-hydrastine and strychnine seems to involve a more elevated chemosensory threshold for behavioral response, resulting in decreased consumption (above 30 spikes/sec for strychnine and almost 50 spikes/sec for hydrastine). It is, however, important to note that, due to the bioassay used to assess antifeedancy (squash disk bioassay), there was a residual dose of phagostimulant cucurbitacin B in the disks that needed

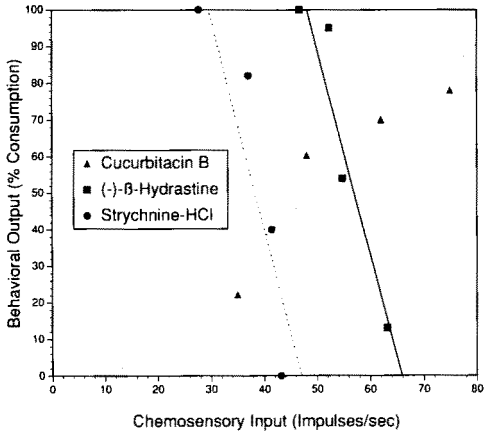

FIG. 10. Correlation between chemosensory input (firing rate of galeal chemosensory cell within the first second of stimulation) and behavioral output (percentage of disk consumed by adult beetle over 24 hr) for cucurbitacin B (triangles), (−)-β-hydrastine (squares), and strychnine HCl (circles). Points in each data series represent mean responses to (from left to right) 10^{-7}, 10^{-6}, 10^{-5}, and 10^{-4} M for cucurbitacin B, and 10^{-6}, 10^{-5}, 10^{-4}, and 10^{-3} M for the two deterrents: (−)-β-hydrastine and strychnine HCl.

to be overcome by the presence of deterrent. This may explain the threshold seen in the correlation plots for strychnine and (−)-β-hydrastine (Figure 10). Antifeedant potency was similar at the behavioral and chemosensory level; strychnine and (−)-β-hydrastine were the strongest antifeedants among the deterrent compounds tested so far (ED_{50} for behavioral response of 2 and 5 nmol/disk, respectively) and also evoked the most potent chemosensory responses (ED_{50} = 0.1 μM, both compounds). The large difference in slope between the chemosensory input–behavioral output lines for the phagodeterrent alkaloids and the phagostimulant cucurbitacin indicates a fundamental divergence in receptor cell binding of these compounds. The increase in firing frequency in response to a 10-fold increase in the deterrent concentration causes ~60% change in consumption for both strychnine and (−)-β-hydrastine, which is about four times as much as cucurbitacin B. This slope differential may represent significantly different sensory weights associated with inputs from phagostimulant and deterrent cells, as postulated by Schoonhoven (1982).

Currently very little is known about sensory processing of taste information in insect CNS, and we can only hypothesize as to how the input from contact chemosensilla is interpreted by the insect's brain. The data presented here show that *D. virgifera virgifera* beetles are able to detect alkaloids at concentrations

of 10^{-6} M, far below those naturally occurring in plants (Levinson, 1976; Wink, 1992). A 1000-fold increase in alkaloid concentration results in complete rejection of previously acceptable diet. At the same time, the taste system is finely tuned to detect the presence of phagostimulants such as cucurbitacins or amino acids. Adults of western corn rootworm feed selectively on pollen, a plant tissue low in deterrent content (Chou and Mullin, 1993, and references therein) and high in phagostimulatory amino acids (Mullin et al., 1993), but readily reject other food sources such as leaves and disk flowers where antifeedant content exceeds the levels expected to evoke a maximal firing rate from the galeal taste cell.

Our results support the hypothesis that a protein complex related to a synaptic GABA/glycine receptor may mediate host and nonhost plant discrimination in *D. virgifera virgifera*. GABA receptors are involved in sensory processing, e.g., in vertebrate vision. A potential role for this GABA receptor in insect taste has been presented elsewhere (Mullin et al., 1994). That net sensory processing of feeding stimulants and deterrents may be determined peripherally, and not exclusively in the CNS, by chemical interactions at amino acid taste receptor proteins is an intriguing hypothesis that needs experimental verification.

Acknowledgments—We would like to thank J. Russell Linderman and Charles H. Mason for technical assistance at the initial stages of this project, Ms. Rosemary Walsh for generous help with SEM imaging, Dr. Russell Y. Zacharuk for help with interpretation of SEM micrographs, and Dr. Frank Hanson for critical comments on the manuscript. Drs. P. Roessingh and E. Städler have kindly provided the updates of their Spike Analysis software. OUTDOOR ATTRACTANCY OF MALES OF *Matsucoccus josephi* (HOMOPTERA: MATSUCOCCIDAE) AND *Elatophilus hebraicus* (HEMIPTERA: ANTHOCORIDAE) TO SYNTHETIC FEMALE SEX PHEROMONE OF *Matsucoccus josephi*

(Received August 1, 1994; accepted November 29, 1994)

Abstract—The active component of the sex pheromone[3] of *Matsucoccus josephi* is (2*E*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one; the chemical is also a powerful kairomone of adult males and females of the bug *Elatophilus hebraicus* the principal predator of *M. josephi*. The presence of the *Z* isomer (2*E*,6*Z*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one does not interfere with the attractancy of the active *E* component for *M. josephi* males or the bug. Our results show a clear dose–response between trap catch of *M. josephi* males and *E. hebraicus*. Conversely, increasing amounts of the *Z* isomer in the mixture did not affect the attraction of the scale insect males or the bug. The catch of *M. josephi* males did not differ significantly among traps of different color, and was significantly higher with traps attached to the tree trunk than those suspended between trees. Comparison of the catch of *M. josephi* among the three forests and between pine species suggests that the level of infestation of *Pinus halepepsis* and *Pinus brutia* ssp. *brutia* is similar, despite the fact that the latter pine is resistant to the scale insect. Both sexes of *E. hebraicus* were trapped in much lower numbers at the more infested sites. This may be related to interference with the activity of *E. hebraicus* due to deterioration

INTRODUCTION

The Israeli pine bast scale, *Matsucoccus josephi* Bodenheimer et Harpaz, (Homoptera, Matsucoccidae) is the most serious pest of pine stands in Israel, killing large areas planted with Aleppo pine, *Pinus halepensis* Mill. (Mendel et al., 1994). The natural distribution of *M. josephi* is in areas in the Near East where its principal host, the brutia pine (*Pinus brutia* Ten. spp. *brutia* Nahal) occurs.

The larvae of *M. josephi* are hidden under bark crevices and at the base of needles. The cryptic occurrence of the scale on adult trees makes visual estimation of the pest densities impractical. At present, sampling of stem sections and crowns for counting the larvae is necessary in order to study infestation levels and population trends of the scale insect. This makes monitoring of *M. josephi* very tedious and expensive.

As in other members of the superfamily Coccoidea, the females display neoteny and the alate males locate their mates over long distances by being attracted to the female sex pheromone. First indications of the presence of a female sex attractant in the Matsucoccidae were observed by Doane (1966). The female sex pheromone has been identified for *Matsucoccus matsumurae* (Kuwana) (=*resinosae* Bean et Godwin) (Lanier et al., 1989), *Matsucoccus feytaudi* Ducasse (Einhorn et al., 1990), and *M. josephi* (Dunkelblum et al., 1993). The identification and the synthesis of the sex pheromone of *M. josephi* (Zegelman et al., 1993) have been a turning point in the possible development of monitoring techniques for this pernicious forest pest.

Unlike other Matsucoccidae, which display one (e.g., *M. feytaudi*) or two (*M. matsumurae* or *Matsucoccus pini* Green) separate generations per year, *M. josephi* produces four to five overlapping generations (Bodenheimer and Neumark, 1955; Mendel and Saphir, in preparation). Hence, year-round male flight in the forest and availability of an efficient mass rearing program (Mendel et al., 1990) allow continuous field and laboratory experiments.

Most insect predators associated with the Matsucoccidae are polyphagous; one particular group, members of the genus *Elatophilus* Reuter (Hemiptera: Anthocoridae) displays specific affinity for the genera *Pinus* and *Matsucoccus* Cockerell (Mendel et al., 1991). *Elatophilus hebraicus* Pericart is a common monophagous predator of *M. josephi* and feeds on all developmental stages. The bug occurs in the natural brutia pine forests in Asia Minor, Cyprus and

FIG. 1. Two geometrical isomer components.

Lebanon (Mendel, 1992; Mendel and Schiller, 1993), as well as in the stands of brutia pine and Aleppo pine in Israel and Jordan (Mendel et al., 1994). Preliminary observations indicated that *E. hebraicus* is attracted to the racemic female sex pheromone of *M. josephi* (Zegelman et al., 1993). The structures of the identified Matsucoccidae sex pheromones are similar. All three known pheromones are unsaturated aliphatic ketones, sharing a common C_8H_{13} diene moiety consisting of one chiral center. The second subunit is different; in *M. feytaudi* and *M. matsumurae*, the side chains are saturated and have a second chiral center (Einhorn et al., 1990; Lanier et al., 1989), whereas in *M. josephi* the chiral center is replaced by a double bond (Dunkelblum et al., 1993). Two geometrical isomer components (Figure 1) in the ratio of 75E:25Z were identified in the natural sex pheromone of *M. josephi* (Dunkelblum et al., 1993). The same isomers were produced in the synthesis of the pheromone at a ratio of 56*E*:44*Z* (Zegelman et al., 1993).

The objectives of the present study were to: (1) study the role of the *E* and *Z* isomers combined and separately in the response of the males of *M. josephi* and *E. hebraicus*; (2) study the dose–response of both insects to the sex pheromone; (3) examine the effect of layout of traps, viz., traps attached to the stem vs. traps suspended between trees; (4) evaluate the effect of trap color on catch efficacy; and (5) conduct a preliminary comparison between populations of the scale insect and its predator in stands planted with brutia pine with (a) high resistance to the scale insect and damage practically nil, and (b) the highly susceptible plantations of Aleppo pine.

METHODS AND MATERIALS

Chemicals. The racemic pheromone mixture of (2*E*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one (56% *E* isomer) and (2*E*,6*Z*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one (44% *Z* isomer) was prepared using the Reformatzky and Wittig reaction as key steps (Zegelman et al., 1993). The isolated *E* and *Z* isomers were obtained by GC separation of the mixture on a packed OV-1 5% column (2 m × 4 mm on CWHP) at 120°C, using a nondestructive thermal conductivity detector.

Study Areas, Trap Activation, and Data Collection. The experiments were conducted in adult plantations of Aleppo pine and brutia pine in the Judean

foothills, Samaria, and Galilee in Israel. Triangular sticky traps made of white plastic, containing a rubber septum as dispenser (Dunkelblum et al., 1987), were used. Traps were attached to the north side of the trunk of living trees, 1.8 m above the ground. The experiments were arranged in a randomized block design. The scale insect males and the anthocorids were counted under a magnification of ×20.

Experiment 1 was conducted during two time periods in the Harel Forest (Judean foothills). Trapping period 1 was between March and April 28, 1993. Ten isomer mixtures were tested; the ratios of *E*:*Z* isomers and concentrations (in micrograms in parentheses) were: 5:95 (100), 5:95 (250), 55:45 (100), 55:45 (200), 55:45 (250), 55:45 (500), 75:25 (100), 90:10 (100), 95:5 (100), and 95:5 (250). Each treatment was replicated five times. The sticky plates were replaced twice during this period. Period 2 was between June 8 and 21, 1994, the ratios and concentrations (in micrograms) of *E*:*Z* isomers being: 3:97 (5) 3:79 (50) 98:2 (5), and 98:2 (50). Each treatment was replicated four times. The sticky plates were replaced once during this period. Traps with an unloaded dispenser served as the control in both periods. The total number of males of *M. josephi* and adults of *E. hebraicus* trapped throughout each period was combined.

Experiment 2 was conducted between February 18, and March 22, 1993 in the Harel Forest to test the effect of trap color and position on the catch of *M. josephi* males. Traps made from plastic board of colors white, black, yellow (yellow-orange group 15A), blue (blue group 101A) and red (red group 52A) (Anon., 1966) were baited with dispensers containing 500 μg of the racemic *E*:*Z* pheromone mixture and attached to the tree or suspended 1.8 m above the ground between trees by a wire, at a minimum distance of 3.5 m from the nearest trunk. Each color and position was replicated four times in a completely randomized block design.

Experiment 3 was conducted in March and April 1993 in three types of pine plantations located in different areas: (1) Midrakh 'Oz forest (Samaria), where Aleppo pine is severely injured by the scale insect, (2) Hanita Forest (Western Galilee), and (3) Biriyya Forest (Upper Galilee), where Aleppo pine was only slightly affected by *M. josephi*. Within each forest two adult stands, one of Aleppo pine and the other of brutia pine, were selected. In each stand four traps, baited with 500 μg of the racemic mixture of the synthetic pheromone, were used.

RESULTS

Results of experiment 1 (Table 1) show a clear dose–response between trap catch of *M. josephi* males and the increasing amounts of the *E* isomer ($R^2 = 0.87$, $P < 0.01$). Conversely, increasing amounts of the *Z* isomer in the mixture

500 (55%)	276	224	71.7 a	5.0 a
Period 2				
5 (3%)	0.15	4.85	0.1 d	0 c
50 (3%)	1.5	48.5	1.5 c	0 c
5 (98%)	4.9	0.1	3.1 b	0.1 b
50 (98%)	49.0	1.0	4.6 a	1.5 a

[a]In both periods the tests were conducted in the Harel Forest. The traps were activated between March 22 and April 28, 1993, and between June 8 and 21, 1994, in period 1 and period 2, respectively.
[b]Within columns, in each period, means followed by the same letter are not significantly different. Duncan's (1955) multiple-range test, $\alpha = 0.05$.

did not affect the attraction of the males. The correlation coefficient of the amount of the *Z* isomer to male catch was close to zero ($R^2 = 0.07$). A similar pattern was observed in the catch of the predatory bug *E. hebraicus*. The correlation coefficients between the dosages of *E* and *Z* isomers and the trapped bugs were $R^2 = 0.81$ ($P < 0.01$) and $R^2 = 0.15$, respectively. Both sexes of the bugs were trapped, but sex ratios were not determined in this experiment due to technical difficulties.

The effect of the trap color and position (experiment 2) on the catches of *M. josephi* is shown in Table 2. The catch with white traps was somewhat less than with other colors, but did not differ significantly. For all colors tested, catches of *M. josephi* males were significantly ($P < 0.01$) higher with traps attached to the tree trunk than those suspended between trees, particularly in the case of red, yellow, and blue traps. The catches of the predatory bugs were

too low in this experiment for proper analysis of the level of attraction to different trap colors or position.

The catches of both *M. josephi* and *E. hebraicus* among three planting areas and between stands of Aleppo pine and brutia pine are given in Table 3. The number of *M. josephi* males and adult bugs caught in the sticky traps differ

Biriyya	*P. halepensis*	2.1 ± 0.9c	0.3 ± 0.2c	1:1.7
	P. brutia	1.6 ± 0.3c	0.5 ± 0.7bc	1:1.3

[a]Within columns, means followed by the same letter are not significantly different. Duncan's (1955) multiple-range test, $\alpha = 0.05$.

significantly between the study areas. The highest male capture was in Midrakh 'Oz and the lowest in Biriyyia. For each forest, the catches of *M. josephi* males did not differ significantly between Aleppo pine and brutia pine. The catch of *E. hebraicus* was the highest in brutia pine at Hanita, and the lowest in Aleppo pine at Midrakh 'Oz (5.7 and 0.1/trap/day, respectively). The overall male–female ratio among the trapped bugs was 1 : 1.4 (range 1 : 1.3–1 : 3.1).

DISCUSSION

The results indicate that the active component of the pheromone of *M. josephi* is (2*E*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one. Our findings also suggest that the presence of the *Z* isomer, (2*E*,6*Z*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one, does not interfere with the attractancy of the active *E* component. This was demonstrated when dispensers loaded with 5 μg of a ratio of 3*E*:97*Z* were significantly more active than the control. Therefore, traps baited with the *E*:*Z* mixture, which is produced by a relatively simple and cheap procedure, can be used for practical purposes.

Despite the fact that the *Z* isomer was found in the volatile natural pheromone of *M. josephi* in a relatively high percentage (25%), it appears that it is not a pheromone component, i.e., neither a synergist nor an inhibitor. In *M. feytaudi*, the corresponding *Z* isomer also was identified in the volatile natural pheromone, but in a low amount (3%), and its possible biological activity is questionable (Einhorn et al., 1990). In the case of *M. matsumurae*, the corresponding *E* isomer was identified as the sole pheromone component; the attractancy of the corresponding synthetic *Z* isomer to the male of *M. matsumurae* was quite similar to the control (analog 2, page 95, Hibbard et al., 1991). Hence, it is suggested that the corresponding *Z* isomers of the three *Matsucoccus* spp. lack biological activity.

In this study we utilized the racemic pheromone of the scale insect. Since the pheromone of *M. josephi* contains one chiral center, the important question relates to the absolute configuration of the natural pheromone and whether one of the enantiomers is an inhibitor. Chemical identification of the pheromone chirality and the activity of the enantiomers is in progress. Preliminary field data indicate that none of the enantiomers displays inhibitive activity. A similar finding was reported by Jactel et al. (1994) regarding the activity of the stereoisomers of the *M. feytaudi* pheromone.

Our findings demonstrate that the sex pheromone of *M. josephi* is also a strong kairomone for *E. hebraicus*, the principal predator of the scale insect. This is the first evidence for the use of a sex pheromone by a predator of homopterous species for prey location. According to Tumlinson et al. (1992), all of the long-range kairomones so far identified are sex pheromones of the

hosts. The use of sex pheromones as olfactory cues for host detection was recorded in several cases among egg parasitoids of lepidopteran pests (e.g., Batisti, 1989; Noldus et al., 1991). Thus, the higher rates of parasitism by *Trichogramma* spp. of moth eggs in previously pheromone-treated plots are explained by the fact that the host sex pheromone caused the parasitoids to land shortly after takeoff (Noldus et al., 1991). Niwa and Daterman (1989) showed that sex pheromone treatment in pine plantations affected either the species distribution or the abundance of the parasitoid complex; abundance of a pupal parasitoid was higher in pheromone-disrupted areas than in the controls. Among the Homoptera, honeydew serves as a kairomone for parasitoids and predators of aphids, whiteflies, and mealybugs (e.g., Budenberg, 1990; Meiracker et al., 1988). Among armoured scale insects, there is ample evidence that aphelinid parasitoids are attracted to the sex pheromone of the scale hosts (e.g., Abdel-Kareim and Kozar, 1988; Kyparissoudas, 1987; McClain et al., 1990; Samways, 1988). The feeding behavior of the Matsucoccidae is very similar to that of armored scale insects; they do not produce honeydew as do members of other closely related margarodids. Hence, it is not unexpected that the specific predator of *M. josephi* uses the sex pheromone as a kairomone (the pine bast scales are not attacked by parasitoids).

Many Anthocoridae of coniferous forests oviposit in the tree needles. *E. hebraicus* readily uses needles of any pine species for oviposition (Carmi, 1989), but not of other tree genera (Mendel, Assael and Carmi, in preparation). Therefore, it is suggested that the sex pheromone of *M. josephi* also serves for host-plant finding. It is important to note that in natural brutia pine forests, *M. josephi* occurs at low levels (Mendel, 1992). Hence, the efficient use of sex pheromones as an olfactory cue to find infested trees hosts is probably the result of the high sensitivity to the pheromone of *M. josephi* of both sexes of *E. hebraicus*. This may explain the latest findings (Mendel, Dunkelblum, Assael, in preparation) that in several cases hundreds of *E. hebraicus* were seen swarming and congregating around traps baited with the racemic mixture of the sex pheromone of *M. josephi*.

Our results indicate that the males of *M. josephi* do not respond better to any of the five colors tested in the present study. Many insect species are highly attracted to yellow. However, small flying insects, especially males of scale insects, are not associated with the crown of the host plant and do not display attraction to yellow (Kirk, 1984; Prokopy and Owen, 1987). Many insects that colonize the woody part of the tree, such as bark beetles, cerambycids, or curculionids, respond to dark objects or dark traps exposed against a bright background (e.g., Tedder and Wood, 1994). McClain et al. (1990) suggested that the reason parasitoids of the San Jose scale, *Quadraspidiotus perniciosus* (Comstock), respond better to black sticky traps baited with the sex pheromone of their host than to traps of other colors is due to the contrast of the trap color

against a given background. Males of *M. josephi*, similar to other *Matsucoccus* species, pupate on the forest floor, usually in the litter, while males of other scale insects that colonize woody plants pupate near the feeding plant tissue. This may explain the higher attraction of the males to traps attached to the tree trunk than to those that were suspended between trees. Naturally, it would be interesting to examine whether the strong attraction to traps attached to the trunks is related to the trunk shape or tree kairomones, or both.

The rate of increase of the *M. josephi* population in *P. halepensis* forests is related to environmental factors, tree age, and time until infestation after natural seeding or planting (Golan et al., 1983; Mendel et al., 1994). Comparison of the catch of *M. josephi* among the three studied forests and between pine species suggests that the level of infestation of *P. halepensis* and *P. brutia* is similar, despite the fact that the latter pine is tolerant to the scale insect (Liphschitz and Mendel, 1989). At present we may not exclude the possibility that equal catches recorded in stands of both host-plant species are due to male flight between plots. The different numbers of searching males among the studied forests are probably related to the effect of diverse climatic conditions. Damage in the Judean foothills and Samaria is higher than in Upper Galilee (Mendel et al., 1988, Mendel et al., 1994).

Elatophilus hebraicus of both sexes were trapped in much lower numbers in the more infested sites. This may be related at least partly to the fact that (1) a high level of injury, as observed in Midrakh 'Oz forest, is associated with deterioration and drying of the low and middle parts of the tree crowns (Mendel and Liphschitz, 1988), which increase the distance between oviposition and feeding sites of the bugs; and that (2) trees severely injured by *M. josephi* are heavily colonized by generalist predators (Halevy, Rosen, and Mendel, in preparation) which feed on, or interfere with, the activity of, *E. hebraicus*.

(Received September 21, 1994; accepted November 29, 1994)

Abstract—The feeding preference of European corn borer larvae for immature whorl tissue of maize was examined by conducting leaf bioassays and quantifying resistance factors along the length of mid-whorl leaves from the maize synthetic BS9(C4) developed by recurrent selection for resistance. Potential resistance factors that were quantified included percent foliar nitrogen, gravimetric determination of soluble metabolites and fiber, soluble phenolics and hydroxamic acids, cell-wall-bound phenolics, leaf toughness, and UV absorbance of the epidermal cell wall determined by microspectrophotometry. Larvae consumed immature tissue at a higher rate than more mature tissue outside of the whorl, despite higher levels of DIMBOA in immature tissue. Consumption rate was highly negatively correlated with epidermal cell wall absorbance and leaf toughness. Fiber content and phenolic fortification of cell walls are proposed as the major resistance components that influence European corn borer feeding preference within the resistant synthetic BS9(C4).

Key Words—*Ostrinia nubilalis*, Lepidoptera, Pyralidae, European corn borer, maize, resistance, phenolics, fiber, diferulic acid, truxillic acid, DIMBOA, toughness.

INTRODUCTION

Maize resistance to the European corn borer (ECB), *Ostrinia nubilalis* (Hbn), (Lepidoptera: Pyralidae) has been extensively studied. For over two decades, the hydroxamic acid 2,4-dihydroxy-7-methoxy-(2H)-1,4-benzoxazin-3-(4H)-one

(DIMBOA) has been recognized as the major component in leaf-feeding resistance (Klun and Robinson, 1969) and is a feeding deterrent in both field and laboratory studies (Robinson et al., 1978). DIMBOA acts on growth and development of corn borer larvae by noncompetitive inhibition of digestive proteases (Campos et al., 1989; Houseman et al., 1992). Other resistance factors that have been less extensively studied include silica, lignin, and fiber content, which may act by reducing the nutritional quality of the leaf or increasing tissue toughness and thereby rendering nutrients less accessible (Rojanaridpiched et al., 1984; Coors, 1987; Peterson et al., 1988; Buendgen et al., 1990).

Breeding for resistance to ECB has resulted in the release of several resistant inbred lines, cultivars, and synthetics. BS9 is a synthetic developed by open pollination of 10 inbreds that had good agronomic traits as well as moderate resistance to ECB damage (Russell and Guthrie, 1982). Using an artificial infestation technique for ECB, four consecutive cycles of selection were conducted to select plants with reduced leaf feeding damage by ECB larvae. Since this germplasm was developed specifically for ECB resistance, changes in its phytochemical composition over cycles of selection have been investigated to better understand maize resistance mechanisms (Buendgen et al., 1990).

Intraplant variation in secondary compounds and nutrients has been studied in maize and would be of value to further our understanding of insect feeding behavior and feeding site preference. The objective of this study was to monitor changes in various secondary compounds and nutritional parameters along the length of mid-whorl leaves of ECB-resistant maize and to relate these changes to ECB feeding performance in both laboratory bioassays and the field. Resistance factors investigated included foliar nitrogen content, leaf toughness, fiber content, soluble and cell-wall-bound hydroxycinnamic acids, hydroxamic acids, and cell wall absorbance using a microspectrophotometer to localize biochemical resistance factors along the entire length of the leaf.

METHODS AND MATERIALS

Plant Samples. The fourth cycle of selection from the maize population BS9 was used with the method of selection outlined by Russell and Guthrie (1982). BS9 is a synthetic that has the following inbreds in its genetic background: B49, B50, B52, B54, B55, B57, B68, CI31A, Mo17, and SD10. Planting occurred in mid-May of 1992 at the Central Experimental Farm, Agriculture Canada, Ottawa, Ontario, Canada. The rows (4.5 m) were spaced 0.9 m apart with 30 plants per row in a sandy loam soil. Three blocks of four rows were planted with one row from each block being infested at the mid-whorl stage with four egg masses (ca. 200 eggs) for field observations. Univoltine ECB normally oviposit at this time on the undersurface of the later-emerging leaves

(leaves 10 through 13). At the mid-whorl stage (approx. 40 days from sowing), the 13th leaf was harvested by pulling the 11th leaf and above whorl out of the plant. Leaves were unwrapped from the whorl to expose the 13th leaf within the whorl. This leaf was green along one quarter, green–yellow along one half, and yellow along one quarter of its length and would emerge from the whorl within four days. Fifteen leaves from each block were harvested for phytochemical analysis. The midrib was removed and the leaves were then cut into eight sections of equal length along the leaf length with four sections being predominantly green and four sections being predominantly yellow. Section 1 was located at the leaf tip and section 8 was located at the auricles. Tissue was frozen at −20°C, thawed for 1 hr to release DIMBOA from its glucoside, refrozen, freeze-dried, and milled on a UD cyclone mill (UD Corp., Boulder, Colorado) with a 1-mm screen. Milled samples were stored at −20°C until analyzed.

Bioassays. Thirty plants were dissected and sectioned as above. Tissue was stored in water for up to 6 hr prior to incorporation into bioassays. A modified Ascher et al. (1981) apparatus was used to determine consumption of a 1.25-cm^2 disk of the leaf tissue exposed to two third-instars. The bioassay apparatus consisted of two top and one bottom halves of plastic Petri plates (5 cm diam.) with the bottom plate having a 1.25-cm-diam. hole. The top plate was inverted and wet cotton was placed inside and covered with filter paper. Leaf tissue was placed onto the filter paper with the top surface facing down. The bottom plate with the hole was taped on top to expose a defined feeding surface. Two early third-instars were placed into the apparatus, a small plastic covering was placed inside to shade the larvae, and the third plate was taped over the top to seal the larvae into the apparatus. The larvae were allowed to feed for 48 hr under controlled conditions of 25:18°C light–dark, 85% relative humidity, and light regime of 16:8 hr light–dark. Mean area consumed was determined from 30 leaf disks per section. Area consumed was measured by placing the consumed disk on top of 1-mm-grid graph paper.

Leaf Toughness. Using the method reported in Bergvinson et al. (1994a), force measurements were taken from the abaxial leaf surface between veins using a 1-mm-diam. probe mounted to an instron (model TM-M, Instron Corp., Canton, Massachusetts). Leaf tissue was held in place using a stainless steel platform fitted with a Plexiglas plate with a 2-cm-diam. hole for probe penetration. Ten samples for each of the eight sections were measured and the peak force recorded. Leaf samples were stored in distilled water at 4°C for up to 2 hr before force measurements were taken.

Protein Determinations. Protein content was estimated with an automatic micro-Kjeldahl nitrogen analyzer (Tecator model 1030, Höganäs, Sweden) using the conversion factor 6.25 to estimate percent protein from percent nitrogen.

Cell Wall UV Absorbance. Five samples from leaf sections 2, 4, 6, and 8

were collected and kept at −20°C. Samples were embedded in water containing glycerol (5 drops/10 ml water). Sections 6 μm were prepared and loaded onto Zeiss quartz slides and cover slips using glycerol. A computer-controlled Zeiss UMSP 80 microspectrophotometer equipped with a high-pressure xenon lamp (XBO 75W/2) was used to determine the absorbance at 326 nm of the adaxial epidermal cell wall (see Bergvinson et al., 1994b for more details).

Phytochemical Analysis. Phenolic conjugates and hydroxamic acids were extracted from a 0.5-g sample of dry tissue. Samples were extracted for 20 sec at ambient temperature in 70% methanol (4 × 20 ml) and mixed with a polytron mixer (model PT-1200, Brinkmann, Westbury, New York). After centrifugation at 500*g* for 10 min, the supernatants were pooled, methanol was removed by rotary evaporator (35°C), and the pH lowered to 2.0 using 1 M HCl. The aqueous fraction was extracted at ambient temperature by solvent partitioning with ethyl acetate (4 × 50 ml) (BDH, Omni-Solv grade). Ethyl acetate fractions were pooled, dried by a rotary evaporator, and stored at −20°C until HPLC analysis.

After extraction, the pellet that remained was washed in a Büchner funnel with 30 ml each of water, methanol, and ethyl acetate to remove chlorophyll and provide a crude cell wall preparation. Cell wall samples were dried in a desiccator for four days. This preparation was weighed, and the weight loss was used as the gravimetric measure of soluble metabolites. Cell wall preparations were shaken in 20 ml of 2 M NaOH for 4 hr under N_2 and wrapped in foil to hydrolyze cell-wall-bound hydroxycinnamic acids. Samples were neutralized with 6 M HCl and the pH lowered to 2.0. After centrifugation, the supernatant was extracted with ethyl acetate (3 × 50 ml). The pellet was resuspended in water and centrifuged twice, with both fractions pooled, and extracted with ethyl acetate (3 × 50 ml). Ethyl acetate fractions were pooled and dried by a rotary evaporator under darkness and stored at −20°C until HPLC analysis. The pellet that remained after extraction was dried and weighed to provide an estimate of fiber content.

HPLC Analysis. All analyses were performed with a Perkin-Elmer (Beaconsfield, England) system consisting of an LC 480 diode scan array detector and a Perkin-Elmer LC250 binary pump fitted with a 10-μl injection loop. Separations were achieved using a C18 ODS reverse-phase column (250 × 4.6 mm, 5-μm particle size, Beckman, Fullerton, California).

Soluble extracts were suspended in 4 ml of 50% methanol and centrifuged at 500*g* for 5 min to remove excess chlorophyll. The supernatant was filtered and injected onto the column. The solvent system consisted of methanol (A) and 10 mM H_2PO_4, pH 2.4 (B), at a flow rate of 1.5 ml/min using the following gradient: 25 to 55% A in 15 min, 55 to 80% A in 5 min, 80 to 100% A in 2 min, 100% A for 8 min, 100 to 25% A in 2 min, and 25% A for 3 min. DIMBOA (R_t = 10.5 min) and MBOA (R_t = 13.6 min) standards were syn-

thetically prepared according to Atkinson et al. (1991). Peak identity was confirmed by on-line UV spectra and spiking of extracts with authentic standards.

Cell-wall-bound phenolic acids were suspended in 1 ml of methanol, diluted 10-fold in methanol, filtered, and injected onto the column. The solvent system was the same as above except the starting mixture was 15% methanol. Standards of (*E*)-*p*-coumaric (R_t = 15.2 min) and (*E*)-ferulic acid (R_t = 15.6 min) were purchased from Sigma (St. Louis, Missouri). Truxillic acid and 5,5′-diferulic acid were obtained from GHN Towers (Vancouver, Britich Columbia).

Statistical Analysis. All statistical analyses were performed on SAS V.6.03 (SAS Institute, 1988). Data satisfied the assumptions of the general linear model and were not transformed. Statistical significance of data was assessed by analysis of variance (ANOVA). When ANOVA indicated there were significant effects, the Student-Neuman-Keuls (SNK) test was used to compare means. Regression analyses between larval consumption and phytochemical parameters were done using the mean values for each of the eight leaf sections.

RESULTS AND DISCUSSION

Field observations of recently hatched European corn borer larvae showed that approximately 80% of the larvae move towards the center of the whorl during daylight hours (unpublished data). Similar observations have been reported for other stem borers such as *Chilo partellus* (Swinhoe) (Lepidoptera: Pyralidae) in which 95–100% of live larvae are within the whorl (Ampofo and Kidiavai, 1987). A possible explanation for this behavior is avoidance of the hot, dry microenvironment on the exposed whorl leaves, which can result in desiccation of neonate larvae. This explanation is supported by the fact that egg mortality is higher at lower relative humidities (Lee, 1988) and larval mortality often exceeds 80% during the first 48 hr after hatching (Ross and Ostlie, 1990).

A profile of leaf consumption by ECB on BS9(C4) is depicted in Figure 1. ECB larvae show the highest consumption rate on immature tissue (sections 6 to 8). The leaf section with the lowest consumption was at the point where the leaf subtends from the whorl (section 4). By conducting leaf feeding bioassays in growth chambers, the effect of relative humidity over the leaf length is controlled and the degree of feeding on mature tissue is obviously lower even when relative humidity is not a restricting factor. This suggests that factors other than microenvironment are influencing larval preference for feeding within the whorl of maize.

Other parameters thought to be associated with feeding behavior are shown in Figure 1. Protein was lower for the sections around the green–yellow interface, reaching a level as low as 17%. Given the low protein levels at the green–yellow interface, one would expect consumption to be higher for this tissue so

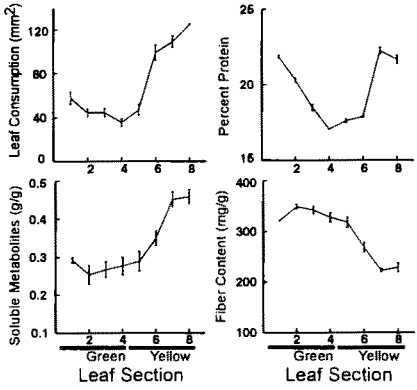

FIG. 1. Maize leaf profile for European corn borer consumption, protein, soluble metabolites, and fiber content for resistant synthetic BS9(C4). Leaf tip is section 1 and leaf attachment is section 8. Standard error of mean shown by vertical lines.

that it is able to fulfill nutritional requirements for development (Scriber and Slansky, 1981), but this was not observed during the 48-hr bioassay. Soluble metabolites washed from milled leaf tissue included sugars, soluble proteins, chlorophyll, phenolic conjugates such as flavonoids and hydroxycinnamic acids, and hydroxamics such as DIMBOA. The trend for soluble metabolites follows that of leaf consumption. Phenolic conjugates from maize have been shown to be phagostimulants (Bergvinson, 1993) and may account for higher consumption, as the level of sugar conjugates of *p*-coumaric acid are higher for immature whorl tissue (Figure 2). Other soluble secondary metabolites such as ferulic acid conjugates or HMBOA fluctuate and show no consistent trend.

DIMBOA was found to be at the highest levels within the yellow whorl tissue, which was also the most preferred by ECB larvae (Figure 2). Based on previous feeding preference studies, the converse would be expected (Robinson et al., 1978). Nutritional studies have shown that DIMBOA incorporated into meridic diet increases larval consumption while reducing the efficiency of nutrient assimilation and various fitness parameters (Houseman et al., 1992). This in part may explain the higher consumption rate of immature, yellow whorl tissue with elevated DIMBOA levels. Elevated levels of DIMBOA do not appear to be a significant deterrent to larval feeding during a 48-hr bioassay but may affect insect performance through reduced fecundity and prolonged development if feeding was restricted to this tissue throughout larval development.

The high feeding preference for tissue with elevated levels of DIMBOA can be rationalized by observing the relative absence of physical defense mechanisms in immature whorl tissue. Fiber content in immature tissue is very low

(Figure 1), and the relative absence of phenolic fortification in epidermal cell walls, as demonstrated by the low microspectrophotometer readings (Table 1), renders nutrients within the leaf more accessible and hence makes the tissue more desirable (Scriber and Slansky, 1981; Bernays and Barbehenn, 1987). The tissue toughness profile found in Figure 3 best illustrates the absence of mechanical resistance factors vis-à-vis fiber and hydroxycinnamic acid fortification of cell walls (Figure 4).

The toughness profile could account for field observations of neonate behavior. Immature whorl tissue would be easier to consume by neonates than tougher, mature leaf tissue. By migrating to the inner whorl, larvae would not

only be in a higher humidity microenvironment but would also be able to easily ingest water and nutrients to avoid desiccation and starvation during early stages of development. During the field study, another insect, the corn leaf aphid, *Rhopalosiphum maidis*, was observed to be most prominent within the whorl of several maize varieties where higher levels of DIMBOA are found (Bergvinson, 1993). DIMBOA in wheat has been identified as a feeding deterrent for aphids (Niemeyer et al., 1989) as well as accounting for varietal differences in maize resistance to the corn leaf aphid (Beck et al., 1983). However, like the ECB,

there may be physical, environmental, or nutritional factors that are of greater importance to aphid performance that necessitate feeding within the whorl despite high DIMBOA levels.

The major cell-wall-bound phenolic acids are (*E*)-ferulic and (*E*)-*p*-coumaric acids, which are attached to hemicellulose through pentose sugars (Kato and Nevins, 1985). Both phenolic acids reach their highest levels in sections 5 and 6, the yellow tissue that will emerge within two days (Figure 4). Cell-wall-bound ferulic and *p*-coumaric acids can form dimers either enzymatically through peroxidase to form 5,5′-diferulic acid (Hartley and Jones, 1976) or through photochemical reactions to form truxillic and truxinic acids (Hartley et al., 1988; Ford and Hartley, 1989). Formation of such dimers may increase the mechanical strength of the cell wall by cross-linking hemicellulose (Ford and Hartley, 1989). From the profiles in Figure 4 no individual biochemical component provides a suitable explanation for leaf consumption or toughness. However, when taken together, hydroxycinnamic acids provide a biochemical explanation for feeding performance. The leaf tip has been exposed to sunlight the longest and shows the highest levels of the photodimers truxillic and truxinic acids, which could cross-link the hemicellulose of mature tissue to provide structural resistance. For sections 4–6, elevated levels of cell-wall-bound *p*-coumaric, ferulic, and diphenolic acids sustain leaf toughness and thereby maintain a moderate leaf consumption rate. For sections 7 and 8, all cell wall phenolics are at their lowest levels, corresponding to increases in leaf consumption (Figure 1).

It is of interest to note the dramatic reduction in cell-wall-bound *p*-coumaric acid, which has been shown to have a positive correlation with lignin in bromegrass, *Bromus inermus* Leyss. (Jung and Casler, 1990). It may be that cell-wall-bound *p*-coumaric acid is an indicator for lignin by facilitating its attachment to the cell wall, as has been proposed for ferulic acid in wheat (Iiyama et al., 1990). Moreover, Akin et al. (1992) showed increased digestibility of bermudagrass leaf with alkaline release of phenolic monomers and their photoactivated dimers. This increase in digestibility was especially noticed in the epidermis. These observations support the hypothesis that phenolic acid monomers and dimers contribute to the mechanical resistance of maturing tissue.

Simple linear regression analysis of leaf consumption against the 12 parameters studied identified three parameters that could account for over 90% of the variation in leaf consumption (Table 2). Epidermal cell wall absorbance, toughness, and fiber content are all components or indicators of mechanical resistance. Elevated fiber content would not only increase the bulk density of the insect's diet to make nutrient and water requirements less attainable (Bernays, 1986), but would also increase the area for phenolic cross-linking. Acting in concert, fiber and hydroxycinnamic acid fortification in epidermal cell wall tissue could increase leaf toughness of "apparent" (*sensu* Feeny, 1976) mature leaf tissue, making it inaccessible to neonate larvae, which are forced to feed on softer,

immature whorl tissue that is defended by high levels of DIMBOA. As the insect matures, its mandibles may be better able to cope with tougher, mature tissue (Bernays, 1986) that has lower levels of DIMBOA. Based on within-leaf variation of feeding preference and biochemical factors, leaf toughness and the biochemical factors responsible for leaf toughness appear to be the predominant factors that influence ECB feeding behavior within maize during the mid-whorl stage of plant development.

(Received April 14, 1994; accepted November 29, 1994)

Abstract—Field trials were conducted in the western Cape Province, South Africa, to develop a sex pheromone dispenser suitable for monitoring the flight activity of false codling moth. A controlled-release dispenser capable of releasing sex pheromone at a predetermined and constant release rate without replacement for more than seven months was produced.

Key Words—*Cryptophlebia leucotreta*, controlled-release pheromone dispenser, sex pheromone.

INTRODUCTION

Various methods of releasing sex pheromone for both the monitoring and mating disruption of insect pests are used worldwide. A variety of dispensers, such as sachets made from polymer film, polyethylene (PE) vial caps and tubes, rubber septa, hollow fibers, and other materials, are utilized (Butler and McDonough, 1981; Kauth and Darskus, 1980; Urahama, 1982; Vrkoč et al., 1988; Weatherston et al., 1985; Yamamoto, 1982a,b). Generally, the inherent shortcoming of these dispensers is having to fulfill a dual function in providing a pheromone-releasing surface as well as serving as a reservoir for the pheromone. As the pheromone is partly or totally dissolved in the dispensing material, the rate at

*To whom correspondence should be addressed.

which it is released decreases as its concentration in the dispensing device, or the surface area wetted by the pheromone, decreases. This means that the dispensers need to be replaced at regular, relatively short intervals to maintain both the integrity of the trapping system and optimum pheromone release levels for the insect concerned. For a trained scientist or technical officer, this requirement does not present a problem, but in practice, recommendations by the supplier to replace dispensers at fixed intervals are often either disregarded as unnecessary or are neglected. This can have serious consequences when the implementation of control procedures depends solely upon data supplied by the monitoring system.

For many years, low-density PE vial caps were used in trapping studies on false codling moth (FCM) *Cryptophlebia leucotreta* (Meyr.). Liquid pheromone was pipetted into the caps, which were then suspended in PVC pipe traps (Hofmeyr and Calitz, 1991). However, the pheromone only partially penetrated into the PE and was released mainly from the liquid phase, necessitating the regular replacement of the dispensers at monthly intervals. Pheromone release rates decreased rapidly to below optimum levels if this interval was exceeded, reducing moth catches. Subsequent dispenser replacement restored the initial pheromone release rate, but also sometimes resulted in the development of artificial population peaks as moth catches increased in response to the higher pheromone levels.

In developing a monitoring system, the following requirements for a pheromone dispenser had to be considered: (1) transport of centrally produced dispensers without fear of pheromone spillage; (2) continual pheromone release for approximately five months, without replacement or replenishment; and (3) pheromone release at a constant, predetermined rate.

In this paper we report the development of a controlled-release pheromone dispenser (CRPD) and the results obtained in preliminary field trials conducted in the western Cape Province, South Africa.

METHODS AND MATERIALS

The prototype CRPD consisted of two main parts: a glass tube acting as a pheromone-impermeable reservoir and, attached to it, a short length of PE tubing, through which the pheromone can diffuse. Although this basic design, as originally suggested by the second author, has been retained, it has evolved through several stages to eliminate various problems encountered during field trials. The design currently used is constructed as described below (Figure 1).

Both ends of a length of Pyrex glass tube (7 mm diameter and 0.9 mm wall thickness) are drawn out in the flame of a glass-blower's torch to form two tapered tips, the resulting glass reservoir having a length of approximately 20

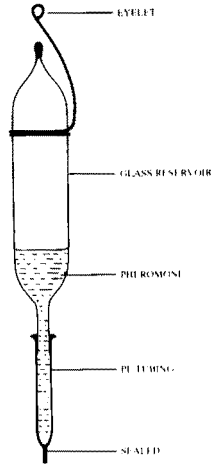

FIG. 1. Schematic presentation of the controlled-release pheromone dispenser.

mm and an overall length, including tapered ends, of 40 mm. The diameter of one of the tapered tips is critical and should be approximately 1.5 mm.

One end of a 15-mm length of low-density PE tubing (1.9 mm outside diameter and 0.25 mm wall thickness; Intramedic Micro Bore, Clay Adams 7400 Series; Becton, Dickinson and Co., Parsippany, New Jersey 07054) is heat-sealed with an impulse heat sealer (TEW Tish-200, Acepak Packaging Systems, P.O. Box 634, Goodwood 7460, South Africa). The other end is heated momentarily in an open flame and cooled down immediately, resulting in a thickened reinforcing collar. The collar end of the PE tubing is slipped over the 1.5-mm-diameter tip of the glass tube. Cyanoacrylate adhesive is used to strengthen this bond, although it is unnecessary if the fit between the glass and PE tubing is tight. A prefabricated eyelet, made from a length of copper wire, is slipped over the glass tube and glued into place with cyanoacrylate adhesive. This eyelet is used to suspend the dispenser from a hook in the trap.

With the aid of a microliter syringe, pheromone is injected into the PE tubing through the open end of the glass tube. Care is taken to prevent any air bubbles from forming during this process. The filled dispenser is placed in a refrigerator at 5°C. Once it has cooled down, the dispenser is removed with a long-nosed forceps, and the open end of the glass tube is immediately heat-sealed with a small glass-blower's torch. The dispenser is held upright momentarily until the glow has faded from the sealed end and is then cooled down with a wet cloth to prevent an excessive increase in temperature and a resulting build-up of air pressure in the dispenser. The object of this procedure is to create a slight positive air pressure in the dispenser at ambient temperature. If this is not

done, an air bubble may eventually be formed in the PE tubing (probably created by a negative pressure caused by pheromone release from the dispenser), which will interfere with the predetermined release rate.

A standard three-component mixture of the following compounds was used in all dispensers: 50% (*E*)-7-dodecenyl acetate plus 50% of a 5:1 mixture of (*E*)-8-dodecenyl acetate and (*Z*)-8-dodecenyl acetate. The (*E*)- and (*Z*)-8-dodecenyl acetate are major components of the sex pheromone of FCM (Persoons et al., 1977; Angelini et al., 1980; Attygalle et al., 1986), while (*E*)-7-dodecenyl acetate was added as a synergist (Hofmeyr and Calitz, 1991). In all experiments, 80 mg of pheromone were used per CRPD. For comparison of CRPD and PE caps, 8 mg of pheromone were pipetted into each PE cap. Although experiments were conducted using up to 40 mg of liquid pheromone per PE cap, this was considered impractical, as the danger of pheromone spillage was already high when only 8 mg of pheromone were used per cap. Furthermore, a fivefold increase in the total amount of pheromone per cap did not result in a corresponding extension in exploitable life, as the release rate was much higher than required (Hofmeyr, unpublished data).

Comparison of CRPDs with Different Sizes of PE Tubing (Experiment 1). To determine the influence of the PE tubing on the release rate of the CRPD, dispensers with tubing of differing lengths and diameters were prepared. One dispenser of each type was suspended from a hook beneath a wooden rack. Five of these racks were, in turn, suspended inside the canopy of as many fruit trees. They were removed once a week and transported to the laboratory, where mass loss of the dispensers was determined with the aid of an analytical balance.

Quantitative Comparison of Pheromone Released from PE Caps and CRPDs (Experiment 2). Ten CRPDs (PE tubing size 15 × 1.9 mm) were compared with 10 low-density PE caps (internal diameter and depth 9 × 9 mm, average mass 0.63 g). All dispensers were field-aged as in experiment 1. Comparisons were terminated after six weeks and the PE caps removed. The CRPDs were left in situ for a further 18 weeks, after which they were taken to the laboratory and maintained at temperatures of 25–27°C. At this stage, 10 fresh CRPDs were added to the trial for comparison, and weekly mass determinations were resumed.

Efficacy of Dispensers in Traps (Experiment 3). A trapping experiment was conducted to compare the efficacy of the CRPDs with that of the standard PE caps. Sticky pipe traps were evenly distributed at a minimum of 50-m intervals across an orchard and suspended from a convenient branch at a height of 1.9 m on the southern side of trees, just inside the foliage canopy. A randomized block design was used for the experiment. Each treatment, consisting of a trap plus dispenser, was randomly allocated to each block. Six blocks per treatment were used. At weekly intervals trapped moths were counted, removed, and each trap moved one position to the adjacent block.

PE caps were replaced with fresh dispensers after six weeks. The original CRPDs were retained for the duration of the experiment. All experiments were conducted between February and August.

Analysis of Trap Data. To test differences between treatments, *t* tests for independent samples were performed.

RESULTS AND DISCUSSION

Pheromone Release Rate of Various Sizes of PE Tubing (Experiment 1). It was found that the release of pheromone from the CRPD could be calibrated for a desired rate simply by adjusting the length and/or diameter of the attached PE tubing (Figure 2). During the sealing process approximately 6 mm of the total length of PE tubing is lost. This loss is constant, regardless of the length of PE tubing used. The effective external surface area of the different dispensers therefore varied from 53.7 mm^2 (15 × 1.9 mm) to 59.7 mm^2 (25 × 1 mm) to 113.4 mm^2 (25 × 1.9 mm). Increasing the tubing length from 15 to 25 mm, while maintaining the same diameter (111% increase in surface area), increased the mean release rate by 135%. The surface area from a 25-mm × 1-mm length of PE tubing, which was 11% greater than that of 15-mm × 1.9-mm tubing, increased the mean release rate by 15%. Theoretically the release rate should have been directly proportional to the surface area of the PE tubing. The reason

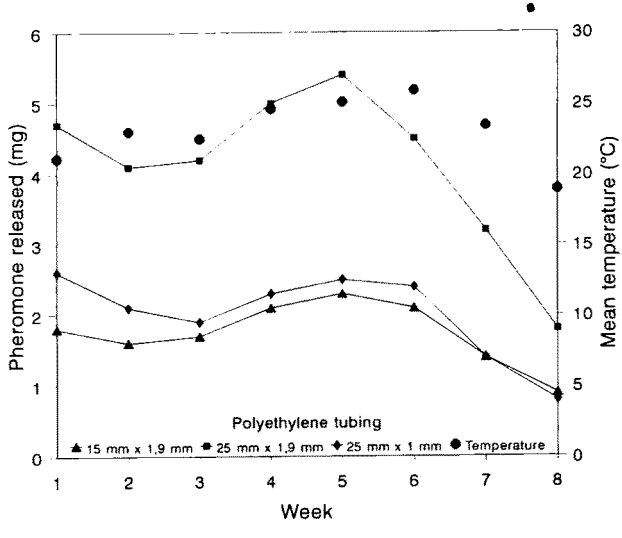

FIG. 2. The influence of polyethylene tubing of different lengths and diameter on the release rate of the controlled-release pheromone dispenser.

for these discrepancies is unknown, but is of little practical importance, since the release rate is easily adjusted.

During the first week of exposure in this experiment, the release rate from all CRPDs did not follow a temperature-related curve, but was higher than expected. This could be a logical consequence of too high a pressure inside the CRPDs, but as the release rate stabilized from the third week onwards, it does not seem to be of practical significance. This phenomenon was, however, also noted in similar experiments with BASF double-receptacle pheromone ampoules used for male disruption. As the internal air pressure probably does not play a significant role in these ampoules, a further unknown factor could be involved.

Pheromone Release Rate of CRPDs and PE caps (Experiment 2). The PE caps maintained an acceptable rate of release for the first four weeks, after which there was a rapid and permanent reduction (Table 1). In contrast, pheromone release from the CRPDs was not reduced. A rise in mean temperatures occurred during the second half of the six-week exposure period, which was responsible for the increase in pheromone release from the CRPDs. However, pheromone had already been depleted to such an extent in the PE caps that temperature had no noticeable effect on the release rate.

After exposure in the orchard for 24 weeks, pheromone was being released from the field-aged CRPDs at a mean rate of approximately 30% less than from

TABLE 1. COMPARISON OF WEEKLY RELEASE RATES OF CONSTANT RELEASE PHEROMONE DISPENSERS (CRPD) AND POLYETHYLENE (PE) VIAL CAPS

Week	Mean release rates (mg) ± SEM

28	1.6 ± 0.07	2.6 ± 0.05

new CRPDs. This is still well within the optimum range for monitoring FCM of 1.0–2.5 mg per trap per week, as found in trapping experiments using PE caps (Hofmeyr, unpublished data).

Efficacy of CRPDs and PE caps in traps (Experiment 3). Moth activity fluctuated inherently from week to week independent of the influence of the two treatments. The results are therefore presented as the size of the moth catch with the PE caps relative to that attracted to the CRPD (Figure 3).

Under late summer conditions (February–March) traps equipped with PE caps remained competitive for only three weeks, before the number of attracted males decreased in comparison to the CRPD-baited traps. After replacement, this period was increased to five weeks as the lower autumn temperatures resulted in a decrease in pheromone evaporation from the PE caps.

During the first three weeks, 23 males were attracted to the six PE cap dispensers, while 28 males were caught in the six traps equipped with the CRPDs. The difference became significant ($P < 0.01$) during the ensuing three weeks when eight and 58 males, respectively, were trapped. Corresponding figures for the period following replacement of the PE caps are as follows: First five weeks, 136 (PE caps) and 160 males (CRPD): ensuing six weeks, 34 and 106 males, respectively.

Experiment 2 did not run concurrently with experiment 3, but was conducted during cooler conditions later in the same season. This explains why

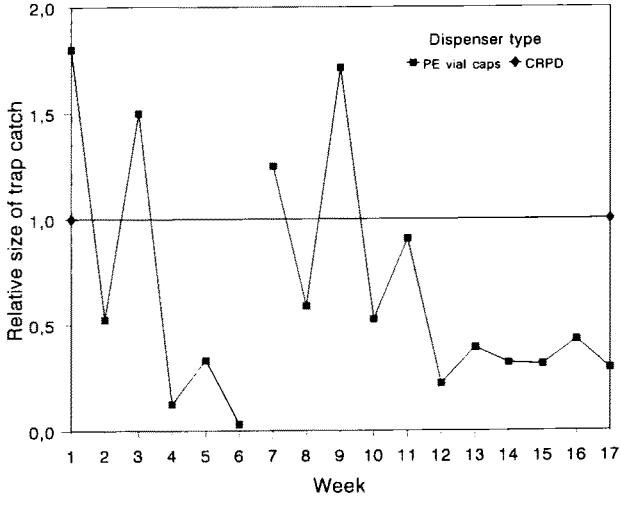

FIG. 3. The relative size of male moth catches in traps baited with sex pheromone released from polyethylene (PE) vial caps and controlled-release pheromone dispensers (CRPD). PE dispensers were replaced at the end of week 6.

pheromone release during week 4 was still at an acceptable level in experiment 2 (Table 1), while male attraction to PE caps had already decreased during week 4 in experiment 3 (Figure 3).

It was demonstrated in the quantitative assessment that the CRPD will release pheromone at predetermined levels for at least 30 weeks under prevailing climatic conditions. The CRPDs retained their activity in traps without replacement for 17 weeks before the experiment was terminated. This is a significant improvement on the performance of the PE caps, bearing in mind that the pheromone in the CRPDs was far from depleted and that the release rate in these dispensers would have been maintained for an even longer period.

In the present study, glass was used for the construction of the pheromone-impermeable reservoir. This allowed detailed observation of the physical behavior of the pheromone in the dispenser. A reservoir constructed from a pheromone-impermeable plastic might, however, be preferred for mass-production purposes.

The influence of oxygen on the integrity of the pheromone composition was not studied in detail. However, in a preliminary investigation of FCM pheromone that had been exposed in CRPDs in traps in orchards for seven months, no evidence of isomerization of any practical importance was found. It remains to be determined whether this CRPD can be used for more labile pheromones having, for example, conjugated or skipped diene systems and whether the use of antioxidants could be effectively used to stabilize such sensitive pheromones.

Using a reservoir made from a pheromone-impermeable material, to keep a short length of PE tubing totally filled with pheromone, was seen as a possible solution to the problem of the continually decreasing rate of pheromone release from other types of dispensers. In such a device, the pheromone-releasing surface, as well as the concentration of the pheromone in the polymeric material acting as releasing agent, remains constant. The rate at which the pheromone is released therefore also remains constant. The relatively simple pheromone dispensers constructed along these guidelines proved to satisfy all the requirements set out in the introduction.

Acknowledgments—We thank Dr. W. Mackenroth of BASF (Germany) for the ample supplies of liquid pheromone involved in the development of the dispensers. We also thank Messrs. J. Carinus and H. van Zyl, of the farm Middelpost, Citrusdal, for experimental sites. We are grateful to Drs. H. Geertsema (Entomology Department, University of Stellenbosch) and T.G. Grout (Outspan Citrus Centre, Nelspruit) for reading the manuscript.

Abstract—The objective of the present study was to evaluate the interrelationship between the cuticular and postpharyngeal glands' hydrocarbons, both in the individual ant and during its interaction with nestmates. In vivo radiochemical assays were employed to monitor the de novo hydrocarbon biosynthesis from acetate in the ant's body. The newly synthesized hydrocarbons appeared first internally and after 24 hr they accumulated in the postpharyngeal gland and on the cuticular surface. Blocking the possibility of external transfer of hydrocarbons between cuticle and postpharyngeal gland led to a significant decrease of labeled hydrocarbons in the postpharyngeal gland. In addition, during encounters between labeled and unlabeled ants, newly synthesized hydrocarbons were transferred, mainly via trophallaxis, but also by allogrooming and physical contact. In view of these results, we propose as a model for their dynamics that hydrocarbons are synthesized in tissues associated with the integument. Through self-grooming, there is a constant exchange of hydrocarbons between the cuticular surface and the postpharyngeal gland. Furthermore, in encounters between nestmates, hydrocarbons are exchanged among them mostly by trophallaxis, with the mediation of the postpharyngeal gland. Thus, this gland acts as a pool for mixing colonial hydrocarbons and may serve to attain a unified colony odor.

Key Words—Postpharyngeal glands, cuticle, hydrocarbons, nestmates recognition, ants, *Cataglyphis niger*.

INTRODUCTION

Nestmate recognition, i.e., the ability to discriminate individuals that belong to the same colony from alien individuals, has been reported in a large number of social Hymenoptera species (see reviews in Hölldobler and Michener, 1980; Gadagkar, 1985; Breed and Bennett, 1987). It provides an effective means for maintaining the coherence of the colony and preventing the invasion of conspecific competitors. It is generally believed that nestmate recognition cues reside among the chemicals found on an individual's cuticle (Hölldobler and Michener, 1980; Bradshaw and Howse, 1984). The cuticular lipids of insects vary in composition and may include fatty acids, alcohols, esters, glycerides, sterols, aldehydes, ketones, wax esters, and hydrocarbons (Lockey, 1988). In ants, hydrocarbons are usually the dominant chemical class found on the cuticle, forming complex mixtures. Hydrocarbon patterns have thus been used as species and/or colony markers, e.g., hydrocarbon patterns are species and colony specific in the fire ant complex (Brill et al., 1985; Ross et al., 1987; Vander Meer, 1986).

Although there is no conclusive evidence linking nestmate recognition behavior with cuticular hydrocarbons, multiple experimental data support this possibility. The acquisition of the host ant cuticular hydrocarbon pattern has been correlated with the acceptance of inquilines into the ant's colony (Dettner and Liepert, 1994). Recognition between alien societies of ants is correlated with a similarity in composition of cuticular hydrocarbons (Bonavita-Cougourdan et al., 1987, 1989; Henderson et al., 1990; Nowbahari et al., 1990). Studies with mixed species groups of ants showed that nonaggressive cohabitation between the species may be correlated with a congruency in hydrocarbon profile. Especially intriguing is the occurrence of heterospecific compounds in members of these groups (Bagnères et al., 1971; Franks et al., 1990; Vienne, 1993).

It was recently demonstrated in several ant species that the chemical profile of the cuticular hydrocarbons is congruent with that of the postpharyngeal gland contents (Bagnères and Morgan, 1991; Do Nascimento et al., 1993; Soroker et al., unpublished data). The postpharyngeal gland, which is specific to ants, occupies a large portion of the head overlaying the brain, with a lateral opening in the bottom of the buccal cavity just in front of the esophagus (Barbier and Delage, 1967). Recently, we were able to show that exudates of the postpharyngeal gland modify nestmate recognition in *Cataglyphis niger* (Soroker et al., 1994). This congruency in hydrocarbon profile between the cuticle and the postpharyngeal gland could be the consequence of several processes: synthesis in the tissues underlying the cuticle and sequestration by the postpharyngeal gland; synthesis in the postpharyngeal gland and application on the cuticle by grooming; or an independent synthesis in both tissues. In addition, workers of mixed groups of *Manica rubida* and *Formica selysi* were shown to have similar

hydrocarbon profiles on both the cuticular surface and in the postpharyngeal gland (Hefetz et al., 1992). One possible route for the acquisition of heterospecific substances in these mixed species groups is a continuous flow of hydrocarbons between members of a colony. Since the postpharyngeal gland exudes to the mouth, it could play a role in the distribution of hydrocarbons between nestmates by trophallaxis and/or grooming.

We present here studies that evaluate the interrelationship between the cuticular and postpharyngeal gland hydrocarbons and its impact on hydrocarbon dynamics between nestmates.

METHODS AND MATERIALS

Collection and Maintenance of Ant Colonies. Colonies of *Cataglyphis niger* were collected from the Tel-Aviv area during October 1992–November 1993. In the laboratory they were transferred to artificial nests and reared in an incubator under controlled conditions of 28 ± 2°C and a photoperiod of 8L : 16D. Colonies were provided with an identical diet of sugar water and minced insects three times a week.

Studies on Hydrocarbon Distribution In Vivo Using Labeled Sodium Acetate. In order to follow the biosynthesis and accumulation of the hydrocarbons in the ants, an *in vivo* radiochemical assay was used. Ants were each injected into the hemolymph through the intersegmental membrane of the abdomen with 0.5 μl medium, prepared according to Katase and Chino (1984) and containing 1 μCi (56 mCi/mmol) [1-^{14}C]sodium acetate (NEN, Boston, Massachusetts). Thereafter, at various time intervals for the time-course studies, or after 24 hr for all the other experiments, the ants were frozen and dissected.

The effect of self-grooming on hydrocarbon distribution within the ants was monitored using ants with blocked mouth parts. The sealing of the mouth parts was done prior to injection by using melted beeswax while the ants were immobilized on ice. Twenty-four hours later, the ants were dissected and monitored for the presence of labeled hydrocarbons on their cuticular surface (cuticle), in their postpharyngeal gland (PPG), and internally as described below. Only those ants that were alive and in good condition were used.

Hydrocarbon Transfer between Nestmates. Donor ants were injected with [1-^{14}C]sodium acetate as described previously and after 24 hr of incubation (26°C) they were presented with a nestmate (recipient), prestarved for 24 hr, in a Petri dish (4.8 cm diameter). To test whether hydrocarbon transfer occurs via trophallaxis, the behavior of the ants was recorded. Each encounter was stopped 30 min after trophallaxis was first observed and encounters did not exceed 90 min. Ants that did not engage in trophallaxis within the first hour were not taken into consideration. To test the successive transfer of hydrocar-

bons between nestmates, the first dyadic encounters were followed by another encounter, this time using the recipient as a donor for a third nestmate. The length of each encounter was 24 hr. Food transfer by trophallaxis was verified by feeding the donor ants with colored food and following its occurrence in the recipient. To test whether hydrocarbon transfer occurs otherwise than by trophallaxis and to assess the magnitude of the label transfer, prelabeled ants were presented with nestmates that had their mouth parts sealed with beeswax (blocked ants) to prevent any trophallaxis or licking, and, vice versa, prelabeled blocked ants were presented with normal recipient nestmates. In addition, encounters between donors and recipients that were both blocked were also conducted. All encounters were stopped 24 hr later by freezing the ants, and both donor and recipient were monitored for the presence of labeled hydrocarbons in the postpharyngeal gland and on the cuticular surface. For comparison between the magnitude of labeled hydrocarbon transfer to the various recipients, the relative amounts of labeled hydrocarbons transferred from their donor's to the recipient's postpharyngeal gland or cuticle were calculated individually for each pair using the following equation (example given for PPG):

$$\% \text{ Hydrocarbons transferred to PPG} = \frac{\text{Labeled hydrocarbons in recipient PPG}}{\text{Total labeled hydrocarbons in donor (PPG + cuticle)}}$$

Extraction and Separation of Labeled Hydrocarbons. Postpharyngeal glands were extracted for 24 hr in 100 μl of pentane. To separate cuticular from internal hydrocarbons and to eliminate the possibility of sample contamination by Dufour's gland hydrocarbons, headless and Dufour's glandless carcasses were first washed by immersion in 400 μl of pentane for 5 min and subsequently extracted for longer periods (24 hr or more). The extracts were subjected to silica gel (polygram Sil G) thin-layer chromatography (TLC) using petrol ether–diethyl ether–acetic acid (95 : 5 : 1) as a running solvent. The various lipid classes were identified by comparing their R_f values with those of cochromatographed standards purchased from Sigma (tricosene, triolein, oleic acid, and palmitoleic acid stearyl ester) and visualized by iodine vapor. The area corresponding to hydrocarbons was cut and placed in scintillation fluid (Opti Fluor, Packard) and its radioactivity was monitored by a scintillation counter (Packard Tri-Carb 4530). The presence of hydrocarbons in this TLC faction was ascertained by comparing their GC profile to that obtained by combined GC-MS analysis of PPG extracts.

Statistics. In all experiments individual ants were analyzed. Different groups were compared by Mann-Whitney U test and Kruskal-Wallis test performed using a Statview 4.01 package in a Macintosh computer. The data from the same individuals were compared by Wilcoxon's signed-ranks test according to Sokal and Rohlf (1981).

RESULTS

Hydrocarbon Distribution within the Ant. The results of the radiochemical assay showed that adult workers synthesized hydrocarbons de novo from sodium acetate (Figure 1A). While the amount of labeling increased with time in all the tissues examined, their distribution in the various tissues progressively changed. At first, a fast increase in labeled internal hydrocarbons was observed, reaching significantly higher levels than on the cuticular surface or in the postpharyngeal gland. Thereafter, the amount of labeling in hydrocarbons increased with time, especially in the postpharyngeal gland. However, after 24 hr, the amount of hydrocarbons in the postpharyngeal gland was not significantly higher than on the cuticular surface. Results of a previous study with decapitated ants, i.e.,

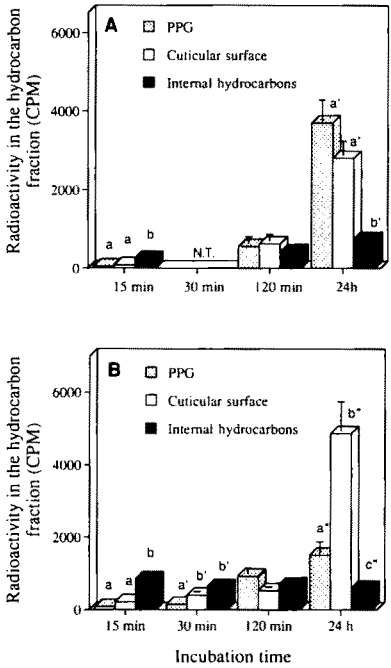

FIG. 1. Time-dependent changes in *in vivo* incorporation of [1-^{14}C]acetate into the hydrocarbon fraction in *C. niger* workers. For every incubation time, different letters indicate the groups that are statistically different (Wilcoxon's signed-ranks test): (A) a vs. b, $P < 0.05$; a′ vs. b′, $P = 0.0001$; (B) a vs. b, $P = 0.0033$; a′ vs. b′, $P = 0.01$; a″ vs. b″ and b″ vs. c″, $P = 0.0001$; a″ vs. c″, $P = 0.018$.

lacking their postpharyngeal gland, that were injected with [1-^{14}C]sodium acetate, implied that this organ is not the site of hydrocarbon synthesis, but that the gland does sequester them (Soroker et al., 1994). The mode of sequestration of these hydrocarbons was further investigated while preventing their external passage via self-grooming by blocking the ants' mouthparts with melted beeswax (Figure 1B). At first, as for untreated ants, a fast increase in labeled internal hydrocarbons was observed, reaching significantly higher levels than on the cuticular surface or in the postpharyngeal gland. Thereafter, the amount of labeling in hydrocarbons increased with time first on the cuticular surface and subsequently in the postpharyngeal gland, but stayed relatively stable in the long-term extracts for internal hydrocarbons ($P = 0.45$, Kruskal-Wallis). In contrast to the previous experiment conducted with normal ants (Figure 1A), after 24 hr of incubation, ants with blocked mouthparts contained significantly higher amounts of labeled hydrocarbons on their cuticular surface than in their postpharyngeal gland. Nevertheless, the postpharyngeal gland still contained significant amounts of newly synthesized hydrocarbons, suggesting an uptake from an internal pool. The comparison with normal ants suggests that the presence of hydrocarbons in the postpharyngeal gland results from both this uptake and an assimilation via self-grooming.

The possibility that hydrocarbons also accumulated in the phostpharyngeal gland by self-grooming is emphasized when we compare the ratio of labeled hydrocarbons on the cuticle and in the postpharyngeal gland between the normal and blocked ants (Table 1). During the first 2 hr, there was little change in the ratios between blocked and normal ants. In contrast, 24 hr later, the ratio in blocked ants was significantly higher than in normal ones. We can conclude that, by that time, sufficient self-grooming was performed by the normal ants to transfer labeled hydrocarbons from the cuticular surface to the postpharyngeal gland, while blocked ants were deprived of this ability.

TABLE 1. EFFECT OF MOUTH BLOCKING ON DISTRIBUTION OF LABELED HYDROCARBONS BETWEEN POSTPHARYNGEAL GLAND AND CUTICLE IN WORKERS OF *C. niger*[a]

Incubation time (min)	Ratio between labeled hydrocarbons in cuticle/postpharyngeal gland		
	Control	Blocked	Probability[b]
15 min	1.83 ± 0.34 ($N = 14$)	2.66 ± 0.67 ($N = 11$)	NS
120 min	2.65 ± 1.20 ($N = 7$)	1.09 ± 0.23 ($N = 13$)	NS
24 hours	1.38 ± 0.27 ($N = 25$)	7.62 ± 2.32 ($N = 22$)	$P = 0.0001$

[a]Results are presented as means ± SEM.
[b]Significant differences between control and blocked ants were assessed by Mann-Whitney U test.

Hydrocarbons Transfer between Nestmates. The possible transfer of newly synthesized hydrocarbons between nestmates was examined by first evaluating the role of trophallaxis in this process. When a prelabeled donor ant was confronted with a nestmate, trophallaxis occurred rather quickly with a consequent transfer of labeled hydrocarbons from the donor to the recipient within 30 min from the beginning of trophallaxis (Figure 2). The amount of labeled hydrocarbons in the recipient's postpharyngeal gland was significantly higher than on their cuticle ($P < 0.01$; Wilcoxon test). The passage of hydrocarbons between nestmates was further tested in two successive dyadic encounters (Figure 3). After 24 hr, a conspicuous accumulation of radiolabeled hydrocarbons was observed in the postpharyngeal gland of both recipients. The labeling in the first recipient's postpharyngeal gland was equal to the level in the donor corresponding to a transfer of 40 ± 11%. However, the amount of labeled hydrocarbons in the second recipient's postpharyngeal gland was significantly lower ($P = 0.001$, Mann-Whitney), reaching only 8 ± 2% of the labeled hydrocarbons observed in the ant it encountered (the first recipient). The labeling of cuticular hydrocarbons in recipients was much lower than in the postpharyngeal gland but remained the same in the two encounters (1.4 ± 0.3% for the first recipient and 1.1 ± 0.3% for the second, $P = 0.4$, Mann-Whitney).

In addition to trophallaxis, the impact of other modes of label transfer between nestmates, such as allogrooming and body contact, were assessed in a series of encounters in which either the donor ants or the recipients or both had their mouthparts sealed. Figure 4 depicts the relative amounts of labeled hydrocarbons present in the recipient's postpharyngeal gland and on the cuticle,

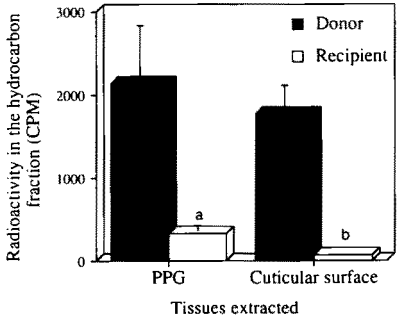

FIG. 2. Hydrocarbons transfer by trophallaxis between *C. niger* workers. Data are expressed as mean labeling in hydrocarbon fraction in the postpharyngeal gland and on the cuticular surface of donors and recipients ± SEM of 15 replicates. Different letters indicate the groups that are statistically different ($P = 0.0019$, Wilcoxon's signed-ranks test).

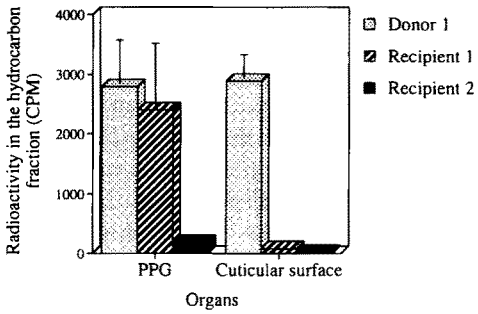

FIG. 3. Hydrocarbons transfer in two successive dyadic encounters between nestmates of *C. niger*. Data are expressed as mean labeling in hydrocarbon fraction in the postpharyngeal gland and on the cuticular surface of donors and recipients ± SEM of nine replicates.

respectively, as a consequence of all the encounters. As expected from the previous experiment, there was a substantial transfer of newly synthesized hydrocarbons to the recipient when free trophallaxis was permitted (RO/DO, Figure 4). On the other hand, transfer to the postpharyngeal gland was abolished completely when the mouthparts of the recipient were blocked (RB/DO or RB/DB). However, normal recipients that encountered blocked donors (RO/DB) acquired radioactive hydrocarbons in their postpharyngeal gland. Since trophal-

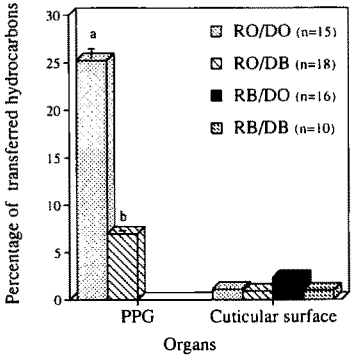

FIG. 4. Hydrocarbons transfer between nestmates of *C. niger*. Data are relative amount of labeling in hydrocarbon fraction found in the recipients, mean percent ± SEM of a minimum of 10 replicates. RO = normal recipient; RB = blocked recipients; DO = normal donor; DB = blocked donor. Statistics: different letters indicate the groups that are significantly different [RO/DO vs. RO/DB, $P = 0.02$, Mann-Whitney U test].

laxis between these two ants was impossible, this acquisition was probably accomplished when the recipient ant groomed the donor, picking up newly synthesized hydrocarbons from its cuticle.

In contrast to the variabilty in hydrocarbon transfer into the postpharyngeal gland in the various treatments, the transfer to the cuticular surface was low (but above the background) and in similar proportions. Nevertheless, the level of labeling that occurred on the cuticle of blocked recipients that encountered nonblocked donors (RB/DO) tended to be the highest. It was also evident that in these ants, the radioactivity on the cuticle was higher than in the postpharyngeal gland (which had only a background level of radioactivity, RB/DO 179 $\pm$ 30.6 cpm vs. 32 $\pm$ 1.8 cpm; $P < 0.01$; Wilcoxon test). These data imply that the donor smeared its postpharyngeal gland secretion on the recipient through licking.

The possibility that the labeled hydrocarbons observed in the recipients were biosynthesized de novo from free [1-^{14}C]acetate that was transferred as such from the donor was examined by comparing the distribution of labeled hydrocarbons in the postpharyngeal gland and on the cuticular surface between donors and recipients (Table 2). Significantly higher ratios of labeled hydrocarbons between cuticle and postpharyngeal gland were found in the donor rather than in the recipient, indicating that there was a transfer of labeled hydrocarbons from donor to recipient's postpharyngeal gland rather than a de novo synthesis from acetate transferred to the recipient.

DISCUSSION

It is currently believed that cuticular hydrocarbons are involved in the process of nestmate recognition in social Hymenoptera, including ants (Blum, 1987). This hypothesis is supported by the findings that the postpharyngeal gland's secretion modifies the aggressive behavior that is generally directed towards alien ants and the congruency between cuticular and postpharyngeal

TABLE 2. DISTRIBUTION OF LABELED HYDROCARBONS IN BODY OF *C. niger* WORKER[a]

gland hydrocarbons that exists in several ant species (Bagnères and Morgan, 1991; Do Nascimento et al., 1993; for *C. niger*, Soroker et al., unpublished data). The primary aim of this study was to explore the dynamics of hydrocarbon synthesis and their distribution in the ant's body tissues as well as between the ants in a colony.

Workers of *C. niger* synthesized hydrocarbons de novo from sodium acetate, as was described previously in other insects (Howard and Blomquist, 1982). Time-course analyses of radioactive hydrocarbon distribution showed an initial elevation in internal hydrocarbons that was followed by an increase in labeled hydrocarbons on the cuticular surface and in the postpharyngeal gland. This corroborates the current knowledge that cuticular hydrocarbons are synthesized by cells associated with the epidermis or the peripheral fat body, probably oenocytes, and are subsequently transferred to the cuticle and other locations through the hemolymph (De Renobales et al., 1988, 1991; Lockey, 1988). The results of the experiments using ants that had their mouthparts blocked indicate that in *C. niger* hydrocarbons reach the gland both internally through the hemolymph and externally through the mouth, probably by self-grooming. The hypothesis that the postpharyngeal gland sequesters rather than synthesizes hydrocarbons is further corroborated by the fact that in decapitated ants (i.e., lacking a postpharyngeal glands) the magnitude of hydrocarbon synthesis is not hampered, but these hydrocarbons accumulate internally (Soroker et al., 1994). Moreover, preliminary *in vitro* experiments revealed that the gland failed to biosynthesize de novo hydrocarbons from acetate. Lipid passage from hemolymph to postpharyngeal gland cells was previously suggested by Barbier and Delage (1967). Since Philips and Vinson (1980) found no evidence for fatty acid and triglyceride sequestration by the postpharyngeal gland, we suggest a specific sequestration of hydrocarbons. Our results suggest that in *C. niger*, and possibly other ant speices, the postpharyngeal gland might function as a site for hydrocarbon storage, thus explaining the congruency between cuticular and postpharyngeal gland hydrocarbons.

The purpose of hydrocarbon storage in the postpharyngeal gland is still unknown. However, our recent data show the importance of postpharyngeal gland constituents in nestmate recognition (Soroker et al., 1994). Considering discrimination cues, there might be an advantage for localization of such cues in the postpharyngeal gland. In encounters between ants, the first contact is an antennal one. The importance of these contacts for the organization of ant colonies and nestmate recognition was recently discussed by Gordon et al. (1993). During our experiments, antennal contacts were often interrupted by antennal cleaning and licking. Hydrocarbons stored in postpharyngeal glands can be easily smeared over the antennae and other body parts during their cleaning and licking, thus providing the cuticular surface with a fresh supply of individual recognition cues.

In dyadic encounters, we clearly showed a significant transfer of hydrocarbons between nestmates within 24 hr. During the passage of labeled hydrocarbons from one ant to the other in succession, the radioactivity declined, probably due to a dilution of the transferred hydrocarbons with the nonlabeled hydrocarbons of the recipient. The low level of labeled hydrocarbons on the recipient's cuticular surface could be the result of a relatively low level of interaction during these encounters and/or to a short exposure time. In the nest, ants are constantly exposed to a large number of nestmates, whereas our experimental setup was limited to dyadic encounters for 24 hr. Within this time interval, transfer to the recipient's postpharyngeal gland seems to be the major route. It is important to point out that hydrocarbon transfer is not merely a side effect of food transfer. Experiments with starved prelabeled donors presented with satiated recipients showed that the direction of the hydrocarbon transfer occurs independent of the direction of the food flow (Soroker et al., 1994). Nonfeeding trophallaxis was reported earlier for other species of ants (Hölldobler and Wilson, 1990) and in honeybees (Korst and Velthuis, 1982). This implies that it may constitute a method for signal transfer between nestmates in the social insects. When two nestmates meet, interactions such as trophallaxis, licking, body contact, and allogrooming normally take place. The distribution of labeled hydrocarbons in the recipients suggests that all these interactions are involved in hydrocarbon transfer between nestmates. From the results of different sets of encounters, using alternatively blocked or normal donors and recipients, we can conclude that hydrocarbons are mostly transferred from the postpharyngeal gland of one nestmate to the postpharyngeal gland of the other by trophallaxis; other ways of transfer are from the donor cuticle to the recipient postpharyngeal gland and vice versa by licking and from cuticle to cuticle by body contact.

These results fit well with accumulating data for the social distribution of colony odor in ants: from older workers to adopted callows through allogrooming (Morel, 1983; Errard, 1986; Morel and Blum, 1988); from nurses to callow workers (Morel, 1983; Morel et al., 1988; Morel and Vander Meer, 1987); between workers of the same colony by grooming (Crosland, 1989; Franks et al., 1990), and among conspecifics from different colonies during relatively short periods of contact (Breed et al., 1992). Our results also support the evidence that harmonization of the changes in hydrocarbon profile, reported by Provost et al. (1993) and by Vander Meer et al. (1989), can be a result of reciprocal transfer of the hydrocarbons. The "Gestalt model" (Crozier and Dix, 1979; Crozier, 1987; Crosland, 1989), states that the individual specific worker cues are distributed to the other workers via social interactions so that each worker's cuticular chemistry (heritable and environmental components) becomes a mean value representing the colony as a whole. The effect is to level out within-colony variation. The results of the present study provide evidence for the involvement

of the postpharyngeal gland in this process during trophallaxis and licking. The postpharyngeal gland, as a site where the ant's own hydrocarbons are mixed with those of conspecifics, may function as a source for the production of a colony Gestalt odor. The transfer of hydrocarbons between nestmates can partly explain the congruency of hydrocarbon patterns between the two ant species of heterospecific colonies (Errard and Jallon, 1987; Bagnères et al., 1991; Franks et al., 1990; Vienne, 1993) and between the myrmecophile insects and their host as result of the integration process into the ants' nest (Dettner and Liepert, 1994). Indeed, working on heterospecific groups of *Manica rubida* and *Formica selysi*, using the same methodology together with behavioral observations, we recently were able to provide evidence for hydrocarbon transfer between allospecific nestmates (Vienne et al., 1995).

Until the nature of recognition cues is defined, the results of the present research can serve as a model for the transfer of heritable chemical cues between nestmates and shed some light on the function of postpharyngeal glands in ants.

Acknowledgments—We thank Dr. Tovit Simon and Mr. Armin Ionescu for their fruitful comments and advice on the manuscript, and Ms. Naomi Paz for revising the English of the manuscript. We are grateful for the most constructive comments by the anonymous referees. The research was supported in part by grants from the Foundation of Higher Council to V. Soroker, by the Foundation Singer-Polignac (Paris, France) and Tel-Aviv University to C. Vienne.

(Received January 20, 1994; accepted December 1, 1994)

Abstract—Examination of *Heliamphora heterodoxa* and *H. tatei* from the Guayana Highlands of Venezuela reveals that the enol diacetal monoterpene, sarracenin, is the major volatile compound present in the spoon-shaped structures of leaves of the pitchers. In addition, erucamide, phenol, cinerone, phenylacetaldehyde, and a series of methyl esters also occur in extracts of the spoon-shaped appendages of pitchers at the time during which they attract insects.

Key Words—*Heliamphora*, carnivorous plants, pitcher plants, sarracenin, insect attractants.

INTRODUCTION

Carnivorous plants are an extreme example of the diversity of insect–plant relationships (Darwin, 1888). The arthropod prey is attracted, caught, and degraded by specially adapted leaves supplementing the limited amount of nutrients available to these plants (Lloyd, 1942; Rymal and Folkerts, 1982; Juniper et al., 1989).

Plants in the genus *Heliamphora* Benth. (Sarraceniaceae) endemic to the Precambrian sandstone formations ("Tepuy") in Venezuela were not included by Darwin (1888) in the first extensive revision of carnivorous plants, and only recently have they been studied in some detail (Jaffé et al., 1992). These plants possess visual cues (Joel et al., 1985) in addition to special leaf appendages producing chemical secretions in order to attract their prey to the pitcher (Jaffé et al., 1992). Brewer-Carias (1972) was the first to describe the feeding behavior of the plant, reporting that a honeylike fluid produced by nectaries in the spoon-shaped appendage of the leaves attracted a variety of insects.

The macroscopic anatomy of a *Heliamphora* pitcher has been described in considerable detail (Lloyd, 1942). The transformed leaf or pitcher has a nectary or spoon, a bell zone, an intermediary constriction, and a funnel or tank (Jaffé et al., 1992). *Heliamphora* leaves have a reddish coloration on the spoon and the surrounding area, which may further act to attract potential prey items. UV light-reflecting guides also have been reported on *Heliamphora* leaves that probably enhance the attraction of certain insect groups (Joel et al., 1985; Juniper et al., 1989). Sun-exposed *Heliamphora* plants have pitchers of a generally constant size within a given species. They have well-developed spoons that are conspicuously red colored and fragrant. However, in instances where pitcher plants grow in the shade of crevasses, shrubs, or small trees, the appearance of the plants is very different. These pitchers are bright green without the red pigment, the hairs in the upper part of the pitcher are lost, and the size of the spoon is reduced. The bell or upper part of the leaf increases while the tank is reduced, becoming thinner and resulting in the pitcher being larger and more slender (Jaffé et al., 1992).

Pitcher leaves have an optimum age for attracting and capturing prey. For example, we know from field observations that fully developed leaves capture the largest number of prey items (arthropod carcasses) compared to very young or very old leaves (Jaffé et al., 1992).

Heliamphora pitchers attract and trap a large variety of arthropod species. Prey is apparently attracted to the spoon-shaped appendage at the tip of each pitcher, which accumulates a sweet-smelling and highly palatable sticky secretion. The odor of the secretion varies according to the location (Tepuy) or species. This secretion is very attractive to insects in various orders, but ants seem to constitute the main prey items (Gonzales et al., 1991; Jaffé et al., 1992).

The present study identifies several of the chemicals produced by the spoon-like leaf appendage in plants actively attracting insects.

METHODS AND MATERIALS

Nectaries of *Heliamphora heterodoxa* Steyermark were obtained at Auyantepuy, Estado Bolivar, by cutting the spoonlike leaf appendages and collecting

them in 5-ml vials with ethyl acetate or methylene chloride. For laboratory studies, we collected plants of *H. heterodoxa* at Auyantepuy, whereas those of *H. tatei* Gleason were from Aracamuni, Estado Amazonas, Venezuela. Nectaries from plants maintained in the laboratory were collected monthly by placing them in glass vials containing 5 ml of either ethyl acetate or methylene chloride. Each extract was concentrated to approximately 0.5 ml using a gentle nitrogen stream, and 1 μl of each extract was injected into the gas chromatograph (GC) or gas chromatograph–mass spectrometer (GC-MS).

GC and GC-MS analyses were performed in two different laboratories. The first GC-MS data identifying sarracenin were obtained on an LKB-2091 mass spectrometer equipped with a Shimadzu model GC-9A gas chromatograph using a J & W Instrument Co. 20-m × 0.18-mm-ID capillary column coated with their DB-5 methyl silicone. The column was programmed from 50 to 270°C at 10°C/min. The ion chamber was set at 270°C and spectra were run at 70 eV. Other GC-MS data in this laboratory came from a Hewlett-Packard 5890A gas chromatograph programmed from 50 to 275°C at 7°C/min using a 30-m Restec RTX-1 dimethylsiloxane capillary column 0.25 mm ID and 0.25 μm film thickness with data collected on a Finnigan Ion Trap Mass Spectrometer (ITMS) using helium as a buffer gas at 150°C. Sarracenin was also isolated here from the nectary extracts by preparative TLC on silica gel using 50:50 toluene–ethyl acetate, its identity being confirmed by GC-MS on the LKB-2091 GC-MS system.

In the other laboratory, samples from *H. heterodoxa* and *H. tatei* plants grown in the laboratory and *H. heterodoxa* grown in the field were analyzed using a Hewlett Packard model 5971A Mass Selective Detector (GC-MS) fitted with a HP 5908 Series II gas chromatograph and an MS-Chemstation data system. The instrument was operated in scan mode at an ionization energy of 70 eV. The temperature program and column were the same as described above.

In order to evaluate qualitatively the attractiveness of spoons (nectaries) of *H. heterodoxa* and *H. tatei* growing in the laboratory, they were cut from the plants and placed in a closed 1-m^3 chamber. Five house flies were released in the chamber and their landing sites observed for over 2 hr. Spoons were also placed on the foraging table of a *Solenopsis geminata* ant colony, and the number of workers recruited to the spoon were recorded.

RESULTS

Analyses of *H. heterodoxa* spoons from field collections revealed the presence of a number of chemical compounds. Sarracenine (an iridoid) was identified using all of the above systems by comparison with mass spectral data reported by Miles et al. (1976). Figure 1 (top) (from *H. tatei* run on the Hewlett Packard 5971A spectrometer) shows a typical chromatogram. Direct comparison of the retention time and mass spectrum was made using the LKB-2091 GC-MS system

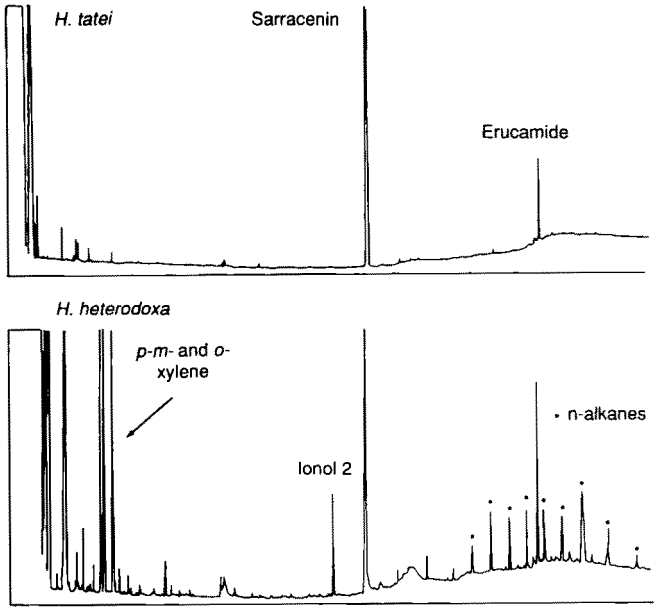

FIG. 1. Gas chromatograms of extracts of attractive spoons from *Heliamphora* pitchers. Samples of *H. tatei* came from CH_2Cl_2 extracts of pitchers growing in the laboratory; the sample of *H. heterodoxa* was an ethyl acetate extract from pitchers collected in the field.

using a sample of sarracenin kindly supplied by Professor J.K. Whitesell, Department of Chemistry, University of Texas. In addition, a sample of sarracenin purified by TLC was examined by gas chromatography–high-resolution mass spectrometry (Edward Larkin, University of Minnesota Mass Spectrometry Service Laboratory) giving a molecular ion at *m/z* 226.0854 (sarracenin $C_{11}H_{14}O_5$, requires 226.0867). Erucamide (13-docosenamide) also seen in Figure 1 as a late-eluting peak, was identified by comparison with its mass spectrum in the Wiley data base. Figure 1 (bottom) also reveals the presence of *o*-, *m*-, and *p*-xylene, 2,6-di-*tert*-butyl 4-ethylphenol (ionol-2), and a series of *n*-alkanes ranging from C_{21} to C_{33}, all identified by comparison with spectra in the Wiley data base. Ionol-2 is a likely contaminant from the solvents since it is employed as a commercial antioxidant.

Further analyses of *H. tatei* on the ion trap mass spectrometer resulted in the identification of phenol and phenylacetaldehyde in approximately equal concentrations. The terpene cinerone, also a significant constituent, was easily identified by its molecular ion at *m/z* 150 and its characteristic mass spectrum with

a base peak at 41 as seen in the NIST-NIH data base (Version 4.5, US Department of Commerce, NIST, Gaithersburg, Maryland). Three esters, methyl palmitate, ethyl palmitate, and methyl linolelaidate were detected in the ethyl acetate extracts.

Using the simple landing-site bioassay (Methods and Materials) the nectaries of the leaves of *H. tatei* and *H. heterodoxa* raised in the laboratory [(as opposed to the field, Jaffé et al. (1992)] did not, in fact, attract flies or ants. GC-MS analyses of three samples of each species of these nonattractive spoons revealed that neither sarracenin nor erucamide were present in these samples. However, on one occasion we did detect nectaries that were attractive to insects. These were found on leaves of a single large *H. tatei* plant grown in the laboratory that produced a sticky secretion on the inside of the spoons similar to that observed in plants in the field (Jaffé et al., 1992). Thus, approximately one third of a spoon was removed from the plant and of 10 observed fly landings, six were on the spoon section. The same section attracted a modest group (> 10) of ant workers during a 15-min period following the placement of the section on the foraging table of the ant colony. Accordingly, the remaining parts of the spoon were extracted with CH_2Cl_2 and is the source of the GC-MS in Figure 1 revealing the presence of sarracenin and erucamide. Figure 1 (bottom) shows a similar chromatogram from field-grown *H. heterodoxa* and these same two compounds are seen to be present. Unfortunately, no samples of wild growing *H. tatei* were available due to difficult and restricted access to the site.

DISCUSSION

The enol diacetal monoterpene sarracenin, first identified in leaf extracts of *Sarracenia flava* (Miles et al., 1976), is seen to be the major volatile compound from the spoon-shaped structure of leaves of *H. heterodoxa* and *H. tatei*. In addition, *o*- and *m*-xylene and phenylacetaldehyde, identified here, were also found in *S. flava* (Miles et al., 1976). Interesting among the other compounds produced by the spoon-shaped appendages of attractive pitchers was erucamide. This compound appears in the literature as an anti-block additive for inks and sticky substances (Nagura et al., 1992; Radosta and Riley, 1991), raising the possibility that plants may produce this compound to endow its nectar secretion with certain advantageous physical properties to entangle or trap insects.

The fact that sarracenin and erucamide were rarely produced in plants growing in the laboratory, and when present, accompanied attraction of insects, suggests they have a biological role. Possible functions could include attraction, trapping, killing, or anesthetizing insects; facilitating feeding on the secretion; maintaining a low viscosity of the secretion; etc. In the case of *S. flava*, Mody et al. (1976) have shown that the insect paralyzing-activity is due to coniine, and it would be interesting to try to detect this base in these plants.

We have previously shown that plants growing in the laboratory lose their attractive properties. This suggests that the morphological changes plants suffer when they lack light in the field (Jaffé et al., 1992) are equivalent to those they suffer when growing in the laboratory. This is in accord with previous proposals (Givinish et al., 1984) suggesting that carnivory is only advantageous to the plant in light-saturated habitats. If plants lose the ability to capture additional nutrients in light-poor environments, they may save energy by not producing attractive chemical secretions or undergoing costly morphological features (Jaffé et al., 1992).

It would be very interesting to know if the ability of the pitchers to attract a large variety of different arthropods (ants, moths, flies, crickets, bees, and scorpions) is due to some or all of the compounds reported in this work.

Acknowledgments—We would like to thank Solange Issa for help with some bioassays. Fran Morales, Carlos Cardenas, and Leonardo Carballo took care of the plants in the laboratory. This work was partially supported by grant BID-CONICIT QF-36.

ON THE APPARENT PERSISTENCE OF DISPARLURE IN THE HUMAN BODY

E. ALAN CAMERON

Department of Entomology
Penn State University
University Park, Pennsylvania 16802

(Received November 18, 1994; accepted December 1, 1994)

Key Words—Gypsy moth; disparlure, *Lymantria dispar*.

Previously I reported on long-term persistence of personal attractiveness to the gypsy moth, *Lymantria dispar* (L.) (Lepidoptera: Lymantriidae) following my exposure to the racemic form of its attractant, disparlure (*cis*-7-8-epoxy-2-methyloctadecane) (Cameron, 1981, 1983). My last known direct contact with disparlure was during the 1977 field season.

For the historical record, I note the following facts. Even though rigorous testing, such as that reported in my 1983 paper, has not been repeated, I have noted during each succeeding field season whether or not attractiveness persisted. Each field season through and including the summer of 1993, male gypsy moths continued to orient to and commonly make contact with me under a variety of conditions; no plausible explanation other than my persisting personal attractiveness to these insects could explain the phenomenon. For example, during casual conversations with colleagues while we were standing in paved parking lots at least tens of meters from the nearest tree, we have observed male moths exhibiting typical response behavior oriented towards my legs and torso but not to other individuals. Subjectively, I suspect a modest diminution of my attractiveness in recent years, but this may only reflect changes in naturally occurring populations.

During the summer of 1994, I participated in trapping tests during which I baited numbers of gypsy moth traps with synthetic lures. Although I took rigorous precautions to avoid direct contact with any of the lures, doubtless at a minimum I inhaled at least small quantities of pheromone. My original "contamination" was through an undetermined route(s), but certainly inhalation would

0098-0331/95/0400-0385$07.50/0 © 1995 Plenum Publishing Corporation

not be excluded. I believe that it reasonably can be argued that my personal "experiment" must be concluded. A few early-season observations in 1994, before my first possible exposure to any disparlure, strongly suggested that I retained attractiveness for 17 years following my last previous known exposure. At a minimum, the period of attractiveness was 16 years, or through the 1993 field season.

(Received June 27, 1994; accepted December 9, 1994)

Abstract—Seasonal changes in the production of primary nutrients (soluble carbohydrates) and secondary metabolites (terpenes, monomeric phenolics, and tannins) in the current needle tissue of Douglas fir were investigated. All four classes of compounds showed significant seasonal changes in concentration during foliage development. Most terpenes increased significantly in concentration from June 11 to August 3, and then showed declining concentrations to September 20. The most dramatic and significant seasonal increases occurred in α-pinene, camphene, and bornyl acetate concentrations. The monomeric phenolics chlorogenic acid, taxifolin glucoside, quercetin galactoside, and those unknown phenolics showed an overall trend of declining in concentration from June 11 through September 20. However, considerable variation between sampling dates in the concentration of these phenolics was noted. Tannin concentration decreased significantly from June 11 to July 9, and then increased in concentration to the September 20 sampling date. Fructose, galactose, glucose, and sucrose tended to decrease from June 11 to September 20. However, significant variation between sampling dates was evident in these compounds as well. Galactose was the major compound in the soluble carbohydrate fraction, amounting to almost 80% of the total concentration throughout the growing season. These data suggest that if phenolics and tannins function as defenses, they would only affect second- and possibly third-instar budworm larvae during the time that these instars mine the buds. Camphene, α-pinene, and bornyl acetate increased in concentration throughout the growing season and may be effective deterrents to the budworm. Both bornyl acetate and

camphene have been shown in field and laboratory studies to increase larval mortality and adversely affect budworm larval growth. Carbohydrates generally act as nutrients that enhance herbivore growth. However, in a previous study, galactose was found to cause reduced budworm larval growth and increased larval mortality.

Key Words—Douglas fir, seasonal variation, carbohydrate, galactose, phenolic, terpene, tannin.

INTRODUCTION

Plant secondary compounds, such as terpenes, monomeric phenolics, and tannins have been reported to confer resistance in plants against phytophagous insects (Cates and Zou, 1990; Lindroth et al., 1988; Rosenthal and Janzen, 1979). Additionally, several types of variation in the production of primary nutrients and secondary metabolites have been suggested as important factors in the interactions between host plants and herbivores (Cates and Zou, 1990; Wagner et al., 1989; Clancy et al., 1988; Denno and McClure, 1983).

The objectives of this study were to investigate the seasonal patterns of variation in individual terpenes, phenolics, soluble carbohydrates, and total tannins in the current year's growth of Douglas fir (*Pseudotsuga menziesii*). As the current year's growth matures, it generally proceeds from a somewhat acceptable food resource to one that adversely affects budworm larval performance. While some terpenes have been found to affect the budworm adversely (Cates and Zou, 1990, Cates and Redak, 1988), little is known about the effect of individual compounds on larval development or of the interaction of carbohydrates and other primary nutrients with secondary metabolites.

METHODS AND MATERIALS

Preparation of Materials. Seven trees of similar age, height, vigor, and crown diameter were selected from a population of about 50 trees at a study site near Island Park, Idaho. These trees were selected because they had been involved since 1985 in all studies at this site dealing with budworm–host tree interactions. Needle samples were collected from four randomly chosen branches in each cardinal direction in the mid-crown of each tree. Two-gram samples of needles were collected from each branch on June 11, June 22, July 9, August 3, and September 20, 1989. After collection, needles were immediately placed in liquid nitrogen, transported to the Chemical Ecology Laboratory, and stored at −80°C.

Isolation and Quantification of Carbohydrate. For each sample, 500 mg frozen tissue were ground with pestle and mortar in liquid nitrogen. The leaf

powder was then extracted with 20 ml methanol and water (80% MeOH–20% water) (2 × 10 ml each). Five milliliters of the MeOH–water extract were placed in a separate vial, 100 μl of the internal standard inositol were added, and then all was taken to dryness. The extract was derivatized by adding 1 ml pyridine, 0.2 ml hexamethyldisilazane (HMDS), and 0.1 ml trimethylchlorosilane (TMCS). Samples were mixed by shaking, kept at 45°C for 10 min, centrifuged (2000 rpm) for 15 min, and then transferred into an autosampler vial using a disposable syringe. Carbohydrate analysis was done on a Hewlett Packard 5890 gas chromatograph equipped with a flame ionization detector. Sample solutions were injected into a 25-m 100% methyl-polysiloxane stationary phase column (0.17 μm film thickness). Temperature programming was as follows: initial temperature was set at 100°C, after 1 min increased to 145°C at a rate of 15°C/min followed by immediate increases of 2.5°C/min to 200°C. Then the temperature was increased at 15°C/min to 245°C, and the oven was kept at 245°C for 15 min. Both cochromatography and GC–mass spectroscopy (GC-MS Hewlett Packard 5995) were used to identify the carbohydrate compounds. Unknown compounds were assigned numbers. The concentration of each compound was determined by area counts and calculated as milligrams per gram fresh tissue. Compounds with area values below 1000 were excluded.

Isolation and Quantification of Terpenes. Frozen tissue (500 mg) was ground with pestle and mortar in liquid nitrogen, and 20 ml of 100% chloroform were added to extract the terpenes (2 × 10 ml each). Five milliliters of the extract were removed and 100 μl of γ-terpene were added as the internal standard. This was reduced to 1 ml, and 2 μl were transferred to an autosampler vial. Temperature programming was as follows: initial temperature was set at 60°C, after 4 min increased to 100°C at a rate of 5°C/min, then followed by an immediate increase of 15°C/min to 220°C, and then held on 220°C for 1 min. Finally, temperature increased at 5°C/min to 250°C and was held at 250°C for 5 min. Concentration of each compound was determined by area counts and calculated as milligrams per gram fresh tissue.

Isolation and Quantification of Tannins. Tannin content was analyzed by the astringency method of Martin and Martin (1984) with the following modifications. Plant needles were carefully separated from bud scales and stem tissue. Approximately 100 mg of frozen leaf tissue were ground in liquid nitrogen in a mortar, extracted in 70% aqueous acetone in a test tube by sonication for 3 min at room temperature, and then contrifuged (4500 rpm) for 10 min. The supernatant was then ready for testing. Hemoglobin solution (2.2 mg of bovine hemoglobin substrate powder type II obtained from Sigma Chemical Corporation per milliliter of phosphate buffer, pH 6.5) was used as the reaction protein. From the Douglas fir needles tannins were extracted, purified, and used as the reference standard.

Isolation and Quantification of Phenolics. Plant needles (300 mg) were

ground in liquid nitrogen in a mortar, and extracted twice each with 10 ml of MeOH–water (80:20). Four milliliters of this solution were then blown dry under nitrogen. One milliliter of MeOH–water (75:25) was then added and sonicated to redissolve the sample. This solution was filtered and injected into a high-pressure liquid chromatograph (Hewlett Packard 1090). HPLC solvents were: solvent A = water–acetic acid (98:2), solvent B = acetonitrile–acetic acid (98:2). Temperature was 50°C, flow was 1 ml/min, and wavelength detection was at 254 nm. The column was a Phenomenex Ultracarb 20, C_{18} reverse-phase 5-μm column. The column was 25 cm × 4.6 mm and fitted with a matching guard column. Compounds were identified by cochromatography, and concentration was calculated as milligrams per gram tissue fresh weight.

Statistical Analyses. Data from all sampling dates were compared using a repeated measures model with season as the fixed factor. From this analysis a determination was made as to whether significant seasonal changes in individual chemicals occurred across all sampling dates (Tables 1, 3, 5, 7; $P < 0.05$). To determine where significant differences ($P < 0.05$) within the growing season occurred, the repeated measures model was used for all possible comparisons taken two at a time (Tables 2, 4, 6, 8). All statistical procedures were accomplished with SAS programs (SAS Institute, 1985).

RESULTS

Seven monoterpenes (α-pinene, β-pinene, camphene, limonene, myrcene, terpinolene, and tricyclene), two sesquiterpenes (α-humulene and longibornyl), and bornyl acetate were identified in the seasonal growth of Douglas fir. Four unknown compounds also were isolated from Douglas fir needles, and tentative identification suggested these to be sesquiterpenes. The major components of the terpene fraction were camphene, bornyl acetate, and α-pinene (79% of the compounds resolved at the July 9 sampling) (Table 1). Total concentration of the volatiles varied significantly between sampling dates within the growing season ($P = 0.006$). Total volatile concentrations in Douglas fir foliage increased significantly from June to August except between the July 9 and August 3 sampling dates and then decreased after the August sampling (Tables 1 and 2). α-Pinene, camphene, limonene, myrcene, terpinolene, tricyclene, and bornyl acetate changed significantly through the growing season. β-Pinene, α-humulene, longibornyl, terpinolene, and unknowns 3, 4, and 5 showed small, and sometimes significant, changes during needle maturation. Unknown 6 decreased throughout the growing season.

Six phenolics were resolved by HPLC in the current year's needles of Douglas fir. Significant changes in the total monomeric phenolic concentration occurred during the growing season ($P = 0.011$) (Table 3). However, the pattern

of variation was the reverse of the volatiles in that the concentrations of phenolic compounds was highest in the early season samples, decreased to the August sample, and then increased slightly by the September sample. Chlorogenic acid did not show a significant change overall (Table 3), but significant decreases did occur from June 11 through August 3, (Table 4). The concentrations of taxifolin glucoside, unknown 1, and unknown 3, along with the major phenolic components quercetin galactoside and unknown 2 decreased significantly during the growing season (Tables 3 and 4).

Condensed tannin, as measured by astringency or by binding capacity of the extract, was significantly higher in swollen buds (June 11), decreased by the July 9 sample, and then increased by the September 20 sampling to concentrations similar to those found in swollen buds (Tables 5 and 6). Although a significant change in tannin concentration was noted over all sampling dates (Table 5), the most significant decreases in tannin occurred between June 11 and July 9 (Table 6).

Concentration of the total soluble carbohydrate fraction, which consisted of five identified compounds, remained at high levels to August 3 and then decreased significantly by September ($P = 0.001$) (Table 7). Galactose made up over 80% of the total carbohydrate concentration (Table 7), and was significantly higher in concentration throughout the growting season compared to all other carbohydrates (Table 7). Galactose concentrations did not change significantly from June to August, but did decrease significantly from August to September ($P = 0.001$) (Table 8). All other carbohydrates showed only small changes throughout the growing season even though some changes were significant (Table 8).

Figure 1 illustrates the seasonal changes for all classes of compounds. At the July 9 sampling date, carbohydrates were highest in concentration (75%), followed by the condensed tannins (14%), terpenes or volatiles (8%), and finally, the monomeric phenolics (3%).

DISCUSSION

The only compounds showing dramatic and consistent seasonal increases were the terpenes α-pinene, camphene, tricyclene, and bornyl acetate (Tables 1 and 2; Figure 1). However, these compounds decreased significantly after the August 3 sampling date. Alternatively, monomeric phenolics decreased from June 11 to August 3 and then significantly increased in concentration to September 20 (Tables 3 and 4; Figure 1). Tannin concentration decreased significantly from June 11 to July 9 and then increased significantly following the July 9 sampling (Tables 5 and 6; Figure 1). Western spruce budworm vigorously feed on the current year's foliage of Douglas fir from June 1 to about mid-July.

TABLE 5. VARIATION IN TANNIN CONCENTRATION WITHIN GROWING SEASON IN DOUGLAS-FIR CURRENT YEAR'S GROWTH[a]

	Sampling date					
	June 11 $\bar{X} \pm$ SE	June 22 $\bar{X} \pm$ SE	July 9 $\bar{X} \pm$ SE	August 3 $\bar{X} \pm$ SE	September 20 $\bar{X} \pm$ SE	P
Tannin	31.99 ± 3.05	18.9 ± 1.65	16.70 ± 1.23	24.32 ± 2.24	27.05 ± 2.77	0.005

[a]A repeated-measures model was used to determine if a significant change occurred in the concentration of tannin across all sampling dates. Table 6 indicates significant changes for tannin for all possible comparisons between dates.

Since monomeric phenolics and tannins decreased in concentration in the current year's growth during this time, they probably are not significant in deterring third- through sixth-instar feeding (Wagner et al., 1989). However, the possibility exists that phenolics or tannins may deter second instars that disperse and mine buds high in tannin and phenolic compounds.

The soluble carbohydrates fructose, glucose, mannose, and sucrose remained at low concentrations during the growing season (Tables 7 and 8). Noteworthy, and the first report we are aware of, is the finding that galactose was produced in significantly higher concentrations during all sampling periods as compared to the other soluble carbohydrates. This occurred despite the significant decrease in galactose that began near the August 3 sampling date and continued to the September sampling (Tables 7 and 8; Figure 1). Coinciding with the decrease in galactose in August is a significant increase in tannin concentration (Tables 5 and 7; Figure 1). Perhaps galactose may be involved in the phenolic pathway being utilized as a source of energy or substrate for various reactions in this metabolic pathway. Because of the high concentration of galactose across the growing season when budworms feed on the current year's growth, we tested this compound against the budworm. Concentrations of total soluble carbohydrates containing galactose in concentrations typical of the current year's foliage, and 6% galactose by itself, resulted in 64–96% and 68% larval mortality, respectively (Zou and Cates, 1994).

The patterns of change in volatiles in the current year's foliage of Douglas fir discussed in this study are similar to those found in other investigations, even though the chemical methods, Douglas fir populations, and sampling dates were different. Since somewhere between 14 and 27 volatiles in the current year's growth of Douglas fir have been reported in various studies, several patterns could be discussed. In this section only the patterns that may impact budworm feeding are addressed for both major and minor components.

[a] Values are milligrams per gram fresh weight. A repeated-measures model was used to determine if a significant change occurred in the concentration of each compound across all five sampling dates. Table 8 indicates significant changes for each compound for all possible comparisons between dates.

As in this study, Gambliel and Cates (1995) and Wagner et al. (1989) found that total terpene concentration increased from June to early July in populations located in New Mexico and Arizona. Individual terpenes, notably α-pinene, tricyclene, camphene, and bornyl acetate, increased within the growing season in the current year's growth of Douglas fir populations from New Mexico (Gambliel and Cates, 1995), Arizona (Wagner et al., 1989) and Idaho (this study). Concentrations of some compounds were similar throughout the growing season in Idaho, Arizona, and New Mexico populations, but other compounds generally showed decreased concentrations in the Idaho (this study) and Arizona (Wagner et al., 1989) populations when compared to the New Mexico population (Gambliel and Cates, 1995). Populations do show several unique changes in concentrations of individual terpenes and volatiles. β-Pinene and myrcene, for example, increased significantly during the June, July, and August sampling dates in the Idaho population reported here, but Gambliel and Cates reported no significant changes within the growing season in the concentration of these two compounds in the New Mexico population. For the Arizona population, β-pinene increased almost sevenfold between the June 6 and 20 sampling dates, and then declined by July 25 to less than a fourth of the highest concentration. Limonene showed little change during the growing season in the current year's growth of the Arizona population (Wagner et al., 1989), but in the Idaho population significant increases occurred through the July 9 date.

Within-season variation in the production of allelochemicals suggests that several compounds may be toxic to the budworm since they were present in high concentrations during the time that the budworm actively feeds on the

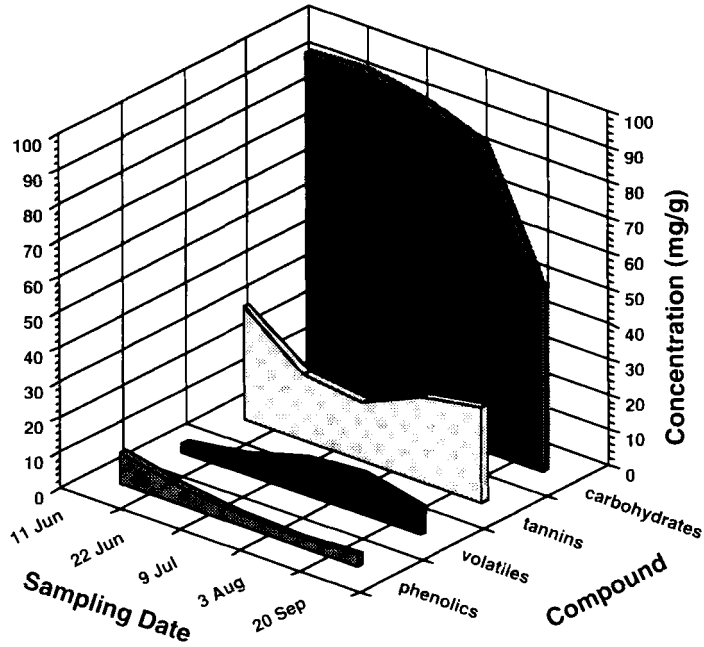

FIG. 1. Seasonal changes in monomeric phenolics, volatiles, tannins, and soluble carbohydrates in Douglas fir from Idaho. Means are plotted. Means and standard errors for the total concentration for each class of compound for each sampling date are found in Tables 1, 3, 5, and 7, respectively.

current year's growth of Douglas fir. For example, seasonal maturation patterns suggest that the volatiles tricyclene, camphene, α-pinene, and bornyl acetate may be associated with resistance in Douglas fir to the budworm. Laboratory and field studies show that camphene and bornyl acetate are highly toxic to several populations of budworm in Idaho, Montana, and New Mexico (Cates et al., 1983; Cates and Redak, 1988; Cates and Zou, 1990; Zou and Cates, unpublished data). Other volatile components enhance this toxicity by forming a mixture of compounds of varying toxicity. In addition, a suite of sesquiterpenes have recently been found to be toxic to the western budworm (Zou and Cates, unpublished data). A new finding is that galactose represents nearly 80% of the total soluble carbohydrate produced by Douglas fir and, either alone or in the presence of a mixture of carbohydrates and terpenes, significantly increased larval mortality (Zou and Cates, 1994).

Significant differences exist among populations both in their qualitative and

quantitative production of individual and total terpenes, as well as different types of terpenes (e.g., sesquiterpenes) (Cates and Zou, 1990, Wagner et al., 1989; Cates and Redak, 1988; Gambliel and Cates, 1995; Zou and Cates, unpublished data). These differences occur during June and July when budworm are feeding heavily on the new foliage. Variation in allelochemics, high concentrations of galactose and other carbohydrates (Zou and Cates, 1994), time of budbreak (Cates et al., 1983), and other foliage parameters (Zou and Cates, 1994, Cates and Redak, 1988), play an important role in creating a diverse, ever-changing mosaic of host resources (among individuals within a population and among populations) that the budworm and other needle-feeding insects regularly encounter. These mosaics are significant to the development of natural stands possessing reduced susceptibility to herbivores and pathogens and must be maintained in current silviculture management schemes (Cates and Zou, 1990; Wulf and Cates, 1987; Carlson et al., 1983).

Acknowledgments—We would like to thank our colleagues James Harper, Stanley Spencer, and Dr. Steven G. Wood for their help in the chemical analysis. Computer facilities used in this study were supplied by Brigham Young University. This research was supported by Professional Development Funds from Brigham Young University and by USDA Competitive Grants Program, Forest Biology Program, grant number 86-02671. We greatly appreciate this support.

SPINED CITRUS BUGS, *Biprorulus bibax* BREDDIN (HEMIPTERA: PENTATOMIDAE), DO NOT DISCRIMINATE BETWEEN ENANTIOMERS IN THEIR AGGREGATION PHEROMONE

DAVID G. JAMES[1,*] and KENJI MORI[2]

(Received October 4, 1994; accepted December 12, 1994)

Abstract—Female spined citrus bugs, *Biprorulus bibax*, in outdoor flight cage tests did not discriminate between synthetic aggregation pheromone blends containing either the racemate, natural (3*R*, 4*S*)-(−) or unnatural (4*S*, 3*S*)-(+) enantiomers of the major hemiacetal component (3*R*, 4*S*, 1′*E*)-3,4-bis(1′-butenyl)tetrahydro-2-furanol. Two to three times as many bugs were attracted to pheromone-baited sites compared to unbaited sites. The racemate of the hemiacetal is easier and less costly to synthesize than the enantiomers and will be used in development of the pheromone as a management tool for this pest.

Key Words—*Biprorulus bibax*, Hemiptera, Pentatomidae, aggregation pheromone.

INTRODUCTION

The spined citrus bug, *Biprorulus bibax* Breddin (Hemiptera: Pentatomidae) is an important pest of citrus in inland southeastern Australia (James, 1989). James and Warren (1989) reported the presence of enlarged dorsal abdominal glands (DAGs) in male *B. bibax*, which produce an aggregation pheromone comprised of linalool, nerolidol, two isomers of farnesol, and a novel hemiacetal identified by Oliver et al. (1992) as *cis*-3,4-bis[(*E*)-1′-butenyl]tetrahydro-2-furanol. The

*To whom correspondence should be addressed.

0098-0331/95/0400-0403$07.50/0 © 1995 Plenum Publishing Corporation

hemiacetal and linalool are major components and comprise 85–90% of DAG secretions. Absolute configuration of the hemiacetal was reported by Mori et al. (1993) to be (3*R*, 4*S*, 1′*E*)-3,4-bis(1′-butenyl)tetahydro-2-furanol.

Teneral and reproductive female *B. bibax* showed attraction in flight cage tests to synthetic blends of aggregation pheromone incorporating the racemate of the hemiacetal (James et al., 1994). Sites baited with synthetic blend attracted 2.3–4.7 times as many bugs as unbaited sites. This pheromone has potential for use in management of *B. bibax* as an aid to population monitoring, but it needs to be determined whether attractivity of the hemiacetal racemate rivals that of the natural enantiomer (3*R*, 4*S*)-(−). The latter is more difficult and costly to synthesize. This paper presents data on the comparative attractancy of natural and unnatural enantiomers and the racemate of the hemiacetal in pheromone blends to *B. bibax*.

METHODS AND MATERIALS

A large (6.6 × 3 × 1.8-m) shade-cloth-covered, steel-framed structure was used as an outdoor flight cage. The cage was situated in a sunlit, grassy area at the Yanco Agricultural Institute and contained two potted citrus trees (var. Valencia orange) of the same age (3 years) and size (1.5 m) at either end. The attractivity of three blends of *B. bibax* aggregation pheromone containing either the racemate or natural (3*R*, 4*S*)-(−) or unnatural (3*S*, 4*R*)-(+) isomers (both ca. 100% enantiomeric purity) of the major hemiacetal component, (3*R*, 4*S*, 1′*E*)-3,4-bis(1′-butenyl)tetrahydro-2-furanol, was evaluated in three experiments, each conducted over four days during February–March 1994. The racemate and two isomers were synthesized in Japan (Mori et al., 1993) and shipped to Australia. In each blend, 17 mg (46%) of the hemiacetal was used with 15 mg (40%) of linalool, 4.5 mg (12%) of farnesol, and 0.5 mg (2%) of nerolidol. This component ratio approximates that found in male DAG extracts and extracts from airborne volatiles of live calling males (James et al., 1994). Linalool, farnesol, and nerolidol (all racemic mixtures) were obtained from Sigma-Aldrich Pty Ltd (Castle Hill, New South Wales). Blends were mixed with 1 ml of heptane in a plastic film-capped glass vial. *B. bibax* shows no response to heptane alone (James et al. 1994). The plastic film was pierced with a pin and a single vial was attached to the trunk of the trees and hidden from direct sunlight to retard evaporation. A vial containing 1 ml of heptane only was placed on the other tree. A new sample of pheromone was used after two days. Baited and unbaited trees were alternated daily. Forty to 50 reproductively active female *B. bibax* collected from district orchards were released in the center of the flight cage in each experiment. An equal number of fruit (oranges and lemons) was placed in each tree to provide food for the bugs. A daily count of bugs on the baited and unbaited trees was conducted at 16:00 hr. Traps were not used

because a type suitable for *B. bibax* has not yet been developed. After counting, bugs were released again in the center of the cage. Records were kept of daily temperature and weather conditions. A limited supply of synthetic pheromone prevented replication of individual experiments, although results for each of the four test dates were treated as replicates.

RESULTS AND DISCUSSION

Weather conditions during the three experiments were always favorable for flight activity of *B. bibax*, with daytime temperatures ranging from 20 to 32°C. Significantly greater numbers of *B. bibax* were attracted to the pheromone-baited tree regardless of the enantiomeric status of the hemiacetal component (Table 1). Two to three times as many bugs were counted on the pheromone-baited tree as on the unbaited tree throughout the experiments. Attraction ratios (baited–unbaited) did not differ significantly between the three experiments ($P < 0.05$, anova). Although linalool appears to occur in *B. bibax* pheromone as a single enantiomer (*S*)-(+) (J. Oliver personal communication), attraction of *B. bibax* in this study to blends using racemic linalool suggests chirality of this compound is also unimportant.

These data indicate that no advantage would be gained in using the natural enantiomer (3*R*, 4*S*)-(−) instead of the racemate of the hemiacetal in *B. bibax*

TABLE 1. ATTRACTIVITY OF FEMALE *B. bibax* IN FLIGHT CAGE TESTS TO AGGREGATION PHEROMONE CONTAINING RACEMATE, NATURAL ENANTIOMER, OR UNNATURAL ENANTIOMER OF MAJOR HEMIACETAL COMPONENT

Enantiomeric status of hemiacetal in pheromone	Female *B. bibax* responding (*N*)	
	Total	Mean ± SE/day
Experiment 1		
Racemate	82.0	20.5 ± 1.1[a]
Heptane	30.0	7.5 ± 0.6
Experiment 2		
Natural enantiomer (3*R*,4*S*,1′*E*)-3,4-bis(1′-butenyl)tetrahydro-2-furanol	44.0	11.0 ± 1.6[a]
Heptane	16.0	4.0 ± 0.3
Experiment 3		
Unnatural enantiomer (4*S*,3*S*,1′*E*)-3,4-bis-(1′butenyl)tetrahydro-2-furanol	61.0	15.2 ± 3.9[a]
Heptane	24.0	6.0 ± 1.5

[a]Significantly greater than heptane treatment, $P < 0.05$ (ANOVA).

pheromone in management of this pest. The natural enantiomer is more difficult and costly to synthesize than the racemate (Mori et al., 1993). Interestingly, the unnatural enantiomer of the hemiacetal was also bioactive, indicating that *B. bibax* does not discriminate between stereoisomers, as is the case for the German cockroach and its sex pheromone (Mori et al., 1981, Mori and Takikawa, 1990).

