Abstract—Butyl acetate is a volatile aroma and flavor compound in apple. Conidia of three strains of *Botrytis cinerea*, a fungus that causes decay of apple fruit in postharvest storage, had greater adhesion to and greater germination on polycarbonate membrane filters on water inside sealed 500 cc glass jars that were injected with 4 μl butyl acetate than conidia not so exposed. Conidial germination was highly correlated with conidial adhesion. The yeasts *Sporobolomyces roseus* and *Cryptococcus laurentii*, but not *Saccharomyces cerevisiae*, reduced the adhesion and germination promoting effect of butyl acetate. Conidia did not readily utilize butyl acetate as a food source, as shown by lack of tetrazolium violet reduction, whereas *S. roseus* and *C. laurentii*, but not *S. cerevisiae* did. Butyl acetate added to suspensions of conidia increased the electrical conductivity of the suspensions and increased the loss of ^{14}C from ^{14}C-labeled conidia compared to conidia unexposed to butyl acetate. Uptake of [^{14}C]glucose by conidia was not increased by butyl acetate. Wounds of Golden Delicious apples inoculated with conidia (strain F-J-4) in a dilute solution of butyl acetate had greater decay than unexposed wounds. *S. roseus* and *C. laurentii*, but not *S. cerevisiae*, added with the conidia decreased the incidence or size of decay. Results indicated that butyl acetate increased conidial adhesion, stimulating conidial germination, and some yeasts can reduce this effect.

Key Words—Fungal spores, yeasts, germination, adhesion, butyl acetate, *Botrytis cinerea*, biological control, volatiles from apple, fungal ecology.

INTRODUCTION

Apple fruit produce acetate esters that influence aroma and flavor of the fruit (Mattheis et al., 1991; Knee, 1993; Fellman and Mattheis, 1995). In addition,

0098-0331/01/0400-0831$19.50/0

acetate esters may affect microbial growth and interactions on the surface of apple fruit. Filonow (1999) found that ethyl, butyl, and hexyl acetate stimulated *in vitro* germination of conidia of *Botrytis cinerea* Pers.:Fr, a fungus that causes a decay of apples and other fruits. These results support earlier findings (Brown, 1922) that ethyl acetate from apples stimulated germination of *B. cinerea* conidia. In addition, Filonow (1999) found that germination of conidia was stimulated by acetate esters on Golden Delicious apples, and apples in jars exposed to butyl acetate had more fungal decay than apples unexposed to butyl acetate. This work was done with one strain (F-J-4) of *B. cinerea*, and it is not known whether other strains will respond to acetate esters in a similar way. There appears to be no other study linking acetate ester exposure to enhanced fungal decay in apple. Furthermore, how acetate esters stimulate the germination of *B. cinerea* conidia is not known. Since adhesion of conidia of *B. cinerea* to substrates appears to be a necessary event preceding conidial germination (Doss et al., 1993, 1995), the present study assessed the link between acetate ester exposure and conidial adhesion.

Acetate esters from apple also may serve as a food source for some yeasts (Vishniac et al., 1997). Yeasts are common inhabitants of apple fruit, and several yeasts are known antagonists of filamentous fungi that cause fruit decay in postharvest storage (Janisiewicz et al., 1994; Filonow et al., 1996; Filonow, 1998). Filonow (1998) found that *Sporobolomyces roseus* FS-43-238 and *Cryptococcus laurentii* BSR-Y22 were highly effective in protecting apple wounds from decay caused by *B. cinerea*, but *Saccharomyces cerevisiae* BY-1 was not. In this study, nutrient competition for sugars played a role, but some other factor was most likely involved. In this regard, Filonow (1999) found that *C. laurentii* BSR-Y22, and *S. roseus* FS-43-238 were more effective than *S. cerevisiae* BY-1 in reducing the stimulatory effect that acetate esters have on *in vitro* germination of *B. cinerea* conidia. The mechanism by which some yeasts reduce this stimulatory effect is unknown.

The objectives of this research were: (1) to determine if conidia of other strains of *B. cinerea* are stimulated to germinate by butyl acetate; (2) to find the cause for the stimulatory effect, in particular to assess the role of conidial adhesion; and (3) to determine why some yeasts are more capable than others in reducing the stimulatory effect.

METHODS AND MATERIALS

Fungi and Culture. The sources for *Botrytis cinerea* F-J-4, *Sporobolomyces roseus* FS-43-238, *Cryptococcus laurentii* BSR-Y22, and *Saccharomyces cerevisiae* BY-1 were previously reported (Filonow, 1999). Strains WMA1 and WMG2 of *B. cinerea* were isolated by the author from infected Golden Delicious apple and geranium, respectively, obtained from a local supermarket. Maintenance of *B. cinerea* strains and the production of conidia on potato-dextrose agar

(PDA; Difco, Inc. Detroit, Michigan) have been reported elsewhere (Filonow et al., 1996). A PDA dish was inverted and tapped on a table to dislodge conidia on the inside of the dish lid. Conidia were suspended in sterile double-distilled (sdd) water with the aid of a rubber policeman, transferred to a 50-ml sterile centrifuge tube, and conidial density determined in a Brightline hemacytometer (Hausser Sci., Horsham, Pennsylvania). Suspensions were adjusted with water and conidial densities varied depending on the experiment. Maintenance of yeasts and their culture have been described (Filonow et al., 1996). Yeast densities in suspensions were 1×10^7 CFU/ml unless otherwise noted.

Effect of Butyl Acetate and Yeasts on Adhesion and Germination of Conidia In Vitro. Two hundred microliters of water (sdd) or a suspension of *S. roseus*, *C. laurentii*, or *S. cerevisiae* were aseptically pipetted into each of two autoclaved stainless steel wells (4 mm $\times$ 250 mm diam.) affixed to double-stick tape on a glass microscope slide. Membrane filters bearing 4×10^4 conidia of each strain of *B. cinerea* were prepared (Filonow, 1999). Membrane filters used in experiments were quarter sections cut from 47-mm-diam. polycarbonate membrane filters (1.0-μm-diam. pore; Osmonics, Inc, Livermore, California). Membranes were placed on the water or yeast suspensions, and two wells were placed inside an autoclaved 500-cc glass Mason jar (Kerr, Inc., Los Angeles, California) resting on its side. The jar was sealed with a lid fitted with a rubber septum. For each strain of *B. cinerea*, there were 24 jars, representing one experiment. Twelve jars were injected with 4 μl of butyl acetate (99.9% pure) (Fluka Chemika), whereas the others were not. There were three jars per treatment or control that were exposed or not-exposed to butyl acetate. Jars were randomized on a bench. After 24 hr at 22°C, one filter from a jar was assessed for germination of conidia (Filonow, 1999), and the other filter was pressed to the inside of a glass funnel (3 cm diam. $\times$ 6 cm stem). The funnel was put into a 15-ml glass centrifuge tube and positioned under a 10-ml glass disposable pipet containing 10 ml of water. The column of water in the pipet was held in place by pinch clamping a rubber tube attached to the top of the pipet, thereby stopping air pressure on the water column. The distance from the tip of the pipet to the top of the filter was 13 cm. Opening the pinch clamp caused the water to stream down on the filter, dislodging conidia. Residual water in the stem of the funnel was blown into the centrifuge tube and the tube capped. The filter in the funnel was discarded, the funnel washed with a squirt of water, and the process repeated for the next sample. Centrifuge tubes were centrifuged at 2800 rpm for 20 min. The supernatant was reduced to 2 ml by gentle suction into a vacuum flask. Then 2 ml were vortex mixed and the number of conidia per milliliter estimated in a hemacytometer from two counts per tube. The total number of conidia in nine fields was considered one count. Percentage adhesion was calculated from the mean number of conidia dislodged from a filter unexposed to butyl acetate minus the mean number dislodged from an exposed filter divided by the mean number dislodged from an unexposed filter $\times 100$.

Utilization of Butyl Acetate by Yeasts or Conidia of B. cinerea *Strains As Indicated by Tetrazolium Violet Reduction In Vitro.* Microorganisms capable of catabolizing certain organic substrates in a colorless tetrazolium violet (TV; Sigma Chemical, Inc., St. Louis, Missouri) solution reduce the TV to a violet-colored formazan (Bochner and Savageau, 1977). This method was used to assess the capability of yeasts or *B. cinerea* conidia to use butyl acetate as food. The TV preparation (TVP) consisted of 2.1 g K_2HPO_4, 0.9 g KH_2PO_4, 0.4 g proteose peptone (Difco, Inc.), 40 mg $MgSO_4 \cdot 7H_2O$, 100 μl 1 M NH_4NO_3, 20 μl 1 mM thiamine HCl, 20 μl 1 mM biotin, and 20 mg TV in 100 ml of water. Brief sonication at different steps helped solubilize some of the ingredients. The very pale yellow solution was filter-sterilized (0.2-μm pore) and stored in sterile centrifuge tubes at 4°C until use. One hundred microliters each of TVP, a suspension of test organisms, and water were aseptically pipetted into autoclaved 22-ml glass scintillation vials. Test organisms were suspensions (3×10^8 CFU/ml) of each yeast or conidia (3×10^7 conidia/ml) of each *B. cinerea* strain in sterile saline (0.9% NaCl). Vials were placed in upright glass jars, and the lids were sealed. Each test organism was in two vials per jar. Half of the jars had 4 μl of butyl acetate injected into them, and the other half did not. Some jars contained vials with TVP, a test organism, and 100 μl of 20 mM glucose or vials with TVP, water instead of a test organism, and 100 μl of 20 mM glucose. These jars were not injected with butyl acetate. There were three jars per treatment. After incubation at 22°C for 24 hr, the color of solutions in the vials was rated: 1 = no purple color, 2 = light purple, 3 = intermediate purple, and 4 = intense purple.

Effect of Butyl Acetate on Electrical Conductivity of Conidia in Water. Five milliliters of water (sdd) containing conidia ($5–7 \times 10^6$ conidia/ml) of each *B. cinerea* strain in 15 ml polypropylene centrifuge tubes were treated with 1 μl or 5 μl of butyl acetate. The tubes were capped, shaken horizontally at 22°C for 1–24 hr at 100 rpm, and electrical conductivity of suspensions measured at 1, 4, and 24 hr with a conductivity probe (Amber Science, Inc., San Diego, California) on the lab bench. Controls were water without conidia, but treated with 5 μl butyl acetate, and water with conidia but no butyl acetate. There were three replicates per treatment or control per experiment.

Effect of Butyl Acetate on Loss of ^{14}C from ^{14}C-Labeled Conidia. Conidia of each strain of *B. cinerea* were produced on 10-cm-diam. PDA dishes that were supplemented with 370 kBq of [^{14}C]glucose per dish. Solutions of [^{14}C]glucose (11.1 Gbq/mM; ICN Biomedicals) were filter-sterilized (0.2-μm-diam. pore) before use. Four hundred microliters of ^{14}C-labeled conidia ($2.4–5.0 \times 10^6$ conidia/ml) of each *B. cinerea* isolate or water (sdd) were aseptically pipetted into a sterile well affixed to double-stick tape on the inside of a 6.5-cm-diam. glass Petri dish cover. Also stuck to the tape was a 22-ml glass scintillation vial containing 200 μl of 1 M NaOH as a $^{14}CO_2$ trap. The cover dish was placed inside an upright 500 cc glass jar that was then sealed. Three jars containing each of the fungi and three

with water were injected with 4 μl of butyl acetate, and three jars each with fungi or water were not. After 24 hr at 22°C, 14 ml of Econolume scintillation cocktail (ICN Biomedicals) were added to the vial with NaOH, and the contents of a well was transferred by pipet to a membrane filter on a sintered-glass suction head and vacuum deposited on the filter. Two 200-μl water washings of the well were also added to the membrane. Liquid was collected in a scintillation vial inside the suction flask. The filter was dissolved in 200 μl chloroform, and the conidia suspended in 10 ml of 4% Cab-O-Sil cocktail (Filonow and Lockwood, 1983). Ten milliliters of Econolume cocktail were added to the liquid from inside the suction flask. Radioactivity was measured as disintegrations per minute (dpm). Total ^{14}C available in a jar prior to an experiment was equal to ^{14}C (dpm) in liquid + in conidia on a filter $+^{14}CO_2$. Percentage ^{14}C lost as leakage from conidia was calculated as (^{14}C in the liquid/total ^{14}C) $\times$ 100. Percentage $^{14}CO_2$ evolved from conidial respiration was calculated from ($^{14}CO_2$/total ^{14}C) $\times$ 100. Total percentage ^{14}C lost from conidia was the sum of ^{14}C leakage $+^{14}CO_2$ evolved.

Effect of Butyl Acetate on Uptake of ^{14}C-Labeled Sugars by Conidia. Two hundred microliters of ^{14}C-labeled glucose (370 kBq) in water were pipetted into a sterile well inside a small glass Petri dish cover. The cover also held a 22-ml scintillation vial containing 200 μl of 1 M NaOH. One membrane filter without conidia as a control or one bearing 1×10^6 conidia of each *B. cinerea* isolate was placed on the ^{14}C-labeled glucose and the dish cover placed inside an upright 500-cc glass jar. There were 24 jars per experiment: six jars with conidia of each isolate and six of a control. The jars were sealed and three jars with conidia of each isolate and a control were injected with 4 μl of butyl acetate. Jars without butyl acetate were the controls. Jars were completely randomized on a bench. After 9 hr at 22°C, 14 ml of Econolume cocktail were added to the scintilliation vial, and membrane filters were transferred to a sintered-glass suction flask and washed (200 μl) twice with cold water. Radioactivity in conidia was measured, as described above. One experiment was done.

Effect of Butyl Acetate and Yeasts on B. cinerea *Infection of Apples*. Golden Delicious apples were purchased from a local supermarket. Apples used in experiments weighed 110–135 g, had a mean firmness of 40–44 N and soluble solids of 11.5–12.7%, and were free of obvious bruises. Apples were used on the day of purchase or stored (4°C) for one week or less before use. Apples from cold storage were equilibrated at 22°C for 16–24 hr before use. Apples were washed with tap water and dried with paper towels. Two wounds (3 mm diam. $\times$ 3 mm deep) were made on opposite sides of an apple at the equator by puncturing the tissue with a nail. The nail was passed through a flame and briefly allowed to cool before the next puncture. Apples were incubated for 24 hr prior to inoculating wounds. Treatments used for inoculation were prepared in 12-ml glass vials by mixing 5 ml suspensions of isolate F-J-4 conidia with 5 ml of water or 5 ml of yeast suspension to give: (1) conidia + *S. roseus,* (2) conidia + *C. laurentii,*

(3) conidia + *S. cerevisiae,* or (4) conidia + water. Density of conidia was 2–4 $\times$ 10^4 conidia/ml, whereas yeast density was 1 $\times$ 10^7 CFU/ml. The control was 10 ml of water in a vial, and one vial per fungal suspension or water was prepared. Water and fungal mixtures (10 ml each) were spiked with 10 μl of butyl acetate or not. Vials were capped, the contents mixed well, and 20 μl of a treatment pipetted into both wounds per apple using a fresh pipet tip for each wound. Fifteen apples per treatment or control on a fruit tray were placed inside a 40-cm $\times$ 58-cm $\times$ 14-cm plastic storage box containing 500 ml of water, and sealed inside a plastic bag. Each box contained a different treatment and was randomized on a bench. After 10 days at 22°C, the number of infected wounds and lesion diameters (Filonow et al., 1996) were recorded.

Data Analysis. All experiments were repeated one or two times, unless otherwise noted. Results from repeated experiments were reproducible. Percentage adhesion of conidia exposed to butyl acetate and yeasts (Figure 2 below) is presented as an increase over the percentage adhesion of unexposed conidia. Percentage germination and percentage infection data were subjected to an arcsine square-root transformation prior to analysis of variance (ANOVA). A two-way ANOVA was performed on data from the apple infection experiments. Means were separated using the Student-Newman-Keul's test or Dunnett's test ($P \leq 0.05$). The relationship between conidial germination and conidial adhesion was analyzed by regression ($P \leq 0.05$).

RESULTS

Effect of Butyl Acetate and Yeasts on Adhesion and Germination of Conidia In Vitro. Preliminary experiments showed that centrifugation of a 10-ml suspension of conidia followed by suctioning off the supernatant consistently gave a 92% recovery of conidia unexposed to butyl acetate. The water-stream method for dislodging conidia yielded 85–88% of unexposed conidia within 3 min of conidia deposition on membranes, indicating a rapid adhesion of some conidia. Since the 85–88% recovery of conidia was consistent for several trials (data not shown), and the method was easy to use, it was considered suitable for assessing conidial adhesion.

Adhesion of unexposed conidia to membrane filters (experimental controls) increased over time (Figure 1), ranging from 11–26% after 4 hr to 22–42% after 48 hr of incubation. Germination of these conidia was typically 0% after 12 hr and only 2–10% after 48 hr (Figure 1). When conidia were exposed to butyl acetate (Figure 1), their adhesion increased 0.3- to 2.3-fold by 4 hr and 1.6- to 3.0-fold by 48 hr over the controls. Conidia exposed to butyl acetate also germinated more (Figure 1), with significant stimulation of germination beginning after 8–12 hr and increasing to 3- to 5-fold greater than controls after 48 hr. Data for germination and adhesion of exposed conidia (Figure 1) were subjected to regression

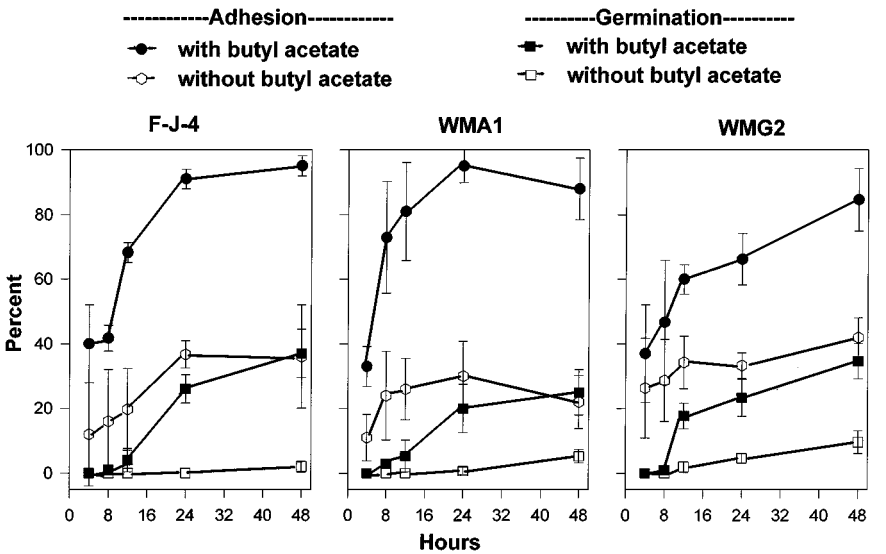

FIG. 1. Adhesion and germination of conidia of isolates F-J-4, WMA1, and WMG2 of *Botrytis cinerea* after 24 hr at 22°C on polycarbonate membrane filters on water inside 500-cc jars injected with 4 μl of butyl acetate. Controls were conidia not exposed to butyl acetate. Data points are the means of three replicates $\pm$ 1 SD.

analysis. Regression of percentage germination (G) to percentage adhesion (A) data best fit second order polynomial models for isolates F-J-4 ($G = 49.96 - 2.00A + 0.019A^2$; $r^2 = 0.99$), and WMA1 ($G = 30.44 - 1.38A + 0.014A^2; r^2 = 0.77$), and a linear model for WMG2 ($G = -31.46 + 0.79A; r^2 = 0.96$).

Sporobolomyces roseus and *C. laurentii* generally reduced the adhesion-promoting effect of butyl acetate on conidia to membrane filters (Figure 2), whereas *S. cerevisiae* did not. *Sporobolomyces roseus* inhibited adhesion of conidia more than *C. laurentii* for isolates F-J-4 and WMA1, but not WMG2. Generally the lower the level of conidial adhesion affected by the yeasts the lower the germination of conidia (Figure 2).

Utilization of Butyl Acetate by Yeasts and Conidia of B. cinerea Isolates As Indicated by Tetrazolium Violet Reduction In Vitro. All yeasts and conidia utilized glucose as a food as indicated by the production of a violet-colored precipitate (Table 1); however, only *S. roseus* and *C. laurentii* utilized butyl acetate. Controls consisting of an organism plus TVP without a food source were colored pale yellow, except for the *S. roseus* control, which often was light violet, but easily distinguishable from the medium-intense violet when *S. roesus* utilized butyl acetate or glucose. By 24 hr most of the formazan production had occurred, but *C. laurentii* often needed another 24 hr to improve color intensity.

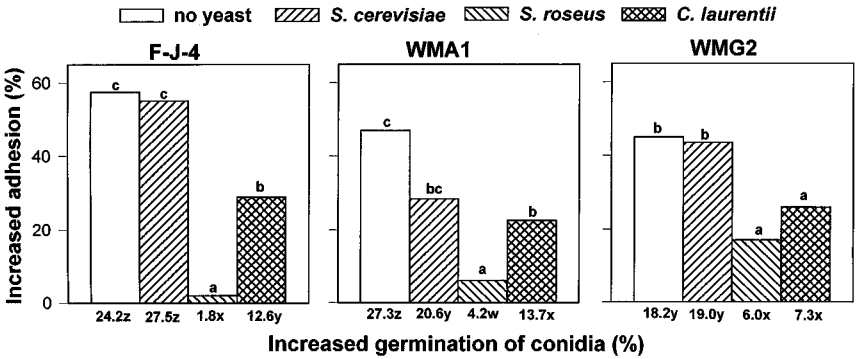

FIG. 2. Adhesion and germination of conidia of isolates F-J-4, WMA1, and WMG2 of *Botrytis cinerea* after 24 hr at 22°C on polycarbonate membrane filters on water or water suspensions of yeasts inside 500-cc jars injected with 4 μl of butyl acetate. Controls were conidia not exposed to butyl acetate. Bars are the means of three replicates and represent the increase in percentage adhesion and germination above controls. Bars with the same letter are not significantly ($P \leq 0.05$) different according to the Student-Newman-Keul's test.

Effect of Butyl Acetate on Electrical Conductivity of Conidia in Water. Addition of small amounts of butyl acetate to suspensions of conidia in water significantly increased the electrical conductivity of the suspensions beyond that of the controls. The conductivity of the suspensions dosed with 5 μl butyl acetate generally increased linearly over time (Figure 3), whereas the 1-μl dose increased conductivity 150–255% after 1 hr, but thereafter conductivity did not increase

TABLE 1. UTILIZATION OF GLUCOSE AND BUTYL ACETATE BY CONIDIA OF *Botrytis cinerea* AND YEASTS USING TETRAZOLIUM VIOLET REDUCTION AS INDICATOR

	Violet color rating with added substrate[a]		
Organism	Water	Glucose	Butyl acetate
F-J-4 conidia	1.0a	2.2b	1.0a
WMA1 conidia	1.0a	2.3b	1.0a
WMG2 conidia	1.0a	2.3b	1.0a
S. cervisiae	1.0a	2.7b	1.0a
C. laurentii	1.2a	2.7b	2.7b
S. roseus	2.0a	4.5c	3.8b

[a] Color was rated using a scale of 1–5, where 1 = no violet color and 5 = intense violet color. Values are the means of six replicates. Means in a horizontal row followed by the same letter are not significantly different using Dunnett's test ($P \leq 0.05$).

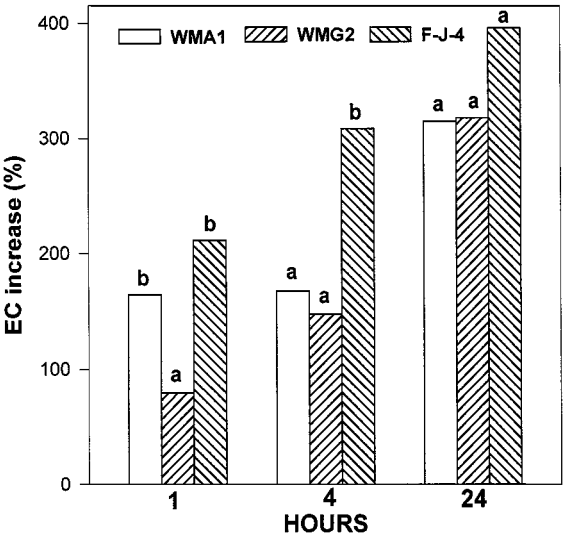

FIG. 3. Electrical conductivity (EC) at 22°C of suspensions of conidia of isolates F-J-4, WMA1, and WMG2 of *Botrytis cinerea* in water dosed with 5 μl of butyl acetate. Controls were conidia not exposed to butyl acetate. Bars are the means of three replicates and represent the EC increase in percentage above controls. Bars with the same letter are not significantly ($P \leq 0.05$) different according to the Student-Newman-Keul's test.

(data not shown). No isolate of *B. cinerea* consistently leaked more than others after butyl acetate exposure.

Effect of Butyl Acetate on Loss of ^{14}C from ^{14}C-Labeled Conidia. ^{14}C-Labeled conidia incubated on water and not exposed to butyl acetate lost 3.4–7.9% of their ^{14}C. Exposure to butyl acetate increased ^{14}C lost to 16.9–25.1% (Figure 4). Generally, respiration was the major route of ^{14}C lost from conidia of isolates WMA1 and WMG2, but not F-J-4,which also leaked considerable ^{14}C. Leakage of ^{14}C from conidia exposed to butyl acetate was 2.2–2.8 times greater than that from unexposed conidia.

Effect of Butyl Acetate on Uptake and Utilization of ^{14}C-Labeled Glucose by Conidia. Exposure of conidia to butyl acetate did not make them more permeable to glucose (Figure 5). Compared to unexposed conidia, neither [^{14}C]glucose uptake by conidia, respiration, nor total ^{14}C recovery from labeled conidia was increased by butyl acetate.

Effect of Butyl Acetate and Yeasts on B. cinerea Infection of Apples. Butyl acetate in water added to wounds of apples increased both the infection frequency and the lesion diameter caused by *B. cinerea* F-J-4 compared to the control (Table 2). Butyl acetate caused little additional disease in wounds treated with

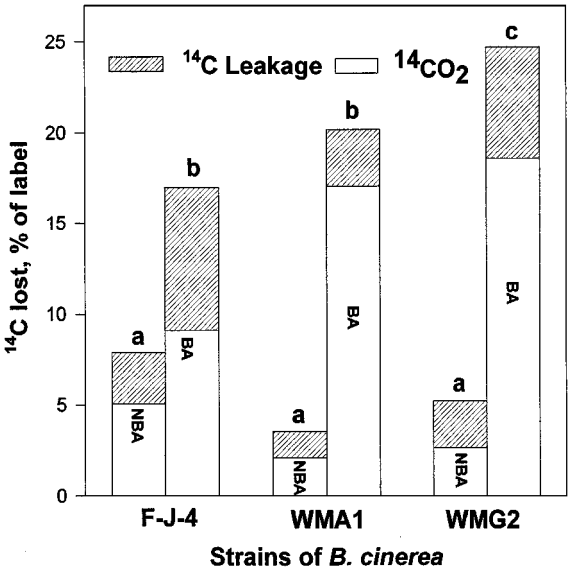

FIG. 4. ^{14}C lost as leakage or evolved CO_2 from ^{14}C-labeled conidia of isolates F-J-4, WMA1, and WMG2 of *Botrytis cinerea* after 24 hr at 22°C on water inside 500-cc jars injected with 4 μl of butyl acetate (BA) or not (NBA). Bars with the same letter are not significantly ($P \leq 0.05$) different according to the Student-Newman-Keul's test.

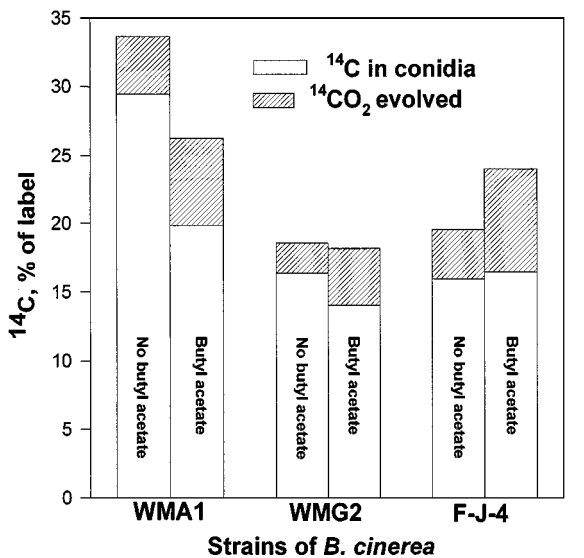

FIG. 5. Uptake and utilization of [^{14}C]glucose by conidia of isolates F-J-4, WMA1, and WMG2 of *Botrytis cinerea* after 24 hr at 22°C on water inside 500-cc jars injected with 4 μl of butyl acetate or not. No significant ($P \leq 0.05$) differences were found between conidia exposed or unexposed to butyl acetate.

TABLE 2. EFFECT OF YEASTS ON INFECTION BY CONIDIA OF *Botrytis cinerea* (F-J-4) IN WOUNDS OF GOLDEN DELICIOUS APPLES TREATED WITH BUTYL ACETATE[a]

Yeast	Infection frequency (%)		Lesion diameter (mm)	
	No butyl acetate	Butyl acetate	No butyl acetate	Butyl acetate
None	70.0aZ	90.0bZ	20.9aZ	31.0bZ
S. cerevisiae	60.0aZ	70.0aY	20.1aZ	23.0aZ
C. laurentii	46.7aY	43.3aX	10.4aY	11.9aY
S. roseus	6.7aX	26.7bW	5.5aY	9.1aY

[a] Values are the means of 15 replicates. Means in a horizontal row followed by a lowercase letter and means in a column followed by uppercase letters are not significantly different using the Student-Newman-Keul's test ($P \leq 0.05$).

yeasts. In wounds treated with butyl acetate, all yeasts reduced the infection frequency compared to the control; however, lesion diameter was only reduced by *S. roseus* and *C. laurentii.* Compared to *C. laurentii, S. roseus* reduced infection frequency but not lesion diameter.

DISCUSSION

Butyl acetate stimulated germination of conidia of *B. cinerea* on polycarbonate filter membranes, a finding that supports early work with butyl acetate and other acetate esters (Filonow, 1999). This phenomenon was found for two other isolates of *B. cinerea* in addition to F-J-4 (Filonow, 1999). My findings plus earlier work (Brown, 1922) suggest a general germination response of *B. cinerea* to acetate esters.

Butyl acetate increased the adhesion of *B. cinerea* conidia to membrane filters, which is a new finding. The percentage germination of conidia was strongly correlated with increasing adhesion. Other workers have reported that fungal spore adhesion plays a role in spore germination (Young and Kauss, 1984; Hamer et al., 1988; Doss et al., 1993, 1995). In the absence of butyl acetate, my results support the findings of Doss et al. (1993) that adhesion of freshly hydrated conidia of *B. cinerea* is a two-stage process with the first stage occurring very rapidly. A second stage, involving germ tube formation, occurs hours later, with adhesion increasing as germlings increase (Doss et al., 1995). Most likely, a minimum adhesive threshold may have to be surpassed by some *B. cinerea* conidia prior to germination.

Other mechanisms were investigated that could account for increased germination of conidia when exposed to butyl acetate. Conidia did not use butyl acetate as a food source, as indicated by the lack of tetrazolium violet reduction, although

this metabolic assay showed that conidia had an active metabolism capable of using glucose. Although tetrazolium dyes are widely used in microbial ecology as colorimetric indicators of organic substrate utilization, their use is sensitive to several factors (Bochner and Savageau, 1977; Konopka et al., 1998), and care must be used in assay interpretation. Nevertheless, under the conditions given in this paper, the TV assay was simple to use and gave unequivocal results.

Butyl acetate increased the permeability of conidia, as indicated by the increase in electrical conductivity (EC) of water suspensions of conidia treated with butyl acetate. Part of the EC rise was due to leakage of organic compounds. An increased loss of ^{14}C occurred from ^{14}C-labeled conidia of all isolates. Altered permeability appeared to favor efflux of material rather than influx, as suggested by the insignificant uptake and use of [^{14}C]glucose by conidia exposed to butyl acetate compared to unexposed conidia. The effect of butyl acetate on permeability of *B. cinerea* conidia is a new finding and raises the question of whether other fungal spores are likewise affected by acetate esters or other volatiles.

The present work also confirmed the finding (Filonow, 1999) that *Sporobolomyces roseus* and *C. laurentii*, but not *S. cerevisiae* reduced the stimulatory effect of butyl acetate on the *in vitro* germination of *B. cinerea* conidia. Reported here for the first time is the capability of some yeasts to reduce the adhesion-promoting effect of butyl acetate on fungal spores. *Saccharomyces cerevisiae* showed much less capability, a result consistent with the poor capability of *S. cerevisiae* to reduce butyl acetate stimulation of germination. The TV assay showed that *S. roseus* and *C. laurentii*, but not *S. cerevisiae* used butyl acetate as a food source, a finding supported by Vishniac et al. (1997) that some yeasts but not others can use acetate esters as food sources. Therefore, depletion of butyl acetate by *S. roseus* or *C. laurentii* from water films surrounding conidia, thereby reducing the adhesion-promoting effect of butyl acetate, is a plausible mechanism explaining the action of these yeasts. However, this hypothesis would be better tested by relating adhesion and germination to butyl acetate depletion rates induced by yeasts. This could be done *in vitro* but is now technically impossible in apple wounds.

Since butyl acetate caused increased leakage of organic compounds from conidia, it is also plausible that the released material or some component of the material may be an adhesive (Stahman et al., 1992; Doss et al., 1995). Depletion of butyl acetate by *S. roseus* and *C. laurentii* may reduce alterations in fungal permeability with less leakage of adhesive. Alternatively or concomitantly, these yeasts may feed on some component of the extracellular material altering adhesive capacity.

Filonow (1999) showed that exposing apples to a butyl acetate headspace in glass jars produced more infection by *B. cinerea.* The work herein expands on this finding to show that *S. roseus* and *C. laurentii*, but not *S. cerevisiae* reduced the infection-promoting effect of butyl acetate. Although this finding is consistent with *in vitro* germination and adhesion results, conclusive evidence awaits investigations of microbial interactions within apple wounds. In this study, wounds of apples were

directly treated with a dilute solution of butyl acetate and the apples incubate in a manner frequently used by workers in the biological control of postharvest diseases (Janisiewicz et al., 1994; Filonow, 1998). The wounds were also allowed to dry overnight to facilitate a quicker absorption of butyl acetate by wounds from the introduced solution.

Butyl acetate and other acetate esters are volatile aroma- and flavor-producing compounds readily emitted by apples (Knee, 1993; Fellman and Mattheis, 1995), but whose concentrations vary according to the physiological state of the apple (Mattheis et al., 1991; Fellman and Mattheis, 1995). Since butyl acetate is one of the most volatile of acetate esters, it has typical concentrations of 200–1000 nppb and 1–3 μppm in the flesh and peel, respectively. During storage, conidia of *B. cinerea* in apple wounds will be exposed to indigenous acetate esters and to volatile acetate esters that partition into and out of water films on the surfaces of apples. In the present study, conidia on filter membranes in glass jars were exposed to 4 μl of butyl acetate or about 7 μppm. Since butyl acetate is slightly soluble in water, it is reasonable to assume that concentrations of butyl acetate used in the *in vitro* studies were most likely similar to the ppb to ppm range typically found in apples.

The relevance of the present findings to the use of yeasts as biological control agents needs additional study, although these findings and those of Filonow (1998, 1999) indicate that other chemicals besides the standard nutrients, e.g., sugars, may influence interactions of fungal pathogen and biocontrol yeasts in apple wounds. The chemical ecology of fungal pathogen interactions with fruit appears to be exceedingly complex (Hamilton-Kemp et al., 1992; Vaughan et al., 1993; Eckert and Ratnayake, 1994; Archbold et al., 1997; Filonow, 1999) and may make the search for a single causal biocontrol mechanism difficult. If so many interacting chemicals affect microbial interactions in an apple wound, is it worthwhile to focus on single mechanisms of antagonism such as antibiosis or nutrient competition for the purposes of antagonist improvement?

Apart from this question, the present findings support the acquisition of further knowledge regarding the physiological and biochemical effects that volatile chemicals from apples or other fruits have on the ecology of fungal plant pathogens.

Abstract—To understand how mammalian herbivores process plant secondary compounds, we examined differences in expression of biotransformation enzyme mRNAs among populations of wild woodrats (*Neotoma lepida*) and laboratory rats. We compared expression of mRNAs for 10 biotransforming enzymes in five families (CYP, mEH, QOR, GST, and UGT) by using Northern blot analysis. We found significant differences in eight of 10 mRNAs tested. We suggest that the differences in mRNA expression among populations of woodrats and laboratory rats may be due to differences in the secondary compound composition of their diets. Our results provide background for future studies of detoxification strategies in mammalian herbivores that combine pharmacological techniques with an ecological perspective.

Key Words—Detoxification, biotransforming enzymes, plant secondary compounds, *Neotoma*, woodrats, xenobiotics.

INTRODUCTION

Mammalian herbivores ingest and detoxify a wide variety of plant secondary compounds. Detoxification and elimination is carried out by a multitude of enzymes collectively referred to as "xenobiotic biotransforming enzymes" or less precisely, "drug-metabolizing enzymes." These enzymes transform hydrophobic molecules into hydrophilic compounds that can be excreted as metabolites in the urine or feces.

To understand how mammalian herbivores detoxify secondary compounds, ecologists have focused primarily on the end products of detoxification by examining metabolites in the urine. Most studies have focused on the excretion of a single compound, glucuronic acid, which is an endogenous compound that can be

0098-0331/01/0400-0845$19.50/0

conjugated to a diversity of secondary compounds (Dearing, 1997; Foley, 1992; Lindroth and Batzli, 1983). Focus on this pathway is due in part to the fact that relatively straightforward, colorimetric assays for glucuronic acid have been developed (Blumenkrantz and Asboe-Hansen, 1973). Quantification of metabolites from other enzymatic pathways often entail more involved chemical analyses, such as gas chromatography, high pressure liquid chromatography, or mass spectrometry (Mangione, 1999; McLean et al., 1993).

In contrast, contemporary pharmacological studies approach mechanisms of detoxification of foreign (xenobiotic) compounds differently. In addition to quantifying metabolites excreted in the urine, *in vitro* techniques are used to identify individual enzymes involved in drug metabolism (Batt et al., 1992; Kato, 1979). One such technique that uses Northern blot analysis (Sambrook et al., 1989) detects messenger RNAs (mRNA) that encode for numerous biotransformation enzymes. This analysis gives an indication of the level of expression of mRNA for a particular detoxification enzyme. Screens of mRNA for biotransformation enzymes typically are employed to determine the pathways of biotransformation that are induced when a known drug is administered.

We took a pharmacological approach to investigate the detoxification mechanisms of mammalian herbivores consuming their natural diet. As a first step, we used Northern blot analysis to quantify the expression of mRNAs for several biotransformation enzymes in the liver of desert woodrats, *Neotoma lepida*. This species occurs in a wide variety of habitats across the American Southwest. We selected two populations of *N. lepida* known to consume different diets. *N. lepida* from the Great Basin feeds primarily on Utah juniper (*Juniperus osteosperma*), whereas *N. lepida* from the Mojave Desert consumes desert almond (*Prunus fasciculata*) and creosote (*Larrea tridentata*) (Egoscue, 1957; Karasov, 1989; Mangione, 1999). These plant species contain high levels of various secondary compounds, particularly terpenes and phenolics (Dearing et al., 2000; Mangione, 1999; Mangione et al., 2000). We compared the results from *N. lepida* consuming natural diets to those from laboratory rats (*Rattus norvegicus*) consuming standard laboratory chow.

For each population, we examined levels of mRNA from five families of enzymes involved in xenobiotic biotransforming enzymes: cytochrome P450s (CYP), microsomal epoxide hydrolase (mEH), NAD(P)H quinone oxidoreductase (QOR), glutathione *S*-transferases (GST), and UDP-glucuronosyltransferases (UGT) (Figure 1). These five families encompass the majority of known detoxification enzymes and include both functionalization (phase I) and conjugation enzymes (phase II). In addition, we probed for the heavy subunit of γ-glutamylcysteine synthase (γ-GCS). CYP, mEH, and QOR encode for functionalization enzymes, whereas GST and UGT produce conjugation enzymes. For CYP and UGT families, we restricted our investigation to isoforms that are known to metabolize foreign compounds.

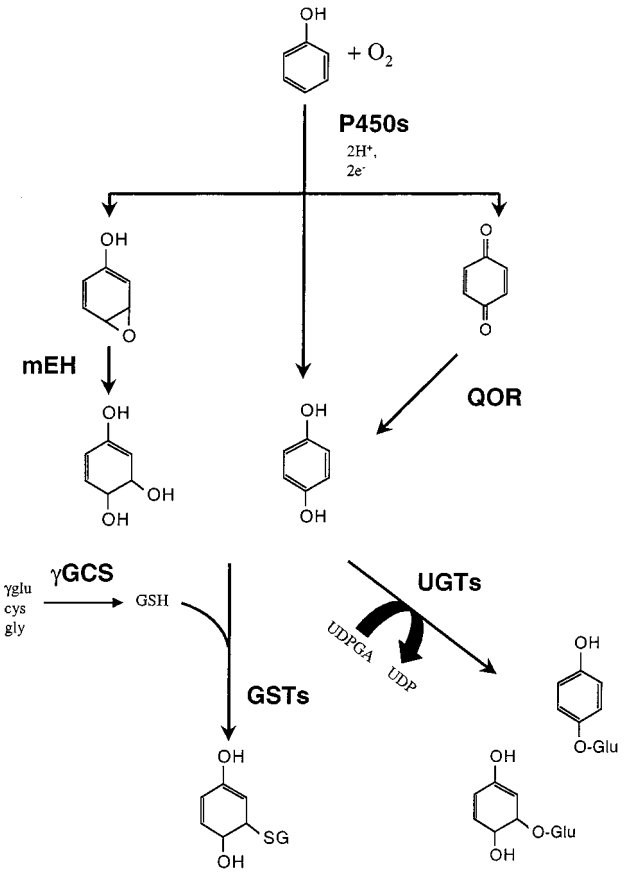

FIG. 1. General pathways of xenobiotic biotransformation. An example of a phenolic compound is shown. P450s: cytochrome P450 enzymes, mEH: microsomal epoxide hydrolase enzyme, QOR: NAD(P)H quinone oxidoreductase, UGTs: UDP-glucuronosyltransferase enzymes, γGCS: γ-glutamylcysteine synthase enzyme, GSH: glutathione, and GSTs: glutathione-S-transferase enzymes.

Enzymes from each of the five families modify xenobiotics in a specific way (Hardman and Limbird et al., 1996) (Figure 1). Cytochrome P450 enzymes catalyze a monooxygenation reaction by inserting one atom of molecular oxygen into the xenobiotic compound while the other oxygen atom is reduced to water. Microsomal epoxide hydrolase catalyzes the addition of water to alkane epoxides, which are commonly produced during cytochrome P450 reactions. QOR catalyzes the two-electron reduction of quinones by oxidation of NAD(P)H. GSTs catalyze conjugation of xenobiotic compounds with the tripeptide, glutathione. An

adequate supply of glutathione is critical for conjugation. The rate-limiting step in the production of glutathione is catalyzed by γ-GCS. UGTs conjugate xenobiotic compounds with a sugar acid moiety from the cosubstrate UDP-glucuronic acid (Dutton, 1980).

We had three objectives in this study: (1) to determine whether complementary DNA (cDNA) probes for biotransformation enzyme mRNAs in laboratory rats (*Rattus norvegicus*) were homologous to mRNAs in woodrats, (2) to determine detoxification pathways induced by woodrats consuming a natural diet, and (3) to compare levels of biotransformation enzyme mRNAs among populations of woodrats and laboratory rats. We hypothesized that *N. lepida* woodrats should express higher levels of mRNA for biotransformation enzymes compared to laboratory rats because woodrats consume plants with measurable quantities of secondary compounds, whereas laboratory rats consume formulated diets low in toxins.

METHODS AND MATERIALS

Laboratory Rats. Male laboratory rats (Muridae: Murinae: *Rattus norvegicus*: strain Sprague-Dawley; 160–180 g) were obtained from Simonson Laboratories and kept on a 12 hour light dark cycle and given free access to rat chow and water.

Collection of Neotoma. We collected *Neotoma lepida* (Muridae: Sigmodontinae) from two populations in Utah in October 1999. Four individuals were collected from a Mojave Desert habitat near Beaver Dam Wash, Utah (37°06'N, 113°58'W). The other four individuals were trapped in the Great Basin Desert near Jericho, Utah (39°57'N, 112°22'W). From here on, we refer to individuals trapped in the Mojave Desert as Mojave woodrats and those collected in the Great Basin Desert as Great Basin woodrats. For a description of each of these sites, see Dearing et al. (1998). Animals were live-trapped with Sherman traps and dispatched in the field with CO_2. Whole animal body mass was recorded. The liver was removed, weighed, and frozen quickly on dry ice. Samples of liver tissue were brought back to the laboratory for total RNA isolation.

Total RNA Isolation and Northern Blot Analysis. Total RNA was isolated from approximately 100 mg of frozen liver tissue by homogenization in 2 ml TRIzol (phenol–guanidine isothiocyante) reagent (Giboco/BRL) and isopropyl alcohol precipitation of the aqueous layer following chloroform treatment. Twenty micrograms of total RNA from each sample (concentration of total RNA was determined from 260 nm absorbance) was subjected to electrophoresis in 1% denaturing agarose gel containing formaldehyde. Sample integrity was determined by visualization of sharp 18S and 28S bands with ethidium bromide. Total RNA was transferred to a Nytran membrane (Schleicher and Schuell) by downward

[a] The Genbank account numbers and approximate region of the cDNA are given.

alkaline transfer, cross-linked with UV light, and hybridized with cDNA probes labeled with [α-^{32}P]dCTP by random primed synthesis (Amersham Multiprime) according to the manufacturer's specifications. The rat cDNA probes used are given in Table 1.

Hybridized blots were washed twice for 30 min at 42°C in 2× SSC, 0.1% SDS, twice for 30 min at 42°C in 0.1× SSC, 0.1% SDS, and once for 45 min at 54°C in 0.1× SSC, 0.1% SDS. Autoradiographic film was exposed for 6–72 hr at −70°C with an intensifying screen, and the developed band intensity was determined by scanning densitometry with Molecular Analyst (Bio-Rad) software. To remove any effects of gel loading and transfer variations, all mRNA bands were normalized to a housekeeping gene, cyclophilin mRNA, in the same sample. Plasmids containing the cDNA probes were provided by Dr. J. Ritter, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia.

Statistics. Statistical analyses were performed by using ANOVA, followed by Fisher's multiple range test.

RESULTS

cDNA Probes. In general, cDNA probes generated from mRNAs for rat biotransforming enzymes gave good results when used on woodrat livers (Figure 2). All probes gave bands that were similar in size to mRNA bands from laboratory rats, with the exception of UGT2B1, where a larger transcript was detected in woodrat samples (Figure 2).

mRNAs for Detoxification Enzymes. Levels of mRNAs varied between woodrats and lab rats and among woodrats. In eight mRNAs tested, there were significant differences between woodrats and laboratory rats and among woodrats, but no consistent pattern in levels of mRNAs emerged. We found no difference in

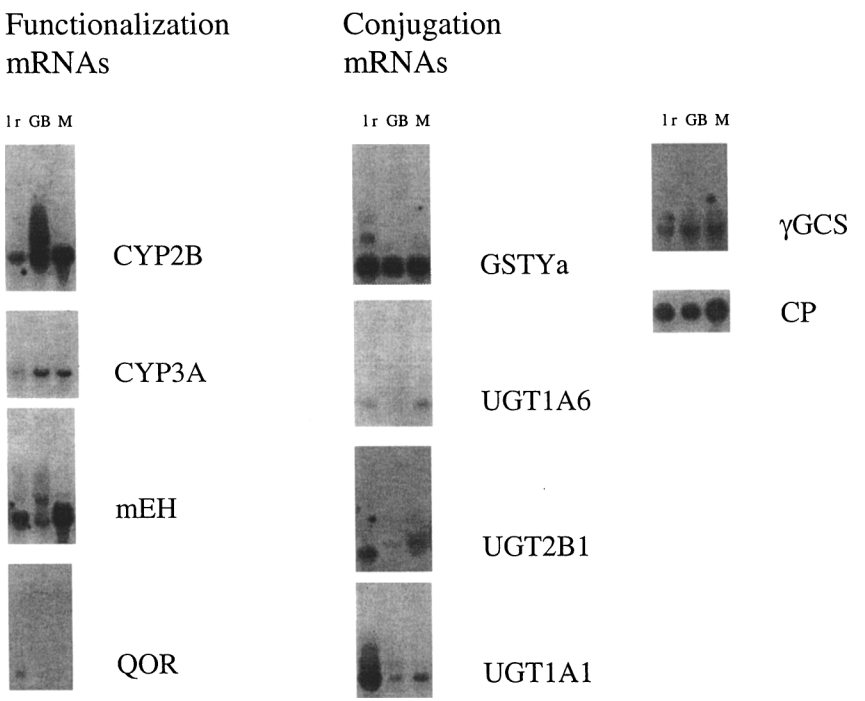

FIG. 2. Northern blots of liver mRNAs. Representative results are shown for each sample. Membranes were probed with the indicated ^{32}P-labeled cDNA probes (see Table 1) for each xenobiotic biotransformation enzyme. Membranes were also probed with ^{32}P-labeled cDNA for cyclophilin to compensate for gel loading and transfer variations. Band order is shown as laboratory rats (lr), Great Basin woodrats (GB), and Mojave woodrats (M).

mRNA levels for two of 10 mRNAs across the three animal groups tested. Details of the results for each mRNA are presented in the following sections.

mRNAs for Functionalization Enzymes. Among functionalization enzyme mRNAs, significant differences were present in mRNA levels for CYP2B and CYP3A. The level of mRNA for CYP2B was greater in Great Basin woodrats compared to Mojave woodrats and laboratory rats (Figure 3). Both populations of *N. lepida* had elevated levels of mRNA for CYP3A in comparison to laboratory rats. There was no detectable message for CYP1A1 in woodrat populations or laboratory rats (data not shown). The level of mEH mRNA was lower in Great Basin woodrats compared to laboratory rats and Mojave woodrats. The level of QOR mRNA was lower in Mojave woodrats than laboratory rats and Great Basin woodrats (Figure 3).

mRNA for γ-GCS and Conjugation Enzymes. The level of mRNA for γ-GCS differed among groups (Figure 4). Mojave *N. lepida* populations had higher

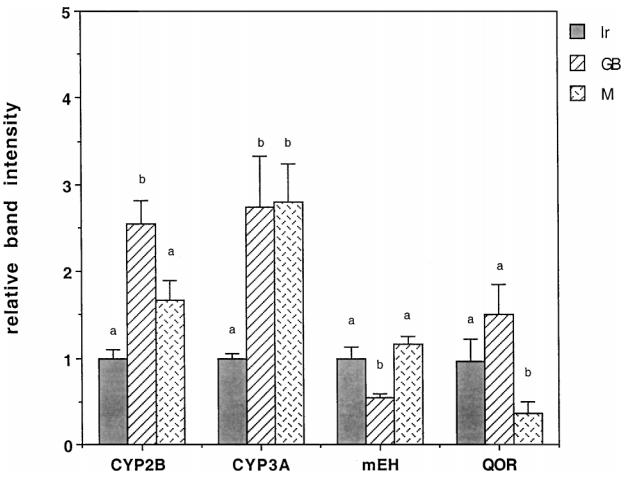

FIG. 3. Mean band intensities ± SE of northern blot analysis for functionalization enzyme mRNAs. Sample sizes were $N = 4$ for laboratory rats (lr), Great Basin woodrats (GB), and Mojave woodrats (M). Relative band intensities were normalized to laboratory rats. Different letters indicate significant differences among groups.

levels of γ-GCS compared to laboratory rats, but the difference between Great Basin woodrats and laboratory rats was not statistically significant. The Mojave population had γ-GCS levels five times that of laboratory rats and two times that of the Great Basin population. There was no difference in levels of mRNA for the GSTYa among woodrats and laboratory rats (Figure 4).

We found differences among animal groups with respect to mRNAs for glucuronic acid conjugation enzymes (Figure 4). Mojave woodrats had significantly higher levels of UGT1A6 mRNA compared to Great Basin woodrats and laboratory rats. Levels of mRNA for UGT1A6 were not significantly different between laboratory rats and Great Basin woodrats. Levels of mRNA for another glucuronidation enzyme, UGT2B1, showed the opposite pattern. Both populations of *N. lepida* exhibited significantly lower levels of mRNA for UGT2B1 compared to laboratory rats. Levels of UGT1A1 mRNA were also significantly lower in both *N. lepida* woodrat species compared to laboratory rats (Figure 4).

DISCUSSION

More than 25 years ago, Freeland and Janzen (1974) integrated the fields of pharmacology and ecology to generate numerous hypotheses on how herbivorous mammals cope with toxins in plants. Since then, diverse analytical techniques have been developed to understand the biotransformation pathways through which drugs

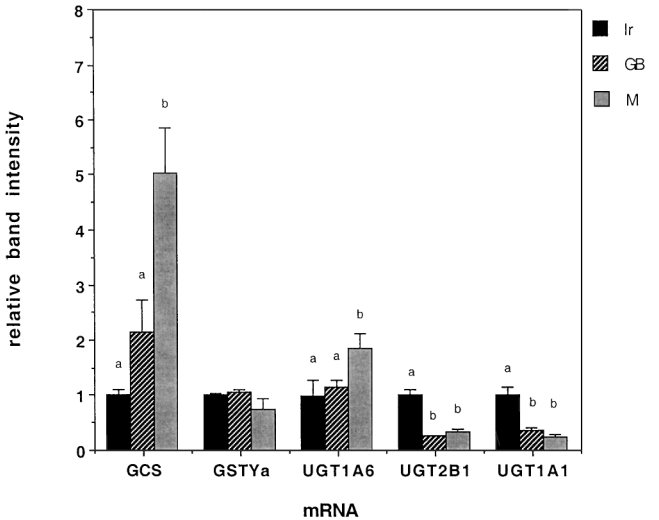

FIG. 4. Mean band intensities ± SE of northern blot analysis for γGCS and conjugation enzyme mRNAs. Sample sizes were $N = 4$ for laboratory rats (lr), Great Basin woodrats (GB), and Mojave woodrats (M). Relative band intensities were normalized to laboratory rats. and other xenobiotics are processed. Few of these techniques have been applied to studies of wild mammalian herbivores. A primary objective of our research was to join pharmacological knowledge and techniques to ecological questions of how wild herbivores detoxify secondary compounds in plants. Our results demonstrate that these approaches can be fruitful.

Use of cDNA Probes from Laboratory Rats in Woodrats. Overall, cDNA probes designed for detoxification mRNAs in laboratory rats gave good results in woodrats. Total RNA isolated from livers of woodrats and probed with cDNA for 10 biotransformation mRNAs of laboratory rats yielded bands of similar sizes to those found in laboratory rats (with the exception of UGT2B1). These results suggest that although laboratory rats and woodrats are different species, the sequences of their respective biotransforming enzyme mRNAs have been conserved. In the future, it would be valuable to have cDNA probes for the various biotransforming enzymes from *Neotoma* species. Knowledge of the exact DNA sequence of a specific biotransforming enzyme may yield valuable information on the evolution of detoxification systems (Lewis et al., 1998).

UGT2B1 did not yield results comparable to the other cDNA probes. The probe for UGT2B1 indicated a longer mRNA in woodrats than in laboratory rats. This result suggests that the mRNA for UGT2B1 in woodrats differs slightly from that of laboratory rats but is similar enough to hybridize to the probe.

Messenger RNA for CYP1A1 was not detected in either woodrat population. The CYP1A1 gene in woodrats may be significantly different from that of laboratory rats and, thus, was not detected by the probe for laboratory rats. This outcome, however, is unlikely given that species such as trout, which are more distantly related to laboratory rats than woodrats, exhibit a high degree of sequence similarity for CYP1A1 to laboratory rats (Heilman et al., 1988). It is more probable that levels of CYP1A1 mRNA in woodrats are undetectable, given that laboratory rats constitutively express CYP1A1 mRNA at low to undetectable levels.

mRNA for Functionalization Enzymes. The greater levels of mRNA for CYP2B in Great Basin woodrats compared to Mojave woodrats and laboratory rats may be attributable to high concentrations of α-pinene and/or other terpenes in the diet of Great Basin woodrats. α-Pinene is an abundant secondary compound in *Juniperus osteosperma*, the primary plant in the diet of Great Basin woodrats (Adams et al., 1981; Mangione, 1999; Mangione et al., 2000). This compound is not present in rat chow and occurs in low quantities in the diet of Mojave woodrats (Karasov, 1989; Mabry et al., 1977). In other studies, administration of α-pinene to laboratory rats increased quantities of the enzyme (P4502B) produced by CYP2B mRNA (Austin et al., 1988; Hiroi et al., 1995). The doses used in these experiments are comparable to those ingested by Great Basin woodrats in their natural diet (Dearing, personal observation). Thus, the elevated CYP2B mRNA in the Great Basin woodrats may be a response to α-pinene in its diet.

Both populations of woodrats had elevated levels of CYP3A mRNA compared to laboratory rats. In humans, the enzyme produced by CYP3A mRNA is responsible for the metabolism of over 60% of known pharmaceutical compounds (Gonzalez, 1989). Treatment of laboratory rats with essential wood oils, which are primarily terpenes, increased levels of the enzyme (P4503A) produced by CYP3A mRNA (Hiroi et al., 1995). It is plausible that the high levels of CYP3A mRNA in both populations of woodrats are induced by and required for detoxification of secondary compounds in their diets.

Neotoma lepida did not show higher levels of mEH and QOR mRNAs and in certain cases exhibited significantly lower levels than laboratory rats. The results imply that although both mEH and QOR mRNAs are subject to transcriptional induction by xenobiotic compounds (Hankinson, 1995; Daniel, 1993), the diets of *N. lepida* populations did not induce these two mRNAs.

Differences in Expression Levels of mRNA for Conjugation Enzymes. Conjugation with glutathione appears to be an important detoxification pathway for Mojave woodrats. Glutathione, a tripeptide thiol, is highly concentrated in liver cells (up to 10 mM) and is important in maintaining cellular redox status and metabolic and oxidative detoxification reactions. Synthesis of glutathione is rate-limited by the enzyme produced from γ-GCS mRNA (Packer, 1995). Mojave woodrats expressed significantly more γ-GCS mRNA than laboratory rats and Great Basin woodrats. However, there were no differences among woodrats and

laboratory rats in levels of mRNA GSTYa, which produces an enzyme that conjugates glutathione to xenobiotics. It is possible that the observed levels of GSTYa in woodrats produced sufficient quantities of enzyme for glutathione conjugation. In addition, there are several other forms of GST enzymes (GST μ and π) (Daniel, 1993) that we did not assay in this study. Thus, woodrats may be using other forms of GST enzymes for glutathione conjugation.

Conventional wisdom does not predict that mammalian herbivores would utilize glutathione (a tripeptide) as a primary detoxification pathway because nitrogen is typically a limiting resource to herbivores. Excretion of toxins conjugated to glutathione could result in marked losses of nitrogen. Utilization of the biochemically costly glutathione pathway by *N. lepida* suggests several intriguing possibilities. The amino acids in glutathione may not be limiting to *N. lepida*. If they are, the loss of amino acids can be minimized by recovering some of them in glutathione through transformation to mercapturic acids by kidney and intestinal γ-glutamyltransferase activity (Hardman and Limbird, 1996). Lastly, detoxification of the secondary compounds found in the diet of Mojave woodrats may be restricted to the glutathione pathway. Thus, elevated losses of glutathione may represent a biochemical cost of consuming plants containing toxins that can only be detoxified via the glutathione pathway. Further study of the use and costs of the glutathione pathway in Mojave woodrats is warranted.

It was interesting that both *N. lepida* populations expressed lower levels of mRNAs for two UGT mRNAs (UGT2B1 and UGT1A1) than laboratory rats. These two UGTs conjugate glucuronic acid to a number of plant secondary compounds common in the diets of *N. lepida*. UGT1A1 glucuronidates opiate alkaloids, while UGT2B1 conjugates "bulky" toxins, such as certain monoterpenes and phenolics (King et al., 1997). Several studies indicate that the glucuronic pathway is used extensively by woodrats (Mangione, 1999; Mangione et al., 2000). Mangione (1999) found that glucuronide conjugates comprised $\sim$70% of the conjugates examined in the urine of *N. lepida*. The *N. lepida* used by Mangione (1999) were obtained from the same site in the Mojave as this study and were fed creosote resin, a mixture of secondary compounds present in their natural diet. Our results in conjunction with those from the literature (Mangione, 1999; Mangione et al., 2000) suggest that *N. lepida* utilize UGTs other than UGT2B1 and UGT1A1 for glucuronidation. There are $\sim$19 different cDNA sequences for rat UGT enzymes (Mackenzie et al., 1997), and we have probed only for three.

Mojave woodrats did express slight but significantly higher levels of one UGT (UGT1A6) than either Great Basin woodrats or laboratory rats. The UGT1A6 enzyme metabolizes planar aromatic compounds (Jackson et al., 1988). The leaves of the creosote bush, a major component of the diet of Mojave woodrats, are coated with a resinous mixture of flavonoids and phenolics that can comprise up to 25% of the dry weight of the leaves (Mabry et al., 1977). It is possible that an increased

level of UGT1A6 expression is used to metabolize phenolic compounds in the diets of Mojave woodrats.

Detoxification in Woodrats and Laboratory Rats. The battery of detoxification enzymes used by woodrats differs from that in laboratory rats. Administration of phenobarbital to laboratory rats simultaneously induces CYP2B, mEH, and UGT2B1 mRNAs (Fujii-Kuriyama et al., 1981; Mackenzie, 1986; Porter et al., 1986). Great Basin woodrats exhibited high levels of CYP2B but had low expression of mEH and UGT2B1.

The pattern of mRNA expression in Mojave woodrats also differed from that of laboratory rats. In laboratory rats fed polycyclic aromatic hydrocarbons, transcription of UGT1A6 in the liver generally increases in concert with CYP1A1, GSTYa, and QOR (Hankinson, 1995). Mojave woodrats expressed slightly but significantly greater levels of UGT1A6 mRNA than Great Basin woodrats and laboratory rats. However, levels of GSTYa and QOR in Mojave woodrats were lower than or equal to those found in laboratory rats and Great Basin woodrats.

We propose two explanations for the differing patterns of functionalization and conjugation mRNAs in Great Basin and Mojave woodrats and laboratory rats. It is possible that the compounds woodrats consume in the wild are not processed through the same battery of enzymes as the drugs that have been given to laboratory rats. Alternatively, differences may be due to disparate constitutive expression of genes required to detoxify the various secondary compounds present in their typical diets. We plan to compare the detoxification series of laboratory rats and woodrats administered the same compound to distinguish between these two alternatives.

CONCLUSIONS

To our knowledge, this study is the first to examine biotransformation enzyme mRNAs of wild herbivores by using cDNA probes designed for laboratory rats. Overall, our results indicate that mRNA for biotransformation enzymes in woodrats and laboratory rats is similar enough that cDNA probes designed for laboratory rats work on woodrats. Our results also suggest that there are substantial differences in expression of biotransformation enzyme mRNAs between laboratory rats and woodrats and among populations of woodrats. Although more research is necessary to adequately address the ideas presented in this paper, the work provides a framework for future research.

Acknowledgments—We thank Drs. Michael Franklin, Gerald Yost, and Rebecca Boyle for editorial comments on this manuscript. We are grateful to Michael Bastiani for assistance in woodrat capture. (Received July 31, 2000; accepted January 12, 2001)

Abstract—A strain of the fungus *Fusarium equiseti* isolated from soybean cyst nematode secretes nematode-antagonistic compounds. Bioassay-guided fractionation of an extract of the culture broth was undertaken to identify the compounds. Fractions were assayed for activity against a root-knot nematode (*Meloidogyne incognita*), a plant pathogen that attacks the roots of numerous plant species. Two trichothecene compounds were isolated that inhibited egg hatch and immobilized second-stage juveniles of this nematode: 4,15-diacetoxy-12,13-epoxy-3,7-dihydroxytrichothec-9-en-8-one (4,15-diacetylnivalenol) and 4,15-diacetoxy-12,13-epoxy-trichothec-9-en-3-ol (diacetoxyscirpenol). This is the first published report of these compounds affecting plant-parasitic nematodes.

Key Words—*Fusarium equiseti*, fungus, *Meloidogyne incognita*, root-knot nematode, trichothecene, nematicide, 4,15-diacetoxy-12,13-epoxy-3,7-dihydroxytrichothec-9-en-8-one, 4,15-diacetoxy-12,13-epoxytrichothec-9-en-3-ol, 4,15-diacetylnivalenol, diacetoxyscirpenol.

INTRODUCTION

Certain strains of *Fusarium* fungi, when grown in laboratory cultures, secrete compounds that are toxic to plant-feeding nematodes (Mani and Sethi, 1984; Meshram

[*]To whom correspondence should be addresssed.

[1]Mention of trade names or commercial products in this publication is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the US Department of Agriculture.

and Goswami, 1989; Hallman and Sikora, 1996; Nitao et al., 1999). The presence of these compounds is manifested by the inhibition of egg hatch or the immobilization of juvenile nematodes in culture broth filtrates; however, the precise identities of the nematode-antagonistic compounds generally are undetermined. In one of the few examples where structures were partially characterized, Mani et al. (1986) determined that a mixture of long-chain alkanes was responsible for the toxicity of *Fusarium solani* cultures to the root-knot nematode, *Meloidogyne incognita*, a major pathogen that attacks hundreds of crop and ornamental plant species. Although not isolated specifically from a nematode-antagonistic fungus strain, several commercially available mycotoxins commonly produced by *Fusarium* species were tested and found to be nematicidal to *Meloidogyne javanica* at low concentrations (Ciancio, 1995).

Identification of nematode-antagonistic compounds from *Fusarium* species is important for at least three reasons. First, nematode-antagonistic compounds potentially can be used to manage nematode pathogens (Jatala, 1986). Natural products from fungi and bacteria are being sought as alternatives to the use of fumigant and nonfumigant nematicides. Second, in studies searching for biological control agents of pathogenic nematodes, *Fusarium* strains are frequently isolated from nematodes or their egg masses (Qadri and Saleh, 1990; Hay and Skipp, 1993; Oduor-Owino and Waudo, 1996; Chen et al., 1996; Viaene and Abawi, 1998). Identifying the nematode-antagonistic compounds produced by these fungi would help determine if such compounds contribute to the detrimental effects of these antagonists. Third, although it is unknown if compounds produced by *Fusarium* in vitro play a role in natural interactions between fungi and plant-parasitic nematodes, identification of nematode-antagonistic compounds can be the first step toward examining such interactions in future studies.

As part of a study searching for biological control agents, the culture broths of over 250 fungi isolated from soybean cyst nematodes (*Heterodera glycines* Ichinohe) were screened for nematode-antagonistic activity (Meyer et al., 1998). *Fusarium* species were common among those isolates producing broth filtrates that inhibited in vitro egg hatch of soybean cyst nematode and root-knot nematode, *M. incognita*. One of these strains, an isolate of *Fusarium equiseti*, was especially active against *M. incognita* (Nitao et al., 1999), and bioassay-guided isolation of culture broth constituents that caused the nematode-antagonistic activity was undertaken. We report herein the isolation and structure of two *F. equiseti* metabolites responsible in part for inhibiting in vitro egg hatch and juvenile mobility of *M. incognita*.

METHODS AND MATERIALS

Root-knot Nematode Bioassay. Bioassays were conducted in vitro as described previously (Nitao et al., 1999). Eggs were obtained from *Meloidogyne*

incognita (Kofoid & White) Chitwood cultured on tomato plants and were surface-disinfested with 0.5% sodium hypochlorite (Nitao et al., 1999). Eggs were placed in 24-well tissue culture plates with sterile-filtered test solutions. Test compounds were solubilized in DMSO before mixing in water (final concentration: 0.5% DMSO). Control solution was 0.5% DMSO in water. After seven days, the number of hatched second-stage juveniles and the numbers of those juveniles that were mobile and immobile were recorded. The percentage of eggs that hatched and the percentage of juveniles that were mobile were calculated. Each bioassay trial consisted of five replicate wells per treatment (200–280 eggs/well).

Differences in egg hatch and juvenile mobility between test and control solutions were tested with one-way analysis of variance (ANOVA) followed by Dunnett's test to compare each treatment against the control. When two trials were conducted for each set of treatments, results from individual trials were observed to be normally distributed with equal variances. Pooling of data from trials resulted in nonnormality and/or unequal variances that could not be corrected by standard transformations. This indicated that combining data sets would be inappropriate. Therefore, data from trials were analyzed separately, but for brevity, means and standard errors are reported on pooled data since the pattern of means was similar among trials. Kruskal-Wallis test on ranks was used when results from one bioassay trial did not satisfy assumptions of normality and homogeneous variances.

Fungus Culture. *Fusarium equiseti* was isolated from soybean cyst nematode females (*Heterodera glycines*) collected in the People's Republic of China in cooperation with Dr. Xing-Zhong Liu (Chinese Academy of Agricultural Sciences) and was identified by Dr. Jean Juba (Fusarium Research Center, Pennsylvania State University) and Dr. Richard Humber (USDA, ARS, Plant Protection Unit, New York) (Meyer et al., 1998). The fungus was deposited and is maintained in the USDA, ARS, Nematology Laboratory, Beltsville, Maryland, as isolate L128. The fungus was grown on potato–dextrose agar for seven days at 25°C. One-liter Erlenmeyer flasks containing 250 ml potato–dextrose broth were inoculated by blending agar plate cultures into the broth. Broth cultures were incubated for three days on a shaker (240 rpm, 25°C).

Isolation of Nematode-Antagonistic Compounds. After incubation, the cultures were centrifuged, and the broth was filtered through a glass-filter funnel. A total of 18.75 liters of broth was processed in six batches. The broth filtrate was extracted by mixing for 2 hr with Amberlite XAD-16 resin equilibrated in H_2O (1 volume gel–6 volumes broth). The resin was removed from the broth, washed with 2.5 bed volumes H_2O, and eluted with 2.5 bed volumes methanol (MeOH). The MeOH eluate was evaporated under vacuum, and the residue (5.1 g) was partitioned in 7% MeOH in H_2O and ethyl acetate (EtOAc). Earlier studies demonstrated that the nematode-antagonistic activity resided in the EtOAc fraction after partitioning (Nitao et al., 1999).

After evaporating to dryness, the EtOAc fraction (0.68 g) was separated in batches of 70–430 mg by using vacuum liquid chromatography (VLC) (silica gel, Merck grade 9385) and eluted with 100% EtOAc followed by MeOH. Five 25-ml EtOAc fractions and one 50-ml MeOH fraction were collected. VLC fractions from one of these batches were bioassayed at 100 μg/ml in one trial (5 replicates).

The first two VLC EtOAc fractions and equivalent fractions from other VLC batches were combined after examining with thin-layer chromatography (TLC). Silica gel plates were developed in 100% EtOAc or 20 : 1 chloroform–methanol ($CHCl_3$–MeOH); C_{18} plates were developed in 70% acetonitrile in H_2O. Spots were visualized by 50% sulfuric acid spray and charring. The pooled VLC fraction (97 mg) was subjected to medium pressure liquid chromatography (MPLC) (silica gel, Merck, grade 9385). A step gradient (80 : 1, 40 : 1, 20 : 1, and 10 : 1 $CHCl_3$–MeOH, and 100% MeOH) was used to elute 21 fractions, and fractions were combined into nine fractions based on TLC. Of these pooled fractions, the five fractions eluted with 40 : 1 and 20 : 1 $CHCl_3$–MeOH had masses substantial enough for bioassay and further processing and were assayed at 50 μg/ml in two trials (five replicates per trial).

Nematode-antagonistic compounds were purified from MPLC fractions with high-performance liquid chromatography (HPLC) (10 $\times$ 250 mm Alltima C_{18} column, Alltech, Deerfield, Illinois; acetonitrile–H_2O gradient, 2 ml/min, 214 nm detection). Purified compounds were bioassayed at 25 μg/ml (two trials; five replicates per trial).

Identification of Compounds. Compounds were identified by mass spectrometry, NMR spectroscopy, and X-ray crystallography. ^{1}H NMR and ^{13}C NMR spectra were acquired in $CDCl_3$ on a Bruker QE 300-MHz spectrometer; chemical shifts are relative to $CDCl_3$. Mass spectra (EI, CI using NH_3) were obtained on a Finnegan INCOS 50 mass spectrometer and Finnegan MAT solid probe. X-ray crystallography was performed on a crystal obtained from aqueous CH_3CN. A colorless crystalline plate (0.43 $\times$ 0.06 $\times$ 0.03 mm) was optically centered on a Bruker SMART1000 single crystal CCD diffractometer. The SAINT+ data reduction program (Bruker Analytical X-ray Systems, Madison, Wisconsin) with 2θ max set to 55.0° was implemented to correct for Lorentz and polarization effects. An empirical absorption correction was applied to 11,861 reflections ($\pm h \pm k \pm l$) with 3328 being unique [R(int) = 0.0399] based upon equivalent reflection measurements using Blessing's method (Blessing, 1995) in the program SADABS (Sheldrick, 1996). The XPREP program (Sheldrick, 1994) was implemented to determine the space group and generate the initial files. The structure was determined by direct methods with the program XS (Sheldrick, 1990) and resulted in the successful location of many atoms comprising the molecule. Full-matrix least-squares refinement with the program XL (Sheldrick, 1993) coupled with difference-Fourier maps was used to locate, input, and complete the configuration of the nematode-antagonistic molecule and an accompanying water molecule.

Hydrogen atoms were placed initially in calculated positions and then allowed to refine freely; those hydrogen atoms comprising the water molecule were located directly from a difference-Fourier map and allowed to refine freely.

RESULTS

Isolation of Nematode-Antagonistic Compounds. Fractions from VLC had a significant effect on egg hatch when tested at 100 μg/ml (ANOVA, $P < 0.001$) (Figure 1). The proportion of eggs that hatched was lower in each fraction compared to the proportion in the control solution (Dunnett's test, $P < 0.05$). Egg hatch in VLC fractions 1 and 5 was 90% lower than that in the control. Of those juveniles that hatched, the percentage that was mobile also was affected by the *Fusarium* fractions (Kruskal-Wallis test, $P < 0.001$). The proportion of juveniles mobile in the fractions eluted with EtOAc (VLC fractions 1–4) was lower than in the control (Dunnett's test, $P < 0.05$). All or almost all of those juveniles that hatched in these fractions were immobile. However, mobility was not reduced by the MeOH fraction (VLC fraction 5) (Dunnett's test, $P > 0.05$).

Combined VLC fractions 1 and 2 were chosen for further separation on MPLC due to their relatively higher activity against both hatch and mobility and the larger

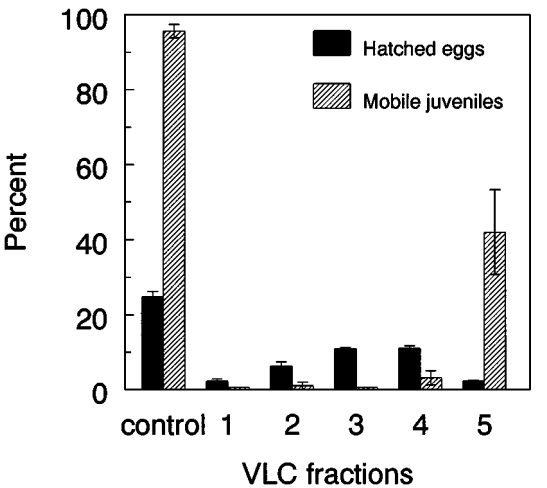

FIG. 1. Percentage of *Meloidogyne incognita* eggs hatched and percentage of hatched juveniles that were mobile after one week in vacuum liquid chromatography (VLC) fractions of *Fusarium equiseti* culture broth. VLC fractions 1–4 were eluted with ethyl acetate; fraction 5 was eluted with methanol. Fractions were tested at a concentration of 100 μg/ml. Data are mean $\pm$ SE of five replications in one trial (230 eggs/replicate).

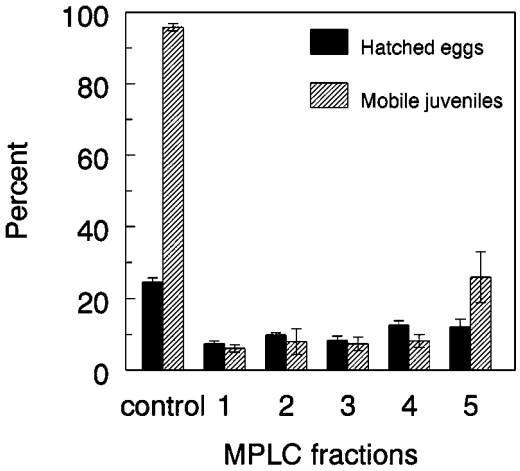

FIG. 2. Percentage of *Meloidogyne incognita* eggs hatched and percentage of hatched juveniles that were mobile after one week in medium-pressure liquid chromatography (MPLC) fractions of *Fusarium equiseti* culture broth. MPLC was performed on combined VLC fractions 1 and 2. Fractions were tested at a concentration of 50 μg/ml. Data are mean $\pm$ SE of 10 replications in two trials (250 and 280 eggs/replicate).

available quantity. In both bioassay trials of MPLC fractions, hatch and juvenile mobility were lower in each MPLC fraction than in the control when tested at 50 μg/ml (ANOVA, $P < 0.001$; Dunnett's test, $P < 0.05$) (Figure 2). Hatch was reduced 25–40% by the fungus fractions compared to hatch in the control solution, and the proportion of juveniles that were mobile was as much as 94% lower.

A major component contained in MPLC fractions 1–3 was purified by HPLC and crystallized (6 mg). X-ray crystallography revealed the crystal unit cell to consist of one molecule of 4,15-diacetoxy-3,7-dihydroxy-12,13-epoxytrichothec-9-en-8-one (4,15-diacetylnivalenol) and one water molecule in proximity to the epoxide group (Figure 3). Crystal data: monoclinic; $C_{19}H_{26}O_{10}$; $[C_{19}H_{24}O_9][H_2O]$; FW = 414.40; space group = $P2_1$; unit cell dimensions: $a = 10.4225(13)$ Å, $b = 7.7034(10)$ Å, $c = 11.9740(15)$ Å, $\beta = 100.072(2)^\circ$; $V = 946.6(2)$ Å^3; $Z = 2$; $D_x = 1.454$ g/cm^3; λ(MoKα) = 0.71073 Å; μ(MoKα) = 0.118 mm^1, F(000) = 40, $T = 173(2)$K. The absolute structure parameter (Flack, 1983), Flack(x), was refined to a value of $-1.0(8)$, indicating that while the structure is both correct and complete, its absolute configuration is inconclusive.

The identification of the molecule as 4,15-diacetylnivalenol (Figure 4) was consistent with NMR and MS analyses: ^{1}H NMR: δ 1.10 (3H, s, H-14), 1.90 (3H, br d, H-16), 1.91 (3H, s, H-20), 2.16 (3H, s, H-18), 3.08 (2H, m, H-13), 3.83 (1H, d, H-2), 4.22 (1H, dd, H-3), 4.27 (2H, dd, H-15), 4.73 (1H, d, H-11), 4.88 (1H, s, H-7), 5.23 (1H, d, H-4), 6.64 (1H, m, H-10). ^{13}C NMR APT: δ 7.5 (C-14, CH_3),

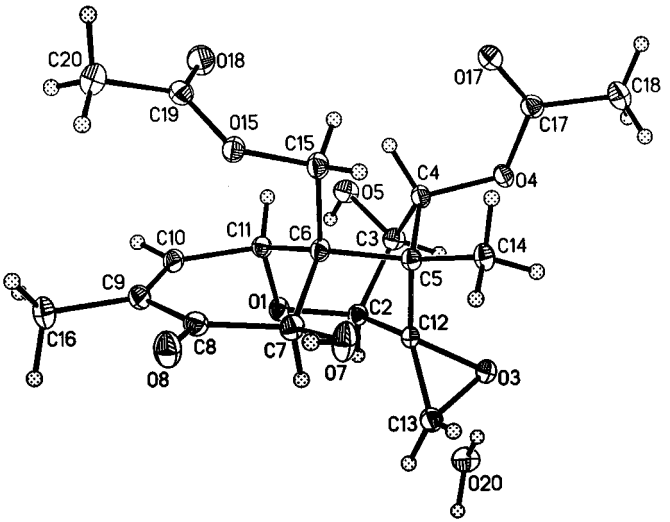

FIG. 3. Oak Ridge Thermal Ellipsoid Plot derived from X-ray crystallography showing the relative conformation of 4,15-diacetylnivalenol. The unit cell of the crystal included one water molecule (O20).

15.2 (C-16, CH_3), 20.6 (C-18, CH_3), 21.0 (C-20, CH_3), 46.1 (C-13, CH_2), 49.4 (C-5, C), 52.2 (C-6, C), 61.8 (C-15, CH_2), 64.3 (C-12, C), 69.3 (C-11, CH), 135.8 (C-9, C), 73.2 (C-7, CH), 78.4 (C-3, CH), 79.7 (C-2, CH), 83.5 (C4, CH), 138.3 (C-10, CH), 170.0 (C-17, C=O), 172.6 (C-19, C=O), 198.9 (C-8, C=O). EI-MS, *m*/*z* (rel. int.): 396 (1) $[M]^+$, 336 (6), 294 (9), 247 (10), 217 (10), 189 (30), 179 (100), 125 (37), 98 (53), 77 (57), 55 (48). CI-MS, *m*/*z*: 414 $[M + NH_4]$.

A second compound (3 mg) was purified from MPLC fraction 1. Based on NMR analysis, this compound was structurally similar to 4,15-diacetylnivalenol, but the hydroxyl group at C-7 and the carbonyl at C-8 were each replaced by

4,15-Diacetylnivalenol, diacetoxyscirpenol, and a third unidentified compound (2 mg) isolated from MPLC fraction 3 decreased egg hatch and juvenile mobility in both trials when tested at 25 μg/ml (ANOVA, $P < 0.001$; Dunnett's test, $P < 0.05$) (Figure 5). Egg hatch was reduced by approximately 40% compared to that in the control. The number of juveniles still mobile after hatching in

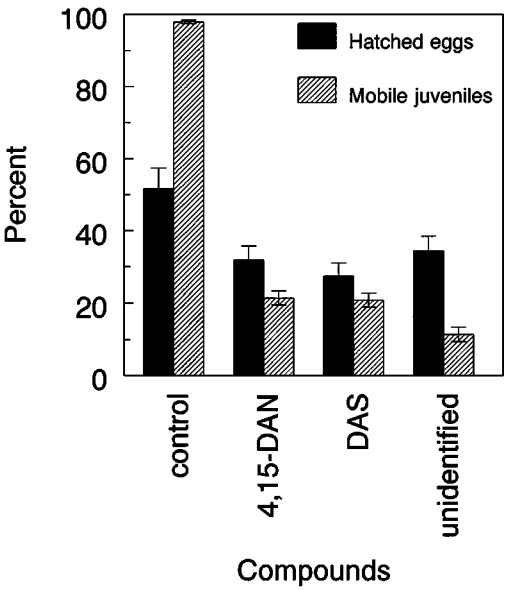

FIG. 5. Percentage of *Meloidogyne incognita* eggs hatched and percentage of hatched juveniles that were mobile after one week in compounds purified from *Fusarium equiseti* culture broth. Fractions were tested at a concentration of 25 μg/ml. 4,15-DAN = 4,15-diacetylnivalenol; DAN = diacetoxyscirpenol. Data are mean $\pm$ SE of 10 replications in two trials (200 and 250 eggs/replicate).

the test compounds was reduced by approximately 80% relative to the number in the control solution.

DISCUSSION

4,15-Diacetylnivalenol and diacetoxyscirpenol are trichothecenes, an important group of tricyclic sesquiterpene mycotoxins that inhibit protein synthesis and are commonly produced by *Fusarium* species (Sweeney and Dobson, 1998). These two compounds were first identified from *F. equiseti* as phytotoxins (Brian et al., 1961; Dawkins et al., 1965) but occur in a number of other *Fusarium* species (De Nijs et al., 1996). The broad-spectrum biological activity of diacetoxyscirpenol (DAS) has been especially well documented (Beasley, 1989); however, this is the first published report of activity against plant-parasitic nematodes for either compound.

The similarity in bioactivity between 4,15-diacetylnivalenol and diacetoxyscirpenol suggests that common structural elements are involved in their nematode-antagonistic activity. The C-7 hydroxyl group and the C-8 carbonyl group are not required for this activity, which suggests a hydrophilic binding site including the oxygens on C-3, C-4, and C-13 in a rigid conformation. The importance of these oxygens for biological activity is consistent with trichothecene structure–activity relationships known for protein synthesis inhibition and anticancer activity (Beasley, 1989). The X-ray data, which is the first such published analysis for 4,15-diacetylnivalenol, suggest a labile hydrophilic binding site could also occur that involves the two acetate groups. The acetate group attached to C-15 folds over the six-membered ring such that the C-16 and C-20 methyl groups are spatially close to each other, bringing the acetate carbonyl close to the C-9 double bond and the O-1 oxygen. The acetate group on C-15 along with that on C-4 is also involved in anticancer activity (Beasley, 1989). The hydrophobic portion of the molecule C-5, C-6, C-7, C-8 is structurally and/or conformationally different between the two compounds and appears not to be involved in nematode-antagonistic activity.

Nematode-antagonistic activity against *M. incognita* was detected in many different fractions during bioassay-guided isolation, indicating that compounds in addition to 4,15-diacetylnivalenol and diacetoxyscirpenol are contributing to the activity of the culture broth. Some of these other compounds, as well as the third nematode-antagonistic compound that was purified but unidentified, could also be trichothecenes, as *F. equiseti* is reported to produce at least four other trichothecenes (De Nijs et al., 1996). One of these, T-2 toxin, has been shown to be nematicidal to *Meloidogyne javanica* (Ciancio, 1995). Despite the predisposition of *Fusarium* species to produce mycotoxins, this should not discourage further investigation of *Fusarium* cultures to find useful natural products with a narrower activity range. Screening procedures to exclude broad-spectrum mycotoxins would increase efficiency of a search for nematode-antagonistic compounds.

It is not known if trichothecenes produced by *Fusarium* strains that parasitize plant nematodes play a role in interactions between fungi and nematodes under natural conditions. Enzymes secreted by parasitic fungi are known to help colonization of nematode eggs by penetrating the egg shell (Segers et al., 1991), but the contribution of nonenzymatic toxins to the success of parasitism has not been studied. If the biology of microbial colonization of insects is an appropriate analogy, then such a contribution would be probable. *Photorhabdus* bacteria that are released into insect hosts by entomophagous nematodes secrete toxins that kill the host and inhibit colonization of the carcass by competing microbes (Bowen et al., 1998). As *Fusarium* species are commonly found in soil environments, there should be ample opportunities for these fungi and their secondary metabolites to interact with root-feeding nematodes.

The broad-spectrum toxicity and nonspecific mode of action of trichothecenes indicate that they would be impractical by themselves as chemical control agents of plant nematode pathogens without significant modification. The production of trichothecenes in a strain isolated from a plant-parasitic nematode suggests that if *Fusarium* species are used for biological control, production of mycotoxins by these strains should be evaluated if incidental exposure to humans is a concern. The occurrence of mycotoxins with broad-spectrum toxicity in a potentially beneficial strain does not automatically preclude use of that fungus for biological control since artificial selection may eliminate or reduce mycotoxin production in that strain. On the other hand, should trichothecenes and other mycotoxins be found to enhance efficacy of parasitism and biological control, the benefits of their production will have to be balanced against their potential negative side effects.

Acknowledgments—We thank David DeVilbiss and Dr. Andre Raw for mass spectra; Dr. Muralee Nair for helpful comments and advice; and Paula Crowley, Steve Rogers, Rob Lee, and Christina Bennett for maintaining nematode cultures. Fungus collection was supported by funds from the Interagency Biological Control Coordinating Committee; the Agricultural Research Service negotiated this activity as part of the Sino-American Biological Control Laboratory Program.

OLFACTION IN THE QUEENSLAND FRUIT FLY, *Bactrocera tryoni*. I: IDENTIFICATION OF OLFACTORY RECEPTOR NEURON TYPES RESPONDING TO ENVIRONMENTAL ODORS

C. D. HULL* and B. W. CRIBB

(Received April 19, 2000; accepted January 1, 2001)

Abstract—The electroantennogram method was used to investigate the number of distinct olfactory receptor neuron types responding to a range of behaviorally active volatile chemicals in gravid Queensland fruit flies, *Bactrocera tryoni*. Three receptor neuron types were identified. One type responds to methyl butyrate, 2-butanone, farnesene, and carbon dioxide; a second to ethanol; and a third to *n*-butyric acid and ammonia. The receptor neuron type responding to methyl butyrate, 2-butanone, farnesene, and carbon dioxide consists of three subtypes. The presence of a limited number of receptor neuron types responding to a diverse set of chemicals and the reception of carbon dioxide by a receptor neuron type that responds to other odorants are novel aspects of the peripheral olfactory discrimination process.

Key Words—Olfaction, electroantennogram, *Bactrocera tryoni*, Diptera, Tephritidae, receptor type, environmental odorants, carbon dioxide.

INTRODUCTION

Bactrocera tryoni, a serious agricultural pest, has been shown to use environmental odorants in orientation behavior. Solvent extracts of the skin of fruits contain volatile chemicals that stimulate orientation to their source and elicit ovipositor probing and egg-laying (Pritchard, 1969; Eisemann, 1980). Olfactometer experiments have also been used to identify various chemicals that elicit positive orientation of female *B. tryoni* to the source (Eisemann and Rice, 1992). The flies are known to respond to stimulation with carbon dioxide (Rice, 1989; Stange, 1999),

0098-0331/01/0500-0871$19.50/0

which may be part of the ovipositional orientation process. Female *B. tryoni* also respond positively to ammonia (Bateman and Morton, 1981), which may be related to their feeding behavior. From these experiments, we have selected chemicals that have a proven behavioral effect, and therefore must be detectable by the olfactory system, in order to undertake physiological investigations of the olfactory system.

The antennae are the principal organs for detecting olfactory signals in insects. The recording of electrical activity across the whole antenna in response to stimulation with odors is known as an electroantennogram (EAG). An EAG is thought to be the summed receptor potentials of the olfactory receptor neurons (Schneider, 1962), but the exact electrical processes are not known (Park and Hardie, 1998). The electrical potential may result from many "leakage" current loops around individual sensilla. Because an EAG indicates activity of the receptor potentials produced by olfactory receptor neurons, by using mixtures of chemicals the EAG technique can be used to show whether two chemicals are accepted on the same or different receptor neuron types. Such EAG methods have been used to indicate separate receptor neuron types for various chemicals in *Helicoverpa zea* (Lepidoptera) (Christensen et al., 1990), various species of *Glossina* (Diptera) (Den Otter, 1991), *Argyrotaenia velutinana* (Lepidoptera) (Baker and Roelofs, 1976), *Psila rosae* (Diptera) (Guerin et al., 1983a), and *Drosophila* (Diptera) (Borst, 1984). Knowing the number of olfactory receptor neuron types responding to a range of chemicals indicates how specific the receptors neurons are and provides information on how environmental information is processed by the nervous system.

Among the Tephritidae, EAG studies have been used to investigate the chemoreceptor response to plant volatiles for *Rhagoletis pomonella* (Fein et al., 1982; Averill et al., 1988), *Ceratitis capitata* (Light et al., 1988, Hernandez et al., 1996, Cossè et al., 1995), *B. dorsalis* (Light and Jang, 1987), *B. oleae*, and *R. cerasi* (Guerin et al., 1983b). However, none of these studies investigated the potential number of receptor neuron types. In this paper, EAGs are recorded from female *B. tryoni* in order to determine the number and specificity of olfactory receptor neuron types responding to a range of behaviorally significant, environmental odorants. These experiments also serve to increase our understanding of the peripheral processing of nonpheromonal semiochemicals and confirm the usefulness of the EAG technique for studying such processes.

METHODS AND MATERIALS

Insects. Bactrocera tryoni (Froggatt) were cultured at the Department of Entomology, University of Queensland, from flies originally obtained from the Department of Primary Industries, Brisbane, Australia. The larval flies were cultured as per Neale (1989). Adults were given unlimited access to sugar and water and regularly provided with protein hydrolysate. Only gravid flies were selected

for experimentation. Intact flies were wrapped in Blu-tack [Bostik (Australia) Pty Ltd] adhesive to constrain head movements and manipulated so that only the antennae were left protruding. We have found that Blu-tack has no discernible effect on the olfactory system of insects when used in electrophysiological experiments.

Electrophysiological Recording Technique. Ag–AgCl electrodes were used for both recording and indifferent electrodes. They were placed in disposable glass capillaries, about 1 cm from the tip. The glass capillaries, drawn to a point on a vertical pipet puller, were cut to a diameter of about 25 μm at the tip and filled with blowfly saline (Chen and Friedman, 1975).

The indifferent electrode was inserted at the base of the antenna, through the circumantennal sulcus. The recording electrode was inserted in the tip of the funiculus. The electrode output was first transmitted to a preamplifier (Grass P16D microelectrode DC amplifier), then to a differential amplifier (Tektronix 5A22N). Signals were displayed on a Tektronix 5103N storage oscilloscope and were also stored as a strip chart using the Delta program (Digital Solutions Pty Ltd). Some signals were collected by using a Syntech probe and data acquisition system and analyzed with the Syntech EAG 2.4 program on a personal computer. Electrical shielding was provided by a Faraday cage, with all metal surfaces within it being grounded.

Test Chemicals. Chemicals were selected because they elicit behavioral activity in *B. tryoni* [see Bateman and Morton (1981), Eisemann and Rice (1992) and Rice (1989)]: 2-butanone (Aldrich Chemical Company, claimed purity 99%), methyl butyrate (Aldrich Chemical Company, claimed purity 99%), *n*-butyric acid (British Drug Houses Ltd, claimed purity 99%), a mixture of isomers of farnesene (TCI Ltd, purity unknown), ethanol (Ajax Chemicals Pty Ltd, claimed purity 99.5%) and ammonia (Ajax Chemicals Pty Ltd 28.0–30.0% w/w), and carbon dioxide (taken from a cylinder of compressed food grade purity, provided by Commonwealth Industrial Gases, Brisbane, Australia).