Acknowledgments—We thank Masayasu Amaike for preparation of pheromones and T. Hasegawa Co. Ltd. and the Australian Horticultural Research and Development Corporation for financial support. Renay Heffer and Merv Graham (Yanco) are thanked for technical support.

(Received July 11, 1994; accepted December 16, 1994)

Abstract—*Diaeretiella rapae* (M'Intosh) (Hymenoptera: Aphidiidae) is a parasitoid of several aphid species, including the Russian wheat aphid (RWA), *Diuraphis noxia* (Mordvilko), and the cabbage aphid (CA), *Brevicoryne brassicae* (L.). The response of mated *D. rapae* females to odors from wheat, cabbage, and plant-host complexes was investigated using a four-choice olfactometer. Experienced parasitoids, but not inexperienced females, responded positively to odors of the wheat-RWA complex in a no-choice test. In choice tests, experienced parasitoids did not respond to odors of uninfested cabbage and wheat leaves, but did respond positively to aphid-infested plants and to aphids alone. The response of *D. rapae* to the cabbage-CA complex and to CA alone was significantly greater than to the wheat-RWA complex and RWA alone, suggesting an innate odor preference for crucifer-feeding aphids.

Key Words—Kairomone, biological control, cabbage, wheat, *Diuraphis noxia*, *Brevicoryne brassicae*, olfactometer, infochemical, preference, host plants.

INTRODUCTION

Chemical orientation plays an important role in host-habitat location and host location by insect parasitoids (Vinson, 1981; Weseloh, 1981). The olfactory

*To whom correspondence should be addressed.

0098-0331/95/0400-0407$07.50/0 © 1995 Plenum Publishing Corporation

cues eliciting the searching process may originate from the host plant, the host, or a combination of plant and host factors (Vet and Dicke, 1992). The utility of olfactory cues depends on their reliability in indicating herbivore presence, identity, accessibility, suitability, and detectability (Steinberg et al., 1993; Vet and Dicke, 1992). Therefore, the information value of odor stimuli from the host and host plant is important to aid the parasitoid in selecting a suitable host.

Olfactometry has been widely used to demonstrate responses of aphid parasitoids to host food plant odors and their aphid hosts (Bouchard and Cloutier, 1985; Powell and Zhang, 1983; Read et al., 1970; Wickremasinghe and van Emden, 1992). In a few studies, flight responses of aphidiids to host plants and hosts have been investigated in wind tunnels (Grasswitz and Paine, 1993; Guerrieri et al., 1993; Sheehan and Shelton, 1989a) or in the field (Sheehan and Shelton, 1989b; Titayavan and Altieri, 1990). Some of these studies have addressed the relative value of volatile infochemicals from the aphid host plant, the aphid host, and the plant-aphid complex (Grasswitz and Paine, 1993; Guerrieri et al., 1993; Wickremasinghe and van Emden, 1992).

Diaeretiella rapae (M'Intosh) (Hymenoptera: Aphidiidae) parasitizes over 30 aphid species on a variety of plants (Mackauer and Stary, 1967), including the cabbage aphid, *Brevicoryne brassicae* (L.), a worldwide pest of cruciferous crops, and cereal aphids such as the Russian wheat aphid (RWA), *Diuraphis noxia* Mordvilko. Various strains of exotic *D. rapae* have been released in the United States for establishment as a natural enemy of the RWA (McKinnon et al., 1992). Some researchers (e.g., Sheehan and Shelton, 1989a) indicate that the cabbage aphid (CA) is the preferred host of this parasitoid, but olfactory or ovipositional preference of this generalist aphid parasitoid has not been directly tested. This study examines the role of experience and odor preferences of mated *D. rapae* females in choice tests to odors from cabbage and wheat, the respective plant-aphid complexes, and the two aphid species alone. An understanding of the olfactory preference of *D. rapae* between the cabbage and wheat systems will aid in our understanding of host-finding behavior, which in turn will be important in the design of programs to manage, manipulate, or select potential parasitoids in biological control.

MATERIALS AND METHODS

The *D. rapae* females used in all tests were a strain (T92008) obtained from China supplied by the USDA/ARS Plant Science Research Laboratory. All parasitoids were reared continuously on the RWA and the TAM-101 or Mit cultivars of winter wheat (*Triticum aestivum* L.). The colony was maintained in a controlled environment chamber at 25°C under a 16L:8D photoperiod. Both the winter wheat and cabbage, *Brassica oleracea* L., were reared in a

greenhouse under a natural light regime. The CA and the RWA were reared on their respective host plants in a cage in a greenhouse under a natural light regime.

The olfactometer used was similar to that designed by Vet et al. (1983) for testing odor responses of small Diptera and Hymenoptera (Bouchard and Cloutier, 1985; De Jong and Kaiser, 1991; Eller et al., 1988; Turlings et al., 1989, 1990). Illumination was provided by a 20-W circular fluorescent lamp (3700 lux) 20 cm above the olfactometer. An airflow meter (Cole-Parmer: P04-N112-02 G) maintained an airflow rate of 300 ml/min through each of the four quadrants. A vacuum pressure pump, placed on the floor, pulled room air through charcoal filters before entering the olfactometer chamber and then was vented into a fume hood. Odor fields were visualized using smokes generated by NH_4OH and HCl. The boundaries of each odor field were marked on the external surface of the olfactometer.

General Experimental Procedures. Parasitized aphids (i.e., mummies) were cut from the wheat plants and isolated in gelatin capsules. Upon emergence, individual parasitoid females were mated with individual males and, in the choice tests, were allowed to oviposit in 7–12 aphids on a plant leaf for 20 min. The parasitoids were then fed honey water and isolated into glass vials prior to testing. All parasitoids were tested within 1 hr of this postemergence treatment.

Test materials were put into vials of two opposite arms, and the two other arms had vials of water to act as humidified air controls. The experimental design of the six choice tests are depicted in Table 1. The odor sources for tests 1 and 2 were two to three small cabbage leaves and 20 tillers of wheat leaves. The odor sources for tests 3 and 4 were two to three cabbage leaves with approximately 250 CA and four to six tillers of wheat with about 250 RWA. Such densities reflect heavy infestations in the field. The cut edge of intact

TABLE 1. EXPERIMENTAL PROTOCOL OF CHOICE TESTS CONDUCTED IN FOUR-ARM OLFACTOMETER

Test	Pretreatment oviposition experience	Odor sources[a]	Number tested

4	CA and cabbage	infested wheat and cabbage leaves	44
5	RWA and wheat	CA and RWA	30
6	CA and cabbage	CA and RWA	30

[a]Controls were humidified air in all tests.

leaves was submerged in water to minimize the release of volatiles from the cut stem base (Turlings and Tumlinson, 1991). The odor choices for tests 5 and 6 were 200 CA and RWA that had been removed from their host plant 45 min prior to testing.

Experiments were conducted during the mid-morning through mid-afternoon (4–9 hr after lights on) at a room temperature of 22.5°C. Parasitoids to be tested were introduced singly into the olfactometer exposure chamber through the exit port in the floor. Once in the chamber, the parasitoids were given 5 min to make their choice between the four air fields. The amount of time spent in each odor field and the number of final choices were recorded for each parasitoid. A final choice was recorded when a parasitoid entered a treatment arm and remained there for at least 10 sec. Once a final choice was made, the remaining time (up to 5 min) was added to that odor field. A positive response was indicated by a significantly greater percentage of time spent in the test fields over the controls, as indicated by the Kruskal-Wallis test (SAS Institute, 1985).

Prior to testing the odor sources, a system bias check was conducted on the olfactometer system by testing the responses of 60 parasitoids to humidified air in all four quadrants. No differences in mean time spent per quadrant were found, and no final choices were made. Before conducting the choice tests, the role of ovipositional experience on the response of *D. rapae* to the wheat–RWA complex was examined in two tests. The protocol for these tests was identical to that used in the choice tests except for the following differences: (1) experienced females were housed with wheat and RWA for 24 hr and inexperienced females were kept in cages without wheat and RWA; (2) the odor source consisted of four tillers of TAM-101 winter wheat (one tiller was finely chopped) and 100 RWA in each of two quadrants with the remaining two quadrants serving as humidified air (Bouchard and Cloutier, 1985); (3) 20 inexperienced and experienced females (four replicates each) were tested singly for 10 min each in the olfactometer; and (4) once a final choice was made the test was completed, and the remaining time was *not* added to the chosen quadrant. Data from the two identical treatments used in opposite quadrants were combined, resulting in a two-group design. The mean time spent in each quadrant was analyzed using the Wilcoxon test (SAS Institute, 1985).

The olfactometer chamber was washed thoroughly with detergent and warm water and rinsed in 75% alcohol at the end of each day of testing or after a set of replicates (five to seven test females).

RESULTS

Only the experienced females showed a significant response to the wheat–RWA complex in the no-choice 10-min tests (Table 2). Seven of the 20 experienced females and no inexperienced females made a final choice to the wheat–

[b] Mean significantly different from control by Wilcoxon test (P = 0.025).

RWA odor. In the first choice test, *D. rapae* with ovipositional experience on RWA did not show any significant response to either the uninfested cabbage leaves or wheat leaves (Kruskal-Wallis P = 0.2671) (Figure 1A). The reciprocal test 2, using parasitoids with experience on CA, also did not show a positive response to the two plant species (Kruskal-Wallis, P = 0.09) (Figure 1B). However, in the subsequent tests 3 and 4, experienced parasitoids responded positively to aphid-infested leaves (Figure 2). The RWA-experienced parasitoids demonstrated a significantly greater response to infested cabbage leaves than to infested wheat leaves (Kruskal-Wallis P = 0.0001) (test 3, Figure 2A). An odor preference for infested cabbage leaves was also observed in test 4 using CA-experienced parasitoids (Kruskal-Wallis P = 0.01) (Figure 2B). The type of aphid ovipositional experience also did not affect their response in aphid choice tests 5 and 6, as parasitoids responded preferentially to CA over RWA (Figure 3).

DISCUSSION

Volatiles from host plants are commonly found to be the sources of attractancts for parasitoids (Nordlund et al., 1988; Powell and Zhang, 1983; Vet and Dicke, 1992). Read et al. (1970) suggested that female *D. rapae* locate the habitat of potential host aphids by an olfactory response to volatile chemicals released by aphid host plants. Sheehan and Shelton (1989a) demonstrated that *D. rapae* flew upwind in response to collard odor, but less so to a nonhost plant, the potato. Evidence indicates that *D. rapae* locates aphids on crucifers by responding to mustard oils, especially allylisothiocyanate (Read et al., 1970; Titayavan and Altieri, 1990), although Sheehan and Shelton (1989b) did not obtain significant attraction to ecologically relevant concentrations of this compound in the field.

Wheat volatiles may also be important plant synomones for parasitoids (Buttery et al., 1985). Wickremasinghe and van Emden (1992) found three

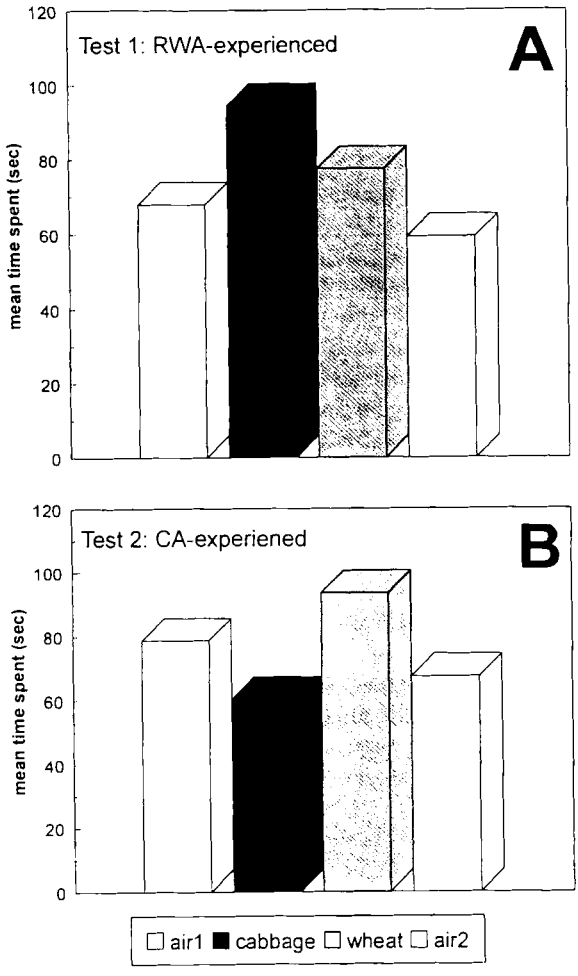

FIG. 1. Mean time spent (seconds) by *D. rapae* females in odor fields of cabbage and wheat leaves and humidified air controls in 5-min tests: (A) test 1 using 60 RWA-experienced females (not significantly different, Kruskal-Wallis, $P = 0.2671$); (B) test 2 using 41 CA-experienced females (not significantly different, Kruskal-Wallis, $P = 0.09$).

volatiles compounds emanating from wheat leaves to be attractive to the cereal aphid parasitoid *Aphidius rhopalosphi*. Females of the generalist aphid parasitoid *Lysiphlebus testaceipes* given postemergence experience with wheat were attracted to uninfested wheat plants in a wind tunnel study (Grasswitz and Paine,

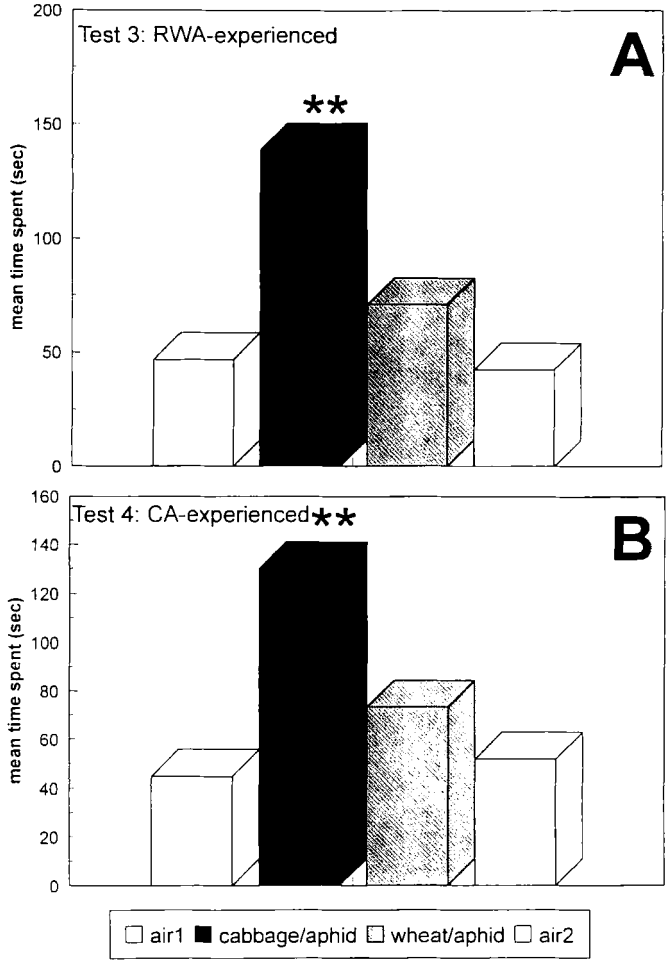

FIG. 2. Mean time spent (seconds) by *D. rapae* females in odor fields of cabbage–CA and wheat–RWA complexes, and humidified air controls in 5-min tests: (A) test 3 using 85 RWA-experienced females (** significantly different, Kruskal-Wallis, $P = 0.0001$); (B) test 4 using 44 CA-experienced females (** significantly different, Kruskal-Wallis, $P = 0.0134$).

1993). Consequently, it is a bit surprising that in our study female *D. rapae* were not significantly attracted to the odor from either uninfested cabbage or Mit winter wheat. However, differing experimental designs may not allow direct comparisons of studies.

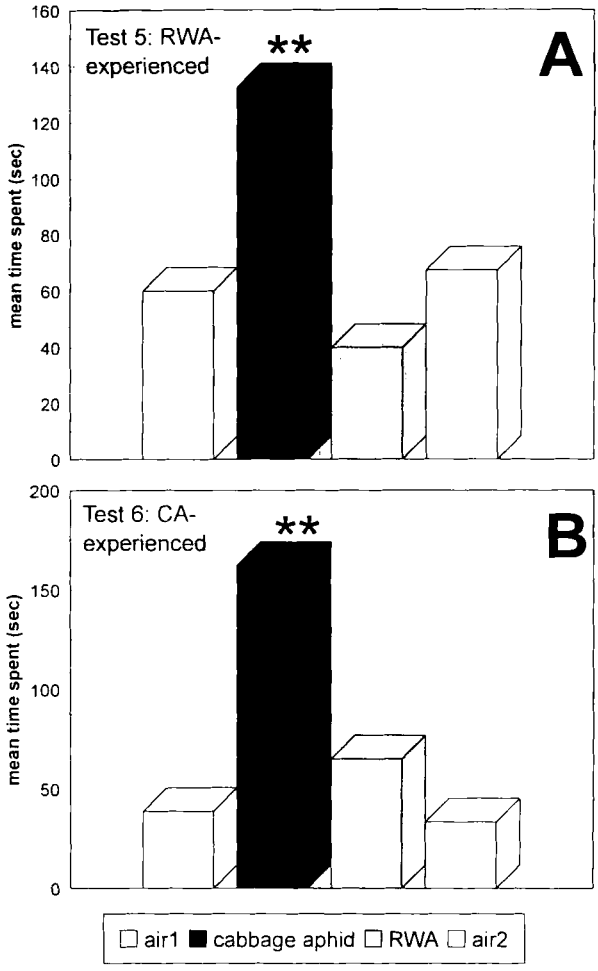

FIG. 3. Mean time spent (seconds) by *D. rapae* females in odor fields of CA and RWA, and humidified air controls in 5-min tests: (A) test 5 using 30 RWA-experienced females (** significantly different, Kruskal-Wallis, $P = 0.0001$); (B) test 6 using 30 CA-experienced females (** significantly different, Kruskal-Wallis, $P = 0.0001$).

The olfactometer used by Read et al. (1970) was a Y-tube design, and tests were limited to one plant odor versus a blank, with no choice tests between two plant materials. Sheehan and Shelton (1989a) also did not offer plant choices to their test insects. Although Wickremasinghe and van Emden (1992) performed

extensive choice tests in their modified Y-tube olfactometer, they introduced 12–40 female parasitoids simultaneously, which may affect their olfactory responses. Perhaps the differential attraction to either plant odor is not strong enough to be discriminated in our olfactometer system. Indeed, the aphid parasitoid *L. testaceipes* responded nearly equally to host plant odor and to host aphid odor in a choice test in a Y-tube olfactometer (Schuster and Starks, 1974).

Another possible reason for the differing results might be that we did not cut the cabbage plants, as did Sheehan and Shelton (1989a), so as to minimize release of plant volatiles. Aphid feeding typically does not cut the tissue. Other studies have shown that aphid parasitoids are not always attracted to plants of their host. Bouchard and Cloutier (1985) found no evidence that female *Aphidius nigripes* responded to host-plant foliage volatiles. Host plants alone did not elicit oriented flight in a related aphid parasitoid, *Aphidius ervi*, in a wind-tunnel study (Guerrieri et al., 1993).

The infested cabbage plants in our study stimulated a very strong response by *D. rapae*, results that are consistent with studies on other parasitoids. More *A. ervi* females exhibited oriented flight to the bean–aphid complex than to the host-damaged plants, aphids alone, or plant alone (Guerrieri et al., 1993). The six species of aphid parasitoids tested by Wickremasinghe and van Emden (1992) each showed an odor preference to the plant–aphid complex over the host plant alone. In a study of *Microplitis croceipes* (Cresson) in a four-choice olfactometer, Eller et al. (1988) found that parasitoids responded in a dose-dependent fashion to volatiles from the plant–host complex and oviposition experience enhanced their response. Furthermore, Steinberg et al. (1993) showed that the plant–host complex was the most attractive odor source for parasitoids in their experiment with *Cotesia glomerata* (L.). Other parasitoids are known to discriminate between volatile chemicals emitted by uninfested plants and plants infested by a particular herbivore species (Vet and Dicke, 1992).

Cabbage aphids alone elicited a response nearly as strong as the cabbage–CA complex. Aphid odor alone has been shown to stimulate olfactory responses (Bouchard and Cloutier 1984, 1985; Powell and Zhang, 1983; Read et al., 1970). The possibility exists that honeydew, a known contact kairomone for aphid parasitoids (Budenberg, 1990; Grasswitz and Paine, 1992; Wickremasinghe and van Emden, 1992), may contain attractive volatile chemicals. However, some experiments have not demonstrated a positive response to aphid odor alone (Guerrieri et al., 1993) or to washed aphids (Wickremasinghe and van Emden, 1992). Read et al. (1970) demonstrated that *D. rapae* females responded to CA freshly removed (15 min prior to test) from collards, but not to CA removed from host plants 24 hr prior to the test, suggesting that the positive response may be due to substances from the plant and not from the aphids. Perhaps our 45-min time was not sufficient to allow the cabbage–CA complex compounds to dissipate. Our results, together with those of Read et al. (1970)

and Sheehan and Shelton (1989a,b), suggest that the source of attractant to *D. rapae* females may originate from the interactions between plants and feeding aphids, i.e., herbivore-induced synomones (Vet and Dicke, 1992).

Although experienced parasitoids did respond positively to the wheat–RWA complex when given no choice of another plant–aphid complex (Table 2), this response greatly decreased in the presence of odor from the cabbage–CA complex. Experienced *D. rapae* preferred infested cabbage over infested Mit winter wheat despite their ovipositional experience. Usually such postemergence exposure tends to enhance parasitoid responses to the experienced host or plant (Vet and Dicke, 1992; Sheehan and Shelton, 1989a, Turlings et al., 1989, 1990). Our data indicate that *D. rapae* has a strong innate odor preference to the CA and the cabbage–CA complex that is not easily overridden by preemergence (i.e., rearing) or postemergence (i.e., oviposition) experience. Perhaps the odor preference for CA is due to the copious amounts of honeydew produced by CA on cabbage in comparison with the relatively minute quantities produced by RWA on wheat. This odor preference may also reflect an innate host preference for CA and other crucifer-feeding aphids, as has been suggested by Sheehan and Shelton (1989a). However, various strains of *D. rapae* may differ in their host preferences. Furthermore, laboratory rearing of the parasitoid on RWA and wheat may decrease the population's sensitivity to cues from the reared host or in some way alter searching efficiency (Geden et al., 1992).

Odor preference is an important factor to consider when attempting to release this generalist aphid parasitoid for control of the RWA and other cereal aphids. Testing of ovipositional preference in laboratory and field experiments would further clarify the host preferences of this generalist aphid parasitoid. Analysis and testing of collected volatiles from plants, aphids, and the plant–aphid complexes are needed to clarify the relative importance of these infochemicals in the host-finding mechanism of *D. rapae*.

Acknowledgments—We are grateful for the assistance of Brian Jones and Ryan Kirk (USDA/ARS) in rearing aphid and parasitoid colonies. Nathan Nelson (ORU Biology Department) conducted several preliminary trials to improve the olfactometer bioassay. Drs. Peter Landolt, Jang-Hoon Lee, and Ray Eikenbary made several suggestions that enabled us to improve the manuscript. This article reports the results of research only. ANTIMICROBIAL ACTIVITY OF DOGWOOD FRUITS (*Cornus drummondii*) FROM WINTER FOOD CACHES OF EASTERN WOODRATS (*Neotoma floridana*)

DIANE M. POST* and JAMES E. URBAN

Manhattan, Kansas 66506-4901

(Received July 5, 1994; accepted December 23, 1994)

Abstract—Post-harvest loss of resources to microbial competitors affects a number of species of animals, and many of them have evolved behaviors that reduce the likelihood of such loss. We previously described the inhibition of *Bacillus psychrophilus* by dogwood fruits (*Cornus drummondii*), which can comprise a significant portion of the winter food cache of the eastern woodrat (*Neotoma floridana*). The present study is a further investigation of the ability of dogwood fruits to inhibit growth of *B. psychrophilus*. Additionally, we tested the antimicrobial activity of dogwood fruits on *Escherichia coli* and *Staphlococcus aureus*. Results of our study indicate that fresh fruits inhibit the growth of *B. psychrophilus* and *S. aureus* but not *E. coli*. However, fruits taken from woodrat dens after four and six months storage inhibited growth of all three species of bacteria. Further, the strength of inhibition increased over the test period. We suggest the presence of an inhibitor allows woodrats to compete effectively for a valuable and limited food resource.

Key Words—Caching, antimicrobial activity, *Neotoma floridana*, eastern woodrat, *Cornus drummondii*, dogwood fruit, *Escherichia coli*, *Staphlococcus aureus*, *Bacillus psychrophilus*

INTRODUCTION

Many animals, including humans, that larderhoard food, experience post harvest loss of food resources to microbial competitors. Acquisition of a larderhoard requires a significant investment of resources and loss could have an important negative impact on the hoarder. For example, loss of stored fruit and vegetable

*To whom correspondence should be addressed.

0098-0331/95/0400-0419$07.50/0 © 1995 Plenum Publishing Corporation

crops has a significant economic impact on human populations, particularly those of less-developed tropical countries (Lund, 1981; 1983). Nonhuman species that larderhoard may also experience loss of resources to microbes (Smith and Reichman, 1984; Vander Wall, 1990), and some have evolved prestorage food-handling behaviors that reduce the likelihood that food stores will be lost to microbes. For example, squirrels (*Tamiasciurus hudsonicus*) (Smith, 1968) and pikas (*Ocotona princeps*) (Connor, 1983) allow foods to dry before they are stored. Clark's nutcracker does not store spoiled food items (Vander Wall and Balda, 1977).

Other species have developed behaviors that act in the poststorage period to reduce loss of stored food to spoilage by microbes. In a laboratory study, kangaroo rats moved seeds between areas with different humidity levels in response to the amount of mold present on the seeds, a behavior that has been suggested to limit loss of resources to microbes (Reichman et al., 1986; but see Frank, 1988).

Our previous investigation of caches from eastern woodrat (*Neotoma floridana*) dens showed most cache foods harbored *Bacillus psychrophilus* and in relatively high amounts as compared to the amount of other bacteria present. However, the bacterium was absent from dogwood (*Cornus drummondii*) fruits (Post and Urban, 1993). The absence of *B. psychrophilus* was intriguing because as a psychrophile, *B. psychrophilus* should have a competitive advantage over other bacteria in woodrat caches. Woodrats begin to store food in early fall and rely on stored resources to supply a portion of the winter diet. Thus, a bacteria that is cold-tolerant should have a competitive advantage over other microbes for access to food stored by eastern woodrats.

In our initial screening of woodrat cache contents for microbes, our storage procedures exposed dogwood fruits to the den environment, but prevented loss of sample material to the resident woodrat (Post and Urban, 1993). However, we were unable to determine whether the absence of *B. psychrophilus* on dogwood fruit was a consequence of the effects of the fruits or a consequence of passive treatment of the fruits by air, liquid, dust, or soil particles within the den. In the present study, we further examined the relationship of cached dogwood fruits and microorganisms and have demonstrated an antimicrobial activity of dogwood fruits on *B. psychrophilus*, *Staphlococcus aureus*, and *Escherichia coli*.

METHODS AND MATERIALS

Samples of dogwood fruits (and attached stem material) were collected on September 8, 1993, and air dried in the laboratory until October 4, 1993. After drying, fruits were packaged in tubes constructed of 11.4 × 3.8-cm PVC pipe

or 8.8 × 5-cm plastic bottles. Pipes and bottles were covered on each end with 2-mm aluminum wire screen. Groups of two tubes and one bottle were then placed in 1.5 × 1.5-cm wire mesh containers, which resulted in six packages of samples. Containers of sample tubes were inserted into woodrat dens (one sample container per den) in the space within the den where the cache material was located. Dens were located at a site approximately 20 km south of Manhattan, Kansas, which consisted of hedgerow habitat surrounded by agricultural land. Sets of sample tubes were removed from each of three woodrat dens on January 10, 1994. The three remaining sets of tubes were removed on March 10, 1994. Fruits retrieved from woodrat dens in January and March were held at 5°C for 24 hr or less prior to being tested for antimicrobial activity. Samples of fresh dogwood fruit and stem material were collected into new plastic food bags (a relatively sterile environment) from trees within a 10-km radius of Manhattan, Kansas on October 4, 1993. Fruits were held at 5°C for 24 hr or less after harvesting and were then tested for antimicrobial activity. Samples that were collected to assess antimicrobial activity, and samples that were collected and stored in dens were gathered after fruits had ripened.

Inhibition assays were modeled after the Bauer-Kirby qualitative antibiotic susceptibility assay (Bauer et al., 1966) routinely used in clinical laboratories. Actual assays were begun by spreading 0.2-ml suspensions of individual bacterial species (which had been adjusted to a density of 5.0×10^7 cells/ml) onto an agar surface in 150 × 15-mm Petri dishes (Falcon 1058, Becton Dickinson Labware, Lincoln Park, New Jersey). The bacteria tested were *Bacillus psychrophilus* [a natural isolate as described in Post and Urban (1993)] and *Staphlococcus aureus* (a gram-positive bacteria; strain S_6 obtained from J. Iandolo, College of Veterinary Medicine, Kansas State University, Manhattan) and *Escherichia coli* (a gram-negative bacteria; American Type Culture collection 25922). *B. psychrophilus* and *E. coli*, were grown on R2A agar and *S. aureus* was grown in TSA agar. R2A agar (Difco, Detroit, Michigan) is described in Post and Urban (1993) and TSA agar consists of 15 g Tripticase, (Difco, Detroit, Michigan) 5 g Phytone, (Difco, Detroit, Michigan), and 5 g NaCl per liter (pH 7.3). Cultures on R2A agar were incubated at 23°C and *S. aureus* was incubated at 30°C.

While incubated plates dried and equilibrated, fruits and receptacles obtained from stem material were prepared for assay. A preliminary study showed that inhibitory activity of dogwood fruit occurred in the area of the receptacle (the site on the stem where the fruit is attached). Therefore, fruits were placed on inoculated plates such that the part of the fruit previously attached to the receptacle was in direct contact with the agar surface of the inoculated medium. The receptacle was severed from the stem and placed in contact with the agar surface. Forceps and scissors that had been rinsed with 95% ethanol and flamed were used to separate and manipulate the fruit and receptacle.

To serve as both standard and control, antibiotic sensitivity disks were placed on prepared and inoculated dishes identical to those used for the inhibition study. Antibiotic sensitivity disks containing ampicillin (10 μg/7-mm-diameter paper disk), chloramphenicol (30 μg/7-mm-diameter paper disk), novobiocin (30 μg/7-mm-diameter paper disk), streptomycin (10 μg/7-mm-diameter paper disk), and tetracycline (30 μg/7-mm-diameter paper disk) were used.

Plates containing fruit bodies, stem nodes, or antibiotic disks were incubated for 48 hr, after which they were examined for zones of growth inhibition. Use of zones of growth inhibition is a typical method used to assess antibiotic activity (Bauer et al., 1966; Ziaka, 1988). When inhibition was observed, the diameter of the zone was measured with a clear plastic ruler with metric markings. The ruler was always held such that the diameter measure passed through the center of the disk, node, or fruit body. Data were analyzed by use of the General Linear Model procedure on SAS (SAS Institute, Cary, North Carolina) computer software. The analysis tested the null hypothesis of no difference in the diameter of the zone of inhibition between testing periods.

RESULTS

Results of our experiments showed no inhibition of bacterial growth by dogwood fruit in any period for any of the bacteria tested. Receptacles from fresh dogwood stem material showed inhibition of *B. psychrophilus* and *S. aureus*. However, no inhibition of *E. coli* by fresh material (Figure 1) was found. Receptacles from dogwood stems taken from woodrat dens in January and March 1994 showed inhibition of growth of all three bacteria.

For *Bacillus psychrophilus* inhibition of growth increased over the test period ($F = 4.03$, $df = 3$, $P = 0.01$). The strength of the inhibition was greater in January than October ($P = 0.001$) and greater in March than October ($P = 0.001$). There was no difference in inhibition noted between January and March ($P = 0.30$). An increase in inhibitory activity was noted for *Staphylococcus aureus* between all three test periods ($F = 73.87$, $df = 3$, $P = 0.0001$; October < January, $P = 0.0001$; October < March, $P = 0.0001$; January < March, $P = 0.0001$). As indicated above, no inhibition of *Escherichia coli* was observed by fresh material tested in October. However, inhibition of growth by *E. coli* was seen in January and March, and there was no difference in the amount of inhibition between these two periods ($F = 5.44$; $df = 3$, $P = 0.002$; October < January, $P = 0.0006$; October < March, $P = 0.002$; January = March, $P = 0.31$).

The efficacy and comparability of individual fruit and receptacle assays were confirmed by the control antibiotic sensitivity tests run with each assay. Each of the control antibiotic sensitivity tests showed levels of inhibition within

tacle. Furthermore, the strength of the inhibitor appears to increase over time. There are several possible explanations for the observed increase in the strength of the inhibitor. Plant material is biologically active and may undergo a variety of biochemical changes in the postharvest period. Thus, the observed increase in inhibitor strength may be the result of an increased production of the inhibitor or the breakdown of some inhibition repressor. Alternatively, desiccation of stored material may play a part in the observed increase of the strength of the inhibitor. Dogwood fruits loose water rapidly after harvest and continue to decline in water content during storage (Post, 1992). Thus, the relative amount of the inhibitor may remain constant, but its specific activity may increase with a concomitant reduction in the water content of the receptacle.

Regardless of the mechanics by which dogwood fruits inhibit microbial growth, the presence of the inhibitor effectively allows woodrats to store a large supply of a valuable resource. Dogwood fruits are an energy-dense and lipid-rich resource used by a number of species, notably fall migrating birds and, once ripe, the supply of fruits declines rapidly. Woodrats have been observed to store large amounts of dogwood fruit and include it in their diet from fall until early spring (Post, 1991). If dogwood fruits were not resistant to microbially mediated spoilage, woodrats would not be expected to store large amounts of the fruit because to do so would result in a loss of investment in the cache. Therefore, we suggest that the presence of an inhibitor allows woodrats to compete effectively for a valuable and limited winter food resource.

A CRITICAL BODY SIZE FOR USE OF PHEROMONES IN MATE LOCATION

DAVID B. DUSENBERY* and TERRY W. SNELL

(Received July 8, 1994; accepted December 23, 1994)

Abstract—Pheromones have demonstrated importance in mate location in many insect species. Because chemoreception is the most universal sense, it has been assumed that pheromones also are important in aquatic organisms, including bacteria, but few have been found. The physical limits on effective strategies for organisms to come into contact for mating were modeled with assumptions appropriate for organisms less than a millimeter in size in an open aquatic environment. One sex was assumed to be motile, while the other sex was passive or devoted energy to locomotion or to diffusible pheromone production. Assuming spherical organisms, random locomotion by the second sex at the same velocity as the first sex increases the chances of contact by a factor of 4/3 over being passive; this ratio is independent of size. For detection by contact, the effectiveness of searching increases with the third power of the radius of the organisms; for detection by pheromones, search effectiveness increases with the seventh power of the radius above a critical size. Diverting energy from motility to pheromone production is not productive for organisms smaller than the critical size, which corresponds to a radius of 1.8 times the square root of the diffusion coefficient of the pheromone times the threshold concentration for detection divided by the rate of pheromone production per unit volume of organism. Thus, pheromone production is very favorable for organisms much above the critical size, which appears to be between 0.2 and 5 mm in water. On the other hand, bacteria are probably too small to use diffusable pheromones for mate location; most protozoans and rotifers may also be too small.

Key Words—Attraction, bacteria, chemoreception, crustacean, efficiency, mate location, pheromone, plankton, protozoan, rotifer, sex, size.

INTRODUCTION

A common problem for sexually reproducing species is for the two sexes to come together. In species with motile adults, the first step is for one or both adults to direct their locomotion so that two adults of opposite sex come together. The ability of a species to accomplish this affects the minimum population density required for its survival and has implications for its life history strategies (Gerritsen, 1980). Among vertebrates, a variety of sensory systems are employed. In simpler animals, including many crustaceans, released chemical pheromones are believed to be important (Dunham, 1988), and researchers often assume microorganisms and plankton likewise use released pheromones (Kochert, 1978; Crease and Hebert, 1983; Stephens, 1986). However, observations on rotifer zooplankters suggest that mates are not recognized at a distance; rather they rely on random locomotion and contact chemoreception (Gilbert, 1963; Aloia and Moretti, 1973; Snell and Hawkinson, 1983; Snell and Nacionales, 1990). This raises the question of whether diffusible pheromones are generally useful to small free-swimming organisms.

In an open aquatic environment, the utility of diffusible pheromones in mate location can be addressed rigorously for rotifers and other small organisms that are less than a millimeter in size, because the spread of a pheromone in this size range is dominated by diffusion, and turbulence has little effect (Atema et al., 1988). In addition, organisms in this size range swim at Reynolds numbers less than 1 and the minimum energetic cost of locomotion can be reliably estimated from Stoke's law (Rouse, 1961, p. 215; Vogel, 1981, p. 245).

We assume that one sex is always motile, recognition occurs on contact, and contact is efficiently achieved once a pheromone is detected. We then ask what the relative chances of contact are if the other sex: (1) does nothing, (2) moves in random directions, or (3) produces a diffusible pheromone that attracts the other sex; and whether the relative effectiveness of each behavior varies with the size of the organism.

METHODS AND MATERIALS

For simplicity, we assume that both sexes can be represented as spheres of the same size (radius = r_0).

Power. We assume that both sexes have the same amount of metabolic energy available for mate location. Furthermore, the available energy is proportional to the volume of the organism, and the power (rate of energy use) per unit volume of organism (power density) available for mate location is a constant P_V. This is the power available at the metabolic level. To determine the power effectively applied to propulsion, the metabolic power must be multiplied by the

locomotor efficiency, E. To determine the power effectively applied to pheromone release, the metabolic power must be multiplied by a conversion factor, K.

The magnitude of the metabolic power potentially available for propulsion or synthesis of pheromone can be estimated from the rate of oxygen consumption. Consulting Altman and Dittmer (1974, pp. 1613–1659), one finds values for oxygen consumption (milliliter if O_2 per gram wet weight of tissue per hour) of 0.01–0.1 for algae, reptiles, and amphibians; 0.1–1 for fungi and most animals; and 1–10 for bacteria and birds. Measurements for a rotifer gave 1.0 and 1.5 for females and males, respectively (Epp and Lewis, 1979), and we assume a value of 1. These numbers can be multiplied by 5.6×10^4 to convert to ergs per cubic centimeter per second. This is the total metabolic power density available to the organism for all functions including inefficiencies. If 10% of the energy budget is devoted to mate location, $P_V = 6 \times 10^3$ erg/cm^3/sec.

Propulsion. The organisms are assumed to be sufficiently small and slow-moving that Stoke's law describes the power required for propulsion; this means a Reynolds number less than 1. Stokes' law says that the force necessary to propel a sphere through a viscous fluid is equal to $6\pi\eta r_0 v$, where η is the viscosity of the medium, r_0 is the radius of the sphere (organism), and v is the velocity (of locomotion). Since work is force times distance or force times velocity and time, and power is work per unit time, the power required for propulsion is $6\pi\eta r_0 v^2$. If the power devoted to propulsion per unit volume of the organism is P_V, then

$$\tfrac{4}{3}\,\pi r_0^3 P_V E = 6\,\pi\eta r_0 v^2$$

Solving for v, gives

$$v = \frac{\sqrt{2}}{3}\sqrt{\frac{EP_V}{\eta}}\,r_0 \tag{1}$$

The first fraction is a pure number ($\cong 0.47$), and the second has units of inverse time. This relation illustrates why one sees a proportionality between velocity and size across a wide range of organisms.

Reasonable values for the overall efficiency of propulsion are based on the following considerations. The mechanical efficiency of propulsion of bacteria is thought to be not more than 1% (Purcell, 1977; Berg, 1983) and the efficiency of conversion of electrochemical energy of the proton gradient to torque in bacteria is estimated as 5% (Meister et al., 1987). The overall efficiency is the product of these or $E \leq 0.05\%$ for bacteria. Measurements indicate that a rotifer must be at least $10^{-4}\%$ efficient (Epp and Lewis, 1979), and a copepod is at least 0.1% efficient (Vlymen, 1970). We assume an efficiency of 0.1% for Figure 1. Others have assumed an efficiency of 1% (Fenchel and Finlay, 1983;

Crawford, 1992). Note below (equation 8) that the efficiency of propulsion does not enter into determining the critical size.

Search. We assume a clean-sweep search (Dusenbery, 1992, p. 386) with the searching organisms moving in straight paths. Search rate (S) is the rate at which a volume is swept for detection of a target. It is equal to the velocity of swimming (v) times the cross section for detection. The latter is equal to the square of the range of detection (r_d) times pi. (All distances are measured from the center of the spherical organisms.) In symbols:

$$S = \pi r_d^2 v \tag{2}$$

Pheromones. The energy required for synthesis and release of a pheromone is difficult to estimate. Taking data from the heat of combustion of organic molecules, 6- to 18-carbon molecules have heats of combustion ranging from about 1000 to 2000 kcal/mol (Weast, 1985, pp. D272–D278). This equals the minimum energy necessary to synthesize these compounds from carbon dioxide and water. However, animals would make them from other molecules, which might reduce their costs. On the other hand, there will be inefficiencies in synthesis that will increase the energetic costs. We assume the efficiency of conversion, K, is 10^{-3} mol/kcal or about 10^{-14} mol/erg. Thus, the best estimate of pheromone release is 10^{-14} mol/erg times 6000 erg/cm^3/sec $= 6 \times 10^{-11}$ mol/cm^3/sec.

The diffusion coefficient, D, varies relatively little around 1×10^{-5} cm^2/sec for small molecules in water [For example, glycine is 1.06×10^{-5} and sucrose is 0.52×10^{-5} (Weast, 1970, p. F-47) and even small globular proteins are only 0.1×10^{-5} (Tanford, 1961, p. 358).] We assume a value of 1×10^{-5} cm^2/sec.

Threshold concentration, C_{Th}, can vary over a wide range. Theoretical analysis suggests that the lowest practical thresholds for small organisms are about 10^{-12} molar (Dusenbery, 1992, p. 129) or 10^{-15} mol/cm^3. Actually measured thresholds among microorganisms are generally in the range 10^{-9} to 10^{-12} molar (Maier and Müller, 1986; Dusenbery, 1992, p. 137). This range also applies to many fish responses, although there are a few examples of greater sensitivity (Hara, 1993). However, during the initial evolution of pheromone use, detection sensitivities would not generally be optimized, and the pheromone may have to function with less sensitive receptors. The lowest thresholds for chemotaxis of bacteria are 10^{-7} molar (Adler, 1975), and we consider this a more appropriate value.

RESULTS

Detection by Contact. If no pheromones are involved, mates can detect one another only upon contact. In this case, the range of detection is equal to the

sum of the radii of the two organisms ($r_d = 2\ r_0$). Consequently, when one organism is stationary and one moves at velocity v, we can use equation 2, and

$$S = 4\pi r_0^2 v \tag{3}$$

If both organisms move at velocity v, the search rate is increased by a factor of 4/3 (Kauzmann, 1966; pp. 174–175; Gerritsen and Strickler, 1977). Substituting in equation 1 for v,

$$S = 4\pi r_0^2 \frac{\sqrt{2}}{3} \sqrt{\frac{EP_V}{\eta}}\, r_0$$

which we rearrange to get

$$S = \frac{4\pi\sqrt{2}}{3} \sqrt{\frac{EP_V}{\eta}}\, r_0^3 \tag{4}$$

This indicates that the search rate increases with the cube of the size of the organism and in direct proportion to its volume, assuming a constant amount of energy per unit volume is devoted to propulsion.

Detection by Pheromone. In order to improve the chances of a successful search, the target organism can release a chemical, which may extend the range of detection. We assume that the organism devotes a certain amount of metabolic energy per unit volume to producing the chemical and that there is a conversion factor of K relating the amount of energy to the amount of chemical released. We assume that the chemical is produced and released at a constant rate, so energy is used at a constant rate, and the power consumed is the constant P_V. The total rate of chemical release (J) is then K times P_V times the volume of the organism:

$$J = KP_V \frac{4\pi}{3} r_0^3$$

On a scale of less than a millimeter, transport of chemicals is dominated by diffusion, and we can generally ignore convection. In this circumstance, the steady-state concentration (C) of chemical around a small source releasing a chemical at a constant rate (J) is described by (Dusenbery, 1992, p. 66):

$$C(r) = \frac{J}{4\pi Dr}$$

where D is the diffusion coefficient of the chemical in water, and r is the distance from the source. If detection occurs at a concentration C_{Th}, the range of detection will be

$$r_d = \frac{J}{4\pi DC_{\mathrm{Th}}}$$

Substituting for the rate of chemical production,

$$r_d = \frac{1}{4\pi DC_{\mathrm{Th}}} KP_V \frac{4\pi}{3} r_0^3$$

which we rearrange to

$$r_d = \tfrac{1}{3} \frac{KP_V}{DC_{\mathrm{Th}}} r_0^3 \tag{5}$$

The range of detection now increases as the cube of the size of the organism rather than being equal to $2r_0$ as for contact detection. If the chemical is to be at all effective, it must be present at a concentration above threshold outside the organism. This requires that $r_d > 2r_0$ or, from equation 5,

$$\frac{1}{3} \frac{KP_V}{DC_{\mathrm{Th}}} r_0^3 > 2r_0$$

which is rearranged to

$$r_0 > r_0(\min) = \sqrt{\frac{6DC_{\mathrm{Th}}}{KP_V}} \cong 2.45 \sqrt{\frac{DC_{\mathrm{Th}}}{KP_V}} \tag{6}$$

Below this minimum size, pheromone diffuses away too fast relative to its rate of production for a detectable concentration to build up around the organism.

Substituting for r_d (equation 5) and v (equation 1) into equation 2,

$$S = \pi \left(\frac{1}{3} \frac{KP_V}{DC_{\mathrm{Th}}} r_0^3 \right)^2 \frac{\sqrt{2}}{3} \sqrt{\frac{EP_V}{\eta}}\, r_0$$

Rearranging gives

$$S = \frac{\pi\sqrt{2}}{27} \sqrt{\frac{EP_V}{\eta}} \left(\frac{KP_V}{DC_{\mathrm{Th}}} \right)^2 r_0^7 \tag{7}$$

The first term is a pure number ($\cong 0.165$), the second has units of inverse time, and the third term has units of length to the inverse fourth power. Note that the search rate varies with an exponent of 2.5 on the metabolic power density devoted to mate location. However, the most important feature is that the search rate depends on the seventh power of the size of the organism, indicating that diffusing pheromones are much more useful to large organisms.

Figure 1 shows a plot of the search rates for the three types of alternative behaviors of the target organism (passive, random locomotion, and pheromone production), assuming reasonable values for the parameters, as discussed in Methods and Materials. The important thing to note about the plot is that there is a critical size of organism below which pheromone production is useless. In

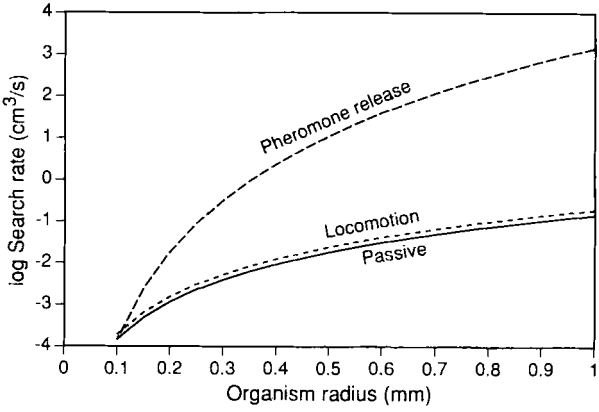

FIG. 1. Search rate dependence on size and target behavior. The target organism can remain passive (equation 3) or devote energy to random locomotion (equation 3 times 4/3) or to pheromone release (equation 7). Calculations assumed spherical organisms of the indicated radius; power applied to mate location, $P_V = 6000$ erg/sec/cm^3 of organism; conversion efficiency for pheromone release, $K = 1 \times 10^{-14}$ mol/erg; threshold sensitivity to pheromone, $C_{Th} = 1 \times 10^{-7}$ molar; efficiency of propulsion of 0.1%, $E = 0.001$, which gives a swimming speed of about 10 diameters per second. The justification for these assumptions is given in Methods and Materials. With these assumptions, the Reynolds number is 0.1 at the critical size and increases to 23 at 1 mm diameter; consequently, at the larger sizes, there is more drag than we have calculated and the advantages of pheromone release are underestimated. The critical size in this case is defined by $r_0(\text{min}) = 100$ μm and $r_0(\text{equiv}) = 108$ μm, and the critical diameter is 215 μm.

contrast, pheromone production by larger organisms can increase the search rate thousands of times above what could be obtained by devoting the energy to locomotion.

Size Limit. What is the critical size where pheromone production becomes useful, and what parameters influence it? In order to answer these questions, we determined the size at which the equal search rates are obtained when one organism (the target) devotes its energy to propulsion (equation 4 times 4/3) or alternatively to pheromone production (equation 7):

$$\frac{4}{3}\frac{4\pi\sqrt{2}}{3}\sqrt{\frac{EP_V}{\eta}}\,r_0^3 = S = \frac{\pi\sqrt{2}}{27}\left(\frac{KP_V}{DC_{Th}}\right)^2\sqrt{\frac{EP_V}{\eta}}\,r_0^7$$

Solving for r_0, we get

$$r_0(\text{equiv.}) = \sqrt[4]{48}\sqrt{\frac{DC_{Th}}{KP_V}} \cong 2.63\sqrt{\frac{DC_{Th}}{KP_V}} \qquad (8)$$

TABLE 1. BREAK-EVEN RADIUS IN MICROMETERS

Pheromone release, KP (mol/cm^3 sec)	Threshold concentration, C_{Th} (mol/liter)					
	1×10^{-12}	1×10^{-11}	1×10^{-10}	1×10^{-9}	1×10^{-8}	1×10^{-7}
1×10^{-10}	0.3	0.8	3	8	30	80
1×10^{-11}	0.8	3	8	30	80	300
1×10^{-12}	3	8	30	80	300	800
1×10^{-13}	8	30	80	300	800	3000
1×10^{-14}	30	80	300	800	3000	8000

It can be seen that the break-even size for pheromone production varies with the square root of the ratio of threshold sensitivity over rate of production (KP_V). In fact, the break-even size (equation 8) is a constant factor (fourth root of $4/3 \cong 1.075$) times the minimum size for pheromone production to be at all effective (equation 6). Thus once the minimum size is reached, only a trivial increase in size makes it more efficient for one sex to devote energy to pheromone release rather than locomotion.

What is the magnitude of this size limit above which pheromone production is effective? We inserted some specific estimates for the parameters into the two equations and made quantitative estimates. Using a range of plausible values discussed in Methods and Materials, the results shown in Table 1 are obtained. With this wide range of possible values, the threshold size could lie anywhere between 1 μm and a few millimeters. This wide range of possible values is a consequence of the lack of quantitative data on chemical communication.

DISCUSSION

Relatively few observations have been made on the mechanisms of mate location among aquatic organisms (Carr, 1988). The data we could find is presented in Table 2. All crustaceans larger than 5 mm seem to employ pheromones, while cladocerans, rotifers, and bacteria do not. In well-studied rotifers, males contact females entirely by random locomotion (Gilbert, 1963; Snell and Garman, 1986). Among ciliates, there is strong evidence for such a pheromone in one genus that is 200 μm in size, but not in many other ciliates examined. In short, there is a strong correlation between the use of mate location pheromones and size, as predicted by the model. The critical size appears to be between 0.2 and 5 mm.

In air, the same basic argument applies, except that the energy of locomotion is more difficult to estimate. It might be thought that the 10^4 increase in

TABLE 2. OBSERVATIONS OF DIFFUSIBLE PHEROMONES FOR MATE LOCATION

Organisms	Adult size (mm)	Mate location pheromones?	References

[a]Although there is evidence for pheromones in ciliates other than *Blepharisma* (Luporini and Miceli, 1986), there is no evidence that they are involved in attracting one mating type to another.
[b]Rotifers: Gilbert (1963), Aloia and Moretti (1973), Snell and Hawkinson (1983).
[c]Copepods: Jacobs (1961), Haq (1972), Katona (1973), Griffiths and Frost (1976), Blades (1977); Blades and Youngbluth (1979, 1980); Jacoby and Youngbluth (1983), Watras (1983), Burton (1985), Chow-Fraser and Maly (1988), Uchima and Murano (1988), Lazzaretto et al. (1990).

diffusion rate in air would increase the critical size by 100-fold, but there is reason to expect that the increased diffusion rate will decrease the potential threshold concentration proportionally (Dusenbery, 1992, pp. 128–129). Consequently, the critical size may be similar in air.

There is evidence that gametes of water molds (Allomyces) (Pommerville, 1981) and brown algae (Boland et al., 1984), which are only about 10 μm long, make use of diffusible pheromones. This is at the low end of our estimates of the critical size. However, gametes are a special case because they can utilize energy provided by a much larger parent. Consequently, it may be expected that the critical size for gametes may be smaller than for independent organisms.

Although ameboid cells of the cellular slime mold *Dictyostelium discoideum* are only about 10 μm in diameter (Raper, 1935; Soll, 1988), they employ a pheromone (cyclic AMP) in a complicated pulsed system of communication to facilitate aggregation of the cells for the formation of fruiting stalks (Devreotes, 1989). Two factors may contribute to making it feasible for these small cells to employ a diffusible pheromone. Most obviously, many cells work in concert to build up the concentration of pheromone, less obviously, these organisms normally live in the two-dimensional world of a thin film of water. Consequently,

the pheromone is not diluted nearly as rapidly as in the three-dimensional environment we have considered.

The realization that the benefit of pheromones varies with size offers a potential explanation for why the two gametes of most species are very different in size. Having a large immobile gamete (egg), which can efficiently release an attractant pheromone, and many small mobile gametes (sperm) improves the probability of appropriate gametes coming together compared to the situation of equal-size gametes.

This model makes very specific predictions relating the amount of pheromone release, detection threshold, and range of detection. Studies of chemical communication among small organisms is particularly attractive, because the spread of the signal is by diffusion, which can be analyzed rigorously. This situation contrasts strongly with that of insects, where air turbulence makes the spread of the signal very difficult to analyze. We hope this analysis will stimulate more quantitative studies of chemical communication among small organisms.

(Received September 16, 1994; accepted December 30, 1994)

Abstract—The frass of the pyrgo beetle (*Paropsisterna tigrina*) feeding on commercial plantations of the terpinen-4-ol chemical variety of the Australian tea tree, *Melaleuca alternifolia*, was found to contain a volatile oil almost identical to the essential oil of the ingested leaf. When beetles were fed leaf containing substantial quantities of 1,8-cineole, the predominant frass metabolite as determined by MS, IR, ^{13}C and ^{1}H NMR, GC, and CoGC was (+)-2β-hydroxycineole. Both male and female adults and larvae metabolized *Melaleuca* oils in similar ways.

Key Words—Coleoptera, Chrysomelidae, *Paropsisterna tigrina*, pyrgo beetle, *Melaleuca alternifolia*, *M. linariifolia*, Myrtaceae, volatile oil, metabolism, 1,8-cineole, hydroxycineole, (+)-2β-hydroxycineole.

INTRODUCTION

Extensive plantings of *Melaleuca alternifolia* (Maiden and Betche) Cheel (Myrtaceae) over the last 10 years have been responsible for the production of Australian tea tree oil increasing beyond one hundred tonnes per annum (Southwell, 1988; Brophy et al., 1989; Merry, 1991). To distinguish the commercial product from other less efficacious *Melaleuca* oils, this oil is designated as Oil of *Melaleuca*, Terpinen-4-ol type (Standards Association of Australia, 1985; Interna-

*To whom correspondence should be addressed.

tional Standards Organisation, 1992) derived from *M. alternifolia*, *M. linariifolia*, *M. dissitiflora*, and any other *Melaleuca* species giving similar (+)-terpinen-4-ol (**1**) -rich oils. The abundant intermediate and high 1,8-cineole (**2**) chemical varieties are considered unsuitable sources of oils for antimicrobial application (Brophy et al., 1989).

Paropsisterna tigrina Chapuis (Coleoptera: Chrysomelidae), commonly known as the pyrgo beetle (Colton and Murtagh, 1990), is a major defoliator of plantations of *M. alternifolia* in the Northern Rivers district of New South Wales. Both larvae and adults show a strong feeding preference for the young flush growth (Maddox, 1994), which contains substantial quantities of terpenoids (Brophy et al., 1989; Southwell and Stiff, 1989, 1990; Southwell et al., 1992).

The use of dietary plant volatiles by insects both with and without structural modification as pheromones is well known (Harborne, 1988), especially in the case of *Dendroctonus* and *Ips* pine bark beetles (Wood, 1982; Byers et al., 1979, 1984; Birgersson et al., 1984). Dietary monoterpenes also play a role in the stimulation of the mixed function oxidase (MFO) activity in the mid-gut of some insects, and the ingestion of monoterpenes can enhance the tolerance of the insect to host plant allelochemicals (Brattsen et al., 1977; Yu et al., 1979; Yu 1987).

This investigation identifies the volatile frass constituents of adult and larval male and female *P. tigrina* beetles feeding on terpinen-4-ol (**1**), cineole (**2**), and terpinolene (**3**) chemical varieties of *M. alternifolia* and *M. linariifolia* (Figure 1). The frass volatiles were compared with the leaf volatiles ingested and the structure of the major metabolite of 1,8-cineole determined as the first stage of our investigations into the chemical ecology of *Paropsisterna–Melaleuca* relationships.

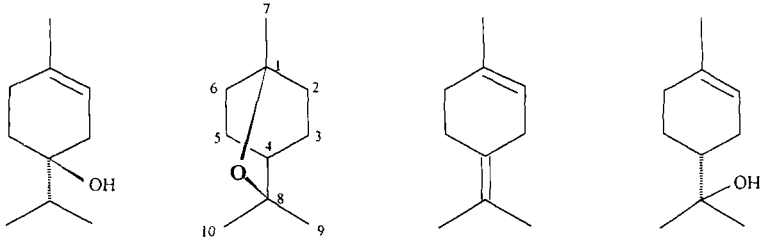

FIG. 1. Chemical structures of compounds in leaves fed to *P. tigrina* beetles. (**1**) terpinen-4-ol, (**2**) 1,8-cineole, (**3**) terpinolene, (**4**) (+)-α-terpineol.

METHODS AND MATERIALS

Melaleuca Food Source. Trees for metabolite screening were 2 to 3-year-old garden specimens of known oil type growing in the Lismore district, New South Wales, Australia. The *M. alternifolia* specimens of commercial oil type (MA1, MA2) were obtained from Australian Plantations, Wyrallah, and cultivated at the Wollongbar Agricultural Institute (28°49'S, 153°24'E). The low cineole *M. linariifolia* (ML1) specimen came from Bryants Nursery, Corndale; the intermediate cineole *M. alternifolia* (MA3) from South Lismore; and the intermediate cineole *M. linariifolia* (ML2) from Wollongbar. The high terpinolene (MA4) and high cineole (ML3) samples came from plants previously identified during surveys and feeding studies growing at South Lismore and Richmond Hill, respectively (Maddox, 1994). Freshly growing tips were fed to the beetles and typical samples retained for GC analysis.

Beetles and Frass Collection. Adult and third– fourth-instar *P. tigrina* larvae were collected from the Wollongbar Agricultural Institute commercial grade (terpinen-4-ol type) plantings. Experimental groupings consisted of mixed sex adults, male adults, female adults, or larvae. Adults were sexed using fore/mid-tarsal structure and body size/shape (Reid and Ohmart, 1989; Maddox, 1994). Each group was kept separate in 70-ml sterile plastic containers in groups of 7–10 and maintained at room temperature with normal daylight. Each group was prefed for two days on new foliage before being rehoused, and frass collected at 8 hr intervals using stainless steel probes to lift the pellet from the leaf or container surface into the receptacle. Frass was stored at −10°C until extraction. Fresh leaf was provided daily. Flush (leaves 1–3 from tip) and mature leaves (> 15 from tip) were retained at the beginning and end of frass collection, and frozen until GC analysis.

For larger-scale frass collections for NMR analysis, *M. linariifolia* twigs with flush growth were placed in water and suspended over filter paper with up to 100 insects. A lag time of 24 hr after a change of diet was more than sufficient to clear the gut of the previous diet. Frass was collected with small spatulas and brushes, even though the chance of contamination by leaf fragments was greater. Samples were collected directly into ethanol and stored at −10°C to prevent the excessive loss of volatiles.

Instrumentation. Analytical chromatography was performed on a Hewlett Packard 5890 gas chromatograph with HP7673A controller, HP3393 integrator, a 60-m × 0.25-mm-ID FSOT AT35 column, H_2 as carrier gas, FID detector, and a 10°/min program rate from 50° (1 min hold) to 250°C. Retention indices were measured against *n*-alkanes. Tridecane was used as a quantitation internal standard. GC-MS was carried out on a Shimadzu QP 1000 with a 30-m × 0.22-mm-ID FSOT DB-17 column for both 70 and 20 eV determina-

tions. Both ^{1}H (300 MHz) and ^{13}C (75 MHz) NMR spectra were determined in $CDCl_3$ on a Bruker AC-3 instrument.

Comparison of Ingested and Excreted Volatile Constituents. Leaf volatile constituents of all food sources were determined by leaf extract analysis in ethanol by a modified microanalytical method (Brophy et al., 1989) in which 30-hr extraction times (20°C) were reduced to 1 hr following 10 sec of microwave (700 W) irradiation. GC peak identification was by retention time, comparison with authentic samples, and correlation with published data (Brophy et al., 1989; Southwell and Stiff, 1989, 1990; Southwell et al., 1992). Frass constituents were identified similarly, with the addition of GC-MS data for the metabolites present in the frass extracts and absent from the leaf extract.

Isolation and Identification of (+)-2β-Hydroxycineole (8). Larval frass (0.96 g, contaminated with minute leaf fragments) in ethanol was filtered and the filtrates made up to 10 ml with absolute alcohol. Water (5 ml) was added and nonpolar constituents were partitioned into hexane (25 ml). The ethanol–water layer was concentrated under vacuum, extracted into $CDCl_3$, and dried ($MgSO_4$) to give (+)-2β-hydroxycineole (57.4 mg) (**8**). IR ν_{max} cm^{-1} (film): 3261, 1259, 1212, 1072, 1036, 729, 703; ^{1}H NMR, δ ($CDCl_3$) 1.10 (3 H s, 7-Me), 1.26, 1.28 (2 × 3 H s, 9,10-Me), 0.80–2.10 (numerous multiplets; 3,4,5,6-Hs), 3.50 (1 H dd, $J_{3\beta}$ 3.4 Hz, $J_{3\alpha}$ 9.1 Hz, 2-H); ^{13}C NMR 22.1 (5-C), 23.1 (7-C), 28.2 (9 or 10-C), 29.0 (6 and 9 or 10-C), 33.4 (4-C), 35.4 (3-C), 70.4 (2-C), 72.6 (1-C), 74.0 (8-C). GC-MS (20 eV) *m/z* (%): 170(5), 137(2), 126(50), 111(38), 108(75), 93(40), 83(25), 71(75), 69(45), 43(100). GC-MS (70 eV) *m/z* (%): 170(3), 126(24), 111(18), 108(36), 83(18), 71(36), 69(21), 43(100)·$[\alpha]_D$+21.8° (c 0.03 in $CHCl_3$), lit. + 28.0° (Carman et al., 1986).

RESULTS AND DISCUSSION

A GC comparison of the volatile constituents of leaf ingesta and frass excreta was made for *P. tigrina* male adults, female adults, and stage three and four instars on seven different diets (Table 1). The four *M. alternifolia* diets represented very low cineole (MA1), low cineole (MA2), intermediate cineole (MA3), and terpinolene (MA4) chemical varieties. The three *M. linariifolia* diets included low cineole (ML1), high cineole (ML2), and very high cineole (ML3) varieties. These diets were typical of the varieties likely to be encountered in nature with only MA1, MA2, and ML1 being sources of commercially acceptable oils (International Standards Organisation, 1992). The predominance of sabinene and sabinene hydrates in the flush growth, and of γ-terpinene and terpinen-4-ol in the mature leaf, of *M. alternifolia* and *M. linariifolia* has been described (Southwell and Stiff, 1989; 1990). *Paropsisterna* feed almost entirely on flush growth for reasons (physical or chemical) currently under investigation (Maddox, 1994).

14	α-Terpineol	0.8	1.6	2.1	3.2	0.5	3.2	9.5

[a] Peak No. refers to peaks in chromatogram of figure 3.

The ability of adults and larvae of *P. tigrina* to excrete low-cineole tea tree leaf volatiles virtually unchanged was shown by the almost identical chromatograms for volatiles from leaf ingesta and frass excreta for MA1, MA2, and ML1 diets. The GC-determined constituent percentages for the volatile components of host *M. alternifolia* MA1 (flush growth and mature leaf) and frass extracted by adult males, adult females, and larvae are shown in Table 2. The *M. linariifolia* ML1 diet gave similar results. Diets containing significant concentrations of cineole (MA3, MA4, ML2, and ML3) gave frass volatiles containing a constituent not present in the ingesta with a retention index (1316) higher than (+)-terpinen-4-ol (**1**) (1258) and (+)-α-terpineol (**4**) (1277) (Figure 1). The percentage of this frass constituent was proportional ($R^2 = 0.99$) to the percentage of cineole ingested (Figure 2). An increase in percentage of dietary cineole corresponded with an increase in the concentration of this constituent, suggesting that it was a metabolite of cineole. Comparative gas chromatograms of high-cineole (ML3) ingesta and excreta are shown in Figure 3.

GC-MS analysis of the laval frass volatiles from a *M. linariifolia* high-cineole diet (ML3) indicated a molecular ion at *m/z* 170 for the major constituent, consistent with one of the 12 isomers possible for hydroxy-1,8-cineole (**5–16**) (Figure 4). Retention time comparison with authentic samples of (−)-2α-

[a]Peak No. refers to peaks in chromatogram of Figure 3.

hydroxycineole (**5**),[3] (+)-2α-hydroxycineole (**6**), (−)-2β-hydroxycineole (**7**), (+)-2β-hydroxycineole (**8**), (±)-3β-hydroxycineole (**11, 12**), 4-hydroxycineole (**13**), 7-hydroxycineole (**14**), (+)-(9S)-hydroxycineole (**15**), and (−)-(9*R*)-hydroxycineole (**16**) showed that only (−)- and (+)-2β-hydroxycineole had identical retention times to the *P. tigrinis* metabolite. The only isomers unavailable for comparison were (−)- and (+)-3α-hydroxycineole (**9**, **10**). Coinjection with both (−)- and (+)-2β-hydroxycineole (**7** and **8**) showed peak enhancement. The high-cineole *M. linariifolia* diet (ML3) was used for larger-scale feeding with approximately 100 larvae to obtain enough hydroxycineole for NMR spectroscopy. Measurement of absolute quantities ingested and excreted was not possible because of the small size of the larvae and the difficulty in separating frass from leaf fragments. Ingesta containing 1.5 mg of 1,8-cineole per 1 g leaf

[3]The trivial stereochemical α and β nomenclature is used here in preference to *exo* and *endo* terminology because of the ambiguity arising from some authors referencing substituent groups with respect to the cyclohexane ring (Asakawa et al., 1988a; Gandini et al., 1972; Liu et al., 1988; Orihara and Furuya, 1994; Miyazawa et al., 1991a, b; 1992a–c) and others, with respect to the pyran ring (Bitteur et al., 1990; Liu and Rosazza, 1990; MacRae et al., 1979; Nishimura et al., 1982; Williams et al., 1989).

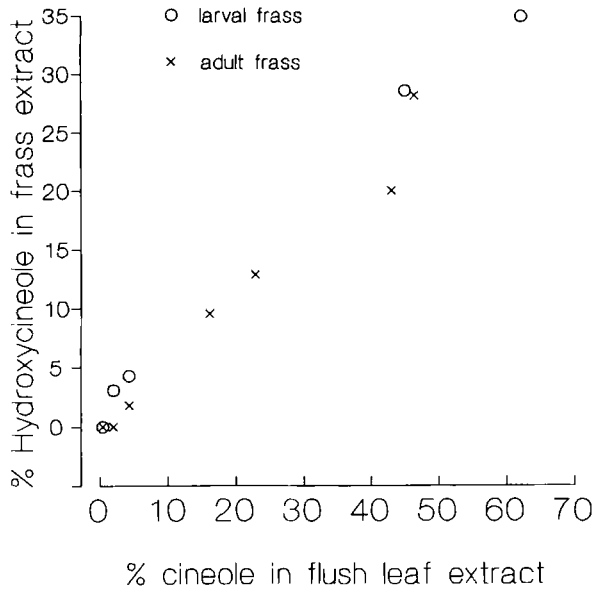

FIG. 2. Percent of (+)-2β-hydroxycineole (**8**) in *P. tigrina* frass extracts with respect to the percentage of 1,8-cineole in the diet.

(62.1% of the volatiles) gave 2.0 mg of hydroxycineole per gram of frass (39.8% of the volatiles). Both ^{1}H and ^{13}C NMR shifts were identical with published values for the enantiomers of 2β-hydroxycineole (Gandini et al., 1972; Carman and Fletcher, 1984; de Boggiatto et al., 1987; Asakawa et al., 1988a; Miyazawa et al., 1989; Carman et al., 1994). Assignment as (+)-2β-hydroxycineole[(1S, 4*R*, 6*R*)-1,3,3-trimethyl-2-oxabicyclo[2.2.2]octan-6-ol] (**8**) followed measurement of optical rotation ($[\alpha_D]+21.8°$).

Comparison of the gas chromatographic percentages of cineole and hydroxycineole in ingesta and excreta suggests that the metabolism of the former to the latter proceeds in approximately 84% yield. The meticulous separation of all visible leaf fragments from the frass did not increase this percentage. Much of the remaining 16% of seemingly unmetabolized cineole may arise from undigested leaf within the frass. Very few other metabolites were detected on GC that could not be accounted for as unmetabolized ingesta. The most significant of these was a 1% constituent with an identical retention time and mass spectrum to 2α-hydroxycineole (**5** or **6**).

There have been numerous attempts to relate levels of herbivory by insects to plant chemistry in Australian Myrtaceae, mainly *Eucalyptus* spp. (Fox and

Macauley, 1977; Fox and Morrow, 1983; Morrow and Fox, 1980; see Ohmart and Edwards, 1991, for a review). Most recent studies have concentrated on terpenoid composition, with levels of cineole in particular implicated in tree variation in herbivore damage, both within and among tree species (Edwards et al., 1990, 1993; Stone and Bacon, 1994). There is much conjecture on how insects that feed on Myrtaceae process terpenoids, mainly due to the lack of detailed studies. Thus, Morrow and Fox (1980) concluded that the eucalypt herbivores they tested tolerated these compounds. This conclusion was based on the "close similarity" of terpenoid profiles of leaf ingesta and frass. Edwards et al. (1993) concluded that eucalypt herbivores (specifically *Anoplognathus* spp.) could not detoxify or metabolize terpenoids. This conclusion was based on a negative correlation between levels of tree damage and the percentage of cineole in the terpenoid composition of the trees. More detailed studies showed sequestrian in sawfly larvae (Morrow et al., 1976) and possible absorption of some terpenoids in a chrysomelid (Ohmart and Larsson, 1989). The latter authors reported a terpenoid budget for *Paropsis atomaria* (Olivier) feeding on *E. blakelyi* and concluded that larvae of this beetle absorbed and/or somehow metabolized to other compounds 86% of ingested cineole. Other terpenoids present in the diet were also greatly reduced in the egesta. Although they did not identify the metabolites, their efficiency of conversion figure, based on a nutrition budget approach, is very similar to our own estimates for another chrysomelid. Pierce et al. (1987) found that pine bark beetles could also detoxify terpenoids.

An obvious question that stems from our results is: Are the terpenoids simply being detoxified or are they being utilized as an essential component of the diet? If the latter, then high levels of herbivore damage on low-cineole trees or species may simply reflect higher feeding rates to increase the rate of intake of cineole. Studies based on levels of damage alone will not answer this question. In fact, studies that concentrate solely on levels of herbivore damage are likely to be misleading on a number of counts. Damage is the end product of the number of adults and immatures feeding on a tree, reflecting the various recruitment and attritional processes affecting the population as well as the physiology of feeding. Correlation of feeding damage with plant chemical attributes without independent measures of the contributing processes would not be a sensible research paradigm to follow.

CONCLUSION

With the exception of 1,8-cineole (**2**), *Paropsisterna tigrina* excretes all volatile *Melaleuca* ingesta constituents unchanged in the frass. Some of the less chemically stable constituents (e.g., the thujenes: sabinene, *cis*-sabinene hydrate and *trans*-sabinene hydrate) are present in reduced concentrations. Adult male,

adult female, and larvae metabolized *Melaleuca* volatiles similarly; 1,8-cineole is largely metabolized to (+)-2β-hydroxycineole or (1*S*, 4*R*, 8*R*)-1,3,3-trimethyl-2-oxabicyclo[2,2,2]octan-6-ol (**8**), with a trace of the 2α-hydroxycineole (**5** or **6**). This oxidation is in contrast to the metabolism of 1,8-cineole in the brushtail possum, *Trichosurus vulpecula* (Flynn and Southwell, 1979; Southwell et al., 1980; Carman and Klika, 1992; Bull et al., 1993) where oxidation of the most sterically available positions gives as major urinary metabolites the 9-hydroxycineoles (**15** and **16**) and cineole-9-oic acids (**17** and **18**). Trace amounts of the 2α, 3α, 3β, 2α-(8*R*), and 2α-(8*S*) alcohols and diols have also been isolated from the possum (Carman et al., 1994). The rabbit metabolizes cineole similarly to *Paropsisterna* to give urinary (+)-2β-hydroxycineole (**8**) as the major component (Miyazawa et al., 1989). The fungus *Glomerella cingulata* transforms 1,8-cineole into (+)-2α-hydroxy-1,8-cineole (**6**) (Miyazawa et al., 1991a). The less common 1,4-cineole (**19**) is metabolized by *Bacillus cereus*, *Streptomyces griseus*, and *Aspergillus niger* to 2α(**20**), 2β(**21**), 3α(**22**), 8(**23**), and 9(**24**) -hydroxy-1,4-cineole (Liu et al., 1988; Miyazawa et al., 1991b; 1992a–c). The rabbit metabolizes 1,4-cineole to 9-hydroxy-1,4-cineole (**24**) 1,4-

FIG. 5. Structures for metabolites of 1,8-cineole and 1,4-cineole. Compound **8** is (+)-2β-hydroxycineole, the major metabolite in frass of *P. tigrina* after ingestion of 1,8-cineole. Compounds **17** and **18** are cineole-9-oic acids, metabolites of 1,8-cineole by brushtail possum. Compounds **19–24** are major metabolites produced by various microorganisms from 1,4-cineole, and compounds **24–28** are metabolites of 1,4-cineole by rabbits.

TABLE 3. METABOLITES OF 1,8- AND 1,4-CINEOLE

[a] Normalized against the major metabolite (100).
[b] Cell suspension culture.
[c] Isolated as the *O*-β-D-glucopyranoside.
[d] Isolated as the *O*-β-D-glucopyranosyl-(1 → 6)-β-D-glucopyranoside.
[e] Natural metabolite.
[f] Of unspecified enantiomeric purity.

cineol-9-oic acid (**25**), 3α,8-dihydroxy-1,4-cineole (**26**), 8,9-dihydroxy-1,4-cineole (**27**), and 9-hydroxy-1,4-cineol-8-ene (**28**) (Asakawa et al., 1988b). (Figure 5). 2α-Hydroxy-1,8-cineole (**5, 6**) is also a known volatile from the Sauvignon variety of grape (Bitteur et al., 1990). Cultured cells of *Eucalyptus perriniana* produce glucosides of 2- and 3α-hydroxycineole (**5, 6, 9, 10**) (Orihara and Furuya, 1994). A summary of the metabolism of 1,4- and 1,8-cineole by the above species is shown in Table 3. This is, to our knowledge, the first definitive report of a metabolite of cineole from insects. The gas chromatographic investigations of the frass of *P. atomaria* feeding on *E. blakelyi* (Ohmart and Larsson, 1989) have indicated an unidentified metabolite that may also be (+)-2β-hydroxycineole.

Although paralleling the hydroxylation of α-pinene by *Dendroctonus* to produce the repellant (*E*)-verbenol (Harborne, 1988), the ecological significance of the excretion of 1,8-cineole as (+)-2β-hydroxy-1,8-cineole (**8**) by *Paropsisterna* awaits further investigation. In addition, the oxidase source (microbial or gut enzymes) needs identification.

Acknowledgments—We thank David Tucker, Department of Chemistry, University of New England, Armidale, for NMR spectra; Rob Black, Chemical Residues Laboratory, Lismore, for GC-MS data, and Michael Russell and Rebecca Barnes, Wollongbar Agricultural Institute, Wollongbar, for technical assistance.

(Received September 23, 1994; accepted December 30, 1994)

Abstract—The heartwood of the tropical tree *Lonchocarpus castilloi* Standley (Leguminosae) is highly resistant to attack by the drywood termites *Cryptotermes brevis* (Walker); nevertheless successive extraction with hexane, diethyl ether, acetone, methanol, and water reduced its resistance to these organisms. Antitermitic properties of the extracts were bioassayed using impregnated filter paper disks. Although the five extracts reduced both feeding and survival of *C. brevis*, no significant differences among them were detected. Choice feeding tests showed that termites avoided eating the paper treated with the extracts. Two flavonoid compounds isolated from the heartwood, castillen D and castillen E, impregnated into filter paper showed concentration-dependent feeding deterrent activity, but were not toxic to *C. brevis*.

Key Words—Feeding deterrents, termites, *Cryptotermes brevis*, Isoptera, *Lonchocarpus castilloi*, Leguminosae, heartwood, flavonoids, antitermitic activity, castillen D, castillen E.

INTRODUCTION

Lonchocarpus castilloi Standley (Leguminosae) is a tree indigenous to the tropical subhumid forest in southern Mexico, Central America, and northern South America. It can reach 30 m in height and 40 cm diameter at breast height (Ortega-Escalona et al., 1991). In Mexico it is known as "machiche." Locally,

*To whom correspondence should be addressed.

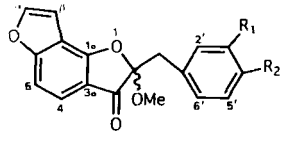
0098-0331/95/0400-0455$07.50/0 © 1995 Plenum Publishing Corporation

the timber is used in bridges, housing, rural wagons, and for manufacturing veneer, plywood, staves, and parquet. It is also recommended for railroad crossties, stakes, fenceposts, and post cross-arms (Echenique-Manrique, 1970).

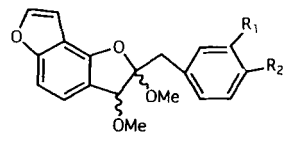
Lonchocarpus castilloi heartwood has been reported to be very durable in accelerated field tests (Bárcenas-Pazos, 1995); it is also highly resistant to several wood-rotting fungi (Reyes-Chilpa et al., 1987) and to the drywood termite *Cryptotermes brevis* (Walker) (Pérez-Morales et al., 1984).

Current evidence indicates that natural resistance to fungi (Laks, 1988; Déon et al., 1980; Hart and Shrimpton, 1979) and termites (Scheffrahn, 1991; McDaniel, 1992) is primarily determined by the concentration and type of secondary compounds found in the heartwood. In this context, it has been shown that the natural decay resistance of *Lonchocarpus castilloi* heartwood is also chemically determined. Extraction of the heartwood with a series of organic solvents reduced its decay resistance (Reyes-Chilpa et al., 1987), and the extracts showed antifungal activity in vitro (Reyes-Chilpa, 1986). Chromatographic separation of the hexane extract afforded four 2-methoxyfuran auronols named castillens A, B, C, and D, as well as one α-hydroxy-dihydro-chalcone, castillen E (Gómez-Garibay et al., 1990). These flavonoid compounds (Figure 1), inhibited the mycelial growth of the fungus *Lenzites trabea* Pers. ex Fr. The most active compound was the castillen E, followed by castillen D (Gómez-Garibay et al., 1990).

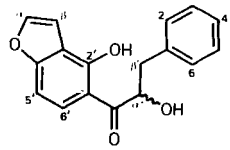
We now have examined the effect of *L. castilloi* heartwood extracts and of



1.- Castillen A: $R_1 = R_2 = H$
2.- Castillen D: $R_1 + R_2 = OCH_2O$



3.- Castillen B: $R_1 = R_2 = H$
4.- Castillen C: $R_1 + R_2 = OCH_2O$



5.- Castillen E

castillens D (**2**) and E (**5**) on the feeding and survival of *C. brevis*. We also report the isolation of two additional compounds, pongaglabrone and 4-hydroxybenzofuran, from the heartwood.

METHODS AND MATERIALS

Lonchocarpus castilloi was collected at the "Lacandona" tropical rain forest, Chiapas, México (Bárcenas-Pazos et al., 1980). Wood samples and voucher specimens are deposited at the Ecology Institute's Herbarium (Xal) in Xalapa, Mexico.

Termite Collection. Cryptotermes brevis termites were obtained from old beams in Xalapa City. The beams were sawed and stored under controlled conditions (23°C, 75% relative humidity) until employment, and bioassays also were conducted under these conditions. Beam pieces were split on a paper; termites were taken up with entomological tweezers. Only active pseudergates above the third instar were used for bioassays. Selection of active specimens was done as follows. A group of 40 pseudergates was placed inside a 50-ml beaker, and that beaker was placed perpendicular to another. The first 30 termites that passed to the second beaker were chosen (Pérez-Morales et al., 1984).

Wood Block Bioassays. Sapwood and heartwood blocks (2 × 1 × 0.5 cm, smallest dimension being parallel to the fiber) were cut from a board. The blocks were carefully sand-papered, oven dried (105°C, 24 hr), and weighed. Heartwood blocks were successively extracted in a Soxhlet apparatus with hexane, diethyl ether, acetone, methanol, and water. After each extraction step (10 hr), an equal number of blocks were removed. Extractive yields were calculated as the percentage of oven-dried weight loss (Table 1).

Sapwood and heartwood (extracted and unextracted) blocks were tested against *C. brevis*. Each block was placed in a glass vial with 30 pseudergates. The vials were capped with filter paper. Each treatment was replicated five times. Mortality was recorded periodically, and the wood consumption was determined at the end of the test period (seven weeks) as the percentage of oven-dried weight loss.

Filter Paper Bioassays. Lonchocarpus castilloi heartwood shavings (500 g) were extracted under reflux with the same sequence of solvents described previously. The extracts were concentrated in a rotary evaporator and freeze-dried when the solvent was water. Solutions (2.5% w/v) of each extract were prepared in order to impregnate filter paper disks. This concentration was chosen since 2% was the mean extractive yield from blocks. Hexane and diethyl ether extracts were dissolved in a mixture of hexane–ethyl acetate 1:1 (HE), and acetone and methanol extracts were dissolved with a mixture of acetone–meth-

anol 70:30 (AM). Each solution was poured into a Petri dish, and filter paper disks (Whatman No. 1, diameter = 7 cm) were dipped for 30 sec and then air dried. Impregnated disks were then placed in a hood for 12 hr. Control disks were treated with the solvent mixtures only.

Two bioassays were run with the impregnated filter paper: (1) For force feeding, a disk was placed into a Petri dish and 15 termites were added. (2) For the choice test, one disk of each treatment, including the AM control, was sectioned into six equal slices. A slice of each treatment was then fixed to the bottom of a Petri dish (Figure 2) with a bit of "Blue Tac" plaster (Williams, 1980) and 15 termites were added. Five replicates per test were run. Mortality was recorded periodically. Paper consumption was quantified at the end of the test (36 days).

Isolation of Compounds. Heartwood shavings (650 g) were extracted at room temperature with hexane and then with methylene chloride. After concentration, the methylene chloride extract was chromatographed over silica gel. The compounds were obtained by preparative TLC and identified by ^{1}H NMR, ^{13}C NMR, IR, UV, and MS.

Castillens D and E were tested using impregnated filter paper and following the force-feeding protocol. The solutions tested were 0.025, 0.05, 0.1, and 0.15% w/v with acetone as solvent. Control paper disks were treated with the solvent only.

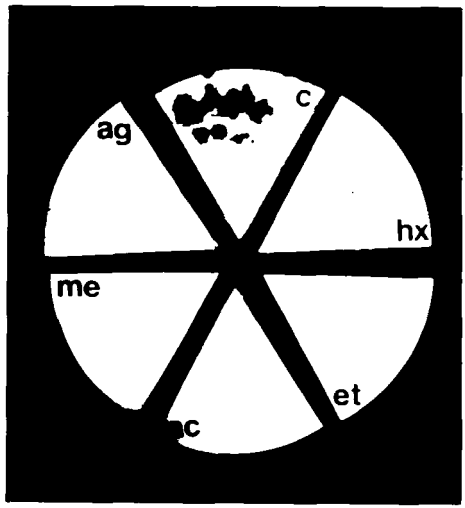

FIG. 2. Choice test. Feeding of termites on filter paper impregnated with hexane (hx), diethyl ether (et), acetone (ac), methanol (me), or water (ag) extracts of *Lonchocarpus castilloi* heartwood. Control disks (c) treated only with a mixture of acetone–methanol (7:3).

RESULTS

Extracted Wood. Cryptotermes brevis pseudergates ate over six times more of *Lonchocarpus castilloi* fully extracted heartwood blocks than of the sound heartwood (Table 1). The most efficient solvent that rendered heartwood more susceptible was methanol and then water. Heartwood blocks successively extracted with hexane, diethyl ether, and acetone were eaten equally when compared with sound heartwood. Termites consumed 1.7 times more of extracted heartwood blocks than sapwood. Sapwood seemed also to be eaten more than sound heartwood, but the difference was not significant when examined by ANOVA (Table 1); nevertheless, it was significant ($P = 0.001$) by Student's t test. At the end of the test period, termite survival was similar among all treatments (Table 1).

Effects of Extracts. All the heartwood extracts incorporated into filter paper reduced both the paper consumption and the survival of termites (Table 2). No significant differences among the extracts were detected. On average, there was a fivefold reduction in consumption when the treatments were compared with the control; there was also a twofold reduction in termite survival. The above data suggested that all the extracts contained antitermitic compounds.

In the choice feeding test, pseudergates consumed only the control and avoided all the filter paper slices treated with the heartwood extracts (Figure 2). Survival in this test was similar to that depicted for controls in the force-feeding experiment (see Table 2).

Compounds Isolated. TLC of the hexane extract of *L. castilloi* heartwood showed the presence of castillens A, B, C, D, and E as compared with authentic

samples. The methylene chloride extract rendered castillen D (25 mg), castillen E (49 mg), pongaglabrone (6 mg), and 4-hydroxy-benzofuran (13 mg) by column chomatography and preparative TLC. Castillens D and E were then crystallized, and the spectral data from the purified compounds agreed with those previously reported (Gómez-Garibay et al., 1990).

Castillen D. Colorless solid, mp 121°C. ^{13}C NMR ($CDCl_3$, 50 MHz): 197.0 [C = 0], 166.5 [C-6], 162.2 [C-1a], 147.1 [C-3'], 146.4 [C-4'], 145.6 [C-α], 126.4 [C-1'], 123.8 [C-4], 119.7 [C-6'], 115.2 [C-3a], 113.3 [C-7], 110.9 [C-5'], 110.1 [C-2], 107.7 [C-2'], 107.2 [C-β], 103.7 [C-5], 100.7 [OCH_2O], 52.5 [OCH_3], 41.0 [Ar-CH_2].

Castillen E. Colorless solid, crystallyzed from diethyl ether, mp 72–73°C. ^{13}C NMR ($CDCl_3$, 50 MHz): 204.5 [C = 0], 159.4 [C-4'], 144.8 [C-α], 136 [C-2'], 130.8 [C-6'], 129.4 [C-3], 128.8 [C-5], 128.4 [C-2], 126.9 [C-6], 125.5 [C-4], 118.1 [C-1], 112.3 [C-1'], 111.1 [C-3'], 105.1 [C-β], 104.5 [C-5'], 77.8 [C-α'], 42.9 [C-β'].

Pongaglabrone (Khanna and Seshadri, 1963) and 4-hydroxy-benzofuran were also obtained as solids and identified by their spectral data.

Effects of Castillens D and E. Consumption by termites of filter paper impregnated with castillen D decreased as the concentration of this compound increased (Table 3). The highest concentration tested (0.15% w/v) caused a 3.7-fold reduction in the amount of paper eaten as compared to the control. Survival of termites was not affected by any concentration of castillen D tested.

Similar results were obtained with castillen E (Table 4). In this case, the 0.15% treatment caused a 2.6-fold reduction in paper consumption. Survival of termites was not affected at any concentration tested.

Since small amounts of castillen C, and a mixture of castillens A and B

were available, the substances were also tested at the lower concentration (0.025% w/v) following the force-feeding protocol. Neither paper consumption nor survival of termites was significantly different from controls.

DISCUSSION

The heartwood of *Lonchocarpus castilloi* contains antitermitic compounds to *Cryptotermes brevis* pseudergates. These compounds were extracted with four organic solvents and water as indicated by the force-feeding test with impregnated filter paper (Table 2). At the concentration tested, all the extracts were equally effective. Similar results have been reported for other tropical hardwoods (Carter and de Camargo, 1983; Carter et al., 1975). Feeding-deterrent activity, but not toxicity, was detected for the previously known fungistactic flavonoids (Gómez-Garibay et al., 1990), the castillens D and E (Tables 3 and 4). These

compounds could be removed by hexane and other nonpolar solvents; nevertheless, reduction of the heartwood termite resistance was only noted after extraction with methanol and water (Table 1). The above results suggests that other compounds could be directly involved in *L. castilloi* termite resistance or could play a synergistic role.

Besides castillens D and E, other flavonoids have been previously tested against termites (Scheffrahn, 1991; Supriana, 1983). Several flavonoids were able to repell *C. brevis* attack when impregnated into a highly susceptible wood (Wolcott, 1953). Most of them showed poor activity, but taxifolin and pomiferin were considered outstanding. For instance, treatment with 0.05, 0.10, or 0.2% taxifolin solutions for 10 min was enough to protect susceptible wood for two years (Wolcott, 1953). Rotenone, a well-known insecticidal isoflavonoid, which can be isolated from the roots of several legume species, has also been found to be toxic and to deter the feeding of subterranean termites *Coptotermes formosanus* Shiraki (Křečková et al., 1988). Afzelin also has been reported to be toxic to *Heterotermes indicola* Wasmann (Supriana, 1983). At present, however, flavonoids seem to be more involved in the resistance of wood to fungi than to termites. Antifungal properties of monomeric and polymeric wood flavonoids are documented (Déon et al., 1980; Hart and Hillis, 1972). On the other hand, antitermitic compounds identified from wood have been found to be predominantly terpenoids (from monoterpenes to triterpenes), aliphatic acids, naphtho- and anthroquinones, simple quinones, stilbenes and, naphthopyrans (Scheffrahn, 1991). Therefore, in the case of *L. castilloi* heartwood resistance to *C. brevis*, it seems probable that besides the feeding deterrents castillen D and E, other active compounds, probably of a nonflavonoid nature, remain to be identified.

(Received November 4, 1994; accepted January 3, 1995)

Abstract—Garden nasturtium, *Tropaeolum majus* (Tropaeolaceae), is an acceptable host plant for the cabbage butterfly, *Pieris rapae*. Eggs are readily laid on the plant and hatching larvae feed and develop into normal pupae and adults. However, when second- to fifth-instar larvae were transferred from cabbage to nasturtium, they refused to feed and starved to death. Similar results were obtained when larvae were transferred from other host plants to nasturtium. However, larvae that were reared on nasturtium readily accepted cabbage as a new host plant. We have demonstrated the presence of strong antifeedants in nasturtium foliage and identified the most prominent active compound as chlorogenic acid. However, larvae reared on nasturtium had limited sensitivity, and larvae reared on a wheat germ diet were completely insensitive to the antifeedants. Larvae apparently develop sensitivity to the deterrent as a result of feeding on other host plants, whereas continuous exposure to the deterrent causes habituation or suppression of sensitivity development. The results demonstrate that dietary experience can dramatically affect the response of an insect to a potentially antifeedant compound in a plant.

Key Words—Sensitization, habituation, dietary experience, feeding deterrents, *Pieris rapae*.

INTRODUCTION

Behavioral responses of phytophagous insects to chemical constituents of their host plants are known to be affected by previous learning experience, which may involve habituation, conditioning, or imprinting (Szentesi and Jermy, 1989). The most common examples of learning appear to be the result of an associative

*To whom correspondence should be addressed.

0098-0331/95/0400-0465$07.50/0 © 1995 Plenum Publishing Corporation

process, whereas habituation and sensitization are generally considered to be nonassociative. Therefore, quite different neural mechanisms are thought to be involved. Most previous studies of altered feeding behavior have focused on induced food preferences as a result of initial experience. When late-instar larvae are transferred from one acceptable host plant to another, they may initially refuse or lower their consumption rate of the new food (Hanson, 1976; Schoonhoven and Meerman, 1978; Scriber, 1982; Grabstein and Scriber, 1982). However, in a no-choice situation, the new host is generally accepted after a period of temporary starvation. Similar changes in behavior have been observed for insects that were transferred from plants to artificial diet. Some insects will refuse to feed on diet after feeding on a plant (Schoonhoven, 1977; Städler and Hanson, 1978), whereas others may actually perform better (Hajek, 1989). On the other hand, larvae reared on artificial diet may accept a wider range of potential host plants, and, in the case of *Manduca sexta*, this change in behavior can be explained by changes in the sensitivity of chemoreceptors (Schoonhoven, 1967, 1969).

When late-instar larvae of *Pieris brassicae* were given a choice of food plants, they generally preferred the plant on which they were reared (Johansson, 1951). Larvae reared to fifth instar on *Tropaeolum majus* L. (nasturtium) also developed a preference for this plant, so induced preference was clearly indicated. However, when *P. brassicae* larvae were transferred from *Brassica oleracea* to *T. majus*, they refused to feed (Ma, 1972). Larvae of *P. brassicae* also refused to feed on artificial diet after feeding on cabbage, even when a feeding stimulant was added (David and Gardiner, 1966). However, no explanation for the rejection behavior was provided. Recent studies on both *P. brassicae* and *P. rapae* indicate that caterpillars reared on artificial diet have reduced sensitivity to deterrents compared to those reared on a host plant, and this could be related to changes in chemosensory activity (van Loon, 1990). However, the mechanisms responsible for induced preference or changes in sensitivity to plant constituents have not been studied.

Here we report a phenomenon of diet-induced changes in the acceptance of a host plant by larvae of the cabbage butterfly, *Pieris rapae* L., similar to that reported for *P. brassicae* (Ma, 1972) and further show that this can be explained by differential development of sensitivity to antifeedants in that plant. Larvae that were transferred from cabbage to nasturtium refused to feed and consequently starved to death. We have investigated the temporal and dietary requirements for this extreme rejection behavior and have isolated the primary deterrent constituent from nasturtium foliage.

METHODS AND MATERIALS

Insects. Pieris rapae larvae were obtained from a colony that is continuously maintained in the laboratory but is renewed annually by the addition of

field-collected butterflies. Experimental larvae were reared from eggs laid on the plant that served as the initial food. Oviposition occurred in greenhouse cages with supplemental lighting, and as the larvae developed, additional plants were provided to ensure an adequate supply of the specific food. Neonate larvae were obtained from eggs laid on a 4-cm strip of Parafilm wrapped around beakers that were covered with a cabbage leaf, so that tarsal contact provided the necessary stimulant for oviposition (Webb and Shelton, 1988; Renwick et al., 1992). The naive neonates were then transferred to either 2- to 3-week-old nasturtium or 4- to 6-week-old cabbage plants, using a small paint brush. Survival rates for neonates transferred from Parafilm to either cabbage or nasturtium were generally ca. 70%. For rearing on wheat germ diet, larvae were allowed to hatch from eggs laid on Parafilm strips that were subsequently placed in the diet cups.

Plants and Diet. All plants were grown under the same conditions, in Cornell Mix (Boodley and Sheldrake, 1977), with supplemental lighting in an air-conditioned greenhouse maintained at ca. 25°C. Seeds of nasturtium, *Tropaeolum majus* var. Double Gleam, were obtained from Thompson & Morgan, Jackson, New Jersey; *Cleome spinosa* var. Pink Queen, from The Page Seed Co., Greene, New York; and *Reseda luteola* (Weld) from Otto Richter & Sons Ltd., Goodwood, Ontario, Canada. Seeds of *Sinapis alba* were a gift from B. Gabrys and *Brassica juncea* was obtained from Agway, Inc., Syracuse, New York. All plants were 4–6 weeks old when used in experiments. Wheat germ diet was prepared according to the recipe of Bell et al. (1979) and poured into 250-ml styrofoam cups.

Bioassays. Acceptance of new food plants was tested by allowing butterflies to oviposit on a plant and rearing the hatching larvae to third instars on this plant, before transferring them to their new host plant. Acceptance of nasturtium foliage by larvae was tested by placing one larva on a nasturtium leaf contained in a 250-ml ice cream cup. The petiole of each leaf was passed through a hole in the bottom of the cup and immersed in water, so that the leaf remained fresh for the duration of the experiment. Larval transfers were made with a small paint brush, and 50 replications of each transfer were performed. Nasturtium plants were 2–3 weeks old when used for these assays. Continued feeding and frass production on test leaves within 24 or 48 hr was considered to be acceptance, whereas small nibbles followed by avoidance or a complete lack of biting was considered to be rejection.

The feeding deterrent assay (Dimock et al., 1991) consisted of a choice of four leaf discs, 13 mm diameter, cut from fresh cabbage leaves with a cork borer. Two of these were treated with the test extract and the other two with solvent (methanol) alone. Five larvae (early fourth instars) of *P. rapae* were introduced at the center of each cup and allowed to feed for a period of 6 hr (when ca. 50–70% of the control disk area had been eaten) under controlled conditions of high humidity in an incubator. Leaf area consumed was measured

using a Li-Cor 3100 area meter. A feeding deterrent index (FDI) was calculated, based on the areas consumed from all the disks. $FDI = 100\ (C - T)/(C + T)$ where C is the area consumed of control disks and T the area consumed of treated disks. The area of treated disks consumed was expressed as a proportion of the total (treated + control) disk area consumed, and the data were subjected to arcsine square-root transformation. Differences between treatments and controls were analyzed using a one-sample t test on the transformed data, under the null hypothesis that the total area consumed was distributed evenly over treated and control disks. Differences among treatments were analyzed using a Waller-Duncan K-ratio t test ($K = 100$) on the transformed data.

Extraction of Foliage. Foliage was extracted following a standard procedure for the isolation of deterrents (Renwick and Radke, 1987). Fresh foliage was dropped into boiling ethanol, followed by homogenization and filtration. The ethanolic extract was evaporated under reduced pressure and the residue was defatted with hexane before dissolving in water. The aqueous extract was partitioned 3× with 1-butanol, and all fractions were tested for deterrent activity.

Isolation of Deterrent. Butanol extracts were first fractionated by flash chromatography on a 45 × 2-cm column packed with 30 g 55–105 μm C_{18} silica, and fractions were eluted with 90 ml each of water, 10%, 20%, 50%, and 100% acetonitrile in water. The most deterrent fraction was subjected to reverse-phase HPLC, using a semipreparative C_{18} column, with a gradient of 100% water to 100% acetonitrile to further isolate fractions for bioassays. The most prominent active component was isolated by repeated HPLC and characterized by UV and NMR spectroscopy. Details of the isolation, identification, and deterrent activity will be published elsewhere (Huang and Renwick, unpublished data).

RESULTS

In an initial experiment, *P. rapae* larvae at each stage from second to fifth instar were removed from cabbage plants on which they had been reared and placed on foliage of nasturtium. Observations of possible feeding were made after 24 and 48 hr. None of these larvae initiated feeding on nasturtium. Most individuals left the leaves and all eventually died, apparently as a result of starvation. However, when neonate (naive) larvae were placed on nasturtium plants, ca. 70% of these fed successfully, and the percentage surviving was similar to that for neonates placed on cabbage plants.

The possibility of induced dependence on the first host plant as a general mechanism for refusal behavior was tested by performing the reverse transfer. *P. rapae* butterflies were allowed to oviposit on nasturtium plants, and when the resulting larvae reached third instar, they were transferred to cabbage. These larvae readily accepted cabbage as their new food plant (Table 1). Similarly,

TABLE 1. ACCEPTANCE OR REJECTION OF NEW HOST PLANTS BY *Pieris rapae* LARVAE ($N = 50$) REARED TO THIRD INSTAR ON VARIOUS PLANTS OR ARTIFICIAL DIET[a]

Initial diet	New plant	Feeding on new plant (%)
Cabbage	Brassica juncea	98
(Brassica oleracea)	Sinapis alba	100
	Cleome spinosa	98
	Reseda luteola	96
	Nasturtium	0
Nasturtium	Cabbage	100
(Tropaeolum majus)		
Cabbage	Nasturtium	0
Brassica juncea		2
Sinapis alba		6
Cleome spinosa		4
Reseda luteola		14
Wheat germ diet		94

[a]Larvae on the initial host plants hatched from eggs laid on these plants. The larvae on wheat germ diet were from eggs laid on a strip of Parafilm so that no previous contact with a plant occurred.

the nasturtium-reared larvae accepted a range of alternate hosts, including members of the Cruciferae (*Brassica juncea* and *Sinapis alba*), Resedaceae (*Reseda luteola*) and Capparidaceae (*Cleome spinosa*). Cabbage-reared larvae also fed readily when transferred as third instars to these alternate host plants. Thus, nasturtium is unique among this group of experimental plants in its unacceptability to *P. rapae* from cabbage.

The requirements for development of refusal behavior were examined by rearing larvae to third instars on each of the alternate host plants as well as wheat germ diet, and then transferring these insects to individual leaves of *T. majus*. In general, almost all larvae that had developed on the test plants refused nasturtium foliage. Only a few larvae that were transferred from *Reseda luteola* showed a tendency to accept the nasturtium. However, larvae reared on the "artificial" diet readily fed on nasturtium leaves within 24 hr (Table 1).

Since neonate larvae accept nasturtium for feeding, the onset of rejection behavior must occur during the first-instar stage of larval development. The time required to trigger this behavioral change was measured by allowing neonate larvae to feed on cabbage foliage for increasing periods of time, from 0 to 24 hr, before transferring them to nasturtium leaves. Since these neonates were initially transferred from Parafilm, ca. 30% of them did not feed successfully on either nasturtium (0 time) or cabbage, probably as a result of handling. No change in behavior was induced after 2 hr of feeding, but the number of larvae

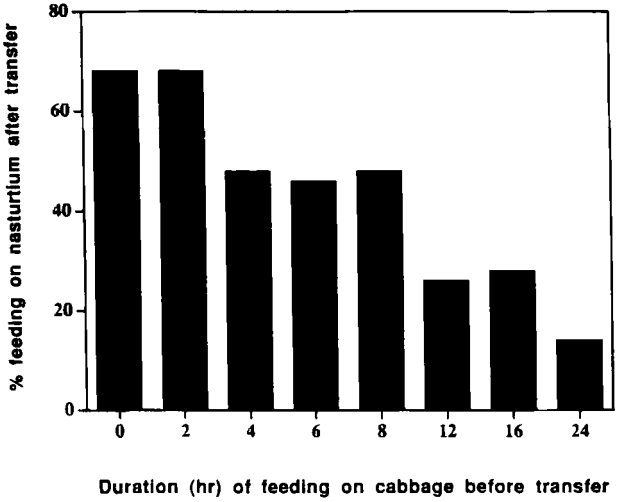

FIG. 1. Change in acceptance of nasturtium by first-instar *P. rapae* after feeding for an increasing length of time on intact cabbage plants. After each time period, 50 larvae were transferred to individual leaves of *Tropaeolum majus*, and the number feeding was recorded after 24 and 48 hr. The data are shown for 24 hr, at which time acceptance or rejection generally was clear, based on either distinct consumption of tissue or lack of damage to the leaf.

accepting the new host declined steadily thereafter with increasing time spent on cabbage (Figure 1).

The possible presence of antifeedants in nasturtium was investigated by extraction of foliage with hot ethanol, fractionation by solvent partitioning, and bioassay of the fractions. When aqueous fractions of the nasturtium extracts were partitioned with *n*-butanol, the butanol fraction proved to be highly active in standard feeding deterrent assays. At concentrations of 0.1 g leaf equivalents (gle), fourth instars that had been reared on cabbage were completely deterred from feeding on treated cabbage leaf disks. Deterrent activity was obtained at concentrations as low as 0.004 gle/disk (between treatment and control $t = 2.25$, $P < 0.05$), but disappeared at 0.001 gle/disk ($t = 0.16$, $P > 0.05$) (Figure 2). A significant difference was found between FDIs for these two treatments. Reverse-phase HPLC of the active fraction on a C_{18} column with a diode array detector revealed the presence of compounds that gave UV spectra typical of phenolic derivatives. The most prominent compound was isolated and found to be strongly deterrent on its own. This compound was subsequently

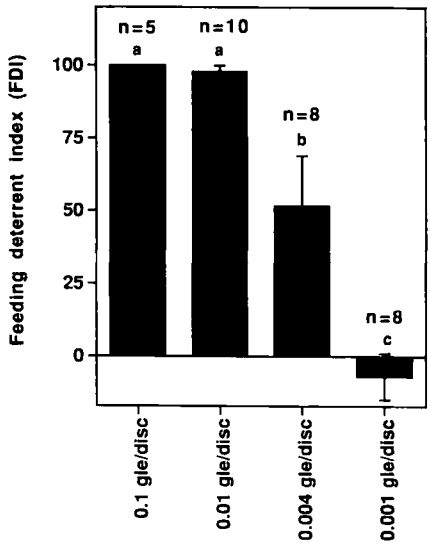

FIG. 2. Feeding deterrent activity of the butanol-soluble components of nasturtium on *P. rapae* larvae reared from hatching to early fourth instar on cabbage, and then given a choice of feeding on two cabbage disks treated with butanol extract of nasturtium at doses of 0.1, 0.01, 0.004, or 0.001 gle/disk, or feeding on two control cabbage disks each treated with solvent only. Concentrations are expressed as gram leaf equivalents (gle) based upon fresh weight of extracted foliage. The feeding deterrent index (FDI) is based on areas of discs consumed. FDI = 100 × (control − treated)/(treated + control). Means (±SE) with the same letters are not significantly different according to a Waller-Duncan *K*-ratio *t* test ($K = 100$) on the transformed data; n = number of replications of the bioassay.

identified as chlorogenic acid, on the basis of spectral analyses, acid and base hydrolysis, and comparison with a sample of the authentic chemical.

Feeding deterrent assays of the butanol extract of nasturtium were performed to compare the sensitivities of fourth-instar *P. rapae* that were reared on cabbage, nasturtium, or wheat germ diet. At a deterrent concentration of 0.01 gle/disk, the cabbage-reared larvae were strongly deterred. However the nasturtium-reared larvae were much less responsive to the deterrent (between treatment and control, $t = 3.00$, $P < 0.05$), and the diet-reared larvae were completely unaffected ($t = 0.11$, $P > 0.05$) (Figure 3). Significant differences were found between FDIs for cabbage-reared larvae and larvae reared on nasturtium or diet.

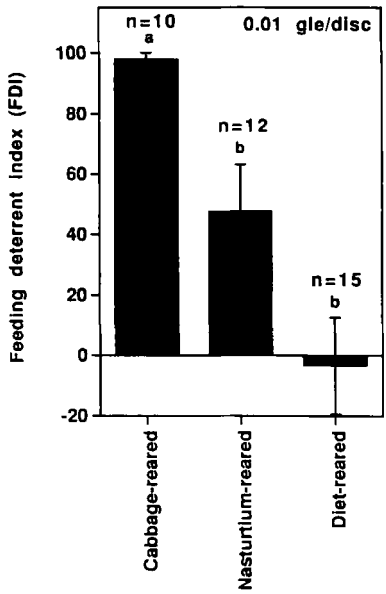

FIG. 3. Response of *P. rapae* larvae reared from hatching to early fourth instar on cabbage, nasturtium, or artificial diet, and then given a choice of feeding on two cabbage disks each treated with butanol extract of nasturtium at doses of 0.01 gle/disk or two control cabbage disks each treated with solvent only. The feeding index was calculated as in Figure 2. Means ($\pm$SE) with the same letters are not significantly different according to a Waller-Duncan K-ratio t test ($K = 100$) on the transformed data; n = number of replications of the bioassay.

DISCUSSION

Absolute rejection of a normally acceptable host plant by an insect appears to be relatively unique. This behavior differs from the more typical induced preference behavior that occurs as a result of an insect becoming conditioned on a plant (Szentesi and Jermy, 1989). However, the refusal of artificial diet after feeding on a plant has been observed for some insects (Schoonhoven, 1977; Städler and Hanson, 1978), as has the reverse situation where conditioning on artificial diet actually increases the host acceptance range of *Manduca sexta* larvae (Schoonhoven, 1967). Rejection of nasturtium by cabbage-reared larvae of *P. rapae* can now be explained by the presence of antifeedants, the most prominent of which is chlorogenic acid, in the new food plant. However, sensitivity to the deterrents is dependent on the previous experience of these larvae. Newly hatched first-instar larvae appear to be insensitive to the negative stimuli,

but, by the time they have molted to second instar on cabbage or other host plants, sensitivity to deterrents has developed. This could mean that an inducer present in these plants, but absent in nasturtium, is responsible for triggering the development of sensitivity. However, relative insensitivity of larvae reared on nasturtium might also suggest that habituation to the deterrents occurs. The lack of sensitivity of diet-reared larvae would then indicate the presence in diet of compounds that cause habituation, or suppression of development of sensitivity, to the nasturtium semiochemicals. A similar development of refusal behavior in *P. brassicae* was reported by Schoonhoven (1977), who transferred larvae to artificial diet after various periods of time feeding on cabbage. After three days, the proportion of larvae accepting the artificial diet was negligible. Schoonhoven suggested that the larvae become "fixed" to cabbage in this time, thus making the artificial diet unacceptable.

The development of deterrent sensitivity in first instars may occur gradually, but the timing appears to be highly variable. The majority of larvae required about 12 hr of feeding on cabbage, but 4 hr was sufficient for some individuals. Actual consumption by individual larvae is highly variable, so the physiological trigger responsible for the change in behavior may depend on the quantity of food consumed. However, individual differences in dose dependency may also occur, and, if changes in sensory peception are involved, individual variation in thresholds for response is likely. Another source of variation is the time taken for an individual larva to initiate feeding. More precise measurement of feeding times would require recording the time at which each larva actually begins to ingest leaf material.

The concept of sensitization to a negative stimulus may suggest new approaches to understanding nonassociative learning in insects. Previous studies of sensitization have focused on increased response to a positive cue after repeated presentation, a reaction referred to as "pseudoconditioning" (McGuire, 1984). *Manduca sexta* larvae were deterred by constituents of wheat germ diet after feeding on a host plant (Städler and Hanson, 1978). However, when reared on wheat germ diet, they were less sensitive to the deterrents. This has been interpreted as meaning that the larvae became habituated to compounds in the diet, resulting in sensitization of these larvae to feeding stimulants in plant leaves (Szentesi and Jermy, 1989). Our results would suggest an alternative explanation, i.e., that the larvae became sensitized to the deterrents in the diet as a result of their feeding on a host plant.

Possible habituation or adaptation of insects to feeding deterrents is a major concern that could limit the practical application of such natural compounds for insect pest control. The physiological mechanisms of habituation and sensitization in vertebrates as well as invertebrates have yet to be elucidated in detail. In insects, sensory adaptation or increased activity of deterrent receptors may occur, or more basic effects on the central nervous system could be involved

(Szentesi and Bernays, 1984). *Pieris rapae* may well serve as a model for future study of the physiological processes involved in the changing responses of organisms to chemical stimuli.

EVOLUTION AND FUNCTION OF LINGUAL SHAPE IN LIZARDS, WITH EMPHASIS ON ELONGATION, EXTENSIBILITY, AND CHEMICAL SAMPLING

WILLIAM E. COOPER, JR.

Department of Biology
Indiana University-Purdue University Fort Wayne
Fort Wayne, Indiana 46805

(Received July 27, 1994; accepted January 4, 1995)

Abstract—Major squamate taxa exhibit extreme variation in lingual morphology, presumably due to correlated variation in trophic and chemosensory functions. Data are presented on evolution of lingual shape documenting several trends: (1) Resting lingual elongation is greatest in families specialized for lingual chemosensory sampling. (2) The greatest increase in elongation achievable by intralingual means including elasticity and foretongue retractility occurs in families with intermediate degrees of lingual specialization for chemosensory sampling. Sampling efficiency may be enhanced by the ability to extend the tongue well beyond the mouth, with resting elongation and intralingual extensibility perhaps jointly determining distance extended. In families lacking sufficient resting elongation, augmentation of intralingual extensibility may be a means of approaching optimal protrusion distances. Decreased extensibility evolved in tandem with the greatest resting elongation, suggesting that resting elongation may be more efficient for protrusion and that elasticity declines as optimal resting length is approached. The optimal shape for chemosensory sampling may be predicted to be highly elongate, as in teiids, varanids, and colubrids. The tongue should be broad at the tip for prehension (as in iguanians), fleshy for manipulation and swallowing, and broad at the base for tamping prey into the esophagus. (3) Lingual surface area relative to that of a rectangle of dimensions length × base width varies accordingly. Relative area is high in families that do not tongue-flick much while foraging because tongues are broad and fleshy throughout their length. It is low in families that have wedge-shaped tongues and intermediate specialization for chemosensory sampling. Narrowing of the anterior tongue may improve chemical sampling. Relative lingual area in chemosensory specialists is very high, with progressive narrowing toward the base as optimal sampling shape is approached in taxa lacking lingual function in swallowing, prehension or prey manipulation.

Key Words—Tongue, chemoreception, vomerolfaction, Squamata, lizard, snake.

INTRODUCTION

The squamate tongue shows dramatic structural and functional variation among families. Great and consistent interfamilial differences are evident in numerous features, including the presence and development of forking (McDowell, 1972; Schwenk, 1994), the distribution and abundance of taste buds (Schwenk, 1985), and muscular anatomy (Schwenk, 1993; Bels et al., 1994). Behaviorally, the tongue is used for lingual prey prehension (Schwenk and Throckmorton, 1989) in one of the two major clades of lizards, Iguania, but not in the other, Scleroglossa.

Functions of lingually mediated chemoreception also vary with lingual structure. All families studied appear to show some degree of pheromonal communication involving lingual chemical sampling (Mason, 1992; Cooper, 1994a). Families of scleroglossan active foragers and iguanid herbivores additionally use the tongue to gather chemical samples for locating and evaluating food prior to biting (Cooper and Alberts, 1990; Cooper, 1990a, 1994a,b). Forked tongues enhance the ability to follow scent trails (Ford and Low, 1983), and a relationship between foraging mode and development of forking is expected and has been confirmed. Tines are absent in most ambush-foraging lizards but are present in several families and higher taxa of active foragers (Schwenk, 1994).

The tongue's major role in detection and identification of prey is sampling chemicals from the environment for analysis by vomerolfaction (Cooper and Burghardt, 1990). Tongue-flicking extends the tongue beyond the mouth, where it contacts chemicals in the air and on any substrate that it touches. Molecules adhere to the moist tongue and are transported to the mouth when the tongue is withdrawn. They reach the vomeronasal ducts at the roof of the mouth by an unknown mechanism and pass through the ducts to the vomeronasal epithelium, where they contact the vomerolfactory chemoreceptor cells (Young, 1990; Halpern, 1992).

Forking is the most obvious lingual adaptation of squamates for chemical sampling, but other features of the tongue may strongly affect sampling ability. Such features might also be related to chemosensory behavior and foraging mode. For example, tine development is positively correlated with active foraging mode (Schwenk, 1994). Excluding the tines, the most obvious lingual characteristic affecting sampling ability for vomerolfaction is the degree of elongation. A long tongue that can be extended further outside the oral cavity could enhance both the area sampled during a tongue-flick and the maximal distance from which a substrate can be sampled.

Another aspect of lingual shape that might be related to the evolution of

chemosensory sampling abilities is the degree to which the tongue resembles a rectangle or a wedge. In several families the tongue is broad and roughly rectangular; in others it is wedge-shaped, tapering from its broad base to the tip; in still others it is narrow yet roughly rectangular.

Data are presented in this paper on the lingual shapes of 18 species representing 10 major squamate families. Three measures of static lingual elongation are described, in addition to measures of intralingual extensibility and the degree to which the tongue resembles a wedge or a rectangle. Variation of each variable within and between families is documented. In a cladistic context, interfamilial correlations among the variables are discussed in relation to the evolution of lingual shape. Relationships between the shape of the tongue and its chemosensory and other functions are considered.

METHODS

Several aspects of lingual shape were measured in specimens of 18 species representing major lizard families, snakes, and all of the grades of lingual structure described by McDowell (1972). Availability and cost dictated which species were chosen within families. Although major features of squamate lingual anatomy are consistent at the familial and sometimes subfamilial levels, multiple species were studied in five families to allow a preliminary assessment of intrafamilial variation in the shape of the tongue.

After a long period of relative stability, lizard taxonomy is in a state of flux, necessitating a choice between competing schemes. The families used here are taxa recognized without formal familial designation by Estes et al. (1988) supplemented by the families named by Frost and Etheridge (1989) in reclassifying Iguania, which formerly consisted of Iguanidae, Agamidae, and Chamaeleontidae, but is now divided into numerous families.

The phylogeny adopted here is shown in Figure 1 and representation of taxa in the study appears in Table 1. Frost and Etheridge's (1989) classification of Iguania affects only four species, *Anolis carolinensis*, *Holbrookia maculata*, and *Sceloporus malachiticus*, all of which were formerly in Iguanidae but now are divided between Phrynosomatidae and Polychrotidae, and *Calotes mystaceus*, formerly in Agamidae, which is now the subfamily Agaminae of Chamaeleonidae. Having 11 versus 10 families made very little difference in the outcomes of numerous statistical tests that were conducted using both taxonomies. Therefore, results at the familial level are reported for only the newer classification (Frost and Etheridge, 1989).

Prior to 1991 specimens were killed by freezing and thawed prior to measurement. Subsequently, they were euthanized using sodium pentobarbital. With one exception, only preserved specimens were available for Helodermatidae,

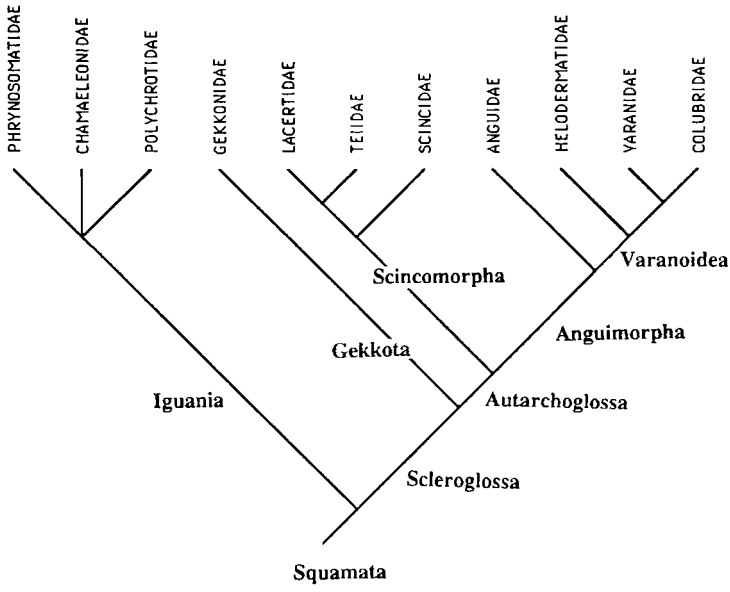

FIG. 1. Phylogeny of squamate reptiles, modified from Estes et al. (1988) to include snakes within Anguimorpha as suggested by chemosensory characters studied by Schwenk (1988, 1993) and the recent revision of Iguania by Frost and Etheridge (1989). Only families for which data are presented are included.

precluding measurement of stretched tongue length and therefore intralingual extensibility. Variables were measured to the nearest millimeter by ruler or to the nearest 0.1 mm by vernier calipers. Lingual measurements were made using a dissecting microscope or illuminated magnifying glass except for *Holbrookia maculata* and *Cnemidophorus sexlineatus*, which were measured in the field using the naked eye.

For each specimen, the following variables were measured: snout–vent length (SVL) in millimeters; resting tongue length from tip to base of the tongue (RTL) in the midline to the nearest millimeter with the tongue lying unextended in situ; stretched tongue length (STL) from tip to base (in the midline to the nearest millimeter with the tongue being grasped at the base of the notch or tines by forceps and stretched to its maximal extent), base width (BW) of the resting tongue to the nearest 0.1 mm; and tip width (TW) to the nearest 0.1 mm measured 1.0 mm posterior to the base of the tines or notch. All lingual variables were measured on the dorsal surface.

Several derived variables reflecting the tongue's intrinsic shape were cal-

TABLE 2. DERIVED VARIABLES REFLECTING FORM OF TONGUE AND ITS MEASUREMENTS RELATIVE TO HEAD SIZE

Variable	Formula	
BASELONG	RTL/BW	Elongation of the resting tongue relative to base width
RELONG	RTL/TW	Elongation of the resting tongue relative to tip width
SELONG	STL/TW	Elongation of the stretched tongue relative to tip width
EXTEND	(STL/RTL) − 1	Elasticity in resting tongue lengths
RELAREA	(TW + BW)/(2BW)	Area of upper lingual surface relative to maximum possible rectangular area

culated from the measured variables (Table 2). The variables BASELONG, RELONG, and SELONG reflect the resting elongation relative to base width and tip width and in part, the tongue's stretchability beyond its resting length. The variable EXTEND gives the increase in length due to stretching, the units being numbers of resting tongue lengths. EXTEND indicates the proportional increase in degree of extensibility during protraction that is attributable to hydrostatic lengthening and intralingual sheathing. RELAREA gives the tongue's area as a proportion of the area of a rectangle of length RTL and width BW. It is calculated from the formula for a trapezoid having height RTL and end lengths TW and BW.

Preliminary regressions showed highly significant correlations of the variables with SVL. An attempt was made to remove allometric effects of body size by analysis of covariance using logarithmically transformed variables with SVL as the covariate, but the preliminary tests revealed pronounced heterogeneity of slope, eliminating that technique.

Another method for removing effects of body length is analysis of residuals of regressions of variables on SVL, but the heterogeneous slopes among families also eliminated that possibility. However, correlations between SVL and the derived lingual variables need not indicate allometry. Such correlations necessarily exist whenever the families differ in both SVL and the values of derived variables. Fortunately, much of the effect of body length is removed because the derived variables are ratios.

A second difficulty is that despite the statistical pooling of data for both sexes, body proportions such as head size differ between the sexes in some species. This effect might tend to obscure interfamilial differences. However, the problem was reduced by including data for only two female *Eumeces laticeps*, a species having strongly sexually dimorphic head size.

The primary statistical analyses were nested analyses of variance for unequal cell frequencies (Sokal and Rohlf, 1981), species being nested within families. Individual comparisons between families were made by using Duncan's multiple-range tests. Some tests for differences between pairs of species within families were conducted by analysis of variance at the specific level followed by Duncan's multiple-range tests.

The derived variables were tested for normality. Significant nonnormality was discovered in BASELONG, EXTEND, and RELAREA. Raising the raw data to the 0.1 power rendered the distribution of EXTEND normal. Applying a logarithmic transformation to RELAREA reduced, but did not eliminate, nonnormality. Nonnormality could not be removed for BASELONG. Differences among families in BASELONG and RELAREA were therefore tested nonparametrically by Kruskal-Wallis one-way analysis of variance followed by Mann-Whitney U tests for individual comparisons (Siegel, 1956).

Relationships between derived variables at the familial level were studied by conducting regressions using family means. Some of the derived variables show intercorrelations at the individual level due to shared defining variables. Nevertheless, the various derived variables might or might not be significantly correlated with each other at the familial level. Statistical tests were two-tailed unless otherwise indicated, with $\alpha = 0.05$, with the exception of the unprotected sign tests and Mann-Whitney U tests used for multiple comparisons with BASELONG, for which a significance level of 0.01 was adopted.

Evolutionary histories of elongation and extensibility were examined using the TRACE function of MacClade 3.01 (Maddison and Maddison, 1992). BASELONG was selected to represent elongation because that variable produced the greatest statistical resolution among taxa and the three elongation variables were highly intercorrelated. Characters were coded as unordered multistate transformation series with each character corresponding to a family or group of families for which the variable was statistically distinct. Although extensibility was treated as a single transformation series, lingual elasticity and retractility of the foretongue in Anguidae are distinct traits having effects that are summed as extensibility. Zero was used to represent the lowest quantitative character values and progressively higher integers to represent greater elongation or extensibility. The single data point of 0.52 was used for extensibility in Helodermatidae.

LINGUAL VARIABLES AND CORRELATIONS

Individual Variables: Interfamilial and Intrafamilial Variation

BASELONG. Other things such as hydrostatic elongation and hyoid structure being equal, a highly elongated tongue may be best suited to extension well

beyond the mouth during tongue-flicking. Elongation of the tongue relative to its width at the base varied dramatically among squamate families (Table 1), reaching a pinnacle in snakes over 19 times that in agamine chamaeleonids. By far the greatest elongation among lizards was found in varanids, but even these lizards had less than one third the elongation of the snakes. Among the other lizards, the most pronounced elongation occurred in Teiidae, Lacertidae, and Helodermatidae, all of which tongue-flick at high rates while active. The range of mean elongation was quite small (1.29–1.73) in the lizard families exclusive of these three.

Differences in BASELONG among families were highly significant (X^2 = 213.18, df = 10, $P < 0.001$). Given the distinctness of mean BASELONG values, it is not surprising that Colubridae, Varanidae, Teiidae, and Lacertidae all differ significantly from any of the other families (Table 3). Even with the small sample size, Helodermatidae differed significantly from all but Gekkonidae. The difference between Helodermatidae and Gekkonidae, which approached significance at $P = 0.016$, is very likely a real difference that will be detectable with a larger sample. Even the relatively small differences among the remaining families were consistent enough to be significant with two statistically indistinguishable exceptions: (1) polychrotids, gekkonids, and anguids; and (2) phrynosomatids and chamaeleonids.

Species within three families differed in BASELONG. The teiids *Cnemidophorus sexlineatus* and *Tupinambis rufescens* each had significantly greater

elongation than *C. tigris* ($U = 1.5$; $df = 9, 30$; $P < 0.001$ and $U = 4$; $df = 6, 9$; $P < 0.007$, respectively), but did not differ significantly from each other. The intrageneric difference might be the result of the different measurement procedure used for *C. sexlineatus*. In Anguidae, *Elgaria coerulea* and *E. multicarinatus* each had significantly lower elongation relative to base width than did *Ophisaurus ventralis* ($U = 13$; $df = 12, 14$; $P < 0.001$ and $U = 22$; $df = 11, 12$; $P < 0.007$, respectively), but were themselves quite similar in elongation ($U = 51$; $df = 11, 14$; $P > 0.10$). The colubrids *Thamnophis sirtalis* and *Elaphe guttata* differed significantly in BASELONG ($U = 0$; $df = 5, 12$; $P < 0.001$), the mean being much greater in the former (Table 3). No significant differences in BASELONG occurred in Phrynosomatidae or Scincidae.

RELONG. As with BASELONG, the greatest resting elongation occurred, as expected, in those taxa that tongue-flick most extensively. Lizard families differed markedly in degree of resting lingual elongation relative to the width of the tongue's tip, elongation being greatest in varanids and teiids (Table 1). Snake tongues showed much greater resting elongation than those of any lizard family. There was considerable overlap in RELONG among several of the remaining families, but RELONG was notably lower in phrynosomatids than in the remaining families.

RELONG clearly differed among lizard families ($F = 634.76$; $df = 10, 224$; $P < 0.001$) and among species within families ($F = 18.57$; $df = 7.224$; $P < 0.001$). Differences among families and among species within families accounted for 97% of the variance in RELONG. Colubrids, varanids, and teiids had significantly higher and phrynosomatids significantly lower RELONG than any of the other families (Table 4). Lacertidae, the family with the fourth

[b] NS, not significant; *$P < 0.05$.

greatest mean RELONG, was statistically distinct from all families except Anguidae. Gekkonidae, Polychrotidae, and Agamidae had relatively low mean RELONG values that did not differ significantly; the same is true for Helodermatidae, Scincidae, Agamidae, and Gekkonidae. In addition, several families at intermediate levels of RELONG did not differ significantly: Anguidae, Helodermatidae, and Scincidae. Despite the numerous nonsignificant comparisons, there is a clear gradient of RELONG from low values in iguanian families to higher ones in autarchoglossan lizards and snakes. Use of preserved specimens of helodermatids may possibly have lowered RELONG artificially if the tongue shrank proportionally more in length than in width at the tip.

Individual comparisons following significant ANOVA at the specific level ($F = 381.04$; $df = 17, 224$; $P < 0.001$) revealed some differences among species within families. For the colubrids, mean RELONG was significantly greater in *Thamnophis sirtalis* than in *Elaphe guttata*. Among teiids, *Cnemidophorus sexlineatus* had significantly greater RELONG than either of the other two species, which did not differ from each other. The presence of an intrageneric difference in the absence of an intergeneric difference among teiids suggests the possibility of a measurement artifact due to lack of magnification during measurements for *C. sexlineatus*. However, the results admit several interpretations, including artifact, lower elongation in *C. tigris*, and possibly allometric differences among the taxa or some combination of these. There were no significant differences in RELONG between species within Anguidae, Scincidae, and Phrynosomatidae.

SELONG. Because SELONG combines resting elongation with any other features allowing additional extension intrinsic to the tongue, but not including any contribution by the hyoid apparatus to protraction, this variable should give the best estimate of overall extensibility during tongue-flicking. As for RELONG, SELONG varies among families by over an order of magnitude. For families other than Helodermatidae, for which data were lacking, SELONG varied significantly among families ($F = 459.88$; $df = 9, 220$; $P < 0.001$) and among species within families ($F = 8.27$; $df = 7, 220$; $P < 0.001$). Differences among families and among species within families accounted for 95% of the variance in SELONG.

The ranks of families were similar to those for RELONG in that colubrids, varanids, and teiids showed the greatest and phrynosomatids and polychrotids the least SELONG (Table 1). Comparison of the significances of differences between families for RELONG (Table 4) and SELONG (Table 5) reveals only two differences: Scincidae differs significantly from Chamaeleonidae and Anguidae for SELONG, but not RELONG. These differences reflect increasing extensibility in the order Chamaeleonidae, Scincidae, Anguidae. There were some differences in ranks of familial means between total elongation, reflected in SELONG, and RELONG, but these were minor and for the most part did

TABLE 5. SIGNIFICANCE OF DIFFERENCES IN SELONG BETWEEN FAMILIES

not correspond to significant differences among pairs of families having reversed ranks.

SELONG also varied significantly among species within families ($F = 262.30$; $df = 16, 220$; $P < 0.001$). The two colubrid species differed significantly, *T. sirtalis* having the greater SELONG. In Teiidae, *C. sexlineatus* and *T. rufescens* had significantly greater SELONG than did *C. tigris*, presumably for the same reasons discussed above. There were no significant differences among species in the anguids, scincids, and phrynosomatids.

EXTEND. The capacity to extend the tongue beyond the mouth for chemical sampling might be accomplished by increasing the tongue's resting length, by making the tongue more elastic, or by a combination of these and intralingual ensheathment. Because hydrostatic stretchability may be important in iguanian lizards that use the tongue to capture prey (Schwenk and Throckmorton, 1989), as well as during lingual feeding cycles (Bels et al., 1994), it was predicted that EXTEND would be greatest in families that use the tongue extensively for chemosensory sampling and in those in which great extension of the tongue occurs during lingual prey prehension.

The predictions that stretchability should occur in families that use the tongue to capture prey and rely on chemical sampling to locate food are contradicted. The tongue of an agamine chamaeleonid exhibited low stretchability despite marked protrusion during lingual prey prehension. Presumably, prey prehension depends on lingual projection (Bels et al., 1994) rather than hydrostatic elongation.

EXTEND was also low in the families most specialized for lingual che-

mosensory sampling. From these first data (Table 1), it would appear that the greatest stretchability is found in families of autarchoglossans that tongue-flick at relatively high rates, but have not evolved either great resting elongation or great proportional tine length. Enhanced stretchability may be interpreted as a possible means of compensating for relatively short resting tongue length by providing greater extensibility and access to chemicals in the external environment. However, it is unclear whether or not EXTEND reflects a real capacity for voluntary lingual elongation.

The tongue was somewhat stretchable in all families studied, but the degree of intralingual extensibility varied considerably (Table 1). It was lowest in the families having greatest BASELONG, i.e., Colubridae, Varanidae, and Teiidae, and in those having the least, Phrynosomatidae and Chamaeleonidae. The greatest intralingual extensibility occurred in Anguidae, in which the tongue was slightly over twice as long when stretched as when resting.

EXTEND differed significantly among families ($F = 75.71$; $df = 9, 220$; $P < 0.001$) and among species within families ($F = 17.16$; $df = 7, 220$; $P < 0.001$), the two factors accounting for 0.78 of the variance. The two families having lowest mean extensibility, Phrynosomatidae and Colubridae, differed significantly from each other, and both had significantly lower means than any of the other families (Table 6). Varanidae, Teiidae, and Chamaeleonidae did not differ significantly from each other, and had mean extensibilities significantly higher than Phrynosomatidae and Colubridae. Varanidae and Teiidae had significantly lower means than the remaining families.

No differences in extensibility were statistically detectable in representatives of Gekkonidae, Polychrotidae, Scincidae, and Lacertidae, but EXTEND

in these families was greater than in all other families except Anguidae, with the exceptions that no significant differences occurred between Scincidae, Gekkonidae, and Agamidae. In Anguidae, EXTEND was significantly greater than in all other families. Statistical tests were not conducted for Helodermatidae due to lack of data. However, measurement of a single fresh specimen allowed estimation of a degree of extensibility (Table 1) close to that of varanids and chamaeleonids.

Considerable intrafamilial and intrageneric variation in extensibility was found in phrynosomatids and teiids. In Phrynosomatidae, *Sceloporus malachiticus* had substantially and significantly greater extensibility than *Holbrookia propinqua*, which could be a real difference or an artifact of the lack of magnification during measurements of the latter species. Among the three teiids, the only significant differences were significantly greater extensibility in *Cnemidophorus tigris* and *Tupinambis rufescens* than in *C. sexlineatus*. This might indicate either that the tongue of *C. sexlineatus* is less elastic or that its resting elongation was overestimated relative to that of the other species. No other significant differences were found within families.

RELAREA. RELAREA was conceived as a proportion in which low values would indicate narrowing of the tip of the tongue, which may indicate specialization of the tongue for chemosensory sampling. The tongue's base was always substantially wider than its tip in the lizards. However, in the groups having tongues with the most advanced chemical sampling features, narrowing has continued past the tip of the tongue toward its base. This trend is complete in snakes. Values of RELAREA greater than 1.00 occurred in snakes because the tongue was slightly wider just posterior to the tines than at its base. As a result, lingual surface area was closest to that of a rectangle having dimensions base width and resting length in those squamate families having some of the most elongated and least elongated tongues and the most and least specialized tongues for chemosensory purposes (Table 1).

RELAREA differed significantly among families ($X^2 = 199.24$, $df = 10$; $P < 0.001$). Snakes had much higher RELAREA than any of the lizards (Tables 1 and 7). Phrynosomatids and varanids, having the second and third greatest means, had significantly greater RELAREAs than the remaining families and differed significantly from each other. For Polychrotidae, the mean was significantly greater than for Teiidae and Gekkonidae, but the other differences among Polychrotidae, Teiidae, Helodermatidae, and Gekkonidae were nonsignificant.

Three families, Chamaeleonidae, Scincidae, and Anguidae, had the identical lowest value of RELAREA, i.e., their tongues flared the most from tip to base. These families did not differ significantly from each other, but each had significantly lower RELAREA than any of the other families. Lacertidae, having a RELAREA intermediate to those of the last two groups of families, differed significantly from all families.

[a] Familial abbreviations are in Table 3.
[b] NS, not significant; ***$P < 0.001$. Probabilities of no difference are less than or equal to the numerical values given.

Because deviation from normality occurred in only two families and was not large, ANOVA of logarithmically transformed RELAREA were conducted for comparison, yielding nearly identical results. Differences were highly significant among families ($F = 171.00$; $df = 10, 224$; $P < 0.001$) and among species within families ($F = 3.78$; $df = 7, 224$; $P < 0.001$); they accounted for 0.89 of the variance. The only difference from the nonparametric analysis was that Polychrotidae did not differ significantly from either Gekkonidae or Teiidae.

Differences among species within families were also significant ($X^2 = 200.93$, $df = 17$, $P < 0.001$). The colubrid species had significantly different RELAREAs ($U = 1.5$; $n = 5, 12$; $P < 0.003$), *Thamnophis sirtalis* often having greater width at tip than at the base of the tongue. There were no significant intrafamilial differences in RELAREA for Phrynosomatidae, Scincidae, Teiidae, and Anguidae.

Relationships among Variables

Familial means were significantly correlated for several pairs of lingual variables (Table 8). Very strong relationships occurred between BASELONG, RELONG, and SELONG. These high correlations were expected because the three variables all indicate the degree of elongation relative to different lingual width referents and states of lingual stretching. That the greatest statistical resolution was achieved with BASELONG may merely reflect the larger variation of tip width than base width among families.

Of greater interest are the significant correlations between all three intrinsic

TABLE 8. CORRELATIONS BETWEEN FAMILIAL MEANS OF LINGUAL VARIABLES

	RELONG	SELONG	EXTEND[a]	RELAREA
BASELONG	0.97***[b]	0.94***	0.46[NS]	0.87***
RELONG		0.99***	0.21[NS]	0.80**
SELONG			0.01[NS]	0.71*
EXTEND				−0.68*

elongation variables and RELAREA. The relationships with RELAREA are somewhat misleading because two of the four highest values of relative area were found in the two families having the lowest elongation. The relationship is driven by the high lingual elongation in snakes, varanids, and teiids and their correspondingly high values of RELAREA due to narrowing of the tongue further toward the base than in other taxa.

Extensibility was significantly correlated only with lingual area relative to that of a rectangle. Inclusion of Helodermatidae in correlations involving extensibility by using the single measurement of EXTEND as the family mean strengthens the correlation to $r_s = -0.80$, $N = 11$, $P < 0.005$). This relationship highlights the finding that extensibility is greatest in those families that use the tongue in several contexts for chemosensory investigation but have evolved neither great anterior narrowing of the tongue nor narrowing proceeding to the base of the tongue. Intralingual extensibility is maximized in families that are intermediate between extreme vomerolfactory specialists and those that use the tongue little or not at all while foraging.

STABILITY, EVOLUTION, AND FUNCTION

Relative Stability of Shape Within and Between Families

Based on the limited number of species sampled, pronounced, reliable differences appear to occur among squamate families for each of the lingual variables. The high proportions of variance explained by differences among families indicate that several variables clearly partition the families. Differences among families are clearer for elongation than intralingual extensibility or degree of narrowing of the tongue from posterior to anterior, but even the latter variables differ substantially among some families.

Significant intrafamilial variation occurred for all of the lingual variables, but the range of this variation was quite small in comparison to that of inter-

familial variation. One indication of this is that the ratios obtained by dividing F values among species within families by F values among families were quite low, ranging from 0.02 to 0.23, being highest for the variables accounting for the lowest proportions of the total variance. Smaller F values might be expected within families in part due to the large number of families relative to species, but this can account for only a small portion of the large observed difference.

A stronger indication that variation is greater between than within families is that despite the numerous significant differences among species within families, the total range of variation within families invariably occupies only a small fraction of the total range for all families on a given variable. For example, significant differences in BASELONG occurred among species in Teiidae, Anguidae, and Colubridae. However, the total ranges of values for all species of teiids (5.56–11.67) overlapped minimally with those of anguids, but with no other families; ranges for colubrids (17.36–30.00) did not overlap with those of any other families. In addition, the range for Anguidae (3.79–5.82) overlaps with those of the families showing relatively little elongation, but does not overlap with those for Colubridae and Varanidae. Intrafamilial variation in the lingual variables does occur, but its magnitude is much less than that of interfamilial variation.

Chemosensory anatomy and behavior in squamates have long been considered phylogenetically conservative; indeed, they have been used as important taxonomic characters (e.g., Camp, 1923; Schwenk, 1988, 1993). The present findings of much less intrafamilial than interfamilial variation show that lingual shape variables also reflect phylogeny at the familial level. An equally important set of findings, some of which were predictable qualitatively from earlier studies (e.g., McDowell, 1972), is that the lingual variables differ sufficiently to clearly separate numerous squamate families.

Shape Relationships

Relationships among elongation, intralingual extensibility, and relative surface area are summarized in Table 9. The groupings emphasize the opposing trends of elongation and intralingual extensibility and association of intermediate elongation and relative area with high intralingual extensibility. Lingual chemosensory roles during foraging are minimal (Cooper, 1994a,b) in all of the taxa showing combined high relative areas, low elongation, and low to medium elasticity. The low elongation, elasticity, and relative areas of Chamaeleonidae, which lacks lingually mediated prey chemical discrimination, may be attributable to the unique lingual projection mechanism of this family.

In Scincidae the tongue is used to detect and locate prey during foraging. This chemosensory function may account for the wedged shape of the tongue and its low relative area. The scincid tongue exhibits a slightly greater resting elongation (RELONG) than BASELONG due to anterior narrowing, perhaps to

TABLE 9. PATTERNS OF LINGUAL ELONGATION, ELASTICITY, AND DORSAL SURFACE AREA

Relative area[a]	Elongation	Elasticity	Family
High	low	low	Phrynosomatidae
High	low	medium	Polychrotidae, Gekkonidae
Low	low	low	Chamaeleonidae
Low	low-medium	medium	Scincidae
Low-medium	low-medium	high	Anguidae

enhance chemosensory sampling. However, it has low values of BASELONG and its elasticity is no greater than the plesiomorphic squamate value. The anterior narrowing produces a wedged lingual shape.

In all of the remaining families, lingually mediated prey chemical discrimination is important to foraging and there is clear corresponding evidence of progressive adjustments in lingual morphology related to chemosensory sampling. Lacertids and anguids show intermediate lingual elongation and the highest levels of intralingual extensibility. They are the first groups of lizards mentioned in this section having forked tongues and have relatively poorly developed forking compared to several other families. Correspondingly, surface areas are low or intermediate, reflecting the wedged shape.

In Helodermatidae, lingual area is high, elongation is slightly greater than in anguids but nearly identical to that of lacertids, and development of forking is slightly greater than in lacertids (Schwenk, 1994). The moderate lowering of extensibility may have been made possible by increasing elongation and improved chemical sampling by the forked portion of the tongue. The high relative area possibly may represent no change from the ancestral condition.

In the two lizard families having the greatest lingual specialization for chemical sampling, Varanidae and and Teiidae, the relative area is high and the tongues are highly elongated. In Varanidae, and perhaps Teiidae, this is attributable to narrowing toward the base, so that the tongue has, in effect, passed its maximal wedging and is returning due to a more rectangular condition. Low elasticity corresponds to great elongation in these families. These trends are more pronounced in Varanidae, presumably due to the loss of a lingual role in swallowing.

Colubrid snakes exhibit by far the greatest specialization for lingual chem-

ical sampling. The greatest elongation is combined with very low elasticity and the greatest relative area. Relative area is great, presumably due to loss of lingual functions unrelated to chemical sampling. That elasticity is less and elongation greater in colubrids than in varanids suggests both an increased importance of lingual chemical sampling in snakes and continued evolution toward the optimal shape and resting elongation for chemical sampling.

Evolution and Functional Significance

Lingual shape may be expected to reflect important lingual functions including chemosensory behavior as well as food manipulation (prehension, reduction, transport, swallowing) and possibly drinking (Bels et al., 1994). For example, all three measures of elongation have strong positive correlations with quantitative measures of chemosensory responses to prey chemicals and with degree of activity during foraging, which is in turn related to use of the tongue to locate prey (Cooper, unpublished data). The probable evolutionary histories of the shape variables are outlined below and their possible adaptive significances are addressed.

Elongation. Based on statistically distinct ranges of character values, the evolution of lingual elongation (BASELONG) is shown in Figure 2. This portrayal suggests that the degree of elongation in polychrotids and gekkonids is plesiomorphic. Within Iguania, elongation may have decreased in Phrynosomatidae and Chamaeleonidae. Due to unresolved familial relationships in Iguania, it is unclear whether any decreases occurred independently in these families.

The state of elongation is uncertain in ancestral scincomorphans (the ancestors of Scincidae, Teiidae, and Lacertidae among others), but the tongue is less elongated than the plesiomorphic condition in Scincidae and more elongated in both Lacertidae and Teiidae. The relatively low BASELONG value of skinks may be somewhat misleading because RELONG and SELONG are both greater than in the plesiomorphic condition. It is clear that elongation increased beyond the plesiomorphic values either in ancestral scincomorphans or in the ancestors of Lacertiformes (Lacertidae, Teiidae, and Gymnophthalmidae).

All three varanoid families (Helodermatidae, Varanidae, and Colubridae) have greater lingual elongation than did plesiomorphic lizards, and this increase appeared independently of that in Lacertiformes. The condition in ancestral varanoids is shown as equivocal because it is uncertain to what degree the tongue elongated. Nevertheless, some degree of elongation occurred in ancestral varanoids and further increases may have occurred in the common ancestor of snakes and varanids and autapomorphically within Serpentes.

There is a striking correspondence between the evolutionary origins of lingual elongation and the evolution of forked tongues. Lingual tines appear to have had independent origins in Lacertiformes and Varanoidea, based on current

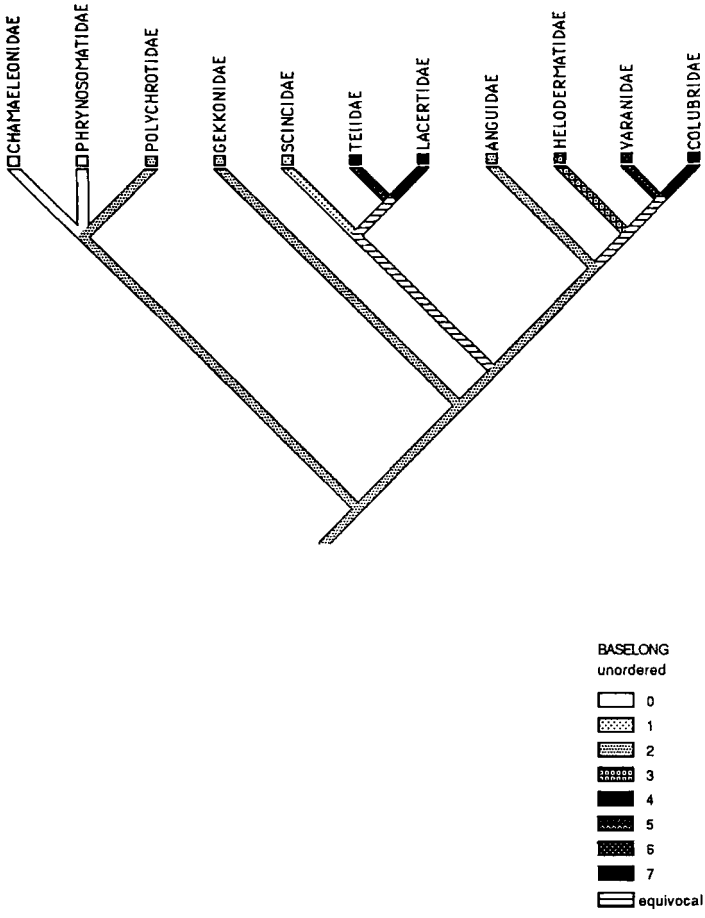

FIG. 2. Evolution of lingual elongation (BASELONG) in Squamata. Zero was used to represent the lowest quantitative character values and progressively higher integers to represent greater elongation.

views of the probable relationships of Serpentes and Amphisbaenia (Schwenk, 1994). However, up to four independent origins are possible if Amphisbaenia is not part of Lacertiformes and Serpentes is not correctly placed in Varanoidea (Schwenk, 1994). Although data are lacking on elongation in Amphisbaenia, the data do indicate the independent evolution of increased elongation in the same two taxa in which tines originated, with a possible additional independent origin in Serpentes.

The exact correspondence of origins between lingual forking and elongation strongly suggests a functional link between these traits. The obvious commonality is that both traits improve lingual chemosensory sampling ability. Forking enhances the ability to follow trails, likely by tropotaxis (Schwenk, 1994), and may also increase the surface area involved in gathering samples from substrates. Elongation presumably improves the ability to bring the tip of the tongue, including tines, into contact with substrates to be sampled. Forking and elongation appear to have coevolved as joint participants in lingual chemical sampling in those taxa that rely most heavily on the lingual–vomeronasal system in foraging and exhibit lingually mediated prey chemical discrimination and strike-induced chemosensory searching (Cooper, 1994a,b).

Using RELONG as the measure of elongation, anguids have tongues that are somewhat elongated beyond plesiomorphic values. The correspondence between origins of forking and elongation breaks down because all autarchoglossans have greater than plesiomorphic elongation. Nevertheless, the greatest elongation originates in the taxa where forking originates. This statement also requires some qualification based on the definition of forking. Whereas McDowell (1972) states that tines are present in anguids, Schwenk (1994) does not recognize the abbreviated structures of Anguids as tines. Whichever definition is used, the underlying relationships are unaffected.

Provided that elongation allows the tongue to be protruded further out of the mouth, it presumably facilitates chemosensory sampling of areas from which the head is excluded, such as narrow crevices. Any increase in the ability of the tongue to collect molecules from substrates a greater distance outside the mouth might also aid in chemosensory investigation of potential prey or other objects without approaching as closely. Greater elongation would also permit sampling volatiles from a greater volume of air.

Protrusion distance for chemosensory sampling could be enhanced in several ways. First, the resting tongue length could be augmented, possibly in conjunction with lengthening of the head. The pattern of interfamilial variation in BASELONG and RELONG to be discussed next shows that this has occurred during squamate evolution. Second, an increase in lingual elasticity (capacity for hydrostatic lengthening) might allow greater protrusion distance even if resting elongation were constant. Elasticity might be important for the alternative or additional reason that it might provide increased flexibility (see discussion of lingual musculature, flexibility, and chemosensory sampling in Bels et al., 1994), perhaps facilitating lingual sampling in crevices or at large angles to the head. Third, a portion of the tongue could be folded or the anterior portion ensheathed within the remainder of the tongue while at rest, as in anguids. Fourth, mechanisms for lingual protraction could be altered by evolutionary changes in intrinsic lingual musculature (reviewed by Bels et al., 1994) even in the absence of the other changes. All of these changes might occur simultaneously.

The hypothesized importance of elongation for chemosensory sampling is supported by the observations that: (1) Some of the least elongated tongues occur in three iguanian families lacking lingually mediated prey chemical discrimination (Cooper, 1989a, 1994c). These families have the lowest values of total possible elongation as indicated by stretched elongation. The only apparent exceptions are that the species sampled in the iguanian family Polychrotidae has slightly greater BASELONG than that measured in members of the scleroglossan family Scincidae and the sole chamaeleonid species has slightly (but not significantly) greater RELONG than the gekkonid. The resting and basal elongation in Polychrotidae does not reflect any current chemosensory adaptation related to vomerolfaction because polychrotids have very poorly developed vomeronasal organs (Gabe and Saint Girons, 1976) and show no signs of lingually mediated detection of prey chemicals (Cooper, 1989a). (2) There is consensus among all three measures that the greatest elongation is found in Colubridae, Varanidae, and Teiidae, the three families most specialized for lingual–vomeronasal chemoreception. (3) Intermediate values are found in four autarchoglossan families (Lacertidae, Scincidae, Anguidae, and Helodermatidae) that are less extreme chemosensory specialists but are capable of lingually mediated prey chemical discrimination (Cooper, 1989b,c, 1990a,b, 1991) and in Gekkonidae, a family in which the presence of a high percentage of chemoreceptor cells in the vomeronasal organ suggests a greater capacity for making vomerolfactory discriminations than in iguanians (Gabe and Saint Girons, 1976).

Extensibility. Intralingual extensibility (Figure 3) has a very different history than elongation and forking. As for elongation, the plesiomorphic condition of extensibility is an intermediate value indicating a fairly high capacity for being stretched. Elasticity may have decreased in Phrynosomatidae and Chamaeleonidae, but as for elongation, it is unclear whether the decrease represents one or two independent origins. The lowest values occur not only in iguanian families, but also in the most extreme chemosensory specialists, i.e., Colubridae, Varanidae, and Teiidae. The families having the greatest intralingual extensibility are Anguidae and Lacertidae, families in which lingually mediated prey chemical discrimination is important but in which tines are either absent or relatively small.

The only significant increase in elasticity beyond the plesiomorphic condition is seen in Anguidae, but it is uncertain whether any change in extensibility occurred in ancestral anguimorphans (anguids + varanoids). Elasticity in ancestral varanoids is less than the plesiomorphic condition. Regarding the equivocal condition in ancestral anguimorphans, some decrease might have occurred along that internode prior to a great increase in Anguidae, but the proposed function of extensibility to increase lingual protrusibility suggests that the decrease is more likely to have begun in ancestral varanoids. A further decrease occurred in snakes. The only other decrease in elasticity is in Teiidae.

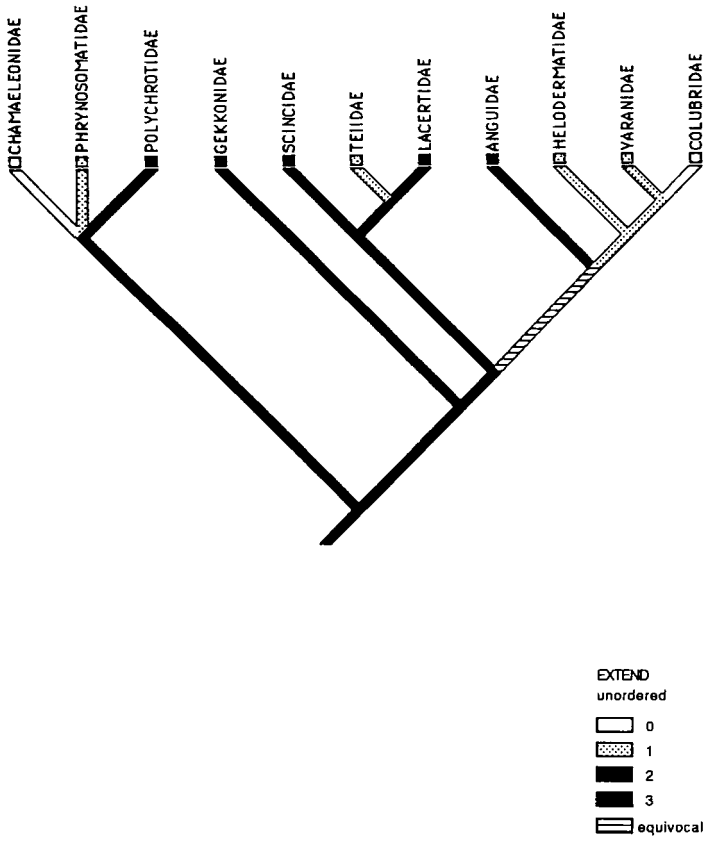

FIG. 3. Evolution of intralingual extensibility in Squamata. The primary contributing factors are elasticity and (in Anguidae) retractility of the foretongue into the anterior portion of the hindtongue. Zero was used to represent the lowest quantitative character values and progressively higher integers to represent greater extensibility.

There is a close, but imperfect relationship between changes in forking and elongation and changes in elasticity. Elasticity decreased and both forking and increased elongation evolved in Varanoidea, with further decrease in elasticity corresponding to the greatest elongation in Colubridae. In Iguania, no change in forking occurred, but both elongation and elasticity decreased in Phrynosomatidae and Chamaeleonidae. The correspondence is imperfect in Lacertiformes because forking originated and elongation increased in both Teiidae and Lacertidae, but elasticity decreased only in Teiidae.

These correlated evolutionary changes support the conjecture that lingual elasticity and elongation may be alternative, but jointly acting, mechanisms of increasing the maximum distance that the tongue may be protruded beyond the mouth. If so, the absence of a decrease in elasticity in Lacertidae despite the presence of tines and a slight degree of elongation may indicate that the resting tongue is not long enough to permit optimal chemical sampling without some degree of augmented extension afforded by elasticity.

If extensibility is a mechanism permitting greater lingual extension when the tongue is too short to permit optimal sampling, maximal extensibility should occur in those families that rely heavily on chemosensory sampling, but lack great lingual elongation. Anguids and lacertids have the most extensible tongues. In both families, the tongue is elongated slightly above plesiomorphic values and the degree of RELONG is very similar. Anguids either lack or have very short tines and lacertids have the relatively shortest tines among the remaining taxa having forked tongues (Schwenk, 1994). The prediction is thus borne out by the occurrence of greatest extensibility in the two families showing intermediate specialization for chemosensory sampling.

The great similarity of SELONG in Anguidae and Lacertidae suggests that additional elongation provided by elasticity and/or retractility of the foretongue may be especially advantageous when the total achievable elongation is about 9.5 times the width at the tip of the tongue. Teiids, varanids, and colubrids have SELONG values over 12 and the other families have SELONG values of roughly 2.5–7.0. The expectation of high extensibility in the range above 7 and less than 12 can be tested in Amphisbaenia and Xenosauridae.

Although lingual elongation and extensibility are not significantly correlated, intralingual extensibility and elongation might be importantly related as alternative means of achieving protrusibility. In squamates having the greatest resting tongue length, the needed protrusibility is achieved without exceptionally great intralingual extensibility. However, any initial evolutionary development of a highly elastic or otherwise extensible tongue for chemosensory sampling might have been effected by muscular innovations such as acquisition of a well-developed intrinsic circular muscle system, which is absent or weakly developed in iguanians but strongly developed in scleroglossans (Schwenk, 1988, 1993).

In all of the families studied here other than Anguidae, EXTEND is a measure of lingual elasticity. In anguids the foretongue is ensheathed in a region of invagination between the foretongue and hindtongue (McDowell, 1972). Because the foretongue of anguids is retractile, measures of the tongue's resting length underestimate its total length. Thus, EXTEND in anguids measures the total proportional increase in length due to both elasticity and extension of the foretongue from its sheath.

Elasticity as measured here could be a quantitative measurement of the degree of hydrostatic lengthening (Smith, 1984; Schwenk, 1986) or bear some

functional relationship to it. However, it seems unlikely that the degree of elasticity observed can be accounted for entirely by hydrostatic lengthening (Schwenk, personal communication). The extent to which elasticity permits voluntary elongation, whether by hydrostatic lengthening or other mechanisms, is unknown.

Although variation in intralingual extensibility among families could be epiphenomenal, it will likely prove to be explicable in terms of lingual functions in swallowing and chemical sampling. Competing demands for efficient swallowing, intraoral prey handling, lingual prey prehension, grooming, and chemosensory sampling presumably result in selective compromises reflected in lingual resting and extended shapes. Beyond the obvious potential benefits of increased extensibility and flexibility for lingual chemical sampling, some degree of elasticity may be important for the other lingual roles noted above.

Selective compromise might account for the restriction of highest levels of extensibility to families having short tines and relatively unelongated resting tongues. This restriction also is consistent with the hypothesis that greater extensibility evolved to permit behavioral compensation for limitations on lingual extension for chemosensory sampling in families lacking great resting elongation. These hypotheses are not mutually exclusive.

The decrease in elasticity and high resting elongation found in families having the most highly developed tines also is consistent with the compensatory interpretation. According to the hypothesis, resting elongation and elasticity initially increase as chemosensory demands result in evolution of distinct tines. As this process continues in families having very strong chemosensory orientation, tines increase in proportional length and resting elongation continues to increase. When the resting elongation in concert with means of protrusion other than intralingual extensibility becomes sufficient to meet the heightened need for chemical sampling, intralingual extensibility begins to decrease, falling to levels as low as in families not relying on the tongue to detect prey vomodors.

A reconstruction of the evolutionary history of SELONG by MacClade's trace function suggests that the initial evolutionary increase in total achievable elongation occurred in the common ancestor of autarchoglossa, which includes the vast majority of actively foraging lizards and all lizards and snakes showing forking, elongation, and behavioral specializations for lingual chemosensory sampling. This reinforces the hypothesis that the total elongation due to the combination of resting elongation and extensibility is important for chemosensory sampling.

A different interpretation might be that elasticity decreases in those families having the greatest resting lingual elongation, but for reasons unrelated to chemosensory sampling. The decrease might be thought to have occurred simply because the tongue has lost its role in swallowing (as in varanids and snakes) (McDowell, 1972). However, although retention of some degree of elasticity may be important for glutitional function, elasticity is also low in Teiidae,

Phrynosomatidae, and Chamaeleonidae, families in which the tongue does participate in swallowing (Bels et al., 1994). The unique lingual projection mechanism of chamaeleonids may explain the decreased elasticity in that family, but not in the other two families. Lingual function during swallowing cannot explain the high extensibility in Anguidae or the increase in total elongation in the common ancestor of Autarchoglossa in the absence of an increase in resting elongation.

Surface Area. The probable evolution of dorsal lingual surface area relative to that of a rectangle is shown in Figure 4. The surface area of the tongue is a

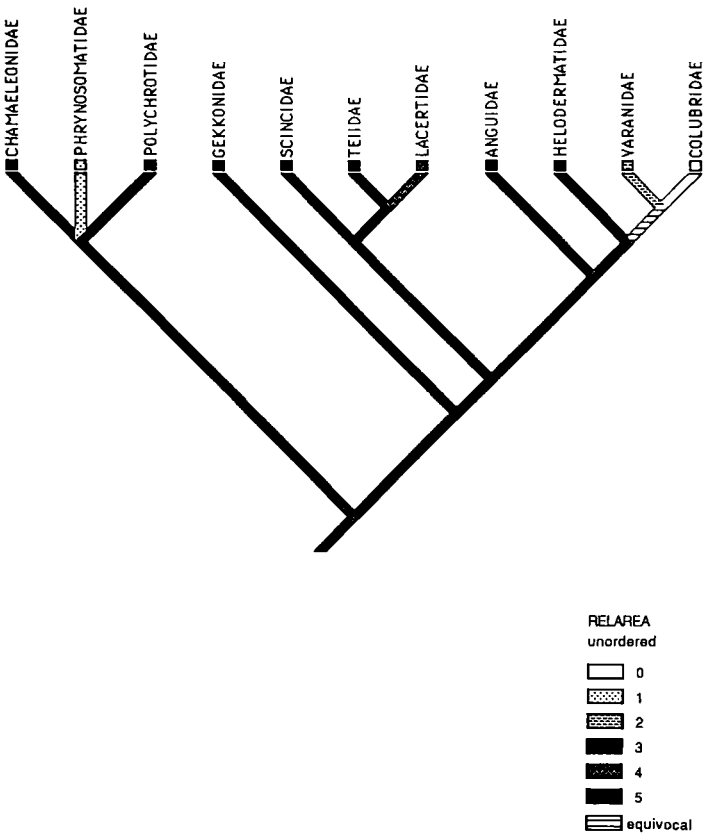

FIG. 4. Evolution in Squamata of lingual surface area relative to that of a rectangle having sides equal to resting tongue length and base width. Zero was used to represent the highest quantitative character values and progressively higher integers to represent lower relative lingual area.

relatively high proportion of that of a rectangle with sides equal to resting tongue length and base width in phrynosomatids, polychrotids, and gekkonids, families of lizards having tongues that are relatively unelongated and lack tines. Relative area may have decreased from the plesiomorphic level in Chamaeleonidae and increased in Phrynosomatidae. These changes may be related to the lingual projection mechanism of chamaeleonids or to relative widths of posterior arms of the tongue that may function in manipulation of food (McDowell, 1972; Bels et al., 1994).

The evolutionary path shown in Scincomorpha (represented here by Scincidae, Lacertidae, and Teiidae) illustrates the hazards of using shape variables that may be based on multiple underlying factors. A decrease in relative area occurred in Lacertidae and Scincidae, but not in Teiidae. As teiids have nearly the plesimorphic value of relative area, the plesiomorphic condition is depicted as present in the ancestors of Scincomorpha and Lacertiformes.

It is far more likely that RELAREA actually decreased in ancestral scincomorphans and may have decreased further in the ancestor of Lacertiformes. The decrease in Scincidae and Lacertidae primarily reflects narrowing toward the tip of the tongue, resulting in a wedged shape. As the tongue becomes progressively elongated, it also tends to become narrower posteriad. Thus, in Teiidae, in which the tongue is more elongated than in any families save Varanidae and Colubridae, the effect of the narrow tongue tip is just offset by the posterior narrowing to produce the observed relative area.

In Anguimorpha relative area appears to have decreased in anguids and increased in Varanoidea, presumably increasing in ancestral varanoids and further in colubrids. The most likely interpretation of the depicted evolutionary path is that narrowing at the tip began in the ancestor of Autarchoglossa or of Anguimorpha, then RELAREA returned to the apparently plesiomorphic condition in Helodermatidae as progressive elongation with narrowing toward the base occurred, and finally RELAREA increased above plesiomorphic levels in Varanidae and Colubridae as posterior narrowing continued.

In taxa having relatively broad tongues, tapering from base to tip might increase lingual sampling abilities by: (1) allowing access of the sampling surface to restricted spaces and (2) concentrating the sample in a narrow region having the primary responsibility for indirect transfer of chemicals to the vomeronasal ducts. Retention of a broad base might be important for swallowing or other lingual functions. In taxa such as Serpentes and Varanidae, which have narrow, rectangular tongues, the lack of participation of the tongue in swallowing or manipulation of food (McDowell, 1972) likely eliminated the need for a wide base, freeing the tongue to evolve toward the optimal shape for chemosensory sampling.

The negative correlation between extensibility and relative area may also reflect lingual chemosensory roles. The families having high extensibility, puta-

tively for chemosensory sampling, are precisely those having some anterior narrowing without exceptional resting elongation, a combination yielding low relative area. Other families have low extensibility combined with high relative areas due either to the relative unimportance of chemosensory sampling or to evolution of alternative means obviating the need for great intralingual extensibility.

Caveats

In this study I have speculated from a very narrow data base. Nevertheless, the major findings regarding lingual shape are presumably robust because lingual structure tends to be very conservative within squamate families. The generalizations that I have attempted to infer from the limited taxonomic base must be considered hypotheses requiring verification by data on a wider range of squamate families, genera, and species. This is especially clear for the preliminary reconstructions of evolutionary histories of the shape variables; these must be taken as provisional hypotheses.

I have speculated also about evolutionary and functional relationships among lingual elongation, intralingual extensibility, and lingual surface area relative to that of a rectangle. Behavioral data on the importance of these aspects of lingual shape are needed to verify or refute several of my functional assumptions. Perhaps the most conjectural topic covered is the importance of intralingual extensibility due to a combination of elasticity and extension of any folded portion. The data suggest the hypothesis that intralingual extensibility compensates for resting elongation insufficient to allow optimal protrusion of the tongue beyond the mouth for chemosensory sampling. It must be emphasized that this novel idea is not to be taken as a conclusion. It is merely a preliminary hypothesis that must be tested. Information is needed regarding intralingual extensibility in additional taxa, including the families noted earlier.

Kurt Schwenk (personal communication), who has thoroughly studied squamate lingual anatomy (e.g., Schwenk, 1984), has suggested that the lengthening caused by stretching the tongue is an artifact, not a natural ability. For the hypothesis to be valid, squamates must be able to voluntarily increase the length of the tongue. It is not necessary that they be able to do so to the maximal extent that I measured by stretching the tongue artificially, but the magnitude of voluntary extension must be proportional to the stretched extension. Data on the magnitude of voluntary intralingual lengthening are unavailable, but are crucial to the hypothesis.

Acknowledgments—This work was partially supported by contract DE-AC09-76SR00819 between the U.S. Department of Energy and the University of Georgia through its Savannah River Ecology Laboratory (SREL). Much of the data collection was completed while the author was a visiting faculty research participant at SREL in 1987, supported in part by Oak Ridge Associated

Universities. Additional support was provided by a grant-in-aid from Auburn University at Montgomery and by Indiana University Purdue University at Fort Wayne. I am grateful to George Zug and the Smithsonian Institution for a loan of gila monsters.

(Received September 14, 1994; accepted January 20, 1995)

Abstract—In this study we tested whether pyrrolizidine alkaloids (PAs) of *Cynoglossum officinale* serve as antifeedants against herbivores. Total PA N-oxide extracts of the leaves significantly deterred feeding by generalist herbivores. Specialist herbivores did not discriminate between food with high and low PA levels. Three PAs from *C. officinale*, heliosupine, echinatine, and 3'-acetylechinatine, equally deterred feeding by the polyphagous larvae of *Spodoptera exigua*. Although the plants mainly contain PAs in their N-oxide form, reduced PAs deterred feeding by *S. exigua* more efficiently than PA N-oxides. On rosette plants, the monophagous weevil *Mogulones cruciger* significantly consumed more of the youngest leaves, which had the highest PA level and the highest nitrogen percentage. Larvae of *Ethmia bipunctella*, which are oligophagous within the Boraginaceae, did not discriminate between leaves. All generalist herbivores tested significantly avoided the youngest leaves with the highest PA levels. In the field, the oldest leaves also were relatively more damaged by herbivores than the youngest leaves. It is hypothesized that the skewed distribution of PAs over the leaves of rosette plants reflects optimal defense distribution within the plant.

Key Words—*Cynoglossum officinale*, Boraginaceae, pyrrolizidine alkaloids, chemical defense, specialist herbivores, generalist herbivores, *Ethmia bipunctella*, *Mogulones (Ceutorhynchus) cruciger*, *Spodoptera exigua*, *Helix aspersa*, *Frankliniella occidentalis*, *Locusta migratoria*, *Lyriomyza trifolii*.

INTRODUCTION

Like philosophers who search for the meaning of life, chemical ecologists look for the "raison d'être" of secondary plant substances (Fraenkel, 1959) or, more specifically, alkaloids (Wink, 1993). Pyrrolizidine alkaloids (PAs) are mainly found in the Asteraceae and the Boraginaceae (Hartmann, 1991). Although the toxicity of PAs to vertebrates has been well documented (Greimer, 1900; Mattocks, 1986; Anonymous, 1989; Wink, 1993), their role as defenses against insect herbivores is less clear. It is often assumed "intuitively" (Wink, 1993) that PAs protect the plant against insect herbivores as well, although evidence for this assumption is sparse (Hartmann, 1991) and even contradictory (see Bentley et al., 1984).

Plants containing PAs still can suffer considerable herbivore damage. In the first place, the plants can be damaged by specialist herbivores that have adapted to PAs (Prins and Nell, 1990; Van der Meijden et al., 1991). Secondly, the total PA content may not be related to herbivory, because the different types of PAs in the plant are not equally deterrent (Bentley et al., 1984; Dreyer et al., 1985; Speiser et al., 1992). Thirdly, some plant parts contain less PAs than others (Hartmann and Zimmer, 1986; Hartmann et al., 1989; Van Dam et al., 1994).

In order to generate a hypothesis on the role of PAs in the feeding behavior of herbivores on the whole plant, we have to consider both the plant's and the herbivore's point of view. Young leaves are more valuable for the plant than old leaves, because they have the highest photosynthetic rates and the longest life expectancy (Harper, 1989). Meanwhile, young leaves are more attractive for herbivores (Hodkinson and Hughes, 1982; Soldaat and van der Meijden, 1990) because they contain higher nitrogen and water percentages (Mooney and Gulmon, 1982). According to optimal plant defense theory, the young leaves should thus be protected best (Zangerl and Bazzaz, 1992). Based on theories of coevolution of plants and herbivores (Ehrlich and Raven, 1964), it can be expected that specialist herbivores will not be deterred by high chemical defense levels in the youngest leaves, while generalists will (Cates, 1980).

In this paper we test whether PAs of rosette plants of *Cynoglossum officinale* L. (Boraginaceae) act as defenses against herbivores. PA levels differ significantly between leaves on the same rosette plant; the youngest leaves have 50–190 times higher PA concentrations than the oldest leaves (Van Dam et al., 1994). *C. officinale* contains several PAs, such as echinatine, 3′-acetylechinatine, heliosupine, trachelanthamine, and viridiflorine (De Jong et al., 1990; Hartmann and Witte, 1994; Van Dam et al., 1995), which are mainly present in the N-oxide form (Sykulska, 1962; Van Dam et al., 1995).

C. officinale is a host plant for a range of herbivores (De Jong et al., 1990). Nevertheless, herbivory on *C. officinale* is usually less than 10% of the leaf

area (Prins and Nell, 1990), indicating that the plants are well defended. For our experiments, we chose two specialist herbivore species, the monophagous weevil *Mogulones cruciger* and the oligophagous larvae of *Ethmia bipunctella*. Both herbivores are commonly found on *C. officinale* in The Netherlands (Prins and Nell, 1990; Prins et al., 1992). We also tested the deterrency of PAs on five herbivore species that are not specialized on *C. officinale*. The polyphagous snail, *Helix aspersa*, is the only one of these five species that is naturally occurring in the plant population we studied (Gittenberger et al., 1970). *Lyriomyza trifolii*, *Frankliniella occidentalis*, and *Spodoptera exigua* all are imported, horticultural pest species from different orders within the Insecta. Finally, we used *Locusta migratoria*, which is an oligophagous leaf-chewer that mainly feeds on grasses (Bernays and Chapman, 1977).

METHODS AND MATERIALS

Plant Species. Cynoglossum officinale L. (Boraginaceae) is a facultative biennial that is commonly found throughout the temperate zones of Europe and Asia (De Jong et al., 1990). The plants used in these experiments originated from the calcareous dune area, Meijendel, near The Hague, The Netherlands. In addition to PAs, the leaves of *C. officinale* are known to contain several other secondary metabolites, such as flavonoids, naphthoquinones, and saponins (Hegnauer, 1964; De Jong et al., 1990).

Herbivores. Mogulones (Ceutorhynchus) cruciger Herbst (Coleoptera, Curculionidae) is monophagous on *C. officinale* (Freese, 1990). The genus *Ceutorhynchus* has recently been revised by Colonelli (1986). The name of this weevil, therefore, has been changed to *Mogulones cruciger* (Heijerman, 1993). The adults feed on the leaves, and the larvae develop in the rootcrown (Dieckmann, 1972), by which they significantly reduce plant weight and seed output (Prins et al., 1992). Adults of *M. cruciger* were sampled in the coastal dune area, Meijendel, The Netherlands, and were kept on leaves of *C. officinale* until they were used for experiments. The larvae of *Ethmia bipunctella* F. (Lepidoptera, Ethmiidae) are oligophagous and feed exclusively on leaves of Boraginaceae (Sattler, 1967). Larvae of *E. bipunctella* were also sampled in Meijendel and propagated on *C. officinale* leaves in the lab (25°C/16 hr light, 18°C/8 hr dark, 70% relative humidity). For the experiments we used second and third stage lab-reared larvae.

Helix aspersa Müller (Gastropoda, Helicidae) occasionally damages leaves of *C. officinale* plants in our experimental garden (K. Vrieling, personal communication). *H. aspersa* individuals were sampled in the garden around the laboratory and kept on wet filter paper and nettle leaves at room temperature before they were used in the experiments.

Lyriomyza trifolii Burgess (Diptera, Agromyzidae) is a polyphagous leafminer, known to feed on over 100 plant species (Harborne, 1988). The larvae feed in the leaf on the mesophyll layer, producing contorted mines (Minkenberg and van Lenteren, 1986). *Frankliniella occidentalis* Pergande (Thysanoptera, Thripidae) also is an extremely polyphagous herbivore. Both adults and larvae feed by piercing leaf cells with their mandibles and ingesting the content through the stylet (Hunter and Ullman, 1989). *Frankliniella* spp. are deterred by lupine alkaloids (Gustafsson and Gadd, 1965). Both *L. trifolii* and *F. occidentalis* were reared on chrysanthemum plants, cv. Ultra Light (20°C continuous 12 L:12 D photoperiod, 70% relative humidity, and 25°C continuous 16 L:8 D photoperiod, 70% relative humidity, respectively). The larvae of *Spodoptera exigua* Hübner (Lepidoptera, Noctuidae) are polyphagous leaf-chewing herbivores (Heath, 1983). *S. exigua* and other *Spodoptera* species are commonly used in antifeedant tests and are known to be sensitive to several types of alkaloids (Aerts et al., 1992; Krug and Proksch, 1993). The larvae were reared in our laboratories on an artificial diet (Aerts et al., 1992) at 25°C/16 hr light, 18°C/8 hr dark and 70% relative humidity. For the experiments we used second to fourth stage larvae. Adults of *Locusta migratoria* L. (Orthoptera, Acrididae) were kept on grass at room temperature before experimentation.

Choice Tests. Disks (2 cm diam.) were punched from young, fully expanded leaves and from old leaves of rosette plants of *C. officinale*. Two disks were placed in every Petri dish (9 cm diam.), which was lined with wet filter paper. One herbivore was placed in each Petri dish. All choice tests were replicated 10 to 20 times, depending on availability of the species. The choice tests with *L. migratoria* were conducted in transparent plastic cups, 9 cm diam., 7 cm high. The disks were fixed in the cups with needles.

We tested two choice situations: a disk of a young leaf versus a disk of an old leaf, and a disk of an old leaf treated with MeOH (control) versus a disk of an old leaf treated with PA N-oxide solution in MeOH. Every disk was painted with 3 μg PA/mg fresh weight (FW), which is comparable to the mean PA level of the youngest three to four leaves. The control disks were treated with the same volume of pure MeOH to rule out solvent effects. The area eaten was scored after three days, except for the *L. migratoria* adults, which were so voracious that the amount eaten had to be scored after one day.

Deterrency of Different PAs. The difference in deterrency between different types of PAs was tested with *S. exigua* larvae. For this experiment leaves of lettuce (*Lactuca sativa* L.) were used as a carrier for the PA solutions, since they are well accepted by *S. exigua* larvae and do not contain PAs. The deterrency of the PAs was tested in a no-choice situation, using lettuce disks (2 cm diam.) treated with MeOH or a methanolic solution of either heliosupine, 3′-acetylechinatine, or echinatine. Since we did not want to fully deter feeding, we applied a relatively low dose of 0.5 μg PA/mg FW. Dose–response experiments with total PA extracts showed that at this concentration the feeding

deterrency was about 50% relative to control disks (Van Dam et al., unpublished data). Four disks treated with the same solution were placed in a Petri dish lined with wet filter paper. Per Petri dish, two second or third stage *S. exigua* larvae were allowed to feed overnight. Every treatment was replicated 10 times. Leaf disks were copied onto quadrille paper and damage was scored as square millimeters area eaten.

PA N-Oxides versus Reduced PAs. Disks from lettuce leaves received 2 μg PA N-oxide/mg FW or 2 μg reduced PA/mg FW, respectively. The two treatments were offered in a choice situation to second stage *S. exigua* larva (20 replicates).

Whole Plant Experiments: Herbivory in the Lab. Seeds of *Cynoglossum officinale* plants were sampled in Meijendel in 1992, scarified, and soaked for two weeks at 20°C/16 hr light, 10°C/8 hr dark. The seedlings were potted in 1-liter pots, each containing a mix of dune sand and compost (1 : 1). Nutrients were supplied by adding 3 g Osmocote Plus (15% N, 11% P, 13% K, 2% MgO, Sierra Chem. Co., Milpitas, CA, USA) per pot. At the start of every experiment, plants of the same half-sib family that had equal numbers of leaves were selected and placed in transparent cylinders. The herbivores were released on the ground near the plant. Since the herbivores differed in voracity, the number of individuals released per plant differed. Per plant, either three adults of *M. cruciger* (six replicates), one individual of *E. bipunctella* (10 replicates), two individuals of *H. aspersa* (21 replicates), 20 females of *F. occidentalis* (12 replicates), or one larva of *S. exigua* (20 replicates) were released near every plant. The herbivores were allowed to feed until a substantial amount of damage was visible. After this period, the absolute amount of damage (area eaten) and the leaf area were scored separately for every leaf. For *F. occidentalis* the percentage of leaf area with silver damage was measured.

For the leaf-miner, eight plants were left for 1 hr in the *L. trifolii* breeding room to allow female flies to lay eggs in the leaves. Seven days later the number of large mines was counted. With this method, the combined effect of antixenotic effects on the choice of female flies and antibiotic effects on the larvae was measured.

Some control plants were kept apart to measure PA content, percentage of nitrogen, leaf toughness, and the number of hairs on individual leaves.

Herbivore Damage in the Field. On June 23, 1994, ten field populations of *C. officinale* in Meijendel were selected to measure the natural herbivory per leaf on rosette plants. Five populations were in a shaded habitat, and five were in an open habitat. In each population the percentage of area damaged per leaf of 12 randomly selected rosettes was estimated. The presence of *E. bipunctella* and *M. cruciger* was noted. The presence of blotch mines caused by *Agromyza* spp. (De Jong et al., 1990) was scored.

Extraction and Purification PA N-Oxides. In order to obtain purified PA N-oxides, dried leaves of *C. officinale* were ground in a Waring blender and

extracted overnight with 10 ml MeOH/g leaf powder. The extract was filtered over cotton wool, and the residue was reextracted twice for 1 hr. The volume of the combined extracts (±500 ml) was reduced in vacuo to ±15 ml and was placed on a Silica-60 (Merck) column. The column was eluted with 150 ml dichloromethane (DCM), followed by 200 ml 10% MeOH in DCM, and three times 200 ml MeOH. The PA N-oxides were eluted in the MeOH fraction. Purity and presence of PA N-oxides were checked by TLC on Silica gel 60 precoated plates that were developed in DCM–MeOH–NH_3 (82:15:3). PA N-oxides were detected with acetic anhydride and Ehrlich reagent (Molyneux and Roitman, 1980). If the extract was still impure, the extract was placed on a preparative Silica plate (Merck, layer thickness 2 mm), which was developed as above. The PA-containing bands were scratched off, and the silica was extracted three times with MeOH with continuous stirring. The MeOH fraction containing the PA N-oxides was evaporated and the residue dissolved in 25.0 ml MeOH. The concentration of the PA N-oxide solution was determined with a spectrophotometric color reaction (Mattocks, 1967). By omitting the oxidation step in this color reaction, we could specifically determine that the solution contained N-oxides only.

Extraction and Purification of Individual PAs. Dried leaf material was extracted with 0.5 M H_2SO_4. After 1 hr, Zn dust was added to reduce the PA N-oxides. The acid extract was filtered and extracted twice with DCM to remove apolar impurities. Subsequently the extract was made alkaline with ammonia (25%) and placed on an Extrelut (Merck) column. After 20 min, the column was washed with two times 100 ml DCM. The volume of combined DCM extracts was reduced with a rotary evaporator to ±10 ml and placed on a Silica-60 column. The column was eluted with a gradient of DCM–MeOH–NH_3 (60:40:1), DCM–MeOH (1:1), DCM–MeOH (25:75), and pure MeOH. Presence of PAs in the fractions was checked on TLC (system as above). The PA-containing fractions were evaporated, dissolved in MeOH, and the PAs were identified with GC-MS (DB-1 column, method II as described by Witte et al. (1993). The concentration of the solutions containing the PAs was determined with a spectrophotometric color reaction (Mattocks, 1967).

PA and Nitrogen Analysis. Individual leaves of five control plants were extracted for PAs as described in Van Dam et al. (1993). Monocrotaline (Sigma, 99% pure) was used as a reference compound in the spectrophotometric color reaction (Mattocks, 1967). The percentage of organic nitrogen in the leaves of two control plants was determined according to the semimicro-Kjeldahl method (Chapman and Pratt, 1961).

Physical Characteristics. Leaves of three control rosette plants were sampled separately and weighed to determine FW. After two days of drying at 50°C, the dry weight (DW) was determined in order to calculate the water content. *C. officinale* leaves are covered with thick-walled, unicellular hairs (De

Jong et al., 1990), which might serve as a barrier against small herbivores. Of three other control plants, the number of hairs was counted in two randomly chosen circles of 1 mm^2 per leaf.

Leaf toughness (in Newtons) was measured on the same leaves as the hairiness, with the use of a penetrometer (Prins and Laan, 1988). Every leaf was punctured on four places, avoiding the midvein, in order to obtain an average toughness over the whole leaf.

Statistical Analysis. Standard statistical tests were performed with Statgraphics 5.0 (Statgraphics Company, 1992). The differences in physical characteristics and damage between leaves were analyzed with the Friedman analysis of variance, since the groups (leaves) were not independent (Sokal and Rohlf, 1981)

RESULTS

Choice Tests

Leaf disks from young and old leaves differed significantly in both PA content and nitrogen percentage; the young leaves had higher levels of both (Table 1). As predicted, PAs did not deter the specialist herbivores *M. cruciger* and *E. bipunctella*. In fact, they ate more of the disks punched from young leaves, but their preference was not significant (Table 1). Both generalists, *S.*

TABLE 1. CHOICE TEST WITH DISKS OF OLD AND YOUNG LEAVES OF *Cynoglossum officinale* AND DISKS TREATED WITH METHANOL (CONTROL) AND PA N-OXIDE (PAs) EXTRACT[a]

	First experiment			Second experiment		
	Old	Young	*P*	Control	PAs	*P*
PA (mg/g FW) (SE)	0.93 (0.22)	4.54 (1.36)	0.03	0.93	3.93	
Nitrogen, % (DW) (SE)	3.30 (0.26)	4.30 (0.26)	0.01			
Specialist herbivores						
Mogulones cruciger	4	6	0.48	9	3	0.11
Ethmia bipunctella	4	9	0.33	12	8	0.18
Generalist herbivores						
Spodoptera exigua	19	0	0.0001	19	0	0.0001
Locusta migratoria	16	2	0.002	10	0	0.004

[a]The table gives the number of individuals that chose to eat more of the treatment. *P* values of Wilcoxon's signed-ranks matched-pairs test. SE = standard error of mean.

exigua larvae and *L. migratoria* adults, preferred the disks with the lowest level of PAs. In the first experiment they preferred to feed on disks from old leaves, which also had the lowest nitrogen percentage (Table 1). In the second experiment, the disks treated with PA N-oxides were totally avoided by both herbivores. This indicates that the PA N-oxides extracted from *C. officinale* had a strong deterrent effect on these herbivores, which normally do not feed on this plant species.

Different PAs

Since *S. exigua* larvae were clearly deterred by PAs, they were used as test animals to assess the difference in deterrency between individual PAs. After separation and purification of a tertiary PA extract, we obtained three different types of PAs in quantities large enough to perform the deterrency test: echinatine [RI = 2172, M^+ (m/z) = 299] 88% pure, 3′-acetylechinatine [RI = 2220, M^+ (m/z) = 341] 89% pure, and heliosupine [RI = 2557, M^+ (m/z) = 397] 87% pure. The purity and identity of the alkaloids were determined with GC-MS. For some unknown reason, we did not obtain saturated PAs such as viridiflorine, although they form 20–30% of the PAs present in the leaves (Van Dam et al., 1995). Although the PA concentration on the leaf disks was relatively low (0.5 μg/mg FW), all PAs clearly reduced feeding by *S. exigua* larvae compared to the methanol treatment (Figure 1, Kruskal-Wallis analysis of variance, H = 13.7, P = 0.004). However, there was no statistically significant difference in

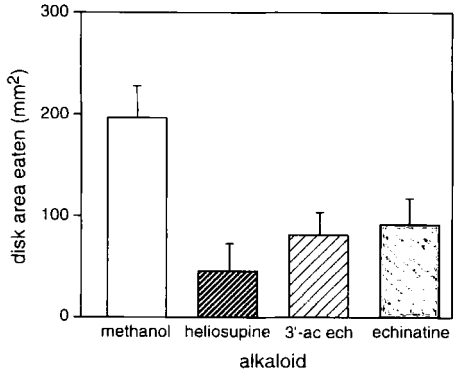

FIG. 1. Feeding deterrency of different types of pyrrolizidine alkaloids (PAs) of *Cynoglossum officinale* against *Spodoptera exigua* larvae. All PAs were applied on lettuce disks (0.5 μg PA/mg FW). Abbreviation: 3′-ac ech = 3′-acetylechinatine. Error bars denote standard error of the mean.

deterrency between the single PAs (Kruskal-Wallis on results of PA treatments only, $H = 3.90$, $P = 0.14$).

PA N-oxides versus Tertiary PAs

For the reason mentioned above, the difference in deterrency between PA N-oxides and their free bases was tested with *S. exigua* larvae. In a choice test, the larvae clearly preferred disks with PA N-oxides over disks with the same concentration (2 μg/mg FW) of tertiary PAs (Table 2). However, this does not mean that PA N-oxides are not deterrent at all. In the first choice experiment, both *S. exigua* and *L. migratoria* were deterred by high PA N-oxide concentrations in their food (Table 1).

Whole Plant Experiments

Physical and Chemical Leaf Characteristics. Again the PA levels differed significantly between the leaves (for results of Friedman analysis of variance see legend to Figure 2): they decreased from the youngest to the oldest leaf (Figure 2a; linear regression on ranks $R = -0.98$, $P < 0.001$). The percentage of nitrogen also declined with leaf age; young leaves had higher nitrogen percentages than old leaves (Figure 2b; linear regression on ranks $R = -0.98$, $P < 0.001$).

Contrary to our expectations, the water content of young leaves was significantly smaller than that of middle-aged leaves (Figure 2c) and was not significantly correlated with leaf number ($R = 0.54$, $P = 0.21$). Not surprisingly, the youngest leaves had more hairs per square millimeter than the older leaves (Figure 2d, $R = -1.0$, $P < 0.001$). Both the increase in water content and the decrease in hairs per area with age probably result from cell stretching. The toughness did not significantly differ between the leaves (Friedman, $\chi^2 = 7.4$, $P = 0.19$) and there was no correlation with leaf number ($R = 0.01$, $P = 0.98$).

TABLE 2. CHOICE TEST WITH GENERALIST HERBIVORE *Spodoptera exigua*[a]

	PA N-ox	*tert*-PA	*P*
Mean eaten (mm^2 ± SE)	42.3 (± 4.3)	13.4 (± 2.8)	0.0004
Animals that ate more of (*N*)	18	2	

[a]Pyrrolizidine alkaloid N-oxides (PA N-ox) of *Cynoglossum officinale* and their corresponding free bases (tertiary PAs) were both applied at 2 μg/mg FW, on disks from lettuce leaves. Differences were analyzed with Wilcoxon's signed-ranks matched-pairs test.

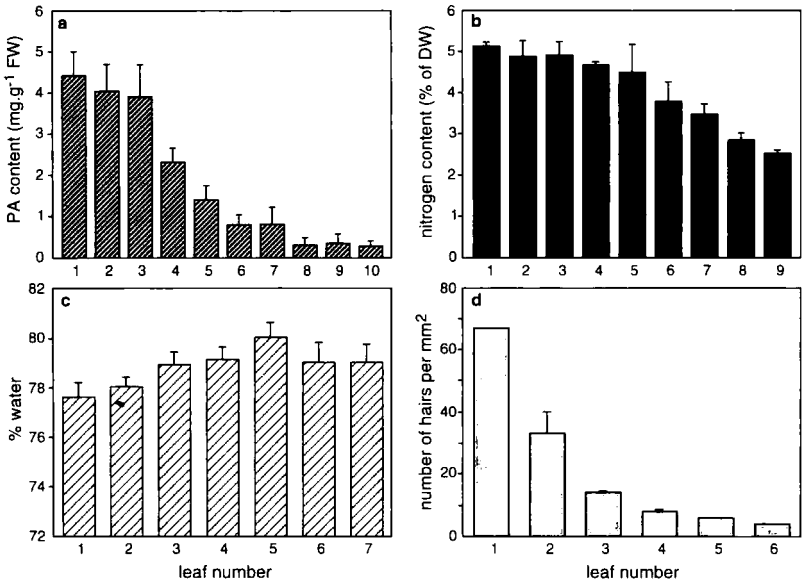

FIG. 2. Chemical and physical leaf characteristics of rosette plants of *Cynoglossum officinale*. Leaf number 1 is the youngest leaf. χ^2 and P value of Friedman analysis of variance are given in parentheses after each characteristic: (a) pyrrolizidine alkaloid (PA) level ($N = 5$, $\chi^2 = 31$, $P = 6.2 \times 10^{-5}$); (b) nitrogen percentage ($N = 2$, $\chi^2 = 14.8$, $P = 0.063$); (c) water content ($N = 8$, $\chi^2 = 13.8$, $P = 0.031$); (d) number of hairs ($N = 3$, $\chi^2 = 15$, $P = 0.01$).

Herbivory in the Lab. The amount of herbivory was measured as the area eaten (square millimeters) per leaf. We choose to express herbivory as the fraction of the leaf that was eaten (square millimeters per square centimeter or percentage). In this way we corrected for the greater chance that larger leaves have to be found by randomly searching herbivores. Without this correction, the differences in damage between leaves were even greater. The monophagous *M. cruciger* adults significantly preferred young leaves over older leaves (Figure 3a, for results of Friedman analysis see legend to Figure 3; linear regression on ranks, $R = -0.99$, $P = 0.00001$), which may be due to the higher nitrogen levels. PAs again did not deter feeding by these monophagous weevils. *E. bipunctella* larvae did not discriminate between leaves (Figure 3b). The negative correlation between damage and leaf number was not significant ($R = -0.55$, $P = 0.12$). This is consistent with our earlier findings that *E. bipunctella* larvae are not deterred by high PA levels in the younger leaves. However, unlike *M.*

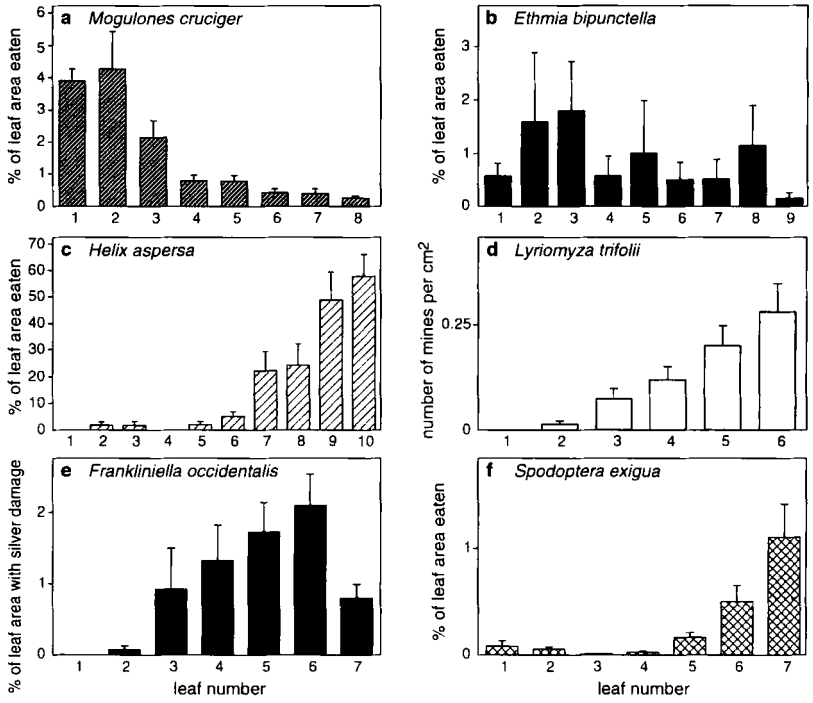

FIG. 3. Fraction of leaves eaten by different herbivores on rosette plants of *Cynoglossum officinale*. Leaf number 1 is the youngest leaf. χ^2 and P value of Friedman analysis of variance are given in parentheses after each species name. (a) *Mogulones cruciger* (N = 6, $\chi^2 = 32.7$, $P = 3.10^{-5}$); (b) *Ethmia bipunctella* ($N = 9$, $\chi^2 = 4.66$, $P = 0.79$); (c) *Helix aspersa* ($N = 21$, $\chi^2 = 86.4$, $P = 8.5 \times 10^{-15}$); (d) *Lyriomyza trifolii* ($N = 8$, $\chi^2 = 33.4$, $P = 3.12 \times 10^{-6}$); (e) *Frankliniella occidentalis* ($N = 12$, $\chi^2 = 45.5$, $P = 3.7 \times 10^{-8}$); (f) *Spodoptera exigua* ($N = 19$, $\chi^2 = 40.8$, $P = 3 \times 10^{-7}$).

cruciger, they did not feed significantly more on leaves with higher nitrogen percentages, as we would have expected.

All generalist herbivores in this experiment significantly discriminated between the leaves (Figure 3c–f). The older the leaves, the more they were consumed (linear regressions on ranks: *H. aspersa*, $R = 0.92$, $P = 0.0002$; *L. trifolii*, $R = 0.996$, $P = 0.000$; *F. occidentalis*, $R = 0.80$, $P = 0.03$; *S. exigua*, $R = 0.90$, $P = 0.006$). Consequently, these generalist herbivores strongly prefer those leaves with a low PA content, which is in accordance with the results of the choice tests (Table 1). Since *L. trifolii* fed and developed in the leaf, the

difference in number of large mines per leaf may be a combination of antixenotic and antibiotic effects of PAs. Because the leaf number differed between experiments, we were unable to correlate herbivory directly to leaf characteristics.

Herbivory in the Field. Although in each population at least one specialist herbivore species was present, the youngest leaves overall had relatively less herbivore damage than the older leaves (Figure 4). Since the Friedman analysis requires equal numbers of observations per leaf number, the differences between leaves were analyzed per group of plants with the same number of leaves. Except for the small group of plants with eight leaves, the herbivore damage was significantly different between leaves (Table 3, Friedman analysis). The amount of damage and leaf number were significantly correlated for all groups, which indicated that independent of number of leaves on the plant, the older leaves were relatively more damaged than the youngest leaves.

The average damage on the leaves, 3.8%, was comparable to earlier reports (Prins and Nell, 1990). Mines of *Agromyza* spp. caused a significant loss of photosynthetically active leaf surface. On average the mines caused a loss of 11.7% of the leaf surface, while leaves without mines suffered only 3.12% damage (Wilcoxon test, $Z = 8.36$, $P < 0.001$). Blotch mines were only found on older leaves, on average on leaf number 4. This indicates that, like *L. trifolii*, the naturally occurring leaf-miners avoid the youngest leaves with the highest PA levels.

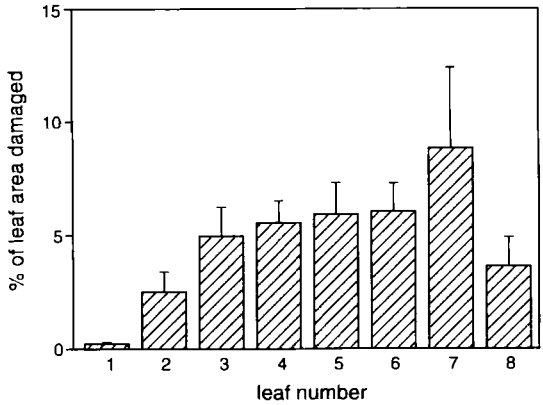

FIG. 4. Average percentage of herbivore damage per leaf, observed on rosette plants of *Cynoglossum officinale* in the dune area in Meijendel near The Hague, The Netherlands, on June 23, 1994. Leaf number 1 is the youngest leaf.

TABLE 3. RESULTS OF FRIEDMAN ANALYSIS OF VARIANCE AND SPEARMAN RANK CORRELATION ANALYSIS FOR DIFFERENCES IN HERBIVORY BETWEEN LEAVES OF FIELD PLANTS

Leaves (*N*)	Plants (*N*)	Friedman ANOVA		Spearman RC	
		χ^2	*P*	R^2	*P*
3	17	19.3	6×10^{-5}	0.54	0.01
4	41	58.3	1×10^{-12}	0.67	<0.001
5	25	53.5	6×10^{-11}	0.62	<0.001

DISCUSSION

In this paper we showed that PAs in *C. officinale* rosettes act as deterrents against generalist herbivores. Despite different ways of feeding, all generalist herbivores avoided the young leaves, which had the highest PA levels. The results of the disk choice tests with PA N-oxide extracts indicate that PAs indeed are responsible for deterring generalist herbivores.

The specialist herbivore species we tested were unaffected by PAs in their food. The monophagous *M. cruciger* preferably consumed the youngest leaves, which are richest in nitrogen, thus maximizing intake of nitrogen. For many insect herbivores, fitness increases with nitrogen intake (Raupp and Denno, 1983; Scriber, 1984). In this case, PAs might even serve as feeding stimulants, since high PA levels coincide with high nitrogen percentages.

In contrast to *M. cruciger*, the oligophagous *E. bipunctella* does not significantly prefer the plant parts with the highest nitrogen levels. However, this has no negative effects on the fitness of *E. bipunctella*. Time to pupation and pupal weight were not significantly different between individuals reared on the oldest three leaves and on the youngest three leaves (Van Dam and Bergshoeff, unpublished data). The difference in nitrogen levels in leaves of *C. officinale* may have been too small to cause significant differences in fitness parameters. Only a factor of 1.6 existed between the youngest three and the oldest three leaves (Figure 2b).

In earlier reports on retarded development of *E. bipunctella* larvae on damaged *C. officinale* plants, it was suggested that this effect on the herbivore's fitness was due to induction of PAs (Prins and Laan, 1988). However, data on

induced changes were lacking. This makes them unsuitable for comparison. Unfortunately, data on the effect of leaf quality on the fitness of *M. cruciger* are hard to get, because these weevils spend their larval stage in the roots.

We found that low concentrations of echinatine, 3′-acetylechinatine, and heliosupine all deterred feeding by a nonadapted herbivore in a no-choice situation. Contrary to our findings, Bentley et al. (1984) reported that echinatine and echinatine N-oxide, in concentrations comparable to those we used, did not significantly deter feeding by spruce budworm. This indicates that not all nonadapted herbivore species are equally sensitive to the antifeedant effect of PAs.

Since all types of PAs we tested reduced feeding equally well, the question arises as to why *C. officinale* maintains such a variety of different PAs. The reason may be that a mixture of compounds is even more effective, because of synergistic effects (Berenbaum, 1985) or because it reduces the probability of adaptation by herbivores (Jones, 1983). Moreover, plants are attacked not only by all sorts of herbivores but also by pathogens. Specific PAs might have evolved as protection against different species of natural enemies. These three hypotheses all need further testing, which is beyond the scope of this paper.

Although the reduced form of PAs seemed more effective as a defense against herbivores (Speiser et al., 1992; this paper), the PAs in the leaves of *C. officinale* almost exclusively occur as N-oxides (Sykulska, 1962; Van Dam et al., 1995). The reason may be that PA N-oxides are better suited for specific phloem transport and safe vacuolar storage within the plant (Hartmann et al., 1989). Moreover, the difference in deterrency between the two forms of PAs is only relative. The choice experiment clearly showed that moderate concentrations of PA N-oxides also strongly deter feeding by generalist herbivores.

Furthermore, our experiments showed that the youngest leaves with the highest PA levels suffer less damage from generalist herbivores. Since generalist herbivores form the greatest potential number of enemies (Wink, 1993), we may conclude that, overall, the youngest leaves are better protected against herbivory. However, the fact that these leaves contain the highest PA levels does not preclude that other characteristics may play a role. High hair densities, which coincide with high PA levels in *C. officinale*, may also act as a defense against herbivores.

The damage we observed in the field, of course, is a combination of feeding by specialist and generalist herbivores. Although the damage pattern in the field seems more comparable to that of generalist herbivores, the difference in damage between the leaves is less extreme than in the lab experiments. Nevertheless, these data show that in the field also, the youngest leaves are the best protected. The lab data show that this is not due only to the fact that old leaves have been exposed to herbivory for a longer time. The observation that the youngest leaves are best protected, may reflect the plant's optimal defense strategy. Two aspects

of plant organs are important for optimal defense distribution: the photosynthetic value and the vulnerability of a leaf (Mooney and Gulmon, 1982; Zangerl and Bazzaz, 1992). On both aspects young leaves score higher than old leaves (Harper, 1989). If a rosette plant should have to maintain the same PA level of the youngest leaves throughout the whole plant, the investment in PA synthesis should be more than 50 times higher (see Van Dam et al., 1994). Assuming that it is too costly to do so, investing in defense for young leaves to optimize plant growth thus seems an optimal strategy for *C. officinale* rosettes.

In conclusion, the "raison d'être" of pyrrolizidine alkaloids in rosettes of *C. officinale* is that they protect the most valuable organs of the plant against generalist herbivores. Our paper also shows that to study the possible defensive functions of secondary metabolites, one should test these chemicals against several specialist and generalist herbivores to gain insight into their ecological role.

Acknowledgments—We thank Ineke Jaarsma of Philips Duphar for kindly providing *Spodoptera exigua* egg-batches, Ludger Witte for GC-MS analyses of the PA samples, and Karin van der Veen-van Wijk for her help with the gathering of the field data. Our thanks are also due to Martin Brittijn, who skillfully drew the figures for this paper. Peter Klinkhamer, Tom de Jong, Martine Rowell-Rahier, Bernd Haegele, and Rob Verpoorte are acknowledged for critically reviewing earlier versions of the manuscript.

(Received September 30, 1994; accepted January 20, 1995)

Abstract—The origin of olfactory stimuli involved in the host microhabitat location in *Cotesia flavipes*, a parasitoid of stem-borer larvae, was investigated in a Y-tube olfactometer. The response of female *C. flavipes* towards different components of the plant–host complex, consisting of a maize plant infested with two or more larvae of the stem borer *Chilo partellus*, was tested in dual-choice tests. The concealed lifestyle of the stem-borer larvae did not limit the emission of volatiles attractive to a parasitoid. A major source of the attractive volatiles from the plant–host complex was the stem-borer-injured stem, including the frass produced by the feeding larvae. Moreover, the production of volatiles attractive to a parasitoid was not restricted to the infested stem part but occurs systemically throughout the plant. The uninfested leaves of a stem-borer-infested plant were found to emit volatiles that attract female *C. flavipes*. We further demonstrate that an exogenous elicitor of this systemic plant response is situated in the regurgitate of a stem-borer larva. When a minor amount of regurgitate is inoculated into the stem of an uninfested plant, the leaves of the treated plant emit volatiles that attract female *C. flavipes*.

Key Words—Infochemicals, *Zea mays*, stem borer, *Chilo partellus*, parasitoid, *Cotesia flavipes*, host searching, herbivore-induced synomones, systemic effect, exogenous elicitor, caterpillar regurgitate.

INTRODUCTION

In the evolutionary arms race between herbivores and their natural enemies, herbivores have evolved several traits to reduce their vulnerability to enemies.

*To whom correspondence should be addressed.

0098-0331/95/0500-0525$07.50/0 © 1995 Plenum Publishing Corporation

One of these traits can be a specific behavior that reduces the recognition and detection by natural enemies. It has been argued that the stem-boring habit of several herbivore species avoids proximity of feeding damage cues and reduces accessibility for natural enemies, which may have been one of the reasons for its evolution (Strong et al., 1984). However, absolute safety from natural enemies is virtually impossible. Although attack by enemies imposes selection in victims to reduce vulnerability, counter-selection works on enemies to improve their efficiency in finding hiding hosts (Jeffries and Lawton, 1984). Despite their hidden lifestyle, stem-borer larvae have a broad range of natural enemies, which are able to locate and attack the larvae that feed inside the plant tissue (Baker et al., 1949; Smith et al., 1993). The response of stem-borer parasitoids to contact chemicals is well described (Leerdam et al., 1985), but there are only a few studies that focus on the volatile stimuli involved in the host searching for stem-borer parasitoids (Roth et al., 1982; Ding et al., 1989a,b; Ma et al., 1992).

For other parasitoids, the use of volatile infochemicals in their long-range search for suitable hosts is well documented (Vinson, 1976; Nordlund et al., 1988; Vet and Dicke, 1992). Many natural enemies are known to discriminate between volatile chemicals emitted by uninfested and herbivore-infested plants. Chemical stimuli emanating from the plant–host complex can orginate from the herbivore, the plant, or from interactions between the herbivore and the plant. The response to volatile cues from the plant–host complex is well described for parasitoids of leaf-feeding caterpillars. For instance, the braconids *Cotesia marginiventris*, *Cotesia glomerata*, and *Cotesia rubecula* are highly attracted by odors emanating from herbivore-damaged plants, whereas odors from larval frass or the larvae themselves are far less attractive to these parasitoids (Turlings et al., 1991a; Steinberg et al., 1992; Geervliet et al., 1994). Although odors from the host or host products are very reliable indicators for host presence, their long-range detectability is very low (Vet et al., 1991). Turlings et al. (1991b) demonstrated that larvae and frass only release volatiles in very low quantities, whereas plant volatiles are released in relatively large amounts. Plant odors play an important role in the foraging behavior of larval parasitoids, especially plant volatiles that are released by plants infested by herbivores. Damage by hervibores can increase the emission of plant volatiles enormously (Dicke et al., 1990a; Turlings et al., 1990), and these plant volatiles can be specific indicators of herbivore identity (Dicke et al., 1990a,b). If these chemicals attract natural enemies whose activities are favorable to the plant, they are called herbivore-induced synomones (Vet and Dicke, 1992). Recent studies have demonstrated that the plant has an active role in the production of such herbivore-induced synomones (for review see Dicke, 1994). The release of these chemical signals is not restricted to the infested plant parts, but occurs systemically

throughout the plant (Dicke et al., 1990b; Takabayashi et al., 1991; Turlings and Tumlinson, 1992; Dicke and Dijkman, 1992).

In contrast to leaf-feeding herbivores, the larvae of stem borers have a concealed lifestyle and feed inside the plant. This present research deals with the foraging behavior of *Cotesia flavipes* (Hymenoptera: Braconidae), a gregarious larval endoparasitoid of tropical stem borers. *C. flavipes* attacks the last larval instars, by ingressing the stem through the entrance hole of the stem-borer tunnel (Smith et al., 1993). *C. flavipes* is indigenous to Southeast Asia, where it attacks several stem-borer species in maize, sorghum, rice, sugercane, and various wild grasses. This parasitoid has been extensively used in classical biological control programs against *Chilo partellus* (Alam et al., 1972; Overholt, 1994), *Diatraea saccharalis* (Gifford and Mann, 1967; Alam et al., 1971; Fuchs et al., 1979), and *Chilo sacchariphagus* (Betbeder-Matibet and Malinge, 1968). Earlier reports on the searching behavior of *C. flavipes* mainly focused on the short-range searching behavior, in particular the contact-response to larval frass (Kajita and Drake, 1969; Mohyuddin, 1971; Mohyuddin et al., 1981; Leerdam et al., 1985). Potting et al. (1993) and Ngi-Song et al. (1994) demonstrated that female *C. flavipes* are attracted to odors emanating from stem-borer-infested maize plants.

The purpose of the present research was to elucidate the sources of the volatile stimuli responsible for this attraction. This was achieved by testing the attractiveness of different components of the plant-host complex, which consisted of a maize plant with two or more feeding *C. partellus* larvae in the stem. We provide evidence that the production of volatiles attractive to a parasitoid is not restricted to the infested part of a plant but occurs systemically throughout the plant. We further demonstrate that an exogenous elicitor of this systemic plant response is present in the regurgitate of a stem-borer larva.

METHODS AND MATERIALS

Insects

The *Chilo partellus* culture originated from a colony maintained by the International Centre for Insect Physiology and Ecology in Nairobi, Kenya. The culture was maintained in temperature-controlled rooms (25°C) at 50–70% relative humidity, and a light–dark regime of 16L:8D. Adult moths were kept in an oviposition cage lined with waxed paper to provide suitable oviposition sites. Egg masses were cut from the paper daily and transferred to a closed Petri dish containing moist cotton wool to maintain high humidity. Three to four egg masses (blackhead stage) were transferred to 1-liter glass jars with 125 ml artificial diet prepared according to the procedure described by Seshu Reddy and

Davies (1978) and Ochieng et al. (1985). The covers of the jars were provided with a hole and were lined with a stainless steel screen to prevent escape of the larvae. As moths emerged they were transferred to an oviposition cage.

The larvae used in the experiments and for the maintenance of the parasitoid culture (see below) were always removed from the artificial diet as fourth instars and allowed to feed on fresh maize stems for at least 24 hr.

Cotesia flavipes was obtained from the International Institute for Biological Control in Rawalpindi, Pakistan, where it was collected from *C. partellus* in maize. In Wageningen, the parasitoid culture was maintained on *C. partellus* at 25°C, 70% relative humidity, and a 16-hr photophase. Individual, mated, females (1 day old) were offered one host larva with some fresh larval frass to stimulate oviposition. Parasitized larvae were reared on cut maize stems kept in one liter jars.

Cocoons were collected from the stem pieces one to two days prior to emergence and transferred to a 250-ml bottle with agar medium lined with a polyester top with a drop of honey. One day after emergence the adult wasps were placed in an incubator at 15°C. All experiments were conducted with naive (no oviposition experience), mated females that were 2 to 4 days old.

Plants

Maize plants (*Zea mays* cv. Anjo) were grown in a greenhouse at 20–25°C, 50–80% relative humidity, and a 16L:8D light regime. When the light intensity dropped below 500 lux in the photophase, artificial light was used. Plants were watered daily and, when necessary, treated with AA Kasaerosol (Schering AAgrunol B.V.) against aphid infestation.

Olfactometer Setup

Responses of *C. flavipes* females to volatile chemicals emitted by different odor sources were measured in a Y-tube olfactometer. The olfactometer consisted of a glass Y-shaped tube. The two arms of the Y tube were connected to a flowmeter and an odor source container. Odor sources were placed in containers, which consisted of 500-ml glass bottles. Air was blown through the odor source containers and introduced into the arms of the Y tube. By balancing the input through the arms (4 liters/min) and the output through the common tube (8 liters/min), two laminary airflows were created. For more details of the olfactometer, see Steinberg et al. (1992). The environmental conditions in the bioassay room were 25–27°C and 40–70% relative humidity.

Bioassay Procedure

Individual female parasitoids were introduced into the base tube of the Y-tube olfactometer, and their behavior was observed during a 5-min period. If

the test female walked towards an odor source and crossed the choice line (4 cm after division of the base tube) and stayed there for more than 15 sec, it was recorded as a choice for the odor source in that arm. To circumvent any asymmetrical bias in the setup, the odor sources were exchanged after testing five parasitoids. For each combination, 40–50 wasps were tested. The choice of the females was analyzed with a chi-square test ($\alpha = 0.05$).

Odor Sources

Uninfested vs. Infested Maize Plants. Uninfested plants consisted of 4- to 6-week-old plants (40–50 cm tall). An infested plant was obtained by introducing two fourth-instar *C. partellus* larvae into two holes bored 10 cm apart in the stem of a plant. The larvae were allowed to feed overnight. Prior to the bioassay, the test plant was cut into four parts: three pieces of stem and the remaining part with the leaves of the plant. Care was taken that the tunnel of the stem-borer larvae never reached the part with the leaves. The four parts of each test plant were introduced into the odor source container. Three odor sources were tested: (1) clean air, which consisted of an empty odor source container (AIR); (2) the complete plant–host complex (PHC) with two feeding larvae; and (3) an uninfested plant (UNINFEST). The combinations tested were AIR versus UNINFEST and UNINFEST versus PHC. In an additional experiment it was tested whether an artificially damaged maize plant emitted attractive volatiles. In this test the plants were not cut into pieces. An artificially damaged plant (ART-DAMAGE) was obtained by puncturing five holes in the stem. To mimic feeding behavior of the stem-borer larvae, this was repeated every 15 min. The combination tested was ART-DAMAGE versus AIR. Forty wasps were tested in each choice situation.

Stem vs. Leaves. To investigate which part of the PHC emitted attractive volatiles, the following combinations were tested: (1) stem pieces of an uninfested plant (CONTROL-STEM) versus stem pieces of an infested plant (PHC-STEM), (2) leaves of an uninfested plant (CONTROL-LEAF) versus leaves of an infested plant (PHC-LEAVES), and (3) leaves of an infested plant (PHC-LEAVES) versus stem pieces of the same infested plant (PHC-STEM). All three combinations were tested on the same day and 47 wasps were tested in each choice situation.

Stem. To determine the origin of attractive volatile chemicals, the different components of an infested stem were tested in dual-choice tests. These were infested stem pieces with or without feeding larvae, larvae, larval frass, and artificially damaged (uninfested) stem pieces. The stem of 2-month-old maize plants (flowering stage) was cut into 12-cm pieces. Five pieces of stem were used as odor source. A standard infested stem piece was obtained by boring a hole on each side of the piece and introducing one larva in each hole. The 10 larvae were allowed to feed for 60 hr. The following odor sources were tested:

INFESTED	Five stem-borer-infested stem pieces, consisting of maize stems with two larvae in their stem-borer tunnel filled with frass.
HERB-DAM	As INFESTED but larvae removed prior to experiment.
DAM-STEM	As HERB-DAM but all frass removed prior to experiment.
LARVAE	10 water-washed larvae, removed from INFESTED.
FRASS	Frass removed from INFESTED.
ART-DAM	Artificially damaged stem pieces (10 holes bored in each stem piece, 12 hours prior to the start of the experiment).

The following choice tests were made: (1) INFESTED vs. ART-DAM, (2) HERB-DAM vs. ART-DAM, (3) INFESTED vs. HERB-DAM, (4) DAM-STEM vs. FRASS + LARVAE, and (5) LARVAE vs. FRASS (in this test both odor sources were placed directly into the Y tube). The choice tests were performed on separate days and 40 wasps were tested in each choice situation.

Leaves. In this series of experiments the odor sources consisted of the leaves of treated plants. All plants used consisted of singly potted maize plants, 4–6 weeks old. In the stem of each plant two holes were bored 10 cm apart. The leaves were obtained by cutting the stem just below the whorl in such a way that all the leaves were still attached to the stem apart.

The treatments tested were undamaged leaves that were removed from a host-infested plant 24 or 48 hr after infestation (LARVAE-24 hr; LARVAE-48 hr) and undamaged leaves from a regurgitate-treated plant (REGURGITATE).

To obtain a regurgitate-treated plant, 5 μl regurgitate from fourth-instar *C. partellus* larvae was inoculated in each hole and the test plant was incubated for 24 hr at 25°C before removing the leaves. The regurgitate was collected following the method described by Mattiacci et al. (1994). A larva was held with a pair of soft forceps and teased at the mouthparts with a microcapillary tube. In this way 5–10 μl regurgitate could be obtained from one larva. In all tests the control (CONTROL) odor source consisted of the leaves of a standard treated plant (with two artificially bored holes), incubated as long as the treatment it was tested against.

In the first series the choice tests, CONTROL vs. LARVAE-24 hr and CONTROL vs. LARVAE-48 hr were tested on the same day (40 wasps tested in each combination). In a second series, the choice tests CONTROL vs. REGURGITATE and CONTROL vs. LARVAE-24 hr were tested on the same day (50 wasps tested in each combination).

RESULTS

Uninfested vs. Infested Maize Plants. Volatiles emanating from a stem-borer-infested maize plant attracted all responding parasitoids, when offered versus an uninfested plant (Figure 1A). Parasitoids were not attracted to odors

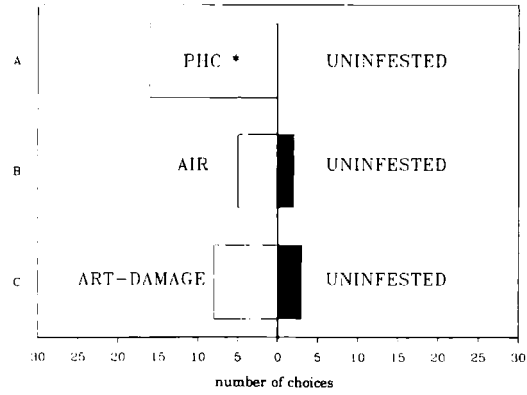

Fig. 1. The response of *C. flavipes* to volatile chemicals emitted by *C. partellus*-infested and uninfested maize plants in a Y-tube olfactometer. In each dual-choice test 40 females were tested. The bars indicate the number choosing a particular odor source. Asterisks indicate statistically significant preferences within tests (chi-square, $P < 0.05$).

emanating from uninfested maize plants or artificially damaged maize plants (Figure 1B and C).

Stem vs. Leaves. Although the response level was low, the females that made a choice preferred the odors emanating from the undamaged leaves of a stem-borer-infested plant, when offered together with undamaged leaves from an uninfested plant (Figure 2A), hence the emission of attractive volatiles is not restricted to the site of damage, but occurs throughout the plant. Volatiles emanating from the infested stem part of the plant (with the feeding larvae) attracted the majority of the parasitoids when tested against undamaged stems or the leaves of the very same infested plant (Figure 2B and C).

Stem. The parasitoids were clearly more attracted to odors emanating from stem-borer-damaged stem pieces when tested against artificially damaged stem pieces (Figure 3A). A stem-borer-damaged stem consists of feeding larvae in their tunnel filled with larval frass. The infested stems remained attractive even when the feeding larvae were removed (Figure 3B). The feeding activity of the larvae did not significantly enhance the attractiveness of the infested stems. The parasitoids did not make a distinction between infested stems with or without larvae (Figure 3C). When the larvae and their frass were removed from the infested stems and tested against the remaining stem, the latter was the most attractive (Figure 3D). Frass by itself is also an attractive component of a stem-borer-infested stem. The majority of the parasitoids was attracted to frass when tested against larvae (Figure 3E).

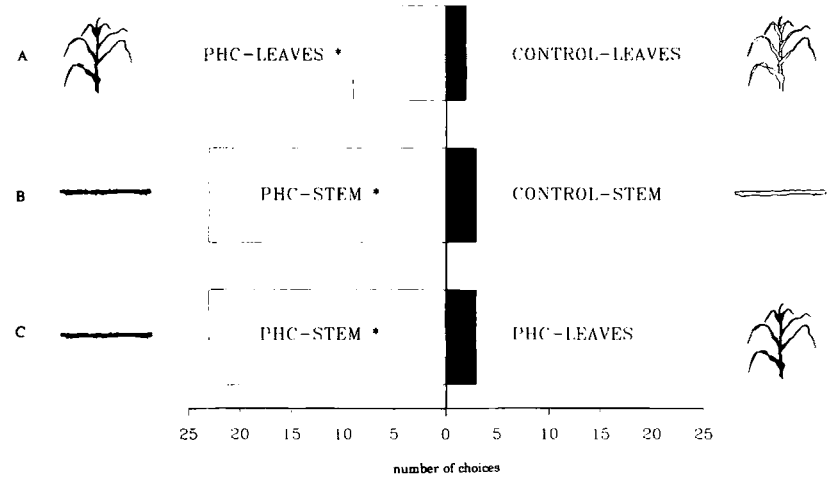

Fig. 2. The response of *C. flavipes* to volatile chemicals emitted by different parts of the plant-host complex in a Y-tube olfactometer. In each dual-choice test 47 females were tested. The bars indicate the number choosing a particular odor source. Asterisks indicate statistically significant preferences within tests (chi-square, $P < 0.05$).

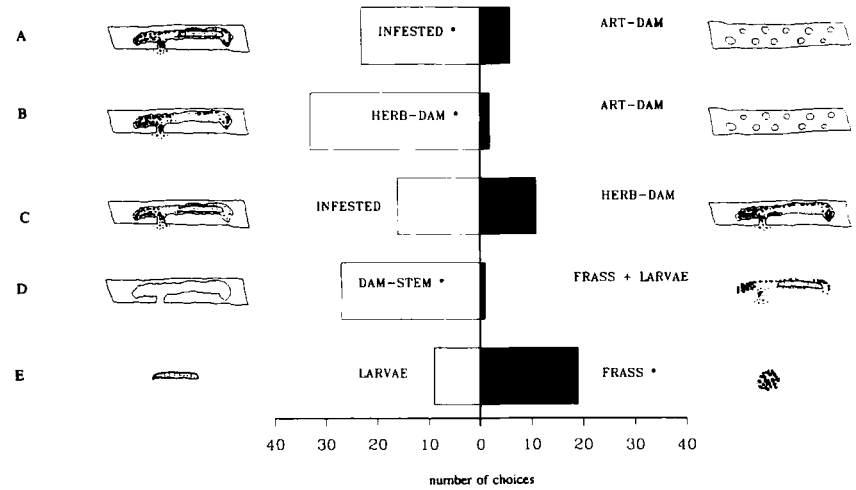

FIG. 3. The response of *C. flavipes* to volatile chemicals emitted by different components of *C. partellus*-infested stem pieces. In each dual-choice test 40 females were tested. The bars indicate the number choosing a particular odor source. Asterisks indicate statistically significant preferences within tests (chi-square, $P < 0.05$). For more information on odor sources see Methods and Materials.

Leaves. Leaves of a stem-borer-damaged plant that had not been in contact with the feeding larvae in the stem, emitted attractive volatiles (Figure 4). Leaves from a plant where two stem-borer larvae were allowed to feed for 24 or 48 hr attracted the majority of the parasitoids when tested against leaves from a plant with two artificially bored holes. The induced effect was clear after 24 hr of feeding and was not significantly enhanced by a longer feeding time (Figure 4). An elicitor of the systemic production of the plant-produced synomones seems to be present in the regurgitate of the feeding larva. If larval regurgitate was inoculated into the stem, the leaves of the treated plant started to emit attractive volatiles, and a similar response was obtained as with the leaves from a plant with two feeding larvae inside the stem (Figure 4).

DISCUSSION

Plants have evolved several characteristics to defend themselves against herbivore attack. These direct defense mechanisms include plant structures that prevent herbivore settlement, detrimental chemicals in the plant tissue, or the systemic production of defensive chemicals (Juniper and Southwood, 1986; Tallamy and Raupp, 1991). An indirect defense mechanism of plants is to promote the effectiveness of natural enemies of the herbivore (Price et al., 1980; Dicke and Sabelis, 1988). This may be achieved by mediating an interaction between the herbivore and its natural enemies. Evidence is accumulating that plants are actively involved in the release of chemical signals that attract natural enemies of the herbivore (see Dicke, 1994, for review). The emission of these volatiles by infested plants is not limited to the damaged sites but occurs throughout the plant, even in undamaged leaves (Dicke et al., 1990b, 1993; Takabayashi et al., 1991; Turlings and Tumlinson, 1992). All this research involves externally feeding herbivores. The present study provides evidence that even when a plant is injured by an herbivore that feeds inside the stem, the whole plant emits chemical signals that attract a natural enemy of the herbivore. The concealed lifestyle of the stem-borer larvae was found not to limit the emission of plant synomones. Female *C. flavipes* can discriminate between odors emitted by uninfested and stem-borer-infested maize plants (Potting et al., 1993) (Figure 1). A major source of the attractive volatiles from the plant–host complex is the stem-borer-infested stem (Figure 2). A stem-borer-infested stem consists of a feeding larva inside a tunnel filled with larval frass. The larvae feeding inside the stem appear to trigger the emission of attractants by the plant, but do not emit attractants themselves. The frass produced by the feeding larvae was an attractive component, but odors emanating from a stem-borer-injured stem are even more attractive (Figure 3). This parallels results from other studies in which herbivore-damaged plants or plant parts were more attractive to natural enemies

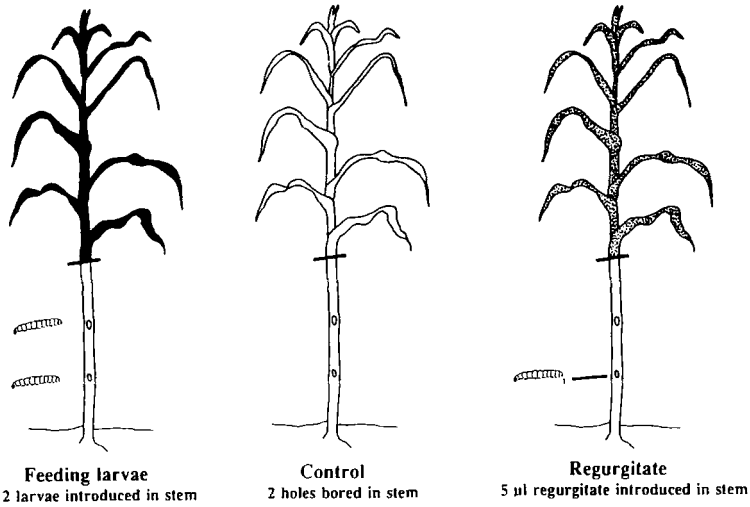

FIG. 4. The response of *C. flavipes* to volatile chemicals emanating from the undamaged leaves of stem-borer-infested maize plants vs. control leaves and to undamaged leaves from a regurgitate treated plant vs. control leaves. For more information on odor sources see Methods and Materials. The bars indicate the number choosing a particular odor source. Asterisks indicate statistically significant preferences within tests (chi-square, $P < 0.05$).

than the herbivore or its products (Roth et al., 1982; Turlings et al., 1991a; Steinberg et al., 1993; Geervliet et al., 1994).

The release of the attractive volatiles is not restricted to the infested stem part but occurs systemically throughout the plant. Female *C. flavipes* are attracted to volatiles released by the undamaged leaves of a stem-borer-infested plant (Figure 4). The systemic release of these volatiles probably enhances the detectability of the infested plant for natural enemies. However, when given a choice between the odors emanating from the leaves and from the stem of an infested plant, the majority of the parasitoids was attracted to the infested stem. This may indicate that at close range the parasitoid is able to find the infested part of the plant. A similar result was reported by Dicke et al. (1993), who found that predatory mites preferred host-damaged leaves when offered them versus undamaged leaves that emitted herbivore-induced synomones in response to an endogenous elicitor.

A factor that induces the systemic response seems to be present in the regurgitate of the larva. When regurgitate was inoculated into the stem, the leaves of the treated plant emitted volatiles that attracted female *C. flavipes*. It

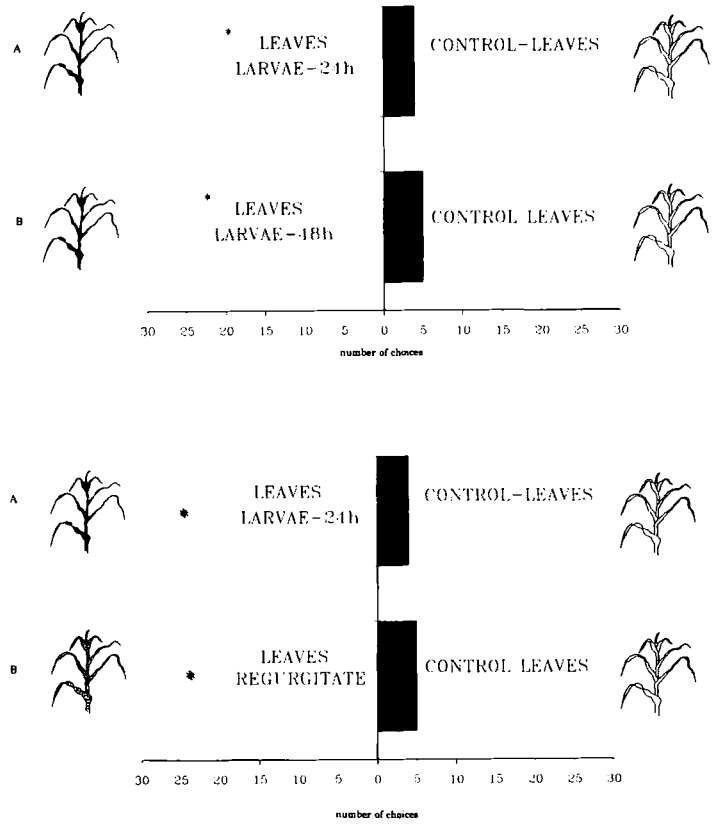

FIG. 4. Continued

remains to be investigated whether a regurgitate component itself or an endogenous elicitor induced by the regurgitate is transported through the stem to the leaves, which start to produce attractive volatiles. Some recent studies have focused on the elicitor that triggers the systemic response of herbivore-infested plants. Dicke et al. (1993) extracted an elicitor that is transported from infested leaves to uninfested leaves. Turlings et al. (1993) could induce the production of plant volatiles by placing maize seedlings in diluted regurgitate from several species of caterpillars and a grasshopper. Recently Mattiacci et al. (1995) shed more light on the elucidation of the factor responsible for the induced plant response. They showed that an elicitor present in the gut regurgitate of *Pieris brassicae* caterpillars induced the release of synomones by mechanically dam-

aged cabbage leaves (Mattiacci et al., 1994). They identified the enzyme β-glucosidase, a component of the regurgitate of *P. brassicae* caterpillars, as an elicitor of the synomone release by *P. brassicae*-infested leaves (Mattiacci et al., 1995). Glucosidases seem to be common enzymes among herbivorous insects (Mattiacci et al., 1995), and it remains to be investigated if they are responsible for the induced plant responses in different plant–host complexes, which could indicate that the plant response is a general response to attack by herbivorous insects.

A detailed analysis of the specific chemicals involved can establish whether there are qualitative and/or quantitative differences in the volatile blends emanating from the stem or the leaves of an infested plant. An identification of the specific chemicals may also reveal whether the same terpenoids are involved, as is shown for the maize–*Spodoptera exigua*–*C. marginiventris* system (Turlings et al., 1990, 1991b) and the maize–*Pseudaletia*–*Cotesia kariyai* system (Takabayashi et al., 1995).

In their search for the host habitat, parasitoids may exploit volatile cues from uninfested plants (Vinson, 1976; Nordlund et al., 1988; Vinson and Williams, 1991). For example, a response towards volatiles from uninfested maize plants was demonstrated for *Macrocentrus grandii* (Ding et al., 1989a; Udayagiri and Jones, 1992) and *Eriborus terebans* (Ma et al., 1992), two larval parasitoids of *Ostrinia nubilalis*. In the present study, female *C. flavipes* were not attracted to odors from uninfested or artificially damaged maize plants (Figure 1). However, Ngi-Song et al. (1994) reported that *C. flavipes* was attracted to uninfested maize plants in a bioassay similar to the one used in our study. The discrepancy in these results could be due to different maize cultivars or to a different method of rearing the plants. In our study plants were grown in a greenhouse and treated regularly against aphids and other herbivores when necessary. Ngi-Song et al. (1994) used plants grown under field conditions, and it is likely that they were infested with herbivores, which could have resulted in nonhost damage and subsequent release of herbivore-induced synomones. Vinson and Williams (1991) reported a similar finding: the parasitoid *Campoletis sonorensis* was attracted to uninfested plants grown in a greenhouse, which were exposed to aphids and thrips, whereas it did not respond to uninfested plants grown in a herbivore free environmental chamber.

Through their concealed lifestyle stem-borer larvae have created a partially enemy-free space, especially for predators such as birds and spiders. However, parasitoids, in particular, have evolved the ability to successfully locate and attack the larvae inside the plant tissue (Smith et al., 1993). Stem-borer larvae have to feed and defecate, and although they do this inside the plant tissue, it does not prevent the release of attractive volatiles either through the frass they produce or through the volatiles that are produced systemically by the plant as a response to the feeding activity of the larvae. This study demonstrates that a

stem-borer parasitoid can exploit these plant-produced volatiles to locate the host microhabitat.

Acknowledgments—We thank Leo Koopman, Henk Snellen, and André Gidding for insect rearing and Marielle Wintgens for the drawings. ODORS IN TRAPS: DOES MOST RECENT OCCUPANT INFLUENCE CAPTURE RATES FOR HOUSE MICE?

LEE C. DRICKAMER

Department of Zoology,
Southern Illinois University,
Carbondale, Illinois 62901

(Received July 20, 1994; accepted January 26, 1995)

Abstract—Responses of house mice (*Mus domesticus*) to odors in live traps were studied in a series of eight 0.1-ha outdoor field enclosures. It was assumed that the most recent mouse capture would provide the predominant odor in a trap for at least one week. Three different populations were tested, one in 1989 and two in 1992, involving over 800 different mice. Similar response patterns were recorded from all three groups. Two types of questions were tested: (1) Were there any biases contingent upon what had been previously caught? (2) Were there consistent responses of mice of particular age, sex, or reproductive classes to trap odors? Traps soiled by juvenile females caught adult females significantly less often than expected, but there were no consistent relationships in terms of the effects of specific residual odors on the subsequent capture at a particular trap. For various age, sex, and reproductive classes, (1) adult males preferred odors from juvenile and estrous females and avoided odors of other males significantly more than expected, (2) juvenile females selected traps with odors of other juvenile females and avoided all other types of female odors significantly more than expected, (3) nonestrous females exhibited a significant preference for adult male odor, and (4) estrous females selected traps containing odors from adult males but avoided those that had previously contained either nonestrous or pregnant/lactating females significantly more than expected. These findings have potential implications with regard to both the methods used for trapping small rodents and the social biology of house mice.

Key Words—*Mus domesticus*, chemical cues, chemosignals, pheromones, social behavior, mate finding, odor avoidance, live traps.

INTRODUCTION

Chemical cues are important for the social biology of a variety of rodents including voles (*Microtus* spp.) (Wolff and Johnson, 1979; Ferguson et al. 1986),

0098-0331/95/0500-0541$07.50/0 © 1995 Plenum Publishing Corporation

deermice (*Peromyscus* spp.) (Bronson and Marsden, 1964; Doty, 1972), rats (*Rattus* spp.) (Barnett, 1963; Galef and Clark, 1971, Galef and Stein, 1985), and house mice (*Mus* spp.) (Vandenbergh, 1983; Drickamer, 1986; Vandenbergh and Coppola, 1986). House mice (*Mus musculus* and *M. domesticus*) use odor cues for recognition by sex, age, reproductive condition, or dominance status (Hurst, 1990a–c), mate choice (Drickamer, 1992), reproductive processes, particularly in females (Vandenbergh and Coppola, 1986), and spatial relations (Hurst, 1990a–c).

Because many rodents are small and nocturnal, live trapping and similar methods are often used to investigate aspects of their behavior and ecology. Several previous investigators have employed live traps to explore putative functions of chemical signals in a variety of rodent taxa with varying degrees of success. Mazdzer et al. (1976) reported that *Peromyscus leucopus* preferred traps containing odors from conspecifics of the opposite sex, in agreement with an earlier report from a laboratory study by Doty (1973). Daly et al. (1980) found seasonal differences in the tendency of *Peromyscus maniculatus gambelli* to enter traps containing conspecific odors. In a similar study, Heske (1987) reported that California voles (*Microtus californicus*) exhibited significant preferences for conspecific odors. Daly et al. (1980) showed that for *P. m. gambelli*, traps baited with conspecific odors were preferred by mice in reproductive condition, but mice not in reproductive condition preferred neutral, unbaited traps. Drickamer (1984) found that *Peromyscus leucopus noveboracensis* and *P. maniculatus gracilis* avoided heterospecific odors and preferred homospecific odors, and within each species, there was a strong preference for heterosexual odors.

Soiled traps are entered more frequently than clean traps by a variety of rodents, including *Microtus townsendii*, *M. agrestis*, *Apodemus sylvaticus*, *A. flavicollis*, and *Clethrionomys glareolus* (Boonstra and Krebs, 1976; Stoddart, 1982; Gurnell and Little, 1992). Recently, Drickamer et al. (1992) reported that house mice exhibited some odor cue preferences for traps baited with particular homospecific odors, but only when both volatile and nonvolatile cues were present. Adult, but not juvenile, house mice exhibited preferences for odor cues from their own age/sex class. One feature of this last study was that the traps were cleaned after each capture and were then provided with only the specific odor cue to be tested.

Based on previous findings with other rodents and a knowledge of house mouse biology from laboratory and field settings, I questioned the findings of Drickamer et al. (1992). I would have expected more specific preferences for particular odors and more age/sex class discrimination. Perhaps cleaning the trap after each capture was removing some significant information used by the mice. In addition, the urine odors used to bait the traps in the earlier study were from unfamiliar mice, not part of the population in that particular enclosure. This led to the current study based on data sets obtained from the enclosures

during years when odor-baiting experiments were not being conducted. My objectives were: (1) to test the importance of odor cues, particularly those that were erased when traps are cleaned after each capture; (2) to test odor preferences of mice when they respond to traps that contain both a series of odors from previous occupants and a recent capture; (3) to test which types of mice, by age, sex, and reproductive condition, are caught in traps that contain a mixture of odors, assuming the most recent capture constituted a predominant odor, which involves testing the effects of residual trap odors with regard to any bias in terms of what is caught next; and (4) to test specific odor preferences by mice of different ages, sex, and reproductive condition, under such conditions, which involves testing for the possible preferences of the mice for particular odors.

METHODS AND MATERIALS

Enclosures. Eight 0.1-ha enclosures located in an abandoned pasture were used for these experiments (see Drickamer and Mikesic, 1990, for full description of the enclosures and their construction). Each enclosure was 25 × 40 m, had wire mesh and aluminum side walls, and contained four symmetrically placed 2-m-diameter structures (called mouse cities; King, 1983) made of 2-m-high aluminum affixed to wooden posts. These mouse cities have a plywood roof, two entrances on opposite sides just above ground level, nesting cavities in cinder blocks located in the interior, and are supplied weekly with food and water. A 1.5-m strip was mowed around the interior perimeter of each enclosure and around each mouse city approximately once a month; in all areas of each enclosure the vegetation was allowed to grow uncut, attaining heights of 1–1.5 m. The mowed strips served as pathways for human travel in the enclosures and also prevented vegetation from attaining heights that would have enabled mice climbing to escape. Each enclosure contained a 6 × 9 trapping grid with 5-m intervals between trap stations. The trapping grid thus had 26 trap stations located along the walls of each enclosure and 28 in the interior.

Procedures. Data were collected in 1989 and 1992, years when the odor-baiting experiments mentioned previously (Drickamer et al., 1992) were not conducted. In late March 1989, populations were introduced in six of the eight enclosures with second- and third-generation stock from wild mice originally captured at Little Egypt Grain Co. (Crab Orchard National Wildlife Refuge, Williamson County, Illinois). Populations were introduced by placing groups of four females and one male into each mouse city (total of four males and 16 females into each enclosure). Two separate stocks of mice were used to populate the enclosures in 1992. Four enclosures (designated A, B, E, and F) were supplied with second- and third-generation mice produced from crosses of indi-

viduals captured at the Southern Illinois University Swine Farm with mice from the Little Egypt Grain Co. Eight females and two males of the Illinois stock were placed in each city (total of eight males and 32 females into each enclosure). The other four enclosures (C, D, G, and H) were supplied with mice from a stock originally captured near Fort Collins, Colorado, and cross-bred in the laboratory of Dr. Sarah Lenington at Rutgers University, Newark, N.J., with an inbred stock (LT.MA). Four females and two males were placed in each city (total of eight males and 16 females into each enclosure). Thus there were three separate test groups for analysis: 1989—Illinois mice, six enclosures; 1992—Illinois mice, four enclosures; and 1992—Colorado mice, four enclosures.

Starter mice were all 110–160 days of age at the time enclosures were stocked, and they had been held in same-sex groups of three to five per cage since weaning at 25–30 days of age. One week prior to initiating enclosure populations, each mouse was weighed to the nearest 0.5 g with a Pesola scale, reproductive condition was checked, and each was given a unique toe-clip ear-punch number. Mice were defined as juveniles until they reached 15 g body mass with the testes descended (males) or 13 g body mass with the vagina open (females); after those criteria were attained, they were defined as adults.

Populations were allowed to grow freely for 30 weeks. Beginning in mid-October, the mice were removed from the enclosures, first by continuous live trapping and then by using kill traps.

Trapping Procedure. One Sherman folding live trap was located at each of the 54 stations in each enclosure. Traps were placed inside 1.75-liter wax-coated milk or juice cartons to provide extra inclusion and protection from the elements. Each trap contained one cotton square (2.54 × 2.54 × 0.3 cm thick) called a Nestlet (Ancare Corp., Belmont, New York). From early May of each year through mid-October, the live traps were operated in each enclosure for two nights per week, with at least one night (range of one to three) separating the two trap nights. Traps were opened and baited between 1600 and 1800 hours and then were checked the next morning between 0600 and 0900 hours. Captured mice were checked for identification, body mass, and reproductive condition and were released at the site of capture. Previously uncaptured individuals were given a toe-clip and ear-punch number. Traps were not cleaned between captures and cotton squares were replaced on an as needed basis, as they disintegrated or, in a few instances, became soaked when it rained. All traps were checked once each month to ensure that they were functioning properly, and approximately 10 traps were replaced each summer due to malfunctions. No traps were moved between trap stations in any of the enclosures. While such a manipulation could be quite interesting, it would likely result in alterations of general contextual cues surrounding each trap and could have produced a prob-

lem similar to that associated with the trap cleaning and odor manipulation carried out by Drickamer et al. (1992).

Although it has been tested in previous studies of this type (Montgomery, 1987; Gurnell and Little, 1992), one potential problem with interpreting mouse responses in the current design could be a position effect. That is, mice caught in a particular trap simply because it is located within their home range rather than as a response to odors in the trap. This would be true, however, only if the number of potential traps that the mouse could enter on a given night was severely limited. I believe that the following chain of logic ensures that in this study such a position effect is unlikely. The average ($\pm$SE) home ranges for male and female house mice in the enclosures are 240 $\pm$ 21 m^2 for females and 400 $\pm$ 54 m^2 for males. With the 5-m interval trapping grid used in the enclosures that would mean that there are 10–18 traps within the average female home range and 16–24 traps within the average male home range. From the trapping data, it is possible to calculate that, on average, for a particular trap night, there were 18–22 traps (of the 54 present) in each enclosure that had caught a mouse on one of the two previous trap nights and thus served as the basis for the predominant odor. Combining the previous two items results in a determination that for females there were three to seven odorized traps in her home range on the average trap night and there were five to 10 odorized traps in the home range of each male. Thus, I would conclude that there were sufficient choices available to each mouse to indicate that, when it was captured, the result was a choice or preference by the mouse and not a position effect.