Odorant Delivery. Humidified analytical grade compressed air was continuously blown over the fly at a rate of 500 ml/min, with the nozzle for the airstream placed 1 cm from, and directly in front of, the fly. The tube carrying the airflow was 3-mm-ID teflon tubing and was connected to a glass nozzle (same internal diameter). Test odorant samples were taken as saturated vapor, at room temperature, using gas-tight syringes. They were manually injected into the airstream through a rubber septum, 50 cm from the delivery point. Injection time was 0.5–1.0 secs. All samples were injected at the same time segment after the recording program had been activated, so that onset of stimulation could be easily identified. For carbon dioxide, a 100-ml flask was filled directly from a gas cylinder and then sealed with Parafilm (American National Can). A sample was then taken up by a gas-tight syringe inserted through the Parafilm. Preliminary experiments confirmed the method of odorant delivery for carbon dioxide and the other chemicals to be a reliable way of presenting specific quantities of chemicals to the

antenna. The relationship between the syringe volume and the actual concentration of the chemical at the preparation was not established because we only needed to know that the receptors were saturated. This was achieved by establishing dose–response curves (see below). For the mixture experiments, two chemicals were collected into one syringe and then injected into the continuous airstream. Stimulus delivery controls (see below) were undertaken to ensure volume artefacts were excluded.

Experimental Procedure. In all experiments the responses were compared to a standard of 50 μl methyl butyrate vapor. The standard was tested, followed by three injections of the test sample, then the standard again. At least 2 mins was left between each injection to allow disadaptation of the antenna. Responses from the three sample injections were averaged and expressed as a percentage of the standard. Standardizing each test vapor allowed comparison between individual flies and between different test chemicals and corrected for time dependent variability within preparations (Roelofs and Comeau, 1971; Light and Birch, 1979; Light, 1983). The EAG responses were initially measured in millivolts, recorded as the height of the initial depolarization.

Establishing Saturation Volumes of Test Chemicals. Saturation volumes are defined as the volume of vapor at which the standard error of the mean response overlapped the standard error of the mean response of the highest volume (Dickens, 1984). The saturating volumes had to be established, as it is a requirement of mixture experiments that all the receptor neuron types be fully activated. Differences in volatility, and therefore the number of molecules of each chemical in the test sample, will affect the size of the EAG (Brockerhoff and Grant, 1999). Applying enough of each chemical to maximally stimulate the receptor neurons will avoid this problem. To find the saturation points, the antennae were stimulated with volumes of vapor ranging between 5 μl and 400 μl.

Mixture Experiments. Chemicals were tested as binary mixtures to determine how many different receptor neuron types were present. First, the antennal response was determined for two individual chemicals at a volume in excess of the saturation volume (for all chemicals 400 μl was used). Second, a mixture containing 400 μl of each of the two chemicals was applied. Chemicals were always presented at a volume in excess of the saturation volume to ensure that the sensory dendrites for that chemical were maximally activated. The order of presentation of the mixture series and the chemicals within a mixture series were randomized.

Before statistical analysis, the mean result of stimulation with a control injection of clean air (see stimulus delivery controls below) was subtracted from the antennal response of each of the samples in the mixture experiments. The mixture experiments were then analyzed using paired sample *t* tests. Initially a one-way test was conducted to determine if the response to the mixture of chemicals was greater than the response of the largest of the two individual chemicals (i.e., a summating response). If the response to the mixture was summating, then a two-way test was

conducted to determine if the response to the mixture was equal to the calculated additive response of the two individual chemicals (i.e., fully summating).

Control Stimuli. Each test chemical used in the mixture experiments was applied using 400 μl and 800 μl of vapor to determine whether any of the responses to the binary mixtures were the result of artifacts of the stimulus delivery system. A larger EAG at 800 μl would indicate a stimulus delivery artifact, as the chemicals have been shown to saturate the antenna at volumes below 400 μl. To see if the delivery of a burst of odor produced a response in the nervous system, separate from the effect of the odor itself, 400 μl and 800 μl of clean air were tested. An EAG response to clean air was found and was therefore subtracted from all of the responses of the test chemicals and mixtures. This ensured that the calculated additive response for each mixture accurately reflected the EAG response to the individual chemicals. Consideration of extraneous elements in EAGs is particularly important when dealing with small EAG responses.

Local Potential Controls. Three of the mixtures were tested with the recording electrode in a different position to see if the results of the mixture experiments were influenced by local voltage potentials from specific sensillar fields at the tip of the antenna. The mixtures tested were methyl butyrate with ammonia, methyl butyrate with 2-butanone, and ethanol with 2-butanone. In these mixture experiments the recording electrode was inserted into the basal region of the funiculus, with all other parameters remaining as before.

Electrode Potential Controls. To determine whether any of the responses were electrode potentials (artifacts), methyl butyrate, 2-butanone, farnesene, ethanol, *n*-butyric acid, and ammonia were tested on recently killed flies. Flies were killed by freezing at -20°C, but were tested at room temperature. This technique shows how much of the EAG is the result of physiological activity within the antenna, and how much (if any) is the result of an interaction of the chemical with the electrodes. All other parameters were as previously mentioned.

RESULTS

Saturation Volumes of Test Chemicals. The largest responses were obtained with 2-butanone, followed by methyl butyrate, *n*-butyric acid, ethanol, carbon dioxide, ammonia and farnesene (Table 1). All the chemicals had antennal response values at 400 μl that were significantly larger than the response to stimulation with clean air, indicating a chemoreceptor response within the antenna, rather than an artifact. The actual EAG responses ranged from 0.2 to 4.0 mV.

Mixture Experiments. The results of the mixture experiments are displayed according to the outcome of the statistical tests, i.e., divided into fully summating, nonsummating, and partly summating groups (Figures 1 and 2). Ethanol was fully summating with methyl butyrate (two-way paired sample t test; $t = 0.836$)

TABLE 1. SATURATION VOLUMES AND EAG RESPONSES AT POINT OF SATURATION FOR CHEMICALS USED IN MIXTURE EXPERIMENTS

Chemical	Saturation volume (μl)	EAG response at saturation (mean $\pm$ 1 SE)
Methyl butyrate	100	119 ± 3
2-Butanone	250	151 ± 7
Farnesene	250	35 ± 9
n-Butyric acid	150	61 ± 10
Ammonia	250	40 ± 6
Ethanol	300	59 ± 3
Carbon dioxide	15	33 ± 11

(Figure 1A), 2-butanone (two-way paired sample t test; $t = 0.311$) (Figure 1D), farnesene (two-way paired sample t test; $t = 2.055$) (Figure 1G), carbon dioxide (two-way paired sample t test; $t = 0.574$) (Figure 1L), *n*-butyric acid (two-way paired sample t test; $t = 2.323$) (Figure 1J) and ammonia (two-way paired sample t test; $t = 1.946$) (Figure 1K). Ammonia also had fully summating responses when mixed with farnesene (two-way paired sample t test; $t = 1.650$) (Figure 1I), methyl butyrate (two-way paired sample t test; $t = 1.483$) (Figure 1C), 2-butanone (two-way paired sample t test; $t = 0.827$) (Figure 1F) and carbon dioxide (two-way paired sample t test; $t = 0.288$) (Figure 1N). Similarly, *n*-butyric acid was fully summating with farnesene (two-way paired sample t test; $t = 0.858$) (Figure 1H), methyl butyrate (two-way paired sample t test; $t = 0.055$) (Figure 1B), 2-butanone (two-way paired sample t test; $t = 0.714$) (Figure 1E) and carbon dioxide (two-way paired sample t test; $t = 0.942$) (Figure 1M).

The combination of ammonia and *n*-butyric acid gave a response that was not larger than the largest response of the individual chemicals (produced by the ammonia) (one-way paired sample t test; $t = -3.490$) (Figure 2F), that is nonsummating. Methyl butyrate was nonsummating when presented in combination with farnesene (one-way paired sample t test; $t = 0.612$) (Figure 2B), 2-butanone (one-way paired sample t test; $t = 1.133$) (Figure 2A) and carbon dioxide (one-way paired sample t test; $t = 0.263$) (Figure 2C). 2-Butanone was nonsummating when presented in combination with farnesene (one-way paired sample t test; $t = -2.498$) (Figure 2D) and carbon dioxide (one-way paired sample t test; $t = -3.259$) (Figure 2E).

The combination of farnesene with carbon dioxide resulted in a partly summating response. The mixture of these two chemicals gave a bigger response than the largest response of the two individual chemicals (produced by the carbon dioxide) (one-way paired sample t test; $t = 3.529$), but the mixture was not equivalent to the calculated additive response of the two individual chemicals (two-way paired sample t test; $t = 4.038$) (Figure 2G).

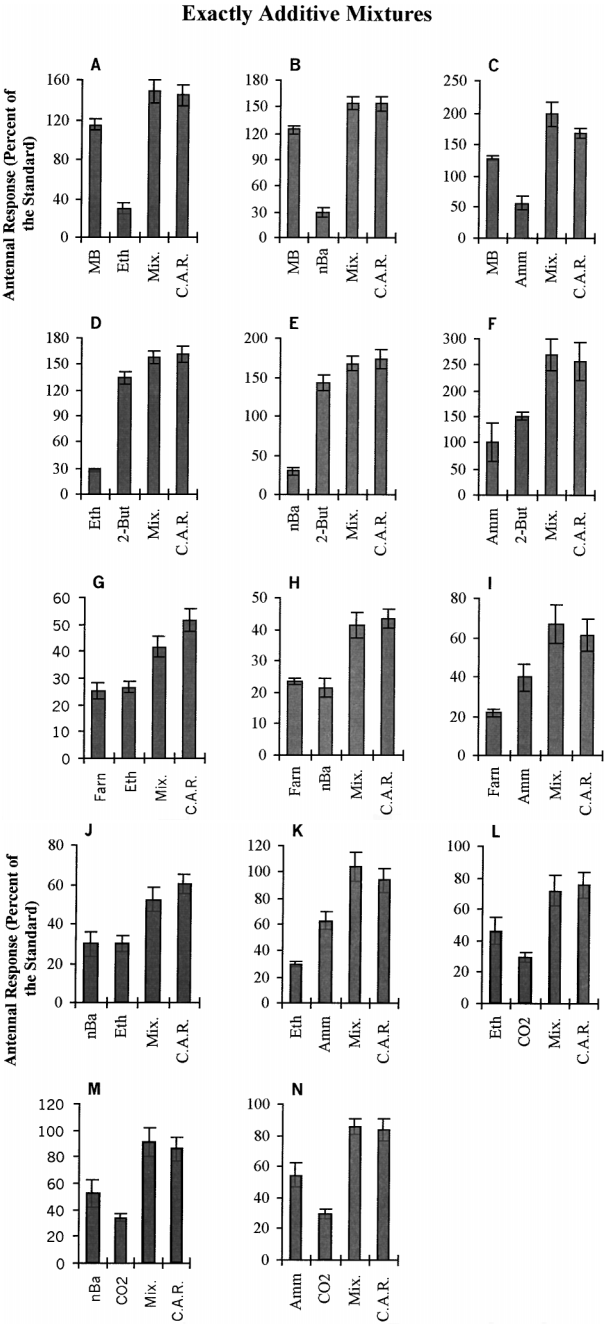

FIG. 1. Results of the mixture experiments showing those mixtures of chemicals that produced additive EAG responses. The EAG responses represent the mean response $\pm$ 1 SE ($N = 6$). MB = methyl butyrate, 2-But = 2-butanone, Farn = farnesene, Eth = ethanol, nBa = *n*-butyric acid, Amm = ammonia, CO2 = carbon dioxide, and C.A.R. = calculated additive response.

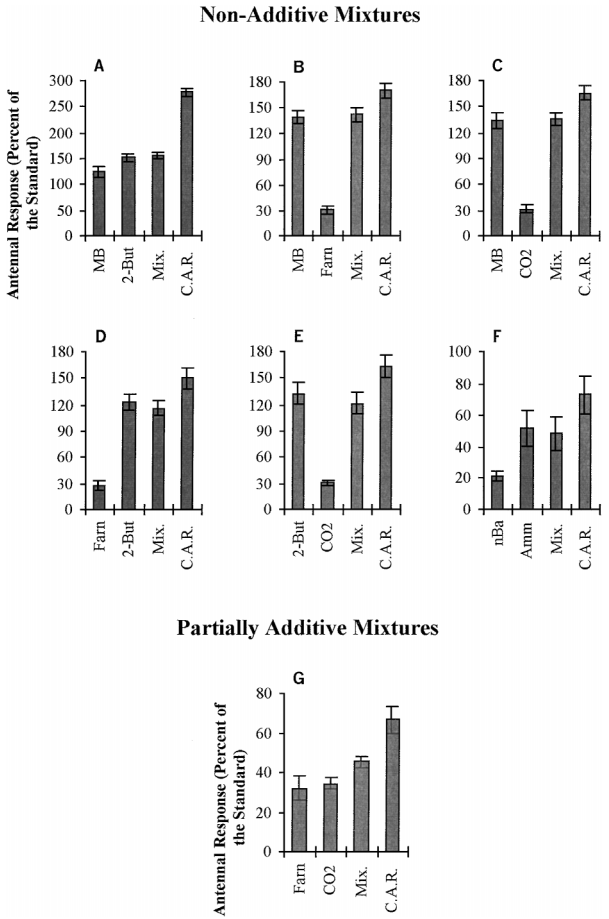

FIG. 2. Results of the mixture experiments showing those mixtures of chemicals that produced nonadditive or partially additive EAG responses. The EAG responses represent the mean response ± 1 SE ($N = 6$). MB = methyl butyrate, 2-But = 2-butanone, Farn = farnesene, Eth = ethanol, nBa = *n*-butyric acid, Amm = ammonia, CO2 = carbon dioxide and C.A.R. = calculated additive response.

Control Stimuli. We compared the mean responses from stimulating with 400 μ and 800 μl for each of the odors. The use of 800 μl of a single chemical simulates the presentation of a binary mixture, but with only one chemical present any increase in response compared to 400 μl represents a stimulus delivery artifact. The two means were compared by using two-way paired sample *t* tests. In all cases the null hypothesis (that the difference between the two means was equivalent to

zero) was accepted at the 95% significance level (ammonia, $t = 0.085$; 2-butanone, $t = 1.432$; carbon dioxide, $t = 0.553$; ethanol, $t = 0.775$; farnesene, $t = 0.990$; methyl butyrate, $t = 0.202$; *n*-butyric acid, $t = 0.119$). The means for the control stimulus experiments using 400 μl and 800 μl of analytical grade air were compared using a two-sample *t* test, and found to be equal ($t = 0.616$).

Local Potential Experiments. Three of the mixtures were tested with the recording electrode in different positions, to see whether the position of the electrode had any effect on the types of responses (i.e., nonsummating, partly summating, or fully summating). The mixture of ethanol with 2-butanone showed a fully summating response (two-way paired sample *t* test, $t = 0.562$). The mixture of methyl butyrate with 2-butanone showed a nonsummating response (one-way paired sample *t* test, $t = -0.227$). The mixture of methyl butyrate with ammonia showed a response that was fully summating (two-way paired sample *t* test, $t = 2.370$). In all three cases the types of summating and nonsummating responses are the same as for the initial mixture experiments, indicating that the position of the recording electrode in the funiculus was not a contributing factor.

Electrode Potential Experiments. In the experiments with recently killed flies, the EAGs were eliminated for most chemicals (Figure 3). In comparison, the responses from live flies showed large, negative potentials. Only ammonia showed any potential deflection. However, the potential generated for ammonia was small in comparison to those obtained from living flies and was a positive potential. The positive potential of approximately 0.1 mV compares to the average negative deflection obtained from living flies of -1.8 mV.

DISCUSSION

Number of Olfactory Receptor Neuron Types. The results of the mixture experiments indicate that at least three types of receptor neurons are being used by gravid *B. tryoni* in detecting the seven tested chemicals. One receptor neuron type detects ethanol, another type detects ammonia and *n*-butyric acid, and the third type detects farnesene, methyl butyrate, 2-butanone and carbon dioxide.

The division of the mixtures into fully, partly, or nonsummating categories was based solely on the results of the statistical tests. Ethanol, therefore, appears to be detected by a different receptor neuron type than the other six chemicals. The remaining chemicals can be divided into two groups based on the types of responses they elicited when presented in combinations. Ammonia is detected by the same receptor neuron type as *n*-butyric acid because a mixture of these two chemical vapors was not summating, not larger than the largest of the individual chemicals. However, these two chemicals showed fully summating responses with all other chemicals, indicating separate receptor neuron types. The nonsummating response to the mixture of ammonia and *n*-butyric acid is not likely to be due to an

FIG. 3. Comparison of electroantennogram traces between standard and control preparations. The control preparation used a recently killed specimen; therefore any resultant potentials were artifacts. (a) 400 μl of methyl butyrate, (b) 400 μl of ethanol, (c) 400 μl of *n*-butyric acid, (d) 400 μl of ammonia. The arrow represents the point of stimulus injection.

interaction between the two chemicals in the syringe. We believe that significant association between the weak base ammonia and the weak acid butyric acid in the vapor phase can be ruled out on the grounds that there is no visible evidence of solid ammonium butyrate. This contrasts with the situation where an ammonium chloride "smoke" forms between hydrochloric acid vapor and ammonia.

Farnesene, methyl butyrate, 2-butanone, and carbon dioxide are likely to be detected by a separate, third type of receptor neuron, but the results are not as simple to interpret as the previous two groups. Methyl butyrate and 2-butanone are nonsummating when presented together, indicating common receptor neuron types. Farnesene is also nonsummating when tested in combination with either methyl butyrate or 2-butanone, showing that it is detected by the same receptor neuron types. Similarly, carbon dioxide is nonsummating when tested in combination with methyl butyrate or 2-butanone. If carbon dioxide and farnesene both

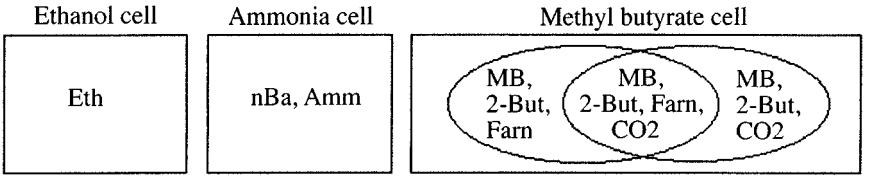

FIG. 4. Model of the olfactory receptor cell types. The receptors are divided into three broad types. The ethanol cell types only receives ethanol (Eth). The ammonia cell type receives *n*-butyric acid (nBa) and ammonia (Amm). The methyl butyrate receptor cell type is divided into three subgroups, comprising one that receives methyl butyrate (MB), 2-butanone (2-But), and farnesene (Farn); a second subgroup that receives MB, 2-But, Farn and carbon dioxide (CO2), and the third subgroup receives MB, 2-But, and CO2.

use the same receptor neuron types as methyl butyrate and 2-butanone, we would expect the mixture of farnesene and carbon dioxide to also produce a nonsummating response. Instead, a partly summating response was detected. This partly summating response for farnesene and carbon dioxide suggests that different receptor neuron types are used for these two chemicals but that there is some cross-reactivity between the two.

How, then, are farnesene and carbon dioxide both detected by the same receptor neuron types that detect methyl butyrate and 2-butanone? Rather than having one highly selective receptor mechanism, as was found for ethanol and for ammonia and *n*-butyric acid, we propose that farnesene, methyl butyrate, 2-butanone, and carbon dioxide are detected by a group of receptor neurons that show variation in their acceptance of odor ligands. The receptor neuron type for these four chemicals consists of three subgroups of the one basic receptor type. Figure 4 shows a model of these receptor subgroups that is consistent with the experimental results. One subgroup detects methyl butyrate, 2-butanone, and farnesene. A second subgroup detects methyl butyrate, 2-butanone, farnesene, and carbon dioxide; and the third subgroup detects methyl butyrate, 2-butanone, and carbon dioxide. In this model, when methyl butyrate or 2-butanone are tested, all three subgroups would be activated. There would therefore be nonsummating responses when farnesene or carbon dioxide were added to either methyl butyrate or 2-butanone, as all of the receptors would already be activated. When either farnesene or carbon dioxide was presented individually, only two of the three subgroups would be activated. When farnesene and carbon dioxide were presented together, however, all three subgroups would be activated, which would give a response that is larger than the response to farnesene or carbon dioxide on their own, but would not equal the calculated additive response for farnesene with carbon dioxide. The calculated additive response would be the equivalent of adding the two receptor groups for farnesene to the two receptor subgroups for carbon dioxide, assuming no cross-reactivity between the two. The larger EAG responses to methyl butyrate and

2-butanone compared to farnesene and carbon dioxide may also indicate that more receptor neurons respond to methyl butyrate and 2-butanone than for the other two chemicals, which supports our hypothesis.

Furthermore, if each of the subgroups of receptor neuron types for farnesene and carbon dioxide produced approximately the same amount of electrical potential when stimulated, then the model suggests that the response to the mixture of farnesene with carbon dioxide should be about 50% larger than the responses to individual treatments of farnesene or carbon dioxide. The experimental results come close to matching that prediction. The EAG response to farnesene was 32% $\pm$ 6, the response to carbon dioxide was 35% $\pm$ 3, while the response to the mixture of the two was 46% $\pm$ 3. These antennal responses to carbon dioxide are of great interest on their own (especially the nonsummating responses with methyl butyrate and 2-butanone) and will be investigated in more depth in a separate study.

The EAG results seem to support our model; however, they should not be seen to be conclusive. The EAG responses to some of the chemicals (*e.g.*, farnesene and carbon dioxide) were quite small, which makes interpretation of the results difficult. While our hypotheses were based on the results of statistical tests, single-unit electrophysiology will be needed to confirm the specificity of these receptor neuron types. Single-unit electrophysiology will also allow us to test whether the high stimulus dosages affect the responses of the receptor neurons. For instance, there may be inhibition of nerve impulses at high stimulus doses. High stimulus concentrations can also affect the selectivity of sensory cells, for example, the pheromone sensitive cells of *T. ni* lost some of their selectivity when high stimulus concentrations were applied (Mayer and Mankin, 1987). Finally, the receptor neuron types indicated in these experiments should not be seen as the only types present. Only a limited number of chemicals were tested, and it is likely that there are many more receptor neuron types on the antenna.

Comparison with Behavioral Experiments. Eisemann and Rice (1992) looked at behavioral responses of *B. tryoni* to some of the chemicals we tested and postulated that at least three olfactory receptor neuron types were responding. However, their predictions were based on assigning receptor neuron types according to gross differences in the chemical structure of the odors. They postulated that the long-chain hydrocarbons (such as farnesene) would be detected by separate receptor neuron types, compared to the short-chain aliphatic acids, alcohols, esters, and ketones, and that *n*-butyric acid would activate the same receptor neuron types as methyl butyrate and 2-butanone. However the electrophysiological results indicate that farnesene activates the same receptor neuron types as methyl butyrate and 2-butanone and that *n*-butyric acid activates separate receptor neuron types from the other short chain chemicals.

The chemicals for this EAG study were selected because they are known to have a behavioral effect on the flies. All the chemicals (except for ammonia) are volatile chemicals that have been found to be emitted from fruits (Nursten, 1970).

Ammonia is a common emission from bacterial activity and the attractancy of *B. tryoni* to it is most likely a feeding response (see Courtice and Drew, 1984; Drew et al., 1983; Lloyd, 1991). 2-Butanone is also produced by bacterial cultures (Drew, 1987). However, the concentrations of chemicals used may be much greater than normally experienced. As such they may negate or even reverse the behavioral action of the chemicals. Therefore, this study should not be taken out of context. Our experiments are looking at the physiological mechanisms associated with the initial reception and transduction of the odorants.

The EAG responses have provided us with valuable information on the initial reception of nonpheromonal chemicals in *B. tryoni*. By examining the antennal responses when stimulated with mixtures of behaviorally active chemicals, we have shown that three basic receptor neuron types are likely to be present and that there is little cross-reactivity between them. The use of these olfactory receptor neuron types represents an important part of the peripheral discrimination process and results in a selective neural input to the central nervous system. The results have also raised some important questions, particularly concerning the response of the olfactory receptor nurons that detect carbon dioxide as well as other environmental odorants. Carbon dioxide receptors are generally thought to be a specialist class of receptors (Stange, 1996). The responses of the carbon dioxide receptors are investigated in more detail in the accompanying paper.

Saturation Volumes of Test Chemicals. The saturation points for most of the chemicals were between 100 μl and 300 μl. Carbon dioxide saturated at only 15 μl; however, the figure is not directly comparable with the other chemicals, as the concentration of carbon dioxide in the syringe was close to 100%. The concentration of the other chemicals would have been lower, depending on the vapor pressures. Nevertheless, the EAG response to carbon dioxide was smaller than for methyl butyrate and 2-butanone, suggesting that there are fewer dendrites on the antenna sensitive to carbon dioxide compared to methyl butyrate or 2-butanone. Alternatively the receptor potentials produced by the dendrites receiving carbon dioxide may be small compared to the receptor potentials produced for the other chemicals.

Control Experiments. There was only one artifact identified from the control experiments: a small EAG response was found when clean air was injected, meaning that there is an antennal response in the absence of test odor stimulation. The response to the control stimulus air treatment was a stimulation technique artifact and was taken into account when interpreting the results. The antennal response to the air treatments may come from more than one source. First, mechanoreceptors, located solely on the scape and pedicel (Giannakakis and Fletcher, 1985; Hull and Cribb, 1997), may have been stimulated by the mechanical effect of the puff of air from the syringe. The response may also come from delivery-line contaminants, most likely Teflon plasticizers (Mayer et al., 1984). However, the continuous flushing of the stimulus delivery system would have negated the build-up of such

contaminants. The continuous air flow would also have reduced the chance of odorants from previous stimulations adhering to the tube walls and being released at a later time. The comparatively small response to the air treatments compared to the EAGs of the test chemicals shows that the larger part of the antennal responses resulted from an interaction of the chemicals with the olfactory receptor mechanisms of the antennae.

We found no local potential effect. Other researchers have found that local potentials (EAG responses that are more strongly influenced by sensilla in the immediate vicinity of the recording electrode) can be recorded from the antennae of tephritid flies (Crnjar et al., 1989; Bigiani et al., 1989). In the above cases the EAG response depended on the position of the recording electrode. Because sensilla are not equally distributed over the surface of the antenna, different responses occurred as a result of different recording sites. Our results showed that the types of EAG responses to the mixtures were consistent and did not depend on the position of the recording electrode. The difference between these findings is likely to be due to the recording method used: the authors referred to above gently pressed the tip of the recording electrode against the surface of the antenna. The recording electrode would only have been in contact with the external surface of the antenna. This may increase the resistance of the electrical connection, thus restricting the recording range of the electrode. Bigiani et al. (1989) estimated that the effect of local potentials was limited to a radius of about 30 μm around the recording electrode. Inserting of the electrode does have an effect on the dynamics of the potentials recorded. With a deep insertion, Kay (1971) found that some transient elements of the EAG response were eliminated. Nearly equal EAG responses were also found between different regions of the antenna of *Trichoplusia ni* when the electrodes were implanted through the cuticle (Payne et al., 1970). In our experiments, the recording electrode was inserted into the antenna. Therefore, we suggest that the different electrical contact achieved with our methods accounts for the absence of local potentials.

One potential source of error in EAG experiments is an interaction of the chemicals with the electrodes, resulting in artificial electrical potentials (so-called electrode potentials). Kafka (1970) recorded electrode potentials that were the result of interactions between chemicals and the electrodes, upon stimulation with both acid and alkaline substances. The aim of the control experiments with the dead fly was to see if significant electrode potentials were produced. The potentials from living flies had an initial negative deflection. With the dead fly the negative potentials were eliminated, showing that the chemicals were not significantly interacting with the electrodes. A small, positive electrode potential was produced with ammonia, but the effect of this potential with a live fly is minimal compared to the normal negative antennal response. The negative potentials recorded from the live flies in the dose–response and mixture experiments were therefore the result of physiological activity within the antenna.

Acknowledgments—The authors wish to thank Mr. Andrew Noskoff for technical assistance; Ms. Joan Hendrikz, the Faculty of Biological and Chemical Sciences, for assistance in the statistical analyses; Dr. Chris Moore, Department of Primary Industries, for help in interpreting some of the results and Dr. E. Rumbo for his constructive criticism and advice.

Abstract—Single-unit electrophysiology was used to record the nerve impulses from the carbon dioxide receptors of female Queensland fruit flies, *Bactrocera tryoni*. The receptors responded to stimulation in a phasic-tonic manner and also had a period of inhibition of the nerve impulses after the end of stimulation, at high stimulus intensities. The cell responding to carbon dioxide was presented with a range of environmental odorants and found to respond to methyl butyrate and 2-butanone. The coding characteristics of the carbon dioxide cell and the ability to detect other odorants are discussed, with particular reference to the known behavior of the fly.

Key Words—Olfaction, electrophysiology, *Bactrocera tryoni*, Diptera, Tephritidae, sensilla, receptor, environmental odorant, carbon dioxide.

INTRODUCTION

Carbon dioxide receptors have been studied electrophysiologically for several hematophagous Diptera, including the mosquito *Aedes aegypti* (Kellogg, 1970), the sheep blowfly *Lucilia cuprina* (Stange, 1975), and the tsetse flies *Glossina palpalis* (Bogner, 1992) and *G. morsitans* (Den Otter and Van der Goes van Naters, 1992). In phytophagous insects these receptors have received less attention. The CO_2 concentration gradients around plants are far less than those encountered by hematophagous insects, so the receptors of phytophagous species must have high sensitivity (Stange, 1997). This has been found to be the case

0098-0331/01/0500-0889$19.50/0

in the moths *Helicoverpa armigera* (Stange, 1992) and *Cactoblastis cactorum* (Stange, 1997; Stange et al., 1995). It is thought that CO_2 levels around plants alert the insect to potential feeding or oviposition sites (Rasch and Rembold, 1994; Stange, 1997). No electrophysiological studies are available for the CO_2 receptors of phytophagous Diptera, except for our electroanntenogram (EAG) study of the antennae of *Bactrocera tryoni* (Diptera: Tephritidae) (Hull and Cribb, 2001, the first in this series of papers), where we showed a response to CO_2 and developed a model of receptor types including one class containing three subsets: one that responds to methyl butyrate, 2-butanone, and farnesene; a second responding to methyl butyrate, 2-butanone, and CO_2; and a third responding to all four chemicals. Although EAGs do not indicate the significance of a response, Rice (1989) and Stange (1999) have shown that these flies respond behaviorally to CO_2. The putative CO_2 receptor cells of the Queensland fruit fly, *Bactrocera tryoni* (Diptera: Tephritidae), with their characteristic lamellate dendrite in a multiporous peg, have been located using electron microscopy (Hull and Cribb, 1997). This makes them an ideal candidate for single unit electrophysiology.

Single-unit electrophysiology has been used previously to determine the number of receptors present on the dendrites of a sensory cell in adaptation experiments. Multiple olfactory receptor proteins were indicated on sensory cells of the beetle *Dendroctonus frontalis*, which correlated with EAG experiments from that species (Payne and Dickens, 1976). However, single-unit electrophysiological studies from Tephritidae are rare, because the small size and dense packing of the sensilla makes them difficult to record from. Dickens et al. (1988) have recorded from single trichoid sensilla of *C. capitata*. They found that the sensilla responded to trimedlure (a known behavioral attractant) by increasing the rate of firing of nerve impulses. In this paper single-unit electrophysiology is used to investigate the encoding characteristics of the carbon dioxide receptors of *B. tryoni* and test our model for the response spectrum developed from EAG data.

METHODS AND MATERIALS

Test Subjects. Bactrocera tryoni (Froggatt) were cultured as per Hull and Cribb (2001). Only gravid flies were selected for experimentation. Intact flies were wrapped in Blu-tack [Bostik (Australia) Pty Ltd] adhesive to constrain head movements and manipulated so that only the antennae were left protruding. The fly was then put onto a microscope slide, and a portion of Blu-tack was placed underneath the protruding antennae. Melted wax (melting point of approximately 52°C) was used to secure the antennae to the Blu-tack. Small drops of wax were placed at the tip of the funiculus and at the pedicel of the antenna.

Electrophysiological Recording Technique. Tungsten electrodes, mounted on micromanipulators, were used. Due to the small size and the dense packing of the

sensilla, the recording electrode had to be repositioned by chance until there was an adequate electrical connection. The recording electrode was always inserted into the same region of each antenna, which was between the sensory pit and the base of the funiculus. Preliminary experiments showed that this region contained numerous receptors responsive to CO_2. The indifferent electrode was inserted at the base of the antenna, through the circumantennal sulcus. The preparations remained viable for between 30 min to over 2 hr. The extracellularly recorded action potentials ranged in size from 0.2 to 1.5 mV. Signals were transmitted through a Grass high-impedance probe to a preamplifier (Grass P16D microelectrode DC amplifier). The signals were then transferred to a Syntech data acquisition system and analyzed with the Syntech AutoSpike V. 3.1 program on a personal computer. For all recordings, the nerve impulses were counted for the first 0.5 sec of stimulation. Electrical shielding was provided by a Faraday cage, with all metal surfaces within it being grounded.

Test Samples. The chemicals were carbon dioxide (Commonwealth Industrial Gases, food grade purity from a cylinder of compressed CO_2), 2-butanone (Aldrich Chemical Company, claimed purity 99%), methyl butyrate (Aldrich Chemical Company, claimed purity 99%), *n*-butyric acid (British Drug Houses Ltd, claimed purity 99%), a mixture of isomers of farnesene (TCI Ltd, purity unknown), ethanol (Ajax Chemicals Pty Ltd, claimed purity 99.5%), and ammonia (Ajax Chemicals Pty Ltd 28.0–30.0% w/w).

Dose–Response Relationship for Carbon Dioxide Receptor. The dose–response relationship for carbon dioxide was obtained using volumes of vapor between 5 and 800 μl. The saturation point was then determined from the curve and was taken to be the volume of gas at which the standard error of the mean response overlapped the standard error of the mean response of the highest volume of stimulation (Dickens, 1984).

Responses to Other Behavior-Modifying Chemicals. Once the response of the sensory cell to CO_2 had been characterized, the remaining test chemicals were applied. A volume of 400 μl was used in all cases, as it had been shown in previous EAG experiments that this volume was in excess of the saturation volume for each chemical. Using a volume of test chemical vapor in excess of the volume needed to maximally stimulate the cell meant that even chemicals having only a small effect on the receptor neurons would be detected. Those chemicals that produced an increase in the firing rate of the neurons were then tested in mixture experiments. One of the stimulating compounds (methyl butyrate) was also tested for a dose–response relationship to see whether the response curve was similar to that of carbon dioxide.

Mixture Experiments. Different cells within a sensillum may be difficult to identify if their nerve impulses are of similar size. If two chemicals are acting on the same sensory cell, then the binary mixture of the two should not produce more nerve impulses compared to the single most effective stimulant. A mixed injection

containing 400 μl of each chemical was applied. Chemicals were always presented at a volume in excess of the saturation volume to ensure the sensory dendrites were completely activated. All chemicals that produced an increase in the firing rate of the neurons were tested in combination with each other. The order of presentation of the mixture series and the chemicals within a mixture series were randomized. The responses to 400 μl of each chemical were analyzed with a random-blocks ANOVA, with a post-hoc Dunnett's test. They were compared to the response obtained with the average stimulation of clean, analytical grade air.

Odorant Delivery. Humidified analytical grade compressed air was continuously blown over the fly at a rate of 1 liter/min, with the nozzle for the airstream being placed 1 cm from the fly. The method of test odour injection was the same as for Hull and Cribb (2001). The relationship between the syringe volume and the actual concentration of the test samples at the preparation was not established.

Control Experiments. An experiment was conducted to see if the dilution of a chemical within a syringe would significantly affect the nerve impulse firing rate within the first 0.5 sec of the stimulation. 2-Butanone, 400 μl, was tested six times in a row and was then repeated a further six times using 400 μl of 2-butanone with an additional 400 μl of clean air. In each case the same number of odor molecules would have been present, but the concentration of the odorant within the stimulation burst would have differed. This experiment tested whether there were differences in spike numbers with variation in the volume of the stimulation burst, rather than as a result of the number of molecules of odor vapor. The experiment also tested if adding a small amount of carbon dioxide (present in 400 μl of analytical grade air) to a sample of odorant had a significant effect on the number of nerve impulses.

Injecting the test stimuli by hand involved a degree of variability in terms of the strength and time course of the injection (injections took between 0.5 and 1 sec). To gauge the reproducibility of the stimulation technique, a preparation was stimulated six times in a row with 400 μl of methyl butyrate, and then again with 400 μl of carbon dioxide (preliminary experiments indicated that the sensory cells did not become adapted with repeated stimulation). The six injections of 2-butanone from the previous experiment were also used to gauge the reproducibility of the stimulation technique. At least 2 min elapsed between each injection to allow disadaptation of the receptors after the stimulus-induced activity.

Identification of Sensillum Type. Scanning electron microscopy was used to identify the sensillum type we recorded from. After recording, the electrode was pushed further into the antenna to make a larger hole. The antenna was then removed from the insect and dehydrated through a graded series of alcohol. Following dehydration the ethanol was exchanged for hexamethyl disilazane (HMDS) and left for 2–4 hr. After the HMDS was removed, the antenna was air dried and mounted on an aluminum pin-type stub using double-sided adhesive tape and silver conductive paint. The preparations were then coated with gold in a sputter coater and viewed on a JEOl JSM6400F scanning electron microscope.

RESULTS

Response to Carbon Dioxide. The average basal firing rate for the carbon dioxide-sensitive receptor was 14 ± 2 nerve impulses per 0.5 sec (Figure 1). The saturation point was obtained with 50 μl of CO_2-saturated air and was 61 ± 8 nerve impulses for the first 0.5 sec of stimulation ($N = 9$).

The pattern of firing of the nerve impulses showed some variability according to the stimulus load. At low stimulus intensities, the responses were tonic in nature and showed an even level of firing throughout the stimulus burst (Figure 2B). At high stimulus intensities, the pattern changed to phasic-tonic, with an increase in the firing rate at the start of stimulation followed by a lower level of firing (Figure 2D). The increased level of nerve impulse firing continued for up to 2 sec, but did show some variability according to the stimulus strength (compare Figure 2C and 2D). This variability was associated with the method of stimulation, and so to avoid problems, the spikes were only counted for the first 0.5 sec of the stimulation burst. This initial period included the phasic portion for all of the responses. Although not ideal, the stimulation method is adequate for the large volumes tested. After stimulation with large quantities of CO_2-laden air (50–800 μl), the nerve impulses stopped for a period of up to 3 sec, although periods of 1–2 sec were more common. On some of the recordings the amplitude of the nerve impulses decreased when stimulated with large quantities of CO_2 (Figure 2D). However, this could usually be compensated for by the AutoSpike program, but in one recording (not shown) the response of the cell had become completely adapted after the initial phasic burst and the spikes eventually could

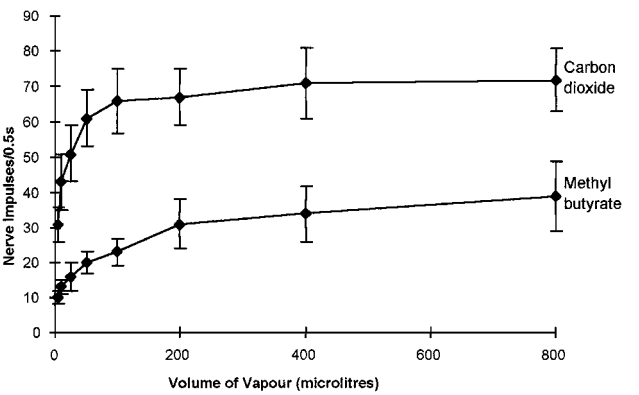

FIG. 1. Dose–response curves of receptor cells on the antenna of female *B. tryoni* in response to stimulation with carbon dioxide and methyl butyrate (each data point represents the mean number of nerve impulses/0.5 sec ± 1 SE; $N = 9$ for carbon dioxide, $N = 5$ for methyl butyrate).

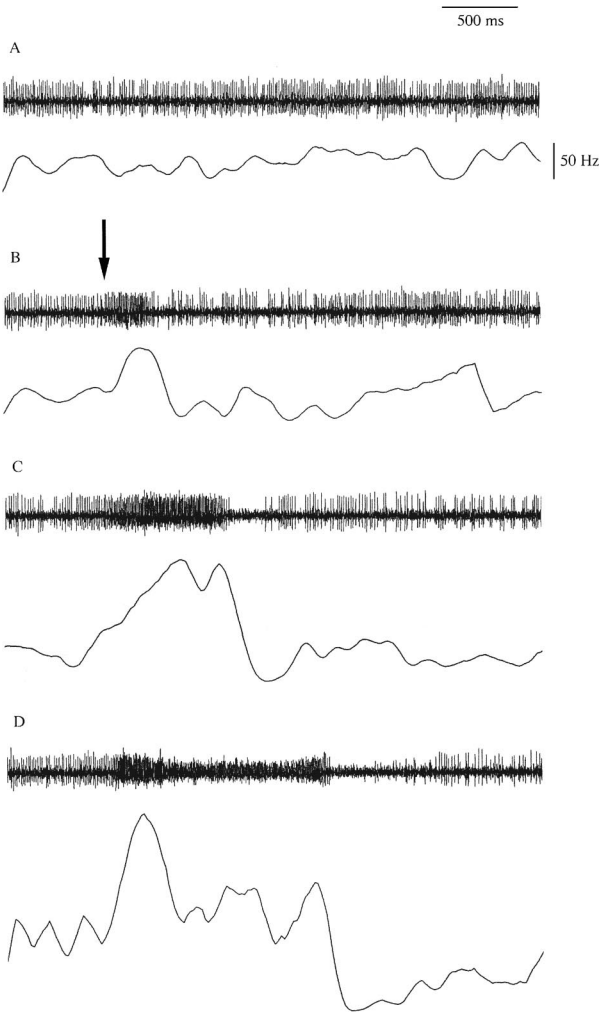

FIG. 2. Electrophysiological responses from a sensory cell on the antenna of female *B. tryoni* in response to stimulation with various concentrations of carbon dioxide. The line below each electrophysiological recording is a computer generated frequency curve, with the same time scale, showing the firing frequency of the nerve impulses. (A) Basal level of firing in the absence of stimulation (but with the background air supply on); (B) stimulation with 5 μl of carbon dioxide; (C) stimulation with 50 μl of carbon dioxide; (D) stimulation with 400 μl of carbon dioxide. Arrow indicates the point of stimulus injection.

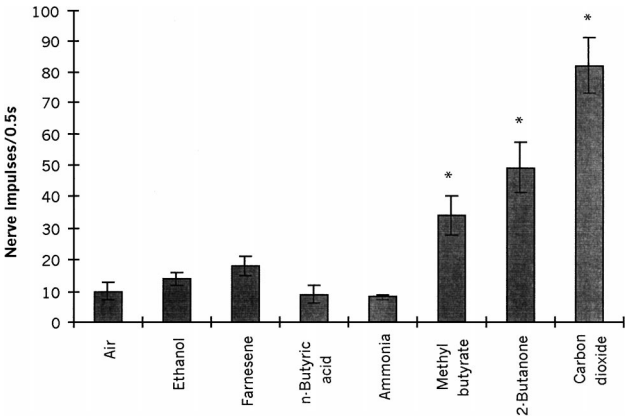

FIG. 3. Relative responses of carbon dioxide sensory receptors on the antenna of female *B. tryoni* to stimulation with 400 μl of each of the test chemicals. The asterisks indicate those chemicals that were significantly different from stimulation with clean air. Only methyl butyrate, 2-butanone, and carbon dioxide could be detected by the sensory cell. $N = 8$.

not be distinguished from the background noise, although they reappeared at the end of the stimulus burst and reached the original spike amplitude. The decrease in spike amplitude occurred after the first 0.5 sec of stimulation; therefore it did not affect the counting of nerve impulses during the initial phasic burst. Only one spike height could be reliably identified in the recordings. This was confirmed during stimulation with high concentrations of carbon dioxide: At the end of stimulation, when the spikes from the carbon dioxide receptor were inhibited, no other spikes were visible. Furthermore, if a second cell was firing, a more irregular pattern of nerve impulses would have been seen, and we should have seen some spikes of double the normal amplitude (produced when spikes from two cells coincide).

Responses to other Behavior-Modifying Chemicals. The relative responses of the sensilla containing the CO_2 receptors to other odorants are shown in Figure 3. The only chemicals that showed a significant increase in firing rate were methyl butyrate, 2-butanone, and CO_2. Farnesene, ethanol, *n*-butyric acid, and ammonia did not show a significant increase in the firing rate compared to stimulation with clean air. Ammonia often interacted with the electrodes to produce electrode potentials, which obscured the recordings for that chemical, although the onset of the electrode potentials was usually delayed long enough to determine the number of spikes within the first 0.5 sec of stimulation.

The responses to methyl butyrate and 2-butanone were not as strong as to carbon dioxide. The average number of spikes within the first 0.5 sec of stimulation with 400 μl of methyl butyrate-saturated air was 34 ± 6 spikes and for 2-butanone

it was 49 ± 8 spikes, compared to 82 ± 9 spikes for carbon dioxide. The pattern of spikes also showed some differences, with the responses to methyl butyrate and 2-butanone not showing a strong phasic response at the start of stimulation with large stimulus loads (Figure 4). The responses were tonic in nature. In most of the recordings (78%) a cessation of nerve impulses after the stimulus burst could be seen after stimulation with 400 μl of methyl butyrate and 2-butanone. The cessation of impulses after stimulation was similar to that for carbon dioxide, although the duration was smaller (0.8–1 sec; maximum of 2 sec). The duration of the increased level of firing after stimulation with methyl butyrate or 2-butanone

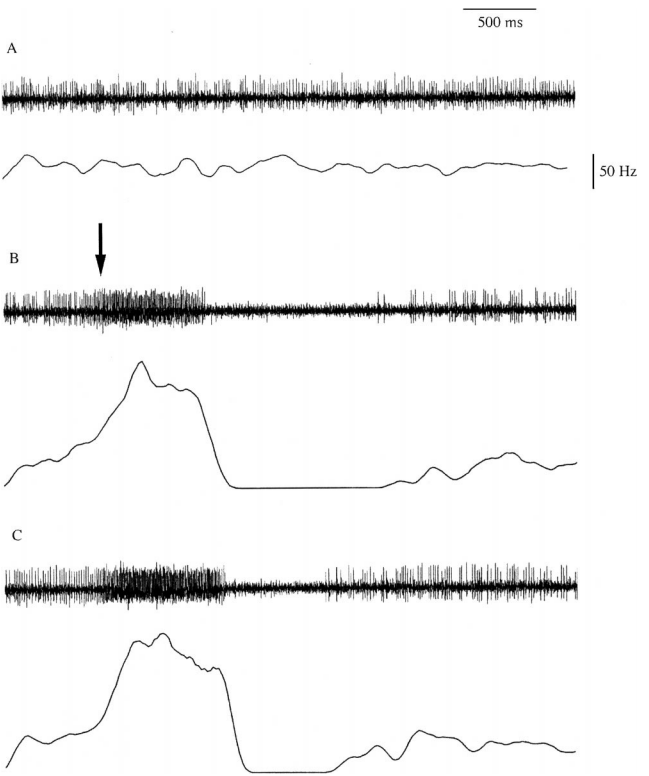

FIG. 4. Electrophysiological responses of a carbon dioxide sensory receptor on the antenna of female *B. tryoni* to other stimulating compounds. The line below each electrophysiological recording is a computer generated frequency curve, showing the firing frequency of the nerve impulses. Only methyl butyrate and 2-butanone produced significantly larger responses compared to an injection of clean air. (A) Control injection of 400 μl of clean air; (B) 400 μl of methyl butyrate saturated air; (C) 400 μl of 2-butanone saturated air. Arrow indicates the point of stimulus injection.

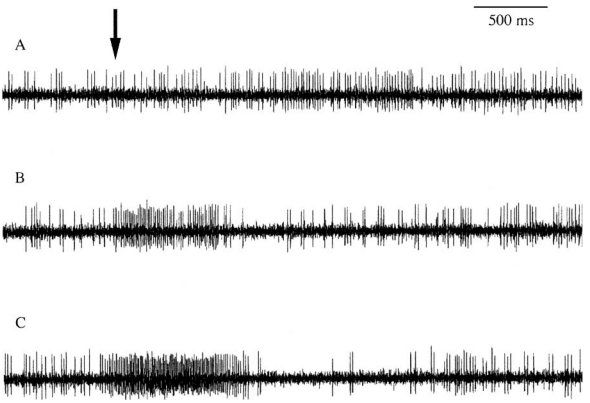

FIG. 5. Electrophysiological recordings from a carbon dioxide receptor cell on the antenna of female *B. tryoni* in response to stimulation with various concentrations of methyl butyrate. (A) Stimulation with 5 μl of methyl butyrate saturated air; (B) 100 μl of methyl butyrate saturated air; (C) 400 μl of methyl butyrate saturated air. Arrow indicates the point of stimulus injection.

was shorter compared to stimulation with carbon dioxide. At the higher stimulus intensities the duration of firing was between 1.0–1.5 sec.

The dose–response relationship for methyl butyrate is shown in Figure 1. The saturation volume for methyl butyrate is 200 μl, and resulted in 31 ± 7 nerve impulses for the first 0.5 sec of stimulation. The saturation volume is higher than that for carbon dioxide, and the number of nerve impulses obtained at all the stimulus volumes was lower for methyl butyrate compared to carbon dioxide. However, the shape of the dose–response curves are similar for both chemicals. A selection of the recordings of the methyl butyrate responses are shown in Figure 5.

Mixture Experiments. During the recordings, only one spike height could be reliably identified, regardless of the stimulating chemical. This result suggested that the nerve impulses of only one sensory cell were being recorded despite the range of stimulatory chemical types. To test this, mixture experiments involving methyl butyrate, 2-butanone, and CO_2 were conducted (Figure 6). The mixtures were analyzed by one-way paired sample *t* tests, to determine if the response to the mixture of chemicals was greater than the response of the largest of the two individual chemicals (i.e., an additive response). An additive response would indicate that the two chemicals are acting on different sensory cells within the sensillum. However, all three combinations of chemicals showed nonadditive responses (methyl butyrate with CO_2 $t = -2.205$; 2-butanone with CO_2 $t = -0.862$; and methyl butyrate with 2-butanone $t = -2.998$). The nonadditive responses confirm that only one receptor cell is responding to all three chemicals.

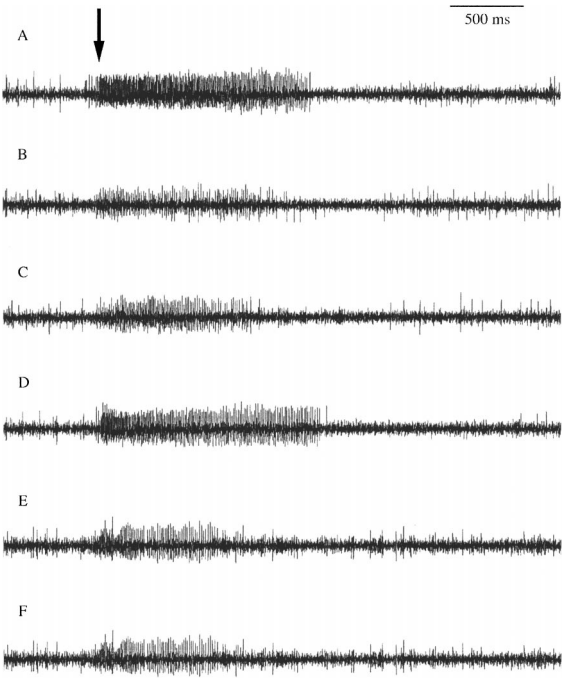

FIG. 6. Electrophysiological recordings from a sensory cell on the antenna of female *B. tryoni* in response to stimulation with mixtures of chemicals. (A) stimulation with 400 μl of carbon dioxide saturated air; (B) stimulation with 400 μl of methyl butyrate saturated air; (C) stimulation with 400 μl of 2-butanone saturated air; (D) stimulation with a mixture of carbon dioxide and methyl butyrate; (E) stimulation with a mixture of carbon dioxide and 2-butanone; (F) stimulation with a mixture of methyl butyrate and 2-butanone. Arrow indicates the point of stimulus injection.

Control Experiments. For the experiment on the effect of dilution of the chemicals, the mean number of spikes for the undiluted sample of 2-butanone was 32 ± 1.2 spikes for the first 0.5 sec. The mean for the sample of 2-butanone, diluted with clean air, was 30 ± 2.4 spikes for the first 0.5 sec. The two samples are not significantly different (two-sample t test, $t = 0.6903$), indicating that diluting the sample of a test chemical within the syringe does not effect the number of nerve impulses generated within the first 0.5 sec of stimulation. The addition of the small amount of carbon dioxide (present in the air used to dilute the sample) did not produce a significant change in the number of nerve impulses.

The percentage of the variation that is due to differences between the two runs (the R^2 value) of 2-butanone and 2-butanone plus air could be calculated. The R^2 value of 4.6% indicates that only a small amount of the variability between

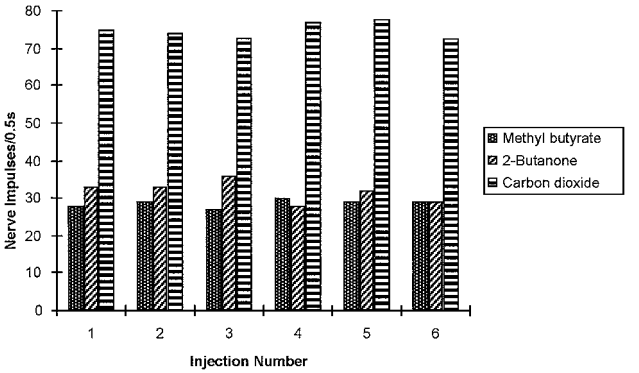

FIG. 7. Variability of the receptor cells and the stimulation technique. For each of the three test chemicals, six repeated stimulations (on the same sensillum) using 400 μl of test compound vapor produced little variability in the number of nerve impulses recorded. Methyl butyrate mean response: 29 $\pm$ 0.4 spikes, 2-butanone mean response: 32 $\pm$ 1.2 spikes, and carbon dioxide mean response: 75 $\pm$ 0.9 spikes.

the 12 values of the replicates can be accounted for by differences between the two treatments. The remaining variability is attributable to the pooled variation among the six replicates for each treatment. While most variability between the 12 values is attributable to the six replicates for each treatment, the actual level of variability for each treatment is low, as shown by the low standard errors for the treatments. The experiments testing the reproducibility of the stimulation technique showed a similarly low level of variation between the different repetitions (Figure 7). The standard error for the six repetitions of methyl butyrate was 0.4 impulses/0.5 sec, for carbon dioxide it was 0.9 impulses/0.5 sec, and for 2-butanone it was 1.2 impulses/0.5 sec. These results show that the method of injecting the odorants by hand did not contribute significant variability to the numbers of nerve impulses recorded. The use of large volumes of vapor may also have assisted in reducing variability. By having a large number of odor molecules presented to the antenna each time, any variability caused by the hand injections may have been compensated for, because both the diluted and undiluted stimuli are still at a level that saturates the receptors. However, for future experiments with low dosages, a stimulation method with even lower variability would be preferable.

Identification of Sensilla. The identification was made by locating the hole made by the insertion of the electrode. This was not possible for all of the recordings because some of the antennae required numerous attempts at inserting the electrode before a suitable recording site was found. In these antennae the large number of holes made identification of the correct one difficult. However, some recordings

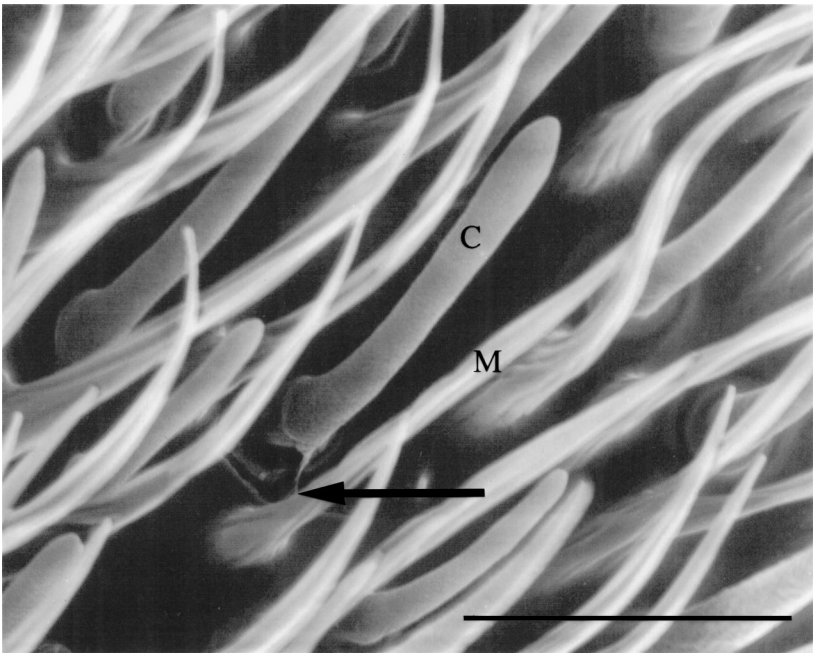

FIG. 8. Scanning electron micrograph identifying the type of sensillum recorded from in the single-unit electrophysiological experiments. The sensillum is a thin-walled multiporous type 3 (clavate) sensillum. The arrow shows the hole (enlarged for recognition) made by the insertion of the recording electrode at the base of the sensillum. C = clavate sensillum, M = uninnervated sensillum, bar = 10 μm.

were achieved with the first or second insertion attempt. Here, the position of the recording electrode was noted, and a larger hole made. Where identification was made (from four separate antennae), the sensilla were always subtype 3 Mp-sw thin-walled sensilla (clavate sensilla) (Figure 8).

DISCUSSION

Response of Cell to Carbon Dioxide. A high basal firing rate is common in general olfactory receptor cells even in the absence of stimuli, as well as in CO_2-receptive cells (Grant et al., 1995; Stange, 1996). In our study, the sensory cell was continuously exposed to a current of air (which contains CO_2), and was, therefore, constantly stimulated. The basal level of firing we recorded is then the plateau of maintained activity at that level of stimulation (the tonic response). Because CO_2 is present in the atmosphere, the tonic response we recorded can

be thought of as the normal level of firing. No tests were conducted to determine the rate of firing of the CO_2 receptor cells in *B. tryoni* to carbon dioxide–free air. The constant firing of the CO_2 sensory cells means that they must be adapted to signal changes in the concentration of CO_2 levels, which has been shown in other species (Stange, 1996). The signaling of changes in CO_2 concentration is achieved by either increasing or decreasing the level of firing of the action potentials. For *B. tryoni* the sensory cells showed a phasic-tonic response pattern to increased stimulation with CO_2. In other words, the firing of action potentials showed an initial increase, which leveled off to a lower, constant level of firing. Some of the sensory cells also showed a cessation of firing at the end of stimulation with high stimulus concentrations. The action potentials were inhibited, although the background airflow, containing CO_2, was still flowing over the antenna. Similar responses were found in the CO_2 receptors of the moth *C. cactorum* (Stange et al., 1995) and also in the pheromone receptors of the silkmoth *Bombyx mori* (Kaissling, 1986). The suppression of action potentials at the end of stimulation can be thought of as the equivalent of a phasic off-response. The ability to use both an increase and a decrease in action potential firing means that the insect can potentially encode a greater amount of information from this one stimulus and may correlate with the ability of CO_2 receptor cells to signal rapid changes in concentration (Rumbo and Kaissling, 1989).

Do CO_2 Receptors Detect Other Chemicals? During the periods of stimulation with CO_2 and when the antenna was exposed solely to the background airflow, only one action potential spike height could be reliably identified. This is despite the fact that the sensilla containing the CO_2-receptive cell also contains two other sensory cells (Hull and Cribb, 1997). When methyl butyrate and 2-butanone were presented to the antenna, the rate of firing of the nerve impulses increased. The results indicated that these compounds are being detected by the same sensory cell that detects CO_2. However, the possibility still existed that more than one sensory cell was responding during the recordings, but that all of them had identical spike heights. To test this, binary mixtures using methyl butyrate, 2-butanone, and CO_2 were conducted. If more than one sensory cell was responding, then a mixture of two of the chemicals should produce more action potentials than for either of the chemicals presented individually (Payne and Dickens, 1976). However, for all combinations of those chemicals, the mixtures produced responses that were no greater than for the larger of the two individual chemicals. These results confirmed that methyl butyrate, 2-butanone, and CO_2 are detected by the same sensory cells. This was a surprising result as CO_2-sensitive sensory neurons have generally been regarded as being specialized for that stimulus, and are, therefore, usually treated as a separate class of receptors from general odor and pheromone receptors (Stange, 1996). However, care should still be taken in interpreting these results as the response of the CO_2-sensitive sensory neurons to other volatiles may have been affected by the high dosage levels (see later discussion).

There are some cases where CO_2-sensitive cells respond to other chemicals. For instance, CO_2 receptors on the antennae of the termite *Schedorhinotermes lamanianus* can detect general odors, such as 1-pentanol, 1-hexanol, and 2-hexanol (Ziesmann, 1996). However, in this case the CO_2 had an inhibitory effect, whereas the general odors had an excitatory effect. Within the same sensillum was another sensory cell that also responded positively to general odors, but was not affected at all by CO_2. Ziesmann concluded that CO_2 was acting as a modulator of the olfactory signals and thereby allowed context specific signal interpretation. Modulation of sensory cell responses, similar to the termite CO_2 receptors, has been found in the moth *Trichoplusia ni*. In this case, dodecyl acetate was not detected by the sensory cells on its own, but when it was present in mixtures with other chemicals, it produced a modulation of the sensory cell response (O'Connell, 1986). However in *B. tryoni* no modulation of the receptors was evident. All of the detectable chemicals produced excitatory responses that were not inhibited when mixtures of chemicals were applied.

Responses of CO_2 receptors to other chemicals have also been found in *Rhodogastria* moths (Lepidoptera: Arctiidae). By using single-unit electrophysiology, the CO_2-sensitive cells in the labial palps were excited weakly by cyclopentane and inhibited by acetic acid (Bogner et al., 1986). The cells also responded positively to headspace odors of other insects and *Brassica* leaves, but this latter result is questionable. Bogner (1990) found the CO_2 receptors of *Pieris brassicae* also responded to headspace odors of insects and plants. Removing the carbon dioxide from the samples, however, greatly reduced the number of nerve impulses (from 100 impulses/sec to 0.2 impulses/sec). The receptors were, in this case, only responding to CO_2. This experiment shows the difficulty in interpreting results, particularly for CO_2 receptors, where the stimulant is present in other test samples. The CO_2 sensitive cells in the temporal organ on the head of the centipede *Thereuonema hilgendorfii* were also excited by amines, such as butylamine, amylamine, and hexylamine (Yamana et al., 1986). The same cells were inhibited by fatty acids, such as acetic acid and butyric acid, but alcohols had no effect. Volatile anesthetics have been shown to act on CO_2-sensitive cells, although the site of interaction in this case is not thought to be the primary transduction process, but a later stage of the signal cascade (Stange and Kaissling, 1995).

The response of the carbon dioxide sensory cell to methyl butyrate and 2-butanone may be due to the high stimulus concentrations used. In the gypsy moth, *Lymantria dispar*, the specialist receptor cell for disparlure (which contains only one type of receptor molecule) responds to analogs of disparlure when they are applied in high concentrations (Schneider et al., 1977). However, for *B. tryoni*, methyl butyrate and 2-butanone were the only two chemicals of the five other chemicals tested that produced a significant increase in firing of the carbon dioxide cell. The selectivity of the cell, therefore, suggests that there is some

functional significance in its ability to detect methyl butyrate and 2-butanone. Furthermore, both methyl butyrate and 2-butanone are behaviorally active chemicals (Eisemann and Rice, 1992), which adds strength to our assertion that the response of the carbon dioxide receptor to these other chemicals has a functional role. Whether the behavioral response to carbon dioxide, methyl butyrate, and 2-butanone is mediated by these receptor cells alone cannot be determined from this study. The physiological responses of only one cell type within a single sensillum type have been determined. Other cells in the antenna may also respond to some or all of these chemicals. Our EAG studies indicate another subtype of CO_2 receptor is present (Hull and Cribb, 2001). The full content of the information may only become apparent to the insect when it is taken in the context of all the responding cell types.

To determine if the cell could respond to low concentrations of an odor chemical, methyl butyrate was tested at a range of volumes. The dose–response relationship shows that the cell can detect methyl butyrate at lower volumes, although the sensitivity of the cell is lower for methyl butyrate compared to carbon dioxide. Even at the smallest volume tested (5 μl) the cell could detect carbon dioxide (i.e., the response is larger than the basal firing rate). For methyl butyrate, the responses did not increase above the basal firing rate until the stimulus volume was around 50 μl of odor-saturated air. The lower sensitivity of the cell to methyl butyrate was evident at all of the odor volumes tested. The difference in apparent sensitivity may be because the carbon dioxide samples were taken directly from a gas cylinder, and, therefore, would have been at a much greater concentration compared to the chemicals that had been taken as saturated air samples. Nevertheless, this result shows that the CO_2-sensitive sensory neurons can detect methyl butyrate at volumes well below the saturation level.

Temporal Firing Patterns and Variability. The generalist olfactory receptor cells of *Bombyx mori* show variability among cells of the same type (Heinbockel and Kaissling, 1996). Variability was also found in the firing characteristics of the carbon dioxide receptors of *H. armigera* (Stange, 1992). Therefore, it was not unexpected when we found some variability among the carbon dioxide receptors of *B. tryoni*. A range of response patterns for each receptor type may enable the insect to encode more information. However, confirmation of this hypothesis will require data from a larger number of receptor cells. Also, we recorded only from one region of the antenna. The clavate sensilla are distributed over the entire funiculus, and the patterns of nerve impulses of carbon dioxide receptors from other regions may show even larger differences.

The ability to detect changes in CO_2 concentration may be affected by changes in temperature (Stange and Wong, 1993). Small-scale temperature compensation may account for why only some of the recordings showed a cessation of firing after stimulation with high concentrations of CO_2. However, all of the recordings were

conducted in a laboratory maintained at a temperature of $24 \pm 2^{\circ}$C and with the same level of background air flow; therefore, any compensation of the responses would have been minimal.

How Do Responses of CO_2 Receptor Relate to Insect Behavior? At concentrations similar to that of vertebrate breath, CO_2 increases general flight activity (Rice, 1989). However, at low CO_2 concentrations (similar to concentrations produced by plants) gravid *B.tryoni* are attracted to the source (Stange, 1999). The difference in behavioral action may be encoded for at the peripheral level. Our experiments have shown differences in the firing characteristics of the cells that are dependent on the stimulus concentration. The behavioral activity at high concentrations may be encoded for in the initial phasic burst or in the longer period of nerve impulse firing or inhibition. Furthermore, the detection of other chemicals by the CO_2 sensitive sensory neurons may signify that the old demarcation of carbon dioxide as a separate olfactory class may not be appropriate in all cases; to *B. tryoni*, carbon dioxide is probably just another behavioral marker, which is processed along with the other olfactory stimulants.

All of the recordings were acquired from sensilla within a particular region of the funiculus, at the base near the olfactory pit. The sensilla were identified as subtype 3 Mp-sw thin-walled sensilla (clavate sensilla). These sensilla are distributed all over the funiculus, but are more abundant in the basal region. There are around 270 clavate sensilla on female *B. tryoni* antennae out of a total of about 2500 (Giannakakis and Fletcher, 1985). The relatively large number of carbon dioxide receptors confirm that this sensory modality is a significant one for the insect. The subtype 3 Mp-sw thin-walled sensilla house up to three sensory cells (Hull and Cribb, 1997). The lamellated dendrite of one of the sensory cells, extending up past the dendritic sheath, marks it as the carbon dioxide receptor (Zacharuk, 1985; Sutcliffe, 1994). The function of the other two sensory cells in the sensilla has not been determined. They did not produce an identifiable basal level of firing, and none of the other test chemicals elicited a response. Characterization of these other cells will require a greater range of test chemicals.

Our first paper in this series (Hull and Cribb, 2001). developed a hypothesis, from EAG data, that there was one class of receptor (the methyl butyrate receptor) within which three subtypes existed. Two of these subtypes responded to carbon dioxide as well as other general odorants; one responded to CO_2, methyl butyrate, and 2-butanone and the other responded to CO_2, methyl butyrate, 2-butanone, and farnesene. This present paper tests the hypothesis by looking at the response of individual sensilla and supports it in the occurrence of at least one of these two subtypes. The second subtype may be located on a separate region of the antenna and awaits further experimentation. In this previous paper, we also concluded, from EAG data on mixture experiments, that these receptors were broadly tuned rather than specific. This current study supports our EAG findings with electrophysiological data from individual dendrites.

(Received March 29, 2000; accepted January 4, 2001)

Abstract—In wind-tunnel bioassays, dispensers loaded with 1 μg of the synthetic major component (3*E*,8*Z*,11*Z*)-3,8,11-tetradecatrienyl acetate (TDTA) of the sex pheromone emitted by *Tuta absoluta* (Meyrick) females were found to be highly attractive to conspecific males. Field experiments were conducted to evaluate the efficacy of five trap designs. The best trap, baited with 100 μg of the synthetic sex pheromone caught on average 1200 males per trap per night, while those baited with virgin females caught only 201 males. The male response to this pheromone is restricted to the same early-morning time window during which females exhibit calling behavior. The high biological activity of the synthetic pheromone suggests that it could be useful for pest monitoring and in mating disruption.

Key Words—*Tuta absoluta*, sex pheromone, (3*E*,8*Z*,11*Z*)-3, 8,11-tetradecatrienyl acetate, field tests, monitoring.

INTRODUCTION

Tuta (=Srobipalpuloides) absoluta (Meyrick) (Lepidoptera:Gelechiidae) is a key pest of tomato *(Lycopersicon esculentum* Mill.) due to the damage it causes and the lack of ecologically acceptable methods for its control. It has been considered to be the major limiting factor for tomato production in South America (Bahamondes and Mallea, 1969; Quiroz, 1976).

IPM programs for *T. absoluta* may be achieved through the use of sex pheromone. Populations of other Gelechiidae, such as *Keiferia lycopersicella* (Walsingham) have been efficiently monitored with traps baited with sex pheromone (Jenkins et al., 1990). Trumble and Alvarado-Rodriguez (1993) reported a successful management strategy (sex pheromone for monitoring the population as well as for mating disruption) for the control of *K. lycopersicella* in industrial tomato crops. For *Phthorimae operculella* (Zeller), pheromone traps have been used as part of IPM strategies (Kennedy, 1975; Raman, 1984; Salas et al., 1985).

Using *T. absoluta* virgin females, Quiroz (1978) captured more than 100 males/trap/day, and Uchôa-Fernandes and Vilela (1994), using the same technique, compared different trap designs, heights, and displacement in tomato fields for capturing *T. absoluta* males. They reported high specificity and sensitivity of traps baited with natural pheromone, besides being more economical and convenient than the light traps.

In this work we report laboratory and field evaluations of the major synthetic component of the sex pheromone of *T. absoluta*, (3*E*, 8*Z*, 11*Z*)-3,8,11-tetradecatrienyl acetate (TDTA), which was identified and synthesized by our group (Attygalle et al., 1995, 1996). Its structure was confirmed by Griepink et al. (1996).

METHODS AND MATERIALS

Insect Rearing. Larvae of *T. absoluta* were collected on tomato in fields around Viçosa, MG, Brazil and reared on artificial diet (Pratissoli, 1995) at 23 ± 2°C, 75 ± 5% relative humidity and a 14L:10D photoregime. After separation of females and males (Coelho and França, 1987), pupae were maintained in separate rooms to avoid exposure of males to female sex pheromone and consequent development of habituation (Bartell, 1977).

Wind-Tunnel Bioassays. Bioassays were conducted in a wind tunnel (1.5 m long and 0.5 m height) at 24 ± 1.5°C, 83 ± 3%, relative humidity, and air flux of 30 mm/sec. The TDTA source was placed at a height of 0.3 m and 1.0 m from the point of insect release. After each bioassay, the tunnel and its accessories were thoroughly cleaned with neutral detergent and water. The synthetic pheromone was dissolved in doubly distilled hexane and appropriate volumes were impregnated on a rubber septum and allowed to air dry for 24 hr. For field trials, treated septa were sealed in aluminum foil and transported in an ice box. All septa used for

impregnating the pheromone were previously extracted for 24 hr with distilled CH_2Cl_2 in a Soxhlet extractor.

The attractiveness of the synthetic acetate (0.01, 0.1, 1 and 10 μg/septum) was compared to that of nine virgin females during their calling period (Hickel and Vilela, 1991; Hickel et al., 1991; Uchôa-Fernandes et al., 1995a). Hexane (100 μl) was placed on a rubber septum, air dried, and used as control. The experimental design was entirely randomized with 10 replications, each consisting of three males (1 to 3 days old), released from glass tubes open on both sides. Each observation lasted 5 min and the response of males was computed once, after which they were eliminated.

Field Experiments. Field experiments were conducted in two tomato crops (staked and industrial) to evaluate the efficiency of five types of traps as well as to determine the attractiveness of TDTA. In addition, the variation of insect capture during the day and during the tomato plant phases was studied.

Staked Tomatoes. These experiments were conducted in a 20-ha staked (commercial) tomato crop (Santa Clara variety), in Araguari, MG, Brazil during April 1–11, 1994. The following five trap designs were evaluated: (1) commercial Delta sticky trap (AgriSense Ltd.) with a vertical height of about 7 cm at the triangular opening and a base of 29 $\times$ 30 cm; (2) CICA-Q trap (home made), which consisted of a white square plastic tray (24 $\times$ 37 $\times$ 6 cm) covered with a thin plate (V shaped) and held together with four strong metal wires; (3) CICA-R trap (home made) consisted of two black round trays (commonly used for house gardening in Brazil), with the larger one (32 cm in diameter) serving as the base and the smaller one (20 cm in diameter) serving as the top. The two plates were held together by three strong metal wires equidistant from each other. Both traps contained water and detergent to trap the insects; (4) home made PVA 200 trap (Uchôa-Fernandes and Vilela, 1994) made up of a white PVC tube (200 mm diameter) and an adhesive cardboard inside, similar to the Delta trap, and (5) home made PVC-M 200 trap, which was a modification of PVA 200 trap with two lateral longitudinal openings.

Each trap was baited with 1 μg of TDTA and placed at 30-m intervals and at 1.2 m above ground (Uchôa-Fernandes and Vilela, 1994) during three days. The experimental design was a Latin square (Perry et al., 1980), and the number of insects caught in each trap, with five replicates (25 traps) was counted daily. The highest number of insects caught was with CICA-R traps and, hence, some of the subsequent tests were conducted with this type of trap.

The periodicity of male capture over a 24-hr period was evaluated by using Delta traps containing 1 μg of the synthetic TDTA impregnated on a rubber septa, with four replicates, for four 24-hr periods.

Industrial Tomatoes. These experiments were conducted in Petrolina, PE, Brazil during June 25–July 5, 1994 on a commercial 20-ha industrial tomato crop (cultivar IPA). The five traps described in the previous experiment were evaluated at 0.4 m above the ground over a five-day period. Each trap was baited with a

rubber septum containing 1 μg of the synthetic TDTA and its position remained unchanged during the experiment. The experiment was arranged in a randomized block with five replications.

In order to evaluate the variation of insect capture during the day, traps containing 1 μg of the TDTA (five replications) were spaced 30 m apart. To evaluate the effect of trap height, CICA-R traps were placed in three different crop phases. CICA-R traps containing 1 μg of the TDTA were placed at 0.2, 0.4, 0.6, 0.8, and 1.0 m above ground in the first crop phase, i.e., just before planting. CICA-R traps containing 1 μg of the TDTA were placed at 0.2, 0.4, 0.6, 0.8, and 1.0 m above ground in second crop phase (0.2-m high plant). CICA-R traps containing 1 μg of the TDTA were placed at 0.2, 0.4, 0.6, 0.8, and 1.0 m above ground in the third crop phase, which was crop with flowers. Five replications were used.

Statistical Analyses. The data obtained in wind-tunnel bioassays were transformed into arcsine (X). After that they started to present normal distribution and were statistically analyzed at 5% significance (Scott and Knott, 1974). The following statistical analyses were utilized for three parameters evaluated: in field experiments: The attraction data were transformed into log ($X + 1$). After that, they started to present normal distribution and they were statistically analyzed at 5% significance (Scott and Knott, 1974). The data of periodicity of male capture were transformed into $\sqrt{(X + 0.5)}$. After that, they started to present normal distribution and were statistically analyzed at 5% significance (Duncan). The trap design data with staked tomatoes presented normal distribution and were analyzed without transformation. The trap design data obtained in the field experiments with industrial tomatoes were transformed into $\sqrt{X}$. After that they started to present normal distribution and were statistically analyzed at 5% significance (Scott and Knott, 1974).

The data for height of traps for the first phase (before planting) as well as for the second phase, (20-cm-high plants), presented normal distribution and were analyzed without transformation, whereas the data for the third phase (plants with flowers) were transformed into $\sqrt{X}$. All data were subjected to ANOVA analysis and the averages were compared by Scott-Knott test (Scott and Knott, 1974) or the Duncan test at 5% significance.

RESULTS

Wind-Tunnel Bioassays. The response of *T. absoluta* males to the synthetic TDTA was immediate (within 1–5 min), with males landing on the pheromone source, indicating a possible application in insect trapping. The highest response was obtained with 0.1, 1.0 and 10.0 μg (Figure 1). Male wing fanning was significantly higher with 1 μg than that obtained with other doses of the synthetic pheromone (Figure 1).

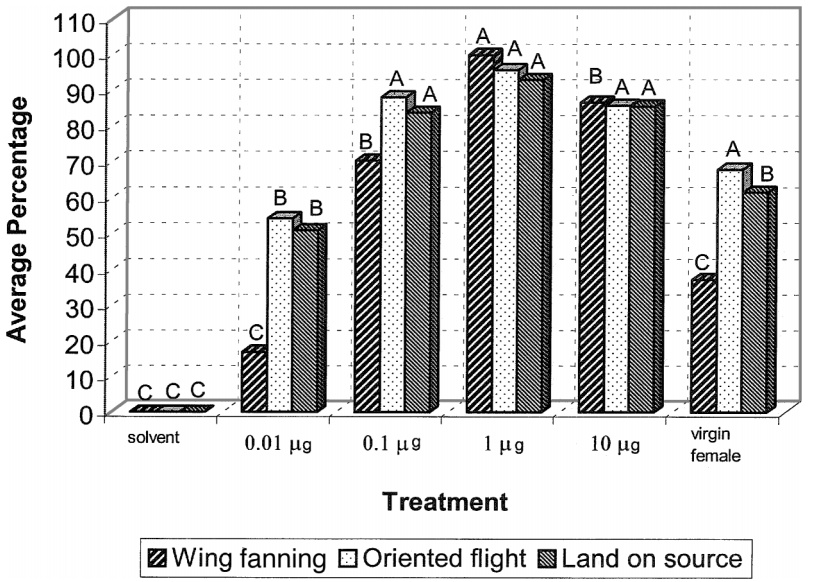

FIG. 1. Average percentage of *T. absoluta* males that respond to different amounts of TDTA, to virgin females, and to the solvent in a wind tunnel. Bars followed by the same letter are not significantly different ($\alpha = 0.05$, Scott-Knott test, $N = 10$).

Response to Trap Design in the Field. The results of the experiments with staked and industrial tomatoes are shown in Figures 2 and 3, respectively. In staked tomato plantations, both CICA-R and CICA-Q traps provided the best insect captures (Figure 2) while in the industrial tomato crops, at initial insect infestation (low), the CICA-R and PVC traps captured the highest number of males, but the captures were not significantly different from the CICA-Q and Delta traps (Figure 3). The adhesive cardboard of the PVC traps presented the disadvantage of not retaining newly attracted insects due to surface saturation. This was not observed with traps that used water and detergent to trap the insects in highly infested fields. Consequently, a greater number of insects was trapped with both CICA-Q and CICA-R traps. However, in a low infestation situation, CICA-Q traps did not present significant difference in the number of insect trapped. The CICA-R trap, which was black and totally open, was more efficient probably due to its format.

Concentrations of TDTA in the Field. The highest response of *T. absoluta* males was obtained at a concentration of 100 μg of the main component of the sex pheromone TDTA per trap (Figure 4).

Periodicity of Male Captures. In the staked and industrial tomato crops, the capture of the males occurred between 5 and 9 AM, with a peak around 7 AM

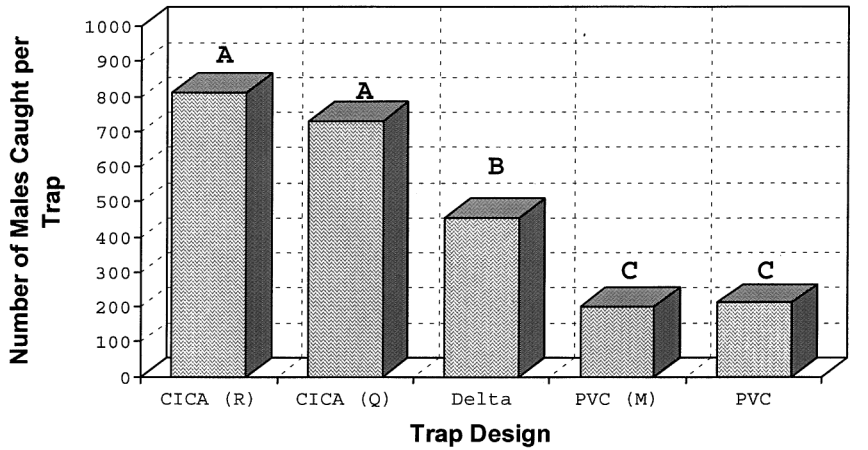

FIG. 2. Average number of males of *T. absoluta* caught per morning per trap in a staked tomato crop in Araguari, MG, Brazil, during 1994, with five different trap designs. Each trap was baited with 1 μg of synthetic TDTA. Histograms followed by the same letter are not significantly different ($\alpha = 0.05$, Scott-Knott test, $N = 5$).

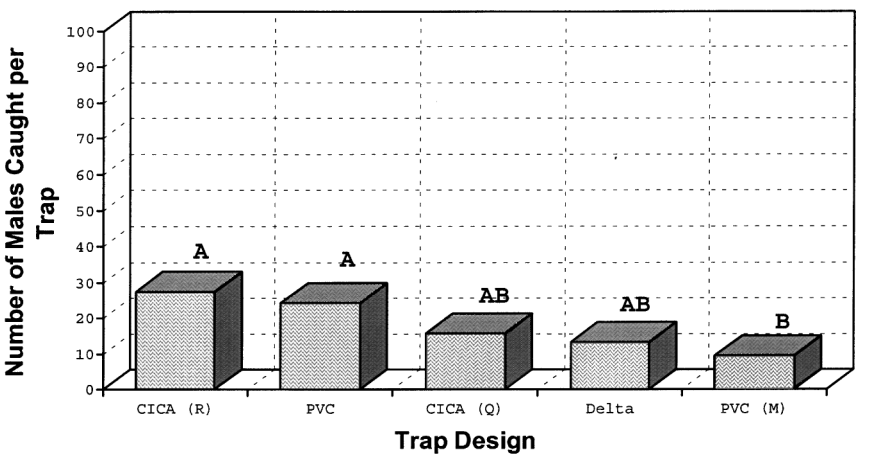

FIG. 3. Average number of males of *T. absoluta* caught per morning per trap in an industrial tomato crop in Petrolina, PE, Brazil, during 1994, with five different trap designs. Each trap was baited with 1 μg of synthetic TDTA. Histograms followed by the same letter are not significantly different ($\alpha = 0.05$, Duncan test, $N = 5$).

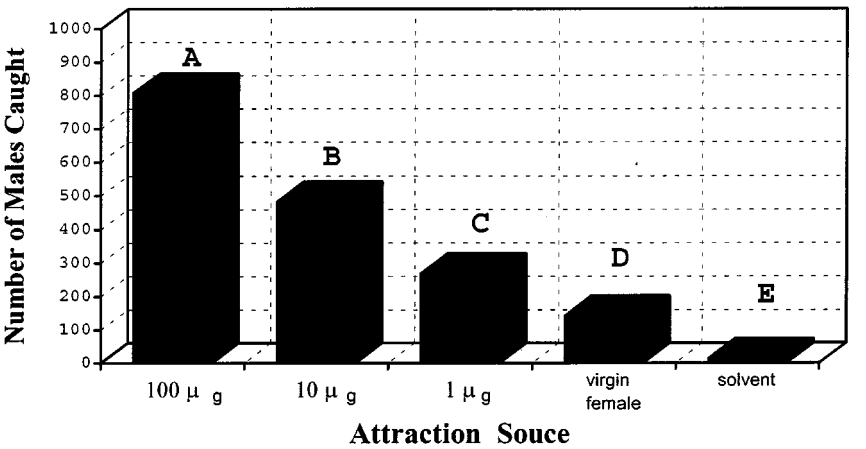

FIG. 4. Average number of males of *T. absoluta* caught per morning per trap in a staked tomato crop in Araguari, MG, Brazil, during 1994, with different concentrations of the synthetic TDTA. Histograms followed by the same letter are not significantly different ($\alpha = 0.05$, Scott-Knott test, $N = 5$).

(Table 1). Insect infestation was lower during the evaluation period in the industrial tomato crops compared to the staked tomato crops. Insect capture with synthetic pheromone baits was affected by temperature. Earlier capture generally took place when the temperature was lower ($r = -0.79$, $P < 0.01$). However, no effect of relative humidity was noted ($r = 0.79$, $P = 0.14$).

Height of Traps. In the industrial tomato crops, when the soil was prepared for tilling, traps placed at a height of 20 cm above ground presented the best results, capturing the highest number of *T. absoluta* males (Figure 5). When the tomato plants were about 20 cm high, traps placed at heights of 20, 40, and 60 cm captured

TABLE 1. AVERAGE NUMBER ($N = 4$) OF MALES OF *Tuta absoluta* CAUGHT PER MORNING PER TRAP, IN DELTA TRAPS BAITED WITH 1 μG OF SYNTHETIC TDTA IN A FIELD WITH STAKED TOMATO CROP (ARAGUARI, MG, BRAZIL, 1994)

Evaluation date	5-6 AM	6-7 AM	7-8 AM	8-9 AM	General average
April 8	13.98cAB	511.91aA	190.00Ba	3.48dA	111.02A
April 9	22.90cA	432.48aB	48.53bB	0.00dA	69.03B
April 10	2.30aC	6.69aC	5.68aC	2.00aA	3.93C
April 11	5.96aBC	9.98aC	0.46bC	0.00bA	2.97C
General average	9.83c	151.79a	36.27b	1.06c	

Averages followed by the same small letter in a row or capital letters in a column did not differ significantly (Duncan test, $P < 0.05$).

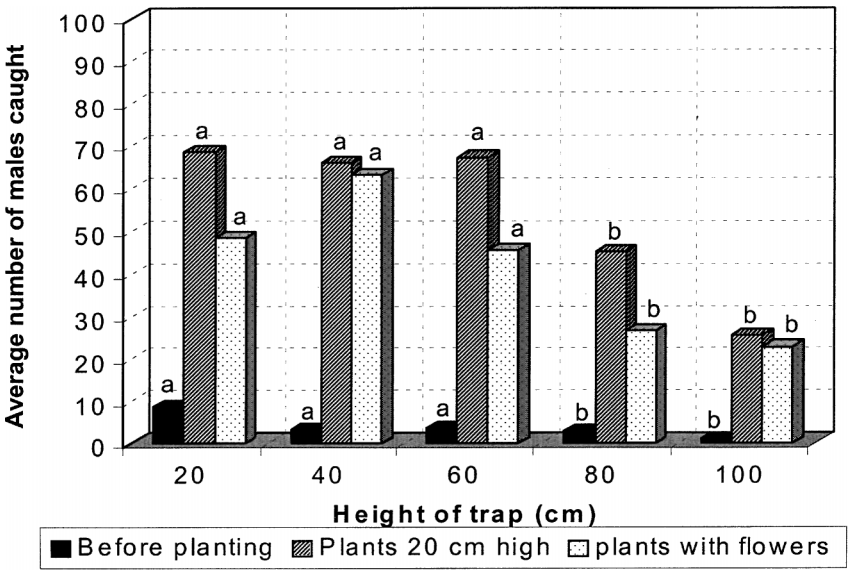

FIG. 5. Average number of males of *T. absoluta* caught per morning per trap in three different stages of an industrial tomato crop in Petrolina, PE, Brazil, during 1994. Each trap was baited with 1 μg of synthetic TDTA. In each stage, histograms followed by the same letter are not significantly different ($\alpha = 0.05$, Scott-Knott test, $N = 5$ for each stage).

a higher number of insects. However, the results obtained from different heights were not significantly different.

DISCUSSION

Wind-Tunnel Bioassays. Typical responses were recorded in wind-tunnel bioassays. Wing fanning represents a state of high sexual excitement in males (Cardé, 1984) and most of the time resulted in landing on the pheromone source. Males flew towards the source impregnated with 0.1, 1.0, and 10 μg of TDTA, as well towards virgin females, whereas there was no significant difference between 0.01 μg and solvent (Figure 1). Similar results have been reported by Hickel et al. (1991), working with virgin females.

Response to Trap Design in the Field. The best results were obtained with the CICA-R trap, which was probably due to its completely open shape. These results were in agreement with those of Wyman (1979), working on monitoring of *Keiferia lycopersicella* using synthetic pheromone. He concluded that a high trap efficiency was related to ease access of insects to traps. The cost of each unit of the CICA-R trap, Delta trap and its sticky cardboard, CICA-Q trap, and PVC

trap was of US$2.95, 5.00, 7.00, and 1.92 (not including the sticky cardboard), respectively.

Concentrations of TDTA in the Field. Each higher concentration of TDTA trapped more insects, possibly due to greater amounts of pheromone released. Tumlinson et al. (1994) have reported a higher release rate of the synthetic pheromone of *Manduca sexta* (L.) in the field from the rubber septa impregnated with higher amounts.

Periodicity of Male Captures. In the staked tomato crops, the results on periodicity of male captures were in agreement with those of Uchôa-Fernandes et al. (1995b), who used virgins female as baits. The difference in the number of insects captured in the two areas was most likely due to the lower insect infestation during the evaluation period in the industrial tomato crops compared to the staked tomato crops.

The influence of temperature on pheromone catch is in agreement with that reported by Cardé and Roelofs (1973), for *Holomelina immaculata* (Rearkirt), for which the temperature influenced both the initiation and periodicity of captures. Cardé et al. (1974) confirmed that temperature can modify the calling period or the male response. McNeil (1991) reported that several factors affect the emission and reception of pheromones, mainly temperature, which affected the calling period of the females and, consequently, the male response.

In summary, these results suggest that a partial application of low cost CICA-R traps loaded with 100 μg of the synthetic pheromone (TDTA) for monitoring *T. absoluta* populations. In soil prepared for sowing, the height of the trap should be 20 cm, and for plants that are around 20 cm high, the traps should be placed at a height of 20–60 cm and should remain in place until harvest. With growing plants, the height of the traps should be about 60 cm, since a higher degree of attack takes place in the medium and top parts of the canopy (Coelho and França, 1987; Pratissoli, 1995; Picanç et al., 1995).

(Received October 4, 1999; accepted January 10, 2001)

Abstract—Chemical analyses revealed that the labial gland complex of worker honeybees possesses a series of hydrocarbons dominated by odd-numbered carbon chain alkanes along with minor amounts of alkenes and branched alkanes. Foragers contained significantly more secretion than nurse bees. Experiments with bees from colonies induced to have a division of labor independent of age revealed that the differences in the amount of secretion were task, but not age dependent.

Key Words—Honeybees, labial glands, exocrine glands, secretion, hydrocarbons, forager bees, task specificity.

INTRODUCTION

The labial (salivary) gland complex comprises two pairs of glands, one in the head and one in the thorax, both of which connect through a common duct to the mouth (Cruze Landim, 1967). They are intermittently developed in bees, and little is known about the chemistry or function of their secretion. In the mason bee, *Chalicodoma siculum*, the head gland secretion is composed of hydrocarbons that are used to waterproof brood cells (Kronenberg and Hefetz, 1984). Male carpenter

bees, *Xylocopa varipuncta*, presumably use the secretion from the thoracic gland as a long-range sex attractant, but the chemistry remains elusive (Minckley et al., 1991). The chemistry and function of the labial gland secretion of male bumble bees was extensively studied, revealing a plethora of compounds (Bergström et al., 1981; Genin et al., 1984). The secretion is species-specific, and in the species studied it is used for marking the flight path to which queens and other males are attracted (Kullenberg et al. 1970, 1973; Bergman and Bergström 1997; Hovorka et al., 1998; Kindl et al., 1999). The labial glands are also well developed in *Bombus terrestris* queens and contain mostly a series of dodecyl esters (Hefetz et al., 1996).

The posterior part of the head gland and the thoracic gland were reported to be involved in partial food digestion in the honeybee. The secretion of the thoracic gland contains watery saliva that dissolves sugars, whereas the head gland produces an oily secretion of unknown function (Simpson, 1960; Arnold and Delge-Derachen, 1978). We present here a comparative analysis of the volatile constituents of the head and thoracic gland secretions of worker honey bees as a function of age and task.

METHODS AND MATERIALS

Bee and Hive Manipulations. Workers of European honeybees (*Apis mellifera ligustica*) were obtained mostly from the Tzrifin apiary (Ministry of Agriculture), Israel, and from one colony from an apiary at the University of Illinois Bee Research Facility. Nurse bees were collected on brood combs and foragers returning with pollen were collected at the hive entrance. To dissociate possible effect of age and behavioral status on glandular composition, a single-cohort colony was established with about 1000 1-day-old adult bees from a field colony. These bees were obtained by taking frames containing old pupae and placing them in an incubator (34°C and 80% relative humidity). Newly emerging adults were marked with paint dots on the thorax. The colony was given a single frame of food and a mated queen. Under these conditions some of the workers become precocious foragers, whereas three weeks later some workers still remained as old nurses (Robinson et al., 1989). Four groups of bees were collected for comparative analyses: young (precocious) foragers and young nurses were collected after one week, and old foragers and old (over-aged) nurses were collected after three weeks. Bees for the GC-MS analyses were obtained from several commercial colonies at the Tzrifin apiary. Quantitative analyses were conducted using bees from one "typical colony" and one "single cohort colony."

Chemical Analyses and Compound Identification. Head and thoracic labial glands were dissected under a stereo microscope ($\times 20$) and extracted in 100 μl dichloromethane (to enable proper detection of the peaks by gas chromatography

each sample comprised a pool of glands from five bees). The head glands were separated from the hypopharyngeal glands and the thoracic glands were separated from the thoracic muscles. Extracts were analyzed by combined capillary gas chromatography–mass spectrometry (EI 70 eV, and CI using methane as a reagent gas) using a 30-m DB-5 fused silica column that was temperature programmed from 120°C to 300°C at a rate of 3°/min with initial hold of 3 min. Quantitative analyses were done by gas chromatography using a 30-m SE-54 or DB-1 capillary column that was temperature programmed from 60°C to 100°C at 20°/min and to 270°C at 5°/min (final hold: 30 min). Identity of the components was verified by comparing their retention time with standard compounds. Quantification of the glandular secretion was performed by peak integration (FID detector) using eicosane (1 μg/sample) as an internal standard.