Analyses. The data used for analyses consisted of those mice caught in a trap where there had been a capture during one of the two preceding trap nights. In addition, instances where the same mouse was caught twice in a row in the same trap were eliminated from the data sets. Analyses of contingency tables for each data set were carried out using the G test or log likelihood ratio method (Sokal and Rohlf, 1981). All tests involved six response categories and, thus, there were six degrees of freedom for all tests. Because of the large number of analyses carried out ($N = 18$) on each data set, statistical significance values are reported for both $\alpha = 0.05$ and $\alpha = 0.005$; the latter value should aid in adjusting for any possible comparison-wise error problem associated with multiple tests. Calculation of the experiment-wise error rate using the Dunn-Sidák method (Ury, 1976) results in a value of 0.009.

RESULTS

Tabulated data for sample sizes revealed that 213 different adult males and 361 different adult females were captured at least once across the three data sets

TABLE 1. NUMBERS OF MICE OF TWO AGES AND BOTH SEXES CAUGHT FROM THREE STOCKS USED IN 1989 AND 1992 FOR TESTS OF RESPONSES TO CONTEXTUAL ODORS IN TRAPS

Age/sex class	1989	1992 (ABEF)	1992 (CDGH)
Juvenile female	64	90	106
Adult female[a]	78	83	200
Juvenile male	48	38	67
Adult male[a]	42	65	106

[a] Adults consist of original mice used to stock the enclosures and juveniles that matured during the field season. Thus, some mice may appear as both a juvenile and an adult in this table.

combined. In addition, 153 different juvenile males and 260 different juvenile females were captured at least once across the three data sets combined. Of the 153 mice first caught as juvenile males, 48 (31%) were later caught at least once as adults and, for females, 86 of the 260 (33%) first caught as juveniles were later captured at least once as adults.

Because some mice were caught more than once during the course of the study and because some mice matured during the course of an annual field season, there may be a question with regard to the independence of data points. I tabulated the number of different mice represented in each of the three data sets (Table 1). Calculations of the mean numbers of times male and female mice of the two ages were captured (Table 2) indicate that some mice were caught up to seven or eight times in a few of the classes in one or more years. Repeat captures were more frequent for adult males than for adult females or juveniles of either sex, and adult female repeat captures occurred more often

TABLE 2. MEAN FREQUENCY OF CAPTURES PER MOUSE AND RANGES OF NUMBERS OF CAPTURES FOR ADULT AND JUVENILE MALE AND FEMALE HOUSE MICE IN THREE DATA SETS INVOLVING MULTIPLE CAPTURES FOR SOME INDIVIDUALS

	1989		1992 ABEF		1992 CDGH	
Age/sex class	Mean	Range	Mean	Range	Mean	Range
Junveile female	1.1	1–3	1.2	1–4	1.3	1–4
Adult female	3.7	1–6	4.1	1–7	2.6	1–5
Juvenile male	1.4	1–4	1.3	1–4	1.2	1–4
Adult male	5.4	1–8	5.3	1–7	4.8	1–8

than repeat captures of either sex of juvenile. An examination of 40 mice, caught five or more times, sampled from across all three data sets indicated that the responses of each repeat capture individuals were not concentrated in a single odor-source type of trap or at a particular trap location. Both the large overall sample size and the lack of any consistent biases in terms of mice that were caught multiple times makes it unlikely that the statistical tests would be confounded by lack of independence for some of the data points involving repeat captures. In addition, the G test is relatively robust with respect to this problem (Sokal and Rohlf, 1981).

There could also be some concern about the availability of the various trap odors on a given night. If only limited numbers of odors were available, then some biases could be introduced because mice caught on those particular nights would have limited choices in terms of being caught with only certain odors in the traps. Analyses revealed that for 1989, there were, on average, 5.2 $\pm$ 0.3 odors available (range = 3–6) for 48 trap nights; for 1992 in enclosures C, D, G, and H there were, on average, 5.4 $\pm$ 0.2 odors available (range = 2–6) for 47 trap nights; for 1992 in enclosures A, B, E, and F there were, on average, 5.4 $\pm$ 0.4 odors available (range = 2–6) for 47 trap nights. These values indicate that there were, on most occasions, high percentages of the six test odors available in the traps.

Capture data for 1989, 1992 (enclosures A, B, E, and F), and 1992 (enclosures C, D, G, and H) are shown in Tables 3–5 such that two types of questions can be tested using the log likelihood ratio statistic. First, examining the tables

in terms of the previous capture, that is, from the perspective of the trap, we can ask whether there is any bias in terms of what types of mice, by age and sex, are captured next, depending upon the class of the odor source mouse. I call this a methods approach. Second, the tables can be examined looking across the rows according to respondents to determine whether mice of a particular class have any bias in terms of significant differential responses to particular types of odor sources in the traps. This examination of the data is from the mouse's perspective, and I call it a biosocial approach.

TABLE 6. RESULTS FROM G TESTS CONDUCTED ON MOUSE RESPONSES TO ODORS IN TRAPS INVOLVING DIFFERENTIAL RESPONSES ACCORDING TO PREVIOUS CAPTURE BY EXAMINING DATA FROM A METHODS PERSPECTIVE[a]

Previous capture	1989 (all)	1992 (ABEF)	1992 (CDGH)
Juv M	4.40	2.78	12.38[b]
Ad M	10.74	10.30	19.82[c]
Juv F	12.02[b]	11.80[b]	25.90[c]
NE F	5.22	10.04	12.30[b]
ES F	22.66[c]	6.46	10.80
PG/LA F	16.62[b]	5.66	1.04

[a] See Table 3 for explanation of abbreviations. $df = 5$ for all tests.
[b] $P < 0.05$ (critical value for significance = 11.07).
[c] $P < 0.005$ (critical value for significance = 16.75).

For the methods approach (trap perspective; Table 6), there are only three values of 18 log-likelihood ratios that are significant at $\alpha < 0.005$. These three significant test results are each for a different class of mouse and can be examined further by reference to Tables 3–5; (1) Traps odorized by adult males caught more nonestrous, estrous, and pregnant/lactating females than expected. (2) Traps that had previously contained a juvenile female caught fewer nonestrous, estrous, and pregnant/lactating females than expected. (3) Traps that were occupied previously by an estrous female caught more adult males than expected. There are no consistent trends with respect to whether particular odor types in the traps resulted in significant differential responses by the mice (Table 6).

For the biosocial approach (mouse perspective; Table 7), 10 of the tests were significant at the $\alpha < 0.005$ level, and there are some clear patterns of consistent differences. Adult males, as well as juvenile, nonestrous, and estrous females all exhibited significant differential responses to particular odors in the traps. Examination of the significant findings in Table 7 in conjunction with Tables 3–5 reveals the following explanations for the significant differences: (1) Adult males exhibited a preference for traps that had contained juvenile or estrous females and avoided traps that had previously contained adult males. (2) Juvenile females showed a preference for traps that had contained a juvenile female, but consistently avoided traps whose previous occupant had been an estrous female, a nonestrous female, or a pregnant/lactating female. (3) Nonestrous females exhibited a preference for traps that had contained an adult male. (4) Estrous females showed a preference for adult males and consistently avoided traps that had contained nonestrous or pregnant/lactating females.

In order to know whether some of the recorded differences were due to

ES F	14.52[b]	18.74[c]	67.60[c]
PG/LA F	8.14	2.08	9.70

[a] See Table 3 for explanation of abbreviations. $df = 5$ for all tests.
[b] $P < 0.05$ (critical value for significance = 11.07).
[c] $P < 0.005$ (critical value for significance = 16.75).

either variations in capture rates of mice or possibly differences in densities, it was necessary to calculate values for these parameters for each of the four years 1989–1992. Because most mice are captured at the interior 28 traps of each trapping grid, only those trap stations have been used to assess variations in capture rates. Rates of mouse captures at interior traps in the years with odor-baiting (1990 + 1991 = 16.6 ±1.9 mice/100 trap nights) did not differ significantly ($t = 0.40$, $df = 28$; $P > 0.20$) from the two years used for the present analyses of odors in traps (1989 + 1992 = 15.5 ± 2.0 mice/100 trap nights). Three-week intervals were used for calculating population size in the enclosures as minimum number known alive. Analysis of those interval estimates of density across the enclosures revealed no significant difference ($t = 1.67$; $df = 28$; $P > 0.10$) for the two years (1990 + 1991 = 29.2 ± 3.6 mice/enclosure) with odor-baiting compared to the two years (1989 + 1992 = 21.6 ± 2.9) used for the present analyses involving residual odors in traps.

DISCUSSION

The foregoing analyses provide the basis for two key conclusions and interpretations. (1) From a methods or trap perspective, there is minimal reason for concern about odors in traps from previously captured mice exerting a specific bias on what is captured next; these effects are not as pervasive as one might expect. (2) From the perspective of the mice, there are clear odor choices for specific odors by mice of most age, sex, and reproductive groups.

That findings revealed by the analyses of trapping data from years in which no specific odor-baiting was carried out show very clear choices suggests that

cleaning the traps, as was done in earlier experiments (Drickamer et al., 1992), resulted in the removal of contextual odor cues necessary for the mice to exhibit preferences. This effect could be due to mice avoiding clean traps or the need for the odor cues provided by a general soiling of the trap. It may also be due, at least in part, to the fact that the urine odors that were used by Drickamer et al. (1992) were, in fact, from mice not part of the test population. This would suggest that for odor-baiting experiments, the sources of the odors should come from within the test population to avoid confounding the results with unfamiliar scents.

Rates of captures at interior traps in the years with odor-baiting did not differ significantly from rates of capture for the two years used in the analyses reported here (Drickamer et al. 1992). Mean densities of mice per enclosure were also not statistically different for years when odor-baiting was conducted compared with years when traps were allowed to remain soiled throughout the season. Thus, effects recorded in the analyses reported here and the rather striking differences between the present findings and the data reported by Drickamer et al. (1992) are not, it seems, due to either variations in capture rates of mice or to some density-related difference.

It thus appears that contextual odors must play a significant role in the ability of mice to respond to traps. This finding contributes to our understanding of house mouse biology, as discussed in more detail below, and to our knowledge about methods used in rodent trapping. In attempting to avoid the sorts of biases that could occur when traps are cleaned after each capture, we actually may be biasing the findings by removing important cues. My data are in partial agreement with earlier reports for species of *Microtus*, *Apodemus*, and *Clethrionomys* (Boonstra and Krebs, 1976; Gurnell and Little, 1992). These investigators all report that rodents entered soiled traps more readily than clean traps. The results of Drickamer et al. (1992) differed in that the rates of capture do not differ between soiled and clean traps, but there is a significant change in the pattern with which traps are entered when they are left soiled between captures. The finding by Stoddart (1982) that for *M. agrestis* more mice were caught in recently cleaned traps than in traps that remained soiled seems to be unique in the literature on odors in rodent traps and is quite distinct from the present findings.

Examining the present findings from a methods or trap perspective revealed that no responder class of mouse exhibited the same significant bias in all three sets of data that were analyzed. Only three of the 18 tests were statistically significant at the $P < 0.005$ level. Perhaps the most consistent bias was that traps that had most recently contained a juvenile female were avoided by all other types of adult females, although not by other juvenile females. From these analyses, I would conclude that for house mice there is little overall concern about introducing biases into trapping data because of what was previously

captured in each particular trap. Earlier reports on other rodent species have not generally examined the data from the perspective of whether there are biases in what is captured subsequent to catching mice of a particular age, sex, or reproductive condition, although Gurnell and Little (1992) do conclude for wood mice (*Apodemus sylvaticus*) and bank voles (*Clethrionomys glareolus*) that there should not be any real concern about biases in trapping due to resident odors. My findings do substantiate something that has been "known" by many who trap rodents, namely, the live traps should be left in the field during the course of an experiment so that they become part of the olfactory environment of the animals. In terms of a methods perspective, it is also worth noting that for some species, particularly vole species that could be cycling and at high population density, there must be sufficient traps present to avoid any bias in terms of captures with particular odors due to a paucity of available open traps. With the house mice in this study, the proportion of traps occupied after a night of trapping was consistently less than 50%, making it unlikely that any major bias of this type was introduced. I did not note any differences in responses in terms of odor selections across a range of mouse densities that ranged from only four to six mice known to be alive in an enclosure for a given trapping week to situations with approximately 50 mice in an enclosure.

If we examine the analyses reported here from the perspective of olfactory communication and social biology of the mice, several significant conclusions emerge. Adult males and females in estrous selected traps most recently occupied by estrous females and adult males, respectively. Clearly, for house mice, the two sexes apparently actively seek each other when reproduction is possible. It is noteworthy that this level of odor preference may lead to further steps in mate selection by the mice, as in the recent report from laboratory tests indicating that estrous females can discriminate dominant and subordinate males (Drickamer, 1992). Since I did not have data for dominance status of the individual males in the enclosures in either of the years analyzed here, it is not possible to test this hypothesis further. Such tests should be conducted in the future under field conditions. House mice may differ in this regard from *Apodemus* spp. and bank voles (*Clethrionomys glareolus*), where there were no significant heterospecific trap odor preferences (Gurnell and Little, 1992). The results for house mice are similar to the findings of preferences for traps containing heterospecific odors reported earlier for *Peromyscus maniculatus* and *P. leucopus* (Drickamer, 1984).

That male house mice consistently avoided traps odorized by other males may be a reflection of the function of olfactory communication in terms of the spatial relations of the mice. House mice living in commensal situations are generally territorial (Anderson and Hill, 1965; Crowcroft, 1973), but in feral settings the sociospatial system appears to be more one of overlapping home ranges (Dunn, 1960; Mikesic and Drickamer, 1992). As indicated in Methods

and Materials, males do have a tendency to be captured again in traps containing their own odor; they appear to recognize and discriminate their own odor from those of conspecific males. This is similar to findings reported by Hurst (1989, 1990a) concerning the frequency of urine marking and investigation of urinary cues.

Nonestrous females exhibited a significant preference to enter traps that had previously contained an adult male. This result may be interpreted in several ways. First, these females may simply inhabit an area that includes the trap site. Second, if some of the nonestrous females were nearing estrous, then they may have been engaging in the initial stages of seeking a mate. Third, such females may also be exposing themselves to odors from males because such odors have the effect of accelerating the onset of estrus (Whitten, 1956; McClintock, 1983). Thus, responses to odor cues by mice may have both a communication function and a physiological function in terms of affecting the reproductive endocrinology of those responding to the odor cues.

Juvenile females avoided the odors of most types of females, except those of the same age, toward which they exhibited a significant preference. It is possible that this avoidance pattern reflects resource competition. In the feral situation, such juvenile females may emigrate from the natal site, dispersing to areas where there is less competition for mates, nest sites, or food. This sort of dispersal has been hypothesized previously for house mice by Bronson (1979). A similar hypothesis may be used to explain why estrous females significantly avoided traps that had been previously occupied by other adult females, regardless of reproductive condition. Females in estrous, should they become pregnant, will need to establish and maintain a sufficient resource base to achieve successful parturition and rearing of their young. Seeking an area free of potentially competing females may be part of the reason I detected the avoidance of traps from those other adult females. That the avoidance seems strongest to nonestrous females and weakest toward pregnant or lactating females may be due to some form of mate competition.

Acknowledgments—I thank Heather Rice, Lynn Louise Gillie, Ami Sessions Robinson, Lisa M. Marriner, Catherine Clover, John Petzing, and Kimberly S. Shaffer for assistance with trapping. George A. Feldhamer, Ami Sessions Robinson, Stephen H. Vessey, Lynn Louise Gillie, and two anonymous reviewers provided helpful comments on earlier drafts of the manuscript. Financial support for portions of this research were supplied by the Department of Zoology and College of Science at Southern Illinois University at Carbondale and by a grant from the Harry Frank Guggenheim Foundation.

UPTAKE AND SEQUESTRATION OF OUABAIN AND OTHER CARDIAC GLYCOSIDES IN *Danaus plexippus* (LEPIDOPTERA: DANAIDAE): EVIDENCE FOR A CARRIER-MEDIATED PROCESS

C. FRICK and M. WINK*

Universität Heidelberg,
Institut für Pharmazeutische Biologie,

(Received August 1, 1994; accepted January 26, 1995)

Abstract—Larvae of *Danaus plexippus* feed almost exclusively on milkweed species of the genus *Asclepias*, whose characteristic secondary metabolites are cardiac glycosides (CGs). Aposematic last-instar larvae were fed with ouabain and other cardiac glycosides of differing polarities. Time course experiments show that ouabain is sequestered in the integument within 48 hr after feeding, whereas midgut tissue and hemolymph function as transient CG storage compartments. About 63% of ouabain was transferred from larvae to the butterflies, whereas 37% of ouabain was lost with larval and pupal exuviae and with the meconium. The main sites of storage in imagines are wings and integument. If mixtures of CGs are fed to *D. plexippus* larvae, differential sequestration can be observed: The polar ouabain contributes 58.8% of total CGs, followed by digitoxin (19.6%), oleandrin (10.6%), digoxin (4.9%), digoxigenin (4.6%) and proscillaridin A (1.5%). Thus, uptake and sequestration must be selective processes. Uptake of [^{3}H]ouabain in vitro by isolated larval midguts was time-, pH-, and temperature-dependent and displayed an activation energy of 49 kJ/mol. Furthermore, the in vitro uptake of ouabain was inhibited (probably competitively) by the structurally similar convallatoxin. These data provide first evidence that ouabain uptake does not proceed by simple diffusion but with the aid of a carrier mechanism, which would explain the differential cardenolide uptake observed in living larvae.

Key Words—*Danaus plexippus*, cardenolides, uptake, carrier, sequestration, chemical defense, midgut, integument.

INTRODUCTION

Larvae of the monarch butterfly, *Danaus plexippus* L., feed on milkweed plants of the genus *Asclepias* that produce cardiac glycosides as characteristic secondary metabolites. *D. plexippus* is a specialized herbivore and is closely adapted to the secondary chemistry of Asclepiadaceae. Monarch larvae and imagines store CGs and are aposematic, similar to the situation in a number of other aposematic Lepidoptera, Hemiptera, and Coleoptera (Duffey and Scudder, 1972; Duffey, 1980; Malcolm, 1990; Harborne, 1993). Several experiments and observations have shown that cardenolide-rich monarch butterflies may become distasteful and toxic to predators (Reichstein et al., 1968; Brower et al., 1975, 1982; Brower, 1984; Cohen, 1985; Fink and Brower, 1981; Brower and Fink, 1985; Seiber et al., 1980, 1986; Ritland, 1991).

The sequestration and storage of cardiac glycosides by monarchs is a selective process in both quantitative and qualitative terms (Reichstein et al., 1968; Roeske et al., 1976; Seiber et al., 1980, 1986; Brower et al., 1982; Lynch and Martin, 1987; Martin and Lynch, 1988; Malcolm, 1990; Malcom and Brower, 1989): Monarchs appear to regulate their overall content of cardiac glycosides in such a way that an appropriate cardenolide capacity necessary for chemical defense is achieved, although a substantial part of the monarch population has a low cardenolide content (Brower et al., 1972; Brower and Mofitt, 1974; Ritland, 1991). Out of the complex pattern of cardenolides that are present in food plants, monarch butterflies selectively store polar cardenolides, but not the more lipophilic apolar glycosides (Brower, 1984; Brower et al., 1988; Malcolm et al., 1989; Groeneveld et al., 1990).

Cardiac glycosides are apparently not stored in all tissues of the monarch, but preferentially in the exoskeleton of the butterfly, i.e., the wings and the cuticle (Brower and Glazier, 1975; Seiber et al., 1986; Brower et al., 1988). This peripheral storage seems to provide a chemical defense barrier against nonadapted enemies, but adapted predators (birds and mice) can avoid the cardenolide-rich tissues (Fink and Brower, 1981; Brower et al., 1988; Glendinning, 1990).

In this communication we have further characterized the kinetics and tissue specificity of cardiac glycoside sequestration in larvae and adults of *D. plexippus* with respect to differing polarities of particular compounds such as ouabain, digitoxin, oleandrin, digoxin, digoxigenin, and proscillaridin A. In addition, biochemical transport studies with isolated larval midguts have been carried out with the polar ouabain (which resembles the naturally occurring CGs of the *Asclepias* food plants; Scheme 1), providing the first evidence for a cardenolide carrier mechanism.

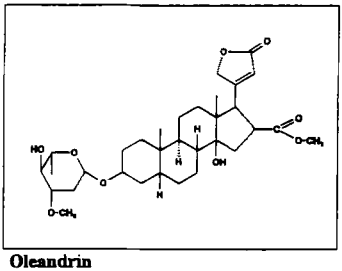
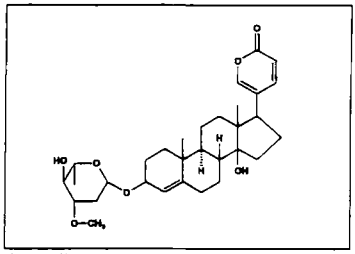
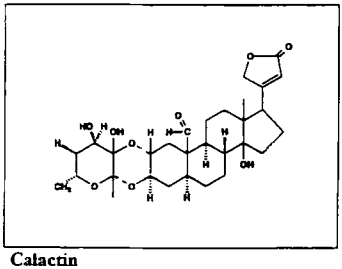
Digoxigenin



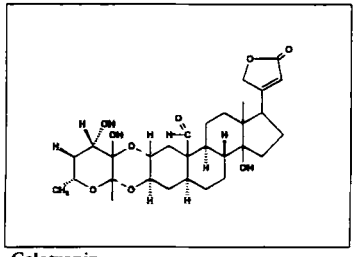
Oleandrin



Proscillaridin A



Calactin



Calotropin

SCHEME 1. Structures of the main cardiac glycosides employed in this study (ouabain, digitoxin, digoxin, digoxigenin, oleandrin, and proscillaridin A); typical cardiac glycosides of *Asclepias* are calactin and calotropin (Reichstein et al., 1968).

METHODS AND MATERIALS

Animals. Eggs of *D. plexippus* came from a laboratory colony kept at the Boyce Thompson Institute for Plant Research at Ithaca, New York (USA). In Germany, larvae were reared on *Asclepias syriaca* and a few generations of monarchs were grown in a greenhouse in the summers of 1991, 1992, and 1993. We chose *A. syriaca* (in North America *A. incarnata* or *A. tuberosa* would have been preferable) because it was locally available and HPLC analyses showed that only very low levels of endogenous cardenolides were produced. These endogenous compounds did not interfere with our experiments, because larvae that were reared on these plants were almost devoid of cardenolides.

Feeding Experiments. Concentrated solutions of ouabain and other CGs were applied on small leaf areas (12 × 12 mm) of *A. syriaca.* When solutions were dried, the leaves were fed to last-instar larvae, which were kept individually in plastic containers. Following the application of CGs (feeding was always finished after 45 min), larvae were given untreated *A. syriaca* leaves ad libitum. At time intervals given, larvae were collected (and their corresponding feces) and immediately dissected into hemolymph, guts (their contents were separately collected), fat body, and integument. After metamorphosis, larval and pupal exuviae were also collected. Meconium was taken from freshly emerged imagines.

Quantitation of Cardiac Glycosides. Larvae or dissected organs were stored at −20°C until processing. Tissues were ground in liquid nitrogen in a mortar. Then, 10 ml 90% ethanol was added and the homegenate was thoroughly mixed for 45 min at 70°C. After centrifugation (10 min at 10,000 rpm), 5 ml of the supernatant were collected. After adding 2 ml of Kedde reagent (100 mg 3,5-dinitrobenzoic acid in 10 ml methanol), samples were measured in a spectrophotometer at 540 nm (background). Then 1 ml 1 M NaOH was added and the optical density again measured after exactly 5 min at 540 nm. This value was then evaluated with a calibration curve established with respective reference glycosides.

When larvae were fed with mixtures of cardenolides, individual cardenolides were separated and quantified by HPLC analysis (Groeneveld et al., 1990; Wiegrebe and Wichtl, 1993). A Hewlett Packard 1040 with photodiode array detection was used; the column was an RP 18-100, 250 × 4 mm, 5 μm particles (Lichrocart, Merck, Darmstadt, Germany). Acetonitrile/water gradient elution: 3 min isocratically at 28% acetronitrile, 3–15 min linearly to 60% acetronitrile, then 2 min isocratically followed by 2 min with 95% acetronitrile. An elution profile is illustrated in Figure 1.

Carrier Studies. Larvae were dissected in modified Ringer solution, which consisted of 8000 mg NaCl, 200 mg KCl, 1000 mg glucose, 1000 mg Tricine, pH 8, in 1000 ml distilled water. Guts were excised and slit open to remove

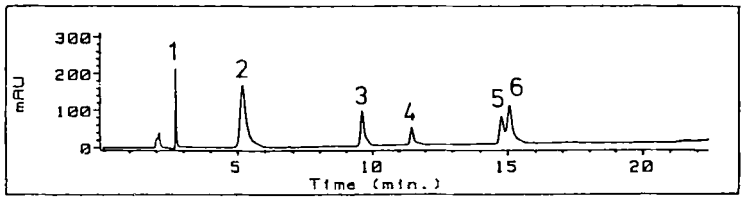


FIG. 1. Separation of a mixture of cardenolides by reversed phase HPLC. 1 = ouabain, 2 = digitoxigenin, 3 = digitoxin, 4 = proscillaridin A, 5 = oleandrin, 6 = digoxin. (For HPLC conditions see Methods and Materials).

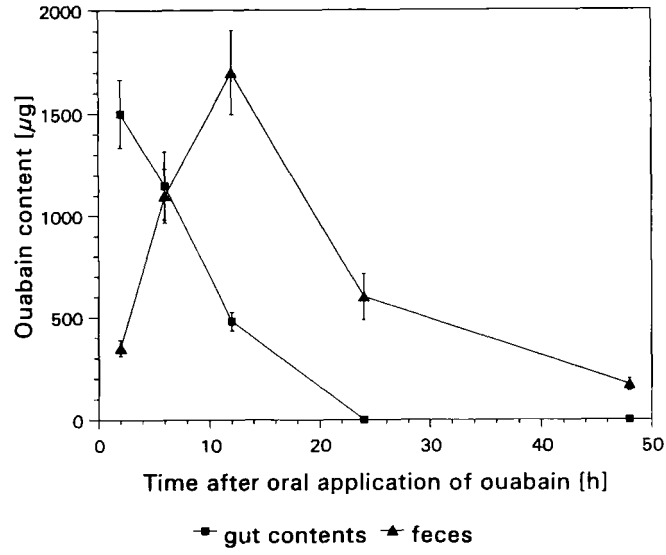
the peritrophic membrane and the gut contents. Midguts were cut into pieces 2 mm long, which were immediately used for the uptake experiments. For each data point, three or four gut pieces were added to 200 μl buffer in Eppendorf vials and left there for equilibration for 15 min. Experiments were started by adding [^{3}H]ouabain (ca. 200,000 cpm; specific activity 28.8 Ci/mmol). Experiments were terminated by taking out the gut segments and washing them in "cold" incubation buffer for 2 min. Then they were individually transferred to Eppendorf vials containing 100 μl 1 M HCl. Tissues were homogenized by hand with a small glass rod and then in an ultrasonic disintegrator for 30 min. Homogenates were quantitatively transferred into scintillation vials containing 10 ml scintillation cocktail. The radioactivity was determined in a scintillation counter. In addition, the radioactivity of the incubation buffer was measured to calculate the percentage of radioactivity taken up by the gut segments. As a control, gut segments were incubated with tritiated water and processed in the same way as in the ouabain experiments.

RESULTS

Kinetics and Selectivity of Sequestration of Ouabain and Other Cardiac Glycosides. Whereas most authors have studied the sequestration of cardenolides present in the respective host plants (Reichstein et al., 1968; Brower et al., 1975, 1982, 1988; Brower, 1984; Cohen, 1985; Fink and Brower, 1981; Brower and Fink, 1985; Seiber et al., 1980, 1986; Roeske et al., 1976; Lynch and Martin, 1987; Martin and Lynch, 1988), we have chosen a different approach: We have applied pure cardiac glycosides from nonhost plants that differed in structure and polarity and studied their kinetics and the tissue specificity of sequestration in larvae and butterflies.

In a first time-course experiment, last-instar larvae were fed with a single dose of 3.5 mg ouabain, which was applied on leaves of the host plant, *Asclepias syriaca.* At the time intervals shown in Figure 2, larvae were collected and



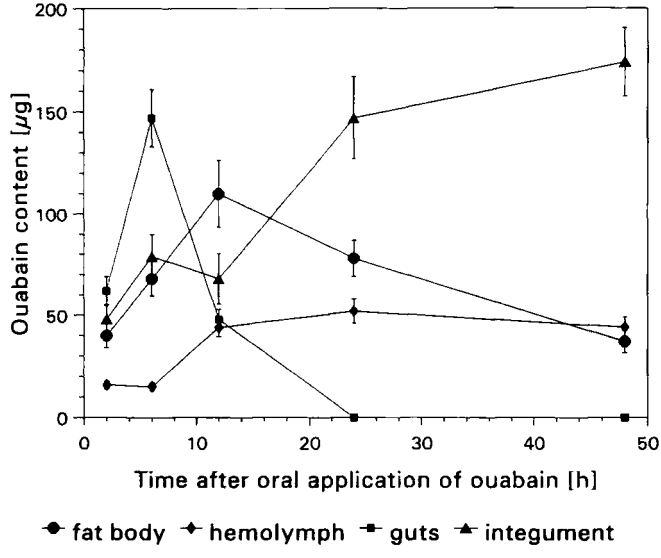


FIG. 2. Time course of ouabain uptake and sequestration in last-instar larvae of *Danaus plexippus*. (A) Kinetics in guts and feces; (B) kinetics in gut epithelia, hemolymph, fat body, and integuments. Bars represent standard deviations (N = 3–5).

dissected to separate hemolymph, guts (gut tissue separated from gut contents), fat body, and integument. Fecal pellets were also collected from the corresponding animals. Whereas the majority of the ouabain was excreted via the feces (a peak is reached 12 hr after feeding), 255 μg ouabain was retained by the larvae after 48 hr and was predominantly sequestered in the larval integument (Figure 2). Ouabain reached a transient maximum after 6 hr in the midgut epithelia. As ouabain decreased in this tissue, it increased transiently in hemolymph and the fat body and was eventually concentrated in the integument.

Another set of larvae was allowed to develop into imagines. As shown in Figure 3, the integument and wings represented the main storage sites for ouabain containing 82% of the total ouabain stored, whereas the fat body and muscles had significantly less ouabain; the ovaries and eggs, testes, and hemolymph were almost ouabain-free. Larval and pupal exuviae and the meconium contained 37% of the total amount of ouabain originally sequestered by the larvae, which qualitatively agrees with a previous study (Malcolm and Brower, 1989).

For comparison, a polar (i.e., ouabain) and several apolar cardiac glycosides [i.e., digoxin, digitoxin, oleandrin and digoxigenin (an aglycone)] were individually fed to last-instar larvae. Resorption, which was determined after 24 hr, was observed in all instances and was highest for digitoxin and digoxin, followed by ouabain, digoxigenin, and oleandrin (Table 1). The integument was again the main storage site.

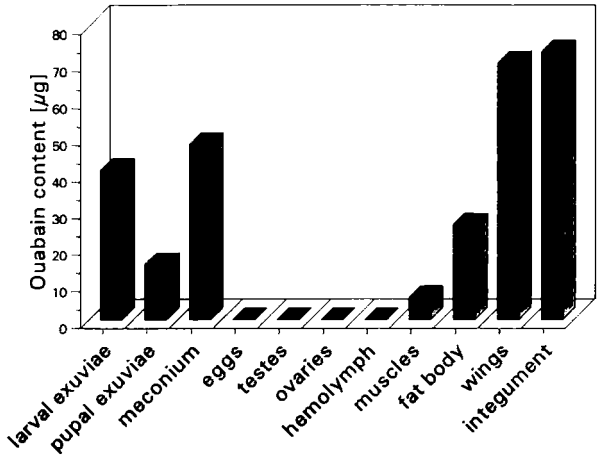

FIG. 3. Distribution of ouabain in monarch butterflies. Larvae had obtained 3.65 mg ouabain.

TABLE 1. SEQUESTRATION OF INDIVIDUALLY APPLIED CARDIAC GLYCOSIDES IN LARVAE OF *Danaus plexippus*[a]

Compound	Amount applied (μmol)	Amount taken up (μmol, %)[b]
Polar CG		
Ouabain	4.80	0.37 (7.7)
Medium polarity		
Digoxin	4.48	0.44 (9.6)
Apolar CG		
Digitoxin	4.58	0.52 (11.3)
Digoxigenin	8.97	0.55 (6.1)
Oleandrin	6.07	0.24 (3.9)

[a] Determination after 24 hr. Pure cardenolides applied on *Asclepias* leaves were injested by the larvae within 45 min.
[b] CG contents were determined photometrically.

In another set of experiments the glycosides were given as a mixture to find out whether the same distribution pattern appeared or the uptake was structure-specific. As can be seen from Table 2, the polar ouabain was clearly sequestered selectively (88% of the ouabain given was taken up) to account for 58.8% of the total resorbed CGs (Table 2). When a mixture of ouabain and its aglycone ouabagenin was applied, resorption of the aglycone (which accounted for 15.3%) was almost identical to that of ouabain (uptake = 14.6%) (Table 2).

A comparable pattern can be seen in imagines, indicating that the data in Table 2, which are derived from a 24-hr experiment only, are already representative. From the mixture of six CGs that was analyzed by HPLC (same as in Table 2, mixture I) the sequestration of ouabain was significantly favored: Ouabain contributed 51.7% of total CGs (= 0.52 μmol/animal), followed by digitoxin (15.3%), oleandrin (18.3%), digoxin (12.2%), digoxigenin (0.25%) and proscillaridin A (0%). Both integument and wings represented the main site of CG accumulation in most instances (Figure 4), except for oleandrin, which was predominantly found in fat-body tissue. Like the situation described in Figure 3, the meconium and larval and pupal exuviae also contained CGs (0.18 μmol/animal) and show a pattern that resembles that of the integument (Figure 4).

Evidence for Carrier-Mediated Ouabain Uptake. For the in vitro uptake studies, ouabain was selected because this glycoside is polar and does not diffuse across biomembranes by simple diffusion. Commercially available [^{3}H]ouabain was rapidly resorbed by larvae and a maximum of radioactivity occurred in the

[b] Determined by HPLC.

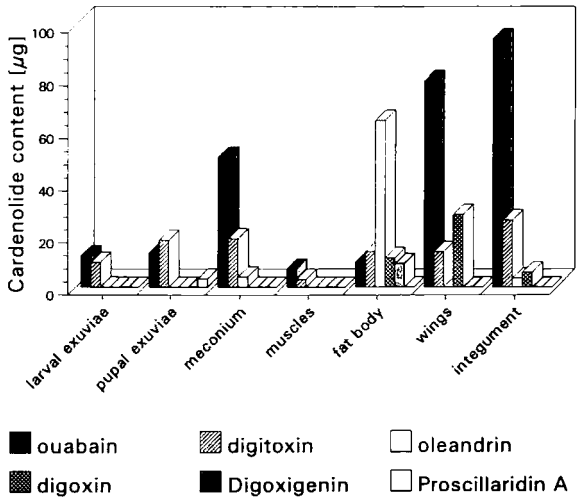

FIG. 4. Tissue-specific distribution of ouabain, digitoxin, oleandrin, digoxin, digoxigenin, and proscillaridin A in monarch butterflies. Quantitative determinations by HPLC.

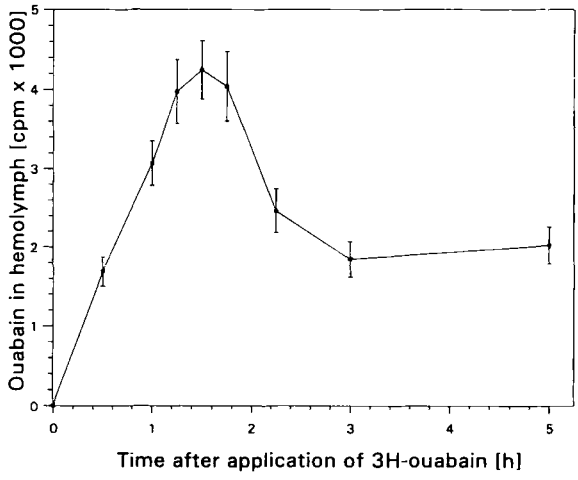

FIG. 5. Kinetics of [^{3}H]ouabain in the hemolymph. Larvae were fed 5 μCi [^{3}H]ouabain. At the time intervals given, animals were taken and their hemolymph was collected. The radioactivity of the hemolymph was measured in a scintillation counter. Bars represent standard deviations (N = 3–5).

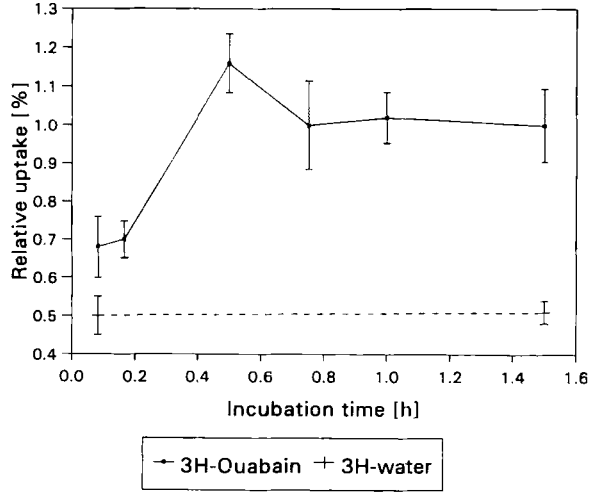

FIG. 6. Time course of the uptake of [^{3}H]ouabain and [^{3}H]H_2O by isolated gut segments of *D. plexippus*. Experiments were performed at pH 7 and 24°C. Bars represent standard deviations (N = 3–5).

hemolymph about 90 min after feeding (Figure 5). This provides some insight into the expected kinetics.

Since uptake and carrier experiments are difficult with intact larvae or complete midguts, midguts were prepared from last-instar larvae and cut into small pieces of equal size. These midgut segments were incubated with [^{3}H]ouabain for differing time intervals, and the incorporation of [^{3}H]ouabain was monitored by measuring its radioactivity. Uptake of [^{3}H]ouabain followed an almost linear increase with time for the first 30 min (Figure 6). [^{3}H]H_2O, which freely diffuses across membranes, was taken up at 0.5%, whereas [^{3}H]ouabain became enriched in the midgut epithelia and reached a maximum

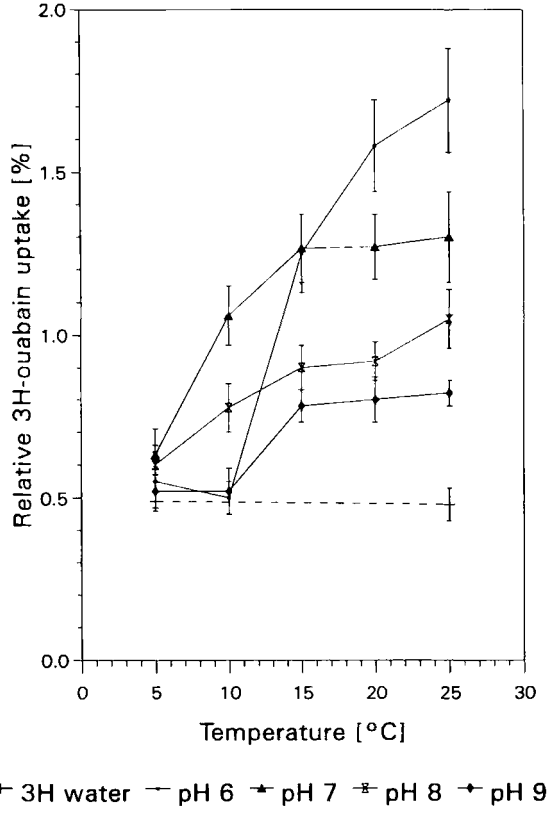

FIG. 7. Influence of hydrogen ion concentration and temperature on the uptake of [^{3}H]ouabain by midgut segments of *D. plexippus*. Reaction time is 50 min. Bars represent standard deviations (N = 3–5).

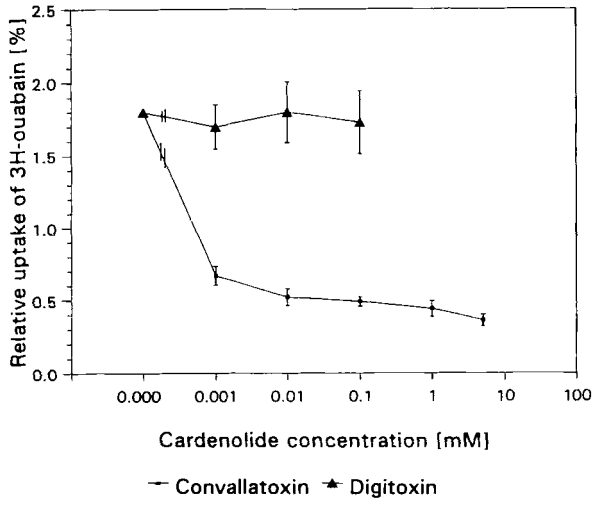

FIG. 8. Inhibition of the uptake of [^{3}H]ouabain by the structurally related cardenolide convallatoxin (final concentrations between 0.001 and 8 mM). Ouabain uptake was not influenced by the apolar digitoxin, which could not tested at higher concentrations because of solubility problems. Reactions were performed at 24°C for 50 min at pH 6.

of 1.15%. This indicates that [^{3}H]ouabain is taken up by the tissues in vitro and that it may even accumulate against a concentration gradient.

Experiments were carried out to determine the effect of temperature and hydrogen ion concentrations on uptake. As can be seen from Figure 7, uptake was optimal at pH 6 and displayed a clear temperature dependence. An activation energy of 49 kJ can be derived from an Arrhenius plot performed with data from pH 6 experiments. In addition, [^{3}H]ouabain uptake was inhibited by the structurally similar convallatoxin, but not by the apolar digitoxin (Figure 8).

DISCUSSION

If the patterns of cardenolides present in the host plant are compared with those in the monarch butterfly, it is apparent that they do not match either qualitatively or quantitatively; polar cardenolides are often present in higher amounts than in the host plant (Reichstein et al., 1968; Roeske et al., 1976; Seiber et al., 1980, 1986; Lynch and Martin, 1987; Martin and Lynch, 1988; Malcolm, 1990; Malcom and Brower, 1989). A selective cardenolide sequestration has also been reported for *Caenocoris nerii*, *Spilosthethus pandurus* (Euw

et al., 1971), *Poikilocerus bufonius* (Euw et al., 1967), and *Oncopeltus fasciatus* (Scudder and Meredith, 1982a; Scudder et al., 1986).

How is Selective Sequestration Achieved? It has been shown that *Danaus* and *Oncopeltus* are able to metabolize some of their dietary cardenolides (Scudder et al., 1986; Brower, 1984). For example, a cardenolide may be hydrolyzed to obtain the corresponding aglycone (Seiber et al., 1980), but metabolism can only partly explain the difference of CG profiles between host plants and insects. Some cardiac glycosides are highly apolar and lipophilic and can be resorbed by simple diffusion, whereas others are polar and more hydrophilic, such as ouabain. Physicochemical characteristics of the hydrophilic compounds imply that they do not freely diffuse across membranes. When feeding CGs to moth larvae (*Syntomis mogadorensis* and *Creatonotos transiens*), which do not encounter cardenolides in their diet, we found that the cardiac glyclosides were not taken up but eliminated with the feces (Wink and Schneider, 1990). Furthermore, the midguts of *Schistocerca gregaria* and *Periplaneta americana* were impermeable to ouabain and other cardenolides (Scudder and Meredith, 1982b). These data suggest that ouabain and other polar CGs do not diffuse nonspecifically across gut membranes.

In larvae of *Syntomeida epilais*, which also store CGs for chemical defense, we obtained evidence that CGs are resorbed from the guts by a carrier-mediated process (von Nickisch-Rosenegk et al. 1990). For comparison, in this study we analyzed whether ouabain is taken up by midguts of *D. plexippus* larvae using a similar mechanism.

Isolated midgut segments of late-instar larvae of *D. plexippus* took up [^{3}H]ouabain in a time-dependent way (Figure 6). Because ouabain uptake exceeded that of [^{3}H]H_2O, which can freely equilibrate between cells and the incubation medium, these results could be interpreted as ouabain accumulation against a concentration gradient. We cannot rule out, however, that the ouabain taken up was only bound to membranes or a binding protein that would mimic an accumulation against a concentration gradient. [^{3}H]Ouabain uptake depended on the hydrogen ion concentration of the incubation medium and was optimal at pH 6, which is in the range of carrier systems for secondary metabolites in other Lepidoptera: uptake of pyrrolizidine alkaloid N-oxides in *Creatonotos transiens:* pH 5 (Wink and Schneider, 1988); uptake of 13-hydroxylupanine in *Uresiphita reversalis:* pH 9 (Wink et al., 1991); and uptake of digoxin in *Syntomeida epilais:* pH 4. The hydrogen ion concentration in the gut of *Danaus plexippus* is between pH 7.2 (hindgut) and 8.4 (midgut) (Appel and Martin, 1990). Because of the apparent discrepancy between overall gut pH and the pH optimum, we assume that the carrier should have a microenvironment with a hydrogen ion concentration closer to pH 6.

[^{3}H]Ouabain uptake was temperature dependent and, similar to the situation in *Creatonotos*, *Syntomeida*, and *Uresiphita*, was highest at approximately 24°C

(Figure 7). Carrier transport (facilitated diffusion and active transport) is a catalyzed process. Temperature-dependence data can be evaluated with an Arrhenius plot to calculate the corresponding activation energy. For pH 6, we obtained an activation energy of 49 kJ/mol, which indicates that the uptake is a catalyzed process (carrier-free diffusion shows values below 20 kJ/mol) and not due to simple diffusion or any unspecific adsorption. Similar values were determined in other carrier systems: *C. transiens* 55–81 kJ/mol (Wink and Schneider, 1988), *S. epilais* 59 kJ/mol (Nickisch-Rosenegk et al., 1990a), and *U. reversalis* 55–78 kJ/mol (Wink et al., 1991). Furthermore, the uptake of [^{3}H]ouabain was inhibited (probably competitively) by adding another polar, but structurally similar CG, convallatoxin, to the incubation mixture (Figure 8). A simple diffusion process would not be influenced by such an addition.

Nonspecific adsorption (probably to biomembranes) also can be observed in Figures 6 and 7: Immediately after starting the experiments, 0.68% of [^{3}H]ouabain was bound and at 5°C when catalyzed processes do not work, "uptake" values were between 0.53 and 0.65%. Since the "real" uptake under optimal conditions was significantly higher (Figure 6 and 7), this background adsorption can be neglected as an explanation for the results obtained.

These experiments provide first evidence that a simple carrier-free diffusion cannot be responsible for the resorption of [^{3}H]ouabain in *D. plexippus* larvae. Instead, the experimental data suggest the presence of a cardenolide carrier mechanism. Although experiments with whole tissue samples are better for studying the activity of a carrier than studies with living larvae, they still leave certain questions unanswered. Certainly more experiments are required for a more complete characterization of the putative cardenolide carrier. Similar transport systems are better known for the uptake of primary metabolites (sugars, amino acids) or ions into living cells of bacteria, fungi, plants, or animals.

In 1988, we obtained queen butterflies (*Danaus gilippus*) from Florida, which were used in preliminary uptake experiments with cardenolides and pyrrolizidine alkaloid N-oxides. Isolated midgut segments resorbed [^{3}H]digoxin in a time-dependent way: uptake was almost linear for 45 min. Female midguts were 30–100% more active than those of males [a similar discrimination has also been observed in nature (Cohen, 1985; Brower et al., 1988)]. From temperature-dependence data, an activation energy between 35 and 50 kJ/mol was derived. We assume that these data also reflect the presence of a cardenolide carrier in the midguts of adult queen butterflies (M. Wink, E. von Nickisch-Rosenegk, and D. Schneider; unpublished observations). Since adult butterflies do not feed on a CG-rich diet, such a CG carrier in adult midguts seems to be superfluous but might be the result of the constitutive expression of a carrier gene.

Such a carrier system in *Danaus plexippus* and *D. gilippus* would provide a means to discriminate cardiac glycosides already in the midgut lumen and to

discharge all those compounds that do not bind to the carrier with the feces. This concept is also supported by the *in vivo* feeding experiments shown in Tables 1 and 2, which suggest that ouabain appears to have the highest affinity for the carrier and is preferentially taken up from CG mixtures, whereas the lipophilic cardenolides come second (Table 2). When cardiac glycosides were given as a single compound, the rate of ouabain uptake was nearly equal to that of the other compounds (Table 1). Considering the chemical structure of cardiac glycosides, the sugar side chain and the stereochemistry of the A/B rings seem to be of minor importance (Tables 1 and 2), whereas the five-membered lactone ring appears to be critical because proscillaridin A, a CG of the bufadienolide type, was not sequestered (Table 2). Even if the affinity of these CGs for the carrier was low, they could still use the carrier when it is not occupied by a more suitable CG, such as ouabain. However, in nature, where only CG mixtures exit, the polar CGs are preferred.

Lipophilic CGs may also be resorbed by an animal by simple diffusion, but as shown in Table 2, this process does not exceed the carrier-mediated uptake. Lipophilic CGs are either converted into more polar CGs or are eliminated via the Malpighian tubules (Seiber et al., 1980). The selective uptake and retention of polar glycosides provides the advantage that these compounds cannot easily diffuse across biomembranes and can thus be concentrated in certain tissues such as the integument.

The exact biochemical mechanisms that lead to storage of a secondary metabolite in insects are not well understood, but it is remarkable that plant-derived toxins are often deposited in the integument or cuticle: pyrrolizidine alkaloids in arctiid moths (Wink et al., 1988; Nickisch-Rosenegk et al., 1990b) and ithomiine butterflies (Brown 1984); cannabinoids in *Arctia caja* and *Zonecercus elegans* (Rothschild et al., 1977), cardenolides in *Danaus* (Brower and Glazier, 1975; Nishio, 1989; Brower et al, 1988; this study), *Syntomeida epilais* (Nickisch-Rosenegk et al., 1990a), and *Oncopeltus fasciatus* (Scudder et al., 1986); cyanogenic glycosides in *Zygaena* (Franzi et al., 1988); phenols in tree locusts, *Anacridium melanorhodon* (Bernays and Woodhead, 1982); cannabinol in *Arctia caja* (Rothschild et al., 1977); and quinolizidine alkaloids in *Uresiphita reversalis* (Wink et al., 1991). In *Oncopeltus fasciatus*, which also stores dietary cardenolides in the integument, a characteristic morphological adaptation towards CG storage was observed: This bug has a modified integument that is composed of a double-layered epidermis with an inner layer (the dorsolateral space) that constitutes the cardenolide storage compartment. On both sides of the thorax and abdomen thin cuticle areas exist that rupture when the bug is attacked. As a result, the cardenolides are released from the dorsoventral space and the predator is immediately confronted with the bitter cardenolides (Scudder and Meredith, 1982a; Scudder et al., 1986). The kinetics of uptake from the midgut via hemolymph to integument were almost identical in *Danaus* larvae sequestering

ouabain or in *Creatonotos transiens* taking up pyrrolizidine alkaloids (Nickisch-Rosenegk et al., 1990b), i.e., 48-hr after feeding the majority of allelochemicals had found their way to the integument.

Feeding experiments in three mouse species (*Peromyscus melanotis*, *P. aztecus*, and *Reithrodontomys sumichrasti*) with intact monarch butterflies of differing CG content have shown that CG-rich cuticular material (wings, integuments) was clearly rejected, whereas CG-free butterflies and tissues of low CG content were preferred (Glendinning, 1990). Mice mouthed CG-rich butterflies but immediately dropped them. It appeared that the mice tasted the cuticle and no signs of biting and chewing were observed. As a consequence, a number of CG-rich butterflies were left undamaged (Glendinning, 1990). This response is only possible if an allelochemical is deposited in the integument, which would explain an advantage for storing CGs in this part of the body of larvae, pupae, and imagines. The presence of CGs in the meconium could also be advantageous: freshly emerged imagines are able to spray the meconium towards a predator. If it contains bitter-tasting CGs, the defense response should be enhanced.

In addition, further mechanisms must be present in the monarch to avoid autotoxicity of CGs. Since CGs inhibit Na^+, K^+-ATPase in insects and other animals, *Danaus* must have evolved insensitivity at this molecular target or other detoxification mechanisms (such as storage in the integument). It has been shown experimentally that *D. plexippus* larvae can tolerate CG doses exceeding 1200 mg/kg body weight (which would kill almost any other animal) and its Na^+, K^+-ATPase cannot be inhibited by CGs (Vaughan and Jungreis, 1977; Holzinger et al. 1992). At the molecular level we found that one amino acid is different in the putative ouabain binding site (length 12 amino acids) in monarch Na^+, K^+-ATPase, and we have suggested that ouabain can no longer bind and thus insensitivity is achieved (Holzinger et al., 1992). In *Oncopeltus fasciatus* a comparable pattern emerged, indicating a high degree of molecular and physiological adaptation towards CG utilization. Besides a carrier-mediated uptake (Detzel and Wink, 1995), a predominant storage of the cardenolides in the dorsoventral space, Na^+, K^+-ATPase is ouabain-insensitive and the insect can tolerate high doses of cardenolides (Scudder and Meredith, 1982a; Scudder et al., 1986).

Acknowledgments—Financial support by the Deutsche Forschunsgemeinschaft (Wi 719/10-1) is gratefully acknowledged. Eggs of *D. plexippus* were kindly supplied by Dr. A. Renwick (Boyce Thompson Institute for Plant Research, Ithaca). Prof. Dr. D. Schneider made helpful suggestions and provided *D. gilippus* for some pilot experiments. We also thank two anonymous referees for helpful comments.

Abstract—Bank vole, *Clethrionomys glareolus*, pups, similar to many other infant rodents, emit ultrasonic vocalizations when they are removed from the nest and cooled. Infants exposed to bedding from their home cage produced fewer and shorter calls than infants tested without bedding. Sound frequencies were significantly higher in infants exposed to home bedding than in other experimental groups. These results provide evidence that infant bank voles are able to identify the presence of home bedding, probably on the basis of odor. This appears to be the first report of shifts in frequency of pup ultrasonic calls in response to olfactory cues.

Key Words—Bank vole, chemosignals, infants, pups, rodents, ultrasonic vocalization.

INTRODUCTION

Infant rodents during the first two weeks after birth depend on the warmth of the mother's body and of siblings present in the same nest. Lower ambient temperature is one of the factors that strongly influences behavior of pups. This may be manifested as emission of ultrasonic calls by animals when they are removed from the nest and cooled. The vocalization of infants can be perceived by adult females and stimulates maternal behavior. Calls of infant rats at a frequency of 40 kHz prompt lactating females to return to the nest (Jams and Leon, 1983) and in various species of voles, *Microtus*, mothers are attracted to the source of ultrasonic calls in a Y maze (Colvin, 1973).

In bank voles *Clethrionomys glareolus*, locomotory activity increases during the second week of life and infants are able to move out of their nest. However, the pelage of small rodents is still poorly developed, and they cool relatively easily. They also become less tolerant of lowered body temperature, and both rates and intensities of ultrasonic calling reach peak values at around 7–10 days (Okon, 1972; Blake, 1992). At this age bank vole pups are still blind, but their olfactory system is well developed and must therefore be a major source of sensory input. Our hypothesis is that pups can distinguish conspecifics of different familiarity, probably on the basis of odor, and this will be detectable by differences in their vocalizing. In these experiments, bedding from cages were used as a source of typical odor of animals. To test this, we elicited ultrasonic calls from pups exposed to cooling temperatures under four olfactory conditions: bedding from their home cage, bedding from a unfamiliar adult male, bedding from a unfamiliar adult female, and no bedding. Response was measured in terms of the calling rate, duration of individual calls, and the sound frequency of calls.

METHODS AND MATERIALS

Animals. The bank voles used in the experiments came from an outbred stock colony reared at the Institute of Zoology, Jagiellonian University, Krakow. The animals were maintained in metal cages (40 × 20 × 25 cm) at 18 ± 2°C, on photoperiod of 14 hr light and 10 hr dark (lights on at 6:00 AM). Standard pelleted rabbit chow diet (Motycz, Poland) and water were available ad libitum. Wood shavings were provided as bedding and nesting material and were changed once a week.

Sixty-five (32 males and 33 females) 6- and 7-day-old infants with a mass of 3.0 ± 0.16 g were selected. Two to four pups per litter were raised with both parents. The animals were blind, the external auditory meati open, and pelage was poorly developed. Approximately equal numbers of males and females were used in each treatment. As indicated by our previous results, 6- and 7-day-old males and females do not differ in calling rate (Marchlewska-Koj et al., 1995), and therefore the results obtained for both sexes have been combined.

Experimental Procedure. Animals in the home cage were transferred from colony room to the laboratory in the morning, and all tests were performed between noon and 2 PM. The influence of the presence or absence of bedding and of the presence of familiar or unfamiliar bedding was tested. Unfamiliar bedding came from nests of either adult male or female conspecifics. Pups were randomly assigned to one of four groups (no bedding, home bedding, unfamiliar male, unfamiliar female). The numbers of tested animals are given in the appro-

priate tables below. An individual pup was removed from the home cage, placed on a plastic dish, and kept warm for 10 min. After this period, it was either observed with no bedding or approximately 2 cm^3 of the appropriate bedding material placed on the dish next to the pup. The tested animal was then introduced to an acoustically isolated chamber with an ambient temperature of 18–20°C. One minute after the bedding was presented, or after a further minute for the pups observed with no bedding, the vocalization of the animal was monitored for 3 min. Calls were monitored with an ultrasound receiver suspended 5 cm above the tested animals. The microphone was connected to a QMC ultrasound detector, type S25, coupled to a cassette recorder (Sony, HX PRO). The detector was used in the frequency division mode, and the frequency of the incoming signal was divided by 16 so that the resulting output could be recorded directly onto cassette tape.

Samples of recorded ultrasonic calls were analyzed using a Kay Sonograph, type 7029A. Cassette recordings were played directly into the sonograph. Where possible samples were chosen at regular intervals throughout the tape. Calls were often emitted at a steady rate per minute. The numbers of calls analyzed are given in the appropriate tables. Duration of calls and the initial, terminal, maximum, and minimum frequencies of the calls were determined from the resultant sonograms using a specially prepared transparent graticule with axes in milliseconds and kilohertz. The number of calls in each 3-min recording was counted using a BBC B computer and a specially written program that allowed the computer to be used as an event recorder. Data were analyzed by using ANOVA and Duncan's new multiple-range test.

RESULTS

Bank vole pups produced ultrasound calls when they were taken out of the home cage and cooled. They vocalized in all four conditions, i.e., in the absence of bedding as well as in the presence of home cage bedding or of bedding from unfamiliar male or female adults (Table 1). Infants exposed to bedding from the home cage produced fewer calls per minute than animals tested without bedding. The duration of calls produced by infants tested in the presence of home bedding tended to be shorter than in other experimental groups, but differences were not statistically significant.

The calls of newborn bank voles are 20–55 kHz and 30–70 msec long (Sales and Pye, 1974; Stoddart and Sales, 1985). We found the fundamental frequency to be modulated slightly, first rising and than falling, with a bandwidth of about 3 kHz. Bedding affected the sound frequency of ultrasounds emitted by pups. With one exception, the initial frequency as well as the terminal frequency of calls were significantly higher in infants tested in the presence of

home bedding than in other experimental groups. Only in pups without bedding was the initial frequency similar to those of pups with home bedding (Table 2). There were statistically significant differences between minimal and maximal frequencies (Table 2). The highest sound frequencies were recorded when animals were tested in the presence of bedding from home cages. No differences were found between the frequencies of calls of pups tested without bedding and those produced in the presence of bedding from a strange male or female.

DISCUSSION

In adult rodents, social interaction is one of the factors that provokes vocalization at low or high frequency. Ultrasonic calls can be stimulated by olfactory signals released by conspecifics. Adult female hamsters vocalized in response to male odor (Johnston, 1992), and males produced ultrasounds when exposed to vaginal discharge (Johnston and Kwan, 1984). Vocalization in prairie voles (*Microtus ochrogaster*) also is evoked by the presence of odor of opposite sex (Lepri et al., 1988). In laboratory mice and laboratory rats, adult males emit ultrasonic calls in response to olfactory signals produced by females (Nyby et al., 1977; Barfield et al., 1979).

Infant rodents, too, modify ultrasonic calling in response to olfactory cues. Laboratory rats are capable of discriminating between the presence and absence of home odor, and cooled pups increased ultrasound production after removal of familiar nest odor (Oswalt and Meier, 1975; Hofer and Shair, 1987). They can also discriminate between different sources of conspecific odor; fewer ultrasonic calls were emitted in the presence of bedding from the home cage or from the cages of adult males than with bedding from the cages of females, either virgin or lactating (Conely and Bell, 1978; Lyons and Banks, 1982). In this study we have shown that bank vole pups can identify home odor.

The number and duration of calls were lower in the pups exposed to home bedding than in the other groups, although few of the differences were statistically significant. However, the vocalizations of animals tested with home bedding differed significantly in sound frequency and were generally at a higher frequency than those of any other experimental group. Differences were found for initial and terminal frequencies as well as for maximal and minimal frequencies. This appears to be the first report of such shifts in the frequency of pup ultrasonic calls in response to olfactory cues.

In adult rodents the effects of odor on the rate of ultrasonic calling have been documented for several species, including laboratory rats, laboratory mice, and hamsters (Nyby and Whitney, 1978). In woodmice, *Apodemus sylvaticus*, odor also has a marked effect on the frequency pattern of the ultrasonic calls elicited from males (Gyger and Schenk, 1980). Our results provide additional evidence that indicates a similarity between the high-frequency calls of infants and those of adults. In both, the rate of ultrasonic calling and, in some cases, the frequency characteristics of the calls, can be modified by sensory processes evoked by chemosignals of conspecifics. Ultrasonic calls and pheromones have complementary roles in a communication chain that regulates reproduction in hamsters (Floody and Pfaff, 1977). Possibly, acoustic and odor cues have similarly complementary roles in regulating parent–infant interactions in a number of rodent species.

Abstract—Callus of the fungus- and insect-resistant corn inbred, Mp313E, of differing ages and degrees of brownness was tested for effects on neonate larvae of the corn earworm, *Helicoverpa zea*. Older, browner, 8-week-old callus caused significantly higher mortality of *H. zea* after two days compared to larvae fed 5-week-old callus (brown or not) or pinto bean diet. Larvae fed on the 5-week-old callus were significantly smaller after nine days compared to those fed on nonbrown callus of the same age. Ferulic acid, *p*-coumaric acid, and sinapic acid, corn allelochemicals associated with cell walls, were oxidized (produced a brown product) up to 10-fold more rapidly by peroxidase preparations of the brown callus compared to nonbrown callus. Peroxidase isozymes from both types of brown callus separated by conventional gel electrophoresis and isoelectric focusing showed more intense anodic/acidic bands compared to peroxidase isozymes separated from the nonbrown callus. Some additional peroxidase isozymes were also present in the brown callus and were able to oxidize ferulic acid. Conventional extraction techniques for phenolic acids indicated free ferulic acid levels were similar for same-age callus, but somewhat less for older callus; no free *p*-coumaric acid was detected. For esterified and insoluble-bound phenolic content, the level of *p*-coumaric acid was higher than that of ferulic acid and was somewhat greater in insoluble-bound fractions for the old callus compared to the younger callus. Color ratings of aqueous extracts and phenolic acid extract residues indicated much brown material remained, which was proportional in color to the original material. The differential insect response to, and peroxidase activity of, brown vs. nonbrown callus were similar to results previously noted for brown pericarps of corn compared to nonbrown pericarps. This information suggests the peroxidases are contributing to the browning through oxidation of phenolic acids and thereby enhancing resistance to insects.

Key Words—*Helicoverpa*, peroxidase, quinone, ferulic acid, callus tissue, resistance, corn.

INTRODUCTION

Tissue culture can be used to more readily investigate some physiological features associated with insect or pathogen resistance compared to the intact plant due to continuous availability of uniform plant material. For example, many of the pathways of flavonoid biosynthesis have been elucidated using various plant tissue cultures (Barz and Nicholas, 1978). Corn callus has been used to screen rapidly for resistance to insects; ratings obtained often correspond well with whole plant material, such as leaves (e.g., Williams et al., 1983).

Mechanisms of corn plant resistance to insects are diverse and include production of flavonoids such as maysin (Waiss et al., 1979), benzoxazolinones such as 6-methoxybenzoxazolinone (Meyer, 1988), and phenolic compounds such as ferulic acid (Serratos et al., 1987; Classen et al., 1990). Oxidation of phenolics appears to cause antinutritive effects in insects fed tomato foliage (Felton et al., 1989), and trichome adhesiveness in wild potato (Steffens and Walters, 1991). The pericarp of the corn inbred Mp313E has kernel-based resistance to *Aspergillus flavus* (Scott and Zummo, 1988) and the dusky sap beetle, *Carpophilus lugubris* (Dowd, 1994a). The rapid browning of the pericarp when damaged, which appears to be promoted by peroxidases, is a likely mechanism of insect resistance (Dowd, 1994b). Corn callus cultures are known to produce some of the peroxidases (Fransz et al., 1989) that appear to be the same as those reported in differentiated tissues of corn such as leaves and kernels (Brewbaker and Hasegawa, 1975) based on band positions when peroxidases were separated by gel electrophoresis. In order to further explore the browning reaction as it relates to insect resistance, we examined the ability of insects to survive on browned vs. nonbrowned callus and determined the potential involvement of peroxidases and phenolic acids in the browning reaction.

METHODS AND MATERIALS

Insects. The *H. zea* larvae (stock originally obtained from the Department of Entomology, University of Illinois, Urbana, Illinois) were reared on pinto bean-based diet at 27 ± 1°C 40 ± 10% relative humidity, and a 14L:10D photoperiod as described previously (Dowd, 1988). Neonate larvae were used for assays.

Chemicals. Bovine serum albumin, *trans*-caffeic acid, *trans*-cinnamic acid, *trans-p*-coumaric acid, coniferyl alcohol, 1-chloronaphthol, dimethyl-*p*-phenylenediamine, *trans*-ferulic acid, and MS medium salts and vitamins were obtained

from Sigma Chemical Co. *trans*-Sinapic acid was obtained from Aldrich Chemical Co. 2,4-Dichlorophenoxyacetic acid was obtained from Chem Service. The *cis* isomers of ferulic and *p*-coumaric acids were prepared as previously described (Norton, 1994). All other chemicals were of reagent grade.

Tissue Culture. Kernels of selfed Mp313E grown in Peoria, Illinois, during the summer of 1991 by conventional practices (Dowd, 1994a) were removed from ears 35 days after pollination. The kernels were sterilized by placing them in a Petri dish containing 70% ethanol for 1 min, and then for 15 min in 15% laundry bleach with a few drops of detergent, with agitation throughout the process. The kernels were rinsed four times with sterile distilled water and germinated in Petri dishes containing 1% water agar. Six days after germination, hypocotyl segments were excised and transferred to callus growth media consisting of MS medium salts and vitamins (Murashige and Skoog, 1962), supplemented with 3% sucrose, 2 mg/liter of 2,4-dichlorophenoxyacetic acid, and 7 g/liter agar, with the pH adjusted to 5.7 with 0.1 N sodium hydroxide. The callus was grown in 100-mm-diameter Petri dishes in the dark at 25°C and subcultured every six weeks.

Bioassays. Several clumps of callus tissue from 8-week-old cultures that were uniformly brown (no nonbrown material available), and both brown (<5% nonbrown over the entire clump) and nonbrown (<5% brown over the entire clump) callus from cultures that were 5 weeks old were lyophilized for 48 hr. In order to provide uniform material for the insects, all of each type of callus was weighed and powdered together using a smooth glass mortar and pestle (Figure 1). Because preliminary tests with both unlyophilized and lyophilized callus removed from cultures indicated callus would subsequently become contaminated with molds within a few days after insects were introduced, sorbic acid was used as a mold inhibitor. Sorbic acid was added as 2.4 mg in 4 ml of acetone to 600 mg of dried callus so that the final concentration, when rehydrated to 75% moisture, would be 1000 ppm [approximately the same concentration used in artificial diets for these insects (Dowd, 1988)]. Acetone was evaporated in a fume hood, and the callus rehydrated with sterile distilled water. The rehydrated callus was divided into 20 approximately equal-sized parts and added to 20 wells of a 24-well tissue culture plate. A newly hatched (ca. 1 day old) *H. zea* larva was added to each of the 20 wells containing callus (i.e., 20 larvae per treatment), and plates were sealed as described previously (Dowd, 1988) and held under the same conditions as described for rearing. An additional plate was set up with caterpillars using the pinto bean diet as a food source. All assays were set up on the same day with the source of caterpillars. Assays were examined after two, four, and nine days for mortality. Because of high mortality of insects fed on the old, brown callus at nine days, the assay was ended. Both dead insects and survivors were frozen and subsequently weighed on a Mettler

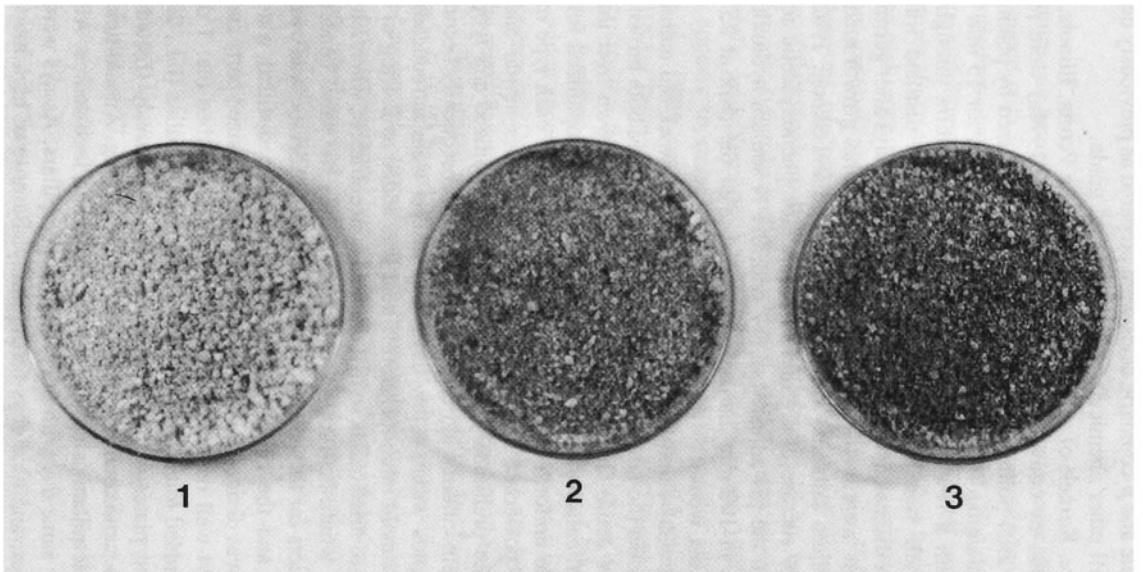

FIG. 1. Relative degree of browness of callus material used in assays. 1 = 5-week-old nonbrown (color rating of 10YR 8/2), 2 = 5-week-old brown (color rating of 10YR 6/4), 3 = 8-week-old brown callus (color rating of 10YR 5/4). Color ratings from Kollmorgan Instruments Corp. (1992).

AE 163 analytical balance to the nearest 0.01 mg in order to determine both weights of survivors and weights the dead insects had reached prior to death.

Enzyme Assays. Two intact callus clumps of each type and of the same three types and ages described above that were as close as possible in size (measuring 0.5–1.0 cm across) were homogenized individually in 2 ml of ice cold, pH 7.4, 0.1 M sodium phosphate buffer with a ground glass tissue grinder. Each homogenate was centrifuged at 1000*g* for 10 min, and the supernatant was used in the assays. Peroxidase activity of fresh callus was examined with *p*-coumaric acid, ferulic acid, sinapic acid, and coniferyl alcohol, which are known to be present in corn and many other plants (Fry, 1986). As described previously (Dowd, 1994b), assays consisted of 700 μl of pH 7.4, 0.1 M sodium phosphate buffer, 100 μl of 0.3% hydrogen peroxide (mixed from a 30% concentrate, considered to be 100%), 100 μl of callus homogenate supernatant (diluted 1 : 10), and 100 μl of 0.1% substrate. When solvents other than water or buffer were used to dissolve the substrate, they were also used in controls. Changes in absorbance for the respective substrates were monitored with a Perkin-Elmer Lambda 4B spectrophotometer for 10 min at 30°C at the following absorbances as determined by differential scanning of generated products (Dowd, 1994b): phenolic acids, 420 nm; and coniferyl alcohol, 800 nm. All assays were run in duplicate with two separate sources of callus of each type. Protein content was determined with the Bio-Rad packaged protein assay (Bio-Rad, 1985), with bovine serum albumin as a standard.

Enzyme Separation. Differences in peroxidase type and activity were determined using nondenaturing polyacrylamide gel electrophoresis and wide-range (pH 3.5–9) isoelectric focusing. Gel electrophoresis was performed as described previously (Dowd and Sparks, 1986; Dowd, 1994b) using 1-mm-thick, 7.5% polyacrylamide gels run on a LKB Multiphor II electrophoresis system. Bromophenol blue was used as the tracking dye. Isoelectric focusing was performed as described previously (Dowd and Sparks, 1986; Dowd 1994b) using precast, pH 3.5–9, Pharmacia gels on the Multiphor system. Gels were run at 25 W constant power at 2000 V for 1.5 hr; Evan's blue was used as the tracking dye. For isoelectric focusing gels, 1-cm sections of the gel across the pH gradient were placed in 1 ml of deionized water overnight, and the pH readings were taken to the nearest 0.001 pH unit with a Corning Ion Analyzer 250. Graphical analysis indicated pH ranges were uniform within 0.1 pH unit across the gel. Each sample homogenate was run in duplicate (total of four replicates for each callus type).

Gels were stained for general peroxidase and phenolic acid peroxidase activity with a histochemical procedure (Conyers and Kidwell, 1991) modified for staining of polyacrylamide gels (Dowd, 1994b). Briefly, for general peroxidase activity, 12 ml of 0.3% peroxidase solution and 6 ml each of 0.0067% ethanol solutions of 1-chloronaphthol and DMPD were added to 100 ml of pH

7.4 sodium phosphate buffer at room temperature. Gels were incubated for approximately 15 min, and the resulting banding pattern was photographed. For detection of peroxidase oxidation of ferulic acid, both uncoupled reactions and prereacted, coupled assays were run (Dowd, 1994b). Uncoupled reactions had 0.1% ferulic acid alone. Coupled reactions had the same concentration of ferulic acid for 15 min, followed by 12 ml of dilute (1:30 in the phosphate buffer) solutions of 1-chloronaphthol—DMPD allowed to react for 15 min. Coupled reactions to detect peroxidase oxidation of *p*-coumaric acid and sinapic acid were run in an analogous manner (Dowd, 1994b).

Allelochemical Analysis. Phenolic acids were extracted from lyophilized callus according to the method of Krygier et al. (1982) with the following modifications. Instead of the initial preparation steps used by Krygier et al. (1982) with flour, ca. 0.2 g of dry callus was powdered with a mortar and pestle and extracted with 6 ml of methanol–acetone–water 35:35:30 (v/v/v), vortexed for 15 sec, centrifuged, and the supernatant removed. The residue was extracted six times. Instead of using diethyl ether–ethyl acetate (Krygier et al., 1982), ethyl acetate was used after the hexane extraction step to extract the free acids from the aqueous solutions obtained from free, esterified, and bound fractions. The extracts were dried with Na_2SO_4, evaporated with N_2, and made up to volume with ethyl acetate. To minimize the formation of *cis* isomers, all manipulations of callus and extracts were carried out with laboratory lights off. Samples were analyzed by HPLC with a Beckman Ultrasphere 5-μm, C-18 column that was 25 cm × 4.6 mm. The flow rate was 1 ml/min. The solvent system was acetic acid–tetrahydrofuran–water (2:10:88) (solvent A) and tetrahydrofuran–methanol (1:9) (solvent B). A linear gradient solvent program was used as follows: from 0% to 15% B over 20 min, from 15% to 80% B over 15 min, isocratic for 10 min, 80% B to 0% B over 15 min, and isocratic for 5 min, all at ambient temperature. The 20-μl injections were made by the filled-loop method. Standard curves for caffeic, cinnamic, *p*-coumaric, ferulic, and sinapic acids (315 nm) were derived by averaging four injections at concentrations of 0.033, 0.104, and 0.320 mg/ml. Phenolic acid levels reported are the average of duplicate callus samples run at least twice each. Portions of buffer extracts prepared for use in enzyme assays that were lyophilized and extract residue remaining from the phenolic acid extractions were color rated using soil color charts (Kollmorgan Instruments Corp., 1992). Values were analyzed for statistical significance by least significant differences after analysis of variance.

RESULTS

Survival of all *H. zea* larvae fed callus was significantly ($P < 0.05$ by chi-square analysis) reduced compared to larvae fed pinto bean diet (Table 1).

TABLE 1. EFFECT OF DIFFERENT CORN CALLUS TYPES ON *H. zea* LARVAE[a]

Material	Mortality (%)			9-day weight (mg)	
	2 days	4 days	9 days	Alive	Dead
Pinto bean diet	0.0a	0.0a	0.0a	21.8 ± 2.8a	
Nonbrown callus	0.0a	0.0a	60.0b	0.9 ± 0.1b	0.7 ± 0.1a
Brown callus	0.0a	0.0a	60.0b	0.4 ± 0.1c	0.1 ± 0.0b
Old brown callus	44.7b	86.6b	93.3c	0.02	NW

[a]Weights are means ± standard errors. Values in columns followed by the same letter are not significantly different at the 5% level of probability by chi-square analysis (mortality) or least significant differences in analysis of variance (weights). NW = due to the small size, dead insects caged with old brown callus were not weighed. Only one insect survived for nine days on the old brown callus, hence there was no variance and no analysis of variance.

However, the 8-week-old brown callus caused significantly higher mortality ($P < 0.05$ by chi-square analysis) of *H. zea* larvae compared to larvae fed on either type of the 5-week-old callus. Although mortality of larvae fed both types of younger callus was similar over the intervals examined, the weights of both dead and live larvae at nine days fed the younger, brown callus were significantly lower ($P < 0.05$ by analysis of variance) than the weights of the larvae fed the younger, nonbrown callus.

The older brown callus oxidized all phenolic acids at the highest rate, while the rate of oxidation of the phenolic acids by the younger brown callus was significantly lower (Table 2). Ferulic acid was oxidized at the highest rate. The *p*-coumaric acid had the greatest difference in oxidation rate from nonbrown to old brown callus, ca. 10-fold. No oxidation of coniferyl alcohol was detected for any of the callus homogenates at the enzyme concentration tested.

TABLE 2. OXIDATION OF ARYL ALCOHOLS BY CALLUS HOMOGENATES[a]

Compound	Change in absorbance/mg protein/min for callus		
	Nonbrown	Brown	Old
Coniferyl alcohol	ND	ND	ND
p-Coumaric acid	0.0069 ± 0.0005a	0.035 ± 0.005b	0.077 ± 0.004c

[a]Values are means ± standard errors. Values in rows followed by the same letter are not significantly different at the 5% level of probability by least-significant differences in analysis of variance.

Conventional gel electrophoresis and subsequent general peroxidase activity staining showed several different peroxidase isozymes (Figure 2). Although overall intensity of bands was higher for both browned sources, it appeared that the cathodic bands present in the nonbrown callus samples were more prevalent (based on intensity) than those from both types of brown callus. Some of the anodic bands were more intense in both ages of the brown callus compared to the nonbrown callus. Additional bands were also seen for both ages of brown callus as compared to the nonbrown callus. Differences in intensity of the bands of the two replicates of nonbrown callus corresponded to differences in protein content (and the smaller size of one of the nonbrown callus clumps used). Isoelectric focusing separated many peroxidase "isozymes" from each callus type (Figure 3A). It appeared that some acidic forms were less intense in the nonbrown vs. brown callus of both types and that some additional isozymes were present in both ages of the brown callus vs. nonbrown callus. More specific ferulic acid peroxidase staining of isoelectric-focused gels indicated most intense staining in basic and acidic regions corresponding to general peroxidase (Figure 3B). Both uncoupled (not shown) and coupled assays with ferulic acid yielded the same areas of intense staining. As was seen for general peroxidase, coupled ferulic acid peroxidase assays indicated the appearance of more intense acidic isozymes in the brown vs. the nonbrown callus material. These differences were less noticeable for isozymes detected using *p*-coumaric acid as a substrate (Figure 3C). Isozymes detected with sinapic acid were mainly limited to the two intensely staining bands in the acidic region seen for ferulic acid and were in the same proportional intensity for the different callus types as was seen for ferulic acid (data not shown).

Chemical analyses indicated that ferulic acid was the only free acid detected, at levels significantly lower in the old callus compared to the younger callus (Table 3). Low levels of esterified *p*-coumaric were detected that were similar for the three callus types, but no esterified ferulic acid was detected. Bound *p*-coumaric was approximately twofold higher in the old vs. younger callus, while bound levels of ferulic acid were approximately the same for all three types of callus. Bound *p*-coumaric acid was at least 10 times higher than esterified *p*-coumaric acid, while the levels of bound ferulic acid were two- to fourfold higher than the levels of free ferulic acid. The higher levels of bound *p*-coumaric acid were reflected in the higher overall levels of phenolics seen in the old vs. younger callus. No caffeic, cinnamic, or sinapic acid was detected, nor were *cis* isomers of *p*-coumaric acid or ferulic acid detected.

Color ratings for brown portions of lyophilized aqueous extracts were 2.5Y 8/2, 2.5Y 7/4, and 2.5Y 6/4 for nonbrown, brown, and old brown materials, respectively. Color ratings for residues of ferulic acid extractions were 2.5Y 8/3, 2.5Y 7/4, and 2.5Y 6/4 for nonbrown, brown, and old brown materials, respectively.

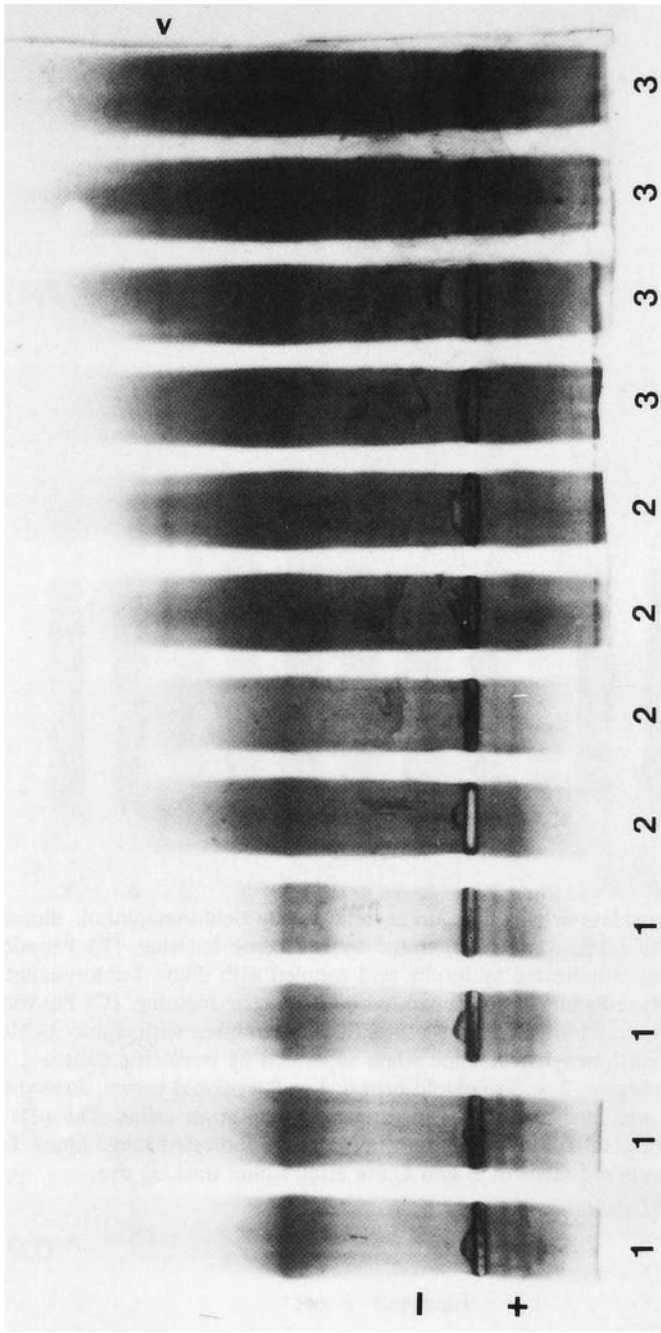

FIG. 2. Peroxidase activity of callus as indicated by 1-chloronaphthol, dimethylphenylenediamine assays when separated by nondenaturing polyacrylamide gel electrophoresis. 1 = 5-week-old nonbrown, 2 = 5-week-old brown, 3 = 8-week-old brown. Arrowhead indicates additional isozyme.

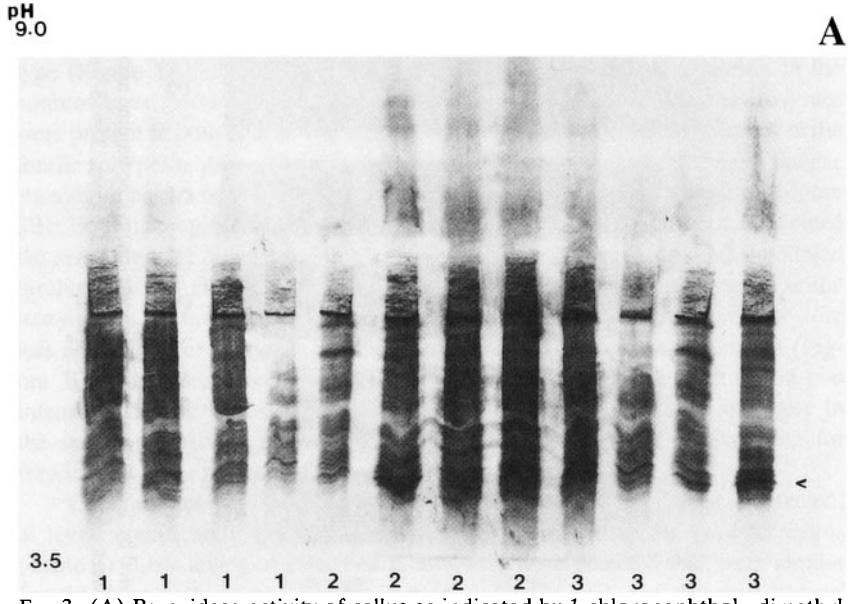

FIG. 3. (A) Peroxidase activity of callus as indicated by 1-chloronaphthol, dimethylphenylenediamine assays when separated by isoelectric focusing. (B) Peroxidase activity of callus is indicated by ferulic acid coupled with dilute 1-chloronaphthol, dimethylphenylenediamine when separated by isoelectric focusing. (C) Peroxidase activity of callus as indicated by *p*-coumaric acid coupled with dilute 1-chloronaphthol, dimethylphenylenediamine when separated by isoelectric focusing, 1 = 5-week-old nonbrown, 2 = 5-week-old brown, 3 = 8-week-old brown. Arrowheads indicate additional isozymes seen with brown vs. nonbrown callus. The pHs are uniformly distributed within 0.1 pH unit between the indicated range limits. Dark bands in unnumbered lanes of B and C are Evan's blue tracking dye.

TABLE 3. PHENOLIC ACID CONTENT OF CALLUS TISSUE EXTRACTS[a]

Extract	Acid Content (ppm)		
	Nonbrown	Brown	Old
Coumaric acid			
Free	ND	ND	ND
Esterified	13 ± 1a	18 ± 1b	8 ± 3a
Insoluble bound	300 ± 9a	231 ± 2b	646 ± 62c
Total	313 ± 10a	247 ± 1b	654 ± 60c
Ferulic acid			
Free	113 ± 16a	149 ± 26a	51 ± 9b
Esterified	ND	ND	ND
Insoluble bound	161 ± 19a	137 ± 3a	153 ± 27a
Total	275 ± 27a	286 ± 26a	204 ± 19a
Total phenolics	587 ± 38a	533 ± 25a	838 ± 78b

[a] Values are means ± standard errors for two samples, each run in duplicate. Values in rows followed by the same letter are not significantly different at the 5% level of probability by least significant differences in analysis of variance. ND = not detected.

DISCUSSION

As would be expected from many prior studies, artificial diet was more satisfactory for *H. zea* compared to the plant-derived callus. Compared to corresponding leaf material, callus can be more satisfactory for insect growth (Williams et al., 1983). This disparity may be due to more uniform temperatures in the laboratory as opposed to field assays where results with leaves were obtained (Williams et al., 1983). The *H. zea* in the present study appeared to grow much more poorly compared to results with other callus material reported in previous studies (Williams et al., 1987). There were some minor differences in callus culture conditions in our study vs. that of Wiliams et al. (1987), so it is possible that these differences may have contributed to the differences in growth seen. We also prepared our callus differently for presentation to insects, which may have produced differences in growth. Although we do not have comparable Mp313E leaf feeding data for *H. zea*, the kernels are known to be highly resistant to penetration and subsequent damage by the dusky sap beetle, *Carpophilus lugubris*, compared to the susceptible inbred SC212M (Dowd, 1994a). Thus, we believe the general resistance properties of the kernels were reflected in the callus and caused the poor survival of the *H. zea*, even on the initially nonbrown callus. Because even this callus browned over the course of the study, the resistant properties of the brown material would suggest that this material would subsequently become increasingly resistant to *H. zea*.

Regardless of the reasons behind the poor survival of *H. zea* on the callus

material used, the study did indicate that *H. zea* larvae were less successful in feeding on brown vs. nonbrown callus. Oxidized chlorogenic acid bound to protein significantly reduces the nutritive quality of tomato foliage (Felton et al., 1989) and other protein sources (Felton et al., 1992) for *H. zea* and *Spodoptera exigua*. The tissues of tobacco and tomato genetically engineered to overexpress a tobacco anionic peroxidase, which brown rapidly when damaged, are less suitable as a food source for neonate *H. zea* larvae and *C. lugubris* adults (Dowd and Lagrimini, unpublished data). As indicated earlier, the kernel pericarp of Mp313E browns rapidly when damaged and is resistant to penetration by *C. lugubris* adults (Dowd, 1992, 1994a). Corn kernel powder containing ferulic or *p*-coumaric acid that was browned enzymatically was also more resistant to feeding by insects compared to nonbrowned powder (Dowd, 1994b). Thus, our results with the brown callus tissue are consistent with those obtained using other materials in that insects are consistently less able to feed on oxidized materials.

The results of the enzyme assays indicate that extracts of the browner callus material can more rapidly oxidize phenolic acids. Gel electrophoresis and isoelectric focusing indicate enhanced activity of anodic, acidic peroxidases in brown vs. nonbrown callus. Differences were especially prominent when ferulic acid was used as a substrate. This relative activity difference corresponds to the relative activity differences seen in location of peroxidase isozymes in the pericarp of Mp313E, which are absent in the slowly browning *A. flavus* and *C. lugubris* susceptible inbred SC212M; as well as brown and nonbrown Ch mutant pericarp (Dowd, 1994b). Enzymes of corn responsible for peroxidase activity appear generally to be identical to those responsible for polyphenol oxidase activity (Grison and Pilet, 1985; Dowd, 1994b). Thus our results indicate that enhanced activity of particular peroxidase isozymes is associated with enhanced browning and reduced suitability of material for insect feeding. The results with the callus in the present study parallel results seen with the pericarp of Mp313E vs. SC212M and cold-shocked (nonbrowning) and normal Ch (chocolate) mutants in terms of browning, insect resistance, and peroxidase activity (Dowd, 1994b). In this earlier study with pericarps and enzymatically browned corn flour, in nearly all cases browner material was more resistant to insects compared to less brown material. In all cases, additional peroxidase activity and isozymes were present in brown vs. nonbrown material.

Past reports on corn kernel material (Sosulski et al., 1982; Classen et al., 1990) and bm3 corn leaf (Eraso and Hartley, 1990) have generally indicated higher levels of ferulic than *p*-coumaric acid, with the *trans* isomers predominating, and very low to undetectible levels of caffeic, cinnamic, and sinapic acids overall. These results are consistent with what we have seen for the callus in terms of levels of caffeic, cinnamic, and sinapic acids. However, the higher levels of *p*-coumaric acid compared to ferulic acid are similar to results reported

for stem tissue of bm3 corn, which also has more *p*-coumaric acid than ferulic acid. Free levels of ferulic acid and *p*-coumaric acid were approximately equal in corn flour, but levels of ferulic acid were much higher in the soluble ester fraction and insoluble-bound fractions of corn flour (Sosulski et al., 1982). Our studies indicated differences in the callus material, in that free ferulic acid was higher than free *p*-coumaric acid, but the opposite was true for the esterified and bound insoluble fractions. Whether these ratios for the callus are variety specific or are a general phenomenon for all corn callus remains to be determined. However, the relatively low ratio of bound to free ferulic acids approximates what occurs in milk-stage developing wheat (McCallum and Walker, 1991) and presumably corn (Dowd, 1994b). Thus, the callus tissue may be a suitable model for some reactions that occur in a developing corn kernel. This information also suggests that the ferulic acid is being regenerated as it becomes bound (regardless of the enzymatic method and whether it is an ester or ether linkage), as indicated by similar levels in brown and nonbrown callus of the same age, so the free ferulic acid pool remains relatively constant. This is relevant not only for the bound material quantitated in this study, but also for the ferulic acid that is presumably bound to protein or lignin, which would not be quantitated in the methods we used but would be expected based on relative differences in browning seen for the aqueous extract and extracted residue. The distribution of the ferulic acid in these nonquantitated, brown fractions would also explain the higher toxicity of the old material because total differences in phenolics that were quantitated are not that different between younger and older callus. This free ferulic acid distribution is consistent with the feedback inhibition that is known for some enzymes in the ferulic acid biosynthesis pathway (Kahl, 1974; Ralph and Helm, 1993). This information supports prior hypotheses (Dowd, 1994b) that peroxidases are responsible for taking ferulic acid out of the free pool, which ultimately increases total ferulic acid content of tissue due to the continual replacement of ferulic acid in the free pool.

Portions of corn cells (e.g., Harris and Hartley, 1970), including the pericarp (e.g., Classen et al., 1990), can contain significant levels of ferulic acid in various forms. Thus, it is appropriate that the peroxidases induced during browning would be able to oxidize ferulic acid. Because coniferyl alcohol (a direct percursor, along with coumaryl and sinapyl alcohols, of lignin) was not acted on relative to ferulic acid (several biosynthetic steps from coniferyl alcohol) by the same tissue homogenates, it appears classical lignification is less important in the browning reaction than is the oxidation of ferulic acid (and perhaps analogs of coumaric and sinapic acid). Formation of dimers of ferulic acid conjugates or other forms of ferulic acid cross-linking is a likely role of the peroxidases detected (see Fry, 1986), contributing to insect resistance (Arnason et al., 1994; Dowd, 1994b), although many other reactions involving oxi-

dized phenolic acids could contribute to insect resistance as well (Dowd, 1994b). The presence of brown material in aqueous extracts and phenolic acid extract residues indicates additional interactions are occurring, few of which would be recovered using the phenolic extraction that is standard, due to intractible ether linkages. The peroxidase-catalyzed generation of quinones that subsequently react with proteins to form ether linkages is a likely source of brown material in the aqueous extracts. Prior studies have indicated oxidation products generated from phenolic acids related to ferulic acid were bound to protein and subsequently reduced digestibility (Felton et al., 1989, 1992). Ferulic acid is also known to form ligninlike polymers when acted on by peroxidases (Stafford, 1960). Peroxidase-generated ferulic acid quinones could thus form a variety of ether linkages with other materials in the callus that would not be hydrolyzable, and thus not extracted, by the conventional techniques used, and thus remain in the residue. Again, this material is likely to be tougher and/or less digestible by the insects and would occur at higher levels in the brown materials.

Resistance of oxidized plant tissue to insects has been attributed to binding of quinones to proteins, which makes them more difficult to digest (Felton et al., 1989, 1992). The quinones themselves are more toxic to bacterial (Kojima, 1931) and fungal (Byrde et al., 1960; Urs and Dunleavy, 1975) plant pathogens than are the corresponding precursors. With the exception of maysin-containing silks, silk browning was inversely correlated with resistance to *H. zea* (Byrne et al., 1989). Subsequently, oxidation of high maysin silks was shown to be important in the resistance response (Wiseman and Isenhour, 1993). Sugar-water solutions containing allelochemicals oxidized by peroxidases or tyrosinases are more toxic to the leafhopper *Dalbulus maidis* than are solutions containing the corresponding unoxidized allelochemical (Dowd and Vega, unpublished data). Thus, the browning of the corn plant tissue is often, but not always, a likely indication of production of quinones or other reactions catalyzed by peroxidases that produce material that is more toxic and/or less nutritious to insects than precursors such as ferulic acid.

Attempting to understand how phenolic oxidations affect insect growth is likely to be difficult due to the complexity of conditions involved (Appel, 1993). Our results indicate that browned corn callus is more resistant to *H. zea* than nonbrown material. The browning is associated with an enhanced ability of the tissue to oxidize phenolics, such as ferulic acid, and ultimately results in a higher accumulation of phenolics at a variety of sites. This ability is associated with an enhanced activity and presence of certain peroxidases. This work further demonstrates the potential importance of peroxidase activity in promoting plant resistance to insects through oxidation of associated allelochemicals. This peroxidase activity may also be involved in cross-resistance to plant pathogens (Dowd, 1994b).

Acknowledgments—We thank G.E. Scott for supplying initial seed of Mp313E, C.M. Anderson for technical assistance, T.C. Nelsen for suggestions on appropriate statistical analyses, and M.R. McGuire and T.C. Sparks for comments on prior versions of this manuscript.

Abstract—This study characterized the chemical response of healthy red pine to artificial inoculation with the bark beetle-vectored fungus *Leptographium terebrantis*. In addition, we sought to determine whether stress altered this induced response and to understand the implications of these interactions to the study of decline diseases. Twenty-five-year-old trees responded to mechanical wounding or inoculation with *L. terebrantis* by producing resinous reaction lesions in the phloem. Aseptically wounded and wound-inoculated phloem contained higher concentrations of phenolics than did constitutive tissue. Trees inoculated with *L. terebrantis* also contained higher concentrations of six monoterpenes, α-pinene, β-pinene, 3-carene, limonene, camphene, and myrcene, and higher total monoterpenes than did trees that were mechanically wounded or left unwounded. Concentrations of these monoterpenes increased with time after inoculation. Total phenolic concentrations in unwounded stem tissue did not differ between healthy and root-diseased trees. Likewise, constitutive monoterpene concentrations in stem phloem were similar between healthy and root-diseased trees. However, when stem phloem tissue was challenged with fungal inoculations, reaction tissue from root-diseased trees contained lower concentrations of α-pinene, the predominant monoterpene in red pine, than did reaction tissue from healthy trees. Seedlings stressed by exposure to low light levels exhibited less extensive induced chemical changes when challenge inoculated with *L. terebrantis* than did seedlings growing under higher light. Stem phloem tissue in these seedlings contained

lower concentrations of α-pinene than did nonstressed seedlings also challenge inoculated with *L. terebrantis*. It is hypothesized that monoterpenes and phenolics play a role in the defensive response of red pine against insect–fungal attack, that stress may predispose red pine to attack by insect–fungal complexes, and that such interactions are involved in red pine decline disease. Implications to plant defense theory and interactions among multiple stress agents in forest decline are discussed.

Key Words—Monoterpene, phenolics, α-pinene, β-pinene, red pine, bark beetles, *Leptographium*, *Ips*, *Hylastes*, defense, stress, decline, growth-differentiation balance.

INTRODUCTION

In several coniferous tree species, monoterpenes (Russell and Berryman, 1976; Cates and Alexander, 1982; Raffa and Berryman, 1982, 1983; Cook and Hain, 1986; Paine et al., 1987; Lewinsohn et al., 1991a) and phenolics (Jorgensen, 1961; Shain, 1967; Lieutier, 1993) occur in increased concentrations in host tissue following failed attack by bark beetles (Scolytidae) and their associated fungi. Hence, these compounds have been hypothesized to exert defensive pressures against both insects and pathogens. Supporting evidence includes inhibition of mycelial growth of beetle-vectored fungi by monoterpenes, as well as toxic and/or repellent effects on bark beetles (Smith, 1963; Cobb et al., 1968; Shrimpton and Whitney, 1968; DeGroot, 1972, Coyne and Lott, 1976; Bordasch and Berryman, 1977; Raffa et al., 1985; Bridges, 1987; Delorme and Lieutier, 1990; Raffa and Smalley, 1995). Recently, Klepzig (1994) demonstrated inhibition of fungal propagule germination, mycelial growth, and beetle tunneling by monoterpenes and inhibition of mycelial growth by phenolics that are found in red pine resin.

Critical gaps remain in our knowledge of the dynamics of conifer chemical defenses. Although trees can usually resist attack by most parasitic organisms, numerous examples exist of widespread mortality caused by beetle–fungal complexes. In many of these cases, mortality appears to follow some biotic and abiotic stress (Nebeker et al., 1993). Such relationships may provide insights into basic theories of plant defense and of insect–microbial complexes that jointly encounter host resistance. Likewise understanding the relationships among trees, bark beetles, fungi, and stress may assist in our ability to manage damaging species, as well as identify important parameters in complex forest declines. The relative extents of the natural, management-related, and anthropogenic causes of forest declines have become the subject of increasing research (Klein and Perkins, 1988; Oren et al., 1988; Manion, 1991). This study concerns host–fungal interactions in a decline disease that occurs in Lake States red pine (*Pinus resinosa* Ait.) plantations.

Red pine decline disease (RPDD) is characterized by expanding, relatively circular zones of dead trees (Klepzig et al., 1991). Living trees that surround this zone of mortality show reduced growth rates. Living trees near the zone of tree mortality also have root systems exhibiting high levels of mortality and infestation with facultatively parasitic (Klepzig, 1994) fungi. Among these, the strain fungi, *Leptographium terebrantis* Barras and Perry and *L. procerum* (Kendrick) Wingfield, are most prevalent. Trees further from the area of mortality and decline have higher growth rates, lower levels of root mortality, and lower levels of fungal infection than do trees at or near the margin of mortality. Five species of parasitic root- and lower stem-infesting insects are also associated with RPDD (Raffa and Hall, 1988; Klepzig et al., 1991). These include *Hylobius radicis* Buchanan (Curculionidae), *H. pales* Herbst (Curculionidae), *Pachylobius picivorus* (Germar) (Curculionidae), *Dendroctonus valens* LeConte (Scolytidae), and *Hylastes porculus* Erichson (Scolytidae). These beetles carry the above fungi in the field and are demonstrated vectors of plant parasitic fungi (Klepzig et al., 1991; Nevill and Alexander, 1992; Klepzig, 1994). An additional subcortical insect species, *Ips pini* (Say) (Scolytidae), colonizes the aboveground portion of the stem, consistently carries the plant parasitic fungus *Ophiostoma ips* (Rumb.) Nannf., and is invariably associated with the ultimate death of declining trees (Klepzig et al., 1991, Raffa and Klepzig, 1995).

The primary objective of this study was to identify and quantify the major components of the induced chemical response of red pine to attack by the insect–fungal complex associated with RPDD. Because of the frequent association between tree mortality to bark beetle–fungal complexes and environmental stress (Lorio and Hodges, 1968; Lorio, 1986; Christensen and Ericsson, 1986; Paine and Stephen, 1987; Nebeker et al., 1993), we also compared the chemical responses of vigorous and stressed trees. In particular, we evaluated the effects of: (1) a predisposing, controlled abiotic stress (reduced light availability) on the ability of trees to induce chemical defenses, and (2) a naturally occurring biotic stress (root disease) on subsequent defensive capability against stem-invading complexes.

METHODS AND MATERIALS

Host Response to Wounding and Fungal Infection. One of three treatments were applied to healthy, 25-year-old, field-grown red-pines: mechanical wounding, wound inoculation with *L. terebrantis*, and control consisting of unwounded trees. These are hereafter referred to as "mature" trees as they are reproductively mature and nearing commercial cutting age (we recognize that "mature" is a relative term as trees undergo developmental changes throughout most of their lives). Samples of phloem from these trees were analyzed for total phenolic and monoterpene content.

Mature trees were located in a plantation in the Bakken's Pond Wildlife Management Unit, near Spring Green, Wisconsin. A modified cork-borer technique (Wright, 1933) was used to administer mechanical wounds and wound inoculations. A 12-mm-diameter disk of bark and phloem was removed at 1.5 m height with a sterile cork borer. A disk of the same size was cut from an actively growing, pure culture of *L. terebrantis* (isolate K9013) on potato dextrose agar (PDA). This culture originated from the collection of E.B. Smalley (University of Wisconsin–Madison) and is deposited in the American Type Culture Collection and the collection of Dr. Hal Burdsall (USDA Forest Products Laboratories, Madison, Wisconsin). The inoculum disk was removed from the Petri plate with a surface disinfected spatula and placed on the exposed surface of the xylem. The bark/phloem disk was returned to the wound surface to seal the inoculation site. Trees were mechanically wounded as above, but with a surface-disinfected cork borer. The cork borer and spatula were surface disinfected with 90% ethanol between treatments. Constitutive control trees remained unwounded until collection of tissue samples. At the termination of each experiment, the section of phloem containing the visibly apparent reaction tissue from inoculated and mechanically wounded trees, or an approximately equivalent portion of unwounded phloem tissue from unwounded trees, was removed.

In 1986, 24 trees were left unwounded, 24 trees were mechanically wounded, 25 trees were inoculated with living *L. terebrantis*, and 23 trees were inoculated with dead (autoclaved) *L. terebrantis*. In 1993, 23 trees were left unwounded, 17 trees were mechanically wounded, 18 trees were inoculated with living *L. terebrantis* and sampled after one week, and 24 trees were inoculated with living *L. terebrantis* and sampled after three weeks. These trees were analyzed for total phenolic content. In 1993, additional trees were sampled for monoterpene content: 22 trees were left unwounded, 24 trees were mechanically wounded, 25 trees were inoculated with living *L. terebrantis* and sampled after one week, and 26 trees were inoculated with living *L. terebrantis* and sampled after three weeks.

Analysis of Subcortical Tissue. Subsamples of phloem were finely chopped ($< 1 \times 1$-mm pieces) on a Plexiglass cutting board with a razor blade, weighed, and placed in vials. Vials were sealed and stored at $-80°C$ until extraction.

Acetone and methanol were used to extract phenolics. In 1986, tissue samples were extracted in 10 ml of 50% methanol for 24 hr at 25°C. In 1993, tissue samples were extracted in 10 ml of 70% acetone for 24 hr at 25°C. Extracts were filtered through qualitative-grade, medium-porosity paper (Fisher products) and analyzed using a modified version of the techniques of Kelsey and Harmon (1989) and Julkunen-Tiito (1985). Aliquots (200 μl) of extract were dispensed into 10-ml test tubes and diluted to 2 ml with distilled water. Folin-Ciocalteu reagent (1 ml) was added to each tube, and the tube was shaken vigorously for 5 sec. Aliquots (5 ml) of 20% Na_2CO_3 were added, and the tubes were shaken

vigorously for 5 secs. After 20 min at 25°C, percent light absorbances at 735 nm were measured with a Beckman DB-G grating spectrophotometer. Total phenolic concentrations (tannic acid equivalents, micrograms per milligram of tissue) were calculated based on comparison with a standard curve derived from control solutions containing various concentrations of tannic acid. Mean concentrations of total phenolics were calculated and compared by treatment using analysis of variance and the protected least square means (LSM) method in SuperANOVA (Abacus Concepts, 1989).

Monoterpenes were extracted in pentane. Constitutive and reaction tissues were weighed and extracted in 10 ml of 0.1% *p*-cymene in pentane solution for 24 hr at 25°C. Extracts were then filtered through qualitative-grade, medium-porosity paper (Fisher products), placed in vials, and stored at −30°C until analysis. Monoterpenes were analyzed by gas chromatography (GC). Extracts were passed through a 25-m × 0.25-mm Superox II Carbowax 20 M column (Alltech Associates, Deerfield, Illinois) in a Shimadzu GC-9A gas chromatograph (Shimadzu Scientific Instruments, Inc., Columbia, Maryland) using modified methods of Raffa and Steffeck (1988). Identities of individual monoterpenes were determined by comparison of relative retention times of individual peaks within the extract profile with relative retention times of commercially available synthetic pure monoterpenes. Synthetic monoterpenes used included (±)-α-pinene (97%), (+)-camphene (80%), (*S*)-(−)-β-pinene (99%), 3-carene (95%), myrcene (99%), (*S*)-(−)-limonene (96%), and γ-terpinene (98%) (Aldrich, Milwaukee, Wisconsin). Concentrations of each monoterpene were determined by integrating peak areas with a Shimadzu C-R3A Chromatopac (Shimadzu Scientific Instruments), and comparing each peak with *p*-cymene, the internal standard. Mean concentrations of individual and total monoterpenes were calculated and compared by treatment using analysis of variance and the protected least square means (LSM) method in SuperANOVA (Abacus Concepts, 1989).

Analysis of Subcortical Tissue in Biotically Stressed Trees. To determine the effects of biotic stress on defensive chemistry, responses by healthy and root-diseased mature red pines within the same plantation were compared. Test trees were inoculated with *L. terebrantis*, sampled, and analyzed. A site undergoing RPDD (Klepzig et al., 1991) was selected within a 25-year-old plantation in the Bakken's Pond Wildlife Management Unit near Spring Green, Wisconsin. The location of every tree in relation to the margin of decline symptoms was carefully mapped. The relationship between distance from the margin of decline and level of root disease (Klepzig et al., 1991) was used to estimate the percentage of diseased roots in any given tree. At the Bakken's Pond plantation, this relationship is expressed by the linear equation:

$$P_m = 1.234 - 0.053D$$

where P_m is the arcsin [square root (proportion of mortality in root system)], and D is the distance (meters) from the decline margin.

This equation was used to determine the distance at which trees would have an estimated average root mortality of 0–25% and could thus be considered to be healthy. The same equation was used to determine the distance at which trees would have an estimated average root mortality of 90–100% and could thus be considered diseased. Twenty-one "healthy" and 20 "diseased" trees were selected in this manner. Inoculations, sampling, extractions, and analyses were conducted as described above.

Analysis of Subcortical Tissue of Abiotically Stressed Seedlings. Two experiments were conducted to determine the effects of reduced light availability and resulting variations in photosynthate on the constitutive and induced subcortical chemistry of red pine seedlings. Two-year-old seedlings were grown at four light intensities, in two separate experiments, in the University of Wisconsin–Madison Biotron. In both experiments 2-year-old seedlings were obtained from the Wilson State Nursery at Boscobel, Wisconsin, and planted in 1-liter plastic pots containing a 1:2 mixture of sand and field soil. Roots were pruned to fit into the pots, the seedlings were placed in the soil, and a 2- to 4-cm-thick layer of acid sphagnum moss was placed over the soil surface to maintain proper pH. Seedlings were released from dormancy in a greenhouse and were watered as needed with a 0.6 g/liter solution of Peters Acid Greening Special fertilizer (Grace-Sierra Horticultural Products Company, Milpitas, California). Seedlings with terminal bud expansion were transferred to a growth room. Seedlings with unexpanded terminal buds were discarded.

In the first experiment, 72 two-year-old seedlings were placed in a 3.7 × 2.6-m growth room under cool white fluorescent lamps (General Electric, Cleveland, Ohio), which provided an average photosynthetic photon flux density (PPFD) of 200 μmol/m^2/sec at the top of a metal frame covered with neutral density shade cloth, which reduced PPFD by 60% to an average of 80 μmol/m^2/sec. Growing conditions included an average day–night air temperature of 20°C relative humidity of 60%, and a 12-hr photoperiod. Soil moisture was monitored in a subsample of pots with soil tensiometers and maintained at field capacity in both treatments by watering as necessary with the fertilizer solution described above. Seedlings were grown for eight weeks, and any that died in the interim were discarded. Sixteen seedlings within each of the two light treatments were randomly assigned to one of two inoculation treatments ($N = 8$). Seedlings were either mechanically wounded with a 7-mm cork borer or wounded and then inoculated with *L. terebrantis* (isolate K9013). Seedlings were inoculated as described for the mature trees. A 7-mm-diameter cork borer was used to remove a disk of phloem and outer bark from the main tap root just below the root collar. Seedlings were then inoculated or mechanically wounded as above. Roots were covered with soil, and seedlings were destructively harvested after three weeks. Extraction and analyses of phenolics and monoterpenes were conducted using the methods described above for mature trees.

On the day before destructive harvest, needle photosynthesis and stomatal conductance were measured using an ADC LCA-2 Portable Infrared Gas Analyzer with a Parkinson Broadleaf chamber (Analytical Development Co., Hoddesdon, U.K.). Needles were measured in their growth light environments.

In a subsequent experiment, seedlings were grown in two additional light environments—one with a higher irradiance than full light in the first experiment, and the other with an irradiance intermediate between full and reduced levels in the first experiment. In the second experiment, 72 two-year-old seedlings whose terminal buds had begun to expand were transferred from the greenhouse to a growth room (3.7 m × 2.6 m) equipped with 1000-W high-pressure sodium vapor lamps (General Electric, Cleveland, Ohio) suspended 3 m from the floor. Thirty-six seedlings were placed under a metal frame covered with three layers of neutral density shade cloth (PPFD = 120 μmol/m^2/sec). The other 36 seedlings were grown without shade cloth (PPFD = 350 μmol/m^2/sec). Daily integrated PPFD in the four light treatments ranged from 3.5 to 15.1 mol/m^2, which was equivalent to 8% to 34% of full sunlight on a clear midsummer day in Wisconsin (E.L. Kruger, unpublished data). The average temperature was 20°C, the average relative humidity was 60% and the photoperiod was 12 hr. Soil moisture was maintained as before. Seedlings were grown for seven weeks, and any seedlings that died in the interim were discarded. All remaining seedlings were randomly assigned to one of three inoculation treatments. Six seedlings in reduced light and seven seedlings in full light were left unwounded and uninoculated. These seedlings were designated constitutive controls. In the second treatment, 12 seedlings in each light treatment were inoculated with *L. terebrantis* (isolate K9013). In the third treatment, 12 seedlings in each light treatment were mechanically wounded as described above. Seedlings were inoculated as described above, but with a 4-mm-diameter cork borer. Roots were covered with soil, and seedlings were destructively harvested after five weeks. Extraction and analyses of phenolics and monoterpenes were conducted using the previously described methods.

Needle photosynthesis and stomatal conductance were measured as described above at the time of inoculation and one week later. Needle water potential was measured with a pressure chamber (P.M.S. Instruments, Corvallis, Oregon) at the time of, and one and four weeks after, inoculation. All root and stem tissue within 5–10 cm (or as far as the extent of the lesion) was removed and stored at −80°C. All new shoot growth, as well as the entire root system, was clipped from each seedling, weighed, and stored at −80°C.

RESULTS

In all experiments, mature red pine trees reacted to wound inoculation with *L. terebrantis* by forming elliptical, brown to black, resin-soaked lesions within

the phloem and across the xylem surface. Lesions typically became shorter and narrower with increasing depth in the xylem. Lesions that formed in response to aseptic mechanical wounding were much lighter in color and much less resinous than those resulting from inoculation with *L. terebrantis*. Unwounded (constitutive) tissues were free of discoloration and resinosis at the time of sampling.

Analysis of Subcortical Tissue in Healthy Trees. Increased concentrations of total phenolics and monoterpenes accompanied the response of red pine to simulated insect and pathogen attack. The phenolic concentrations within red pine tissue subjected to simulated attack were higher than those found in constitutive tissue. However, this response was relatively nonspecific to the type of attack. Preliminary characterization of methanol- and acetone-extractable fractions via thin-layer chromatography indicated the presence of pinosylvin and pinosylvin monomethyl ether (Klepzig, 1994). Spectrophotometric analysis revealed significant differences in total phenolics among treatments. Lesions formed in response to wound inoculation with *L. terebrantis* contained higher concentrations of total phenolics than did constitutive tissues in both 1986 and 1993 (Figure 1).

Mechanical wounding elicited a similar response. Total phenolic concentrations in lesions resulting from inoculation with *L. terebrantis* and mechanical wounding did not differ significantly in 1986 inoculations (Figure 1a). However, in 1993, polar extracts of *L. terebrantis* inoculations contained higher concentrations of total phenolics than did extracts of mechanical wounds (Figure 1b). The concentrations of total phenolics in lesions one week after inoculation with *L. terebrantis* did not significantly differ from the concentrations in lesions three weeks after inoculation with *L. terebrantis* (Figure 1b). Differences in levels of phenolics between 1986 and 1993 may be due to variation in host response, methods, and/or amount of tissue sampled. Increased but relatively nonspecific accumulation of phenolics has been reported in Scots pine (Lieutier, 1993).

Mechanical wounding and wound inoculation with *L. terebrantis* also caused significant increases in pentane-extractable compounds. However, the monoterpene fraction of the resin formed in response to simulated parasite attack exhibited changes more consistent with a specific plant defensive response. Nonpolar extracts were comprised primarily of six monoterpenes. These were, in order of decreasing abundance, α-pinene, β-pinene, 3-carene, limonene, camphene, and myrcene (Table 1). γ-Terpinene was present only in trace quantities that did not significantly differ according to treatment. Concentrations of α-pinene, camphene, β-pinene, 3-carene, myrcene, and limonene were all higher in inoculated than in mechanically wounded or constitutive tissues. Inoculated tissues also contained significantly higher concentrations of total monoterpenes than did mechanically wounded or constitutive trees. Concentrations of α-pinene, cam-

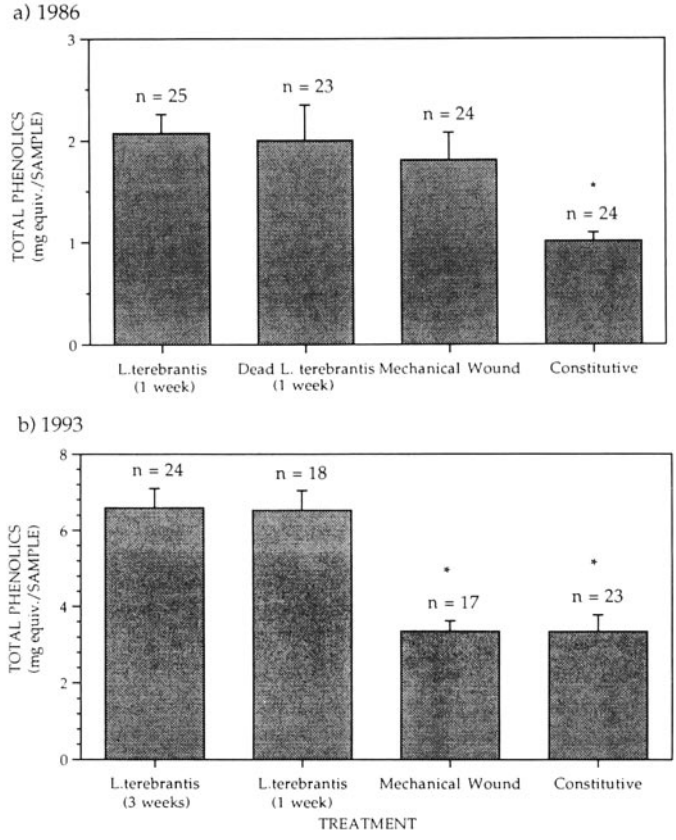

FIG. 1. Phenolic content (mean ± SE) of red pine constitutive phloem tissue and reaction tissue one week after mechanical wounding, one and three weeks after inoculation with viable *L. terebrantis*, and one week after inoculation with nonviable *L. terebrantis*. An asterisk indicates significant difference at $P < 0.05$ by protected least squares means in ANOVA. (a) $df = 3$, $F = 4.26$, $P < 0.01$; (b) $df = 3$, $F = 16.31$, $P < 0.0001$.

phene, myrcene, and limonene were higher in mechanically wounded than in constitutive tissue, but mechanically wounded and constitutive tissues did not significantly differ in total monoterpene concentrations. Total monoterpene concentrations, as well as concentrations of α-pinene, camphene, β-pinene, 3-carene, myrcene, and limonene in lesions one week after inoculation with *L. terebrantis* did not differ significantly from the concentrations in lesions three

TABLE 1. MONOTERPENE CONTENT OF RED PINE REACTION RESIN[a]

Monoterpene	Control	Mechanically wounded	Inoculated		F^b	P
			1 week	3 week		
α-Pinene	8.0 (7.5)a	113.5 (1.8)b	306.1 (34.7)c	288.6 (47.9)c	18.80	0.0001
Camphene	0.003 (0.0)a	1.1 (0.1)b	3.1 (0.3)c	2.9 (0.5)c	17.24	0.0001
β-Pinene	0.1 (0.0)a	38.9 (7.6)b	102.4 (17.0)b	118.2 (24.2)b	11.40	0.0001

[a] Mean concentration (mg monoterpene/g dry weight) (standard error) of reaction resin in red pine unwounded (control), mechanically wounded, wound inoculated with *L. terebrantis* and sampled after one week, and wound inoculated with *L. terebrantis* and sampled after three weeks. Means followed by different letters are significantly different from other means within the row at $P < 0.05$ level, as determined by protected least squares means in ANOVA.

[b] Degrees of freedom = 3; F and P (determined by protected least squares means procedures in ANOVA) given for each monoterpene by treatment.

TABLE 2. MONOTERPENE CONTENT OF RED PINE REACTION RESIN[a]

Monoterpene	Control	Mechanically wounded	Inoculated		F^b	P
			1 week	3 week		
α-Pinene	73.6 (2.5)	72.8 (1.8)	73.1 (1.7)	69.4 (2.0)	0.88	0.45
Camphene	0.0 (0.0)a	0.7 (0.0)b	0.7 (0.0)b	0.7 (0.0)b	99.72	<0.0001
β-Pinene	26.1 (2.5)	22.8 (1.9)	22.6 (1.7)	25.1 (2.3)	0.66	0.57
3-Carene	0.4 (0.2)a	2.4 (0.5)b	2.1 (0.4)b	3.1 (1.0)b	3.03	0.03
Myrcene	0.0 (0.0)a	0.5 (0.1)b	0.6 (0.0)b	0.6 (0.1)b	42.37	<0.0001
Limonene	0.0 (0.0)a	0.9 (0.1)b	0.9 (0.0)b	1.0 (0.0)b	81.54	<0.0001

[a] Mean percent composition (standard error) of reaction resin in red pine unwounded (control), mechanically wounded, wound inoculated with *L. terebrantis* and sampled after one week, and wound inoculated with *L. terebrantis* and sampled after three weeks. Means followed by different letters are significantly different from other means within the row at $P < 0.05$ level, as determined by protected least squares means procedure in ANOVA.