RESULTS AND DISCUSSION

Table 1 presents a list of the volatile components found both in the head and thoracic labial gland secretion of honeybee, nurses, and foragers. The main components in both worker groups were straight-chain alkanes ranging from C_{21} to C_{35}, accompanied by minor amounts of alkenes and methyl-branched alkanes. In most cases the major components in all groups of workers were the same (e.g., odd-numbered carbon chain alkanes), but there was a degree of specificity in the minor components.

Quantification of the glandular extracts revealed that the total amount of secretion was normally distributed among samples (Kolmogorov-Smirnov $P > 0.2$, for both head and thoracic glands). We assessed the differences between treatments (age and task) by ANOVA followed by Fisher post-hoc test. There was a significant effect of task, but not age on the total amount of secretion for both the head and thoracic glands (Table 2, ANOVA). Foragers had higher amounts of secretion than nurses, irrespective of their age.

For the head glands, specific comparison between the group of bees showed that among the hive bees (of undetermined age) foragers had larger amounts of secretion than nurses in the head but not in the thoracic glands (Table 3, typical colony, ANOVA followed by Fisher's PLSD; $P < 0.0001$). Analyses of bees from a single-cohort colony indicated that the quantitative differences in the head gland secretion are mostly related to differences in behavior, and not to age (Table 3, single cohort colony bees). Although old foragers that originated from the single cohort colony tended to have less secretion in the head labial glands as compared to foragers from a typical colony, it was not significant ($P = 0.057$). The amount of secretion in precocious foragers was lower than that of foragers from a typical colony, but not than of old foragers from the single cohort colony ($P = 0.03$ and $P = 0.68$, respectively). Foragers from the single-cohort colonies had greater

amounts of secretion than nurse bees that originated from the same cohort colonies, irrespective of age. While the differences between the old foragers and the two types of nurses were significant, secretion of precocious foragers was higher than that of old nurses, but not that of young nurses.

Typical colony and single-cohort colony nurse bees did not differ in secretionary quantities in the head gland (ANOVA Fisher's PLSD $P = 0.97$ and $P > 0.99$ for young and old nurses, respectively).

For the thoracic glands, there were no differences between typical colony foragers and foragers from the single-cohort colony, whether old or precocious foragers, in the amount of glandular secretion (ANOVA Fisher's PLSD $P = 0.87$ and $P = 0.82$ for old and precocious foragers, respectively). In contrast, there were differences in the thoracic gland secretion between nurses from a typical colony and old foragers from a cohort colony, but not from young or overaged nurses, ($P = 0.04$ for old foragers and $P = 0.38$ and $P = 0.67$ for young and old nurses, respectively).

Differences in the amounts of material in the head gland suggest that as bees begin to forage, their glands start to fill up with hydrocarbons. Although this process appears to be largely age independent, there does seem to be an effect of a maturation or experience maturity component. The somewhat lower amounts found in precocious foragers may be explained by the short time (just a few days) that they had spent as foragers. The tendency of task-related greater amount of secretion was also noticeable in thoracic gland, although it was not statistically different.

Honeybee labial glands were previously thought to be solely involved in processing sugar. The secretion was thought to be mostly water soluble and to

contain digestive saliva (Simpson, 1960). The presence of copious amounts of hydrocarbons in the glands, suggests that the glandular secretion may have additional functions. There are only a few studies pertaining to the chemistry and function of the labial glands in other bee species. The gland is intermittently developed in bees and its use as well as its chemistry may have evolved several times independently. The head gland in the mason bee, *Chalicodoma siculum*, possesses an array of hydrocarbons similar to that of honeybees, used in this species in nest construction. The secretion is mixed with saliva and provides the brood cells with a waterproof layer (Kronenberg and Hefetz, 1984). It may have a similar function in the honeybee, e.g., assisting the preforager bees to manipulate the wax while constructing the brood comb. We think that this function is unlikely since foragers had larger amounts than nurses, opposite to what is expected from the above function.

The hydrocarbons detected in the labial glands of the honeybee are also present on the epicuticule (Arnold et al., 1996, and personal observation). This raises the possibility of a link between these two body parts. If this is so, the honeybee labial gland may function in a manner comparable to the postpharyngeal gland (PPG) of some ant species in which it serves as a reservoir of hydrocarbons that arise both from internal sources and through exchanges with nestmates (Soroker et al., 1994; Soroker and Hefetz, 2000). The postpharyngeal gland in the ant *Cataglyphis niger* is the source of hydrocarbon nestmate recognition cues (Lahav et al., 1999). This implies a hydrocarbon exchange between the labial gland and the cuticle of individual bees, as well as interindividual exchanges via trophallaxis and allogrooming. Worker honeybees can discriminate members of the same subfamily (super sister) from workers of other subfamilies (half sisters) (Moritz and Hillesheim, 1990). This is thought to be based partly upon cuticular hydrocarbons (Page et al., 1991). Different studies have revealed that none of the major cuticular hydrocarbons gave a positive result in recognition bioassays, whereas hydrocarbons present in smaller quantities gave positive results. The complete recognition mixture probably contains minute amounts of hydrocarbons, perhaps along with other as yet unidentified components that can be either produced by the workers or acquired from external sources, e.g., flowers, the queen, or the wax comb (Breed, 1998).

This study shows that the labial glands constitute yet another set of exocrine glands that are affected by honeybee age polyethism. The results suggest that the glandular secretion has a role that is specific to foragers. One possibility is that the secretion may be involved in regulation of the age at which bees begin to forage. One regulatory model postulates the presence of an inhibitor (as yet unidentified) that inhibits the rate of behavioral development and delays the age and onset of foraging (Huang and Robinson, 1992, 1996). The inhibitor is hypothesized to be produced and/or transferred in greater amount by old bees (Huang and Robinson, 1992), and recent results indicate that this transfer is done by trophallaxis (Huang et al; 1998; Schultz et al., 1998). This idea fits with the hypothesis,

based on behavioral observations, that trophallaxis functions in communication as well as in food transfer (Korst and Velthuis 1982). Because the labial glands open to the buccal cavity, it is tempting to speculate that the secretion in foragers constitutes part of the hypothesized inhibitory system, but this awaits further experimentation.

Acknowledgments—We thank the Tzrifin apiary for assistance in establishing experimental hives, Dr. T. Simon for her advice, Roy Fayman for his technical assistance, Nomi Paz for editorial help, and A. J. Ross for expert technical assistance in Illinois. (Received September 19, 2000; accepted January 15, 2001)

Abstract—There are two separate, and presumably opposing, processes that affect colony odor in the desert ant *Cataglyphis niger*: (1) biosynthesis and turnover of these chemicals by individual ants, and (2) homogenization of colony odor through exchange of cues. The first increases signal variability; the latter decreases it. The impact of these factors was tested by splitting colonies and monitoring the profile changes occurring in the postpharyngeal glands (PPG) and cuticular hydrocarbons.

From each of two polygynous nests four daughter colonies were formed, three monogynous and one queenless. Thereafter, 10 ants from each were randomly selected each month, for three successive months, for analyses of their PPG and cuticular hydrocarbons. From two colonies we also obtained ants from a known matriline. Over time, there was a shift in hydrocarbon profiles of both the PPG and cuticular washes in each of the tested colonies. Moreover, by subjecting selected hydrocarbon constituents to a discriminant analyses based on their relative proportions, all of the daughter colonies (queenright and queenless) were distinguishable from each other and from their respective mother colonies. In each of the queenright daughter colonies, the queen profile was indiscriminable from that of the workers and often was in the center of the group. Full sisters were clearly distinguishable from their nestmates, emphasizing the genetic versus environmental processes that govern colony odor. The effect of time was always superior to the separation effect in contributing to odor segregation. Comparison of the Mahalanobis distances indicated that the shift in hydrocarbon seems to proceed along parallel lines rather than in divergence. However, there was no

overt aggression between ants that originated from the different subgroups in dyadic encounters. It appears that in this species a three-month separation period is not sufficient to change the hydrocarbon profile beyond the recognition threshold.

Key Words—Hydrocarbons, *Cataglyphys niger*, nestmate recognition, postpharyngeal gland, gestalt.

INTRODUCTION

Studies pertaining to nestmate recognition have focused in recent years on the nature of the recognition cues and the modes by which colony odor is obtained. In ants, and to some extent in termites, we have indirect, correlative evidence on the role of cuticular hydrocarbons (HCs) as recognition cues (Bonavita-Cougourdan et al., 1987a,b, 1993). Direct evidence for the specific involvement of HCs, but not the more polar cuticular lipids, in interspecific recognition was obtained for *Reticulitermes* (Bagnères et al., 1991), and for intraspecific nestmate recognition in *Cataglyphis niger* (Lahav et al., 1999).

The finding that cuticular HC composition appears congruent with that of the postpharyngeal gland (PPG) (Bagnères and Morgan, 1991), has focused research on the role of this gland in nestmate recognition. PPG extracts were indeed able to modify aggressive behavior in two phylogenetically remote species, *Manica rubida* (Hefetz et al., 1996) and *C. niger* (Soroker et al., 1994). Using HCs as a model for recognition cues and *C. niger* as a model ant, it was further demonstrated that the PPG acts as a "gestalt organ" that enables the admixing and rapid integration of odors from various sources (Soroker et al., 1994, 1995b). This provided empirical evidence supporting the "gestalt model" for creation and acquisition of a general colony odor (Crozier and Dix, 1979). At the individual ant level, there is an exchange between epicuticle and PPG HCs through self-grooming, which explains the chemical congruency between them. This was also confirmed for *Camponotus vagus*, where deposition of (*Z*)-9-tricosene on the cuticle of a worker resulted in its occurrence in the PPG (Meskali et al., 1995). At the colony level, mutual exchanges of cuticular and PPG HCs between nestmates takes place through trophallaxis, allogrooming, and physical contact. This was determined for several species belonging to remote ant subfamilies, as well as for artificially mixed species groups (Soroker et al., 1995b). Evidence for HC exchange was also observed in a species of termite, but the exchange was achieved only through physical contact (Vauchot et al., 1996, 1998). Blending of individual odors into a uniform colony odor seems to be a system common to social insects.

There are two separate processes that presumably govern the chemical nature of the recognition signal within ant colonies: (1) biosynthesis and turnover of these chemicals by each individual in the colony, and (2) the homogenization of colony

odor through continuous exchange of recognition cues. These opposing factors affect the variability of the chemical signal. Individual production increases variability, whereas signal exchange decreases it. Signal production by each individual is probably genetically based, and we can assume that it remains qualitatively constant, although it has been shown in other ant species that quantitative changes (relative amounts) in cues can occur over time (Vander Meer et al., 1989; Provost et al., 1993; Boulay et al., 2000). In polygynous colonies variability in signal composition is increased by the cohabitation of several matrilines (and possibly several patrilines within each matriline). Despite this individual variability in signal composition, a unified colony odor is maintained by mutual exchanges of the signal among members of the colony. Because population composition of a given colony changes with time, we hypothesized that colony odor is dynamic and also changes with time. We tested this hypothesis by following the changes in HC profiles with time in polygynous mother colonies of *C. niger*, as well as their monogynous or queenless daughter colonies.

METHODS AND MATERIALS

Collection and Maintenance of Ant Colonies. Two polygyne colonies of *C. niger*, A (with 11 queens) and B (with 18 queens), were collected from the Tel-Aviv area, transferred to artificial nests in the laboratory and reared under controlled conditions ($28 \pm 2^{\circ}$C, 8L : 16D photoperiod). All colonies were provided with an identical diet of sugar water and minced insects three times a week. Three monogyne fragments and one queenless (QL) group (daughter colonies) were created from each of the two polygyne colonies (mother colonies) (Figure 1). The mother and daughter colonies were then separated for three months. Each original mother colony consisted of about 3000 ants, and each daughter colony of 250 ants. Before separation a random sample of 10 ants was taken from each of the mother colonies for chemical analyses of the PPG and cuticular washes. Thereafter, once a month, for three months, 10 ants were sampled from the mother colonies and from one of the daughter colonies for chemical analyses. The three other daughter nests were sampled after three months of separation. From two monogyne daughter colonies (A1 and A3) matriline workers were obtained. These were separated from their respective colony as pupae and the emerging adults (manually assisted) were analyzed separately at the age of seven days.

Chemical Analysis. Detailed chemical analyses of PPG and cuticular HC profiles have been published previously (Soroker et al., 1995a; Soroker and Hefetz, 2000). A sample from each mother colony was analyzed by GC-MS to verify that HC profiles from workers of the two mother colonies were qualitatively identical to previously published results.

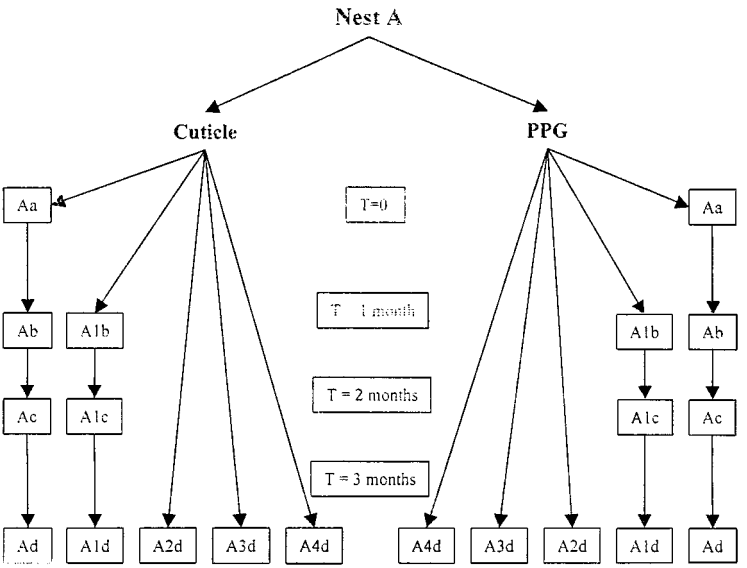

FIG. 1. Flow chart showing the procedures of nest separation and chemical analyses of PPG extract and cuticular washes of ants from a polygyne mother nest and its daughters' monogyne or queenless fragments. Abbreviations are as follows: Aa, mother nest at time 0, before the separation; Ab–Ad, mother nest after one, two, and three months, respectively; A1b–A1d, daughter nest after one, two, and three months, respectively; A2d, A3d, A4d, daughter colonies after three months of separation.

Extraction was accomplished by immersing dissected glands or isolated thoraces in 100 μl of pentane. Thoraces were extracted for 5 min only, to avoid internal contamination. Eicosane (750 ng) was added to each as an internal standard. Samples were run on a Varian 3700 gas chromatograph (Varian Analytical Systems, Walnut Creek, California) equipped with a split/splitless injector, a flame ionization detector, a Leap Technologies autosampler, and a fused silica capillary column (30-m DB-1, 0.32 mm ID, 0.25-μm film thickness capillary column; J&W Scientific Incorporated, Folsom, California). The oven was temperature programmed from 120°C to 285°C at 5°C/min. The carrier gas was hydrogen and the make-up gas nitrogen. Quantification of the various components was achieved by peak integration in comparison to the internal standard using the TurboChrome Workstation, software version 6.1.0.1:F04 (Perkin Elmer Corporation, Norwalk, Connecticut).

Statistical Analysis. To assure equal treatment of the data we selected 18 HC peaks (out of a total of 72) that could be accurately and reliably quantified (Figure 2) and performed a canonical discriminant analysis, using the relative proportions of each of the above-mentioned peaks. This analysis takes a classification variable (mother or daughter colony) and quantitative variables (the selected

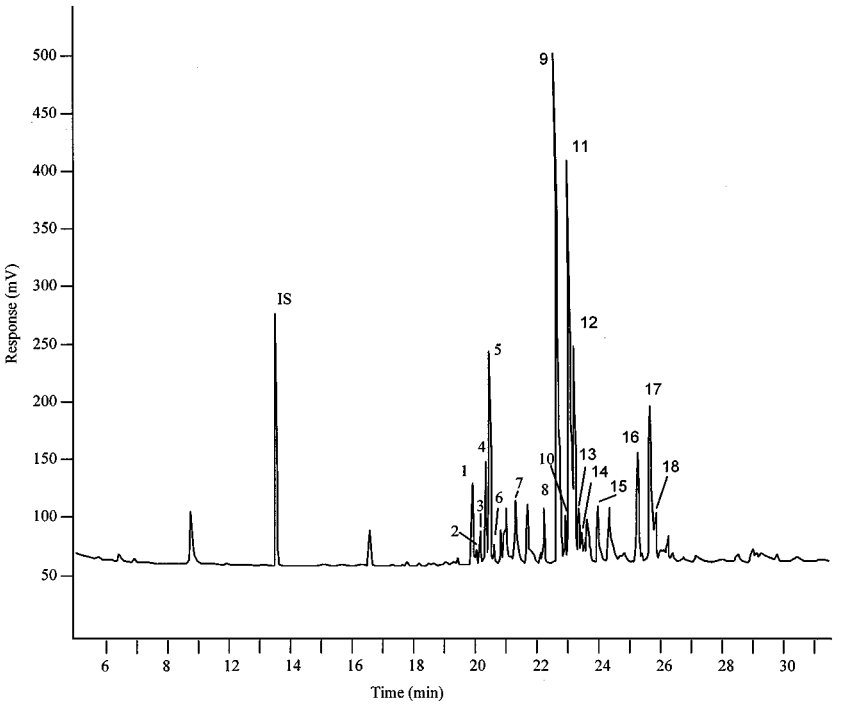

FIG. 2. Gas chromatogram of PPG secretion of *C. niger* workers delineating the peaks used in the discriminant analyses to assess the effects of time and social environment on hydrocarbon profile expression. Peak numbers are designated as follows: 1, 13- + 11-methylheptacosane; 2, 7-methylheptacosane; 3, 5-methylheptacosane; 4, 11,15-dimethylheptacosane; 5, 3-methylheptacosane; 6, 5, *x*-dimethylheptacosane; 7, 12-methyloctacosane; 8, *n*-nonacosane; 9, 9- + 11- + 13- + 15-methylnonacosane; 10, 5-methylnonacosane; 11, 11, 15- + 11, 17- + 11, 19- + 9, 13-dimethylnonacosane; 12, 3-methylnonacosane; 13, 5, 13-dimethylnonacosane + 5, 9-dimethylnonacosane; 14, *x*, *y*, *z*-trimethylnonacosane; 15, *x*, *y*-dimethyltriacontane; 16, 11- + 13- + 15-methylhentriacontane; 17, 11, 15-dimethylhentriacotane; 18, 7, 15-dimethylhentriacontane.

18 peaks from each chromatogram) and derives a canonical variable that summarizes between-class variation. The statistical analysis was performed using Statistica 5.0 for IBM.

Behavior Assays. Behavioral assays were carried out between workers of the subgroups after three months of separation, to test whether the separation had an affect on nestmate recognition. Dyadic encounters between workers from a daughter colony and workers from their respective mother colony were conducted ($N = 19$ for each colony). Encounters between nestmates from the daughter as well as the mother colony served as a control ($N = 15$ for each of the four respective

colonies). The behavior of the ants was registered every 3 min for the first 3 hr of the encounter. The protocols for registering the behavior and construction of the aggression index were as previously published (Lahav et al., 1999).

RESULTS

Figures 3–6 present the results of discriminant analyses performed on the HC profiles (based on the selected 18 peaks) for colonies A and B. In general, the within-group compositions of cuticular extracts were more heterogeneous than those of the PPG extracts. Consequently, the groups were less separated using cuticular hydrocarbons when compared to analyses using PPG extracts. This was expressed by the consistently higher values of Wilk's lambda (a measure of the extent of separation among the groups tested and displayed in each of the discriminant analysis graphs). Nonetheless, in all cases the between-group separation was significant ($P < 0.001$, ANOVA) for both the PPG and cuticular extracts. Figure 3 depicts the differences in HC profiles of PPG and cuticle, separately, of the mother colonies A and B and their daughter fragments. In both nests, regarding the HC profiles of PPG, the mother colonies were clearly separated from the daughter colonies. Separation between daughter colonies was less pronounced, with some overlap of the 95% confidence limit ellipsoids. The between-group separations, however, were significant and the centroids were clearly distinct. Two points should be emphasized: (1) the ants from the queenless daughter fragment were clustered and well separated from the queenright daughter fragments, suggesting that their homogeneity was not inferior to that of the queenright daughter fragments; and (2) queens (marked with an arrow and the letter Q in Figures 3, 5, and 6) of the queenright daughter colonies were often the closest to the group centroid (except for the queens of daughter colonies 1 and 2 for colonies A and B, respectively). Although the homogeneity of the cuticular profiles was less apparent, albeit the between-group separation was significant, the same trends as seen for the PPG occurred.

Figures 4 and 5 depict temporal changes in the HC pattern of both mother and daughter colonies for which ants were sampled and analyzed monthly. In these figures $T = 0$ is representative of the HC profile (PPG and cuticle, respectively) of the mother colonies A and B before the queenright and queenless fragments were created. Figure 4 shows a clear shift in PPG HC profiles of ants sampled from the mother colonies at each of the time points analyzed. Although the direction of changes can not be determined, it can be seen that the changes in colony A were of similar magnitude every month. In colony B the changes were not as symmetrical, and those between months 2 and 3 were slightly less pronounced. Cuticular profiles also changed with time in the mother colonies, but again this was less pronounced. Similar changes with time were observed in the two queenright daughter colonies (Figure 5) for which monthly samples of ants were analyzed.

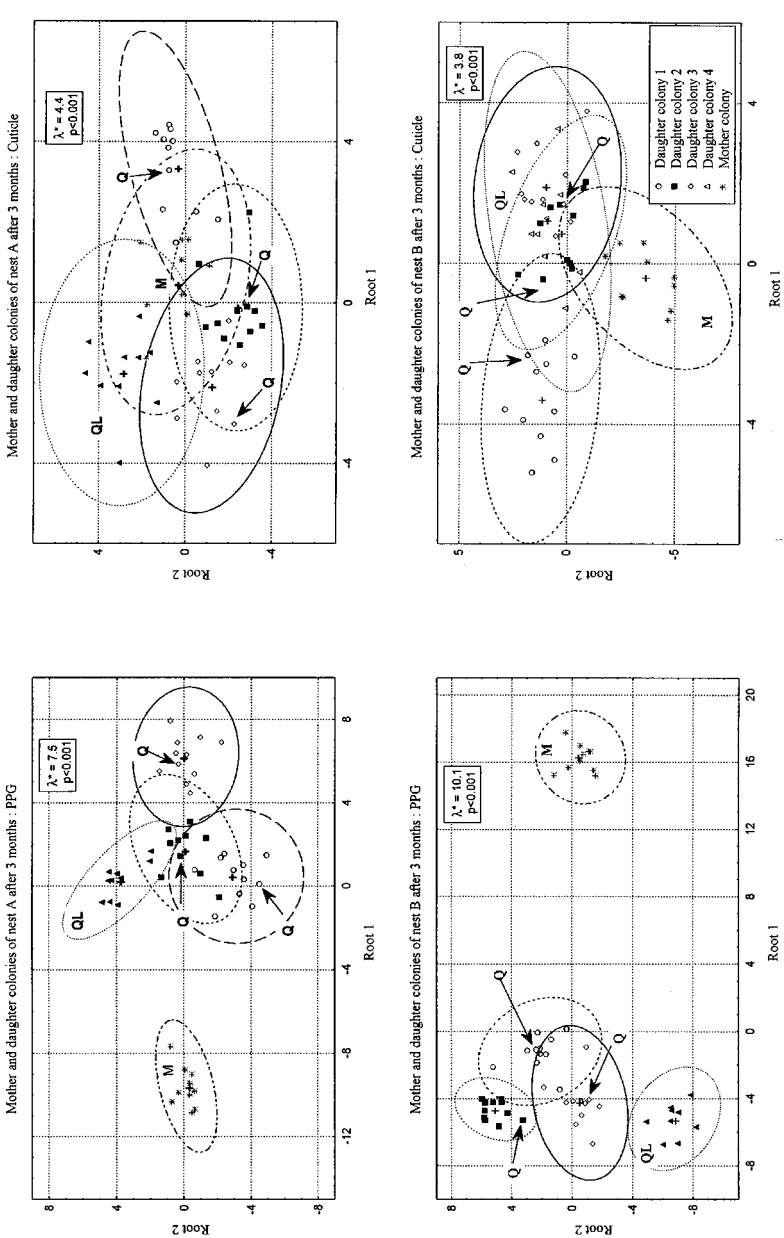

FIG. 3. Signal segregation estimated by a discriminant analysis based on hydrocarbon profiles of the polygyne mother nests and the monogyne queenright or queenless daughter colonies after three months of separation. The ellipses around each group delineate the 95% confidence limits. λ^* was calculated from Wilk's λ after Ln $1/\lambda$ transformation for linearity. The centroid of each group is marked by a plus sign. The HC profile of the queen in each of the queenright daughter groups is marked by an arrow and the letter Q. The queens were considered as a member of the appropriate daughter group for the discriminant analyses.

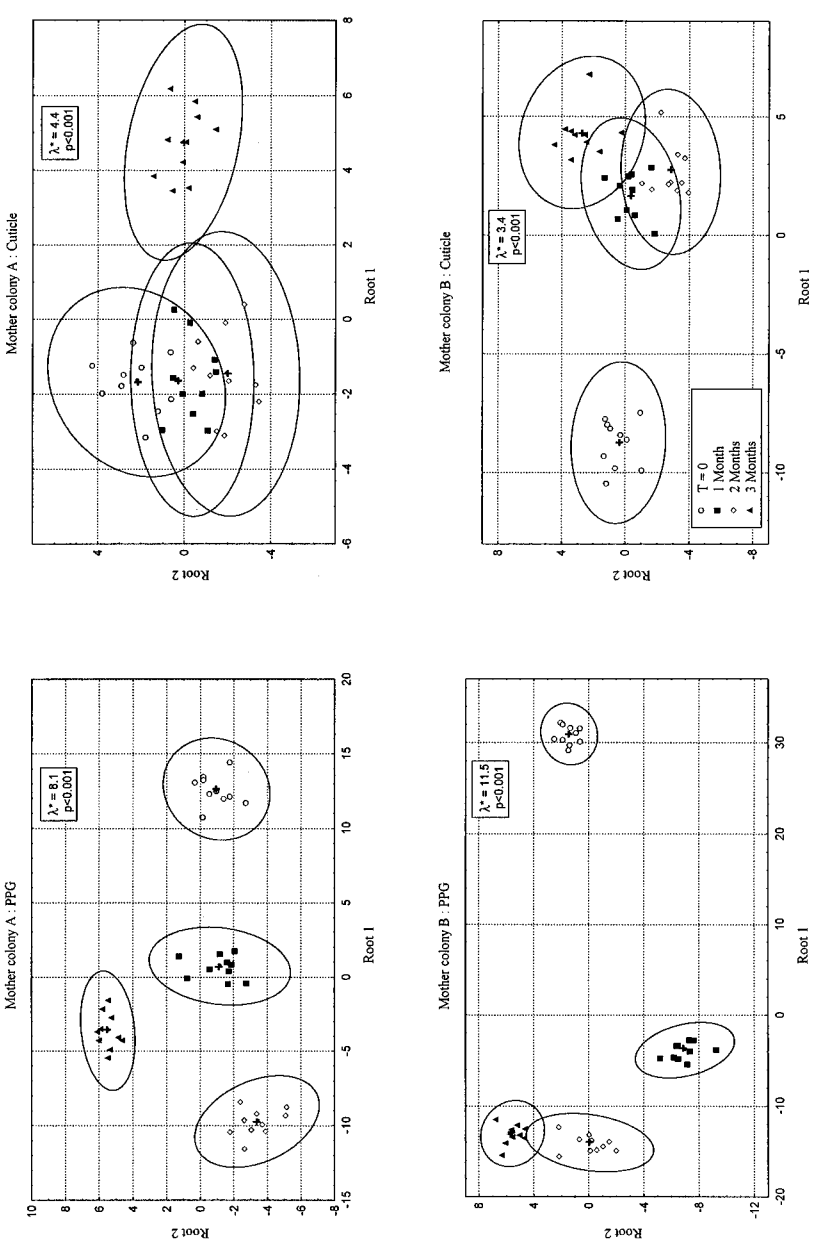

FIG. 4. Time-dependent signal segregation estimated by a discriminant analysis based on hydrocarbon profiles of the polygyne mother nests A and B. $T = 0$ represents the mother colony before it was split. Thereafter the mother nests were sampled after one, two, and three months. The centroid of each group is marked by a +.

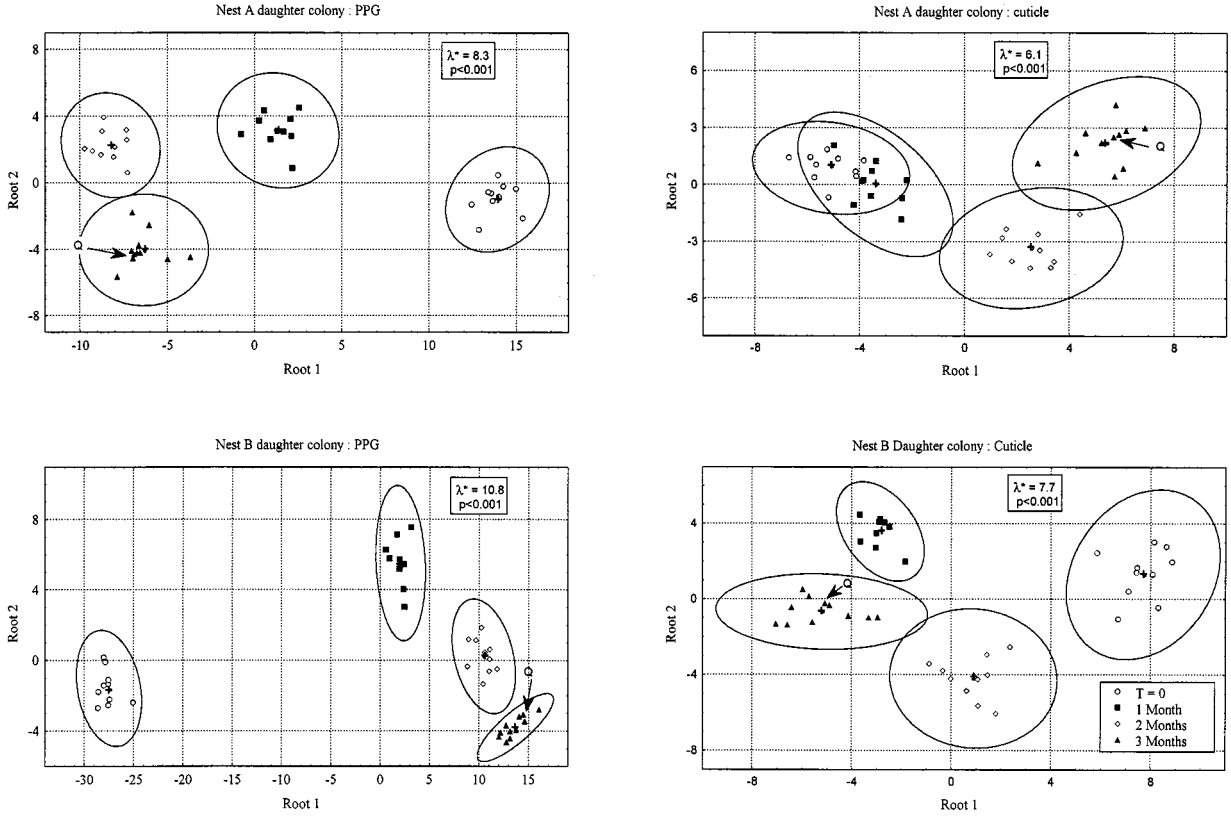

FIG. 5. Time-dependent signal segregation estimated by a discriminant analysis based on hydrocarbon profiles of the monogyne daughter nests. $T = 0$ represents a sample of the mother colonies at the onset of the experiment before separation. Thereafter, the daughter colonies were sampled after one, two, and three months. The centroid of each group is marked by a plus sign. The HCs profile of the queen in each of the queenright daughter groups is marked by an arrow and the letter Q. The queens were considered as a member of the appropriate daughter group for the discriminant analyses.

In this case separation of both PPG profiles and cuticular profiles was good. For these colonies the queen was killed at the end of three months. Both queen HC profiles (PPG and cuticle) were near the centroid (Figure 5).

Figure 6 shows HC profile similarities between a group of matrilines and their randomly selected nestmates. In this figure we include the profile of ants from the mother colonies at time 0 as a reference point. As can be seen, the matriline HC profiles are grouped together and are distinctly separated from their nestmate. For both cuticle and PPG HC profiles the corresponding colony queen profile of each colony was positioned in between the profiles of the matriline and colony worker groups.

The above discriminant analyses represent a combined effect of the changes with time and the separation from the mother colony. In order to investigate the relative impact of each of these factors we compared the mean squared Mahalanobis distance (MSMD) between the HC profile of one group and the centroid of a second group (Table 1). Greater MSMD corresponds to larger deviations of the HC profiles between the groups. For example, the MSMD between group Aa (mother colony at $T = 0$) and the centroid of group A1b (daughter colony 1 after 1 month) represent the divergence of the daughter colony profile after one month from that of the mother colony at $T = 0$. This represents the combined effect of colony separation and the time factor. On the other hand, comparing Aa with Ab (mother colony after one month) represents the effect of time only on profile divergence. Likewise, comparing the profiles of Ab and A1b (mother and daughter colonies respectively after one month) represents the effect of group separation on profile divergence. Table 1 presents the results of such analyses over the three-month period of the experiment for colonies A and B. For both colonies the MSMD was consistently highest when both time and separation were taken into account. Of the two factors, time was the most influential in all cases, as revealed by its larger MSMD, when compared to the separation factor. The fact that the physical separation between the colonies caused the lowest shift in HC profiles suggests that the profiles of each group changed in a similar way, i.e., it reflects the genetic similarity between the groups. To test this hypothesis, the MSMD was plotted as a function of the time of separation for these factors (time and separation) alone or combined. As depicted in Figure 7, the lowest slope is for the separation factor, and for colony B there was no slope at all. Although the sample size was small, these results suggest that, although each of the colony HC profiles changed with time, the magnitude of the changes was similar rather than divergent.

Behavioral Assays. In all the encounters performed, aggressive behavior was rare and limited to mandibular opening. The level of aggression of workers from the mother colony towards workers from the daughter colony was 0.08 ± 0.03. The aggression of workers from the daughter colonies towards workers from the mother colonies was similarly low, amounting to 0.11 ± 0.04. Neither was statistically

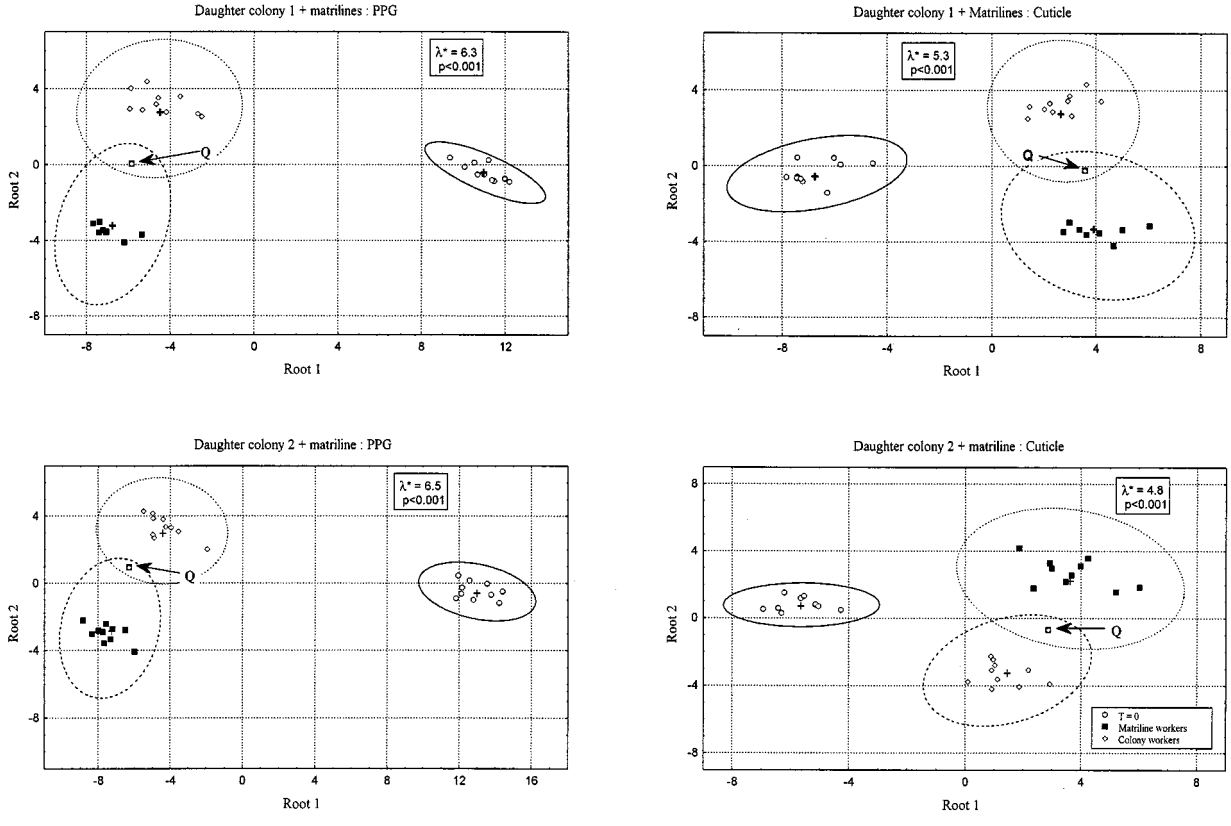

FIG. 6. Signal segregation estimated by a discriminant analysis based on hydrocarbon profile of the polygyne mother nest A at $T = 0$ and two of its monogyne daughter colonies (1 and 2, respectively). The daughter colonies constituted two groups—random workers that originated from the polygyne mother colony and matriline workers that were laid by the respective queens and that emerged in isolation.

TABLE 1. EFFECT OF GROUP SEPARATION AND TEMPORAL CHANGES ON HC PROFILE DIVERGENCE IN *C. niger* WORKERS[a]

Group	Factors affecting profile divergence	Time of separation (mo)	Mean squared Mahalanobis distance	
			PPG	Cuticle
Nest A				
Aa-Alb	Time + separation		139.7 ± 27.1	27.1 ± 10.1
Aa-Ab	Time	1	88.1 ± 17.4	24.1 ± 7.6
Ab-Alb	Separation		44.4 ± 12.4	33.9 ± 25.8
Aa-Alc	Time + separation		280.5 ± 23.5	33.6 ± 8.5
Aa-Ac	Time	2	222.2 ± 24.6	24.7 ± 10.0
Ac-Alc	Separation		124.7 ± 18.3	22.4 ± 10.8
Aa-Ald	Time + separation		236.5 ± 27.6	64.1 ± 11.6
Aa-Ad	Time	3	177.4 ± 22.3	41.8 ± 9.4
Ad-Ald	Separation		103.7 ± 6.3	30.8 ± 18.7
Nest B				
Ba-Blb	Time + separation		767.7 ± 52.6	64.1 ± 11.6
Ba-Bb	Time	1	474.5 ± 40.6	68.9 ± 23.7
Bb-Blb	Separation		83.3 ± 28.7	46.1 ± 16.6
Ba-Blc	Time + separation		1108.0 ± 56.9	67.3 ± 24.4
Ba-Bc	Time	2	852.9 ± 51.6	76.4 ± 23.5
Bc-Blc	Separation		54.7 ± 13.6	25.3 ± 9.1
Ba-Bld	Time + separation		1133.8 ± 58.6	101.4 ± 28.1
Ba-Bd	Time	3	869.9 ± 49.8	104.9 ± 30.0
Bd-Bld	Separation		71.2 ± 21.6	37.9 ± 23.7

[a] Values are expressed a mean squared Mahalanobis distance (MSMD), obtained from the discriminant analyses, between individuals of selected groups and the centroid of the appropriate second group.

different from aggression between nestmates, which equaled 0.13 ± 0.04 (pooled data from the mother and daughter colonies; Mann-Whitney $P = 0.38$).

DISCUSSION

The temporal chemical analyses revealed that HC profiles of colonies of *C. niger* appear to shift with time. This was true irrespective of number of queens in the colony, polygyne, monogyne, or queenless. The results corroborate earlier findings in several ant species, e.g., *Solenopsis invicta* (Vander Meer et al., 1989), *Leptothorax lichtensteini* (Provost et al., 1993), *Cataglyphis iberica* (Dahbi and Lenoir, 1998), and *Formica truncorum* (Liebig et al., 2000). Since the rearing conditions were constant during the three months of separation and only a few new workers emerged, we can exclude the possibility that changes in HC profiles over time are due to the physical environment and/or population changes. The ants were sampled at random and were all well matured workers, also excluding a possible

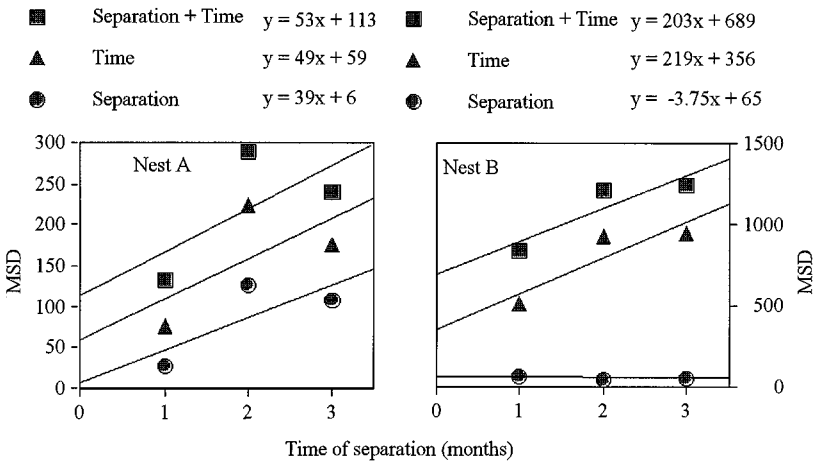

FIG. 7. Changes in Mahalanobis distance as a function of time of separation. The slopes delineate the effects of the factors time and separation combined, time alone, and separation alone.

age effect on the HC composition. We suggest, rather, that these changes are the result of genetically based changes in HC expression. These are not qualitative differences, i.e., disappearance or appearance of specific compounds, but quantitative changes expressed as shifts in the relative intensities of existing compounds. Because in polygyne *C. niger* genetic heterogeneity is large, it was predicted that individual differences in HC composition would create divergent odor compositions in the individuals within a group; however, within-group homogeneity was clear for all groups.

The PPG has been postulated to be the nestmate recognition "gestalt" organ (Soroker et al., 1994, 1995b), where heritable and environmental contributors to colony odor (including recognition cues) are continuously blended and dispersed through trophallaxis. Recent time-course experiments revealed that at any one time the PPG content is more mobile and changes faster than that of the cuticle and that the rate of PPG content change is dependent on the rate of trophallaxis exhibited by the species (Lenoir et al., 2001). Our data clearly support a "gestalt" organ function for the PPG. Similar results were obtained in *C. iberica*, where groups of workers separated from their mother nest for five months exhibited differences in their PPG HC profiles, while remaining homogenous within each group (Dahbi and Lenoir, 1998). It was also demonstrated in this species that when isolated groups of nestmates are reunited, trophallaxis between groups was significantly higher than trophallaxis within group (Dahbi et al., 1999), which would be expected to lead to homogenization of the recognition cues associated with each of the reunited groups.

A recent study corroborates the assumption that changes in HC compositions are individual and may lead to divergent odor composition. Worker *Camponotus fellah* ants that were isolated for up to 40 days showed a higher mean Euclidean distance between individual HC profiles than their nestmates that were reared in groups (Boulay et al., 2000). In our study the matriline ants were reared separately and each worker could not exchange HCs with any of the others. Nonetheless, they showed within-group homogeneity as good as groups that had the opportunity for social interactions (grooming and trophallaxis). The newly eclosed ants were reared under consistent conditions excluding all possible environmental influence. This suggests that, within the timeframe of our experiment (seven days after eclosion), heritable cuticular HC patterns change in parallel rather than at random. It is unknown whether *C. niger* mates with only one male or with several; however, our results suggest that matrilines in *C. niger* have high genetic relatedness.

The HC composition of the PPG was more homogenous within groups, and between-group separation was better than the corresponding cuticular HC samples. Quantitatively, the cuticle contains larger amounts of *n*-alkanes, in particular *n*-nonacosane, than are present in the PPG (Soroker and Hefetz, 2000). Thus, there is no direct quantitative correspondence between HCs derived from the cuticle and those derived from the PPG. To date, behavioral bioassays have shown a causative nestmate recognition role for total PPG HCs (Lahav et al., 1999), but the role of the specific types of HCs in nestmate recognition is unknown. Therefore, we can not assess whether or not the differences in PPG and cuticular homogeneity have any consequences on nestmate recognition. This indicates that the controlling mechanisms are different for the two systems. We suggest that interaction occurs between the PPG and cuticular lipids (monitored through HC analysis), analogous to an environment/gene interaction.

How the cuticular HC profiles are influenced by the PPG contents is complex and not well understood. There are external and internal mechanisms for the PPG to interact with cuticle chemical profiles. Transfer of material between body surfaces of nestmates is done mainly by allogrooming and/or by self-grooming that takes place after trophallactic exchanges (Soroker et al., 1995b). Internally, the PPG (the "gestalt" organ) has been shown to obtain hydrocarbons from the hemolymph (Soroker et al., 1995b), presumably via lipophorin transport; however, there may be active bidirectional exchange, thus permitting the hydrocarbon content of the PPG to influence the hydrocarbon pattern on the cuticle. The contents of the PPG as colony blend subject to constant updating can be considered as a continuous environmental impactor on the individual worker's heritable cuticular hydrocarbon profile. Our results demonstrate that in this environment (PPG)–genetic (an individual's heritable cuticular hydrocarbon profile) interaction is not perfect, since cuticular hydrocarbon variability is greater than PPG hydrocarbon variability; however, the observed variability is not great enough to cause a behavioral reaction (aggression). The "gestalt" PPG hydrocarbon pool influences, but does not dictate

the hydrocarbon composition on the cuticle. Qualitative and quantitative selectivity may occur with lipophorin transport and/or at the site of hydrocarbon uptake at the epicuticle, but the main point is that the cuticle hydrocarbon profile does not have to mimic the PPG composition. The position of the queen's profile in relation to that of her matriline workers and that of her randomly selected nestmates is especially interesting. In both cases the queen's profile was positioned in-between the two worker groups and was almost completely congruent with one of the matriline ants. This illustrates well the factors affecting colony odor composition in the polygyne *C. niger*. Genetic influences create within-matriline uniformity but multiple matrilines yield within-colony heterogeneity, while the continual nondiscriminatory cue exchanges between all workers eventually results in a uniform colony odor.

The contribution of the queen to the changes in HC profile can be deduced indirectly by comparing the monogyne and queenless daughter colonies. The results revealed homogeneity within each daughter colony, whether queenright or queenless. This finding differs from previously reported observations on the queen effect on HC uniformity in *Formica sp.* workers (Yamaoka and Kubo, 1990), and highlights interspecific variability and the dangers of generalization. In *C. niger* we have demonstrated by biochemical means that the direct impact of queen on the composition of colony odor and on nestmate recognition is minor. In fact, the queen donates smaller amounts of HCs than she gets in trophallactic exchanges, which, combined with the very low HC biosynthesis rate exhibited by queen, results in her always being in the center of the gestalt (Lahav et al., 1999). This hypothesis is supported by the present study's findings that queen profile was often in the center of the group.

Divergence in HC profiles did not affect nestmate recognition. Workers separated for three months still reacted to each other as nestmates despite measurable differences in HC patterns. This suggests that the observed differences are still within the cue variation that normally occurs in *C. niger* colonies. Interestingly, in encounters between workers from the separated subcolonies, there were some cases of mutual transport. This behavior was never observed between nonseparated nestmates, indicating that the separated workers may have sensed chemical differences that were not drastic enough to elicit aggression, but were sufficient to induce carrying behavior. A similar phenomenon was found in *C. iberica*, where, after hibernation, transport of callow workers could be correlated with chemical disparity (Dahbi et al., 1997).

Recognition mechanisms involve an interplay between the label (recognition cues) and the mechanism for its detection and interpretation, i.e., the template. It follows that the temporal changes in recognition cues (HCs in the case of *C. niger*) must also affect the characteristics of the template. While the nature of this template is still obscure, we can spectulate on the consequences of the above-shown change in HC profiles. Recognition based on matching self-odor or nestmate odor with the

odor of the encountered ant is presumably not affected by our observed temporal shifts in odor. The effective formation of a uniform colony odor on the resident as well as its nestmates buffers these changes, resulting in congruence between the individual odor and that of nestmates at all times. If the template is neural, the temporal changes in referent (cues), regardless of the referent source, self or nestmate, should also be reflected in neural plasticity with regards to the template. Although we only monitored the changes in HC profiles at monthly intervals, we can assume that these changes are continuous rather than abrupt. This, coupled with the continuous homogenization within the colony, should facilitate the constant updating of the experience-based neural template despite the odor shifts within the colony, as demonstrated in this work.

(Received June 28, 2000; accepted January 3, 2001)

Abstract—A method has been developed to assign the absolute configuration and enantiomeric excess of anabasine based on small amounts of material (in the microgram range), by derivatization with (+)-menthylchloroformate followed by capillary GC analysis of the resulting carbamate(s). This method was applied to three samples of anabasine isolated from *Messor* and *Aphaenogaster* ants. In *Messor sanctus*, only (2′*S*)-anabasine was present, whereas in *Aphaenogaster subterranea* and *A. miamiana* (2′*S*)-anabasine was determined to have an ee of 78 and 24%, respectively.

Key Words—Alkaloids, anabasine, ants, *Messor*, *Aphaenogaster*, absolute configuration.

INTRODUCTION

The alkaloid anabasine (**1**) has been isolated from several plant genera, such as *Anabasis*, *Nicotiana*, *Duboisia*, *Malacocarpus*, and *Marsdenia* (Leete, 1983). (−)-Anabasine ($[\alpha]_D^{20}$ −82.2, neat) from *Anabasis aphylla* L. was shown to have the (2′*S*) absolute configuration (Lukes et al., 1962) (Figure 1), but values of the optical rotation of anabasine from different sources vary considerably (from −82.2 to 0) (Leete, 1983). More recently, anabasine has also been reported from animal sources, e.g., in two of the 19 species of hoplonemertine worms surveyed

(Kem, 1988), in the poison gland of the ants *Messor ebeninus* (Coll et al., 1987) and *M. bouvieri* (Jackson et al., 1989), and as a minor component in *M. capensis* (Brand and Mpuru, 1993) and *Aphaenogaster rudis*, where it coexists with anabaseine (**2**) (Figure 1) (Attygalle et al., 1998).

From a biosynthetic point of view, it would be interesting to compare the absolute configuration of anabasine (**1**) isolated from plants and from animals (worms and ants). To this end, an effective and practical procedure to assign the absolute configuration of this alkaloid and applicable to quantities in the microgram range was needed. Although the separation of the enantiomers of anabasine as their trifluoroacetyl derivatives on a dipentyl β-cyclodextrin GC column has been reported (Armstrong et al., 1990), this method is not very convenient since this column is not commercially available. Our attempts to separate the anabasine enantiomers on two commercial chiral columns (CP-Chirasil Val and CP-Chirasil-Dex CB) were unsuccessful as the alkaloids did not elute from these columns at the temperature limit. In this paper, we have developed a method based on the reaction of (±)-anabasine with (+)-menthylchloroformate, affording the corresponding menthoxycarbonyl derivatives, followed by comparison of their retention time in capillary gas chromatography with that of a standard of known absolute configuration. This procedure allowed us to assign the absolute configuration and to measure the ee of anabasine (**1**), which was detected in three ant species: *Messor sanctus*, *Aphaenogaster subterranea*, and *A. miamiana* (Myrmicinae: Myrmicini).

METHODS AND MATERIALS

Sample Collection. Colonies of *Messor barbarus* and *M. sanctus* were collected at Port Leucate (southern France). Colonies of *Messor structor* were collected in the area of Toulouse (southern France). Colonies of *Aphaenogaster subterranea* were collected in Bouconne forest (Midi-Pyrénées), whereas *Aphaenogaster senilis* were collected at Consprons (Banyuls-sur-Mer, southern France). Colonies of *Aphaenogaster miamiana* were collected near Gainesville, Florida.

Analyses of Ants for Alkaloids. Ants were separated manually from the soil and dipped into MeOH. Five hundred ants of each species were then exhaustively

extracted with $CHCl_3$–MeOH (1 : 1). The extract was evaporated under vacuum and submitted to filtration on an alumina column, first eluting with CH_2Cl_2 (10 ml) to remove nonpolar compounds, then with CH_2Cl_2–MeOH (1 : 1; 20 ml) to yield a polar fraction which was analyzed by TLC and GC-MS for the presence of alkaloids.

Chemical Analyses. UV spectra were taken on a Philips PU 8700 UV-VIS spectrophotometer in MeOH. IR spectra were recorded on a Bruker IFS 25 instrument as a film on a NaCl disk. NMR spectra were recorded in $CDCl_3$ at 600 and 150.87 MHz (Varian Unity 600 instrument) or at 250 MHz (Bruker WM 250). Chemical shifts (δ) are reported in parts per million from internal TMS, and the coupling constants are given in hertz. Mass spectra were performed on a Fisons VG Autospec mass spectrometer in the electron impact (70 eV) mode. Optical rotations were measured on a Perkin Elmer 141 polarimeter (Na vapor lamp) in a 10-cm cell at room temperature. Flash liquid chromatography was performed over Macherey-Nagel Si gel (0.04–0.063 mm) and thin-layer chromatography analyses (TLC) on Polygram SilG/UV_{254} precoated plates (0.25 mm). The compounds were visualized under UV_{254} light, and/or by spraying with Dragendorff reagent. GC-MS analyses were carried out on a Fisons VG Autospec mass spectrometer in the electron impact (70 eV) mode, coupled to a Carlo Erba GC 8065 gas chromatograph equipped with a split injector, and with a 25-m × 0.25-mm CP-Sil 5CB fused silica column (Chrompack). The conditions were: 1 min at 150°C, then increased 10°C/min to 320°C, then maintained 2 min at 320°C. Carrier gas was helium, and injector and detector temperatures were 250°C. GC analyses were performed on a Varian gas chromatograph equipped with a 25-m × 0.53-mm CP-Sil 19CB fused silica column (Chrompack). The carrier gas was nitrogen, and oven and injector temperatures were maintained at 250°C and the detector temperature at 270°C.

*Derivatization of (±)-Anabasine with (+)-(1S,2R,5S)-Menthylchloroformate [(+)−**3**]*. To (±)-anabasine (1.0 mg, 0.0062 mmol) in a 300-μl Reacti-vial was added anhydrous THF (150 μl), NEt_3 (5 μl, 0.036 mmol) and finally (+)-**3** (4.0 μl, 0.018 mmol). After stirring at 60°C under argon for 2 hr, the reaction mixture was poured into 10% aqueous NaOH (2 ml), and the aqueous phase extracted with diethyl ether (3 × 1 ml). Drying and concentration of the combined organic extracts *in vacuo* afforded an oily residue, which was purified by flash chromatography on silica gel (CH_2Cl_2, then CH_2Cl_2–MeOH 9 : 1) to quantitatively afford a mixture of (2′*R*)-**4** and (2′*S*)-**4** (2.1 mg, 0.0061 mmol). They were separated by reverse-phase HPLC (Chromspher C_{18}, 5 μm, 10 × 250 mm, CH_3CN–H_2O, 65 : 35, flow: 5 ml/min).

(2′R)- [(1S,2R,5S)-Menthoxycarbonyl]anabasine [(2′*R*)−***4***]. $[\alpha]_D^{20}$ +110 (c 0.135, CH_2Cl_2); EI-MS (70 eV) m/z 344 ($M^{+\cdot}$, $C_{21}H_{32}N_2O_2$, 6), 216 (10), 207 (100), 206 (66), 189 (22), 162 (38), 138 (7), 133 (14), 128 (7), 92 (21), 83 (53), 69 (26), 55 (38); IR (film) 2928–2866, 1694, 1422, 1265, 1169, 1037, 810-714 cm^{-1}; UV (MeOH) λ_{max} (ε) 203 (6800), 262 (1900); GC: t_r = 13.0 min; ^{1}H NMR

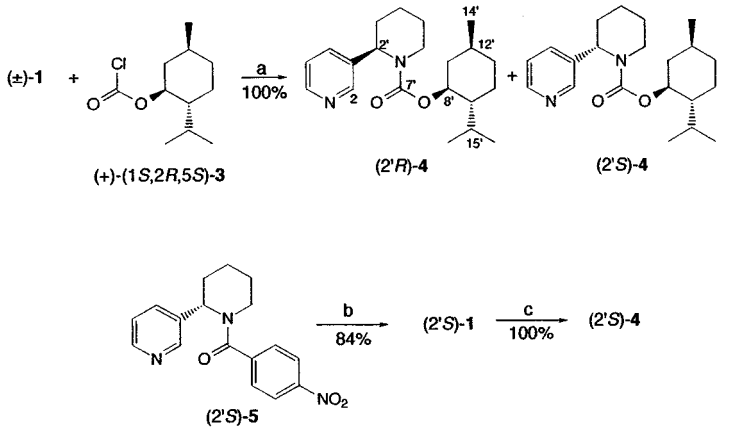
*(2′S)-[(1S,2R,5S)-Menthoxycarbonyl]anabasine [(2′S)-**4**].* $[\alpha]_D^{20}$ −100 (c 0.485, CH_2Cl_2); EI-MS (70 eV) m/z 344 ($M^{+\cdot}$, $C_{21}H_{32}N_2O_2$, 6), 216 (10), 207 (100), 206 (66), 189 (22), 162 (38), 138 (7), 133 (14), 128 (7), 92 (21), 83 (53), 69 (26), 55 (38); IR (film) 2956–2872, 1699, 1410, 1261, 1038, 963, 815-712 cm^{-1}; UV (MeOH) λ_{max} (ε) 203 (4600), 262 (1800); GC: $t_r = 13.5$ min; ^{1}H NMR (250 MHz, $CDCl_3$) δ 8.54 (m, 2 H, H-2, H-6), 7.62 (d, $J = 8.0$, 1 H, H-4), 7.36 (dd, $J = 8.0, 4.0$, H-5), 5.53 (bs, $J = bd$, 1 H, H-2′), 4.61 (td, $J = 11.0, 4.0$, 1 H, H-8′), 4.13 (bd, $J = 14.0$, 1 H, H-6′eq), 2.79 (ddd, $J = 14.0, 11.0, 4.0$, 1 H, H-6′ax), 0.92 (d, $J = 6.7$, 3 H, CH_3-14′), 0.79 (d, $J = 6.9$, 3 H, CH_3-16′ or -17′), 0.73 (d, $J = 6.9$, 3 H, CH_3-16′ or 17′). The derivatization procedure described above was applied to the alkaloid fractions coming from *M. sanctus*, *A. subterranea*, and *A. miamiana*. The menthoxycarbamates thus obtained were analyzed by capillary GC and by GC-MS.

*Hydrolysis of (2′S)-Anabasine-p-NO_2-Benzamide [(2′S)-**5**] into (2′S)-Anabasine.* (2′*S*)-**5** (Pfrengle and Kunz, 1989) was kindly provided by Prof. H. Kunz (University of Mainz). (2′*S*)-**5**, $[\alpha]_D^{20}$ −130 (c 3, MeOH) (19.6 mg, 0.063 mmol) was dissolved in a mixture of 33% HBr–AcOH (0.6 ml) in a 1 ml Reacti-vial. The mixture was stirred at 80°C for 45 hr and was then poured into NH_4OH (8 M) and the aqueous phase quickly extracted with CH_2Cl_2. The combined organic extracts were concentrated *in vacuo* to afford an oily residue that was purified by flash chromatography on a silica gel column (CH_2Cl_2–MeOH 9 : 1) to afford (8.5 mg) (2′*S*)-anabasine in an 84% yield.

*(2′S)-Anabasine [(2′S)-**1**].* $[\alpha]_D^{20}$ −21 (c 0.5, MeOH); ^{1}H NMR data of *(2′S)*-**1** were identical to those of our synthetic material and to literature data (Yang and Tanner, 1997). Treatment of this sample with (+)-**3** as described above furnished (2′ S)-[(1S,2*R*,5*S*)-menthoxycarbonyl]anabasine [(2′S)-**4**], which gave a single peak at $t_r = 13.5$ min in capillary GC.

RESULTS

Development of a Procedure to Assign the Absolute Configuration of Anabasine. We first applied to a sample of (±)-anabasine [(±)-**1**], synthesized according



SCHEME 1. Derivatization of (±)-**1** with (+)-(1*S*,2*R*,5*S*)-menthylchloroformate, and synthesis of (2′*S*)-**4**. Reagents and conditions: (a) NEt_3, THF, 60°C, 2 hr; (b) 33% HBr–AcOH, 80°C, 45 hr; (c) (+)-(1*S*,2*R*,5*S*)-**3**, NEt_3, THF, 60°C, 2 hr.

to Deo and Crooks (1996), the procedure that was developed for the solenopsins (Leclercq et al., 1994), but we could not separate the resulting diastereomeric MTPA amides by capillary GC or by HPLC. In contrast, treatment of (±)-**1** with an excess of (+)-menthylchloroformate [(+)-**3**] quantitatively furnished the diastereomeric carbamates (2′*R*)-**4** and (2′*S*)-**4** (Scheme 1), which could be separated by reverse-phase HPLC on a C_{18} column. Moreover, their retention times in capillary GC on a CP-Sil 19CB column were also different (Figure 2). The two diastereomers were identified by GC comparison with a reference sample of (2′*S*)-**4**, which was prepared from (2′*S*)-anabasine-*p*-nitrobenzamide [(2′*S*)-**5**] (Pfrengle and Kunz, 1989) (Scheme 1). Under our GC conditions, the retention time of (2′*R*)-**4** was 13.0 min and that of (2′*S*)-**4**, 13.5 min (Figure 2). We have also assigned all the proton signals of (2′*R*)-**4** by a 2D NMR study at 600 MHz.

Detection of Anabasine and Anabaseine in Messor *and* Aphaenogaster *Ants*. Five hundred ants of each species were exhaustively extracted, and each extract was checked for the presence of anabasine (**1**) by TLC and GC-EI-MS. Compound **1** was present as the sole alkaloid in two of the six species, *Messor sanctus* and *Aphaenogaster miamiana*. In TLC, the alkaloidic fraction of *A. senilis* exhibited one major spot less polar than anabasine. GC-EI-MS analysis revealed the presence of one major peak identified as anabaseine (**2**) (Wheeler et al., 1981). No trace of anabasine was detected in this species. In contrast, the two compounds were present in the venom of *A. subterranea*, in an approximately 60 : 40 ratio. Finally, neither anabasine nor anabaseine could be detected in the venom of *M. barbarus* and *M. structor*. The relative amounts of anabasine (**1**) and anabaseine (**2**) identified in the venom of *Messor* and *Aphaenogaster* ants are reported in Table 1.

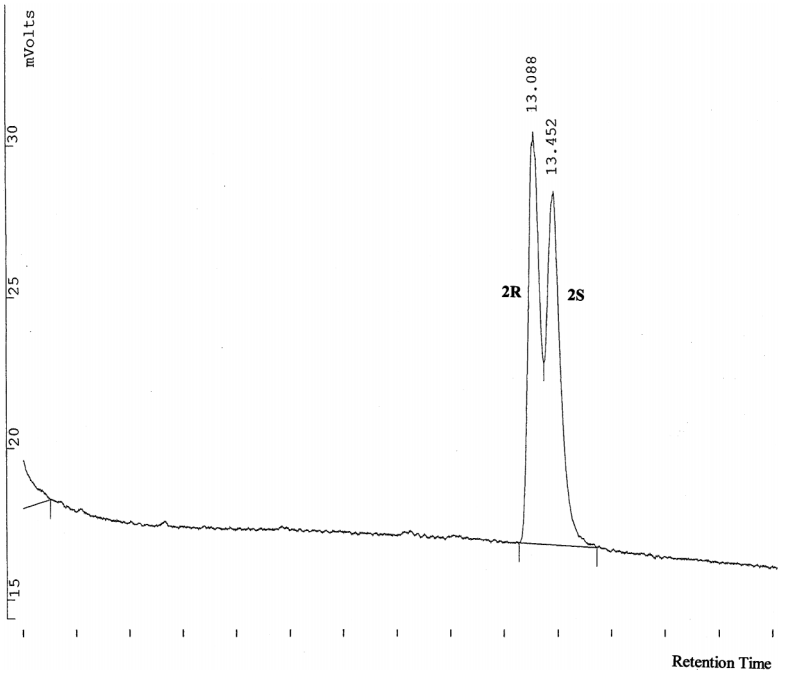


FIG. 2. GC (FID) separation of (2′*S*)-**4** and (2′*R*)-**4**.

Absolute Configuration and Enantiomeric Excess of Anabasine from Messor *and* Aphaenogaster *Ants*. The procedure described above was applied to determine the absolute configuration of anabasine isolated from the venom of *M. sanctus*, *A. subterranea*, and *A. miamiana*. In *M. sanctus*, only one diastereoisomer was present after derivatization, whose retention time corresponded to that of synthetic

TABLE 1. RELATIVE AMOUNTS OF **1** AND **2** IN VENOMS OF *Messor* AND *Aphaenogaster* ANTS

	Anabasine (**1**)	Anabaseine (**2**)
M. sanctus	100	0
M. barbarus	0	0
M. structor	0	0
A. subterranea	60[a]	40[a]
A. senilis	0	100
A. miamiana	100	0

[a] Approximate figures, due to peak superimposition.

(2′*S*)-**4**. Thus, anabasine is present in the venom of *M. sanctus* as a single enantiomer having the 2′*S* configuration.

In *A. subterranea* and *A. miamiana*, anabasine was present as a mixture of *R* and *S* enantiomers, with the *S* enantiomer predominating. Since we have checked that no kinetic resolution occurs during conversion of anabasine into diastereoisomers **4**, the enantiomeric excess of (*S*)-anabasine from *A. subterranea* and *A. miamiana* could be determined to be 78% and 24%, respectively, from the (2′*S*)-**4**/(2′*R*)-**4** ratio.

DISCUSSION

The data reported here on the ee of anabasine from ants are too limited to make any generalization. However, it should be pointed out that our results are similar to those obtained with plants, where anabasine either exists as a single enantiomer with the *S* configuration or as *S*/*R* mixtures, with the *S* enantiomer being generally predominant (Leete, 1983). Several hypotheses can be put forward to explain the wide range of enantiomeric purity observed for anabasine samples isolated from both plants and ants: (1) poor stereochemical control of the enzymatic reaction leading to the formation of the (2′*S*)-stereogenic carbon, (2) co-occurrence of two different biosynthetic routes for the (+) and (−) enantiomers, and (3) chemical or enzymatic isomerization of enantiomerically pure anabasine. The relative contribution of these different possibilities is not known yet. In any case, the detection of a single anabasine enantiomer in *M. sanctus* shows that our method of analysis does not lead to any racemization.

The presence of anabasine and anabaseine in the genus *Aphaenogaster* could be of taxonomic significance, since it supports the current classification of these ants with both genera being placed within the same tribe Pheidolini (Bolton, 1995); the genus *Messor* was even once considered as a subgenus of *Aphaenogaster* (Forel, 1890). However, it is striking that two of the three *Messor* species analyzed in this study do not contain alkaloids, at least in amounts sufficient to be detected by TLC and CG-MS.

Acknowledgments—We are grateful to Prof. Luc Passera (University of Toulouse) for collecting *M. structor* ants and to Dr. R. K. Vander Meer (USDA, Gainesville, Florida) for collecting *A. miamiana* ants. We also thank Mr. S. Rossay for his participation in the preliminary aspects of this work, Dr. M. Luhmer for the NMR spectra and Mr. C. Moulard for the mass spectra. S. A. and S. L. thank the Fonds National de la Recherche Scientifique of Belgium for financial support.

ALLOMONAL AND HEPATOTOXIC EFFECTS FOLLOWING METHYL EUGENOL CONSUMPTION IN *Bactrocera papayae* MALE AGAINST *Gekko monarchus*

SUK-LING WEE* and KENG-HONG TAN

School of Biological Sciences

(Received January 12, 2000; accepted January 10, 2001)

Abstract—Methyl eugenol (ME), is converted into two major phenylpropanoids, 2-allyl-4,5-dimethoxyphenol and *trans*-coniferyl alcohol, following consumption by the male fruit fly *Bactrocera papayae*. Chemical analysis of wild male *B. papayae* rectal glands, where the compounds are sequestered, revealed the presence of ME metabolites in varying quantities. These phenylpropanoids are shown to be involved in the fruit fly defense both in no-choice and choice feeding tests against the Malayan spiny gecko, *Gekko monarchus*. After being acclimatized to feeding on fruit flies, geckos consumed significantly fewer ME-fed male flies than controls that consumed all the ME-deprived male flies offered throughout a two-week period. Diagnosis of dissected livers from geckos that consumed ME-fed male flies revealed various abnormalities. These included discoloration and hardening of liver tissue, whitening of the gallbladder, or presence of tumor-like growths in all geckos that consumed ME-fed male flies. Control geckos fed on ME-deprived male flies had healthy livers. When given an alternative prey, geckos preferred to eat untreated house flies, *Musca domestica* to avoid preying on ME-fed fruit flies.

Key Words—Methyl eugenol, 2-allyl-4,5-dimethoxyphenol, *trans*-coniferyl alcohol, *Bactrocera papayae*, allomone, hepatotoxicity, *Gekko monarchus.*

INTRODUCTION

The fruit fly, *Bactrocera papayae* Drew and Hancock (Diptera: Tephritidae), is a serious pest to fruit production in Malaysia and its neighboring countries. Sexually mature males of *B. papayae* are strongly attracted to, and voraciously feed on, methyl eugenol (ME). ME is attractive to males of several *Bactrocera* species

* To whom correspondence should be addressed.

0098-0331/01/0500-0953$19.50/0

and occurs naturally in at least 200 plant species from 32 families (Tan and Toong, 1993). It is usually contained in the leaves, blossoms, and fruits where it is a component of the essential oil.

ME has been shown to act as a precursor of the male sex pheromone (Tan and Nishida, 1998). After consumption of ME, males of *B. papayae* produced 2-allyl-4,5-dimethoxyphenol (DMP), *trans*-coniferyl alcohol (CF), and trace quantities of (*Z*)-3,4-dimethoxycinnamyl alcohol (DCA) (Nishida et al., 1988a,b). These phenylpropanoids were released by ME-fed males during the courtship period to form lek (male aggregation) and to boost their sexual competitiveness in mating (Tan and Nishida, 1998).

ME was recently found to play a role in the fruit fly's defense strategy by deterring predation by the Asian house gecko, *Hemidactylus frenatus* Dumeril and Bibron (Tan and Nishida, 1998). However, nothing is known about the presence of ME metabolites and their levels in wild male fruit flies, or about their pheromonal and allomonal roles. Furthermore, little is known about the physiological significance of the aversion effect by ME-fed males on predators, i.e., their toxicity. This information could help shed light on the tritrophic plant–fruit fly–predator relationship. In addition, the amount of ME a male is able to consume and, subsequently, the phenylpropanoids produced were also investigated.

Here we report on the presence and variation of ME metabolites in the rectal gland of wild *B. papayae* males, on the allomonal effect of the male pheromone of *B. papayae* on the Malayan spiny gecko, *Gekko monarchus* Dumeril and Bibron (Squamata: Gekkonidae), and on induced hepatotoxicity in the gecko after consumption of ME-fed male fruit flies.

METHODS AND MATERIALS

Chemicals. ME (1-allyl-3,4-dimethoxybenzene; 99.8% purity) was obtained from International Pheromone System Limited, England. Authentic compounds, CF (96.0% *trans*) and DMP (>96.0% purity), for peak identification and quantification using gas chromatography were supplied by R. Nishida (Kyoto University, Japan).

Flies. B. papayae was cultured in the laboratory using artificial medium and adult diet as described by Tan and Nishida (1998). Flies were sexed within five days of emergence. Virgin male and female flies were maintained in separate cages.

The common house fly, *M. domestica*, was cultured using moistened rat food pellet as larval medium. Adults were given water, milk powder (as a source of protein), and a mixture of sucrose and vitamin B complex. Flies were kept in the insectary at $30 \pm 2^{\circ}$C and relative humidity $73 \pm 5\%$ with a 12L : 12D photoperiod.

Malayan Spiny Gecko. G. monarchus was captured from the Universiti Sains Malaysia campus in Penang. Geckos were acclimatized to laboratory conditions

and offered live untreated fruit flies (male and female) for a minimum period of one month. Geckos that consumed a minimum of 10 flies/day were selected for feeding tests.

ME Consumption by an Individual Male. The mean quantity of ME consumed by a male *B. papayae* was determined as follows. Sexually mature virgin males (14–19 days old) were lightly anesthetized with carbon dioxide and placed ventrally with plasticine fixed on the wings to reduce struggling. A 1-μl microcapillary pipet (32 mm long) (Drummond) containing ME was placed 3–5 mm away from a male. Upon sensing the ME, the male would reach for the lure by stretching out its proboscis. The fly was then allowed to consume the ME from the microcapillary pipet mounted on a micromanipulator stand. The source was removed when the male stopped stretching out its proboscis or when it moved its proboscis away. The amount of ME consumed was then recorded with the help of a micrometer calibrating glass slide. Most males stopped feeding within 5 mins. This experiment was conducted in the morning (08:00–11:00 hr) during the fly's peak period of response to ME (Tan, 1985). Twenty males were used on each day of feeding. A total of five replicates were performed, each using flies from a different cohort.

Accumulation of Phenylpropanoids in Rectal Gland. ME (20 μl) was dispensed onto a piece of Whatman No. 1 filter paper (2.5 $\times$ 0.5 cm^2) with a 50-μl Hamilton syringe. ME was allowed to be adsorbed by the filter paper before being presented to the males. A group of 10 males was allowed to feed *ad libitum* on the filter paper containing ME for 15 min. A similar procedure was employed to prepare ME-fed fruit fly males [one day after treatment (1-DPT)] for subsequent choice and no-choice feeding tests.

The fruit fly's rectal gland was extracted the following day (1-DPT). The extracted rectal gland was placed into a narrow V-shaped glass tube (5 mm diam.) containing 20 μl or appropriate quantity of redistilled ethanol containing an internal standard (50 ng/μl of dodecanol). The content was then thoroughly homogenized with a fine glass rod. After sonicating for 5 min, 1 μl was then injected into the gas chromatographic column for separation and detection of volatile components.

Quantification of the volatile components was done on a Shimadzu GC 14A using a HP Ultra-1 column (nonpolar; 25 m $\times$ 0.25 mm $\times$ 0.33 μm fused silica column coated with cross-linked bonded dimethylpolysiloxane). Temperature was programmed from 80°C (approx. 1 min holding time) to 220°C at a rate of 10°C/min. Quantities were determined by comparing the FID intensities with standards of known concentration using a Shimadzu C-R6A Chromatopac reporting integrator.

Chemical Analysis of Wild Male Rectal Gland. ME-baited traps were set in three regions of Penang Island (i.e., northern region = Tanjung Bungah, central region = Ayer Itam, southern region = Minden and Greenlane). All sites were located near hillside forests. Traps were designed to prevent attracted males from feeding on the ME source. Trapping was conducted from June to July 2000 on

different days. Some of the male fruit flies were caught using specimen vials before the flies entered the traps. Trapped male fruit flies were transported back to the laboratory, and the extraction of individual male rectal glands was carried out within 6 hr of trapping. The male rectal glands were processed in the similar manner as described above.

No-Choice Feeding Test. Ten geckos were randomly assigned to two groups with five (**A**–**E**) as treatments and five as controls. Geckos were individually caged and fed with fruit flies to satiety daily. Prior to the feeding experiment, they were starved for three days to ensure a similar degree of hunger (a fully satiated gecko could stop feeding for two days) and their individual weights were determined. The effectiveness of ME-fed males as a deterrent was then evaluated by offering 10 ME-fed males per day to treatment geckos and the same number of untreated males to the control geckos for a period of two weeks. Consumed or dead flies were replaced daily. Daily consumption of each gecko was recorded. Comparison of the mean number of flies consumed per gecko per day was done using the Student's *t* test (one-tailed) at $P = 0.01$.

At the end of the experiment, both groups of geckos were weighed individually. Geckos were killed by exposing them to ethyl acetate vapor for 10 min or longer, and then they were dissected for observation of liver abnormalities.

Choice Feeding Test. To examine the effectiveness of the fruit fly allomone in the presence of a palatable prey (similar in size but without aposematic coloration as the fruit fly), the house fly, *M. domestica* was used. To show that geckos had no intrinsic preference for the house fly after being acclimatized to feed on fruit flies, each gecko was simultaneously offered 15 house flies and 15 untreated male fruit flies in the pretreatment feeding. Consumption for each category of fly was recorded. After three days of fly deprivation, geckos were offered eight ME-fed male fruit flies and eight untreated house flies daily for one week. Dead and consumed flies were replaced daily and fly consumption by each gecko was noted. Ten geckos were used in this experiment. Data was analyzed using paired *t* test ($P = 0.01$).

RESULTS

Ninety-four geckos from four common species of Malaysian gecko, were caught including the Asian house gecko (*Hemidactylus frenatus*), Malayan spiny gecko (*Gekko monarchus*), flat-tailed gecko, (*Cosymbotc platyurus*), and *Gehyra mutilatus* (which has translucent body skin). Among the 94 geckos, *G. monarchus* was the only species that consumed 10 or more fruit flies and thus was the only species selected for further testing.

Geckos are often used as a model predator to study prey–predator relationships. In this experiment, not all geckos readily fed on fruit flies. Insectivorous geckos are not a common predator of fruit flies. The daily activity rhythm of

G. monarchus and *B. papayae* are asynchronous, i.e., the former is an indoor nocturnal predator, while the latter is an outdoor diurnal insect. This may partly explain the low consumption rate of fruit flies by this gecko. It is likely also that geckos may have learned from previous bad experience that fruit flies are not palatable or that the aposematic coloration of the fruit fly, which mimics a wasp, may result in aversion.

The average quantity of ME (mean $\pm$ SE) consumed by each male was 0.58 ± 0.02 μl. Most flies consumed a minimum of 0.1 μl ME. Approximately 22% of the males consumed below 0.2 μl while two individuals consumed as much as 2.3 and 2.7 μl of ME.

Accumulation of Phenylpropanoids in Laboratory-Reared Males. When laboratory-reared males were fed ME, two major phenylpropanoids, DMP and CF, were detected in their rectal glands. These were absent from the rectal glands of ME-deprived males. The average contents (mean $\pm$ SE) of DMP and CF in the rectal glands of ME-fed males one day after ME consumption, was 5.9 ± 1.1 and 12.7 ± 2.8 μg/male, respectively. The quantity of CF was consistently higher than DMP.

Chemical Analysis of Wild Male Rectal Gland. Among 78 male *Bactrocera* spp. trapped (Ayer Itam: 36, Tanjung Bungah: 23, Minden: 12, and Greenlane: 7), all were *B. papayae* except two *B. carambolae* (one each from Ayer Itam and Minden).

All wild male fruit flies contained varying quantities of ME metabolites in their rectal glands ranging from a trace to as high as 55.1 μg for DMP and 47.5 μg for CF in a single male. Overall, 34 of 76 males (45%) contained at least 5 μg of either DMP or CF in their rectal gland.

The ratio of DMP:CF in wild fruit flies was different from that of the laboratory strain. Forty-one of 76 males (54%) contained almost equal quantities of DMP and CF. Thirteen males (17%) contained at least 1.5 times more DMP than CF, and 22 males (29%) contained at least 1.5 times more CF than DMP.

No-Choice Feeding Test. Treatment geckos substantially reduced their consumption of ME-fed males compared to control geckos ($t = 7.35$; $P < 0.0005$) (Figure 1). Consumption of ME-fed males by geckos was consistently low throughout the two-week period. Some of the ME-fed flies were regurgitated by geckos. This was indicated by the remains of body parts of ME-fed flies offered. Control geckos consumed all the fruit flies offered to them.

A significant increase of body weight (445.4 ± 61.1 mg) was observed in control geckos at the end of experiment ($t = 7.29$; $P < 0.005$). However, the decrease in the weight (3.8 ± 112.0 mg) of treated geckos was not significant ($t = 0.03$, $P > 0.05$) even though the consumption rate was significantly reduced compared to control geckos (Figure 1).

Morphological examination of control geckos indicated that their livers were healthy without any abnormality (Figure 2a). However, all treated geckos had

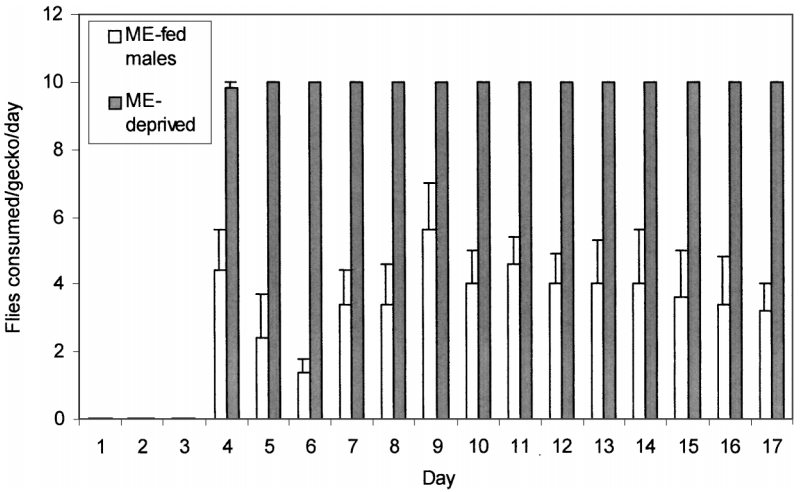

FIG. 1. Deterrent effect of methyl eugenol-fed male *Bactrocera papayae* against *Gekko monarchus* in a no-choice feeding test (bar = SE; $P < 0.005$). After deprivation: each treatment gecko was offered 10 ME-fed males; each control gecko was offered 10 ME-deprived males daily for two weeks.

various abnormalities, ranging from anemia to hardening of, and tumor growth in, the liver (Figure 2b–2f).

Table 1 shows the total ME-fed *B. papayae* males and the estimated doses of phenylpropanoids consumed by each gecko. Gecko **B** consumed the fewest ME-fed males and had light discoloration in its liver (Figure 2b). As the consumption

TABLE 1. TOTAL METHYL EUGENOL (ME) -FED MALE *Bactrocera papayae* CONSUMED BY EACH GECKO, *Gekko monarchus*, IN TWO WEEKS AND ESTIMATED DOSES OF T*rans*-CONIFERYL ALCOHOL (CF) AND 2-ALLYL-4,5-DIMETHOXYPHENOL (DMP) CONSUMED IN RESPECTIVE GECKOS

Gecko	Body weight (mg)		ME-fed males consumed	Estimated dose consumed (μg)[a]	
	Initial weight	Weight change		CF	DMP
B	4421.9	−144.4	18	229	106
D	5651.0	−184.0	38	483	224
E	5714.2	−81.5	53	673	313
A	5317.0	−43.8	57	724	336
C	4008.9	+434.8	91	1156	537

[a]The estimated phenylpropanoid doses consumed per gecko was based on the results obtained from gas chromatographic analysis on the individual rectal gland of *B. papayae* males ($N = 9$; a group of 10 males was allowed to feed on 20 μl of ME dispensed on a filter paper for 15 min).

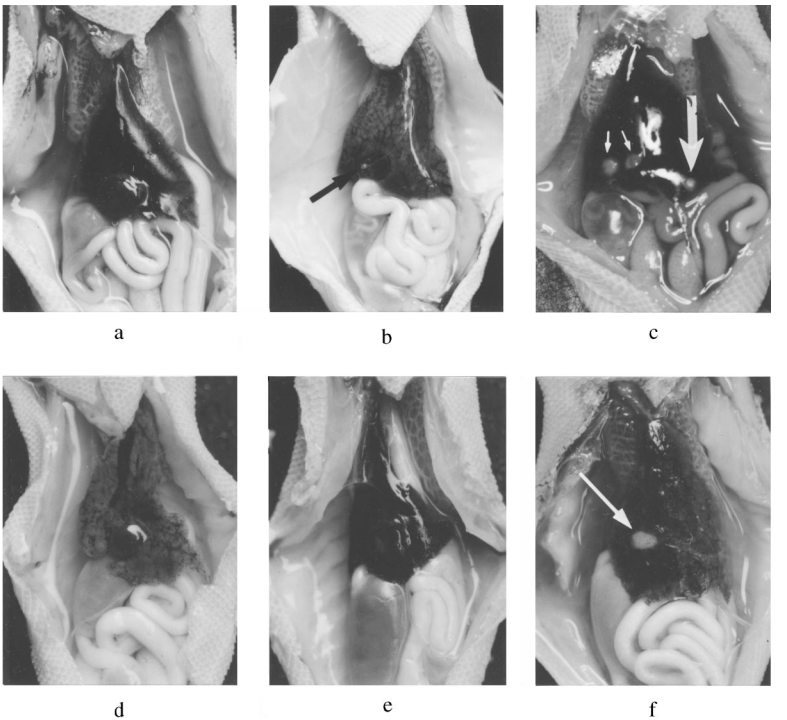

FIG. 2. Photos show liver lobes (*in situ*) of geckos: (a) healthy liver lobes of a control gecko; (b) gecko **B** with anemic liver lobes—arrow shows whitish tumorlike growth; (c) arrows show whitish tumorlike structures in gecko **D**; (d) advanced discoloration on the liver lobes of gecko **E**; (e) gecko **A** with darkened and hardened liver lobes; and (f) gecko **C** with a hardened dark liver—arrow shows whitish gallbladder.

of ME-fed males increased, more discoloration and/or whitish tumorlike growths were observed in geckos **D**, **E**, and **A** (Figure 2c, 2d, and 2e). Gecko **C** consumed the highest number of ME-fed males and had a liver that was hardened and darkened with a whitish gall bladder (Figure 2f).

Choice Feeding Test. Geckos preferred to prey on fruit flies rather than house flies after a month of acclimatization feeding on untreated fruit flies ($t = 5.77$; $P < 0.001$). However, prey preference was immediately reversed when ME-fed male fruit flies were offered to them instead of untreated males ($t = 3.54$; $P < 0.01$) (Figure 3). After their first encounter with the treated fruit flies, geckos were observed to prey on significantly more house flies than ME-fed fruit flies throughout the experimental period ($P < 0.001$).

Besides decreased consumption of treated fruit flies, undigested ME-fed fruit fly bodies were excreted together with uric acid (Figure 4; labeled **P**). All house

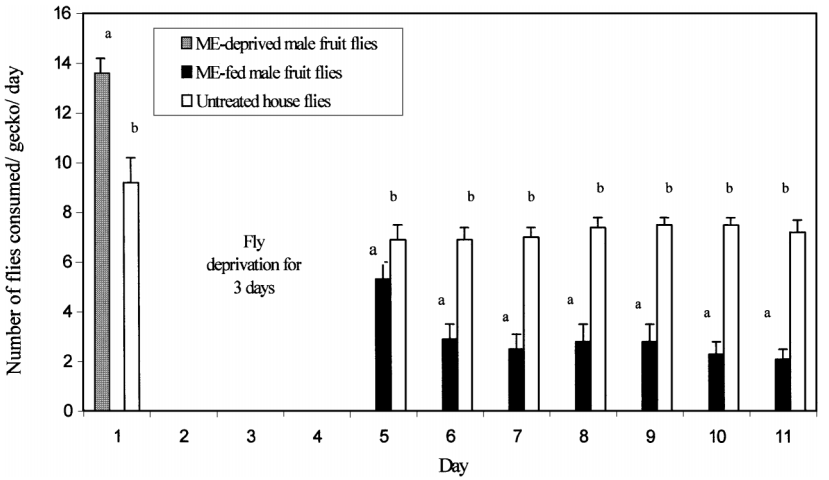

FIG. 3. Deterrent effect of methyl eugenol (ME) -fed male *Bactrocera papayae* against *Gekko monarchus* in the presence of an alternative prey, *Musca domestica* in a choice feeding test (bar = SE; bars with different letters are significantly different at $P = 0.01$, paired *t* test). Before deprivation, geckos were offered 15 flies each of fruit and house flies. After deprivation, each gecko was offered 8 ME-fed fruit flies and 8 untreated house flies daily.

flies offered to control geckos were consumed and there were no undigested body parts in their excrement (Figure 4; labeled **K**). There was a significant increase in gecko body weight before and after the feeding test (259.0 ± 44.0 mg) ($t = 5.88$; $P < 0.001$). Observation of the livers showed no abnormalities.

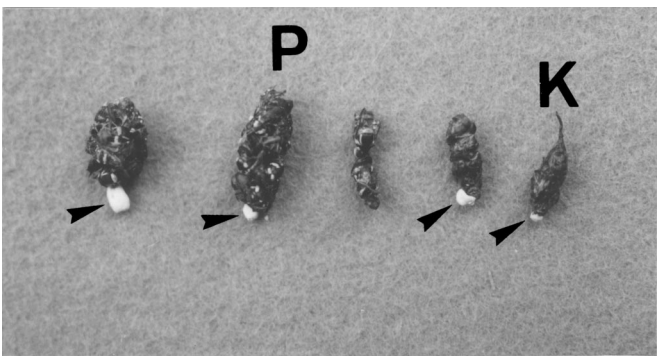

FIG. 4. Gecko excrement showing undigested methyl eugenol-fed fruit flies (labeled with **P**). Arrowheads indicate the uric acid portion of the excrement. Control is labeled with **K**.

DISCUSSION

Males of *B. papayae*, after consumption of methyl eugenol, deterred geckos. Our results showed that ME-fed males 1-DPT produced high amounts of DMP and CF in their rectal gland. These large amounts of ME metabolites function as allomones to deter the geckos. Results from no-choice and choice feeding tests point to the allomonal property of ME metabolites and are consistent with Tan and Nishida (1998) working with the Asian house gecko, *H. frenatus.* ME-fed *B. papayae* were also found to deter the toad, *Bufo asper*, in a recent study (Tan, unpublished observation).

Field trapping results revealed the presence of ME metabolites in all wild male fruit fly rectal glands. However, the quantity of phenylpropanoids varied tremendously between individuals. The fact that over 45% of wild males contained high amounts of DMP and CF in their rectal glands, similar to the levels found in laboratory-ME-fed males, strongly supports claims that these compounds have a defensive function in nature, as well as a pheromonal role in the wild population (Nishida et al., 1988b; Tan and Nishida, 1996, 1998; Shelly, 2000). In addition, Tan and Nishida (1998) also reported that 83% of *B. papayae* males trapped in the wild contained ME metabolites in their rectal glands.

The high variability of ME metabolites in individual wild males is consistent with the findings of Nishida et al. (1988b). This variability might result from differences in the quantity of ME consumed by individual male fruit flies in the wild. Individual laboratory-reared male flies consumed 0.1–2.7 μl of ME. It is possible that males had previously consumed ME from different plant sources with varying levels of ME. ME consumption as high as 4 μl in *B. papayae* males was reported by Tan and Nishida (1998). Cunningham (1989) observed that a *B. dorsalis* male continued to feed on pure ME until its crop was filled and it subsequently died. This amazing affinity to ME and compulsive feeding behavior indirectly reflects the ecological significance of ME to *Bactrocera* males.

It is possible that repeated feeding on ME occurs in the wild. The fact that males respond to ME-baited traps while the rectal gland still contains substantial quantities of ME metabolites is self-explanatory. Laboratory experiments showed that ME metabolites can be detected in the rectal gland of *B. papayae* males 20 days after feeding on 0.1 μl ME (unpublished data). Furthermore, ME occurs naturally in at least 200 plant species (Tan and Toong, 1993). In view of the rich floral diversity in the tropics, there could be more ME-containing plant species that await discovery.

The ratio of DMP and CF contents in wild males as compared to lab-reared strains may be of ecological significance. By treating grains before offering them to the Japanese sparrow, DMP was observed to deter birds better than ME, followed by CF (Nishida and Fukami, 1990). In addition, DMP was reported to be a weak sex attractant to *B. papayae* females while CF was found to attract significantly

more male and female *B. papayae* (Hee and Tan, 1998; Tan and Nishida, 1996). Comparing the two compounds, DMP (i.e., a phenolic compound) is a more potent deterrent; CF is a better sex pheromone component. In the laboratory, sex pheromones are more crucial than allomones where the need to deter predators is greatly reduced. Fruit flies may be adapted to produce higher CF than DMP in the laboratory. Therefore, it is suggested that the production and ratio of DMP to CF may be indirectly related to the contemporary needs of the individual fly.

Tan and Nishida (1998) reported that after an initial exposure and distasteful experience, Asian house geckos totally avoid feeding on ME-fed *B. papayae* males. Therefore, further investigation on the toxic effect of ME metabolites was conducted. In this experiment, using a different predator model, *G. monarchus*, the antipredation effect of ME-fed *B. papayae* males together with the induced hepatotoxic effect on predatory geckos were demonstrated. ME-fed *B. papayae* males were unpalatable to geckos, as indicated by regurgitation and reduced consumption in no-choice tests. However, as the spiny geckos continued to consume a small number of ME-fed flies each day to overcome hunger during the two-week experimental period, the diagnosis of the liver abnormality was made possible.

While the carcinogenic activities of DMP and CF are not known, formation of phenolic compounds from ring oxidation of ME or metabolism of the methoxy substituents might be involved in determining toxicity, i.e., the induced hepatotoxicity. Furthermore, to demonstrate the role of ME in fruit fly–predator relationships, ME-fed *B. papayae* males were offered as whole flies to geckos. The possible ME residue in the fruit fly body might also contribute to the results obtained. Methyl eugenol residue was detected in the crop, but not in the rest of the alimentary canal including the rectal gland of *B. papayae* males following ME consumption (Tan, unpublished data). In mouse liver, ME has been reported to be as active a carcinogen as safrole (1-allyl-3,4-methylenedioxybenzene) and estragole (1-allyl-3,4-methoxybenzene) (Miller et al., 1983). Therefore, the combination of ME, DMP, and CF may have synergistic effects in the antifeeding test as well as the induced hepatotoxicity of geckos. The toxicity of individual chemicals on the predator certainly warrants further investigation.