[b] Degrees of freedom = 3; F and P given for each monoterpene by treatment. Gamma-terpinene levels were less than 0.00% and are not presented here.

weeks after inoculation with *L. terebrantis*. However, 3-week-old inoculations contained significantly higher concentrations of total monoterpenes than did 1-week-old inoculations.

The composition of reaction tissue also varied somewhat with respect to treatment (Table 2). These changes were limited to the minor components.

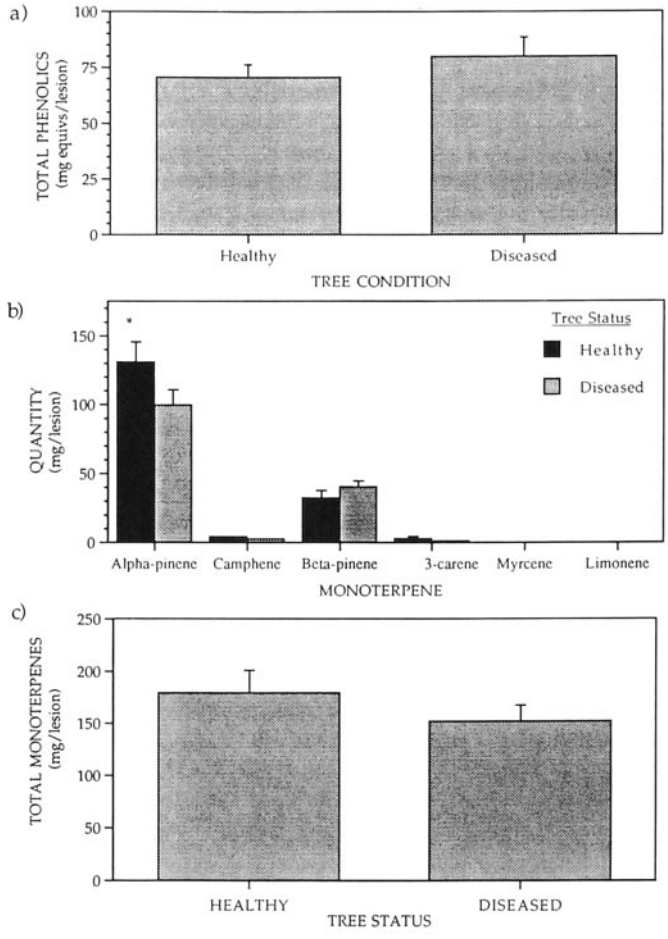

FIG. 2. Defensive chemistry of stem phloem reaction tissue of healthy and root diseased red pine one week after inoculation with *L. terebrantis*. An asterisk indicates significant difference by tree status at $P < 0.001$ by protected least squares means in ANOVA. (a) $df = 1$, $F = 1.491$, $P < 0.43$. (b) $df = 7$, $F = 2.66$, $P < 0.01$. (c) $df = 1$, $F = 0.96$, $P < 0.33$.

Camphene, 3-carene, myrcene, and limonene represented a higher proportion of the total monoterpene profile in mechanically wounded or inoculated tissue than in constitutive tissue. However, the proportions of the major monoterpenes in red pine phloem, α-pinene, and β-pinene, did not vary significantly among treatments.

Analysis of Subcortical Tissue in Biotically Stressed Trees. The effects of root disease on the subcortical chemistry of red pine varied according to the chemical fraction. Total phenolic concentrations within reaction lesions did not significantly differ between root-diseased and healthy trees (Figure 2a). However, significant differences were found in the composition of the nonpolar fraction.

α-Pinene concentrations in lesions formed in response to inoculation with *L. terebrantis* were significantly lower in diseased than in healthy trees (Figure 2b). However, concentrations of camphene, β-pinene, 3-carene, myrcene, limonene, and total monoterpenes did not vary significantly with root status (Figure 2b and c). The relative composition of the reaction resin differed between healthy and root-diseased trees (Table 3). α-Pinene comprised a higher pecentage of the total monoterpene composition within lesions from healthy trees than it did in lesions from root-diseased trees. Conversely, β-pinene comprised a lower proportion of total monoterpenes within lesions from healthy trees than in lesions from root-diseased trees. The constitutive monoterpene content did not vary

TABLE 3. MONOTERPENE CONTENT OF REACTION RESIN IN HEALTHY AND ROOT-DISEASED RED PINE.[a]

	Tree status			
Monoterpene	Healthy	Diseased	F^b	P
α-Pinene	74.2 (1.2)a	61.3 (4.6)b	7.803	0.008
Camphene	1.8 (0.3)	1.5 (0.4)	0.42	0.52
β-Pinene	16.9 (0.7)a	31.1 (4.5)b	10.08	0.002
3-Carene	1.3 (3.8)	0.6 (0.3)	0.70	0.40
Myrcene	0.0 (0.0)	0.0 (0.0)	1.05	0.31
Limonene	0.0 (0.0)	0.0 (0.0)	0.36	0.55

[a] Mean percent composition (standard error) of reaction resin in red pine located near a margin of decline and mortality (diseased), vs. far from a margin of decline and mortality (healthy) and wound inoculated with *L. terebrantis*. Trees were sampled after three weeks and extracted. Means followed by different letters are significantly different from other means within the row at $P < 0.05$ level, as determined by Protected Least Squares in ANOVA.

[b] Degrees of freedom = 1; F and P given for each monoterpene by tree status interaction. Gamma-terpinene levels were less than 0.00% and are not presented here.

significantly between healthy and diseased trees (Klepzig, 1994). These results are similar to those of Werner and Illman (1994), who reported that the relative proportions of α-pinene were lower in mature Lutz spruce that had been attacked by spruce beetles and then inoculated with *L. abietinum* (Peck) Wingfield than they were in inoculated trees that showed no bark beetle damage.

Physiology, Growth, and Subcortical Chemistry of Abiotically Stressed Seedlings. Reduced light resulted in significant differences in several physiochemical parameters. However, due to differences in seedling size and possible variation in other parameters, caution should be used when comparing the results of the two experiments. In both experiments, seedlings grown under reduced light photosynthesized at significantly lower rates per unit area (Figure 3a) and per unit mass (Figure 3b), and they had significantly lower stomatal conductance (Figure 3c) than trees grown under full light. In the second experiment only, root and shoot growth were significantly lower in seedlings grown under reduced light than they were in seedlings grown under full light (Figure 4). Xylem water potentials were highly variable in both experiments and did not differ significantly according to treatment.

Total phenolic concentrations differed between mechanically wounded seedlings grown under full light and reduced light in the first (Figure 5a) but not the second experiment (Figure 5b). Phenolics did not differ by light treatment in the second experiment. Both monoterpene concentration (Figures 6 and 7) and relative composition (Table 4, Table 5) varied with light intensity. In the first experiment, concentrations of individual monoterpenes did not differ significantly between seedlings grown under full and reduced light and then inoculated. However, total monoterpene concentrations were significantly higher in seedlings grown under full light and wound inoculated with *L. terebrantis* than in seedlings grown under reduced light and wound inoculated with *L. terebrantis* (Figure 6d). In the first experiment, the composition of reaction resin differed significantly with respect to light treatment for two monoterpenes, camphene and β-pinene (Table 4). Percent composition did not differ significantly by treatment for any of the other monoterpenes detected in the first experiment.

In the second experiment, α-pinene concentrations were significantly higher in seedlings grown under full compared to reduced light following wound inoculation with *L. terebrantis* (Figure 7c). No other differences in concentrations of individual monoterpenes between seedlings grown under full and reduced light were observed. As with the mature trees, total monoterpene concentrations were higher in seedlings wound inoculated with *L. terebrantis* than they were in constitutive or mechanically wounded seedlings (Figure 7d). Although the intensity of light under which seedlings were grown was not found to be correlated with any significant changes in total monoterpene concentrations, the relative composition of the monoterpene fraction differed according to treatment

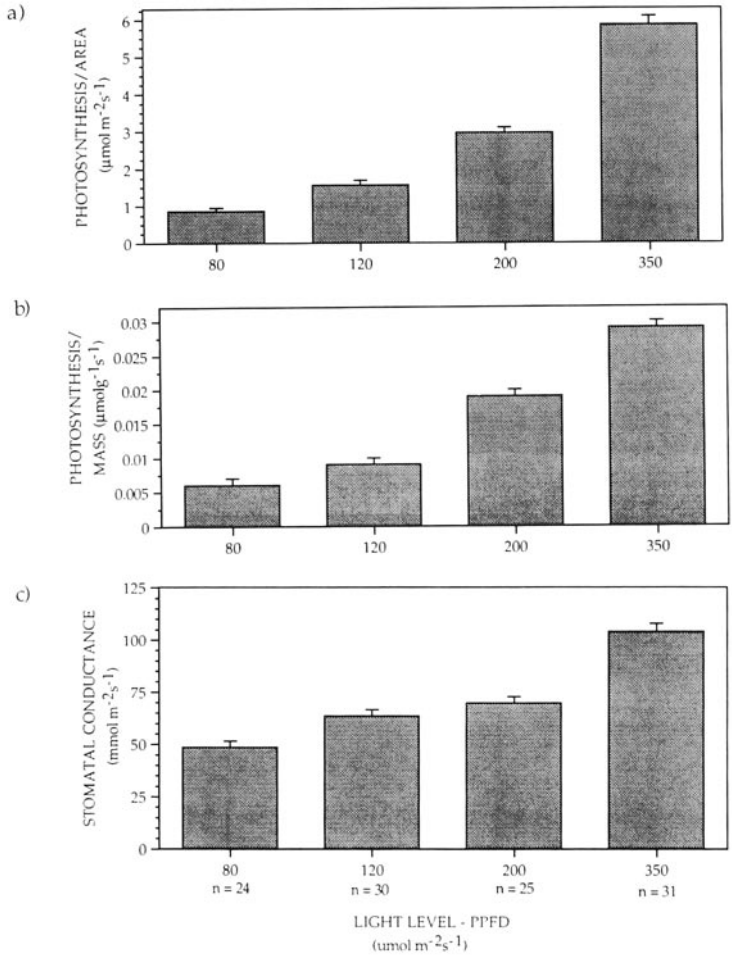

FIG. 3. Effects of irradiance on physiological parameters (mean ± SE) of red pine seedlings. (a) Photosynthesis per unit area. PPFD = photosynthetic photon flux density. First experiment, PPFD = 80 and 200 μmol/m^2/sec, $df = 1$, $F = 175.40$, $P < 0.0001$. Second experiment, PPFD = 120 and 350 μmol/m^2/sec, $df = 1$, $F = 281.0$, $P < 0.0001$. (b) Photosynthesis per unit mass. First experiment, PAR = PPFD = 80 and 200 μmol/m^2/sec. $df = 1$, $F = 87.69$, $P < 0.0001$. Second experiment, PAR = 120 and 350 μmol/m^2/sec. $df = 1$, $F = 160.61$, $P < 0.0001$. (c) Stomatal conductance per unit area. First experiment, PAR = 80 and 200 μmol/m^2/sec. $df = 1$, $F = 24.27$, $P < 0.0001$. Second experiment, PAR = 120 and 350 μmol/m^2/sec. $df = 1$, $F = 58.60$, $P < 0.0001$.

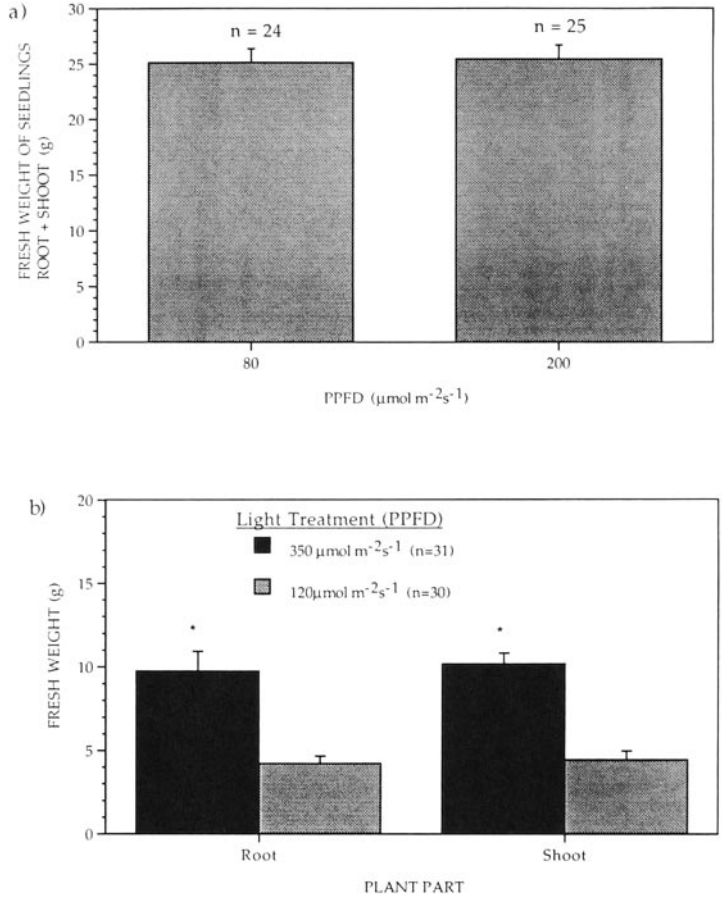

FIG. 4. Growth (mean ± SE) of red pine seedlings under various light levels. PPFD = photosynthetic photon flux density. An asterisk indicates significant difference at $P < 0.0001$ by protected least squares means in ANOVA. (a) First experiment: $df = 1$, $F = 0.0006$, $P < 0.93$. (b) Second experiment: roots—$df = 1$, $F = 19.26$, $P < 0.0001$; shoots—$df = 1$, $F = 45.36$, $P < 0.0001$.

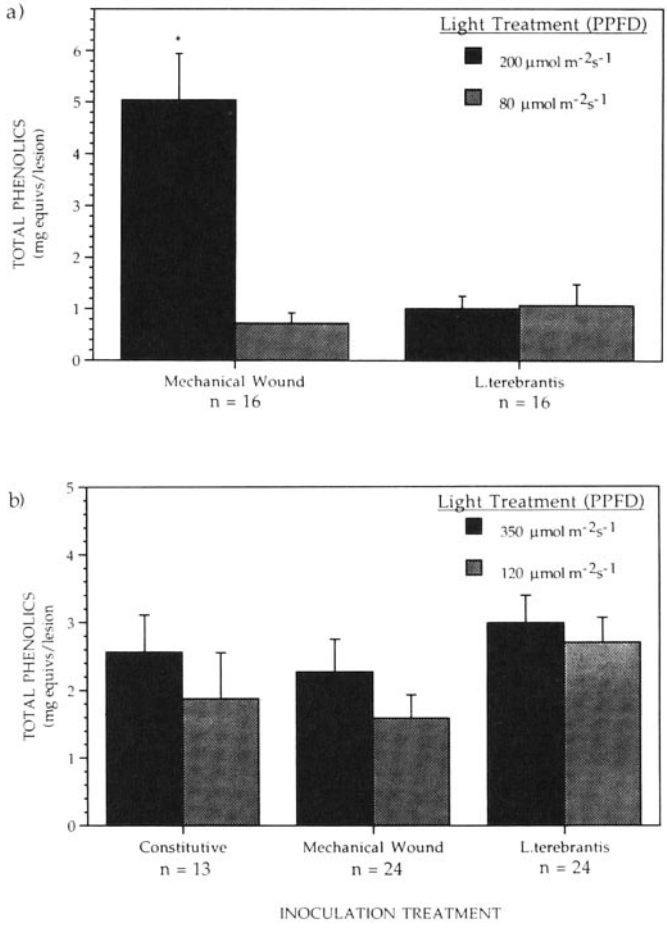

FIG. 5. Phenolic content (mean ± SE) of red pine constitutive phloem tissue and reaction tissue three weeks after mechanical wounding and inoculation with *L. terebrantis* in healthy and shade stressed seedlings. PPFD = photosynthetic photon flux density. An asterisk indicates significant difference at $P < 0.0001$ by protected least squares means in ANOVA. (a) First experiment: $df = 3$, $F = 0.08$, $P < 0.96$. (b) Second experiment: $df = 2$, $F = 0.13$, $P < 0.87$.

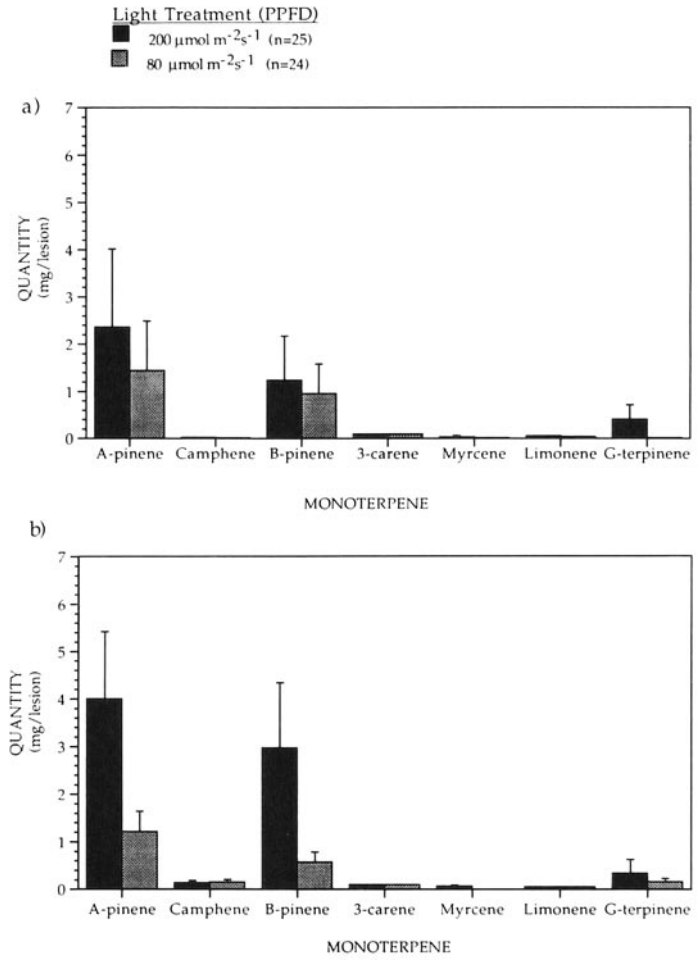

FIG. 6. Monoterpene content (mean ± SE) of red pine reaction tissue three weeks after mechanical wounding, inoculation with *L. terebrantis*, or *L. wageneri* in healthy and shade-stressed seedlings in first experiment. PPFD = photosynthetic photon flux density. No significant differences found at $P < 0.05$ by protected least squares means in ANOVA. (a) Mechanical wound, (b) inoculation with *L. terebrantis*, and (c) inoculation with *L. wageneri*. Light treatment × inoculation treatment × monoterpene: $df = 52$, $F = 2.49$, $P < 0.0001$. (d) Total monoterpenes: means followed by same letters are not significantly different at $P < 0.05$ by protected least squares means in ANOVA. $df = 3$, $F = 3.49$, $P < 0.03$.

TABLE 4. MONOTERPENE CONTENT OF REACTION RESIN IN HEALTHY AND SHADE STRESSED RED PINE.[a]

Monoterpene	Mechanical wound: light treatment		*L. terebrantis* inoculation: light treatment	
	Full ($N = 8$)	Reduced ($N = 8$)	Full ($N = 8$)	Reduced ($N = 8$)
α-Pinene	49.3 (7.7)	40.2 (16.1)	50.1 (2.0)	50.6 (2.3)
Camphene	0.5 (0.3)a	0.3 (0.3)a	2.0 (0.7)a	5.6 (1.6)b
β-Pinene	27.7 (3.2)ab	39.8 (4.9)b	36.7 (6.0)ab	23.5 (1.8)a
3-Carene	9.4 (7.0)	11.0 (7.2)	1.9 (1.0)	6.5 (2.1)
Myrcene	0.3 (0.3)	0.2 (0.2)	0.6 (0.3)	0.1 (0.1)
Limonene	4.8 (3.2)	5.0 (3.4)	1.1 (0.7)	3.3 (1.0)

[a] Mean percent composition (standard error) of reaction resin in red pine grown under full (200 $\mu mol/m^2/sec$) vs. reduced light (80 $\mu mol/m^2/sec$), and mechanically wounded, or wound inoculated with *L. terebrantis*. Means followed by different letters are significantly different from other means within the row at $P < 0.05$ level, as determined by protected least squares means in ANOVA. Degrees of freedom = 7; F and P for each monoterpene by inoculation × light treatment interaction: α-pinene, $F = 0.64$, $P = 0.71$; camphene, $F = 6.47$, $P = 0.0003$; β-pinene, $F = 2.35$, $P = 0.05$; 3-carene, $F = 0.62$, $P = 0.72$; myrcene, $F = 1.81$, $P = 0.13$; limonene, $F = 0.90$, $P = 0.52$.

for several monoterpenes (Table 5). α-Pinene consistently comprised a greater proportion of the total monoterpene concentration in seedlings grown under full compared to reduced light. However, these differences were not always significant at $P < 0.05$. The percentage of camphene was significantly higher in seedlings inoculated with *L. terebrantis* than in all other seedlings, and the percentage of limonene was significantly lower in seedlings grown under reduced light and wound inoculated with *L. terebrantis* than in all other seedlings.

DISCUSSION

Many of the compounds detected in these experiments can affect the attacking beetles, fungi, or both. Both the total phenolic fraction and several individual monoterpenes can inhibit insect tunneling, fungal growth, and fungal germination to varying degrees, at concentrations similar to those found previously (Klepzig, 1994). In particular, α-pinene, consistently the most abundant monoterpene in red pine phloem extracts, exhibits a high degree of biological activity towards the insects and fungi associated with RPDD. Together, these data indi-

TABLE 5. MONOTERPENE CONTENT OF REACTION RESIN IN HEALTHY AND SHADE STRESSED RED PINE[a]

[a]Mean percent composition (standard error) of reaction resin in red pine grown under full (350 μmol/m^2/sec) vs. reduced light (120 μmol/m^2/sec), and left unwounded (constitutive), mechanically wounded, or wound inoculated with *L. terebrantis*. Means followed by different letters are significantly different from other means within the row at $P < 0.05$ level, as determined by protected least squares means in ANOVA. Degrees of freedom = 5; F and P for each monoterpene by inoculation × light treatment interaction: α-pinene, $F = 2.99$, $P = 0.02$; camphene, $F = 5.29$, $P = 0.0007$; β-pinene, $F = 0.01$, $P = 0.01$; 3-carene, $F = 1.08$, $P = 0.38$; myrcene, $F = 1.46$, $P = 0.22$; limonene, $F = 3.09$, $P = 0.01$.

cate that α-pinene and perhaps other monoterpenes exert an important role in the defense of red pine against parasitic attack.

The chemical responses to stress reported here correspond to field observations and laboratory studies on RPDD and its associated organisms (Klepzig et al., 1991; Klepzig, 1994; Raffa and Smalley, 1995). Stressed red pines are significantly more susceptible to the two species of bark beetles, the stem colonizing *I. pini*, and the root colonizing *H. porculus*, and the bark beetle-vectored fungi, *L. terebrantis* and *L. procerum*, associated with declining plantations. Similarly, reduced light levels have been shown to lower concentrations of phenolics and increase susceptibility to root disease in other conifers (Entry et al., 1991). In bioassays with red pine extracts, lower α-pinene concentrations were highly correlated with increased beetle and fungal success (Klepzig, 1994). At very high concentrations, β-pinene sometimes appeared to have slightly stimulatory effects on insect feeding and fungal germination, suggesting a possible benefit to some insect-fungal complexes at certain concentrations and conditions. Thus, the dynamics of monoterpene profiles in red pine during phenological, stress-related, and wound-induced events may have a significant role in explaining changes in plant resistance to parasitic attack.

In this system, certain stresses can concurrently reduce both plant growth and allelochemical concentrations. A naturally occurring biotic stress, root infection, and an artificially administered abiotic stress, reduced light resource availability, each generated this pattern. These results are not entirely consistent with predictions based on the growth-differentiation balance hypothesis. Rather they support recent views that rapid alterations in the metabolic demand for allelochemicals (Gijzen et al., 1991; Lewinsohn et al., 1991b; Gershenzon, 1994) must also be incorporated into allocation models in systems where induced defenses are important (Lerdau et al., 1994). In red pine phloem, constitutive allelochemicals were not affected, but phytochemical induction and growth both decreased with stress (Figure 4b); (Klepzig et al., 1991). Our results also indicate that allelochemical responses to stress can vary among chemical groups. In red pine reaction phloem, for example, monoterpene, but not phenolic, concentrations were affected.

These relationships between plant defensive responses and parasitic organisms may also relate to the onset and spread of inciting factors in forest declines. In the instance of RPDD, reduced light availability may lead to the establishment of *Leptographium* spp. and its vectors within the red pine root system. Thereafter, the proposed decline disease cycle of RPDD may continue (Klepzig et al., 1991). Although these data improve our understanding of this complex decline disease, the modes of action of inhibition of propagule germination and mycelial growth by monoterpenes and the pathways by which stress interferes with defensive compound synthesis need to be addressed.

(Received October 4, 1994; accepted January 31, 1995)

Abstract—(*R*)- and (*S*)-10,14-dimethyl-1-pentadecyl isobutyrates were synthesized from (*S*)- and (*R*)-citronellols, respectively. The *R* enantiomer was as active as the natural pheromone but the *S* enantiomer was less active in the electrophysiological analyses, which provided conclusive proof that the absolute configuration of the natural pheromone is *R*.

Key Words—Tea tussock moth, *Euproctis pseudoconspersa*, sex attractant pheromone, 10,14-dimethyl-1-pentadecyl isobutyrate, citronellol, dihydrocitronellol, chirality, absolute configuration.

INTRODUCTION

The tea tussock moth, *Euproctis pseudoconspersa* (Strand) (Lepidoptera: Lymantriidae), is a notorious pest of the family Theaceae, including *Camellia sinensis*, *Camellia japonica*, and *Camellia sasanqua*. The larvae have venomous spicules on their backs. The spicules are hazardous to human skin on contact (Ogata, 1958).

The major sex pheromone of *E. pseudoconspersa* has been identified as 10,14-dimethyl-1-pentadecyl isobutyrate (**1**) (Wakamura et al., 1994). The synthetic **1** (racemate) was found to show a potent attractant activity for the male, although the absolute configuration of C-10 remained to be determined.

Important advances in the asymmetric syntheses of insect pheromones (Mori, 1994) prompted us to synthesize *R*-**1** and *S*-**1** from (*S*)- and (*R*)-citronellols (*S*-**2** and *R*-**2**), respectively (Scheme 1). The biological activities of the

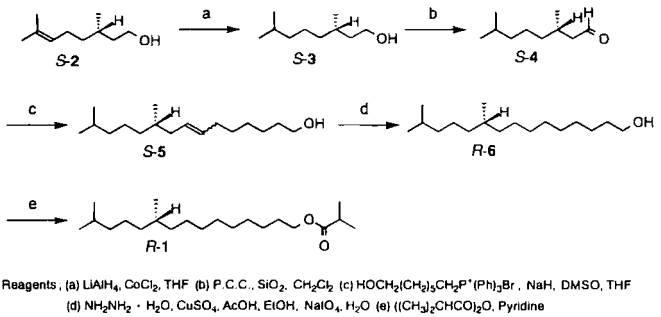


SCHEME 1. Synthetic pathway for *R*-**1**.

synthetic *R*-**1** and *S*-**1** were compared with that of the natural pheromone by a gas chromatograph equipped with an electroantennographic detector (Struble and Arn, 1984).

METHODS AND MATERIALS

General. Column chromatography was conducted employing a Wako C-100 or Wako C-200. NMR spectra were obtained on a JEOL EX90 or a JEOL GSX270 in $CDCl_3$ with TMS as an internal standard. IR spectra were recorded on a Shimadzu 8200 or a JASCO IR Report 100. GC-MS data were obtained from a Hewlett-Packard 5890 Series II gas chromatograph combined with an HP 5971A mass selective detector using DB-WAX (polyethylene glycol 20 M, 30 m × 0.25 mm ID × 0.25 mm film thickness, J & W Scientific). High-resolution mass spectra (HR-MS)(EI) were measured with a JEOL JMS-SX102A mass spectrometer. Optical rotations were determined on a JASCO DIP140 or a JASCO DIP181 digital polarimeter. CD spectra were recorded on a JASCO J-20 spectropolarimeter.

Commercially available (*S*)-citronellol (Aldrich 30,348-8) and (*R*)-citronellol (Aldrich 30,346-1) were used for the starting materials.

(S)-3,8-Dimethyl-1-octanol (S-3). *S*-**3** was synthesized from *S*-**2** in the same manner as previously reported by Mori et al. (1991) and Naoshima et al. (1991). A small amount of 1-butanol, probably derived from THF, was also obtained. We used the mixture without purification because the open column chromatography after PCC oxidation gives pure *S*-**4**.

(S)-3,8-Dimethyloctanal (S-4). Pyridinium chlorochromate (4.8 g) and SiO_2 (Wako C-100, 2.3 g) were dissolved in dry CH_2Cl_2 (15 ml) and cooled in an ice bath. *S*-**3** (500 mg) dissolved in CH_2Cl_2 (8 ml) was added dropwise to the solution. Two hours later, the mixture was directly added to a SiO_2 column and eluted by CH_2Cl_2. Further purification on the SiO_2 column gave *S*-**4** (280 mg).

(S)-10,14-Dimethyl-7-pentadecen-1-ol (S-5). *S*-**5** was synthesized in the same manner as used for *n*-alken-1-ol syntheses (Horiike et al., 1978). (7-Hydroxyheptyl)-triphenylphosphonium bromide (700 mg) in warm DMSO (2.2 ml) was added to a THF solution of methylsulfinylmethanide ion [prepared from sodium hydride (200 mg) and DMSO (1.8 ml) under nitrogen at 75°C] with cooling in an ice bath. The yellowish red solution of phosphorane was stirred at room temperature for 15 min, then *S*-**4** (180 mg) was added at 0°C. After stirring for 1 hr, the reaction mixture was poured into 20 ml of water and extracted three times with hexane. After removal of the solvent, subsequent open column chromatography gave *S*-**5** (52 mg).

Prolonged reaction time (5 hr) and increased phosphorane improved the yield. IR ν cm^{-1}: 3325 (br), 2925 (s), 2850 (s), 1465 (m), 1360 (m), 1055 (m). ^1H NMR (90 MHz): δ 5.4 (2 H, m), 3.63 (2 H, t, J = 7 Hz), 0.9–2.3 (2OH, m), 0.87 (9 H, d, J = 7 Hz). ^{13}C NMR (22.5 MHz): δ 130.43, 128.61, 62.98, 39.29, 36.90, 34.52, 33.41, 32.76, 29.68, 29.09, 27.95, 27.24, 25.65, 24.88, 22.70, 22.58, 19.60. MS: 254 (8%, M^+), 179 (1), 169 (6), 151 (12), 137 (4), 126 (46), 109 (33), 95 (57), 81 (55), 71 (89), 57 (100). HR-MS: $C_{17}H_{34}O$ (observed: 254.2611; calculated: 254.2610).

(R)-10,14-Dimethyl-1-pentadecanol (R-6). The solution of sodium metaperiodate (545 mg) in water (1 ml) was added dropwise during 1 hr to the ethanol solution (3 ml) of *S*-**5** (19 mg), hydrazine monohydrate (1 g), acetic acid (two drops), and sat. $CuSO_4$ (two drops). One week later, ethanol was removed in vacuo, and the resulting aqueous solution was extracted with hexane. The hexane solution was dried (Na_2SO_4) and concentrated in vacuo. The yield was 16 mg.

IR ν cm^{-1}: 3325 (br), 2915 (s), 2850 (s), 1460 (m), 1380 (m), 1055 (m). ^1H NMR (270 MHz): δ 3.62 (2 H, t, J = 7 Hz), 0.9–1.7 (24 H, m), 0.87 (6 H, d, J = 7 Hz), 0.82 (3 H, d, J = 7 Hz). ^{13}C NMR (67.5 MHz): δ 63.10, 39.36, 37.31, 37.09, 32.81, 32.75, 29.99, 29.62, 29.62, 29.44, 27.96, 27.07, 25.73, 24.79, 22.71, 22.62, 19.71. M^+-H_2O: $C_{17}H_{34}$ (observed: 238.2661; calculated: 238.2661).

(R)-10,14-Dimethyl-1-pentadecyl isobutyrate (R-1). *R*-**6** (20 mg) was dissolved in pyridine (0.4 ml) and isobutyric anhydride (0.4 ml). After 10 hr, the solution was poured into cooled 5% hydrochloric acid and extracted with hexane. After the usual work-up, the crude product was purified by open column chromatography (20.9 mg).

IR ν cm^{-1}: 2925 (s), 2850 (s), 1740 (s), 1470 (m), 1190 (m), 1155 (m) ^1H NMR (90 MHz): δ 4.06 (2 H, t, J = 7 Hz), 2.55 (1 H, sept, J = 7 Hz), 1.3–1.8 (24 H, m), 1.15 (6 H, d, J = 7 Hz), 0.87 (9 H, d, J = 7 Hz). ^{13}C NMR (22.5 MHz): δ 177.28, 64.41, 39.35, 37.29, 37.08, 34.04, 32.76, 29.98, 29.59, 29.59, 29.23, 28.64, 27.98, 27.06, 25.89, 24.79, 22.70, 22.61, 19.69,

19.00. 19.00 MS: 326 (4%, M^+), 283 (2), 239 (1), 210 (1), 183 (1), 168 (3), 153 (8), 126 (13), 111 (21), 97 (32), 89 (100), 88 (62), 83 (28), 71 (56), 69 (29), 57 (38), 55 (30). HR-MS: $C_{21}H_{42}O_2$ (observed: 326.3194; calculated: 326.3185). CD (*c*1, hexane): no measurable absorption was observed from 220 to 400 nm.

Reduction of 3,8-dimethyloctanal (4). *S*-**4** (30 mg) was dissolved in ether (1.5 ml) and cooled in an ice bath. Lithium aluminum hydride suspension (1.5 ml) in ether (1 mol/dm^3) was added to the solution. After 25 min, the reaction mixture was poured into cooled 3% hydrochloric acid. Then the solution was extracted with hexane two times. Work-up gave *S*-3 (quantitative). *S*-**3** (from *S*-**4**): $[\alpha]_D^{25}$ −5.7° (*c*0.72, MeOH). *R*-**3** (from *R*-**4**): $[\alpha]_D^{25}$ +5.6° (*c*2.0, MeOH); lit. (Mori et al., 1991) $[\alpha]_D^{20}$ +5.3° (neat, d = 0.827).

(S)-3,8-Dimethyl-1-octyl (R)-α-methoxy-α-trifluoromethylphenylacetate (S-7). *S*-**3** (1.6 mg, derived from *S*-**4**) was dissolved in 0.2 ml of dry pyridine. Then 15 μl of (*S*)-MTPA chloride was added. After 19 hr, the reaction mixture was poured into cooled 3% hydrochloric acid. Then the solution was extracted with hexane two times. Work-up gave crude *S*-**7** (7 mg). The ^{1}H NMR spectrum was measured without purification. The starting material *S*-**3** disappeared.

IR ν cm^{-1}: 2950 (s), 2925 (m), 1740 (s), 1270 (m), 1165 (s), 1120 (m), 1050 (m), 700 (m). ^{1}H NMR (270 MHz): δ 7.3–7.6 (5 H, m), 4.36 (2 H, dd, J = 8, 6 Hz), 3.55 (3 H, q, J = 0.5 Hz), 1.72 (1 H, m), 1.0–1.6 (9 H, m), 0.88 (3 H, d, J = 7 Hz), 0.85 (6 H, d, J = 7 Hz). MS: 344 (M^+-30, 1%), 189 (100), 158 (4), 141 (9), 139 (4), 127 (5), 119 (7), 105 (14), 99 (6), 91 (4), 85 (23), 71 (25), 69 (10), 57 (23), 55 (9).

(R)-3,8-Dimethyl-1-octyl (R)-α-methoxy-α-trifluoromethylphenylacetate (R-7). *R*-**7** was prepared in the same manner used for *S*-**7** synthesis. The starting material *R*-**3** also disappeared. IR ν cm^{-1}: 2950 (s), 2925 (m), 1740 (s), 1265 (m), 1160 (s), 1120 (m), 1050 (m), 700 (m). ^{1}H NMR (270 MHz): δ 7.3–7.6 (5 H, m), 4.36 (2 H, m), 3.57 (3 H, q, J = 0.5 Hz), 1.72 (1 H, m), 1.0–1.6 (9 H, m), 0.89 (3 H, d, J = 7 Hz), 0.86 (6 H, d, J = 7 Hz)., MS: 190 (M^+-184, 9%), 189 (100), 141 (9), 127 (5), 119 (7), 105 (14), 99 (6), 85 (23), 77 (6), 71 (23), 69 (8), 57 (22).

(S)-3,8-Dimethyl-6-octen-1-yl (R)-α-methoxy-α-trifluoromethylphenylacetate (S-8). *S*-**2** (2.0 mg), (*R*)-MTPA (11.0 mg), dicyclohexylcarbodiimide (15.0 mg), and pyridine (10 μl) were dissolved in 0.5 ml of dry dichloromethane. After 24 hr, the reaction mixture was directly added to the SiO_2 column and eluted by hexane–CH_2Cl_2. The yield was 4.0 mg. IR ν cm^{-1}: 2960 (s), 2920 (s), 1740 (s), 1445 (m), 1260 (m), 1180 (s), 1165 (s), 1120 (m), 1020 (m), 715 (m). ^{1}H NMR (270 MHz); δ 7.3–7.6: (5 H, m), 5.06 (1 H, br t, J = 7 Hz), 4.36 (2 H, dd, J = 7, 6 Hz), 3.55 (3 H, q, J = 0.5 Hz), 1.95 (2 H, m), 1.72 (1 H, m), 1.68 (3H, s), 1.60 (3H, s), 1.1–1.6 (4H, m), 0.90 (3 H, d, J = 7 Hz). MS: 203 (1%), 189 (78), 138 (M^+-MTPA, 51), 123 (34), 105 (30), 95 (46), 82 (40), 81 (57), 69 (100), 67 (21), 55 (32), 41 (54).

(R)-3,8-Dimethyl-6-octen-1-yl (R)-α-methoxy-α-trifluoromethylphenylacetate (R-8). *R*-**8** was prepared in the same manner used for *S*-**8** synthesis. The yield was 3.4 mg. IR ν cm^{-1}: 2960 (s), 2920 (s), 1740 (s), 1445 (m), 1265 (m), 1180 (s), 1165 (s), 1120 (m), 1020 (m), 715 (m). ^1H NMR (270 MHz): δ 7.3–7.6 (5 H, m), 5.06 (1H, br t, J = 7 Hz), 4.36 (2 H, m), 3.56 (3 H, q, J = 0.5 Hz), 1.95 (2 H, m), 1.72 (1 H, m), 1.68 (3 H, s), 1.60 (3 H, s), 1.1–1.6 (4 H, m), 0.90 (3 H, d, J = 7 Hz). MS: 203 (1%), 189 (73), 138 (M^+-MTPA, 49), 123 (33), 105 (29), 95 (46), 82 (40), 81 (58), 69 (100), 67 (22), 55 (32), 41 (56).

Gas Chromatograph–Electroantennographic Detection (GC-EAD). A Hewlett-Packard 5890 II gas chromatograph equipped with a cool on-column injector and flame ionization detector (FID) was operated using helium as carrier gas at a column head pressure of 55 kPa. Injections (0.6 μl) were made directly on a DB-1 fused silica capillary column (15 m × 0.25 mm ID, 0.25 μm film thickness; J & W Scientific, Folsom, California) at an initial column temperature of 50°C. After 1 min, oven temperature was programmed at 20°C/min to 190°C, then 10°C/min to 220°C, and held at the final temperature for 4 min.

The GC-EAD system was set up according to Struble and Arn (1984). Makeup gas (He, ca. 50 ml/min) was introduced at the end of the fused silica capillary column, and then the column flow was split into the FID and EAD lines at ca. 1 : 1 ratio.

RESULTS AND DISCUSSION

The terminal structure of **1** resembles the terpenoids such as the citronellols. Citronellol has been widely used as a chiral building block for the syntheses of optically active pheromone compounds (Mori et al., 1991; Naoshima et al., 1991).

(*S*)-Citronellol (*S*-**2**) was reduced with lithium aluminum hydride and cobalt(II) chloride to (*S*)-3,8-dimethyl-1-octanol (*S*-**3**) (Mori et al., 1991; Naoshima et al., 1991). This was oxidized with pyridinium chlorochromate to (*S*)-3,8-dimethyloctanal (*S*-**4**). Then *S*-**4** was coupled with the ylide (Horiike et al., 1978).

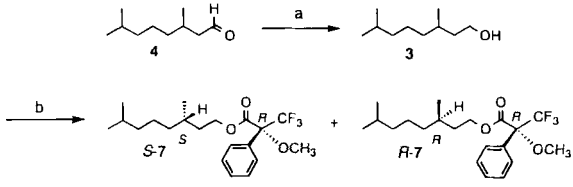
The alcohol *S*-**5** was reduced to *R*-**6** by diimide, which was generated in situ by the oxidation of hydrazine (Corey et al., 1961; Hoffman and Schlessinger, 1971; Wright et al., 1988). To avoid possible racemization (Mori et al., 1991; Naoshima et al., 1991), the catalytic hydrogenation was not adopted. Note that *R*-**6** was derived from *S*-**5**. Acylation of *R*-**6** by isobutyric anhydride in pyridine gave isobutyrate *R*-**1**. The physical properties of *R*-**1** were coincident with those of the natural pheromone and the racemic compound, which were previously reported (Wakamura et al., 1994).

S-**1**, the enantiomer of *R*-**1**, was also synthesized from (*R*)-citronellol

(*R*-**2**) in the same manner. Neither *R*-**1** nor *S*-**1** gave an $[\alpha]_D^{25}$ value (*c*1, CH_2Cl_2). Some predecessors had met similar phenomena, i.e., (*R*)- and (*S*)-15-methyltritriacontane, the sex stimulant pheromone of the stable fly *Stomoxys calcitrans* L., exhibited no measurable optical rotations at the sodium D-line (Naoshima and Mukaidani, 1987). Several other cases where the two enantiomers could not be distinguished by optical rotation were also listed in the literature. Racemic **1** showed a single GC peak on a chiral capillary column (Chirasil DEX CB, 0.25 mm ID × 25 m length, 0.25 μm film thickness) at 200°C when the carrier gas was helium at a column head pressure of 100 kPa. These circumstances compelled us to evaluate the enantiomeric purity at an earlier stage of the syntheses.

Both (*S*)- and (*R*)-3,8-dimethyloctanal (*S*-**4** and *R*-**4**) were reduced to *S*-**3** and *R*-**3** by lithium aluminum hydride in ether. *S*-**3** and *R*-**3** were then converted to the corresponding (*R*)-MTPA esters (Dale and Mosher 1973; Ohtani et al., 1991) (*R*-**7** and *S*-**7**, respectively) by treating with (*S*)-MTPA chloride in pyridine (Scheme 2). The C-1 methylene protons of *S*-**7** and *R*-**7** showed different coupling patterns. No isomer peak was observed in either sample (Figure 1), which indicated that the *S*-**4** and *R*-**4** employed for the Wittig reactions were enantiomerically pure. We therefore considered that the resulting compounds (*R*-**1** and *S*-**1**) were also optically pure because later reaction conditions suggested no isomerization reaction took place.

In the case of *S*-**7**, Figure 1 reveals that C-1 methylene protons form an A_2 pattern. On the other hand, *R*-**7**'s C-1 methylene protons form an AB pattern, and they couple with the diastereotopic C-2 methylene protons. Thus, C-1 methylene protons of *R*-**7** show a complicated coupling pattern. Most probably, the major cause of this difference is the magnetic anisotropy of the phenyl groups. We also synthesized *S*-**2** and *R*-**2** (*R*)-MTPA esters (*S*-**8** and *R*-**8**, respectively). The coupling patterns of the C-1 methylene signals of *S*-**8** and *R*-**8** (^{1}H NMR) were coincident with those of *S*-**7** and *R*-**7**, respectively. We think that we can determine the C-3 absolute configurations of some terpenoids possessing the 3-methyl-1-ol system by MTPA esterification.



SCHEME 2. Consideration of the optical purity of **4**.

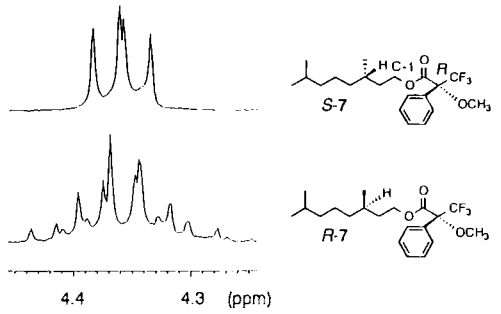


FIG. 1. ^{1}H NMR spectra of *S*-**7** and *R*-**7** (C-1 methylene region) (270 MHz, $CDCl_3$).

Electrophysiological activities of *R*-**1** and *S*-**1** were evaluated using a gas chromatograph equipped with an electroantennographic detector. The dose-response curve of *R*-**1** (3 pg–3 ng) based on the relative voltage generated by the male antenna of *E. pseudoconspersa* was well adjusted with that of the natural pheromone (Figure 2). *S*-**1** was apparently less active than *R*-**1**. We therefore concluded that the major sex pheromone component of *E. pseudoconspersa* is (*R*)-10,14-dimethyl-1-pentadecyl isobutyrate.

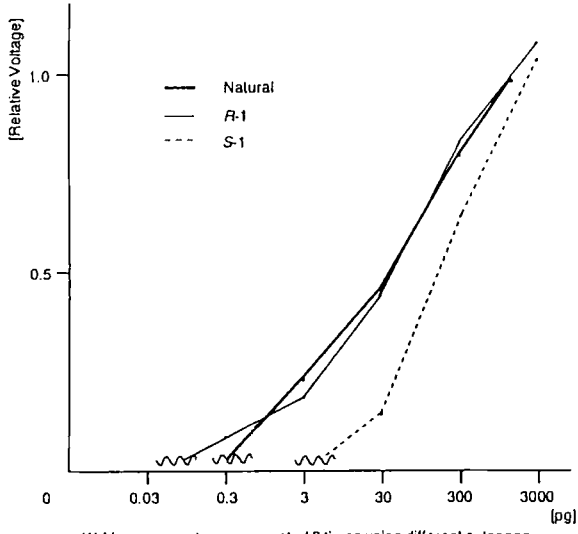

FIG. 2. Dose–response curves of GC-EAD experiment.

Acknowledgments—A.I. wishes to thank Associate Prof. Yoshinobu Inouye (Department of Chemistry, University of Tsukuba) for his helpful discussions. We thank Prof. Yoshinobu Naoshima (Faculty of Science, Okayama University of Science) for his kind donation of the experimental data. The authors are grateful to Mr. Katsushi Esaki (National Institute of Health Sciences) for his measurement of NMR spectra. We thank the GL Sciences (Tokyo) for the GC analysis with a chiral fused silica capillary column. Finally, we thank JEOL for the HR-MS measurement.

Abstract—Wild rats, *Rattus norvegicus*, *R. exulans*, and *R. rattus*, avoided wire-cage live traps that had previously captured mongooses, *Herpestes auropunctatus*. Replacing traps soiled by mongooses with clean traps would increase rat capture success and reduce a source of experimental bias.

Key Words—*Herpestes auropunctatus*, predator odors, *Rattus*, semiochemicals, trap success.

INTRODUCTION

Many animals utilize olfactory cues to detect potential danger from predators (Griffith, 1920; Weldon, 1990; Ylönen et al., 1992; Epple et al., 1993; Jędrzejewski et al., 1993). Recently much interest has focused on the use of predator odors to reduce damage by agricultural pests (Shumake, 1977; Sullivan et al., 1988c; Müller-Schwarze, 1990; Mason et al., 1994). Predator odors have been used to repel mountain beavers (*Aplodontia rufa*) (Epple et al., 1993; Nolte et al., 1993), voles (*Microtus* spp.) (Merkens et al., 1991; Sullivan et al., 1988a, 1990a), pocket gophers (*Thomomys talpoides*) (Sullivan et al., 1988b, 1990b), house mice (*Mus musculus*) (Coulston et al., 1993), snowshoe hares (*Lepus Americanus*) (Sullivan et al., 1985; Sullivan, 1986), woodchucks (*Marmota monax*) (Swihart, 1991), deer (*Odocoileus hemionus*) (Müller-Schwarze, 1972;

Melchiors and Leslie, 1985), elk (*Cervus elaphus*) (Andelt et al., 1992), and sheep (*Ovis aries*) (Arnould and Signoret, 1993).

Predator odors can also substantially depress rodent population estimates obtained by live trapping (Stoddart, 1976, 1982). Short-tailed voles (*Microtus agrestis*) avoided traps scented with weasel (*Mustela nivalis*) anal gland secretions (Stoddart, 1976, 1979, 1982). Capture success of Orkney voles (*Microtus arvalis*) was lower in traps soiled with red fox (*Vulpes vulpes*) fecal odors (Calder and Gorman, 1991) or stoat scent (Gorman, 1984). House mice (Dickman, 1992), wood mice (*Apodemus sylvaticus*) (Dickman and Doncaster, 1984), and voles (*Clethrionomys glareolus* and *Microtus agrestis*) (Dickman and Doncaster, 1984) shunned traps tainted with red fox fecal odors.

Personnel at the Hawaii Field Station of the Denver Wildlife Research Center, US Department of Agriculture, routinely capture rats (*Rattus norvegicus*, *R. rattus*, and *R. exulans*) for laboratory and field studies related to crop pest management. Small Indian mongooses (*Herpestes auropunctatus*) frequently enter live traps set for rats, potentially biasing trap results. We analyzed trapping records from a study conducted on a Hawaiian sugarcane plantation to determine whether mongoose captures affected subsequent capture success for rats.

METHODS AND MATERIALS

We conducted the study at the Mauna Kea Agribusiness Company, Inc., a 6000-ha sugarcane plantation on the windward coast of the island of Hawaii. We divided each of six fields with sugarcane 16–26 months of age into three comparable sections of 12–18 ha each. We set 50 steam-cleaned Haguruma wire-cage live traps (22 × 28 × 15 cm) along a 150-m transect starting from an interior road and extending into the interior of each section. At each trap site, we cleared an area approximately 30 × 30 cm to one side of the transect and secured a trap directly on the ground with a numbered wire flag. We scattered grated coconut along the traplines three days before baiting the traps with coconut chunks and setting them. Between 0630 and 1200 hr on each of the succeeding four days, we checked, rebaited, and reset traps as necessary; we collected the traps on the fourth day. We identified and released captures at their respective trap sites.

To determine whether capturing a mongoose in a trap affected subsequent rodent capture success, we compared rat capture success during nights 2–4 for traps that captured a mongoose on the first night versus traps that did not capture a mongoose on the first night. We excluded traps with mongoose captures on nights 2, 3, and 4 to avoid potential bias due to repellent effects and due to the traps already being occupied and unavailable to rodents part of the time.

TABLE 1. NUMBER OF MONGOOSES CAPTURED DURING 4 DAYS OF TRAPPING AND SUBSEQUENT NUMBER OF RATS CAPTURED IN SAME TRAPS

	Day			
	1	2	3	4
Mongooses captured (N)	17	9[a]	3	4
Rats subsequently captured in same traps (N)	1	1	0	

[a]Two traps that captured a mongoose on day 2 subsequently captured another mongoose on day 4.

RESULTS

We captured 33 mongooses in 31 different traps during 3600 trap-nights (Table 1). Two traps that captured mongooses during the second day subsequently captured another mongoose during the fourth day; no other traps captured > 1 mongoose. Four traps captured mongooses during the final 24 hr of trapping and thus had no subsequent chance to capture rats. Of the 29 traps that captured a mongoose with trap-nights remaining, only two captured a rodent during 72 subsequent trap-nights. Seventeen traps captured a mongoose on the first night, of which only one (6%) subsequently captured a rat. This is a substantially smaller proportion than the 208 of 869 traps (24%) that did not capture a mongoose but captured ≥ 1 rat on days 2–4 ($P = 0.06$, one-tailed Fisher's exact test).

DISCUSSION

Pheromones serve several functions in mammals, including regulating social behavior, marking territories, and signaling reproductive receptiveness. Predator odors generally attract other predators (Teranishi et al., 1980; Fagre et al., 1981), and many commercial predator lures and baits utilize predator-derived compounds (Blom, 1993). That only two of our traps captured > 1 mongoose may indicate that captive mongooses emitted a stress odor that repelled other mongooses.

Most rodents are under intense selective pressure to assess and avoid predatory risks (Lima and Dill, 1990). By signaling the recent presence of predators in an area, residual predator odors may provide an early warning that enables potential prey to avoid fatal encounters with predators. Such predator avoidance behavior is widespread among rodents (e.g., Epple et al., 1993; Sullivan et al., 1988a,b; Coulston et al., 1993; Swihart, 1991) and is generally resistant to

habituation (Swihart, 1991; Arnould and Signoret, 1993; Epple et al., 1993). Rats form a major portion of the diet of mongooses in and around Hawaiian sugarcane fields (Baldwin et al., 1952; Kami, 1964), and one would expect them to avoid areas frequented by these predators. Clearly most of the rats in our study avoided traps soiled with mongoose odor. This avoidance persisted for up to three days after mongooses visited the traps.

Our results indicate that replacing traps soiled by mongooses with clean traps would increase rat capture success and reduce a source of experimental bias. Further investigation is warranted to explore the use of predator odors as nonlethal repellents to reduce crop damage by rats.

(Received October 27, 1994; accepted January 31, 1995)

Abstract—*S. latifascia* and *S. descoinsi* are closely related species that occur sympatrically over limited areas in French Guiana. We examined allopatric populations, *S. latifascia* originating from Barbados and *S. descoinsi* from French Guiana. Studies on nocturnal activity cycles showed temporal partitioning of female calling behavior, male sexual activity, and mating behavior. *S. descoinsi* were sexually active in the first half of the scotophase whereas *S. latifascia* were sexually active in the second half. Seven compounds (*Z*9-14:Ac, *Z*9,*E*12-14:Ac, Z11-16:Ac, *E*9,*E*12-14:Ac, *Z*9-14:Ald, *Z*9,*E*11-14:Ac and Z11-14:Ac) were identified in females of both *S. latifascia* and *S. descoinsi* extracts. *Z*9-14:Ac was a main pheromone component for the two species. The major difference between the pheromones of *S. latifascia* and *S. descoinsi* was the proportion of *Z*9,*E*12-14:Ac in the extracts: 7% for *S. latifascia* and 42% for *S. descoinsi*. The proportion of *Z*9,*E*12-14:Ac relative to the sum of *Z*9-14:Ac and *Z*9,*E*12-14:Ac in individual gland extracts was 4 ± 1% (mean ± standard deviation) for *S. latifascia* and 44.8 ± 6% for *S. descoinsi*. Electrophysiological studies showed no major differences between species in the morphology and physiology of the pheromone receptors of males. Receptors were identified for *Z*9-14:Ac and *Z*9,*E*12-14:Ac, but no receptor was found for the other compounds. In the wind tunnel, synthetic blends with *Z*9-14:Ac and *Z*9,*E*12-14:Ac gave the same behavioral responses as conspecific female extracts for the males of the two species. Some cross-attraction was observed with synthetic blends and female extracts. Nethertheless, previous field trapping experiments in French Guiana

were species-specific and suggested differences in the attractivity of males. In the laboratory, *S. latifascia* and *S. descoinsi* could hybridize in both reciprocal crosses. Female *S. descoinsi* × male *S. latifascia* mating rate was significantly lower than for the reciprocal cross, and 26.7% of female *S. descoinsi* could not separate from male *S. latifascia* after mating. These copulatory problems may involve genital incompatibilities between males and females. Several barriers against interbreeding between *S. latifascia* and *S. descoinsi* seem to combine including differences in nocturnal activity cycles, pheromone differences, and genital barriers. The study of sympatric populations will be necessary to define the role of sex pheromones in the reproductive isolation of *S. latifascia* and *S. descoinsi*.

Key Words—Lepidoptera, Noctuidae, *Spodoptera latifascia*, *Spodoptera descoinsi*, pheromones, (*Z*)-9-tetradecenyl acetate, (*Z,E*)-9,12-tetradecadienyl acetate, sexual activity rhythms, cross-attraction, electrophysiology, reproductive isolation.

INTRODUCTION

When different species occur sympatrically, precopulatory (ecological or ethological) and/or postcopulatory barriers (mechanical isolation, gametic mortality or incompatibility, inviability or sterility of hybrid zygotes) are necessary to keep them reproductively isolated (Mayr, 1942; Dobzhansky, 1970). In moths, differences in pheromone communication systems between species may be an important barrier against interspecific matings. The specificity of the pheromone blend emitted by females is the most common factor limiting reproductive interactions (Roelofs and Cardé, 1974). In some cases, this specificity is not sufficient to prevent hybridization, and other mechanisms are required to ensure complete reproductive isolation. Hence, in order to understand the role of pheromones in reproductive isolation, it is critical to study their specificity.

Spodoptera latifascia (Walker) is a noctuid moth of the *Amphipyrinae* subfamily. It occurs from Brazil to the United States where it can cause damage to vegetable crops (King and Saunders, 1984; Godfrey, 1987). Field-trapping experiments with sexual attractants in French Guiana enabled us to discover a new population of *Spodoptera* morphologically close to *S. latifascia* but attracted by a different pheromone blend (Lalanne-Cassou et al., 1994). While *S. latifascia* males were mainly caught by binary mixtures of (*Z*)-9-tetradecenyl acetate (*Z*9–14 : Ac) with 4–24% of (*Z,E*)-9,12-tetradecadienyl acetate (*Z*9,*E*12–14 : Ac), the new population of males was attracted by mixtures containing 32–48% of *Z*9,*E*12–14 : Ac. Furthermore, males and females of this particular population could be distinguished from *S. latifascia* by small differences in wing and body coloration and by the morphology of the genitalia. The stability of these phenotypical differences, the sympatry of the two moth populations in limited areas, and the differences in sexual attractants led us to consider this population, which

seems to be endemic to French Guiana, as a new species. It was described and named *S. descoinsi* (Lalanne-Cassou et al., 1994).

The present work deals with a comparison of pheromone communication systems between allopatric populations of *S. latifascia* and *S. descoinsi*. Female calling rhythms and pheromone composition were determined for the two species. Male olfactory and behavioral responses to pheromone were studied by electroantennography and single sensillum recordings and by wind tunnel experiments, respectively. The potential role of these characters in the reproductive isolation of *S. latifascia* (SL) and *S. descoinsi* (SD) is discussed.

METHODS AND MATERIALS

Rearing of Insects. A SL culture was established from larvae collected in the field in Barbados in 1990 and a SD culture from adults caught by light traps in French Guiana in 1992. Larvae were fed on a semiartificial diet supplemented with cabbage and corn powders. They were maintained at 23°C and 70% relative humidity under a 12 : 12 hr light–dark regime. At pupation, males and females were separated in distinct rooms.

Female Calling Behavior and Mating Rhythms. At emergence, females were placed individually in 250-cm^3 plastic boxes for observation of calling behavior or placed with a male in 690-cm^3 plastic boxes for observation of mating periods. Preliminary studies showed no calling behavior during the photophase. Observations were then performed during the scotophase every 0.5 hr with a red lamp at a light intensity of 1 lux on 1- to 8-day-old females for SD and on 1- to 6-day-old females for SL. The day of emergence was designated day 1. Mating rates were estimated on groups of 15 pairs per box by dissecting females after death and searching for spermatophores transferred by males during copulation. Mating rhythms were observed during the scotophase every 0.5 hr on pairs formed with individuals of the same age. The origin of time measures for calling and mating was fixed at lights off.

Chemical Analysis. Pheromone glands of calling females were dissected during the scotophase between 3 and 7 hr after lights off for SD and between 6 and 10.5 hr after lights off for SL. Glands were individually soaked in 15 μl of hexane during 40 sec to study interindividual variation or extracted in batches of 15–30 in 250 μl of hexane during 2 hr to determine the average composition of pheromone in the populations and to detect minor compounds. Global extracts were analyzed by gas chromatography–mass spectrometry (GC-MS) in the electronic impact ionization mode on a Nermag R10-10C quadrupole interfaced with a Girdel 32 gas chromatograph. A WCOT capillary column (25 m × 0.32 mm ID Chrompack) with a polar phase FFAP-CB or a CPSil 88-CB column (60 m × 0.32 mm ID, Chrompack) was temperature programmed from 140 to 240°C

at 5°C/min. Compounds in the extracts were identified by comparison with retention times and mass spectra of synthetic standards analyzed under the same conditions. Individual gland extracts were subjected to GC analysis with a Girdel 300 or a Carlo Erba Fractovap 2900 chromatograph with flame ionization detectors and splitless and Ross injectors, respectively, for the Girdel 300 and the Carlo Erba. Helium was used as carrier gas at approximately 27 cm/sec linear velocity. A capillary column WCOT (25 m × 0.32 mm ID Chrompack) with a polar phase FFAP-CB was used. The temperature program for the Girdel 300 was 120 to 240°C at 3°C/min, with injector and detector temperatures at 240°C. The program for the Carlo Erba Fractovap 2900 was 55 to 140°C at 35°C/min, 140 to 210°C at 5°C/min with injector temperature at 225°C and detector temperature at 250°C. In each individual gland extract, the peaks for *Z*9,*E*12-14:Ac and *Z*9-14:Ac were identified by comparison with the retention times of synthetic standards analyzed under the same conditions.

Electrophysiology. Electrophysiological activity of SL and SD male antenna was measured by electroantennographic (EAG) and single sensillum recording (SSR) techniques as previously described by Lucas and Renou (1989). All experiments were carried out on whole insect preparations. Briefly, for EAGs, the apex of the antenna was excised and inserted into the recording electrode. The reference electrode was implanted in the neck of the insect. Both electrodes were connected to a Neurolog NL102 preamplifier through chloridized silver wires. The EAG responses were filtered (DC, 300 Hz) and amplified (×1000). In order to eliminate the differences in absolute sensitivity between individuals, corrected EAG data were calculated. For each individual, the response to a given compound was divided by the mean of the responses to all compounds tested (Renou et al., 1988). The responses of 10 males were measured for each species. Means of the corrected data and their confidence intervals were calculated. For SSRs, the tip recording technique of Kaissling and Thorson (1980) was used. Glass electrodes were filled with sensillar saline for the recording electrode and with hemolymph saline for the reference electrode. The reference electrode covered the tip of the antenna, the last segments of which had been cut. The tips of several sensilla were cut off using sharpened forceps, and the recording electrode was slipped over the cut end of one hair. The SSR responses were filtered (DC, 5000 Hz) and amplified (×1000). The recordings were stored on a PC-AT-compatible microcomputer via a DASH 16 (Metrabyte) analog-to-digital conversion board. Acquisition and analysis of the recordings were performed by specific programs developed in our laboratory and written in Asyst language (Macmillan Software Company).

The olfactory stimulations were delivered from Pasteur pipets containing a piece of filter paper on which 500 ng of diluted test compound had been deposited. The antenna was continuously flushed with humidified air (1.0 liter/min) and stimulations were achieved by blowing a puff of air (1 sec, 0.5 liter/min)

through the Pasteur pipet. Nineteen stimulus compounds were tested in a random order.

Male Sexual Activity and Behavioral Response to Pheromone. Male sexual activity was first tested with a simple bioassay. Four males, one to three days after the emergence, were kept together in boxes and maintained separated from females to prevent any contact with pheromone. A piece of filter paper impregnated with conspecific female gland extract at a dose of 0.5 female equivalent (FE) was introduced for 5 min into a box containing four males. A group of four males was tested every hour during the scotophase, and each group was tested only once. When sexually excited, the males behaved in a characteristic way by rapidly beating their wings (wing fanning), displaying genitalia, and displaying a pair of hairpencils situated on eversible epithelial pouches on the genital valvae. Wing fanning was chosen as a behavioral indicator of male sexual activity.

Male attraction to pheromone blends was studied in a 200 × 90 × 70-cm Perspex wind tunnel. The air speed was approximately 0.2 m/sec and the temperature 23°C. Red fluorescent tubes were placed above the tunnel to provide illumination of 0.3 lux. Tests were performed on 2- to 4-day-old males, between 3½ and 6 hr after the onset of the scotophase for SD, and between 7½ and 10 hr after the onset of the scotophase for SL. Males were placed on a wired cage at 1.5 m from the source made of a piece of filter paper impregnated with natural or synthetic pheromone. A dead male was fixed as a decoy on the source of pheromone. We chose seven phases of the behavioral response to describe male attraction to pheromone blend: (1) walks with or without wing fanning (W); (2) taking flight (Tf), males flew away from the wired cage; (3) orientation (O), males flew up the odor plume; (4) touching the source in flight without landing (T); (5) landing at the source (L); (6) precopulatory behavior (Pb), hairpencil or genital displays; (7) copulatory attempts *sensu stricto* (Ca).

Previous field-trapping experiments in French Guiana (Lalanne-Cassou et al., 1994), suggested to us to test two binary mixtures of *Z*9–14 : Ac and *Z*9,*E*12–14 : Ac at different doses: (1) SL 50 and SL 500: the ratio of *Z*9,*E*12–14 : Ac to *Z*9–14 : Ac was 5 : 95 at 50 and 500 ng, respectively, of *Z*9–14 : Ac; and (2) SD 50 and SD 500: the ratio of *Z*9,*E*12–14 : Ac to *Z*9–14 : Ac was 50 : 50 at 50 and 500 ng, respectively, of *Z*9–14 : Ac. Furthermore, female SD extracts were tested at a dose of 0.5 FE and female SL extracts at doses of 0.15, 0.5, and 1.5 FE. Each male was tested only once.

The percentage of male response was calculated for each of the seven behavioral steps as the number of males exhibiting a given behavior divided by the number of tested males. Differences in the behavioral responses to the extracts and the synthetic blends were analyzed by using χ^2 tests for each behavioral step (2 × 4 for SD and 2 × 7 for SL) with the threshold of significance set at 0.05. When heterogeneity was detected, all treatments were compared using 2

× 2 contingency tables. To minimize the risk of error arising from the increase of degrees of freedom, the threshold of significance was set to 0.01.

Chemicals. Compounds used as standards in the chemical analysis of the pheromone, as stimulus compounds in electrophysiological studies, or in wind tunnel experiments were all synthesized in the laboratory according to the procedures described by Mori (1981), Ramiandrasoa and Tellier (1990), and Renou et al. (1979, 1981). Their chemical purity was at least 98% as determined by gas chromatographic analysis.

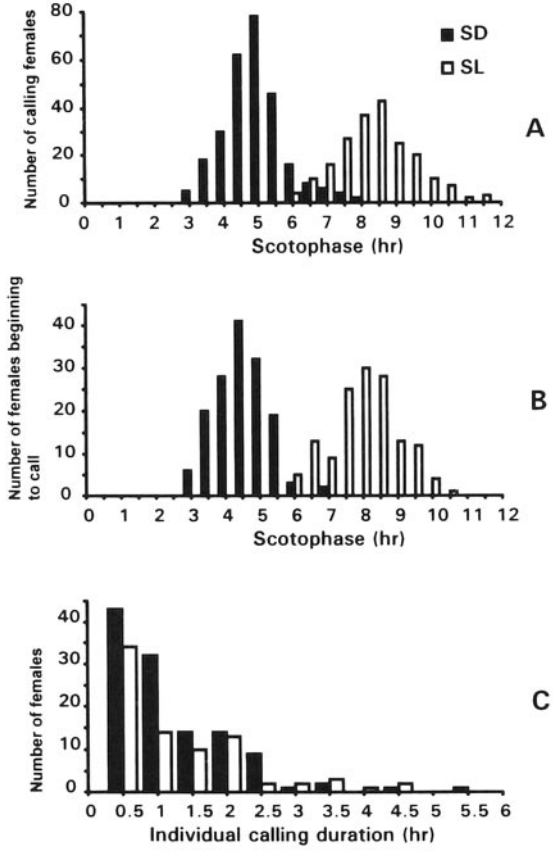

FIG. 1. Nocturnal calling periods of female SD and SL (A), beginning of calling behavior (B), and individual calling duration (C).

RESULTS

Female Calling Behavior. Calling behavior studies indicated marked temporal differences between species (Mann-Whitney test, $P < 0.001$) despite a slight overlap (Figure 1A). For SD, the maximum calling activity occurred in the first half of the scotophase, 5 hr after onset. Calling began at 4.5 $\pm$ 0.8 hr (mean $\pm$ SD) with a variation from 3 to 7 hr (Figure 1B). In contrast, for SL, the peak calling activity occurred in the second half of the scotophase (8.5 hr) (Figure 1A). Calling began at 8.2 $\pm$ 1 hr with a variation from 6 to 10.5 hr (Figure 1B). The beginning of calling was significantly different between SL and SD (Mann-Whitney test, $P < 0.001$). Individual calling durations (Figure 1C), 1.2 $\pm$ 0.9 hr and 1.3 $\pm$ 0.9 hr, respectively, for SD and SL, were not significantly different between species (Mann-Whitney test) at the 5% level of significance.

Mating Behavior. SL and SD matings occurred at significantly different times of the night (Mann-Whitney test, $P < 0.001$) despite an overlap of 2.5 hr (Figure 2A). Copulation durations (Figure 2B), 1.1 $\pm$ 0.7 hr and 1 $\pm$ 0.5 hr, respectively, for SL and SD, were not significantly different between species

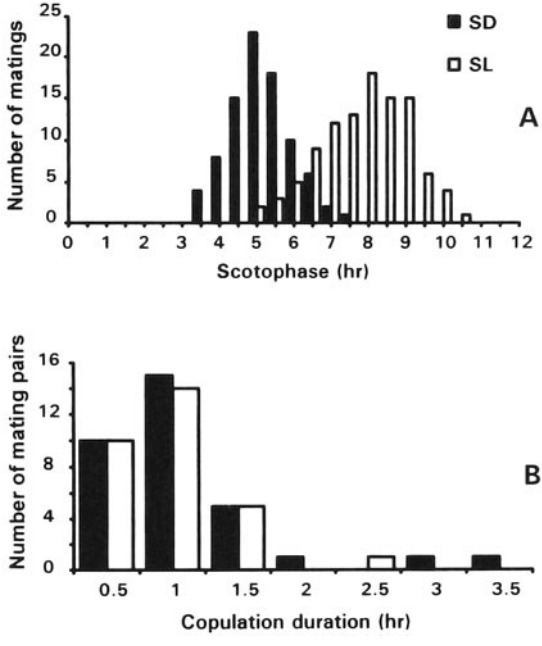

FIG. 2. Mating periods in SD and SL (A) and mating duration (B)

TABLE 1. MATING EFFICIENCY IN SL AND SD CROSSES[a]

Cross ♀ × ♂	Pairs (*N*)	Fertile matings (%)	Stuck pairs (%)
SD × SL	60	81.7b	0
SD × SD	60	83.3b	0
SL × SD	60	65.0b	0
SD × SL	60	10.0a	26.7

[a]Numbers followed by the same letter are not significantly different by χ^2 test at the 5% level of significance. Stuck pairs: male and female could not separate after copulation.

(Mann-Whitney test, $P > 0.05$). Fertile interspecific matings (giving offspring) could be obtained in both reciprocal crosses between SL and SD (Table 1). The SL × SD mating rate (65%) was not significantly different from those of the parental crosses (81.7% and 83.3% for SL × SL and SD × SD, respectively), (χ^2 test, $P > 0.05$). However, SD × SL mated less effectively than the reciprocal (SL × SD) and the parental crosses. Only 10% of pairs gave offspring and 26.7% of females could not separate from males after copulation.

Pheromone Composition. Analysis of an extract of 23 female SD glands showed the presence of six acetates and one aldehyde (Table 2). *Z*9–14:Ac [mass spectrum, *m/z* 41, 43 (100%), 53, 55, 61, 67, 81, 82, 96, 109, 194 (M-$CH_3COOH)^+$] and *Z*9,*E*12–14:Ac [mass spectrum, *m/z* 41, 43 (100%), 55, 61, 67, 68, 79, 81, 93, 95, 107, 121, 135, 149, 192 (M-$CH_3COOH)^+$] were found to be the main pheromone compounds in the extract with 41% of *Z*9–14:Ac and 42% of *Z*9,*E*12–14:Ac. Minor compounds could be identified as *Z*11–

TABLE 2. PERCENTAGES OF COMPOUNDS IN GLAND EXTRACTS FROM FEMALE SD AND SL

Compounds	SD (%) (23 females)	SL (%) (14 females)

16:Ac (11%) [mass spectrum, *m/z* 41, 43, 55 (100%), 61, 67, 81, 82, 96, 110, 123, 137, 151, 222 (M-$CH_3COOH)^+$], *E*9,*E*12-14:Ac (3%) [mass spectrum, *m/z* 41, 43 (100%), 55, 61, 67, 68, 79, 81, 93, 95, 107, 121, 135, 149, 192 (M-$CH_3COOH)^+$], *Z*9-14:Ald (2%) [mass spectrum, *m/z* 41, 43, 55 (100%), 67, 69, 81, 95, 98, 107, 121, 192 (M-$CH_3COOH)^+$], *Z*9,*E*11-14:Ac (1%) [mass spectrum, *m/z* 41, 43, 55, 61, 67 (100%), 79, 82, 93, 95, 107, 121, 135, 149, 192 (M-$CH_3COOH)^+$] and *Z*11-14:Ac (<1%) [mass spectrum, *m/z* 41, 43 (100%), 55, 61, 68, 82, 96, 110, 127, 194 (M-$CH_3COOH)^+$]. The retention times of these compounds were identical to those of synthetic references both with the WCOT column (*Z*9-14:Ac 4.3 min, *Z*9,*E*12-14:Ac 5 min, *Z*11-16:Ac 6.6 min, *E*9,*E*12-14:Ac 5.3 min, *Z*9-14:Ald 3 min, *Z*9,*E*11-14:Ac 5.9 min, and *Z*11-14:Ac 4.5 min) and with the more polar CPSil 88-CB column (*Z*9-14:Ac 11 min, *Z*9,*E*12-14:Ac 12.3 min, *Z*11-16:Ac 13.8 min, *E*9,*E*12-14:Ac 12.8 min, *Z*9-14:Ald 9.8 min, *Z*9,*E*11-14:Ac 13.7 min, and *Z*11-14:Ac 11.2 min). These same pheromone compounds were identified in the female SL extract (14 glands). *Z*9-14:Ac was the major pheromone compound (75%). *Z*11-16:Ac (8%), *Z*9-14:Ald (8%), *Z*9,*E*12-14:Ac (7%), *E*9,*E*12-14:Ac (1%), *Z*9,*E*11-14:Ac (1%), and *Z*11-14:Ac (<1%) were found as minor compounds. The pheromone compositions of SL and SD differed by the proportion of *Z*9-14:Ald in the extracts (2% for SD and 8% for SL), but the main difference was the proportion of *Z*9,*E*12-14:Ac (42% for SD and 7% for SL).

To confirm the differences found between the global extracts of female SL and SD, we analyzed individual gland extracts. The proportions and quantities of *Z*9-14:Ald were low for the two species. Therefore, we chose to calculate the percentage of *Z*9,*E*12-14:Ac relative to the sum of *Z*9-14:Ac and *Z*9,*E*12-14:Ac {[*Z*9,*E*12-14:Ac/(*Z*9-14:Ac + *Z*9,*E*12-14:Ac)] × 100}. This percentage averaged 4 ± 1% (mean ± SD) and ranged from 2 to 7.4% for SL, while it averaged 44.8 ± 6% and ranged from 29.1 to 59.2% for SD (Figure 3). Individual variation was high for the two species with coefficients of variation [CV = (SD/mean) × 100] reaching 26% for SL and 13.3% for SD. Despite this intraspecific variation, SL and SD distributions were significantly different (Mann-Whitney test, $P < 0.01$) and did not overlap. Percentages were stable among generations, allowing data pooling. *Z*9-14:Ac amounts averaged 61.1 ± 53 ng for SL and 56.5 ± 49.5 ng for SD. They were highly variable in the individual gland extracts (CV = 86.9% for SL and 87.6% for SD), but not significantly different between species (Mann-Whitney test, $P > 0.05$) (Figure 4).

Electrophysiology. *Z*9,*E*12-14:Ac was the most active compound for both SL and SD males (corrected EAG responses SD: 2.0; SL: 2.5) (Figure 5). *Z*9-14:Ac showed significant lower levels of responsiveness for the two species (one-way ANOVA, Newman-Keuls test, $P < 0.05$), whereas this compound

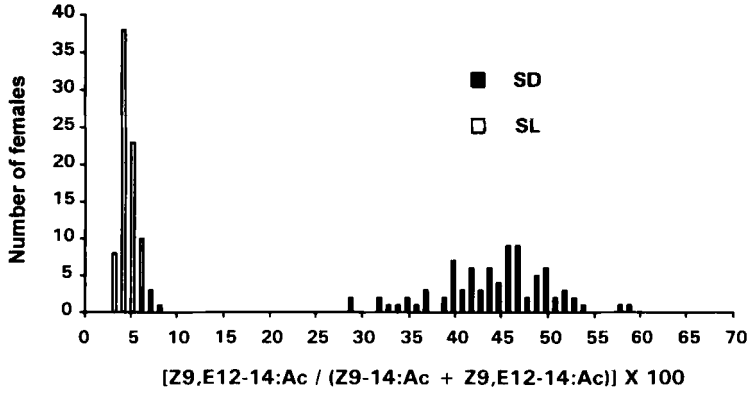

FIG. 3. Percentages of *Z*9,*E*12–14 : Ac relative to the sum of *Z*9–14 : Ac and *Z*9,*E*12–14 : Ac measured by gas chromatography in 84 individual gland extracts of female SD and 83 individual gland extracts of female SL.

was in equivalent proportion to *Z*9,*E*12–14 : Ac in the pheromone of female SD and was the major compound in the pheromone of female SL. *Z*9–12 : Ac also gave strong responses, although it is absent from the pheromone of the two species. Other compounds, except *Z*9,*E*12–14 : OH for male SD, had no significant EAG activity when compared to the control. Among them Z11–16 : Ac, present for 11% in the pheromone of female SD and for 8% in the pheromone

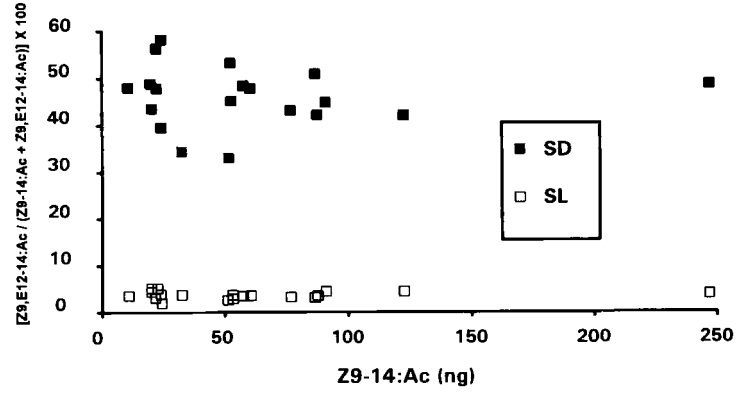

FIG. 4. Relation between the percentage of *Z*9,*E*12–14 : Ac relative to the sum of *Z*9–14 : Ac and *Z*9,*E*12–14 : Ac, and the quantity of *Z*9–14 : Ac from 23 individual female SD extracts and 19 individual female SL extracts.

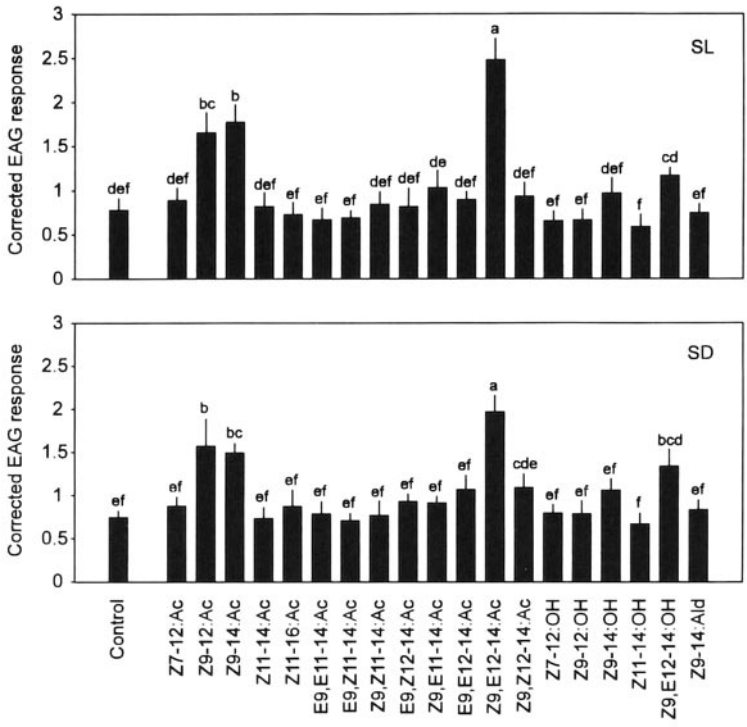

FIG. 5. EAG recordings of male SL and SD with a series of 19 pheromone compounds or analogs and pure air as control. Each compound was tested at 500 ng. Mean of the responses of 10 males. Error bars represent 95% confidence intervals. Bars associated with the same letter are not significantly different at the 5% level of significance (one-way ANOVA, Newman-Keuls test).

of female SL, showed no significant responses compared to the control (corrected EAG responses SD = 0.9; SL = 0.7).

Antennae are filiform in SD and SL. Observation of their morphology under light microscopy demonstrated the presence of at least two classes of sensilla trichodea on the unscaled ventral side of the antenna. These hairs were separated according to their length and location. Each flagellar segment exhibited the same sensillar organization. The longer hairs were located on the lateral parts of the ventral sensory area. They are referred to as the lateral hairs (LHs). Shorter hairs were located medioventrally on the flagellar segments and are referred to as medial hairs (MHs).

The activity of 30 LHs in SL and 43 in SD was recorded (Figure 6). In each LH, the firing activity clearly consisted of two amplitude classes of action potentials, indicating the presence of at least two neurons. The cell firing high-amplitude action potentials, up to 2.8 mV, is referred to as cell A. Action potentials emitted by the other cell, referred to as the B cell, were much smaller (50% of the amplitude of the A cell action potentials). In SD, the amplitude of B-cell spikes was smaller than in SL and was often hardly discriminated from the noise. In both SD and SL, A cells responded specifically to Z9,*E*12–14 : Ac. B cells were less specific since they had two key-compounds, Z9–14 : OH and Z9,*E*12–14 : OH. Moreover in SL, B cells also slightly responded to a third alcohol, Z9–12 : OH, and to a minor pheromone compound, Z9–14 : Ald.

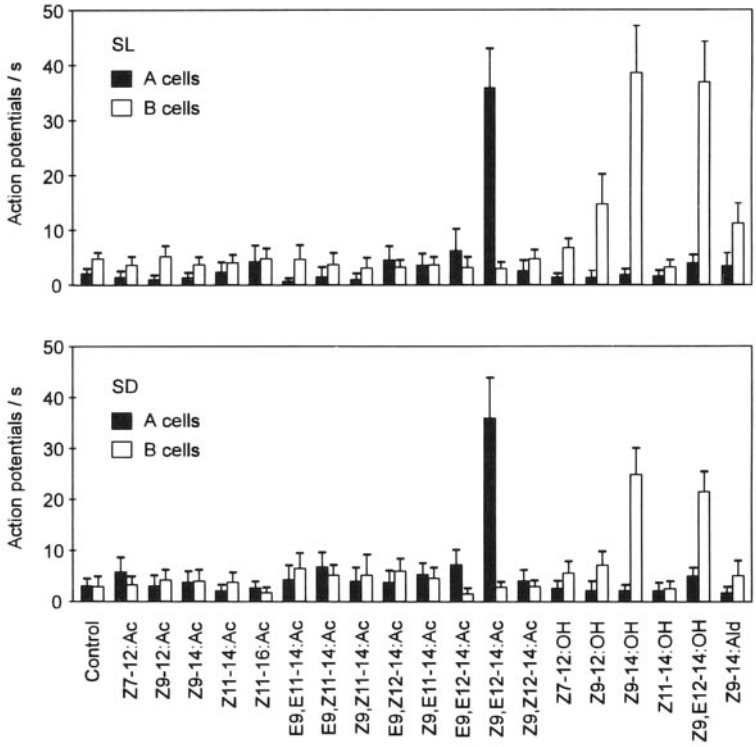

FIG. 6. Response profiles obtained by single sensillum recordings of A and B cells in long lateral hairs of SL (N = 30 hairs) and SD (N = 43 hairs) to 19 pheromone compounds or analogs. Each compound was tested at 500 ng, on 11–30 different hairs for SL and on 11–40 hairs for SD. Vertical bars represent 95% confidence intervals.

MHs appeared to be in smaller number and to be slightly shorter in SD than in SL. Electrical contacts were very unstable in SD. For these reasons, the activity of only three MHs was recorded in SD and Z9–14 : Ald, Z11–16 : Ac, and *E*9,*E*12–14 : Ac were not tested on these hairs because these compounds were not available at the time of the experiments. Analysis of the activity of MHs in both SL and SD always revealed the presence of only one class of action potential amplitudes, with a mean amplitude of 1.4 mV (Figure 7). Equal responses were recorded to the two pheromone compounds Z9,*E*12–14 : Ac and Z9–14 : Ac. None of the other compounds increased the firing activity.

No other sensillar type was discovered. In particular, unlike *S. littoralis*

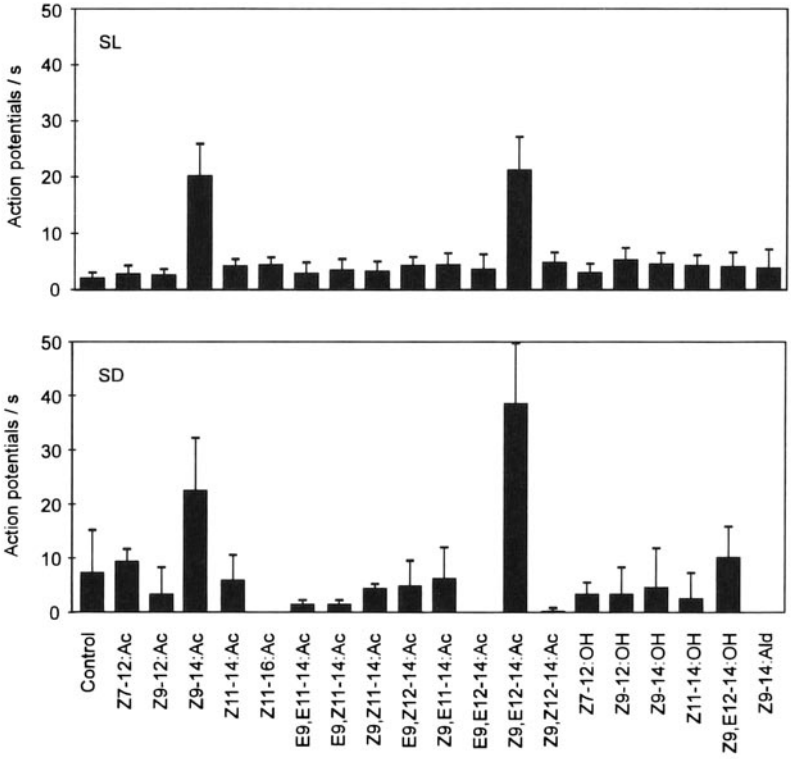

FIG. 7. Response profiles obtained by single sensillum recordings of short medial hairs of SL (N = 23 hairs) and SD (N = 3 hairs). Nineteen pheromone compounds or analogs were tested for SL and 16 compounds for SD. Each compound was tested at 500 ng, on 10–22 hairs for SL and on 2–3 hairs for SD. Z9–14 : Ald, Z11–16 : Ac and *E*9,*E*12–14 : Ac were not tested in SD. Vertical bars represent 95% confidence intervals.

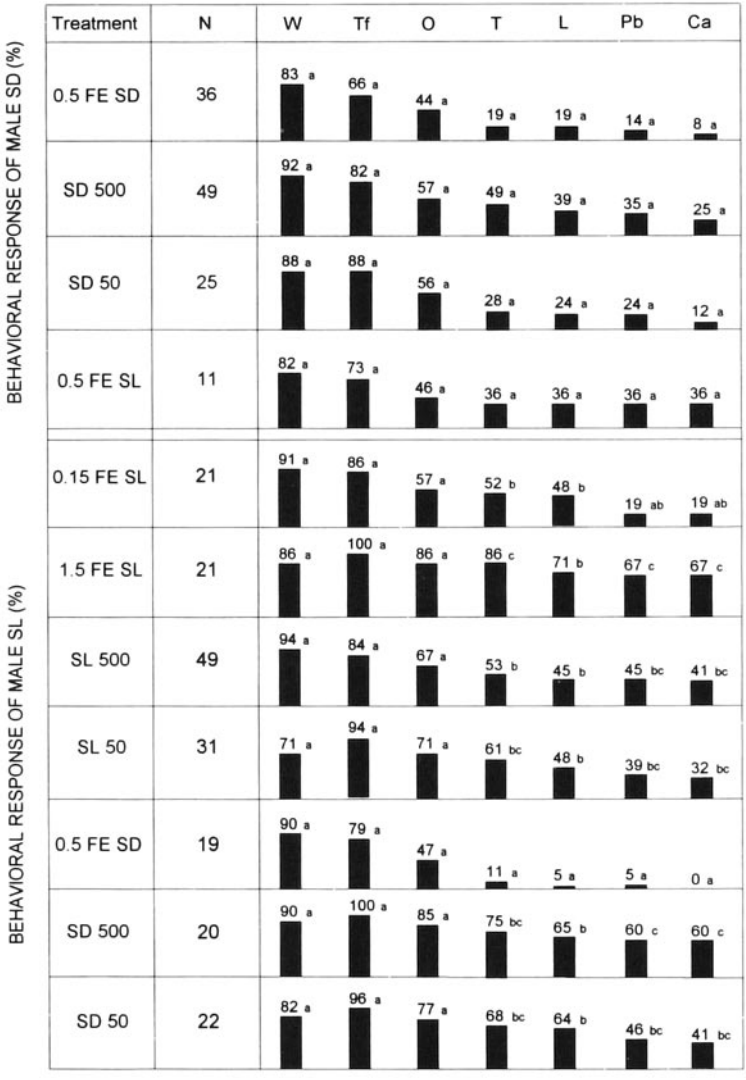

FIG. 8. Behavioral response of male SD and SL to female extracts and synthetic blends in the wind tunnel. For each species, the percentages in the same column followed by the same letter are not significantly different (χ^2 2 × 4 test, $P > 0.05$; χ^2 2 × 2 test, $P > 0.01$ for SD and χ^2 2 × 7 test, $P > 0.05$; χ^2 2 × 2 test, $P > 0.01$ for SL).

(Ljungberg et al., 1993), the most lateral LHs had the same response pattern as other LHs.

Male Sexual Activity and Behavioral Response to Pheromone. Male SL and SD showed distinct peaks of "wing-fanning" response to the pheromone of their conspecific females. The peak occurred at 4–5 hr in the scotophase for SD and at 9 hr for SL. Periods of male sexual activity were significantly different between species (Mann-Whitney test, $P < 0.001$) although they widely overlapped. SL and SD were simultaneously sexually active from 4 to 9 hr. The levels of responsiveness were high for the two species ranging from 20 to 89% for SD and from 34 to 88% for SL. However, wind-tunnel experiments showed low frequencies of behavioral response of male SD (Figure 8). Especially with the 0.5 FE SD treatment, only 8% achieved the complete behavioral sequence until "copulatory attempts." Blends with synthetic components SD 500 and SD 50 were as effective in eliciting behavior as the female extract. No significant difference was observed between these blends. SD males were also attracted by the female SL extract (0.5 FE SL) and completed the behavioral sequence until "copulatory attempts." In that case, frequencies of behavioral categories were not significantly different from all other treatments. Wind-tunnel experiments on male SL revealed that the female extract 1.5 FE SL was more effective than the 0.15 FE SL extract in the last steps of the behavioral sequence ("touching," "precopulatory behavior," and "copulatory attempts"). Blends with synthetic compounds SL 500 and SL 50 showed no significant difference and induced similar levels of behavioral response as female extracts (except SL 500, which gave less "touching" than 1.5 FE SL extract). SL males also showed behavioral response to heterospecific extracts and blends. No significant difference was observed between SD 500 and SD 50 that gave similar levels of behavioral response as conspecific blends and extracts. However, the female extract 0.5 FE SD elicited lower "touching," "precopulatory behavior," and "copulatory attempts" than the other treatments.

DISCUSSION

Female calling behavior studies in SL and SD showed temporal partitioning of nocturnal calling activities. Female SD called in the first half of the scotophase, whereas female SL called in the second half. Mating activities showed the same pattern. Peaks of male sexual activity were distinct between species and concomitant with their respective female ones, but sexual activity periods were longer than in the population of females, showing more substantial overlaps between SL and SD. Some SD males were found to be responsive at the time of the peak calling activity of female SL. Some SL males showed sexual activity at the peak calling activity of female SD. These results suggest that differences

mainly observed in the nocturnal activities of female SL and SD are not sufficient to allow a complete premating isolation between species. A similar case of temporal partitioning of mating activities was observed in *S. frugiperda* between the corn and rice strains. While corn strain females mate in the first two thirds of the scotophase, rice strain females mate in the last one third. This difference in mating rhythms seems to be a strong barrier against interbreeding between the two strains (Pashley et al., 1992).

The same compounds were identified in the female SL and SD extracts. The main difference in the pheromone composition between species was the proportion of *Z*9,*E*12–14:Ac in the extracts: 7% for SL and 42% for SD. Teixeira et al. (1989) identified *Z*9–14:Ac and *Z*9,*E*12–14:Ac as pheromone compounds of female SL. The analysis of the proportion of *Z*9,*E*12–14:Ac relative to *Z*9–14:Ac from individual gland extracts showed that in spite of intraspecific variation, the two species were completely discriminated. While the proportions ranged from 2 to 7.4% for SL, they ranged from 29.1 to 59.1% for SD. Quantities of *Z*9–14:Ac were highly variable between individuals of a given species but not significantly different between species. Differences in pheromone composition between closely related species that depend more on relative proportions of compounds than on different chemical structures have frequently been observed in moths. In the *Yponomeuta* complex, *Y. evonymellus* and *Y. cagnagellus* share the same pheromone compounds, and pheromones mainly differ by the amount of *E*11–14:Ac relative to the *Z* isomer (*Z*11–14:Ac) (Löfstedt and Van Der Pers, 1985). Similarly, in the sibling taxa *Diachrysia chrysitis* and *D. tutti*, pheromone compositions differ by the proportions of *Z*5–10:Ac and *Z*7–10:Ac almost in opposite ratios (Löfstedt et al., 1994).

Electrophysiological studies showed no major differences in the morphology and physiology of the pheromone receptors on the antennae of male SL and SD. Two size classes of sensilla trichodea were identified for both species. While longer hairs were located on the lateral parts of the ventral side (LHs), shorter hairs were distributed medioventrally (MHs). This sensillar organization, found in other noctuid moths such as *Agrotis exclamationis* (Hansson et al., 1986), *Mamestra suasa* (Lucas and Renou, 1991), or *M. brassicae* (Renou and Lucas, 1994), was correlated with sensitivity to different compounds. Receptors to *Z*9–14:Ac and *Z*9,*E*12–14:Ac were identified for SL and SD. *Z*9,*E*12–14:Ac induced the strongest EAG response even for SL, where it is a minor pheromone compound. For the two species, receptors to *Z*9,*E*12–14:Ac were found in the two sensillar types, while receptors to *Z*9–14:Ac were only identified on MHs. No receptor was found for the minor compounds of the pheromone except in SL for *Z*9–14:Ald slightly detected by B cells on LHs. Although not produced by female SL or SD, *Z*9–12:OH, *Z*9–14:OH, and *Z*9,*E*12–14:OH activated olfactory neurons of B cells on LHs. The role of these compounds in the behavior

of males is unknown. Z9–12 : Ac gave strong EAG responses for SL and SD, although it did not increase the firing activity of any of the two sensillar types.

The flight-tunnel bioassay showed that for the two species, binary mixtures with Z9–14 : Ac and Z9,E12–14 : Ac were as effective in eliciting reproductive behavior as female extracts. Hence, these chemicals were critical to the expression of male behavior. Some mutual cross-attraction was observed between SL and SD with synthetic compounds and female extracts. Thus, male behavioral response was initiated whatever the proportion of Z9,E12–14 : Ac relative to Z9–14 : Ac. However, for male SL, the female SD extract elicited significantly fewer behavioral responses than any other treatment, particularly than SD 50 and SD 500. In the SD extract, another (other) component(s), seems to be responsible for these low responses. Further tests are required to confirm this hypothesis. The high levels of mutual cross-attraction with synthetic blends were not in accordance with previous field-trapping experiments. Traps with binary mixtures of Z9–14 : Ac and Z9,E12–14 : Ac, in different proportions and in which positions were rerandomized every night, were tested on pasturelands surrounded by the forest in French Guiana (Matoury) during January 1982 and July–August 1983 (Lalanne-Cassou et al., 1994). These traps caught specifically male SL or SD. Field experiment results suggest differences in male attractivity between species. The flight-tunnel bioassay did not confirm these differences that may occur in the timing of behavioral sequences or in the way of approaching or landing on the trap. Similar cases of cross-attraction in the wind tunnel were found for several species of *Orgyia* (Grant, 1977), for the *Euxoa declarata* group (Byers et al., 1981), and for several members of the stored-product complex of phycitine moths (Phelan and Baker, 1986). The above authors supposed that these interspecific attractions were favored by the similarity of the pheromones used by the closely related species. Grant et al. (1975) observed interspecific courtship between the Indian meal moth, *Plodia interpunctella*, and the almond moth, *Cadra cautella*, but several isolating mechanisms before and during courtship prevented cross-mating. In the small ermine moths (*Yponomeuta*), wind-tunnel experiments also showed a high level of cross-attraction, particularly between *Y. evonymellus* and *Y. vigintipunctatus*, two species with very similar pheromones (Hendrikse, 1986). However, field-trapping experiments with synthetic attractants were species-specific in the natural habitat of the respective species (Löfstedt et al., 1991). The case of *Y. evonymellus* and *Y. vigintipunctatus* is, however, different from that of SL and SD because these species are reproductively isolated by their asynchronous occurrence and differences in habitats (Löfstedt and Van Der Pers, 1985).

In the laboratory, if confined in boxes, SL and SD hybridized and produced fertile offspring in both reciprocal crosses. However, mating frequency was significantly lower in the cross SD × SL than in the reciprocal one. Several

pairs SD × SL could not separate after copulation. Differences in the morphology of genital structures between SL and SD (Lalanne-Cassou et al., 1994) suggest that failure to separate could be linked to genital incompatibilities between males and females. However, further studies are required to understand the importance of morphological features in male–female mating success.

No individual with intermediary morphology between French Guiana populations of SL and SD has been found in the field so far. During the two trapping campaigns in French Guiana in 1982 and 1983, 476 SL and 254 SD of 730 males caught by sexual attractants could be identified in regard to the morphology of the genitalia (Lalanne-Cassou et al., 1994). On the several dozens of individuals caught by light traps, no hybrid form between SL and SD has been found either (Lalanne-Cassou, personal communication).

In the laboratory, with SL individuals originating from Barbados, we found a combination of several mechanisms involved in the reproductive isolation of the species: (1) differences in nocturnal activity cycles may be a partial premating barrier; (2) pheromone specificity has not been proved by flight-tunnel experiments, but it seems to be an effective isolating factor in the field (Lalanne-Cassou et al., 1994); (3) genital differences might constitute a mechanical barrier against interbreeding; and (4) other isolating factors such as differences in host plants might be involved.

Reproductive isolation is generally thought to evolve as an incidental by-product of divergence between allopatric populations. If, upon secondary contact, unfit hybrids are produced, increased isolation will occur. Butlin (1985, 1987) called this process "reinforcement." He distinguished it from the "reproductive character displacement" process of divergence in the mate recognition systems of species already reproductively isolated. In the case of SL and SD, no hybrid morph has been found in French Guiana so far, suggesting that reinforcement is less likely to occur. However, a detailed study of French Guiana sympatric populations, including both enzymatic and pheromonal approaches, is necessary to determine the potential for gene flow between populations and to draw conclusions on the role of sex pheromones in the reproductive isolation. The comparison between allopatric and sympatric populations will be critical to understanding the evolutionary history of the species.

Acknowledgments—We wish to thank Marguerite Leverve for technical assistance. We are grateful to Dr. Christer Löfstedt for reviewing the paper. We also thank Drs. Françoise Lemeunier, Frédéric Marion-Poll, Michel Renou, Didier Rochat, and Pierre Zagatti for comments and advice for the statistical analysis of the data.

This issue of *Journal of Chemical Ecology* contains three papers from a symposium on Plant Allelochemicals in Mammalian Foraging: Current Status and Future Prospects, presented at the Sixth International Theriological Congress (ITC) held in Sydney, Australia, July 4–10, 1993. The contributors to the symposium were asked to seek general patterns or mechanisms by which plant allelochemicals could influence either diet selection or the nutritional quality of different diets in mammals. Not all the papers presented were prepared for final publication. The topics discussed in this symposium were the physiological consequences of ingestion of allelochemicals and the adaptations of mammals that minimize these consequences. An ITC symposium especially directed toward these topics seemed timely, because there is good evidence allelochemicals deter herbivory by mammals. By comparison, little is known about the physiological consequences of ingesting allelochemicals or adaptations mammals have evolved to counter plant chemical defenses. The three papers presented here go a long way toward correcting this deficiency, and furthermore, I would suggest that the ideas presented in them will become paradigms in the study of chemically mediated interactions between plants and mammals that eat plants.

McArthur, Sanson, and Beal review information on the structure and function of salivary proline-rich proteins (PRPs). After reviewing information on the structure of PRPs, and discussing the benefits of binding tannin with PRPs, they provide a scenario of how increased production of PRPs evolved. Their hypothesis is that the original function of PRPs was maintenance of homeostasis, but as tannin-rich plant tissue increased in the diet, increased production of PRPs became selectively advantageous, because it minimized the negative effects of eating tannin. If this hypothesis is correct, mammals such as browsers that feed regularly on tannin-containing plant tissue should produce more salivary PRP than mammals that eat less tannin-rich plant tissue.

The paper by Foley, McLean, and Cork focuses on the physiological consequences of absorbing plant allelochemicals. Their thesis is that detoxification of these substances by mammals results in production of organic acids, which must be buffered and excreted from the body. Since this is likely to occur in all mammals and with all allelochemicals, the hypothesis of Foley et al. provides a unifying theme for future research on chemically mediated interactions between plants and mammals.

Building on the ideas of Foley et al., Illius and Jessop have mathematically modeled the metabolic costs of allelochemical absorption by mammals. This model predicts an interaction between allelochemical dose and nutrient status, so the ratio of allelochemical to nutrient absorption rate defines the tolerance of the animal to the absorbable allelochemical concentration in foods. Since this interaction is nonlinear, the negative effect of allelochemical chemical absorption is expected to be especially high for starving animals. This prediction has important implications for interactions between plants and mammalian herbivores when the herbivore population is at or near its nutritional carrying capacity.

(Received November 7, 1994; accepted February 28, 1995)

Abstract—We review information on the structure of proline-rich proteins (PRPs), their various functions related to oral homeostasis and dietary tannin, and the structural basis of these functions. Consideration of the multifunctional nature of these salivary proteins helps explain both the subtle and large variations found in structure and secretion rates both within individuals and between species. We propose that the ancestral function of PRPs is in maintaining oral homeostasis and that counteracting dietary tannins by binding with them is a derived function. PRPs are effective in oral homeostasis at low secretion levels, whereas counteracting tannin depends on high secretion levels. In the dietary habits ranging from carnivores through omnivores to exclusively plant-eaters, the dietary nitrogen level is progressively reduced, and plant allelochemical intake, including tannins, increases. We suggest that during this evolution from meat-eater to plant-eater, there was some point in omnivory at which selective pressure from nitrogen limitations, arising from a low nitrogen/high tannin diet, became sufficiently great for the evolution of increased secretion level and diversification of PRPs for dealing with tannin. If this hypothesis is correct, carnivorous mammals should secrete low levels of PRPs for oral homeostasis, but should never secrete high levels, unless they are secondarily carnivorous. Omnivores consuming a diet of very little animal tissue but higher levels of tannin-containing foliage or fruit should generally have the capacity to produce high levels of salivary PRPs. Browsers and frugivores should also produce high levels of PRPs, but grazers may have reduced secretion rates depending on the antiquity of the dietary habit. This hypothesis is consistent with the limited information available on the abun-

dance, type, and distribution of PRPs in mammals. Studies are suggested which would test the functional and evolutionary arguments presented.

Key Words—Diet, calcium, carnivore, herbivore, omnivore, oral homeostasis, proline-rich proteins, saliva, secretion, tannin.

INTRODUCTION

Many mammals secrete a group of proteins from parotid and mandibular salivary glands that are characterized by unusually high proline levels. Two main functions have been attributed to these proline-rich proteins (PRPs): maintaining oral homeostasis, and reducing digestibility and toxic costs of consuming dietary tannin. Functions in maintaining oral homeostasis include, most importantly, associations with calcium and its salts (Bennick, 1982), but also roles in lubrication and bacterial aggregation (Bennick, 1982; Hatton et al., 1985; Bergey et al., 1986). Tannin-related function involves preferentially binding tannins, possibly in large amounts per unit protein, thereby increasing the amount of dietary protein available to the consumer (Hagerman and Butler, 1981; Mehansho et al., 1983). Generally the two functions have been considered separately, the first in the human dental literature and the second in the ecological physiology literature. It is informative and necessary, however, to consider both functions together if we are to understand structural, functional, and evolutionary relationships of these proteins in mammals.

There is a wealth of detailed information on some aspects of PRPs. Overall amino acid composition has been described for PRPs from about 15 species (Kauffman and Keller, 1979; Muenzer et al., 1979; Mehansho et al., 1985, 1987; Oppenheim et al., 1985; Austin et al., 1989; Spielman and Bennick, 1989; Mole et al., 1990a; Hagerman and Robbins, 1993). Genetic coding, amino acid sequencing, and posttranslational modifications have been determined for some PRPs, mainly from humans and rats (Wong and Bennick, 1980; Ziemer et al., 1984; Clements et al., 1985; Oppenheim et al., 1985; Kauffman et al., 1991). Some relationships between structure and function have been established (Oh et al., 1980; Wong and Bennick, 1980; Bennick et al., 1981; Hagerman and Butler, 1981; Asquith et al., 1987; Hay et al., 1987). Our aim is to synthesize information on structural/functional relationships of PRPs and to attempt to place this in an evolutionary context.

CHEMICAL AND STRUCTURAL CHARACTERISTICS OF SALIVARY PROLINE-RICH PROTEINS

PRPs vary in chemical composition and associated characteristics, size, and possibly shape. These characteristics and their subtle variations ultimately determine how, and how effectively, they function.

Chemical Composition

Chemical and structural characteristics that vary include amino acid composition, residue sequence, regional and overall charge, and extent of phosphorylation and glycosylation. These properties are best described in relation to the amide (*N*) terminal and the carboxyl (*C*) terminal regions of the molecule.

PRPs are broadly classified as acidic or basic. This reflects overall charge but does not indicate variation in degree of polarity. There are some important functional differences between basic and acidic PRPs, as will be seen below, although some structurally intermediate PRPs have mixed characteristics (Kauffman et al., 1991).

Basic PRPs (BPRPs) are comprised mainly of residues that are uncharged or basic at neutral pH. They are relatively uniform, since just four amino acids make up 70–90% of the total. These are proline (Pro), glutamine (Gln), glutamic acid (Glu), and glycine (Gly) (Kauffman and Keller, 1979; Muenzer et al., 1979; Mehansho and Carlson, 1983; Mehansho et al., 1987). Overall proline levels are generally high (30–45%), but not always. Rabbit BPRPs, for example, contain only 17–21% Pro (Spielman and Bennick, 1989).

Acidic PRPs (APRPs) have two distinct structural domains. The *C*-terminal region is structurally equivalent to the whole BPRP and makes up about 70–80% of the molecule. In contrast to BPRPs, however, APRPs also have a distinct *N*-terminal extension with many highly acidic residues but very little proline (Wong and Bennick, 1980; Ziemer et al., 1984; Oppenheim et al., 1985). The overall amino acid composition of APRPs differs from BPRPs because of this second region, both in the number of acidic versus basic residues and also in the generally lower proline content (15–30%).

At neutral pH, many residues in both BPRPs and APRPs are uncharged. However, the isoelectric pH (pI) of BPRPs is generally high (pI $\geq$ 9), since most of the polar amino acids are basic. In APRPs the pI is low (4–5) (Muenzer et al., 1979), because acidic residues in the *N*-terminal extension dominate. In rats at least, BPRPs are moderately hydrophobic, more so than APRPs (Muenzer et al., 1979).

The "skeletal" PRPs may have phosphate and/or sugar groups added in posttranslational modifications. Phosphorylation, usually of serine, occurs in the acidic *N*-terminal domain and hence is generally a modification of APRPs (Hay et al., 1987, 1988). Up to five phosphoserines have been recorded in APRPs (Oppenheim et al., 1985). Glycosylation of threonine, asparagine, and/or serine may occur throughout BPRPs and in the neutral/basic *C*-terminal region of APRPs. The resulting glycoprotein may be up to 40% carbohydrate (Mehansho and Carlson, 1983; Bergey et al., 1986). To date, glycosylation appears more common in BPRPs, but some APRPs are also glycosylated (Spielman et al., 1991). The major acidic PRP in macaque parotid saliva, for example, is about 30% carbohydrate (Oppenheim et al., 1985), although this extent appears exceptional for an APRP.

Size

Accurate estimates of the molecular weight of PRPs, determined from amino acid sequencing, range from a low of 5000 (Robinson et al., 1989; Kauffman et al., 1991) to at least 25,000 (Muenzer et al., 1979). Apparent molecular weights of up to 220,000 for glycosylated PRPs, based on comparison with standards run on SDS-polyacrylamide systems (Mehansho et al., 1983), are likely to be overestimates because of abnormally slow migration rates of PRPs (Beeley et al., 1991).

Shape

A fundamental and significant feature of PRPs is their shape. In complete contrast to most proteins, whose biological activity depends on specific conformation and folding, PRPs have very little tertiary structure. In solution they are highly elongated rods or random coils (Henkin et al., 1978; Muenzer et al., 1979; Hagerman and Butler, 1981; Hagerman and Klucher, 1986). The lack of folding is largely, but not exclusively, due to proline, whose structure both prevents rotation of the N–C bond of the peptide linkage and prohibits intrachain hydrogen bonding (Lehninger, 1970, p. 113). In polar solutions the open structure of PRPs exposes hydrophobic residues, in contrast to most proteins, in which folding hides these residues. No differences have been noted in the overall shape of acidic and basic PRPs, probably because of the dominating influence of proline. However, subtle or localized differences may exist, particularly given the distinct low-proline acidic *N*-terminal extension of APRPs.

Phosphorylation, a feature of APRPs, is unlikely to have much influence on overall shape for two reasons. First, the extent of phosphorylation is generally small (one to five residues), and second, it is always confined to the acidic *N*-terminal region. Since this acidic region only makes up 20–30% of the molecule, any influence on shape should be confined to local conformation.

Glycosylation may enhance the open conformation of proteins (Hagerman, 1989), although to what extent this can occur in PRPs, which are already long and unfolded, is not clear. Hydroxyproline-rich glycoproteins are less compact than their deglycosylated forms (Asquith et al., 1987), so it is possible that PRPs are also more extended when glycosylated. Consistent with this is some evidence that affinity for tannin, which relies on an open structure (described below), is enhanced by glycosylation (Asquith et al., 1987).

FUNCTIONS OF SALIVARY PROLINE-RICH PROTEINS

Oral Homeostasis

The role of proline-rich proteins in oral homeostasis has been studied mainly in humans, but information from this work should be relevant to other animals.

PRPs contribute to three aspects: calcium homeostasis, lubrication, and bacterial attachment or aggregation.

Teeth are exposed to variable conditions of the semiexternal environment of the mouth, including the potentially wearing chemical and physical properties of food. For reptiles with teeth that are continually being replaced, tooth degradation may not be particularly costly. For mammals, with teeth that may have to last essentially a lifetime, the problem becomes significant. To emphasize the difference, a single tooth position may be replaced 50 times in the lifetime of a crocodile (Miles and Poole, 1967), but only once in a mammal. Tooth enamel became thicker in the evolution from reptiles to mammals (Poole, 1967), providing, among other factors, a greater buffer against degradation. Dental enamel of both reptiles and mammals is composed largely of hydroxyapatite, a basic calcium phosphate salt. While hydroxyapatite is relatively insoluble in aqueous solutions, it will nevertheless gradually be worn away by food and dissolve in saliva, unless counteractive mechanisms prevent this (Hay and Moreno, 1989).

In humans, and the only other toothed mammals investigated, saliva is supersaturated with basic calcium phosphate salts, including hydroxyapatite (Schlesinger and Hay, 1977; Schluckebier et al., 1989). This supersaturation acts to stabilize, protect, and repair tooth surface enamel, by maintaining an equilibrium of calcium salts in and out of solution. Equilibrium is not achieved automatically, however, but relies on inhibitory activity to prevent excess precipitation of hydroxyapatite on tooth surfaces (Hay et al., 1987). Acidic PRPs, in particular, appear to play a major role in preventing this precipitation. They achieve this through three closely related functions: calcium binding in solution, hydroxyapatite binding at the tooth surface, and inhibition of hydroxyapatite formation (Bennick, 1982). These processes have been examined in detail mainly with human salivary PRPs (Schlesinger and Hay, 1977; Hay et al., 1979, 1987; Moreno et al., 1979; Aoba et al., 1984), but structurally similar salivary PRPs from other species behave in a similar manner (Oppenheim et al., 1985; Schluckebier et al., 1989; Spielman et al., 1991).

Lubrication of food and tooth surfaces aids food processing, at the same time as reducing tooth wear by reducing friction. Mucin glycoproteins are the major lubricating molecules in saliva, but glycosylated BPRPs (gBPRPs) also have lubricating properties (Hatton et al., 1985).

Glycosylated PRPs can adsorb to bacteria in the mouth, with both positive and negative effects. Agglutination may inhibit attachment of bacteria and remove them through swallowing. Alternatively, some APRPs are bound as part of the tooth pellicle to dental enamel, and adhesion of bacteria to these APRPs may lead to enamel erosion through production of acidic products from bacterial metabolism (Bennick, 1982). There appears to be some specificity between different bacteria and PRPs (Bergey et al., 1986; Gibbons and Hay, 1988), but the significance of this is unclear. Whether the tooth pellicle, including APRPs, can play an important role in this aspect of oral homeostasis in herbivores, as

distinct from omnivores, with the much higher intakes of abrasive food in the former, is unknown.

Counteracting Dietary Tannin

Tannins are phenolic compounds found in foliage and fruits of many trees and shrubs (Goldstein and Swain, 1963; Haslam, 1979; Wrangham and Waterman, 1983). Their defining functional characteristic is a capacity to bind with proteins (Zucker, 1983). From an ecological perspective, their significance lies in their perceived role as plant defense compounds (Feeny, 1976; Swain, 1977; Mole and Waterman, 1987b). Tannin–protein complexes may be less digestible than free proteins. Animals that consume tannin-containing food, such as omnivores, frugivores, and browsers are confronted with a diet with potentially reduced levels of digestible nitrogen.

Salivary PRPs have a very high affinity for tannins, similar to polyproline polymers, an affinity at least three orders of magnitude greater than some other proteins (Oh et al., 1980; Hagerman and Butler, 1981). Hagerman and Butler (1981) suggested that salivary PRPs may protect dietary proteins and digestive enzymes from tannin, since tannins bind preferentially to PRPs even in the presence of 100-fold molar excess of other proteins of lower affinity.

Austin et al. (1989) hypothesize that on chewing tannin-containing food, salivary PRPs bind to tannin released from vacuoles (in the case of leaves), and the indigestible tannin–PRP complex, which is often soluble, passes through the digestive tract and is excreted in feces. Presumably less protein is required to bind all the tannin, providing a quantitative nitrogen saving, and the nonessential amino acids of PRPs are excreted instead of essential amino acids from dietary protein, providing a qualitative nitrogen saving (Robbins et al., 1991). There is accumulating evidence consistent with this hypothesis (Mole et al., 1990b; Robbins et al., 1991; Hagerman and Robbins, 1993).

Toxicity of tannins can be reduced in animals producing sufficient PRPs to prevent degradation and absorption of tannin itself. This is particularly likely in consumption of hydrolyzable tannins, which are often readily degraded to toxic components, but may also be relevant to consumption of some condensed tannins (Clausen et al., 1990; McArthur and Sanson, 1991).

STRUCTURAL BASIS FOR FUNCTIONS OF SALIVARY PROLINE-RICH PROTEINS

Structural Basis of Functions for Maintaining Oral Homeostasis

Activity and binding sites associated with processes maintaining equilibrium of calcium and its salts in and out of solution is confined to the acidic *N*-terminal region of PRPs (Wong and Bennick, 1980; Bennick et al., 1981;

Bennick, 1982; Hay et al., 1987). Activity therefore is almost exclusively a function of APRPs. The acidic residues, aspartic acid, glutamic acid, and serine, are particularly important; aspartic acid probably has a greater effect on activity than glutamic acid (Hay et al., 1979), but phosphorylated serine provides the major activity (Bennick, 1982; Hay et al., 1987). Subtle differences in amino acid composition, such as the substitution of a single aspartic acid residue for asparagine, can have a large effect on affinity (Moreno et al., 1982; Hay et al., 1988).

Larger APRPs may have lower activity than smaller APRPs because the proline-rich *C*-terminal region is extended rather than the acidic *N*-terminal region. The number of active sites in the acidic region is, if anything, reduced in larger PRPs (Bennick et al., 1981), probably due to increased steric hindrance from the longer proline-rich region (Wong and Bennick, 1980). In humans, small acidic phosphopeptides are produced from degradation of larger APRPs in the mouth. Activity of these phosphopeptides, measured as inhibition of hydroxyapatite formation from seeded crystals, is 6–30 times that of APRPs and 20–420 times that of any BPRPs with any activity (calculated from Madapallimattam and Bennick, 1990; Kauffman et al., 1991), again emphasizing the significance of the acidic region to activity.

No studies have directly examined the effect of glycosylation of the *C*-terminal region on calcium function in PRPs, but if anything, it may enhance activity. The major APRP of the crab-eating macaque (*Macaca fascicularis*) prevents both primary and secondary precipitation of calcium salts from supersaturated solutions. This PRP is both highly glycosylated in the *C*-terminal region and highly phosphorylated in the *N*-terminal region (Oppenheim et al., 1985). Unglycosylated APRPs in humans only inhibit secondary precipitation; primary precipitation is inhibited by another protein, statherin (Hay et al., 1984; Schwartz et al., 1992). Whether glycosylation contributes to the high activity in the macaque APRP is unknown, but comparison of calcium-related activity of the native and deglycosylated form could determine this. Similarly, although most of the calcium-related activity of human PRPs is associated with the APRPs, glycosylated BPRPs show some activity, but unglycosylated BPRPs do not (Hay et al., 1982; Oho et al., 1992), indicating that glycosylation is important if the acidic *N*-terminal region is absent. The exception is two human BPRPs, which have some activity, but since these have intermediate structural characteristics including one phosphoserine (Kauffman et al., 1991), this activity is not surprising.

Several properties appear to influence lubricating activity of PRPs. The presence of carbohydrates, the type of carbohydrates, the extent of glycosylation, and therefore the presence and abundance of certain amino acids for linkage are important factors. Glycosylated PRPs have greater lubricating activity than deglycosylated forms (Hatton et al., 1985). Acidic sugars, such as sialic acid,

repel each other, producing an extended molecule that enhances viscosity (Dawes, 1976). Neutral sugars present in some glycosylated PRPs (Keller et al., 1975; Oho et al., 1992) may contribute less to this effect. Glycosylation of PRPs occurs by linkage with asparagine (Hatton et al., 1985), threonine, and serine (Oppenheim et al., 1985). These amino acids are therefore important. The rheological properties of mucins are related to their high level of glycosylation. Similarly, extent of glycosylation in PRPs should also be important, and this varies considerably. Glycosylated PRPs are 9–19% carbohydrate (w/w) in mice (Oppenheim et al., 1985), 6–36% in rats (Muenzer et al., 1979; Mehansho and Carlson, 1983), 5–16% in rabbits (Spielman and Bennick, 1989), and 30% in the macaque (Oppenheim et al., 1985). It is not known whether there are any differences in lubricating properties of these proteins.

Glycosylation of PRPs also influences interactions with bacteria. The type of carbohydrate confers specificity towards certain bacteria. This specificity appears to result from recognition by lectins on the bacterial cell surface of particular carbohydrates (Bergey et al., 1986). Some bacteria bind with nonglycosylated APRPs, but only when these proteins are attached as part of the tooth pellicle. Possibly, segments of APRPs that are normally hidden in solution become exposed after attachment to tooth enamel (Gibbons and Hay, 1988; Gibbons et al., 1988). The structural basis for this interaction with APRPs is not known, but a longer *C*-terminal region enhances bacterial attachment (Gibbons and Hay, 1988), indicating that this region is important.

Structural Basis for Interactions with Dietary Tannin

Less is known about the specifics of interactions of salivary PRPs and dietary tannin than about PRPs and functions associated with oral homeostasis. Anticipating potentially significant structure–function relationships relies on understanding how tannins interact with proteins in general. In polar solutions, tannins interact with proteins through both hydrogen bonding and hydrophobic interactions (Oh et al., 1980; Artz et al., 1987; Hagerman, 1989). It has been suggested that tannins associate with hydrophobic regions of proteins first, followed by hydrogen bonding between hydroxyls of the tannin and polar groups of proteins, including the carbonyl in peptide linkages (Spencer et al., 1988). However, some evidence indicates that if sufficient hydrophobic regions of protein are exposed for interaction with tannins, then hydrophobic interactions predominate. If these regions are hidden, however, hydrogen bonding is more important (Artz et al., 1987). Whatever the type(s) of interaction, conformational flexibility of both the protein and the tannin seems to maximize the interaction, presumably in the case of protein by exposing more binding sites (McManus et al., 1985). Therefore, long open-structured proteins have higher affinity for tannins than compact globular proteins (Hagerman and Butler, 1981;

Butler et al., 1984). Tannin–protein interactions are generally strongest at the isoelectric point of the protein, but proteins with a high isoelectric point seem to interact with tannin over a wide pH range (Hagerman and Butler, 1978).

Structurally, a high proline content is the major feature associated with the exceptional affinity of salivary PRPs for tannin (Butler et al., 1984), as a result of its effect on the shape of the protein. Proline may also strengthen tannin–protein interactions, because hydrogen bonding to a peptide linkage with proline is strengthened by the substituted nitrogen next to the carbonyl (Hagerman and Butler, 1981).

It has been suggested that tannin binding by PRPs is not strongly amino acid dependent provided proline levels are relatively high (Mehansho et al., 1987; Kauffman et al., 1991). This makes sense because of the multiple, unspecific sites available on PRPs for hydrogen bonding and hydrophobic interactions. Furthermore, in general, it does seem that specific amino acid composition and sequence differences of various salivary PRPs have less impact on affinity for tannin than on functions related to oral homeostasis. That is, all salivary PRPs examined have a high affinity for tannin compared with many other proteins. However, there is evidence that PRPs from different species do have different affinities for different tannins (Mole et al., 1990a; Hagerman and Robbins, 1993). Presumably there is a structural explanation for this, which may include differences in amino acid composition or other characteristics.

Amino acids other than proline may alter affinity for tannin by altering the extent of local hydrophobic interactions or hydrogen bonding or by changing local or general conformation. This effect may be more important in salivary PRPs with lower proline levels, with more localized regions less influenced by proline. The affinity of acidic and basic PRPs to tannins may differ because of the acidic amino acids in the *N*-terminal extension in APRPs. Tannins interact poorly, if at all, with acidic polyamino acids, at least at pH $\leq$ 6 (Oh et al., 1980), so tannins may bind weakly or not at all to the acidic domain of APRPs. Given that this region can be 30% of an acidic PRP, its effect may be significant and deserves attention. Examining the interaction of tannins with acidic *N*-terminal and proline-rich *C*-terminal fragments from APRPs, as done for calcium-related activity (Bennick et al., 1981), would be useful.

Salivary PRPs are always high in glutamic acid/glutamine and/or glycine, not just in proline. We suggest that, as with proline, these amino acids should also exert a significant influence on tannin-binding characteristics, because of their likely effect on protein shape. Amino acids can be classified according to their impact on conformation, as α-helix and β-sheet formers or breakers (or no impact) (Chou and Fasman, 1974). Both proline *and* glycine are strong breakers of α-helices. Similarly, glutamic acid is a strong breaker at pH $\geq$ 6, illustrated by the observation that polyglutamic acid exists as a random coil at pH $\geq$ 6 (Lehninger, 1970, p. 113). At salivary pH (6.5 or greater), therefore, the influ-

ence of both glycine and glutamic acid on conformation should be similar to proline. Theoretically, proteins could be functionally similar to PRPs even if they have low Pro levels, provided the level of Glx/Gly is high. Therefore, the total amount of Pro/Glx/Gly in PRPs is probably more important than just the level of proline alone. If so, a more descriptive chemical name such as "PGGRP" (Pro/Gly/Glx-rich proteins) may be more appropriate than PRP. Differences are found in the total amount of Pro/Glx/Gly in PRPs; for example, 47% in the PRP from deer but 90% in PRP from rats (Austin et al., 1989). If a higher Pro/Glx/Gly level produces a molecule that has an extended rather than folded backbone, then it may also increase affinity for tannin. Rat PRP may therefore have higher affinity for tannins than deer PRP.

Other factors, such as total number of residues and extent of glycosylation or phosphorylation, may also confer differences in affinity for tannins. There is little information on the effect of size. It is likely that increasing molecular weight increases affinity, just as it does in polyproline peptides (Hagerman and Butler, 1981); particularly as the appropriate domain for activity, that is, the basic/neutral *C*-terminal end of the molecule, seems to be extended in PRPs rather than the acidic *N*-terminal domain.

There is also little direct information on the effect of glycosylation and phosphorylation on tannin binding. If acidic amino acids in the *N*-terminal domain of APRPs reduce affinity even locally, then phosphorylation may exacerbate this effect. Glycosylation, on the other hand, may enhance affinity and may even confer some specificity for particular tannins (Asquith et al., 1987). This may in part be due to further extension or looseness in molecular shape, exposing more binding sites. It may also result from some interaction with the carbohydrate residues themselves, since tannins interact with polysaccharides as well as proteins (McManus et al., 1985).

Another potential difference between APRPs and BPRPs, when they occur together in saliva, relates to the observation of a wide pH range over which proteins with high isoelectric points precipitate tannin. If BPRPs form complexes with dietary tannin over a similarly wide pH range compared with APRPs (even though the complexes tend not to precipitate), BPRPs may be the major group of PRPs interacting with tannins throughout a mammalian gut (pH range about 2.5–8). Competitive binding curves comparing affinity for one tannin of a BPRP and two APRPs at a given pH showed slight differences between PRPs, but this was insignificant compared with the much higher affinity they all had compared with another protein (Mehansho et al., 1987). However, different conditions, such as pH, or different tannins may alter this affinity (Martin and Martin, 1983; Asquith and Butler, 1986; Mole and Waterman, 1987a) and indicate more subtle differences between the PRPs. The ratio of BPRPs to APRPs varies between species [for example, it is 50:50 in humans (Kauffman and Keller, 1979) but

90:10 in rats (Muenzer et al., 1979)], the consequences of which may therefore be affected by any differences between the two types of PRP.

Clearly, many questions are yet to be answered regarding the significance of structural differences in PRPs on affinity for tannins.

SIGNIFICANCE OF SECRETION LEVEL OF SALIVARY PROLINE-RICH PROTEINS FOR FUNCTION

There is an absence of direct comparative quantitative information on the concentration and rates of secretion of PRPs needed for the two main functions of oral homeostasis versus tannin binding. However, from less direct evidence, it generally appears that the amount of PRPs required to function effectively in oral homeostasis is much lower than for dealing effectively with dietary tannin. Theoretically, mammals consuming tannin-free diets should be in normal oral homeostasis. Secretion of PRPs should therefore be sufficient for any roles in maintaining this homeostasis. One study using rats does indicate that levels of PRPs are both important in and adequate for oral homeostatic function on normal tannin-free diets. If salivary PRP production is inhibited in rats fed a high sucrose diet, their teeth are more prone to demineralization and caries than those of rats with normal PRP production (Watson et al., 1990). The functional implication is clear, even though these salivary and dietary conditions are extreme; that is, PRPs protect teeth under normal secretion rates. Such normal secretory levels, however, are often insufficient for dealing with dietary tannin. Evidence includes the induction of PRP production level and change in parotid gland size by some animals on tannin-rich compared with tannin-free diets, and detrimental consequences in animals in which this does not occur.

Dramatic induction of PRPs occurs in rats and mice fed tannin-rich diets, and the extent of the detrimental effects of tannin on growth and protein digestibility is consequently reduced (Mehansho et al., 1983, 1985; Mole et al., 1990b). In contrast, hamsters produce low levels of PRPs on tannin-free diets, but dietary tannin does not induce production of high PRP levels, and detrimental effects are severe, with growth impairment or death (Mehansho et al., 1987). In rabbits, APRPs make up only about 4% of the total parotid proteins [calculated from Spielman et al. (1991)]; yet since they appear to be the major type of PRP inhibiting hydroxyapatite formation, they are apparently effective in calcium-related activity. Parotid glands in domestic rabbits (presumably on tannin-free diets) are smaller than those in feral rabbits (possibly on diets containing tannin) (Mole et al., 1990a). Similarly, both parotid gland size and the concentration of PRPs for tannin binding is much higher in mountain hares on a tannin-rich diet compared with a tannin-free diet (A.E. Hagerman, G.R. Iason, and C. McArthur, 1993 unpublished data).

Some animals, including humans, produce high levels of PRPs on both tannin-free and tannin-rich diets. It has been proposed (Austin et al., 1989; Robbins et al., 1991; Hagerman and Robbins, 1993) that there is an association between levels of production of PRPs and feeding niche, with mammals that regularly consume high tannin diets producing large quantities of salivary PRPs. Such a pattern would be consistent with the argument that dealing with dietary tannin requires higher levels of PRPs than do functions in normal oral homeostasis.

We have measured salivary protein secretion levels in a number of marsupial species. Table 1 lists the nominal maximum protein secretion rates from parotid glands obtained for several marsupial species. Protein secretion rates vary considerably. Wombats (grazers) secrete very low protein levels and much of this is amylase (Beal, 1991). In contrast, swamp wallabies (browsers) secrete much higher protein levels, and a major proportion is protein with very high affinity for a number of tannins (C. McArthur, A.M. Beal, and G.D. Sanson, 1993 unpublished data). Protein secretion of the grazing parma wallaby is also low compared with swamp wallaby. This comparison would be meaningless unless the samples contain PRPs. Figure 1 illustrates that a large number of the proteins in these parotid secretions from the species that have been tested are indeed rich in Pro/Glx/Gly, although at this stage it is not possible to quantify the exact proportion. However, we conclude from the electrophoretic results (Figure 1) combined with the total protein secretion data (Table 1) that there are different levels of salivary PRP secretion between species and that this reflects potential differences in the capacity to deal with tannin. We are currently examining the salivary protein characteristics of these animals further to determine, among other factors, how much this secretion level may alter on a tannin-rich diet.

IMPLICATIONS FROM STRUCTURE-FUNCTION AND SECRETION-FUNCTION RELATIONSHIPS

Table 2 summarizes types of salivary PRPs described previously, their relative importance in oral homeostasis and counteracting tannin, and the secretion levels required to be effective. Differences in activity have been demonstrated between the various PRPs in relation to oral homeostasis. While all PRPs may have a high affinity for tannins, it is not possible at this stage to generalize about any differences in activity between them.

It is clear that salivary proline-rich proteins must be considered as multifunctional in order to understand the variety of structures and secretion rates. Subtle differences in amino acid composition at the *N*-terminal region of APRPs, for example, are difficult to explain from a tannin-binding function but are

TABLE 1. MAXIMAL FLOW RATES, ASSOCIATED PROTEIN CONCENTRATIONS, AND NOMINAL MAXIMUM PROTEIN SECRETION AS A FUNCTION OF METABOLIC BODY WEIGHT OBTAINED FROM ONE PAROTID GLAND, FOR A RANGE OF MARSUPIALS SPECIES[a]

Species	Predominant dietary habit	Animals (N)	Metabolic body weight ($kg^{0.75}$)	Maximal flow rate (ml/min)	Protein conc. (mg/liter)	Nominal maximum protein secretion ($\mu g/min/kg^{0.75}$)

[a]Results are mean (±SE). Values were obtained during maximal flow stimulated by parasympathetic stimulation in anaesthetized animals (see text for details). Values should be doubled for total parotid output. Species have been grouped on the basis of gut structure (foregut or hindgut fermenter). Predominant dietary habit is indicated, but it should be noted that dietary habits are a continuum. ** indicates that much of the protein in these samples is amylase. Data obtained from Beal (1989a, 1990, 1991, 1992), Scott and Beal (1994), and some data collected here described in Materials and Methods.

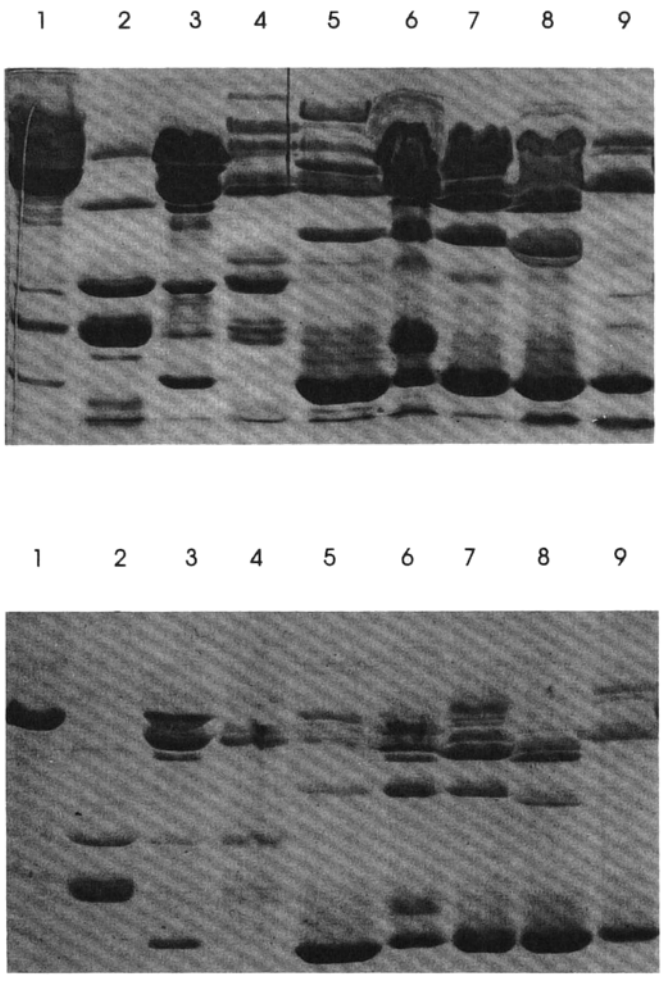

FIG. 1. PAGE analysis of salivary protein samples from eight marsupial species. Upper and lower samples and gels are identical, apart from the destaining solutions used. The upper gel is destained to detect all proteins, including those rich in Pro/Gly/Glx, whereas the destain used in the lower gel detects Pro/Gly/Glx-rich protein poorly if at all (see text for details). All samples are parotid saliva except for lane 4, which is mandibular saliva. Lane 1: wombat (*V. ursinus*), lane 2: common brushtail possum (*T. vulpecula*); lane 3: rufous rat-kangaroo (*A. rufescens*); lanes 4 and 5: mandibular and parotid samples respectively from red kangaroo (*M. rufus*); lane 6: grey kangaroo (*M. giganteus*); lane 7: parma wallaby (*M. parma*); lane 8: red-necked pademelon (*T. thetis*); and lane 9: swamp wallaby (*W. bicolor*). Note the presence of many protein bands in the upper gel which either are completely absent or stain relatively poorly in the lower gel. These bands are proteins which are Pro/Gly/Glx-rich.

TABLE 2. FOUR TYPES OF SALIVARY PROLINE-RICH PROTEINS, THEIR FUNCTIONS, AND SECRETION LEVELS REQUIRED FOR ORAL HOMEOSTASIS, AND COUNTERACTING DIETARY TANNIN[a]

	Oral homeostasis				Counteracting dietary tannin	
Type of PRP	Calcium equilibrium	Lubrication	Bacterial binding	Secretion level required	Tannin binding	Secretion level required
APRP	+++	−	+	low	+?	high
gAPRP	++	+	++	low	+?	high
gBPRP	+	+	++	low	+?	high
BPRP	−	−	−	n.a.	+?	high

[a]Unglycosylated acidic PRP = APRP; glycosylated APRP = gAPRP; glycosylated basic PRP = gBPRP; and unglycosylated basic PRP = BPRP. Under oral homeostasis, the role and relative importance of the various proteins are indicated as no perceived role (−), or a role with increasing importance (+ < ++ < +++). Under counteracting dietary tannin, tannin binding in all cases is shown as: +?, which reflects the lack of information on any differences in activity between the different types of PRPs. n.a. = not applicable.

clearly significant when considered in the context of calcium equilibrium in the mouth.

Nonglycosylated BPRPs *per se*, and differences in amino acid composition of these BPRPs, cannot be explained from a calcium-related or lubricating function, but may be related to tannin affinity. The variation in amino acid composition may reflect a weak functional constraint in residue requirements for affinity to tannin, provided proline levels are high (Kauffman et al., 1991), or they may confer differences in tannin affinity. If the latter proves correct, the apparent lack of functional differences assumed today may simply reflect a lack of studies on detailed structure–function relationships.

Similarly, secretion of high levels of PRPs in some animals, for example, deer and rats, is difficult to explain in relation to oral homeostasis alone. It is explicable, however, if the significance of PRPs in dealing with dietary tannin is considered (Hagerman and Butler, 1981; Mehansho et al., 1983; Robbins et al., 1987; Austin et al., 1989). For humans, we suggest that the high levels of PRPs reflect selective pressure from exposure to a low-nitrogen, high-tannin diet during our evolutionary history.

CONSTRAINTS IN GENERATING GENERAL CONCEPTS FROM AVAILABLE DATA

The patterns of structure, secretion, and function described above have been developed from a fairly restricted group of species, and their generality

needs confirmation from other studies. Hagerman is examining the distribution of PRPs in relation to tannin binding and feeding niche in eutherians, and we are carrying out a similar study with marsupials. Studies are also required on the detailed structure–function relationships of different PRPs in relation to tannin affinity, using better defined proteins (and tannins) than have been examined to date. Information is needed on exactly what influence characteristics such as the presence of an acidic *N*-terminal region, phosphorylation, or glycosylation have on tannin affinity, in order to determine whether these structural differences are significant in this context.

Information is also required on the significance of PRPs in the various functions associated with maintaining oral homeostasis in a broader range of carnivores, omnivores, and herbivores. Is saliva always supersaturated with calcium salts, with an unstable equilibrium potentially leading to excess precipitation of these salts, and therefore requiring inhibitory molecules? If so, are PRPs or other proteins generally present? How important are glycosylated PRPs compared with mucins in lubrication? If their role is always minor, is this function merely incidental?

Much of the information relating to oral homeostasis has been gathered on human saliva. We suggest that there are sufficient similarities in results when other species have been examined to generate hypotheses from the human data. Acidic PRPs, for example, have been found in animals as evolutionarily diverse as other primates, rodents, lagomorphs, and marsupial macropods (Ziemer et al., 1984; Oppenheim et al., 1985; Schluckebier et al., 1989; Spielman et al., 1991; Ferreira et al., 1992), and calcium-related activities have mainly been established in these groups. Similarly, the importance of tooth protection from acids has been demonstrated in rats as well as humans (Watson et al., 1990).

The importance of various functions of salivary proteins in different animals will depend partly on diet. The importance of calcium- and bacteria-related functions in oral homeostasis in humans, for example, is most relevant to other omnivores and frugivores, which consume broadly similar amounts of acidic and tannin-containing fruits or foliage. The functions may be less important to grazing herbivores, which consume much larger quantities overall, but of acid-free and tannin-free herbage. However, these functions should still be necessary, because grazers still suffer related problems of tooth wear but for different reasons; that is, much higher chewing levels combined with abrasiveness of silica bodies in grasses. Presumably they have similar salivary systems of high mineral content also requiring mechanisms to maintain an equilibrium. Certainly calcium and phosphate levels in saliva of grazing ruminants are not insignificant (Manas-Almendros et al., 1982).

Finally, there is little information on the oral microflora of mammalian carnivores, omnivores, or herbivores. Consequently its significance is unknown.

There is no reason to believe, however, that animals other than humans should be less prone to the colonization of potentially detrimental bacteria, and therefore they are just as likely to require some means of influencing both the establishment of benign bacteria and the removal of detrimental ones.

The limitations in the data now available simply mean some caution must be taken when generalizing. Provided implications of the differences as well as the similarities in, for example dietary habits, are considered, some interesting and testable hypotheses can be generated regarding the evolution of the structural and functional diversity of salivary proline-rich proteins.

EVOLUTIONARY PERSPECTIVE OF MULTIFUNCTION SALIVARY PROLINE-RICH PROTEINS

Two evolutionary hypotheses could explain the abundance, variety, and distribution of salivary PRPs in mammals. The first hypothesis is that PRPs evolved originally as proteins involved in maintaining oral homeostasis, and their role in dealing with dietary tannin is a derived feature, depending on higher secretion levels than that used in oral homeostasis, and improved by changes in, or diversification of, structure. The second hypothesis is essentially the opposite, that dealing with dietary tannin is the fundamental function of PRPs, and roles in oral homeostasis are derived. We suggest that the evidence available favors the first hypothesis.

Evolutionary Hypothesis of Functional Expansion of Salivary Proline-Rich Protein in Relation to Dietary Niche

A generalized scheme of the grades of dietary niche in mammals is shown in Figure 2. In both eutherians and marsupials, there has been an evolutionary progression from carnivory (generally insectivory) through omnivory to herbivory (including fruit-eating). Carnivores consume a nitrogen-rich diet. Omnivores eat a mixture of animal tissue and plant material. This plant material is generally much lower in nitrogen than animal tissue and contains structural and chemical defenses. Omnivores eating mainly animal tissue consume a nitrogen-rich diet, but as less animal tissue and more plant material is eaten, intake of digestible nitrogen decreases and intake of plant allelochemicals increases. Digestible nitrogen is reduced both because of lower nitrogen levels in plants and also from tannins that can further reduce digestibility. Herbivores consume a nitrogen-poor diet, with various levels of allelochemicals.

We suggest that along the omnivore gradient to mainly plant-eater, two dietary costs—nitrogen limitation and toxicity—increased, requiring counteractive mechanisms. When nitrogen is potentially unavailable due to tannin, secre-

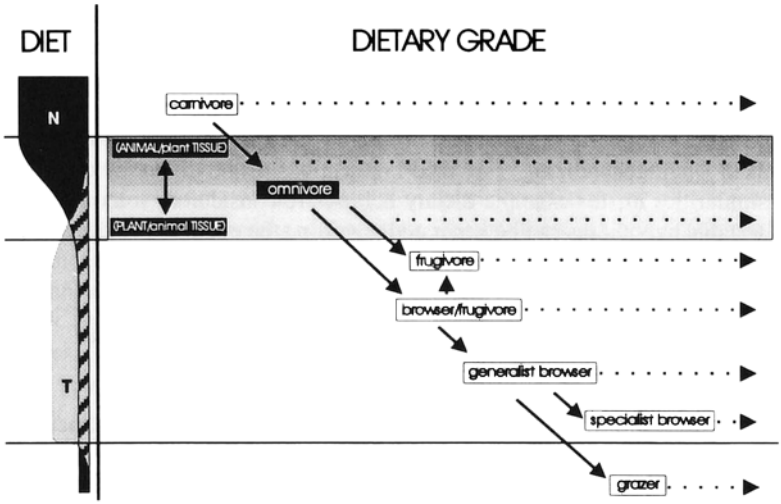

FIG. 2. A generalized scheme of the evolution of dietary grades in mammals and their associated dietary characteristics. Carnivory (insectivory) is the primitive dietary grade. Omnivores follow a gradient from eating mainly animal tissue to eating mainly plant tissue. This is associated with decreasing dietary nitrogen (N) and increasing dietary allelochemicals including tannin (T). Browsers/frugivores also consume low nitrogen, high tannin diets, whereas grazers consume low-nitrogen diets with little or no tannin. (See text for details).

tion of high levels of high-affinity tannin-binding salivary proteins (generally PRPs) reduces the loss of available nitrogen and also reduces the toxicity of tannins by preventing any degradation. Another mechanism, which will not be discussed further, is an increased capacity for degrading and eliminating absorbed toxic components. These mechanisms should be reinforced in herbivores consuming mainly browse foliage and fruits. We suggest, therefore, that one major evolutionary change required in the dietary shift to predominantly plant material was a significant increase in the secretion levels of the already-present PRPs. This enabled a functional expansion from simply maintaining oral homeostasis to counteracting dietary tannin as well.

A second evolutionary change may have been a diversification in structure of PRPs, with associated differences in affinity for tannin. Figure 3 illustrates a proposed sequence in the evolution of different types of PRPs. All PRPs, *except* unglycosylated BPRPs, function in oral homeostasis (Table 2), therefore APRPs and possibly gBPRPs probably evolved in early carnivores (if not in reptilian

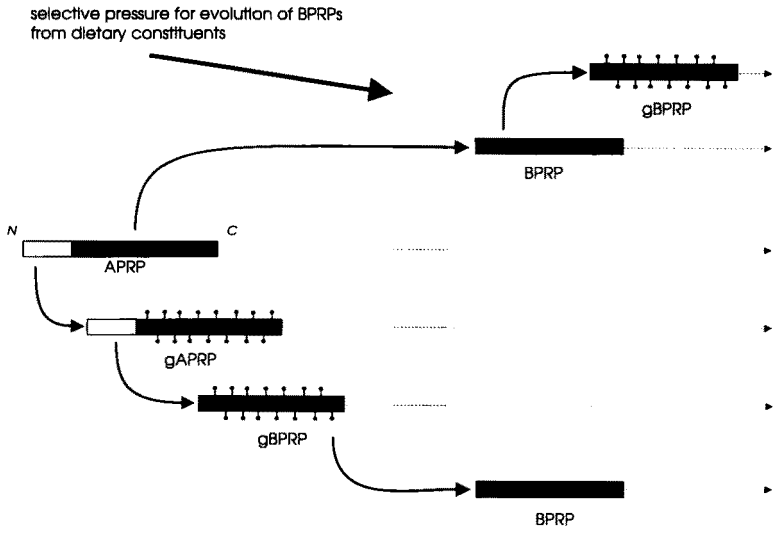

FIG. 3. Proposed pathways in the evolution of different types of proline-rich proteins (PRPs). In the lower pathway, the APRP first becomes glycosylated in the proline-rich region (bobbles attached to the *C*-terminal darkly shaded section) (gAPRP). Next the acidic domain is lost, producing a glycosylated basic PRP (gBPRP). Finally, deglycosylation leads to a simple basic PRP (BPRP). The alternative (upper) pathway has just two steps. First, the APRP loses the acidic domain to produce a BPRP. Second, the BPRP is glycosylated (gBPRP). Either or both pathways are possible. The evolution of BPRPs required selective pressure associated with costs of dietary constituents (mainly low nitrogen and high tannin levels) (See text for details).

ancestors). We suggest that BPRPs evolved when mammals began to consume a diet that was both low in nitrogen and had the additional cost of tannins. This scenario should be reflected in the variety, secretion level, and distribution of PRPs in mammalian species from different dietary niches today.

Support for Hypothesis of Changes Associated with Functional Expansion of Salivary PRPs

Given that the level of PRPs required to counteract tannin appears to be much higher than required for oral homeostasis, a proposed evolution of increased secretion of PRPs with functional expansion is understandable, particularly if

there are costs in producing high levels of PRPs unnecessarily. PRPs are relatively poorly digested, because many peptide bonds involving proline are resistant to cleavage (Muenzer et al., 1979; Wong and Bennick, 1980; Oppenheim et al., 1985). Production of excess PRP may therefore incur a nitrogen cost. Grazers consume a nitrogen poor diet that generally lacks tannins, so selective pressure should be strong for reduced secretion rates of PRPs (Robbins et al., 1987; Austin et al., 1989), even if their ancestors produced higher levels.

Evolution of PRP diversification, including BPRPs, can only be understood in a multifunctional context. Effective functioning in calcium homeostasis, lubrication, bacterial aggregation, and tannin binding require some different and sometimes slightly conflicting structural characteristics. Presumably there is variation in tannin binding associated with some structural differences in PRPs, but there is insufficient information at this stage to make any generalizations. Clearly this is an important area for future research.

There is evidence that BPRPs function specifically in dealing with tannin and are associated particularly with the parotid salivary gland, and that the parotid gland is more responsive to dietary tannin than other salivary glands. Where PRP production differs among salivary glands, BPRPs are present or induced in parotid but not mandibular glands. For example, APRPs are present in mandibular and parotid secretions in rabbits, but BPRPs and mRNA coding for BPRPs are only produced in the parotid (Ferreira et al., 1992). Exactly the same pattern is seen in humans (Robinson et al., 1989; Kauffman et al., 1991), except for a single BPRP in submandibular secretions. This single BPRP is a telling exception because it is apparently derived by postsecretional cleavage of an APRP, whereas all the other BPRPs are secreted by the parotid essentially unchanged (Kauffman et al., 1991). Furthermore, dietary tannin induces a massive increase in production of PRPs in rats and mice, but only in the parotid gland (Mehansho et al., 1983, 1985), even though the β-agonist isoproterenol increases production in both parotid and mandibular salivary glands (Muenzer et al., 1979; Mehansho and Carlson, 1983; Mehansho et al., 1985). Finally, a tantalizing piece of evidence for the evolution of BPRPs from APRPs is that in humans the decoded nucleotide sequences for BPRPs are much longer than the secreted sequences, and the extra region not appearing in the secreted BPRP corresponds to an acidic *N*-terminal region found in APRPs (Minaguchi and Bennick, 1989).

PRPs are not the only proteins involved in oral homeostasis in different animals. This is not surprising given that at least one major role (calcium-related function) relies mainly on the proline-poor end of the molecule. The implication is, however, that some mammals may not use PRPs at all, provided they have other proteins, such as histatins or cystatins (Shomers et al., 1982; Oppenheim et al., 1986; Minaguchi and Bennick, 1989) to perform the same functions. This is fascinating in an evolutionary sense, because these proteins have low

levels of proline (and Gly/Glx) and therefore are unlikely to have a high affinity for tannin. If any ancestral carnivores produced only these proline-poor proteins for oral homeostasis, then the capacity to evolve the changes required to counteract dietary tannin by salivary proteins would be difficult and may even have constrained the evolution of such groups to different dietary niches.

Predictions and Suggested Tests of the Hypothesis

The first major point of the above hypothesis is that secretion levels of PRPs increased significantly during the evolution from omnivores consuming a nitrogen-rich diet to those consuming a nitrogen-poor, allelochemical-rich diet including tannins. Carnivores should therefore secrete much lower levels of PRPs than browser/frugivores. The second point of the hypothesis is that BPRPs seem related only to counteracting dietary tannin. BPRPs should therefore only be produced by animals that, or whose ancestors, had to deal with significant levels of dietary tannin on a nitrogen-poor diet. Examining salivary characteristics of related species from a range of dietary niches would test these predictions.

Shrews, for example, which are in many ways similar to early mammals and which are always insectivorous, should never produce high levels of PRPs and should lack BPRPs. Carnivores that are secondarily derived, however, may produce high levels of PRPs if their evolutionary history includes the adaptive threshold in diet type provoking changes in PRP secretion. Polar bears (*Ursus maritimus*), which are largely but not exclusively carnivorous, may have evolved from mid-Pleistocene *Ursus arctos* (brown and grizzly bears) (Kurten and Anderson, 1980) that are omnivorous. The related omnivorous black bear (*Ursus americanus*) secretes high levels of PRPs (Robbins et al., 1991; Hagerman and Robbins, 1993), and polar bears may too.

In primates, the suborder Prosimii includes carnivorous, omnivorous, and herbivorous species that would provide a reasonably closely related group to test for functional and structural differences in PRPs. In Madagascar, a comparison of *Microcebus murinus* (gray mouse lemurs) and *Lepilemur ruficaudatus* could be made. *Microcebus* has a diet of about 35% insects, 50% gum, and only 15% leaves, a nitrogen-rich diet; while *Lepilemur* eats no animal tissue, but nearly 75% browse leaves and the rest fruits, a nitrogen-poor diet (Fleagle, 1988). *Microcebus* should produce low levels of PRPs, probably lacking in unglycosylated BPRPs. *Lepilemur* should secrete high levels of PRPs, including BPRPs.

Bats appear to have evolved from primitive insectivorous mammals similar to shrews (Anon., 1983). The order Chiroptera is divided into the suborder Megachiroptera (fruit-bars and their relatives) and the suborder Microchiroptera (insectivorous bats). A comparison of salivary characteristics between these

would also test the hypothesis. Even better, some microchiropterans have secondarily become adapted to a diet of fruit, nectar, and pollen, so a comparison between these and the insectivorous species from the same suborder would be fruitful.

SUMMARY

As indicated by this review, proline-rich proteins and their roles in maintaining oral homeostasis and counteracting dietary tannin have been examined by a number of research groups from a variety of angles. At this stage, more is known about the effects of amino acid composition, phosphorylation, and glycosylation of salivary PRPs on their function in oral homeostasis than in binding with tannin. We have synthesized the information available and proposed an evolutionary hypothesis that we believe clarifies our understanding of the variation in both type and secretion level of salivary PRPs found in mammals today. Predictions from the hypothesis are testable. However, at this stage more studies on structural and functional characteristics of saliva from species from a broader range of dietary niches are required.

Methods and Materials

Saliva Collection. Parotid saliva was obtained from eight marsupial species: common wombat (*Vombatus ursinus*), common brushtail possum (*Trichosurus vulpecula*), rufous rat-kangaroo (*Aepyprymnus rufescens*), red kangaroo (*Macropus rufus*), grey kangaroo (*Macropus giganteus*), parma wallaby (*Macropus parma*), red-necked pademelon (*Thylogale thetis*), and swamp wallaby (*Wallabia bicolor*). These herbivorous marsupials include both foregut and hindgut fermenters and provide a range of species having natural diets with different levels of tannin.

A brief synopsis of the methods used to obtain samples is given here, as the protocols for particular animals have been published in detail elsewhere [possum, Scott and Beal (1994); rat-kangaroo and other small macropods, Beal (1992); wombat, Beal (1991); and kangaroos, Beal (1987, 1989a,b)]. Anesthesia was induced either by intraperitoneal injection of sodium pentobarbitone in animals with body weights up to 3 kg (possum and rat-kangaroo) or by intramuscular injection of ketamine hydrochloride in larger species. A peripheral blood vessel was cannulated (possums, saphenous artery; wombat, saphenous vein; other species, lateral tail vein) to allow maintenance of anesthesia by vascular administration of pentobarbitone. The trachea was intubated through its pharyngeal orifice and salivary ducts were catheterized via their oral openings to facilitate collection of uncontaminated saliva.

Saliva samples were obtained under two conditions. First, samples were

collected at maximum flow rate. These were used for determination of nominal maximum protein secretion rates. Maximum salivary flow was stimulated parasympathomimetically using either bethanechol or acetylcholine chloride. In the smaller species, bethanechol was infused via the peripheral vascular cannula at rates dependent on the size and response of the particular animal. In kangaroos and wombats, acetylcholine was infused into the carotid artery, just upstream from the salivary glands, via a chronic cannulation of the artery (wombat) or temporary cannulation of the artery either *in situ* (grey kangaroo) or exteriorized in a loop (red kangaroo). This treatment produces saliva having flow rates and composition similar to that produced by natural reflex stimulation.

Second, samples were collected at maximum protein concentration. These were used for detecting PRPs by gel electrophoresis. Isoprenaline (β-sympathomimetic) stimulation was used to maximize salivary protein concentrations. Isoprenaline was infused via the vascular cannulae and was superimposed on a background level of parasympathomimetic stimulation. This method increased the protein concentration but did not alter the pattern of protein bands detected by gel electrophoresis (C. McArthur, A.M. Beal, and G.D. Sanson, 1993 unpublished data). One essentially mandibular salivary sample was obtained from a red kangaroo by collection of saliva accumulating in the mouth when the parotid glands were cannulated.

Total protein concentrations were assayed by the method of Daughaday et al. (1952). Saliva was stored at $-90°C$ until analyzed for PRPs by gel electrophoresis. No changes in protein bands were detected over months of storage.

Determination of Nominal Maximum Protein Secretion Rates. Nominal maximum protein secretion rates were determined as a function of protein concentration at maximum flow rate. Examination of available data on protein concentration as a function of different flow rates (Beal, 1987, 1989a, 1991; Scott and Beal, 1994) indicated that maximum total protein secretion was generally achieved at this maximum flow rate, rather than at some intermediate or low flow rate. Data were then expressed in relation to metabolic body weight. These secretion rate values are nominal in the sense that they were obtained under anesthetic. Differences may occur when chewing or feeding on tannin-rich food, and these could not be taken into account here. However, the values are at least comparable between individuals and species because they were all collected under essentially equivalent conditions.

Detection of Salivary Proteins by Polyacrylamide Gel Electrophoresis. Previous electrophoresis of saliva from two to four individuals from each species (except *A. rufescens*: only one individual available) had demonstrated little if any difference in the pattern of protein bands from individuals of the one species, but obvious differences among species (C. McArthur, A.M. Beal, and G.D. Sanson, 1993 unpublished data). Only one sample from each species is illustrated (Figure 1). For each sample, a volume of saliva equivalent to 80–100 μg

total protein was made up to 20 μl with water. If samples were too dilute (*M. rufus* samples), the appropriate volume was reduced on a rotary vacuum evaporator. Each sample was mixed with 4 μl β-2-mercaptoethanol (Sigma M-6250) and 8 μl of a solution containing (1 : 1 v/v) glycerol and 0.5M Tris HCl buffer (pH 6.8), 4% (w/v) sodium dodecyl sulfate (SDS), 0.02% (w/v) bromophenol blue, and boiled for 4 min. Half of each sample (40–50 μg protein) was loaded onto each gel.

Samples were analyzed by polyacrylamide gel electrophoresis (PAGE) (Laemmli, 1970), using the Bio-Rad Mini-Protean II dual-slab electrophoresis system. Chemicals were electrophoretic grade from either Sigma or ICN Biomedicals. The resolving gels were 12% acrylamide with dimensions of approximately 50 × 80 × 0.75 mm, and the stacking gels were 3% acrylamide. Running buffer was 0.025M Tris, 0.192 M glycine, and 0.1% (w/v) SDS. Two gels were run simultaneously for 50 min at a maximum of 250 V and 35 mA (constant amperage).

Gels were fixed and stained in a solution of 0.1% (w/v) Coomassie brilliant blue R-250 in ethanol–acetic acid–water (40 : 10 : 50), for 1 hr. Destaining to detect Pro/Glx/Gly-rich proteins followed Beeley et al. (1991). Proteins rich in these amino acids stain poorly, if at all, if destained in the usual solution of ethanol–acetic acid–water (40 : 10 : 50). However, they appear as pink/violet bands if destained in acetic acid–water (10 : 90). Gel 1 was destained in acetic acid–water (10 : 90), and gel 2 was destained in ethanol–acetic acid–water (40 : 10 : 50), with several changes over two days. Comparison of gel 1 and gel 2, which are identical apart from the destaining solutions used, indicate protein bands that are Pro/Glx/Gly-rich.

Acknowledgments—We would like to thank A.E. Hagerman (Miami University, Ohio) for continuous helpful advice and discussion about tannin-binding salivary proteins. We are very grateful to A. Smilie, A. Bennick, and particularly D.I. Hay for discussions on the roles of PRPs in oral homeostasis. Thanks also to S.J. Cork for initiating our thinking about why PRPs are there in the first place. This paper was written with support from the Australian Research Council (ARC grant 20.091.019).

MODELING METABOLIC COSTS OF ALLELOCHEMICAL INGESTION BY FORAGING HERBIVORES

A.W. ILLIUS* and N.S. JESSOP

Division of Biological Sciences, University of Edinburgh
West Mains Rd, Edinburgh
EH9 3JT, UK

(Received November 7, 1994; accepted February 11, 1995)

Abstract—A mathematical model of intermediary metabolism of allelochemicals by vertebrate herbivores is presented and used to quantify the metabolic costs of detoxification. Conjugation with glucuronic acid and maintenance of acid–base status causes catabolism of amino acid and is shown to result in loss of body protein and depletion of glucose. An interaction between allelochemical dose and nutrient status is found, and the ratio of allelochemical to nutrient absorption rate defines the tolerance of the animal to absorbable allelochemical concentration in foods. The interaction is nonlinear and the ecological implications of this for foraging behavior and diet choice are discussed.

Key Words—Allelochemical, detoxification, acid–base balance, conjugation, glucuronidation, foraging behavior, metabolic cost.

INTRODUCTION

Viewed from one standpoint, life is about making economic choices. For example, animals must allocate time, which is a scarce resource, to competing activities such as foraging and resting, and compare the benefits of including food types in their diet with the costs in time and energy needed to find and process the food (see Stephens and Krebs, 1986 for a formal treatment). Recent interest in the pathways of detoxification of plant allelochemicals by herbivores has suggested that disruption of acid–base balance is an important consequence of allelochemical absorption (Foley, 1992; Foley et al., 1995; Foley and McArthur,

*To whom correspondence should be addressed.

0098-0331/95/0600-0693$07.50/0 © 1995 Plenum Publishing Corporation

1993). Thus, consumption of foods containing absorbable allelochemicals will require the expenditure of energy and materials during detoxification and excretion and maintenance of acid–base balance. These represent metabolic costs that weigh against the nutrient content of the food.

It is the purpose of this paper to estimate these costs, in order to address the question of how they affect the economics of diet choice. We have chosen to approach this by modeling intermediary metabolism and the control of acid–base status. This is intended to complement whole-animal physiological studies (e.g., Foley, 1992; Foley et al., 1995) by isolating and describing the effects of specified metabolic pathways and by testing whether these pathways can actually account for observed responses and are a sufficient description of the system. Modeling also offers the opportunity to examine responses over a far wider range of allelochemical doses and nutrient intake levels than would be possible in physical experiments and, therefore, offers a better chance of detecting interactions and non-linearities in response.

METHODS AND MATERIALS

Model Description

The model is based on that of Gill et al. (1984), with some modifications and extensions. The main changes are to the description of the animal's characteristics, protein synthesis and breakdown, addition of acid–base control, and partitioning metabolic activity between two sites, liver and body. We also distinguish between blood, extracellular fluid volume, and intracellular fluid volume, rather than describing metabolic activity within a single blood volume, as in the original model. A consequence of the changes made to the model, particularly to protein metabolism, is that the model now no longer needs to incorporate an ATP degrader, which Gill et al. (1984) found to be necessary to prevent the accumulation of ATP. Details of the changes made are given below.

The model depicts metabolites, or state variables, as a series of compartments connected by fluxes arising from the appropriate metabolic transformation and fed by steady-state absorption of metabolites from the gut (Figure 1 and Table 1). Fluxes arising from metabolism are given by equations in Michaelis-Menten form. Thus fluxes are primarily dependent on the concentrations of substrates but may be inhibited or augmented by the concentrations of end products. Nomenclature and units follow Gill et al. (1984). Concentrations and quantities of state metabolite i are given by Ci and Qi, fluxes by dQi/dt, and production of j from i by Pij. All these are further identified by the physical compartment, of which there are six: blood, extracellular, and intracellular (bl, ex, in) in either liver or body (l, b); hence Qiexl is the quantity of i in the extra

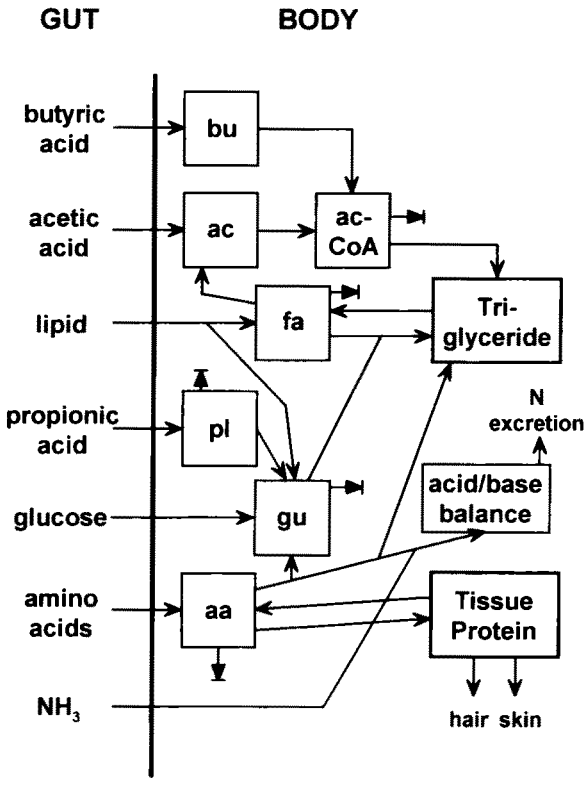

FIG. 1. Simplified compartmental structure of the model showing the metabolic reactions that occur either in liver and/or body intracellular space(s). The reactions involved in acid–base homeostasis are shown in greater detail in Figure 2.

cellular space in the liver, and so on. Mass is given in units of kilograms, volume in cubic meters, time in days, amount of substance in kilogram-moles and concentration in kilogram-moles per cubic meter. The model is programmed in BASIC, and numerical integration is performed by Euler's method. The timestep, dt, was chosen to be 4.167×10^{-5} day, (i.e., 1000 timesteps per hour). Longer timesteps were found to give unstable results, due to the wide range in the magnitudes of the rate constants producing stiffness in the set of differential equations, as noted by Gill et al. (1984). This is a problem that cannot be solved by more sophisticated methods of numerical integration, such as Runge-Kutta.

TABLE 1. METABOLITES, STATE VARIABLES, AND THEIR ABBREVIATIONS

Absorption	Liver	Body	Abbreviation
Acetic acid	Acetic acid	Acetic acid	ac
Propionic acid	Propionic acid	Propionic acid	pl
Butyric acid	Butyric acid	Butyric acid	bu
Glucose	Glucose	Glucose	gu
Lipid	Fatty acids	Fatty acids	fa
		Triglyceride	tg
Amino acids	Amino acids	Amino acids	aa
	Protein	Protein	pt
	Glutamine	Glutamine	gn
	Urea	Urea	ur
NH_3	NH_3	NH_3	ammon
	NH_4^+	NH_4^+	nh
Allelochemicals	Allelochemicals		tp1&2
		Conjugates	cg
	H^+	H^+	h
	HCO_3^-	HCO_3^-	bc
	ATP	ATP	at
	NADPH	NADPH	np
	Acetyl CoA	Acetyl CoA	cz
	O_2	O_2	ox
	CO_2	CO_2	cx

Animal Characteristics. In order to be able to apply the model to ruminants of any body weight (W, kilograms), animal characteristics are scaled with mature mass (A) (Taylor, 1980a). The composition of the live animal is estimated as follows. Gut contents of ruminants and hindgut fermenters is taken to be 0.1766W (Illius and Gordon, 1992 and unpublished) and thus empty body weight, W_{body}, is 0.8234W. Taylor and Murray (1987) suggest the mean lipid proportion of the empty body of mature animals, 0.184, may be taken as a standard, and describe the maturation of fatness by:

$$u_{fat} = u^{0.65} \tag{1}$$

where u_{fat} and u are the degrees of maturity of fatness and of the whole body, respectively. Thus, the proportion of fat in the empty body is $0.184u^{0.65}$ and the weight of adipose tissue in the body is:

$$W_{adip} = 0.184W_{body}\, u^{0.65} \tag{2}$$

Assuming triglyceride to have a molecular weight (MW) of 890, the quantity of triglyceride, Qtg, is $Q_{adip}/890$. After the animal has reached about 0.3

of its mature size, the composition of the lipid-free body remains virtually constant at 23% protein, 5% ash, and 72% water (Taylor and Murray, 1987). Therefore the weight of protein in the body, W_{pt}, is:

$$W_{pt} = 0.23(W_{body} - W_{adip}) \quad (3)$$

If the MW of protein, considered as amino acid, is taken to be 110, then the quantity of protein, Qpt, is $W_{pt}/110$. Finally, Stahl (1965) gives liver weight, W_{liver} as $0.0333W^{0.87}$.

Transport of Metabolites. Circulation of metabolites between the liver and body is achieved by blood flow, with substances absorbed from the gut passing into the portal blood. Within liver and body compartments, concentrations of metabolites in blood and extracellular fluid are assumed to be in equilibrium, while exchange with the intracellular volume is governed by diffusion, or, in the case of glucose and amino acids, by active transport. Full details are given in Appendix 1.

Maintenance of Acid-Base Homeostasis. The scheme depicting maintenance of acid/base homeostasis is shown in Figure 2. With no perturbation to acid–base homeostasis, the production of HCO_3^- from amino acid catabolism is matched by removal of HCO_3^- through ureogenesis. No distinction is made within the model as to the site of amino acid catabolism (be it within the rumen, hind gut, or body) since the net effect is assumed to be the same, i.e., production of NH_4^+ and HCO_3^- within the body. A proton load, caused by an increase in the concentration of acidic compounds, can be neutralized with HCO_3^- diverted from ureogenesis forming carbonic acid and then CO_2, which can be cleared via the lungs. Additionally, there is an increase in excretion of nitrogen in the form of NH_4^+ by the kidney, lowering the concentration of this substrate and hence the rate of ureogenesis, sparing HCO_3^- for use in maintenance of systemic

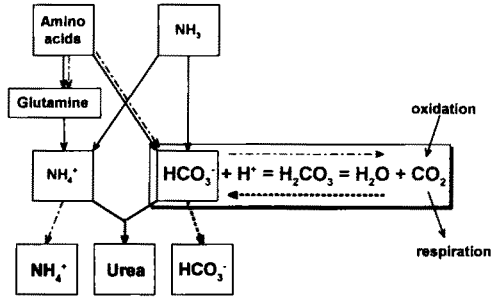

FIG. 2. The metabolic transactions concerned with maintenance of acid–base homeostasis. Fluxes that increase under acidosis are shown with a broken line and those that increase under alkalosis with a dotted line.

pH (Welbourne, 1988). Recent evidence shows that acidosis can lead to an increase in amino acid catabolism (Reaich et al., 1992) increasing buffering capacity.

Seven additional pools have been added in order to model acid–base homeostasis. Full details of these and the metabolic interactions between them are given in Appendix 2.

Conjugation. Allelochemicals absorbed into the body are metabolized in the liver to form acid conjugates to aid excretion (Caldwell, 1982). In the model it is assumed that all conjugation occurs with glucuronic acid derived from liver glucose and that conjugation is not limited by the activity of the enzyme systems involved. The acidic conjugate is exported to the liver extracellular space (Figure 3). Clearance is via the urine, assuming that the kidney receives 20% of cardiac output and of this 20% is filtered by the glomerular structure. There is assumed to be no reabsorption of conjugates from the glomerular filtrate.

Protein Metabolism. Both protein synthesis and breakdown are modeled in the two intracellular compartments. The maximum rate of synthesis and breakdown varies with degree of maturity and the absolute rates also depend on the concentrations of amino acids and ATP within the respective compartments. The pattern of protein turnover achieved is similar to that of Reeds and Fuller (1983). Further details of the description of protein metabolism are given in Appendix 3.

Partition of Metabolism. Fluxes of metabolites described in the model have the same units as the V_{max} terms: kilogram-moles per day per kilogram of tissue. The value given to V_{max} for any particular reaction is assumed to be the same wherever the reaction occurs, for example, in the liver and the body, and thus whole-tissue fluxes are determined by tissue weight and the flux rate per kilogram.

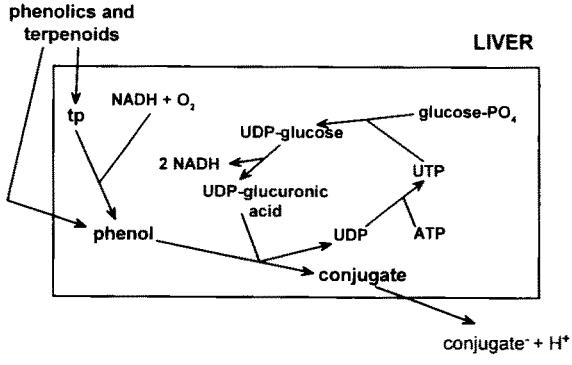

FIG. 3. Representation of conjugation in the model.

TABLE 2. PARAMETER VALUES ADDITIONAL TO GILL ET AL. (1984)[a]

Reaction	Kij(k)	Jij(k)	Yij(k)	Rij(k)	Mij(k)
aabc			1		
aacxbc		8.0×10^{-3}			4
aagn			0.5		
aapm	2.5×10^{-4}				
aapt	4.5×10^{-4}				2
aaptat	3.2×10^{-5}				
aatr	8.0×10^{-3}				4
bcur	1.0×10^{-2}				4
gnnh	2.0×10^{-3}		2		
gnur	2.0×10^{-3}				
gnurh		6.0×10^{-8}			8
gutr	1.1×10^{-2}				4
hpump				0.33	
nhgn	2.5×10^{-3}		0.5		
nhgnat				1	
nhur	5.0×10^{-4}		0.5		
ptaa	3.0×10^{-4}				

[a]For example, Yaabc is the yield of bicarbonate on catabolism of amino acid requied in equation 33, and Jaacxbc is the inhibition parameter for bicarbonate on the metabolism of amino acids to carbon dioxide (equation 37). Rhpump is the requirement of ATP for the Na^+/H^+ antiporter on the plasma membrane.

Parameters: V_{max}. It is assumed that the maximum rate of ATP use (Vat) is that which occurs at three times the rate at maintenance and that the maximal rate of triglyceride synthesis (Vtg) is such that it consumes ATP at Vat. Most other V_{max}s are set in relation to Vtg or Vat (see Gill et al., 1984). Other values for V_{max} are given in the text.

K_m values are given either by Gill et al. (1984) or are shown in Table 2.

Model Performance

Predictions from the model were obtained for a ruminant at 75% of its expected mature size of 50 kg. This was chosen to be consistent with the original model of Gill et al. (1984) and to make any departures from its results more apparent. Similarly, nutrient absorption was provided by values from the roughage diet of Gill et al. (1984), varying as required the amount but not the ratio of nutrients, and maintaining constant rates of absorption throughout each run.

The estimated efficiency of metabolizable energy (ME) use for maintenance, k_m, was 0.74, close to that expected from Agricultural Research Council (1980), while the efficiency of ME use for gain, k_g, was 0.61. This is higher

than Agricultural Research Council estimate (1980), but no higher than the estimate of Ørskov et al. (1979), obtained from lambs maintained by intragastric infusion. The composition of empty body gains during normal growth of sheep at 75% maturity is predicted by the Agricultural Research Council (1980) to be 12.3% protein and 56.7% fat (mean of male and female sheep). By comparison, the model predicts 9.3–13.8% and 71.2–57.1%, respectively, for the protein and fat content of empty body gain at intakes 1.25–2 times maintenance for an equivalent animal.

Changes in the pattern of N excretion following steady-state infusion of a proton load are shown in Figure 4. The effect of acid load on this pattern is similar to that reported previously (Häussinger et al., 1988; Foley, 1992). The slow decline in urinary urea, despite cessation of ureogenesis, can be explained by the large body pool of urea in our modeled animal (W = 37 kg) in comparison with that in the smaller (W = 1 kg) animals studied by Foley (1992).

Table 3 shows a comparison of the model's predictions with the empirical data of Pehrson (1979, 1983), and Palo et al. (1983) on mountain hares (*Lepus timidus* L.) consuming three age-classes of birch twigs (*Betula pubescens*). They found that the youngest twig sections (0–1.5 mm diameter) were eaten in lower quantities, apparently due to their higher allelochemical content and despite higher digestibility than older twig sections. Pehrson (1983) commented that the extent of weight losses by hares fed on *Betula* were partly due to the high Na losses experienced as a consequences of allelochemical intake. To generate predictions from the model, we assumed that daily rates of allelochemical absorption were some multiple of the urinary excretion of phenolics reported by Palo et al. (1983) (see Table 3), since biliary excretion may be three to four times the urinary glucuronide loss in rats (Mulder et al., 1982) and could have

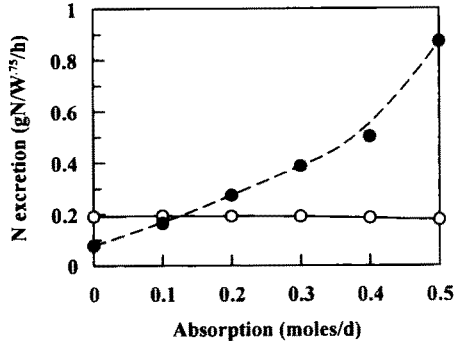

FIG. 4. Predicted changes in the pattern of nitrogen excretion as urea (○) or NH_4^+ (●) as the absorption of protons increases from 0 to 0.5 mol/day.

1.5–3	269	10.0	37.1	117.7	1.06	0.17	0	+11	+ 1	−16
3–5	231	2.5	10.8	110.5	0.86	0.04	−33	−34	−36	−42

[a] Data from Pehrson (1979), Palo et al. (1983), and Pehrson (1983).

been much higher in the experiment of Foley (1992). We therefore made predictions for three rates of allelochemical absorption: 1, 3, and 10 times the observed rate of urinary phenol excretion. Despite these uncertainties, comparable model predictions show reasonably good agreement between predicted and observed daily weight losses, with a tendency to underpredict weight loss in animals feeding on high-allelochemical twigs. This may arise from effects on Na balance, which are not modeled.

Experiments Performed with the Model

We wished to estimate the changes in metabolism arising from absorption of allelochemicals. The allelochemical was represented by a phenolic or terpenoid with a MW of 150, such as terpineol, cineole, or cymene, which are typical constituents of the foliage of *Eucalpytus* (Eberhard et al., 1975). If it is assumed that 25% of the phenolics and 100% of the terpenes consumed were absorbed by animals in Foley's (1992) experiment, then dose rates of up to 0.03 mol/$W^{0.75}$/day can be estimated, equivalent to 0.4 mol/day for our modeled animal. Accordingly, doses of 0–0.5 mol allelochemical were examined using the model, in combination with nutrient absorption rates of 0.01–3 times the amounts estimated to maintain energy balance. The rate of allelochemical absorption was held constant over the course of each run, as was the case for nutrients. The rates of glucuronidation required by these doses do not exceed those implied by the data of Price et al. (1987) estimated in rats.

Two forms of experiment were performed. First, the short-term effect on metabolism was estimated from fluxes occurring 12 hr after the beginning of each run. To distinguish effects of acid-base perturbation from the effects of conjugation of allelochemical with glucuronic acid, a comparison was made of fluxes arising from allelochemical absorption and from an equimolar quantity of protons. Maintenance quantities of nutrients were supplied throughout in the ratios presented by Gill et al. (1984) to represent a forage diet. Second, the long-term tolerance to allelochemical dose was estimated at a range of nutrient intake rates. Tolerance was arbitrarily defined as the maximum dose sustainable over a four-day period, on the assumption that enzyme systems involved in cosubstrate supply and conjugation would be induced over that timescale. This would maintain indefinitely the tolerance to a dose that was at critical concentration over the initial four days. Once tolerance had been estimated over a range of nutrient intakes, three investigations were pursued. Metabolic responses to a combination of doses and nutrient intakes could be established, choosing the hour 24 after commencement as a time when steady-state solutions had been achieved in all cases. The concentration of maximum tolerable absorbable allelochemical in foods was estimated by assuming a nutrient density of 10 MJ ME/kg dry matter (DM). Last, the interaction with fiber content was examined. The

model of Illius and Gordon (1991, 1992) was used to estimate the minimum potential digestibility (calculated from the sum of the cell contents and digestible cell wall) of a browse diet required to sustain a range of nutrient intake rates (0.4–3 times maintenance) in the absence of allelochemicals. The diminution in energy yield was then calculated: (1) from the dilution effect of the presence of absorbable allelochemical (and assuming that all allelochemical was absorbed), and (2) from the energy costs of allelochemical metabolism and excretion.

RESULTS

Short-Term Responses. Steady-state amino acid breakdown arising from proton absorption is contrasted with that from allelochemical absorption in Figure 5a. The absorption of amino acids is also shown. Without either allelochemical or exogenous proton sources, the positive balance of amino acid absorption over breakdown represents the daily rate of endogenous protein loss in hair and sloughed skin. The dose–response to proton absorption shows an excess of amino acid breakdown over absorption and represents the catabolism of amino acids to bicarbonate for neutralization of the proton load. Allelochemical absorption imposes the further cost of increased amino acid catabolism in gluconeogenesis to glucuronic acid for conjugation and formation of the hydrophilic acid glucuronide which can be excreted.

The resulting changes in body protein and fat masses are shown in Figure 5b. Protein losses range up to 12 g/day from allelochemical absorption, but only 4 g/day from protons. Due to the net flux of amino acids away from protein synthesis, the energy cost of the latter is spared, causing increased fat synthesis under proton absorption, while this energy is used for glucuronic acid under allelochemical absorption. The net effects on the body weight of the whole animal, shown in Figure 5c, indicate losses of 250 g/day arising from costs of allelochemical metabolism, but only 50 g/day from the costs of maintaining acid/base status under an exogenous proton load. The majority of this weight loss is in the form of water associated with protein.

Long-Term Responses. Stable solutions to the combination of allelochemical dose and nutrient absorption rate were obtained by 24 hr after the start of each run, and the results presented are taken from them and expressed as daily rates (Figure 6). The effects of dose (x axis) and nutrient intake rate (z axis) on weight change (y axis) are depicted. This response surface is not planar, indicating an interaction between the two independent variables. At high rates of nutrient intake (e.g., three times maintenance) the dose–response to allelochemicals is less steep than at low rates (less than maintenance). The contours of response surface are isoquants of weight change, connecting combinations of

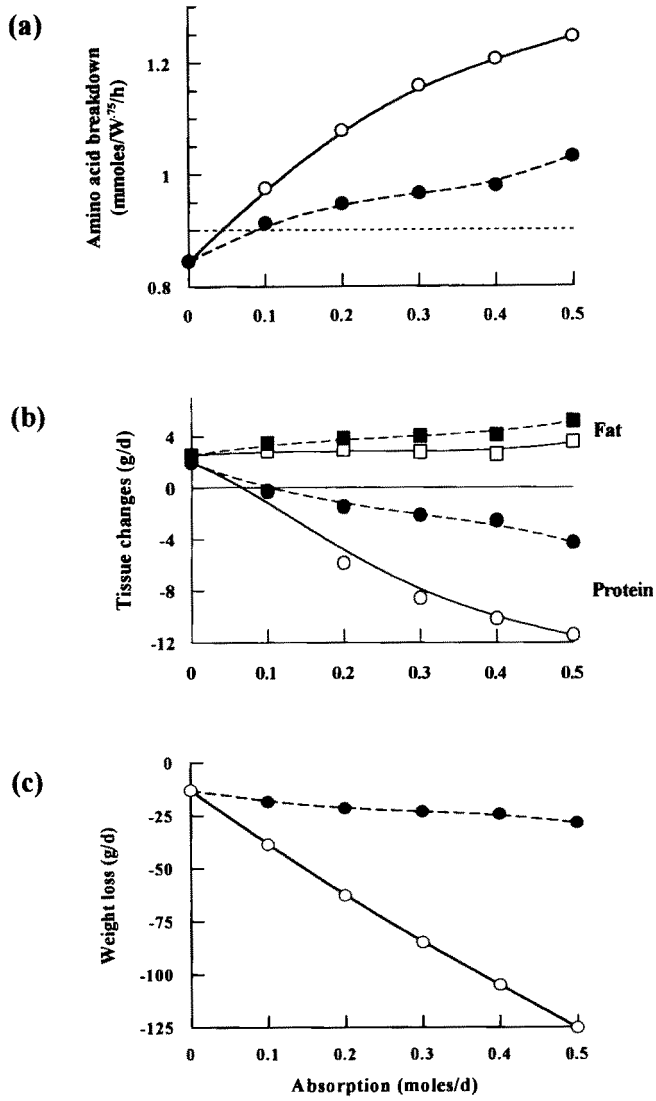

FIG. 5. (a) Predicted changes in the rate of amino acid catabolism caused by the absorption of either protons (closed symbols) or allelochemical (open symbols) at rates up to 0.5 mol/day. Amino-acid absorption (------) was constant throughout. (b) Equivalent changes predicted for body fat (□, ■) and protein (○, ●), and (c) body weight, following proton or allelochemical absorption.

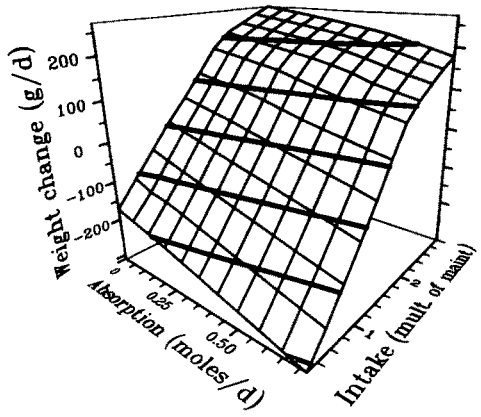

FIG. 6. The influence of allelochemical absorption across a range of intakes on the predicted weight change of the modelled animal. The contours show the combinations of allelochemical absorption and nutrient intake which result in equal weight changes.

allelochemical dose and nutrient intake which produce equal rates of weight change.

The interaction of allelochemical dose and nutrient intake rate is examined further by determining the tolerance of the modeled animal to allelochemicals (Figure 7). The maximum daily rate of allelochemical absorption sustainable over a four-day run of the model (our definition of tolerance) varies nonlinearly with nutrient intake rate. The minimum rate of nutrient intake below which no

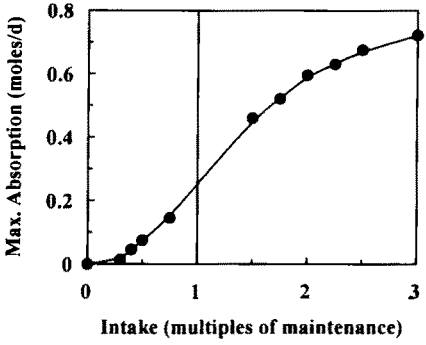

FIG. 7. Predicted allelochemical tolerance over a range of intakes from 0 to 3 times maintenance.

allelochemical could be tolerated was that equivalent to 0.25 maintenance. Above this threshold, tolerance increased exponentially until decelerating at high nutrient intakes, with an inflection approximately at maintenance nutrient intake.

By assuming that the nutrient intake is provided by a food with an energy density of 10 MJ ME/kg DM at zero allelochemical content, we can calculate the maximum tolerable concentration of allelochemicals in foods eaten at the rates supplying 0.25–3 times maintenance (Figure 8). At low nutrient intakes, especially those below maintenance, only low concentrations of allelochemical can be tolerated. Maximum tolerable concentrations are obtained when nutrient intake of around twice maintenance can be sustained. As the modeled animal approaches the limit to metabolism assumed in the model (3× maintenance), the increase in tolerance diminishes.

Contrasts between the effects of allelochemicals and fiber composition on the ability of a food to provide nutrients can be drawn from Figure 9. The solid curve shows the predicted maximum nutrient intake rate that foods varying in potential digestibility can provide the modeled animal assuming it eats to the limits imposed by gut capacity and food turnover time (Illius and Gordon, 1991). Potential digestibility is the sum of the cell contents and the digestible cell wall fractions but can also be written as 1 minus the indigestible cell wall fraction. The dashed line to the right indicates the reduction in nutrient supply rate as a consequence of the passive, diluting effect of the presence of allelochemical at the maximum tolerable concentration defined above. The dotted line shows the further diminution in nutrient supply rate due to the metabolic costs of detoxifying and excreting that dose of allelochemical. It can be seen that a food that has a potential digestibility of 0.7 provides a maintenance intake if no allelochemical is present, but the animal must choose a diet that has a potential

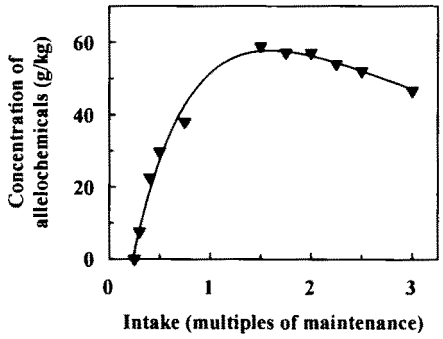

FIG. 8. The maximal tolerable concentration of allelochemical in the food over a range of intakes from 0 to 3 times maintenance.

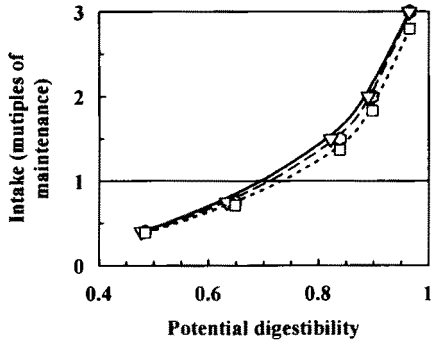

FIG. 9. The relationship between forage digestibility and maximum intake, assuming intake is limited by gut capacity (solid line, from Illius and Gordon, 1991); showing the diluting effect of including allelochemicals at the maximum tolerable concentration (dashed line) and additional effects of the metabolic costs of detoxifying and excreting that dose of allelochemical (dotted line).

digestibility of 0.75 to counteract both dilution and metabolic costs when allelochemical is present. A food with a potential digestibility (recall that the definition permits allelochemical to be part of the cell contents fraction without changing potential digestibility) of 0.7 with allelochemical present would only provide an intake of about 0.9 times maintenance, at which the concentration of allelochemical that can be tolerated is lower. The point of this example is to demonstrate the diminution in the nutritive value of a food due to dilution and detoxification costs. It also shows that this diminution may cause the allelochemical : nutrient ratio to cross the tolerance threshold, resulting in the food becoming unacceptable.

DISCUSSION

The Model. In this modeling study we have quantified the cost of allelochemical detoxification and excretion and have shown that a limit of tolerance to allelochemical absorption exists that is nonlinearly related to nutrient intake rate. Our results confirm that the metabolic pathways described by Foley (1992) and Foley et al., (1995) as being important in allelochemical excretion do indeed function at quantifiable cost. On forage diets supporting limited glucose absorption, the primary cost is expressed in terms of amino acid breakdown to maintain glucose levels for formation of glucuronide conjugates and to provide bicarbonate to neutralize excess protons. Thus, the critical step appears to be gluconeo-

genesis from amino acid precursors. High rates of allelochemical absorption deplete the glucose pool, resulting in failure of the modeled animal's obligate glucose requirement for supply of energy to nervous tissue.

The interaction of allelochemical and nutrient ingestion takes two forms. First, the model revealed that tolerance to allelochemical absorption is dependent on the rate of nutrient absorption. Tolerance of allelochemical was progressively reduced at nutrient intakes that would have been insufficient to maintain energy balance in the absence of allelochemicals. When modeled nutrient absorption was insufficient to maintain weight, the flux of amino acids via gluconeogenesis to conjugation and acid–base control was markedly curtailed. Conversely, at very high nutrient intakes, the surplus of nutrients over utilization capacity produced saturation of the ability to withstand acid load. Second, slightly less amino acid needs to be catabolized per mole of allelochemical at high nutrient intakes, because the excess of amino acid supply over requirements for net protein synthesis leads to normally high rates of amino acid breakdown. Allelochemical conjugation and excretion utilizes this "spare capacity" by diverting the flux of gluconeogenesis to conjugation rather than to lipogenesis, thus reducing the amino acid breakdown specifically for allelochemical metabolism.

The body's reduced tolerance of toxins when under nutritional stress is well known. For example, reduced dietary supply of the sulfur-containing amino acids methionine and cysteine can reduce serum inorganic sulfate in rats and reduce acetaminophen (paracetamol) conjugation with sulfate (Glazenberg et al., 1983). Fasting increases acetominophen toxicity in rats, due to reduced rates of glucuronidation and sulfation and hence reduced clearance (Price et al., 1987). Glucuronidation is partially dependent on liver glycogen stores, since treatment with acetaminophen depletes liver glycogen in normally fed rats, while significant glucuronidation capacity is maintained in fasted rats with virtually no liver glycogen. The capacity of the liver to synthesize the cosubstrate, UDP-glucuronic acid (UDPGA), is reduced in fasted rats and appears to be the rate-limiting process that determines tolerance of acetaminophen (Price and Jollow, 1988). In fasted rats, the UDPGA precursor, UDP-glucose, was lower than in fed rats both before and after an acetaminophen dose, which induced markedly higher blood glucose in both groups. Thus, reduced UDPGA synthesis is not apparently related to inadequate glucose supply from gluconeogenesis or peripheral glucose (Price and Jollow, 1989). The implication of these acute experiments is that the rate of UDPGA synthesis is limited by the rate of formation of glucose-1-phosphate from gluconeogenic precursors, but we have no evidence of whether this limitation applies under chronic conditions and have not attempted to model it. In general, the evidence of nutritional interactions with detoxification strongly supports the qualitative and quantitative behavior of the model.

Ecological Implications. There are a number of ecological implications of

our results. First, we show that the diminution in energy yield of foods to herbivores as a result of the dilution effect of the allelochemicals and the metabolic costs of detoxification is not substantial (Figure 9). It seems likely that allelochemical deterrence of vertebrate herbivory may rely more on effects of amino acid and nitrogen loss and on limited tolerance under nutritional stress. This arises primarily from the interaction between nutrient intake rate and detoxification capacity, and its effect on diet selection.

We have defined "tolerance" to be the maximum absorbed allelochemical dose sustainable by the rate of supply of cosubstrate for conjugation. It therefore comprises the balance between two variables: allelochemical intake rate and nutrient intake rate. An animal cannot consume a food that exceeds the threshold ratio of allelochemical : nutrient unless it can dilute the ratio by adding other foods to its diet. Below the threshold, detoxification ability is sustained by nutrient intake, provided that an animal can eat *enough* of such a food to maintain tolerance. For example, referring to Figure 8, a food with 40 g/kg of absorbable allelochemical is tolerable at intakes that provide more than maintenance energy intakes, but not at lower intakes. This is due to the nonlinearity shown in Figure 7. If the food is scarce enough to limit intake to below maintenance, then insufficient nutrient supply is available for detoxification and so none should be eaten. The way animals will or should modify diet selection and food intake when allelochemical dose is below the limit of tolerance is a question of how the animal weighs the costs of detoxification against the cost of alternative dietary choices. While the loss of body protein during detoxification is a cost that may not be sustainable indefinitely, it may be preferable in the short term to rates of weight loss that would ensue from reducing food intake. Moreover, reducing food intake and hence nutrient suppy will reduce tolerance. So, without alternative food sources that offer lower allelochemical/nutrient ratios, the animal must sustain its intake to supply adequate nutrients to maintain detoxification.

These inferences from the model's results could explain some of the dietary choices observed in vertebrate herbivores. Animals facing depletion of food resources during winter or the dry season have often been observed to discard or avoid current-season's growth of woody browse in preference for more mature growth (Bryant and Kuropat, 1980; Palo et al., 1983; Provenza and Malachek, 1984; Reichardt et al., 1984) (see also Table 3). Current-season's growth is less lignified than older twigs and thus is more digestible and should provide higher nutrient intakes if available in sufficient quantity. However, allelochemical concentration is also higher in current growths, and this acts as a strong deterrent to browsing (Bryant, 1981). It has therefore been concluded that herbivores avoid plant tissues with high concentrations of secondary chemical constituents and that they do not select forage purely on the basis of its proximal nutrient

content (Bryant and Kuropat, 1980). This dietary response is anomalous in the sense that the more digestible plant parts should be preferred by an animal seeking to maximize nutrient intake, but are in fact avoided.

We predict that diet breadth will vary according to the composition and abundance of the variety of forages available. First, if a food contains a high concentration of absorbable allelochemicals, it may be consumed if it is abundant enough and can be eaten at a rate sufficent to provide nutrients for detoxification. Under these circumstances, it could be the only food eaten. If the allelochemical concentration exceeds the threshold of tolerance defined by the rate of nutrient supply (see Figure 8), then the animal must supplement its nutrient supply from sources with lower detoxification requirements in order to reduce the allelochemical/nutrient ratio. Initially, this will broaden the diet (as first suggested by Freeland and Janzen, 1974). If these alternative food sources have low digestible nutrient content, or are scarce, then total nutrient supply will be reduced and tolerance of allelochemicals reduced further until none of the food sources with the higher concentration of allelochemicals can be consumed. Thus, when food supply becomes limiting, we can predict that animals will respond to declining nutrient intake by reducing their intake of current-season growths and narrowing their diet to consist of foods that have sufficiently low allelochemical concentration to be tolerable at low nutrient intake. There is indeed evidence for this narrowing of diet occurring in subarctic herbivores (J.P. Bryant, personal communication). When low abundance of foods limits intake, then the model shows that low concentrations of allelochemicals are sufficient to deter herbivory.

APPENDIX 1. TRANSPORT OF METABOLITES

Circulation is described by reference to blood volume and cardiac output. Blood volume is given by $6.55W \times 10^{-5}$ m^3 (Schmidt-Nielsen, 1984) and apportioned between the liver and body compartments by assuming that the total portal volume, Vbll, is twice that of the liver. Volumes of extracellular and intracellular fluid in liver and body (Vexl, Vinl, Vexb, Vinb) are derived from the fraction of the body water not in blood, apportioned according to the volumes of liver and body, and assuming the extracellular: intracellular volume ratio is 1:3.75 (Eckert and Randall, 1983). Schmidt-Neilsen (1984) gives cardiac output, Tbl, as a function of oxygen consumption (dQox/dt): $\text{Tbl} = a\ d\text{Qox}/dt$, where a is 20, the ratio of Tbl to dQox/dt at an arteriovenous oxygen concentration difference of 50 ml O_2 per liter of blood. Portal blood flow is taken to be 0.25 of cardiac output. The proportion of the portal blood entering the general circulation per timestep is thus 0.25 Qh/Vbll. The transport by the circulation of substance i from the liver to the body, Tilb, and from the body to the liver,

Tibl is:

$$\text{Tilb} = 0.25\ \text{Qh/Vbll Qibll} \tag{4}$$

$$\text{Tibl} = 0.25\ \text{Qh/Vbll Qiblb} \tag{5}$$

Transport by diffusion between extracellular and intracellular compartments follows the standard description, e.g., Tiinl = *ps* (Ciinl-Ciexl), where *p* is the permeability of membranes to substance i and *s* is the total surface area of the cell membrane. The membrane permeability of uncharged/lipophilic substances, such as undissociated VFA and long-chain fatty acids, was taken to be 1×10^{-3} cm/sec while that for charged/lipophobic substances, such as dissociated VFA and glucose, was taken to be 3×10^{-7} cm/sec (Hume and Thomas, 1989; Sharp and Thomas, 1981).

Additionally, for certain metabolites, there are specific transporting mechanisms on the cell surface. Those for glucose and amino acids are represented in the model. The active transport of glucose is described thus:

$$\text{Tguinx} = \frac{\text{Vgutr}}{\left[1 + \left(\frac{\text{Kgutr}}{\text{Cguexb}}\right)^{\text{Mgutr}}\right]} \tag{6}$$

where Vgutr is the sum of V_{max}s of glucose utilizing pathways. For amino acids two types of carrier are represented, the A and L types (Christensen, 1990). These are described thus:

A type:

$$\text{Taainx} = \frac{\text{Vaatr}}{\left[1 + \left(\frac{\text{Kaatr}}{\text{Caaexb}}\right)^{\text{Maatr}}\right]} \tag{7}$$

L type:

$$\text{Taainx} = \frac{\text{Kaapm} \times (\text{Caainb} - \text{Caaexb})}{[(1 + \text{Caainb}) \times (1 + \text{Caaexb})]} \tag{8}$$

where Vaatr is the sum of V_{max} values of amino acid utilizing pathways.

APPENDIX 2. MAINTENANCE OF ACID-BASE HOMEOSTASIS

Liver Periportal Glutamine (gn1inl). Glutamine reaching the liver in portal blood is taken up into the intracellular space by active transport (see above) and enters the liver periportal glutamine pool. It is deaminated to provide one source of NH_4^+ from which urea is synthesized. The rate of production of NH_4^+ from

gn1 is:

$$\text{Ugnnhl} = \frac{\text{Vgnnh}}{\left(1 + \frac{\text{Kgnnh}}{\text{Cgn1inl}}\right)} \tag{9}$$

where Vgnnh is equivalent to the maximum rate of urea synthesis, Vnhur, divided by the yield of NH_4^+ from gn1, Ygnnh. Thus the change in quantity of gn1inl due to metabolism is:

$$\frac{d\text{Qgn1inl}}{dt} = -\text{Ugnnhl} \tag{10}$$

Liver Perivenous Glutamine (gn2inl). Liver perivenous glutamine is synthesized from 2-oxo-glutamate and NH_4^+ released from either amino acid catabolism or escaping ureogenesis in the periportal region of the liver (Häussinger et al., 1988). This glutamine is released from the liver into the general circulation. The production of gn2inl is:

$$\text{Paagnl} = \text{Yaagn} + (\text{Uaacxl} + \text{Uaagul} + \text{Uaatgl}) \tag{11}$$

$$\text{Pnhgnl} = \text{Ynhgn} + \text{Unhgnl} \tag{12}$$

Thus the change in the quantity of gn2inl is:

$$\frac{d\text{Qgn2inl}}{dt} = \text{Paagnl} + \text{Pnhgnl} \tag{13}$$

Liver Ammonium (nhinl). The NH_4^+ pool within the liver is added to by diffusion of NH_4^+ from the extracellular space, or by production from gn1inl:

$$\text{Pgnhl} = \text{Ygnnh} + \text{Ugnnhl} \tag{14}$$

and is utilized either for synthesis of urea or gn2inl:

$$\text{Unhurl} = \frac{\text{Vnhur}}{\left\{\left[1 + \left(\frac{\text{Kbcur}}{\text{Cbcinl}}\right)^{\text{Mbcur}}\right] + \left(1 + \frac{\text{Knhur}}{\text{Cnhinl}}\right)\right\}} \tag{15}$$

$$\text{Unhgnl} = \frac{\text{Vnhgn}}{\left(1 + \frac{\text{Knhgn}}{\text{Cnhinl}}\right)} \tag{16}$$

where Vnhur is the sum of the V_{max}s for amino acid catabolism and Vnhgn is the maximum rate of NH_4^+ production from gn1, Vgnnh, divided by the yield of gn from NH_4^+, Ynhgn. The rate of change of NH_4^+ is:

$$\frac{d\text{Qnhinl}}{dt} = \text{Pgnnhl} - \text{Unhurl} - \text{Unhgnl} \tag{17}$$

Liver urea (urinl). The production of urea is defined by Unhurl (equation 15) together with Ynhur:

$$\text{Pnhurl} = \text{Ynhur} + \text{Unhurl} \tag{18}$$

Thus the change in the quantity of urea is simply:

$$\frac{d\text{Qurinl}}{dt} = \text{Pnhurl} \tag{19}$$

Liver bicarbonate (bcinl). Bicarbonate is formed from catabolism of amino acids, entry of NH_3 into the liver and its subsequent hydration, and is consumed during urea synthesis in equivalent amounts to that of NH_4^+:

$$\text{Paabcl} = \text{Yaagc} * (\text{Uaacxl} + \text{Uaagul} + \text{Uaatgl}) \tag{20}$$

$$\text{Pamminbc} = \text{Tammoninl} \tag{21}$$

$$\text{Ubcurl} = \text{Unhurl} \tag{22}$$

Thus the change in bcinl is

$$\frac{d\text{Qbcinl}}{dt} = \text{Paabcl} + \text{Pamminbc} - \text{Ubcurl} \tag{23}$$

If there is net HCO_3^- use, then this is replaced from hydration of CO_2 to maintain HCO_3^- levels.

Additional fluxes to the liver ATP pool account for the energy cost of synthesis of glutamine and:

$$\text{Unhgnatl} = \text{Rnhgnat} * \text{Unhgnl} \tag{24}$$

$$\text{Uhpumpatl} = \text{Rhpump} * \text{Pcbbcinl} \tag{25}$$

Acid–Base Status in Liver Extracellular Pools. Protons enter portal blood from absorption of undissociated VFA from the gut, which then exist primarily in their dissociated form at normal blood pH; from liver intracellular space in response to an acid load; and from the uptake of NH_3 formed from NH_4^+ into liver. Protons are removed from portal blood when VFA diffuse into liver intracellular space (as the undissociated molecule), on absorption of NH_3 from the gut, which exists principally as NH_4^+ at normal pH and by blood flow to the rest of the body. The change in the quantity of protons is thus:

$$\begin{aligned} d\text{Qhpo} = {} & \text{Aac} - \text{Tacinl} + \text{Apl} - \text{Tplinl} + \text{Abu} - \text{Tbuinl} + \text{Pcbbcinl} \\ & - \text{Aammon} + \text{Tammoninl} + \text{Icopv} * \text{vpo} * (\text{Chexb} - \text{Chexl}) \end{aligned} \tag{26}$$

An acid load causes HCO_3^- to be used to neutralize protons:

$$\text{Ubccbl} = d\text{Qhpo} \tag{27}$$

An alkaline load causes carbonic acid to dissociate into protons and HCO_3^-

$$\text{Ucbbcl} = -d\text{Qhpo} \tag{28}$$

so

$$\frac{d\text{Qbcpo}}{dt} = -\frac{d\text{Qhpo}}{dt} \tag{29}$$

Body glutamine (gninb). Ammonium produced from amino acid catabolism in the body is transported in the form of glutamine. Thus gn is formed:

$$\text{Paagnb} = \text{Yaagn} * (\text{Uaacxb} + \text{Uaatgb}) \tag{30}$$

Glutamine in blood can be deaminated in the kidney, resulting in NH_4^+ release into urine. This reaction has a high capacity but is inhibited at normal blood pH, increasing substantially as acidosis develops (Brosnan et al., 1988). It is assumed that the kidneys receive 20% of cardiac output, of which 20% enters the glomerular filtrate:

$$\text{Ugnurb} = \frac{\text{cardo} + 0.2 \times 0.2 \times \text{Cgnbl}}{\left\{\left(1 + \frac{\text{Kgnur}}{\text{Cgnbl}}\right) \times \left[1 + \left(\frac{\text{Jgnurh}}{\text{Chexb}}\right)^{\text{Mgnurh}}\right]\right\}} \tag{31}$$

Thus the change in body gn is

$$\frac{d\text{Qgninb}}{dt} = \text{Paagnb} - \text{Ugnurb} \tag{32}$$

Body HCO_3^- (bcinb). Bicarbonate is formed from amino acid catabolism:

$$\text{Paabcb} = \text{Yaabc} * (\text{Uaacxb} + \text{Uaatgb}) \tag{33}$$

If the concentration of HCO_3^- in blood exceeds 27mmol/liter then HCO_3^- is lost in urine (Eckert and Randall, 1983):

$$\text{Ubcun} = (\text{Qbcbl} - 0.027 * \text{Vbld}) * 0.2 * \text{carbo} * 0.2 \tag{34}$$

where Vbld is blood volume in the body. So

$$\frac{d\text{Qbcinb}}{dt} = \text{Paabcb} - \text{Ubcun} \tag{35}$$

Acid–Base in Body. Protons enter body blood from portal blood and are removed as VFA diffuse into the intracellular space:

$$\frac{d\text{Qhbl}}{dt} = \text{lcopv} \times \text{vpo}(\text{Chexl} - \text{Chexb}) - \text{Tacinb} - \text{Tbuinb} - \text{Tplinb} \tag{36}$$

Additionally the equations determining the rate of amino acid breakdown (to CO_2 in liver and body and also to glucose in liver) are modified to include an extra term in the denominator to enable the flux to respond to changes in HCO_3^- levels:

$$\ldots \times \left[1 + \left(\frac{\text{Cbcinl}}{\text{Jaacxbc}}\right)^{\text{Maacxbc}}\right] \tag{37}$$

APPENDIX 3. PROTEIN AND ENERGY METABOLISM

The daily protein requirement for maintenance (grams per day) is given by Emmans and Fisher (1986) to be $0.01W_{ptm}^{-0.27}$Qpt. The maximum rate of net protein synthesis, Pptmax, is scaled with the animal's potential growth rate. Taylor (1980b) presents data for the growth of nine mammalian species (ranging from mouse to horse) showing unrestricted growth till weaning. This can be described by a Gompertz function:

$$W = Ae^{-e(2.7-0.037\theta)} \tag{38}$$

where θ is metabolic age, given by $A^{-0.27}(t - 3.5)$, t being time since conception. Potential maturation rate at any degree of maturity is thus:

$$\frac{du}{d\theta} = 0.037u \log_e\left(\frac{1}{u}\right) \tag{39}$$

Maximum growth rate (kilograms per day) is thus

$$\frac{dW}{dt} = 0.037u\, A^{0.37} \log_e \frac{1}{u} \tag{40}$$

Combining this with the description of body composition (above) gives:

$$\text{Pptmax} = \frac{0.001565uA^{0.73}(4.475 - u^{0.65}) \log_e \frac{1}{u}}{110} \tag{41}$$

Pptmax (kilogram-moles per day) is the difference between synthesis and breakdown. In order to define the maximum rate of protein synthesis and breakdown, the fractional synthesis rate (FSR) was regressed on fractional growth rate (FGR) for data collected from sheep (Davis et al., 1981; Attaix et al., 1987), pigs (Reeds et al., 1980), rats (Goldspink and Kelly, 1984), wallaby (Nolan, 1987), wombats (Barboza et al., 1993), and humans (Reeds et al., 1985). FSR was determined to be:

$$\mathrm{FSR} = 0.036 + 2.5\mathrm{FGR} (r^2 = 0.87, P < 0.001) \tag{42}$$

The fractional breakdown rate (FBR) is the difference between FSR and FGR. Thus, the maximal FSR and FBR, Vaapt and Vptaa, respectively, that would be achieved under optimal nutritional environment were determined. Protein synthesis and protein breakdown are represented as two Michaelis-Menten fluxes:

$$\mathrm{Uaapt} = \frac{\dot{}\mathrm{Vaapt}}{\left[1 + \left(\frac{\mathrm{Kaapt}}{\mathrm{Caainx}}\right)^{\mathrm{Maapt}} + \frac{\mathrm{Kaaptat}}{\mathrm{Catinx}}\right]} \tag{43}$$

$$\mathrm{Uptaa} = \frac{\mathrm{Vptaa}}{\left[1 + \frac{\mathrm{Kptaa}}{\mathrm{Caainx}}\right]} \tag{44}$$

Kaapt and Maapt are set so that protein synthesis responds to amino acid concentration only at low amino acid concentrations, above which energy availability has a greater influence on flux (Gill and Oldham, 1993).

Energy Metabolism. The total daily energy requirement for maintenance, Ema (megajoules per day), is given by Emmans and Fisher (1986) as a function of protein mass:

$$\mathrm{Ema} = 1.63\ W_{ptm}^{-0.27} W_{pt} \tag{45}$$

where W_{ptm} is the expected protein mass in the mature animal. The model calculates the energy expended in a number of transactions that are normally included with total maintenance costs. At food intakes that maintain energy balance, the rates of utilization in the model of adenosine triphosphate (ATP) due to protein synthesis, oxidation of acetyl-CoA, and gluconeogenesis from propionate were estimated to be, resepctively, 0.397, 0.19, and 0.05 of the total ATP utilization for maintenance. The remaining expenditures (e.g., costs of maintaining ionic balances, cost of muscular activity) were thus be estimated by difference and are assumed to apply at all levels of intake.

Acknowledgments—We are especially grateful to Bill Foley for helpful discussions throughout, and to John Bryant, Glenn Iason, and at least two reviewers for helping us improve the manuscript.

CONSEQUENCES OF BIOTRANSFORMATION OF PLANT SECONDARY METABOLITES ON ACID–BASE METABOLISM IN MAMMALS—A FINAL COMMON PATHWAY?

Abstract—Regulation of acid-base homeostasis is essential for mammals and birds. Biotransformation and metabolism of absorbed plant secondary metabolites (PSMs) results in the production of organic acids that threaten acid–base homeostasis. Consequently these acids must be buffered and excreted from the body. The production of an acid load from detoxified PSMs should occur in herbivorous mammals and birds and with most PSMs and so may provide a unifying theme to explain many effects of PSMs on animal metabolism. Since the organic acids will be largely ionized at physiological pH, disposal of the hydrogen ion and the organic anion may proceed independently. Most hydrogen ions (H^+) from organic acids are eliminated by one or more of three ways: (1) when they react with bicarbonate in the extracellular fluid to form carbon dioxide and the carbon dioxide is exhaled, (2) when they bind to dibasic phosphate and are excreted by the kidney as monobasic phosphate, and (3) when they are buffered and retained in the skeletal system. The secretion of phosphate ions and ammonium excretion are two ways in which the kidney replaces bicarbonate ions that have been eliminated as carbon dioxide. Secretion in the kidney tubule is an important means of excreting excessive organic anions rapidly. This process is saturable and may be subject to competition from a variety of different metabolites. Lagomorphs have limited capacity to form new bicarbonate from ammonium excretion and may therefore be obliged to excrete other cations such as sodium to balance the excretion of organic anions from PSMs. Acidemia has wide-ranging impacts on animals but browsing mammals and birds may have to break down muscle tissues to provide for urinary ammonium in order to generate bicarbonate for

buffering. Acidemia also can affect the extent of urea recycling. Animals consuming browse diets may have to regulate feeding so that the rate of formation of hydrogen ions does not exceed the rate of disposal. The mechanisms by which this could occur are unknown.

Key Words—Plant secondary metabolites, biotransformation, detoxification, herbivore, marsupial, lagomorph, acidosis, ammonium, phosphorus, sodium, organic acids, kidney.

INTRODUCTION

There is an increasing recognition that plant secondary metabolites (PSMs) are important influences on mammalian foraging and diet selection (Palo and Robbins, 1991). To date, however, our understanding of these interactions is only rudimentary and relies largely on correlations between diet selection and PSM profiles. Some mammals avoid particular plants in their diets because of the occurrence of specific PSMs, but any mammal that feeds on browse cannot avoid ingesting substantial quantities of PSMs such as phenolics and terpenes (Bryant et al., 1992).

Accordingly, the diversity of PSMs ingested by herbivores makes it difficult to measure individual effects. For example, folivorous marsupials eating *Eucalyptus radiata* leaves may ingest up to 60 different terpenes (Foley et al., 1987; Boland et al., 1991) and at least 20–30 broadly different phenolics (Hillis, 1966). With such diverse diets, relating composition and effects is extremely difficult. Clearly some way of characterizing and evaluating the common effects of such a wide range of compounds would be useful.

One of the early dichotomies in the study of plant–animal interactions was between PSMs that exerted a supposed toxic effect and those that acted primarily in the gut to reduce digestibility of foods (Rhoades and Cates, 1976). However, the latter idea has not been supported by detailed studies of digestion and metabolism in a range of animal species. Most investigators now recognize that all classes of PSMs, including broad categories such as phenolics, usually do exert effects beyond the gastrointestinal tract if absorbed (Foley and McArthur, 1994).

Whereas some PSMs are so toxic that they can kill some herbivores quickly (Bryant et al., 1992), most animals are likely to ingest toxic plants that elicit subacute or chronic toxicosis, but the mechanisms are poorly described. Careful studies of the variety of compounds eaten by herbivores may reveal certain adaptive patterns in the metabolism. For example, several studies have now identified apparent thresholds beyond which animals are reluctant to increase their consumption of PSMs (e.g., Jakubas et al., 1993). The best explanation of these effects is that animals would exceed their capacity to biotransform and eliminate toxic PSMs (Freeland and Janzen, 1974).

In this article, we propose that in place of the traditional emphasis on the PSM content of the diet, ecologists should refocus on the biotransformed and excreted metabolites of ingested PSMs (Foley, 1992). Viewed in this way, the effects of absorbed PSMs can be directly explained and evaluated in terms of powerful, existing knowledge about physiological homeostasis and regulation. We emphasize that here we are concerned largely with the PSMs that occur in large concentrations (in particular terpenes and phenolics) that no browser can avoid, rather than alkaloids or cyanogenic glycosides, which typically occur at lower concentrations (Harborne, 1991).

CREATION OF AN ACID LOAD

The effect of PSMs on mammalian herbivores depends on the amount ingested and the degree to which they are neutralized before reaching susceptible tissues. A broader discussion of the effects of PSMs and particular countermeasures employed by mammals can be found in Foley and McArthur (1994).

Most PSMs that are absorbed from the gut must be biotransformed and excreted (Foley et al., 1987). While hydrophilic substances may be readily excreted by the kidney, lipophilic PSMs would tend to accumulate in vivo. Even relatively nontoxic PSMs would eventually produce nonspecific adverse effects at high concentrations. Enzyme systems have evolved to enable animals to transform dietary lipophilic compounds into water-soluble, excretable metabolites (Williams, 1959; Scheline, 1991; Sipes and Gandolfi, 1991).

The principal enzyme systems for metabolizing PSMs are located in the liver and gut wall (Smith, 1992), and they are characterized by an extremely low substrate specificity, in accordance with their function of metabolizing a virtually unlimited variety of substances. Thus most types of PSMs can be biotransformed, including terpenes, phenolics, steroids, and alkaloids.

Biotransformation has two phases and is similar for most vertebrates, although there can be important differences between species in specific reactions. Phase I reactions involve oxidation, reduction, or hydrolysis and introduce or uncover a functional group in the PSM. Phase II reactions are conjugations of the PSM or its phase I metabolite (via a functional group) and an endogenous molecule such as glycine, glutathione, or sulfate, or glucuronic acid. Phase I reactions usually make the PSM more polar, while phase II conjugation almost always produces a very water-soluble and highly ionized product. This greatly increases excretion by the renal or biliary–fecal routes, often involving active transport systems. The chemical change from PSM to metabolite(s) can also alter biological activity, but this is incidental to the increase in water solubility. Often toxicity is lost through metabolism, especially after conjugation, but in some cases the metabolite is more toxic than the parent PSM.

The best understood phase I enzymes are the P-450-dependent mixed-function oxidases (MFOs), which are located in the endoplasmic reticulum (Nebert and Gonzalez, 1987). Four P-450 gene families are considered to have evolved and diverged in animals during the past one billion years in response to their exposure to PSMs. About two dozen enzymes are involved, with overlapping substrate specificities. The types and amounts of P-450 present vary between and within species, and polymorphisms also occur. Glucuronide formation is a major phase II reaction, catalyzed by UDP-dependent glucuronosyltransferase, which has several forms leading to species differences in this reaction (Sipes and Gandolfi, 1991).

Glucuronosyltransferase is also located in the endoplasmic reticulum of the liver, kidney, gut wall, and other tissues, where it may be integrated with P-450 MFOs, enabling an efficient sequence of oxidation and conjugation. Most other conjugating enzymes are found in the cell cytosol. Large-molecular-weight (>350) glucuronides are secreted in the bile, while smaller ones are excreted in urine. Glutathione conjugates are also secreted in bile, while conjugates with sulfate, amino acids, mercapturic acid, and acetate are usually excreted renally.

Conjugation is a key process in our argument because, as well as making the metabolites water soluble, conjugation with glucuronide, sulfate, or amino acids can convert compounds that are neutral or weakly acidic into strong organic acids (Robinson et al., 1953; Scheline, 1991; Sipes and Gandolfi, 1991).

Some examples emphasize the importance of the process. For example, the pK_a of the terpene menthol is about 18 and of menthol glucuronide 3.7; the pK_a of benzoic acid is 4.2 and that of benzoyl glycine (hippuric acid) is 3.7. Significant species differences occur in these phase II reactions, largely related to the type of compound used for conjugation. For example, common brushtail possums (*Trichosurus vulpecula*) conjugate phenol with glucuronic acid, while carnivorous marsupials employ sulfate conjugation (Baudinette et al., 1980). However, the excreted products are strong organic acids.

Not all PSMs are prepared for excretion by being conjugated, and substantial quantities can be excreted in a nonconjugated form. For example, in common ringtail possums (*Pseudocheirus peregrinus*) fed *Eucalyptus radiata* foliage, only a minor proportion of leaf metabolites were excreted as conjugates. The bulk was excreted as polyoxygenated molecules (mainly dicarboxylic acids), which are highly polar and acidic (McLean et al., 1993). Presumably, these dicarboxylic acids are not conjugated because they are not sufficiently lipophilic to reach the site of glucuronosyltransferase in the endoplasmic reticulum membrane.

Other PSMs that may be ingested as acids are often sufficiently polar to be excreted without further metabolism. One of the best examples is salicylic acid, which in many species is largely excreted unmodified (Scheline, 1991). Whereas most alkaloids are bases, some have ester groups that can be metabolized to

acids (Harborne, 1991). Alkaloids generally occur in substantially lower concentrations compared with terpenes and phenols, and accordingly we expect their influence (whether basic or acidic) on acid–base metabolism to be minor.

In summary, the excretion of PSMs is aided by their metabolism to polar acidic compounds usually through phase II conjugation reactions but often through phase I reactions alone. Our thesis, therefore is that the processes of biotransformation and excretion of the vast majority of absorbed PSMs in mammals and birds result in the need to excrete a load of organic acids.

This means that once a compound has been absorbed and becomes a substrate for the MFO system, we can simply regard it as part of an organic acid load. Instead of being concerned with the effects of the native terpene or phenol, the effects may be viewed as those of a metabolically produced organic acid. We believe this is a useful rationalization because the effects of acid loads on animals is well studied and there are clear links between dietary acid loads and whole body protein and energy balance. This may allow nutritional ecologists to integrate better the effects of dietary PSMs with the traditional measures of dietary nutrients.

BUFFERING AND DISPOSAL OF AN ACID LOAD

All acid metabolites will be almost completely ionized at physiological pH (Robinson et al., 1953). Thus, the hydrogen ion and accompanying anion need not necessarily be disposed of together. The hydrogen ion can be either neutralized in the body by reaction with bicarbonate, buffered and retained in the body, or excreted in the urine as titratable acid. The accompanying anion is most often excreted into the urine by the organic anion transport system of the kidney and passed as ammonium or sodium salts. In the ensuing discussion of these processes, we focus on possible rate-limiting steps and, where appropriate, emphasize differences in mechanisms between species. We conclude the section with a discussion of the factors limiting the excretion of PSMs. A schematic illustration of the disposal of H^+ and organic anions is given in Figure 2 below.

Intracellular and Extracelluar Buffers

Ingestion or endogenous production of an acid results in a decline in plasma bicarbonate, which is the major extracellular buffer in mammals. The degree to which plasma bicarbonate concentrations are diminished depends on additional intracellular buffers, especially hemoglobin. In humans and laboratory animals, about half of an acute acid load can be titrated by intracellular buffers (Schwartz et al., 1957). Generally these processes are very rapid, occurring within 4–6 hr of an acute dietary acid load.

Following this initial buffering, respiratory adaptations become important.

Depletion of blood bicarbonate will eventually lead to changes in blood pH and therefore a fall in arterial P_{CO_2}. This in turn will tend to return blood pH to normal levels. Interestingly, the response in terms of plasma bicarbonate is in fact maladaptive (Madias et al., 1977) because hypocapnia induced by the respiratory response will decrease plasma bicarbonate beyond the level induced by the initial acidosis.

Buffering of Acid Loads by the Skeletal System

The skeletal system plays a role in the buffering of acid loads, but there is disagreement as to its importance under different conditions. Enormous reserves of alkaline salts are held in bone, and acidemia dissolves bone, releasing its alkaline, calcium salts. Bicarbonate is also leached from the active surface of bone and drives hydrogen ions into the bone matrix (Barzel and Jowsey, 1969).

Balance experiments over several weeks (Lemann et al., 1965, 1966) have shown that not all acid is excreted or buffered by intracellular or extracellular fluids. The remainder is believed to be buffered by the skeletal system. In humans made acidotic for six days, there was no progressive depletion of plasma bicarbonate, but a substantial excretion of calcium, magnesium, and phosphorus. These and other lines of evidence (Green and Kleeman, 1991) suggest that bone is a sink for hydrogen ions (protecting plasma bicarbonate stores) and the source of the extra urinary calcium. Although the skeletal system is accepted as a buffer of acid in the short term (days to months), there is less agreement about its role in long-term (three to five years) acidosis. Green and Kleeman (1991) suggest that skeletal sodium and potassium are more important in the defense against acute acidosis whereas efflux of calcium carbonate is augmented in the chronic acidotic state. Oh (1991) has argued that bone reserves of alkali salts are too limited to explain long-term responses, and this remains a controversial topic.

At least in the short-term chronic state, however, it is clear that metabolic acidosis leads to losses of bone calcium via an increase in urinary calcium loss. The mechanisms by which this occurs are not fully elucidated, but appear to involve an integrated response of the kidneys with an accompanying increase in the rate of bone resorption (Green and Kleeman, 1991). In lambs made acidotic with dietary ammonium chloride, no changes have been detected in the uptake of calcium from the gut (Abu Damir et al., 1991) even though urinary excretion was elevated.

Differences in the retention of calcium and phosphorus have been observed in lambs eating acid-promoting diets or which have been made acidotic by the addition of ammonium chloride to their food (Abu Damir et al., 1990). Mineral wastage in response to acidosis is important in domestic animal production, but we are aware only of anecdotal evidence to suggest that these effects are realized in browsing species. Robbins (personal communication) observed frequent bro-

ken bones in several species of deer that were maintained on browse diets in captivity but we can not be certain as to the cause. Although Pehrson (1983) and Reichardt et al. (1984) found that hares (*Lepus timidus* and *L. americanus*) were very often in negative calcium balance when fed browse, this was largely because of fecal calcium loss rather than urinary losses. Unfortunately, there are no simple markers of bone metabolism that reflect changes in acid–base status, but attempts have been made to use hydroxyproline as an index of bone mobilization during acidosis in domestic ruminants (Takagi and Block, 1991).

Given the central role played by the skeletal system in buffering acid loads, future studies of mineral balance in response to acid-loading, browse diets could be worthwhile. In such studies it will be important to distinguish between the excretion of endogenous and diet-related sources of calcium.

Excretion of Acid–Urinary Titratable Acid

Only a small percentage of the daily H^+ production can be excreted directly in the urine. In humans, dogs, and rats, the minimum urine pH is about 4.5. The limit to urine acidity is set by the gradient between blood and urine, and evidently the difference between blood hydrogen ion concentration and urine cannot be greater than 1000-fold. There is no reason to suspect that minimum urine pH is any different in wild species.

This being so, all animals need buffers so that the necessary acid load can be excreted in the urine. As with any buffer system, the capacity (in this case acid excretion) depends on the pK_a of the buffer and the total amount of buffer present. Buffers in the urine include organic anions such as citrate, acetate, hydroxybutyrate, and even creatinine (Hamm and Simon, 1987). However, all these have a $pK_a < 6$ and so can contribute little to hydrogen ion excretion over the physiological range of urine pH. Buffers are only effective one unit either side of the pK_a. In contrast, phosphate has a pK_a of about 6.8 (the exact value depends on a range of factors) and so is an ideal buffer at the typical pH values found in mammalian urine (Figure 1). At pH 7.4, 80% of phosphate is in the dibasic form (HPO_4^{2-}) and is capable of buffering hydrogen ions. At pH of 4.8, 99% will be in the monobasic ($H_2PO_4^-$) form. The bulk of the titration occurs between 6.8 and 5.8, so the phosphate can contribute to H^+ excretion at typical urine pH (Hamm and Simon, 1987).

Urinary excretion of phosphate is the major contribution to titratable H^+ excretion and changes in phosphate excretion alter urinary titratable acid (Scheiss et al., 1948). Acute dietary phosphate loading leads to a greater urinary titratable acid in direct proportion to the increase in phosphate excretion. However, this occurs because inorganic phosphate (P_i) stimulates hydrogen ion excretion, not because buffer excretion is a rate-limiting step for H^+ disposal (Gennari and Maddox, 1992). Similarly, animals that are P_i depleted retain part of an H^+

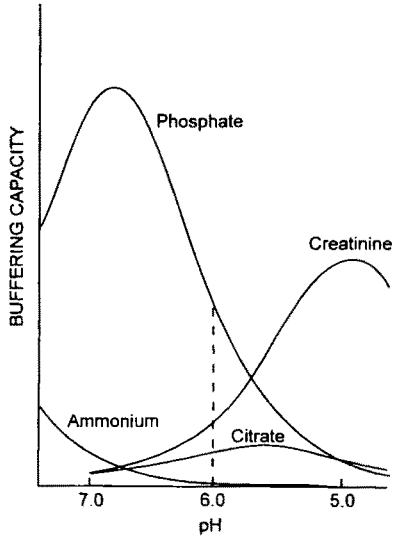

FIG. 1. Schematic representation of the relative importance of urinary buffers of H^+ in common ringtail possums. Concept and data on pK_a from Hamm and Simon (1987). Data for common ringtail possums from Foley (1992), Foley (unpublished), Johnson and Foley (unpublished). Note that ammonium is a poor buffer at typical urine pH and that phosphate is the predominant urinary buffer.

load, but again this is not because buffer excretion is limiting but because P_i depletion inhibits the secretion of H^+ ions in the distal tubules of the kidney. However, during metabolic acidosis in humans, phosphate excretion does increase and so does titratable acid excretion. The mechanisms involved are complex and interact with other factors affecting phosphate excretion, such as dietary phosphorus intake and parathyroid hormone (Hamm and Simon, 1987).

In summary, the excretion of titratable acid is an important route to dispose of excessive plasma H^+, but there is no evidence that acid excretion is regulated by changes in renal phosphate handling. An animal eating a diet that is rich in dibasic phosphate has the potential to excrete more titratable acid depending on how well that phosphate is absorbed. At present it is difficult to say how actively this is regulated.

Several studies of folivorous marsupials (Cork, 1992; Hume and Esson, 1993) and other herbivores (e.g., prairie voles, *Microtus ochragaster*) (Lindroth and Batzli, 1984) and ruffed grouse (*Bonasa umbellus*) (Jakubas and Guillon, 1991) have shown a correlation between diet choice and ratios of phenolics to nitrogen or phenolics to phosphorus in the foliage. Such correlations could be

explained by a need to maintain intakes of nitrogen and/or phosphorus sufficient to provide glutamine for production of new bicarbonate (see below) or for excretion of titratable acid in the urine. Cork and Foley (1991) and Cork (1992) suggested that ratios of nutrients to PSMs are important in relation to toxicity; if ratios are below thresholds, long-term utilization of a diet is not possible. Above the threshold, other factors might determine the selection and utilization of the diet.

Urinary Ammonium—The Measure of "New" Bicarbonate

The augmentation of urinary ammonium excretion is one of the most widespread responses to loading an animal with either exogenous or endogenous acids. For mammals, the major nitrogen-containing compound in the urine is typically urea; ammonium, although present, is a minor constituent. During acid loading, however, ammonium production is increased 10 to 20-fold and forms the dominant part of urinary nitrogen.

Until recently, the idea that ammonium was a urinary buffer of acid was firmly entrenched. Renal physiologists believed that since NH_3 diffuses into the lumen of the kidney tubules and then combines with a secreted H^+ ion, ammonium was in effect a buffer to convey acid out of the body (Pitts, 1964). There are two problems with this scheme. First, metabolism of amino acids gives rise to NH_4^+, not NH_3, so no matter how the resulting ammonium was changed in the body, urinary NH_4^+ could not represent any net transfer H^+ from the body (Atkinson and Bourke, 1987). This is shown below for alanine (equation 1).

$$CH_3-\underset{\displaystyle NH_3^+}{\underset{|}{CH}}-COO^- + 3O_2 \rightarrow 2CO_2 + HCO_3^- + NH_4^+ + H_2O \qquad (1)$$

Secondly, the pK_a of the NH_3/NH_4^+ buffer system is 9.2, so at physiological pH almost all the ammonia is in the acid form (NH_4^+) and no buffering could occur. It follows that ammonium does not in any way carry acid out of the body as many textbooks still claim. Nonetheless, ammonium does play a very special role in acid–base regulation. To understand how this is so, we need to consider the biochemistry of ammoniagenesis (Figure 2).

Urinary ammonium arises from the metabolism of glutamine (and to a lesser extent alanine and asparagine) in the cells of the proximal kidney tubules. Glutamine extracted from circulating plasma is metabolized to NH_4^+ and α-ketoglutarate. The α-ketoglutarate is then metabolized to generate HCO_3^-. The ammonium, after a somewhat elaborate transport process, ends up in the kidney's collecting duct. Therefore, each molecule of ammonium ion that appears in the urine represents a process that also generates one molecule of bicarbonate. If the ammonium from glutamine had been transported back to the liver, it

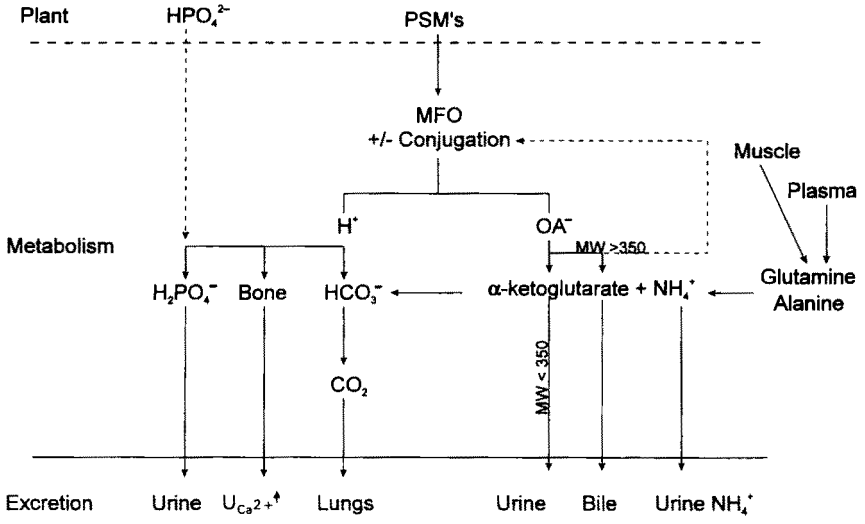

FIG. 2. Pathways of disposal of organic acids produced during the biotransformation of phenols and terpenes in mammals. Note the relationship between the urinary excretion of ammonium and the formation of "new" bicarbonate.

would have been converted into urea (equation 2):

$$2NH_4^+ + 2HCO_3^- \rightarrow H_2N{-}CO{-}NH_2 + CO_2 + 3H_2O \qquad (2)$$

This equation shows that urea formation consumes bicarbonate, and the overall process would have made no change to acid–base status. If, instead, the ammonium is excreted in the urine, then the new bicarbonate from the metabolism of α-ketoglutarate is available to titrate part of the acid load. Therefore, urinary ammonium excretion does not represent H^+ excretion per se, but it is an index of the amount of "new" bicarbonate produced and hence the amount of the acid load that is neutralized in the body.

There are several limitations to the excretion of ammonium as a metabolic response to acidemia that are worth noting. First, it takes some days for ammoniagenesis to reach full capacity. In humans and laboratory animals, this lag time between an acid load and maximum ammonium excretion is on the order of three to six days (Halperin et al., 1992). This means that if an H^+ load is to be produced every day during this adaptation period, then it must either be buffered within the body until there is sufficient ammoniagenesis or else excreted as titratable acid.

The other limitation of renal ammoniagenesis as a counter to metabolic acidosis concerns damage to the kidney that occurs during prolonged periods of

elevated ammonium production (Halperin et al., 1989). These disorders include nephrocalcinosis. Finally, circulating glutamine may be insufficient to meet the demands of ammoniagenesis and additional glutamine may have to be derived from muscle protein catabolism. We will discuss this final point in more detail later.

Renal Organic Acid Secretion—An Active and Saturable Process

Thus far we have mainly discussed the excretion of hydrogen ions arising from an endogenous acid load. Recall that, at physiological pH, organic acids will be almost completely ionized, and so disposal of the hydrogen ion is only part of the solution. It remains to dispose of the organic anion as well.

The kidney plays a major role in eliminating metabolites of biotransformation processes from the body. Many organic metabolites can be filtered from the blood and so become part of the excreted urine. However, of particular importance is the secretion of organic anions by the organic acid transport system of the kidney. There has been a large amount of research to elucidate the nature and controls on these processes (reviewed in Moller and Sheikh, 1983).

The renal clearance rate should be highest for secreted substances, and it can equal renal plasma flow when there is no reabsorption from the kidney tubules, which should be the case for most conjugates. In contrast, clearance by glomerular filtration alone will be much lower even when there is no reabsorption because only 20% of plasma is filtered.

One important feature of the renal transport system is the wide variety of substrates that are accepted—the number of compounds is unlimited and includes many (but not all) glucuronides, hippurates, mercapturic acids, dicarboxylic acids, and hydroxy acids of both endogenous chemicals and metabolites of xenobiotics. As a general rule, conjugated metabolites are far more likely to be actively secreted than their parent compounds (Caldwell, 1982). A good example is the amino acid conjugates of aromatic acids; hippuric acid is actively secreted while benzoic acid is not. Conjugates are also far less readily reabsorbed from the kidney tubule than are the free acids because of their greater polarity and lower lipophilicity (Caldwell, 1982).

Early studies show that secreted anions were capable of competitively inhibiting the secretion of other anions, and so organic acid transport was believed to be a single system (Pritchard and Miller, 1992). This concept is important to our arguments because it suggests that the system can be easily saturated and, in these circumstances, the capacity of the organic anion transporters may set some limit on the speed with which the body can rid itself of organic anions formed by biotransformation of PSMs.

Whether or not there is a single renal organic acid transport system has bearing on our argument that biotransformed PSMs can be seen to have a com-

mon effect. If saturation of the organic anion transport system does constitute a rate-limiting step to the disposal of acid loads, then it is of little importance whether the anions are derived from the PSMs of one plant or another. In other words, animals choosing a mixed diet should not be advantaged necessarily by different pathways of biotransformation unless the cosubstrates of elimination (e.g., glutathione, glycine) are in short supply.

Ullrich and Rumrich (1988) questioned the notion of a single organic anion transport system and have revealed at least three separate organic acid transporters. One system handles oxalate (and sulfates), a second handles dicarboxylates, while the third was elucidated with paraamino hippurate and so corresponds to the classical model of organic anion transport.

Puzzlingly, some mammals (e.g., common ringtail possums) excrete ingested terpenes as dicarboxylic acids rather than as conjugates of glucuronic acids, as might be expected (but see above). However, it is unlikely that this is to avoid saturating the main transport system. The dicarboxylate anion produced by common ringtail possums are all 10-carbon compounds derived from monoterpenes, and the dicarboxylate acid transporter elucidated by Ullrich and Rumrich (1988) is restricted to compounds of five to seven carbons. We would not anticipate many PSM metabolites to be less than 10 carbons, and so it seems unlikely that much capacity is spared by the use of these two alternative organic anion transports. Sulfate conjugates, however, may be able to be excreted via an alternate transporter.

Renal organic anion transport is highly complex, and there are few data of relevance to whole animal metabolism of PSMs. However, in spite of the recent research on alternative transport pathways, it seems reasonable to continue with the classical view of regarding organic anion excretion as a saturable system whose capacity may impose a rate-limiting step on the excretion of anion loads from the body.

Differences between Species—Sodium Wasting in Rabbits

Often, animals are divided into those that excrete net acid in the urine and those that excrete net base. Digestive physiology and the particular metabolism of a species affects whether it will be an acid excreter or a base excreter. The focus of our argument is that some diets may often have an overriding effect on this, but metabolic differences between species can mediate dietary effects.

In this context, the acid–base metabolism of lagomorphs is of particular interest. Many lagomorphs eat diets that expose them to significant levels of absorbable PSMs, and studies of domestic rabbits indicate that most of these are metabolized to acid end products (Williams, 1959; Scheline, 1991). Thus we might expect lagomorphs to display the responses seen in species such as common ringtail possums to endogenously produced acid loads. However,

domestic rabbits cannot normally augment urinary ammonium excretion in response to acid loads (Richardson et al., 1978) and so, even during severe metabolic acidosis, urinary ammonium remains at low levels. In contrast to laboratory rats at least, rabbits convert a greater proportion of dietary components into bicarbonate in the gastrointestinal tract, and this bicarbonate is then absorbed. Consequently, it is possible that rabbits are rarely, if ever, faced with the problem of generating new bicarbonate in the kidneys and so have no need to excrete substantial quantities of ammonium in the urine. Furthermore, there is some evidence (Cruz-Soto et al., 1982) that early exposure to acid-loading diets may alleviate this metabolic defect in domestic rabbits. Thus, browsing lagomorphs may be better able to augment urinary ammonium than their grazing kindred.

To our knowledge, there are no data on net acid excretion (or even urine pH) of any lagomorph fed browse diets. It is difficult, therefore, to evaluate whether rabbits are essentially immune to acidemia resulting from biotransformation processes. Nonetheless, the metabolism of absorbed PSMs will still result in the creation of organic anions and, even if the H^+ formed is neutralized by bicarbonate absorbed from the gastrointestinal tract, the animal must still excrete the organic anions in the urine.

These organic anions must be accompanied by some cation and, in the absence of ammonium, a highly probable alternative cation is sodium or potassium. Consistent with this suggestion is the observation that several species of lagomorphs, when fed browse or browse extracts, excrete substantial quantities of sodium in the urine (Pehrson, 1983; Reichardt et al., 1984; Iason and Palo, 1991) sufficient to ensure that they are in severe negative sodium balance for the duration of the browse diet. In addition, Iason and Palo (1991) found that mountain hares (*Lepus timidus*) lost significantly less sodium in the urine than did grazing European hares (*Lepus europaeus*) when both were fed browse.

Normally urinary losses of sodium are closely regulated by the renal system. The kidney would be expected to reabsorb sufficient filtered sodium to prevent a negative sodium balance unless that loss was obligatory. Pehrson (1983) suggested that negative sodium balance in mountain hares could occur through one of two mechanisms. Sodium imbalance could be due to the effects of a high dietary potassium intake. However, there is no evidence that the levels of potassium in any of these diets was notably high. Pehrson's second hypothesis was that many browse plants contain (unspecified) compounds that lead to sodium wasting.

We suggest that in lagomorphs, sodium is excreted in the urine in amounts equivalent to urinary excretion of organic anions and that the loss is therefore obligatory. In other words, organic anions arising from biotransformational reactions are excreted as sodium salts in lagomorphs, whereas in most other species they are excreted as ammonium salts.

However, there are alternative explanations that need to be explored. Most of the experiments in which sodium wastage has been observed were of short duration, and it may be that the sodium loss is not sustained in the longer term. In other species, urinary sodium is often elevated in the early days of a metabolic acidosis because it takes several days for renal ammonium excretion to be elevated (Halperin et al., 1992). It should also be noted that changes may have occurred in the animals' extracellular fluid volumes, and this alone may have been sufficient to account for the extra urinary sodium.

EFFECT OF ACIDEMIA ON ANIMAL METABOLISM

Disturbances of acid–base status have wide-ranging effects on biochemical and physiological processes of animals (Hills, 1973; Gennari and Maddox 1992). Very often the effects of acute and chronic acidosis differ, and so it is important to consider which state prevails in each instance. However, metabolic acidosis has wide-ranging effects on organ systems and whole body homeostasis. In particular, effects on the respiratory system, the cardiovascular system, and the skeletal system have been described. There are pronounced effects on carbohydrate metabolism (e.g., an impaired insulin response) (De Fronzo and Beckles, 1979) and on protein metabolism. All these may involve some compensatory response from the animal. However, from an ecological perspective, the effects of most interest are those on protein and nitrogen metabolism.

Protein Metabolism

We have described above the mechanisms that allow the rapid augmentation of urinary ammonium during acidosis. Urinary ammonium is derived largely from plasma glutamine and, to a lesser extent, alanine. The key question involves the source of these ammoniagenic amino acids. Previously, it was thought that there was a quantitative switch between urea excretion and ammonium excretion during acidosis so that total urinary nitrogen excretion remained constant (Hills, 1973). However, there is now clear evidence that in many species and under different conditions, this simple switch from urea to ammonium does not occur and that during acidosis urinary ammonium excretion is increased without changing net urea production. For example, in calves (Scott et al., 1971), red deer (*Cervus elaphus*) (Scott, 1971a), and pigs (Scott, 1971b) ammonium excretion was elevated during infusions of hydrochloric acid, but there was little change in urinary urea excretion.

In common ringtail possums, Foley (1992) found that animals excreting an acid urine lost more nitrogen at similar nitrogen intakes than animals excreting an alkaline urine. These possum data are confounded by the different species of leaf offered to produce the different excretory patterns, and so it is not certain

that the effects observed in other species during acid infusions occur during diet-induced acid loading. An increased loss of urinary N would be a clearly measurable cost of biotransformation and could be linked directly to measures of nitrogen requirements and the suitability of different diets.

When dietary protein levels are adequate, glutamine required for urinary ammonium can be met from circulating plasma glutamine. However, the diets consumed by browsing mammals often contain only maintenance levels of protein. When humans and laboratory animals are acidotic and are consuming insufficient dietary protein, their is insufficient plasma glutamine to meet requirements for urinary ammonium (Hannaford et al., 1975).