In choice-feeding tests, geckos learned through experience that ME-fed male fruit flies were not palatable and would search for alternative prey. The yellow markings on the fruit fly's thorax serve as very effective aposematic coloration to predators. It is obvious that feeding on the limited number of house flies provided was not sufficient, and therefore, geckos would attempt to feed on ME-fed male flies to satisfy their hunger. However, undigested ME-fed male bodies were excreted. This may account for healthy livers found in these geckos upon dissection.

Many local farmers refer to the fruit fly as "fruit fly wasp/bee." The reason being the distinctive yellow marking (aposematic color) on the thorax, petiolate abdomens, as well as a jerky, wasp-like walk of most of the tropical fruit flies, i.e., *B. papayae*, *B. carambolae*, and *B. cucurbitae* all resemble wasps. Therefore,

the fruit fly may be considered as a Batesian mimic and hence might gain some protection against vertebrate predators that have had a bad experience with the wasp. However, after pharmacophagy of ME, *B. papayae* males offered a better protection via automimicry to both ME-deprived and conspecific females, as they do not produce an allomone to deter geckos (Tan and Nishida, 1998).

ME-fed males may also serve as a model for many other fruit fly species through Mullerian mimicry. For instance, in the case of the male melon fly, *B. cucurbitae*, which is attracted to cue-lure (CL) and raspberry ketone (RK), it produces an endogenous compound, 1,3-nonanediol when it attains sexual maturity. This compound acts as a potent deterrent against gecko predation (Tan, 2000).

Similarly, the Oriental fruit fly, *B. dorsalis* (nonendemic in Malaysia) after pharmacophagy of ME produces the same phenylpropanoids as in *B. papayae* males and stores it in their rectal glands (Tan and Nishida, 1996). Therefore, it is not surprising that ME-fed *B. dorsalis* males are also able to deter gecko predation apart from being sexually more competitive than ME-deprived males as demonstrated by Tan and Nishida (1998).

Sequestration of allomonal components originating from nonhost plants and incorporation into their defensive repertoire by pharmacophagus insects was documented in a few insect orders. These include several lepidopterans associated with pyrrolizidine alkaloids, such as danaid butterflies (Meinwald et al., 1969; Boppré, 1978; 1986) and arctiid moths (Schneider et al., 1982). Such tritrophic associations also exist between turnip sawflies, *Athalia rosae* (Hymenoptera) and clerodendrins (Nishida and Fukami, 1990), dibroticite leaf beetles, *Diabrotica speciosa* (Coleoptera) and cucurbitacins (Nishida and Fukami, 1990), and between fruit flies, *Bactrocera* spp., and methyl eugenol (Nishida and Fukami, 1990; Tan and Nishida, 1998). Predators were either deterred/repelled from preying on the pharmacophagus insects or vomited/regurgitated to rid themselves from the ill effect of allomones. This experiment has taken a further step in understanding the underlying physiological significance of the allomone to the predator. It has been shown that allomones are indeed hazardous to the predator (geckos in this instance). Thus, it can be concluded that ME and its metabolites play a significant role in the fruit fly's anti-predation strategy.

(Received October 6, 2000; accepted January 14, 2001)

Abstract—Four recently identified isoflavonoids, isolated from wild relatives of chickpea, *Cicer arietinum*, were shown to deter larval feeding by *Heliocoverpa armigera* at 100 ppm, judaicin and maackiain retained their antifeedant activity at 50 ppm and 10 ppm, respectively. The isoflavonoids were tested in combinations and with chlorogenic acid; the combinations containing judaicin and maackiain were most active, and chlorogenic acid enhanced the antifeedant activity of all four isoflavonoids. *H. armigera* was the only one of four noctuids to be deterred by all four isoflavonoids. *Spodoptera littoralis* was deterred by judaicin alone and *S. frugiperda* by maackiain alone. *Heliothis virescens* and *S. exigua* were not deterred from feeding by any of the isoflavonoids. When incorporated into a diet, isoflavonoids decreased the weight gain of early stadia larvae of *H. armigera* more than they did later stadia, and maackiain and judaicin were most potent. We conclude that the isoflavonoids, especially maackiain and judaicin, could play a role in decreasing the susceptibility of *Cicer* to attack by *H. armigera.*

Key Words—*Heliocoverpa armigera, Cicer arietinum,* isoflavonoids, chlorogenic acid, *Heliothis virescens, Spodoptera littoralis, Spodoptera exigua, Spodoptera frudiperda,* maackiain, judaicin, antifeedant.

INTRODUCTION

The chickpea, *Cicer arietinum* L., is an important staple food resource in semi-arid tropical regions. The plant is susceptible to attack by a range of pathogens and insects, especially by the noctuid caterpillar, *Heliocoverpa armigera*. Previous studies have shown that the foliar and root isoflavonoids, medicarpin and

0098-0331/01/0500-0965$19.50/0

maackiain, contribute to the resistance of chickpea to attack by fungi (Daniel and Barz, 1990; Stevenson et al., 1997; Stevenson and Haware, 1999). Other recent studies have shown that isoflavenes and arylbenzofurans from the roots of wild relatives of chickpea contribute to *Fusarium* resistance in these species (Stevenson and Veitch, 1998a), but as yet the role these compounds play in insect–plant interactions is unclear.

Heliocoverpa armigera larvae exhibit differential responses when feeding on different genotypes of chickpea (Cowgill and Lateef, 1996), and these responses have been attributed to the presence of organic acids on the pods and leaf surfaces (Yoshida et al., 1995). For example, exudates from the trichomes on chickpea leaves contain high levels of malic acid (Lazzaro and Thomson, 1995). Many legumes also contain caffeoyl-quinic acids, which inhibit the development of *H. armigera* and other Heliothine larvae when consumed at high concentrations (Isman and Duffey, 1982; Kimmins et al., 1995). Despite this knowledge about potential resistance mechanisms in chickpeas, little progress has been made in breeding *H. armigera*-resistant chickpeas, and *Heliocoverpa* continues to be the number one insect pest of chickpea.

In this study, we have tested four recently identified isoflavonoids that occur in the wild relatives of chickpea, *C. bijugum*, *C. judaicum*, and *C. pinnatifidum* (Stevenson and Veitch, 1998b), to see whether they could influence the behavior and development of *H. armigera*. The objectives were to investigate the effect of: (1) isoflavonoids on the feeding behavior of *H. armigera* in choice and no-choice tests; (2) combinations of isoflavonoids on feeding behavior; (3) isoflavonoids in combination with the phenylpropanoid chlorogenic acid on feeding behavior; (4) isoflavonoids on the development of different stadia of *H. armigera*; and (5) isoflavonoids on the feeding behavior of a range of other polyphagous noctuids.

METHODS AND MATERIALS

Compounds. Judaicin 7-*O*-glucoside **(1)**, judaicin **(3)**, and maackiain **(4)** were isolated from the roots of *Cicer judaicum* Boiss. (Stevenson and Veitch, 1996) and 2-methoxyjudaicin **(2)** was isolated from the roots of *C. bijugum* Rech.f. (Veitch and Stevenson, 1997) (Figure 1). Freeze-dried root material was ground in methanol and extracted at 4°C for 18 hr. The extract was filtered and the filtrate evaporated to dryness and then taken up in methanol to provide an extract equivalent to 1 g/ml. Aliquots (150 μl) were injected directly onto a Spherisorb 5 ODS column (10.0 mm ID × 250 mm). A Waters HPLC system consisting of a 717 autosampler, a LC 600E pump, and a 996 photodiode array detector was used in semipreparative gradient elution mode where A = 2% acetic acid and B = 2% acetic acid in acetonitrile. A = 50% at $t = 0$ min; A = 40% at $t = 20$ min; and A = 20% at $t = 30$ min at 4.7 ml/min. Chlorogenic acid was purchased from Sigma Chemical Company Ltd.

FIG. 1. Structures of isoflavonoids from *Cicer*: judaicin 7-*O*-glucoside **(1)**, 2-methoxy-judaicin **(2)**, judaicin **(3)**, and maackiain **(4)**.

Plant Material. *Cicer judaicum* ICCW 89 and *C. bijugum* ICCW 42 were obtained from the Genetic Resources Unit, International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Hyderabad, India. Vouchers of the plants are retained within ICRISAT.

Insects. *H. armigera* were originally from Hyderabad, India, and had been in a laboratory culture at Kew for two to four generations. The other noctuids were from established laboratory cultures in Britain. For example, the culture of *S. littoralis* from Egypt has been in culture at Kew for 28 generations. All species were reared on a wheat-based diet (Simmonds et al., 1992). The behavioral bioassays were all undertaken on larvae 36–48 hr in their final stadium. They were deprived of food for 2–4 hr prior to the experiments. The developmental bioassay used insects 8–12 hr into the stadium. The numbers of replicates varied among experiments and are presented in the Tables.

Behavioral Tests. A choice bioassay that used glass-fiber disks was used to calculate the feeding index $[(C - T)/(C + T)] \times 100$, an index used to compare the effect of compounds on insects feeding (Simmonds et al., 1990). Glass-fiber disks (2.1 cm dia., Whatman) were treated with 100 μl of sucrose and left to dry. The treatment disks were then treated with 100 μl of one of the test compounds at

either 100 ppm (0.28 μg/cm^2), 50 ppm (0.14 μg/cm^2), 10 ppm (0.028 μg/cm^2), or 1 ppm (0.0028 μg/cm^2) in methanol. The disks were dried, weighed, and placed in pairs, one control and one treatment disk, into a Petri dish (9.1 cm diam.). Prior to placing the standardized final stadium larvae into the dishes, the disks were each treated with 100 μl distilled water to make them more palatable to the larvae. To avoid the bioassay changing from a choice to no-choice bioassay, the larvae were removed after 8 hr, the time taken for the larvae to eat about 50–70% of either disk. After removing the larvae the disks were left to dry and reweighed. The feeding index was calculated by using the amount of control (C) and treatment (T) disks eaten: a positive value indicates an antifeedant, a negative value a phagostimulant.

The choice bioassay was used to compare the effect of different concentrations of the compounds against *H. armigera* and to test the compounds at 100 ppm against a range of noctuids. The bioassay was also used to evaluate whether applying two compounds to the treated disk would result in additive or synergistic increases in activity. Due to the limited amounts of compounds available for the combination experiments, we did not make fresh solutions with the compounds combined in a solution. We used the original 50 ppm solutions. For example, the treatment disks were treated with 100 μl of one compound at 50 ppm, left to dry, and then treated again with 100 μl of another compound at 50 ppm. The isoflavonoids were also tested in combination with chlorogenic acid. In this test, a 100-μl aliquot of chlorogenic acid (50 ppm) was applied to the treatment disks, which were then dried before being treated with 100 μl of one of the isoflavonoids at 50 ppm. In these combination experiments, the second solution was applied with a zigzag movement across the disk to avoid the compounds accumulating at the outer edge of the disk.

A no-choice glass-fiber bioassay was used to evaluate the effect of the compounds on rejection behavior and to evaluate whether, if active, the insects would habituate to the compounds. The disks were treated with sucrose and a test compound at 100 ppm, as outlined above. However, in this experiment the disks were placed singly in the center of a Petri dish and pinned to the dish. The dishes were then placed onto a square of blue card. The disks were pinned down to prevent them being moved by the larvae during the course of the experiment, and the blue background was to provide contrast for the disk and the larvae to enable us to record the movement of the larvae onto a computer.

H. armigera fifth stadium larvae were placed singly in each Petri dish; their behavior was observed continuously for 120 min and then recorded by camera onto a computer running Ethovision software (video tracking, motion analysis and behavior recognition system software v 1.7; Tracksys Ltd. and Noldus Ltd.) for a further 6 hr. During the first part of the experiment, the behavior of eight larvae was input manually into a computer that was running Observer software (Noldus, 1991). During the first observation period, records were made of the larvae contacting the disk and feeding on the disk. Feeding included both biting and rasping the disk.

Whether insects accepted or rejected a disk at first contact, the time taken to accept a disk and then time spent in contact with a disk were calculated. However, because over 75% of the larvae rejected both the control and treatment disks when they first encountered it, the behavior on first contact was not used as a measure of palatability. Instead the latency (to feeding or sampling) before the insects were observed to bite and consume part of the disk was measured. Sampling a disk was defined as when the larvae contacted and removed a section either by biting or rasping. The behavior of the eight insects was recorded over a 6-hr period and the time spent on disks calculated. The larvae were removed and the disks dried before they were reweighed to calculate the amount eaten. Contact with a disk was recorded if any part of the insect was in contact with the disk. However, this does not mean that the insects were feeding, as the mouthparts of the insect were often obscured from the camera, and the insects spent time stationary on the disks as if "resting." The number of replicates recorded at a session was eight: this consisted of two treatments of either four disks from two isoflavonoids or an isoflavonoid and a control.

Development Bioassay. Larvae were placed individually on diet (1.5 ml/well) in wells of a Bioserve bioassay tray (C-D International Inc.) treated with 100 μl of one of the test compounds at 100 ppm. First and second stadia larvae, 8–12 hr into the stadium were placed on the diet and weighed after five days. Third, fourth, and fifth stadia larvae were weighed, and those that weighed within the range of ± 1 SEM were then placed on the diet for five days and reweighed. In all cases, the weights of larvae are compared with those of their respective control, which had been exposed to control diets treated with 100 μl of the solvent methanol. This type of bioassay has been criticized by Freedman et al. (1979), as they reported that insects can avoid ingesting the test extract by boring under the treated diet. However, this bioassay is frequently used in industry to evaluate the activity of plant extracts or compounds. Earlier stadia larvae are usually tested as they are more responsive to compounds than later stadia. In our experience, if the surface of the diet is scored with a knife before the test solution is applied, it will penetrate the surface and disperse through the 1.5-ml aliquot of diet.

Behavioral Bioassays Analysis. The Wilcoxon matched-pairs test was used to analyse the data in the choice bioassays and the Mann-Whitney U test in the no-choice bioassay.

Development Bioassay Analysis. The *t* test was used to test whether the actual weights of the larvae on the compound-treated diets differed from the weights of the larvae exposed to the control diet.

RESULTS

Effect of Isoflavonoids on Feeding Behavior of H. armigera *in Choice and No-Choice Tests*. In the choice bioassay, all four isoflavonoids showed significant

antifeedant activity at 100 ppm, the highest concentrations tested (Table 1, Part A). The isoflavonoids all showed a dose-dependent decrease in activity, with maackiain retaining its antifeedant activity down to 10 ppm and judaicin down to 50 ppm. Similarly, all four isoflavonoids decreased the amount eaten by *H. armigera* larvae in the no-choice bioassay when tested at 100 ppm (Table 1, Part B). Although all four isoflavonoids showed antifeedant activity in both the choice and no-choice bioassay, the observations made during the no-choice bioassay indicated differences in their mode of action. For example, judaicin 7-*O*-glucoside and maackiain deterred the larvae from sampling the isoflavonoid-treated disks (latency to sampling) for longer than 2-methoxyjudaicin or judaicin. However, data from the whole 8-hr experiment showed that maackiain was the only isoflavonoid to decrease the amount of time larvae spent in contact with treated disks. When the behavior of the insects was videotaped, it was not possible to measure ingestion patterns with accuracy because the insects would often position themselves with their mouthparts out of view of the camera. Therefore, we could not accurately record the time spent feeding or the amount consumed per hour. However, despite this limitation, the results suggest that insects were deterred from feeding on maackiain-treated disks from the start of the experiment, and although they did eat some of the maackiain-treated disk, the insects did not habituate to the compound during the course of the experiment. In contrast, the initial deterrent activity of judaicin-7-*O*-glucoside decreased, and the insects spent as much time on the disks treated with this compound as they did on the control disks or disks treated with 2-methoxyjudaicin or judaicin. Thus, although the judaicin-based isoflavonoids deter *H. armigera* larvae from feeding, they are not as active as maackiain.

Effect of Combinations of Isoflavonoids on Feeding Behavior. The feeding index was highest for combinations that had either maackiain or judaicin, and the highest indices were obtained from those combinations that contained judaicin with either judaicin-7-*O*-glucoside or maackiain (Table 1, Part C). The feeding indices recorded did not reflect a consistent interaction among the isoflavonoids. For example, the feeding indices for the combinations of maackiain (50 ppm) with judaicin (50 ppm) and of judaicin-7-*O*-glucoside (50 ppm) with judaicin (50 ppm) were higher than those recorded for the compounds tested singly at 50 ppm. This suggests additive interactions. In contrast, the feeding index for the combination of 2-methoxyjudaicin with judaicin-7-*O*-glucoside was similar to that recorded for 2-methoxyjudaicin at 50 ppm, but lower than that recorded for judaicin-7-*O*-glucoside at 50 ppm. This suggests an antagonist interaction between the compounds. These differences in behavioral responses to the combinations could reflect differences in the molecular interactions between the compounds and the receptors on the larvae's maxillary taste sensilla. For example, the judaicin-type isoflavonoids could be competing for similar receptor sites that differ from those

TABLE 1. EFFECT OF COMPOUNDS ON FEEDING BEHAVIOR OF FIFTH STADIUM LARVAE OF *Helicoverpa armigera*

Maackiain			59 ± 8.4*[b]

Part D. Choice bioassay: treatment disk (T) treated with an isoflavonoid (50 ppm) and chlorogenic acid ((50 ppm) $N = 10$)

	Feeding index[a] (mean ± SEM)[a]			
Judaicin-7-*O*-glucoside	2-Methoxy judaicin	Maackiain	Judaicin	Chlorogenic acid
18 ± 7.7	32 ± 8.4*[b]	49 ± 9.4**[b]	51 ± 4.8**[b]	18 ± 12.4

[a] [(C − T)/(C + T)] %.
[b] **$P < 0.01$, *$P < 0.05$, Wilcoxon matched pairs test.
[c] **$P < 0.05$, **$P < 0.01$ Mann-Whitney U test:isoflavonoids compared with control.

stimulated by maackiain. If this were the case, then more receptors could be stimulated by combinations that contained maackiain and judaicin-type isoflavonoids, than combinations that contained two judaicin-type compounds. However, this theory would not support the additive antifeedant activity recorded for the judaicin and judaicin-7-*O*-glucoside combination (Table 1, Part C).

Effect on Feeding of Isoflavonoids in Combination with Chlorogenic Acid. When tested in combination with sucrose, chlorogenic acid did not elicit an antifeedant response from *H. armigera* larvae in the choice experiment (Table 1, Part D). However, when chlorogenic acid was tested in combination with an isoflavonoid at 50 ppm, an antifeedant response was recorded from three of the isoflavonoids; 2-methoxyjudaicin, maackiain, and judaicin. The antifeedant activity of 2-methoxyjudaicin and maackiain in this combination was greater than when the compounds were tested singly (Mann-Whitney U test, $P < 0.01$). Thus, chlorogenic acid increased the potency of these two isoflavonoids.

Effect of Isoflavonoids on Development of Different Stadia of H. armigera. All four isoflavonoids decreased the weight gain of first stadium larvae, over a five-day exposure, whereas the weight gain of second, third, and fifth stadium larvae was only reduced by maackiain and judaicin (Table 2). None of the isoflavonoids decreased the weight gain of fourth stadium larvae. Overall, judaicin had the greatest effect on larval development.

Effect of Isoflavonoids on Feeding Behavior of a Range of Polyphagous Noctuids. *H. armigera* was the only one of the four species of noctuids to be deterred from feeding by all four isoflavonoids (Table 3). *S. littoralis* was deterred from feeding by judaicin, and *S. frugiperda* by maackiain, whereas none of the isoflavonoids elicited an antifeedant response from *H. virescens* or *S. exigua*.

DISCUSSION

In the last decade, there has been a steady increase in our understanding of the defense mechanisms in plants. This is due in part to advances in genomics and related technologies that have increased our knowledge about the functional basis of plant defenses. However, unequivocal evidence that a specific mechanism or compound stops an insect from damaging a plant is rare. This could be due to the complexity of the interactions involved in plant–insect relationships and our tendency to concentrate on evaluating the activity of a narrow group of stimulating "sign" compounds present in host plants rather than the level of specific deterrents in nonhost plants (Bernays and Chapman, 1994). A role for sign compounds in host-selection behavior of monophagous or oligophaguos species is easier to justify than in polyphagous species such as *H. armigera.* It is clear, however, that individual polyphagous insects show preferences for plants, but the factors influencing these preferences are still unclear (Simmonds and Blaney, 1990; Bernays and Chapman, 1994).

Wild relatives of the cultivated chickpea contain a higher diversity of isoflavonoids (Stevenson and Veitch, 1998b); many might have been lost from cultivars in breeding for high yield and palatable crop plants. If we can identify antiinsect compounds in wild relatives of crops that are either missing or at low levels in the crop plant, then manipulating the level of these compounds in a crop plant could decrease the susceptibility of that crop to damage by polyphagous pests. This is a traditional approach and was used recently to screen wild relatives for trypsin inhibitors (Patankar et al., 1999). The diversity of protein inhibitors was greater in wild relatives than in cultivated species, but *H. armigera* had adapted to the inhibitors. Thus, before manipulating crop plants either via traditional breeding techniques or via molecular techniques, it is important that we have knowledge about the insects' responses to the target compounds.

This study has shown that four of the isoflavonoids that occur in wild relatives of chickpea modulate the feeding behavior and development of larvae of *H. armigera*. Overall, the most potent of the isoflavonoids tested was judaicin and maackiain, although their activity varied depending on the bioassay and the stadium being tested. Previous studies have shown that both isoflavonoids inhibit germination of the spores of *Fusarium oxysporum* f.sp. *ciceri* (Stevenson and Veitch, 1998a), but the antifungal activity of maackiain varies among pathogens (Gordon et al., 1980).

In the no-choice feeding bioassay, the fact that a high proportion (75%) of *H. armigera* larvae rejected the sucrose-treated control glass-fiber disks at first contact could indicate that sucrose at 0.05 M was not a potent stimulant on the disks. Sucrose is known to stimulate *H. armigera* larvae to feed on glass-fiber disks over a 18 to 24-hr bioassay (Simmonds et al., 1990), but the influence of sucrose on the acceptance or rejection behavior of sucrose-treated wet glass-fiber disks by larvae has not been previously reported. However, the fact that two of the isoflavonoids extended the duration of time taken before the insects fed on the disks, relative to the sucrose-treated disks, would suggest that these compounds decreased the palatability. This could be because they modulate the ability of the larvae to perceive sucrose, or they stimulate deterrent neurons in the insects' taste sensilla. The differences in activity among the isoflavonoids could reflect differences in the magnitude of the interaction with sucrose, the magnitude of the response of deterrent neurons, or the ability of the larvae to adapt to the compounds (Schoonhoven et al., 1998).

None of the compounds totally deterred the insects from feeding or contacting the disks, and often the insects remained motionless for periods of time before either moving off the disk or feeding. There was no evidence of acute postingestive toxicity in either the behavioral (Glendinning and Slansky, 1995) or development bioassays, as no larval mortality was recorded during the experiments. The reduction in growth could result from the antifeedant activity of the compounds or some interaction of the compounds with the utilization of nutrients (Felton and Gatehouse, 1996).

When the isoflavonoids were applied to a diet, the weights gained over the five-day experiment by early stadia larvae were affected more by the isoflavonoids than the later stadia. This could reflect an ability of the later stadia to tolerate or detoxify them. In this experiment, one concentration (100 ppm) was applied to the diet, so the ratio of compound to insect weight would differ among the stadia, and the early stadia would be exposed to a higher dose (larval weight relative to concentration on diet) than the later stadia. Despite these differences, the weights of second, third, and fifth stadia larvae exposed to maackiain- and judaicin-treated diets were lowered. Whether this would have resulted in larval mortality or just an increased duration of larval development before pupation was not investigated. Any compound that extends larval development has the potential to decrease larval

fitness and increase the probability of predation. However, the interactions between phenolics, such as the isoflavonoids, and plant oxidative enzymes in chickpeas could modulate the effect on insect development as well as decrease the efficacy of microbial agents, such as baculoviruses that are increasingly being used to control lepidopterous pests (Hoover et al., 1998).

The behavioral responses to the isoflavonoids varied among the different noctuids. *H. virescens* was not deterred by any of the isoflavonoids, and of the three species of *Spodoptera* tested, only *S. littoralis* and *S. frugiperda* were deterred by judaicin and maackiain, respectively. In fact, *H. armigera* was the only species to be responsive to the four isoflavonoids. The fact that the insects differ in their behavioral responses to the compounds suggests that specificity of the receptors in the peripheral sensory system varies among species. Because of our lack of knowledge about the specificity of the taste receptors on the gustatory neurons of these insects, we can not predict how a species will respond to a group of compounds. For example, previous experiments with azadirachtin-derived compounds showed that *S. littoralis* was more responsive to a range of the derivatives than heliothines, and *H. virescens* was more responsive than *H. armigera* (Blaney et al., 1990). In contrast, Simmonds et al. (1990) showed that *H. armigera* was more responsive to polyhydroxyalkaloids than polyphagous species of *Spodoptera* and *H. virescens*. Thus, modulating the levels of isoflavonoids in chickpeas might decrease the palatability of the plants to target insects such as *H. armigera* and susceptibility to fungal pathogens, but further experiments are needed to evaluate the activity of the isoflavonoids against other pests of *Cicer*.

This is the first study to have evaluated the role of these isoflavonoids in the resistance of chickpeas to *H. armigera*. We suggest that isoflavonoids in *Cicer* could play an important part in the ecology of *Cicer*–herbivore interactions and that the isoflavonoids accumulated in wild relatives of chickpea, if expressed in chickpeas, could decrease susceptibility to target pests and pathogens.

Acknowledgments—Insect bioassays were undertaken at RBG, Kew, under a MAFF licence. We acknowledge GlaxoWellcome for financial support to purchase the video equipment used in this study. The isoflavonoids were isolated as part of a Darwin Initiative Grant to P.S.

(Received September 22, 1999; accepted December 17, 2000)

Abstract—Brown treesnakes (*Boiga irregularis*) responded with more tongue flicks to blood (from rabbits, rats, and mice) than to water. When rat blood was centrifuged at 3500 rpm for 5 min, separating serum from cellular residue, snakes responded strongly to serum but not to cellular residue.

Key Words—Predation, foraging, blood, serum, cellular residue, brown treesnakes, bait, attractant, Guam, traps.

INTRODUCTION

Problems on Guam subsequent to the introduction of the brown treesnake (*Boiga irregularis*) near the end of World War II have been described by several authors (e.g., Engbring and Fritts, 1988; Fritts, 1988; Savidge, 1987). Consequently, great attention has been given to *B. irregularis* in an attempt to measure and reduce its populations on Guam and to prevent the spread of this snake to other Pacific islands (Fritts, 1987; Fritts and Scott, 1985; Rodda and Fritts, 1992). Part of this effort required study of the diet and predatory behavior of *B. irregularis* (Greene, 1989; Fritts and McCoid, 1991; Rodda, 1992; Savidge, 1988) and the development of baits to lure snakes to traps (Chiszar et al., 1988, 1999; Fritts et al., 1989;

0098-0331/01/0500-0979$19.50/0

Rodda et al., 1992, 1999). In this context it, was discovered that *B. irregularis* responded strongly to mammalian blood in laboratory tests (Chiszar et al., 1992, 1993). Whole blood was used in those tests. Here we report experiments that separate the effects of serum and cellular residue.

Because serum contains blood proteins, especially albumin and globulins, and because these materials are biologically active in attracting predators and scavengers and as allergens (e.g., Chen, 1967; Goodman, 1958; Gurin and Carr, 1971), we expected serum to be responsible for the effects of whole blood seen in our earlier studies.

METHODS AND MATERIALS

Preliminary Experiment. By using the methods of Burghardt (1970), 10 *B. irregularis* from Guam were presented on alternate days with cotton-tipped applicators soaked in tap water, rabbit serum, or cellular residue (in random order; one trial with each chemical), and we counted the number of tongue flicks (TF) during the 60 sec immediately after the presentations. The mean TFs for water, serum, and residue presentations were 15.2, 31.4 and 15.8, respectively (pooled SE $= 7.5$). The mean for serum presentations was significantly higher than the means for either of the other presentations by paired *t* tests ($t = 2.97$, 2.55, respectively, $df = 9$, $P < 0.05$). These results encouraged us to conduct additional studies.

Experiment 1. Although cotton-tipped applicators are quite effective in laboratory tests, especially with small snakes and lizards (see Burghardt, 1970; Cooper, 1994; Halpern, 1992; for reviews), we wanted a technique that could also be used to present chemical cues in traps on Guam. Tampons can absorb considerable quantities of liquid (6–15 g) and can easily be incorporated into traps. Since specimens of *B. irregularis* attacked and ingested tampons soaked with human menstrual blood (Chiszar et al., 1993), tampons were used as vehicles in experiment 1. Our first step, then, was to demonstrate that rodent blood in tampons was a salient stimulus for *B. irregularis*.

Tampax tampons, super absorbency size, were used to present chemical cues. Two tampons were presented simultaneously to snakes, each wrapped in hardware mesh bags to prevent ingestion, but to permit chemical diffusion and inspection by snakes. One tampon contained 1.0 cc of tap water, the other contained 1.0 cc of whole blood from either mice (*Mus musculus*) or rats (*Rattus norvegicus*). Blood was collected through cardiocentesis by Albert Petkus, DVM and chairperson of the University of Colorado Animal Care Committee, and was stored at 6°C until used (within 48 hr). The mesh bags containing tampons were fastened to a plywood base (23 × 19 cm), and this apparatus was gently placed into a snake's cage for 5 min, during which we recorded TFs directed at each bag. This method of presenting objects to snakes has been used successfully in previous studies

(e.g., Duvall et al., 1980). Five *B. irregularis* were observed with water and rat blood and five additional snakes were observed with water and mouse blood. All snakes were adult, long-term captives, maintained at 26°C on a 12L:12D photoperiod with the photophase centered at noon. Snakes had been deprived of food (mice and rats) for one week prior to all tests. Water and blood were warmed to 37°C prior to being absorbed into tampons. Following each trial, tampons were discarded and the mesh baskets were washed, rinsed thoroughly, and dried.

Experiment 2. Having shown that tampons can be used as vehicles for whole rodent blood, our next step was to partition blood into serum and cellular residue, presenting each of these substances to *B. irregularis* as in experiment 1.

Tampons were prepared with either 1.0 cc of water, 1.0 cc of rat serum, or 1.0 cc of rat cellular residue. Only the cellular residue produced red colored tampons. Five *B. irregularis* received tampons containing cellular residue and water, and five additional snakes received tampons containing serum and water. The tampons were placed in the same wire mesh baskets as in experiment 1, and trials were again 5 min long. Tongue flicks directed at each of the two tampons were recorded with hand-held counters. Rat blood was collected by cardiocentesis as in experiment 1 and was centrifuged at 3500 rpm for 5 min. Supernatant and residue were separated and the cuvettes were stored at 6°C until used (within 48 hr). As in experiment 1, materials were warmed to 37°C prior to being absorbed into tampons. Tampons were used only once, and the mesh baskets were washed, rinsed, and dried prior to the next trial.

RESULTS

Experiment 1. Table 1 presents mean TFs during the 5-min tests, where it can be seen that significantly more TFs were directed at blood-soaked tampons than at water-soaked ones. Relative effectiveness of mouse and rat blood was assessed by a 2×2 mixed analysis of variance (ANOVA) in which donor species was a between-subjects factor since different snakes responded to mouse and to rat blood,

TABLE 1. TONGUE FLICKS BY BROWN TREESNAKES TO TAMPONS CONTAINING WATER AND WHOLE RODENT BLOOD[a]

Source of blood	Snakes observed (N)	Tongue flicks/5 min (mean ± SEM)		Paired t tests ($df = 4$)
		Water	Whole blood	
Mice	5	93.6 ± 28.5	280.2 ± 53.3	2.85[a]
Rats	5	48.0 ± 4.5	169.2 ± 32.7	4.21[a]

[a] $P < 0.05$.

TABLE 2. TONGUE FLICKS BY FIVE BROWN TREESNAKES TO TAMPONS CONTAINING WATER AND CELLULAR RESIDUE FROM RAT BLOOD OR TAMPONS CONTAINING WATER AND RAT SERUM

	Tongue flicks/5 min (mean ± SEM)		
Content of experimental tampon	Control (water)	Experimental	Paired t tests ($df = 4$)
Cellular residue	49.8 ± 20.3	31.0 ± 9.1	0.67
Serum	26.8 ± 10.6	63.8 ± 10.5	2.89[a]
t tests for independent groups ($df = 8$)	0.98	3.01[a]	

[a] $P < 0.05$.

and experimental (blood) versus control (water) trials were treated as a repeated measures factor as each snake responded to both conditions. Number of TFs aimed at each tampon during the 5-min tests was the dependent variable. This analysis revealed a strong effect of experimental versus control trials ($F = 41.76$, $df = 1$, 8, $P < 0.01$), but neither the main effect of donor species nor the interaction of donor species × experimental versus control trials was reliable ($Fs = 1.99$, 1.87, respectively, $df = 1$, 8, $P > 0.05$). Hence, the snakes responded strongly to blood, and the source of the blood exerted no significant effect.

Experiment 2. Table 2 presents a summary of the data, and it is clear that the snakes' response to cellular residue did not differ from their response to water, but the snakes responded significantly more strongly to serum than to water. These assertions are confirmed by the t tests for paired comparisons reported in the right column of Table 2. We also compared responses to the two control tampons and to the two experimental tampoons (see t tests for independent groups reported in the last row of Table 2). Mean number of TFs aimed at the two control tampons did not differ significantly; but, the mean number of TFs aimed at the tampon containing serum exceeded the value aimed at the tampon contaning cellular reside.

Hence, based on the paired comparisons as well as the independent ones, we conclude that response to serum was stronger than response to cellular residue.

DISCUSSION

Most previous tests of *B. irregularis* response to blood have used cotton-tipped applicators to present whole blood. Now we show that another methodology produces convergent results, revealing that positive responses seen earlier were not restricted to the protocol used in those experiments. Further, we demonstrated that serum, rather than cellular residue, contained the components responsible for the snakes' response to blood.

Similar results were obtained by Gurin and Carr (1971) with the marine snail, *Nassarius obsoletus*, a deposit feeder and a facultative carrion feeder. Snails extended their proboscises to a variety of substances arising from dead animals (Copeland, 1918; Carr, 1967). Subsequent research showed that human plasma elicited a strong response, and the active components had molecular weights of 1000 or greater. Lipoproteins and fibrinogen had relatively little stimulative capacity (DeLalla and Gofman, 1954), whereas serum albumin had strong effects on the snails, accounting for up to 70% of the total activity of plasma (Gurin and Carr, 1971). Accordingly, we intend to try similar experiments with *B. irregularis* in our attempt to identify attractants that can increase the success of trapping efforts on Guam (see Burghardt et al., 1988; Halpern et al., 1984; Liu et al., 1999; for cognate experiments on garter snakes).

(Received June 5, 2000; accepted January 15, 2001)

Abstract—Although several studies have elucidated the role of plant epicuticular waxes in host recognition and oviposition by herbivorous insects, there is little known about this subject in Chrysomelidae. In the present study, chemical cues for host recognition behavior and oviposition by the monophagous chrysomelid species *Cassida stigmatica* were investigated with special regard to surface waxes of the host plant, *Tanacetum vulgare* (Asteraceae). After hibernation in the soil, adults of this species must climb the plant's petioles, which emerge from the ground in spring. The response of adult *C. stigmatica* to contact and volatile cues from petioles and leaves of *T. vulgare* was investigated in a "stem arena," in which differently treated petioles and petiole dummies were offered. Volatile and contact cues of *T. vulgare* petioles served as well for host recognition. The contact cues were isolated from the petioles and leaves by hexane extraction and by cellulose acetate treatment, which removed cuticular waxes. The attractive volatiles were not extracted sufficiently by hexane. To examine the role of cuticular waxes of the host leaf surface in oviposition, female *C. stigmatica* were offered intact leaflets and leaflets from which cuticular waxes had been stripped by cellulose acetate treatment. Females did not discriminate between intact and stripped leaflets when only the upper leaf surfaces were offered. However, when the lower leaf surfaces that are generally used as oviposition sites were offered, *C. stigmatica* preferred to lay eggs on intact leaflets. We conclude that waxes of the lower leaf surface contain crucial information for oviposition in *C. stigmatica*.

Key Words—*Cassida stigmatica*, Chrysomelidae, *Tanacetum vulgare*, Asteraceae, surface waxes, oviposition, host finding.

INTRODUCTION

Herbivorous insects are attracted to their host plants by visual and volatile cues. Upon contact with the host plant, surface morphology and chemistry offer numerous additional stimuli for host recognition and acceptance by the insect. The influence of plant epicuticular waxes on insect host plant acceptance has become an area of increasing interest (Bernays et al., 1976, 1985; Städler and Roessingh, 1990; Eigenbrode and Espelie, 1995; Spencer, 1996; Eigenbrode et al., 1998, 1999). Plant waxes can affect arthropod herbivores (and also their natural enemies) in different ways. The morphology of the cuticle influences the ability of the insect to attach to the host plant via its tarsi (Stork, 1980; Schoonhoven et al., 1998). Extracts of surface waxes, mainly composed of *n*-alkanes, alkyl esters, free fatty alcohols, and free fatty acids (Eigenbrode and Espelie, 1995), can evoke arresting behavior (Klingauf, 1971; Varela and Bernays, 1988) and stimulate feeding (Bernays et al., 1976; Eigenbrode and Pillai, 1998; Lin et al., 1998) and oviposition of insects (Städler, 1986; Renwick et al., 1992). Morphological and chemical characteristics differ with respect to the upper and lower leaf surfaces (Premachandra et al., 1993; Eigenbrode and Espelie, 1995; Eigenbrode et al., 1998, 1999). The effects of these differences on host plant acceptance by insects have yet to be investigated.

The removal of cuticular waxes from plants has traditionally been carried out by dipping the plant material in various solvents for a few seconds (Bohm and Constant, 1990; Renwick et al., 1992; Brooks et al., 1996). This procedure chemically alters the plant material. Oxidative enzymatic reactions in the leaf tissue cause the treated leaves to turn brown and wilt (Whitaker and Lee, 1995). To remove the surface waxes without further damage of the plant tissue, Baker et al. (1983) developed the cellulose acetate stripping method, which removes the epicuticular waxes, but keeps the remaining plant tissue intact.

The role of plant surface waxes in host finding and oviposition of herbivorous insects has been investigated mainly in species of the taxa Orthoptera, Lepidoptera, Diptera, and Aphidinae. To our knowledge, only two studies examined the effect of plant surface waxes on feeding behavior of Chrysomelidae (Adati and Matsuda, 1993; Lin et al., 1998). Possible impacts of plant waxes on chrysomelid oviposition behavior have not yet been considered.

The monophagous chrysomelid species *Cassida stigmatica* Suffr. is specialized on tansy (*Tanacetum vulgare* L., Asteraceae) (Koch, 1992; Müller, 1999). Adults of *C. stigmatica* must find and recognize their host plant when they emerge in spring from the soil after hibernation. Their host plant, *T. vulgare*, is usually in the initial stages of development at this time. The young leaves with petioles and 10–20 leaflets have emerged from the ground, but the plant stem is not yet developed. The adults climb the petioles of the young leaves searching for feeding and oviposition sites.

This study focuses on the olfactory and contact surface cues, in particular plant surface waxes, that influence the host plant recognition process of adult *C. stigmatica*. The beetle's choice of petiole to climb and leaflet on which to oviposit was investigated by laboratory bioassays.

METHODS AND MATERIALS

Insects. Adults of *C. stigmatica* were collected at ruderal sites in Berlin, Germany, in May 1998, and placed in plastic containers (20 × 20 × 6 cm) with a gauze lid (120 μm mesh). The bottom of each container was covered with filter paper and the adults were fed on leaves of *T. vulgare*. Insects were reared at 20°C, 75% relative humidity, and 16L : 8D.

Extract of T. vulgare. To isolate components of low polarity from petioles and leaves of *T. vulgare*, material was harvested from young plants and lyophilized (Christ, alpha 2–4) for 24 hr. Two grams of dry leaf material was extracted with hexane in a Soxhlet apparatus (100 ml) for 8 hr. The extract was concentrated to 8 ml, using a rotary evaporator.

Removal of Plant Cuticular Waxes. To obtain plant material of *T. vulgare* without surface waxes, the cuticular waxes were removed from the surface of leaflets and petioles using the cellulose acetate stripping method (Baker et al., 1983). Cellulose acetate was dissolved in acetone (5–10% w/v) by ultrasonic treatment for 2 hr. leaflets or petioles of young leaves were dipped for 1 sec in the solution. After evaporation of the acetone, the white film that appeared on the surface of the sample material was carefully removed with forceps.

General Procedure of Host Plant Recognition Bioassays. In order to examine the role of petiole stimuli in the host finding of adult *C. stigmatica*, the "stem arena" described by Müller and Hilker (2000) was employed in a modified form. Petioles (2.5 cm) of freshly sprouted, field-collected *T. vulgare* and differently treated, wooden petiole dummies (toothpicks) were offered vertically to adult *C. stigmatica* in an open Petri dish (5.5 cm dia. × 1 cm high). Four test and four control petioles were placed in alternating sequence and equidistant near the outer edge of the dish. The bottom of the Petri dish was filled with soil and covered by filter paper to fix the petioles and dummies in place. Bioassays were conducted at 25°C under a central spotlight (55 cm above the arena, 1200 lux) in a dark room.

Adult females were starved for a period of 3 hr prior to testing. An individual was placed in the center of the arena. After 2 min of acclimatization, the time spent by the beetle walking (climbing) on test and control petioles during a 10-min period was recorded using the software Noldus Observer program 3.0 (Wageningen, Netherlands) (Noldus et al., 1991). Each bioassay was replicated 20 times. Solvents used were allowed to evaporate for 2 min prior to each bioassay. All petioles and treated petiole dummies were renewed for every trial. Females

that were inactive for more than 50% of the observation time were excluded from the analysis. Durations of walking (climbing) on test and control petioles were statistically compared by the Wilcoxon signed-rank test for paired differences.

Host Plant Recognition Bioassay of Volatile Cues. To study the females' response to volatiles, test and control petioles were offered wrapped with perforated filter paper tubes (dia. 0.5 cm) to prevent direct contact. The perforation of the filter paper was done with a needle (20 holes/cm^2; hole diameter: 0.5 mm). The following samples were offered to a female: (a) petioles of *T. vulgare* (test) and untreated petiole dummies (control), (b) test petiole dummies with 15 μl hexane extract of *T. vulgare* (see above) (15 μl is equivalent to 40 mg fresh plant material, the average weight of a 2.5-cm-long petiole) and control petiole dummies with 15 μl hexane.

Host Plant Recognition Bioassay of Contact Cues. To test the females' response to a combination of volatile and contact cues, the following samples were offered allowing direct contact (without filter paper tubes): (a) petioles of *T. vulgare* (test) and untreated petiole dummies (control), (b) petiole dummies with 15 μl hexane extract of *T. vulgare* (test) and petiole dummies with 15 μl hexane (control), (c) petioles of *T. vulgare* with intact wax cover (untreated) and petioles of *T. vulgare* after cellulose acetate treatment.

Oviposition Bioassays of Plant Cuticular Waxes. To test the influence of leaf surface characteristics for oviposition, a gravid female *C. stigmatica* was offered two young field-collected adjacent leaflets of *T. vulgare* in a Petri dish (5.5 cm dia. $\times$ 1 cm high). The dish was lined with moistened filter paper (200 μ water) to keep the leaflets turgid. One of the leaflets was offered untreated (with intact wax layer), while the other was treated with cellulose acetate. Both leaflets were offered either with their upper surface up or with their lower surface up. Prior to testing, females were kept without plants for 2 hr. After 9 hr, the number of eggs was counted on both leaflets and statistically compared by the Wilcoxon signed-rank test for paired samples.

RESULTS

Host Plant Recognition Bioassay of Volatile Cues. Volatiles from young petioles serve females of *C. stigmatica* as cues to recognize the host plant. The beetles significantly preferred wrapped *T. vulgare* petioles with no access to petiole contact cues over wrapped petiole dummies. The duration of walking was longer on the wrapped petioles than on petiole dummies (Figure 1, treatment A). Dummies treated with a hexane extract of *T. vulgare* petioles and leaflets and then wrapped with perforated filter paper were not attractive to the females (Figure 1, treatment B). The duration of walking on test and control petioles did not differ significantly. Thus, the attractive volatiles of petioles could not be isolated by our hexane extraction of host leaves with petioles and leaflets included.

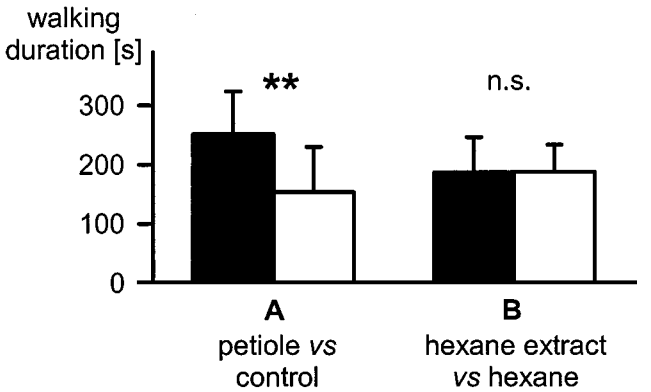

FIG. 1. Effect of volatile stimuli of the host plant *Tanacetum vulgare* on females of *Cassida stigmatica* (seconds, Duration of walking mean ± SD) on differently treated petioles during an observation period of 10 min is given. Test and control petioles were wrapped with filter paper to prevent contact. Mean duration of walking: (A) on petioles of *T. vulgare* (black bars) and petiole dummies (white bars); (B) on dummies treated with a hexane extract of *T. vulgare* (black bars) and dummies with the solvent only (white bars); $N = 20$ replicates per bioassay. $^{**}0.01 > P > 0.001$); n.s. = not significant; Wilcoxon signed-rank test for paired differences, two-sided.

Host Plant Recognition Bioassay of Contact Cues. When both unwrapped petioles that provided access to contact cues and petiole dummies were offered, the females preferred the host petioles (Figure 2, treatment A). The contact cues enhancing the walking activity could be isolated by hexane extraction of young leaves (petioles plus leaflets) of *T. vulgare*. On petiole dummies treated with this hexane extract the females walked significantly longer than on control dummies when contact was allowed (Figure 2, treatment B). Furthermore, the adults were observed to walk for a longer time on leaf petioles with an intact wax layer compared to petioles from which waxes had been removed (Figure 2, treatment C).

Oviposition Bioassays of Plant Cuticular Waxes. When the upper surface of the leaves was offered for oviposition, females of *C. stigmatica* did not discriminate between leaflets with an intact wax layer and leaflets treated with cellulose acetate. However, when the lower surface of leaves was offered with and without the wax layer, 2.5 times more eggs were laid on the leaves from which no waxes had been removed (Table 1).

DISCUSSION

Host plant recognition in *C. stigmatica* was shown in this study to be guided by both volatile and hexane-soluble, most probably waxy, contact cues of

T. vulgare petioles and leaflets (Figure 1, treatment A; Figure 2). Attraction by host volatiles has been shown in several other chrysomelid species (Feeny et al., 1970; Anderson and Metcalf, 1986; Visser, 1986; Mitchell, 1994; Müller and Hilker, 2000). The attractive host volatiles for chrysomelids identified so far are known to be both common plant volatiles such as the so-called general green leaf volatiles (e.g., Visser, 1986) and very host-plant-specific chemicals such as allyl isothiocyanate in Brassicaceae (e.g. Vincent and Stewart, 1984). *C. stigmatica* might respond to both the pattern of green leaf volatiles of *T. vulgare* and typical

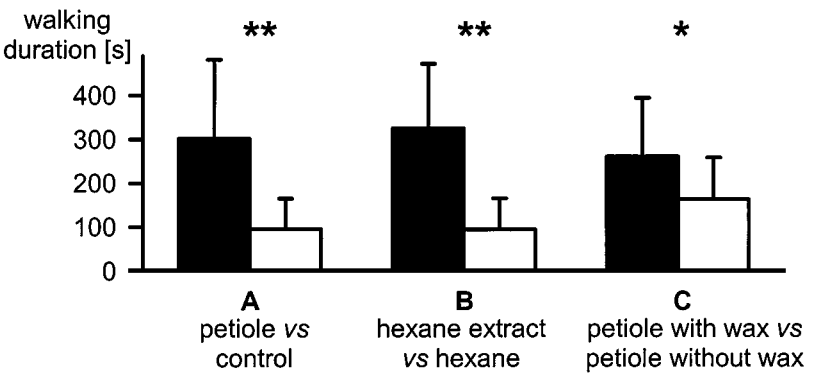

FIG. 2. Effect of volatile and contact stimuli of the host plant *Tanacetum vulgare* on females of *Cassida stigmatica* (seconds, Duration of walking mean ± SD) on differently treated petioles during an observation period of 10 min is given. Test and control petioles were offered for direct contact in the petiole arena. Mean duration of walking: (A) on petioles of *T. vulgare* (black bars) and petiole dummies (white bars); (B) on dummies treated with a hexane extract of *T. vulgare* (black bars) and dummies with the solvent only (white bars), and (C) on petioles of *T. vulgare* with an intact wax layer (black bars) and petioles of *T. vulgare* whose waxes had been removed (white bars); $N = 20$ replicates per bioassay. $^{**}0.01 > P > 0.001$; $^{*}0.05 > P > 0.01$; Wilcoxon signed-rank test for paired differences, two-sided.

volatiles of *T. vulgare* such as monoterpenes (e.g., thujone) and their derivatives (Teuscher and Lindequist, 1994). The hexane extraction used in this study did not sufficiently isolate the volatiles attractive to *C. stigmatica*. The concentration of possibly attractive compounds might have been too low or compounds might have been lost due to fast evaporation. Other extraction methods and behavioral studies of adult *C. stigmatica* are needed to identify the plant volatiles that serve as host recognition cues for this chrysomelid species.

Considering the role of contact cues for host recognition in *C. stigmatica*, two bioassay results strongly indicate that cuticular waxes of the petioles are important. These cues could be isolated from the petioles by the cellulose acetate stripping method, and the active compounds are soluble in hexane. However, with the methods we used we can not rule out the possibility that minute amounts of nonwaxy compounds were removed in addition to the plant waxes to elicit the beetle's response.

Two explanations are possible for these oviposition results:

1. The wax load is larger on upper leaf surfaces in several plant species (Premachandra et al., 1993). The cellulose acetate treatment removes only loose wax crystals and the outermost amorphous layer of waxes, as scanning electron microscopic investigations of *T. vulgare* leaves have shown (Müller, 1999). Therefore, while the waxes were most probably completely removed from the lower surfaces after cellulose treatment, some may have remained on the upper surface. These remaining waxes may have been sufficient to stimulate oviposition.
2. The upper surface offers suboptimal oviposition conditions resulting in faliure of *C. stigmatica* to differentiate between a suboptimal leaf surface with or without waxes. Numerous insects, including leaf beetles, are known to prefer the lower leaf surface for egg deposition (Kosior, 1975; C. Müller, personal observations). Ovipositions on upper leaf surfaces expose eggs to sunlight and, thus, unfavorable microclimatic conditions (Willmer, 1986). Furthermore, eggs are exposed to visually oriented egg predators and parasitoids. In the field, the upper leaf surface may be recognized by orientation of the leaf in space. However, in our bioassay, the leaves were placed horizontally onto a filter paper so that *C. stigmatica* could only encounter either of the offered leaf surfaces.

Females of *C. stigmatica* may have recognized the upper leaf surface by its texture and/or its wax composition. The upper leaf surface of *T. vulgare* has a different texture from the lower one. Size and frequency of glands and trichomes on upper and lower leaf surface differ in *T. vulgare*, as in several other Asteraceae (Gershenzon and Croteau, 1991; Müller, 1999). The trichomes were not removed by the cellulose acetate treatment. The wax composition of the upper leaf surface of *T. vulgare* may differ from that of the lower surface. Several other studies showed

that the chemical composition of the plant epicuticular waxes are different on the ab- and adaxial leaf surfaces (Jeffree, 1986; Premachandra et al. 1993; Yang et al., 1993; Eigenbrode et al. 1998, 1999).

Chemical stimuli present in wax have been shown to elicit oviposition in several other insect species. Surface extracts of cabbage plants contain oviposition stimulants for *Pieris rapae* L. (Lepidoptera: Pieridae) (Renwick et al., 1992) and *Delia floralis* (F.) (Diptera: Anthomyiidae) (Hopkins et al., 1997). In *Delia radicum* (L.), chemoreceptors on the tarsi are sensitive to the cabbage surface extracts (Städler and Roessingh, 1990). In the legume podborer *Maruca testulalis* (Geyer), contact chemoreceptors of the ovipositor respond to leaf washes (Waladde and Ochieng, 1990). 1-Octacosanal and 6-methoxy-2-benzoxazolinone (MBOA) elicit oviposition in the Hessian fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae) (Morris et al., 2000).

Acknowledgments—This study was financially supported by a grant from the Universities of Berlin. We thank Sanford Eigenbrode, Johannes Steidle, Joachim Ruther, and two anonymous reviewers for their critical and helpful comments on an earlier version of the manuscript.

(Received July 5, 2000; accepted January 6, 2001)

Abstract—Leaf and bark volatiles from nonhost angiosperm trees were tested on *Ips duplicatus* by gas chromatographic–electroantennographic detection (GC-EAD) and by pheromone-baited traps in Sweden and Inner Mongolia, China, respectively. GC-EAD analysis of the headspace volatiles from fresh bark chips of *Betula pubescens* revealed *trans*-conophthorin, two green leaf volatiles (GLVs): 1-hexanol and (*Z*)-3-hexen-1-ol, and two C_8 alcohols: 3-octanol and 1-octen-3-ol, that consistently elicited antennal responses by *I. duplicatus*. The identification of these EAD-active compounds was confirmed in further GC-EAD recordings with synthetic mixtures. Antennal responses were also found to synthetic (*E*)-2-hexen-1-ol and linalool, which have been identifed from the leaves of nonhost birch and aspen species. No antennal responses of *I. duplicatus* were found to hexanal, (*E*)-2-hexenal, and (*Z*)-3-hexyl acetates. In field trapping experiments, blends of EAD-active green leaf alcohols or C_8 alcohols, or *trans*-conophthorin alone resulted in significant reductions (27–60%) in the number of *I. duplicatus* captured compared with pheromone-baited traps. The unsuitable host compound, verbenone (Vn), also significantly reduced trap catches by up to 60% in both experiments. The strongest disruptive effect resulted from the addition of the combination of green leaf alcohols, C_8 alcohols, and verbenone

* To whom correspondence should be addressed. e-mail: qing-he.zhang@vv.slu.se

0098-0331/01/0500-0995$19.50/0

to the pheromone trap, which caused an 84% reduction in trap catch. The blend of two green leaf aldehydes plus the acetate increased the trap catches in 1998 and had no negative or positive effects in 1999. Our results suggest that these nonhost volatiles (NHVs) are important olfactory signals used by *I. duplicatus* in host selection. They may have great significance in developing semiochemical-based management programs for *I. duplicatus* by reducing or stopping attacks on suitable hosts.

Key Words—Coleoptera, Scolytidae, host selection, nonhost volatiles, green leaf volatiles, 1-hexanol, 3-octanol, 1-octen-3-ol, *trans*-conophthorin, verbenone.

INTRODUCTION

The double-spined spruce bark engraver of Eurasia, *Ips duplicatus* (Sahlb.), occurs in the Paleartic from central Scandinavia, across eastern Europe to Siberia and NE China, and in the mountains of central Europe (Postner, 1974; Lekander et al., 1977; Pfeffer, 1995; Zhang, 2001). In Europe, *I. duplicatus* usually occurs on spruce trees that are under attack by *Ips typographus* L., where it occupies the top position of the tree trunk (Schlyter and Anderbrant, 1993). It has so far not been considered as a major forest pest (Postner, 1974), but recent outbreaks in Czech Republic (Knizek and Zahradnik, 1996) and continuous outbreaks since the 1950s in Inner Mongolia, China (Zhang et al., 1995; Liu et al., 1998), as well as its status as a vector of phytopathogenic fungi (Krokene and Solheim, 1996), might alter its economic status. Therefore, the development of efficient and environmentally sound control measures, such as mass trapping with aggregation pheromones or disruption by nonhost volatiles, is needed to control outbreaks of this species.

Suitable hosts of bark beetles are highly scattered throughout mixed species forests and are distributed unevenly in space and time (Atkins, 1966). Therefore, bark beetles commonly utilize specialized and complex semiochemical signals to locate suitable breeding trees (Borden, 1997; Schlyter and Birgersson, 1999). While seeking suitable hosts in flight, bark beetles will less often encounter suitable host trees and their odors, but mostly unsuitable hosts and nonhost trees (Schroeder, 1992; Borden, 1997). Rejection of the latter two types of trees could be based on an imbalance of certain host characteristics and/or a negative response to some nonhost stimuli (Schlyter and Birgersson, 1999).

Recent field studies have shown that the attraction of pheromone/kairomone in over 15 species of conifer-infesting scolytids are disrupted by green leaf volatiles (GLVs: mostly six carbon alcohols, aldehydes, and derivative esters), lately confirmed in Sweden and North America to be produced by the leaves of nonhost taiga angiosperms (Visser, 1986; Whitman and Eller, 1990; Dickens et al., 1991, 1992; Schlyter et al., 1995; Wilson et al., 1996; Borden et al., 1997; Deglow and Borden, 1998a,b; Poland et al., 1998; Byers et al., 1998, 2000; Zhang et al., 1999a,b; de Groot and MacDonald, 1999). Furthermore, the attraction of

I. duplicatus females to its synthetic pheromone in a walking bioassay was strongly inhibited by a combination of verbenone and a mixture of six GLVs (Schlyter et al., 1995).

There is also evidence that volatiles from nonhost bark might play an important role in the host selection of conifer bark beetles (Borden et al., 1998; Byers et al., 1998; Zhang et al., 2000). Guerrero et al. (1997) showed that benzyl alcohol identified in eucalyptus callus elicited electrophysiological responses from the antennae of *Tomicus destruens* (Woll.) and might at high doses (700 mg/day) reduce attacks on host logs. Gas chromatographic–electroantennographic detection (GC-EAD) analysis of the headspace volatiles from fresh bark chips of three nonhost species (*B. pendula* Roth., *B. pubescens* Ehrh. and *P. tremula* L.) revealed five compounds that consistently elicited antennal responses by *I. typographus* (Zhang et al., 2000). Inhibitory effects of these electrophysiologically active nonhost bark volatiles (in combination or alone), including (±)-*trans*-conophthorin (*t*C) and C_8 alcohols, on *I. typographus* have been shown in the field (Zhang and Schlyter, in preparation). In Canada, Borden et al. (1998) and Huber et al. (1999, 2000) found over 10 bark volatile compounds from nonhost angiosperm trees, *Populus* spp., *B. papyrifera* Marsh, and *Acer macrophyllum* Pursh, that elicited antennal responses in five conifer-attacking scolytid species, including three *Dendroctonus*, one *Ips*, and a *Dryocoetes* species. A disruptive effect of these nonhost bark volatiles on the response to a pheromone-kairomone blend by *Dendroctonus* spp. also has been found (Borden et al., 1998; Huber et al., 1999). In addition, single cell responses to unknown compounds from nonhost birch bark have been demonstrated in Scandinavian *Trypodendron lineatum* (Oliver) and *I. typographus* (Tømmerås, 1989; Tømmerås and Mustaparta, 1989).

Our objectives were: (1) to determine whether the nonhost leaf and bark volatiles are detected by *I. duplicatus* antennae, and (2) to test the EAD-active nonhost volatiles (NHVs), alone or combined, for their capability to reduce captures of *I. duplicatus* in pheromone-baited traps in the field.

METHODS AND MATERIALS

GC-EAD Responses to Nonhost Volatiles

Volatiles from fresh bark chips of nonhost birch, *B. pubescens* (one of the most common nonhost species of *I. duplicatus* and *I. typographus* in Europe) were collected by headspace sampling in June 1998, Asa, Småland, southern Sweden, and analyzed by GC-MSD as described by Zhang et al. (2000). The aeration extracts were stored at −20°C before GC-EAD analysis.

Overwintering *I. duplicatus* were collected from the litter around infested spruce trees, in late October at Baiyinaobao, Inner Mongolia, China. They were

immediately sent to Alnarp, Sweden and kept alive at 4°C until used in the electrophysiological experiments.

GC-EAD analysis was carried out with antennae (with the severed head) of both sexes of the overwintering beetles on an HP 6890 gas chromatograph containing a fused silica polar column (HP-Innowax; 30 m × 0.25 mm; 0.25 μm) as described by Zhang et al. (1999b, 2000). The antennal signals were stored and analyzed on a PC equipped with an IDAC-card and the program EAD ver. 2.3 from Syntech, Hilversum, The Netherlands. Two microliters of an aeration extract of fresh *B. pubescens* bark chips was injected. In addition, the EAD activity to two synthetic mixtures (1 μl/injection) was studied to confirm compound identity and obtain replicates of electrophysiological activity. The synthetic mixtures consisted of: (1) GLVs (100 ng/μl for each compound) commonly found from intact leaves of the nonhost birches and aspen (Zhang et al., 1999a) (Figure 1B); (2) nonhost bark compounds (Zhang et al., 2000) and two aggregation pheromone components, (±)-ipsdienol (Id) and (*E*)-myrcenol (EM) (Byers et al., 1990; Schlyter et al., 1992), plus the general inhibitor, verbenone (Vn) (Schlyter et al., 1989) (100 ng/μl for each compound) (Table 1, Figure 2). Each sample (both bark aerations and synthetic mixtures) was tested on four male and two female antennae. In addition, the second synthetic mixture was also analyzed with GC-EAD on a nonpolar column (HP-1; 30 m × 0.25 mm; 0.25 μm, through the cooled on-column injector) on both sexes (two males, one female). Hydrogen was used as the carrier gas. The column temperature was 40°C for the first 2 min, rising to 200°C at 10°C/min, and held for 2 min. Only those compounds that elicited electrophysiological responses (obviously different from background noise) by at least three antennal preparations were considered as antennally active.

Field Response to Nonhost Volatiles

All the field trapping experiments were carried out in an ~2000 ha natural reserve of spruce [*Picea mongolica* (Wu, H.-Q.) Xu, formally *P. koraiensis* Nakai or *P. meyeri* Rehd. or *P. meyeri* var. *mongolica* Wu, as discussed by Xu et al. (1998)] at Baiyinaobao (43°30′–36′N, 117°06′–16′E), Inner Mongolia, China, which is situated in the grassland at the east edge of Hunshandake desert, with a thick layer of sandy soil. Since the 1950s this isolated natural spruce forest has been severely infested by the web-spinning sawflies [*Cephalcia abietis* (L.), *C. alashanica* (Gussakorskij) and *Acantholyda peiyingaopaoa* Hsiao] and *I. duplicatus* (Zhang et al., 1995; Liu et al., 1998). The larger bark beetle competitor, *I. typographus* has not been recorded here.

Experiment 1 (Green Leaf Volatiles, GLVs). This was conducted in early June 1998 in an old clear-cut at the margin of the surrounding stand of dead trees killed by *I. duplicatus* the previous year. Eight black nonsticky, flight barrier

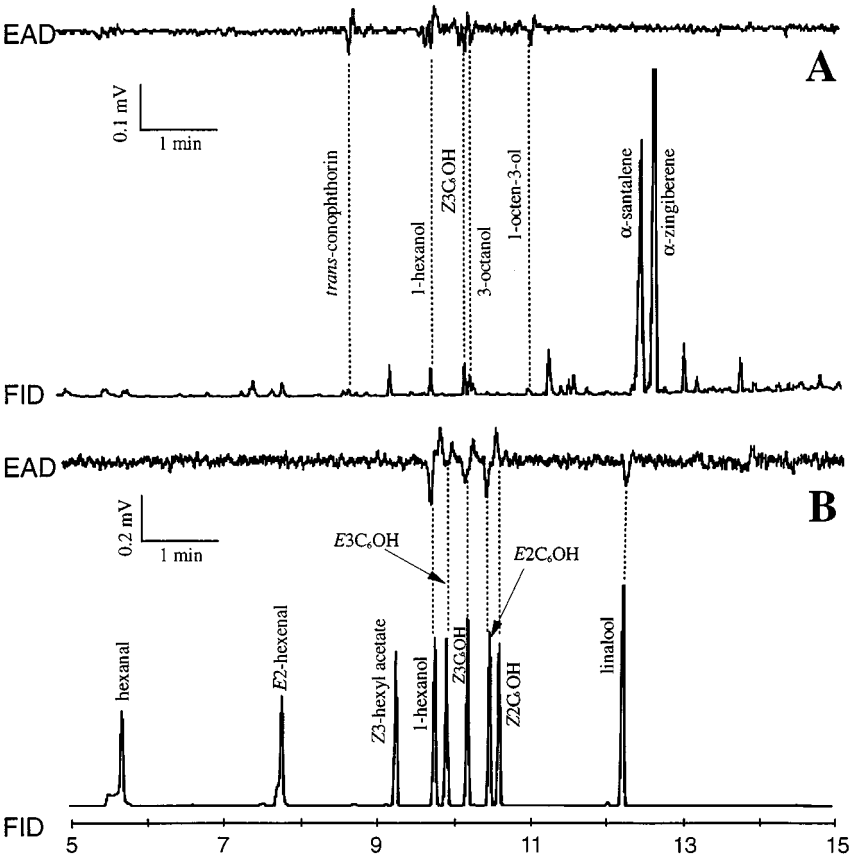

FIG. 1. Flame ionization detector (FID) and electroantennographic detector (EAD) responses of *Ips duplicatus* antennae to nonhost volatiles: (A) headspace volatiles from fresh bark chips of *Betula pubescens*, (B) a synthetic mixture of eight GLVs and linalool (50 ng/compound), commonly found from leaves of nonhost birch and aspen species.

(slot) traps (Theyson, Germany) were arranged in a curve in order to ensure a similar distance (~20–25 m) to the insect source (the dead trees) for each trap. The distance between traps was ~8 m. The GLVs were chosen and grouped based on their emission from leaves of European birches (*B. pendula* and *B. pubescens*) and aspen (*P. tremula*) (Zhang et al., 1999a), and their electrophysiological activity on *I. duplicatus*.

Experiment 2 (Nonhost Bark Volatiles). Ten flight barrier traps were set up in mid June 1999 in a small glade at the margin of the surrounding stand of dead trees killed by *I. duplicatus* the previous year. The traps were set up in a similar fashion

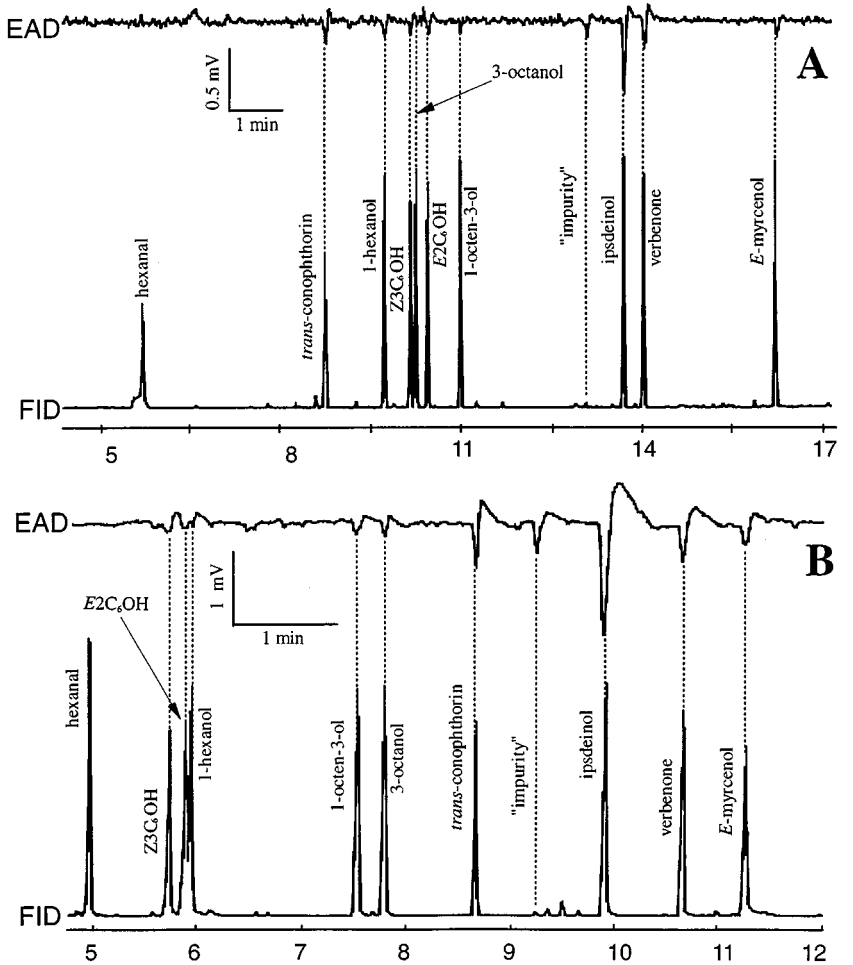

FIG. 2. Flame ionization detector (FID) and electroantennographic detector (EAD) responses of *Ips duplicatus* antennae to a synthetic mixture of 10 compounds containing nonhost bark volatiles, two pheromone components, and an unsuitable host compound, verbenone (50 ng/compound): (A) on polar GC-column (HP-Innowax), (B) on nonpolar GC-column (HP-1).

to experiment 1 with ~8 m between traps. Nonhost bark volatiles were selected according to their presence in the headspace of fresh bark chips of *B. pendula* and *B. pubescens* and *P. tremula* (Zhang et al., 2000), and their antennal activity on *I. duplicatus*. A blend of nonhost leaf volatiles (2Ald-Ac) tested in 1998 was also repeated in this experiment.

All chemicals, sources, release devices, and release rates are listed in Table 1. In both field experiments, three control treatments were used to assess the effectiveness of candidate NHVs: (1) the positive control, i.e., synthetic pheromone lure (Id + EM, at 1:1, dissolved in octane as 1% solution in a wick-dispenser) (Schlyter et al., 2001); (2) the negative control, consisting of pheromone lure plus the unsuitable host compound, verbenone (Vn); and (3) the blank control, containing only the solvent, octane. The positions of traps together with dispensers were initially randomized and rotated after each replicate (when $\geq$50 beetles were caught in the best trap).

Statistical Analysis

Because of considerable variations in the numbers of beetles captured between replicates and experiments, the counts were converted to proportion (p) of total captured beetles within each replicate. The data were then transformed by arcsin $\sqrt{p}$ in order to fit the assumption of homogeneity of variances for ANOVA. The means were compared by ANOVA followed by Duncan's multiple range test (SPSS 8.0 for Windows) at $\alpha = 0.05$. The sex ratios for the treatments within each experiment were compared with 95% binomial confidence intervals (Byers and Wood, 1980).

RESULTS

GC-EAD Responses. In the GC-EAD analysis of volatiles from *B. pubescens* fresh bark chips, *I. duplicatus* antennae of both sexes consistently responded to *trans*-conophthorin (1.5–2.0 ng), two green leaf alcohols: 1-hexanol (4–5 ng) and (*Z*)-3-hexen-1-ol (6–7 ng), and two C_8 alcohols: 3-octanol (2 ng) and 1-octen-3-ol (1 ng) (Figure 1A). Identification of these EAD-active compounds was done on a combined gas chromatograph and mass selective detector (GC-MSD) by comparison of retention times and mass spectra to those of authentic compounds and was published in detail in Zhang et al. (2000). No repeatable antennal responses were found to any other compounds in the bark aeration extract, including the dominant components, α-santalene (80 ng) and α-zingiberene (100 ng). From the first synthetic mixture mainly containing GLVs (50 ng/compound), all five C_6 alcohols and ($\pm$)-linalool elicited repeatable antennal responses in both sexes (Figure 1B). 1-Hexanol and (*Z*)-3-hexen-1-ol, commonly emitted from both leaves and bark, and (*E*)-2-hexen-1-ol from leaves of nonhost birches and aspen (Zhang et al., 1999a, 2000), seemed to elicit stronger antennal responses than those elicited by (*E*)-3-hexen-1-ol and (*Z*)-2-hexen-1-ol, which are not detected from the nonhost trees. The green leaf aldehydes, hexanal and (*E*)-2-hexenal, and the green leaf acetate, (*Z*)-3-hexyl acetate, did not elicit any GC-EAD responses at the doses

tested. GC-EAD recordings with two different GC-columns (polar and nonpolar) on the second synthetic mixture containing the nonhost bark volatiles and aggregation pheromones showed that both male and female *I. duplicatus* antennae responded strongly to the two pheromone components, (±)-ipsdienol and (*E*)-myrcenol, the nonhost bark volatile, (±)-*trans*-conophthorin, and the unsuitable host compound, Vn (Figure 2A and 2B). Weaker, but repeatable, responses were recorded to 1-hexanol, (*Z*)-3-hexen-1-ol, (*E*)-2-hexen-1-ol, (±)-3-octanol, and (±)-1-octen-3-ol. No responses were found to the green leaf aldehyde, hexanal, at the dose tested. The major pheromone component, ipsdienol, elicited the strongest EAD response, which was at least twice as strong as those of (*E*)-myrcenol and the nonhost volatiles. Surprisingly, a strong and repeatable response to a small amount of an unknown impurity (<1 ng) from the synthetic mixture was also found, which is now subject to further identification by GC-MS. There were no differences in antennal responses between males and females.

Field Response to Nonhost Volatiles. In the GLVs experiment (experiment 1), a total of 12,200 beetles were caught during 31 replicates in 1998. The individual green leaf alcohols, 1-hexanol, (*Z*)-3-hexen-1-ol, and (*E*)-2-hexen-1-ol, did not significantly reduce any trap catches. The blend (3OH-B) of (*E*)-3-hexen-1-ol, (*Z*)-2-hexen-1-ol, and linalool also did not decrease trap catches. Interestingly, addition of the blend (2Ald-Ac) of two aldehyedes, hexanal and (*E*)-2-hexenal, plus (*Z*)-3-hexenyl acetate to the pheromone trap seemed to significantly increase the trap catches (Table 2). However, the negative control, Vn reduced the trap catches by 40% (Table 2). When considering the sex ratios of beetles caught, the proportion of males was lower in the traps with individual GLV alcohols, 2Ald-Ac, and Vn than that in traps baited with pheromone alone (Table 2). No differences in sex ratio between traps baited with pheromone alone and pheromone plus 3OH-B were found. Thus, the individual GLV alcohols had a inhibitory effect on males (with male catch reduction ranging from 30 to 70%) even though the total number of beetles was not reduced. The addition of 2Ald-Ac to pheromone traps increased the female catches, but not male catches.

In the nonhost bark volatiles experiment conducted in 1999 (experiment 2), a total of 2467 beetles were caught during 18 replicates. Unlike experiment 1, the blend of 2Ald-Ac did not have any significant effect on the trap catches. However, the (±)-*trans*-conophthorin (*t*C), the blend of three GLVs: 1-hexanol, (*Z*)-3-hexen-1-ol and (*E*)-2-hexen-1-ol, and the blend of two C_8 alcohols (C_8-OHs): (±)-3-octanol and (±)-1-octen-3-ol, resulted in significant reductions (27%, 33%, and 60%, respectively) in the number of *I. duplicatus* captured compared with the trap baited with pheromone alone (Table 2). Vn, the negative control, also significantly reduced the trap catches by 63%, but its combination with *t*C was not different from the Vn alone. The strongest inhibition of attraction resulted from the addition of the combination of 3GLVs, C_8-OHs, and Vn to the pheromone trap, which caused an 84% reduction in trap catch

TABLE 2. FIELD BEHAVIORAL RESPONSES OF *Ips duplicatus* TO NONHOST LEAF AND BARK VOLATILES AND VERBENONE (VN) ADDED TO ATTRACTANT SOURCE, BAIYINAOBAO, CHIFENG, INNER MONGOLIA, CHINA

Experiment and treatment	% of total beetles captured (mean ± SE)[a]	Males (%)	95% CI	Total catch

Ph + 3GLVs + C_8-OHs + Vn	2.7 ± 0.6a	21.1	13.2–32.0	71
Ph + 3GLVs + C_8-OHs + Vn + *t*C	3.2 ± 0.7a	24.1	16.0–34.5	79
Blank	0.8 ± 0.3[c]	38.9	20.3–61.4	18

[a] Numbers in the column with the same letter, within the same experiment, are not significantly different ($P > 0.05$) by ANOVA on arcsin $\sqrt{p}$ followed by Duncan's multiple-range test.
[b] Significantly different from the positive control (pheromone alone; **Ph**), by comparison with 95% binomial confidence intervals.
[c] Blank not included in the ANOVA and the range tests to acheive homogeneity.
[d] One outlier removed for this treatment to acheive homogeneity (mean and SE includes the outlier).

(Table 2). The addition of *t*C to this combination showed no further catch reduction. The active nonhost volatiles seemed to reduce males more than females, but the sex ratios were not significantly different from the traps baited with pheromone alone (Table 2).

DISCUSSION

Electrophysiological Activity. Our results clearly show that *I. duplicatus* antennae are able to consistently detect *trans*-conophthorin, 1-hexanol, (*Z*)-3-hexen-1-ol, 3-octanol, and 1-octen-3-ol, which were commonly found from the headspace samples of bark chips of the nonhost *B. pubescens* (Figure 1A) and other nonhost species such as *B. pendula* and *P. tremula* (Zhang et al., 2000). In similar amounts, *trans*-conophthorin seems to elicit higher antennal responses than the other EAD-active NHVs do. This is the first electrophysiological evidence that *I. duplicatus* antennae not only strongly respond to their aggregation pheromone components, ipsdienol and (*E*)-myrcenol, but also can detect some nonhost leaf and bark volatiles, and the unsuitable host compound, Vn. An identical response pattern has recently been reported for *I. typographus*, the major competitor species of *I. duplicatus* in Europe (Zhang et al., 2000). In addition, a similar antennal activity was found in *Tomicus piniperda* and *T. minor* (Schlyter et al., 2000). However, in this study *trans*-conophthorin was EAD inactive (Schlyter et al., 2000). In a GC-EAD analysis with nonhost bark volatiles, Huber et al. (1999, 2000) found that *trans*-conophthorin elicited antennal responses by five species of North American bark beetles, *D. ponderosae* Hopkins, *D. pseudotsugae*, *D. rufipennis* Kirby, *Ips pini* (Say), and *Dryocoetes confusus* Swaine.

The GC-EAD active green leaf alcohol, (*E*)-2-hexen-1-ol, has not been detected from the nonhost bark, but was found together with 1-hexanol and (*Z*)-3-hexen-1-ol to be abundant in the volatile emission from intact leaves of nonhost birches and aspen (Zhang et al., 1999a). Similar GC-EAD responses to these green leaf alcohols have been reported in *I. typographus* (Zhang et al., 1999a,b), *D. ponderosae* Hopkins (Wilson et al., 1996) and two *Tomicus* species (Schlyter et al., 2000; Poland and Haack, 2000). Surprisingly, hexanal and (*Z*)-3-hexyl acetate, the most common green leaf aldehyde and acetate from many nonhost angiosperm species (Visser, 1986; Zhang et al., 1999a, 2000), did not show any antennal activity in any Eurasian bark beetle species tested (Zhang et al., 1999b, 2000; Schlyter et al., 2000; and this paper).

Field Trapping. In the 1998 test, the blend of the EAD-inactive green leaf aldehydes and acetate increased the trap catches; however, the enchancement was not repeated in the 1999 test. Further study with individual compounds and their combination is needed to clarify these conflicting results. In addition, the EAD-active green leaf alcohols were inactive when tested individually (Table 2).

However, in experiment 2 the combination of 1-hexanol, (*Z*)-3-hexen-1-ol, and (*E*)-2-hexen-1-ol reduced the number of beetles captured. This might be due to either the synergistic effect of different GLV compounds or a density dependent effect of beetle's populations, with higher population density in 1998 than in 1999.

Consistent with our GC-EAD results, field trapping experiments also disclosed the inhibitory effects of (±)-*trans*-conophthorin, a blend of the two EAD-active C_8 alcohols, (±)-3-octanol and (±)-1-octen-3-ol, and the unsuitable host compound, Vn on *I. duplicatus*. Such interruptive activity by these nonhost volatiles has been found in *I. typographus* (Zhang et al., in preparation), and partly in other bark beetle species, such as *T. piniperda, T. minor* (Schlyter et al., 2000), *D. ponderosae*, and *D. pseudotsugae* Hopkins (Huber et al., 1999). When combining GLV-alcohol and C_8 alcohol blends with Vn, a significant reduction of trap catches was achieved in *I. duplicatus*. This may indicate either an additive or a synergistic effect of combined stimuli (Deglow and Borden, 1998a; Poland and Haack, 2000; Schlyter et al., 2000). However, further experiments with controlled overall release rates and dose–response studies are needed to clarify the type of effect.

In the natural habitat of *I. duplicatus* in Inner Mongolia, China, *P. mongolica* is the only dominant and protected tree species of the natural reserve (Zhang et al., 1995). However, there are spruce stands mixed with birch (*B. platyphylla* Suk.) and aspen (*P. davidiana* Dode) as well. Thus, it would be adaptive for *I. duplicatus* to recognize and further avoid the nonhost birch and aspen by the olfactory means when seeking for the host in flight. Attacking a nonhost birch or aspen tree would typically result in death of the attacking beetle. The nonhost volatiles tested in the current study are based on the data and materials of European birches (*B. pubescens* and *B. pendula*) and aspen (*P. tremula*). Recognition and avoidance of the Far East *I. duplicatus* to the leaf and bark volatiles of European angiosperm trees may indicate a similarity in the volatile emissions between the European and Chinese birch and aspen species. However, further study on the volatile emissons of the native *B. platyphylla* and *P. davidiana* from Baiyinaobao Natural Reserve and their potential electrophysiological and behavioral activity on *I. duplicatus* is needed. Particular active volatiles from the nonhost trees in the *I. duplicatus* natural environment in Inner Mongolia, if any, may prove to be even more disruptive than the general GLVs and NHVs found in the European species.

These results show that the nonhost leaf and bark volatiles and the unsuitable host compound, Vn, can significantly reduce the positive responses of *I. duplicatus* to its pheromone sources. This may have potential for the management of *I. duplicatus* by reducing risk of attacks on suitable hosts. In addition, combination of active NHVs and Vn with the pheromone mass-trapping in a "push–pull" fashion may strengthen our combative force against serious outbreaks of *I. duplicatus* in this natural reserve.

Acknowledgments—We thank Dr. F.-M. Yan, Beijing University, for his careful shipment of live beetles and Dr. T. Poland for comments. The permission to "thin" spruce stands at Björnstorp Estate for bark beetle breeding is highly appreciated. This study was supported by grants from the Swedish Council for Forestry and Agricultural Research (SJFR: No.23.0521/96; No.24.0293/98) and an EU-INCO project (CT 98-0151).

(Received October 24, 2000; accepted January 15, 2001)

Abstract—Beavers store and consume tree parts in the bodies of water where they live. We examined whether such soaking renders food more palatable by leaching out undesirable compounds. In experiment 1, saplings of red maple, *Acer rubrum* (RM), were first soaked in a pond for periods of 2, 18, and 36 days, then offered to free-ranging beavers. Soaking for two days rendered RM slightly more acceptable to beavers. To further examine the time window around two days, RM sticks were soaked in distilled water in the laboratory for 1, 2, 4, and 6 days before presenting them to beavers (experiment 2). In experiment 3, twigs of three species were placed on land. Beavers placed RM in the water for 1 to 3 days before consuming the twigs. In experiment 4, sticks were provided in the water at Cranberry Lake Biological Station (CLBS). Most quaking aspen (QA) was consumed during the first night, and most witch hazel, *Hamamelis virginiana* (WH), during the third night. At Allegany State Park (ASP), no such difference was found. Twigs were provided in the water in experiment 5. At ASP, WH was taken after three days in the water, and at CLBS little WH was consumed, and only during the third night. A meta-analysis of all experiments shows that relatively more WH is consumed after two days than any other species. Experiment 6 traced the time beavers left their own harvested branches in the water. Unlike other tree species, WH remained in the water for two to four days before being consumed. Experiment 7 measured the phenolics leached into water from RM twigs and small pieces of bark soaked for 10 and 8 days, respectively. Shredded bark lost 50–60% of leachable phenolics into the water, and twigs 70–80%. We conclude that beavers can use water to leach undesirable compounds from their food. Although this effect was not robust, our study is the first of its kind.

Key Words—*Acer rubrum*, beaver, *Castor canadensis*, food conditioning, food processing, *Hamamelis virginiana*, leaching, red maple, soaking, witch hazel.

INTRODUCTION

Beavers (*Castor canadensis*) handle, eat, and store food in the bodies of water where they live. In northern climes, they stockpile branches in the water near their lodges as winter food. In addition to these longer-term food caches, beavers also leave harvested branches and logs in the water for one or more days before they consume the bark. Finally, beavers eat bark and leaves while sitting in shallow water. Thus, water is an important medium for storing food and feeding, in addition to its well-known role for floating logs and branches from harvest areas to feeding sites.

We now ask the question: Do beavers use water to process their food? Are they taking advantage of water's ability to leach potentially noxious compounds from pieces of wood to render their food more palatable? If so, beaver might turn otherwise unpalatable tree species into useful food. In turn, such behavior on the part of beavers might force us to reassess what constitutes a suitable food supply and hence, beaver habitat. Many habitat analyses might have to be revised, yielding more available forage than previously thought, after possible food conditioning by beavers.

Humans have long used water for leaching out undesirable, astringent compounds from food. For instance, native North Americans used to soak crushed acorns in streams to render them more palatable by leaching out astringent tannins (Johns, 1990), and to this day South American indigenous farmers soak cassava (manioc, *Manihot esculenta*, Euphorbiaceae) in water (D. M. S; personal observation) to rid it of dangerous cyanogenic compounds, notably linamarin (Johns, 1990).

Food processing by animals has seldom been described. The meadow vole *Microtus pennsylvanicus* cuts winter branches of white and Norway spruce and white and Norway pine and leaves them on the snow for two to three days before eating them. This treatment reduces levels of phenolics by one half, that is, to their summer levels. The high level of protein (12%) and decreased phenolics (1.5%/ dry matter) render the food acceptable. The twigs lose the phenolics possibly by polymerization or oxidation (Roy and Bergeron, 1990).

Pikas, *Ochotona princeps*, of the North American Rocky Mountains are known for the hay piles they accumulate for the winter. In contrast to their phenolics-poor summer diet, they collect phenolics-rich plants, notably alpine avens, *Acomastylis rossii*, for these food caches. As the winter progresses, the phenolic content decreases. When it reaches levels of the summer diet, the pikas consume the stored food (Dearing, 1997).

Mountain beavers (*Aplodontia rufa*) store toxic, alkaloid-containing plants in food caches called haystacks. These plants include tall larkspur (*Delphinium glaucum*), corydalis (*Corydalis caseana*), and corn lily (*Veratrum californicum*) (O'Brien, 1981). We suggest that these alkaloids might be denatured during storage.

The assumption that acorns, buried in the ground by squirrels or jays, lose tannins over the winter has not been confirmed (Dixon et al., 1997).

We noted that beavers in our study area avoid red maple (*Acer rubrum*) (RM). It is often one of the last or even only tree species remaining at the edge of a beaver pond (Müller-Schwarze et al., 1994). Other wildlife also avoid red maple. For instance, porcupines (*Erethizon dorsatum*) reject red maple in both bud and leaf stage, eating it in only one of 812 feeding episodes, while consuming sugar and striped maple more often (Roze, 1989). It is not known what compounds render red maple bark unpalatable. However, red maple leaves contain high levels of phenolics (Shure and Wilson, 1993), including gallic acid and methyl gallate (Abou-Zaid et al., 2000). Red maple also contains small amounts of gramine, an alkaloid (Barbosa et al., 1990). In other studies, beavers consumed RM (e.g., Busher, 1996), even in large amounts, compared to other tree species (Jenkins, 1980), and stored it in their winter food caches roughly in proportion to its abundance at the beaver site (Busher, 1991). However, red maple has less energy content and is less digestible than aspen and alder (Fryxell and Doucet, 1993). Red maple takes almost 30–50 hr to pass through the intestinal tract of a beaver, compared with only 10–20 hr for aspen (Doucet and Fryxell, 1993).

Here, we report results of experiments designed to test whether beavers improve palatability of bark of RM and WH, which are usually less preferred species in our study area, by soaking them in water before eating. In addition, with field observations we tried to establish whether beaver-harvested limbs of different tree species remain in the water for different lengths of time, suggesting leaching of unpalatable species.

METHODS AND MATERIALS

Study Sites

The primary study site was the 250-km^2 forested Allegany State Park (ASP) in Cattaraugus Country in western New York State. It contains about 30 beaver colonies on streams totaling about 70km in length. Additional experiments were performed at Cranberry Lake Biological Station (CLBS), located at the lake of the same name in the mountains of Adirondack Park in northern New York State. There are up to six beaver colonies along the lakeshore and on streams feeding the lake on the 2.6-km^2 forested property owned by the State University of New York.

General Procedures

In experiments 1–3, the sticks or twigs presented on land were stuck in the ground vertically, 30 cm apart, in one row 50 cm above the water's edge, and parallel to it on the evening of day zero. Sticks or twigs were offered in the water in experiments 4 and 5. They were placed in bundles (to mimic bushes and to better find them again) of the same tree species in a shallow part of the pond, and as close as possible to the lodge. The leaves were above water, and the butt ends on the pond bottom. The following morning, and for four mornings thereafter, we recorded the beavers' responses to the samples during the previous night and counted the remaining samples. We found the food samples either left intact and in place, dragged into the water, sampled, removed, or the bark (and leaves, where applicable) fully or partially consumed. Since beavers are active during the night hours, we use "days" in the sense of 24-hr periods in the graphs. In experiment 1, all sticks were replaced every day, and no sticks or twigs were replaced in experiments 2–6.

Experiment 1: Leaching Red Maple Poles in Pond

Experiment 1 duplicated natural behavior of beavers as much as possible. Eighty 2-m-long sections of winter-dormant red maple saplings [mean diameter at thick end 1.97 ± 0.07 (SE) cm; thin end: 1.15 ± 0.076 cm] were harvested at a beaver site on March 2 at 10°C air temperature. They were transported frozen, and the first batch of 20 poles (to be soaked for 36 days) sunk in an ice-covered pond on the following day. A second batch of 20 poles was kept frozen in a snow bank (0°C) and placed in the pond 18 days later. Because the snow bank was receding, a third batch was kept frozen in a walk-in freezer at −10°C, and placed in the pond 34 days after the first. Thus, the batches were soaked in the pond for 2, 18, and 36 days, respectively. Water temperature was +2°C. The pond was ice-covered, with 40–50 cm snow cover. A nonsoaked control sample of 20 poles was kept frozen at −10°C in a walk-in freezer.

For the field tests, the poles were cut into 30-cm-long segments and fed to free-ranging beaver at their colony sites. In addition to the frozen controls, fresh red maple was harvested at the time of provisioning and offered to the beaver as a second control. Finally, sticks of the preferred quaking aspen (*Populus tremuloides*) were also offered as controls. Thus, six treatments in all were used. Consumption of the preferred aspen indicated that beavers were present and attracted to the experimental food.

The sticks were presented in April simultaneously at 10 beaver colonies in a randomized complete block design. The beaver sites represented blocks. (A total of 14 colonies was used because new sites had to be substituted when beavers proved absent at some). For each of the six treatments, two sticks were used per

site per night. The experiment lasted five nights. A total of $6 \times 2 \times 10 \times 5 = 600$ sticks were used, 100 for each treatment. All sticks were replaced on each of the five days of the experiment.

The water temperatures of three streams at beaver sites were +5, +9, and +12°C, respectively. Daily low air temperatures averaged 2.3 ± 1.7°C and daily highs 13.5 ± 1.6°C.

Experiment 2: Leaching Sticks in Containers

To narrow down the effective time window, 30-cm-long RM sticks were collected from saplings at a beaver site not used for preference tests. The sapling pieces were then soaked in tubs with local groundwater and placed on a covered outdoor porch for one, two, four, and six days. To facilitate leaching, the sticks received multiple punctures by rolling them over a nailboard. Half of the water in each tub was replaced each day. Punctured RM sticks, and intact RM sticks. Freshly cut quaking aspen sticks served as controls.

Unlike experiment 1, five trials were run (September 22 to November 27, 1996). The sticks were placed in rows on the shore or the dam, 30 cm apart. Three sticks per treatment (two in trial 1) were placed together, and the sequence of treatment randomized for each site. A total of 770 sticks was offered at eight beaver sites (seven in trial 1), and not replaced for the five days of the experiment.

Cumulative removal and consumption of sticks during each five-day period were recorded by counting intact, sampled, removed, and consumed sticks. The area of bark consumed by beaver on each accepted log was also measured.

Experiment 3: Twigs Provided on Land

In April 19–24, 1999, winter-dormant twigs were provided at five colonies. Altogether 33 QA twigs, 53 RM twigs, and 30 WH twigs were placed. The twigs were not replaced during the five days of the experiment. Minimum air temperatures ranged from −0.5°C to +7.2°C, maximum temperatures from 8.3°C to 14.4°C.

Experiment 4: Sticks Provided in Water

Experiment 4a. From May 3 to 8, 1999, 10 sticks each of RM, QA, and WH were placed at five colonies, for a total of 50 sticks of each species at ASP. Minimum air temperatures ranged from 1.1 to 13.9°C, and maximum temperatures from 21.2 to 27.8°C.

Experiment 4b. A smaller sample of QA, RM, and WH sticks was provided in the water at Cranberry Lake Biological Station (CLBS) in the Adirondack Mountains of New York between July 6 and 16, 1999. The sticks were not replaced during the five days of the experiment.

TABLE 1. TREE SPECIES USED IN EXPERIMENTS

American beech	*Fagus grandifolia*
American hornbeam	*Carpinus caroliniana*
Black cherry	*Prunus serotina*
Black locust	*Robinia pseudoacacia*
Juneberry (serviceberry)	*Amelanchier canadensis*
Quaking aspen	*Populus tremuloides*
Red maple	*Acer rubrum*
Red oak	*Quercus rubra*
Striped maple	*Acer pensylvanicum*
Sugar maple	*Acer saccharum*
White ash	*Fraxinus americana*
Northern wild raisin	*Viburnum cassioides*
Willow	*Salix sp.*
Witch hazel	*Hamamelis virginiana*
Yellow birch	*Betula alleghaniensis*

Experiment 5: Twigs Provided in Water, ASP, and CLBS

Experiment 5a. From May 21 to 27, 1999 a total of 636 twigs (with leaves) were provided in the water at seven sites at ASP. Twelve species of trees and shrubs were used (Fig. 5). The species provided at each site depended on which ones occurred there naturally. Minimum air temperatures ranged from 2.7°C to 10.5°C, maximum temperatures from 11.1 to 23.3°C.