The maintenance of acid–base homeostasis is of such importance that animals may break down skeletal muscle to provide the necessary glutamine for ammoniagenesis. Skeletal muscle can supply the necessary glutamine in the short term, but clearly extensive muscle wasting can take place if the acidemia is prolonged and if energy balance is negative. This is why obese humans lose valuable body protein as well as body fat during starvation. The ketoacidosis that develops requires them to consume their muscle to provide for urinary ammonium (Halperin et al., 1992).

Chronic acidosis in children (Cooke et al., 1960) and rats (Williams et al., 1991) can lead to retarded growth. That the growth retardation can be corrected by giving sodium bicarbonate confirms that the effects are linked to the effect of acidosis on whole body protein metabolism. Ruminant herbivores fed silage or grain diets are particularly susceptible to acidosis, and a review of a number of studies suggests that addition of sodium bicarbonate spares body protein and improves nitrogen balance (Phillip, 1986).

In conclusion, there is growing evidence in a variety of species that metabolic acidosis changes the balance between body protein synthesis and breakdown. Studies with rats suggest that these effects are mediated by glucocorticoids (May et al., 1986), but the exact mechanisms have yet to be determined (Reaich et al., 1992).

Recycling of Endogenous Urea

In most herbivores, urea is not a waste product but a valuable source of nitrogen that can be recycled back to the gut and used by microorganisms for growth. It is likely that all mammals recycle a substantial proportion of endogenously produced urea and incorporate the nitrogen into microbial protein, but only foregut fermenting herbivores and coprophagic species can use the microbial protein as a source of essential amino acids. Therefore, the diminution of urea production and recycling could be deleterious to the protein metabolism of these species. The extent of urea recycling is most closely related to rates of fermentation in the gut (Kennedy and Milligan, 1980), but during acidemia,

urea production is substantially reduced and the quantity recycled may be independent of fermentative activity.

Foley (1992) showed that, in common ringtail possums, animals fed on foliage diets that led to net acid excretion (*Eucalyptus radiata*) synthesized and degraded in the gut far less urea than animals fed foliage that resulted in net alkali excretion (*E. ovata*)—even though the nitrogen intake of each group was the same (Figure 3).

If urea recycling is as important to the nitrogen economy of marsupial folivores, as Chilcott and Hume (1984) have argued, then clearly the consumption of acid-producing plants can have a significant impact on the process.

Ability to Concentrate Urine

Many animals fed high protein diets are able to concentrate their urine more than other animals (Jamison, 1981). This has been attributed to an effect of urea in the urinary concentrating process. This accumulation of urea in the interstitium of the kidney medulla allows a greater concentration gradient can be reached than possible when urea is absent. Most folivores eat low protein diets but, in the absence of acidosis, urinary urea concentrations can be substantial (Cork, 1981; Foley and Hume, 1987; Foley, 1992). In cases where acidosis leads to a rapid cessation of urea production in favor of ammonium production, acidotic animals may be unable to concentrate their urine as well as can those in the nonacidotic state. Controlled experiments are needed to evaluate whether the magnitude of the effects could mean a significantly greater water demand for animals during acidemia.

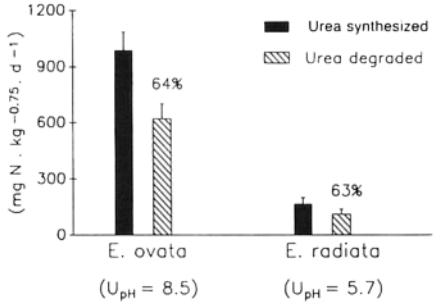

FIG. 3. Effect of diet on urea synthesis and urea degradation in common ringtail possums fed two foliage diets, *Eucalyptus radiata* and *Eucalyptus ovata*. Note the interrelationships between diet, urine pH and urea synthesis and degradation. The percentage value is the proportion of urea synthesized which was degraded in the gut (Foley, 1992).

CAN ACID-BASE HOMEOSTASIS PROVIDE FEEDBACK TO REGULATE FOOD INTAKE?

We have shown that in arboreal marsupials, at least, feeding on diets rich in absorbable PSMs leads to a large organic acid load that must be excreted. The H^+ ions are clearly diet-related and are a consequence of the metabolism and biotransformation of foliage PSMs (Foley, 1992). Given that the maintenance of acid–base homeostasis is among the most important regulatory necessities of any animal, we argue that factors that promote acid production must be controlled so that the capacity to buffer and excrete acids is not exceeded.

We have already discussed the mechanisms that allow animals to buffer and excrete acid loads from the body very rapidly. Although these processes are not a universal panacea (see discussion above on ammonium excretion), the immediate control problem is to prevent the capacity of these buffering and excretory systems from being exceeded. What then are the possible mechanisms that might provide an appropriate signal for the animal to increase hydrogen ion excretion?

Changes in Systemic pH

It is tacitly assumed that a change in systemic pH is the signal needed by the kidney to increase urinary acid excretion (Tannen, 1980). This is a controversial area because important experiments by De Sousa et al. (1974) showed that administration of some acid loads did not lower the blood pH or plasma bicarbonate content of dogs. Doses of hydrochloric acid led to a prolonged decrease in blood pH and plasma bicarbonate, whereas nitric acid had no detectable effects. These results were important in formulating a theory of H^+ excretion that is based on the nature of the accompanying anion. They suggested that since the nitrate ion is poorly reabsorbed, it will be delivered rapidly with endogenous sodium to the distal nephron, whereas anions such as chloride will be largely reabsorbed and reenter the circulation. For example, Bank and Schwartz (1960) showed that sodium-depleted subjects excreted acid urine when infused with sodium sulfate, but that sodium chloride had little effect on urine acidity.

Although these ideas appear to be largely correct, a repeat of the experiments by Madias and Zelman (1986) showed that the failure of De Sousa et al. (1974) to observe declines in blood pH and plasma bicarbonate was because they collected only a single blood sample 24 hr after acid loading. In fact, more frequent sampling showed that animals fed nitric acid did show a decrease in blood pH and plasma bicarbonate but that the effects were only transitory. It would seem, therefore, that although the anion that accompanies the hydrogen ion is an important mediator of the length of acidosis, changes in blood pH cannot be excluded in urine acidification.

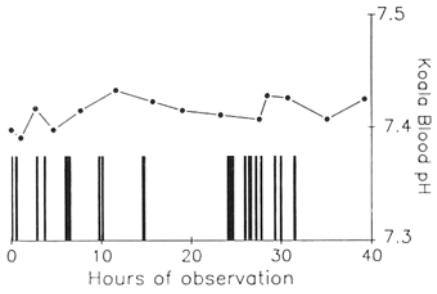

FIG. 4. Arterial blood pH in relation to feeding on *Eucalyptus robusta* by a koala. The vertical bars show duration of feeding bouts. Blood was drawn from an in-dwelling catheter in the femoral artery and analysed within four minutes (Foley and Handasyde, unpublished).

Nonetheless, this does not necessarily mean that systemic pH exerts control over renal acid excretion (Tannen, 1980). The types of anions derived from the biotransformation of absorbed PSMs are, like nitrate, likely to be poorly reabsorbed. In fact, as we have described above, many are secreted by the kidney. Thus any acidemia that results from the accumulation of organic acids, such as after a feeding bout, may itself be only transitory. There are few data to support or refute this suggestion. Foley and Handasyde (unpublished) measured the arterial acid–base status in relation to feeding bouts in a pilot study with koalas (*Phascolarctos cinereus*). Data for a single animal are shown in Figure 4. During these experiments, the animals were excreting urine of pH 5.3–5.5, which contained substantial concentrations of ammonium but the variation in blood pH and plasma bicarbonate were only minor. In addition, there was no relationship between blood pH or bicarbonate and the cessation or intensity of feeding bouts. Although these data are very limited, they suggest that changes in blood pH during the ingestion of browse diets are only small and not involved with the regulation of renal acid excretion or feeding.

Changes in Arterial P_{CO_2}

Changes in the arterial carbon dioxide tension (P_aCO_2) have a direct effect on renal hydrogen ion secretion. High P_aCO_2 depresses renal hydrogen ion secretion whereas the reverse is true under conditions of low P_aCO_2. These effects occur even within the normal day-to-day variation in P_aCO_2, but it is generally believed that they do not mediate routine adjustments in renal hydrogen ion excretion (Gennari and Maddox, 1992).

Aldosterone

The mineralocorticoid aldosterone has been implicated as a controller of renal hydrogen ion excretion because it stimulates hydrogen ion secretion in the distal nephron. An aldosterone deficiency directly depressed hydrogen ion secretion and results in a sustained metabolic acidosis. Whether or not the effects are sufficient to account for day-to-day regulation in acid excretion is uncertain because animals without adrenal glands and given constant doses of mineralocorticoids can respond to acid loads normally (Gennari and Maddox, 1992).

Potassium Status

Changes in potassium supply affect an animal's ability to produce ammonium in the kidney. In laboratory animals and in humans, ammoniagenesis is stimulated by deficiencies of potassium and depressed by potassium loading. However, the differences in ammonium excretion are countered by changes in titratable acid excretion, and there is no change in net acid excretion. Therefore it seems that the potassium status of the body is unlikely to play a major role in controlling renal acid excretion (Tannen, 1980; Gennari and Maddox, 1992).

CONCLUSION

In spite of widely varying daily acid loads that animals can encounter, plasma bicarbonate and systemic pH are kept within very narrow ranges in all homeotherms. A major question is whether these effects are sufficiently great that animals need to regulate their diets in order to control acid production. Humans eating typical diets and with normal renal function probably do not need to control their diets. However, the acid loads of mammals eating diets rich in PSMs are substantially greater. Any theory of food intake must invoke some sort of feedback signal so that intake can be modified, but at present, simple factors such as systemic pH cannot be invoked as part of the feedback process. A similar conclusion has been reached in the study of acid–base effects on silage intake in ruminants (Philip and Simpson, 1991). Nonetheless, even if the regulatory process is not known, it is clear that acidemia is a major consequence of the ingestion of diets rich in PSMs.

(Received March 30, 1994; accepted February 11, 1995)

Abstract—A model was developed to describe release of two formulations of tetradecenyl acetates in Shin Etsu polyethylene tubing pheromone dispensers. Change in pheromone column length in the polyethylene tubing was modeled by $dl/dt = l \cdot (a + bT)/dt$ (where l is column length, t is time interval, and T is average temperature for that time interval). Regression of the natural log of relative change in liquid length against time interval and accumulated day degrees in orchards produced the coefficients a and b. The model was validated by comparing predicted and actual liquid length remaining in field-aged dispensers, as well as measuring release rates by using gas chromatography. Mean daily orchard temperatures and measurement of column length of dispensers on a single date were used to accurately predict column length within 15%, after six months. Predictions of instantaneous release rate were also made from this model, and other possible model uses and limitations are discussed.

Key Words—Pheromone, polyethylene dispenser, release rate, model.

INTRODUCTION

Mating disruption, achieved by releasing relatively large quantities of female insect sex pheromone, is becoming an important pest control technique (Cardé,

*To whom correspondence should be addressed.

1990). A wide variety of different types of dispensers for releasing these chemicals have been developed. Unfortunately, many have a short field life and are difficult to apply, release rates are often inconsistent, and the quantity of remaining pheromone is difficult to measure. In these cases, it is difficult to estimate release rates without the use of a gas chromatograph and controlled laboratory conditions (Brown et al., 1992).

Dispensers consisting of sealed polyethylene tubes containing wire fasteners have useful release characteristics for a range of pheromones (Sexton, 1989) and are finding increasing acceptance, especially for orchard use (Suckling, 1993). Their advantages include ease of application, without the need for any specialized equipment, simple construction (reducing the cost), and the potential for observing the loss of pheromone over the season by visibility of the remaining liquid. This latter attribute assists in determining the optimum replacement time. Their disadvantages include a logarithmic decline in release rate and differing release rates for different pheromone components, features they share with many other types of dispensers.

Sealed polyethylene dispensers have been studied in New Zealand orchards since 1984 (Suckling et al., 1990). Release rates have often been presented during these trials as weekly means, deduced from weekly change in liquid length. Knowledge of daily release rate would be valuable for understanding trial results, but changes in liquid length could not be measured reliably and precisely in the field over intervals shorter than one week. Estimation of release rates at a given point in time would be useful for interpretation of field trial results and could provide an indication of the probability of a mating occurring on a given night. We saw the need for a simple model, based on field data and remaining liquid length, to permit prediction of instantaneous pheromone release rates. As mating disruption of six leafroller species is being investigated in New Zealand, we also required a model where coefficients for different pheromone blends could be obtained with relative ease.

Many authors have produced descriptive models of pheromone release rate as a function of time or day degrees (Audemard and Leblon, 1987; Ioriatti and Dalla Serra, 1992; Neuman, 1992; Charmillot and Pasquier, 1993), but they have not proceeded to calculate instantaneous release rates, describe the mechanisms involved, or predict release rate under a variety of conditions. Two recent exceptions to this are the models of McDonough et al. (1992) and Brown et al. (1992), for codling moth dispensers, which, like the dispensers described here, were hollow plastic tubes filled with pheromone and sealed at both ends.

The Model. A simple physical model for pheromone release from the Shin Etsu polyethylene tubing dispenser was developed by using the observation that pheromone release from these dispensers is relatively independent of wind speed (T. Bellas personal communication and unpublished data). Freedom from wind effects implied that the resistance to transfer of pheromone through the walls of

the dispenser limited the rate of release, as opposed to the boundary-layer resistance of the air surrounding the dispenser. Furthermore, since radial resistance is large, it was inferred that very little diffusion of the contents occurred along the dispenser above the capillary. Therefore it was assumed that the active length of the dispenser was essentially that occupied by the liquid, l (millimeters). This was later tested (see below).

Our model proposes that the rate of pheromone release is proportional to the length of the capillary and the transfer conductance of the wall of the plastic dispenser. It was assumed that the same conductance is appropriate for all components of the pheromone mixture since the components in our tests were of similar chain length, polarity, and saturation. The conductance of the dispenser walls probably varies with temperature, so the conductance can be written as $g(T)$, but the exact form of the relationship is unknown. Ideally $g(T)$ would be found from laboratory studies. Whatever its exact form, $g(T)$ can be represented as a Taylor series $g(T) = a + b(T - T_m) + y(T - T_m)^2 + \ldots$, where the expansion is about a mean operating temperature, T_m. Here it is assumed that linear terms are sufficient to represent the function over the seasonal range of temperatures. That is, we propose a relationship of the form

$$\frac{dm}{dt} = l \cdot (a + bT) \tag{1}$$

where m is the mass of pheromone released, T is air temperature, and a and b are unknown constants. The mean temperature term has been absorbed into the constant a. In this paper a and b are found by regression using field data. For this we present equation 1 in integral form.

The mass of pheromone in the dispenser is proportional to the length of capillary, so the symbol m in equation 1 can be replaced by l. This gives a simple ordinary differential equation, which can be solved by separation of variables to give

$$\ln\left(\frac{l_0}{l_1}\right) = a(t_1 - t_0) + b\int_{t_0}^{t_1} T\,dt \tag{2}$$

where the first term is the time interval between readings, Δt, in days, and the second is the temperature sum accumulated between readings in degree days. This can be written in simpler notation as

$$\ln\left(\frac{l_0}{l_1}\right) = a \cdot \Delta t + b \cdot DD_0 \tag{3}$$

and used as a regression model. The coefficients a and b can then be found by fitting this model to field data. With these, equation 1 can be used to calculate

instantaneous rates of change of capillary length. Rates of pheromone mass release are then obtained using the capillary diameter and the pheromone density.

METHODS AND MATERIALS

Dispensers. Both dispensers were produced by Shin Etsu Chemical Co. (Tokyo) and consisted of 200 mm lengths of sealed polyethylene tubing, with ca. 1.4 mm outer diameter, 0.8 mm internal diameter, and 0.3 mm wall thickness (schematic diagram in Figure 5 below).

Dispensers for the light brown apple moth, *Epiphyas postvittana* Walker (LBAM), contained 54.9 mg (*E*)-11-tetradecenyl acetate (*E*11–14:OAc), 2.5 mg *E*9, *E*11–14:OAc, 19.7 mg *Z*11–14:OAc, 8.7 mg of stabilizers, and 3.1 mg of other (unknown) additives. To use this model for the mass of pheromone release, it was necessary to multiply the column length by the amount of pheromone per millimeters of liquid length. Initial liquid length was 170 mm, resulting in 0.337 mg pheromone/mm liquid length. A dispenser for the greenheaded leafroller, *Planotortrix octo* Dugdale (OCTO), contained 58.7 mg *Z*8–14:OAc, 19.6 mg *Z*5–14:OAc, 3.5 mg of stabilizers, and 6.2 mg of other additives. This yielded 0.460 mg pheromone/mm capillary length.

Dispenser liquid was shaken to one end, the tubing straightened, and suspended by thin wire at ca. 1.5 m in apple or shelter trees. Dispenser series consisted of liquid length measurements of 2–10 dispensers at 3–5 day intervals (mostly weekly). Dispenser liquid lengths were measured to the nearest 0.5 mm with a clear plastic ruler.

Twenty dispensers were also wrapped around small branches of apple trees in the Millbrook orchard, following normal commercial procedure. On June 3, 1993, 119 days after application, these dispensers were removed from around tree branches, straightened, and the liquid shaken down to a single column, which was then measured. These column lengths were later compared with those of dispensers that had been suspended and measured weekly for modeling.

Locations and Climate. Two orchard sites were used for the study of LBAM dispensers in Canterbury. The sites were Stafford Orchard (S43°34′E172°31′), which was well sheltered, and Millbrook Orchard (S43°36′E172°25′), which was less sheltered and more typical of Canterbury. Canterbury's climate and temperature are strongly correlated with wind direction, with sudden temperature changes associated with change in wind direction, and mean daily variation often not being sinoidal (Ryan, 1987). Summer temperatures are often greatly affected by a strong sea breeze. Data loggers (model CR10, Campbell Scientific, Logan, Utah) at both of these orchards recorded hourly temperatures from temperature probes placed under the canopy at 1.5 m. Daily maximum and minimum temperatures were obtained from hourly data.

The effect of temperature on release rate was studied in Central Otago at two sites for both LBAM and OCTO dispensers. The Clyde Research Centre (S45°12'E169°18') data logger (LI-1000, Li-Cor Inc., Lincoln, Nebraska) was placed in an existing open site meterological station, while the measured dispensers were in a nearby well-sheltered orchard block. The second data logger was at an orchard in Ettrick (S45°38'E169°22'), where dispensers were placed in rows of apple trees alongside the logger (model CR10, Campbell Scientific). Dispensers were also measured in three Dumbarton orchards 4 km away. Central Otago is characterized by greater seasonal extremes of temperature in summer and winter, reminiscent of a more typically continent climate, compared to Canterbury (Anon., 1980).

Analysis. Change in liquid column length, in the first week was not used, due to initial erratic patterns of release (Suckling and Shaw, 1990; McDonough et al., 1992). The multiple linear regressions were conducted by using Quattro Pro (Borland International, 1992).

Validation Experiments. Gas chromatography was used to investigate the relationship between the liquid column length and the instantaneous release rates of major components in the two dispensers. Thirty-three of each type of dispenser were suspended from one end in trees along the edge of a field in Lund, Sweden. Between August 28 and October 8, 1993, the liquid length was measured and a sample of three dispensers of each formulation was collected and frozen at −20°C until measurement of release rates. Sample dates were August 25, 26, 28, and 31; September 4, 10, 17, and 28; and October 8.

Intantaneous rates were measured after the dispensers had been removed from the freezer and suspended in the back of a fume hood for 24 hr. The dispensers ($N = 3$) were then individually suspended in a 250-ml round-bottom glass flask (Bengtsson et al., 1994) at 22°C for 1 hr, which had been shown to be much shorter than the time required for saturation of the flask (ca. 24 hr). The flasks were washed three times with redistilled heptane (5 ml altogether), and an internal standard of 10 μl of saturated tetradecenyl acetate (or dodecenyl acetate for native leafroller dispensers) was added. For quantification, we used a Hewlett Packard 5890 A gas chromatograph with a DB-Wax column and flame ionization detector, programmed at 80°C initial temperature for 2 min, followed by a rise to 230°C at a rate of 10°/min. The carrier gas was hydrogen at 30 kPa.

A further experiment was conducted to investigate the extent of capillary action, whereby pheromone enters the wall of the dispensers above the meniscus. We examined the pheromone present in the walls of aged LBAM dispensers ($N = 3$) as a function of distance from the main well, which contained 45 mm of liquid. Short sections of dispensers (10 mm) were cut at varying distances from within the pheromone column (0–10 mm) or towards the distal end (57.5–67.5 mm, 105–115 mm, 147.5–157.5 mm, and 190–200 mm). The pheromone

contents (if any) were removed by physical cleaning. The sections were then placed in 1 ml of distilled heptane and agitated for 24 hr before analysis as above.

RESULTS

Estimating Coefficients. Repeated application of the model on different data sets showed that the coefficient a, the model intercept, ranged from -0.00104 to 0.00244 for significant LBAM regressions (Table 1) and from -0.00141 to 0.00008 for significant OCTO regressions (Table 2). The model slope, b, was less variable ranging from 0.00014 to 0.00049 for LBAM (Table 1) and from 0.00028 to 0.00054 for OCTO (Table 2). The correlation coefficient, r^2, showed a wide range. Data points from all series that produced significant regressions were regressed together to give parameters used in the validation of the model, and the predictions of release rate compared with the actual data.

General Validation of the Model. The parameter estimates with greatest correlation coefficients for each region and for each dispenser type were used to determine how well the model described actual release rates (Figure 1). The initial length put into the model must be recorded a week or two after application to avoid the initial period of erratic release. An effect of compounding of error in the estimate of the volume of remaining pheromone can result in inaccuracy later in the season, although this can be readily solved by input of additional readings during the season. The size of any accumulated error of column length appears to be relatively minor in terms of the magnitude of effect on predicted release rate (15% below the actual release rate after six months). Predictions from hourly, daily, and weekly mean temperatures closely followed actual column lengths (Figure 1), although the daily maximum–minimum temperatures caused a slight underestimate in release rate.

Figure 2 shows how the use of the model can yield far more information than weekly column loss, which only provides weekly average release and may contain measurement errors. The modeled release rate follows the weekly release rate based on the measured losses in column length.

Effect of Measurement Interval and Experiment Duration. The longest series of observations (i.e., highest number of sampling occasions) for the two dispensers gave better correlations in the model, although the correlation did not change predictably with the shorter series (Tables 1 and 2). Some of the shorter series gave significant correlations (Tables 1 and 2). There was a difference between the experiment duration required between regions, and the Canterbury example indicates that at least six months should be studied to give a significant correlation. This period is similar in length to a typical growing season and would give a good variety of weekly day-degree accumulations.

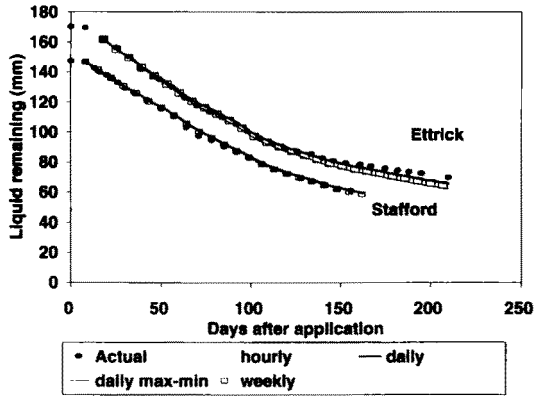

FIG. 1. Actual and predicted changes over time in pheromone column lengths in polyethylene tubing dispensers containing tetradecenyl acetates used for mating disruption of *Epiphyas postvittana* in two regions of New Zealand. Predictions from hourly temperature records were identical to those from daily records.

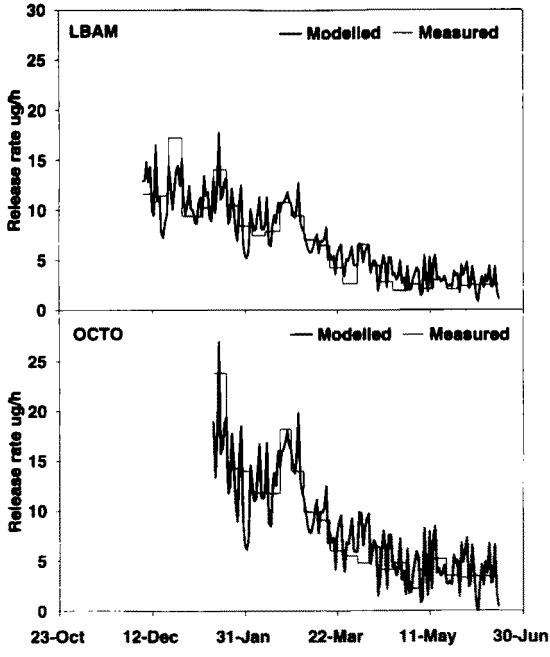

FIG. 2. Measured (weekly) and modeled (daily) release rate from polyethylene tubing pheromone dispensers containing tetradecenyl acetates used for mating disruption of *Epiphyas postvittana* (top) and *Planotortrix octo* (bottom).

In order to extend this model to new dispenser formulations, the parameters must be estimated from field data. It appears from our results that dispenser measurements at two-week intervals for six months would be sufficient to permit prediction of release rates, when accompanied by hourly temperature recordings over that period.

Effect of Data Logger Location. The prediction of column length was seen to be superior at locations where the temperature data was collected on site, compared to where it was collected at distances of several kilometers. An example of this is the measurements on dispensers in orchards at Dumbarton (Booth, Kane, and Preedy orchards) using temperature data from a site 4 km away (Table 2). While these still gave significant regressions, the correlation was lower than with the Ettrick series. Correlation decreased with increasing distance from the data logger in this situation. In an extreme situation at Clyde, where dispensers were in an overhead-irrigated, well-sheltered orchard, and temperature was recorded in an exposed, nonirrigated meterological station, the prediction of column length was not possible, as coefficients could not be estimated.

Instantaneous Release Rates. The parameters a and b were estimated for use with daily mean temperature and can be used to calculate the release rate each day (Figure 3). However, if instantaneous release rates are needed, these parameters must be divided by an appropriate time interval (dm/dt) (i.e., divide by 24 for hourly estimates). In addition, the current temperature and column length can be used to estimate the instantaneous pheromone release rate. The fluctuations over a single day can be traced more precisely with more frequent time intervals, and this can be useful for comparison with the biologically important period of insect flight (e.g., Figure 3). This figure illustrates that the bulk

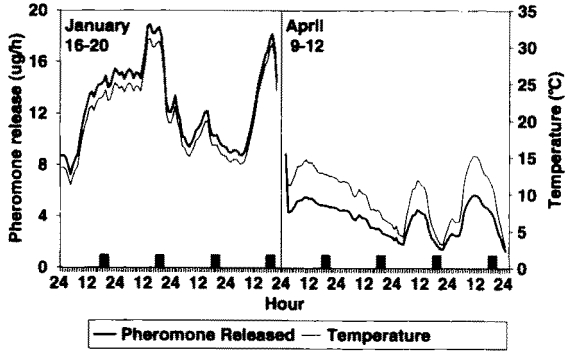

FIG. 3. Modeled hourly pheromone release rates over January 16–20 and April 9–12, 1993, compared to temperature. Bars show periods of flight activity at dusk.

of the pheromone is released during the day, when it is not needed, and that the release rate relative to temperature decreases between January and April.

Difference between Hanging and Twisted Dispensers. After 119 days, there was a significant difference ($t = 4.04$, $df = 28$, $P < 0.001$) between liquid length in dispensers suspended from one end, such as those upon which the model was based (86.3 ± 0.97 mm), and those that were twisted when applied for pest control purposes (78.5 ± 1.28 mm). The data indicated that the twisted dispensers released 9% more than the hanging dispensers. However, this difference was likely to be in part due to measurement error, because adhesion to the walls of the twisted dispensers, which were shaken down just before measurement, would have shortened the column length.

Validation Experiments. The instantaneous release rates of *E*11- and *Z*11-14:OAc decreased in proportion to the length of liquid remaining in the capillary, with a ratio that reflected the original contents. Our model gave predictions of release rates in still air that were within the experimental error, except for the initial period (Figure 4). The slower decline in release rate was better predicted by the model. The release rates of *Z*5-14:OAc and *Z*8-14:OAc were also adequately described by the model, after an initial period of higher release rate (data not shown for brevity). The proportion of *Z*5-14:OAc in the blend varied from 24 to 28%, but no trend in release was shown over time.

The most likely explanation for this early behavior is that the wall of the polyethylene capillary had a finite storage capacity and that this was more fully charged at the beginning when the dispensers had just been removed from their sealed packaging. During this period, pheromone could be conducted more rapidly to the surface. Measurements of changes in pheromone content of the

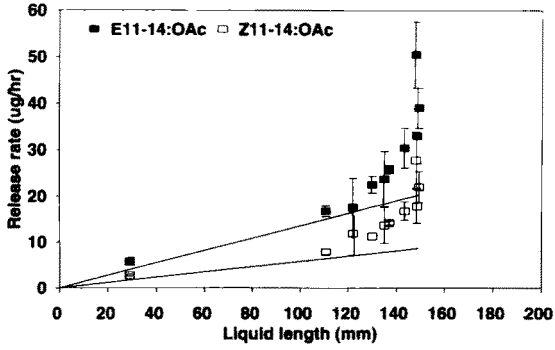

FIG. 4. Actual (data points) and predicted (lines) release rate of *E*11-14:OAc and *Z*11-14:OAc from polyethylene tubing pheromone dispensers maintained at 22°C in still air (bars show one standard error).

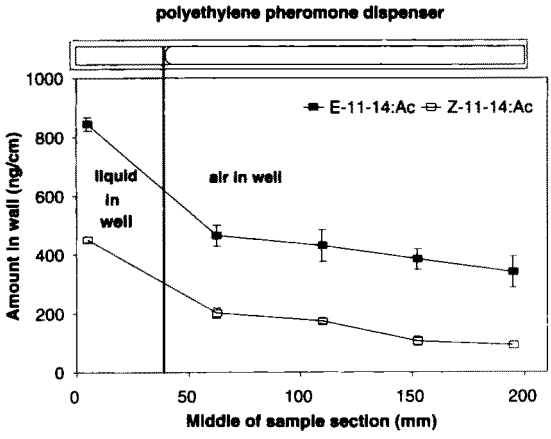

FIG. 5. Amount of *E*11–14:OAc and Z11–14:OAc in the wall of polyethylene tubing pheromone dispensers with either pheromone liquid or air adjacent to the wall.

walls above and below the capillary (Figure 5) support this view, as does the slower change in column length in the first one to two weeks (Figure 1). Walls adjacent to the pheromone liquid contain about 40 ng/mm more pheromone than that around the empty capilliary. A similar change in wall storage from initial saturation to the linear-region concentration is a sufficient source for the initial period of rapid release. Field data for the first one to two weeks were discarded so as not to include the period of rapid loss without associated column length change.

The amount of pheromone present in the wall of the dispensers adjacent to the pheromone liquid in the well was about twofold greater than the amount present in the wall when air was in the adjacent section of the well, and there was little change with distance from the meniscus (Figure 5). The amount of pheromone in the wall also declined with distance from the pheromone column, indicating limited longitudinal movement. The presence of detectable quantities of *E*- and Z11–14:OAc in the wall of dispensers may well be due to the adhesion of these materials within the polyethylene tubing, without indicating transport. Pheromone storage in the polyethylene material changes with time, so some pheromone is released from empty parts of the capillary tube. The loss from the tube wall as the capillary withdraws is about 10% as much as the loss from within the capillary. Up to a further 3% is desorbed and released later. This latter loss can be ignored. Although the model ignores the release from the portion of the dispensers with air in the well, the effect of this factor appears to

be quite small, since the model predictions quite accurately describe pheromone loss from the dispensers.

DISCUSSION

The need for a model of pheromone release rate from dispensers has arisen in the context of understanding the mechanisms and limitations associated with mating disruption of leafrollers. The model proposed here offers a practical first attempt to determine pheromone release rates, based on a minimum of inputs. In the past, weekly measurements of column length have not provided adequate resolution of pheromone release rate to explain the frequency of mating in a seven-day period, because daily fluctuations in temperature and release rate can confound the analysis (Suckling and Shaw, 1992).

This model appears to be versatile (able to predict both season-long trends and instantaneous release rates), and requires only a minimum of equipment for estimation of the inputs, in the case of stable blend components. Once the coefficients have been derived for a dispenser type and blend combination, only a single column-length and temperature reading is needed to produce estimates of current release rate. Conversely, a single column-length measurement accompanied by season-long temperature recordings provides sufficient input for at least a rough estimate of release rates over the season (although more frequent column-length measurements would improve the model prediction).

The GC analysis indicated that the release rates of individual components of the blends were not significantly different over time. In the case of LBAM (Figure 4), Suckling and Clearwater (1990) also demonstrated that the ratio of (*E*):(*Z*)-tetradecenyl acetate did not change over time. They reported a slightly faster rate of loss of the minor (3.2%) component, a diene (*E*9,*E*11:14OAc), which has been ignored in our model. Analysis of the OCTO dispensers also indicated similar release characteristics for the two components. These results were in agreement with the report of Sexton (1989), who noted the lack of effect of double-bond position on release rate in similar polyethylene tubing dispensers.

Our model may not be suitable for dispensers containing mixtures of alcohols and acetates which diffuse at different rates (e.g., codling moth) (Brown et al., 1992).

The model of McDonough et al. (1992) was developed using gas chromatographic (GC) analysis of polyethylene codling moth dispensers and showed how different components were released at different rates over time (not day-degree accumulation). They mentioned variation in day-degree accumulation between years, but they did not include this variation in their model, which was based on three constants and column length. They considered that photodegradation was the main cause of reduction in pheromone rather than liquid loss

and/or temperature accumulation. McDonough et al. (1992) did attempt to explain what was happening with dispenser release rates over the first few days, a period that our model ignores.

Complex models, such as that proposed by Brown et al. (1992), appear to have important limitations and lack portability to other linear or tubing dispenser types. The main difference between earlier models and our model involves the relationship between temperature and release. The model of Brown et al. (1992) was based on the exponential increase of pheromone release with temperature, a relationship based on the Clausius-Clapeyron equation. We considered this inappropriate for our dispenser system, since it is based on a model where release is controlled by boundary layer resistance and surface vapor pressure. The Shin Etsu dispensers that we used are relatively insensitive to wind speed (note the fit of the field model to data from still air), a factor that has been ignored by both Brown et al. (1992) and McDonough et al. (1992). Wind is also reported to have little effect on hollow-fiber dispensers, where diffusion from the liquid–vapor interface to the open end of the fiber is the rate-determining step (Bierl-Leonhardt, 1982).

Our model uses a linear release rate–temperature relationship, which seems to work well over the relevant temperature range. Pheromone release rates were found to increase exponentially with temperature by Van der Kraan and Ebbers (1990) for a polymeric or laminar dispenser, where boundary-layer resistance is much more important.

The other major difference between the model of Brown et al. (1992) and the model we present is that their decline in release rate over time was based on temperature accumulation, whereas in our model it is based on column length change. Since the ratio of dispenser components changes greatly in Brown et al. (1992), the use of temperature accumulation seems appropriate in their case. Our model, which so far only applies to the relatively stable tetradecenyl acetates, uses column length change for ease of use. Since our model is based on temperature, a relationship between column length and temperature accumulation is easily derived, once coefficients are found.

Weekly observation of dispensers for six months can give the coefficients for subsequent prediction of release rates. Temperature monitoring, often performed for other orchard applications, such as disease forecasting, can now replace regular field measurements of dispensers. However, compounding errors (15% after six months) could be reduced by occasional measurement of dispenser column lengths. Hourly modeling can provide additional information, for example, predicting release rate during evening flight periods (Figure 3) (Suckling et al., 1994).

Predictive Applications. A significant unknown in mating disruption applications is the minimum atmospheric concentration required to obtain effective

disruption. This concentration is likely to be dependent on biological factors specific to the insect species, as well as the crop growth form (e.g., green tea bushes compared to orchards), but other variables will also be very important. In addition to release rate, wind has been shown to have a large effect on atmospheric concentration (Uchijima, 1988). Crop foliage affects wind speed, as well as adsorbing and releasing pheromone (Karg et al., 1994). In future, it may be possible to use a dispenser release rate model as an input for an atmospheric pheromone concentration model to predict concentrations as a function of meteorological conditions. Such a model could provide opportunities for optimizing the effectiveness and economics of mating disruption. Once criteria such as the period and atmospheric concentration required are defined, then optimal dispenser deployment could be determined. McDonough et al. (1992) used the thresholds of other authors to recommend deployment timing, but since their model was based on time rather than temperature accumulation, their analysis was very simplistic. Our model could provide the basis for predicting the probability of dispensers lasting the required period. The risk of failure could be found through an analysis of long-term climate data, since the life of dispensers will be affected by annual changes in accumulated temperature.

Acknowledgments—Thanks to Craig Howard and Helen Ogle (HortResearch), who regularly measured dispensers. We also thank Dr. Tom Bellas (formerly CSIRO) for initial work on some of our LBAM dispensers.

(Received October 26, 1994; accepted February 16, 1995)

Abstract—The *Nr*-gene-based resistance of lettuce to the aphid *Nasonovia ribisnigri* (Mosley) has previously been shown to be located in the phloem. Since chemical analyses of the phloem sap had shown no differences between resistant and susceptible lines, a bioassay was developed in order to test samples from resistant and susceptible plants on aphid feeding. For this, whole-plant extracts, honeydew, and EDTA-collected phloem extracts were obtained, and a sensitive bioassay was developed using EDTA samples. The EDTA was removed, and samples were added to a simple sucrose solution or to a complex artificial diet and presented in a choice situation comparing extracts from resistant and susceptible plants. EDTA-collected phloem sap samples from susceptible plants were preferred to those from resistant plants. The resistance is probably based on a feeding deterrent activity of the phloem sap in the resistant plant.

Key Words—Aphididae, *Nasonovia ribisnigri*, *Lactuca sativa*, phloem sap, bioassay, resistance mechanism, artificial diet, aphid honeydew, EDTA chelation.

INTRODUCTION

Resistance of plants to aphids is difficult to investigate because of the highly specialized feeding behavior of these insects. In many cases the resistance is

*To whom correspondence should be addressed.

0098-0331/95/0600-0761$07.50/0 © 1995 Plenum Publishing Corporation

based on an interruption of the feeding behavior after the phloem sieve element has been reached by the mouthparts of the insect (Kimmins, 1989; Padgham et al., 1990; Caillaud et al., 1992; Cole, 1993; Helden and Tjallingii, 1993). Elucidation of the (chemical) resistance mechanism(s) is very difficult (Dreyer and Campbell, 1987; Harrewijn, 1990; Wink and Witte, 1991). So far investigations into resistance to homopteran insects have often used correlations of total plant levels of certain chemical compounds with performance traits (Todd et al., 1971; Argandoña et al., 1980; Dreyer and Jones, 1981; Herrbach, 1985; Leszczynski et al., 1985; Niemeyer, 1990; Kanehisa et al., 1990; Luczak and Gaweda, 1992). Phloem sap, the only plant component ingested as food by aphids, represents only a small part of total plant extracts. When resistance is based on a chemical component of the phloem sap, it will very likely be lost in whole plant preparations.

The absolute, monogenic resistance of lettuce (*Lactuca sativa* L.) to the aphid *N. ribisnigri* (Nr gene) (Eenink et al., 1982; Reinink and Dieleman, 1989; Helden et al., 1993) is based on an early interruption of sap uptake after the aphid stylets have reached a phloem vessel (Helden and Tjallingii, 1993). Although a mechanical resistance mechanism, like blocking of the stylets or sieve elements during attempted feeding, cannot be excluded as a possible resistance mechanism, our current working hypothesis is that a chemical difference in the phloem sap may interfere with host plant recognition or acceptance in the resistant plants (Helden and Tjallingii, 1993; Helden et al., 1994a,b; Wink and Witte, 1991).

Phloem sap samples were obtained by stylectomy, facilitated excudation [using ethylene diamine tetraacetate (EDTA) chelation], and honeydew collection and analyzed for sugars, amino acids, proteins, and UV-absorbing secondary plant compounds, which showed no consistent differences between resistant and susceptible lettuce lines (Helden et al., 1994a,b). Lettuce contains many secondary compounds (Gonzalez, 1977), but little is known about their presence in the phloem and their biological activity. Exhaustive analysis of secondary compounds in the phloem sap of lettuce, without knowledge of the biological activity of the active substances (allomones), is very time consuming.

The development of a bioassay using EDTA-collected phloem sap extracts of the plants, as described here, could make a "classical" bioassay-guided fractionation, isolation, and identification of the allomones involved in the resistance feasible.

METHODS AND MATERIALS

Plants and Aphids

Plants were grown and aphids reared as described earlier (Helden et al., 1993, 1994). Larvae were used when 5 days old (L3 stage) unless otherwise

stated. Two sets of near-isogenic lettuce lines were used: SUS (susceptible, genotype *nrnr*) and RES (resistant, *NrNr*) (SET1), SUS2 (*nrnr*) and RES2 (*NrNr*) (SET2), lettuce cv. Taiwan (susceptible, *nrnr*) and oilseed rape cv. Olymp (*Brassica napus* L.) (Helden et al., 1994a,b). The two near-isogenic sets 1 and 2 have genetically different backgrounds (except for the source of the *Nr* gene, Helden et al., 1994a).

Plant and Phloem Extracts

Whole-Plant Extracts. Whole plants were heated in a microwave oven for 20 sec to destroy all enzymatic activity in the sap. Sap was pressed from the leaves, filtered, and used directly. Methanol extracts were prepared from 0.2 g lyophilized leaves in 10 ml of MeOH, followed by ultrasonic mixing for several minutes, centrifugation, filtration, and vacuum drying.

Honeydew. Honeydew from oilseed rape and Taiwan lettuce was collected using *Myzus persicae* Sulzer (biotype WM1). For the collection of honeydew from the lines RES and SUS, *Macrosiphum euphorbiae* Thomas (biotype WMe1) had to be used because the *Nr* gene also causes partial resistance to *M. persicae.* Honeydew was collected in hexadecane (Helden et al., 1994a), stored at −80°C, and lyophilized prior to use. Occasionally honeydew was collected directly on Petri dishes that were placed underneath large quantities of aphid larvae on leaves. This "dry-collected" honeydew was dissolved in a water–MeOH (1 : 1) mixture, MeOH was evaporated in vacuo and the aqueous extract was lyophilized.

Sample Preparation from Crude EDTA Extracts. Phloem sap exudate was collected by placing excised leaves in an aqueous solution with 8 mM EDTA and 5 mM phosphate buffer at pH 6 for 20 hr (King and Zeevaart, 1974; Groussol et al., 1986; Helden et al., 1994a). Initially 5 mM sodium metabisulfite ($Na_2S_2O_5$) was used as an antioxidant, but later this was omitted because of toxicity to the aphids. The crude EDTA extract was stored at −20°C. To remove the EDTA from the crude EDTA extract, the following procedure was used: 0.5 g of a weak cation exchange column (Varian Bond Elut CBA 500, carboxylic acid) was activated with 5 ml ammonium buffer (pH 10), washed with H_2O, and loaded with 10 ml of a 0.01 M lead nitrate solution. After washing with H_2O, 10 ml of crude EDTA extract was added and 2-ml fractions were collected. Fractions were tested for the presence of EDTA (see below). EDTA-free fractions (usually the first four) were combined, lyophilized, and stored at −20°C until use. These EDTA-free samples will be referred to as Ed samples (EDTA-derived samples) throughout this paper. After cleaning with 10% formic acid in water, the columns were reused.

Control Treatments. Together with the Ed-samples, two different control treatments were used. The first was a blank control (Blank) (nothing added). The second control treatment (Control) was used to compensate for the amino

acids and sugars in the Ed samples and to counterbalance the possible artifacts introduced by the EDTA extraction procedure. A complex artificial diet (consisting of 15% sucrose, amino acids, vitamins and salts) (Harrewijn and Noordink, 1971) was diluted around 30 times in the original EDTA chelation solution (8 mM EDTA and 5 mM phosphate buffer). This solution was then treated identically to the crude EDTA extracts (Pb-EDTA extraction, lyophilization, storage). The resulting samples are referred to as Ed diet. To make the Control treatments, this Ed diet was dissolved in the sugar (sugar tests) or in a complex diet (diet tests) in the same amounts as the Ed samples (see below).

EDTA Detection. EDTA was detected using a color reaction with Eriochrome black T as an indicator. Two droplets of indicator (0.1% w/v), 1 ml H_2O, and two droplets of ammonium buffer were mixed in a test tube. Lead nitrate solution was added until the color changed to purple. To test for the presence of EDTA, five (or more) droplets of a fraction were added to a test tube. A color change to blue indicated the presence of EDTA (detection limit $\pm$ 2 μM of EDTA).

Preparation of Tests

All tests were prepared in a laminar flow cabinet. Materials were cleaned with 70% ethanol prior to use. All test slutions were filtered through a 0.22-μm micropore filter.

No Choice Tests. Test solutions consisted of 15% sucrose in water with one of the following additions: whole plant sap (5 or 10% v/v); methanol extracts (50 mg/ml); crude EDTA extracts (10% v/v); EDTA at 0, 5, 10, 25, 100, or 200 mM; or $Na_2S_2O_5$ at 0, 5, 10, 25, or 100 mM. Test solutions were presented between two layers of Parafilm, stretched over a 26-mm-diameter plastic ring to form a test cage. Eight freshly molted adult aphids were introduced, and survival and reproduction were scored after 48 hr.

Multiple Choice Tests. These were prepared according to Dorschner and Kenny (1992). Parafilm sachets with different sucrose concentrations (0, 5, 10, 20% w/v in H_2O) in different combinations were presented through six holes in the lid of a 9-cm Petri dish and a large number (>100) of aphids of mixed age were introduced into the dish. Distribution of the aphids over the six sachets was determined after 24 and 44 hr. Plant extracts were not tested.

Dual Choice Tests. For the honeydew tests, sugar tests, and artificial diet tests, we constructed sachets with two adjacent test solutions separated by only a few millimeters (Figure 1). The two layers were firmly pressed together by rolling a 2-mm-wide rubber wheel over them.

Twenty larvae of *N. ribisnigri* were introduced, and the tests were placed in a 24°C incubator with weak illumination from the top. Transparent yellow plastic foil was placed below the light source to stimulate settling on the Parafilm surface. Aphid distribution was determined several times (after 8–72 hr). Usu-

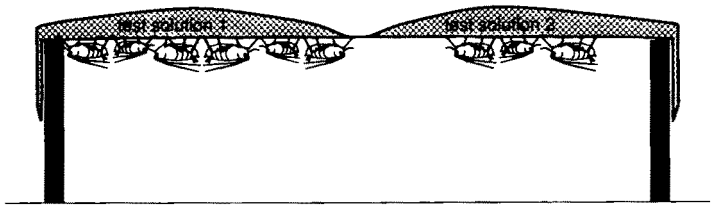

FIG. 1. Cross section of the test cage with a dual-choice sachet. Twenty larvae of *N. ribisnigri* can freely select a feeding site on a test solution.

ally at least six replicates (minimum for statistical differences) were included in each test (see results).

Honeydew Tests. Test solutions for these dual-choice tests were made by adding freeze-dried honeydew (10 mg/ml) to a 15% aqueous sucrose solution. Dual-choice tests also included 15% sucrose solution (Blank).

Testing of Ed Samples

Acceptability Test. Ed diet was dissolved at 20 mg/ml in artificial diet and tested against artificial diet to which 20 mg/ml of lyophilized artificial diet (not treated on the column) was added.

Sugar Tests. Tests were performed using Ed samples from RES and SUS (treatment RES and SUS) dissolved at 5 mg/ml in 15% aqueous sucrose solution. These were compared with two controls: a blank control (Blank, 15% sucrose with nothing added) and a second control (Control) consisting of a 15% sucrose solution to which 5 mg/ml of Ed diet was added. These four treatments make six possible pairs for a dual-choice test. The same combinations were also tested at 20 mg/ml. The extracts of RES2 and SUS2 were also tested in all possible combinations with Blank and Control at 5 mg/ml and 20 mg/ml.

Artificial Diet Tests. For these tests, all samples were dissolved in a complex artificial diet. There was no Blank treatment. The control treatment (Control) consisted of complex artificial diet to which 5 (or 20) mg/ml of Ed diet was added. For comparison of SET1, this gives RES, SUS, and Control (so only three possible dual-choice combinations) at 5 mg/ml, and the same at the higher concentration of 20 mg/ml. The same concentrations and combinations were tested for the near-isogenic SET2 (RES2, SUS2, and Control).

Statistics

Choice test results were compared by Wilcoxon's signed-rank tests at the 5% significance level.

RESULTS

No Choice Tests. Tests with whole plant sap or methanol extracts showed 10–50% mortality of the adults and very low reproduction as compared to complex artificial diet. No differences were observed in mortality or reproduction between test solutions containing the resistant or susceptible whole-plant extracts.

EDTA affected survival at concentrations over 10 mM, and at 100 mM or higher most aphids died within 24 hr. Little mortality occurred at lower concentrations but reproduction was low (< 1 larvae per adult per day). The antioxidant sodium metabisulfite caused high mortality, even at concentrations below 10 mM.

Tests with crude EDTA extracts (containing EDTA and antioxidant) showed low acceptance of the test solutions, low reproduction, and high mortality. When the antioxidant was omitted during collection and the EDTA extracted, no mortality was observed and more than 80% of the aphids settled on the test solutions. Multiple choice tests gave no discrimination among sucrose solutions of different strengths. Aphids settled poorly and appeared restless (data are not given). In the dual choice tests, observations after 8, 20, or 28 hr showed no or less pronounced differences, whereas during later observations (>48 hr) microbial contamination of the test solutions was sometimes visible. Figures 2–4 only show the results after 40 hr.

Acceptability Test. The acceptability tests suggested that the lyophilized diet was slightly preferred to the Ed diet (distribution after 40 hr diet–Ed diet $= 10.1:6.6$, $N = 11$), but this difference was not statistically significant.

Honeydew Tests. Honeydew of host (Taiwan lettuce) and nonhost plants (oilseed rape) was strongly favored over the sucrose treatment Blank (Figure 2a), and honeydew from lettuce was preferred to honeydew from oilseed rape. When testing honeydew of near-isogenic resistant (RES) and susceptible (SUS) lines, these were both selected over sucrose only and honeydew of resistant plants was preferred to susceptible plants (Figure 2b).

Ed Samples in Sugar Tests. In the sugar test, comparing Ed samples of the SET1 aphids showed a slight, but significant, preference for SUS to RES at low concentration (5 mg/ml, $N = 16$) while all other combinations showed no significant difference (Figure 3a). At the higher concentration, Ed samples of SET1 were preferred to Blank but not to the Ed diet (Control), and SUS was selected over RES (Figure 3b). Ed diet was selected over Blank at the high concentration (Figure 3b and d).

The tests of SET2 showed that RES2 was preferred to SUS2 at 5 mg/ml (Figure 3c), while none of the other combinations showed significant discrimination by the aphids at this low concentration, not even Ed diet against Blank. At higher concentrations (Figure 3d), RES2 was not favored over SUS2, but all

(a) Comparison of honeydew produced by *M. persicae* on lettuce cv. Taiwan (susceptible), oilseed rape (nonhost), or Blank (just sugar); (b) comparison of honeydew produced by *M. euphorbiae* on *Nasonovia*-resistant (RES) and susceptible (SUS) lettuce and sugar-only (Blank). Bars represent mean number of *N. ribisnigri* aphids on each of the test solutions after 40 hr. Numbers above bars are number of replicates. *significant difference at 5% level.

of the other combinations showed a significant deterrence of Ed samples compared to Blank or even Control.

Ed Samples in Artificial Diet Tests. The tests based on the addition of extracts to a complex artificial diet (Figure 4) showed very distinct discrimination of different test solutions by the aphids, except for the low concentration of the SET1 Ed samples (Figure 4a). At 5 mg/ml samples of SET2, there was a preference of SUS2 to RES2 but SUS2 was not selected over Ed diet (Figure

See text for details on processing of extracts. (a) SET1 (RES, SUS) lines or Ed diet (Control) at 5 mg/ml and Blank; (b) at 20 mg/ml; (c) SET2 (RES2, SUS2) or Ed diet (Control) at 5 mg/ml and Blank; (d) at 20 mg/ml. (d) Bars represent mean number of aphids on each of the test solutions after 40 hr. Numbers above bars are number of replicates. *significant difference at 5% level, N.T. = not tested.

4c). At the high concentration, Ed diet was selected over Ed samples and the Ed samples from susceptible plants over resistant plants (Figure 4b and d).

DISCUSSION

Whole-plant extracts were toxic, probably due to secondary compounds present in cell vacuoles and released or activated upon the crushing of the cells during extraction (Matile, 1984). We did not succeed in designing a test using whole-plant samples that resulted in a discrimination.

Of the methods available to collect phloem sap from lettuce, only honeydew and EDTA chelation yield sufficient quantities (Helden et al., 1994a,b). The

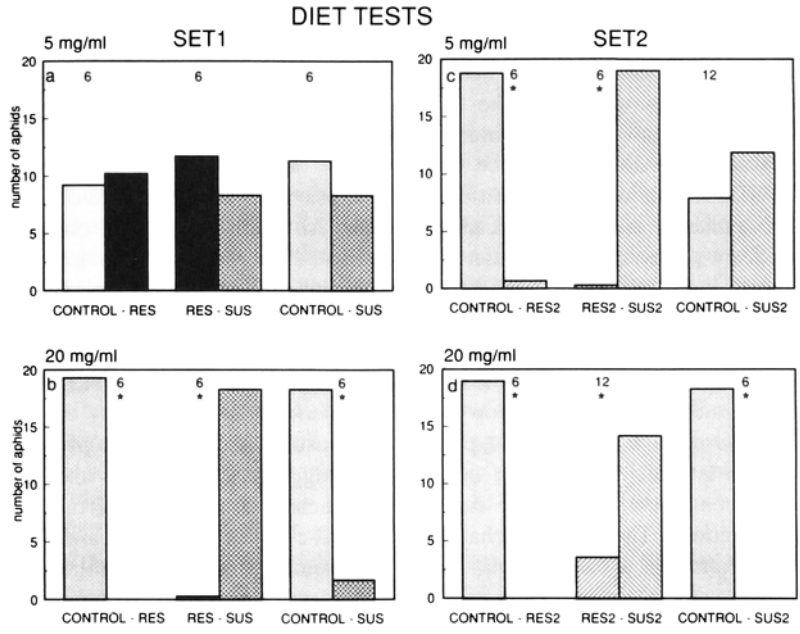

FIG. 4. Diet tests. Results of the dual-choice tests using Ed samples from different lettuce lines dissolved in complex artificial diet. See text for details on processing of extracts. (a) SET1 (RES, SUS) lines or Ed diet (Control) at 5 mg/ml; (b) at 20 mg/ml; (c) SET2 (RES2, SUS2) at 5 mg/ml; (d) at 20 mg/ml. Bars represent mean number of aphids on each of the test solutions. honeydew is bioprocessed (by the aphids) and different species (*M. persicae* and *M. euphorbiae*), which might differ in their bioprocessing, had to be used. EDTA chelation exudates are considered to be reliable representations of phloem sap. Contamination with substances from other plant parts and from the cut (wounded) surface of the petiole might occur, but this has not been shown to be of major importance (Fisher and Frame, 1984; Weibull et al., 1990; Girousse et al., 1991; Helden et al., 1994a,b). The crude EDTA extracts were not accepted by the aphids because of the presence of EDTA and sodium metabisulfite. Omission of the antioxidant during EDTA exudation increased the browning of the extracts. Although we cannot check it, this might have affected the biological activity against *N. ribisnigri* in the tests.

During the processing of the samples the EDTA was retained by the lead

ions on the column as a Pb–EDTA complex. It is possible that other components of the crude EDTA extracts also may have been retained on the column. Some column components may have been released (lead ions or Pb–EDTA complex), and EDTA removal during the EDTA extraction procedure may have been incomplete (below detection limit). In initial experiments, traces of lead (precipitation test with Kl) could be shown in the "EDTA-free samples" when a pure EDTA solution was processed. In the Ed samples we sometimes observed a precipitate, presumably of lead phosphate. Although we did not observe a significant preference for Ed diet over nontreated diet (acceptability test), this may still have affected the aphids. However, since the treatment of all samples included the step of EDTA removal, artifacts will occur in all Ed samples and Ed diet in roughly equal amounts, so this does not affect our conclusions.

Design of the Test. The bioassay of Dorschner and Kenny (1992), which demonstrated preference for hop (*Humulus lupulus* l.) honeydew by the hop-aphid *Phorodon humili* Schrank, proved to be unsuitable for *N. ribisnigri*, which feeds on lettuce. *N. ribisnigri* often showed aggregation behavior and accumulated on one or two of the six available sachets (irrespective of the sugar concentration). Therefore we changed to a dual-choice test (Mittler and Dadd, 1964; Harrewijn and Noordink, 1971). Our setup, using two parafilm membranes pressed together in the middle, uses very little solution to fill the two compartments and has no border between the adjacent compartments that can act as a barrier (Figure 1). Therefore, the aggregation behavior will not influence the results strongly. Still an individual aphid cannot be considered as independent from the others in the same test. The simplicity of the dual-choice test makes it possible to make many (at least six) replicates, necessary to show statistically significant differences.

Unequal distribution of the aphids over the two sides became apparent only after 20 hr or more. This is much later than observed by Mittler and Dadd (1964) on artificial diets and also much later than expected from the rejection of the phloem sieve element once this is reached by the aphid (Helden and Tjallingii, 1993). The latter may be explained by the level of compounds in the choice tests, which will be around 10 times lower than in the real phloem sap. Only 20 mg/ml of Ed sample is added, while normal lettuce phloem sap has a dry weight of around 20% (200 mg/ml). It cannot be excluded that the test solutions changed over time, e.g., because of continued enzymatic activity (Helden et al., 1994b), but this would also mean that there is a chemical difference between fractions.

Test Results. The preference for lettuce honeydew (susceptible cv. Taiwan) over the nonhost plant (oilseed rape) suggests that the host-plant honeydew has a feeding stimulant effect or the nonhost a feeding deterrent effect (Dorschner and Kenny, 1992). Preference for the honeydew to sucrose only (Blank) (Figure 2) is probably caused largely by the amino acids present in the honeydew (Dor-

schner and Kenny, 1992; Mittler and Dadd, 1964; Helden et al., 1994b). The choice for RES honeydew over SUS honeydew (Figure 2b) shows that there is a chemical difference, but this is surprising since the inverse would be expected (discussed below).

The sugar tests at 20 mg/ml (Figure 3b and d), just like the honeydew tests, clearly show that attractiveness of a combination of sucrose with amino acids. In the test combinations that include a Blank treatment, the small quantity of amino acids present in the Ed samples or the Ed diet makes these treatments strongly preferred to Blank, which lacks amino acids. At the low concentration (5 mg/ml) most choices show no significant preference. The absence of response in Blank versus Ed diet at 5 mg/ml (Figure 3c) suggests that this might be caused by the low quantity of the compounds added.

The comparison of Ed samples with Ed diet (Control) gives more valuable results since little interference due to amino acid concentration differences (or EDTA extraction artifacts) will occur. Ed samples (Figure 3b and d) are not preferred to Ed diet, and in some cases (higher concentration test) not even to Blank (Figure 3d), suggesting the presence of feeding deterrents in the Ed samples.

We decided to use a complex artificial diet as a base for the tests in order to decrease the sensitivity to variations in amino acids and sugars in the Ed samples, which is not related to the resistance (Helden et al., 1994b). This could also increase the sensitivity to other compounds that might only show biological activity in a "phloem-like" environment. The results of these artificial diet tests (Figure 4) show a profound increase in the response of the aphids.

The artificial diet test demonstrated significant preferences for Ed diet (Control) to plant extracts (except for SET1 at 5 mg/ml). This suggests that all Ed samples (of both sets and for both resistant and susceptible plants) contain a certain feeding deterrence. The preference for SUS and SUS2 to RES and RES2, respectively, proves that there is a chemical difference between these extracts, which (at 20 mg of Ed sample/ml) causes a stronger feeding deterrence in the Ed samples from resistant plants.

The total absence of significant differences in the diet tests of SET1 at 5 mg/ml (Figure 4a) compared to SET2 (Figure 4c) suggests that the concentration of the feeding deterrents in SET1 are lower than, and in this case under, the behavioral threshold for the aphid, as for the low concentration sugar tests (Figure 3a and c). This suggests that modifications in the level of the resistance do occur in spite of the supposed monogenic nature of the resistance. This could be caused by minor genes that influence the resistance caused by the *NR* gene, or other genes that provide additional (partial) resistance.

In a few cases, extracts from resistant plants were preferred to susceptible extracts (honeydew tests, Ed samples in sugar tests of SET2 at 5 mg/ml). Feeding deterrents have been reported to act as feeding stimulants at low con-

centrations (Bodnaryk, 1991). Deterrence of the resistant extracts at 20 mg/ml could change to a feeding stimulant at 5 mg/ml, and allomones could also be present in the susceptible plant but at lower concentration. To test this hypothesis more test series should be performed, comparing different concentrations of Ed samples from the same or different plants, and in combination with appropriate controls. However, possible interactions with other biologically active substances will not make this easy.

When honeydew is used, a feeding deterrent could be metabolized and excreted in the honeydew, with its degradation products acting as feeding stimulants. The reverse might be true in the case of a feeding stimulant. Since little is known about the fate of secondary plant chemicals in aphids (Wink and Witte, 1991, Givovich et al., 1992, Helden et al., 1994b), this remains speculative.

The sensitivity of the test might be improved by adjustment of the amino acid composition of the complex artificial diet (and the Ed diet) to that of lettuce phloem sap (Helden et al., 1994b) and total removal of possible interfering compounds from the Ed samples. The use of higher concentrations of the samples would require large quantities of plants.

Although the results of the honeydew and sugar tests cannot be explained easily, the diet test results show that there is a clear chemical difference between extracts from resistant and susceptible plants. This allows some optimism that this bioassay can be used to isolate the active substances through bioassay-guided fractionation. Still, the physical and chemical resemblance (pressure, concentration, etc.) of the test to the in vivo system remains very approximate, and the EDTA sample processing needs to be improved. Direct extrapolations of the in vitro test results to the in vivo situation are hazardous. The phloem sap origin of any isolated compound needs to be confirmed and the mode of action should be studied in the plant.

(Received October 7, 1994; accepted February 17, 1995)

Abstract—The basis for differential allelopathic potentials among sorghum (*Sorghum bicolor* L. Moench) hybrids was investigated by conducting quantitative and qualitative studies of their phenolic contents. Total phenolic content in sorghum plant parts varied within hybrids, among hybrids, and between growing seasons. Inhibition of wheat (*Triticum aestivum* L.) radicle growth was positively associated ($r = 0.66$) with concentrations of total phenolics contained in plant parts. Extracts from culms contributed the highest proportion of toxicity from sorghum plants, inhibiting radicle growth up to 74.7%. Concentrations of five phenolic acids, *p*-hydroxybenzoic (POH), vanillic (VAN), syringic (SYR), *p*-coumaric (PCO), and ferulic (FER), differed in all plant parts of the three sorghum hybrids. Concentrations of POH, VAN, and SYR were consistently higher than PCO and FER. PCO and FER were absent from some plant parts, with FER being the most frequently missing. Inhibition of wheat radicle growth was found to be positively associated with the concentration of each phenolic acid. Vanillic acid was most highly associated ($r = 0.44$) with inhibition. Thus, above-ground sorghum tissues contained phenolic acids that contributed to allelopathic potential. Additionally, sorghum roots exuded POH, VAN, and SYR that may enhance the overall allelopathic potential of sorghum during growth and after harvest when residues remain on the soil surface or are incorporated prior to planting a subsequent crop.

Key Words—Bioassays, phenolic acids, phytotoxicity, *Sorghum bicolor* L. Moench.

INTRODUCTION

Plants produce a large variety of secondary products containing hydroxylated aromatic rings. These substances are classified as phenolic compounds, most of which are synthesized from phenylalanine, a product of the shikimic acid pathway (Taiz and Zeiger, 1991). Sorghum (*Sorghum bicolor* L. Moench) contains phenolic compounds at all stages of growth, with higher levels in leaves and glumes compared to culms and caryopses (Waniska et al., 1988). Within the same plant part, bird-resistant hybrids contain more soluble phenolics than non-bird-resistant hybrids (Reed and Tedla, 1987). In four sorghum genotypes, phenolics such as coumaric and ferulic acids were found to be more concentrated in culms than in leaf blades or leaf sheaths (Cherney et al., 1991).

Plant polyphenols known as tannins are important in the defense mechanisms that plants develop to resist predators. This is largely due to the ability of tannins to bind proteins, which is characterized in the mouth of herbivores as a feeling of constriction, dryness, and roughness (Haslam, 1988). Levels of phenolic acids in healthy plants of sorghum differ considerably among cultivars and always decrease as the plants mature. However, attack by insects and pathogenic fungi increases the phenolic content of plants by varying degrees depending on cultivar and stage of growth (Woodhead, 1981). Sorghum contains a mixture of hydrolases that can transform "inactive" phenolic esters and glycosides into "active" phenolic acids at concentrations high enough to significantly reduce feeding by *Locusta migratoria* (Woodhead and Cooper-Driver, 1979).

In addition to phenolic acids in aerial plant parts, roots of allelopathic crops actively exude phenolics (Abdul-Rahman and Habib, 1989; Alsaadawi et al., 1986; Einhellig and Souza, 1992; Tang and Young, 1982). Caffeic, chlorogenic, isochlorogenic, *p*-coumaric, *p*-OH-benzoic, and ferulic acids were detected in alfalfa root exudates and vegetative residues (Abdul-Rahman and Habib, 1989). Bioassays of trapped root exudates of bigalta limpograss (*Hemarthria altissima*), an allelopathic tropical forage, showed that the inhibitors were mainly phenolic compounds (Tang and Young, 1982). Root exudates of sorghum consist primarily of sorgoleone, a hydroquinone that is quickly oxidized to a benzoquinone, which at extremely low concentrations (0.01–0.125 mM) can potentially inhibit weed growth, suggesting a strong contribution to sorghum allelopathy (Einhellig and Souza, 1992). Water extracts from decaying residues of four sorghum cultivars revealed that all cultivars significantly reduced redroot pigweed (*Amaranthus retroflexus* L.) growth, with greatest inhibition achieved by cultivars having toxic root exudates (Alsaadawi et al., 1986).

The realistic concentrations of phenolics necessary for inhibitory action under field conditions are estimated to be 3.3 mM for ferulic, *p*-coumaric, and vanillic acids. At this concentration, a synergistic effect on germination of sorghum has been reported (Rasmussen and Einhellig, 1979). Phenolic compounds such as *p*-hydroxybenzoic, vanillic, *p*-coumaric, and ferulic acids were found in the soil solution at 0.003–0.39 mM. These compounds are produced by decomposing straw or degradation of humic acids (Whitehead, 1964). Analysis of sorghum residues revealed that *p*-coumaric acid was present in the highest concentration followed by ferulic, syringic, vanillic, and *p*-hydroxybenzoic acids at variable concentrations. Under ideal conditions for decomposition, *p*-coumaric acid could be released in sufficient quantities in localized soil microsites to affect plant growth (Guenzi and McCalla, 1966).

At a concentration of 1.0 mM, *p*-coumaric, ferulic, and vanillic acids significantly reduced dry matter production, leaf expansion, leaf production, height, and net assimilation rate of soybean [*Glycine max* (L) Merr.]. Furthermore, net photosynthetic rate and stomatal conductance were severely reduced, and marked losses of chlorophyll were registered (Patterson, 1989). Leaf diffusive resistance of sorghum seedlings increased and water potential decreased following treatments with ferulic acid, *p*-coumaric acid, and extracts from several allelopathic weeds. Water potential changes resulted from reduction of both osmotic potential and turgor pressure (Einhellig et al., 1985). Treatments with 0.25 mM ferulic acid reduced phosphorus content of roots and shoots of 2-week-old sorghum seedlings. Roots of treated plants also had lower concentrations of potassium and magnesium. In some cases, shoot potassium and iron were lower but magnesium and calcium were higher (Kobsa and Einhellig, 1987). Roots of alfalfa inhibited by water extracts of alfalfa shoots had 46% fewer and 54% shorter root hairs compared to the control, but an anatomical study showed no clogging of root xylem vessels of treated plants (Hedge and Miller, 1992).

The objective of this study was to investigate the chemical basis of the differential allelopathic potential among three sorghum hybrids (Asgrow Topaz, Taylor Evans Y-101G, and Warner W-744DR) reported previously (Ben-Hammouda, 1994). Total phenolic content and concentrations of phenolic acids that have been previously implicated in allelopathic activity of sorghum (Guenzi and McCalla, 1966) were determined.

METHODS AND MATERIALS

Collection and Processing of Sorghum Plant Parts

Randomly selected sorghum plants grown at the University of Missouri Agronomy Research Center in 1991 and 1992 were collected intact at harvest

maturity. Sorghum plants collected both years were free of disease and insect infestations. Roots were washed with tap water to remove the soil, and whole plants were stored frozen until analysis. Sorghum hybrids studied included Asgrow Topaz, Taylor Evans Y-101G, and Warner W-744DR and represented the range of suspected allelopathic potential identified in previous field and laboratory studies (Ben-Hammouda, 1994). Briefly, field studies involved planting wheat after sorghum harvest and using wheat grain yield as a measure of response to potential allelopathy. Subsequent laboratory studies relied on the response of wheat seedling radicle growth to extracts of sorghum plant components in agar bioassays.

Extraction

Sorghum plants were washed gently with distilled water, blotted, and separated into heads, leaves, culms, and roots. Heads were hand-threshed and separated into seeds and glumes. Leaves, culms, and roots were chopped into 1-cm-long pieces. All sorghum plant parts were dried at 50°C for 24 hr. A 2.5-g portion of each plant part was placed in 50 ml distilled water and agitated on a rotary shaker for 24 hr at 200 rpm. Extracts were filtered (Whatman No. 2 filter paper) under vacuum, centrifuged at 12,500 rpm for 20 min at 8°C, and filter-sterilized (0.2-μm membrane) under vacuum prior to total phenol analysis.

Soil samples from a controlled study in which one plant of each sorghum hybrid was grown to full maturity in a separate 20-liter container were extracted for total phenol analysis. Soil extraction followed the procedure described by Read and Jensen (1989). Briefly, a sample of 250 g dry soil was extracted in 250 ml of distilled water by shaking for 24 hr at 200 rpm. Soil suspensions were filtered (Whatman No. 2 filter paper) under vacuum prior to total phenol analysis.

Determination of Total Phenolics

The Folin-Denis method was used for total phenol analysis (A.O.A.C., 1990) except that ferulic acid was used as the standard, since it is an allelopathic agent (Haslam, 1988) and has been previously isolated from sorghum residues (Guenzi and McCalla, 1966).

Folin-Denis Reagent. A mixture of 10 g Na_2WO_4, 2 g phosphomolybdic acid, and 5 ml H_3PO_4 in 75 ml distilled water was refluxed for 2 hr, cooled, and diluted to 100 ml with distilled water.

Sodium Carbonate-Saturated Solution. Anhydrous Na_2CO_3 (4 g) was added to 10 ml distilled water and dissolved for 1 hr at 70–80°C, cooled overnight, and filtered through glass wool.

Ferulic Acid Standard Solution. Ferulic acid (10 g) was dissolved in 100 ml distilled water. Aliquots of 0, 0.2, 0.4, 0.6, 0.8, and 1 ml of the standard

ferulic acid solution were dispensed into tubes containing 0.5 ml Folin-Denis reagent and 1 ml saturated Na_2CO_3 solution. The standards were diluted to 10 ml with distilled water and quickly shaken. Absorbance was determined after 30 min at 750 nm (Blum et al., 1991) on a spectrophotometer (Pharmacia Ultrospec III).

Determination of Total Phenolics. Each sorghum or soil water extract (1.0 ml) was prepared by adding Folin-Denis and Na_2CO_3 reagents. Absorbance was determined, and the total phenolic content was obtained using the standard curve. Units of total phenolics were expressed in milligrams of ferulic acid equivalents per milliliter extract. For soil extracts, total phenolics in ferulic acid equivalents per milliliter of extract were expressed on a per gram basis since the ratio of extraction was 1 : 1 (w/w). For sorghum extracts, ferulic acid equivalents were multiplied by 20 based on an extraction ratio of 1 : 20 (w/w).

Determination of Phenolic Acids by HPLC Analysis

Water extracts of sorghum plants and soils used for estimation of total phenolics were analyzed for five individual phenolic acids. The pH of each water extract sample was lowered to 2.6–3.0 with dilute H_3PO_4. An aliquot of 5 ml from each sample was partitioned with an equal volume of diethyl ether two times by shaking the mixture for approximately 1 min and allowing it to stand until diethyl ether partitioning occurred. The pooled partitioned volumes of diethyl ether from each sample were dispensed into a 50-ml Erlenmeyer flask and evaporated to near dryness in a suction chamber. Residues in the flask were dissolved in 2 ml methanol and filtered through a 0.2-μm sterile membrane.

Methanol extracts were analyzed for phenolic acids using a Beckman model 338 HPLC system. The system consisted of two model 110B pumps operated at a 1 ml/min flow rate, a model 507 autosampler with a 100-μl sample loop, and a model 166 variable-wavelength UV detector set at 280 nm. A Beckman octadecyl (C18) reversed-phase column (Ultrasphere ODS, 5 μm) with dimensions at 250 $\times$ 4.6 mm (ID) was used. The mobile phase was methanol–water (30:70, v/v).

Five different phenolic acids (POH, VAN, SYR, PCO, and FER) were identified in the samples by comparing their relative retention times with that of the standard chromatogram. The identified peaks were then quantified by preparing standard curves using peak areas for each phenolic acid.

Bioassay

Potential allelopathic activity of water extracts of sorghum plant parts was assessed using a wheat seedling bioassay (Ben-Hammouda, 1994). Water extracts (2.5 g plant tissue per 50 ml water shaken for 24 hr) were incorporated in 1.0% agar and dispensed into test tubes. Pregerminated Cardinal wheat seeds were

placed on the solidified extract-agar (one pregerminated seed per tube) and incubated in the dark at 28°C for 48 hr. Radicle lengths were measured and compared to controls containing no plant extracts. Each determination consisted of measurements from 10 tubes per treatment, including controls, replicated four times.

Statistical Analyses

Root length data from bioassays were subjected to analysis of variance followed by the LSD test to determine significant differences among mean values at the 0.05 level of probability. Regression and correlation analyses of wheat radicle growth inhibition were conducted with total phenolics, individual phenolic acid (POH, VAN, SYR, PCO, FER) concentrations estimated from sorghum plant parts, and total phenolic content as quantitative variables and the sources of phenolics (hybrid, growing season, plant parts, and plant parts within hybrid) as qualitative variables.

RESULTS AND DISCUSSION

The three sorghum hybrids were presumed to be allelopathic on wheat based on wheat grain yield depression in field tests over two years and on wheat seedling radicle reduction in laboratory bioassays of sorghum extracts. Relative to water controls, extracts of one or more plant parts from each hybrid reduced wheat radicle growth (Table 1). Wheat radicle inhibition was positively correlated ($r = 0.66$) with total phenolic content (Table 2) in individual plant parts (Figure 1). When inhibition of wheat radicle growth was regressed on total phenolics as a quantitative variable and the source of phenolics as qualitative variables, significant factors in the best fitting regression were total phenolics and the plant parts glumes and culms. Parameters in this best fitting equation were: $b_0 = -4.3$, $b_1 = 267.0$, $b_2 = -14.8$, and $b_3 = 28.0$ with $Y =$ inhibition (dependent variable), $x_1 =$ total phenolics, $x_2 =$ glumes, and $x_3 =$ culms (independent variables). Phenolics from glumes reduced the inhibition by an average of 14.8 times more than any other source of phenolics. However, phenolics from culms increased the inhibition 42.8 times more than phenolics from glumes and 28 times more than any other source of phenolics.

Ranges of total phenolics in seeds, glumes, leaves, and roots were small (Table 2) but inhibition varied significantly (Table 1). This suggested that inhibition may be associated with qualitative rather than quantitative components of phenolics.

Three phenolic acids (POH, VAN, SYR) were found in different amounts in all plant parts of the three sorghum hybrids during both growing seasons (Table 3). Concentrations varied among plant parts within and between sorghum

hybrids. Of the five phenolic acids analyzed, only PCO or FER was absent from any plant part, with FER absent in 53% of the cases. In 1991, Taylor Evans Y-101G did not have any detectable FER. Wheat radicle inhibition was found positively associated with each of the five phenolic acids, the highest correlation occurring with VAN (Table 4). While significant individually, asso-

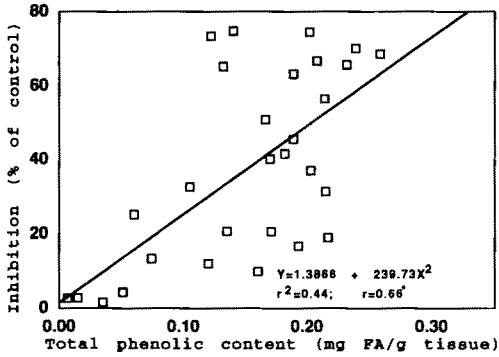

FIG. 1. Relationship of wheat radicle inhibition to total phenolic content in water extracts of plant parts from sorghum hybrids grown in 1991 and 1992. Total phenolic content expressed in ferulic acid equivalents per gram of sorghum tissue.

ciations were small, accounting for less than 20% of the variation in inhibition. Together, the five phenolic acids accounted for 72% of the variability in inhibition of wheat radicle growth due to total phenolics. Plant species are known to contain many phenolic acids in addition to those assayed, and many are phytotoxic (Chou and Patrick, 1976). Total inhibitory effects on sorghum may therefore involve other phenolic compounds and/or allelochemicals of different chemical types. Sampling intensity did not permit detection of statistically significant relationships between total phenolic content or individual phenolic acid levels and inhibition within individual plant parts, hybrids, or years.

Bioassays of water extracts from soils on wheat radicle growth showed that soil with no plants, and soils planted to Warner W-744DR and Asgrow Topaz were relatively equal in allelopathic potential (Ben-Hammouda, 1994). The minimal differences among total phenolic contents in these soils likely account for the low inhibitory activity (Table 5). However, inhibition by soil extracts from Warner W-744DR and Asgrow Topaz were significant ($P \leq 0.05$) compared to control soil, suggesting that allelochemicals other than the detected phenolics were released by sorghum roots. Extracts from Taylor Evans Y-101G soil contained the highest total phenolic content and were significantly higher in allelopathic potential, indicating a relationship between quantity of phenolics released by roots and inhibitory activity, similar to that illustrated for plant extracts (Figure 1). Other phytotoxins exuded from roots have been reported, including sorgoleone from sorghum (Einhellig and Souza, 1992) and phenolic acids from alfalfa roots, a known allelopathic crop (Abdul-Rahman and Habib, 1989; Read and Jensen, 1989). Identification of individual phenolic acids in sorghum root exudates has not been previously reported.

Soil extracts analyzed by HPLC contained only POH, VAN, or SYR (Table

6). The highest phenolic acid content, which was predominantly SYR, was found for Taylor Evans Y-101G soil extract. Taylor Evans Y-101G soil extract also exhibited the highest inhibition toward wheat seedling growth (Table 5), suggesting that SYR may be a major source of allelopathic activity in this sorghum hybrid. SYR was detected in the other soil extracts at about 47% lower concentrations and only slightly inhibited wheat seedling growth. Antagonism of activity of SYR by other phenolic compounds in these extracts may partially account for the lower inhibitory activity (Patterson, 1989).

Phenolic acids detected in control soil extracts may have originated from microbial synthesis (Waniska et al., 1988) or humic acid degradation (Kobsa and Einhellig, 1987). Phenolic acids released from above-ground plant parts were prevented from reaching soil, thus phenolic acids detected were of root or soil origin. Higher amounts of POH and SYR in Asgrow Topaz and Taylor Evans Y-101G soil extracts, respectively, compared to control soil indicated root exudation. High concentrations of POH and SYR in vegetative tissues of

TABLE 6. PHENOLIC ACID CONTENT OF SOILS PLANTED TO SORGHUM

	SYR	0.020
Taylor Evans Y-101G	POH	0.000
	VAN	0.000
	SYR	0.038

[a]FER and PCO were not detected in any soil extract.

Asgrow Topaz and Taylor Evans Y-101G suggest that excess production of these phenolic acids may be released by roots into soil. VAN was not detected in control extracts, consequently VAN detected in Asgrow Topaz soil extracts suggests that root exudates are also a primary source of VAN in soil.

In conclusions, the allelopathic potential of sorghum plant parts was positively correlated with total phenolic content. Within plant parts, the relationship was more qualitative than quantitative. Three phenolic acids (POH, VAN, SYR) were found in all sorghum plant parts, while PCO and FER were detected inconsistently. Individual phenolic acids were significantly associated with inhibition of wheat radicle growth. The variability of allelopathic potential of plant parts within a sorghum hybrid was difficult to attribute to individual phenolic acids or a combination of phenolic acids. Allelopathic potential may be a result of either antagonism or synergy, depending on the presence of a specific phenolic acid, its proportion relative to other phenolic acids, or a combined action of several other allelochemicals present in plant tissues and exudates.

Sorghum roots exuded phenolics including POH, VAN, and SYR. Under favorable field conditions, exudates may contribute to the overall allelopathic potential of sorghum during growth and after harvest when vegetative and root residues remain in the field prior to planting a subsequent crop.

(Received September 12, 1994; accepted February 22, 1995)

Abstract—Extracts of sex pheromone glands obtained from females of *Plodia interpunctella* contained detectable amounts of (*Z*,*E*)-9,12-tetradecadien-1-ol acetate (*Z*9,*E*12–14:Ac) and (*Z*,*E*)-9,12-tetradecadien-1-ol (*Z*9,*E*12–14:OH) 4 hr prior to the first scotophase after adult emergence. The amount of pheromone increased during the first 4 hr of the scotophase and then declined to low levels during the subsequent photophase. Decapitation of females immediately after emergence, prior to expansion of the wings, inhibited production of pheromone during the subsequent 48 hr. Injection of extracts of the heads of 1-day-old females of *P. interpunctella* of partially purified extracts of the cephalic ganglia of females of the corn earworm moth into decapitated females stimulated production of both *Z*9,*E*12–14:Ac and *Z*9,*E*12–14:OH as well as production of (*Z*,*E*)-9,12-tetradecadienal (*Z*9,*E*12–14:Al). This aldehyde was subsequently identified from extracts of pheromone glands obtained from naturally calling females as well as from volatiles emitted by calling females. Studies on the terminal steps in biosynthesis of the pheromone showed that *Z*9,*E*12–14:OH was produced from the corresponding acetate and that *Z*9,*E*12–14:Al was produced from the alcohol via the action of an oxidase(s).

Key Words—*Plodia interpunctella*, sex pheromone, pheromone biosynthesis, Indian meal moth.

INTRODUCTION

Plodia interpunctella, the Indian meal moth (IMM), is a worldwide pest of stored products. This insect has been the target of numerous studies aimed at development of semiochemical-based monitoring and control programs because of the limited number of pesticides available for control of pests in food storage facilities (Vick et al., 1981). The principal component of the sex pheromone produced by IMM females, (*Z*,*E*)-9,12-tetradecadien-1-ol acetate (*Z*9,*E*12-14:Ac) was identified concomitantly by Kuwahara et al. (1971) and Brady et al. (1971). Although this compound was sufficient to stimulate attraction of males, Brady et al. (1971) hypothesized that additional pheromone components were probably also used for communication. This led to the identification of the corresponding alcohol analog, (*Z*,*E*)-9,12-tetradecadien-1-ol (*Z*9,*E*12-14:OH) from rinses of containers that housed females (Sower et al., 1974). Although initial studies indicated that *Z*9,*E*12-14:OH did not enhance the effect of *Z*9,*E*12-14:Ac in bioassays using IMM males, this compound inhibited the response of males of the almond moth, *Ephestia cautella* (Sower et al., 1974). Subsequent studies by Soderstrom et al. (1980) and Vick et al. (1981) demonstrated that both *Z*9,*E*12-14:Ac and *Z*9,*E*12-14:OH were important components of the pheromone communication system of the IMM.

Studies have been conducted on the diel periodic production of these two pheromone components by IMM females (Coffelt et al., 1978). These studies showed that only small amounts of pheromone were present in gland washes obtained during the first photophase after emergence, although a significant number of females exhibited calling behavior during this period (Coffelt et al., 1978). Smithwick and Brady (1977) showed that extracts obtained from ethanol homogenates of abdomen tips as well as a fraction obtained from gas chromatographic (GC) separation of the ethanolic extracts from newly eclosed females stimulated male wing fluttering and resulted in attempted copulation by 50% of the males at concentrations of 6.4×10^{-4} gland equivalents (ethanol extracts) and 9.8×10^{-4} gland equivalents (GC fraction). This, plus evidence that a significant behavioral response by males could be evoked from ethanolic extracts obtained from pharate adults (Smithwick and Brady, 1977), suggested that females were biosynthesizing pheromone even as pupae.

We were interested in determining if pheromone was present in extracts of pheromone glands of newly emerged females and in determining the periodicity of production and release of pheromone by females. In addition, we were interested in the biosynthetic relationship between *Z*9,*E*12-14:Ac and *Z*9,*E*12-14:OH. The studies reported here were conducted to address these questions. We also report the identification of a new compound, produced and released from pheromone glands of females during the reproductive period, that is biosynthetically related to previously identified sex pheromone components.

METHODS AND MATERIALS

Insect Rearing and Holding. Insects were reared using standard procedures described by Silhacek and Miller (1972). After pupation, females were segregated and held in vented 19.0 (long) × 14.0 (wide) × 7.5 cm (deep) clear plastic boxes at 27 ± 2°C and 60 ± 4% relative humidity in a 16L:8D reversed photoperiod. Newly emerged females were transferred to new containers prior to expansion of the wings on a daily basis and were provided with cotton balls soaked in a solution of 10% sugar in water. Adults were maintained under the same environmental conditions as pupae. For most studies females from a colony maintained at our laboratory since 1972 (Silhacek and Miller, 1972) were used as test individuals. Additional experiments were conducted using insects obtained from a colony maintained at the Stored Product Insect Research Unit, USDA, Madison, WI. This colony has been in culture for less than five generations. Insects from this colony were reared under the same conditions as those of the Gainesville colony.

Periodicity of Pheromone Production. In initial studies the terminal abdominal segments, which contain the sex pheromone gland, were excised from pharate adults (black stage of Smithwick and Brady, 1977) or from females immediately after emergence and prior to wing expansion and from females at 2-hr intervals for the first 8 hr after emergence as well as from females at 4-hr intervals throughout the subsequent 40 hr. Excised abdomen tips from three females were extracted for 15 min in 10 μl of hexane containing 5 ng each of octadecane and nonadecane (internal standards) in the same vial, and the extracts were stored at −60°C until analysis by capillary gas chromatography (GC) and GC-mass spectroscopy (GC-MS).

Volatile Collections. Volatile pheromones released by females were collected using the push–pull system described by Heath et al. (1992). Compressed air was purified through two charcoal filters and passed through a glass frit near the upwind end of glass chambers (5 cm OD × 30 cm long) to provide a laminar airflow. Airflow through the chamber was pulled through a collector trap by vacuum. Each collection apparatus was fitted with three collector traps, any one of which could be selected for collection of volatiles without disturbing the insects by using manually activated external valves. Airflow through the system was set at 0.9 liters/min with a slight positive pressure of 0.2 cm H_2O established in the chamber using the vacuum (Heath et al., 1992). Volatile collections were obtained from groups of 20 females with collector traps that were changed at 2-hr intervals throughout the scotophase. After collection of volatiles, the Super Q collection traps (see Heath et al., 1992) were extracted with three 20-μl portions of CH_2Cl_2 and 20 ng of the above internal standards in hexane were added. The extract was then concentrated to ca. 25 μl under argon and analyzed by GC and GC-MS.

Endogenous Regulation of Pheromone Production. The heads were removed immediately after emergence in studies to assess the effect of decapitation on pheromone production. Pheromone glands were excised at 2-hr intervals thereafter. Females decapitated at emergence and aged for 4 hr were also used in studies to determine if neurohormones were involved in regulation of induction of pheromone production. These females were injected with 5 μl of saline (Christensen et al., 1991) or saline containing one equivalent of an extract of the heads of 12-hr-old IMM females or one head equivalent of a partially purified extract from females of the corn earworm moth, *Helicoverpa zea*. Injections were made by inserting a 0.1-mm-ID fused silica needle attached to a 10-μl syringe through the front of the thorax and into the abdomen. Insects were not used if fluid escaped from the injection site after removal of the needle. The pheromone glands of females were excised and extracted as described above at 30 min intervals after injection of test samples.

Extracts of the heads of females were prepared by homogenizing 20 heads in 50 μl of saline as described by Teal et al. (1989). The homogenate was centrifuged at 18,000*g* for 10 min and the supernatant removed. The pellet was then rehomogenized in 50 μl of saline and centrifuged. The volume of the combined supernatants was adjusted to 100 μl with saline. Extracts of the cephalic ganglia of females of the corn earworm moth were obtained by homogenizing the cephalic ganglia in H_2O containing 0.1% trifluoroacetic acid (TFA) as described elsewhere (Teal et al., 1993). These extracts were partially purified by reverse-phase solid-phase extraction using a Bakerbond SPE octadecyl (500 mg) column. The aqueous extract was applied to the preconditioned column (see Teal et al., 1993) and the column washed with 6 ml of H_2O containing 0.1% TFA. Peptides, including pheromone-biosynthesis-activating neuropeptide were then eluted with 4 ml of 80:20 acetonitrile–H_2O containing 0.1% TFA. This fraction was concentrated to dryness with a Speed Vac concentrator, and the residue was dissolved in sufficient saline to yield a concentration of 1 head equivalent/5 μl.

Terminal Steps in Pheromone Biosynthesis. All experiments conducted on the terminal steps involved in biosynthesis of pheromone were conducted with females that had been decapitated immediately after emergence. The terminal abdominal segments, containing the pheromone glands, were exposed and excised from the abdomens 4 hr after decapitation. In initial experiments five isolated abdomen tips were placed in a conical microvial (300 μl capacity), and 5 μl of hexane containing 20 ng of the internal standard with or without 200 ng of either *Z*9,*E*12–14:OH or (*Z*)-11-tetradecen-1-ol (*Z*11–14:OH) was added. The vials were capped with screw-cap GC autosampler caps having Teflon septa and incubated at room temperature for 1 hr prior to the addition of 10 μl of hexane and removal of the solvent. The extract was analyzed by GC. In other experiments the same procedure was followed, except that the vials were purged with N_2 for 15 min prior to placing the glands, substrate, and internal standard

into the vials. Some samples were held continuously in a N_2 saturated environment while others were held in air. After 30 min, 10 μl of hexane was added to the vials to extract pheromone and the extract was analyzed by GC.

Experiments to determine if acetates were converted to alcohols were conducted using (*Z*)-11-tetradecen-1-ol acetate (*Z*11–14:Ac) or *Z*9,*E*12–14:Ac as the substrate. A 2-μl drop of hexane containing 1 μg of acetate was placed in a conical microvial, the hexane was evaporated under a stream of N_2, 25 μl of saline containing 0.5% acetone was added, and the vial was sonicated for 15 min. After sonication the excised terminal abdominal segments from five females were added to the capped vial and the sample was sonicated for 15 min. After sonication the sample was incubated for an additional 45 min prior to extraction of the sample two times with 25-μl aliquots of hexane-containing internal standard. The hexane extracts were concentrated to 10 μl prior to GC analysis.

Chemical Analysis. All GC analyses were conducted using Hewlett-Packard 5890 GCs equipped with split/splitless and cool on-column injectors and flame ionization detectors. For routine analyses of gland extracts, samples were analyzed using split/splitless injectors and 30-m × 0.25-mm-ID (0.25-μm film thickness) fused silica columns coated with SE 30 or Carbowax 20 M (Altech, Econocap columns). Samples were injected in the splitless mode at an oven temperature of 60°C with the injector being purged at 1 min. After 2 min, the oven temperature was increased at 10°C/min to final temperatures of 185°C (SE 30) and 180°C (Carbowax). Helium was used as the carrier gas at a linear flow velocity of 19 cm/sec.

Samples obtained from collection of volatiles emitted by females were analyzed using the cool on-column injector. The injector was attached to a 10-m × 0.25-mm-ID deactivated fused silica retention gap column as described by Murphy et al. (1993). The retention gap column was interfaced to a 30-m × 0.25-mm-ID fused silica column coated with Carbowax 20 M. Conditions of chromatography were the same as those described above. Data from all GC analyses were acquired using Nelson Analytical 900 Intelligent Interfaces and analyzed with Nelson Analytical 2600 software. Chemical ionization (methane reagent gas) MS analyses were conducted using a Nermag R10-10 MS interfaced to a Hewlett-Packard 5790 GC. Columns and conditions of chromatography used for GC-MS analyses were the same as those used in GC analyses. The spectra and retention times of compounds eluting during the analyses of natural product samples were compared with those obtained from analyses of synthetic standards.

RESULTS AND DISCUSSION

Periodicity of Pheromone Production. Initial studies quantitated the total combined amounts of *Z*9,*E*12–14:Ac and *Z*9,*E*12–14:OH in extracts obtained from abdomen tips of groups of three females at emergence and at intervals

during the subsequent 48 hr. However, because Z9,E12–14:Al was subsequently identified from extracts, the amounts of this compound were also included in the data presented in Figure 1. Extracts from newly emerged females did not contain detectable amounts of pheromone. Pheromone was detected in extracts obtained from 4-hr-old females, and the amounts of pheromone increased to a peak at 12 hr after emergence (Figure 1). This corresponded to the fourth hour of the first scotophase after emergence. The amount of pheromone declined during the subsequent 12 hr and remained low during the second photophase. The periodicity of production was repeated during the next scotophase (data not shown). Extracts obtained from groups of 10 pheromone glands from pharate adults (black stage pupae) did not contain detectable amounts of pheromone (five replicates). The inability to detect pheromone in extracts obtained from pharate and newly emerged females agrees with results obtained by Coffelt et al. (1978) but does not account for the positive bioassay results obtained using extracts from pupae and newly emerged females by Smithwick and Brady (1977). This discrepancy could result from differences in techniques used to extract the pheromone components. Smithwick and Brady (1977) used ethanolic homogenates of the pheromone glands, which probably resulted in much more efficient disruption and extraction of lipid-containing vesicles than was achieved in our

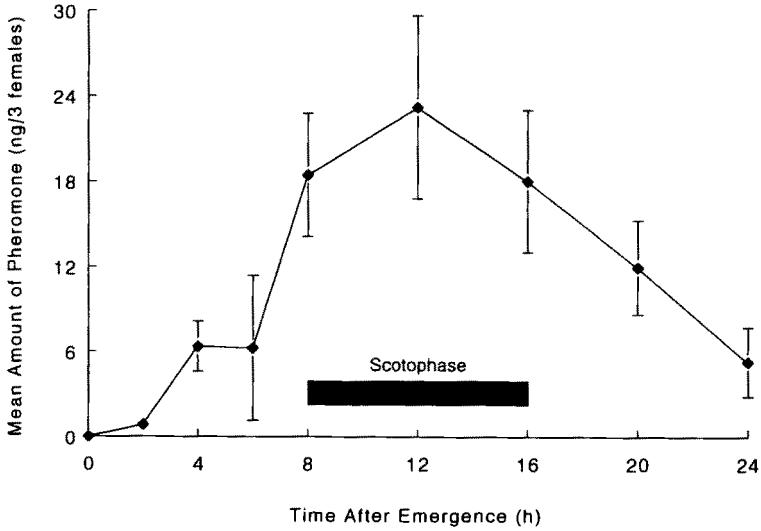

FIG. 1. Mean amounts of pheromone recovered from combined extracts of three glands of IMM females obtained at intervals (N = 13 groups/interval) during the first 24 hr after adult emergence. Means reflect the combined amounts of the three compounds identified (Z9,E12–14:Ac, Z9,E12–14:OH, and Z9,E12–14:Al) ± SE.

study using hexane. Thus, although we did not find pheromone in these extracts, it, or precursive compounds, could be present in subcellular structures that were not extracted using hexane.

Inhibition and Regulation of Pheromone Production. Decapitation of females at emergence resulted in complete inhibition of production of pheromone during the subsequent 24 hr. Injection of extracts of heads of IMM females (1 equivalent/female) into decapitated females stimulated production of pheromone, injection of saline had no effect. The amount of pheromone in gland extracts obtained at 30-min intervals after injection of the cephalic extracts increased over the first 2 hr and then declined (Figure 2). No pheromone was present in extracts obtained 6 hr after injection. Injection of partially purified extracts obtained from the cephalic ganglia of the corn earworm moth also stimulated production of pheromone. The maximum amount of *Z*9,*E*12-14 : Ac in extracts of three glands (3.67 ng ± 2.26, $N = 5$) was obtained from extracts 2 hr after injection. These results show that IMM females regulate the diel periodic production of pheromone with neurohormones, as do most other moth species (see Raina, 1993), and that pheromonotropic neuropeptides, present in the partially purified extracts of the corn earworm moth, will mimic the pheromonotropic effect of homogenates of IMM female brain extracts.

Interestingly, another compound was also detected with regularity in extracts obtained from insects that had been injected with homogenates of the cephalic ganglia. The amounts of this compound increased over the first 2 hr after injection of cephalic extracts and then declined (Figure 2). GC analyses conducted

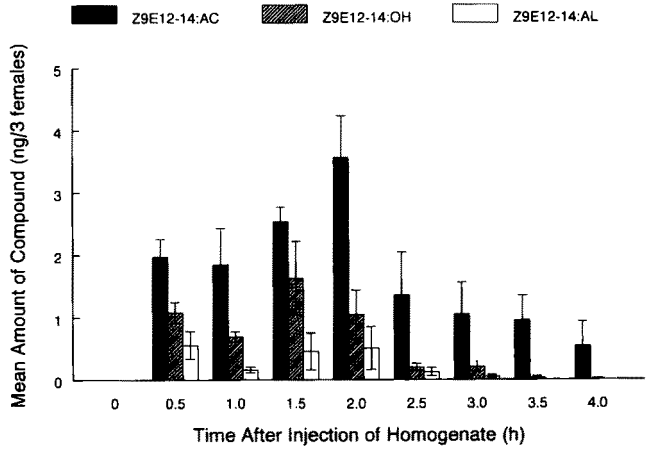

FIG. 2. Mean amounts of pheromone extracted from groups of three glands extracted at intervals after injection of extract of the cephalic ganglia ($N = 5$ groups/interval, ±SE).

using both polar and apolar capillary columns indicated that the compound had the same retention index as (*Z*,*E*)-9,12-tetradecadienal (*Z*9,*E*12–14:Al). Subsequent analyses of pheromone gland extracts from groups of 10–20 females obtained during the peak period of production of pheromone during the first scotophase (12 hr after emergence) showed that this compound was also present in these extracts (Figure 3a). Structural confirmation for *Z*9,*E*12–14:Al was provided by GC-MS analyses using both polar and apolar capillary columns (Figure 3b). The mean amounts of the three compounds present in pooled extracts of five females obtained at the peak of pheromone production during the sco-

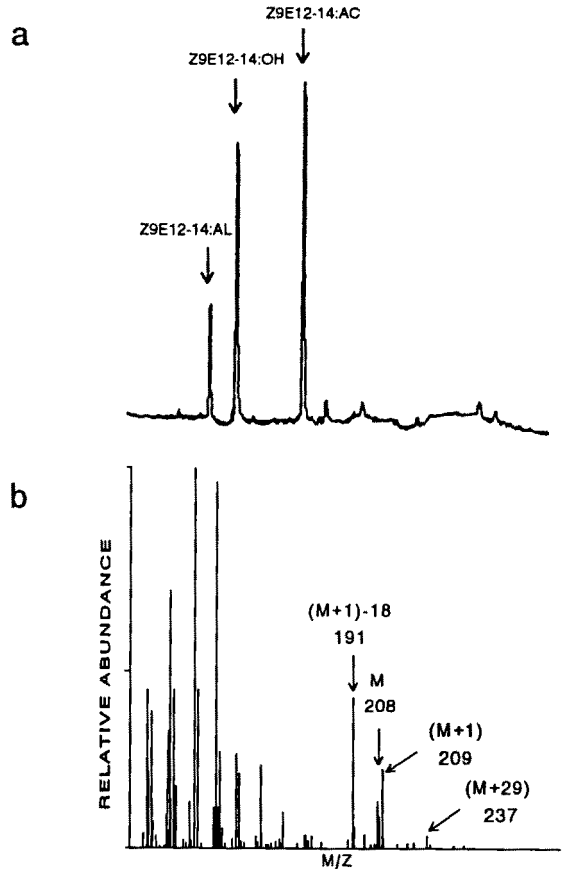

FIG. 3. GC-MS analysis of an extract of 20 glands of IMM females obtained 12 hr after emergence chromatographed on a 30-m × 0.25-mm-ID SE 30 fused silica column. (a) Total ion current chromatogram. (b) CI Mass spectrum of *Z*9,*E*12–14:Al.

tophase was determined to be (± SE): 19.38 ± 3.17 ng Z9,E12-14:Ac, 4.02 ± 0.46 ng Z9,E12-14:OH, and 1.42 ± 0.18 ng Z9,E12-14:Al (five replicates). The ratio present in extracts obtained from groups of three glands obtained from females 2 hr after injection of the cephalic extract was 69.6% Z9,E12-14:Ac, 20.8% Z9,E12-14:OH, and 9.6% Z9,E12-14:Al (Figure 2) while that in the extracts obtained from females at the peak of production was 78.1% Z9,E12-14:Ac, 16.2% Z9,E12-14:OH, and 5.7% Z9,E12-14:Al.

Analysis of Volatiles. Both GC and GC-MS analysis of volatiles emitted by females during the 2-hr collection intervals in the scotophase indicated that Z9,E12-14:Ac, Z9,E12-14:OH, and Z9,E12-14:Al were all released by calling females. Pheromone was released by females during the first 2-hr sample period but significantly more was released between 2–4 hr and 4–6 hr in the scotophase (Figure 4). Very little pheromone was released by females after the photophase began. Interestingly, the ratio of the three components determined from analysis of volatile collections was distinctly different from that present in extracts obtained from glands of calling females. This difference was not due to the ratio of Z9,E12-14:Ac to Z9,E12-14:OH, which was approximately the same as that determined from gland extracts (79% Z9,E12-14:Ac and 21% Z9,E12-14:OH in volatiles during hours 2–4 and 83% Z9,E12-14:Ac and 17% Z9,E12-14:OH in extracts obtained at hour 4), but was due to release of relatively large amounts of Z9,E12-14:Al.

The identification of Z9,E12-14:Al from both extracts of pheromone glands and volatiles emitted by calling females and the relatively large amounts of this compound found in volatile collections was somewhat surprising because, although a large number of studies have been conducted on the pheromones produced by IMM females, Z9,E12-14:Al had not been identified. To determine if Z9,E12-14:Al was produced by other colonies we obtained pupae from a colony of IMM maintained at Madison, Wisconsin. As indicated in Figure 4b these females also released significant amounts of Z9,E12-14:Al as well as the other two components. The ratio of aldehyde to acetate in these insects was not different at any time interval from the ratio found in volatiles collected from females of the laboratory colony.

Terminal Steps in Biosynthesis. The relatively high ratio of Z9,E12-14:Al found in volatile collections and the structural similarities between the three compounds suggested that the aldehyde might be the final product of the biosynthetic process involved in pheromone production. This situation has been found to occur in females of *Heliothis subflexa*, a noctuid moth that uses acetate, alcohol, and aldehyde analogs for pheromone communication (Teal et al., 1981; Klun et al., 1982; Heath et al., 1991). Extracts of the pheromone glands from calling females of *H. subflexa* contain a disproportionately low amount of aldehyde relative to the ratio present in volatiles released by females. In addition to the fact that the acetate and alcohol analogs are less volatile that the aldehydic components, both the acetates and alcohols are biosynthetic precursors of the

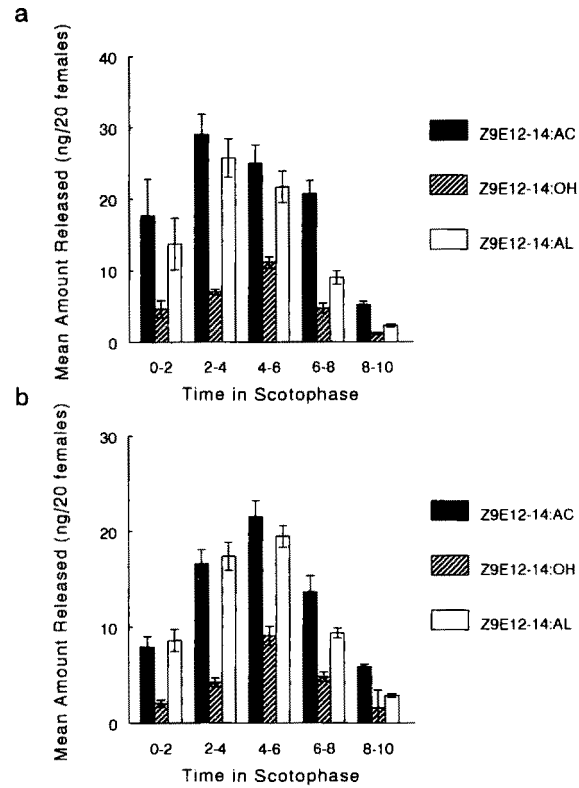

FIG. 4. Mean amounts of *Z*9,*E*12-14:Ac, *Z*9,*E*12-14:OH, and *Z*9,*E*12-14:Al detected in volatile collections obtained from groups of 20 females at 2 hr intervals during the scotophase. (a) Collections from females of the laboratory colony ($N = 5$, $\pm$ SE). (b) Collections from females of the Madison, Wisconsin, colony ($N = 5$, $\pm$ SE).

aldehydes, in addition to being pheromone components (Teal et al., 1989; Heath et al., 1991). Thus, the pheromone gland must contain relatively more acetate and alcohol in order to allow for release of the correct amount of aldehyde in the pheromone blend. To determine if a similar situation was occurring in the IMM, we conducted experiments to determine if exogenously applied alcohols would be converted to aldehyde by IMM females. Incubation of glands obtained from five decapitated females in hexane containing 200 ng of *Z*9,*E*12-14:OH and extraction of the samples after 1 hr resulted in recovery of 43.38 $\pm$ 7.77 ng ($N = 4$) *Z*9,*E*12-14:Al. Extracts of glands that had been incubated only in hexane did not contain any *Z*9,*E*12-14:Al ($N = 4$). Similar experiments con-

ducted using Z11-14:OH, an alcohol that has not been identified from pheromone glands or in volatile collections using IMM females, resulted in recovery of 48.25 ± 6.07 ng (N = 4) of (Z)-11-tetradecenal (Z11-14:Al) after a 1-hr incubation. Extracts from control experiments did not contain any Z11-14:Al. Incubation of glands in hexane containing Z11-14:OH for 30 min under N_2 did not completely inhibit the conversion of alcohol to acetate but did result in a threefold decrease in production of aldehyde with respect of samples obtained from parallel experiments in which glands were incubated under air. This strongly suggests that the conversion of alcohol to aldehyde results from the action of an alcohol oxidase, as has been described for *Heliothis* moths (Teal et al., 1989).

To determine if Z9,E12-14:Ac was the precursor for the alcohol analog, we first attempted to incubated isolated glands from decapitated females in hexane containing Z9,E12-14:Ac. However, no alcohol was recovered from any of the five replicate samples. In as much as the esterase responsible for converting acetates to alcohols in *Heliothis* species is a cellular enzyme and will not function in organic solvents (Teal et al., 1989), we repeated our experiment using Z9,E12-14:Ac that had been distributed into buffer by dissolving the acetate in acetone and then sonicating in buffer. Incubation of groups of five glands under these conditions for 1 hr and subsequent extraction with hexane resulted in recovery of 160 ± 18.84 ng (N = 5) of Z9,E12-14:OH and 10.41 ± 0.97 ng (N = 5) of Z9,E12-14:Al. Extracts from control experiments in which the glands were incubated in the same medium, but which did not contain Z9,E12-14:Ac, did not contain any Z9,E12-14:OH or Z9,E12-14:Al (N = 5). This study was repeated using Z11-14:Ac as a substrate. As expected, extracts from controls did not contain Z11-14:OH or Z11-14:Al, whereas extracts from glands incubated with Z11-14:Ac contained 187.1 ± 19.2 ng (N = 5) of Z11-14:OH and 12.22 ± 2.02 ng (N = 5) of Z11-14:Al. Results of these studies indicate that the pheromone glands of IMM females can convert Z9,E12-14:Ac to the corresponding primary alcohol and that this is subsequently converted to Z9,E12-14:Al by the pheromone gland. This implicates the action of acetate esterases and alcohol oxidases in the terminal steps of biosynthesis of pheromone components by IMM females and corroborates the identification of Z9,E12-14:Al from both gland extracts and volatiles released by calling females.

In summary, we have shown that IMM females regulate production of pheromone with neurohormones and that females can be stimulated to produce pheromone under circumstances in which pheromone would not normally be produced by injection of pheromonotropic substances. Using this technique to stimulate pheromone production, we were able to identify Z9,E12-14:Al from extracts of pheromone glands and then identify this component in extracts from naturally calling females as well as from volatiles released by calling females. Results of our studies on the terminal steps of biosynthesis have shown that

IMM females have the ability to produce *Z*9,*E*12–14:Al and that biosynthesis can proceed by converting *Z*9,*E*12–14:Ac to *Z*9,*E*12–14:OH, which is then converted to *Z*9,*E*12–14:Al. Although behavioral studies aimed at determining the biological effect of *Z*9,*E*12–14:Al on conspecific males or males of other competing species have not been completed, we believe that *Z*9,*E*12–14:Al could be an important component of the semiochemical communication system of this insect.

(Received November 14, 1994; accepted February 26, 1995)

Abstract—Insecticidal and growth-reducing properties of extracts of 14 species of American neotropical Piperaceae were investigated by inclusion in diets of a polyphagous lepidopteran, the European corn borer, *Ostrinia nubilalis*. Nutritional indices suggested most extracts acted by postdigestive toxicity. *Piper aduncum*, *P. tuberculatum*, and *P. decurrens* were among the most active species and were subjected to bioassay-guided isolation of the active components. Dillapiol was isolated from the active fraction of *P. aduncum*, piperlonguminine was isolated from *P. tuberculatum*, and a novel neolignan from *P. decurrens*. The results support other studies on Asian and African *Piper* species, which suggest that lignans and isobutyl amides are the active defence compounds in this family.

Key Words—Piperaceae, botanical insecticide, isobutyl amides, lignans, dillapiol, conocarpan, piperlonguminine, European corn borer.

INTRODUCTION

The role of plants from the pepper family (Piperaceae) in traditional pharmacopeia is well established in tropical areas where these vines and shrubs are

* To whom correspondence should be addressed.

0098-0331/95/0600-0801$07.50/0 © 1995 Plenum Publishing Corporation

particularly abundant (Atal et al., 1975; Schultes and Raffauff, 1990). Throughout the world, *Piper* plants have traditionally also been used against pests. For example, the Amazonian species, *Piper rotundistipulum*, is used locally as an insecticide and a fish poison (Schultes and Raffauf, 1990). *P. guineense* and *P. nigrum* are used as insecticides and molluskicides in several parts of Africa (Su and Horwat, 1981; Ivbijaro and Bolaji, 1990). The Indian species *P. longum*, *P. betle*, *P. peepuloides*, and *P. cubeba* have demonstrated insecticidal activity against mosquitos and flies (Srivastava, 1970; Miyakado et al., 1989) and were shown to repel grain pests (Kokate et al., 1980). The leaves of *P. futokatsura* from Taiwan and Japan are known as a feeding deterrent to the larvae of *Spodoptera litura* (Matsui and Munskata, 1975), and the leaves of *P. umbellatum*, *P. hispidum*, *P. auritum*, and plants reported only as *Piper* spp., which are native to Central America and the Northwest Amazonian basin, are used by indigenous peoples to prevent malaria and to remove head lice (Schultes, 1975, 1980).

Our knowledge about the compounds responsible for all of these insecticidal activities is limited. However, it is known that amides are frequently found in the Piperaceae (Greger, 1988), in particular olefinic or alkyl isobutylamides such as piperine, piperettine, trichostachine, peepuloidin, piplartin, and trichonine (Atal et al., 1975). They are toxic to fruit flies, azduki bean weevils, cockroaches, and several other insect species (Gbewonyo et al., 1993; Miyakado et al., 1983, 1989; Su and Horwat, 1981), and they act as neurotoxins (Gbewonyo et al., 1993).

Phenylpropanoids are another group of potentially active chemicals of common occurrence in *Piper* spp. They include monolignols, such as apiol, dillapiol, myristicin, eugenol, and safrol, and dimers of phenylpropanoids, such as the lignans sesamin, cubebin, yangambin or diaeudesmin. They often constitute a large part of the essential oil of the plant, as for instance, 85% safrol in the oil of the leaves of *P. auritum* (Castro and Poveda, 1983). However, the toxicity of these substances, with a few exceptions such as safrol, which has long been used as a natural insecticide (Coats, 1994), has not been established.

On the other hand, several of these compounds are known to synergize natural and synthetic insecticides. Sesamin and sesamolin, for instance, synergize the activity of natural and synthetic pyrethrins (Singh et al., 1976), and their synthetic analog, piperonyl butoxide, is currently included in most commercial preparations of pyrethrum (Worthing and Walker, 1993). Dillapiol, related to piperonyl butoxide, synergizes not only pyrethrins but also several carbamates and organochlorates (Handa and Dewan, 1974; Mukerjee et al., 1979; Parmar and Tomar, 1983). In addition, lignans and their monomers are known to repel or act as antifeedants to several grain pests (Harmatha and Nawrot, 1988; Nawrot and Harmatha, 1994; Pelter, 1986; Tomar et al., 1979). Kobusin and dillapiol reduce the growth of larvae of insect pests (MacRae and

Towers, 1984), including the larvae of a major pest of maize in North America, the European corn borer, *Ostrinia nubilalis* (Bernard et al., 1990).

These observations, together with our interest in the bioactivities of lignans in insects (Bernard et al., 1989, 1990), prompted us to investigate the activities of a group of *Piper* spp. from the neotropics (Costa Rica), a group largely unstudied from the point of view of their chemical ecology, against our model insect, the European corn borer. One African (*P. guineense*) and one Asian species (*P. betle*) were included for comparison with previous studies. We also report here the structure of a neolignan isolated for the first time from this family and the occurrence of piperlonguminine as the component responsible for the insecticidal activity of another newly investigated *Piper* species.

METHODS AND MATERIALS

Instrumentation

Melting points were determined on a Kofler hot stage and are uncorrected. ^{1}H NMR spectra were obtained on a Bruker 500 MHz spectrometer, and chemical shifts (δ) are reported in parts per million downfield from TMS. The number of protons, multiplicity (s = singlet, d = doublet, q = quartet, quint = quintet, m = multiplet, non = nonet), coupling constant, and assignment are presented in parentheses.

Mass spectrometry was carried out by a VG analytical 7070E spectrometer. UV visible and IR absorption spectra were both recorded on Perkin-Elmer spectrophotometers.

Plant Material

Plants collected in Costa Rica by C. Bernard, L. Poveda, and C. Hasbun in February 1992 included: *Piper aduncum* L., *P. auritum* Kunth, *P. aequale* Vahl, *P. hispidum* Sw., and *P. reticulatum* L. (E.A.R.T.H. station in Guapiles); *P. decurrens* C.DC, *P. marginatum* Jacq., and *P. pseudo-lindenii* C.DC. (C.A.T.I.E. in Cartago); and *P. tuberculatum* Jacq. in the city of Colon. *P. lanceiaifolium* Kunth was collected by J.T. Arnason, L. Poveda, and P. Sanchez in July 1993 near Colon; *P. obliquum* Ruiz & Pav. near Wilson botanical garden; *P. guanacastense* C.DC. near Mirador, Guanacaste; and *P. carrilloanum* C.DC. and an unidentified *Piper* sp. on the Peninsula de Osa in October 1993 by J.T. Arnason, K. Downum, L. Poveda, N. Moreno, and P. Sanchez. The fruits of *P. guineense* Schum & Thom came from Nigeria and were provided by F. Ewete, while the leaves of *P. betle* L. were collected in 1991 in Java, Indonesia, by J.T. Arnason and Y. Razali. Identification of species was carried out by L. Poveda and P. Sanchez, and voucher specimens were retained at the Universidad Nacional de Heredia and the University of Ottawa.

Fresh leaves or fruits were immediately immersed on site in 95% ethanol (EtOH), and were stored in this state two weeks or more, until processed. This first EtOH extract was set aside, and leaves were blended in a similar volume of EtOH and macerated for another two days. Both EtOH extracts were combined, filtered, and concentrated to dryness on a rotary evaporator under reduced pressure at 30°C. Water was further removed by freeze-drying the material for 12 hr, which resulted in a powder or a gum, i.e., crude extract, depending on the plant species. Dry weight of plant material was calculated from the plant solids remaining on the filter paper and the dry crude extract.

Insect Bioassays

Larvae of *O. nubilalis* Hübner (Lepidoptera: Pyralidae) from a laboratory colony were maintained according to procedures described previously (Arnason et al., 1985). The freeze-dried crude EtOH extract of each *Piper* spp. (leaves, or fruits) was incorporated into a meridic diet at 30°C at final concentrations of 4% and 0.4% (w/w). Twenty naïve second instars (6-day-old larvae weighing 8–12 mg) per *Piper* diet were individually distributed in 12-ml glass vials, which were closed with a cotton plug, and returned to the rearing conditions of the colony culture. The weights (wt) of each larva, the diet deposited, the diet remaining, and the frass in each vial were determined at five-day intervals. The relative growth rate (RGR = wt gain/mean wt during the period of study), and nutritional indices were calculated by the following equations as described in Reese (1979).

Consumption index (CI) = wt of food ingested/wt of larvae

Approximate digestability (AD)
= [(wt of food ingested − fecal wt)/wt of food ingested] × 100

Efficiency of conversion of ingested food (ECI)
= (wt gained/wt of food ingested) × 100

Efficiency of conversion of digested food (ECD)
= [wt gained/(wt of food ingested − wt of feces)] × 100

All statistical analysis were performed using Tukey's general linear models procedure (Tukey, 1949) with SAS for PC.

A second insect species, the rock hole breeding mosquito, *Aedes atropalpus* L. (Diptera: Culicidae), was used to monitor the isolation of chemicals from the plants. The small amount of material needed for the bioassays with larvae of these species when compared to the ECB, as well as the rapidity of the toxic response, made it a system of choice to follow the activity of the successive fractions of the plant extracts. Rearing conditions were previously reported (Watt et al., 1981). Ten second instars were pipetted into each of the glass vials containing the plant crude extract at concentrations of 10, 50, and 100 ppm.

TABLE 1. INSECTICIDAL ACTIVITY OF *Piper* SPP. CRUDE EXTRACTS TO MOSQUITO LARVAE

	Concentration of extract

P. not identified	9(1)	8(2)	8(2)

[a]Number of surviving larvae after 24 hr: mean (± SD) from three trials of 10 larvae/trial.

After 24 hr at room temperature, the surviving larvae were counted. The experiment was repeated three times. The pattern of toxicity of the 16 *Piper* extracts to mosquito larvae generally paralleled that to the ECB, confirming the suitability of these insect species as assay guides for the isolation of compounds with activity to both species (Table 1). For assays on fractions of the crude extracts, a concentration of 100 ppm was arbitrarily selected. The activity of the fraction was expressed as the percentage of the toxicity of the corresponding crude extract at the same concentration (Table 2).

TABLE 2. DISTRIBUTION OF INSECTICIDAL ACTIVITY TO MOSQUITO LARVAE OF FRACTIONS FROM THREE *Piper* SPP

	Mortality (%) at 100 ppm[a]			
Piper spp.	HEX	CH_2Cl_2	EtOAc	MeOH
aduncum	26(3)	72(7)	2(1)	0
decurrens	88(3)	8(2)	3(1)	1(1)
tuberculatum	54(6)	44(7)	2(1)	0

Phytochemical Isolations and Identifications

P. aduncum. Fifteen grams of dry crude leaf extract were suspended in minimal volume of acetone, adsorbed on 30 g of silica gel 70–230 mesh, and the solvent evaporated under reduced pressure. The resulting powder (silica–crude extract) was deposited in a Buchner funnel. Five hundred milliliters of the following solvents were added successively: hexanes (HEX), methylene chloride (CH_2Cl_2), ethyl acetate (EtOAc), and methanol (MeOH). Each fraction was then evaporated to dryness, weighed (0.2 g, 1.02 g, 0.01 g, and 0.2 g, respectively), and redissolved in the water of the mosquito bioassay to achieve the proper concentration. Most of the activity was found in the first two fractions (Table 2). These two were combined, and a pale yellow oil, dillapiol (Figure 1a), the major component, was isolated following the method described by Orjala et al. (1989). Its identification was made by comparison with the spectral data of a sample of pure compound provided by one of us (H.G.K.).

P. decurrens. The chemistry of this species had not been previously reported. Sixty grams of the crude dried extract were adsorbed on silica gel and washed successively with four solvents (HEX, CH_2Cl_2, EtOH, and MeOH), as described above. This resulted in the repartition of the toxicity shown in Table 1. The HEX and CH_2Cl_2 fractions were combined and passed through a column of Silica gel (70–230 mesh; 200 g) with HEX and EtOAc as eluents (100:0 to 0:100). From the resulting fractions, a fine white solid (92 mg) was isolated by crystallization from cold HEX. Its physical and spectroscopic data allowed it to be identified as the neolignan, conocarpan (Figure 1b). IR (KBr pellet, cm^{-1}) 3410(br), 3242(br), 2963, 1607, 1607, 1520, 1476, 1239, 925, 830; ^1H Nmr ($CDCl_3$, ppm) δ 1.40 (3H, d, J = 6.8 Hz, CH−C$\underline{H}_3$), 1.87 (3H, dd, J = 6.5 Hz, 1.5 Hz, CH=CH−C$\underline{H}_3$), 3.40 (1H, apparent quint, J = 7.3 Hz, C$\underline{H}$−CH_3), 5.09 (1H, d, J = 8.8 Hz, O−C$\underline{H}$), 6.45 (1H, dq, J = 15.7 Hz, 6.5 Hz, CH=C$\underline{H}$−CH_3) 6.37 (1H, dd, J = 15.7 Hz, 1.5 Hz, C$\underline{H}$=CH−CH_3), 6.77 (1H, D, J = 8.2 Hz, Ar−H ortho to OR), 6.83 (2H, d, J = 8.5 Hz, Ar−H ortho to OH), 7.13 (1H, d, J = 8.2, Ar−H ortho to CH=CH), 7.30 (2H, d, J = 8.5 Hz, Ar−H meta to OH); MS (EI, *m/z*) 267(28), 266(100), 251(17), 233(10), 159(12), 133(12), 131(11), 121(12), 119(18), 107(17); Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81.