Experiment 5b. A total of 108 [RM, WH, QA, and willow (*Salix sp*.)] were placed at one lake beaver site at CLBS between July 6 and 16, 1999.

Experiments 6a and 6b: Tracing Beaver-Harvested Tree Limbs, Fall and Spring

Limbs and saplings harvested by the beavers themselves were labeled with permanent markers and followed for their fate. On day 0, all branches already in the water were removed. Recording started on day 1 when new branches appeared in the water. The beavers either left branches on land or dragged them into the water. They ate the bark at either location, or built the material into lodge, dam, or (in autumn only) into their food cache. Only a portion was identifiable on subsequent days, since some logs sank to the bottom or were placed on the lodge or into the food cache and covered with other materials such as sticks and/or mud.

Experiment 6a. In fall, at one beaver colony, trees were divided into those that served as immediate food and those that were stored. In the immediate food category we distinguished branches that were eaten ashore from those dragged into the water and then eaten. We recorded the number of days branches and logs remained in the water before consumption after beaver had dragged them into the water.

Experiment 6b. In spring, again all branches found in the water at seven sites were removed on day 0. New branches in the water were marked with permanent markers every meter (because beavers cut them into sections), starting on day 1. We followed the dismemberment of these branches by the beavers. The observations continued for seven days. The water temperatures ranged from 9.5 to 16.5°C at the seven sites over three days.

Experiment 7: Chemical Testing for Amount of Phenolics Leached into Water

The total amount of phenolics available for leaching was tested by extraction of lyophilized bark with methanol–water (8:2). The ground, dry bark was suspended in the solvent and homogenized in a blender. The centrifuged supernatant solution was assayed by the Folin-Ciocalteau method according to Box (1983). This procedure was repeated using distilled deionized water. The average water content was determined by shaving several twigs and lyophilizing the bark. The average proportion of bark to woody material was determined as well.

To test for the loss of phenolic material into water, entire twigs (harvested in the fall at ASP, and stored at −80°c (until use) were soaked in deionized water for 10 days at 4°C and at 25°C, and tested for phenolics after 1, 2, 3, 4, 7, and 10 days, using the Folin-Ciocalteau method.

In a slightly different study, bark from RM twigs of the same origin was cut into small pieces (several mm long) and soaked in deionized water at 4°C for eight days. The concentration of phenols in the water was tested after two, four, six, and eight days, also using the Folin-Ciocalteau method.

RESULTS

Experiment 1. Sticks Soaked in Pond, Presented on Land

We classified the responses as complete consumption, i.e., removal of all bark from a stick; sampling, i.e., leaving bite marks or peeling less than 20% of a stick; and no response. Missing sticks were counted as no response. Eight colonies responded by taking at least one stick; five colonies sampled or ate RM samples. Overall, the beaver responded to only 63 of the 600 logs (10.5%). Of these, 46 (73%) were completely consumed. As expected, the aspen controls were consumed most readily. Thirty-seven percent of these sticks were completely peeled. None was only sampled. The numbers of RM sticks accepted were small (Figure. 1). A Cochran Q test of the overall consumption pattern gave a Q of 56.6 ($P < 0.0001$). However, the acceptance of aspen is responsible for this significance. For RM samples alone, $Q = 6.74$ (not significant). More two-day sticks (10) were accepted

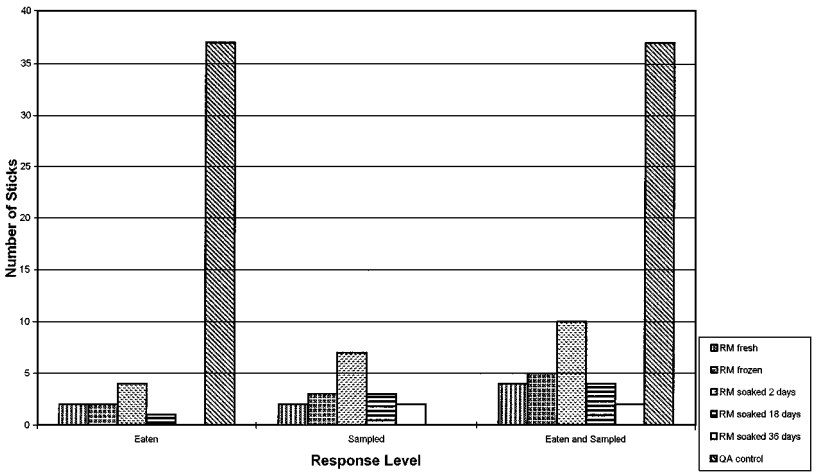

FIG. 1. Responses of beavers to sticks soaked in a pond for 2, 18, or 36 days, and controls (fresh and frozen red maple and fresh quaking aspen). Beavers handled slightly more sticks soaked for two days than other red maple samples. RM = red maple; QA = quaking aspen.

or sampled than the two controls, fresh or frozen RM (4 and 5, respectively). However, the difference is not significant ($\chi^2 = 7.2; df = 4$; NS). The difference between frozen and two-day RM is not significant ($\chi^2 = 2.29$; McNemar test). The difference between 2-day and 36-day samples is significant ($\chi^2 = 6.13$; $P < 0.025$; McNemar test).

Experiment 2. Sticks Soaked in Laboratory, Presented on Land

Of the 770 sticks, 82 (10.7%) were accepted by the beavers. As expected, QA was the most preferred sample, with 29 sticks (35%) peeled totally or partially. Of these, 26 were peeled totally. Beavers handled (consumed and sampled) RM soaked for one day slightly more often (39 sticks) than RM soaked for two, four, or six days (34, 33, and 29, respectively; Figure 2). The differences between consumption of RM soaked for one, two, four, and six days were not significant. However, in trial 2 (of five trials) one-day soaked RM and four-day-soaked RM did differ marginally ($P < 0.10$; Waller-Duncan *k* Ratio *t* test).

Experiment 3. Twigs Provided on Land

The beavers treated the three different species differently: QA was completely removed (consumed?) on the second day. On that day, only 54.7% of the RM and

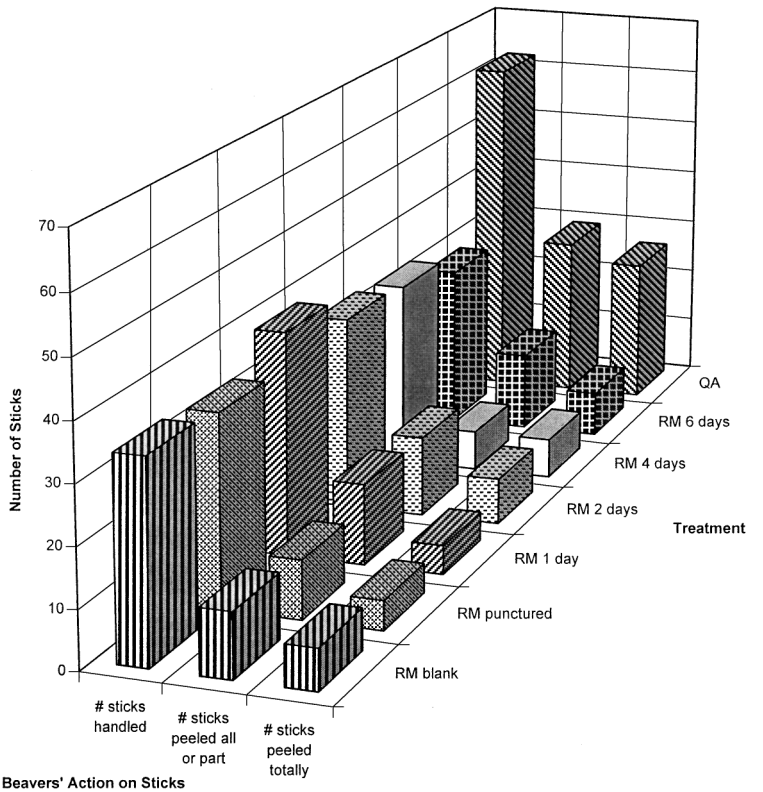

FIG. 2. Numbers of laboratory-leached RM sticks handled or peeled by beavers. Summary of five trials. A total of 770 sticks was offered, 110 sticks per treatment.

43.3% of the WH had been taken. After four days, only 60.4 of the RM, and 63.3% of the WH had been removed. Thirteen of 53 RM twigs were dragged into the water after the first night. After the third night, none was found in the water, but 32 were missing (eaten?) and 21 remained in place (Figure 3). This suggests that the beavers left the RM twigs in the water for one to three nights before further using them, presumably for food.

Experiment 4. Sticks Provided in Water

Experiment 4a. At ASP, beavers removed 33 of 53 aspen sticks presented in water (62.3%), 27 of 54 RM sticks (50%), and 21 of 54 WH sticks (38.9%). In this experiment, there was no indication that some tree species remained longer in the water than others.

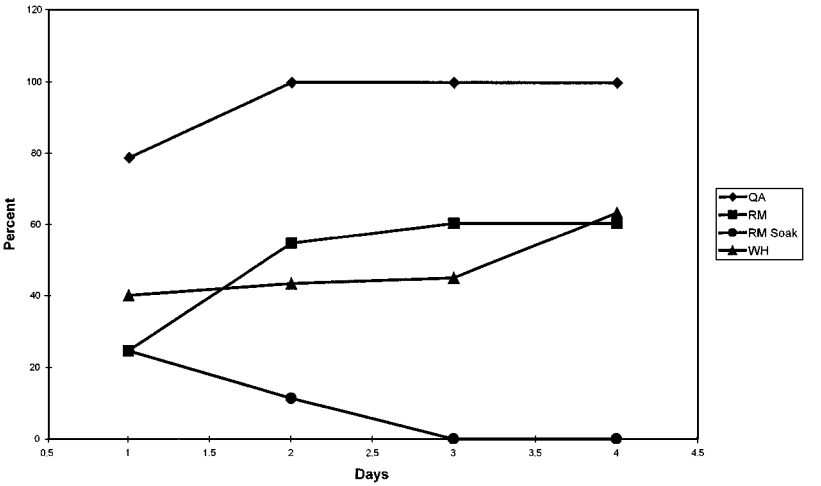

FIG. 3. Consumption and soaking of twigs experimentally provided on land. Abscissa: the four activity periods (nights); ordinate: percent twigs consumed or soaked. QA: quaking aspen ($N = 33$); RM: red maple ($N = 53$); RM Soak: RM pulled into water and not (yet) eaten; WH: witch hazel ($N = 30$).

Experiment 4b. At CLBS, the trend was similar: Of 20 sticks each, 19 aspen sticks, 13 RM sticks, and 12 WH sticks were removed. However, in contrast to ASP, WH was left in the water longer before consumption: On day 1, only one WH stick was taken (=5%), on day 2, five more, and on day 3, six more, for a cumulative total of 12 (60%). This compares with 11 aspen sticks on day 1 (55%), and a cumulative total of 19 on day 3 (95%); and 10 RM logs on day 1 (50%), 3 more on day 2 (65%), and none on day 3, for a cumulative total of 13 on day 3 (65%). After that, very few sticks of any species were taken until day 6. It appears that WH is accepted only after some time in the water (Figure 4). The differences are marginally significant (χ^2test; $P < 0.07$).

Experiment 5. Twigs Provided in Water

Experiment 5a. ASP Site. All willow accepted in this experiment (67%) and most aspen, striped maple, and black cherry were consumed after the first night (day 1) (Figure 5). By contrast, the beavers consumed most of the WH after it had been in the water for three nights. This is similar to the results of experiment 4 (fall). RM was rarely consumed, and hawthorn and black cherry often remained in the water for several nights before being removed.

Experiment 5b. CLBS Site. As usual, most of the quaking aspen twigs (14 of 20) disappeared during the first night. Little RM (6 of 20) and WH (4 of 20) were

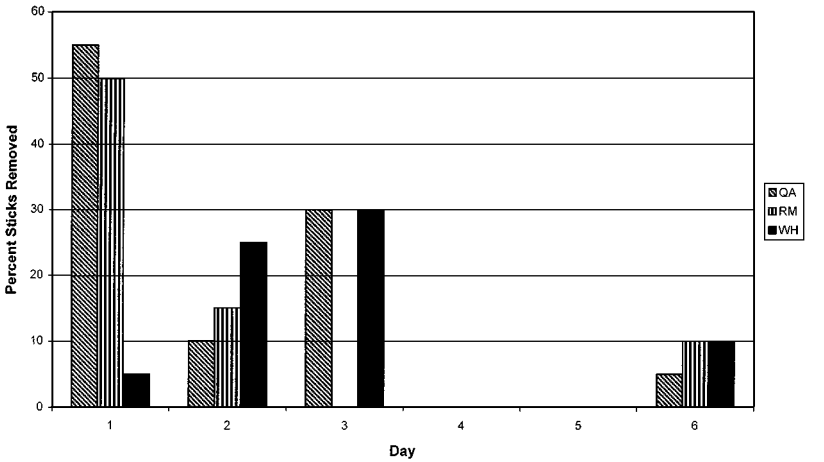

FIG. 4. Removal of experimental sticks at CLBS. Note that most witch hazel sticks were consumed after two or three days in the water.

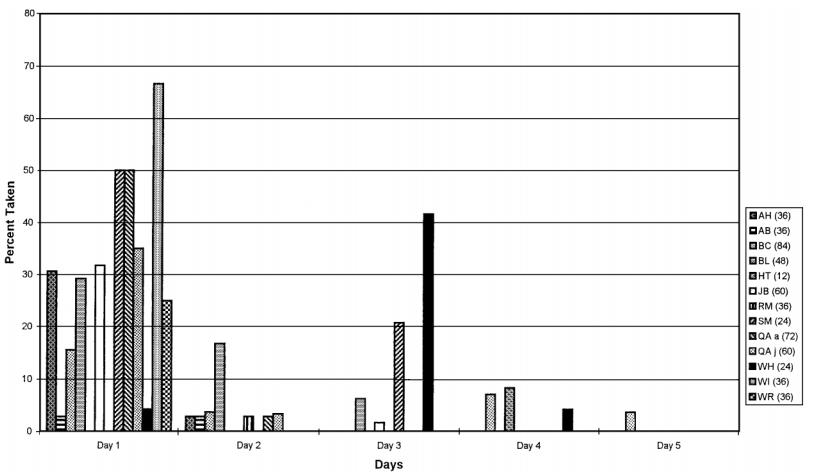

FIG. 5. Time in water of experimental twigs provided in water at ASP. Abscissa: activity periods, ordinate: percent twigs removed by beavers. AH: American hornbeam; QA j: quaking aspen, juvenile growth form; QA a: quaking aspen, adult growth form; AB: American beech; BC: black cherry; BL: black locust; HT: hawthorn; JB: juneberry; RM: red maple; SM: striped maple; WH: witch hazel; WI: willow; WR: wild raisin. Sample sizes in parentheses. Note that witch hazel is eaten after three days, and red maple almost not at all.

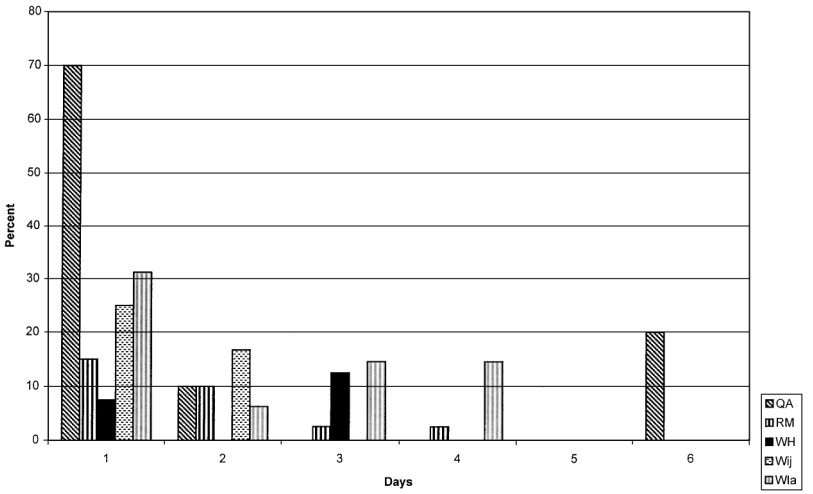

FIG. 6. Consumption of twigs, provided in water at CLBS, over six days.

accepted. Beavers removed WH and also adult willow at high, but not significantly higher levels, during the third night (Figure 6).

A meta-analysis of the numbers of samples taken by beavers in all six cafeteria experiments (food presented in water or land) yields significant ($P < 0.001$) results because the small differences in each experiment point in the same direction. A higher proportion of WH pieces is consumed after three or even four days, than of QA or RM (Figure 7). The pattern for RM is intermediate between QA and WH: About 76% (100 of 131 accepted pieces) of the QA is consumed on the first day, but only 57% (45 of 79) of RM, and 59%(43.5 of 74) of WH. On the second day, the beavers removed a high percentage of RM (26 of 79 = 33% of all RM taken), but only 15% (20 of 131) and 11% (8 of 74) of QA and WH, respectively. During the third night, 31% (23 0f 74) of the WH was removed, but only 7% (9 of 131) of the QA and 8% (6.5 of 79) of the RM. Similarly, on day 4 the relative level of accepted WH was higher (8.5 of 74 = 11.5%) than those for QA (2 of 131 = 1.5%) and RM (1.5 of 79 = 1.9%). It should be pointed out that the animals did not deplete one species before proceeding to the next, less palatable species.

Experiment 6: Beavers' Own Harvest

During the fall, a total of 23 trees were debarked on shore. These belonged to five species: white ash, American beech, American hornbeam, quaking aspen, and sugar maple. Twenty-one trees representing nine species were peeled in the water: witch hazel, American hornbeam, American beech, white ash, yellow birch, sugar maple, quaking aspen, red maple, and red oak. Four trees representing three

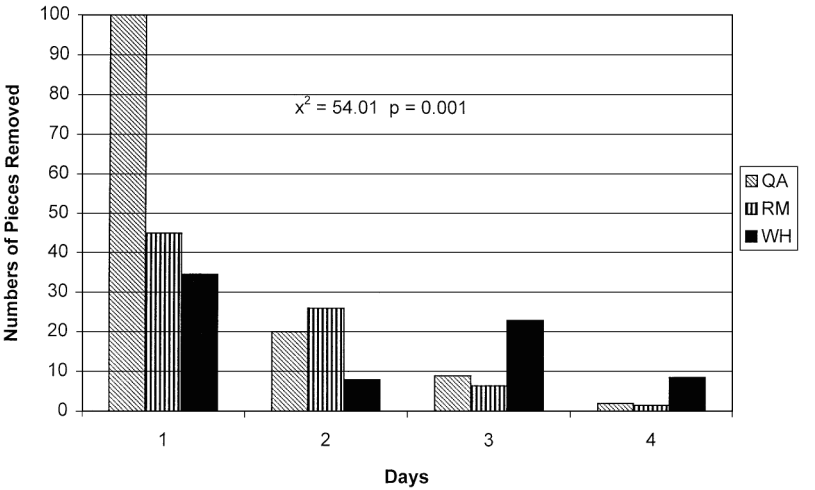

FIG. 7. Meta-analysis of all six cafeteria experiments that measured responses to sticks or twigs presented in water or on land. Abscissa: activity period, ordinate: number of pieces (sticks or twigs) accepted by beavers. QA: quaking aspen; RM: red maple; WH: witch hazel. Relatively more witch hazel is consumed after three days.

species were debarked partially on shore and partially in the water: black cherry, red maple, and white ash. All seven witch hazel limbs were eaten in the water, while most of the white ash and American beech were eaten on land (Figure 8).

As for the time limbs were left in the water before eating, witch hazel stands out. Most WH logs (4) were left in the water for three days, with one for two days and two for four days. Red maple (only two) and yellow birch (also only two) limbs spent two days in the water before consumption. Other tree species, such as striped maple, remained in the water for varying amounts of time, ranging from 0 to 15 days (Figure 9).

In the spring, most (60%) of 10 aspen branches harvested and brought into the water by beavers at four sites were eaten after one day. Of six branches present for two days, two (33%) were consumed, and one of three present for three days (33%).

Experiment 7. Amount of Phenolics Leached into Water

Assays of extracts of the freeze-dried bark consistently revealed the presence of 1.4–1.6% of leachable phenolic material in the dry bark. The mass of twigs consists of an average of 26.7%bark. The bark contains an average of 43.6% water. Thus, twigs contain a total of approximately 22.6 mg of leachable phenolics per 10 g of twig, the amount extracted by the methanol–water mix. Use of distilled, deionized water resulted in only 11.5 mg of leachable tannins per 10 g of twig. This is half the amount that was leached into the methanol–water mix.

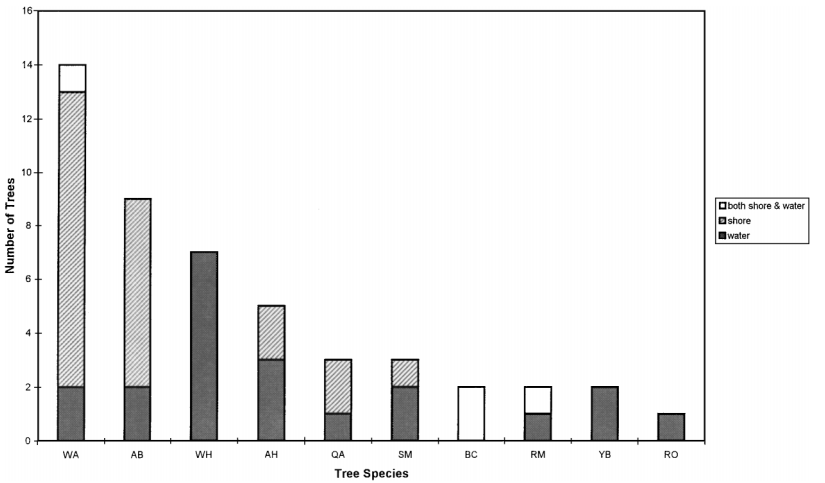

FIG. 8. Tree species selected and cut by beavers and then consumed on land, in water, or both. WA: white ash; AB: American beech; WH: witch hazel; AH: American hornbeam; QA: quaking aspen; SM: sugar maple; BC: black cherry; RM: red maple; YB: yellow birch; RO: red oak.

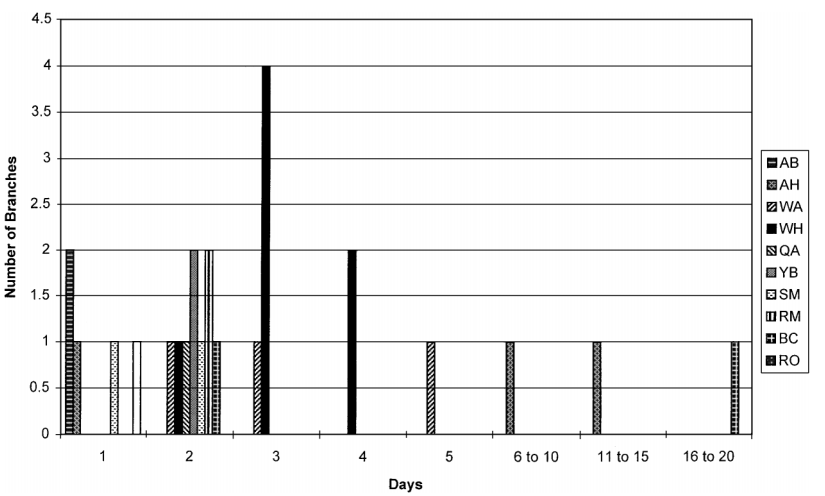

FIG. 9. Numbers of days after harvesting that beavers left trees in the water before they consumed the bark. Tree species, as in Fig. 8. One beaver colony at ASP, fall.

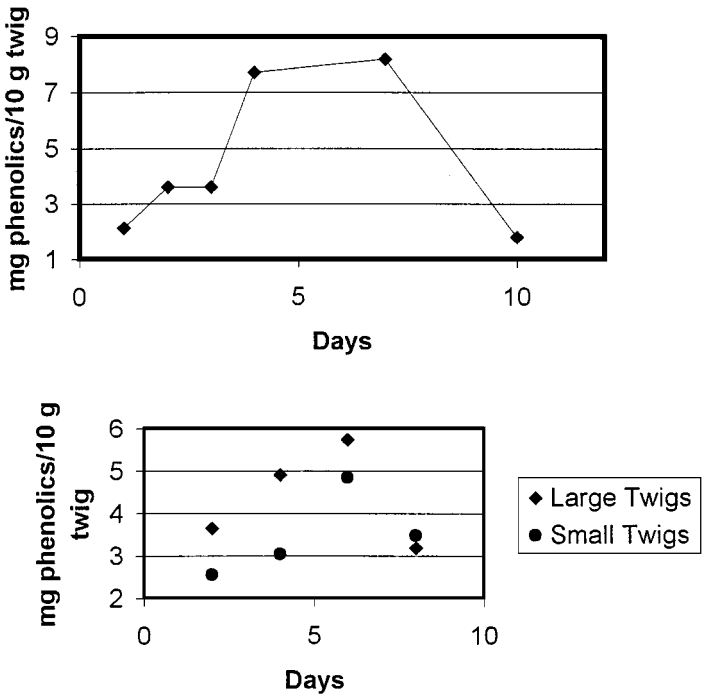

FIG. 10. Top: cumulative amount of phenolics leached into deionized water from RM twigs after 1, 2, 3, 4, 7 and 10 days. Bottom: cumulative amounts of phenolics leached into dionized water from large and small RM twigs. Note the decrease of accumulated phenolics after several days.

Soaking *whole twigs* shows a linear increase in the amount of phenolics during the first six days, followed by a drop during the last two days of the experiment (Figure 10). During the first six days, the concentration of phenolics in the water increased to 70–80% of the leachable phenolics. Essentially no difference was observed when the experiment was carried out at 25°C.

The soaking of *bark pieces* in water produced similar results. Again, phenolic concentration dropped during the latter part of the experiment (Figure 10). In this study, 50–60% of the material leachable in water was removed from the woody material.

DISCUSSION

Our experiments repeatedly revealed that beavers leave certain tree species, especially witch hazel, in the water one to three days before eating them. Although

the effect is not robust, several experiments showed the same tendency. Therefore, pooling of the data of several experiments yielded highly significant differences among the tree species' time periods in the water before being eaten. Busher (1996) found that beavers in Massachusetts store a higher percentage of witch hazel than of other tree species in the water near their lodge as part of their fall food cache. They consumed very little witch hazel immediately after harvesting. Witch hazel may be more palatable after some time in the water.

We have to distinguish the physical process of leaching from the biological process of degradation of phenolics by fungi. A compromise between leaching out of undesirable compounds and loss of nutrients also, has to be reached. Therefore, soaking may be effective during a "window of opportunity" of about two to three days. This is indicated by two lines of evidence: Leaching in the pond for longer than two days did not improve palatability (experiment 1). In the laboratory (experiment 7), chemical leaching of phenolics reached a peak after two days of soaking.

In the published literature, two other mammals appear to process food in an analogus fashion, even though water is not involved. Voles cut conifer twigs and leave them on snow for two to three days (while the levels of phenolics drop) before they eat them. (Roy and Bergeron, 1990). Pikas reduce phenolics in their haypiles by long-term storage. In this case, the phenolics also serve as food preservatives (Dearing, 1997).

Water-soluble compounds from food leach better at higher water temperatures, with longer extraction times, and at smaller particle sizes. Running water possibly enhances extraction, too. The beavers have running water and long extraction times for winter-stored branches. Beavers in more southern climates do not store food for the winter. Whether they utilize the warmer water for leaching in their day-to-day feeding remains to be investigated.

Except for experiment 1, our tests were designed without replacement of sticks during the five days of the experiment. Therefore, the density of the offered sticks decreased over the five days. This may have affected the choice by the beavers, although, in contrast to laboratory experiments with forced choices, they had vast amounts of natural food available. Replacement of consumed food would most likely have led the beavers to consume more aspen and reject more of the undesirable samples. Experiment 5 indicates how the cafeteria of a variety of available food can influence choice: red maple twigs were hardly eaten at all when several other, more palatable species were also offered.

Familiarity with certain tree species at each particular site may also play a role. Experiment 5a tried to address this aspect of food choice by offering tree species that occur at a particular site.

It is clear from the chemical study that phenolic material is gradually released into water when RM twigs or bark are soaked. This provides a viable way for beavers to render the RM (and possibly other species) twigs more palatable.

The chemistry suggests that soaking for a period of five days leaches out more than half of the phenolics capable of being leached, and this agrees with the field observations that beavers will take RM logs after two to three days of soaking.

Less clear is the reason for the drop in the concentration of the phenolics in the water during the last days of the study. While the tannins may be subject to enzymatic or chemical degradation, it is not likely that the phenolic material would be removed from the solution. More likely is polymerization, catalyzed by oxygen or traces of acid, of the released phenols to begin removing them effectively from the solution.

If beavers indeed use leaching of less palatable tree species regularly, management implications arise: As preferred tree species become depleted, the animals can switch to processing less palatable species. Witch hazel does not occur at many sites and is not present in large numbers. Use of RM, however, may indicate depletion and current quality of food resources. For instance, Shadle and Austin (1939) found that the first beavers to colonize Allegany State Park in recent times used mostly aspen (44.1% of their diet) and very few maples, birches, black cherry trees, beeches, and ash trees (combined 19.6%), while today these latter species are a substantial part of the beavers' diet (combined 57.4%) in the same study area (Müller-Schwarze and Schulte, 1999).

Acknowledgments—We thank the managers of Allegany State Park for providing facilities and continued support. We are grateful to the staff of the Cranberry Lake Biological Station of the College of Environmental Science and Forestry, State University of New York, for supporting our work. Christine Müller-Schwarze assisted in the winter collection of red maple.

LABORATORY AND FIELD EVALUATION OF PREDATOR ODORS AS REPELLENTS FOR KIORE (*Rattus exulans*) AND SHIP RATS (*R. rattus*)

GARY N. BRAMLEY[1,*] and JOSEPH R. WAAS

(Received February 22, 2000; accepted January 6, 2001)

Abstract—Predator odors may serve to stop rats from entering conservation areas or to decrease predation, food consumption, and other damage by rats in areas tainted with predator odor. We compared the efficacy of real predator odors and synthetic odors (derived from the urine and feces of carnivores) as rat repellents with real herbivore odors as controls in a Y maze. We tested six predator odors: cat (*Felis catus*) urine and feces, mongoose (*Herpestes auropunctatus*) feces, *n*-propylthietane, *S*-methyl, methyl butanol, and isopentyl-methyl sulphide. The herbivore odors we used were: red deer (*Cervus elaphus*) urine, guinea pig (*Cavia porcellus*) feces, and white rabbit (*Oryctolagus cuniculus*) urine. Ship rats (*Rattus rattus*) and kiore or Polynesian rats (*R. exulans*) showed no aversion to any of the six predator odors when compared with herbivore odors. Ship rats, however, may have avoided synthesized odors more than real ones. We applied two odors (*S*-methyl, methyl butanol and *n*-propylthietane) to purpose-built feeders in native forest but recorded no change in either visitation rate or duration of visits for rodents [rats and mice (*Mus musculus*)] or possums (*Trichosurus vulpecula*). The consumption of maize at feeders was correlated with the number and duration of possum visits, but only weakly correlated with the number of visits by rodents. Consumption of maize was unaffected by the odor associated with the feeder. It is unlikely that the odors we tested will be useful in deterring rodents or possums from areas where they have been removed for economic, public health or conservation reasons.

Key Words—*Rattus rattus*, ship rat, semiochemicals, odor avoidance, predator odors, Polynesian rat, *R. exulans*, rat repellents, brushtail possums, pest management.

INTRODUCTION

Predator-based repellents have been used experimentally to reduce damage to crops caused by wildlife (Sullivan et al., 1985a,b; Boag and Mlotkiewicz, 1994) and food consumption by domestic herbivores (Arnould et al., 1993). Mason et al. (1994) believed that volatile sulfurous compounds in the feces and urine of carnivores, derived from the digestion of meat, mediated the responses of prey animals, and this is supported by data (e.g., Nolte et al., 1994). Mason et al. (1994) used the term semiochemical to describe these sulfurous chemicals that provide biologically important information to other animals. They hypothesized that omnivores such as rats (genus *Rattus*) should be attracted to semiochemicals because they may provide them with reliable information on sources of food, while herbivores should be repelled from areas contaminated with semiochemicals to avoid encountering a predator. However, many authors have reported that rats avoid predator odors or show reduced activity in their presence (reviewed by Kats and Dill, 1998). The behavioral and physiological responses of prey species to repellents include the avoidance of treated food and traps, freezing, hiding, analgesia, and physiological arousal (Kats and Dill, 1998).

Burwash et al. (1998) tested eight artificially synthesized semiochemicals (and one real one) and, despite no statistically significant results, concluded from trends in their data that ship rats (*Rattus rattus*) avoid odors derived from carnivores. They went on to suggest that the application of such chemicals might reduce rat damage to the economically important macadamia nut (*Macadamia integrifolia*) crop in Hawaii, by causing rats to reduce their consumption.

Published accounts of mammals' ability to discriminate and avoid predator odors have been contradictory, in part because different authors have interpreted the same behavior in different ways (Burwash et al., 1998 and references therein). Interpretations may have been further clouded because the efficacy of predator-based repellents varies with cover (Merkens et al., 1991), different test arenas can produce different results (Garbe et al., 1993), and both these factors have varied in different trials. Rodent responses to semiochemicals appear to be dependent on the context of the experiment and might also vary with experience (e.g., Wuensch, 1992), although this remains untested. Furthermore, responses to semiochemicals appear to differ in different congeneric species, subspecies, strains, and populations. For example, Bramley et al. (2000) showed that rats from a predator-naïve population of Norway rat (*Rattus norvegicus*) avoided semiochemicals, but rats from another (predator experienced) population did not. Differences in laboratory mouse strains in response to predator odors have also been recorded (Dell'Omo et al., 1994).

In addition to the variability found in different populations, subspecies and strains of rodent, some authors have used "no odor" treatments as a control for predator odors and in so doing have failed to provide adequate experimental

controls. This may have produced erroneous results in some cases (see Wolff and Davis-Born, 1997 and Mappes et al., 1998, for a critique).

In New Zealand, there are four species of rodent [roof or ship rat, Norway rat, Polynesian rat or kiore (*R. exulans*) and the house mouse[2]]. All four species were introduced with human voyagers (Atkinson and Moller, 1990; Holdaway, 1996). Although the four species do not occur in the same places (Atkinson and Moller, 1990) or habitats (King et al., 1996; King and Moller, 1997; Bramley, 1999), all are regarded as pests because of their adverse effects on native wildlife and vegetation (Atkinson, 1985; Towns, 1991). Ship rats are most common on the two main islands of New Zealand (Innes, 1990), while kiore are limited to smaller offshore islands, having been replaced, first by Norway rats and then ship rats in most habitats on the two main islands (Atkinson and Moller, 1990; King and Moller, 1997).

Control of rodent populations has relied on extensive poisoning using second-generation anticoagulants (MacDonald, 1984). In New Zealand, rat populations have been eradicated from offshore islands and greatly reduced in large areas of forest on the main islands using these poisons (Taylor and Thomas, 1993; Innes et al., 1995). Reinvasion to mainland management areas is rapid (Innes et al., 1995), and the threat of reinvasion to often-visited island reserves is always present (Wace, 1986). Thus, if rats could be shown to reliably avoid predator odors, then this response could be exploited by conservation managers as part of an arsenal of techniques to protect native species from rats in New Zealand. It could also be economically useful since ship and Norway rats are two of the most serious world-wide pests of corps and stored foods and they harbor diseases such as bubonic plague and typhoid (MacDonald, 1984). Repelling rats from areas such as zoological gardens and wildlife parks or sanctuaries may also prove beneficial to the animals living there.

We determined whether two species of rat (kiore and ship rat) would discriminate and avoid odors derived from the urine and feces of predators in a Y-shaped maze. Garbe et al. (1993) showed that mouse responses to odor varied with the kind of arena used. Moreover, when animals are housed in captivity, there is always the possibility that their behavior will change as a result of being held captive (Ward et al., 1996). Because of these important considerations, we also examined the responses of ship rats in the wild to two of the odors we used in our laboratory trials. The two semiochemicals we tested in our field trials (*S*-methyl, methyl butanol and *n*-propylthietane) had both proved effective in deterring Norway rats from Kapiti Island in laboratory trials (Bramley et al., 2000). Both the artificial semiochemicals we used are components of predator urine or feces [cats (*Felis catus*) and mustelids, respectively]. Both these predators are found on North Island,

[2]There are two species of house mouse recognised *M. musculus* and *M. domesticus*. Mice in New Zealand share morphometric characteristics with both species and await genetic determination (Murphy and Pickard, 1990)

New Zealand. Thus, it is likely that free-living rats on North Island had encountered them or their odors before. All visits to feeders were recorded on videotape, and thus we were also able to collect incidental observations on the avoidance behavior of brushtail possums (*Trichosurus vulpecula*).

METHODS AND MATERIALS

Animals. Thirty animals were used in the laboratory trials: 15 kiore and 15 ship rats. All animals were adults, and 10 ship rats and nine kiore were females. The ship rats were caught in cage traps baited with apple and peanut butter along the banks of the Waikato River at Tamahere, south of Hamilton City, North Island, New Zealand. Kiore were captured using traditional Maori pitfall traps on islands in the Hen and Chickens group near Whangarei, northern North Island, New Zealand, and supplied to us by the Ngati Wai tribal resource management group. Both groups of rats were collected between January and April 1997.

At the University of Waikato facilities, the ship rats were housed individually in plastic bottomed, wire cages (46 × 24 × 20 cm high) and kiore were housed individually in plastic tubs with wire tops (40 × 27 × 15 cm deep). All animals had *ad libitum* access to water and Sharpes Diet 86 rat chow (Sharpes Grains and Seeds, Lower Hutt, New Zealand), occasional seed mixes, and pieces of apple; kiore were also given fresh grass seed heads. Cages were provided with a tin can and a cardboard tube to act as retreats. We used wood shavings as bedding and changed it weekly. The rats were housed in two separate rooms and maintained on a constant 12L:12D photoperiod, with lights on at 22:00 hr. Temperatures in the rooms were between 16 and 24°C. Ship rats were tested in May 1997 and kiore in June 1997.

Odors. We examined the subjects' responses to nine different odors. Six of the odors were natural, from the feces or urine of live animals, and three odors were the commercially synthesized volatile ingredients of urine or feces (provided by New Zealand Industrial Chemists, Gracefield, Lower Hutt, New Zealand). The natural odors were: cat urine (supplied by Five Cross Roads Veterinary Clinic, Hamilton, New Zealand), mongoose feces (collected in Hawaii by A. Woolhouse of New Zealand Industrial Chemists), guinea pig feces, New Zealand white laboratory rabbit urine, and red deer urine. The cat and rabbit urine was collected via catheterization of laboratory animals held at the Veterinary Clinic or Waikato Polytechnic (Hamilton, New Zealand). Guinea pig feces were collected from the guinea pig cages at the Polytechnic. The deer urine was collected from animals kept at the deer unit of AgResearch Ruakura (Hamilton, New Zealand). Artificially synthesized chemicals were provided as 1% solutions in paraffin oil. Chemicals used were isopentyl methyl sulfide [IPMS, found in red fox, (*Vulpes vulpes*) urine], *n*-propylthietane [PT, found in stoat (*Mustela erminea*) and ferret (*Mustela furo*)

anal sac secretions, and hence probably also in their feces], and *S*-methyl, methyl butanol (SMMBO, found in cat urine). Thus, there were three synthesized predator smells, three natural herbivore smells, and three natural predator smells. Of the natural odors, one of the herbivore and two of the predator smells were from feces. Urine and feces was always collected from more than one donor animal, but only one donor was used at a time (i.e., samples were not pooled) except in the case of the deer urine. All natural odors were stored frozen.

Islands in the Hen and Chickens group are free of mammalian predators of kiore. Kiore are the only rat known to live there (Atkinson and Moller, 1990), so kiore collected there should be naïve to all the smells we tested. Ship rats collected on the North Island should be familiar with felids, canids, and mustelids, which have long-established populations on North Island, New Zealand. There were also cows, sheep, deer, goats, and rabbits on farms near where the ship rats were caught. There are no feral populations of guinea pigs in New Zealand (King, 1990), and it is unlikely any of the rats we used had ever come into contact with guinea pig odor.

In the field trials, odors were supplied as 5% w/v impregnated in casein squares measuring approximately 30 × 30 × 5 mm high and weighing 4.8–5.2 g (New Zealand Industrial Chemists, Wellington, New Zealand). Only two odors were used in the field trials (SMMBO and PT). We chose to use 5% w/v concentrations because we wanted the odors to be detectable at some distance in forest, and for them to persist for at least two weeks. The chemistry of herbivore urine and feces has not been well studied (A. Woolhouse, New Zealand Industrial Chemists, Wellington, New Zealand, personal communication), and it was not possible to use synthetic herbivore derived odors as a control. Instead, we used two other controls: odor-free casein squares applied to the feeder and no casein squares. The casein squares had a slight odor of their own, and thus these controls represent an odor (casein) and a no odor (no square) treatment.

Maze Experiments. Animals were collected one at a time from the captive colony and transported in their cages, in darkness, to a separate trial room. They were then transferred into an experimental arena lit with red light. When the animals were in the arena, the red light was turned off and all observations were completed using a 20-cm-diam. spotlight with an infrared filter. A Hitachi 12 V, 7 Ah, sealed lead–acid battery, powered the spotlight. Tests were videoed using a Videotronic Tri-Q CCD camera and a Panasonic AG5260 video recorder. After being tested, animals were returned to their cage and then to the captive colony.

We used a Y maze made of PVC piping (10 cm in diameter) to examine the responses of both groups of rats to odors (Figure 1). The odor stimulus was presented inside an opaque glass container as either 0.1 ml of solution pipetted onto a 1-cm^2 piece of Whatman filter paper or as 0.1 g of thawed feces. Odors were presented in the maze with distilled water controls, presented in the same way, in the other choice arm. The position of the odor (left or right) and the type of odor (numbered 1–9) were recorded on the video tape after the trial, but were unknown

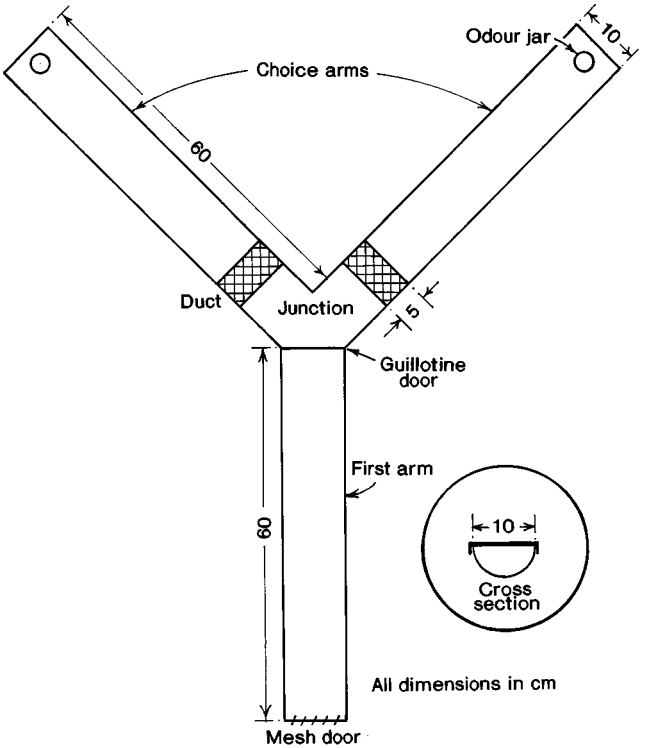

FIG. 1. The Y maze apparatus used to test the responses of rats to the odor of predators and herbivores.

to us when we scored the rats' behavior. Three identical mazes were used and after each test the maze was washed using hot water and Vircon soap powder and then towel dried.

Ship rats and kiore were tested separately according to an incomplete block design using 18 blocks. Each block consisted of five rats. One block (five rats and five odors) was tested per day. Each rat was randomly allocated a position in six blocks (i.e., received each of the six odors once over the 18 days of the trial). Tests began 1 hr after the lights in the colony had gone off and continued sequentially until five animals were tested. Each test was usually conducted within 40 min of the previous one. Prior to the start of each test, rats were placed in the first arm of the maze, with the guillotine door shut (Figure 1). The video recorder was then started and the observer left the room. After 5 min, the guillotine door was opened (from outside the room) and the rats were free to explore the maze for 15 min. We recorded: (1) the time until the rat first visited each of the arms (a visit was

defined as occurring when the rat's head was more than 5 cm down the arm); (2) the number of visits to the odor and control arm; (3) the time spent in each arm; and (4) a total activity score for each rat, which was the number of visits to each arm summed together.

The day before being tested, each rat was introduced to the maze as outlined above, but in the absence of any odors. We recorded the same measures for each rat on videotape to detect any left or right bias and to establish that the rats would explore the maze. In the middle of the series of tests and at the end of the series, the rats were again introduced to clean mazes and their movements recorded. This was to check that each rat would still explore the maze in the absence of smells and that the rats had not developed a left or right preference during the trials. Recordings of rats in a clean maze were done after the day's tests (on other rats) had concluded.

Field Experiments. Four feeding stations (Figure 2) were set up in each of seven different forests or forest remnants on North Island. The feeding stations

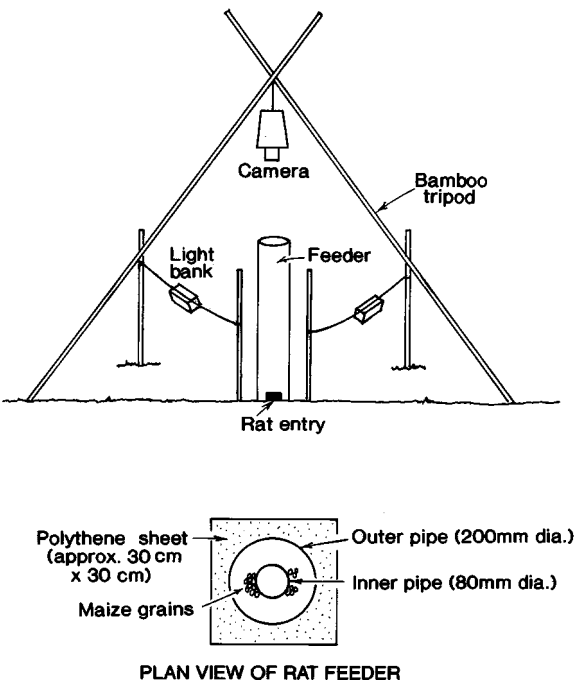

FIG. 2. A rat feeding station and camera used to record visits by rodents (rats and mice) and possums (*Trichosurus vulpecula*). Each feeder consisted of two PVC pipes, and odor sources were attached to the outside of the larger pipe, near the rat entrance. Four stations were positioned in each of seven forested areas. All four cameras were connected to a central time-lapse video recorder.

were positioned approximately 20 m from a central point, one each in a north, south, east, and west direction. The seven forest sites were: Tahae Block (Pureora Forest Park), Pouakani Scenic Reserve (near Pureora), Yarndley's Bush (north of Te Awamutu), Walter Scott Reserve (29 km west of Te Awamutu), Whewell's Bush (Matangi), Te Kauri Scenic Reserve (Kawhia), and Te Tapui Scenic Reserve (13 km east of Matamata). The seven study areas were widely separated geographically (Figure 3). They also differed in topography, climate, altitude, aspect, geology, history, dominant vegetation, and probably in rodent density and species composition too. We expected that each site would have ship rats and mice, but the relative densities of each species were unknown and we did not know whether or not Norway rats were present at any site.

Each feeding station consisted of a feeder (made up of an inner PVC pipe 8 cm diam., 1 m high and an outer PVC pipe 20 cm diam., 1 m high). The inner pipe was filled with approximately 550 g of maize grains and had two small holes cut at the bottom to allow the corn to flow out. The larger pipe had three squares (10×10 cm) removed from the bottom to allow rodents access to the inner pipe (Figure 2). Each feeder was positioned on top of a 30×30-cm piece of black polythene to protect the corn from ground moisture and was held in place by guy ropes attached to surrounding vegetation or support poles. Each feeder was monitored by a Videotronic Tri-Q CCD camera positioned approximately 1.65 m above the ground, suspended on a tripod of three bamboo poles tied together at the top.

The feeder and camera units were numbered according to their position with feeder and camera 1 being the northernmost one. Each camera was secured inside an inverted plastic bucket to protect it from the elements. On either side of the feeder (approximately 55 cm above the ground), a bank of 16 infrared-light-emitting diodes provided illumination for the cameras. These two light banks lit up an area of approximately 50×50 cm around the base of the feeder. The four cameras were connected via approximately 20 m of cable to a Panasonic WJ-420 four-input screen splitter. The splitter was connected to a GYYR VHS timelapse recorder (model TLC 1800X) set to record 48 hr on a 3-hr tape. The splitter, video recorder, and camera control boxes were protected inside plastic boxes and covered with polythene to exclude water. The splitter and video recorder were connected to a Motormate PS-200-2 DC-AC power inverter. The power inverter, lights, and cameras were connected to three 63 Ah Sonnenschein 12 V lead–acid batteries connected in parallel via a Grasslin 12 V electronic timer.

Three casein squares impregnated with the odors were attached to the outer pipe of each feeder by using plastic electrical insulation tape. The casein squares were attached between the entrances shown in Figure 2. A Latin square design was used to assign the four treatments (SMMBO, PT, casein, or no odor) to the four feeders. Study areas at each forest patch were located on the flattest ground we could find. On day 1 of a test, cameras and feeders were assembled and feeders were filled with a known amount of maize. The timer and video recorder were set

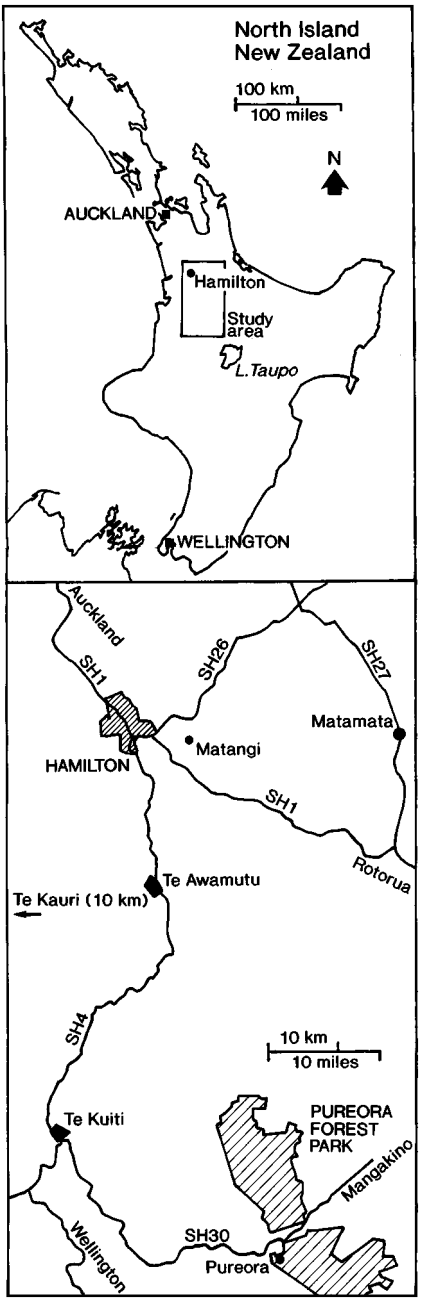

FIG. 3. The location of North Island towns near forest remnants where the field evaluation of ship rat response to predator odors was conducted.

to begin recording after dark and to stop recording before dawn. The exact length of recordings varied slightly with season. Once the system was in place, activity at each feeder was automatically recorded on videotape for the next three nights. After three nights, we returned, weighed the remaining corn, added fresh corn if required, removed the videotape, and left the area for 10 nights. After 10 nights, we returned and removed the casein squares impregnated with odor and weighed any remaining corn. We then wiped the outside of each plastic feeder with methyl alcohol to remove any remaining smell and allowed it to air dry. We refilled the feeders, reset the video recorder, and placed new casein squares impregnated with different odors on each feeding station. We video taped activity for a further three nights, and then returned and weighed the corn again (replenishing it if necessary). We allowed the feeders to remain *in situ* for 10 more days. After this, we reweighed any remaining corn, then moved the feeders to the next site. Thus, from each site we had six nights of recording from two sessions separated by 10 days. Each of the feeders had a different smell associated with it (according to our Latin square design) in each test. We began these experiments on December 20, 1997, and concluded them on June 21, 1998. We watched each video four times (focusing on one feeder during each viewing). We recorded the number of visits made by rodents (rats or mice) and brushtail possums (*Trichosurus vulpecula*) to each feeder and the duration of the visits. We then summed the number and duration of visits for: (1) the first night and (2) the three nights of each session. We separated our data in this way because subjects might habituate to the odors over the three days of a test. We also recorded consumption of maize on nights 1–3 and nights 4–10 of each session for each odor.

Data Analysis. In the *maze experiments*, we used the Generalized Linear Model (GLM) function of MINITAB (version 12.1) to investigate the responses of each species of rat in a Y maze. For each species and each variable, we created a model that included the rat (numbered 1–15) and the block (numbered 1–18) as random effects and the odor as a fixed effect. We then grouped the odors into herbivore, real carnivore, and synthesized carnivore and created models for each measure using odor type as a fixed predictor and rat and block as random predictors. We also created a model investigating the effect of sex on activity for each species. We used Tukey's tests to discriminate pairwise differences where GLM results were significant.

In the *field experiments*, to determine whether rats visited feeders differentially according to the treatments attached to them, we again used the GLM procedure. We created different models for each measure and specified the smell as a fixed predictor and location, test (1 or 2), and feeder (1–4) as random effects. To check that most maize consumption was by the rodent and possum visitors we recorded (and not by, for example, diurnal birds), we correlated the consumption on nights 1–3 with the number of visits by rats and possums for those three nights in both sessions.

RESULTS

Maze Experiments. Exploratory data analysis showed that the number of visits to the arm containing the distilled water control were similar to the number of visits to the odor arm for both groups of rats. Thus, we chose not to use the distilled water arm as a control because it was likely that the odor arm affected the subject's behavior throughout the whole maze. Instead we used the data collected when rats were exposed to herbivore odors as the control.

In our experiments with kiore, neither the odor nor the odor type significantly affected the variables we measured (Table 1). In no case was the block significant either, which indicates that rat behavior did not vary significantly on different days. There was a high level of individual variation in the sample, and the individual rat was a significant predictor for all of our measures except time in the odor arm (Table 1). Male kiore were more active [9.89 $\pm$ 1.56 (mean $\pm$ SE) visits] than female kiore (5.00 $\pm$ 0.87 visits; $F_{1,89} = 8.66$, $P = 0.004$). The effect of sex is implicit in the designation "rat" in our model, and thus is already partially accounted for.

One of the female ship rats escaped during her first test and could not be recaptured alive. Another female rat showed an abnormally high level of activity (approximately 230 visits to the left arm in a 15-min trial) and so was excluded from the analysis. This reduced our sample size to 13 animals. Of the variables we measured, only the number of visits to the odor may have been affected by the odor type ($F_{2,77} = 3.1$, $P = 0.054$) with herbivore and real predator odors being visited more often (14.32 $\pm$ 2.38 visits, and 13.96 $\pm$ 1.78, respectively) than artificially synthesized predator odors (10.33, $\pm$ 1.89; $T = 2.26$, $P = 0.07$). All other variables were unaffected by odor or odor type (Table 2), but some behaviors

TABLE 1. *F* VALUES FROM GENERALIZED LINEAR MODELS DESIGNED TO DETERMINE EFFECT OF SEMIOCHEMICALS ON KIORE BEHAVIOR[a]

		Visits to		Time in		Time to approach	
Factor	Activity	Odor	Control	Odor	Control	Odor	Control
Fixed effects							
Odor	0.72	0.75	0.54	0.69	1.23	0.95	0.65
Odor type	0.17	0.25	0.16	0.53	0.22	1.44	0.51
Random effects							
Rat	2.29*	2.21*	2.15*	1.01	1.22	2.37*	2.55**
Block	1.20	1.01	1.21	1.09	1.08	1.11	1.03

[a] *F* values marked with one asteriks are significant at $P = 0.05$, those marked with two asterisks are significant at $P = 0.01$. Nine odors were tested in all: three real predator odors, three synthesized predator odors, and three herbivore odors. The odors were each tested individually in one model "odor" and then assigned into groups (real predator, synthesized predator, and herbivore) for as "odor type" in a second model to see if kiore differed in responses according to odor source.

TABLE 2. *F* VALUES FROM GENERALIZED LINEAR MODELS DESIGNED TO DETERMINE EFFECT OF SEMIOCHEMICALS ON SHIP RAT BEHAVIOR[a]

		Visits to		Time in		Time to approach	
Factor	Activity	Odor	Control	Odor	Control	Odor	Control
Fixed effects							
Odor	1.14	1.78	1.05	0.73	1.23	1.44	1.13
Odor type	1.92	3.1	0.3	0.24	0.43	1.67	0.12
Random effects

Block	1.89*	1.44	1.91*	0.84	0.71	1.42	2.05*

[a] *F* values marked with one asterisk are significant at $P = 0.05$, those marked with two asterisks are significant at $P = 0.01$. Nine odors were tested in all: three real predator odors, three synthesized predator odors, and three herbivore odors. The odors were each tested individually in one model as "odor" and then assigned into groups (real predator, synthesized predator, and herbivore) for "odor type" in a second model to see if ship rats differed in responses according to odor source.

(activity, number of visits to the control, time to approach the control; Table 2) were affected by the block number, indicating that rats behaved differently on different days. There was no trend in the behavioral changes through the period of the trial, for example, rats did not become predictably more or less active as the trial progressed, rather they were more active on some days than they were on others. The individual rat significantly affected all measures except the time spent in the odor and control arms, and the time to approach the smell, indicating high individual variability among rats. Ship rat activity was also affected by sex ($F_{1,77} = 8.58$, $P = 0.005$). Female ship rats were more active than males (males 17.4 ± 3.06 visits; females 30.5 ± 3.00 visits). The effect of the sex of the rat is again accounted for in our models.

Rats Use of a Clean Maze. Each rat explored an empty maze on three occasions. Kiore made a total of 104 visits to the left choice arm and 109 visits to the right choice arm ($\chi^2 = 0.12$, $df = 1$, NS). Seven of the rats remained in the first arm during their first experience in the maze. A further three rats remained in the first arm on two occasions, thus 10 of the kiore (66%) chose not to explore the maze on at least one occasion.

Ship rats made a total of 339 visits to the left choice arm and 361 to the right choice arm ($\chi^2 = 0.69$, $df = 1$, NS). Only two of the ship rats remained in the first arm on one occasion, and one of those two remained in the first arm on a second occasion. We concluded that both species of rat readily explored the maze in the absence of odors, although kiore were more reluctant to explore the maze when they first experienced it and were less active overall. Neither species of rat showed a preference for one side of the maze.

Field Experiments. On some occasions, either one of the cameras or the time-lapse video recorder failed to work. Two of the cameras stopped recording

after one night at Yarndley's Bush. During the second test at Yarndley's Bush, the video recorder stopped working after one night, thus reducing the number of feeding stations for which we had data for all three nights from 56 to 46. On some occasions, maize weights were not recorded because the remaining maize became wet and heavy due to rain. These losses reduced our sample size for maize consumption on nights 1–3 from 56 to 50, and on nights 4–13 from 56 to 52.

Average maize consumption on days 1–3 varied between 120 g (at feeders with SMMBO) and 159 g (at feeders with odor-free casein squares on them). The amount of maize consumed on days 1–3 of a test did not vary according to odor ($F_{3,49} = 0.31$, $P = 0.82$), but more than five times as much corn was eaten during the second test (219 $\pm$ 30 g) as there was during the first test (48 $\pm$ 10 g, $F_{1,49} = 22.38$, $P = 0.0001$). Maize consumption for days 4–13 of each test did not vary with smell either ($F_{3,51} = 0.36$, $P = 0.78$), but did vary with the test (again more maize was eaten in the second test, $F_{3,51} = 7.48$, $P = 0.009$) and with the location ($F_{6,51} = 9.78$, $P = 0.0001$). The amount of maize consumed on days 4–13 varied from an average of 120 g at Pouakani Scenic Reserve to 519 g at Walter Scott Scenic Reserve.

The number of rodents visiting feeders on night 1 of a test did not vary according to the semiochemical that was attached to the feeder (means ranged from 4.0 to 7.1 visits per feeder, $F_{3,55} = 0.81$, $P = 0.49$), but at some locations rat activity was generally higher (means ranged from 0.6 to 19.3 visits per location; $F_{6,55} = 7.64$, $P = 0.0001$). The number of brushtail possums visiting on the first night of a test did not vary according to odor either (range of means 0.6–2.1 visits per feeders, $F_{3,55} = 1.72$, $P = 0.18$), but there was also more possum activity at some locations (means ranged from 0.1 to 2.4 visits per location, $F_{6,55} = 2.49$, $P = 0.03$). More possum visits were recorded during the first night of the second test (mean = 2.0 visits) than on the first night of the first test (mean = 0.6 visits; $F_{1.55} = 7.35$, $P = 0.01$).

The number of rat and mouse visits over the three-day test did not vary according to odor (range of mean values = 20.1–25.0; $F_{3,45} = 0.21$, $P = 0.89$), but did vary according to location (range of mean values = 1.0–60.9 visits; $F_{6,45} = 9.64$, $P = 0.0001$). The same was true for possums (range of mean values = 4.1–5.8; $F_{3,45} = 0.32$, $P = 0.81$ for odor, and range of mean values = 0.4–12.3 visits; $F_{6,45} = 7.49$, $P = 0.0001$ for location). The amount of time spent at each feeder by rats and mice on night one was not dependent on the odor attached to the feeder (means ranged between 948 sec and 1578 sec; $F_{3,55} = 0.17$, $P = 0.92$), although it did vary with location (range of means = 146–4030 sec, $F_{6,55} = 3.46$, $P = 0.007$). Possums spent more time at feeders on the first night of the second test than they did on the first night of the first test (mean = 110 sec for test 1, mean = 1130 sec for test 2; $F_{1,55} = 10.61$, $P = 0.002$). The amount of time spent at feeders by possums on the first night of the second test did not vary according to smell ($F_{3,55} = 2.12$, $P = 0.11$).

When we considered the total amount of time spent at a feeder during the three nights of video recording, location was the only significant predictor for rodents (mean values between 69 sec and 10279 sec; $F_{6,45} = 3.72$, $P = 0.006$) and for possums (mean values between 77 sec and 8468 sec; $F_{6,45} = 3.59$, $P = 0.008$).

The total maize consumption at each feeder was correlated with the number of possums that we recorded visiting the feeders ($r = 0.57$, $P = 0.0001$) but only weakly correlated with the number of rodents ($r = 0.20$, $P = 0.17$). The maize consumption on days 1–3 was weakly correlated with the amount of time rats and mice spent at a feeder ($r = 0.27$, $P = 0.08$), but moderately correlated with the amount of time possums spent there ($r = 0.57$, $P = 0.0001$). The number of rodent visits and possum visits was unrelated ($r = 0.03$, $P = 0.83$), but the length of time spent at feeders by rodents was correlated with the length of time spent there by possums ($r = 0.332$, $P = 0.02$).

DISCUSSION

It might be expected that rats would be more likely to avoid the odors of predators that they encounter most frequently (Dickman, 1992) or those that pose the most significant threat (Jedrzejewski et al., 1993). We included both familiar and unfamiliar predators of ship rats in our laboratory experiment, yet neither species showed avoidance of any of the odors at the concentrations we used. It appears from both the field and laboratory experiments that semiochemicals would not be effective rat repellents in the sense that we envisaged. Not only do ship rats and kiore visit areas tainted with carnivore odors as often as they visit control areas (tainted with herbivore odors) in laboratory trials, they also spent similar amounts of time and consumed similar amounts of food in treatment and control areas in field trials.

Interestingly, the two species of rat we studied did not appear to be attracted to the predator odors, as predicted by Mason et al. (1994), either. This may be because they cannot tell the odors apart. However, ship rats appeared to be able to discriminate at least some of the odors, since they spent more time in arms containing odors from real predators or herbivores than they did in arms containing synthesized semiochemicals. Since the synthesized chemicals smelled stronger to the human nose than the real ones, it may be that this difference in behavior is due to strength or pungency of the odor stimulus rather than the odor itself. Kemble and Bolwahnn (1997) reported that pungency alone could explain mouse aversion of novel chemicals, although this has not been tested for the species of rat we studied. The laboratory tests conducted by Burwash et al. (1998) used only one (familiar) real odor; the other eight were synthesized. Burwash et al. (1998) do not report any dilution of their chemicals, and although they used small amounts (0.01 ml), the avoidance behavior they report may be a response to strong novel odors, rather

than avoidance of predator odors *per se*. The odors we used in our field trials were stronger than those we used in the laboratory trial, although they were familiar, and there was no effect on rat behavior. Thus, pungency alone cannot explain the different results reported by Burwash et al. (1998) and this study. Kiore showed no differences in their responses to odors, and it remains unknown whether they can discriminate among the odors we tested or not.

Discrimination tests for both species of rat would be useful because they could help to interpret their lack of avoidance behavior. It seems likely that ship rats and kiore can distinguish the odors, because rats are generally well endowed with olfactory neurons (Nef, 1998). Furthermore, olfaction is considered to be one of the most important means of communication (Brown, 1985) and orientation (Lavenex and Schenk, 1998) for rats. Olfaction has been well-documented as a way of detecting predators for laboratory rodents (Kats and Dill, 1998). In order to observe odor discrimination in the absence of an avoidance response, it may be necessary to determine whether rats can be trained to recognize the odor as significant by operant conditioning (e.g., Terry and Johanson, 1996). If the rats are able to discriminate predator odors from others, then it remains to be explained why, in the context of our experiments, they ignore the information these semiochemicals can potentially convey, and what methods they employ to detect and avoid predators in the wild.

Cocke and Thiessen (1986) and Ward et al. (1996) both reported changes in the level of physiological arousal of animals [gerbils (*Meriones unguiculatus*) and hedgehogs (*Erinaceous europaeus*)] in laboratory trials that were not manifested in behavioral changes. It is possible that the rats we studied were showing changes to their metabolism that we could not measure.

Both the ship rats and the kiore we tested in laboratory trials showed a high degree of individual variation. Burwash et al. (1998) suggested that it is the high level of individual variability that has allowed ship rats to become such a globally successful species. We have previously found (Bramley et al., 2000) that, despite high individual variation, individual Norway rats from a predator-naïve population avoided predator odors, while individuals that had presumably come in contact with predators showed no such aversion. We suggested that avoidance might be an innate behavior for Norway rats but that it might be modified by experience, with experienced rats being more accurate at assessing risk. This may also be true for ship rats, since the ship rats we studied had presumably encountered predators or their odors in the past. Because we used odors from only one donor animal at a time, differences in quality of the individual odors may partially explain the high individual variation in our results.

The kiore that we studied were from predator-free islands. They showed no innate aversion to odors. In order to make sense of these observations and understand the development of odor-mediated avoidance, experiments are necessary that manipulate the individual experience of the rats being tested. Only by knowing

the experience of each individual being tested will experimenters be able to draw sensible conclusions about how responses to predator odors might vary with age or experience. The role individual experience plays in discriminating odors and responding to them has usually been studied by changing the background odor in the weaning period (e.g., Terry and Johanson, 1996) or by cross-fostering (e.g., Wuensch, 1992). Neither approach is suitable for studying predator avoidance. In order to mimic the experience of encountering a predator in the wild and to allow meaningful ecological interpretations, it will be necessary to pair the presentation of a semiochemical with a negative stimulus. Measuring the number of presentations necessary to engender avoidance and the length of time individuals maintain avoidance responses after experience would be useful in helping workers determine whether chemicals provide meaningful ecological information or not.

Laboratory studies have shown, usually with laboratory strains of Norway rat or house mouse, that odors are important for individual recognition (Gheusi et al., 1997), social interactions (Hurst et al., 1994; Hurst and Barnard, 1995), orientation in the home range (Lavenex and Schenk, 1998), feeding (Galef, 1993), and mate selection (Kavaliers and Colwell, 1995). Laboratory studies have also shown that laboratory rats and mice recognize and avoid predator odors (see Kats and Dill, 1998, for a review). This reductionist laboratory approach has allowed significant progress in our understanding of rodent social systems. However, little is known about how wild populations of rat respond to either conspecific or heterospecific odors, and whether wild rats and mice use odors when exploring their home range. The few studies that have been conducted in the wild (Dickman, 1992; Stapp and Van Horne, 1996; Bramley, 1999) have produced contradictory results. Large enclosures represent a kind of middle ground between these two approaches and have allowed successful manipulation of the presence, density, and encounters of wild animals (e.g., Drickamer, 1997).

We detected no preference for either side of the maze by ship rats or kiore, but the behavior of ship rats appeared to change according to the experimental block they were assigned to. This change was unexpected but should have had only a minimal effect on our results since smells were positioned in blocks throughout the trial and rats were randomly assigned to blocks. Thus, five randomly chosen rats received one randomly chosen smell each on any given day, and any smell tested on a day when the rats were inactive would also have been presented to other rats on other days.

In the field trials we conducted, the one consistently significant predictor of maize consumption and visitation rate was the location of the test. This is probably because rodent and possum density varied at the different sites, and feeders in areas with more animals received more visits. It appears from our field trials that possums were unaffected by predator odors. This result contrasts with data reported by Woolhouse and Morgan (1995), who applied semiochemicals (one of which

was PT) to pine (*Pinus radiata*) seedlings and recorded a decrease in consumption by possums. It may be that propylthietane has an aversive taste.

The strong correlation between maize consumption and possum visits implies that possums were eating most of our maize. Nonetheless, rodents also visited the feeders often, and since rodent and possum visits were not correlated (either positively or negatively), it appears possums did not exclude rats and mice from visiting. The positive correlation we observed between the amount of time spent at feeders for rats and possums is further support that neither species adversely affects the behavior of the other.

Rats and possums consumed more maize during the second test in an area than they had in the first test. This result is to be expected since resident animals have had longer to locate feeders, overcome neophobia, and assess food palatability by the time the second trial began.

It is apparent from this study and that of Bramley et al. (2000) that all rodents, even congeneric species, do not respond to predator odors in the same way. Studies of the type outlined above looking at the development of aversion and manipulating experimental conditions such as cover and risk are needed to help clarify how heterospecific odors are used by different species, and under what conditions avoidance evolves and is maintained by a population. Future research should also focus on the effect of age on avoidance responses and what other antipredator strategies might operate under different conditions.

Acknowledgments—This work was supported by a grant in aid from the New Zealand Lottery Grants Board (grant AP:52697) to the authors. We wish to thank John Innes, who helped with the grant application and commented on earlier versions of the manuscript; Joanne Baltus, who translated Arnould et al. (1993) from French; and C.M. King, Graham Hickling, and C.R. Dickman, whose comments improved an earlier version of the manuscript. Hori Parata, Moya Armstrong, and Mere Roberts helped me obtain the kiore. Carey Bramley, Gavin Reynolds, and Jackie Todd helped with the field experiments.

(Received June 26, 2000; accepted January 3, 2001)

Abstract—The response of phenolic compounds as a result of long-term low open-field ozone exposure was studied in ozone-sensitive and ozone-tolerant clones of European silver birch (*Betula pendula* Roth). The saplings were exposed to 1.5–1.6 times the ambient (elevated) ozone and ambient air (as control) over three growing seasons from May 1996 until August 1998. Quantification by modified Folin-Ciocalteau assay showed a 16.2% increase in total phenolics in elevated ozone plants as compared to that in controls and a corresponding 9.9% increase of 10 phenolic compounds quantified by HPLC. Five nonflavonoids and five flavonoids showed 8.4% and 11.4% increases, respectively. The phenolic results indicated slightly higher ozone sensitivity of clone 5 as compared to clone 2. The most ozone-responsive phenolic compounds in clone 2 and clone 5 were (+)-catechin (CT), chlorogenic acid (CGA), 5-*p*-coumaroylquinic acid (5CQA), 3-*p*-coumaroylquinic acid (3CQA), myricetin galactopyranoside (MG), quercetin-3-*O*-glucuronopyranoside (QGR), and quercetin-3-*O*-arabinofuranoside (QA). Increased phenolic content in ozone-exposed plants was related to impaired growth and accelerated leaf senescence, indicated by enhanced autumn leaf yellowing and lower chlorophyll and Mg content. The change in carbon allocation towards defensive phenolics at the expense of growth was greater in the ozone-sensitive clone as compared to tolerant clone.

Key Words—*Betula pendula* Roth, silver birch, ozone, phenolics.

INTRODUCTION

Increasing tropospheric ozone levels impose one of the greatest risk factors to the stability of European forest trees and forest ecosystems in the 21st century (Matyssek and Innes, 1999). Although vast literature is available on the effects of ozone on plants, knowledge about the long-term mechanisms of ozone impact on forest trees under natural environmental conditions is still insufficient. This open-field ozone experiment was established in 1996 aiming to highlight current knowledge caps in empirical data (such as carryover mechanisms of ozone) and to provide realistic information about the impact of slightly elevated ozone exposure on European silver birch (*Betula pendula* Roth), the most important deciduous pulpwood species in Finland. In this first step, exposed saplings were harvested and analyzed for chemical and biochemical changes in relation to different growth responses determined for tolerant and sensitive clones. The emphasis was on the variation of relative contents of phenolics in ozone-tolerant and -sensitive birch clones grown over three growing seasons under low open-field ozone exposure and under ambient air (serving as control). Another part of plants in this extensive multiyear experiment will be used in actual quantitative ozone risk assessment after long lasting chronic exposure.

Plants contain a wide variety of phenolic compounds, such as simple phenols, flavonoids, stilbenes, tannins, lignans, and lignin. These substances function as cell-wall constituents providing mechanical stability and forming water and gas impermeable cell wall layers. Phenolics also function as natural pesticides, fungicides, antiherbivore factor, pigments, antibiotics, signal substances, attractants for pollinators, protective agents against UV radiation, excessive light, and air pollutants; as well as taking part in senescence, regeneration, and degradation processes due to cell damage. Pollutant-stress-induced changes in phenolics have been proposed to be connected with higher energy demand and consequent increase in respiration of stressed plants, with oxidation of these substances to quinones, with lignin production separating healthy and damaged (necrotic) leaf tissues, and with accelerated senescence (e.g., Bennett and Wallsgrove, 1994; Giertych et al., 1999). Ozone-caused increases have been reported especially in phenolic acid, tannin and terpenoid concentrations in several tree species (Rosemann et al., 1991; Jordan et al., 1991; Lavola et al., 1994; Wellburn and Wellburn, 1996), providing protection against oxidative damage (Langenheim et al., 1994; Foy et al., 1995; Ormrod et al., 1995). It has been suggested that ozone-induced accumulation of phenolics specifically concerns those compounds that are needed for defense (Richter and Wild, 1988; Foy et al., 1995; Lavola, 1998).

The phenolics of birch species, especially those of European silver birch leaves, have been well documented by Ossipov et al. (1995, 1996) and Keinänen and Julkunen-Tiitto (1998). In our previous study, (Oksanen and Saleem, 1999), hydroxycinnamic acid derivatives, e.g., neochlorogenic acid (NCGA); caffeoylquinic

acid derivatives (CQA); chlorogenic acid (CGA); hydroxybenzoic acid derivatives, e.g., (GPS); 1-(4″-hydroxyphenyl)-3′-oxopropyl-β-*D*-glucopyranose and flavonol glycosides, e.g., myricetin glycosides (MG), quercetin glycosides (QG), and kaempferol glycosides (KG) were tentatively identified and quantified on the basis of study by Ossipov et al. (1996). In the present study, more efficient extraction and chromatographic conditions were used to improve separation, identification and quantification of phenolic compounds.

METHODS AND MATERIALS

Plant Material. Forty saplings of ozone-sensitive *Betula pendula* clone 2 and ozone-tolerant clone 5, determined previously in Pääkkönen et al. (1993), were randomly placed in two replicate open-air elevated-ozone exposure fields and two replicate ambient-ozone control fields in May 1996. These fast-growing, commercially used clones originated from southern (Valkeakoski, clone 2) and central (Ristiina, clone 5) Finland. The plants were grown in 20-dm^3 pots, filled with a mixture of prefertilized *Sphagnum* peat and quartz sand (2 : 1). The saplings were irrigated as needed and fertilized with 0.2% Superex-9 solution (19 : 5 : 20, N-P-K) once a week until July. During the growing seasons, the positions of plants were randomized by rotation within each field throughout the experiment. Each year in October, the pots were protected with excised conifer branches and plants were overwintered at the experimental site covered with snow.

Open-Field Ozone Exposure. The experiment was carried out by using the open-field exposure system at Kuopio University experimental area in central Finland, described in detail by Wulff et al. (1992). Ozone was produced from pure oxygen with a Fisher OZ 500 generator, and dispensed from the upwind vertical tubes. Ozone concentrations were continuously monitored at the center of each exposure field with a Dasibi 1008-RS ozone analyzer. Ozone was administered during the day and night throughout the growing seasons according to the 1.5- to 1.6-Fold ambient ozone profile. During inappropriate weather conditions (rain, fog, dew, and strong wind) ozone fumigation was automatically stopped. The cumulative ozone exposures AOT0, AOT30, and AOT40 (accumulated over threshold 0, 30, and 40 ppb, respectively), and the 7-hr (11:00–18:00) and 24-hr mean values for ozone concentrations are given in Table 1.

Sampling and Extraction. Ten green, mature sun-leaves from five plants per clone and treatment from the middle of the canopy were frozen in liquid nitrogen on August 27, 1998. Freeze-dried leaf material (500 mg) was homogenized for 40 sec with Ultra-Turrax T25 (Janke & Kunkel, IKA-Labortechink, Germany) in 20 ml of 80% methanol at room temperature. The homogenate was subjected to continuous stirring for 1 hr followed by centrifugation at 1500 *g* for 10 min. The pellet was extracted twice, and the combined extract was evaporated to dryness

TABLE 1. OZONE DATA FROM MAY 20, 1996 TO AUGUST 31, 1998.

Ozone	1996		1997		1998	
	A	E	A	E	A	E
AOT0 (ppm hr)	71.2	107.0	67.6	107.1	70.3	104.9
AOT30 (ppm hr)	5.5	33.4	4.7	30.1	3.1	24.7
AOT40 (ppm hr)	1.0	17.3	0.8	13.9	0.3	10.2
7-h mean (ppb)	30.2	45.8	27.5	42.0	26.1	34.0
24-h mean (ppb)	24.1	36.3	22.4	35.5	21.8	31.0

[a] AOT exposures have been calculated for each growing season (May–September) and for each 24 hr/day. Values are means for the two ambient-ozone (control, **A**) and / elevated-ozone blocks (**E**).

under low pressure. Dried extracts were redissolved in HPLC water to a final weight:volume ratio of 0.04 g/ml and stored at -18°C. All chemicals and eluents for HPLC analysis as well as Folin reagent for total phenolics concentration assay were purchased from Fluka BioChemica (Buchi, Switzerland).

Total Phenolics Concentration (TPC). The Folin-Ciocalteau method for quantification of total phenolics, was chosen on the basis of its high sensitivity, lower interference, and speed as compared to other competitive assays (Waterman and Mole, 1994). The assay (Waterman and Mole, 1994) was slightly modified for this study by homogenizing the contents at 1500 *g* for 10 min and measuring the absorbance at 730 nm instead of usual 765 nm. Extract (0.1 ml) was mixed with 5.9 ml water and of the diluted extract 1.0 ml was mixed with 1.0 ml of Folin reagent. The mixture was allowed to stand for 2–5 min and 2 ml of 20% Na_2CO_3 was added. The mixture was stirred and incubated for 10 min at room temperature, homogenized at 1500 *g* for 8 min, and its absorbance was measured at 730 nm on a Perkin-Elmer Spectrophotometer 550. A standard curve was drawn with known concentrations of gallic acid. The results were calculated according to the mathematical procedure of Segal (1975).

HPLC Analysis. Each extract was filtered through a Millex-HV_{13} filter, 0.45 mm (Millipore, Bedford, Massachusetts) before HPLC injection. Separations were performed on a Spherisorb 5 ODS-2 column (250 $\times$ 4.6 mm ID, 5 μm, Phase Separations Ltd.). The HPLC system consisted of an Hitachi L-6200 Intelligent Pump connected to a L-4250 UV-VIS Detector (Merck, Tokyo, Japan) and Chrompac C-R6A Integrator (Shimadzu, Kyoto, Japan). Two solvents were used for elution: A, acetonitrile; B, 5% formic acid. The elution profile was 0–5 min., 100% B (isocratic); 5–60 min, 0–30% A in B (linear gradient); 60–70 min, 30–70% A in B (linear gradient). The flow rate was maintained at 1.0 ml/min and the column back pressure at 70–136 bar. The detection wavelength was fixed at 280 nm. The injection volume of the sample was 20 μl.

HPLC-ESI-MS Analysis. HPLC-ESI-MS analysis was performed with a Perkin Elmer Sciex API-365 triple quadrupole mass spectrometer (Sciex, Toronto,

Canada). The instrument was equipped with a pneumatically assisted ion spray interface and Macintosh data system. The HPLC system consisted of Perkin-Elmer Series 200 HPLC system with a UV-VIS detector. Samples were introduced into the system by a Perkin-Elmer Series 200 Autosampler (Perkin-Elmer, Norwalk, Connecticut). All chromatographic conditions were kept similar to the HPLC-DAD analyses except the use of 0.4% instead of 5% formic acid as eluent B. Before MS, the main part of the flow was split off and only 20% was introduced into the mass spectrometer. The mass spectrometer was operated in negative ion mode with a scan range of *m/z* 100–1100 in 0.30 amu steps. The needle voltage was set at −4000 V, the orifice voltage at −35 V and the ring voltage at −220 V. The nebulizer gas flow was set at 9 and for N_2 curtain gas at 12. The heated nitrogen gas temperature was set at 300°C and the gas flow rate was 7000 cm^3/min.

Growth Measurements. On May 28, 1998, 10 plants per clone per treatment were measured for dry mass of shoot (stem + leaves) and roots. Leaf area growth for another 10 plants per clone per treatment was followed from May 8 to June 5, 1998. On August 31, 1998, 10 plants per clone per treatment were measured for stem height, base diameter, and proportion of yellowed leaves (Percent of all leaves).

Quantitative Analyses. Leaf samples for Rubisco, soluble protein, chlorophyll, and carotenoid concentration determination were collected on August 31, 1998, from mature sun-leaves from 10 saplings per clone per treatment at 10:00–13:00 hr. Frozen leaf disks (2.05 cm^2) were weighed, and a crude extract was prepared for Rubisco concentration using 2 ml of the extraction buffer (Gezelius and Hallen, 1980). The amount of total Rubisco protein was assayed by PAGE as described by Rintamäki et al. (1988), using purified Rubisco protein (Sigma Chemical Co.) as a standard. Rubisco was quantified on a dry weight basis by scanning the areas and intensities of bands in Coomassie-stained gels (Adobe Photoshop Program, version 5.0). An aliquot for soluble proteins was quantified by using Bradford reagent with BSA as standard. Samples for chlorophyll and total carotenoid quantification were taken from the crude extract before centrifugation. Chlorophyll concentrations were determined with a UV-1201 Shimadzu spectrophotometer using buffered 80% acetone as solvent and calculated with corrected equations (wavelengths 646.6 and 663.6 nm) as described by Porra et al. (1989). Total leaf carotenoids were analyzed spectrophotometrically according to Wellburn and Lichtenthaler (1984), measuring absorbance at 470 nm. Bulk samples for starch determination, collected from 10 plants per treatment per clone, were freeze-dried, milled, and analyzed by standard enzymatic techniques (Boehringer kit for food analysis).

Nutrient Analysis. Nutrients were analyzed from dried and ground bulk samples collected from green middle canopy leaves on August 31, 1998. Atomic absorption spectrophotometry (AAS) was used for Ca, K, Mg, and P quantification, and nitrogen concentration was determined by the Kjeldahl method.

TABLE 2. HPLC-DAD (T_R and HPLC-ESI-MS λ_{max}) and (M/Z) data of phenolics of *B. pendula Roth* leaf extract

Peak	T_R(min)	$\lambda^a{}_{max}$ (nm)	*m/z*	Compound[b]
1	17.1	280	305(M-H), 611(2M-H)	(+)-Catechin(CT)
2	21.0	251, 300 sh, 330	353(M-H), 707(2M-H)	Chlorogenic acid (CGA)
3	21.9	315	337(M-H)	5-*p*-Coumaroylquinic acid (5CQA)
4	22.5	285	327(M-H), 655(2M-H)	(GPS)
5	23.3	315	337(M-H), 675(2M-H)	3-*p*-Coumaroylquinic acid(3CQA)

9	41.0	265, 299 sh, 350	477(M-H), 955(2M-H), 301(M-glucuronic acid)	Quercetin-3-*O*-glucuronopyranoside (QGR)
10	43.5	260, 300 sh, 361	433(M-H), 867(2M-H)	Quercetin-3-*O*-arabinofuranoside (QA)

[a]sh = shoulder; [b]GPS = 1-(4″-hydroxyphenyl)-3′-oxopropyl-β-*D*-glucopyranose.

Statistical Analysis. Due to the randomized location and rotation of plants throughout the experiments, no significant field effects were revealed in any parameter by ANOVA with a SPSS/PC package (version 8.0). Two-way ANOVA using plot (field) means (±standard errors) was used to test differences between treatments. Differences were considered significant at $P < 0.05$.

RESULTS

Phenolic Determination. Extraction was carried out with 50%, 60%, 70%, and 80% acetone, methanol, and ethanol to get higher yields of phenolics. Results on the basis of peak areas from HPLC analyses indicated that 80% methanol was the most efficient solvent for extracting phenolics. The Folin-Cioaclteau assay was slightly modified for the determination of total phenolics. The homogenization of the contents immediately before measuring the absorption noticeably reduced the turbidity, and 730 nm proved to be a more suitable absorbance wavelength and gave higher total phenolic concentration than 765 nm. These minor changes provided better reproducibility in triplicate measurements under our test conditions. HPLC-DAD was supported with HPLC-ESI-MS for quick recognition of phenolic compounds of interest in birch leaf extracts. HPLC identification with diode array detection at 280 nm was used to get characteristic UV spectra of individual compounds. The shapes of spectra and UV maximum maxima of each compound were then compared with standard compounds. Ten phenolic compounds were identified and quantified on the basis of results from HPLC-DAD and HPLC-ESI-MS. The *m/z* values (Table 2) from HPLC-ESI-MS confirmed the identification of each compound corresponding to a particular peak (Figure 1).

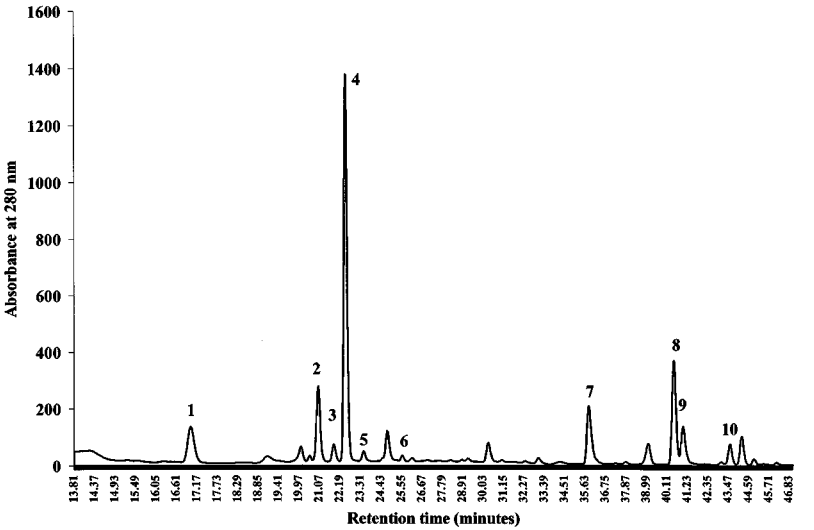

FIG. 1. HPLC chromatogram of *Betula pendula* Roth leaf extract. Numbers in chromatogram correspond to compounds in Table 2.

Phenolics in Different Treatments. The ozone-induced increase in total phenolic contents was determined for pooled data (two clones together) in order to compare TPC and HPLC methods (Figure 2). TPC results showed a 16.2% increase in total phenolics in ozone treatment, while 10 identified phenolics (HPLC) showed a 9.9% increase (Figure 2). The latter rise in 10 selected compounds provided more compact information of the trend due to the nonspecificity of TPC assay (Figure 2). In addition, there was a 2.9% higher ozone response of nonflavonoids as compared to flavonoids in pooled data (Figure 2). Based on 10 identified phenolics, the results showed an 11.4% increase in phenolic contents in clone 5 as compared to clone 2, indicating a greater responsiveness of the sensitive clone 5 (Figure 2 and 3a). The ozone-induced increase in the concentration of 10 phenolics for clone 2 and clone 5 is shown in Figure 3. The highest increases in clone 2 were found in 3CQA (31.5%), CGA (31.2%), MG (30.6%), QA (26%), and QGR (25.3%) and in clone in 5, 5CQA (53.3%), QGR (38.4%), CT (33.7%), CGA (31%), and 3CGA (28.2%) (Figure 3).

Growth Responses and Leaf Yellowing. Mean leaf size in emerging new foliage was significantly smaller in both clones from May 8 to June 5, 1998, in elevated-ozone plants (Figure 4). The difference between treatments was greater in ozone sensitive clone 5 (Figure 4). Stem and root dry weight was unaffected in the tolerant clone 2, whereas in clone 5 lower dry weights in ozone plants were observed on May 31, 1998, accompanied by increased shoot/root ratio (Table 3). Stem height and base diameter growth were unaffected in both clones, when determined on August 31, 1998 (Table 3), indicating ozone-induced

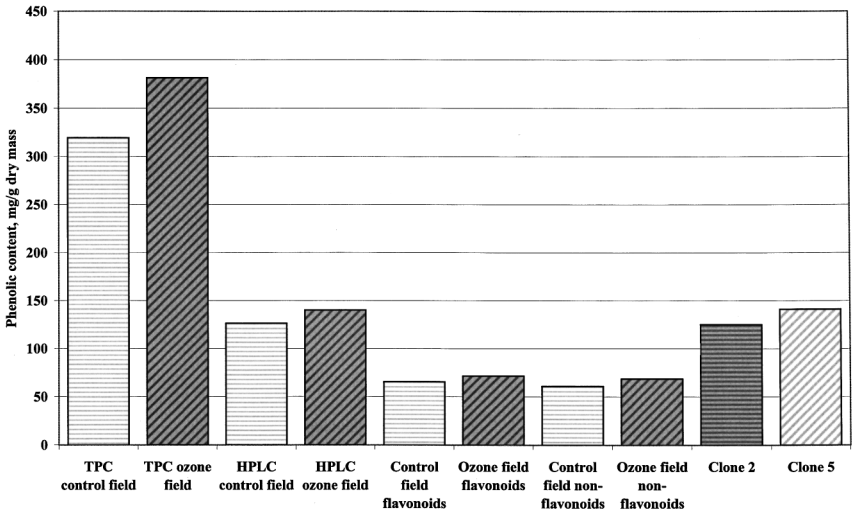

FIG. 2. Overall increase of phenolic concentration in *B. pendula* leaf extracts in elevated ozone plants as compared with controls (data were pooled for two clones). Results are average values of three measurements.

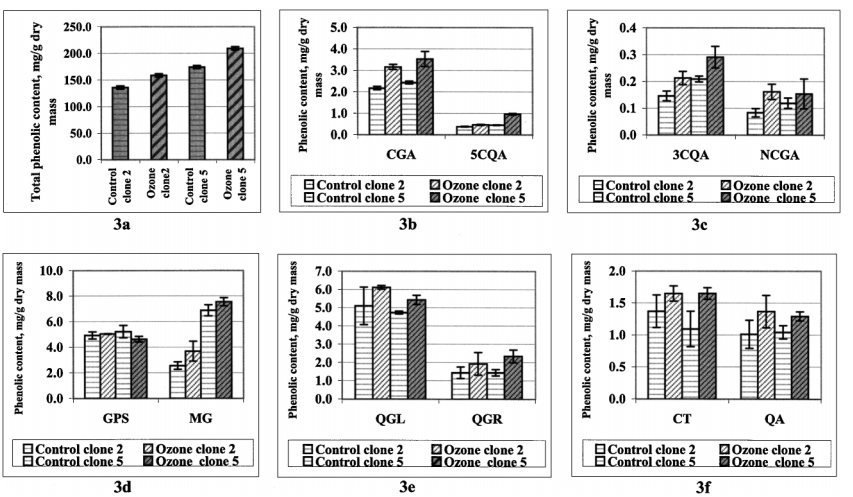

FIG. 3. Response of (a) total phenolic content and 10 phenolics (b–f) of *B. pendula* leaf extracts in elevated ozone plants as compared with control plants in clone 2 and clone 5. Values are means of ± SE, $N = 3$. See Table 2 for names of compounds.

reduction in resource allocation to leaves rather than to stem growth. In addition, yellowing of leaves was (14.3%) enhanced in ozone plants of clone 5 (Table 3).

Quantitative Analysis. Rubisco and soluble protein concentration were not affected by elevated ozone in either clone (Table 4). Total chlorophyll concentration was lower in clone 5 ozone-exposed plants, accompanied by reduced content of Mg. In clone 2, the reduction in chlorophyll and Mg was not significant. Total carotenoid and starch tended to decrease in elevated-ozone plants of both clones but were not significant (Table 4). Foliar N, P, Ca, and K concentrations were also unaffected by ozone (Table 4).

DISCUSSION

The results provide good evidence that elevated atmospheric ozone levels have detrimental effects on the well being of European silver birch (evidenced by elevated phenolic levels) leading to reduced growth and increased leaf senescence.

Changes in Shoot–Root Balance. High ozone sensitivity of clone 5 was confirmed by significantly lower shoot and root growth, a higher proportion of yellowed leaves, as well as lower chlorophyll and Mg concentrations in ozone-exposed plants. In both clones, increased shoot–root ratio in ozone plants indicated shifts in assimilate transport at the expense of roots, leading to altered crown and root architecture, followed by predisposition to other stress factors, such as water and nutrient deficiency and pathogens, and impaired competitiveness in the long term. In recent reviews, changes in resource allocation and disturbed shoot and root balance have been considered as crucial factors underlying the deleterious ozone impact on European forest trees, long-term stand development, and forest ecosystem structure (Skärby et al., 1998; Matyssek and Innes, 1999).

Ozone-Induced Increase in Phenolics. The results of this experiment were consistent with earlier findings, although ozone-induced increases in phenolics were generally higher in our previous study (Oksanen and Saleem, 1999). In our previous work, quantitative comparisons focused on GPS and CGA, which are known to be one among the most abundant nonflavonoid phenolic compounds in *Betula pendula* and *Betula pubescens* (Keinänen and Julkunen-Tiitto, 1998). The ozone-induced increase in phenolics was over two times higher in the sensitive clone 5 as compared to tolerant clone 2 (Oksanen and Saleem, 1999). GPS was less important in the present experiment. The reasons for different responses may be explained by annual variation in ozone concentrations and by seasonal changes in phenolics, relating to phenology of trees, i.e., the samples in the first study were collected in June during a high ozone episode and fast growth period of leaves, whereas in the present study the samples were collected at the end of growing season. Previously, ozone-induced increases in contents of papyriferic acid and flavonoids were also reported in stem samples after low, short-term field ozone exposure in these same silver birch clones (Lavola et al., 1994).

Role of Phenolics in Ozone Stress. Changes in phenolic compounds can be regarded as a phytochemical adaptation to the biotic and abiotic environment (Dixon and Paiva, 1995; Lavola, 1998). Our results support the earlier findings in deciduous trees (Bryant et al., 1987; Julkunen-Tiitto and Meier, 1992; Lavola, 1998) that in birch, a high degree of variation in the production of phenolic compounds is due to phenotypic plasticity, enabling the adaptation to spatial and temporal variation in environmental stress factors like ozone. The accumulation of cell wall phenolics and flavonoids has been shown to prevent water loss and increase the general stress tolerance of the plant (Elstner et al., 1994; Dixon and Paiva, 1995). Induction of antioxidative phenolics such as quercetin and chlorogenic acid may further increase resistance against ozone damage by scavenging free oxygen and hydroxyl radicals and hydrogen peroxide (Appel, 1993; Foy et al., 1995). The increase of chlorogenic acid in ozone-exposed plants in this experiment may indicate an increase in antioxidant activity (e.g., Larson,

1988; Elstner et al., 1994; Rice-Evans et al., 1997), as reported in *Mahonia repens*, where chlorogenic acid was found to be a highly efficient scavenger of free oxygen radicals ameliorating the oxidative stress responses in plants (Grace et al., 1998). In addition, accumulation of triterpenoids on the plant surfaces may contribute ozone resistance by reflectance and ozonolysis of terpenoids (Langenheim, 1994). Recently, in *Pinus nigra* needles collected in a polluted area in Poland, an increase of phenolic levels was concluded to indicate an activation of senescence processes, correlating negatively with the main nutrients (Giertych et al., 1999). Similar relations were observed also in our study with lower Mg and chlorophyll concentrations in the sensitive clone, indicating accelerated leaf senescence.

Growth Versus Phenolic Allocation. The present results are in accord with various carbon nutrient balance (CNB) models (Bryant et al., 1983; reviewed in Herms and Mattson, 1992), which explain that, due to metabolic costs, increased allocation of carbon resources to chemical defense and repair processes under stressful situations results in lower biomass production and growth. The increase in total phenolics and concomitant reduction in growth is also in agreement with the protein competition model (PCM) of plant phenolic allocation of Jones and Hartley (1998). This model assumes that impaired growth and reduced demand for protein synthesis is accompanied by increased investment in carbon-based phenolics in fast-growing species because both processes use the same amino acid precursor—phenylalanine (Jones and Hartley, 1998). The present results indicate that a change in carbon allocation towards defensive phenolics at the expense of growth was greater in the ozone-sensitive clone 5 as compared to tolerant clone 2. Previously, a higher content of flavonol glycoside was detected in ozone-tolerant cultivars of soybean than in sensitive ones (Foy et al., 1995).

Ecological Implications and Conclusions. Because several phenolic biosynthesis-affecting environmental stress factors, such as increased ozone concentration, oxides of nitrogen, UV-B radiation, and elevated CO_2 levels together with increasing temperature and changing precipitation, affect forest trees simultaneously, the amounts of carbon-based phenolic compounds have been predicted to change in forest ecosystems (Jones and Hartley, 1998). Integrating the highly variable effects of single environmental factors to estimate the net effect of global change is a complex task. However, the present results suggest that increasing ozone levels tend to increase phenolic concentrations in birch trees, as proposed by Jones and Hartley (1998) and Lavola (1998). The results indicate an overall ozone-induced increase in foliar CT, CGA, 5CQA, 3CQA, MG, QGR, and QA. This was regarded as a source of concern, because altered resource allocation towards phenolics was accompanied by growth reductions and disturbed shoot/root balance, especially in the sensitive birch clone.

VARIABLE DIETS AND CHANGING TASTE IN PLANT–INSECT RELATIONSHIPS

J. ALAN A. RENWICK[1,*]

Boyce Thompson Institute
Ithaca, New York 14853

(Received January 1, 2001; accepted January 19, 2001)

Abstract—The host ranges of phytophagous insects are determined to a large degree by plant chemistry. Specialist insects are often closely associated with plants that produce characteristic chemicals, which may act as attractants or stimulants to aid in finding or recognizing a host. Generalist insects are generally believed to rely on the presence of repellents or deterrents to ensure avoidance of unsuitable plants. However, the chemistry of any plant can be highly variable, as a result of growth characteristics, genetic variation, or environmental factors. Such variable chemistry may provide windows of opportunity for nonadapted insects to utilize a plant or for a plant to become resistant to a normally adapted herbivore. Differences in insect responses to plant constituents may also result from genetic variation or environmental factors. In particular, dietary experience has been found to influence the ability of insects to taste plant chemicals that may serve as signals of suitability or unsuitability. Certain dietary constituents appear to suppress the development of taste sensitivity to deterrents in an insect, whereas the presence of specific stimulants in the diet may result in the development of dependence on these compounds. These findings further emphasize the fact that the dynamics of plant biochemistry along with plasticity in the sensory system of insects might be expected to play a major role in the evolution of new plant–insect relationships.

Key Words—Host selection, taste, feeding stimulants, feeding deterrents, diet, *Manduca sexta*, *Pieris rapae*, sensory plasticity.

INTRODUCTION

The vast majority of phytophagous insects are known to be specialists on a limited number of closely related plants. The evolution of such plant–insect associations

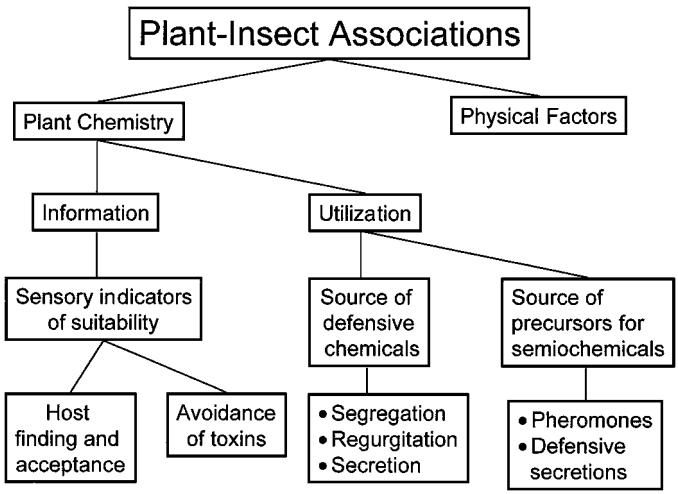

FIG. 1. Schematic representation of the value of plant chemistry to adapted insects.

is believed to be driven in part by the insects' need to avoid competition and to escape from enemies (Bernays and Chapman, 1994; Schoonhoven et al., 1998). This process has involved adaptation to the physical and chemical defenses that plants have developed against generalist herbivores and pathogens. By specializing, these insects may take advantage of unique architecture or characteristic chemistry of their host plants in a variety of ways (Figure 1).

Plant chemicals may be useful to the insect as a basic source of information about the plant, or they may be utilized more directly for defense or communication purposes. Chemicals for defense might be ingested and sequestered in various body parts to discourage potential predators (Brower, 1984). Alternatively, they are often regurgitated directly from the crop, or they may be stored in special glands for secretion when threatened by a potential enemy (Rowell-Rahier and Pasteels, 1993). Some host plant chemicals also are used as precursors for semiochemicals, including pheromones (Hughes, 1974).

The information afforded by plant chemistry is critical in guiding the process of host selection by specialist insects. Chemicals emanating from a plant may have a negative or positive effect on an approaching insect. The presence or absence of specific volatiles can promote landing, and key compounds at the surface may then signal the suitability of a plant, resulting in acceptance for oviposition or feeding (Renwick and Huang, 1994). The presence of repellents or deterrents usually signals unsuitability of a plant, and the resulting rejection behavior allows the insect to avoid contact with, or ingestion of, toxins that are likely to be encountered in the plant. For the Lepidoptera, host finding and acceptance is largely the responsibility

of the female adult, which must select a site for oviposition that is optimal for the hatching larvae. However, larvae must also be capable of recognizing new host plants after completely defoliating a plant or after falling from their first host plant (del Campo, 1999). It is clear, therefore, that discrimination among plants and recognition of specific hosts by adults and larvae are highly dependent on the insect's ability to perceive and respond to specific cues. Although many plant–insect systems have now been studied to elucidate the chemical basis for specialization, the significance of variability in plant chemistry and variability in the insect responses to plant constituents has seldom been addressed. Here we examine the results of experiments with two model systems to illustrate how such variations might play a role in the evolution of host range expansion and/or plant escape from herbivory.

Pieris–CRUCIFER MODEL SYSTEM

The specialization of many insects on members of the Cruciferae (=Brassicaceae) has long been linked to the presence of glucosinolates in these plants (Feltwell, 1982). This chemical association was first demonstrated by Verschaffelt (1910) for *Pieris* species, and the observation has served as a basis for several classical studies on the role of these compounds in host selection. The involvement of glucosinolates in stimulating feeding by larvae and oviposition by adults has since been confirmed for *P. brassicae* and *P. rapae* (Thorsteinson, 1953; David and Gardiner, 1966; Renwick et al., 1992). More recent studies have shown that ovipositing *P. rapae* adults respond most strongly to indole glucosinolates, such as glucobrassicin, and less strongly to aliphatic glucosinolates, especially those with sulfur in the side chain, such as glucocheirolin (Huang and Renwick, 1994). Larval preferences for different glucosinolates have received less attention, but feeding stimulation clearly occurs in response to any one of many aromatic or aliphatic glucosinolates (Renwick and Lopez, 1999).

P. rapae recently has served as a model insect for studying the chemical basis for restricted host ranges. Despite the strong association of this insect with glucosinolate-containing plants (including members of the Tropaeolaceae, Capparaceae, and Resedaceae, as well as most of the Cruciferae), some crucifers are avoided. Work on two of the unacceptable crucifers has shown that these plants contain strong oviposition deterrents. The deterrents in *Erysimum cheiranthoides* have been identified as cardenolides (Sachdev-Gupta et al., 1990), and deterrents that explain rejection of *Iberis amara* were identified as cucurbitacin glycosides (Huang et al., 1993). The fact that these unacceptable plants contain reasonably high concentrations of stimulatory glucosinolates indicates that the deterrent effect must outweigh the effects of the stimulants. These results have reinforced the idea that acceptance or rejection of a plant may depend to a large extent on a balance

of stimulants and deterrents perceived by the insect (Miller and Strickler, 1984; Renwick and Huang, 1994; Renwick, 1996). This idea has been tested by growing the normally unacceptable *E. cheiranthoides* in nutrient solutions containing increasing concentrations of nitrogen. At higher levels of nitrogen, the glucosinolate/cardenolide ratio in foliage increased substantially, and the plants became acceptable for oviposition (Hugentobler and Renwick, 1995).

Comparative studies with *Pieris napi oleracea* and *P. rapae* have shown that these related species have different thresholds for response to the various stimulants and deterrents. Oviposition by *P. napi* was more strongly stimulated by the aliphatic, sulfinyl, and sulfonyl glucosinolates than by the indole representatives of the group (Huang and Renwick, 1994). Furthermore, this species was less deterred by concentrations of cardenolides and cucurbitacin glycosides that effectively blocked oviposition by *P. rapae*. Similar differences were found in the responses of larvae to feeding deterrents in *E. cheiranthoides* and *I. amara*. Both cardenolides and cucurbitacin glucosides deterred feeding by *P. rapae*, but had little or no effect on *P. napi* (Chew and Renwick, 1995). The cardenolides that were most effective as oviposition deterrents were not the most active feeding deterrents. In general, the strophanthidin-based cardenolides were the most active oviposition deterrents, whereas the digitoxigenin glycosides were more effective against larval feeding (Renwick, 1996).

SENSORY PERCEPTION OF CONTACT STIMULI

Recognition of host plants by phytophagous insects clearly depends on a series of behavioral responses to visual, olfactory, and/or gustatory cues. In the case of *Pieris rapae* butterflies, visual cues are important for locating potential hosts, and, after landing, contact with nonvolatile cues at the leaf surface results in acceptance or rejection of the plant (Chew and Renwick, 1995). Taste receptors on the tarsi are responsible for perception of the glucosinolates and possible deterrents such as cardenolides at the leaf surface. Electrophysiological recordings from these receptors have been used to explain observed variation in behavioral responses to individual compounds. In particular, comparisons between *P. napi* and *P. rapae* have shown that differences in responses of the tarsal receptors to compounds could be related to differences in behavioral responses of the butterflies (Du et al., 1995; Städler et al., 1995).

In the case of larvae, host recognition depends almost entirely on the use of taste receptors that are present on the mouthparts. The most important chemoreceptors appear to be the medial and lateral sensilla styloconica located on the maxillary galea of the caterpillars. These sensilla are innervated by neurons that respond to glucosinolates and others that respond to deterrents (Schoonhoven, 1987). Recent studies have shown that *Pieris* caterpillars have specialist deterrent receptors that are particularly sensitive to cardenolides, as well as more general deterrent

receptors that respond to a wide range of compounds (van Loon and Schoonhoven, 1999). As in the case of adults, larvae of the different *Pieris* species are likely to have different sensitivities to both stimulants and deterrents, and electrophysiological responses can be correlated with the observed behavioral responses.

EFFECTS OF DIETARY EXPERIENCE

The responses of insect larvae to chemical cues from potential host plants may often be influenced by dietary experience. Feeding behavior may be affected by various forms of learning, including habituation, sensitization, and imprinting (induction of preference) (Szentesi and Jermy, 1989). Early work on *Pieris brassicae* showed that when late-instar larvae were given a choice of food plants, they generally preferred the plant on which they were reared (Johansson, 1951). Larvae reared to fifth instars on *Tropaeolum majus* also developed a preference for this plant. Thus, induced preference was clearly indicated, although some feeding also occurred on the less preferred plants. However, Ma (1972) found that *P. brassicae* that had fed on *Brassica oleracea* refused to feed on *T. majus*, and the mechanism of this rejection behavior was never explained. Subsequent work with *Pieris rapae* has shown that cabbage-reared larvae of this species also will starve to death rather than feed on nasturtium (*Tropaeolum majus*) (Renwick and Huang, 1995). However, adults from the same colony readily oviposited on nasturtium, and the hatching larvae fed and developed normally. Likewise, when neonate larvae were transferred from a Parafilm substrate to nasturtium, they fed normally. In experiments with different instars, the development of refusal behavior was found to occur in first instars, within 24 hr of inititiation of feeding on cabbage.

Subsequent experiments with other host plants, including noncrucifers, showed that larvae transferred from cabbage to *Brassica juncea* (Cruciferae), *Sinapis alba* (Cruciferae), *Cleome spinosa* (Capparidaceae), and *Reseda luteola* (Resedaceae) all fed readily on their new hosts. These results suggested that nasturtium has some unique deterrent property that is absent in other hosts. The possibility of imprinting as a mechanism for rejection of a new host was tested by making the reverse switch. However, those larvae transferred from nasturtium to cabbage fed almost immediately on the new plants (Renwick and Huang, 1995).

The presence of a feeding deterrent in nasturtium has subsequently been demonstrated, and the major active compound has been identified as chlorogenic acid (Huang and Renwick, 1995a). Additional experiments were performed with larvae reared on a variety of host plants to determine whether some unique factor in cabbage was responsible for triggering sensitivity to the deterrents in nasturtium. However, larvae reared from egg hatch to third instar on *Brassica juncea*, *Sinapis alba*, *Cleome spinosa*, and *Reseda luteola* all refused to feed on nasturtium. These results suggested that many host plants have the qualities necessary for *P. rapae*

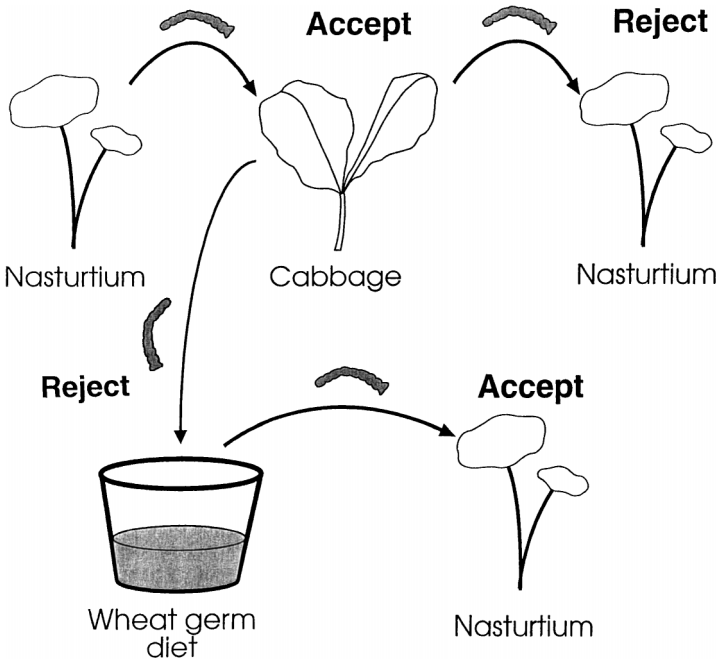

FIG. 2. Effect of dietary experience on acceptance or rejection of new diets by larvae of *Pieris rapae*.

larvae to develop sensitivity to the deterrents. However, when larvae were reared on wheat germ diet, and third instars were transferred to nasturtium, they accepted the plant and fed normally (Figure 2). This means that the wheat germ diet either lacks an inducer or contains chemicals that suppress development of larval sensitivity to the deterrent in nasturtium. Larvae reared on nasturtium from the time of hatching had limited sensitivity, whereas larvae that were reared exclusively on the wheat germ diet remained almost completely insensitive to the deterrents (Renwick and Huang, 1995).

We have suggested that the development of sensitivity to deterrents in plants is suppressed by continuous exposure of *P. rapae* larvae to these compounds. However, it was not clear whether exposure to one deterrent would suppress sensitivity to other unrelated deterrents. Experiments to answer this question were performed by rearing larvae on cabbage leaves that were treated with individual deterrent compounds and then testing the response of these larvae to other deterrents. The results showed that dietary experience can, in fact, affect sensitivity to compounds that are not present in the diet. Thus, a type of cross-habituation exists (Huang and Renwick, 1995b).

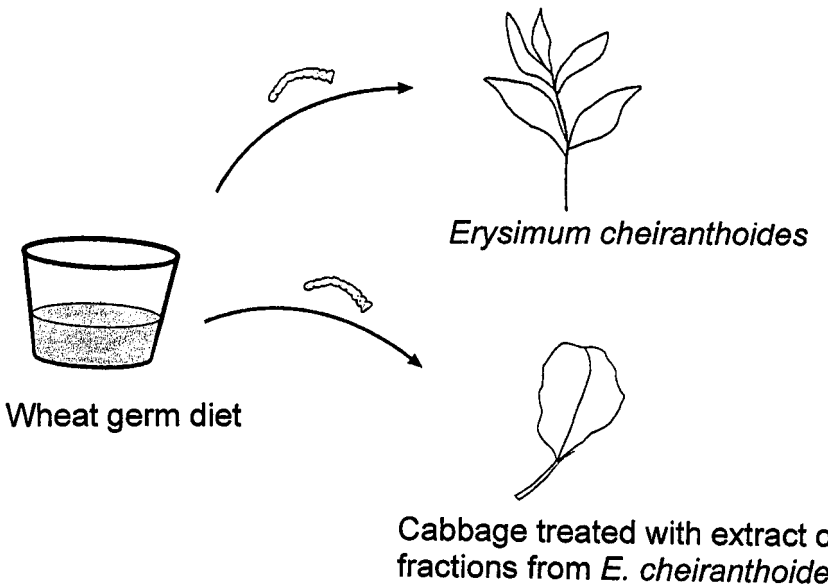

FIG. 3. Bioassay for toxicity of an unacceptable plant to *Pieris rapae* and for monitoring isolation of toxin from plant extracts.

Detailed studies on the development of larval sensitivity to feeding deterrents suggested that the sensory system of second instars is most plastic, but a gradual increase in sensitivity of larvae at any stage occurs after their transfer from artificial diet to cabbage. The evidence suggests that *P. rapae* could serve as an excellent model for analysis of the physiological and biochemical processes involved in sensory development. In addition, suppression of taste sensitivity allows us to test the effects of feeding on a plant that would not normally be eaten. When *P. rapae* larvae are reared on wheat germ diet and then transferred to a normally unacceptable plant, some feeding is likely to occur. This approach has been used to examine possible effects of *P. rapae* feeding on *Erysimum cheiranthoides*. Diet-reared fifth instars consumed considerable amounts of *E. cheiranthoides* foliage but became sick within 48 hr and died soon after (Renwick et al., unpublished results). This provided a clear indication that *E. cheiranthoides* contains compounds that are toxic to *P. rapae* (Figure 3). Solvent extracts of *E. cheiranthoides* applied to cabbage foliage were also toxic to the diet-reared larvae, and preliminary HPLC has resulted in the isolation of several cardenolides that could explain the toxic activity (Renwick, unpublished results).

Recent work has shown that the source of suspected suppressing compounds in artificial diet is the wheat germ itself. Exhaustive extraction and partitioning of

wheat germ, using feeding deterrent assays to monitor for activity, resulted in the isolation of a highly deterrent methanol-soluble fraction. Subsequent separation by HPLC yielded active compounds that have been characterized as apigenin-based flavones (Huang and Renwick, 1997).

Manduca sexta AS A COMPARATIVE MODEL

The discovery of diet-dependent sensitivity to deterrents in *Pieris rapae* prompted additional studies to determine whether other insects exhibit the same phenomenon. *Manduca sexta* appeared to be an ideal candidate, since Städler and Hanson (1978) had already found that plant-reared larvae of this species were deterred by extracts of artificial diet. These authors were the first to suggest that diet-induced changes in food selection behavior of *M. sexta* could be related to changes in sensory responses. Experiments in our laboratory were designed to determine whether diet-dependent acceptance of a nonhost plant (cowpea) by this species could be the result of differences in sensitivity to deterrents. The results clearly indicated that dietary modification of food acceptance was due, not to differences in response to a deterrent, but to the development of dependence on host plant constituents (del Campo, 1999; del Campo and Renwick, 1999). Larvae reared on

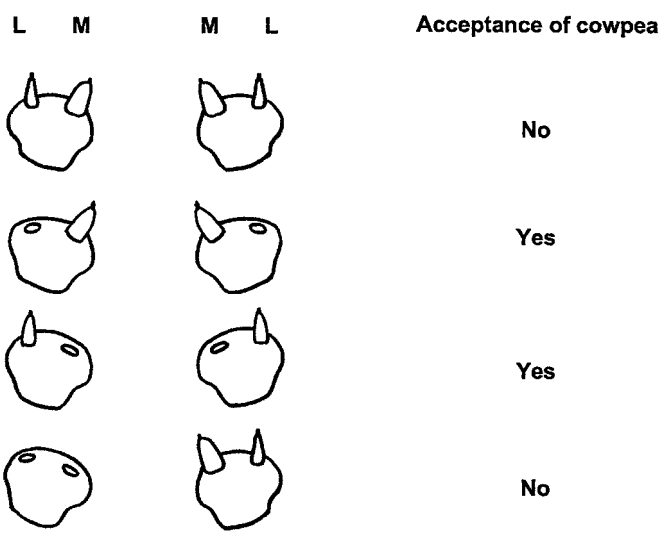

FIG. 4. Effects of selective removal of lateral (L) and medial (M) sensilla styloconica from *Manduca sexta* larvae on acceptance of cowpea leaf discs as food. Test larvae were reared on potato foliage to become dependent on the presence of a specific stimulant for feeding.

a wheat germ diet will feed on the nonhost cowpea, whereas potato-reared larvae require a specific feeding stimulant for acceptance of cowpea as food. A single compound was isolated from potato foliage to explain this effect (del Campo and Renwick, 2000), and the development of dependence on this compound could be related to changes in the responses of a particular chemoreceptor on the mouthparts of the larvae (del Campo, 1999). Since feeding discrimination in caterpillars has been linked to the responses of two maxillary hairs, the medial and lateral sensilla styloconica, to stimulants and deterrents (Schoonhoven, 1987), ablation experiments were performed to determine which of these receptors are involved in the development of this chemical dependence. Discrimination was measured by testing the acceptance of cowpea leaf disks by potato-reared *M. sexta* larvae. The intact larvae refused to feed on the cowpea disks, but after bilateral removal of either the medial or lateral sensilla, the larvae fed on the disks. However, after unilateral removal of both medial and lateral sensilla, the larvae still refused to feed (del Campo, 1999) (Figure 4). Thus, discrimination appears to require input from both sensilla. However, electrophysiological recordings indicated that dietary experience affected the responses of only the lateral sensilla to the potato compound. As a result of these studies, del Campo et al. (2001) have concluded that specialization by this insect involves a peripheral neural mechanism.

DEPENDENCE OF *Pieris rapae* ON A HOST STIMULANT

The possible development of *P. rapae* dependence on specific host compounds was examined by using the same approach as for *M. sexta*. Cowpea disks were generally accepted as food by neonate larvae, but larvae that had fed on cabbage refused the cowpea. The development of this refusal behavior was related to the length of time spent feeding on cabbage. However, when extracts of various host plants were applied to cowpea leaf disks, crucifer-fed larvae were stimulated to feed at rates that were little affected by the plant on which they had been reared. A general addiction to glucosinolates was suggested, and a single glucosinolate was found to be sufficient to elicit feeding by cabbage-reared larvae. Since bioassays of cowpea extracts failed to show any deterrent activity, the conclusion was reached that addiction to glucosinolates is responsible for the fixation of *P. rapae* larvae on their host plants (Renwick and Lopez, 1999).

DEPENDENCY AND SENSITIVITY OF *P. napi oleracea*

Comparative studies on *P. n. oleracea* have revealed the existence of a somewhat different dependence mechanism. Neonate larvae of this species will not feed

on untreated cowpea leaf disks. However, when glucosinolates are applied to the disks, feeding occurs (W. Q. Zhang, unpublished results). Since the naïve neonates require glucosinolates for initiation of feeding, prior experience is not necessary for the development of dependence. Instead, it appears that *P. napi* larvae have an innate craving for glucosinolates upon hatching from the egg.

In the case of feeding deterrents, the development of sensitivity in *P. n. oleracea* may be more similar to that in *P. rapae*. This indigenous North American species will often lay eggs on introduced crucifers that are not suitable for larval growth and development, and deterrents are likely to be involved in restriction of larval feeding. One such plant is garlic mustard, *Alliaria petiolata*, which has become extremely invasive in eastern North America, largely because of a lack of herbivory. Feeding by *P. n. oleracea* is blocked primarily by the presence of two compounds. One of these (compound 1) inhibits feeding by neonates, whereas the other (compound 2) deters feeding by later instars (Renwick et al., unpublished results). Recent experiments have examined the effect of diet on larval responses to these compounds, and two distinct mechanisms have emerged. The responses of larvae that were reared on either wheat germ diet or cabbage plants were measured at each larval stage. For the cabbage-reared larvae, a steady decline in sensitivity to compound 1 was observed as the larvae progressed from first to third instars. On the other hand, sensitivity to compound 2 increased steadily to reach a maximum in fourth and fifth instars. Larvae that fed on a wheat germ diet followed the same pattern of responses to compound 1, but never became sensitive to compound 2. From these results, along with behavioral observations, we concluded that two distinct mechanisms are involved in blocking feeding by the larvae at different stages. Compound 1 appears to be a postingestive feeding inhibitor, whereas compound 2 is a feeding deterrent that is perceived by taste. This conclusion would suggest, therefore, that dietary experience affects the ability of the insects to taste or respond to deterrents, but has no effect on postingestive inhibitory responses. This may mean that rearing larvae on different diets can be used to determine the mechanism involved in rejection of certain foods. From an ecological point of view, this also means that discrimination between potential host plants on the basis of taste may depend on the previous diet of the insect.

VARIATION IN PLANT CHEMISTRY

The compounds in *A. petiolata* responsible for blocking feeding by *P. n oleracea* have now been identified. Compound 1, alliarinoside, is a unique cyanoglycoside (Haribal et al., unpublished data) and compound 2 is a flavone glycoside (Haribal and Renwick, 1998). These compounds can be readily detected in aqueous extracts of foliage after preliminary solvent partitioning and chromatography, and analyses of samples from different sources have revealed considerable quantitative variability. Field observations have indicated that some populations of

P. n. oleracea can survive on isolated populations of *A. petiolata* (Courant et al., 1994). A detailed study of variation in plant chemistry throughout the year has now been conducted for different populations of *A. petiolata* in New York State. The analyses revealed substantial seasonal as well as population variation in the content of these active compounds (Haribal and Renwick, unpublished data). Such variation may well be sufficient to account for observed differences in growth and survival of larvae on the plants. A general dip in concentrations of both compounds 1 and 2 from June to July might suggest that a window of opportunity exists for *P. n. olearacea* to adapt to the variable resistance of garlic mustard (Haribal and Renwick, unpublished data).

CONCLUSIONS

The importance of plant chemistry in the evolution and maintenance of specialist insect–plant associations has been well documented in the past. Here we have focused on the role of plant chemistry in providing information about a plant and the ability of the insect to respond to this information. Chemical messages that signal suitability of a plant are perceived by the insect through a variety of chemoreceptors. For lepidopterous larvae, critical information is most often obtained by the use of taste receptors, although limited ingestion may also be needed for confirmation of suitability. Specialization usually depends on recognition of specific chemicals or classes of chemicals that stimulate feeding. At the same time, negative information allows the insect to avoid plants that may be toxic or unsuitable for continued growth and development.

We now know that variation in plant chemistry may provide opportunities for an insect to feed on plants that are usually considered to be unsuitable. Such variation may be genetically controlled, or it may result from seasonal, climatic, or other environmental factors. Similarly, differences in responses of insects to plant chemicals may be genetically or environmentally based. However, it is now clear that changes in sensory physiology may also play an important role. Diet-dependent sensitivity of the insect to negative signals may affect its ability to avoid plants that are likely to be toxic. The response of larvae to genus-specific feeding stimulants can play a key role in host selection by specialists, and we have now shown that some species become dependent on such stimulants for host recognition and continued feeding. This dependence may be manifested as an innate craving, or it may develop as a result of experience, like a type of addiction. Furthermore, experiments with *M. sexta* indicate that the development of dependence involves changes in the peripheral receptors that are responsible for tasting plant compounds at the leaf surface.

The observed variation in both plant chemistry and insect responses to specific chemicals might suggest that adaptation of a native insect to an introduced plant

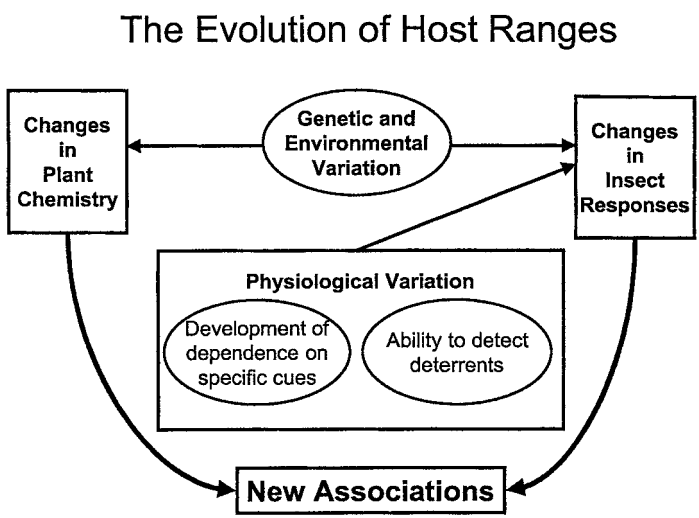

FIG. 5. The possible role of physiological variation, based on dietary experience, on the evolution of new insect–plant associations.

could occur relatively rapidly. Results of our research support the idea that the evolution of host ranges involves physiological as well as genetic and environmental factors (Figure 5). Plasticity in perception of deterrents and the development of dependence on specific chemicals undoubtedly play important roles. Future research in this area will benefit from collaborative efforts that combine experimental input from studies in sensory physiology, behavior, and phytochemistry to provide an integrated view of the processes involved.

(Received October 26, 2000; accepted February 8, 2001)

Abstract—Salicin was administered orally to six brushtail possums by incorporation in food for six days at three dose levels (0.05, 0.5, and 1.5% wet weight), giving mean ± SD daily intakes of 0.31 ± 0.09, 2.76 ± 0.75, and 6.04 ± 1.12 mmol salicin. Metabolites were identified by mass spectrometry and assayed by HPLC. Salicyl alcohol glucuronide accounted for 56–64% of urinary metabolites over the three doses, salicyluric acid 15–26%, salicin 10–18%, and there were smaller amounts of free (2–4%) and conjugated (0–6%) salicylic acid. β,2-Dihydroxyphenylpropionic acid was a minor metabolite. The hydrolysis of dietary salicin enabled reconjugation of its aglycone, salicyl alcohol, with a more polar sugar, glucuronic acid, thus enhancing its renal excretion and resulting in little net loss of substrates for conjugation and a low measurable metabolic cost of excretion.

Key Words—Salicin, metabolism, glucose conjugate, plant secondary metabolite, common brushtail possum, detoxication, costs.

INTRODUCTION

Although there is clear evidence that some plant secondary metabolites (PSMs) influence foraging of herbivores (Foley et al., 1999), the mechanisms by which

*To whom correspondence should be addressed. e-mail: william.foley@anu.edu.au

0098-0331/01/0600-1077$19.50/0

these effects are exerted remain unclear. Some compounds exert clear antifeedant effects (Lawler et al., 1998) or have a demonstrable impact on the metabolism of the animal. Yet most mammalian herbivores ingest large concentrations of many PSMs that do not appear to have major effects on their choices of foods (Palo and Robbins, 1991). Most syntheses of mammal–plant interactions place some importance on the cost of neutralizing and excreting any PSMs that are ingested (Freeland and Janzen, 1974; Foley and McArthur, 1994; Foley et al., 1999). The difficulty with assigning costs to the neutralization and excretion of PSMs is that only rarely are the pathways of metabolism known with any certainty (Freeland, 1991). Available information is generally restricted to laboratory species, and it is hard to place these studies in an ecological context. Costs that might be important in an ecological context could include the cost of maintaining enzyme systems, the cost of conjugates for excretion and the opportunity costs of lost foraging time because of the pharmacokinetic constraints of neutralizing and disposing of metabolites (Foley et al., 1999).

Although all these avenues could potentially be important, only the cost of excreted conjugates has been quantified. For example, Cork (1981) showed that glucuronic acid excretion comprised up to 25% of the fasting glucose entry rate of koalas (*Phascolarctos cinereus*). Lowry et al. (1993) showed that sheep fed diets rich in organic acids excreted 17% of their digestible N intake as benzoyl glycine (hippuric acid). Nonetheless, we think that some compounds, in particular phenolic glycosides, could be excreted with very little cost either because they are excreted unconjugated (Scheline, 1991) or because the glycoside is used as a source of metabolizable energy to compensate for the excretion of a carbohydrate-based conjugate such as a glucuronide.

We evaluated this possibility by studying the metabolism of salicin in common brushtail possums. Salicin [salicyl alcohol glucoside; 2-(hydroxymethyl)-phenyl-β-D-glucopyranoside] is a bitter-tasting phenolic glycoside found in the bark and leaves of various species of *Salix* and *Populus* (Trease and Evans, 1972). Earlier studies had implicated salicin as a cause of selective feeding on *Salix* and *Populus* by common brushtail possums (Markham, 1970; Edwards, 1978) and mountain hares (*Lepus timidus*) (Tahvanainen et al., 1985), but little was known of how such an antifeedant effect could occur. Pass and Foley (2000) examined the effect of isolated salicin on feeding in common brushtails but could find no evidence of postingestive effects and attributed the antifeedant effects of high concentrations of salicin to preingestive effects such as taste. Therefore, we undertook this study of the metabolic disposition of salicin to provide further evidence of the nature of any postingestive effects.

In the only detailed study of the metabolism of salicin, Fotsch et al. (1989a) found that rats excreted oral doses of salicin mostly as free salicylic acid and unchanged salicin. However, after a subcutaneous dose, salicin was excreted virtually unchanged (Fotsch and Pfeifer 1989). In vitro experiments showed that salicin was

hydrolyzed by bacteria in the cecum and colon of rats, indicating that salicin is extensively hydrolyzed in the rat gastrointestinal tract.

METHODS AND MATERIALS

Materials. Salicin (min. 99% purity) was purchased from Sigma. All other chemicals were of good commercial quality. Reference metabolites (salicyl alcohol, salicylic acid, salicyluric acid) were chromatographically pure. Methanol and acetonitrile were HPLC grade (Waters Associates, Sydney, Australia) and acetone was an analytical reagent grade (May & Baker).

Animals and Urine Collection. Animal work was carried out at James Cook University, Townsville, and was approved by that university's ethics committee (Pass and Foley, 2000). Six common brushtail possums were trapped in the wild and kept in an air-conditioned animal house maintained at $22 \pm 2^{\circ}$C and a 12-hr light–dark cycle. The animals were adult males weighing 1.97–2.50 kg (mean = 2.27 kg). They had been living in a mangrove forest and had not been previously exposed to willows or poplars. The animals were fed on a diet of fruit and cereals (Pass and Foley, 2000). In feeding experiments, salicin was added to the dry ingredients of this diet and mixed to give a final uniform distribution of salicin 0.05, 0.5, or 1.5% wet weight of feed. Animals were housed individually and fed each of the three salicin diets for eight days, using a balanced Latin-square design. During each eight-day diet period, 24-hr urine samples were taken on day 6 for metabolite analyses. Urine was collected into bottles immersed in solid carbon dioxide and stored frozen until analyzed. Food intake was measured, by weight, on day 5.

Identification of Metabolites. Most metabolites were identified by mass spectrometry (MS) after separation by gas chromatography (GC). After hydrolysis of conjugates with β-glucuronidase/arylsulfatase (see below), urine samples were acidified to pH 1 with 5 M HCl and extracted three times with ethyl acetate. An aliquot of the extract was then placed into an ice bath in a fume hood, ethereal diazomethane added, and the reaction allowed to stand for 30 min. Excess diazomethane was removed with a gentle stream of nitrogen. The methylated metabolites were dissolved in ethyl acetate and analyzed by GC. The instrument was a Hewlett-Packard 5890 gas chromatograph with 5970B mass-selective detector using HP 59970A Chemstation software (Hewlett-Packard, Melbourne, Australia). GC conditions were: Hewlett-Packard HP1 capillary column (0.52 μm methylpolysiloxane), 25 m $\times$ 0.32 mm ID; oven 100–190°C at 5°C/min, then 190–200°C at 20°C/min; carrier He at 12 psi; injector 250°C; detector 300°C.

Salicyl alcohol glucuronide was isolated by liquid chromatography to enable its identification by high-resolution MS. Salicin and salicyl alcohol glucuronide were separated from urine on a column of Amberlite XAD-4 resin (Serva) using

a method adapted from that of White and Schwartz (1980). The resin (10 g) was washed successively with methanol, water, acetone, acetone–water, methanol, and water. An aliquot of urine (50 μl) was diluted in 75 ml water and passed through the column at 3 ml/min. The column was then washed with 80 ml water followed by successive 30 ml volumes of acetone–water (1:1). Eluted fractions were concentrated to approximately 1–2 ml by rotary evaporation at 40°C and analyzed by HPLC. Salicyl glucuronide eluted with the aqueous wash and gave no HPLC peak for salicin or salicyl alcohol, but after enzyme hydrolysis, produced salicyl alcohol. Salicin eluted with the acetone–water fractions, and enzyme hydrolysis gave salicyl alcohol. The structures of urinary salicyl glucuronide and salicin were confirmed by solid probe mass spectrometry. The instrument (Kratos Concept ISQ, Manchester, UK) used a Cs ion gun at 10 kV for FAB mass spectrometry in a glycerol matrix.

Structures of conjugates were confirmed by liquid chromatography–mass spectrometry (LC-MS) with a Waters Alliance HPLC and Finnegan LCQ mass spectrometer using LCQ Navigator software. Diluted urine samples were chromatographed on a reverse-phase C-18 Nova-Pak column (3.9 mm × 150 mm; Waters Associates) with a mobile phase starting with 90% water–10% methanol containing 2% acetic acid in each and programmed to 100% methanol after 40 min at 0.8 ml/min. Peaks were detected by negative electrospray ionization (ESI). MS-MS analysis confirmed the origin of daughter ions. Retention times were: salicyl alcohol glucuronide, 4.89 min; salicylic acid glucuronide, 6.49 min; and salicyluric acid, 9.93 min. Salicin does not produce a negatively charged ion under the conditions used and was not detected.

Quantification of Metabolites by HPLC. A Varian 9010 solvent delivery system with Rheodyne injector model 7161 was connected to a Varian 9050 UV-VIS absorbance detector and Star workstation (Varian Instruments, Melbourne, Australia). The column was a reverse-phase C-18 Nova-Pak (3.9 mm × 150 mm; Waters Associates) and solvents were pumped at 0.9 ml/min. The injection volume was 10 μl.

Salicin and salicyl alcohol were analyzed with methanol–water (25:75) at a wavelength of 213 nm (HPLC system 1). Calibration curves were prepared using 400 μl predose urine, to which were added known amounts of salicin and salicyl alcohol in methanol (0–500 μl), internal standard (1.32 mg benzyl alcohol in 1 ml 25% aqueous methanol), and water to 5 ml. Elution times were: salicin, 2.34 min; salicyl alcohol, 3.59 min; and benzyl alcohol, 6.49 min. Calibration curves were constructed using the concentration of the final solution and peak areas and were linear for salicin (0–1.76 μmole/ml; $r^2 = 0.998$) and salicyl alcohol (0–4.12 μmol/ml; $r^2 = 1.000$). Urinary concentrations were calculated using dilution factors to account for the varying volumes of urinary aliquots (200–500 μl) that were required to accommodate the large range of metabolite concentrations found at the different doses.

Salicylic acid and salicyluric acid were analyzed with acetonitrile (27%)–acetic acid (2%) in water (73%) at a wavelength of 313 nm (HPLC system 2). Calibration curves were prepared as before using predose urine spiked with standards. The internal standard was *o*-anisic acid (600 μg in 100 μl 25% aqueous methanol), urine volumes were 100–900 μl, and the final volume was made to 1 ml with water. Elution times were: salicyluric acid, 2.30 min; *o*-anisic acid, 2.85 min; and salicylic acid, 4.29 min. Calibration curves were linear for salicylic acid (0–3.62 μmoles/ml; $r^2 = 1.000$) and salicyluric acid (0–2.56 μmoles/ml; $r^2 = 0.999$), using the final concentration as above.

Hydrolysis of Conjugates. To analyze for conjugates of salicyl alcohol, a 500-μl aliquot of urine was mixed with 250 μl water, 200 μl acetate buffer (1.1 M, pH 5.2), and 50 μl of *Helix pomatia* extract (5.5 units β-glucuronidase and 2.6 units arylsulfatase in 1 ml) (Boehringer Mannheim, Germany). After overnight incubation at 37°C, an aliquot was transferred to a vial, 500 μl of internal standard solution (benzyl alcohol, as above) added, and the volume made to 2.5 ml with water before analysis by HPLC system 1. To analyze for conjugates of salicylic acid, 200–600 μl of urine hydrolysate was transferred to a vial with 100 μl internal standard solution (*o*-anisic acid, as above) and made to 1.0 ml with water before analysis by HPLC system 2.

RESULTS

Identification of Metabolites. Metabolites were identified by their chromatographic behavior and comparison with standards. Their structures were confirmed by mass spectrometry. Initial analysis of unhydrolyzed urine using HPLC system 1 showed a small peak for salicin, but no salicyl alcohol. Acid hydrolysis (pH 1, boiling water bath, 30 min) converted the salicin into an equivalent amount of salicyl alcohol. However, after enzymatic hydrolysis, the salicin disappeared, and there was a very large amount of salicyl alcohol, more than could be accounted for by the hydrolysis of salicin alone. This indicated that there was another conjugate of salicyl alcohol that was not detected by HPLC analysis. A glucuronide conjugate subsequently was isolated from urine using a column of XAD-4 resin (see Methods and Materials for details). FAB MS showed a protonated molecular ion (MH^+) at 301.0 and several adducts with Na^+ and K^+ whose structures were supported by high-resolution data, confirming the formula $C_{13}H_{16}O_8$ that corresponds to salicyl glucuronide (Table 1). Salicin, which was found in later fractions eluting from the XAD-4 column, did not give a molecular ion, but high-resolution analysis of ions with masses corresponding to the mono- and di- Na^+ adducts agreed closely with expected values, confirming the formula of $C_{13}H_{18}O_7$.

Salicyl alcohol, salicylic acid, and salicyluric acid were identified in urine by GC-MS analysis of their methylated derivatives (Table 1). Some urine samples

TABLE 1. MASS SPECTRAL DATA OF METABOLITES FOUND IN BRUSHTAIL POSSUM URINE.

Metabolite	Derivative[a]	R_t (min)[b]	Significant EI ions [m/z (% *abundance*)]				
Salicyl alcohol		6.72	124 (M^+) (27)	106 (42)	78 (100)		
Salicylic acid	Methyl	5.75	152 (M^+) (*42*)	120 (*100*)	92 (*87*)		
Salicyluric acid	Methyl	13.27	209 (M^+) (*16*)	121 (*100*)	92 (*24*)		
β,2-Dihydoxy-phenyl propionic acid	Methyl	12.64	196 (M^+) (*66*)	178 (*3*)	123 (*100*)	121 (*34*)	95 (*90*)
		Significant FAB ions (m/z)[c]					
Salicin		309.09541 $[M + Na]^+$		331.1 $[M + 2\,Na - H]^+$			
Salicyl alcohol glucuronide	301.0 $[M + H]^+$	323.07365 $[M + Na]^+$		339.04778 $[M + K]^+$			
		345.0 $[M - H + 2\,Na]^+$		361.0 $[M - H + Na + K]^+$			

[a] Methyl ester.

[c] FAB MS using probe insertion.

also showed traces of gentisic acid by GC-MS. All urine samples contained small amounts of β,2-dihydroxyphenylpropionic acid, which gave a mass spectrum similar to that of β-hydroxyphenylpropionic acid but with ions 16 amu heavier. β-Hydroxyphenylpropionic acid is a urinary metabolite of benzoic acid (Marsh et al., 1982; Awaluddin and McLean, 1985) and β,2-dihydroxyphenylpropionic acid is the analogous metabolite of salicylic acid, containing one extra oxygen atom. β,2-Dihydroxyphenylpropionic acid was not quantified because of its small amount and interference from the hippuric acid peak.

Conjugates were confirmed by LC-MS. Salicyl alcohol glucuronide formed a dimer at m/z 599 (a feature of negative ESI) and showed a deprotonated molecular ion $[M\text{-}H]^-$ at 299. MS-MS showed significant daughter ions at *m/z* 175 and 113 (characteristic of glucuronic acid) and 123 (the anion from salicyl alcohol). Salicylic acid glucuronide showed an $[M\text{-}H]^-$ ion at *m/z* 313, glucuronic acid ions at *m/z* 175 and 113 and a salicylic acid anion at *m/z* 137. Salicyluric acid gave ions at *m/z* 194 $[M\text{-}H]^-$ and 150 $[M\text{-}H\text{-}CO_2]^-$.

Quantification of Metabolites. Predose urine gave no interfering HPLC peaks. The 24-hr recovery of urinary metabolites of salicin for the three consumption levels of salicin is shown in Table 2. The dose of salicin was calculated from the food intake on day 5 and the percentage salicin in the food. Only two thirds of the estimated dose of salicin was recovered in urine as salicin and its metabolites, except at the lowest intake of salicin when recovery was complete. Excretion of individual metabolites is expressed as the percentage of total recovered metabolites in order to enable direct comparisons between animals and doses. The proportion found as unchanged salicin varied from 10% to 18% of total recovered metabolites, while the major metabolites were salicyl alcohol glucuronide (56–64%) and salicyluric acid (15–26%). There were only traces of free salicyl alcohol and small amounts of free and conjugated salicylic acid. There was a significantly greater proportion of salicin excreted as salicyluric acid at the lowest consumption rate compared to the higher doses, but no other significant dose-related differences were found.

DISCUSSION

The major urinary metabolite of salicin in the common brushtail possum was the glucuronide of its aglycone, salicyl alcohol, while very little unchanged salicin was excreted. Thus after an oral dose the glucoside of salicyl alcohol is excreted largely as its glucuronide. The metabolic pathways are shown in Figure 1.

This suggests that there is little measurable metabolic cost in the excretion of metabolites of salicin because, although the compound has been transformed, there is little net loss of substrate in the conjugation reactions. We recognize that the enzyme systems and intermediate reactions leading to the hydrolysis of salicin and the formation of the glucuronide require energy to initiate and maintain. Similarly,

TABLE 2. URINARY METABOLITES OF SALICIN EXCRETED IN 24 HOURS AFTER THREE DIFFERENT DIETARY CONCENTRATIONS

Salicin in diet (%)	Salicin intake (μmol)[a]	Fraction recovered in urine (mean ± SD)	Urinary metabolites as % total recovered (*mean* ± *SD*)

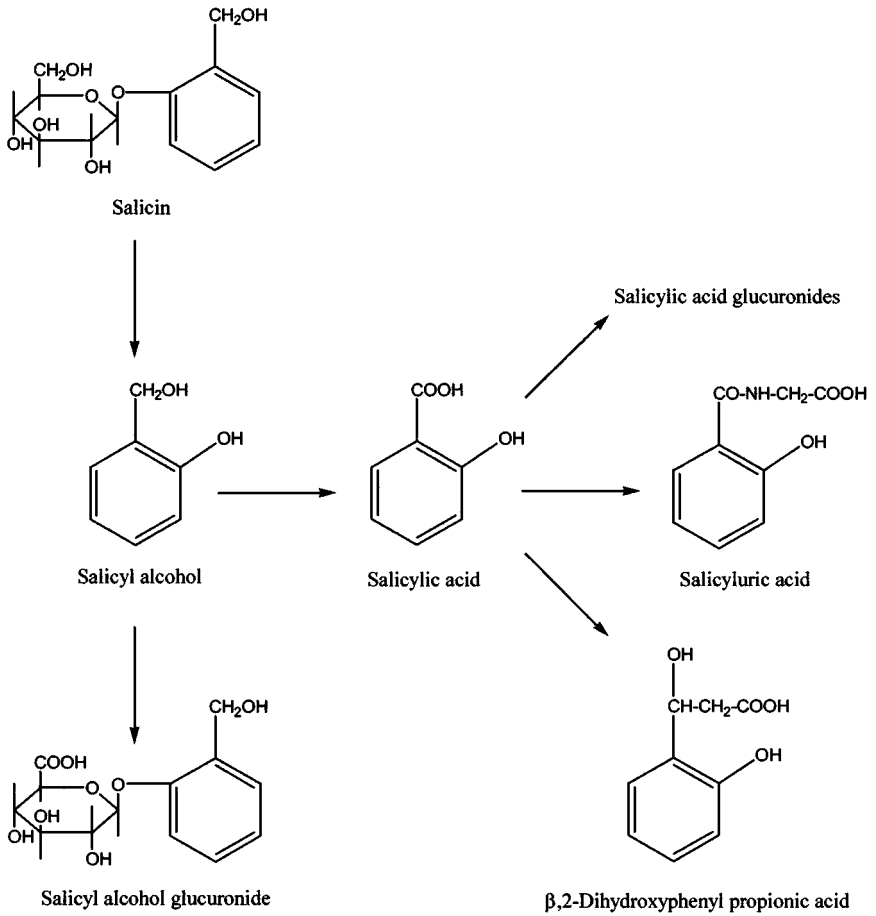

FIG. 1. Metabolic pathways of salicin in the brushtail possum.

there may be unmeasured cell damage or other metabolic disruptions that could constitute a cost, but this seems unlikely in view of the findings of Pass and Foley (2000) that ingestion of salicin did not cause measurable postingestive effects on possums. In an ecological context, the net result is that the phenolic moeity is ingested with a simple sugar derivative and excreted with a simple sugar derivative and the net cost is minimal.

The only other study of the metabolic fate of salicin used rats that were given repeated oral doses (1000 μmol/kg daily) (Fotsch et al., 1989a). Only about half (0.52) of the dose was recovered in urine, somewhat less than found in the present study after comparable doses (Table 2). The major urinary metabolites in the rat were free salicylic acid (57% of total urinary metabolites) and salicin (27%), with

smaller amounts of conjugated salicylic acid (10%), gentisic acid (4%), salicyluric acid (0.2%), and salicyl alcohol (0.2%). Apart from salicin, no urinary conjugates of salicyl alcohol were found. Thus, the metabolic fate of salicin appears to be quite different in the two species, with large amounts of salicyl alcohol glucuronide and salicyluric acid being excreted in the possum whereas salicylic acid was the major rat urinary metabolite. However, this comparison must be treated cautiously because other factors, such as diet, can influence the extent of metabolism (Mulder et al., 1990; Hutt and Caldwell, 1990).

The absorption and excretion of intact salicin may seem surprising, since it is well known that substances must be lipophilic to cross cell membranes, except where specific transport systems exist (Pratt, 1990). Salicin does not appear to interact with rabbit Na^+/glucose cotransporters (Lostao et al., 1994), whereas some other phenylglycosides (e.g., arbutin) are transported. However, Matsumoto et al. (1993) showed that salicin and other monosaccharides are able to permeate the cell membranes of human erythrocytes, although they do so more slowly than the more lipophilic aglycones. Whether this occurs by a paracellular pathway is not known.

After subcutaneous administration of salicin to rats, most of the dose was recovered unchanged in urine, indicating that the hydrolysis of oral doses occurs in the gut (Fotsch and Pfeifer, 1989). In vitro experiments by these authors showed that salicin was hydrolysed by rat caecum or colon contents, but not by liver homogenates.

A broad-specificity β-glucosidase has been found in guinea pig liver that is capable of hydrolyzing various plant glucosides including salicin (LaMarco and Glew, 1986; Gopalan et al., 1992). These authors postulated that the hepatic glucosidase may have evolved as a response of herbivores to the presence of toxic plant glucosides, such as the cyanogenic glycosides amygdalin and prunasin, and vicine, which can cause hemolytic anemia. Gopalan et al. (1992) showed that these three plant glucosides were able to cross segments of guinea pig jejunum in vitro without hydrolysis. Since lipid-soluble substances are reabsorbed from the renal tubules (Pratt, 1990), glucosides with sufficient hydrophobic character to be absorbed from the gut are also liable to be reabsorbed from the renal tubules, resulting in a low renal clearance. However, after hydrolysis, the aglycone can be conjugated with a more polar sugar, glucuronic acid, enabling more efficient renal excretion. Although cecal microorganisms can hydrolyze glucosides, any that are absorbed from the small intestine will escape microbial hydrolysis (unless secreted in the bile). The hepatic glucosidase would be in position to hydrolyze absorbed glucosides, enabling their reconjugation with glucuronic acid. Our data showing the hydrolysis of salicin and reconjugation of its aglycone to salicyl alcohol glucuronide are consistent with this proposed mechanism.

A simple oxidation reaction could convert salicin directly to the corresponding glucuronide, but there is no evidence that this reaction occurs. The glucuronic

acid in conjugates is formed by a specific enzymatic oxidation of UDP-glucose (Mulder et al., 1990), indicating that other glucosides would not be suitable substrates. It is also unlikely that salicyl alcohol is reconjugated with glucose, as β-glucoside formation is very uncommon in mammals, although an unusual α-glucoside formation has been reported in rat liver (Kamimura et al., 1992). When 1-naphthol-β-glucuronide was administered orally to mice, no glucoside was excreted, but administration of 1-naphthol-β-glucoside resulted in the excretion of both the glucoside and glucuronide (Chern and Dauterman, 1983).

Although little has been published on the fate of salicyl alcohol or salicin, there is a vast literature on the metabolism of salicylic acid, the oxidation product of salicyl alcohol (Scheline, 1991). There is considerable variability between and within species in the urinary metabolites of salicylic acid (Scheline, 1991). In the brushtail possum, only traces of free salicyl alcohol appeared in the urine, with small amounts of free and conjugated salicylic acid (presumably the glucuronide), while the major salicylate was the glycine conjugate, salicyluric acid (Table 2). There was relatively less salicyluric acid excreted after the higher doses of salicin, suggesting that the glycine conjugation pathway may be readily saturable in the brushtail possum, as in other species (Hutt and Caldwell, 1990). Other factors including diet and gut microorganisms also can be important determinants of glycine conjugation (Phipps et al., 1998).

This is the first report of the formation of β,2-dihydroxyphenylpropionic acid as a salicylate metabolite. It was presumably formed from the acyl-CoA of salicylic acid, in an analogous fashion to the postulated formation of β-hydroxyphenylpropionic acid from benzoic acid (Marsh et al., 1982). This may represent a general reaction of acyl-CoAs, as it has now been seen for benzoic acid in the horse and rabbit (Marsh et al., 1982), as well as in rats, seven marsupials (including the brushtail possum), and the echidna (a monotreme) (Awaluddin and McLean, 1985). Acyl-CoAs are intermediates in the formation of amino acid conjugates (Hutt and Caldwell, 1990), and the β-hydroxy metabolite has always been seen in animals that form acylglycine conjugates.

Although alcohols and phenols can form sulfate conjugates, there was no evidence of this occurring. Sulfate conjugates have not been reported for salicylic acid, and the brushtail possum is considered to have a low capacity for sulfatation (Baudinette et al., 1980).

Both Fotsch et al. (1989a) and we, in the present study, could recover only part of the salicin consumed. In the present study, some errors may be due to uncertainty in estimating the dose consumed and loss of some of the urine. Some metabolites may have been excreted in bile and eliminated in the feces. There is also the possibility of the formation of unknown metabolites. Chern and Dauterman (1983), using a ^{14}C label, found that oral administration of 1-naphthol-β-glucoside to mice resulted in the urinary excretion of a considerable amount (15–33% dose) of unidentifiable polar material, suggesting the formation of unknown metabolites.

This was not seen after administration of 1-naphthol or its glucuronide. As in the present study, they also found an inverse relationship between the dose of glucoside and both the fraction of dose recovered, and the proportion excreted unchanged in the urine.

Acknowledgments—We thank Mr Robert Gegg for assistance with maintenance of captive animals.

BEHAVIORAL AND ELECTROPHYSIOLOGICAL RESPONSES OF *Arhopalus tristis* TO BURNT PINE AND OTHER STIMULI

(Received July 5, 2000; accepted February 3, 2001)

Abstract—The exotic longhorn beetle *Arhopalus tristis* is a pest of pines, particularly those damaged by fire, and a major export quarantine issue in New Zealand. Actinograph recordings of caged individuals showed that males and females were most active from dusk to midnight. Olfactometer experiments indicated that females moved upwind toward odors from burnt pine (80%, $N = 75$), compared to unburnt pine (20%). Oviposition choice tests showed that eggs were predominantly laid on burnt logs (79%, $N = 20$), compared to unburnt logs. Beetles were trapped by funnel traps baited with burnt (mean catch per trap 7.8) and unburnt (mean catch 4.1 per trap) pine bark from inside a screen cage (4×3 m), while unbaited traps had a mean catch 0.1 beetles ($N = 8$ replicates). The treatment of burnt pine bark with a 1:1:2 mixture of green leaf volatiles (*E*)-2-hexen-1-ol and (*E*)-2-hexenal) in mineral oil as a repellent reduced trap catch by fivefold in a similar experiment (mean catches of 1.2 beetles per trap to burnt pine bark plus repellent treatment and 6.2 beetles per trap to burnt pine bark alone). The treatment of burnt pine bark with this solution also reduced oviposition by 98.5% (mean eggs per log of 11.1 on burnt pine and 0.3 on burnt pine plus repellent), indicating that oviposition cues have the potential to be significantly disrupted. The electrophysiological responses of adult beetles were recorded to a range of odorants. Normalized responses to monoterpenes known to occur in *Pinus radiata* ranged from about 20 to about 150, with α-terpineol giving the greatest responses in both sexes. Green leaf volatiles also gave high responses. The potential exists to improve the management of this insect using chemical cues in various ways.

Key Words—Attractant, *Pinus radiata*, *Arhopalus tristis*, fire, smoke, trap, Cerambycidae, oviposition, bark, repellent.

*To whom correspondence should be addressed.

The burnt pine longhorn beetle, *Arhopalus tristis* (F.) (Coleoptera: Cerambycidae), is native to Europe, Asia, and North Africa (Villiers, 1978). This species was accidentally introduced to New Zealand, probably in the 1950s, and it has since spread throughout the country (Hosking and Bain, 1977). Most references from New Zealand refer to *A. ferus* (Mulsant), but this is an older synonym of *A. tristis*.

Arhopalus tristis has been recorded to attack logs, stumps, and standing dead or damaged trees of pine species (*Pinus* spp.) and, less commonly, Norway spruce [*Picea abies* (L.) Karst] (Freude et al., 1966; Brockerhoff and Hosking, 2001). However, *A. tristis* is best known for its spectacular attacks of scorched trees within a few days to weeks of a forest fire (Hosking and Bain, 1977; Bradbury, 1998), a habit that is shared with other Palaearctic and Nearctic species of *Arhopalus* (e.g., Eaton, 1959; Wickman, 1964; Ehnström et al., 1995). The life cycle of *A. tristis* and the damage caused in New Zealand were described by Hosking and Bain (1977), Brockerhoff and Hosking (2001), and Bradbury (1998). Eggs are usually laid in bark crevices and the larvae feed first in the phloem area but later tunnel up to 10 cm deep into the wood. The risk of timber damage resulting from tunneling by *A. tristis* greatly reduces the salvage time for fire-damaged trees. In addition, *A. tristis* is a major vector of sapstain fungi such as *Ophiostoma* sp., *Sporothrix* sp., and *Graphium* sp. (Bradbury, 1998; Suckling et al., 1999), which further reduce the value of salvaged wood. Aside from this direct damage, *A. tristis* is frequently reported as sheltering in sawn timber at sawmills and in ports. Sawn timber destined for export is fumigated to meet quarantine regulations (Brockerhoff and Hosking, 2001; Cross, 1991). However, the fumigant currently in use (methyl bromide) (Cross, 1991), is being phased out. Alternative treatments or other pest management methods are therefore urgently needed to support timber exports.

The management of other forest and timber pests, for example, bark and ambrosia beetles, often involves the use of attractants such as pheromones and host plant volatiles (e.g., Borden, 1995; Jones, 1998). A strong attraction to odors emanating from forest fires or burnt trees has been documented for some cerambycids and buprestids specializing in the exploitation of postfire habitats (Gardiner, 1957; Parmelee, 1941; Ross, 1960; Evans, 1972, 1973). Circumstantial evidence that *A. tristis* is attracted by odors emitted by burnt pine, peeled bark, and sawn timber suggests that odorants could possibly be used for monitoring and managing populations of this beetle in ports, sawmills, and after forest fires. This could be achieved with an attractant for *A. tristis*, which could also be used in novel pest management tactics such as lure and kill (Suckling and Karg, 2000). Recently it has been established that antennae of a beetle attracted to postfire habitats are specifically tuned to perceive fire-associated volatile compounds (Schütz et al., 1999). Thus, we hypothesize that *A. tristis* also shows an olfactory response to fire-associated compounds and that the olfactory system is tuned to these. Here, we report results of a study investigating behavioral responses from *A. tristis* to

burnt pine odors. We also report results of electroantennogram (EAG) studies investigating responses to individual compounds typically emitted by pines, along with a range of other odorants. In addition, results on the daily activity pattern and local abundance within sawmills are reported.

METHODS AND MATERIALS

Insects. A preliminary experiment was conducted to determine relative beetle density at pine forest and sawmill locations, in order to focus future efforts at beetle collection. Passive funnel traps, consisting of two clear plastic cross vanes mounted above a plastic funnel held above a collecting jar were placed at three sawmills and two sites in *P. radiata* stands at Ashley forest (three replicates per site) near Christchurch, New Zealand. Traps were checked weekly. Based on the greater abundance of beetles at the sawmills, collections for experiments were made at two sawmills. Beetles were collected using passive funnel traps and manual collection after dark (20:00–22:00 hr, see below). To establish the relative abundance of beetles within sawmill sites, the location of collected beetles was recorded from the following areas: old and new sawn timber stacks, around a freshly peeled bark stack, and around drying kilns. The number of beetles present was recorded in the following abundance classes: <5, 6–20, 21–50, 51–80 (hence standard errors are not presented with these data). Beetles were placed individually in plastic Petri dishes (60 mm diam.) with a damp cotton wad to provide sufficient humidity, and kept outdoors under a shelter until used in bioassays. The use of individual containers avoided damage due to fighting, especially among males. Only fit beetles showing normal responses to disturbance were used for bioassays.

Diurnal Activity. The aim of this experiment was to determine the natural period of activity and therefore the best time for conducting behavioral assays with beetles and making field collections. An activity recorder was constructed from a rectangular stainless steel gauze mesh cage $80 \times 70 \times 60$ mm mounted over a sensor window (60×40 mm and shielding an infrared movement detector) as the floor of the cage. The size of the cage was determined by the need to keep the beetles within range of the detector. The apparatus was maintained outdoors under a lean-to roof with natural light. The detector was linked to a data logger (model CR10, Campbell, Logan, Utah), which recorded the number of movement events large enough to trigger the sensor, in successive 1-min periods. Male ($N = 12$) or female ($N = 12$) beetles were placed individually in the cage in the afternoon and records obtained over the following 24 hr.

Olfactometer. An apparatus was constructed from a 20-liter food-grade inert plastic cylinder, 400 mm long $\times$ 300 mm diam., with a plastic funnel attached to each end. Each funnel led to a plastic pipe (35 mm diam.) with a right angle bend ending in the middle of a trap jar with a gauze base and smooth sides, designed

as a one-way system (Figure 2 below). Air was drawn from the geometric center of the cylinder at around 12 liters/min, and the olfactometer inlets passed either over strips of freshly peeled bark or over freshly peeled burnt bark before entering via the two opposing traps. Beetles were unable to touch the bark before making an irreversible choice of trap. The orientation of the apparatus was reversed after each run to control for any potential biases. Groups of 15 quiescent female beetles were placed in the center of the barrel at 16:00 hr (before activity commenced with scotophase) and the pump was programmed with a time switch to run for the first 4 hr of darkness (20:00–24:00 hr), based on the activity cycle determined earlier. The pump was therefore switched on 1 hr before significant beetle activity began. The following morning, the number of beetles in each trap was counted. This approach minimized the duration of pump operation, while operating during the period of most beetle activity. All beetles able to do so made a choice. The exceptions were three beetles that died in the center of the barrel, and two that were trapped there.

Oviposition Choice. A choice test for oviposition site preference was performed using a covered cylindrical arena made from metal gauze (190 mm diam. × 160 mm high), placed over a base of moist sand. Two short sections of *P. radiata* branch (ca. 15 cm long × 5 cm diam.) were placed vertically on the sand on opposite sides of each arena, touching the mesh on the outside of the arena. One branch (treatment), was freshly burnt with a gas torch on the side adjacent to the arena until the outside bark surface was scorched and one (control), was left unburnt. Branch sections were cut from living *P. radiata* and were used within two days. Adjacent sections were used for paired treatments in each arena so that differences in bark roughness or other characteristics were minimized. Two field-collected beetles were placed in the arena, and the top of each arena was covered with a Perspex sheet. Branch positions were alternated between adjacent arenas and also between successive replicates with the same arena. The minimum distance between adjacent arenas was 20 cm.

The arenas were set up in a darkroom with an exhaust fan, expelling air through a 30-cm-diameter duct at 1.8 m/sec, ensuring regular slow clean air replacement. Arenas were set up between 16:00 and 18:00 hr, and eggs were counted the following morning. The room was kept in darkness once the assays were set up, until the following morning when the number of eggs laid on or adjacent to burnt and unburnt *Pinus* sections was counted under a binocular stereo microscope. Eggs laid at the base of each log, between the log and the sand surface (ca. 20% of total eggs laid) were counted, along with those laid on the bark of the log itself. Between replicates, the sand surface was scraped clean to remove any eggs and was moistened again if necessary. The gauze cylinders were brushed clean of any attached eggs and rotated, to present different sectors adjacent to logs in successive trials.

Oviposition Repellency. The above oviposition choice test was repeated in an exploratory experiment on repellency, except that both logs in the choice test were

burnt, and a repellent was applied to one of the logs, before the experiment. The choice of two green leaf volatile compounds tested as a repellent was based on the knowledge that such green leaf volatiles have been found acting as repellents in other species (Dickens et al., 1992; Wilson et al., 1996), in conjunction with the observation that these particular compounds were active in the EAG tests. The repellent mixture was made up of 25 ml each of (*E*)-2-hexen-1-ol and (*E*)-2-hexenal and 50 ml of mineral oil (1:1:2), applied as a liquid at about 35 ml of green leaf volatiles per square meter of log surface ($N = 7$ replicates). The use of mineral oil would have considerably reduced the release rate (Brockerhoff and Grant, 1999).

Field Cage Experiments. These experiments were designed to determine the relative attractiveness of burnt compared to unburnt bark as a lure in a trap, using a known and confined population of beetles. Cylindrical Perspex funnel traps (300 mm × 120 mm diam., with a screen funnel at each end) were used. Burnt (a) and unburnt (b) bark strips were used as lures and catches were compared with unbaited controls containing no bark (c and d). A screened field cage (3 × 4 m) with a roof and floor was used for the trials. Trap cylinders were lined with Mylar sheets, which were replaced after each trial to reduce the possibility of odor contamination of the traps. The four traps (a–d) were placed on the ground, one in each corner of the cage (ca. 300 mm from the wall). Beetles ($N = 20$) were placed on the floor in the center of the field cage at 16:00 hr. Beetles could enter the trap through holes at the apex of each cone but were then unable to leave the trap. Beetles were not able to touch the bark lure inside the trap until after they had entered. The location of trapped beetles was recorded the following morning. The array of four traps was rotated 90° between trials to control for any inherent directional biases, such as sources of light or external odors. The bark strips were replaced after two days. Each bark lure consisted of three strips, each 100 × 40 mm, and the burnt strips were burned as described above. Bark strips were cut from smooth bark on the surface of logs less than 150 mm diam. within 14 days of the trees being felled.

Repellency Test. The trapping test described above was repeated in another exploratory test of repellency, except that the repellent [1 : 1 : 2 of (*E*)-2-hexen-1-ol and (*E*)-2-hexenal in mineral oil as above] was applied to the bark strips in one of the treatments, before the traps were baited ($N = 6$ replicates).

Electroantennograms. EAGs were recorded using excised antennae. These were stimulated with a range of monoterpenes known to be constituents of *P. radiata* bark headspace (Zabkiewicz and Allan, 1975) or oleoresin (Burdon et al., 1992) as well as several other widely available compounds, included to broaden the range screened. Filter papers (5 × 20 mm) were loaded with 10 μl of 10% solutions of each compound in hexane. Antennae were stimulated three times with each substance at 30-sec intervals. The reference standard (α-pinene) was tested at the beginning and end of each series and after every two test substances. The

sequence of substances was changed for each antenna ($N = 10$ for males and 10 for females). Electroantennogram recordings were made using an INR-02 recording unit with amplifier and computer board (Syntech, Hilversum, The Netherlands) and stored on hard disk. Responses were normalized to the reference standard by dividing sample responses by the mean of temporally adjacent responses to the reference standards. Preliminary tests indicated EAG responses to the odors from burnt wood, but no pure chemicals derived from this source were available.

Chemicals. The source and listed purity of the compounds used are shown below. Sigma: farnesol (96%), *n*-decyl alcohol (99%), phytol (97%), (*E*)-2-hexenal (98%), nerol (97%), γ-terpinene (97%), α-humulene (>90%), (−)-(*E*)-caryophyllene (>90%), eugenol (>90%), nerolidol (>90%), (+)-limonene (97%), benzaldehyde (>90%), (±)-2-octanol (>90%), 1-hexanol (98%), 1-heptanol (99%), 1-octanol (98%), 1-nonanol (98%), β-myrcene (90%), α-terpinene (85%), citral (95%), (±)-linalool (95–97%), geraniol (98%), citronellal (85–90%), butanol (99%), (*Z*)-3-hexen-1-ol (>90%); Aldrich Chemical Co.: 3-carene (90%), (1*S*)-(−)-β-pinene (99%), (1*R*)-(+)-α-pinene (98%), terpineol (mixed isomers, approx. 95% α-terpineol); (*Z*)-3-hexyl acetate (99%), amyl acetate (99%), amyl alcohol (99%), benzyl alcohol (98%), (*E*)-2-hexen-1-ol (96%); Merck: α-phellandrene (>80%).

Statistics. Trap catch data were analyzed by *t* test. Olfactometer, repellency, and oviposition choice data were analyzed by paired *t* test. ANOVA was conducted on beetle catches in the field cage tests, followed by a Tukey test to separate treatments. The relationship of male and female EAG responses was examined by correlation analysis. Vertical bars show standard errors of means throughout. Data were analyzed using Minitab or SYSTAT 9.

RESULTS AND DISCUSSION

Diel Periodicity. Both sexes were most active from 21:00 to 24:00 hr, although females showed a broader activity period, including parts of the photophase (Figure 1). There was also some evidence of a secondary peak in male activity around dawn. This primary activity pattern during the early scotophase was confirmed by video analysis of beetle behavior in larger cages, which indicated long periods of continuous movement over this diel period (unpublished data). Bioassays were carried out in the early scotophase, based on these findings.

Field Occurrence. Passive traps used to assess the occurrence of *A. tristis* populations at several locations revealed that mean catches were much higher near sawmills [85.7 ± 29.3 beetles (SEM)] than in pine forests (4.5 ± 3.5 beetles; *t* test on log transformed data: $t = 3.95$, $P = 0.02$; $df = 3$). This led to the focus on sawmills for subsequent beetle collections. It is not known whether *A. tristis* were

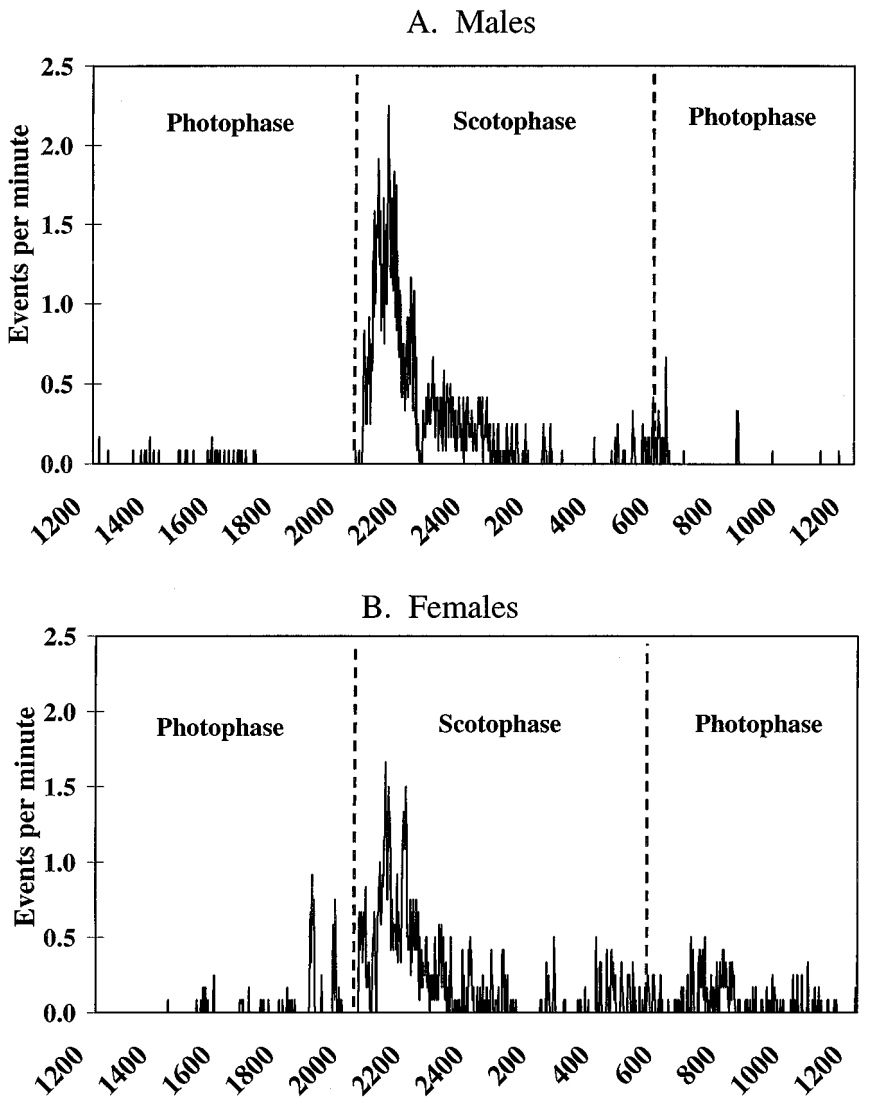

FIG. 1. Diel periodicity of male (A) and female (B) *Arhopalus tristis* movement activity outdoors under natural light as determined by a motion sensor.

brought with logs from the forest to the sawmills and accumulated there or whether they were attracted to the sawmills from surrounding forest areas, independently of log movements. It has also been observed that *A. tristis* breeds in reject logs and other suitable material on site (G. Hosking, personal communication). Most

beetles collected manually during the scotophase at the sawmill were either walking around on the ground or resting on vertical surfaces of timber stacks or wooden structures in the yard. Only three beetles were observed flying, out of a total of nearly 1000 collected individually. Most beetles were collected either near the drying kilns (36 beetles per night) or piles of freshly peeled bark (36 beetles per night), with few collected near sawn timber stacks (5 beetles per night). The first two areas were both concentrated sources of pine volatiles, clearly perceptible to the authors. These results suggest that olfaction might be playing an important role in the beetle behavior.

Olfactory Orientation. In olfactometer bioassays, female beetles showed a very strong preference (80%) for odors associated with burnt over unburnt bark (Figure 2) (paired t test, $t = 2.57$, $P = 0.0002$, $df = 5$). In the field cage experiments, females clearly responded to odorants from both burnt and unburnt bark, and very few beetles were found in the blank traps, which were then pooled (Figure 3; $F_{2,29} = 26.0$, $P < 0.0001$). In this case, the choice of burnt over unburnt bark was only marginally significant (paired t test, burnt versus unburnt $t = 2.01$, $P = 0.07$, $df = 11$). The bark strips used for the field cage trapping experiment had been freshly peeled from recently cut logs, suggesting the release of volatiles from the torn cambium may have been high from both burnt and unburnt strips. However, the composition of volatiles emitted from burnt bark will undoubtedly be different from that of fresh bark (Lomax et al., 1991). A related North American species,

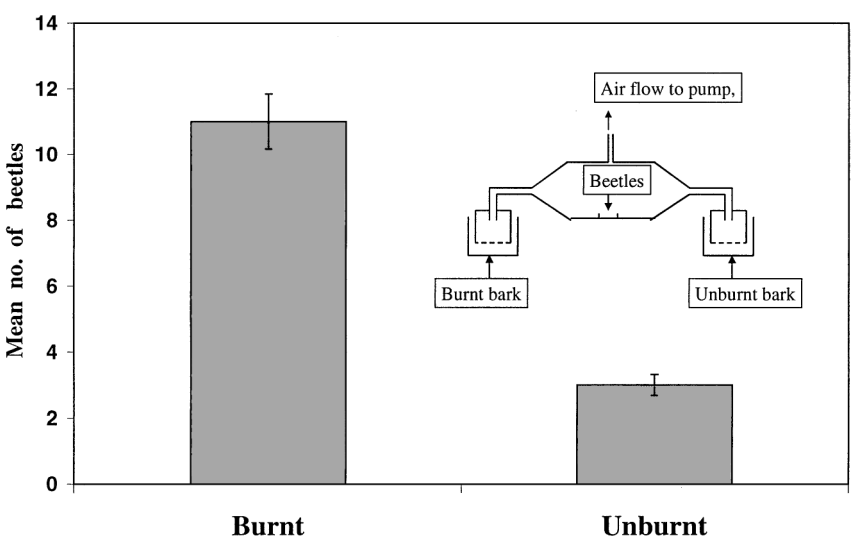

FIG. 2. Preference of female *A. tristis* in an olfactometer test (schematic) between burnt and unburnt bark of *P. radiata* ($N = 5$ replicates).

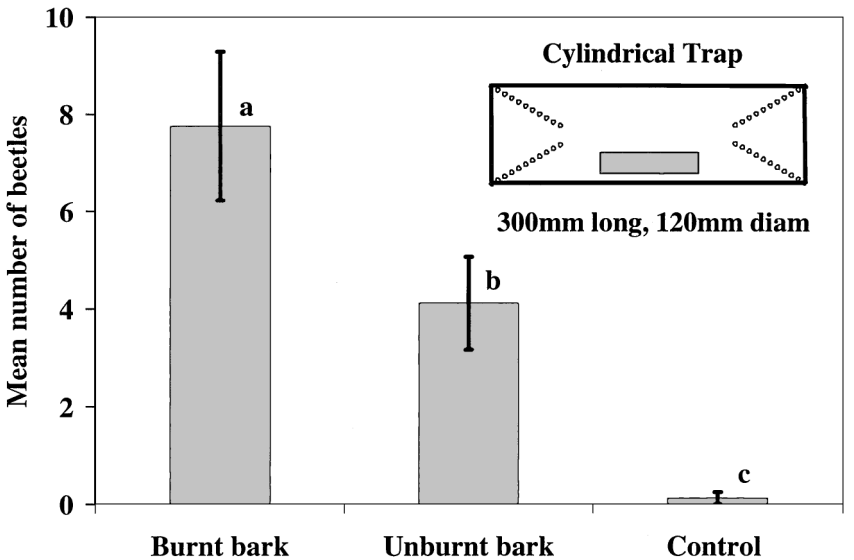

FIG. 3. Number of female *A. tristis* trapped in cylinder traps (schematic) to burnt and unburnt bark of *P. radiata* ($N = 8$ replicates) in a field cage. Treatments with different letters are significantly different according to a Tukey test.

A. asperatus (LeConte), is also known to be particularly attracted by freshly scorched trees (Wickman, 1964).

Repellency Test. Because green leaf volatiles have been reported to disrupt the attraction of beetles to odorants (Dickens et al., 1992; Wilson et al., 1996), we examined whether they may act as repellents for *A. tristis*. The repellent significantly reduced the proportion of beetles trapped in the field cage to treated burnt bark ($N = 88$ beetles in total), compared to burnt bark without repellent ($t = -3.97$, $P = 0.0014$, $df = 14$), by a factor of approximately five (Figure 4). This result suggests that the repellent is active, and hence it may be possible to reduce host location behaviors in the field. The rate used here was very high, and further experiments would need to explore the dose response.

Oviposition Choice. In choice tests, female beetles laid the majority of their eggs (87.6%) on burnt rather than unburnt pine bark (Figure 5) ($N = 558$ eggs laid by 20 female *Arhopalus*, summed over two nights per insect). This difference was highly significant (paired t test on log transformed data, $t = -3.35$, $P = 0.002$, $df = 37$). Because these assays were conducted as choice tests, differences in fecundity among individual females could not have biased the results. Beetles were observed to prefer to lay eggs in areas that were lightly rather than fully scorched, although this was not specifically quantified. This suggests that the attraction of *A. tristis* to

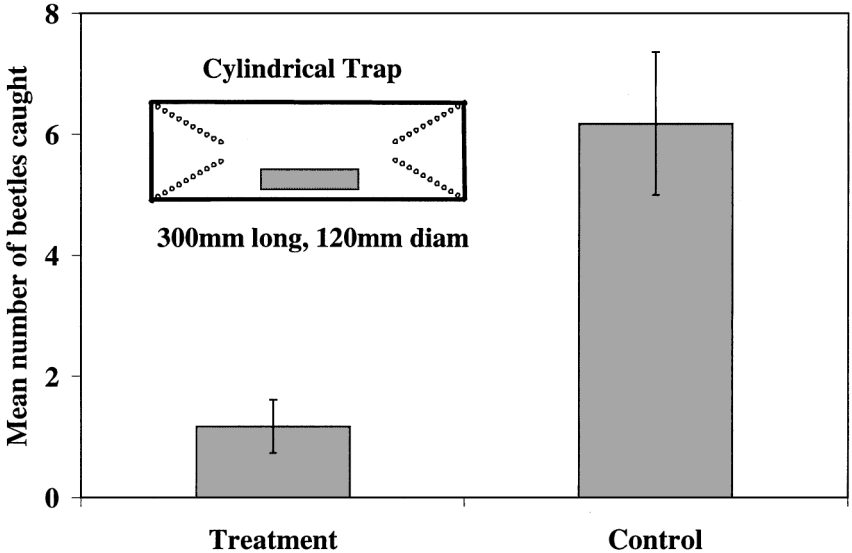

FIG. 4. Effect of green leaf volatile-based repellent treatment applied in mineral oil to strips of burnt *P. radiata* bark on the number of *A. tristis* trapped with strips of treated and untreated burnt bark in field cage trials ($N = 6$ replicates).

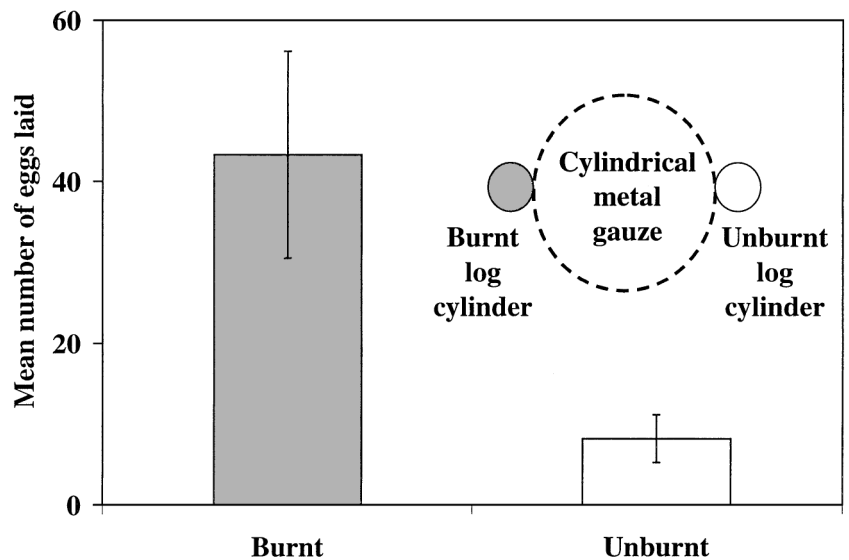

FIG. 5. Preference of female *A. tristis* for oviposition in a choice test of burnt and unburnt logs of *P. radiata* ($N = 5$ tests).

burnt trees may be related to such habitats representing the occurrence of a favored oviposition substrate.

Oviposition Repellency. Green leaf volatiles were also used as potential repellents in the oviposition bioassay. The oviposition test indicated a 98.5% reduction in number of eggs laid on burnt logs treated with the repellent, compared to burnt logs without the repellent (Figure 6). This result indicates that the repellent mixture reduced the suitability of the bark surface for oviposition (paired t test on log transformed data, $t = 4.82$, $P = 0.0001$, $df = 8$). If the repellent was as effective in the field at economically viable application rates, a reduction in egg laying of this magnitude could be expected to have significant potential for pest management, by reducing colonization and potentially vectoring of sapstain.

Electroantennograms. Males generally showed higher EAG responses than females, although there was a high correlation between sexes in olfactory response ($r^2 = 0.948$, $df = 35$). This was despite the considerable differences in the number of several types of olfactory sensillae on antennae of male and female *A. tristis* (Hosking, 1982). Males have more sensillae chaetica, suggesting this receptor type may be most relevant to the perception of monoterpenes and green leaf volatiles. Both sexes showed strong EAG responses to the monoterpenes recorded from *P. radiata*, with the highest responses to α-terpineol and (1*R*)-(+)-α-pinene (normalized values of 100.0 $\pm$ 0.0 and 102.1 $\pm$ 7.4 for females and 100.0 $\pm$ 0.0

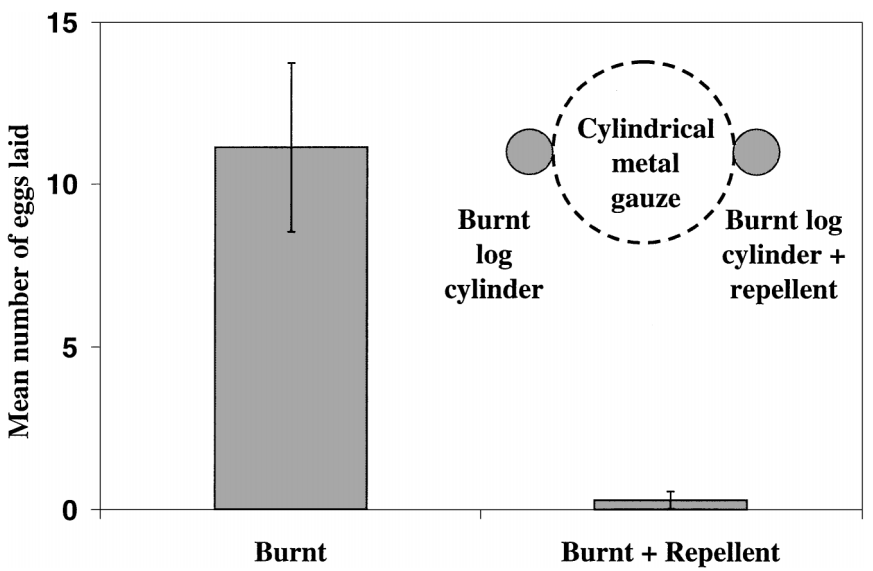

FIG. 6. Effect of green leaf volatile-based repellent treatment applied in mineral oil to burnt logs on the number of *A. tristis* eggs laid on treated or untreated burnt *P. radiata* logs in field cage trials ($N = 6$ trials).

and 149.8 ± 24.2 for males, for the compounds, respectively). Monoterpenes were among the compounds found in volatiles from smoldering wood to which *Melanophila acuminata* DeGeer (Buprestidae), a beetle also attracted to burnt pines, showed high EAG responses (Schütz et al., 1999). However, volatiles from burnt pine wood contain additional, fire-specific compounds that appear to be more important during habitat location by *M. acuminata* (Schütz et al., 1999). The green leaf volatile (*Z*)-3-hexen-1-ol, which was in the repellent mixture tested in reduced attraction and oviposition assays, elicited strong EAG responses (82.1 ± 12.2 and 108.0 ± 12.7 for females and males, respectively), indicating that antennae have receptors for such compounds. Detection of such green leaf compounds could have a functional role for the insect as an indicator of habitat quality, being normally low in the atmosphere immediately after a fire (when host tree quality appears to be most suitable for colonization), but rising as the fire-damaged area was colonized by other plants, indicating a probable decline in the beetles' preferred ecological niche. The least active compounds included phytol, *n*-decyl alcohol, and farnesol (EAG values for both sexes in the range of 15–25% of the standard, α-pinene).

These experiments have demonstrated that olfactory cues are involved in the attraction of *A. tristis* to areas of forest affected by fire or areas with high levels of volatiles associated with burnt or unburnt logs and with sawmills. Numerous ecological adaptations can be observed in insects occurring in forest ecosystems that are naturally prone to regularly experience fires such as boreal forests (McCullough et al., 1998). Our experiments provide further evidence of how such insects are behaviorally and physiologically adapted to exist in such an environment and even exploit these conditions to their advantage. Prospects for applying attractants in the management of *A. tristis* in the forest, at ports, or in sawmills are illustrated by the example of successful trapping of a North American species, *A. rusticus obsoletus* (Rand.), using natural turpentine and ethanol as a lure (Fatzinger et al., 1987). However, attempts to attract *A. tristis* with a comparable blend have so far been unsuccessful (unpublished data). Better traps could be devised if the active components in the blend of volatiles were known (e.g., Schütz et al., 1999), but more experimentation is needed to establish this for *A. tristis*. There are also prospects of using green leaf volatiles as repellents for *A. tristis*. Our results suggest such compounds reduce the attraction of beetles to otherwise attractive host material, and they also reduce oviposition stimuli associated with burnt bark. The ecological significance of these findings could be comparable to that suggested for bark beetles, which presumably perceive green leaf volatiles as nonhost indicators (i.e., broadleaved tree species) (Dickens et al., 1992; Wilson et al., 1996). This repellent could potentially be used to avoid infestations after fires, by reducing postfire colonization and oviposition, and may reduce quarantine problems with export timber products.

Attractants could be useful for pest management by helping forest managers estimate field populations in order to determine the appropriate response to forest fires, etc. Improved trapping systems could also aid in the quarantine risk management of export logs destined for markets where this insect is not present.

Acknowledgments—We would like to acknowledge the help of the managers and staff of Keighleys Waimak Sawmill and McVicars Sawmill of Christchurch, New Zealand, for their cooperation in providing access to their sites for *Arhopalus* trapping and collection, and to the Selwyn Plantation Board for providing logs. We thank G. Hosking, D. Rowan, and Q. Wang for helpful comments on the manuscript. This work was supported by the Foundation for Research, Science and Technology under CO6630.

Abstract—Neurons from chemosensory hairs on the galeae of adult Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say), were investigated for responses to glycoalkaloids of the family Solanaceae. While solanine and tomatine elicited irregular firing by multiple neurons and bursting activity at 1 mM concentration in most sensory hairs, stimulation with leptine I resulted in consistently high-frequency, slowly adapting responses with a dose-dependent effect between 0.03 and 0.3 mM concentrations. Responses to a mixture of solanine and leptine I suggested possible modification of the leptine I response by other glycoalkaloids, resulting in reduced neural activity relative to leptine I alone. These results establish a method for specifically evaluating leptine I and other glycoalkaloids for effects on feeding behavior of CPB and provide a sensory component for incorporating deterrent chemistry into biorational control methods for the CPB.