P. tuberculatum. Seventy grams of crude EtOH extract from fresh leaves were treated as for the two former species. The bioactivity of the four basic fractions is shown in Table 1. The HEX and CH_2Cl_2 fractions were combined and chromatographed on a large silica gel column (70–230 mesh, 500 g) that was eluted successively with pure HEX, mixtures of HEX–EtOAc of increasing polarities, pure EtOAc, and finally with EtOAC–MeOH (1:1, v/v). The largest fraction contained one major compound, white silky needles, recrystallized from cold benzene–hexane mixtures. The physical (mp = 116–118°C) and spectro-

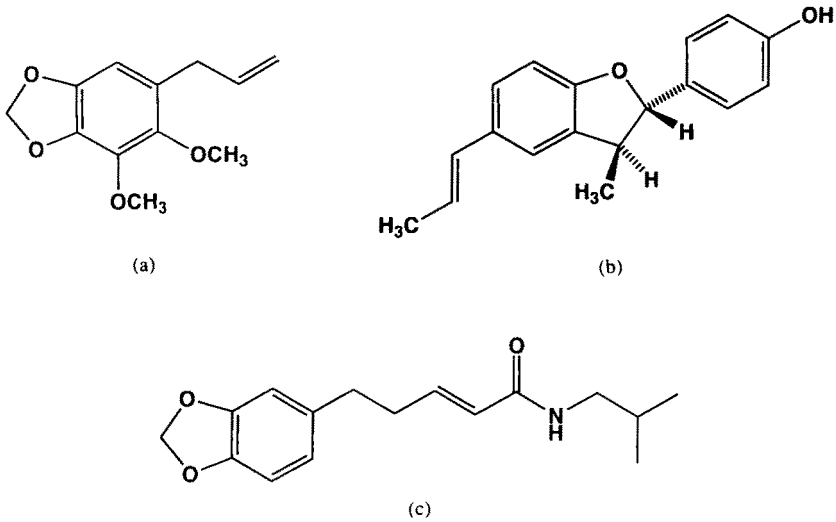

FIG. 1. Compounds isolated in this study: (a) dillapiol, (b) conocarpan, (c) dihydropiperlonguminine.

scopic data were as follows: IR (KBr pellet, cm^{-1}) 3300, 2941, 1667, 1624, 1550, 1490, 1444, 1249, 1041, 928, 812; ^1H NMR (acetone-d6, ppm) δ 0.89 [6H, d, J = 6.9 Hz, $CH(C\underline{H}_3)_2$], 1.77 [1H, non, J = 6.9 Hz, $C\underline{H}(CH_3)2$], 2.44 (2H, dq, J = 7.5 Hz, 1.5 Hz, $C\underline{H}_2-CH=CH$), 2.69 (2H, t, J = 7.5 Hz, $Ar-CH_2$), 3.16 (2H, t, J = 6.9 Hz, $NH-C\underline{H}_2$), 5.95 (2H, s, $O-C\underline{H}_2-O$), 5.96 (1H, dt, J = 15.2 Hz, 1.5 Hz, $CH_2CH=CH$), 6.69 (1H, dd, J = 7.9 Hz, 1.7 Hz, Ar—H meta and para to $O-CH_2O$), 6.75 (1H, dt, J = 15.2 Hz, 7.5 Hz, $CH_2-C\underline{H}=CH$), 6.75 (1H, D, J = 7.9 Hz, Ar—H ortho to $O-C\underline{H}_2O$ and meta to R), 6.76 (1H, d, J = 1.7 Hz, Ar—H ortho to $O-CH_2-O$ and R); HR-MS (m/z M+275, $C_{16}H_{21}O_3N$). These data for this compound matched those given for dihydropiperlonguminine (Figure 1c).

RESULTS AND DISCUSSION

Activity of Crude Extracts to European Corn Borer Larvae. The present study establishes the growth-reducing activity to the European corn borer (ECB) of the majority of the leaf extracts of the *Piper* species collected (Figure 2). *Piper aduncum* (ad), *P. tuberculatum* (tu), and *P. guineense* (gi) had the highest activity in the diet (Figure 2). The mortality data (not shown) generally paralleled the growth-reducing data, and all larvae in the *P. aduncum*, *P. tubercu-*

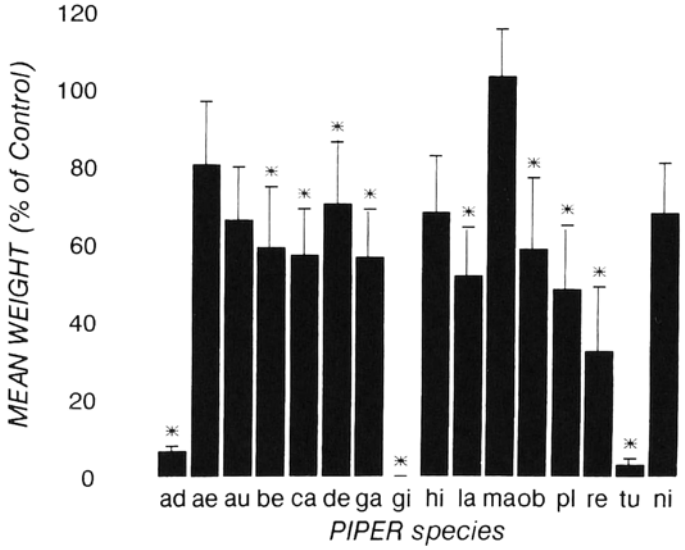

FIG. 2. Growth reducing activity of *Piper* extracts (0.4% in diet) to European corn borer larvae. ad: *P. aduncum*; ae: *P. aequale*; au: *P. auritum*; be: *P. betle*; ca: *P. carrilloanum*; de: *P. decurrens*; ga: *P. guanacastensis*; gi: *P. guineense*; hi: *P. hispidum*; la: *P. lanceiaifolium*; ma: *P. marginatum*; ob: *P. obliquum*; pl: *P. pseudo-lindenii*; re: *P. reticulatum*; tu: *P. tuberculatum*; ni: *P.* not identified. (*Piper* species with an asterisk are significantly different from their control, $P = 0.05$ in Tukey's general linear models procedure). Twenty second-instar larvae (day 6) were fed treated diets and weights were determined on day 20.

latum, and *P. guineense* groups died by day 12 of treatment. In addition, seven other species, *P. betle* (be), *P. decurrens* (de), *P. guanacastensis* (ga), *P. lanceiaifolium* (la), *P. obliquum* (ob), *P. pseudo-lindenii* (pl), *P. reticulatum* (re), and *P. carrilloanum* (ca) significantly reduced the growth of the larvae (Figure 2), with larval weights after a period of 10 days on these diets ranging from 27% to 68% of controls. For the larvae that survived the treatment, the percentage of pupation was decreased in all cases except for *P. marginatum*.

Nutritional indices (Table 1) showed limited effect of the extracts on the food consumption (CI) of the larvae, indicating little feeding deterrency (Table 3). In fact, the three most insecticidal species induced three to eight times higher consumption of food. The digestion of the insect was also little affected by the allelochemicals, but the ECD was lowered, indicating toxicity of the digested food components.

Phytochemical Isolations of Pure Compounds. Dillapiol was the main active

[a]Data are significantly different from their control in Tukey's multiple range test ($P = 0.05$). The mean RGR, CI, ECI, AD and ECD (+SD) values of control groups were: 1.7(0.4), 2.7(0.6), 5.3(1.2), 0.7(0.1) and 0.07(0.03).

component of *P. aduncum* and caused 92% mortality of mosquito larvae at 0.1 ppm (Table 4). High concentrations of dillapiol were also obtained from *P. aduncum* from Brazilian species (74–88% of the leaf essential oil) (Gottlieb et al., 1981), and this monolignan occurred in the leaves, fruits, or wood of at least five other Piperaceae distributed worldwide—*P. banksii*, *P. hispidum*, *P. marginatum*, *P. novae-hollandiae*, and *P. umbellatum* (Loder and Nearn, 1972; Burke and Nair, 1986; Ramos et al., 1986; Loder et al., 1969; Bernhard and Thiele, 1978).

Dihydropiperlonguminine was isolated from the active fraction of *P. tuberculatum*. This isobutylamide has been isolated from other Piperaceae (Tabuneng et al., 1983), along with longuminine and other derivatives. Dihydropiperlonguminine is toxic to mosquito larvae (Table 4).

Conocarpan was isolated from the active fraction of *P. decurrens* extract and could account for part of the insecticidal activity of this plant (Table 4). Conocarpan has been previously isolated from the wood of *Conocarpus erectus* (Combretaceae) (Hayashi and Thomson, 1975), but this is its first isolation from the Piperaceae. Large quantities of sitosterol (118 mg) were also purified from this fraction, as well as a number of less abundant lignans of a similar type.

TABLE 4. ACTIVITY OF NEWLY ISOLATED PURE COMPOUNDS TO MOSQUITO LARVAE

Species	Mortality (%)[a]
P. aduncum	
Dillapiol	92(4)
P. decurrens	
Conocarpan	47(5)
Sitosterol	6(3)
P. tuberculatum	
dihydropiperlonguminine	47(2)

[a]Percent mortality (±SE) from three assays of 10 larvae assay. Concentrations in bioassays were 0.1 ppm for *P. aduncum* and *P. decurrens*, and 0.01 ppm for *P. tuberculatum*.

These are presently being analyzed and will be described elsewhere (Chauret, unpublished data).

Insecticidal Lignans and Amides of Piperaceae. More than 15 species of *Piper* have been reported in the literature to have insecticidal activity. According to Marquis (1991), the highly insecticidal activity of most of the *Piper* spp., which he observed in the field in relation to two phytophagous insects, could not be correlated with the leaf characteristics, the soil, or other environment factors, "leaving the individual chemistry as a possible factor to investigate."

The two species of *Piper* with the highest toxicity to the ECB, *P. tuberculatum* and *P. guineense*, contain large amounts of amides. The isobutylamide, dihydropiperlonguminine, is a major component of *P. tuberculatum* leaves, as described in the present study. In the only other chemical investigation reported on this species, the pyridone alkaloid piplartine and its dimer (Filho et al., 1981), were isolated from the root bark.

P. guineense is, by contrast, well studied. A series of isobutylamides, including pipercide, guineensinamide, guineensine, pellitorine, and kalecide, have been isolated from the roots of *P. guineense* and shown to be responsible for the insecticidal activity of this species (Gbewonyo et al., 1993). The first three amides were the most active against adults of *Musca domestica*. Each of these contain a methylenedioxyphenyl (MDP) structural moiety.

The isobutylamide newly isolated from *P. tuberculatum*, dihydropiperlonguminine (Figure 1c) also has an MDP ring and is the main component of the active fraction of the leaf extract. Greger (1988) pointed out that these types of amides, including olefinic and alkyl isobutylamides, are common to a restricted number of related plant families, namely the Piperaceae, the Asteraceae, and the Rutaceae. All three families are abundant in the tropics, particularly in the

humid tropics in the case of the Piperaceae, where herbivory is a potent selective force. The isobutylamides found in the *Piper* family have low molecular weights, contain a single nitrogen, and presumably are not "expensive" to biosynthesize. The pungent, numbing sensation caused by some of the psychoactive species, such as *P. methysticum*, may be a reason for their avoidance by herbivores, as observed by Marquis (1991), in particular with *P. auritum*. Piperaceae are mostly vines or small shrubs in the tropics, and short life-cycle species such as these would be expected to protect themselves with simply synthesized, low-cost, molecules. The isobutylamides could be described as belonging to this category of defense compounds.

The most active insecticidal species in our bioassays was *P. aduncum*. Surprisingly, no amides have been reported from this species. It does, however, contain several lignans, including dillapiol, first found in the Indian dill, *Anethum sowa* (Fabaceae), where it constitutes up to 35% of the essential oil of the seeds of Indian cultivars (Tomar et al., 1979), and also in the leaves of *P. aduncum* from Panama, where it is the only major component (Gupta and Arias, 1983). Dillapiol can synergize several natural insecticides, including pyrethrum (Mukerjee et al., 1979), azadirachtin (Bertrand, 1992), and tenulin (Bernard et al., 1990), at the concentration of 100 ppm in the diet of the European corn borer, a concentration well below the level in the leaves of *P. aduncum* (approximately 60% of the oil). It previously was found to be toxic to the ECB (Bernard et al., 1989). It is the main insecticidal component of this *Piper* sp. Monolignans and lignans with the MDP moiety are characteristic chemicals from the Piperaceae. Lignan toxicity differs from that of classical neurotoxic insecticides, as it is chronic rather than acute. Several lignans inhibit a vital biochemical defense of herbivores, the polysubstrate monooxygenase (PSMO) detoxification enzymes (Ahmad, 1986; Bernard et al., 1989; Berenbaum and Neal, 1985). Thus, several potentially toxic components in the food of the insect that are usually gradually eliminated could accumulate to a toxic level. These specific lignans, myristicin, dillapiol, epiyangambin, ashantin, and eugenol, are distributed in most of the *Piper* spp. and often occur in large quantities in the plants.

The elucidation of the structure of conocarpan, a neolignan, as the main, but not highly, insecticidal component of *P. decurrens*, further suggests the importance of lignans in the Piperaceae. Only lignans have been isolated from extracts having a growth-reducing rather than an acute toxic effect on insect larvae, i.e., *P. marginatum*, *P. decurrens*, and *P. hispidum* of the present study. These produced the lowest larval mortality. This leads to the possibility that *Piper* lignans not associated with amides, excluding monolignols, may have a long-term effect and low toxicity, as further suggested by the low incidence of pupation in the groups fed on these three species. This possibility warrants further investigation.

In any case, isobutylamides and lignans combined in the same plant constitute an inexpensive and effective means of defense elaborated by a limited number of highly successful plants from the neotropics.

The present study confirms that tropical American *Piper* spp. have insecticidal activities comparable to previously studied African and Asian species. Bioassay-guided isolation suggests the importance of neolignans and amides as the active components.

(Received September 21, 1994; accepted March 1, 1995)

Abstract—In order to test a previous conclusion that chain-elongated analogs of (Z)-5-decenyl acetate (**1**), a pheromone component of the turnip moth, *Agrotis segetum*, adopt a loop conformation of the terminal alkyl chain in the bioactive conformation, a series of alkyl ether and enol ether analogs of **1** and (Z)-5-dodecenyl acetate (**2**) have been synthesized and tested using single-cell electrophysiology. In these analogs a methylene group in positions 7 and 9 of **1** and in positions 7 and 11 in **2** have been replaced by an oxygen atom in order to energetically facilitate the formation of a loop conformation in the chain-elongated analogs. The electrophysiological results in combination with molecular mechanics (MM2 and MM3) calculated conformational energies show that the activity decreases of the chain-elongated ether analogs are significantly smaller than that for **2** and that these activity decreases parallel the conformational energies for a loop formation of the terminal chains in the analogs. The results support our previous conclusion that the terminal chain of chain-elongated analogs of **1** adopts a loop conformation in their bioactive conformations.

INTRODUCTION

In a series of papers we have studied structure–activity relationships for analogs of (Z)-5-decenyl acetate (**1,** Figure 1), a pheromone component of the turnip moth, *Agrotis segetum* (Liljefors et al., 1985, 1987; Bengtsson et al., 1987, 1990; Jönsson, 1991; Jönsson et al., 1991, 1992, 1993). Based on these studies, we have developed a model for the interaction between **1** and its receptor (Liljefors et al., 1987; Bengtsson, 1988; Jönsson, 1991). Three pharmacophore elements have been identified: the terminal methyl group, the double bond, and the acetate group. In a previous study (Liljefors et al., 1987), we found that

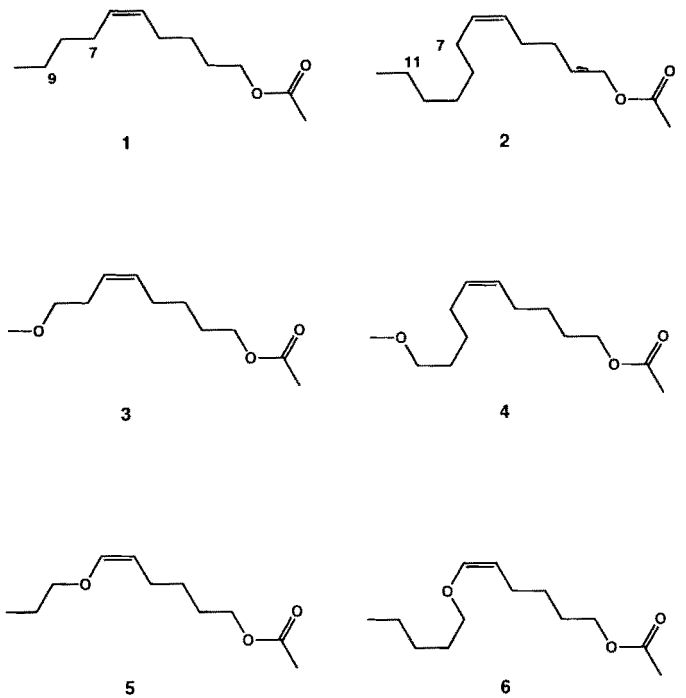

FIG. 1. Compounds studied. Compounds **2, 4,** and **6** are shown with the terminal chain in the loop formation discussed in this paper.

single-cell electrophysiological activities of chain-elongated analogs of **1** were determined by the conformational energies required for the analogs to mimic the proposed bioactive conformation of **1** with respect to the location in space of the pharmacophore elements. For instance, the chain-elongated analog (*Z*)-5-dodecenyl acetate **(2)** was shown to be able to mimic the active structure of **1** provided that the terminal alkyl chain in **2** adopts a loop conformation as shown in Figure 2. Our model is based on the hypothesis that the dimensions of the receptor cavity are such that a close fit between terminal methyl groups of analogs and that of **1** is required. In particular, we propose that the end of the terminal chain of an analog cannot, without excessive steric repulsions, be extended beyond that of the terminal methyl group of **1** in the direction of the terminal C—C bond.

The proposed biologically active conformation of **1** (Liljefors et al., 1987; Bengtsson, 1988) is shown in Figure 3a. Figure 3b shows a molecular least-squares superimposition of the active conformations of **1** and **2** based on the

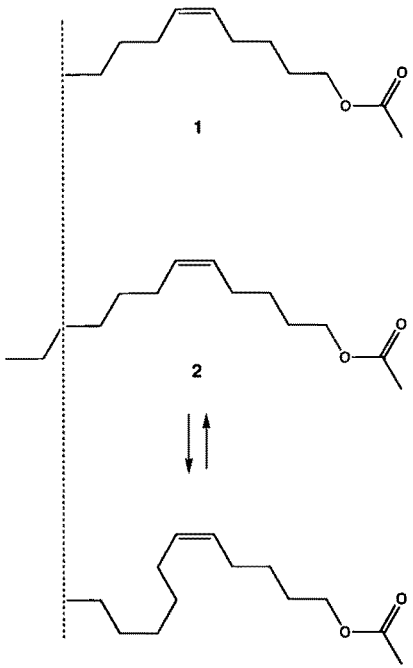

FIG. 2. Loop formation required for (*Z*)-5-dodecenyl acetate **(2)** in order to mimic the active structure of **1** with respect to the position of the terminal methyl group.

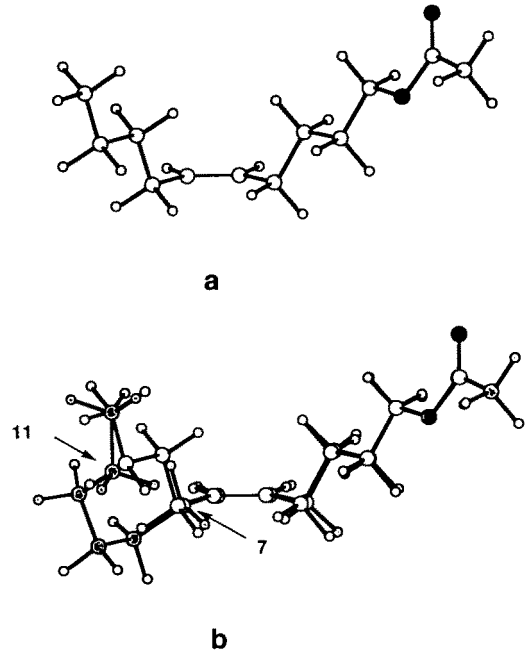

FIG. 3. (a) Compound **1** in the proposed bioactive confirmation. (b) Superimposition of the proposed bioactive conformations of compounds **1** and **2**.

concept of a loop formation of the terminal chain of the chain-elongated analog **2**.

The purpose of the present study is to test our conclusion concerning the loop conformation of the extended chain in the bioactive conformation of chain-elongated analogs of **1**. Preliminary molecular mechanics calculations (J. Palm and T. Liljefors, unpublished results) indicate that the conformational energy of the loop conformation of **2** is largely determined by repulsive van der Waals interactions between the methylene groups at positions 7 and 11 (Figure 3b). Thus, replacement of one of these methylene groups by an oxygen atom implies that the energy requirement for loop formation should be lower for the oxygen analog because of the smaller size of an oxygen atom compared to a methylene group. Consequently, our receptor-interaction model predicts that such ether analogs should display a significantly smaller decrease in activity on chain elongation than is the case for a corresponding chain elongation of **1**.

To test this prediction, the alkyl ether and enol ether analogs **3–6** (Figure 1) have been synthesized, and their electrophysiological single-cell activities

have been determined. The results, in relation to the corresponding results for **1** and **2,** have been interpreted by the use of molecular mechanics calculated conformational energies. Compounds **3** and **5** may also give information on the effect of methylene group replacement by an oxygen atom in positions 7 and 9 in **1.**

Very few ether analogs of moth sex pheromone components have been reported. Hoskovec et al. (1993) recently reported two alkyl ether analogs of (*E*,*Z*)-2,13-octodecadienyl acetate, a pheromone component of the currant clearwing moth, *Synanthedon tipuliformis*. Unfortunately, the activity of these analogs was only determined by the EAG method. To our knowledge, no single-cell electrophysiology measurements of ether analogs of moth sex pheromone components have been reported previously.

METHODS AND MATERIALS

Synthesis. All reactions of air- and water-sensitive materials were performed under a nitrogen atmosphere with oven-dried glassware. Anhydrous diethyl ether (ether) and tetrahydrofuran (THF) were distilled from dark blue solutions of the sodium benzophenone radical anion. *N*,*N*′-Dimethyl-*N*,*N*′-propylene urea (DMPU), purchased from Fluka Chemie AG, was distilled under vacuum from calcium hydride prior to use. The dimethyl sulfide complex of cuprous bromide was prepared by the method of House et al. (1975). Propargyl bromide was distilled prior to use and potassium *tert*-butoxide was purified by sublimation. 2-Bromoethyl methyl ether was purchased from Aldrich-Chemie GmbH. The crude pheromone products were purified by flash chromatography on TLC silica gel 60H. Petroleum ether–ethyl acetate (10 : 1) was used as eluent for compounds **3** and **4** and dichloromethane–ethyl acetate (50 : 1) for compounds **5** and **6.** Flash chromatographed products were further purified by argentation chromatography (Houx et al., 1974). Compounds **3** and **4** were then finally purified by preparative GLC using a 6-m × 4-mm OV-351 column. Compounds **5** and **6** were purified by preparative high-performance liquid chromatography [HPLC, normal-phase column SH-44-20 S-10 120A sil with petroleum ether–ethyl acetate (95 : 5) as eluent and a differential refractometer as monitor].

Analytical GLC was performed with a Varian 3400 capillary GLC fitted with a DB-Wax 30-m column. The purity of the isolated final products was >99%. No sample contained any detectable amount (<0.05%) of the natural pheromone component. ^{1}H and ^{13}C NMR on the final products were recorded on a Varian XL-300 spectrometer. High-resolution mass spectra were recorded on a Jeol JMS-SX 102 spectrometer. The synthetic schemes used are shown in Figures 4 and 5.

Preparation of 4-Bromobutyl Methyl Ether. 4-Bromobutyl methyl ether was

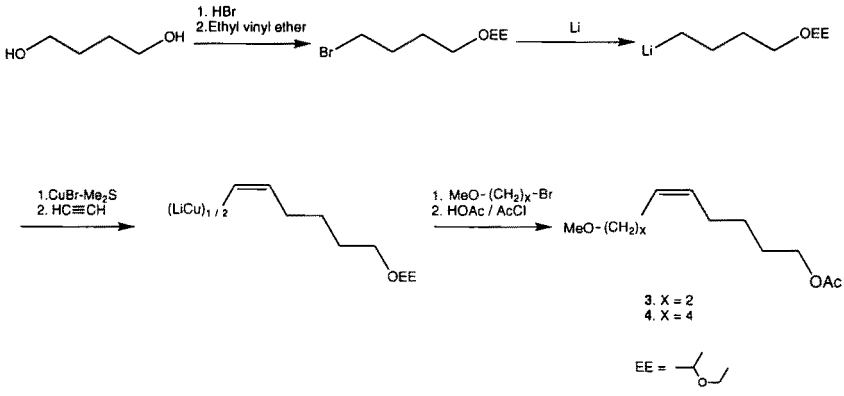

FIG. 4. Synthetic routes to compounds **3** and **4.**

prepared by Williamson's ether synthesis using a phase-transfer catalyst according to the method described by Burgstahler et al. (1977). To a solution of 20 g of sodium hydroxide and 40 ml of water, cooled to 10°C, were added 4 ml (0.1 mol) of methanol, 59.8 ml (0.5 mol) of 1,4-dibromobutane, and 1.7 g (5 mmol) of tetrabutylammonium hydrogen sulfate. After stirring over night at room temperature, the mixture was poured into 500 ml of water, extracted with pentane, and the dried extracts were evaporated. The crude product was distilled given 16 g of product, bp 64–68°C/9 mm Hg (lit: 60°C/15 mm Hg) (Kirrman and Hamaide (1957). According to capillary GLC the product was a mixture of 4-bromobutyl methyl ether and 1,4-dibromobutane in a ratio of 35:65 (yield of about 40%). The mixture was flash chromatographed with dichloromethane as eluent and gave >95% pure product according to capillary GLC.

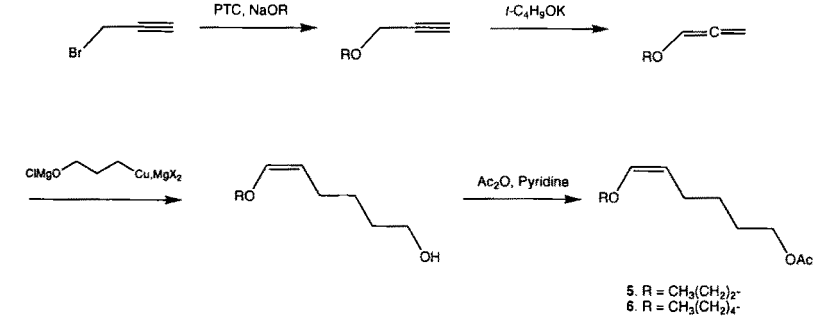

FIG. 5. Synthetic routes to compounds **5** and **6.**

Preparation of 4-(1-Ethoxyethoxy)-butyl Lithium. 4-Bromo-1-butanol was prepared according to the method of Kang et al. (1985). A mixture of 44.6 ml (0.5 mol) of 1,4-butandiol and 62.5 ml (0.55 mol) of 48% HBr in 800 ml benzene was heated at reflux for 7 hr, while the water formed (60 ml) was trapped with a Dean-Stark separator. The mixture was evaporated, and the residue was desolved in anhydrous CH_2Cl_2 (200 ml) and cooled to $<18°C$. Then ethyl vinyl ether (48 ml, 0.5 mol) was added dropwise over 45 min, while the solution temperature was kept between 10 and 16°C. The colorless solution was stirred for another hour at room temperature, washed with saturated Na_2CO_3 solution, dried over Na_2CO_3, and finally the solvent was evaporated. The crude product was distilled in base-washed glassware to give 41 g (37% yield, bp 60–69°C/2 mm Hg) of 4-(1-ethoxyethoxy)-butyl bromide. δ_H (60 MHz) 1.0–1.4 (6H, m, CH_3), 1.5–2.4 (4H, m, CH_2), 3.1–4.0 (6H, m, CH_2Br, CH_2O), 4.7 (1H, q, OCHO).

To freshly cut small chips of lithium (1.7 g, 0.25 mol) in 20 ml ether, a solution of 4-(1-ethoxyethoxy)-butyl bromide (22.5 g, 0.1 mol) in 60 ml ether was added dropwise at −15°C during 1 hr. After the addition, the solution was stirred for 1 hr at 0°C. The greyish turbid solution was transferred to a 100-ml graduated glass cylinder that was carefully purged with argon. The cylinder was stored at −15°C allowing cloudy material to precipitate. The clear pale yellow solution was titrated by the method of Watson and Eastham (1967) and found to be 0.7–0.8 N (yield 70–80%).

Preparation of Lithium Bis[(Z)-6-(1-ethoxyethoxy)-hex-1-enyl]cuprate. This compound was prepared by carbocupration of acetylene according to Gardette et al. (1985). To a well-stirred suspension of CuBr−Me_2S complex (House et al., 1975) (1.23 g, 6 mmol) in ether (25 ml) at −50°C, 12 mmol of 4-(1-ethoxyethoxy)-butyl lithium solution was slowly transferred by using a double-tipped needle. The solution was warmed to −40°C and stirred for 30 min at this temperature. The almost clear solution was cooled to −50°C and acetylene (0.3 liters, 12 mmol) was bubbled slowly into the reaction mixture. Stirring of the resulting solution was maintained for 30 min at −25°C.

9-Oxa-(Z)-5-decenyl Acetate (3). To a stirred solution of lithium bis[(Z)-6-(ethoxyethoxy)-hex-1-enyl]cuprate (12 mmol) at −30°C, DMPU (6 ml) in 40 ml THF and 2-bromoethyl methyl ether (1.69 g, 12 mmol) in 5 ml THF were successively added. The mixture was slowly allowed to reach room temperature and stirred over night. It was then cooled to −20°C and quenched with 5 N HCl (40 ml). After stirring for 15 min with air bubbling into the mixture, 50 ml of petroleum ether (40–60) was added and the precipitate was filtered off with celite. The aqueous layer was extracted once with ether (50 ml), and the combined organic extracts were washed once with 17% NH_3 (25 ml), then with saturated NH_4Cl solution (25 ml), and finally dried over $MgSO_4$. The solvents were removed and the residue treated with glacial acetic acid (8 ml) and acetyl

chloride (1 ml). This mixture was stirred over night at 30–40°C and then poured onto ice (40 ml) in saturated NaCl solution. The acetate was extracted three times with pentane (15 ml). The organic phase was washed with $NaHCO_3$ solution and dried over $MgSO_4$. After evaporation, the crude product was purified by flash chromatography to give 0.4 g (yield 17%) of compound **3**, 63% pure by GLC. δ_H (300 MHz) 1.35–1.47 (m, 2H, $=CCC\mathbf{H}_2$), 1.55–1.68 (m, 2H, $CC\mathbf{H}_2C-O$), 2.03 (s, 3H, $COC\mathbf{H}_3$), 2.07 (dt, 2H, J = 7.3 Hz, J = 6.8 Hz, $=CHC\mathbf{H}_2CH_2$), 2.33 (dt, 2H, J = 6.8 Hz, J = 6.4 Hz, $OCH_2C\mathbf{H}_2CH=$), 3.33 (s, 3H, CH_3O), 3.37 (t, 2H, $OC\mathbf{H}_2CH_2$), 4.04 (t, 2H, $CH_2C\mathbf{H}_2O$), 5.33–5.50 (m, 2H, J = 10.9 Hz, $C\mathbf{H}=C\mathbf{H}$). δ_C (75.4 MHz) 21.0, 25.9, 26.9, 27.8, 28.2, 58.6, 64.4, 72.3, 126.1, 131.2, 171.2. High-resolution CI mass spectrum for $C_{11}H_{21}O_3$ ($M+H^+$): calcd. 201.1491, found 201.1494.

11-Oxa-(Z)-5-dodecenyl Acetate ***(4).*** This compound was prepared from 4-bromobutyl methyl ether (1 g, 6 mmol) in the same manner as compound **3** to give 0.28 g (20% yield) of flash chromatographed product, 80% pure by GLC. δ_H (300 MHz) 1.33–1.46 (m, 4H, $=CCC\mathbf{H}_2$), 1.52–1.68 (m, 4H, $CC\mathbf{H}_2C-O$), 1.95–2.13 (m, 4H, $CC\mathbf{H}_2C=$), 2.03 (s, 3H, $COC\mathbf{H}_3$), 3.32 (s, 3H, $C\mathbf{H}_3O$), 3.36 (t, 2H, $CH_2C\mathbf{H}_2O$), 4.05 (t, 2H, $CH_2C\mathbf{H}_2OCO$), 5.26–5.43 (m, 2H, J = 10.9 Hz, $C\mathbf{H}=C\mathbf{H}$). δ_C (75.4 MHz) 21.0, 26.0, 26.2, 26.8, 27.0, 28.2, 29.3, 58.6, 64.5, 72.7, 129.4, 130.1, 171.2. High-resolution CI mass spectrum for $C_{13}H_{25}O_3$ ($M+H^+$): calcd. 229.1804, found 229.1806.

Preparation of Propyl Propargyl Ether. This ether was prepared according to Mikami et al. (1984), using a phase-transfer catalyst (Dockx, 1973). 3-Bromo-1-propyne (31.0 g, 0.26 mol) was added dropwise to a rigorously stirred mixture of propanol (15 ml, 0.2 mol), 50% NaOH solution (35 ml), and n-Bu_4NHSO_4 (3.5 g, 0.01 mol) at 20–30°C. The resulting mixture was stirred over night at room temperature. The solid formed was removed by filtration. After dilution of the mixture with water and ether, the water phase was extracted three times with ether and the combined organic extracts were washed with brine and dried over $MgSO_4$. Evaporation and distillation of the product gave 14.4 g (70% yield), bp 40–60°C/155 mm Hg. δ_H (60 MHz) 1.0 (t, 3H, $C\mathbf{H}_3C$), 1.3–2.0 (m, 2H, $CC\mathbf{H}_2C$), 2.5 (t, 1H, J = 2 Hz, $\mathbf{H}CCCH_2$), 3.6 (t, 2H, $OC\mathbf{H}_2CH_2$), 4.2 (d, 2H, J = 2 Hz, $HCCC\mathbf{H}_2O$).

Preparation of Propyl Allenyl Ether. The rearrangement of the propargyl ether to give the corresponding allenyl ether was done according to Hoff et al. (1968). To 7.5 g (75 mmol) of propyl propargyl ether was added 0.9 g (7.5 mmol) of potassium *tert*-butoxide. The mixture was stirred for 2–3 hr at 70°C. After cooling to room temperature, the brown reaction mixture was poured onto ice water and extracted with ether. The organic layer was washed with water and dried over K_2CO_3. After evaporation, the product was distilled, giving 1.6 g (22% yield) bp 58–59°C/160 mm Hg. δ_H (60 MHz) 0.9 (t, 3H, $C\mathbf{H}_3CH_2$), 1.1–1.3 (m, 2H, $CC\mathbf{H}_2C$), 3.5 (t, 2H, $OC\mathbf{H}_2CH_2$), 5.4 (d, 2H, J = 6 Hz, $C\mathbf{H}_2=C=CH-O$), 6.7 (t, 1H, J = 6 Hz, $CH_2=C=C\mathbf{H}-O$).

7-Oxa-(Z)-5-decenyl Acetate **(5).** This compound was made via the addition of a magnesium organocopper reagent to an allenyl ether, according to Klein et al. (1976) and Alexakis and Normant (1984), giving predominantly a Z-enol ether. The magnesium organocopper reagent was prepared according to Gardette et al. (1985). CuBr, 1.1 g (8 mmol), and 0.65 g (15 mmol) of LiCl were mixed in 15 ml THF and stirred at room temperature until a clear solution was obtained. The mixture was then cooled to −40°C and 7 mmol of γ-magnesium-protected 3-hydroxypropyl magnesium chloride, prepared in THF according to Cahiez et al., (1978), was added. After the reaction mixture was stirred 30 min at −30°C, it was cooled to −50°C and the propyl allenyl ether (0.7 g, 7 mmol) in THF (5 ml) was added dropwise. After stirring for 1 hr at −15°C, the mixture was hydrolyzed with 14 ml of saturated NH_4Cl and 2 ml of aqueous ammonia. After filtration of the salts, the organic phase, to which 100 ml pentane had been added, was washed once with saturated NH_4Cl-solution, dried over Na_2CO_3, and finally evaporated. The crude product (0.9 g) was added to a mixture of pyridine (5 ml) and acetic anhydride (1 ml) and was stirred for 4 hr at room temperature. The reaction mixture was poured on water, extracted with pentane, and dried over $MgSO_4$. After evaporation, the crude product was flash chromatographed giving 0.4 g of the final product (25% yield, 86% pure by GLC, *Z*:*E* 87:13). Further purification (see Synthesis section above) gave pure *Z* isomer, compound **5.** δ_H (300 MHz) 0.92 (t, 3H, $\mathbf{CH_3}C$), 1.36–1.46 (m, 2H, $CC\mathbf{H_2}C$), 1.56–1.70 (m, 4H, $CC\mathbf{H_2}C$), 2.03 (s, 3H, $CO\mathbf{CH_3}$), 2.10 (dt, 2H, J = 7.3 Hz, $=CHC\mathbf{H_2}CH_2$), 3.66 (t, 2H, $CH_2\mathbf{CH_2}OC=$), 4.05 (t, 2H, $CH_2\mathbf{CH_2}OCO$), 4.30 (dt, 1H, $J(=CHCH_2)$ = 7.3 Hz, J(HC=CH) = 6.3 Hz, $CH=\mathbf{CH}CH_2$), 5.93 (dt, 1H, J = 6.3 Hz, $O\mathbf{CH}=CH$). δ_C (75.4 MHz) 10.2, 21.0, 23.0, 23.4, 26.0, 28.1, 64.6, 73.7, 105.9, 145.3, 171.2. MS (high resolution) for $C_{11}H_{20}O_3$: calcd 200.1413, found 200.1420.

Preparation of Pentyl Propargyl Ether. This compound was prepared by the method described above for propyl propargyl ether. However, the reaction temperature was kept at 50–60°C. The product was distilled giving 19.8 g (78% yield), bp 64–86°C/75 mm Hg. δ_H (60 MHz) 0.9 (t, 3H, $\mathbf{CH_3}C$), 1.1–1.9 (m, 6H, $-\mathbf{CH_2}-$), 2.4 (t, 1H, J = 2 Hz, $\mathbf{H}CCCH_2$), 3.5 (t, 2H, $O\mathbf{CH_2}CH_2$), 4.1 (d, 2H, J = 2 Hz, $HCCC\mathbf{H_2}O$).

Preparation of Pentyl Allenyl Ether. This allenyl ether was prepared as described above for propyl allenyl ether from 9.5 g (75 mmol) of pentyl propargyl ether. For the preparation of pentyl allenyl ether, 12.5 mmol of potassium butoxide was used. The product was distilled, giving 6.6 g (70% yield) bp 66–68°C/35 mm Hg. δ_H (60 MHz) 0.9 (t, 3H, $\mathbf{CH_3}C$), 1.1–2.0 (m, 6H, $-\mathbf{CH_2}-$), 3.6 (t, 2H, $O\mathbf{CH_2}CH_2$), 5.5 (d, 2H, J = 6 Hz, $\mathbf{CH_2}=C=CH-O$), 6.8 (t, 1H, J = 6 Hz, $CH_2=C=\mathbf{CH}-O$).

7-Oxa-(Z)-5-dodecenyl Acetate **(6).** This compound was prepared in the same manner as compound **5** but from pentyl allenyl ether (1.26 g, 10 mmol).

The crude alcohol (1.7 g) was treated with a mixture of 5 ml of pyridine and 2 ml of acetic anhydride for acetylation. Flash chromatography gave 1.1 g (43% yield, 90% pure by GLC, *Z*:*E* 76:24). δ_H (300 MHz) 0.89 (t, 3H, CH_3C), 1.28–1.45 (m, 6H, $-CH_2-$), 1.53–1.70 (m, 4H, $-CH_2-$), 2.03 (s, 3H, CH_3CO), 2.10 (dt, 2H, J = 7.3 Hz, $=CH-CH_2CH_2$), 3.67 (t, 2H, $CH_2CH_2OC=$), 4.05 (t, 2H, CH_2CH_2OCO), 4.30 (dt, 1H, $J(=CH-CH_2)$ = 7.3 Hz, $J(HC=CH)$ = 6.3 Hz, $C=CHCH_2$), 5.93 (dt, 1H, J = 6.3 Hz, $OCH=CH$). δ_C (75.4 MHz) 14.0, 21.0, 22.4, 23.4, 26.0, 28.0, 28.1, 29.4, 64.6, 72.2, 105.9, 145.4, 171.2. MS (high resolution) for $C_{13}H_{24}O_3$: calcd. 228.1726, found 228.1719.

Electrophysiology. The activities of compounds **1–6** were determined by single-cell electrophysiology (Kaissling, 1974). The olfactory receptor cell specifically tuned to (*Z*)-5-decenyl acetate, present in the antennal sensilla type SW1 of *Agrotis segetum*, was used (Hallberg, 1981; Löfstedt et al., 1982; van der Pers and Löfstedt, 1983). The method was modified according to van der Pers and den Otter (1978) and has been previously described (Liljefors et al., 1987; Bengtsson et al., 1990).

The stimulus amounts used for pheromone component **1** were 10^{-4}–1 μg, for compound **3** 10^{-2}–1 μg, and for compound **5** 10^{-2}–10 μg, in decadic steps. For the chain-elongated analogs **2, 4,** and **6,** the amounts used were 10^{-1}–100 μg, in decadic steps. For each stimulus loading, 10 replicates were recorded and the mean value of the number of action potentials generated during 1 sec from the onset of stimulation was used in the construction of the dose–response curves. The errors were expressed as standard errors of the mean (SEM). The electrophysiological activity of each compound in relation to that of **1** is expressed as the reciprocal of the relative quantities required to elicit the same response from the receptor as the natural pheromone component **1.**

Differences in volatility for the compounds were taken into account by correcting the activities by using relative vapor pressures as previously described (Liljefors et al., 1985; Bengtsson et al., 1990). The correction factors for the alkyl ether analogs are based on vapor pressure data (Dykyj and Repas, 1979) for hydrocarbons (pentane to heptane) and their ether analogs (methyl propyl ether, diethyl ether, ethyl butyl ether, dipropyl ether, methyl butyl ether, ethyl propyl ether). The factors for the enol ether analogs are based on data for 1-butene, 1-pentene, 1-heptene, 2-pentene, and their enol ether analogs.

The logarithm of the quotient of the vapor pressure for a hydrocarbon compound and the vapor pressure for its analog (alkyl or enol ether analog) gives the correction factor. The correction factors for carbon chain-elongated compounds were obtained in an analogous way (Liljefors et al., 1985). The mean value of the quotient for each class of compounds (alkyl ethers, enol ethers, chain-elongated) was used. The correction factors were added to the logarithm of the relative activities. A positive factor indicated a lower vapor

pressure for the ether analog than for the corresponding hydrocarbon compound, and the real relative activity for the ether analog was higher than the measured activity. If the factor was negative, the analog was more volatile than the corresponding compound and the relative activity should be lowered. The correction factor for two-carbon chain-elongated analogs is 0.82, for enol ether analogs 0.12, and for alkyl ether analogs −0.03. For those analogs that are both chain-elongated and ether analogs of **1,** an additive scheme was used. The correction factors used were as follows: for compound **2,** 0.82; for **3,** −0.03; for **5,** 0.12; for **4,** 0.79 (−0.03 + 0.82); and for **6,** 0.94 (0.12 + 0.82).

Molecular Mechanics. Energy minimized geometries and conformational energies were calculated by using the molecular mechanics program MM2(91), developed by Allinger and coworkers (Burkert and Allinger, 1982), and implemented in the molecular modeling package MacMimic/MM2(91) version 2.0 (Instar Software AB, Ideon Research Park, S-223 70 Lund, Sweden) and the MM3(92) program (Allinger et al., 1989). The construction of input structures and the molecular superimposition studies were done using the MacMimic program.

RESULTS

Chemicals. The alkyl ether analogs **3** and **4,** were synthesized by carbocupration of acetylene, giving a *Z* double bond with high selectivity (Gardette et al., 1985), followed by alkylation of the cuprate by an alkyl bromide as shown in Figure 4. This method has previously been used for the synthesis of alkyl substituted pheromone analogs by Jönsson et al. (1991).

The enol ether analogs, compounds **5** and **6,** were synthesized via a carbocupration route employing allenyl ethers, as shown in Figure 5. Also in this type of reaction, the (*Z*)-enol ether is formed with high selectivity (Alexakis and Normant, 1984; Klein et al., 1976). The *Z*:*E* ratio for compound **5** was 87:13 and for compound **6,** 76:24. Purification with argentation chromatography gave the pure *Z* isomers. The allenyl ethers were obtained from propargyl bromide in two steps. Propargyl bromide was reacted with a suitable alcohol under phase transfer catalyst conditions giving the alkyl propargyl ether. This compound was then rearranged under basic conditions, to give the allenyl ether.

Receptor Cell Responses. Relative single-cell activities for compounds **1–6,** including corrections for differences in volatilies determined as described in the Methods and Materials section, are shown in Figure 6. All analogs display lower activities than the natural pheromone component **1.** However, there is a significant difference in the reduction of the activity for the two ether analogs **3** and **5.** The alkyl ether **3** is less active than **1** by only a factor of 6, while the enol ether **5** is 150 times less active than **1.** In the chain-elongated series (**2, 4,**

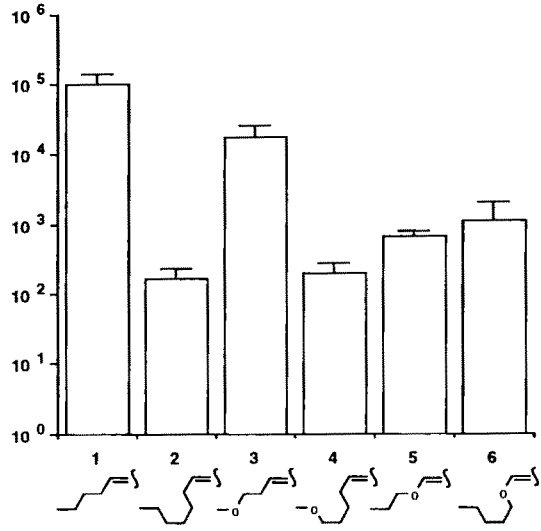

FIG. 6. Relative electrophysiological single-cell activities (+SEM) for compounds **1–6**. The data are corrected for differences in volatility.

and **6**) the effect of a replacement of a methylene group by an oxygen atom differs from that in the series **1, 3,** and **5.** The compound with an oxygen atom in position 11 **(4)** is equipotent with the parent compound **2.** Thus, in this case the replacement of a methylene group by an oxygen atom has no effect on the electrophysiological activity. Interestingly, in this series the chain-elongated enol ether **6** has slightly higher activity than the parent compound **2.**

The effects of chain elongation of compounds **1, 3,** and **5** are also very different. Chain-elongation of **1** by two methylene groups, giving compound **2,** decreases the activity by a factor of about 600, in agreement with previously reported results (Liljefors et al., 1985, 1987). The corresponding chain elongation of compound **3** to **4** gives an activity decrease by a factor of 86. In contrast to these activity decreases, chain elongating the enol ether **5** to **6** does not significantly affect the electrophysiological activity.

Conformational Energies. The main objective of the present study was to investigate if the electrophysiological activities of chain-elongated analogs were determined by the conformational energies required by a loop-formation of the terminal chain. In particular, we wanted to investigate the relationships between the effect of the activity of chain elongation of **1** and of the ether analogs **3** and **5.** Thus, we calculated the conformational energies required by the three pairs **1–2, 3–4,** and **5–6** to acquire the proposed active conformations (Liljefors et

al., 1987) as exemplified by compounds **1** and **2** in Figure 3b. For each compound, the calculations were performed as follows: (1) the energy of the preferred (lowest energy) conformation was calculated and the preferred conformation was identified by energy minimizing a large number of trial structures; and (2) the energy of a conformation was calculated in which the carbonyl carbon, the carbonyl oxygen, the carbon atom of the acetate methyl group, and the carbon atom of terminal methyl group superimposed exactly with the corresponding atoms of the proposed active conformation of the natural pheromone component **1** as shown in Figure 3a. For the chain-elongated analogs this conformation has a loop conformation of the terminal chain, as in Figure 3b. In the superimpositions, it was further required that the *Z* double bond of all analogs must be located in the plane defined by the C—C=C—C fragment of compound **1** in Figure 3a (Liljefors et al., 1987). The conformational energies required for each compound to acquire the proposed bioactive conformation were calculated finally as the difference of the energies calculated according to (2) and (1). In order to investigate the force-field dependence of the results, the calculations were performed using two different force fields, MM2(91), and the more recent MM3(92) (see Methods and Materials section). The results are shown in Table 1.

The chain-elongated analogs **2, 4,** and **6** have higher conformational energies of their bioactive conformations (ΔE) than those of their parent compounds **1, 3,** and **5.** Furthermore, the differences in conformational energies for the bioactive conformations ($\Delta\Delta E$) of the three pairs of chain-elongated analog vs. parent compound vary significantly, as shown in Table 2. Chain elongation of **1** (to **2**) was calculated to require an additional conformational energy of 5.6

TABLE 1. CALCULATED CONFORMATIONAL ENERGY DIFFERENCES (ΔE) BETWEEN PROPOSED BIOACTIVE CONFORMATION (E_{active}) AND PREFERRED CONFORMATION (E_{lowest}) OF COMPOUNDS **1–6**[a]

Compound	$\Delta E = E_{active} - E_{lowest}$		Relative single-cell activity
	MM2(91)	MM3(92)	
1	1.1	0.6	1
2	6.7	6.8	1/603
3	0.8	0.4	1/6
4	4.3	4.0	1/513
5	3.4	2.2	1/151
6	4.4	2.8	1/91

[a]The energies are in kcal/mol. Electrophysiological activities in relation to compound **1** are given in the last column.

TABLE 2. CALCULATED DIFFERENCES ($\Delta\Delta E$) BETWEEN CONFORMATIONAL ENERGIES OF BIOACTIVE CONFORMATION OF CHAIN-ELONGATED ANALOGS **2**, **4**, AND **6** AND OF THEIR PARENT COMPOUNDS **1**, **3**, AND **5**[a]

	$\Delta\Delta E$		
	MM2(91)	MM3(92)	Factor of activity decrease
2 compared to **1**	5.6	6.2	603
4 compared to **3**	3.5	3.6	86
6 compared to **5**	1.0	0.6	0.6

[a]The energies are in kcal/mol. The last column shows electrophysiological activity decreases due to chain elongation.

kcal/mol in order for **2** to acquire the bioactive conformation. The corresponding energies for **3** (to **4**) and **5** (to **6**) were significantly lower. The results in Table 2 for the two different force fields are very similar, demonstrating that the results were not dependent on the particular force field used.

DISCUSSION

The effects on the electrophysiological activity of replacement of the methylene group in either position 7 or 9 in **1** by an oxygen atom are highly dependent on the position of the replacement. The 9-oxa compound **3** is only six times less active than **1**, while the 7-oxa compound **5** is about 150 times less active than **1** (Figure 6). The calculated conformational energy required for the bioactive conformation of **3** is very similar to the corresponding energy required for **1** (Table 1). This implies that the activity decrease of **3** compared to **1** cannot be due to a conformational effect. The small but significant activity decrease of **3** is most probably due to the lower lipophilicity of the terminal chain of **3** compared to that of the hydrocarbon chain of **1**. The logarithms of the octanol–water partition coefficient (log P) for alkyl ethers are significantly lower than those for the corresponding hydrocarbons (Hansch and Leo, 1979). Previous structure–activity studies have demonstrated the importance of the lipophilic interactions between the terminal alkyl chain of **1** and the receptor site (Wenqi et al., 1993).

Compound **5** requires a significantly higher conformational energy than **1** (and **3**) to acquire the bioactive conformation (Table 1). A large part of the activity decrease of **5** is most probably due to this conformational energy effect. Thus, the significant difference in the activities of compounds **3** and **5** can be rationalized on the basis of different conformational energies for their bioactive conformations.

Our electrophysiological result for compound **3** is quite different from that of an EAG study of a 17-oxa analog of (*E*,*Z*)-2,13-octodecadienyl acetate, a pheromone component of the currant clearwing moth, *Synanthedon tipuliformis* (Hoskovec et al., 1993). In this compound, a methylene group of the natural pheromone component is replaced by an oxygen atom at a position corresponding to the ether oxygen position in **3.** Interestingly, in the EAG study of Hoskovec et al. (1993) the ether analog is virtually inactive, while the corresponding compound **3** in our study displays only a small activity decrease compared to **1** (Figure 6). Although it is not possible to directly compare results obtained by single-cell electrophysiology and EAG, this may indicate that the receptor sites interacting with the terminal chains of the pheromone components of the two species, which belong to different families of lepidoptera (Noctuidae and Sesiidae), have different properties.

The ether analogs of **2** (**4** and **6**) have lower calculated conformational energies for their bioactive conformations than that of **2** (Table 1). Replacement of a methylene group in positions 7 and 11 of **2** lowers the energy of a loop conformation due to less severe steric repulsions between a methylene group and an oxygen atom, compared to those between two methylene groups (Figure 3b). Thus, conformational energy considerations imply that these ether analogs should have higher activities than **2.** However, the lower lipophilicities of the ether analogs work in the opposite direction by lowering the activities. Consequently, the balance of the conformational energy effect and the lipophilic effect makes compound **4** equipotent with **2,** while the conformational energy effect dominates for compound **6** due to the higher lipophilicity of enol ether compared to alkyl ethers (Hansch and Leo, 1979), making this compound more active than **2.**

To be able to investigate if the activities of chain-elongated analogs are determined by the conformational energies required for a loop conformation of the terminal chain, it was necessary to compare calculated conformational energy differences and relative electrophysiological activity factors for the chain-elongated analogs **2, 4,** and **6** with respect to their parent compounds **1, 3,** and **5.** These energy differences and activity factors are given in Table 2. By discussing the factor of activity decrease for **2** vs. **1, 4** vs. **3,** and **6** vs. **5,** differences in lipophilicity and electronic effects on the relative activities of the three pairs of compounds should essentially cancel. Thus, the factors of activity decrease in Table 2 reflect the conformational energy effects of chain elongation on the activities. Consequently, these factors can be compared to the calculated conformational energies for a bioactive conformation of the chain-elongated analogs, in which the elongated chain has the proposed loop conformation, in relation to the calculated energies for the parent compounds ($\Delta\Delta E$ in Table 2).

The calculated conformational energies $\Delta\Delta E$ are highest for **2** compared to **1** and lowest for the enol ether analog **6** compared to **5.** This implies that if the chain-elongated analogs adopt a loop conformation of the terminal chain in their

bioactive conformations, as assumed in the calculations, the experimental factors of activity decrease should be largest for **2** compared to **1** and smallest for **6** compared to **5,** with the factor for **4** compared to **3** in between. This is exactly what is found. The experimental data in Table 2 show that the factor of activity decrease for **2** compared to **1** is 603; for **4** compared to **3** 86, and for **6** to **5,** it is 0.6. The activity decrease on chain elongation parallels the calculated increase of conformational energies for loop formation of the terminal chain in compounds **2, 4,** and **6.** Thus, our previous conclusion (Liljefors et al., 1987) that the terminal chain of chain-elongated analogs of **1** adopts a loop conformation in the bioactive conformation is strongly supported by the present study.

CONCLUSIONS

Replacement of the methylene group in the 7 position of **1** by an oxygen atom results in a much larger activity decrease than the corresponding replacement in the 9 position. In contrast, replacement of the methylene group in the 11 position of **2** by an oxygen atom has no effect on the activity, while the corresponding replacement of the 7-methylene group of **2** gives small increase of the activity. Molecular mechanics calculations indicate that these results are due to a combination of different conformational and lipophilic properties of the parent compound and its alkyl ether and the enol ether analogs.

Chain elongation of an alkyl ether **(3)** and an enol ether **(5)** analog of the natural pheromone component **1** results in significantly smaller decreases of the electrophysiological single-cell activity than is found for chain-elongation of **1.** Molecular mechanics calculated conformational energies for a loop conformation of the terminal chain in the chain-elongated analogs **2, 4,** and **6** closely parallel the experimental activity decreases. The results support our previous conclusion that the terminal chain of chain-elongated analogs of **1** adopts a loop conformation in the bioactive conformation.

(Received October 28, 1994; accepted March 1, 1995)

Abstract—Noninhibitory levels of glucose-C [≤ 72 μg carbon (C)/g soil] increased the inhibitory activity of *p*-coumaric acid on morning-glory seedling biomass accumulation in Cecil B_t-horizon soil. The amount of *p*-coumaric acid required for a given level of inhibition of shoot and seedling biomass accumulation decreased as the concentration of glucose increased. Soil extractions with neutral EDTA (0.25 M, pH 7) after addition of combinations of *p*-coumaric acid and glucose (concentrations ranging from 0 to 1.25 μmol/g soil) to the soil showed that utilization of *p*-coumaric acid by microbes decreased linearly as the concentration of glucose increased. The increased inhibitory activity of a given concentration of *p*-coumaric acid in the presence of glucose was not due to a reduction in soil sorption of *p*-coumaric acid or effects of nitrogen-limited microbial growth. Noninhibitory levels of phenylalanine and *p*-hydroxybenzoic acid slowed the utilization of *p*-coumaric acid by microbes in a similar manner as glucose. The presence of methionine, however, did not affect the rate of *p*-coumaric acid utilization by microbes. These observations suggest that differential utilization of individual molecules in organic mixtures by soil microbes can modify, and in this case increase, the effectiveness of a given concentration of an inhibitor such as *p*-coumaric acid on the inhibition of seedling growth such as morning-glory.

Key Words—Morning glory, *Ipomoea hederacea*, *p*-coumaric acid, glucose, methionine, phenylalanine, *p*-hydroxybenzoic acid, allelopathic interactions, microbial substrate utilization.

INTRODUCTION

Studies of allelopathy have emphasized the identification and quantification of inhibitors in soils (Rice, 1984; Kuiters, 1990; Siqueira et al., 1991). Few research studies, however, have been directed towards understanding how other organic molecules in the soil (e.g., carbohydrates, amino acids, etc.) may modify plant responses to these inhibitors. In one study (Blum et al., 1993), addition of low concentrations of glucose or methionine to soil in conjunction with inhibitory levels of *p*-coumaric acid reduced the concentration of that phenolic acid required to inhibit morning-glory seedling growth. Blum et al. (1993) hypothesized that carbon sources such as glucose may have reduced the sorption of *p*-coumaric acid onto soil particles and/or reduced microbial metabolism of *p*-coumaric acid. Either mechanism would result in higher available concentrations of *p*-coumaric acid in the soil solution. The objective of this study was to test this hypothesis by determining the rates of soil sorption and soil microbial utilization of *p*-coumaric acid in the presence and absence of low concentrations of glucose and several other organic molecules.

METHODS AND MATERIALS

Seedling Studies

General Procedures. Cecil B_t-horizon soil material (Typic Kanhaludults, clayey, kaolinitic, thermic) was obtained from the Piedmont of North Carolina, sieved (4 mm), air-dried, and stored at room temperature (Dalton et al., 1987). A soil–sand mixture (1 : 2 by weight) of Cecil B_t soil and river sand rinsed with deionized water and air-dried was used as growth medium. Morning-glory seeds (*Ipomoea hederacea* L. Jacquin.; F&J Seed Service, Woodstock, Illinois) were germinated in the dark at 34°C in 155-ml cups (five seeds per cup) containing 150 g of the soil–sand mixture. After 24 hr, cups with seedlings were placed under light banks with a 12-hr photoperiod (140 $\mu E/m^2/sec$). Cups were inserted in holes in a plywood sheet to prevent direct irradiation to the cups below the soil surface. Seedlings were thinned to one seedling per cup four or five days after seeding. For a more detailed description of the cup system see Blum et al. (1993).

Nutrient Requirements for Morning-glory Seedling Growth. Quadruple-strength Hoagland's solution (Hoagland and Arnon, 1950) (pH 5, without micronutrients) in 0.5-ml increments from 0 to 3.5 ml was added every other

day starting with day 6 from seeding. Water was added daily to achieve a maximum combined cup, soil, water, nutrient solution, and seedling weight of 185 g (160 g initially for cup and soil). Seedlings were harvested 21 days after seeding, oven-dried (105°C), and dry weights of root, shoot, and total plant biomass were determined.

Effects of p-*Coumaric Acid and Glucose Mixtures on Seedling Biomass.* Solutions (pH 5) of glucose of *p*-coumaric acid (Sigma Chemical Co., St. Louis, Missouri) ranging from 0 to 1 μmol/g soil or various combinations of these two compounds were added every other day starting eight days after seeding. Treatments were applied on five days. Solution acidity was adjusted to pH 5 with NaOH or HCl. Quadruple-strength Hoagland's solution (1.5 ml, pH 5, without micronutrients) was added every other day starting seven days after seeding. Seedlings were harvested 18 days after seeding, oven-dried, and weights of root, shoot, and total plant biomass were determined.

Soil Studies

General Procedures. Sieved (0.25 mm) Cecil B_t soil material (1 g) was added to 15-ml Corex tubes (Corning Inc., Rochester, New York). Tubes were capped (Bacti-Capall, Sherwood Medical Industries) and autoclaved (15 min at 1.2 kg/cm^2) three times at three-day intervals. At the start of an experiment, each tube received 0.5 ml double-strength Hoagland's solution (pH 5) without micronutrients, 0.5 ml soil extract (see below), 0.5 ml of phenolic acid and/or other carbon source, and 0.5 ml water. In all cases, final volume in each tube was 2 ml for a single addition or 4 ml for a double addition. Reagent-grade *p*-coumaric acid, glucose, methionine, *p*-hydroxybenzoic acid, and phenylalanine were used (Sigma). Details of specific experiments are provided in Table 1.

Soil Extracts for Reinfestation of Soils with Microbes. Soil extracts to reinfest autoclaved soil materials with microbes were obtained from a cup containing 150 g of a Cecil B_t soil–sand mixture (1:2 by weight) treated with 5 ml *p*-coumaric acid (0.5 mM), 10 ml double-strength Hoagland's solution without micronutrients, and 15 ml water. After four to five days in a dark incubator at 34°C, the soil mixture was combined with 300 ml water in a beaker. The soil particles were allowed to settle in the beaker before the supernatant was decanted and filtered through Whatman No. 1 filter paper in a Buchner funnel. This extract was used to reinfest soil samples. A portion of this extract was also filter sterilized (0.2-μm membrane filter) for addition to soil material that was to remain sterile.

Extraction of p-*Coumaric Acid from Soil.* Soil samples in the tubes were extracted with 0.25 M EDTA (ethylenediamine tetraacetic acid, pH 7; for preparation of solution see Blum et al., 1994) or water at different time intervals by

TABLE 1. EXPERIMENTAL PROTOCOLS FOR SOIL EXTRACTIONS

Experiment[a]	Presence (+)/ absence (−) of microbes	Strength of nutrient solution[b]	Concentrations (μmol/g) of additional carbon sources in soil[c]				
			PCO	GLU	METH	PHENYLAL	P-OH B
1	+/−	2×	1.25	0 or 1.25			
2	+	2×	1.25	0 to 1.25			
3	+	2×, 4×	1.25	0 or 1.25			
4	+	2×	1.25	0 or 1.25	0 or 1.25	0 or 1.25	0 or 1.25
5[d]	+	2×	0 or 1.25	0 to 1.25			

[a] For each experiment, carbon sources in aqueous solutions were added to soil (2 ml total volume) on day 0. In experiment 5, another 2 ml were added on day 6. Two soil samples were extracted with 0.25 M EDTA (pH 7) for each treatment and time interval.

[b] Hoagland's nutrient solution without micronutrients adjusted to pH 5.

[c] Only two-way mixtures were used. Molecular weights of *p*-coumaric acid (PCO), glucose (GLU), methionine (METH), phenylalanine (PHENYLAL), and *p*-hydroxybenzoic acid (P-OH B) are 164.2, 132.1, 149.1, 165.09, and 138.1, respectively. Actual concentrations of *p*-coumaric acid initially in tubes varied somewhat since the soil extracts added to the tubes to reinfest the soil with microbes also contained *p*-coumaric acid. Percentage of carbon in these compounds is as follows: 65.83, 40.00, 40.25, 65.43, and 60.88, respectively. The percentage of nitrogen in methionine and phenylalanine is 9.39 and 8.48, respectively.

[d] *p*-Coumaric acid expressed as millimolar soil solution = 0 or 0.625; glucose mM = 0, 0.3125, or 0.625.

adding 2 ml of 0.5 M EDTA or water to tubes containing 1 g soil material and 2 ml of treatment solution. Tubes were vortexed immediately after addition of the EDTA or water extractant. EDTA tubes were stored in the dark for 5 hr, and vortexed again just before centrifugation (10 min at 12,100*g*). The supernatants were filter-sterilized (0.2-μm membrane filter) for quantification of *p*-coumaric acid (EDTA extracts) by HPLC analysis (Blum et al., 1994). Water tubes were vortexed, centrifuged, and the supernutrients were analyzed for glucose by anthrone (Dische, 1962).

Statistical Analysis

Data were analyzed by PROC ANOVA, PROC GLM, or PROC NLIN of the SAS Institute (1988). For the seedling experiment, seedlings were distributed under three light banks (Blocks) in a randomized complete block design with two replicates per block for each treatment. Morning-glory seedling response was modeled using the modified logistic equation described by Gerig and Blum (1993). For the soil experiments, two soil samples were extracted for each treatment and time period.

RESULTS

Seedling Studies

Nutrient Requirements for Morning-glory Seedling Growth. Maximum morning-glory shoot, root, and seedling biomass was obtained with 1.5-ml applications of quadruple-strength Hoagland's nutrient solution without micronutrients every other day (Figure 1). This nutrient solution treatment was therefore chosen for the seedling biomass experiment.

Effect of p-*Coumaric Acid and Glucose Mixtures on Seedling Biomass of Morning glory.* The relationships between morning-glory seedling biomass (grams), Y, and the concentrations of *p*-coumaric acid (micromoles per gram), X_1, and glucose (micromoles per gram), X_2, *were* described by:

$$Y = \beta_1/(1 + \exp\{\beta_3[\ln(Z) - \beta_2]\}) \qquad \text{for } Z > 0$$

$$= \beta_1, \qquad \text{for } Z = 0$$

where $Z = X_1 \exp(-\beta_4 X_2)$. The estimated values of β_1, β_2, β_3, and β_4 are listed in Table 2. A graphical display of the data and the results from the model are presented in Figure 2. Morning-glory seedling biomass was inversely related to the concentration of *p*-coumaric acid added to the soil–microbe–seedling system. Shoot biomass was more sensitive than root biomass to *p*-coumaric acid. The 50% inhibition dose for root biomass was approximately 13 times that for shoot biomass (Table 2). Glucose alone had no statistically significant effect on morn-

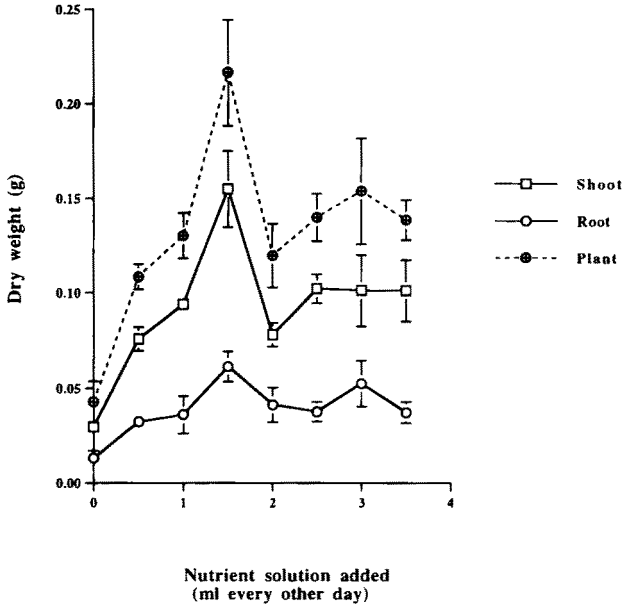

FIG 1. Effect of various amounts of 4× Hoagland's nutrient solution without micronutrients on biomass of morning-glory seedlings (one seedling per cup). Means ± standard error.

ing-glory biomass. However, the presence of glucose modified the level of inhibition on seedling biomass by *p*-coumaric acid (Table 2, Figure 3). The amount of *p*-coumaric acid required for a given level of inhibition of shoot and seedling biomass decreased as the concentration of added glucose increased. For example, a 20% inhibition of seedling biomass required 0.42 μmol/g of *p*-coumaric acid in the absence of glucose and 0.33 μmol/g in the presence of

TABLE 2. SUMMARY OF LOGISTIC MODEL DESCRIBING INTERACTIVE EFFECTS OF *p*-COUMARIC ACID AND GLUCOSE ON MORNING-GLORY SEEDLING BIOMASS

Model parameters	Shoot	Root	Plant
β_1 (control values; g dry weight)	0.07	0.05	0.12
β_2 (dose required for 50% inhibition; μmoles/g)	1.05	13.18	2.89
β_3 (rate parameter)	1.04[a]	1.20[a]	1.03[a]

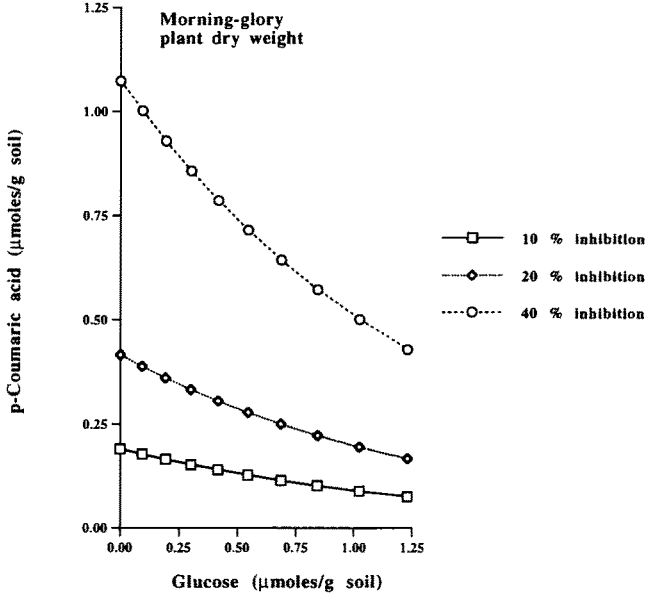

FIG 3. Morning-glory plant biomass isolines for 10, 20, and 40% inhibition of seedlings treated with *p*-coumaric acid and various concentrations of glucose.

0.30 μmol/g of glucose. Addition of glucose did not modify the effects of *p*-coumaric acid on root biomass.

Soil Extractions

Recovery of p-*Coumaric Acid from Soil in Presence and Absence of Microbes and Glucose–Experiment 1.* Soil samples were extracted with neutral EDTA (0.25 M, pH 7) because Blum et al. (1994) observed that this was an effective extractant for estimating the levels of free and reversibly bound phenolic acids available to soil microbes. Recovery of *p*-coumaric acid from Cecil B_t soil in the absence of soil microbes was not significantly affected by the presence of glucose (Figure 4). In the presence of microbes, recovery of *p*-coumaric acid was greater in the presence of glucose than in the absence of glucose. For example, between day 1 and 4 recovery of *p*-coumaric acid from nonsterile soil was reduced by 30% in the absence of glucose but only 5% in the presence of glucose. In sterile soil, recovery of *p*-coumaric acid declined only 5% regardless of glucose addition. Between days 4 and 8, recovery of *p*-coumaric acid in nonsterile soil was reduced by 84% in the absence of glucose

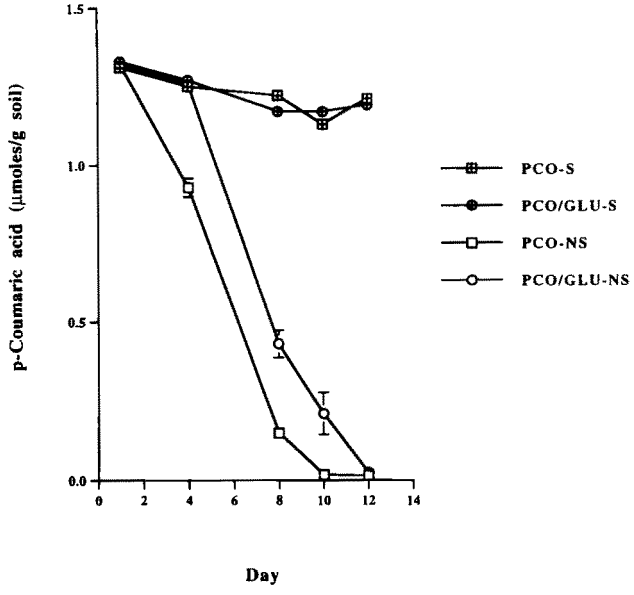

FIG 4. Recovery of *p*-coumaric acid (PCO) from Cecil B_t soil material soil by 0.25 M, pH 7, EDTA in the presence (NS) and absence (S) of microbes and glucose (GLU). Means ± standard error.

but 66% in the presence of glucose. During the same time interval, *p*-coumaric acid was reduced by only 3% in sterile soil.

Recovery of p-*Coumaric Acid from Soil in Presence of Microbes and Various Concentrations of Glucose—Experiment 2.* Once *p*-coumaric acid utilization by microbes was evident (day 3), recovery of *p*-coumaric acid on day 3 and subsequently was related directly to the concentration of glucose added (Figure 5). Effects of glucose on *p*-coumaric acid recovery declined over time (Table 3).

Effects of Glucose and Nutrients on Recovery of p-*Coumaric Acid—Experiment 3.* The glucose effect on recovery of *p*-coumaric acid from nonsterile soil was not significantly affected by doubling the concentration of the nutrient solution (2× or 4× strength Hoagland's solution minus micronutrients; Figure 6).

Recovery of p-*Coumaric in Presence of Methionine, Phenylalanine, or* p-*Hydroxybenzoic Acid—Experiment 4.* The addition of methionine to Cecil B_t soil had little effect on the rate of *p*-coumaric acid recovery in the presence of microbes (Figure 7). The addition of phenylalanine or *p*-hydroxybenzoic acid resulted in greater recoveries of *p*-coumaric acid, similar to that of glucose.

Recovery of p-*Coumaric acid and Glucose—Experiment 5.* Since solution volumes for day 0 to day 6 (2 ml) and day 6 to day 11 (4 ml) were different

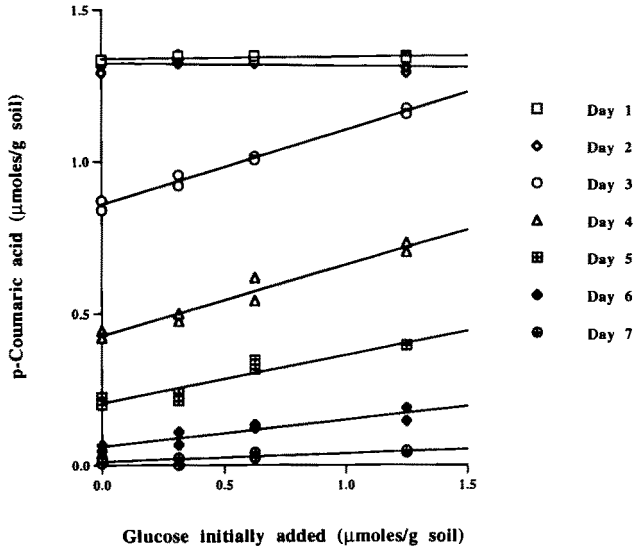

FIG 5. Regression lines for recovery of *p*-coumaric acid from Cecil B_t soil material by 0.25 M, pH 7, EDTA in the presence of microbes and various concentrations of glucose. Significant regression models are presented in Table 3.

for this experiment, concentrations of the two compounds have been expressed as millimolar of soil solution instead of micromoles per gram of soil (Table 4, Figures 8–10). Once *p*-coumaric acid utilization by microbes was evident (day 4), recovery of *p*-coumaric acid on day 4 and for subsequent time intervals

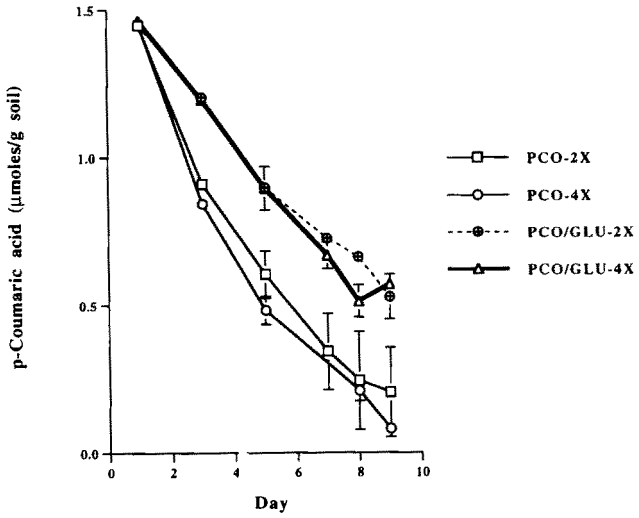

FIG 6. Recovery of *p*-coumaric acid (PCO) from Cecil B_t soil material by 0.25 M, pH 7, EDTA in the absence or presence of glucose (GLU) and two concentrations (2× and 4× strength) of Hoagland's solution without micronutrients. Means ± standard error.

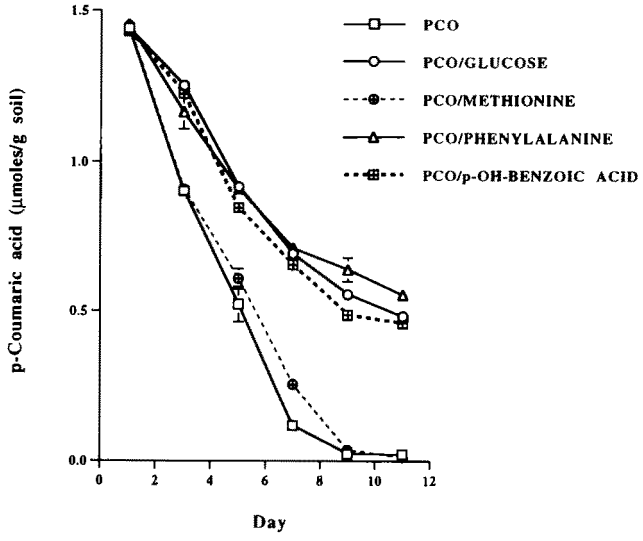

FIG 7. Recovery of *p*-coumaric acid (PCO) from Cecil B_t soil material by 0.25 M, pH 7, EDTA in the absence or presence of glucose, methionine, phenylalanine, and *p*-hydroxybenzoic acid. Means ± standard error.

increased linearly as the concentration of glucose added increased (Table 4; Figures 9 and 10). The initial delay in microbial utilization of *p*-coumaric acid seen for the first addition (days 0–4), however, was not observed for the second addition. Furthermore, the effects of glucose on the recovery of *p*-coumaric acid were greater for the second addition than for the first addition (Table 4).

[a]Where Y = *p*-coumaric acid recovered (millimolar) and X = glucose initially added (millimolar).

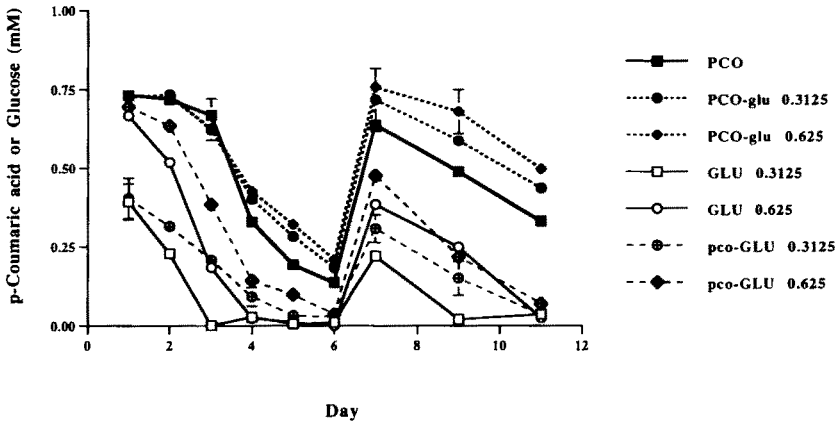

FIG 8. Recovery of *p*-coumaric acid (PCO), glucose (GLU), *p*-coumaric acid in the presence of two concentrations of glucose, and glucose in the presence of *p*-coumaric acid from Cecil B_t soil material. Additions of PCO and GLU occurred on day 0 and day 6. Means ± standard error.

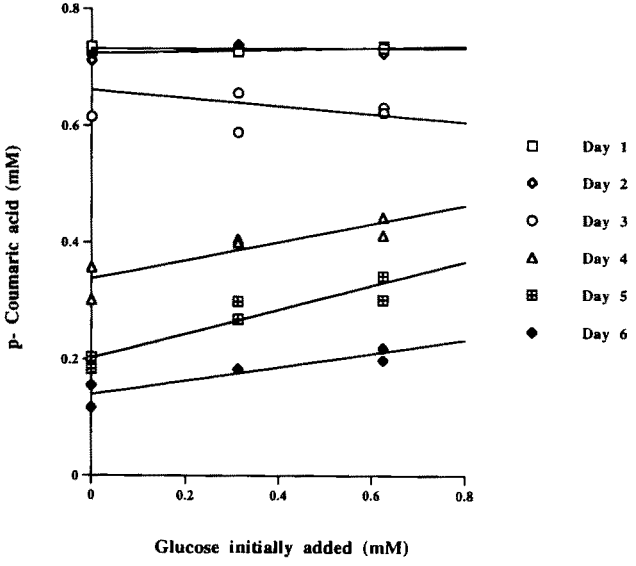

FIG 9. Regressions for the recovery of *p*-coumaric acid from Cecil B_t soil material by 0.25 M, pH 7, EDTA in the presence of microbes and various concentrations of glucose. Significant regression models are presented in Table 4.

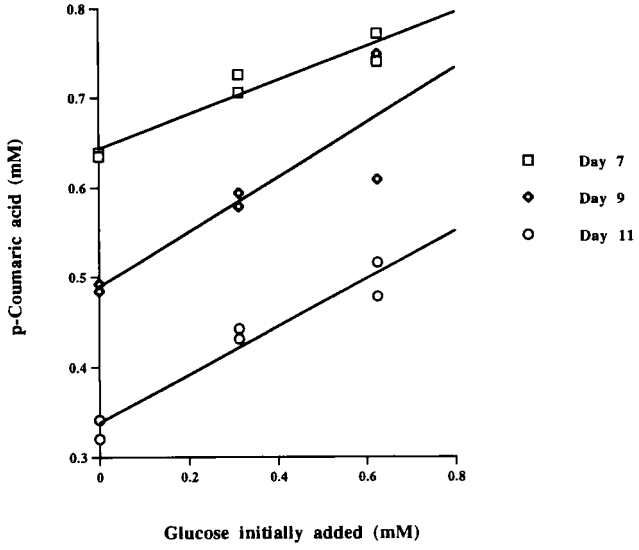

FIG 10. Regressions for the recovery of *p*-coumaric acid from Cecil B_t soil material by 0.25 M, pH 7 EDTA in the presence of microbes and various concentrations of glucose after a second addition of *p*-coumaric acid and/or glucose. Significant regression models are presented in Table 4.

In general, recovery of glucose in the absence of *p*-coumaric acid was lower than in the presence of *p*-coumaric acid (Figure 8). This difference in recovery, however, was statistically significant for only days 2 and 3 for both glucose concentrations, and days 5 and 11 for the 0.625 mM glucose concentration. For example, between days 1 and 3, recovery of 0.325 mM glucose added was reduced 99.75% in the absence of *p*-coumaric acid and 22% in presence of *p*-coumaric acid, and recovery of 0.625 mM glucose was reduced 72% in the absence of *p*-coumaric acid and 45% in the presence of *p*-coumaric acid.

DISCUSSION

In earlier work (Blum et al., 1993), addition of glucose reduced the amount of *p*-coumaric acid required for a given level of inhibition of morning-glory seedling biomass accumulation. They hypothesized that the addition of glucose C below 72 μg C/g soil reduced the microbial utilization and/or sorption of *p*-coumaric acid in the soil and thus increased the inhibitory activity of *p*-coumaric acid on seedling growth. Unfortunately, only two noninhibitory concen-

trations of glucose were included in that study, so the modification of the action of *p*-coumaric acid by such concentrations of glucose could not be adequately determined. Using a Cecil B_t-horizon soil and combinations of four noninhibitory glucose concentrations and three inhibitory *p*-coumaric concentrations, we have demonstrated, as suggested by Blum et al. (1993), that noninhibitory levels of glucose do increase the inhibitory activity of *p*-coumaric acid on morningglory biomass accumulation. Furthermore, our results show that sorption of *p*-coumaric acid onto soil particles of Cecil B_t soil material was not reduced in the presence of glucose. Thus, the increased inhibitory activity of *p*-coumaric acid in the presence of glucose is not attributable to a reduction in sorption of *p*-coumaric acid onto soil particles in the presence of glucose. We have also been able to demonstrate that the microbial utilization of *p*-coumaric acid in the range of glucose concentrations used was reduced in a linear manner and that this occurred in soil systems that were not nutrient limited. The initial C/N ratios for these soil systems were all less than 0.5. Such low initial C/N ratios indicated the addition of C by these compounds did not result in nitrogen-limiting conditions for microbial metabolism. This suggests that the effects of glucose on recovery of *p*-coumaric acid were not attributable to nitrogen immobilization.

Microbial utilization of glucose and *p*-coumaric acid as a carbon source in mixtures was reduced, but the reduction in utilization was far greater for *p*-coumaric acid than for glucose. This preferential utilization of one carbon source over another is consistent with bacteria grown on two different carbon sources in vitro. For example, microbial utilization of one C source in batch cultures is often prevented or inhibited by the presence of a second C source (Harder and Dijkhuizen, 1982; Papanastasiou, 1982; Bachmann et al., 1988). In pure cultures, the resulting sequence in C resource utilization can thus lead to diauxic growth of the microbe. Diauxic growth is characterized by two exponential phases of growth separated by a phase of no net increase in microbial biomass. Different carbon sources are being used for the two growth phases. In multispecies microbial cultures such as ours, one would not expect to see patterns of diauxic growth since different species of microbes would have different C source preferences. Nonetheless, the earlier and more rapid utilization of glucose compared to *p*-coumaric acid suggested sequential C utilization. Therefore, this may be one mechanism by which noninhibitory glucose concentrations in the soil may increase the inhibitory activity of a toxin such as *p*-coumaric acid. Differential C utilization by soil microbes and associated changes in inhibition of toxins such as *p*-coumaric acid may be a more general phenomenon, since the effects of phenylalanine and *p*-hydroxybenzoic acid were similar to those of glucose. This suggests that levels of inhibition of germination and seedling growth after desiccation of a cover crop may be much greater than expected, when this expectation is based on soil toxin levels only. This may also be true for complex organic mixtures in soil resulting from root exudates,

leaf leachates, and leachates from plant debris. Other mechanisms by which noninhibitory C sources may modify the activity of toxic phenolic acids are also possible. These may include effects on the rate of uptake of the toxin by plant roots, metabolic conversion of a substance to a more toxic product, and/or the creation of anaerobic soil conditions that inhibit plant growth. Based on these and previous observations (Blum et al., 1993), we suggest that soil bioassays of individual toxins identified as allelopathic compounds may not provide adequate information on the concentrations required for the inhibition of plant germination and growth in soils.

(Received December 16, 1994; accepted March 1, 1995)

Abstract—The absolute configuration of the sex pheromone of the Israeli pine bast scale, *Matsucoccus josephi*, was determined as (2*E*,5*R*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one, designated here as *R-E* with 10% (2*E*,5*S*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one, designated as *S-E*. The chirality of the quantitatively minor *Z* isomer was (2*E*,5*R*,6*Z*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one (*R-Z*). Chiral assignments were made by comparative gas chromatographic (GC) analysis of natural *M. josephi* pheromone with stereoselectively synthesized stereoisomers on a chiral Cyclodex-B column, which separated the enantiomers with baseline resolution. In gas chromatographic-electroantennographic detection (GC-EAD) analysis of the racemic *Z* and *E* isomers, the latter elicited the stronger antennal response by male *M. josephi*. In GC-EAD of all four stereoisomers, employing the chiral column, *R-E* was the most active stereoisomer. In field tests *R-E* attracted 10 times more males of *M. josephi* than did *S-E*. The racemic *E/Z* pheromone mixture, containing all four stereoisomers in approximately equal amounts, attracted as many male *M. josephi* as did an equivalent amount of *R-E*, indicating that the other stereoisomers are not inhibitory. The same keto-diene moiety with the same chiral center and configuration in all three known Matsucoccidae

sex pheromones implies a common biosynthetic pathway and phylogenetic relationship.

Key Words—*Matsucoccus josephi*, Coccoidae, Homoptera, Matsucoccidae, pine bast scales, sex pheromone, absolute configuration, (2*E*,5*R*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one.

INTRODUCTION

All known female scale sex pheromones are chiral compounds, except for the pheromone of the San Jose scale, *Quadraspidiotus perniciosus* (Comstock) (Fletcher and Bellas, 1988). Sex pheromones of three pine bast scales, *Matsucoccus matsumurae* (=*resinosae*) Bean & Godwin, *Matsucoccus feytaudi* Ducasse, and *Matsucoccus josephi* Bodenheimer and Harpaz, have been identified recently (Lanier et al., 1989; Einhorn et al., 1990; Dunkelblum et al., 1993). All three pheromones share a common $C_9H_{13}O$ keto-diene moiety with a chiral center in the same position. The *M. matsumurae* and *M. feytaudi* pheromones have very similar structures and, unlike the *M. josephi* pheromone with one chiral center, have two chiral centers. Stereoselective syntheses and field bioassays resolved the absolute configuration of the *M. matsumurae* (=*resinosae*) (Cywin et al., 1991; Mori and Harashima, 1993b) and *M. feytaudi* (Cywin and Kallmerten, 1992; Mori and Harashima, 1993a; Jactel et al., 1994) pheromones. We report here the determination of the chirality of the *M. josephi* pheromone by GC and GC-EAD analyses of natural and synthetic pheromones on a chiral column and by field bioassays of synthetic pheromone stereoisomers.

METHODS AND MATERIALS

Chemicals. The racemic *M. josephi* pheromone components (2*E*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one and (2*E*,6*Z*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one were available as a mixture (56% *E* + 44% *Z*) or separately from previous work (Zegelman et al., 1993). The two *E* enantiomers, (2*E*,5*R*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one (*R*-*E*) (96.6% ee) and (2*E*,5*S*,6*E*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one (*S*-*E*) (99.0% ee), were synthesized from a chiral epoxide (Mori and Amaike, 1994). Natural pheromone was collected on Porapak Q and purified as described previously (Dunkelblum et al., 1993).

Insects. Male *M. josephi* pupae were reared in Israel (Mendel et al., 1990) and shipped by special delivery to Simon Fraser University in Canada. The pupae were kept there at room temperature and emerging adults were used in the morning hours.

Instrumental Methods. Racemic, *E* and *Z* isomers, *R*-*E* and *S*-*E* enantiomers

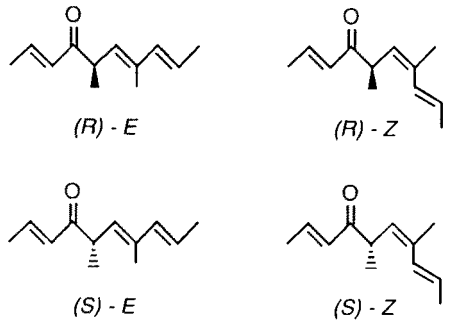

FIG 1. Stereoisomers of *Matsucoccus josephi* sex pheromone.

(Figure 1), and natural *M. josephi* pheromone were analyzed on a Hewlett Packard (HP) 5890 gas chromatograph equipped with a chiral Cyclodex-B column (30 m × 0.25 mm ID) (J & W, Folsom, California). All pheromone samples were also subjected to gas chromatographic–electroantennographic-detection (GC-EAD) analyses (Arn et al., 1975) using an HP 5890 GC equipped either with a DB-23 column (30 m × 0.25 mm ID) (J & W) or with the chiral Cyclodex-B column. As in the case of male moth antennae (Gries et al., 1991), male scale antennae were suspended between glass capillary electrodes for GC-EAD analysis. Preparing the exceedingly small antennae was difficult and may explain the variation in antennal responses.

Field Bioassay. Six-replicate field tests were set up in randomized complete blocks in the Harel forest (Judean foothills) plantations of Aleppo pine, *Pinus halepensis* Mill., and brutia pine, *Pinus brutia* Ten. Variations in topography, plot size limitations, and finding protected locations required testing in two different areas. Means were calculated from both areas despite the fact that their population levels differed. Triangular sticky traps baited with rubber septa impregnated with synthetic pheromone (Dunkelblum et al., 1987) were used. Traps were suspended from tree branches, 1.8 m above ground at least 25 m apart. The trapped scale males and the predatory bug, *Elatophilus hebraicus* Pericart, were counted using a stereomicroscope.

The first experiment tested dosages of the racemic stereoisomeric mixture (10–200 μg) as compared to *R-E* (2.5–50 μg) and *S-E* (2.5–50 μg) enantiomers. The second experiment compared a medium dosage of 25 μg of the two enantiomers. The third experiment retested attractancy of *R-E* and *S-E* at 50 μg, and trapped males were counted in four consecutive days.

Statistical Analysis. Trap catch data were transformed to $\sqrt{x} + 0.5$ and then subjected to analysis of variance followed by the Student-Neuman-Keuls multiple range test (at $P < 0.05$) to determine significance between means.

RESULTS

Laboratory Analysis. Gas-chromatographic analyses on the chiral column allowed separation of the enantiomers of the *E* and *Z* pheromone isomers with baseline resolution. The stereoselectively synthesized *R-E*, but not the *S-E* enantiomer (Mori and Amaike, 1994), coincided with the major female-produced enantiomer, whereas the antipode was present at 10% (Figure 2). Small amounts of the *R-Z* stereoisomer in one of the *R-E* samples (formed in a Wittig step of the synthesis coincided both with the first component in the racemic *Z* isomer and with the minor female-produced component. Thus, the chirality of the major *E* and *Z* pheromone components was assigned as (2*E*,5*R*,6*E*,8*E*)-5,7-dimethyl-

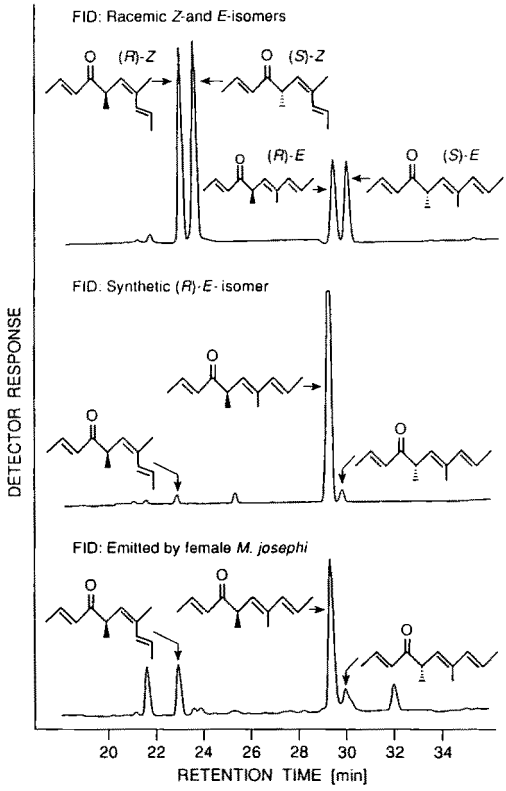

FIG 2. Chiral separation of synthetic and natural *Matsucoccus josephi* sex pheromone stereoisomers (Cyclodex-B column, isothermal at 120°C).

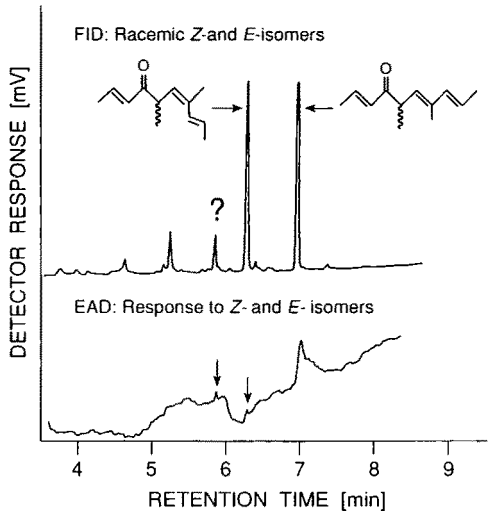

FIG 3. FID and EAD male *Matsucoccus josephi* antenna responses to the racemic *E* and *Z* isomers of the sex pheromone (DB-23 column; 1 min at 100°C, 10°C/min to 200°C).

2,6,8-decatrien-4-one (*R-E*) and (2*E*,5*R*,6*Z*,8*E*)-5,7-dimethyl-2,6,8-decatrien-4-one (*R-Z*), respectively (Figure 2).

In GC-EAD recordings, male scale antennae elicited potentials in the range of 0.2–0.5 mV. In the analysis of the racemic *E* and *Z* pheromone mixture, the *E* rather than the *Z* isomer elicited a strong antennal response. An additional EAD-active isomer of unknown structure, having an identical mass spectrum to those of the *E* and *Z* isomers, eluted prior to the *Z* isomer (Figure 3). In GC-EAD analysis of the stereoisomeric pheromone mixture on the chiral column, *R-Z* and *S-Z*-enantiomers elicited weak responses, whereas the *R-E* enantiomer evoked a strong antennal response (Figure 4). The latter stereoisomer was also the most EAD-active compound in Porapak-Q extracts of female *M. josephi* volatiles (Figure 4).

Trapping Experiments. The *R-E* enantiomer and the racemic *E/Z* pheromone mixture with an equivalent amount of *R-E* were equally attractive, and they were 10 times as active as the *S-E* enantiomer. These results were obtained for a wide range of dosages (Table 1). The high activity of the *R-E* enantiomer as compared with the *S-E* enantiomer was confirmed in a second field test with 25 μg of each enantiomer. In this experiment, the *R-E* enantiomer attracted 7.2 males/trap/day as compared with only 0.8/trap/day caught with the *S-E* enantiomer. The proportion of *M. josephi* males trapped in *R-E*- and *S-E*-baited traps

remained constant during four days (Figure 5), indicating that isomerization of enantiomers in the rubber septa did not occur or was negligible. All pheromone lures also attracted the predator, *E. hebraicus*. Trapping and EAD responses of *E. hebraicus* will be reported separately.

DISCUSSION

The recently identified sex pheromone of *M. josephi* (Dunkelblum et al., 1993) consists of two geometric *E* and *Z* isomers, each with one chiral center of previously undetermined stereochemistry (Figure 1). This chiral center is part of a keto-diene moiety, present also in the pheromones of *M. matsumurae* (Lanier et al., 1989) and *M. feytaudi* (Einhorn et al., 1990) (Figure 6). Stereoselective synthesis, NMR analyses, and bioassays of stereoisomers established the chirality of this center as *R* in both *M. matsumurae* and *M. feytaudi* pheromones (Cywin et al., 1991; Cywin and Kallmerten, 1992; Mori and Harashima, 1993a,b; Jactel et al., 1994). The major pheromone component of *M. feytaudi* has two chiral centers (Figure 6); therefore, four stereoisomers are possible. Synthesis and bioassay of all four stereoisomers (Mori and Harashima, 1993a; Jactel et al., 1994) have revealed that the stereochemistry only of the chiral center in the keto-diene moiety was critical for attractancy. Because *M. matsumurae* and *M. feytaudi* pheromone stereoisomers do not separate on currently available chiral GC columns, it remains unknown whether these female-produced pheromones contain only *R* or also some S enantiomers. Conversely, enantiomers of racemic *M. josephi* pheromone could be readily separated on the

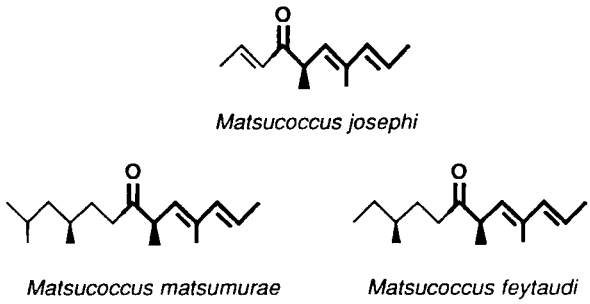

FIG 6. The keto-diene moiety (bold) common to sex pheromones of *Matsucoccus matsumurae*, *Matsucoccus feytaudi*, and *Matsucoccus josephi*.

chiral Cyclodex-B column (Figure 2). When the corresponding *R-E* and *S-E* enantiomers became available (Mori and Amaike, 1994), the chirality of the major female-produced *M. josephi* pheromone could be directly determined as *R* with 10% of the *S* enantiomer (Figure 2).

The use of GC-EAD analyses (Arn et al., 1975) are most efficacious in the identification of insect pheromones and have recently been successfully employed for chiral determination of palm weevil pheromones (Perez et al., 1994). Low responses and enhanced background noise complicated electroantennogram recordings from scale antennae. Moore (1981) obtained EAG responses to crude natural *M. josephi* pheromone (Dunkelblum and Sternlicht, unpublished results) by connecting four male antennae in series for signal amplification. This procedure was particularly difficult with the very fine *M. josephi* antennae and has not been tried since then with other scale insects. No scale antennae have ever been used in coupled GC-EAD analyses. With a GC-EAD system fine-tuned for moth antennae (Gries et al., 1991), and moth and filiform scale antennae being morphologically similar, GC-EAD analysis of *M. josephi* pheromone became possible (Figures 3 and 4). The female-produced *R-E* component elicited the strongest antennal response, whereas the *S-E* antipode was either EAD-inactive or had only slight activity (Figure 4). Interestingly, both *R-Z* and *S-Z* stereoisomers elicited weak but distinct responses (Figure 4).

In field bioassays, the major and most EAD-active (*R-E*) pheromone component was the strongest attractant (Table 1). In a dose–response test it was as attractive as the racemic *E/Z* mixture containing approximately the equivalent amount of the *R-E* stereoisomer (Table 1). Slight to moderate field activity of the *S-E* stereoisomer (Table 1, Figure 5) may be intrinsic or due to its progressive epimerization to the behaviorally very active *R-E* enantiomer. However, similar proportions of males captured in *R-E*- and *S-E*-baited traps during four consecutive days indicated that progressive epimerization did not occur (Figure 5).

Some of the attractancy of the *S-E*-baited traps is certainly due to the trace amounts of *R-E* in the synthetic *S-E*.

It is difficult to decide if the *R-E* enantiomer is the sole component of the *M. josephi* sex pheromone, but it is certainly the major one. The *S-E* enantiomer, present in the pheromone mixture, also has slight activity. Some epimerization during the isolation and purification of the female-released pheromone can not be ruled out. The *Z* component has no activity, and it may have another function. It has been shown previously that large amounts of the nonreactive racemic geometrical *Z* isomer do not interfere with the attractancy of the active *E* isomer (Mendel et al., 1995). Equal reactivity of *R-E* and a racemic mixture, containing the same amount of *R-E*, will facilitate development of a pheromone-based monitoring system for this most serious pest of pine stands in Israel and surrounding countries (Mendel et al., 1994). The lack of inhibition by other stereoisomers that was found in *M. josephi* has also been reported for *M. feytaudi* (Jactel et al., 1994), the California red scale, *Aonidiella aurantii* (Gieselmann et al., 1980), and the white peach scale, *Pseudaulacaspis pentagona* (Heath et al., 1979).

The same keto-diene moiety with the same chiral center and configuration in all three known Matsucoccidae sex pheromones (Figure 6) implies a common biosynthetic pathway and phylogenetic relationship. Pheromone diversification by modification of one chain of the ketonic compounds may have contributed to, or may be associated with, speciation in the Matsucoccidae. It will be interesting to see whether other Matsucoccidae sex pheromones, such as that of the widespread *Matsucoccus pini*, have the same structure frame.

CHEMICAL NATURE OF LARVAL OSMETERIAL SECRETIONS OF PAPILIONID BUTTERFLIES IN THE GENERA *Parnassius, Sericinus* AND *Pachliopta*

KEIICHI HONDA* and NANAO HAYASHI

Study of Environmental Sciences
Faculty of Integrated Arts and Sciences
Hiroshima University, Higashihiroshima 739, Japan

(Received December 16, 1994; accepted March 1, 1995)

Abstract—Volatile components of the larval osmeterial secretion of *Parnassius glacialis* (Parnassiinae, Parnassiini) consisted of isobutyric acid, 2-methylbutyric acid, and their methyl esters. In contrast, the osmeterial exudate of *Sericinus montela* (Parnassiinae, Zerynthiini) was characterized as monoterpene hydrocarbons comprising β-myrcene (Major), α-pinene, sabinene, limonene, and β-phellandrene, whereas that of *Pachliopta aristolochiae* (Papilioninae, Troidini) was composed of numerous sesquiterpene hydrocarbons, including α-himachalene, α-amorphene, and germacrene-A, and a few oxygenated sesquiterpenoids. In these three species, the chemical nature of the secretions of the last and the penultimate instars was essentially of similar quality, suggesting that the three genera, *Parnassius*, *Sericinus*, and *Pachliopta*, are assigned to homogeneous types.

Key Words—Osmeterial secretion, Lepidoptera, Papilionidae, Parnassiinae, Papilioninae, *Parnassius glacialis*, *Sericinus montela*, *Pachliopta aristolochiae*, aliphatic acid and ester, monoterpene, sesquiterpene.

INTRODUCTION

When disturbed, papilionid larvae extrude, from the mid-dorsal intersegmental surface between the head and the prothorax, two-pronged eversible glands (osmeteria) that secrete a characteristic odoriferous liquid. The exocrine secretion is considered to be a chemical weapon to defend themselves against predators, as has been demonstrated by earlier work (Eisner and Meinwald, 1965; Honda, 1983a).

Chemical investigations on larval osmeterial secretions have been conducted for several genera of papilionid butterflies. Isobutyric and 2-methylbutyric acids, and their methyl and ethyl esters are known to be major components secreted by the larvae of *Graphium* (Honda, 1980b) and by the last (fifth) instar of *Papilio* species (Crossley and Waterhouse, 1969; López and Quesnel, 1970; Honda, 1980a, 1981; Burger et al., 1985). The two acids are also encountered in the secretions of *Baronia* and *Eurytides* larvae (Eisner et al., 1970). In contrast, various mono- and/or sesquiterpenic compounds have been identified from *Battus* (Eisner et al., 1971), *Luehdorfia* and *Atrophaneura* larvae (Honda, 1980b), and from the young larvae of *Papilio* species (Honda, 1980a, 1981). Recent reports have described the presence of a few aristolochic acid analogs in the osmeterial exudates of *Atrophaneura*, *Troides*, and *Pachliopta* (Nishida and Fukami, 1989; Nishida et al., 1993).

The derivation of such secretions has also been studied, and it has been substantiated in several species of *Papilio* and *Luehdorfia* that larvae are able to biosynthesize de novo aliphatic acids from amino acids (Seligman and Doy, 1973) and terpenoids from acetate precursors (Honda, 1983b, 1990). However, the chemical properties of osmeterial secretions of many papilionid genera still remain unknown. We wish to report here on the volatile constituents of osmeterial secretions of the last and the penultimate larval instars of three species belonging to distinct genera, *Parnassius* (Parnassiini), *Sericinus* (Zerynthiini), and *Pachliopta* (Troidini).

METHODS AND MATERIALS

Insects. Eggs of *Parnassius glacialis* (a univoltine species), obtained from adult females collected in Kanagawa prefecture, were maintained outdoors until hatching. The larvae were raised on a papaveraceous host plant, *Corydalis incisa*, under a 16L:8D photoperiod throughout the larval development at 15°C during scotophase and 20°C during photophase. Larvae of *Sericinus montela* and *Pachliopta aristolochiae*, which had originated from Kanagawa and Okinawa populations, respectively, were reared at 25°C on a 16L:8D regime. Larvae of *S. montela* were fed with *Aristolochia debilis* (Aristolochiaceae), and those of *P. aristolochiae* with *A. kaempferi*.

Collection of Secretions. The secretion was milked separately from fourth (third for *P. glacialis*) and fifth (fourth for *P. glacialis*) instars of respective species on the third day of larval ecdysis according to the method of Honda (1980a). Each sample for chemical analyses (dichloromethane solution of osmeterial exudate) was prepared from 20–30 larvae and was directly subjected to subsequent examinations.

Chemical Analyses of Volatile Components. The secretion components were

examined by GC and GC-MS. The major part of these analyses was carried out with a fused-silica capillary column (0.25 mm ID × 50 m) chemically bonded with FFAP (column A). Another column of similar dimensions bonded with OV-101 (column B) was also utilized when necessary. GC analyses were conducted with a HP 5890A gas chromatograph equipped with a flame-ionization detector. The injection temperature was 200°C, and the oven temperature was programmed from 50 to 180°C (or 200°C) at 5°C/min. The flow rate of carrier gas (He) was regulated at 1 ml/min. Identification of the components was based on comparison of GC retention data and mass spectra (EI mode) with those of authentic compounds, unless otherwise noted. Mass spectra were recorded at an ionization potential of 25 eV on a Jeol JMS-D300 mass spectrometer interfaced to a Jeol JGC-20KP gas chromatograph. CI mass spectra (reactant gas: isobutane) were also recorded for several constituents to confirm their molecular weight. The percentage composition of each component was calculated by estimating its peak area vs. total peak area on gas chromatograms.

RESULTS

Larvae of *P. glacialis* possess relatively short osmeteria, yellow in color, that secrete a colorless liquid with a slightly offensive odor. Larval osmeteria of both *S. montela* and *P. aristolochiae* are also short and yellow to orange in color. Unlike *P. glacialis*, their secretions are conspicuously colored orange and give out a faint odor. The secretions were found to contain pigmented substance(s) that were sparingly soluble in dichloromethane and appeared not to be amenable to GC. Such substance(s), therefore, were not pursued further in this study.

P. glacialis. GC analysis of the secretion of fourth (last) instar on column A showed the presence of three major components (peaks 2–4, Figure 1). They were assumed to be two aliphatic acids of low molecular weight and a methyl ester of one of the acids from the following mass spectral information. Relative intensity (%) of each ion is given in parentheses except for QM^+ in CI-MS measurement: peak 2: M^+, *m/z* 116(1) and *m/z* 101(18), 88(68), 85(23), 69(7), 59(22), 57(100), and 41(47); peak 3: M^+, *m/z* 88(5) and *m/z* 73(25), 45(8), 43(100), and 41(40); and peak 4: QM^+, *m/z* 103 and *m/z* 87(23), 74(100), 57(75), 45(10), and 41(60). Peaks 2–4 were thus identified as methyl 2-methylbutyrate, isobutyric acid, and 2-methylbutyric acid, respectively. Further GC examination of the acid-free fraction of this sample on column B disclosed an additional component that had overlapped the solvent peak when analyzed on column A. This compound (peak 1), giving M^+ at *m/z* 102(12) and other diagnostic fragment ions at *m/z* 87(21), 71(44), 59(32), 43(100), and 41(21), was readily determined to be methyl isobutyrate. In contrast, from the secretion of

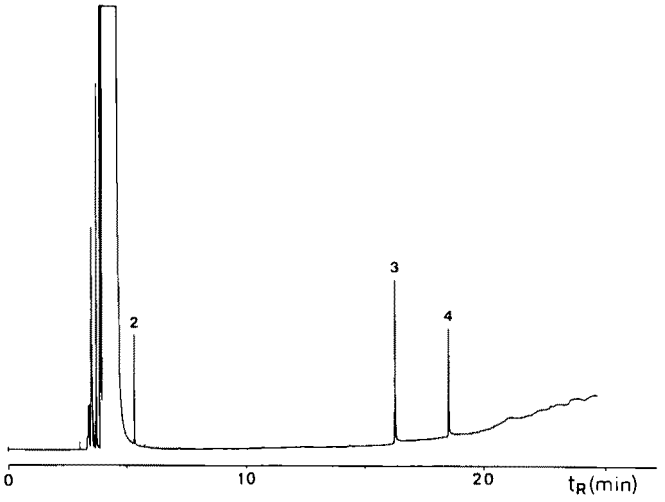

FIG. 1. Gas chromatogram of the osmeterial secretion of fourth (last) instars of *Parnassius glacialis* on a FFAP fused-silica capillary column; 50–180°C at 5°C/min.

third (penultimate) instar only two components were detected, which, upon examination by a similar method, turned out to be isobutyric and 2-methylbutyric acids. Although *P. glacialis* larvae may secrete other substances in trace amounts (Figure 1), these were not examined further because of the meager quantity of osmeterial fluid secreted. The results are summarized in Table 1.

S. montela. The osmeterial exudate of fifth instars was found to contain a major (peak 3) and four minor (peaks 1, 2, 4 and 5) components (Figure 2),

TABLE 1. VOLATILE COMPONENTS OF LARVAL OSMETERIAL SECRETION OF *Parnassius glacialis*

Peak[a]	Component	Composition (%)	
		Third instar	Fourth instar
1	Methyl isobutyrate		69.5
2	Methyl 2-methylbutyrate		6.5
3	Isobutyric acid	64.2	15.0
4	2-Methylbutyric acid	35.8	9.0

[a]Refer to Figure 1 (peak 1 is superimposed upon the solvent peak).

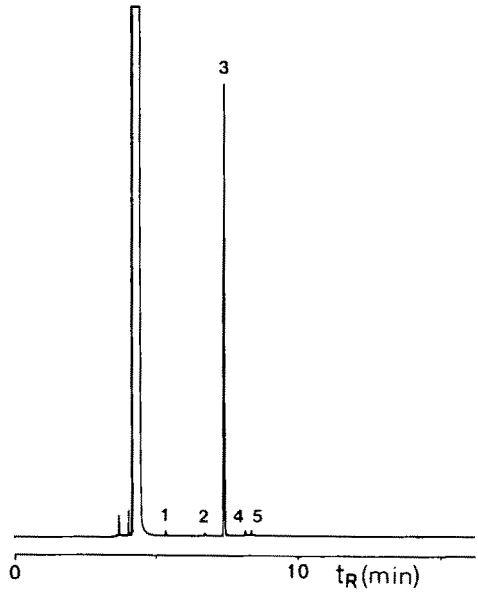

FIG 2. Gas chromatogram of the osmeterial secretion of fifth instars of *Sericinus montela* on a FFAP fused-silica capillary column; 50–180°C at 5°C/min.

and the gas chromatogram of the secretion of fourth instar showed a very similar profile to that of fifth instar. Peak 3, exhibiting a mass spectral pattern characteristic of a monoterpene hydrocarbon [M^+, *m/z* 136(6) and *m/z* 121(4), 93(100), 79(11), 77(10), 69(82), 41(83)], was identified as β-myrcene. All of the other components were also assumed to be monoterpene hydrocarbons from their mass spectral and GC data: peak 1: M^+, *m/z* 136(14) and *m/z* 121(17), 107(5), 105(10), 93(100), 91(25), 79(14), 77(18), and 41(5); peak 2: M^+, *m/z* 136(18) and *m/z* 121(5), 93(100), 91(25), 79(19), 77(31), 69(10), and 41(15); peak 4: M^+, *m/z* 136(31) and *m/z* 121(22), 107(20), 93(58), 79(19), 77(10), 68(100), 53(12), and 41(9); and peak 5: M^+, *m/z* 136(22) and *m/z* 121(6), 93(100), 91(25), 79(15), 77(26), and 41(8). These compounds were identified as α-pinene, sabinene, limonene, and β-phellandrene, respectively. The chemical nature of fourth instar secretion proved to be qualitatively the same as that of fifth instar as shown in Table 2.

P. aristolochiae. The secretion of fifth instar presented a complicated GC profile, consisting of more than 40 constituents (Figure 3). Their mass spectra suggested that they were all sesquiterpene hydrocarbons or oxygenated sesquiterpenes. Peak f, giving M^+ at *m/z* 204(30) and other salient ions at *m/z* 189(40),

TABLE 2. VOLATILE COMPONENTS OF LARVAL OSMETERIAL SECRETION OF *Sericinus montela*

Peak[a]	Component	Composition (%)	
		Fourth instar	Fifth instar
1	α-Pinene	0.7	0.7
2	Sabinene	0.5	0.5
3	β-Myrcene	97.1	97.2
4	Limonene	0.8	0.8
5	β-Phellandrene	0.9	0.8

[a]Refer to Figure 2.

161(37), 134(33), 133(31), 119(67), 105(59), 93(100), 79(63), 69(54), 55(38), and 41(74), and peak h, M^+, *m/z* 204(25) and *m/z* 189(10), 161(48), 133(15), 119(28), 105(100), 94(53), 93(49), 81(23), 55(15), and 41(26), were concluded to be α-himachalene and α-amorphene, respectively, upon comparison with published mass spectra (Stenhagen et al., 1974) and retention indices (Andersen

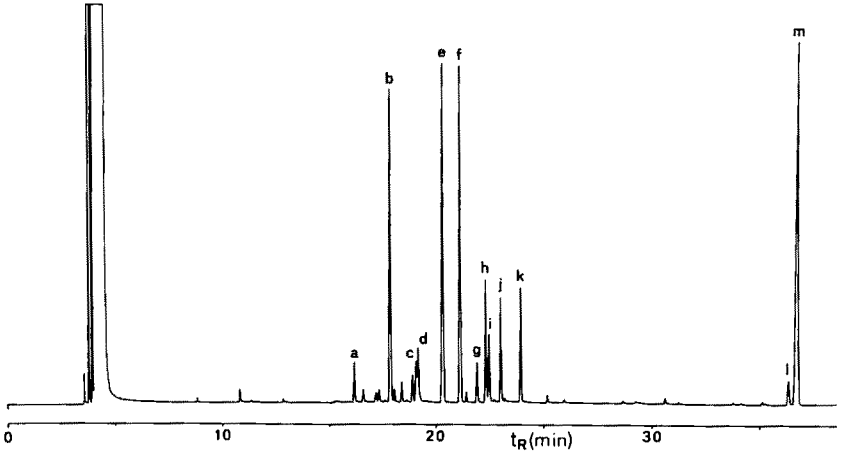

FIG 3. Gas chromatogram of the osmeterial secretion of fifth instars of *Pachliopta aristolochiae* on a FFAP fused-silica capillary column; 50–200°C at 5°C/min.

and Falcone, 1969). The mass spectrum of peak k, M^+, *m/z* 204(2) and *m/z* 189(8), 161(9), 147(19), 121(27), 107(35), 93(64), 81(50), 68(100), 53(36), and 41(55), was quite similar to that of germacrene-A previously reported from the osmeterial secretions of *Papilio* larvae (Honda, 1980a, 1981). Thus, comparison of GC retention data corroborated the identity of peak k with germacrene-A.

Attempts at structural elucidation of other components were unsuccessful; however, other peaks whose relative compositions exceeded 1.0% gave the following molecular ion and base peak: a, 204, and 119; b, 204 and 107; c, 204 and 41; d, 204 and 161; e, 204 and 93; g, 204 and 107; i, 202 and 132; j, 204 and 161; l, 220 and 159; m, 220 and 159. For the molecular weight of 204, which corresponds to representative sesquiterpene hydrocarbons, the molecular formula is assignable to $C_{15}H_{24}$. Likewise, formulae of $C_{15}H_{22}$ and $C_{15}H_{24}O$ seem relevant for 202 and 220, respectively. The secretion of fourth instar showed substantial similarities in both quality and relative quantity to that of fifth instar. The relative proportion of selected components (more than 1.0%) is given in Table 3.

TABLE 3. VOLATILE COMPONENTS OF LARVAL OSMETERIAL SECRETION OF *Pachliopta aristolochiae*

Peak[a]	Component[b]	Composition (%)	
		Fourth instar	Fifth instar
a	$C_{15}H_{24}$	1.1	1.4
b	$C_{15}H_{24}$	9.7	11.7

m	$C_{15}H_{24}O$	34.4	26.8

[a]Refer to Figure 3.
[b]Components less than 1.0% of the total are not listed.

DISCUSSION

In each of the three species presently studied, belonging to different genera, the osmeterial exudates of the last instar were very similar in both quality and quantity to those of the penultimate instar. Although we investigated only one species for each genus, our results strongly suggest that the three genera, *Parnassius* (Parnassiinae, Parnassiini), *Sericinus* (Parnassiinae, Zerynthiini), and *Pachliopta* (Papilioninae, Troidini) are of homogeneous types as are *Luehdorfia* (Parnassiinae, Zerynthiini), *Graphium* (Papilioninae, Graphiini), and *Atrophaneura* (Papilioninae, Troidini) (Honda, 1980b).

The secretion of *S. montela* larvae qualitatively resembles that of *Luehdorfia* larvae in that both species secrete only monoterpene hydrocarbons with β-myrcene as a predominant component (Honda, 1980b). This conforms well to the acknowledged taxonomic disposition of the two genera (tribe Zerynthiini). The larval secretion of *P. aristolochiae* was chemically marked by sesquiterpenes, and previous studies have documented that the osmeterial secretions of *Battus polydamas* (Eisner et al., 1971) and *A. alcinous* (Honda, 1980b) are composed exclusively of sesquiterpenes. The genus *Pachliopta* is considered to be closely related to the genus *Battus* and subgenus *Atrophaneura* (tribe Troidini) (Miller, 1987). The present study provides further evidence for close relationships among these taxa. A subsequent reexamination of the osmeterial secretion of *A. alcinous* revealed the presence of a small amount of germacrene-A (Honda, unpublished). Therefore, *P. aristolochiae* and *A. alcinous* share α-himachalene and germacrene-A, although these compounds are minor constituents of *A. alcinous*. As shown by these findings, comparative studies on the chemistry of larval osmeterial secretion, which seems to reflect phylogenetic relationships among species, would permit chemotaxonomic approaches to the systematics of the Papilionidae.

On the other hand, *P. glacialis* secreted compounds quite different from those of *S. montela*, which is classified in the same subfamily (Parnassiinae). The secretion of *P. glacialis*, containing aliphatic acids and esters, is extremely similar in quality to those of *Graphium* species (Honda, 1980b). In addition, both genera are of homogeneous types. Taking account of the cladistic relationships among tribes in the Papilionidae proposed by Miller (1987), a feasible explanation for such similarity between the two distant genera is that it might perhaps be a result of parallel cladogenesis. However, this hypothesis requires careful and comprehensive verification.

Abstract—Urine and vaginal mucus samples from female white-tailed deer in estrus and mid-cycle were analyzed by combined gas chromatography–mass spectrometry (GC-MS). Forty-four volatiles were found in mucus and 63 in urine. The volatiles common to both vaginal mucus and urine included alcohols, aldehydes, furans, ketones, alkanes, and alkenes. Aromatic hydrocarbons were present only in the vaginal mucus, whereas pyrans, amines, esters, and phenols were found only in urine. Both estrous mucus and estrous urine could be identified by the presence of specific compounds not present in mid-cycle samples. Numerous compounds exhibited dependency on ovarian hormones.

Key Words—Chemosignals, deer, *Odocoileus virginianus*, urine, vaginal mucus, volatiles.