Key Words—Gustation, taste, feeding deterrent, leaf beetle, potato, receptor neuron, glycoalkaloids, Colorado potato beetle, Chrysomelidae.

INTRODUCTION

The Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say), is a major pest of potato, *Solanum tuberosum* (L.), throughout the world. Adaptability of the CPB and heavy use of synthetic pesticides for control has led to development of insecticide resistance in the insect and a shifting focus towards alternative,

multifaceted control options. For example, information on feeding deterrents (Murray et al., 1996) and attractants (Dickens, 1999, 2000) could be incorporated into attracticide bait formulations and "push-pull" strategies of control, where insects are repelled by resistant or deterrent plants in combination with attracticide baits. Glycoalkaloids in potato have long been implicated as resistance factors against the CPB, specifically the leptines associated with *Solanum chacoense* Bitt. (Stürckow and Löw, 1961; Tingey, 1984), and breeding efforts have attempted to incorporate this natural resistance mechanism into control programs for CPB (Lawson et al., 1993; Tingey and Yencho, 1994).

Evidence continues to accumulate associating resistance with leptines. Significant differences between high- and low-leptine *Solanum chacoense* Bitt. clones for five resistance parameters (adult counts, adult feeding damage in the field, adult feeding on leaf disks, larval development, and larval survival) were directly related to concentration of foliar leptines in a study by Sinden et al. (1986). Sikinyi et al. (1997) showed reduced leaf area consumption and increased larval mortality on *S. chacoense* vs. *S. tuberosum*. Larval growth and development were reduced in a dose-dependent manner on artificial diets containing leptine I (Kowalski et al., 1999), although overall purity of the compound was only 60%.

Although there is evidence for a relationship between foliar leptine levels and resistance to CPB for *S. chacoense*, the mechanism or mode of action through which resistance is imparted has remained an open question. Stürckow and Löw (1961) first observed reduced feeding on potato foliage infused with leptine I. Tingey and Yencho (1994) labeled the leptines as potent antifeedants based on reduced feeding rates of adults on potato leaf disks from susceptible (*S. tuberosum* var. Kennebec) and resistant (*S. chacoense*) clones (from Sinden et al., 1986, 1988). Behavioral effects for adults and larvae in the field have been related to leptine levels alone among a number of glycoalkaloids (solanine, chaconine, leptinine I, and leptinine II) analyzed, indicating a feeding deterrent effect (Yencho et al., 2000). The relationship between the observed feeding effects and sensory detection of glycoalkaloids, however, has remained unclear. Leptines have been implicated as feeding deterrents and resistance has been attributed to the presence of these compounds, but these conclusions are based upon partial analysis of whole leaf chemistry. Since leptines of high purity have not been individually tested, the observed effects could be due to synergism with unknown components or other unidentified compounds in the foliage.

Harrison and Mitchell (1988) performed detailed behavioral observations on sampling and first meal feeding behavior of adult CPB on various host plants differing in glycoalkaloid content. Although they did not investigate *S. chacoense*, they questioned the assumption that glycoalkaloids act directly on the sensory system to inhibit feeding, raising the point that such conclusions have been based upon long-term feeding experiments. The possibility of postingestive effects on feeding behavior was discussed, as they found no inhibition of first meal feeding or

altered sampling behavior associated with the glycoalkaloid tomatine, concluding there was no evidence to indicate tomatine acted on the sensory system. The only studies investigating the effect of glycoalkaloids on CPB chemosensory neurons illustrated irregular firing by several neurons housed within sensilla on the tibia and tarsus (Stürckow, 1959) or the galea (Mitchell and Harrison, 1985; Mitchell, 1987). The firing pattern was often burstlike for glycoalkaloids, with the first burst of activity delayed by several seconds after stimulation. They concluded that there was no specialized chemoreceptor in CPB for the glycoalkaloids tested: solanine, chaconine, and tomatine. A survey of responses to seven other alkaloids (strychnine, caffeine, quinine, papaverine, sparteine, atropine, and arecoline) in adult CPB galeal chemosensilla also revealed no specific deterrent receptor for this class of compounds (Mitchell, 1987). There were no cases of phasic–tonic responses for these alkaloids, and bursting activity was observed with strychnine and quinine at concentrations of 5 and 10 mM. The specialized case of the leptines was discussed by Mitchell (1994), who indicated that despite the fact that no differential sensory effect among glycoalkaloids has been measured to date, the leptines deserved further study, as they had yet to be tested in sensory physiological assays.

Our objective here was to determine the nature of chemosensory responses to purified (100%) leptine I. We demonstrate for the first time specific chemosensory neural responses to a glycoalkaloid, leptine I, in adult CPB galeal taste hairs.

METHODS AND MATERIALS

Insects. Adult Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say), were obtained from a colony with all life stages reared on *Solanum tuberosum* var. Kennebeck. Emerging adults were collected daily, sexed, and isolated in Petri dishes with moistened filter paper and fresh potato foliage that was replenished daily. Insects were kept in an environmental chamber (16L: 8D) at 25°C until use. Six-day-old insects were starved at least 4 hr prior to preparation for electrophysiological recordings.

Chemicals. Glycoalkaloids used in this study are illustrated in Figure 1. Tomatine (> 98% purity) and solanine (ca. 95%) were obtained from Sigma Chemical Co., St. Louis, Missouri. Leptine I was purified by using methodology modified from Kowalski et al. (2000).

Partially purified leptine I was obtained by normal-phase and reverse-phase chromatography from crude *Solanum chacoense* leaf extract. The sample was dissolved in methanol, and dissolution of the leptine I powder was aided by alternately heating a capped tube in a water bath, sonicating, and vortexing for a few seconds. A 1-ml aliquot of the sample was taken and transferred to a clean hydrolysis tube. The original sample tube was dried and stored in the cold for future use. Further

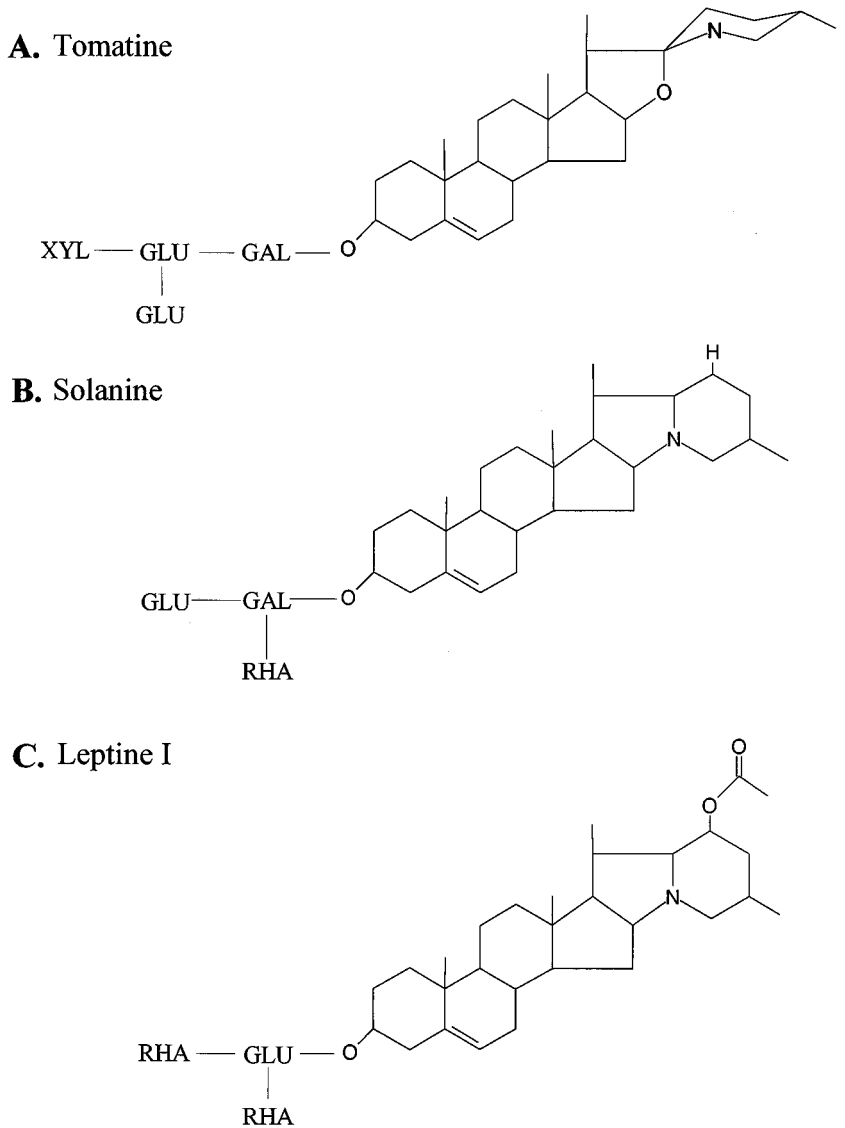

FIG. 1. Molecular structures of the glycoalkaloids used in this study: (A) tomatine, (B) solanine, and (C) leptine I. Abbreviations for sugar groups: GLU = glucose, GAL = galactose, XYL = xylose, RHA = rhamnose.

purification involved high-pressure liquid chromatography (HPLC) with a Waters 510 pump, Lambda-Max 481 wavelength detector, Waters automated gradient controller, Waters 745 data module, and a Waters 717 plus autosampler. A 20-μl volume of the leptine I aliquot was injected into a 3.9 $\times$ 300 mm Steel Resolve 5-μm spherical reverse-phase C_{18} column fitted with a Guard-pak C_{18} column insert to determine leptine I elution time and conditions for the fraction collector. HPLC condition was set at isocratic, with a mobile phase consisting of 1:1 acetonitrile (HPLC grade) –water supplemented with 5 ml 0.1 N phosphoric acid and 0.94 g 1-heptane sulfonic acid per liter. Flow rate was set at 0.7 ml/min and peak area detection was at 205 nm. Based on this initial injection, leptine I elution occurred about 8–9 min after sample injection. Thus, a Gilson FC 205 fraction collector in line with the HPLC was programmed to collect leptine I fractions from 8 and 12 min after sample injection. Fractions were eluted at a rate of 0.28 min per collection tube. Sample injections were done in 20-μl aliquots. Aliquots (5–10 μl) from these fractions were spotted on a Whatman flexible-backed polyester silica plate. Leptine I was visualized by spraying the plate with 0.11 M potassium iodide and 0.6 mM bismuth subnitrate in 3.5 M acetic acid (Dragendorff's spray reagent). Fractions containing leptine I were individually transferred to a new and clean test tube. The total volume in each tube was marked with a pen, and each tube was dried down to half the volume by blowing off acetonitrile. Acetonitrile was evaporated in the fume hood by gently heating the tubes in a beaker containing water set on a hot plate and by applying air into each tube while heating. The remaining solution from each tube was subjected to a final solid-phase extraction by using a vacuum manifold and classic C_{18} Sep-pak cartridges. This process involved conditioning the cartridges with 3 ml methanol followed by 5 ml of the aqueous heptane sulfonic acid extraction reagent. The fractions were loaded on to each conditioned Sep-pak cartridge, followed by a 5-ml acetonitrile: water (20:80) rinse. Leptine I was eluted with 2 ml methanol. Quantification and purity of leptine I was determined by analytical HPLC. α-Solanine (0.1 mg/ml methanol) served as a standard.

Solutions of glycoalkaloids were prepared for electrophysiology with 0.01 M NaCl as reference. Glycoalkaloids were solubilized in 0.01 M NaCl with lowered pH ($\sim$2–3) with HCl, then brought to pH 5.2–6.3 with NaOH. Reference electrolyte (0.01 M NaCl) was treated similarly.

Electrophysiology. Responses of galeal chemosensilla were obtained by using a standard tip-recording technique (Hodgson et al., 1955). A whole body preparation was used with adult CPB affixed inverted on cork with tape, and the head was immobilized with a tungsten collar. The head was pulled to a prognathous position with a tungsten post pressed into the cork that hooked and immobilized the mandibles. A galea was then pulled laterally with a fine nylon thread roped around the maxillary palp and immobilized by pinning between two fine

tungsten needles inserted into the cork. Use of a whole-body preparation and restriction of insect movement allowed us to identify individual sensilla and record from most, if not all ~16 chemosensory sensilla present on individual galea. A sharpened tungsten electrode inserted into the abdomen of the insect served as a reference electrode. Silver wire inserted into a glass capillary, pulled and sized to fit over the tip of one galeal chemosensory hair and filled with treatment chemicals in 0.01M NaCl, served as a stimulating/recording electrode. Both electrodes were connected to a Grass P15D AC amplifier. Chemosensory responses were viewed on an oscilloscope, monitored with a loudspeaker, and digitized for storage and analysis on a computer with Sapid (Smith et al., 1990) and AutoSpike (Syntech, Hilversum, The Netherlands) software. Numbers of nerve impulses within the first 500msec following the onset of stimulation were counted for analyses.

Experimental Protocol. In the first experiment, individual glycoalkaloids and 0.01 M NaCl reference stimulus treatments were tested successively on 5–16 hairs per galea. At least 3 min were allowed between stimulation of individual hairs. Concentrations of glycoalkaloids tested were 0.01, 0.1, and 1 mM for both male and female CPB. Leptine I concentrations tested also included 0.03 and 0.3 mM for construction of an expanded dose–response curve for female CPB. All leptine I concentrations were tested on at least 18 hairs from two to four female CPB galea, with the exception of 0.03 mM (10 hairs from one female CPB). For 1 mM solanine, 70 hairs from five females and three males were recorded; for 1 mM tomatine, 60 hairs from four females and two males were sampled. Contact with sensory hairs was maintained for at least 30 seconds to detect any glycoalkaloid-induced bursting of sensory neurons. Time to first burst was noted, and stimulation ended after a 60-sec period.

The second experiment investigated the effect of solanine on responses to leptine I. Treatments for this experiment were tested in the following order: 0.01 M NaCl, 0.3 mM leptine I (peak of dose–response curve), 1 mM solanine, 0.3 mM leptine I + 1 mM solanine, 0.3 mM leptine I. Records were obtained from nine hairs for one female CPB.

One-way analysis of variance was performed on log $(x + 1)$ transformed data to test for treatment effects on nerve impulse frequency. Duncan's multiple range test at 5% confidence level was used to test for differences between treatment means (Snedecor and Cochran, 1967).

RESULTS

Of the three solanaceous glycoalkaloids tested, only leptine I elicited a normal chemoreceptor response from a single neuron (Figure 2B). Responses increased

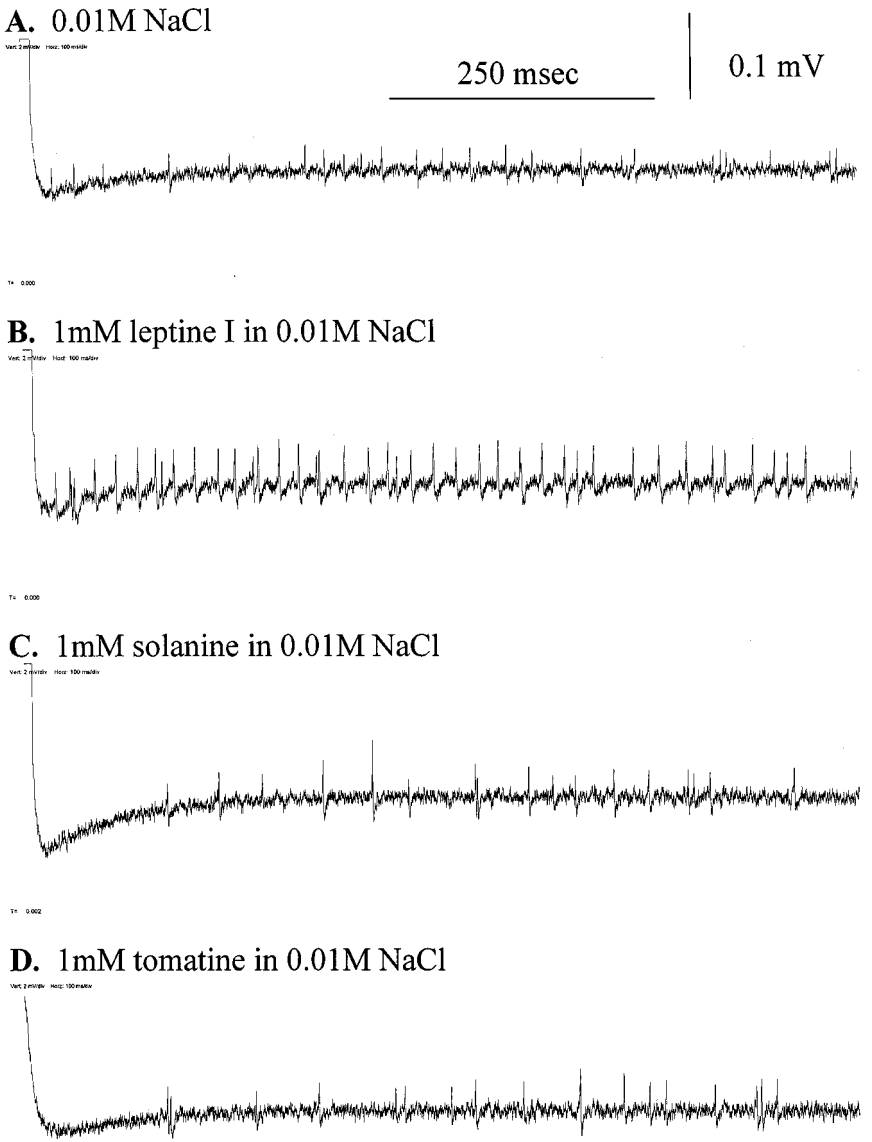

FIG. 2. Neural responses from chemosensory hairs on adult CPB maxillary galea to glycoalkaloids. Traces represent 1 sec after stimulation of sensory hair with: (A) 0.01 M NaCl reference solution, and (B) 1 mM leptine I, (C) 1 mM solanine, and (D) 1 mM tomatine, all in 0.01 M NaCl.

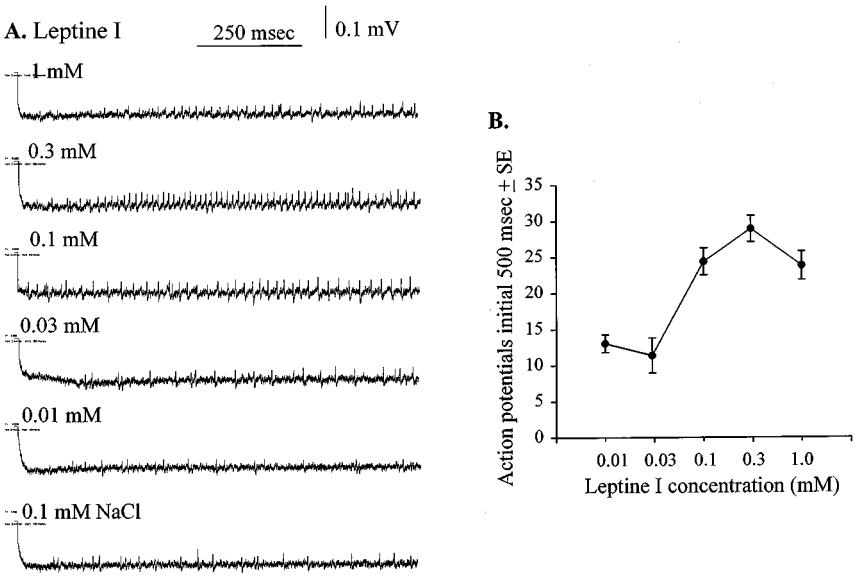

FIG. 3. (A) Representative neural responses to increasing concentration of leptine I. Traces represent 1 sec after stimulation of sensory hair with leptine I. (B) Dose-response curve for adult female CPB galeal chemosensory neurons in response to increasing concentrations of leptine I in 0.01 M NaCl. Action potentials were counted for the initial 500 msec following stimulation. $N = 10$–44 replicates/dose.

in a dose-dependent manner (Figure 3A and B), with a threshold at or above 0.03 mM and maximal response at 0.3 mM concentration. Leptine I did not elicit bursting activity below 1 mM concentration; at 1 mM weak bursting activity was observed in 9% (3/35) of hairs recorded. Percent of hairs stimulated responding to the leptine I concentrations were 12% (3/25) at 0.01 mM, 50% (5/10) at 0.03 mM, 88% (22/25) at 0.1 mM, 100% (18/18) and 83% (29/35) for 0.3 mM and 1 mM leptine I, respectively.

Two glycoalkaloids closely related to leptine I, solanine and tomatine, did not elicit responses greater than the control (Figure 2C and D), with bursting of multiple neurons (spikes of two or three amplitudes) observed only with the 1 mM treatments (Figure 4A and B). Bursting did occur within 60 sec in 53% (42/79) of hairs tested with 1 mM solanine, with an average delay of 13 sec. For 1 mM tomatine, bursting occurred in 32% (19/60) of hairs, with an average delay of 29 sec.

Although solanine has no stimulatory effect on this chemoreceptor neuron, it does have a depressive effect on this neuron's response to leptine I that lasts for at least 3 min (Figure 5).

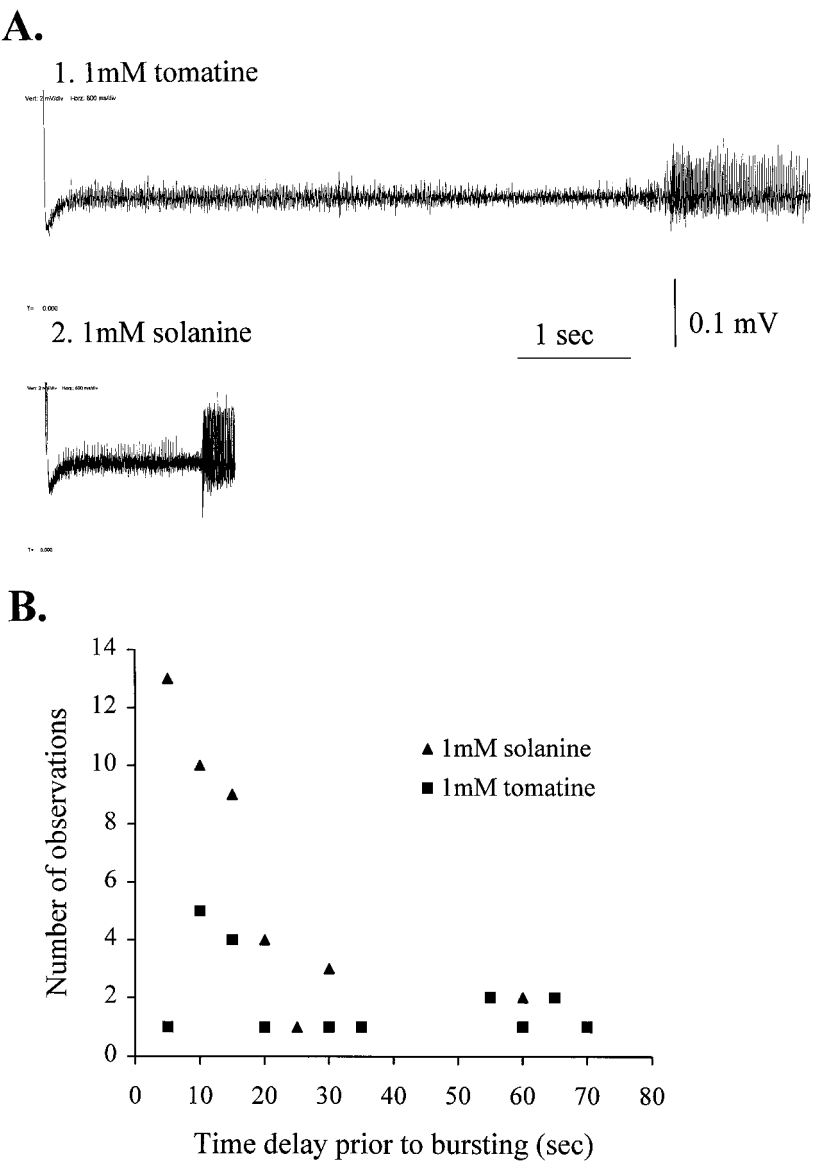

FIG. 4. Bursting response of neurons within adult CPB galeal chemosensory hairs. (A) Neural responses to 1 mM tomatine in 0.01 M NaCl and 1 mM solanine in 0.01 M NaCl illustrating bursts of chemosensory neurons. (B) Plot showing delay times before bursting activity for solanine and tomatine stimuli.

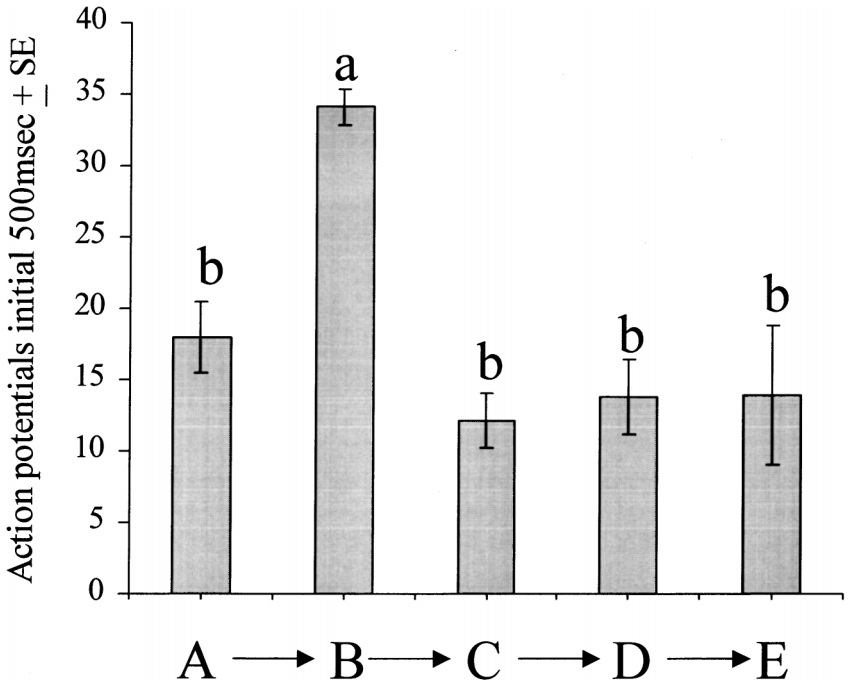

FIG. 5. Mean neural responses from adult female CPB galeal chemosensory hairs to sequential stimuli. Treatments were applied to individual hairs in the following order with three minutes between treatments: (A) 0.01 M NaCl, (B) 0.3 mM leptine I, (C) 1 mM solanine, (D) 0.3 mM leptine I + 1 mM solanine, and (E) 0.3 mM leptine I. $N = 9$ hairs/treatment. Different letters above the bars indicate significant differences between treatment means at the $\alpha = 0.05$ level.

DISCUSSION

We report here the first recordings of a specific chemosensory neural response to a glycoalkaloid in CPB. This slowly adapting response to leptine I is largely of a single neuron and contrasts with the lack of response to two other host plant glycoalkaloids, solanine and tomatine, on adult CPB chemosensory hairs.

The main differences in the three molecules tested here lie in the acetyl group at C-23 of the glycoalkaloid carbon skeleton in leptine I, as well as in the sugar group (Figure 1). Perhaps the differential effect observed is a function of different solubilities of individual glycoalkaloid molecules, with leptine I more readily solubilized and available at the receptor site. The more amphipathic tomatine and solanine may dissolve into and disrupt the dendritic membrane and thereby

elicit sporadic firing of several neurons and bursts of nerve impulse activity in adult CPB galeal taste hairs.

Specialist deterrent chemoreceptors identified for several species of larval Lepidoptera (Schoonhoven, 1982) respond to the alkaloids quinine and strychnine, as well as azadirachtin. In *Pieris* spp., receptors sensitive to cardenolides (threshold of 0.1–0.3 μM) occur in both adults (Stadler et al., 1995) and larvae (van Loon and Schoonhoven, 1999). These compounds are present in cruciferous plants and deter both feeding and oviposition. Such deterrent receptor neurons have only recently been reported for beetles in the family Chrysomelidae. Chyb et al. (1995) showed chemosensory responses in adult western corn rootworm (*Diabrotica virgifera* LeConte) to the feeding deterrents β-hydrastine and strychnine. They also found chemosensory responses to cucurbitacin B isolated from host plants in the family Cucurbitaceae. Cucurbitacins, strong feeding deterrents for most insects, act as potent arrestants and feeding stimulants for western corn rootworm and a small group of closely related species. Messchendorp et al. (1998) reported a deterrent receptor in CPB larvae in epipharyngeal sensilla that respond to the glucosinolate, sinigrin, and a synthetic sesquiterpene analogue, drimane, with threshold concentrations of 0.01 and 0.1 mM, respectively. Maximal numbers of action potentials to drimane were in response to 1 mM. Our observations of the first deterrent receptor neuron in adult CPB reveal a similar response range between 0.03 and 0.3 mM for leptine I. Both sinigrin and the drimane analog are feeding deterrents, but are isolated from non host plant species from the families Cruciferae and Polygonaceae, respectively. Adult CPB response to leptine I is similar to the *Pieris* spp. response to cardenolide in one respect, namely, both are deterrent receptor neuron responses to particular compounds from unacceptable plants in their own host-plant families.

Glycoalkaloids and other deterrents reduce neuronal responses to chemicals that stimulate feeding in CPB. Response to 10 mM γ-aminobutyric acid (GABA) was completely abolished following stimulation of the same hair with 0.5 mM solanine for 20 sec (Mitchell and Harrison, 1984); 1 mM tomatine, papaverine, and sparteine also significantly reduced this response (Mitchell, 1987). Response to 10 mM sucrose was similarly inhibited by 1 mM quinine and papaverine (Mitchell, 1987). Solanine and tomatine suppress neuronal response to (*E*)-2-hexenol, which Mitchell and McCashin (1994) suggest stimulates the same cell as sucrose, alanine, and GABA in some adult CPB galeal chemosensilla. Messchendorp et al. (1998) conclude that drimane inhibits the response of a sucrose cell in larval CPB epipharyngeal sensilla. Schoonhoven (1982) discussed the perception of antifeedants at the sensory level and identifies at least two possible mechanisms: (1) stimulation of specialized receptors by feeding deterrents, or (2) modification of the activity of receptors responding to feeding stimulants. Previous reports provide evidence for the latter mechanism of feeding deterrence. Our observation of sensory neurons

responsive to leptine I provides evidence for both mechanisms. Interestingly, here we also show suppression of a deterrent sensory neuron responsive to submillimolar levels of leptine I by millimolar levels of another glycoalkaloid, solanine, for which no specific taste receptor was identified. Thus, glycoalkaloid effects may be modulated by related compounds, and such interaction effects among the complex mixture of chemicals in host plant foliage must be considered when drawing conclusions about behavioral effects and mechanisms of host-plant selection.

Responses to solanine and tomatine were consistent with those described by Mitchell and Harrison (1985) and Mitchell (1987) for chemosensory neurons within galeal sensilla and by Stürckow (1959) for neurons within sensilla on the palps and tarsi. In both cases, the responses consisted of irregular firing of several neurons and bursting activity after a delay of several seconds. Discovery by us of an identifiable sensory neuron for leptine I provides a mechanism by which glycoalkaloids of the Solanaceae are detected by CPB. Our results not only establish a neural pathway for detection of leptine I but also provide a mechanism of feeding deterrence and resistance to CPB feeding attributed to this glycoalkaloid (Stürckow and Lüw, 1961; Tingey, 1984; Sinden et al., 1986). Previous experiments to determine the effects of leptines on feeding by CPB have either involved correlation of reduced consumption of foliage with levels of leptine, or feeding tests with leptine of partial (60%) purity. Feeding bioassays with purified leptine I coupled with electrophysiological observations will establish input–output relationships to more conclusively relate behavioral effects of leptine I to neural responses of identified chemoreceptor neurons.

(Received December 12, 1998; accepted February 7, 2001)

Abstract—Seven electrophysiologically active compounds were detected in air-entrained headspace samples of live flowers of *Tagetes erecta* analyzed by gas chromatography (GC) linked to a female *Helicoverpa armigera* electroantennograph (EAG) using polar and nonpolar capillary columns. These compounds were subsequently identified using GC linked to mass spectrometry as benzaldehyde, (*S*)-(−)-limonene, (*R*,*S*)-(±)-linalool, (*E*)-myroxide, (*Z*)-β-ocimene, phenylacetaldehyde, and (*R*)-(−)-piperitone. Electrophysiological activity was confirmed by EAG with a 1-μg dose of each compound on filter paper eliciting EAG responses that were significantly greater than the solvent control response from female moths. Wind-tunnel bioassays with *T. erecta* headspace samples, equivalent to 0.4 flower/hr emission from a live flower, elicited a significant increase in the number of upwind approaches from female *H. armigera* relative to a solvent control. Similarly, a seven-component synthetic blend of EAG-active compounds identified from *T. erecta* presented in the same ratio (1.0 : 1.6 : 0.7 : 1.4 : 0.4 : 5.0 : 2.7, respectively) and concentration (7.2 μg) as found in the natural sample elicited a significant increase in the number of upwind approaches relative to a solvent control during a 12-min bioassay that was equivalent to that elicited by the natural *T. erecta* floral volatiles.

Key Words—*Helicoverpa armigera*, *Tagetes erecta*, floral attractant, kairomone.

INTRODUCTION

The cotton bollworm, *Helicoverpa armigera* Hübner (Lepidoptera: Noctuidae), is a serious insect pest throughout much of its distribution in tropical and subtropical

* To whom correspondence should be addressed.

0098-0331/01/0600-1119$19.50/0

regions of the Old World. Its economic importance has increased in recent years because of its propensity for developing resistance to insecticides. Additional means of controlling *H. armigera* are urgently needed because even well—organized resistance management programs, such as the one developed in Australia, have only reduced the rate at which insecticide resistance has evolved rather than stopping it (Forrester et al., 1993).

Improved understanding of *H. armigera*–host plant interactions could increase options available for innovative pest management. One possibility is to develop attractants for female moths that could be used in a lure-and-kill control program, such as the one described by Landolt et al. (1991) for the cabbage looper moth, *Trichoplusia ni*. Female *H. armigera* can produce 1000–1500 individually laid eggs during their lives (Fitt, 1989). To be effective, control strategies based on lures developed from plant odors do not have to be as attractive as Lepidopterous female sex pheromones because killing one female moth before she can oviposit is equivalent to killing many larvae. However, for practical usage in population suppression, floral baited traps would still have to capture or kill a sufficient proportion of the female moths entering a control area to prevent the subsequent larval population exceeding the economic threshold.

Night observations of *H. armigera* have shown that oviposition is interspersed with nectar foraging (Roome, 1975) suggesting that female moths are attracted to flowers while ovipositing. Traps attracting female *H. armigera* could be used for monitoring populations and, for this purpose, lower levels of attraction might be sufficient provided that enough moths were captured to give a reliable indication of the potential threat to the crop.

The role played by olfactory cues in host-plant location by polyphagous moth species, such as *H. armigera*, is uncertain. Some authors (e.g., Ramaswamy, 1988) have suggested that for flight, orientation, and landing no specific olfactory cues are involved and that host location and acceptance are mostly a random process in which phototaxis and anemotaxis play a greater role than chemoanemotaxis, whereas others (e.g., Rembold et al., 1991) have hypothesized that polyphagous insects utilize volatile olfactory cues for host recognition and location. The presence of flowers has been shown to be important for host-plant selection by *H. armigera* (Roome, 1975; Fitt, 1989), and oviposition has been shown to occur on flowering nonhost plants in preference to nonflowering host plants (Firempong and Zalucki, 1990). Thus, if volatile olfactory cues are important in host location, flowers would appear to be the most likely source of attractants.

African marigold, *Tagetes erecta*, is a favored host for oviposition by *H. armigera* and has been successfully used as a trap crop (Patel and Yadav, 1992; Srinivasan et al., 1994). Given the apparent uncertainty about the role of plant odors in host selection by female *H. armigera*, the present study was undertaken to identify electrophysiologically active compounds from headspace samples of *T. erecta* flowers and to elucidate their behavioral activity in a wind-tunnel bioassay.

METHODS AND MATERIALS

Plant Material. An Indian strain of *T. erecta* was grown from seed in glasshouses at the Natural Resources Institute (NRI), Chatham Maritime, UK. Samples of floral volatiles were collected by air entrainment of individual freshly cut flowers or individual flowers still attached to growing plants, referred to here as a live flower. Acetone-washed and air-dried three-necked Quickfit flange lids and flasks (500 ml) were clamped together and a live flower inserted through a B52 neck. The gap between the stem and the flask was packed with charcoal (ca. 20 g, 10–18 mesh, from BDH) and held in place with aluminum foil. Incoming air was filtered through a charcoal filter (20 g, 10–18 mesh) and drawn over the flower at 2 liters/min for 10–14 hr by a diaphragm pump (Charles Austin Pumps Ltd., Weybridge, UK) connected to a Porapak Q filter (200 mg, 50–80 mesh, Phase Separations) that had previously been conditioned by Soxhlet extraction with chloroform for 8 hr, then air dried. Entrained volatiles were subsequently eluted from the Porapak Q filters with dichloromethane (2 ml) and stored at -20°C. A similar setup was used to entrain volatiles from freshly cut flowers except that the flowers were held in fully enclosed flasks.

Experimental Insects. A laboratory strain of *H. armigera* originating from the International Center for Research in the Semi-Arid Tropics, India, was maintained on a semisynthetic chickpea diet at NRI, by using rearing procedures similar to those described by Armes et al. (1992). Groups of 12 male and 12 female moths were kept in Perspex containers (20 cm diam. $\times$ 36 cm high) with metal gauze lids and provided with a 10% sucrose solution with vitamin supplement. The culture was maintained at 25°C, 50% relative humidity, and 14L:10D photoperiod.

Electroantennography (EAG). EAG recordings were carried out using 1- to 3-day-old adult female *H. armigera*. Whole insects were used, held down on a plasticine block by a strip of expanded polystyrene. A glass recording microelectrode filled with saline (0.5 M NaCl in distilled water) was mounted on a micromanipulator (Leitz) and inserted into the distal end of one antenna and a similar reference microelectrode inserted into the proximal end of the other antenna. The microelectrodes were connected via Ag–AgCl junctions to a high-impedance AC/DC amplifier (model UN06, Syntech). EAG data were recorded, stored, and processed on a PC using Turbochrom 4.0 software (Perkin Elmer Ltd., Beaconsfield, UK).

The EAG activity of entrained headspace samples was tested by placing an aliquot of test solution (2–20 μl) onto a Whatman No. 4 filter paper strip (5×15 mm) placed inside a Pasteur pipet and nitrogen pulsed (100 ml/min) through the pipet for 3 sec over the EAG preparation. The EAG preparation was exposed to pulses at 1-min intervals as initial tests had shown that the EAG preparation had fully recovered in that time. EAG responses were measured and compared with those generated by the same volume of solvent on filter paper. When an entrainment

sample was found to elicit an EAG response at least 30% greater than that of the solvent alone, linked GC-EAG analyses were carried out.

The EAG activity of synthetic compounds was measured at a single dose (1 μg on filter paper). Samples were prepared as above by using solutions in dichloromethane (1 mg/ml). Each compound was tested five times on each of nine 1- to 9-day-old female *H. armigera*. The order of exposure of compounds to the EAG preparations was randomized, and only the last four of the five EAG responses elicited per compound were used, because these were found to be more reproducible. Control stimuli (1 μl dichloromethane) were presented at the beginning and end of each EAG analysis. EAG responses elicited by each compound were averaged for each insect tested and compared with the averaged responses for the solvent control with the Student's *t* test.

Gas Chromatography (GC) and Linked GC-EAG Analyses. Linked GC-EAG analyses were conducted as described by Cork et al. (1990) using a modified Carlo Erba 5300 Mega series gas chromatograph equipped with two fused silica capillary columns coated with polar CP-Wax 52CB (30 m $\times$ 0.32 mm ID, Carbowax equivalent, Chrompack) and nonpolar CP-Sil 5CB (25 m $\times$ 0.32 mm ID, methylsilicone equivalent, Chrompack). The GC carrier gas was helium (40 kPa). Samples were introduced onto a GC column in splitless mode using a Grob split/splitless injector at 200°C with the flame ionization detector (FID) at 250°C. The GC oven was held for 2 min at 50°C, then temperature programmed at 20°C/min to 80°C and then at 5°C/min to 240°C. GC column effluent was split 50 : 50 between the FID and EAG outlets. GC column effluent to the EAG preparation was stored in a silanized glass reservoir inside the GC oven and expelled over the EAG preparation for 3 sec at 17-sec intervals in a stream of nitrogen (250 ml/min).

Linked GC-EAG analyses of entrained flower volatiles were replicated four times using different insects and carried out on four different headspace collections. GC retention times of components associated with EAG activity were converted into retention indices (RI) by comparison with the retention times of saturated, straight-chain hydrocarbons; thus, *n*-tetradecane = 1400. The quantity of each compound in an aliquot was calculated by comparison of peak area with that of a known quantity of an external standard, 20 ng tetradecyl acetate, and not corrected for FID response factor.

The enantiomeric composition of natural and synthetic compounds was determined by GC analysis on a β-cyclodextrin column (50 m $\times$ 0.25 mm ID, Scientific Glass Engineering Ltd., Milton Keynes, UK) in a Varian 3700 GC using split injection with helium carrier gas (150 kPa) and oven temperature held at 90°C for 2 min and then programmed at 2°C/min to 190°C.

Analysis by Linked Gas Chromatography–Mass Spectrometry (GC-MS). Headspace collections were analyzed by GC-MS using a Carlo Erba 5160 Mega Series GC linked directly to an Ion Trap Detector 700 mass spectrometer (70 eV, 200°C) (Finnigan MAT, Hemel Hempstead, UK) in electron impact (EI) mode.

GC conditions were as described above. Compounds were identified by comparing their mass spectra with library spectra (Adams, 1995) and confirmed by comparing GC RI and EI-MS with synthetic standards.

Synthetic Chemicals. Benzaldehyde, (*S*)-(−)-limonene [(*S*)-(−)-4-isopropenyl-1-methylcyclohexene], (*R*)-(+)-limonene, (*R,S*)-(±)-linalool [(*R,S*)-3,7-dimethyl-1,6-octadien-3-ol], (*R*)-(−)-linalool, and phenylacetaldehyde were purchased from Sigma-Aldrich Chemical Company Ltd., Gillingham, UK. Myroxide [2,2-dimethyl-3-(3-methylpenta-2,4-dienyl) oxirane] was provided by Quest International, Ashford, UK, as a 50 : 50 mixture of *E*- and *Z*-isomers. The isomers were separated on a flash silica gel column (silica gel 60, 0.040- to 0.063-mm particle size, Merck, Darmstadt, Germany) eluted with aliquots (100 ml) of 40–60 petroleum spirit in which 1%, 2%, 3%, and 5% diethyl ether was added sequentially. The isomeric purity of collected fractions was subsequently determined by GC analysis, and those containing >95% (*E*)-myroxide were combined and used without further purification. β-Ocimene (3,7-dimethyl-1,3,6-octatriene), purchased from Fluka (Gillingham, UK), contained 59% (*Z*)-β-ocimene, 1% (*E*)-β-ocimene, and 40% limonene. (*Z*)-β-Ocimene was separated from this mixture using flash silica gel column chromatography as described for isomers of myroxide. (*R*)-(−)-Piperitone (6-isopropyl-3-methyl-2-cyclohexen-1-one) was a gift from H.E. Daniel Ltd., Cleveland, UK. In order to obtain GC RI and ^{1}H NMR data on the (+)-enantiomer, an aliquot of the (−)-enantiomer was racemized in methanolic potassium hydroxide at room temperature for 24 hr and analyzed both by GC on the β-cyclodextrin column and by ^{1}H NMR in the presence of a chiral shift reagent, (*R*)-(−)-2,2,2-trifluoro-1-(9-anthryl)-ethanol.

Wind-Tunnel Bioassay. A wind tunnel without a moving floor, but otherwise similar to that described by Miller and Roelofs (1978), was used to investigate the behavioral responses of female *H. armigera* to natural and synthetic blends of the putative kairomone components. The wind tunnel was made from a polyethylene sheet placed over a metal frame (225 × 60 × 60 cm). Airspeed, as measured by a smoke test, was 50 cm/sec. All bioassays were carried out under reduced lighting (0.8 lux) provided by a series of three bulbs (60 W) fitted with red filters and a variable power output positioned at 40-cm intervals 1.0 m above the wind tunnel and angled to provide even coverage over the whole apparatus. Bioassays were conducted at 25°C and 50% relative humidity during the first 2–3 hr of the scotophase, which corresponded to the natural time of nectar foraging and oviposition by female *H. armigera* (Roome, 1975).

Test samples (60 μl) were applied to Whatman No. 1 filter papers (7 cm diam.) from stock solutions. This was done in a separate room to avoid contamination. Filter papers were immediately clipped to a vertical support (30 cm height) positioned at the midpoint in the upwind end of the wind tunnel. Behavioral responses to solvent (dichloromethane) control, entrained floral volatiles from live flowers of *T. erecta*, and blends of synthetic compounds identified

from *T. erecta* in the same ratio and concentration as natural material were investigated.

Individual test moths were carefully released into the odor plume (as confirmed by smoke tests) from a holding container placed 200 cm downwind of the source immediately after introduction of a freshly prepared odor source. Each test moth was used only once. Maximum distance flown upwind and number of approaches to within 20 cm of the odor source were scored during a 12-min bioassay period. The control treatment was tested first to ensure there was no contamination from previous sessions. Test treatments were then bioassayed in a randomized order.

Wind-tunnel data on number of upwind approaches and furthest distance flown upwind were analyzed by the Kruskal-Wallis test (Statistical Package for Social Scientists for Windows Release 9.0.0) to determine if there was a significant difference between treatments. If significant, then test treatment medians were compared with control treatment medians using the Mann-Whitney U test.

RESULTS

GC-EAG Analyses. In GC analyses on a polar column with FID, 45 compounds were detected in volatiles from *T. erecta* flowers collected on Porapak Q. Of these compounds, seven consistently elicited EAG responses above background in linked GC-EAG analyses with female *H. armigera* on both polar and nonpolar columns. The EAG responses were typically −0.2 to −0.6 mV above a background of −0.8 mV. Retention indices of EAG-active compounds and abundance expressed as the quantity, relative to an external standard, entrained from a live flower per hour are given in Table 1. There was no apparent correlation between

TABLE 1. ELECTROPHYSIOLOGICALLY ACTIVE COMPOUNDS IDENTIFIED IN VOLATILES FROM LIVE *T. erecta* FLOWERS COLLECTED ON PORAPAK Q

Compound	Ratio with respect to benzaldehyde	Concentration (μg/live flower/hr)	Retention index			
			Polar column		Nonpolar column	
			Natural	Synthetic	Natural	Synthetic
(*S*)-(−)-Limonene	1.62	1.72	1200	1200	1017	1019
(*Z*)-β-Ocimene	0.36	0.38	1234	1232	1027	1028
(*E*)-Myroxide	1.39	1.47	1485	1483	1123	1126
Benzaldehyde	1.0	1.06	1522	1522	925	926
(*R,S*)-(±)-Linalool	0.68	0.72	1539	1541	1085	1088
Phenylacetaldehyde	4.36	4.61	1642	1642	1007	1011
(*R*)-(−)-Piperitone	2.7	2.86	1725	1723	1226	1225

the EAG activity of natural compounds eluting from the GC and their relative abundance.

GC-MS Analyses. Floral volatiles were analyzed by GC-MS to obtain EI-MS of compounds that eluted at the RI where EAG activity was observed in linked GC-EAG analyses. Tentative structural assignments were made on the basis of a comparison of EI-MS with library spectra (Adams, 1995). The assignments were confirmed by comparison of EI-MS and GC RI on polar and nonpolar columns of natural compounds with those of authentic synthetic compounds. Thus, the EAG-active compounds were identified as benzaldehyde, limonene, linalool, (*E*)-myroxide, (*Z*)-β-ocimene, phenylacetaldehyde, and piperitone. The configurations of the natural limonene, linalool, and piperitone were established by comparison of GC retention times with those of authentic synthetic compounds on a β-cyclodextrin column. Synthetic (*R*)-(+)- and (*S*)-(−)-limonene, (*R*)-(−)- and (*S*)-(+)-linalool, and (*R*)-(−)- and (*S*)-(+)-piperitone eluted at 18.25, 18.39, 27.83, 27.96, 40.22, and 40.37 min, respectively. Retention times of compounds in the natural sample were 18.42, 27.87, 27.99, and 40.26 min confirming the presence of (*S*)-(−)-limonene and (*R*)-(−)- and (*S*)-(+)-linalool (König et al., 1990) in a 1 : 2 ratio, and (*R*)-(−)-piperitone.

Comparison of Headspace Volatiles from Live and Cut Flowers. The relative proportions of each of the seven EAG-active compounds in headspace entrainments of individual live and cut *T. erecta* flowers were determined by GC analysis and compared by Student's *t* test. The proportions of aromatic compounds, benzaldehyde ($P = 0.035$) and phenylacetaldehyde ($P = 0.001$), were found to be lower in volatiles from cut flowers compared to those from live flowers while the proportion of (*Z*)-β-ocimene was higher ($P = 0.01$) (Table 2).

TABLE 2. COMPARISON OF RATIOS OF COMPOUNDS EMITTED FROM LIVE AND CUT *T. erecta* FLOWERS

Chemical	Cut flowers (%, mean ± SE)[a]	Live flowers (%, mean ± SE)[a]	P^b
(*S*)-(−)-Limonene	28.0 ± 5.7	16.5 ± 4.6	0.12
(*Z*)-β-Ocimene	14.9 ± 3.5	3.8 ± 1.0	0.01
(*E*)-Myroxide	8.5 ± 1.2	5.0 ± 2.0	0.13

Phenylacetaldehyde	0.75 ± 0.08	<0.001
(*R*)-(−)-Piperitone	0.85 ± 0.16	0.001
(*Z*)-β-Ocimene	0.51 ± 0.06	0.003
(*S*)-(−)-Limonene	0.39 ± 0.03	0.012

[a](1 μg in 1 μl CH_2Cl_2, $N = 9$).
[b]Paired Student's t test between treatments and dichloromethane control means.

EAG Activity of Synthetic Compounds. At a 1-μg dose, each of the synthetic compounds identified from linked GC-EAG analyses elicited an EAG response that was significantly above that of the solvent control (Table 3). EAG responses ranged from −0.39 mV for (*S*)-(−)-limonene to −0.85 mV for (*R*)-(−)-piperitone at the 1-μg dose. The highest EAG responses were elicited by (*E*)-myroxide, (*R*)-(−)-piperitone, and phenylacetaldehyde, although differences in molecular weight and volatility of the compounds tested meant that data were not strictly comparable.

Wind-Tunnel Bioassay. An aliquot of *T. erecta* floral headspace collection from live flowers equivalent to 0.4 flower/hr was tested against a seven-component blend of synthetic compounds containing the same ratio and concentration of EAG-active compounds: 7.2 μg of benzaldehyde, (*S*)-(−)-limonene, (*R*,*S*)-(±)-linalool, (*E*)-myroxide, (*Z*)-β-ocimene, phenylacetaldehyde, and (*R*)-(−)-piperitone in a 1.0 : 1.6 : 0.7 : 1.4 : 0.4 : 5.0 : 2.7 ratio. An equivalent six-component blend in which (*E*)-myroxide was omitted was also tested. Flight responses were compared with those of insects tested when only the control treatment (dichloromethane) was present.

The number of upwind approaches to within 20 cm of the lure increased significantly when natural *T. erecta* floral odors were presented to female *H. armigera* compared to when moths were presented with a solvent control (Mann-Whitney U test, $P = 0.036$) (Figure 1). The six- and seven-component synthetic blends of EAG-active compounds elicited similar increases in number of upwind approaches (Mann-Whitney U test, $P = 0.015$ and $P = 0.006$, respectively). In addition, there was no significant difference between the number of upwind approaches elicited by the natural floral collections and the six- and seven-component synthetic blends. Mean furthest distances flown upwind to the natural floral volatile collection, six- and seven-component blends (171, 171 and 173 cm, respectively) from that to the

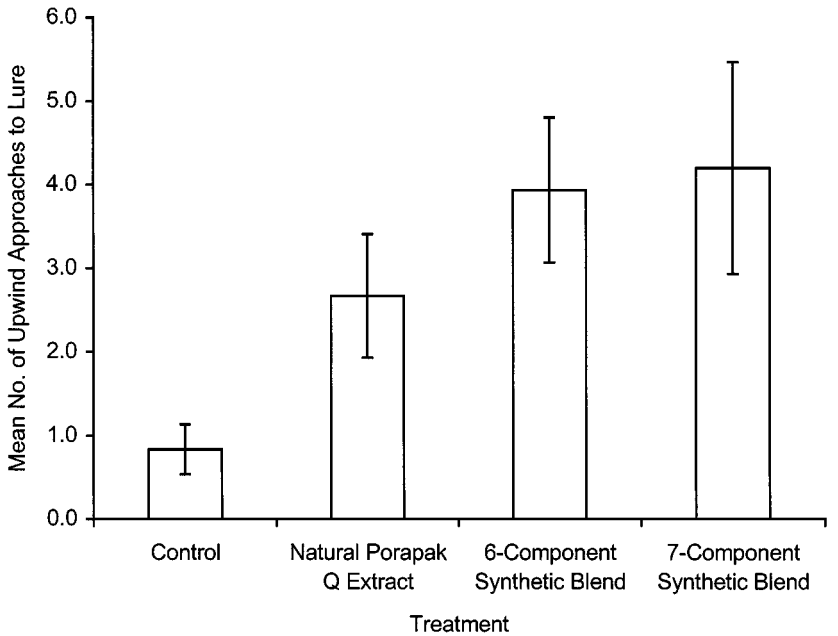

FIG. 1. Mean number of upwind approaches by female *H. armigera* to within 20 cm of air-entrained natural and synthetic blends of *T. erecta* floral odors in a wind tunnel ($N = 30$).

solvent control (143 cm), (Kruskal-Wallis test, $P = 0.25$) differences were not significant.

Replacement of (*E*)-myroxide with a 50 : 50 mixture of *Z*- and (*E*)-isomers in the seven-component synthetic blend resulted in a reduction in the number of upwind approaches to a point where it was not different from that of the solvent control (Mann-Whitney U test, $P = 0.70$). However, a five-component blend, omitting (*E*)-myroxide and (*Z*)-β-ocimene and in which (*R*)-(+)-limonene was used instead of (*S*)-(−)-limonene, was found to elicit a increase in the number of upwind approaches compared to the solvent control (Mann-Whitney U test, $P = 0.003$).

DISCUSSION

The present findings demonstrate that the polyphagous moth, *H. armigera*, can recognize and behaviorally respond to olfactory cues from a host plant in a no-choice situation. Significant increases in the number of upwind flight approaches by female *H. armigera* were observed in a wind-tunnel bioassay in response to floral volatiles collected from *T. erecta* and to synthetic blends of electrophysiologically

active compounds identified from that source (Figure 1). However, this does not preclude the possibility that other cues are involved in host recognition and selection by female *H. armigera*, such as the contrast of a flower silhouette or contact chemoreception upon alighting on a plant, as suggested by Kevan and Baker (1983).

Linked GC-EAG analysis, as originally conceived by Moorhouse et al. (1969), has proven to be of great utility in identifying components of insect sex pheromones and kairomones (Cork et al., 1990) even though the magnitude of EAG responses elicited by natural compounds was not necessarily related to their behavioral activity (Suckling et al., 1996). In the current study, the amplitude of EAG responses elicited by some compounds in linked GC-EAG analyses of floral volatiles, e.g., (*S*)-(−)-limonene, were difficult to discern above the high background responses (on average −0.78 mV) recorded from mechano- and thermoreceptors stimulated by the pulses of nitrogen-containing GC effluent. Nevertheless, the EAG activity of the compounds identified in *T. erecta* floral headspace samples by this procedure were subsequently confirmed by EAG tests using 1-μg doses of synthetic compounds on filter papers (Table 3). EAG activity of floral extracts and compounds identified in the extracts demonstrated that female *H. armigera* possessed chemoreceptors capable of detecting floral volatiles, and this was subsequently confirmed by the wind-tunnel bioassay results.

Two synthetic blends of EAG-active compounds identified from floral headspace samples of *T. erecta* elicited similar levels of upwind flight activity to the natural headspace samples collected from live flowers in the wind-tunnel bioassay. The dose used was approximately equivalent to that emitted by two live flowers over a 12-min period. Repeated upwind approaches observed in the wind-tunnel bioassays to synthetic and natural odor sources were typical of the "seeking flight" reported by Brantjes (1978) in a description of the sensory responses of night-flying moths to flowers. This implied that the presence of volatile host plant cues can induce upwind flight and sustained searching behavior in *H. armigera* and is of particular relevance to our understanding of the mechanisms involved in host location.

Five of the seven EAG-active compounds characterized from the volatiles produced by *T. erecta* have been implicated in the host location of related moth species: phenylacetaldehyde as an attractant for *H. armigera* and other spp. (Landolt et al., 1991); benzaldehyde, in blends containing phenylacetaldehyde, as a floral kairomone for the cabbage looper moth, *Trichoplusia ni* (Haynes et al., 1991); linalool (enantiomer unspecified) as an oviposition attractant for the light-brown apple moth, *Epiphyas postvittana* (Suckling et al., 1996), limonene (enantiomer unspecified) as an oviposition stimulant for *H. armigera* (Blaney and Simmonds, 1990), and piperitone (enantiomer unspecified) as an attractant of the European grapevine moth, *Lobesia botrana* (Gabel et al., 1992). As far as we are aware, there are no published reports of the electrophysiological or behavioral activity of benzaldehyde, (*R,S*)-(±)-linalool, (*E*)-myroxide; and (*R*)-(−)-piperitone specifically

to *H. armigera*, although Burguière et al. (2001) found benzaldehyde and (*R,S*)-(±)-linalool did elicit significant EAG responses from female *H. armigera*.

Linalool, myroxide, and piperitone are known constituents of the essential oil prepared from steam distillates of air-dried *T. erecta* (Gupta and Bhandari, 1974), but benzaldehyde and phenylacetaldehyde have not previously been described. Benzaldehyde and phenylacetaldehyde are prone to oxidation and thus might not occur in samples collected by steam distillation. Indeed, larger quantities of these two compounds were collected from air entrainments with live flowers than in entrainments with cut flowers. Because *H. armigera* is highly polyphagous, it is of interest to note that the behaviorally active volatiles identified from flowers of *T. erecta* also occur in some of its other host plants, although this does not necessarily mean that they have a significant role in the location of those plants. Thus, limonene was the only monoterpene found by Flath et al. (1978) in maize silks, although Buttery et al. (1980) subsequently found benzaldehyde and phenylacetaldehyde in maize silks and Buttery and Ling (1984) identified limonene and linalool in maize leaf volatiles. Limonene, benzaldehyde, and phenylacetaldehyde were identified in tobacco (Loughrin et al., 1990); benzaldehyde and (*R*)-(+)-limonene were identified in chickpea seed volatiles (Rembold et al., 1989). Limonene has been found in the flowers of sunflower (Eteviant et al., 1984) and as a tomato leaf volatile (Buttery et al., 1987).

In preliminary field testing in Israel, traps baited with a four-component synthetic blend of benzaldehyde, (*S*)-(−)-limonene, (*R,S*)-(±)-linalool, and phenylacetaldehyde caught more moths than unbaited control traps ($P = 0.002$), although the actual numbers of moths captured were low (Bruce et al., 2001). It is anticipated that by addition of other behaviorally active compounds and a better understanding of the role of these chemicals in the behavior of *H. armigera* a useful floral bait can be developed for use in monitoring female populations of this economically damaging pest. Floral odors might also be worthy of consideration in breeding programs where the objective is to breed out traits attractive to *H. armigera*.

Acknowledgments—The authors thank Dr. K. Srinivasan, Nagarjuna Agricultural Research and Development Institute, India, for suggesting this work on African marigold and provision of seed material; Quest International Ltd., for a sample of synthetic myroxide; H.E. Daniel Ltd., Cleveland, UK, for a sample of (*R*)-(−)-piperitone; and ICRISAT, Patancheru, India, for supplying the pupae used to start the culture of *H. armigera*. The authors are particularly grateful to Prof. D. R. Hall for constructive comments and advice on the manuscript. T.J.B was funded by a NRI Research Studentship.

(Received May 1, 2000; accepted February 10, 2001)

Abstract—Males of the green capsid bug, *Lygocoris pabulinus*, exhibit a specific courtship behavior, i.e., a vibration of the abdomen. When both live and dead females were offered to males, this vibration behavior was elicited in most of the males tested. When females were dissected into separate body parts, heads, wings, and legs elicited equal responses, while thorax plus abdomen elicited a much lower response. When separate body parts were extracted, the leg extracts elicited significantly stronger responses than any other extract. This suggests that female *L. pabulinus* legs are either the source of a close-range sex pheromone or that pheromone is accumulated on the legs due to grooming behavior. The leg extracts contained several hydrocarbons such as *n*-alkenes, *n*-alkanes, and some methylalkanes. Female extracts contained more (*Z*)-9-pentacosene and male extracts contained more (*Z*)-9-heptacosene. Substrates on which females had walked elicited similar responses as female legs, indicating that the pheromone is deposited on the substrate. This enlarges the functional range of low-volatility compounds, which are thought to function only when sexes are in close vicinity or in contact.

Key Words—Heteroptera, Miridae, contact sex pheromone, male vibration, (*Z*)-9-pentacosene, (*Z*)-9-heptacosene, cuticular hydrocarbons, close-range pheromone, SPME.

INTRODUCTION

Sex pheromones are commonly used by insects to locate mates at long range and to stimulate mating at close range (Carlson et al., 1971; Cardé et al., 1975; Muhammed et al., 1975). Long-range sex pheromones were first described and chemically identified in moths (Butenandt et al., 1959) and are now widely used for

0098-0331/01/0600-1133$19.50/0

monitoring of lepidopterous pests (e.g., Minks and Van Deventer, 1992; Cardé and Minks, 1997). In recent years identification of nonlepidopteran sex pheromones has received growing attention (Hardie and Minks, 1999). In mirids (Heteroptera: Miridae), whose virgin females attract males, long-range sex pheromones have been identified for three species so far (Smith et al., 1991; Millar et al., 1997; Millar and Rice, 1998; McBrien and Millar, 1999).

Close-range sex pheromones initiate courtship behavior. Such pheromones are usually less volatile than long-range pheromones (Blomquist et al., 1993). Despite their low volatility, close-range pheromones may play an important role in the decision of an insect to land at a certain spot (Carlson et al., 1971). Without the addition of such pheromones, arriving males may not enter a trap (Cardé et al., 1975; Kennedy, 1977). In mirids close-range sex pheromones have not yet been reported. Major focus has been on attractive and alarm compounds from the metathoracic and accessory scent glands (e.g., Carayon, 1971; Staddon, 1979; Aldrich, 1988). Compounds identified from these glands have carbon chain lengths of 2–15 and are most commonly acids, aldehydes, ketones, alcohols, and esters (Staddon, 1979; Aldrich, 1988). Close-range pheromones may have carbon chain lengths of 20–30 or even more (Blomquist et al., 1993). The source of long-range pheromones in mirids has been suggested to be the metathoracic scent gland (Aldrich, 1988), or at least the thoracic region (Millar et al., 1997), although Graham (1988) identified the ovipositor region as source of attraction. Since the chemical nature of close-range pheromones may differ completely from long-range pheromones, their sources probably differ as well.

To identify close-range sex pheromones, a specific arousal or courtship behavior of one of the sexes should be distinguished. Males of the green capsid bug [*Lygocoris pabulinus* (L.), Heteroptera: Miridae] exhibit a characteristic sex-specific courtship behavior, a repeated vibration of the abdomen; only males vibrate in the presence of females and only when they are sexually mature (Groot et al., 1998). We used this vibration behavior of male *L. pabulinus* to determine the source of attraction in females at close range. Additionally, we attempted to identify compounds involved in this close-range attraction.

METHODS AND MATERIALS

Insects. *Lygocoris pabulinus* was reared on potted potato plants, (cultivar Bintje) in wooden cages in a greenhouse at $22 \pm 2^{\circ}$C, 65 ± 5 % relative humidity, and 18L : 6D photoregime, following the procedure of Blommers et al. (1997). Every two to three days newly emerged adults were collected from the rearing cages, after which the sexes were isolated in separate rearing cages. In this way, virgin males and females of known age were continuously available for the experiments (Groot et al., 1998).

Bioassays. One to two hours before each test, virgin males 6–9 days old were collected from the separate rearing cages and isolated in small glass tubes. Glass Petri dishes 5 cm diam. were cleaned with acetone, and the bottoms were covered with white filter paper disks of the same diameter. The stimuli to be tested were placed in the Petri dishes, after which one male per dish was introduced. Stimuli consisted of one bug equivalent per Petri dish, and originated from bugs that were virgin and 6–9 days old. All males were observed for 15 min. If a male in a dish started to vibrate within this period, that dish was set aside and counted as a positive response. The number of Petri dishes with positive responses was calculated as a fraction of the total number of Petri dishes in which the stimulus had been applied. Different stimuli were tested at the same time, and stimuli were tested on several different days. All experiments were carried out at 19–23°C between 10:00 and 14:00 hr C.E.T.

In a second experiment, a solid-phase microextraction (SPME) needle (100 μm polydimethylsiloxane coating from Supelco, Bellefonte, Pennsylvania) was positioned on the bottom of the Petri dish through a hole in the side. A metal strip was placed in a V-shape around the needle to reduce the amount of space the bug had, thus increasing the chance of bug–needle contact. One or two bugs were then placed in the Petri dish for 2–3 hr.

Stimuli Tested. First, a series of live females, dead females, live males, and dead males were tested. Bugs were anesthetized with CO_2, after which the heads were clipped off. In a following series freshly anesthetized females were dissected into heads, wings, legs, and thorax plus abdomen. Thorax and abdomen were not subdivided, since clipping would mean cutting through several organs and glands that run from thorax to abdomen, which may then release a variety of chemicals. Third, extracts were made of the different body parts of females, *i.e.*, heads, wings, legs, and thorax plus abdomen. After anesthetizing fresh females with CO_2, the body parts were dissected and placed in 1.8- or 4-ml vials. After dissecting all available females, 15–50 μl of either dichloromethane, pentane, pentane–ether (2 : 1), or water per female was added, the amount of which was set as one female equivalent of the particular extract. The extracts were stored in a freezer (-20 ± 2°C) until used. All extracts were used 1–14 days after the initial dissections. In a fourth series, one female equivalent of a synthetic mixture (2.5 μg in total) was tested. The synthetic mixture consisted of 1-hexanol (40 ng), hexyl butyrate (500 ng), (*E*)-2-hexenyl butyrate (25 ng), (*Z*)-9-tricosene (150 ng), (*Z*)-7-pentacosene (200 ng), (*Z*)-9-pentacosene (1000 ng), (*Z*)-9-heptacosene (200 ng), tricosane (80 ng), and pentacosane (80 ng) (Table 1 below).

Chemical Analysis. Extracts were analyzed with a dual-column GC (HP 6890) equipped with an apolar DB-1 column (J&W Scientific, Folsom, California; 60 m $\times$ 0.25 mm; 0.25-μm) and a polar Stabilwax column (Restek, Bellefonte, Pennsylvania; 60 m $\times$ 0.25 mm; 0.25-μm) and two flame ionization detectors. Oven program: 30°C (2 min hold) to 238°C (25 min hold) at 4°C/min. Hydrogen

TABLE 1. AVERAGE COMPOSITION (%) OF EXTRACTS OF LEGS FROM FEMALE AND MALE *L. pabulinus*

No.[a]	Compound	Composition(%, mean ± SD)	
		Females	Males

[a] Numbers according to Figures 3 and 4.
[b] Compounds used in the synthetic mixture.

was used as the carrier gas (constant flow of 2.4 ml/min, linear velocity: 48 cm/sec). GC-MS analyses were carried out on Varian 3400 GC connected to a Finnigan MAT95 mass spectrometer. The BP5 column (SGE; 25 m × 0.25 mm; 0.25-μm) was programmed from 50°C to 270°C (4 min. hold) at 5°C/min. The mass spectrometer was operated in EI mode (at 70 eV) and scanning was done from mass 24 to 500 at 0.7 sec/dec. ^{1}H NMR (200 MHz) spectra were recorded on a Bruker AC200 spectrometer. FTIR spectra were recorded on a Perkin-Elmer 1725X spectrometer. Identification of compounds in extracts was carried out with GC-MS and by comparison of retention times of reference compounds with GC. The position of the double bond in the alkenes was determined by derivatization with DMDS according to Carlson et al. (1989).

Chemicals. Hexanol, tricosane, pentacosane, 1-bromotetradecane, 1-bromohexadecane, 1-bromooctadecane, triphenylphosphine, nonanal, heptanal, *n*-butyllithium in hexane, DMDS, and urea were all purchased from Acros Organics (Geel, Belgium) and hexyl butyrate from Roth (Karlsruhe, Germany). (*E*)-2-Hexenyl butyrate was synthesized according to Drijfhout et al. (2000). (*Z*)-9-Tricosene, (*Z*)-9-pentacosene, (*Z*)-7-pentacosene, and (*Z*)-9-heptacosene were all synthesized as described below. All the chemicals used were >98% pure. All solvents used were distilled twice before use.

Synthesis of Alkyltriphenylphosphonium Bromide. A mixture of 0.3 mmol of the alkylbromide (1-bromotetradecane, 1-bromohexadecane, or 1-bromooctadecane) and 0.3 mmol of triphenylphosphine was heated to 140°C under a nitrogen atmosphere for 5 hr. The reaction mixture formed a solid when cooled down. Dry acetone (5 ml) and dry diethyl ether (12 ml) were added to the solid and cooled to −20°C (overnight). After filtration, the alkyltriphenylphosphonium bromide was obtained as white crystals.

Synthesis of Alkenes. A slurry of 5 mmol of powdered alkyltriphenylphosphonium bromide in 10 ml of THF was prepared under nitrogen. The mixture was cooled in an ice bath, 5 ml of DMSO was added after which 5 mmol of *n*-butyllithium in hexane was injected. The butyllithium was added at such a rate that the temperature of the mixture remained at 10–15°C. After 5 min, 5 mmol of the aldehyde (nonanal or heptanal) was injected, and the resulting mixture was stirred for 30 min at ambient temperature. The mixture was diluted with water and extracted with petroleum ether 40/60. The dried ($MgSO_4$) extract was filtered and concentrated to give a 90% yield of the alkene. The alkene was further purified with column chromatography on silica gel and eluted with hexane to give a mixture of *Z* and *E* isomers in a ratio of 85 : 15.

Separation of Z and E Isomers. The two isomers of the alkenes obtained during the synthesis were separated making use of their different complexation with urea (Leadbetter and Plimmer, 1979). One part of alkene and five parts of urea were dissolved in 20 parts of methanol. This was left to crystallize at room temperature. The white crystals were separated by filtration. The methanol fraction was evaporated to obtain the (*Z*)-isomer in 97% purity. The procedure was repeated to improve the purity of the *Z* isomer. If the alkene could not be dissolved in methanol, isopropanol was added.

(Z)-9-Tricosene. ^{1}H NMR δ ($CDCl_3$) 0.83–0.89 (t, 6 H, $-CH_3$), 1.2–1.6 (m, 34 H, $-CH_2CH_2-$), 2.0 (m, 4 H, $=CH-CH_2$), 5.3–5.35 (m, 2 H, CH=CH). MS: $m/z = 322$ (M^+); Kovats indices: 2320 on Stabilwax and 2271 on DB-1. IR (film): $\nu_{HC=CH(cis)}$ 722 (m) cm^{-1}

(Z)-7-Pentacosene. ^{1}H NMR δ ($CDCl_3$) 0.83–0.89 (t, 6 H, CH_3), 1.2–1.4, (m, 38 H, $-CH_2CH_2-$), 1.9–2.0 (m, 4 H, $=CH-CH_2$), 5.3, (m, 2 H, CH=CH). MS: $m/z = 350$ (M^+); Kovats indices: 2526 on Stabilwax and 2477 on DB-1; IR (film): $\nu_{HC=CH\ (cis)}$ 722 cm^{-1}

(Z)-9-Pentacosene. ^{1}H NMR δ ($CDCl_3$) 0.83–0.89 (t, 6 H, $-CH_3$), 1.2 (m, 38 H, $-CH_2CH_2-$), 1.9–2.2 (m, 4 H, $=CH-CH_2$), 5.3–5.4 (m, 2 H, CH=CH). MS: $m/z = 350$ (M^+); Kovats indices: 2519 on Stabilwax and 2470 on DB-1; IR (film): $\nu_{HC=CH\ (cis)}$ 722 cm^{-1}

(Z)-9-Heptacosene. ^{1}H NMR δ ($CDCl_3$): 0.9 (t, 6 H, CH_3), 1.1–1.5 (m, 40 H, $-CH_2CH_2-$), 2.2 (m, 4 H, $=CH-CH_2$), 5.3 (m, 2 H, CH=CH). MS: $m/z = 378$ (M^+); Kovats indices: 2721 on Stabilwax and 2671 on DB-1; IR (film): $\nu_{HC=CH\ (cis)}$ 722 cm^{-1}

Statistical Analysis. If males responded to a source, differences in responses towards the different sources were statistically analyzed by fitting a logit regression model with overdispersion to the daily observed counts of responses of a test (McCullagh and Nelder, 1989), using the computer program Genstat 5 (release 4.1, PC/Windows NT, 1997). In the model, source was taken as the explanatory variable and the variance was assumed to be proportional to the binomial variance. First, a chi-square test for the residual deviance was conducted to determine overdispersion. The overall effect of treatments was determined by performing an F test for the ratio of the mean deviance for treatment and the mean deviance of the rest. If the overall test was significant ($P < 0.05$), pairwise comparisons by t test between treatment means on the logit scale were conducted.

RESULTS

Live and dead females elicited similar responses, the fractions of males vibrating being 0.88 ± 0.08 and 0.74 ± 0.09 (mean $\pm$ SE), respectively (Figure 1A). Live and dead males elicited vibration responses in few males. When the bodies of females were dissected, the head, wings, and legs were equally attractive and as attractive as dead females, while the thorax plus abdomen of females were significantly less attractive (Figure 1B). Responses to freshly dissected wings and heads may be due to grooming, which spreads attractive compounds over the body surface. For confirmation of presence of attractive compounds on the whole body surface, small pieces of filter paper were rubbed over female bodies (after anesthetizing and clipping off heads). When these pieces of paper were offered in clean Petri dishes, almost half of the males tested (0.41 ± 0.07, mean $\pm$ SE) started vibrating ($N = 46$).

After extraction of the separate body parts of females, leg extracts elicited significantly more vibrational response than all other extracts (Figure 1C). Extracts from thorax plus abdomen did not elicit a response from males, which may be due to defensive compounds in the metathoracic gland. Therefore, extracts were also made of female thorax plus abdomen, from which the metathoracic gland was removed by gently cutting the cuticle with two sharp tweezers, trying to destroy as little tissue as possible. Few males responded to this extract (Figure 1C). When differences in responses between freshly dissected body parts and their corresponding extracts were statistically compared, male responses to the leg extracts were not different from responses to freshly dissected legs, while wing and head extracts elicited lower responses ($P < 0.05$) than freshly dissected wings and heads.

Organic solvent extracts stimulated significantly more males to vibrate than water extracts (Figure 2). The graph indicates that "water extracts" caused only minimal vibration in males. Legs from female bugs, used for these "water extracts,"

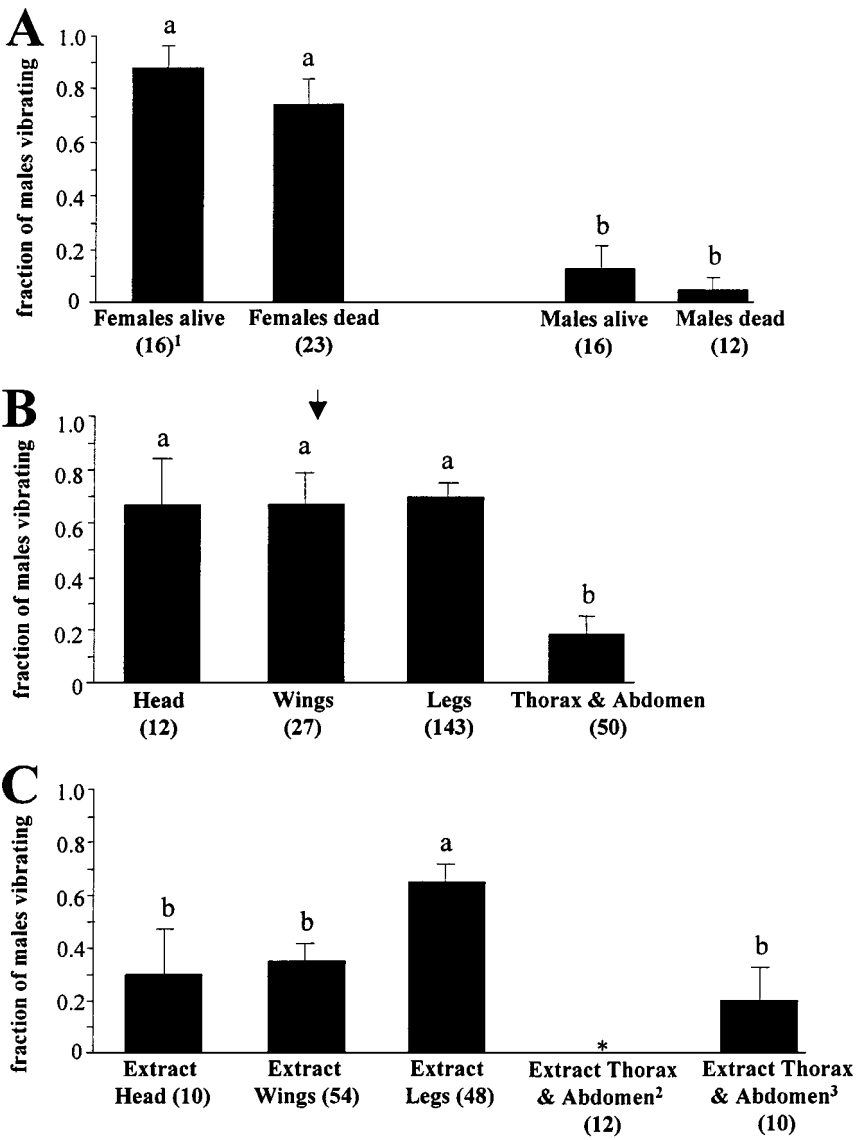

FIG. 1. Male *L. pabulinus* responses (mean ± SE) to different stimuli: (A) whole insects, (B) body parts of females, (C) extracts of female body parts. [1]Total number of males tested; [2]Metathoracic gland left in thorax; [3]Metathoracic gland removed from thorax. Significant differences were determined between sources within one group (A, B, C). Different letters above the bars indicate significant differences in each group at the 5% level. See text for statistical methods used. *Not included in the statistical analyses, as no males had responded.

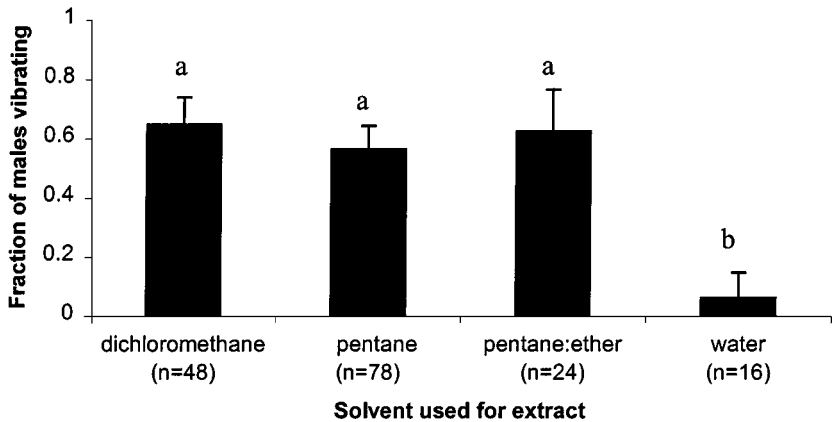

FIG. 2. Response of male *L. pabulinus* to extracts of female legs prepared in different solvents (mean ± SE; n = number of males tested). Different letters above bars indicate significant difference at $P \leq 0.05$ (two-tailed).

still elicited vibratory behavior in males. No significant difference in male vibration occurred using dichloromethane, pentane or the mixture of pentane and ether (Figure 2).

In both male and female leg extracts, the major part of the compounds consisted of hydrocarbons (Figure 3A). These hydrocarbons consisted of alkenes (75%), alkanes (20%), and some monoalkanes (5%). (*Z*)-9-Pentacosene (10) was the most abundant alkene in females, while (*Z*)-9-heptacosene (14) was the most abundant in males. The ratio of (*Z*)-9-pentacosene to (*Z*)-7-pentacosene (11) was opposite in males and females. Furthermore, sometimes the female extracts contained more (*Z*)-9-tricosene than male extracts. (Figures 3B and C). Both male and female extracts contained three oxygen containing compounds: hexyl butyrate (2) and (*E*)-2-hexenyl butyrate (3) and sometimes 1-hexanol (1). Other minor compounds identified in the leg extracts of male and female *L. pabulinus* are listed in Table 1. Table 2 lists some characteristics used to identify the most abundant alkenes present in the extracts.

The vibrational bioassays suggest that female legs are the source of close-range sex pheromone. To determine whether the source of attraction could be defined more precisely, female legs were subdivided into: (A) forelegs, middle legs, and hind legs; or (B) coxae plus femorae, and tibiae plus tarsi. In series A, one pair of forelegs, middle legs, or hind legs of three females was placed in one Petri dish, so that six legs per dish were offered. In series B, the six coxae plus femorae of one female were placed in one Petri dish, and the six tibiae plus tarsi in another. Table 3 shows that all parts of the legs were equally attractive (no significant differences were found between any pair). However, when the overall

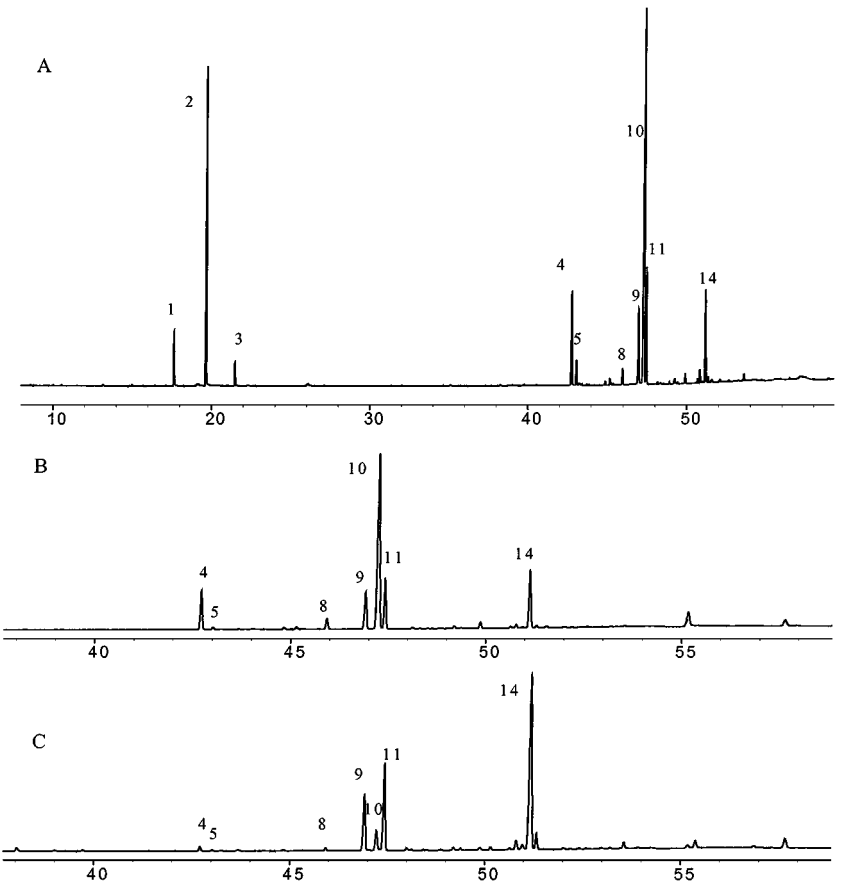

FIG. 3. Gas chromatograms of *L. pabulinus* leg extracts: (A) female leg extract; enlargement of the cuticular hydrocarbon part of female (B) and male (C) extracts. DB-Wax column; FID detector. For explanation of the numbers see Table 1.

response to fore-, middle and hind legs was compared to the overall response to coxae plus femorae and tibiae plus tarsi, responses to entire legs were significantly stronger than to parts.

When legs contain attractive compounds, these compounds may be deposited on the substrate on which female *L. pabulinus* walk. To determine possible deposition of attractive compounds, we tested three different substrates: a piece of potato leaf (cultivar Bintje), a piece of green bean leaf (*Phaseolus vulgaris*, cultivar Miracle), and the glass of an empty Petri dish. One *L. pabulinus* female was allowed to walk in each dish for 75–140 min. As a control, we tested pieces of

potato leaf or empty dishes on which males had walked for 60–120 min, as well as pieces of potato leaves on which no bug had walked. Table 4 shows that males responded to substrates on which females had walked, while no males showed vibration behavior in any of the control dishes. During the 75–140 min that females walked around in the dishes, a characteristic pheromone-laying behavior was not observed. In addition, desorption of the SPME needle (250°C) revealed the same hydrocarbon profile as found in the leg extracts of the concerning sex. From Figure 4 it is clear that when females walked on or near the needle, a high concentration of (*Z*)-9-pentacosene (10) was deposited on the needle. The volatile compounds 1-hexanol (1), hexyl butyrate (2), and (*E*)-2-hexenyl butyrate (3) were not always present.

When the synthetic mixture, containing compounds derived from female leg extracts, was tested in the vibration bioassay, no males started to vibrate. A few males showed vibratory behavior when male legs, loaded with 5 μg (*Z*)-9-pentacosene (instead of 1 μg), were offered (Table 5). Adding (*Z*)-9-tricosene to these legs did not result in more males vibrating. As no biological active compound was found, the possibility of (*Z*)-9-heptacosene acting as a repellent was investigated. Female legs were therefore loaded with a high dose of

(*Z*)-9-heptacosene (5–8 μg). Yet, a similar amount of males showed vibration behavior to these legs as when untreated female legs were offered (Table 5).

DISCUSSION

The legs of *L. pabulinus* females most consistently elicited vibration behavior in males, suggesting that legs are the source of close-range attraction in this species. Legs have been recognized as the site of sex pheromone release in the aphid *Megoura viciae* (Marsh, 1972), the mosquito *Culiseta inornata* (Lang, 1977), the tsetse fly *Glossina morsitans morsitans* (Carlson et al., 1978), the housefly *Musca domestica* (Schlein et al., 1980), and the parasitoid braconid *Ascogaster reticulatus* (Kainoh and Oishi, 1993). In some species, specific glands in the legs have been

[a] Different letters indicate significant difference at $P \leq 0.05$ (two-tailed).

identified as the site of sex pheromone excretion (Marsh, 1972; Schlein et al., 1980). In *L. pabulinus*, response to fore-, middle, and hind legs was similarly strong. The lower response to parts of the legs compared to entire legs may be due to the lower amount of leg biomass per Petri dish in the latter group. From these experiments no specific site of possible glands in legs became apparent.

Specific glands in the legs may not synthesize contact sex pheromones. Cuticular hydrocarbons are probably synthesized by oenocytes, large cells that are rich in smooth endoplasmatic reticulum and mitochondria, which appear to be restricted to epidermal tissue in the thorax and abdomen (Gu et al., 1995; Schal et al., 1998). After synthesis, attractive hydrocarbons may be deposited at specific target sites, as in the German cockroach *Blattella germanica*, where the wings accumulate large amounts of pheromone (Gu et al., 1995). The cuticle of the legs may thus be the specific target deposition site of the attractive compounds.

The presence of a close-range sex pheromone on the legs may also be due to grooming. Grooming may either accumulate pheromone from other body parts on the legs (Howard and Blomquist, 1982), or it may spread the pheromone from leg glands over the whole body surface, as in polistine wasps (Beani and Calloni, 1991), whose territorial marking pheromones from leg glands function as sex attractants as well. *L. pabulinus* males and females groom frequently (Groot et al., 1998) and the attractive compounds are not only present on female legs, but also on other body parts as demonstrated by the male response to female wings and heads and to pieces of filter paper rubbed over female bodies. In short, the site of sex pheromone production does not have to be the site of pheromone release, specific glands are not necessarily involved, and grooming may enhance chemical dispersion or accumulation at specific sites.

In mirids, close-range or contact pheromones have not yet been studied, and to our knowledge this is the first study on cuticular hydrocarbons of a mirid species. In *L. pabulinus* the major part of the hydrocarbons consisted of alkenes, followed by alkanes and some methyl alkanes. All compounds were C_{23}–C_{29}

hydrocarbons. This is also the first time that a clear-cut difference was found in *L. pabulinus* between male- and female-derived compounds, i.e., females produce a high amount of (*Z*)-9-pentacosene, whereas males produce high amounts of (*Z*)-9-heptacosene. Because of the low amount of (*Z*)-9-pentacosene present in males, the ratio of (*Z*)-9-pentacosene and (*Z*)-7-pentacosene is opposite in males and females. To our knowledge, there are only two other studies on cuticular hydrocarbons in heteropteran species, the milkweed bug, *Oncopeltus fasciatus* (Lygaeidae) (Jackson, 1983), and *Triatoma infestans* and *T. mazzotti* (Reduvidae) (Juárez and Blomquist, 1993). In all these species mostly *n*-alkanes, branched monoalkanes, and dimethylalkanes were found. Furthermore hydrocarbons of up to 41–43 carbon atoms were found. More importantly, male and female *O. fasciatus*, *T. infestans*, and *T. mazzotti* had similar profiles, whereas *L. pabulinus* males and females produce a different blend of hydrocarbons.

The hydrocarbons of *L. pabulinus* females appear to elicit vibratory behavior in males, as extracts in water (in which no hydrocarbons are present) were not active. Furthermore, female legs used for water extraction remained active, indicating that the compounds were still present on the legs. Fractionation of the extracts on silica into two fractions (hydrocarbons and oxygenated compounds) suggested that both fractions were needed to elicit vibration behavior in males. The composition of the oxygenated compound fraction of males and females did not show any difference. The similarity of this fraction between males and females was supported by the finding that this fraction from males combined with the hydrocarbon fraction of females did cause vibratory behavior in males (unpublished results).

In various species cuticular hydrocarbons have been identified as contact pheromones (e.g., Muhammed et al., 1975; Carlson et al., 1978; Bolton et al., 1980; Dillwith et al., 1981; Blomquist et al., 1993; Gu et al., 1995; Fukaya et al., 1996; Doi et al., 1997). Alkenes seem to be involved in sexual communication between sexes (Howard and Blomquist, 1982). More precisely, (*Z*)-9-pentacosene is often the main hydrocarbon present in beetles (Baker et al., 1979), ants (Morgan et al., 1992), and bees (Paulmier et al., 1999). In *L. pabulinus*, although (*Z*)-9-pentacosene is the only compound obviously present in much lower amounts in males than in females, the activity of this compound on its own could not be proven in bioassays. Given that the synthetic mixture did not elicit vibration behavior in males, one cannot rule out the possibility of other compounds being part of the contact pheromone. The most abundant male alkene, (*Z*)-9-heptacosene, did not act as a repellent, because female legs sprayed with a high dose of this alkene still elicited vibratory behavior in males (Table 5). More experiments are needed to determine if there are other compounds present in the extracts that act as a vibration elicitor.

The attractive compounds on female legs may be deposited on the substrate. Male *L. pabulinus* showed strong responses to substrates on which females had

walked. The fraction of males responding to potato leaves was even similar to responses to female legs. When females were allowed to walk on a SPME needle, a similar chemical profile was found as in attractive female leg extracts. These results support the hypothesis that these hydrocarbons are deposited on the substrate. As a characteristic pheromone-laying behavior was not observed, we suspect that deposition on the substrate occurs passively or that pheromone is adsorbed to the substrate. Adsorption or deposition of attractive compounds on the substrate increases the probability of sex encounters, as it elicits intensive search by males in these areas (Colwell et al., 1978; Fauvergue et al., 1995). Depending on their volatility, these pheromones are active at some distance, as in *M. viciae* (Pickett et al., 1992), or they elicit response at close range or upon contact, as in the other species mentioned. Adsorption of pheromone to a substrate also increases the surface area from which pheromone evaporates, thereby increasing both the rate of volatilization and the possible communication distance (Colwell et al., 1978). Males may follow a gradient of intensity, created by the decay of the compounds over time, to orient their movements towards females (Fauvergue et al., 1995). In this way, the functional range of low-volatility cuticular hydrocarbons would be greatly enlarged.

Identification of the sex pheromones of mirid species is a challenging task. This study indicates that the sex-specific cuticular hydrocarbons, probably in addition to esters, may play a role in the sexual communication of these bugs. Evidence is accumulating that such hydrocarbons not only function as contact pheromones, but are also involved in attraction at a (short) distance. Uebel et al. (1978) demonstrated that field catches of male *Fannia canicularis* and *F. pusio* increased slightly when alkenes were loaded on the lures. Connor et al. (1980) reported that the pheromone of the arctiid moth *Utetheisa ornatrix* (*Z,Z,Z*-3,6,9-heneicosatriene plus a small quantity of an unidentified C_{21} tetraene), perhaps serves as a close-range orientation cue for locating the female. Recently, Schiestl et al. (1999, 2000) reported that flowers of *Ophrys* orchids also mimic the odor profile of bees by using this class of alkenes in order to attract these bees. Successful pheromone trapping of mirids might also have to take these close-range cues into account.

Acknowledgments—We thank Anneke Heijboer for rearing *L. pabulinus*, Dr. M. A. Posthumus for carrying out all the GS-MS experiments, and Pieter Vereijken for conducting the statistical analyses. Marcel Dicke, Teris van Beek, and Hans Visser are greatly acknowledged for critical comments on earlier versions of the manuscript. OVIPOSITION DETERRENT BY FEMALE REPRODUCTIVE GLAND SECRETION IN JAPANESE PINE SAWYER, *Monochamus alternatus*

HISASHI ANBUTSU[1] and KATSUMI TOGASHI*

Department of Environmental Studies
Faculty of Integrated Arts and Sciences, Hiroshima University
Hiroshima 739-8521, Japan

(Received June 20, 2000; accepted January 28, 2001)

Abstract—Adult females of *Monochamus alternatus* are known to use palpation to recognize oviposition scars that contain eggs and to be deterred from oviposition. This study investigated the oviposition-deterring activity of a jellylike secretion deposited by the females immediately after oviposition and methanol extracts of female reproductive organs in the laboratory. When females searching for oviposition sites encountered artificial oviposition scars, they stopped walking and drummed the surface and inside of the oviposition scars with their maxillary and labial palpi. When the females encountered the artificial scars plugged with the jellylike secretion, most of them left the scars after palpation. In contrast, when females encountered artificial scars not plugged with the secretion, most of them deposited single eggs through the scars. In another experiment, most females left artificial scars treated with methanol extracts of the spermathecal gland or other reproductive organs after palpation, but most of them oviposited through the scars treated with methanol alone. The results showed that females' recognition of egg-containing scars and departure from such scars were mediated by the chemical(s) produced by their reproductive organs.

Key Words—Coleoptera, Cerambycidae, egg recognition, female reproductive organs, *Monochamus alternatus*, oviposition behavior, oviposition-deterring pheromone, oviposition scar, spermathecal gland.

INTRODUCTION

In many phytophagous insects where larval development is confined to a limited food resource, ovipositing females recognize and avoid hosts already occupied

by conspecific eggs (e.g., Prokopy, 1972, 1975; Prokopy et al., 1976, 1977, 1978). In such cases, certain chemicals mediate these behavioral strategies. They are called oviposition-deterring pheromones (ODPs) or host-marking pheromones (HMPs).

The cerambycid beetle *Monochamus alternatus* Hope (Coleoptera: Cerambycidae) is a primary vector of the pinewood nematode, *Bursaphelenchus xylophilus* (Steiner et Buhrer) Nickle, the causative agent of pine wilt disease in Japan (Mamiya and Enda, 1972; Morimoto and Iwasaki, 1972). They oviposit on dying and recently killed trees of *Pinus densiflora* Sieb. et Zucc. and *P. thunbergii* Parl. The larvae feed on the phloem and pupate in xylem (Togashi, 1989).

Prior to oviposition, a female *M. alternatus* searches for a suitable site for oviposition, walking slowly and touching the bark surface with her maxillary and labial palpi and one or both antennae (Anbutsu and Togashi, 2000). On finding a suitable site, the female stops walking and begins to gnaw at the bark surface with her mandibles to make a wound. Then, the female turns 180° to position the ovipositor over the wound, inserts the ovipositor through the center of the wound, and deposits a single egg in the inner bark. Before withdrawing her ovipositor from the wound, the female deposits a jellylike secretion at the bottom of the central hole of the wound. Just after withdrawal, the female rubs the wound with her abdominal tip and then leaves it (Anbutsu and Togashi, 2000). In this paper, wounds with an obvious hole indicating the insertion of the ovipositor are called oviposition scars.

The oviposition scars of *M. alternatus* are distributed uniformly on the bark surface of dead pine trees (Kobayashi, 1975; Shibata, 1984). The females are deterred from ovipositing at all on pine bolts heavily infested with oviposition scars (Anbutsu and Togashi, 1996). When *M. alternatus* females searching for oviposition sites encounter oviposition scars containing eggs, they palpate the scars with their maxillary and labial palpi and then leave the area (Anbutsu and Togashi, 2000).

The deposition of a jellylike secretion and the rubbing of the oviposition scars with the abdominal tip seem to be related to the marking of the oviposition scars. In most cases, however, the departure of females from egg-containing oviposition scars occurs not after the drumming of the bark surface around the oviposition scars rubbed with abdominal tips, but after they insert their maxillary palpi into the central hole of the scars (Anbutsu and Togashi, 2000). Thus, the jellylike secretion is more likely to be related to the female's recognition of the egg-containing oviposition scars and departure from them. Close observation suggests that this secretion comes from the ovipositor of the female.

The objective of this study was to determine the oviposition-deterring activity of the jellylike secretion and of an extract of female reproductive organs.

METHODS AND MATERIALS

Insects. Laboratory cultures of *M. alternatus* were established from collections of dead, infested *P. densiflora* trees at Tokuyama City, Yamaguchi Prefecture, Japan in 1994.

Newly emerged adults were raised individually in plastic containers (9 × 18 × 4.5 cm) on current year to 2-year-old *P. densiflora* twigs at 25°C and under a 12L:12D photoregime. Seven days after emergence, the females and males were paired and provided with *P. densiflora* bolts (see below) for oviposition. Female fertility was confirmed by larval hatching. All adult females used in this study were allowed to oviposit prior to tests.

Pine Bolts. Healthy *P. densiflora* branches were collected in Higashi-Hiroshima City, Hiroshima Prefecture, Japan, and cut into 7-cm-long branch sections referred to as bolts in this paper. The bolts, which were 1.5–2.5 cm in diameter and 5–10 years old, were then placed into polyethylene bags filled with 60–70°C hot water to kill the cells of the inner bark. After cooling the bolts to room temperature over 12–24 hr, they were washed with tap water. After surficial drying at room temperature, both cut ends of each bolt were sealed with paraffin (melting point: 56–58°C) to retard desiccation. The bolts were then placed in polyethylene bags and stored at 25°C until use.

Artificial Oviposition Scars. Artificial oviposition scars were made on 7-cm-long pine bolts. Each artificial scar consisted of one deep, small hole reaching the inner bark and two shallow, smaller wounds running alongside the hole (Anbutsu and Togashi, 2000). The deep hole, ca. 1.0 mm in diameter, was made with the tip of a nail (2.8 mm in diameter) to imitate the trace left by ovipositor insertion. The two shallow wounds were made with sharp-tipped tweezers and imitated marks made with mandibles.

Response of Females to Artificial Scars Plugged with Jellylike Secretion Deposited by Other Females (Experiment 1). Two treatments were designed to test the effect of the secretion on the response of the females to artificial oviposition scars: (1) artificial scars plugged with the jellylike secretion, and (2) artificial scars with no treatment.

To make artificial scars plugged with jellylike secretion, female beetles were placed individually in plastic containers and provided with pine bolts for oviposition. Immediately after the females finished oviposition, an artificial oviposition scar was made at the center of another 7-cm-long bolt and the fresh secretion that was collected from the new, beetle-made oviposition scar was transferred into the central hole of the artificial oviposition scar. The 7-cm-long bolts, each of which contained an artificial scar either with or without the jellylike secretion, were used for tests immediately after making the scars.

A single, 18- to 57-day-old *M. alternatus* female was introduced into a plastic container with a 7-cm-long bolt with one of the two types of the above scars.

The behavior of the female was then recorded for 2–5 hr as she encountered the artificial scar for the first time during her search for an oviposition site. As soon as the beetle departed the scar, the bolt was removed from the container. The scar was then examined, and the number of eggs deposited was determined. All tests were conducted in the laboratory at 25–28°C and under electric light (250–600 lx). Tests for each type of scar were replicated 20 or 21 times. Each female was tested once for each type of scar.

Response of Females to Artificial Scars Treated with Methanol Extract of Female Reproductive Organs (Experiment 2). Since the jellylike secretion deposited into the oviposition scar averaged 1 × 1 × 1 mm, its physiological reservoir was considered to be large and detectable. Dissection revealed that an *M. alternatus* female has a long spermathecal gland (Figure 1). When living females were dissected, the gland contained an almost colorless or slightly yellowish, transparent liquid. However, when females were dissected within a day of their death, the gland was filled with an amber colored, transparent jellylike substance. The substance was very similar in color and viscosity to the jellylike secretion deposited into oviposition scars. Therefore, the spermathecal gland was thought to be the reservoir of the jellylike secretion.

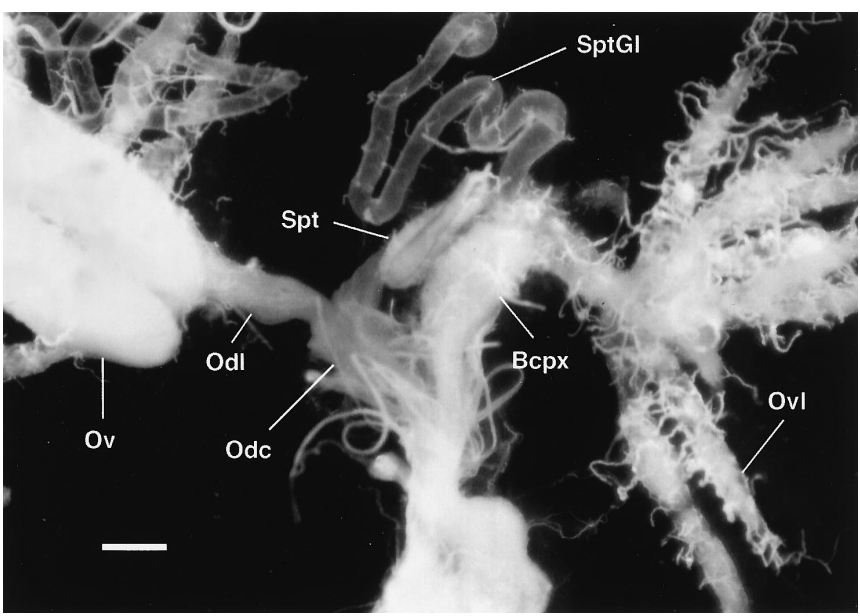

FIG. 1. Reproductive organs of the *Monochamus alternatus* female. Bcpx, bursa copulatrix; Odc, oviductus communis; Odl, oviductus lateralis; Ovl, ovariole; Ov, ovary; Spt, spermatheca; SptGl, spermathecal gland. Scale bar = 1 mm.

Living females anesthetized at 5°C were dissected in a physiological saline solution, the reproductive organs were removed, and the spermathecal gland was separated from the others. The spermathecal gland and other reproductive organs were placed separately in 99.8% methanol, sonicated for 1 min and then allowed to stand at 4°C for 12–24 hr. The methanol containing the spermathecal glands or other reproductive organs was filtered using an injector with a piece of absorbent cotton, the filtrate was then concentrated by evaporation at 25–28°C. The equivalent of four females was placed on a 1 × 10 mm rectangular piece of filter paper (Toyo Roshi Kaisha, Advantec 2) and dried for 30 min in the laboratory. After removing the solvent by evaporation, the paper was cut into 10 square pieces 1 × 1 mm, so that the amount of substances contained in each paper square was 0.4 equivalents of spermathecal glands or other reproductive organs. One microliter of deionized water was put into the central hole of a newly made artificial scar on a 7-cm-long pine bolt, and the filter paper square was then placed in the hole. Immediately after the treatment, the bolt was subjected to testing.

Experiment 2 had three treatments: (1) artificial scars treated with extract of spermathecal glands alone, (2) artificial scars treated with extract of female reproductive organs except the spermathecal glands, and (3) artificial scars treated with methanol alone (control).

The response of females to each type of scar was observed as described for experiment 1. These tests were replicated 20–22 times. A 43- to 74-day-old female was tested once for each type of scar.

Statistical Analyses. The Kolmogorov-Smirnov two-sample test was used to compare the behavioral sequence of *M. alternatus* between treatments. A chi-square test in a contingency table was used to compare the proportion of ovipositing females between treatments.

RESULTS

Response of Females to Artificial Scars Plugged with Jellylike Secretion Deposited by Other Females (Experiment 1). When *M. alternatus* females searching for oviposition sites reached the artificial oviposition scars, they exhibited the same response to the artificial scars as they did to oviposition scars made by the beetles (Anbutsu and Togashi, 2000). They stopped walking and then drummed the surface and central holes of the scars with their maxillary and labial palpi, frequently inserting the former alternately into the central holes. After about 5 sec of palpation, they either left the scars or began to gnaw at them and deposited single eggs.

When the females encountered artificial oviposition scars plugged with the jellylike secretion, 80% left the scars after palpation (Figure 2A). In contrast, when the females encountered artificial scars not plugged with the jellylike secretion,

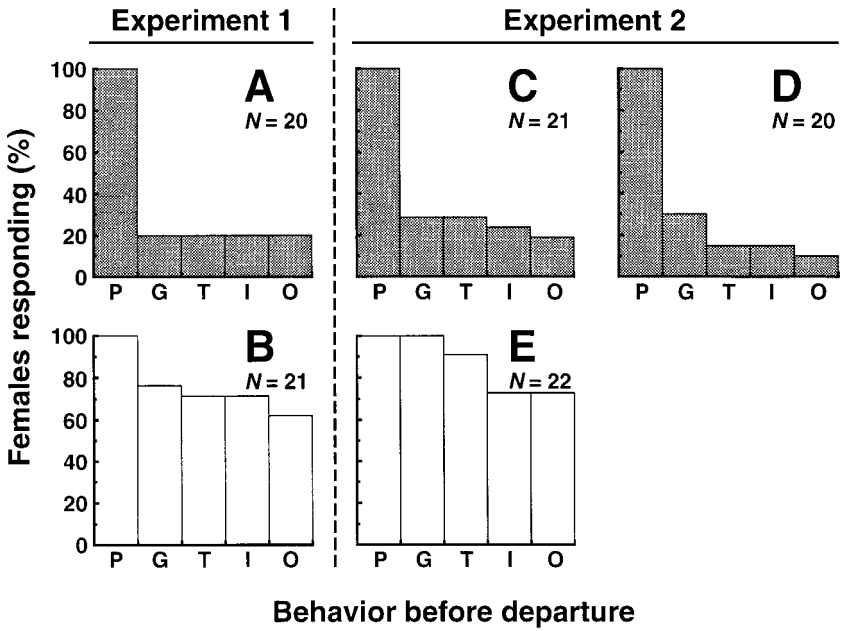

FIG. 2. Response of *Monochamus alternatus* females to the artificial oviposition scars plugged with the jellylike secretion deposited by other females (A); not plugged with the secretion (B); treated with a methanol extract of the spermathecal gland (C); treated with a methanol extract of other reproductive organs including ovariole, oviductus lateralis, oviductus communis, bursa copulatrix, and spermatheca (D); and treated with methanol alone (E). The abscissa shows the behavioral sequence: palpation of the scars (P), gnawing at them (G), 180° body turn (T), insertion of ovipositor (I), and oviposition (O). The ordinate shows the proportions of females exhibiting the particular behavior. N = number of females used in the tests.

76% began to gnaw at the scars after palpation and 62% deposited a single egg each (Figure 2B). The response of females was different between the artificial scars with and without the jellylike secretion (Kolmogorov-Smirnov two sample test, $D = 0.56$, $P < 0.01$) (Figure 2A and B); the proportion of ovipositing females was lower for secretion-containing artificial scars (20%) than for scars without secretion (62%) (contingency table, $\chi^2 = 7.4$, $df = 1$, $P < 0.01$) (Figure 3).

Response of Females to Artificial Scars Treated with Methanol Extract of Female Reproductive Organs (Experiment 2). When females searching for oviposition sites encountered artificial scars treated with methanol extracts of female reproductive organs or methanol alone, they stopped walking and palpated the scars. After palpation, about 70% of the females left the scars treated with methanol

extracts of spermathecal glands or other reproductive organs (Figure 2C and D). In contrast, when the artificial scars were treated with methanol alone, all tested females began to gnaw at the scars and 73% deposited single eggs (Figure 2E). There was no difference in their response between the artificial scars treated with methanol extracts of spermathecal gland and other reproductive organs (Kolmogorov-Smirnov two sample test, $D = 0.14$, $P = 0.98$) (Figure 2C and D). However, the response to artificial scars treated with methanol alone differed from responses to the scars treated with methanol extract of spermathecal gland (Kolmogorov-Smirnov two sample test, $D = 0.71$, $P < 0.001$) (Figure 2C and E) and responses to the scars treated with methanol extract of other reproductive organs (Kolmogorov-Smirnov two sample test, $D = 0.76$, $P < 0.001$) (Figure 2D and E).

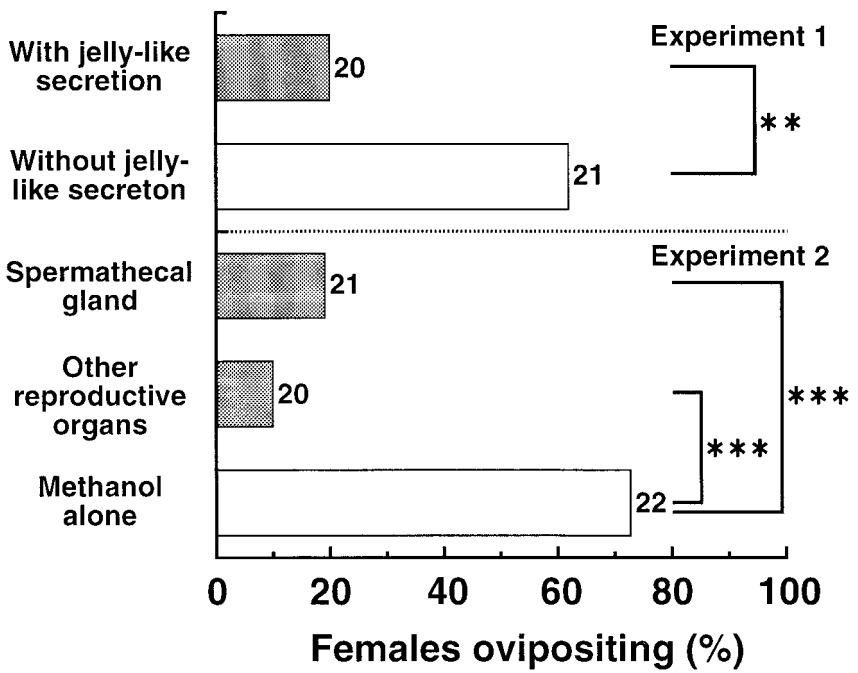

FIG. 3. Ovipositional response of *Monochamus alternatus* females to the artificial oviposition scars plugged with jellylike secretion; not plugged with the secretion; treated with a methanol extract of the spermathecal gland; treated with a methanol extract of other reproductive organs including ovariole, oviductus lateralis, oviductus communis, bursa copulatrix, and spermatheca; and treated with methanol alone. The figures to the right of each column represent the number of females used in the tests. The brackets represent a significant difference by the chi-square test (**$P < 0.01$, ***$P < 0.001$).

The females deposited eggs less frequently through artificial scars treated with methanol extract of spermathecal gland (19%) (contingency table, $\chi^2 = 12.4$, $df = 1$, $P < 0.001$) or other reproductive organs (10%) (contingency table, $\chi^2 = 16.8$, $df = 1$, $P < 0.001$) than through artificial scars treated with methanol alone (73%) (Figure 3).

DISCUSSION

This study showed that *M. alternatus* females were deterred from oviposition both by the jellylike secretion that the conspecific females deposited in the oviposition scars immediately after oviposition and by methanol extract of female reproductive organs (Figures 2 and 3). These results show that females' recognition of the egg-containing scars and departure from such scars were elicited by semiochemical(s) contained in the jellylike secretion they deposited. The semiochemicals were detected in female reproductive organs. Deposition of a jellylike secretion to an oviposition scar after egg laying and avoidance of such a scar also have been reported in the closely related *Monochamus saltuarius* (Gebler) (Anbutsu and Togashi, 1997). The same or similar semiochemical(s) as found in *M. alternatus* may play a role in deterred oviposition in *M. saltuarius.*

When the oviposition scar contains a single egg, the survival rate of the egg is about 0.9 (Anbutsu and Togashi, unpublished), but when an *M. alternatus* female deposits an egg through an oviposition scar already occupied by an egg, the earlier-hatching larva bites and kills the other at the egg or young larval stage. The survival rate of later-deposited eggs was experimentally shown to be less than 0.5 (Anbutsu and Togashi, unpublished).

Sexually mature adults of *M. alternatus* are attracted by a mixture of monoterpenes and ethanol, which are released from *P. densiflora* trees felled by man or inoculated with the pinewood nematode (Ikeda and Oda, 1980; Ikeda et al., 1980, 1986). The concentration of the volatiles is assumed to be higher around the oviposition scars because the bark surface is excavated and the inner bark is exposed. In addition, the oviposition of *M. alternatus* is evoked by nonvolatiles present in the inner bark of *P. densiflora* (Yamasaki et al., 1989). Therefore, if the females could not recognize oviposition scars containing eggs, redundant oviposition might occur more frequently and the fitness of females with secondary oviposition would decrease due to the resulting high mortality of their progeny. The period from egg deposition to larval hatching varies from six to nine days at 25°C in *M. alternatus* (Okuda, 1973). Thus, if the interval between the first and second oviposition events is less than three days, some secondary eggs could hatch before the primary egg and kill it, thus decreasing the fitness of the primary female. Other roles of the jellylike secretion such as maintenance of humidity around eggs and protection from predators are unknown.

The presence of chemical marking to prevent oviposition by other individuals is known in phytophagous insects of the species Coleoptera, Lepidoptera, and Diptera; the Azuki bean weevil, *Callosobruchus chinensis* (L.) (Oshima et al., 1973), the cigarette beetle, *Lasioderma serricorne* (F.) (Kohno et al., 1986; Imai et al., 1990); the cabbage seed weevil, *Ceutorhynchus assimilis* Payk. (Ferguson and Williams, 1991; Mudd et al., 1997); the orange-tip butterfly, *Anthocharis cardamines* (L) (Dempster, 1992); the European grapevine moth, *Lobesia botrana* Den. et Schiff. (Gabel and Thiéry, 1992); and *Hylemya* sp. (Zimmerman, 1979). Many tephritid flies (Diptera) are also known to deposit oviposition-deterring pheromones (Katsoyannos, 1975; Prokopy, 1972, 1975; Prokopy et al., 1976, 1977, 1978; Straw, 1989). In previous studies, the oviposition deterrent was shown to originate from ovaries (Prokopy et al., 1976; Zimmerman, 1979), accessory glands (Schoonhoven, 1990), or the epidermal cells of the seventh urotergite posterior fold (Ferguson et al., 1999). Our study indicated that the spermathecal gland was a reservoir of the jellylike secretion (Figure 2) that contained the deterrent chemical(s). Other reproductive organs also showed oviposition-deterring activity (Figure 2). This suggests that two or more reproductive organs may secrete oviposition-deterring pheromone(s) or that other reproductive organs such as the spermatheca and oviductus communis are contaminated with the secretion from the spermathecal gland (Figure 1).

Oviposition-deterring pheromones are important in pest control. An attempt to prevent infestation of tephritid flies by spraying oviposition-deterring pheromone on its host was successful in the field (Katsoyannos and Boller, 1976, 1980). In a pine forest infested with pine wilt disease, *M. alternatus* females deposit their eggs on pine trees killed recently by the disease. In the following year, the adult beetles carrying pathogenic nematodes emerge from the dead trees, disperse, and transmit the nematodes to healthy trees. The application of oviposition-deterring pheromone(s) of *M. alternatus* or the related chemical(s) to pine trees killed recently by pine wilt disease may prevent *M. alternatus* females from depositing eggs on such trees, resulting in the inhibition of a pine wilt epidemic by the reduced reproduction of such insects. Further investigation is needed to determine the organ that produces the oviposition deterrent and to identify the semiochemical(s).

Acknowledgments—The authors are grateful to the staff of the Tokuyama Forest Experiment Station of Kyoto University for assisting the collection of dead pine trees. (Received March 30, 2000; accepted January 27, 2001)

Abstract—Our objective was to test the hypothesis that the pheromone blend and/or diel periodicity of pheromonal communication differ in populations of the nun moth, *Lymantria monacha* (Lepidoptera: Lymantriidae), from eastern Asia (northern Honshu, Japan) and Central Europe (Bohemia, Czech Republic). Coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses of pheromone gland extract of female *L. monacha* from Japan confirmed the presence of compounds previously identified in pheromone extracts of *L. monacha* from Bohemia, as follows: (*Z*)-7-octadecene, 2-methyl-(*Z*)-7-octadecene (2me-*Z*7–18Hy), *cis*-7,8-epoxy-octadecane (monachalure), and *cis*-7,8-epoxy-2-methyloctadecane (disparlure). Field experiments in Honshu suggested that (+)-monachalure is the major pheromone component of *L. monacha*. 2me-*Z*7–18Hy significantly enhanced attractiveness of (+)-monachalure. Addition of (+)-disparlure to (+)-monachalure plus 2me-*Z*7–18Hy in Honshu and Bohemia increased attractiveness of lures by 1.2 and 20 times, respectively, indicating that (+)-disparlure is of least and most significance in the respective *L. monacha* populations. Moreover, capture of male *L. monacha* in pheromone-baited traps between 18:00 and 24:00 hr in Bohemia and 2:00 and 5:00 hr in Honshu revealed a markedly different diel periodicity of pheromonal communication. Pheromonal communication late at night and use of (+)-monachalure, rather

*To whom correspondence should be addressed.

0098-0331/01/0600-1163$19.50/0

than (+)-disparlure, as the major pheromone component by *L. monacha* in Honshu may have resulted from interspecific competition with coseasonal *L. fumida*, which uses the early night for pheromonal communication and (+)-disparlure as major pheromone component. Whether communication channel divergence of *L. monacha* in Honshu indeed constitutes a case of reproductive character displacement is difficult to prove. The evolution of such divergence in *sympatric* populations of *L. fumida* and *L. monacha* would have to be demonstrated.

Key Words—*Lymantria monacha*, *Lymantria fumida*, *Lymantria dispar*, diel periodicity, interspecific competition, reproductive character displacement, strain, (7*R*, 8*S*)-*cis*-7,8-epoxy-2-methyloctadecane, (+)-disparlure, (7*R*, 8*S*)-*cis*-7,8-epoxy-octadecane, (+)-monachalure, 2-methyl-(*Z*)-7-octadecene, (*Z*)-7-octadecene.

INTRODUCTION

The nun moth, *Lymantria monacha* (Lepidoptera: Lymantriidae), is a significant forest defoliator. Polyphagous caterpillars defoliate gymnosperm trees mainly in the genera *Picea* (spruce), *Pinus* (pine), *Larix* (larch), and *Abies* (fir), but also feed on angiosperm trees, including *Fagus* (beech), *Carpinus* (white beech), *Betula* (birch), and *Quercus* (oak) spp. (Wellenstein, 1978).

The first recorded *L. monacha* population outbreak (1853–1864) occurred in European Russia. In this outbreak, 147,000,000 m^3 of timber were killed (Bejer, 1988). Since then, outbreaks have occurred throughout Europe. Five outbreaks are recorded in Poland between 1946 and 1986 (Sliwa and Sierpinski, 1986). During the largest, from 1978 to 1983, over 2 million ha of spruce, pine, and larch forests (one quarter of Poland's forests) were infested and partly defoliated (Schönherr, 1985).

In Europe and western Asia, the northern border of the *L. monacha* range coincides with the September isotherm of 10.5°C, which extends from the southern part of England and Scandinavia to the Ural Mountains (Wellenstein, 1978; Bejer, 1988). The southern extent of its range coincides with the isotherm of >20°C for June, July, and August. This isotherm line crosses central Spain, Corsica, Italy, the Ariatic coast from Slovenia to northern Greek and the Black Sea. The range of *L. monacha* extends, disjunctly, eastward into eastern China, Korea and Japan. Asian populations consist of white color morphs with black spotting. Melanistic forms, as frequently found in Europe (Keena et al., 1998), are absent.

Pheromone blend and diel periodicity of pheromonal communication in *L. monacha* from Central Europe and Japan could differ, because respective populations: (1) occupy different geographic ranges, (2) are reproductively isolated, and (3) are part of lymantriid communities that contrast in numbers of congeners. For example, the July–August lymantriid community of Honshu (northern Japan) comprises *L. monacha*, gypsy moth, *L. dispar*, pink gypsy moth, *L. mathura*, *L. fumida*, *L. lucescens*, and *L. bantaizana*. Presence (Honshu) or absence

(Bohemia, Czech Republic) of *L. mathura, L. fumida, L. lucescens,* and *L. bantaizana* could conceivably affect interspecific competion for communication channels, and thus pheromonal communication in *L. monacha*.

Pheromonal communication of *L. monacha* in Bohemia is mediated by a complex volatile blend. At a 10 : 10 : 1 ratio, the three pheromone components (7*R*, 8*S*)-*cis*-7,8-epoxy-2-methyloctadecane [(+)-disparlure] (Bierl et al., 1975; Klimetzek et al., 1976), (7*R*,8*S*)-*cis*-7,8-epoxy-octadecane [(+)-monachalure] (Gries et al., 1996), and 2-methyl-(*Z*)-7-octadecene (2me-*Z*7–18Hy) (Grant et al., 1996; Gries et al., 1996), synergistically attract male *L. monacha*, whereas (−)-disparlure, (+)- and (−)-monachalure, 2me-*Z*7–18Hy, and (*Z*)-7-octadecene (*Z*7–18Hy) synergistically prevent cross-attraction of male *L. dispar* (Gries et al., 1996).

This study reports contrasting pheromone blends and diel periodicities of pheromonal communication in two geographically remote populations of *L. monacha,* and suggests reproductive character displacement as a mechanism responsible for these differences.

METHODS AND MATERIALS

Experimental Insects and Chemical Analyses. Pupae of *L. monacha* were collected in northern Japan. Abdominal tips with pheromone glands of calling, virgin female moths were removed and placed in redistilled hexane. These extracts were hand-carried, and light-trapped male moths couriered to Simon Fraser University in Canada. Aliquots of one female equivalent (FE) of pheromone gland extract and authentic standards were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975), using a Hewlett Packard (HP) 5890A gas chromatograph equipped with a fused silica column (30 m × 0.25 or 0.32 mm ID) coated with either DB-210, DB-5, or DB-23 (J&W Scientific, Folsom, California). Synthetic chemicals for laboratory and field testing, including (+)- and (−)-disparlure, (+)- and (−)-monachalure, 2-methyl-(*Z*)-7-octadecene (2me-*Z*7–18Hy), and (*Z*)-7-octadecene (*Z*7–18Hy), were available from previous work (Gries et al., 1996). If indicated, compounds were purified (>95%) by high-performance liquid chromatography (HPLC), employing a Waters LC 626 high-performance liquid chromatograph equipped with a Waters 486 variable wavelength UV visible detector, a Waters 746 data module, and a Nova-Pak C_{18} column (3.9 × 300 mm) with 1 ml/min of acetonitrile flow.

Composition of Pheromone Blends. All field experiments employed a complete randomized block design with 9–12 blocks (replicates) each. Experiments were conducted in forests near (<50 km) the cities of Morioka (Honshu) and Zbraslav (Bohemia). Forests were stocked mainly with Japanese larch, *Larix leptolepsis,* and Norway spruce, *Picea abies,* respectively. Delta-like traps were made from 2-liter milk cartons (Gray et al., 1984), coated with Tanglefoot (The

Tanglefoot Company, Grand Rapids, Michigan), and suspended from trees 1.5 m above ground at 15 to 20-m spacing. They were baited with a gray sleeve stopper (identification # 10600275; West Pharmaceutical Services, Lionville, Pennsylvania) impregnated with candidate pheromone components in HPLC-grade hexane.

Experiment 1 compared attraction of male *L. dispar* and *L. monacha* to (+)-disparlure and (+)-monachalure, respectively. With only (+)-monachalure significantly attractive to male *L. monacha* (and thus likely being the major pheromone component of *L. monacha* in Honshu), experiments 2–3 investigated potential synergists, including (+)-disparlure, 2me-*Z*7–18Hy (the hydrocarbon analog of disparlure), and *Z*7–18Hy (the hydrocarbon analog of monachalure). Experiments 4–6 tested the effect of presence and proportion of (+)-monachalure in pheromone blends on attraction of male *L. monacha, L. fumida,* and *L. dispar*. Experiments 7–10 compared the relative importance of (+)-disparlure in pheromone blends for attraction of male *L. monacha* in Honshu and Bohemia.

Various treatments in several experiments did not attract any male moths. Despite transformation, trap catch data were not normally distributed and were thus analyzed by nonparametric analyses of variance (Friedman's test) followed by comparison of means by Bonferroni (Dunn) *t* test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

Diel Periodicity of Pheromonal Communication. Diel periodicities of pheromonal communication of *L. monacha* in Bohemia (experiment 10) and of *L. monacha* and *L. fumida* in Honshu (experiment 11) were assessed by hourly recording captures of male moths in pheromone-baited traps. Experiment 10 had already been conducted during nine nights in 1989 and employed two sticky beta type traps (ÚOCHB AVCR, Praha, Czech Republic) baited with rubber septa impregnated with (±)-disparlure (100 μg) (ÚOCHB AVCR). For experiment 11, the 20 sticky Delta traps (see above) were suspended from trees ~2 m above ground at 15 to 20-m intervals. Traps were baited with gray sleeve stoppers impregnated with the three-component blend of (+)-monachalure (50 μg), (+)-disparlure (5 μg), and 2me-*Z*7–18Hy (5 μg) for male *L. monacha* or with the two-component blend of (+)-disparlure (50 μg) and 2me-*Z*7–18Hy (5 μg) for male *L. fumida* (Schaefer et al., 1999). Baits for *L. monacha* and *L. fumida* were alternated between traps.

RESULTS

Comparative GC-EAD analyses of pheromone gland extract and synthetic standards on three fused silica columns confirmed the presence of *Z*7–18Hy (peak **1**), 2me-*Z*7–18Hy (peak **2**), monachalure (peak **3**) and disparlure (peak **4**) in pheromone extracts of female moths (Figure 1). Disparlure appeared to be most

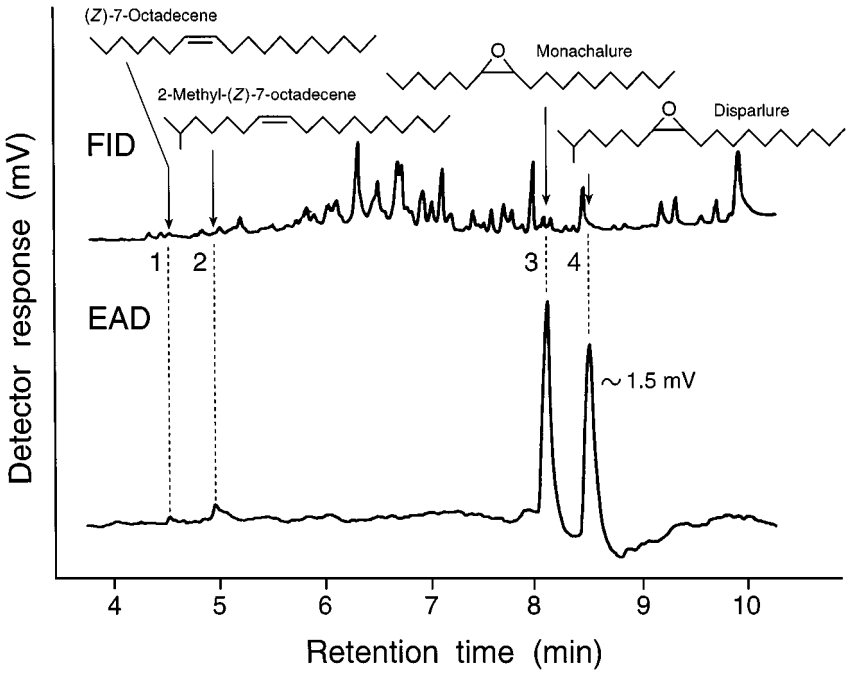

FIG. 1. Flame ionization detector (FID) and electroantennographic detector (EAD: male *L. monacha* antenna) responses to one female (*L. monacha* from Honshu) equivalent of pheromone gland extract. A gas chromatograph was fitted with a fused silica column (30 m × 0.25 mm ID) coated with DB-23; temperature program: 50°C (1 min), then 25°C/min to 100°C then 10°C/min to 220°C (10 min). Compound abbreviations: **1** = (*Z*)-7-octadecene (*Z*7–18Hy); **2** = 2-methyl-(*Z*)-7-octadecene (2me-*Z*7–18Hy); **3** = (7*R*,8*S*)-*cis*-7,8-epoxy-octadecane [(+)-monachalure] or (7*S*, 8*R*)-*cis*-7,8-epoxy-octadecane [(−)-monachalure]; **4** = (7*R*, 8*S*)-*cis*-7,8-epoxy-2-methyloctadecane [(+)-disparlure] or (7*S*, 8*R*)-*cis*-7,8-epoxy-2-methyloctadecane [(−)-disparlure]. Retention indices: *Z*7–18Hy: 1782 (DB-5), 1792 (DB-210), 1825 (DB-23); 2me-*Z*7–18Hy: 1842 (DB-5), 1860 (DB-210), 1877 (DB-23); monachalure: 1971 (DB-5), 2234 (DB-210), 2284 (DB-23); disparlure: 2032 (DB-5), 2306 (DB-210), 2339 (DB-23).

abundant, but GC-mass spectrometry (MS) confirmed that another quantitatively significant compound co-eluted with it. All four EAD-active components occurred at quantities too low to reliably calculate their relative proportion.

In field experiment 1, (+)-monachalure attracted male *L. monacha*, whereas (+)-disparlure attracted male *L. dispar* (Figure 2). The hydrocarbon analog of disparlure, 2me-*Z*7–18Hy, was significantly more effective than (+)-disparlure in enhancing attractiveness of (+)-monachalure (Figure 2, experiment 2). In contrast,

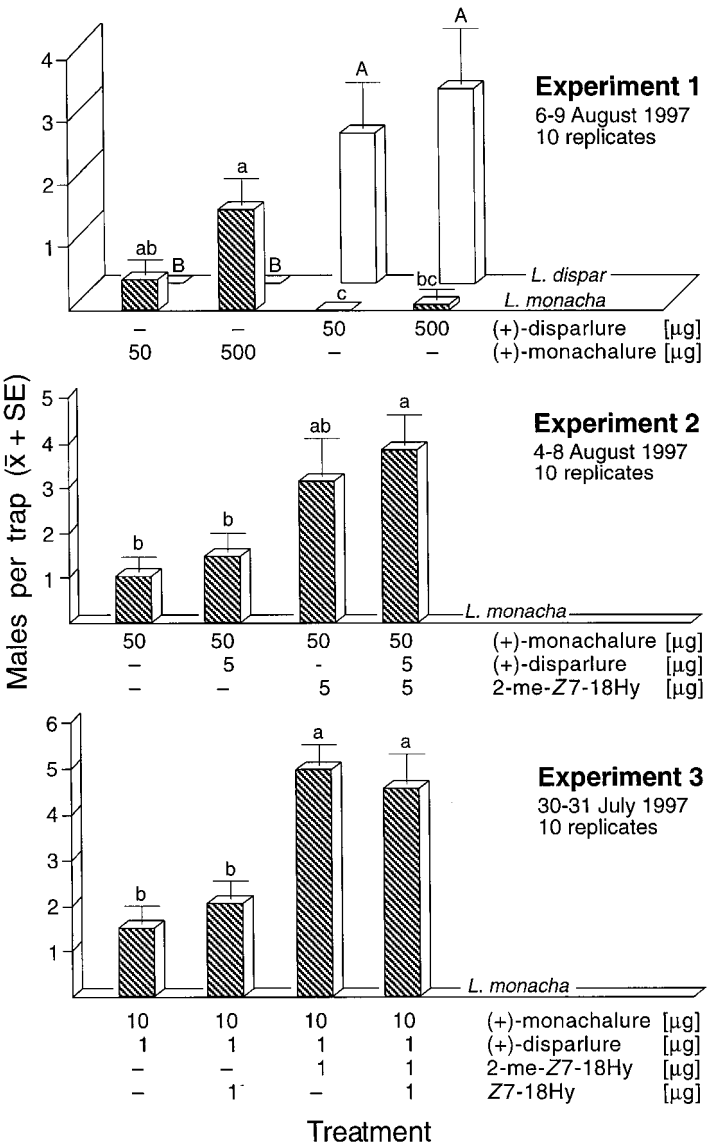

FIG. 2. Mean number of male *L. monacha* or *L. dispar* captured in sticky Delta traps baited with various volatile blends; larch forests near the city of Morioka (northern Honshu, Japan). Compound abbreviations as in Figure 1. Bars within rows of each experiment with the same letter superscript are not significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means [Bonferroni (Dunn) t test, $P < 0.05$] (Zar, 1984; SAS/STAT, 1988).

the hydrocarbon analog of monachalure, *Z*7–18Hy, had no behavioral activity (Figure 2, experiment 3). A low proportion of (+)-monachalure in three-component blends resulted in hardly any captures of males (Figure 3, experiment 4). Conversely, addition of (+)-monachalure at increasing quantities to the two-component blend of (+)-disparlure and 2me-*Z*7–18Hy significantly enhanced trap captures of male *L. monacha,* whereas captures of male *L. fumida* were not affected (Figure 3, experiment 5). Similarly, addition of (+)-monachalure (10 μg) to a blend of (+)-disparlure (10 μg) and 2me-*Z*7–18Hy (1 μg) significantly increased captures of male *L. monacha,* failed to affect captures of *L. fumida,* and suppressed captures of male *L. dispar* (Figure 3, experiment 6). The same three-component blend but with (+)-disparlure at 1 μg attracted only male *L. monacha* (Figure 3, experiment 6). (+)-Disparlure at 5 or 50 μg, but not 500 μg, in admixture with (+)-monachalure (50 μg) and 2me-*Z*7–18Hy (5 μg) doubled trap captures of male *L. monacha* in Honshu (Figure 4, experiments 7 and 8). In Bohemia, addition of 5 and 50 μg of (+)-disparlure to pheromone baits of an equivalent experiment increased trap captures of male *L. monacha* by 10 and 20 times, respectively (Figure 4, experiment 9).

Male *L. monacha* in Bohemia and Honshu were captured in pheromone-baited traps from 19:00 to 24:00 hr and 02:00 to 05:00 hr, respectively (Figure 5).

DISCUSSION

Evidence for Different Strains of L. monacha. Our data support the hypothesis that there are different strains of *L. monacha.* The possibility that we studied different species—rather than strains—was excluded based on comparisons of genitalia (P.W.S., unpublished data) from specimens collected in Honshu and Bohemia. Female *L. monacha* from both strains employ pheromone blends with the same three components but of different relative importance. Moreover, trap captures of males between 19:00 and 24:00 hr in Bohemia and between 02:00 and 05:00 hr in Honshu reflect a marked difference in diel periodicity of pheromonal communication.

In Honshu, (+)-monachalure is the major pheromone component of *L. monacha.* It was more attractive to males than (+)-disparlure (Figure 2, experiment 1), and pheromone blends with no or little (+)-monachalure failed to attract significant numbers of males (Figure 3). The fact that (+)-monachalure suppressed cross-attraction of male *L. dispar* (Figure 3, experiment 6) is supportive evidence that (+)-monachalure is the major component in the *L. monacha* pheromone. Synergistic activity expressed by 2me-*Z*7–18Hy exceeded that of (+)-disparlure (Figure 2, experiment 2), suggesting that the hydrocarbon analog of disparlure is the second most important pheromone component. (+)-Disparlure as

FIG. 3. Spruce forests near the city of Zbraslav (Czech Republic). *Bottom* (adapted from Schaefer et al., 1999): Total numbers of male *L. monacha* and *L. fumida* captured in 20 sticky Delta traps baited with (+)-monachalure (50 μg), (+)-disparlure (5 μg), and 2me-*Z*7–18Hy (5 μg) for male *L. monacha* or with (+)-disparlure (50 μg) and 2me-*Z*7–18Hy (5 μg) for male *L. fumida*. Larch forests near the city of Morioka (northern Honshu, Japan). Black horizontal bars indicate scotophase.

a third pheromone component has only weak behavioral activity. Added to a binary blend of (+)-monachalure and 2me-*Z*7–18Hy, it barely increased (Figure 2, experiment 2) or doubled (Figure 4, experiments 7 and 8) attractiveness of the lure. This marginal effect of (+)-disparlure in the pheromone blend of *L. monacha* from Honshu contrasts with superior importance of (+)-disparlure in the pheromone blend of *L. monacha* from Bohemia. In Bohemia, addition of (+)-disparlure at 5 and 50 μg to the pheromone blend increased captures of males by 10 and 20 times, respectively (Figure 4, experiment 9).

There was no significant difference in antennal response pattern in GC-EAD analyses of pheromone extract of female *L. monacha* from Honshu (Figure 1) and Bohemia (Gries et al., 1996). This result does not reflect the contrasting importance of (+)-monachalure and (+)-disparlure in pheromone blends of the two strains, supporting our contention that GC-EAD analyses help determine the presence but not behavioral significance of (candidate) pheromone components.

With (+)-monachalure and (+)-disparlure being the major pheromone component of *L. monacha* in Honshu and Bohemia, respectively, the question remains whether pheromone-based detection surveys for *L. monacha* in North America ought to deploy strain-specific pheromone lures. The three-component blend of (+)-disparlure, (+)-monachalure and 2me-*Z*7–18Hy at a 10 : 10 : 1 ratio was most attractive to males in Bohemia (Gries et al., 1996). The same blend and blend ratio is effective in attracting males in Honshu (Figure 3, experiment 4), although the amount of (+)-disparlure could be reduced 10-fold without any effect. The presence of (−)-disparlure and (−)-monachalure had no effect on attraction of males in Bohemia (Gries et al., 1996) or Honshu (data not shown). Thus, the recently developed pheromone lure for *L. monacha* detection surveys in North America (Morewood et al., 1999), containing (±)-disparlure, (±)-monachalure and 2me-*Z*7–18Hy at a 20 : 20 : 1 blend remains suitable for attraction of *L. monacha* from both Central Europe and Japan (Gries et al., 1998).

Reproductive Character Displacement in L. monacha *Strain from Japan*? There are numerous local populations of *L. monacha* with *g*eno- and phenotypic characteristics shaped by physical and biological factors of the local environment. If we consider the presence of congeners a biological factor (Linn and Roelofs, 1995), five congeners (*L. dispar, L. fumida, L. mathura, L. lucescens,* and *L. bantaizana*) in Honshu should constitute a greater "factor" than the single congener (*L. dispar*) in Bohemia. With five synchronic congeners emitting communication signals, the forest habitat certainly becomes noisy, with selection pressure to improve the signal-to-noise ratio of communication channels (Baker, 1985; Cardé and Baker, 1984). Competition-induced reproductive character displacement *sensu* Butlin (1987) (divergence of traits that are coincidentally shared by sympatric species after speciation has occurred, so that hybridization is impossible) may cause signal divergence to avoid heterospecific matings. We hypothesize that dissimilar communication channels of *L. monacha* in Bohemia and Honshu

are the result of signal divergence caused by *L. fumida* as a competing species in Honshu.

According to our hypothesis, *L. fumida* seem to have affected both communication time and signal (pheromone blend) of *L. monacha*. With *L. fumida* signaling early at night, signaling of *L. monacha* has shifted to the early morning (Figure 5). With (+)-disparlure being most important in the pheromone of *L. fumida* (Schaefer et al., 1999), it has become insignificant in the pheromone of *L. monacha* (Figure 2, experiment 2; Figure 4, experiments 7 and 8). Our hypothesis that *L. monacha* in Honshu has substituted (+)-disparlure with (+)-monachalure as its major pheromone component (in response to competing *L. fumida*) is supported by the fact that the hydrocarbon analog of monachalure (*Z*7–18Hy) has no behavioural activity (Figure 2; experiment 3), whereas the hydrocarbon analog of disparlure (2me-*Z*7–18Hy) remains a synergistic pheromone component (Figure 2, experiments 2 and 3).

The concept of reproductive character displacement was proposed by Löfstedt et al. (1991) to explain pheromone variation in closely related ermine moths and can be considered in the context of studies that demonstrate geographic differences in a species' pheromone in the presence of competing species. For example, male *Archips argyrospilus* from New York respond to a more narrowly defined blend of pheromone components than do conspecifics from British Columbia, likely due to interference by the sibling species *A. mortuanus* in New York (Cardé et al., 1977; Butlin., 1995). Similarly, contrasting pheromone blends of the oblique-banded leafroller, *Choristoneura rosaceana* from New York (Hill and Roelofs, 1979) and British Columbia (Vakenti et al., 1988) may be attributable to the competing species *Archips rosanus* in British Columbia (Thomson et al., 1991). Finally, saturniid female and male *Hemileuca electra mojavensis* may have modified their pheromone-based communication to minimize interference from congeneric *H. burnsi* (McElfresh and Millar, 1999).

The above-cited examples and our own data favor the hypothesis that interspecific competition *can* be a selective force on a species' communication channel. Whether communication channel divergence of *L. monacha* in Honshu indeed constitutes a case of reproductive character displacement is difficult to prove. The evolution of such divergence in *sympatric* populations of *L. fumida* and *L. monacha* would have to be demonstrated. Greater differences, if demonstrated, in communication channels of *L. fumida* and *L. monacha* in sympatric than in allopatric populations in eastern Asia would support our hypothesis that the pheromone biology of *L. monacha* was shaped, in part, by competition with *L. fumida*.

(Received October 16, 2000; accepted February 13, 2001)

Abstract—The reproductive behavior of the stink bug *Chlorochroa sayi* was studied in the laboratory. There was a sexual maturation period of about 10 days before bugs began mating. Sexually mature adult bugs engaged in courtship consisting of antennation and head-butting of the female by the male, before the female adopted a receptive posture and copulation occurred. Both sexes mated multiple times during their life-spans, with the mean duration of copulations of virgin bugs (42.3 ± 19.6 min) and experienced bugs (37.3 ± 28.4 min) being similar. Most matings were initiated in the late afternoon or evening, when pheromone production by males was greatest. Males transferred sperm and nutrients constituting about 17% of their body weight to females during mating. Three male-specific components, methyl geranate, methyl citronellate, and methyl (*E*)-6-2,3-dihydrofarnesoate in a ratio of 100 : 0.45 : 1.6, were first detected in volatiles collected from male bugs on green beans about 9–12 days after the final molt to the adult stage. In vertical Y-tube bioassays, females were attracted to odors from mature male bugs, and to a blend of the three male-produced components. Low numbers of females also were attracted in field trials with the three-component blend. The relatively weak attraction may be a result of other, as yet unknown cues being required in addition to the pheromone, such as visual or substrate-borne vibrational cues.

Key Words—*Chlorochroa sayi*, Pentatomidae, pheromone, methyl geranate, methyl citronellate, methyl (*E*)-6-2,3-dihydrofarnesoate, Y-tube bioassay, reproductive behavior.

INTRODUCTION

Phytophagous stink bugs (Heteroptera: Pentatomidae) are found in all types of crops, including grain, forage and fiber crops, vegetables, and perennial crops such as tree fruits and nuts (Metcalf and Metcalf, 1993; McPherson and McPherson, 2000). Damage is caused by both immatures and adults, but only adults are winged and capable of long-distance movement. Injury to young seeds, fruits, or nuts produces necrotic lesions and often results in premature abortion, while attacked leaves may wilt and die. Stink bugs are also known or implicated as vectors of plant pathogens such as yeast, fungi, and bacteria (Hoffmann et al., 1987; Panizzi, 1997).

Many stink bug species are polyphagous, and the adults are highly mobile, which exacerbates problems with their monitoring and control. Some crops, such as cotton, alfalfa, and legumes, have chronic problems with bugs, whereas damage to tree crops is more sporadic and difficult to predict, because significant damage only occurs when large numbers of bugs move into a crop from the surrounding habitat (LaRue and Johnson, 1989). These migrations occur in response to natural events, such as the senescence of native vegetation in the habitat, or in response to mowing or harvesting of nearby crops harboring large bug populations (Toscano and Stern, 1976). Effective bug management hinges on the rapid detection of these invasions, so that appropriate control measures can be implemented before serious crop damage occurs. However, monitoring and sampling methods for most bug species are still relatively primitive, consisting mainly of sweep-net or beating tray sampling, or visual inspection of fruits for feeding damage or excrement. Effective monitoring methods based on pheromones or other attractants have not yet been developed for economically important stink bug species.

The identification and development of applications for stink bug pheromones has been complicated by several factors (McBrien and Millar, 1999). First, stink bugs produce voluminous quantities of volatile defensive secretions in response to disturbance, so it can be difficult to obtain extracts uncontaminated with these defensive secretions, which may mask or overwhelm the pheromone components. Second, for the few phytophagous stink bug species that have been studied, pheromone components were produced by mature males from patches of unicellular glands (Borges et al., 1987; Evans et al., 1990) rather than from discrete, macroscopic glands that can be dissected for analysis. Third, bugs must be in an appropriate physiological state to produce or respond to pheromones. After the final molt, stink bugs take a number of days to reach sexual maturity and begin producing and responding to pheromones (e.g., Wang and Millar, 1997). Fourth, adults enter reproductive diapause in response to deteriorating conditions (short daylength, poor food) and stop producing or responding to pheromones (e.g., Strong et al., 1970; Aldrich et al., 1991). Finally, the roles of sex and aggregation pheromones are poorly understood in stink bugs. Sex-specific compounds have

been identified from several phytophagous species, including *Nezara viridula* (L.) (Baker et al., 1987; Brézot et al., 1994), *Euschistus* spp. (Aldrich et al., 1991, 1994; Borges et al., 1998a), *Plautia stali* Scott (Sugie et al., 1996), *Thyanta pallidovirens* Stål (Millar, 1997), *Piezodorus hybneri* Gmelin (Leal et al., 1998), *P. guildinii* (Westwood) (Borges et al., 1998b), and *Biprorulus bibax* Breddin (James et al., 1994). However, the function of many of the compounds that have been identified to date remains unclear. There is some evidence that the major male-produced components function as sex or aggregation pheromones, but in general, the role of minor components in sex-specific odors remains obscure.

The stink bug *Chlorochroa sayi* (Stål) is distributed throughout the western United States, where it damages wheat (Caffrey and Barber, 1919), tomato (Ohlendorf, 1990), cotton (Morrill, 1910), and alfalfa (Russell, 1952). In California, it can have several generations per year, and details of its life history have been reported by Morrill (1910) and Russell (1952). We report here the results of studies on the reproductive behavior and semiochemistry of *C. sayi*. Our overall goal was to identify bug-produced semiochemicals that might be of use for developing better bug monitoring methods. Specific objectives were: (1) to describe the reproductive behavior of *C. sayi*; (2) to identify volatile chemicals produced by *C. sayi*, focusing particularly on sex-specific compounds that might be sex pheromone components; and (3) to test reconstructed blends of sex-specific compounds as stink bug attractants in laboratory and field bioassays.

METHODS AND MATERIALS

Insects. A colony of *C. sayi* was started from bugs collected by sweep-netting at the University of California Agricultural Operations site in Riverside, California. Additional bugs were collected from Russian thistle (*Salsola iberica* Sennen) in Riverside County in the summers of 1998 and 1999. Bugs were reared on a diet of organically grown green-bean pods (*Phaseolus vulgaris* L.), raw shelled peanuts (*Arachis hypogaes* L.), and raw sunflower seeds (*Helianthus annuus* L.). The diet was supplemented with bouquets of alfalfa (*Medicago sativa* L.) or seasonal weeds including mustard [*Brassica campestris* (L.)], London rocket (*Sisymbrium irio* L.), Russian thistle, shepherd's purse (*Capsella bursa-pastoris* L.), and cheeseweed (*Malva parviflora* L.), depending on availability. Bugs were reared in a controlled environment chamber, on a 16L : 8D cycle (lights on 06:00–22:00 hr), with lighting provided by banks of eight fluorescent light tubes (Sylvania Octron, 32W, F032/T35), at $23 \pm 2^{\circ}$C, and $>50\%$ relative humidity. Eggs were collected from the colony every other day and were held in covered Petri dishes through to the second nymphal stage. After the second molt, nymphs were transferred to 1.9-liter cardboard ice-cream containers with muslin lids. Nymphs were fed as described above, with food changed every other day. After the final molt,

adults were collected and sexed, and cohorts of virgin adults were maintained with food in clean ice-cream cartons (5–7 bugs per 0.95-liter container, 10–20 bugs per 1.9 liter container) until used for collection of volatiles or bioassays.

Observations of Reproductive Behavior. Eight pairs of mature (at least 14 days old) virgin laboratory-reared female and male *C. sayi* were put in clear plastic cylinders (4 cm ID $\times$ 15 cm long with small holes in the tube walls for ventilation), with segments of green beans provided for food. A fluorescent light (GE wide-spectrum light for plants and aquariums, F20T12-PL/AQ) provided light during photophase (06:00–22:00 hr), and a red incandescent light bulb (40 W) on a rheostat was used during the scotophase, with light intensity just sufficient for observation with a video camera (about 6 lux). The bugs were video-taped continuously with a video cassette recorder (Panasonic AG-6730) in time-lapse mode (1.6 frames/sec; clock time recorded on each frame), using a desktop video camera (model VCM7310, RockVision). The tubes and the camera were set up in a box (75 $\times$ 60 $\times$ 50 cm) with a removable front panel, which was only open when changing food or bugs, so that the bugs were not disturbed. The tubes were set up in a row so that all were in the camera's field of view simultaneously. Pairs of bugs were put into tubes at 10:00 hr, and video taping was started immediately. The bugs were examined and food was changed every morning at 10:00 hr. If either bug of any pair died, that tube was replaced with a new pair of bugs in a fresh tube. Data recorded included the time each copulation started, duration of each copulation, and the total number of copulations/per pair. To determine diurnal mating rhythms, the numbers of matings initiated per hour were plotted versus the time period. A total of 32 matings from 13 pairs in nine consecutive days were observed.

Weight Change During Mating. Sexually mature ($>$12 days old) virgin adults were weighed to the nearest 0.1 mg, then put into clear plastic cylinders as described above, with one pair per cylinder, without food, between 17:00 and 18:00 hr. Pairs were observed in the bug rearing room (lighting as above, temperature 24 $\pm$ 2°C, humidity 40 $\pm$ 20%) for 3 hr. For those pairs that copulated, immediately after mating, each bug was weighed, and the experienced individuals then were held in same-sex cohorts in a cardboard ice-cream carton with a screen lid, with food provided. Pairs that did not mate within 3 hr were used as controls, and the individuals were weighed after 3 hr and then held in same-sex virgin cohorts for a repeat trial the next evening. Thirty virgin pairs and 39 experienced pairs were observed between March 8 and 16, 2000, with a total of 13 copulations between virgin pairs and 15 copulations between experienced pairs being observed.

Collection of Insect-Produced Compounds by Aeration of Live Bugs. Two to five sexed, virgin adult bugs and two green beans were put into a 300-ml glass aeration chamber lined with hardware cloth screen for the bugs to perch on. Humidified, charcoal-filtered air (6–14 mesh activated charcoal granules) was drawn through the chamber (300 ml/min). Entrained bug volatiles were collected on activated charcoal traps made from glass tubes (4 mm ID.) loaded with a 0.4-cm bed

of 80–100 mesh activated charcoal (Fisher Scientific, Pittsburgh, Pennsylvania), precleaned by heating at 200°C under a flow of clean N_2 (~100 ml/min) overnight. Aerations were conducted continuously for two to three weeks at ~25°C with cohorts of bugs of known age, changing the food and the collectors every other day. Collectors were eluted with pentane (500 μl), and extracts were stored in glass vials with Teflon-lined screw caps at about −20°C until needed. Aeration chambers were set up near the window so that bugs had natural light, and supplementary fluorescent light was provided with a light bank directly overhead to provide long day conditions (lights on from 06:00 to 22:00 hr). Bugs that died were replaced with virgin individuals from a cohort of the same age. Dead bugs were removed as soon as discovered to minimize contamination; as muscles relaxed in dead bugs, the contents of the defensive metathoracic glands were released (Ho, personal observation). As a control, five green beans were aerated for 17 hr, collecting the volatiles as described above.

Dynamics of Pheromone Release. Cohorts of virgin male bugs of known age were aerated to determine the onset of production of male-specific compounds. Cohorts were aerated in 300-ml (300 ml/min; 3–5 bugs) or 1-liter chambers (1 liter/min; 10–15 bugs), respectively. Aerations were continued for two weeks, with the collectors changed daily.

To determine the diurnal pattern of pheromone release, 10–20 sexed, virgin adult male bugs and 5 green beans were aerated in a 1-liter chamber as described above, changing the collectors daily. Once a cohort of bugs was confirmed to be producing male-specific compounds, the collectors were changed every 2 hr between 7:00 and 23:00 hr, for periods of 24 hr. A single collector was used to collect the volatiles produced between 23:00 and 07:00 hr. The 24-hr aeration periods were replicated with five cohorts of males. Internal standard (10-methylnonadecane, 77 ng) was added to each extract so that the amounts of bug-produced compounds could be estimated from GC analyses. The total amounts of the major male-specific compounds produced during each 24-hr aeration period were calculated, and then the amounts produced during each 2-hr interval were calculated as a percentage of the total. For the 8-hr period between 23:00 and 07:00 hr, the average amount per 2 hr was used. Data were analyzed by ANOVA, and differences between means were determined by application of the Student-Newman-Keuls test.

Analysis of Extracts. Crude extracts prepared as described above were concentrated by evaporation under a gentle stream of nitrogen, as required, and analyzed by splitless gas chromatography on a DB-17 column (30 m × 0.25 mm, J&W Scientific, Folsom, California), with a temperature program of 50°C for 1 min and then 10°C/min to 250°C. Injector and detector temperatures were 250°C and 280°C, respectively, with helium carrier gas. Extracts were also analyzed by splitless coupled gas chromatography–mass spectrometry (GC-MS) with a Hewlett Packard 5890 GC fitted with a DB-5MS column (20 m × 0.2 mm ID), and interfaced to an Hewlett Packard 5970B mass selective detector (electron impact ionization,

70 eV). The GC was programmed from 40°C at 1 min, then 10°C/min to 250°C, with injector and transfer line temperatures of 250 and 280°C, respectively. Compounds were tentatively identified from interpretation of the mass spectra and from matches with the NBS-NIH mass spectral data base. Identifications were confirmed by comparison of retention times and spectra with those of authentic standards.

Fractionation of Bug Aeration Extracts. A 2.8-ml solid-phase extraction cartridge (500 mg silica gel, Alltech, Deerfield Illinois; stock # 209250) was flushed with 4 ml of 25% ether in pentane and 4 ml pentane. A concentrated (∼250 μl) bug extract in pentane, prepared by combining 10 extracts prepared from June 1997 to March 1998, was loaded onto the cartridge, rinsing with 2–3 drops of pentane. The cartridge was then eluted with 4 × 1 ml pentane, 3 × 1 ml of 10% ether in pentane, 3 × 1 ml 25% ether in pentane, and 1 × 3 ml ether, collecting each as a separate fraction.

Laboratory Bioassays. Laboratory bioassays were carried out with a vertical glass Y-tube olfactometer (4.5 cm ID, arms 14 cm long, center tube 18 cm long). Each arm of the Y terminated in a female ground glass fitting, with matching male fittings terminating in hose nipples. Teflon tubing connected the Y tube to stimulus flasks, and vinyl tubing connected the bottom outlet to a vacuum source.

Test bugs were reared under long day conditions as described above. Lighting was provided by a light bank fitted with a daylight fluorescent lamp and a wide-spectrum grow-light fluorescent lamp [Sylvania Octron 32W, to mimic natural daylight, as suggested by Shields (1989)] suspended 30 cm above the olfactometer. The light level at the upper end of the Y-tube was ∼600 lux and at the lower end ∼300 lux. Bioassays were conducted at ambient temperature and humidity conditions in the laboratory (26°C ± 3°C and 50 ± 15% humidity). Because preliminary studies had indicated that most reproductive activity took place in early evening, bioassays were started at around 18:00 hr, and continued until ∼22:00 hr.

Bioassays Using Odors from Live Male Bugs as Test Stimulant. Individual sexually mature virgin male bugs were put in a 125-ml Erlenmeyer flask with half a green bean and a piece of screen (7 × 7 cm) for the bugs to perch on. Flasks with male bugs were placed in the bioassay room at about 16:30 hr to allow the bugs to acclimate to the bioassay room conditions. To begin a bioassay, a flask containing a male bug was connected to one arm of the Y-tube olfactometer by Teflon tubing, with the flask placed close to the light bank (∼1000 lux at the flask position). The other arm of the Y tube was connected to a control flask with half a green bean and a screen only. Visual cues were blocked by placing a piece of paper towel in the bottom of the stimulus and control flasks. Room air purified by passage through an activated charcoal trap was pulled through the stimulus and control flasks and then into the Y tube at a total flow rate of 2 liters/min.

Individual sexually mature female bugs were transferred carefully into the bottom end fitting of the Y tube, with a piece of translucent weighing paper placed

on top to prevent escape. The fittings with females were set up in the bioassay room about 1 hr before starting bioassays to allow the females time to settle down after being transferred to the fittings. Female bugs were not provided with food. To begin a bioassay, a flask containing a male bug and a control flask were connected to the Y tube, and air was pulled through the system for 5 min. Then an end fitting with a female test bug was gently maneuvered into place, and the vinyl tubing was attached to the hose nipple to restart flow through the olfactometer. The criterion for a response was that the female test bug crossed the midpoint of either the stimulus or control arm. If the female did not cross the midpoint of either arm after 5 min, she was considered a nonresponder. To avoid any positional bias, the positions of the stimulus and control flasks were switched every two assays. For each bioassay, a new virgin male in a clean flask was used, with a new female bug as a responder, and the Y tube was cleaned after each assay by washing with soapy water, rinsing with distilled water and acetone and oven drying for at least 20 min at 140°C. The Teflon inlet tubing was not changed between replicates, but at the end of each day's bioassays, the tubing was rinsed with acetone and air dried. Using a series of six identical Y tubes, a maximum of 15–20 bioassays could be run per 4-hr session.

Laboratory Bioassays of Extracts of Bug Volatiles, and Synthetic Chemicals. The Y tube olfactometer was used to test the responses of sexually mature, virgin adult female and male bugs to extracts of male volatiles and to single or reconstructed blends of synthesized components. The bioassay was as described above with the following modifications. The test material [an aliquot of a bug extract or a solution of the synthetic chemical(s)] was assayed versus a control consisting of the same amount of clean solvent (pentane) as was used in the dose of the treatment being tested. Pentane solutions of extracts or synthetic chemical(s) were loaded on a filter paper disk (1.5 cm diam.), the solvent was allowed to evaporate for 1 min, and the disk was mounted on a coiled wire hanger placed inside the ground glass end piece. After the aeration extract and pentane controls were set up in the Y tube, bioassays were conducted as described above.

Field Bioassays. The reconstructed blend of the male-specific compounds was used in field bioassays. Lures consisting of 10-cm lengths of amber natural rubber latex tubing (0.15 cm OD, 0.08 cm wall thickness, Fisher Scientific #14-178-5A) were impregnated with methyl geranate (20 mg), methyl citronellate (0.1 mg) and racemic methyl (*E*)-6-2,3-dihydrofarnesoate (0.4 mg). The compounds were dissolved in 1 ml of dichloromethane and added to a Petri dish (9 cm ID) containing a length of tubing. The dish was covered until the solution had been absorbed into the tubing. Lures were hung in the upper portion of Russian thistle plants (one per plant). Control lures consisted of rubber tubes soaked in 1 ml of dichloromethane. Each plant with a treatment or control lure was marked with red flag tape. The height of each plant was approximately 100 cm, and lures were spaced about 10 m apart. Bioassays were carried out in vacant lots overgrown with Russian thistle and wild mustard in or near Moreno Valley, Redlands, Ontario, and

Riverside, California. Lures were put out in the morning around 09:00–10:00 hr. Bioassays were evaluated every evening at around 17:00–19:00 hr, by collecting all the bugs within ~20 cm of the lures by hand and recording the sex and numbers on each plant. In the first set of trials (August 3–16, 1999, different blocks in Ontario, Moreno Valley, Redlands, and Riverside, with three replicates of each treatment in each block), the bugs were collected, counted, and released. In the second trial (August 19–24, 1999, six experimental blocks in Moreno Valley and Riverside, with each treatment and control replicated three times at each site), all responding bugs were collected and taken back to the laboratory to augment laboratory colonies.

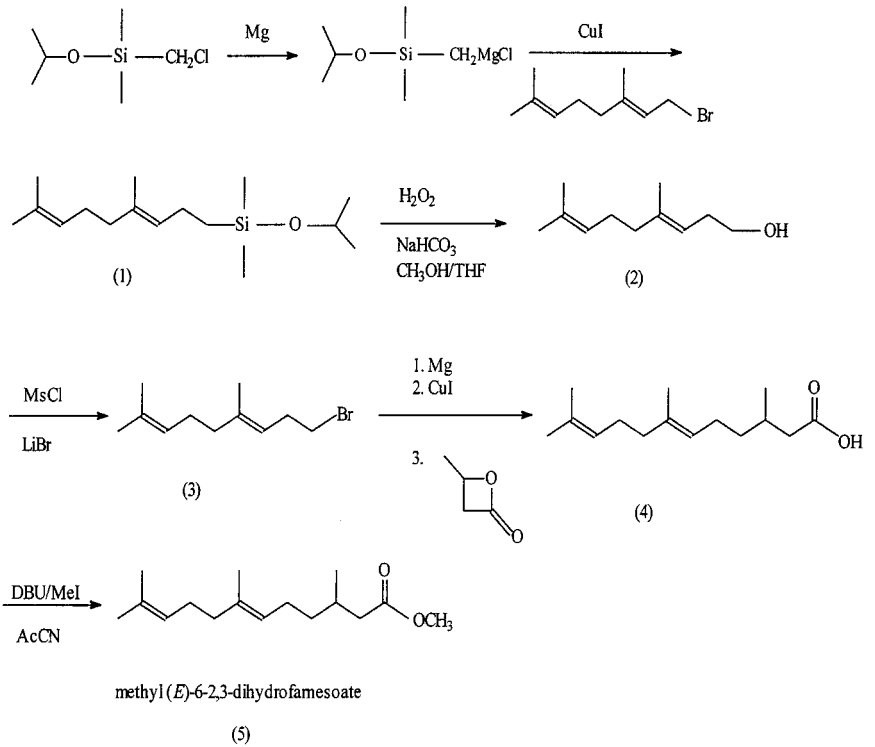
For both trials, where appropriate, the numbers of responding bugs were transformed, using the $\sqrt{(x + 0.5)}$ transformation, and the transformed data were subjected to two-way ANOVA, with differences between treatments and controls determined by Dunnett's method. For those data sets that did not satisfy the assumptions of ANOVA, differences between treatments and controls were determined with the nonparametric multi-response permutation procedure (Biondini et al., 1985; McCune and Mefford, 1999).

Chemicals. Dodecane, (*E*)-2-hexenal, and (*E*)-2-octenal were purchased from Aldrich Chemical (Milwaukee Wisconsin), (*E*)-2-octenyl acetate was obtained from Bedoukian Research (Danbury, Connecticut), and tridecane was obtained from ICN/K&K Laboratories (Irvine, California). (*Z*)-2-Octenyl acetate was prepared by acetylation of (*Z*)-2-octenol by standard methods (acetyl chloride and triethylamine in ether). Commercial methyl geranate (2.5 g) containing ~25% methyl nerate (Bedoukian Research) was purified by flash chromatography on silica gel (5-cm × 25-cm column, 40–63 μm particles), eluting with 1 liter each of 1%, 1.5%, and 2% ether in hexane (Lee et al., 1991), yielding 1.18 g of methyl geranate (97.7% pure) and 0.4 g methyl nerate (100% pure) after Kugelrohr distillation (oven temperature 53°C, 0.2 mm Hg). The ^{1}H NMR spectrum ($CDCl_3$, 300 MHz) of methyl geranate matched literature data (Erman et al., 1969).

Synthesized Compounds. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ at 300 and 75.48 MHz, respectively, using a General Electric QE 300 instrument. GC-MS analyses (electron impact ionization, 70 eV) were performed on a Hewlett Packard 5890 gas chromatograph interfaced to an HP 5970B mass selective detector (Palo Alto, California). A DB-5MS column was used (20 m × 0.2 mm, J&W Scientific). Routine work-up of reactions included drying solutions over anhydrous Na_2SO_4 and concentrating by rotary evaporation under an partial vacuum (~80 mm Hg). All reactions were carried out under an argon atmosphere in oven-dried glassware unless otherwise specified.

Methyl Farnesoate. A reference sample of methyl farnesoate was prepared as described elsewhere (Ho, 2000).

Synthesis of Racemic Methyl (*E*)*-6-2,3-dihydrofarnesoate* **5**. This is shown in Scheme 1.



SCHEME 1. Preparation of racemic methyl (*E*)-6-2,3-dihydrofarnesoate.

Isopropoxy-dimethylsilyl-4,8-dimethyl-3,7-nonadiene (**1**). The synthesis was modified from previous syntheses of similar compounds (McMurry and Bosch, 1987; Nagano et al. 1997). Thus, a solution of (chloromethyl)isopropoxy-dimethylsilane (24.9 g, 150 mmol; Aldrich) in THF (150 ml) was added to magnesium turnings (4.8 g, 200 mmol; briefly ground in a mortar and pestle to expose clean Mg surfaces) over ~2 hr. The reaction was initiated by addition of 15 ml of the solution to the Mg turnings in the flask, with several crystals of iodine and 10 drops of dibromoethane, and stirring until the iodine color disappeared. The rest of the chloride solution was added over 2 hr, maintaining the temperature of the mixture about 30°C. When the addition was complete, the solution was heated at 40°C for 1 hr. After cooling to 0°C, the solution was transferred with a large syringe to a precooled (0°C) flask containing 3 g of CuI. The resulting mixture was stirred and cooled to −78°C, and geranyl bromide (22 g; 100 mmol; Aldrich) was added dropwise with stirring over ~30 min. Stirring was continued (~30 min) at −78°C until all the geranyl bromide had been consumed (checking by GC). When the

reaction was complete, the mixture was warmed to 0°C, and quenched with 10 ml ice water. The mixture was poured into an ice-cold mixture of 250 ml saturated aq. NH_4Cl and 25 ml conc. ammonium hydroxide, and extracted with hexane (1×250 ml). The hexane layer was washed with 0.1 M HCl, sat. aq. $NaHCO_3$, and brine and then dried and concentrated. The crude material was used in the next step without further purification. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 4.9–5.1 (m, 2H, H3 and H7), 3.88 [septet, 1H, $J = 6$ Hz, O–C$H(CH_3)_2$], 1.88–2.0 (m, 6H, H2, H5 and H6), 1.58 (s, 3H, H9), 1.49 (d, 6H, $J = 2$ Hz, H4′, H9′), 1.05 (d, 6H, $J = 6$ Hz, O-CH$(CH_3)_2$], 0.5 (m, 2H, m, H1), 0 [6H, s, Si$(CH_3)_2$]. ^{13}C NMR ($CDCl_3$, 75.48 MHz): δ 133.50, 131.31, 127.60, 124.53, 39.81, 34.37, 26.83, 25.80, 25.39, 21.63, 18.85, 17.77, 15.93, 0.59. EI-MS m/z: 268 (M^+, 0.1), 225 (2.3), 208 (2), 167 (1), 147 (4), 117 (63), 75 (100), 41 (53).

Homogeraniol (**2**). The synthesis was adapted from those previously reported by McMurry and Bosch (1987) and Tamao and Ishida (1984). Thus, MeOH (200 ml), $NaHCO_3$ (30 g), silane **1** (31 g, purity 85%, ~100 mmol) and THF (200 ml) were added to a three-neck 1-liter flask equipped with a stir bar and condenser. Aqueous H_2O_2 (30%, 80 ml; 784 mmol) was added over 10 min. When the addition was complete, the mixture was refluxed overnight. The mixture was then cooled to room temperature and filtered through a 2.5-cm bed of Cellite in a sintered glass funnel, with suction, rinsing the filter pad with 4×50 ml ether. The solution was concentrated to ~100 ml by rotary evaporation, poured into 400 ml water, and extracted with hexane (1×200 ml, 2×75 ml). The combined hexane layers were washed with water and brine, dried, concentrated, and Kugelrohr distilled, oven temperature 80–100°C, 0.2 mm Hg, yielding 13.5 g of homogeraniol **2**. ^{1}H and ^{13}C NMR spectra agreed with those previously reported (Kocieñski and Wadman, 1989).

Homogeranyl Bromide (**3**). Homogeraniol **2** was converted to the corresponding mesylate by standard methods (mesyl chloride and triethylamine;) (e.g., Kocieñski and Wadman, 1989). The crude mesylate was taken up in THF (150 ml) and LiBr (24.4 g, 289 mmol; dried at 100°C under vacuum for 4 hr) was added in one portion. The mixture was stirred at room temperature until the mesylate was consumed (20 hr), then poured into 100 ml water and extracted three times with hexane. The hexane layer was washed with water and brine, dried, and concentrated. The residue was purified by flash chromatography (5×22 cm, 2% ether in hexane), then Kugelrohr distillation (oven temperature 65–80°C, 0.3 mm Hg) yielding 11.74 g of homogeranyl bromide **3** (64% yield, 95% pure by GC). NMR and mass spectra agreed with those previously reported (Oehlschlager et al., 1991).

(*E*)*-6-2,3-Dihydrofarnesoic Acid* (**4**). Racemic acid **4** (84% yield, purity >95%) was prepared by conversion of homogeranyl bromide **3** to homogeranyl magnesium bromide, followed by a CuI-catalyzed reaction with 2-methyl-β-propiolactone (Aldrich), as previously described by Fujisawa et al. (1980) and

Sato et al. (1980). Spectral data agreed with those previously reported (Yamatsu et al., 1981).

Methyl (*E*)*-6-2,3-Dihydrofarnesoate* (**5**). (*E*)-6-2,3-Dihydrofarnesoic acid **4** was converted to the methyl ester by treatment with methyl iodide and 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU) in acetonitrile (Rao, 1980). ^{1}H NMR and mass spectra matched those previously reported (Ahlquist and Ställberg-Stenhagen, 1971;Yamatsu et al., 1981). ^{13}C NMR ($CDCl_3$, 75.48 MHz): δ 173.83, 135.24, 131.39, 124.42, 124.24, 51.46, 41.69, 39.82, 36.84, 30.15, 26.79, 25.79, 25.42, 19.74, 17.78, 16.05.

Racemic Methyl Citronellate and Methyl (*R*)*-3-Citronellate*. Racemic and (*R*)-3-citronellic acids (Aldrich) were converted to their methyl esters as described above for methyl dihydrofarnesoate (Rao, 1980). After Kugelrohr distillation (oven temperature $\sim$80°C, 1 mm Hg) the esters were obtained as colorless oils, $>$99% pure by GC. Spectral data agreed with that reported by Yamatsu et al. (1981).

RESULTS

Reproductive Behavior. Adult *C. sayi* began to mate about 10–14 days after the final molt. Mating was preceded by courtship, consisting of antennation of the female by the male, followed by the male head-butting the female's abdomen. If the female was receptive, she adopted a posture with the head lowered and the abdomen raised, allowing the male to turn around and couple his genitalia with those of the female, copulating in an end to end position. During mating, both bugs remained in an inverted V position with the abdomen higher than the head. When copulation was complete, one of the bugs swung from side to side to disengage from the other.

If the female was not receptive, she walked away. Sometimes, even though the female bug stopped and raised her abdomen in the receptive position, the male would still head-butt for some time before he turned around and mated with her. In cases where the female assumed the receptive position with her abdomen raised, and the male failed to couple with her genitalia, the male resumed antennation and head-butting. In some cases, males were observed to pursue females with periodic bouts of head-butting for $>$1 h before the female acquiesced and copulated with the male. In other cases, the female mated with the male after a relatively brief courtship of a few minutes.

Diurnal Pattern in Mating Behavior. A total of 13 pairs were videotaped from October 20 to 28, 1999, during which 32 matings were observed. One pair died before any mating occurred. Nine pairs mated more than once in this period, with a mean interval of 42 $\pm$ 24 hr (mean $\pm$ SD) between matings (range 8–77 hr). Eggs were laid between matings. The duration of mating ranged from 2 to 125 min, with a mean of 42.3 $\pm$ 19.6 min for virgin bugs ($N = 12$) and 37.3 $\pm$ 28.4 min ($N = 20$)

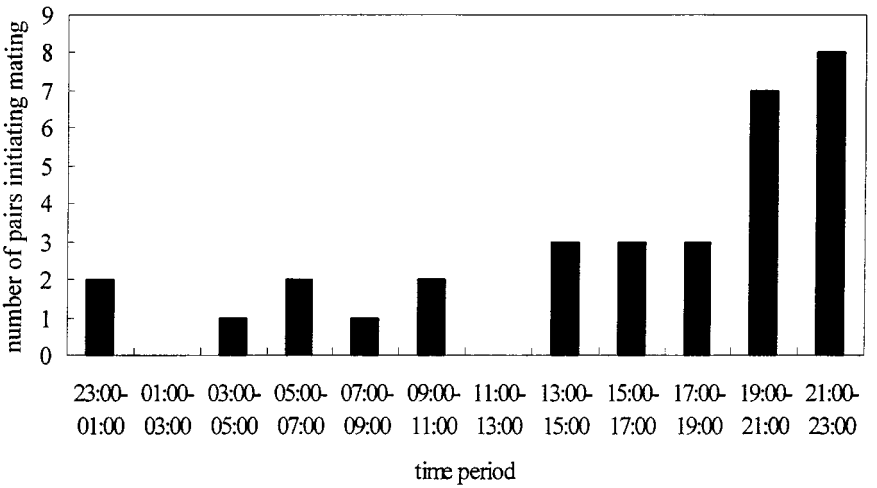


FIG. 1. Diurnal pattern of mating behavior of *C. sayi*. Number of *C. sayi* pairs that initiated a copulation during successive 2-hr time periods. Lights were on from 06:00–22:00 hr each day. The trial was run with 13 individual pairs of insects for nine consecutive days, with 32 matings observed.

for experienced bugs (two-tailed t test, $df = 30$, $P = 0.56$). Most copulations were initiated during the latter part of the photophase (Figure 1).

Weight Change after Mating. Copulations were observed for a total of 13 virgin pairs and 15 experienced pairs of *C. sayi*, and weight changes are plotted in Figures 2 and 3. For virgin pairs, female weights increased 24 ± 8 mg (16.3 ± 6.9% of total body weight) after mating, and male weights decreased by a similar amount (27 ± 12 mg; 16.6 ± 7.8% of body weight). Weight changes of control insects during the same period were negligible (females lost 1 ± 1 mg, males lost 0.4 ± 0.3 mg, $N = 16$). There was a trend for increased weight change with increasing mating duration (virgin females, $R^2 = 0.4397$, $P = 0.013$, virgin males, $R^2 = 0.2481$, $P = 0.08$).

For experienced pairs, females gained an average of 24 ± 9 mg (14.8 ± 5.8% of body weight), whereas males lost 29 ± 12 mg (17.8 ± 7.3% of body weight) during copulation, and there appeared to be a correlation between weight transfer and mating duration (females, $R^2 = 0.2727$; males, $R^2 = 0.3214$). For the experiments with both virgin and experienced pairs, there was a small overall net weight loss, probably due to defecation by some of the test insects during the experiments.

Identification of Compounds from Aeration Extracts of Adult C. sayi. Typical gas chromatograms of female and male aeration extracts are shown in Figure 4. Compounds found in extracts from both sexes included (*E*)-2-hexenal, dodecane,

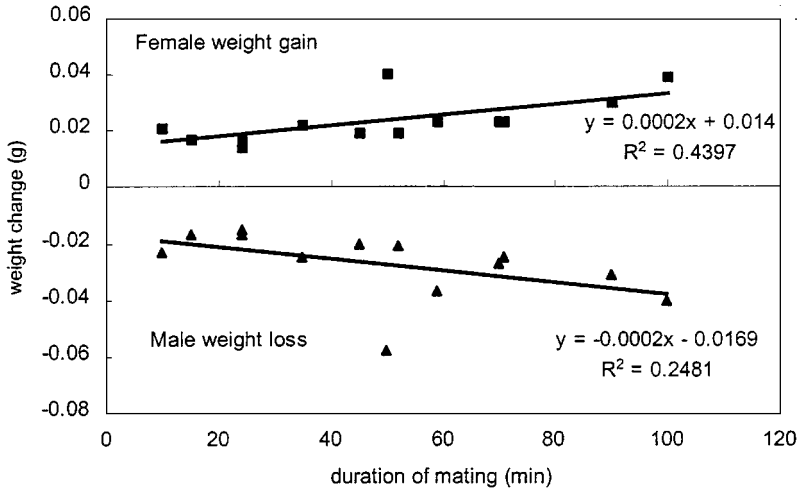

FIG. 2. Weight change of virgin *C. sayi* after mating. Females gained 0.024 ± 0.008 g (mean $\pm$ SD) in weight, and males lost 0.027 ± 0.012 g with every mating. $N = 13$. Results of the *t*-test on overall weight change versus control: $P = 3 \times 10^{-6}$ (female) and $P = 1 \times 10^{-7}$ (male). Linear regression was carried out on the weight change versus duration of mating for each sex. Female weight gain was correlated with duration of mating ($P = 0.0135$); male weight loss was not correlated with mating duration ($P = 0.083$).

(*E*)-2-octenal, tridecane, and (*E*)-2-octenyl acetate, all of which were tentatively identified by interpretation of their mass spectra and match-up with database mass spectra. These compounds also have been identified from the defensive secretions produced by the metathoracic glands in both sexes (Ho, 2000; Ho and Millar, 2001). Aeration extracts from green bean controls contained trace amounts of the common plant volatiles hexanol, (*E*)-2-hexenol, (*E*)-2-hexenal and linalool. Identifications were confirmed by match-up of mass spectra and GC retention times on two GC columns with those of authentic standards.

Aeration extracts from sexually mature males contained one major (peak B, Figure 4) and two minor male-specific compounds (peaks A and C, Figure 4). The relative proportions of these components were peak B, 100%; peak A, $0.45 \pm 0.09\%$ ($N = 3$); and peak C, $1.6 \pm 0.32\%$ ($N = 3$). The mass spectrum of the major component indicated a molecular weight of m/z 182, for a possible molecular formula of $C_{11}H_{18}O_2$. The compound was tentatively identified as methyl-3,7-dimethyl-2,6-octadienoate by comparison of the mass spectrum with the mass spectral database. The compound was confirmed to be the *E* isomer of this compound (methyl geranate) by comparison of its retention times on two GC columns and its mass spectrum with those of authentic standards of methyl

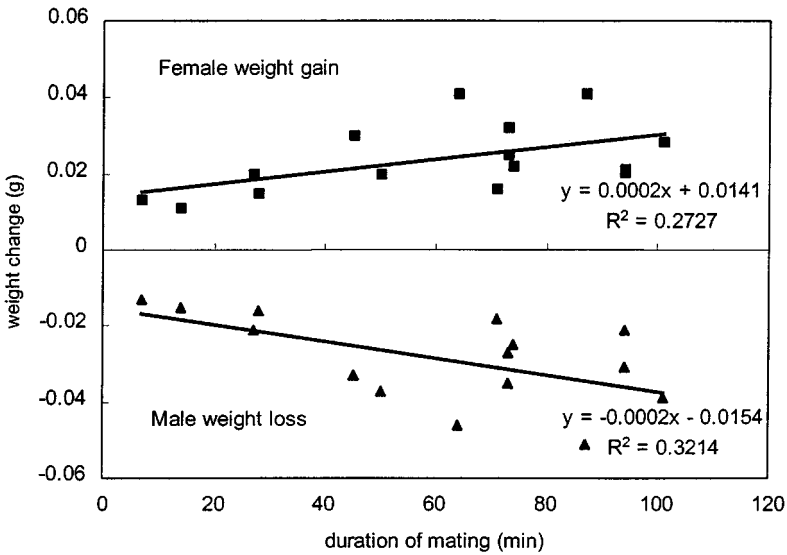

FIG. 3. Weight change of experienced *C. sayi* after mating. Females gained 0.024 ± 0.009 g (mean $\pm$ SD) in weight, and males lost 0.029 ± 0.012 g with every mating. $N = 15$. Results of the t test on overall weight change versus control: $P = 3 \times 10^{-6}$ (female) and $P = 4.9 \times 10^{-8}$ (male). Linear regression was carried out on the weight change versus duration of mating for each sex. Female weight gain was correlated with duration of mating ($P = 0.0458$), and male weight loss was correlated with mating duration ($P = 0.0275$).

(*E*)-2-3,7-dimethyl-2,6-octadienoate (methyl geranate) and methyl (*Z*)-2-3,7-dimethyl-2,6-octadienoate (methyl nerate).

The mass spectrum of the minor male-specific compound A exhibited a molecular ion at m/z 184, 2 mass units more than methyl geranate, and major fragment ions of m/z 69, 95, 110, and 152. The compound also had a shorter retention time than methyl geranate, suggesting that it might be the analog of methyl geranate lacking the double bond in conjugation with the carbonyl, that is, methyl 3,7-dimethyl-6-octenoate (methyl citronellate). This tentative identification was corroborated with a match with a reference spectrum of methyl citronellate in the mass spectral database. The identification was confirmed by comparison of the mass spectrum and retention times of the insect-produced compound with those of an authentic standard.

The mass spectrum of the third male-specific compound, peak C, exhibited a molecular ion at m/z 252, for a possible molecular formula of $C_{16}H_{28}O_2$, with major fragment ions of m/z 69 (possible C_5H_9 isoprene fragment), 109 (possible C_8H_{13} fragment), 123, 177, and 209. The possible presence of an isoprene unit, and the fact that the molecular weight was 68 mass units ($= C_5H_8$) higher than that

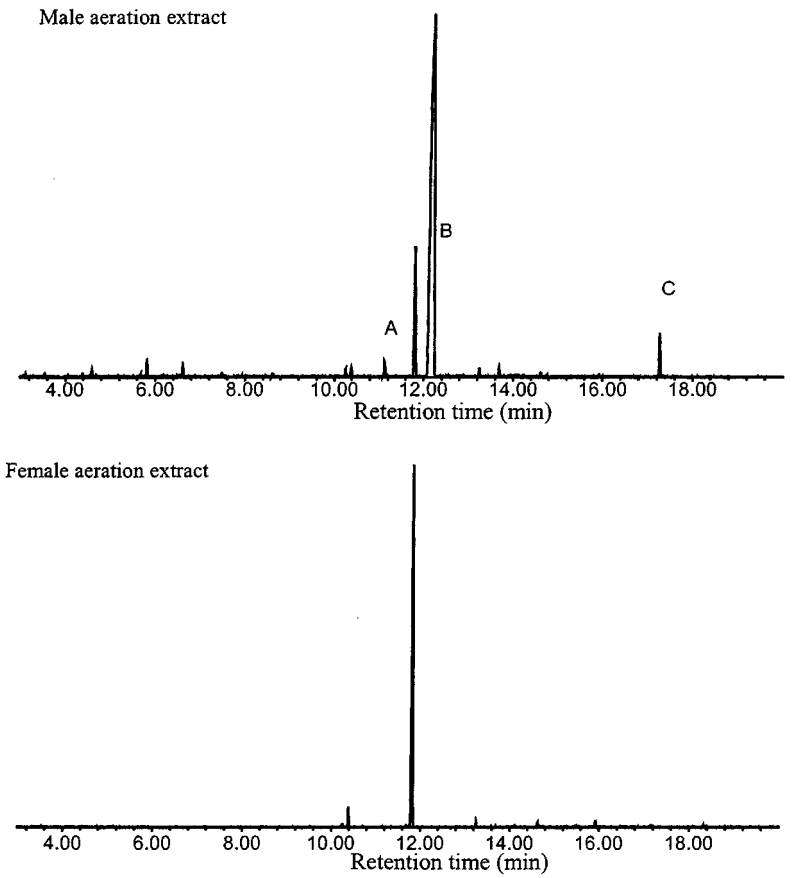

FIG. 4. Gas chromatograms of aeration extracts of female and male *C. sayi*. GC conditions: column DB5-MS (20 m × 0.2 mm ID), initial temperature 50°C (1 min), 10°C/min to 250°C, 250°C (10 min). Three compounds were found only in male aeration extract: A, methyl citronellate; B, methyl geranate; C, methyl (*E*)-6-2,3-dihydrofarnesoate.

of methyl citronellate suggested that this compound might be the sesquiterpenoid homolog, that is, methyl (*E*)-6-2,3-dihydrofarnesoate. The retention times of the insect-produced compound were significantly less than those of a methyl farnesoate standard (m/z 250) on two GC columns, further suggesting that the ester carbonyl was not conjugated. The identification was confirmed by comparisons of GC retention times and mass spectrum with those of an authentic standard.

An attempt to determine the enantiomeric composition of the insect-produced methyl citronellate and methyl (*E*)-6-2,3-dihydrofarnesoate by the formation of diastereomeric derivatives from the free acids (Huffer and Schreier, 1990) was not

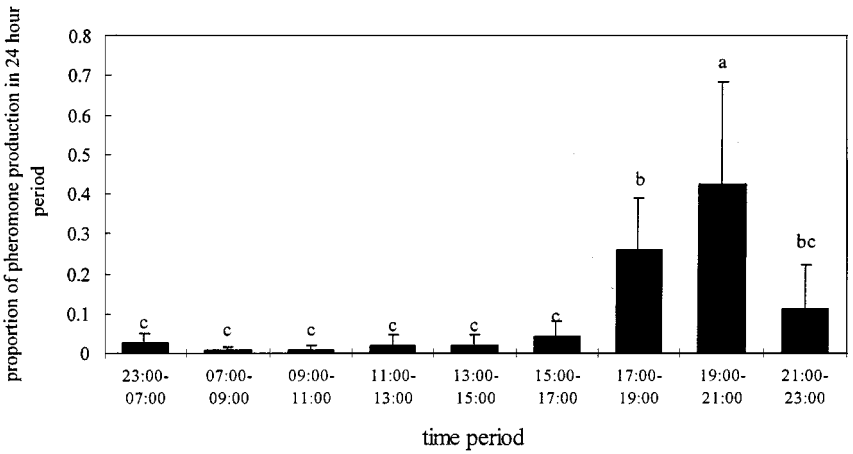

FIG. 5. Diurnal rhythm of production of male-specific compounds by male *C. sayi*. Five cohorts were aerated and the amount of the major male-specific compound, methyl geranate, produced per time interval is plotted as a proportion of the total amount produced in 24 hr. Two-way ANOVA for cohort effect, $F = 0.0419$, $DF = 4, 32$, $P = 0.9965$; for time interval effect $F = 6.9862$, $DF = 8, 32$, $P < 0.0001$. The maximum amount of the major male-specific compound, produced from 19:00–21:00 hr, was 51.6 ± 35.4 ng/bug hour. Bars surmounted by the same letter(s) are not significantly different (Student-Newman-Keuls test, $P < 0.05$).

successful due to the small amounts of the compounds in the extracts. Furthermore, we were unable to resolve racemic samples of these compounds on a capillary GC column with a chiral stationary phase (Cyclodex B, J&W Scientific).

Dynamics of Production of Male-specific Compounds. In aerations of 21 separate cohorts of male bugs, male-specific compounds were first detected between 9 and 12 days after the final molt. All cohorts produced sex-specific compounds, indicating that they had reached sexual maturity under the laboratory rearing conditions. The diurnal pattern of production of male volatiles is shown in Figure 5. Production was greatest during the late afternoon and evening hours, peaking during 19:00–21:00 hr.

Laboratory Bioassays. Female bugs were attracted to odors from live males in vertical Y-tube olfactometer bioassays (treatment = 20, control = 7; 4 nonresponders; chi-square test, $P = 0.012$). However, olfactometer bioassays with aeration extracts from males failed to elicit significant responses from females ($N = 24$) versus the solvent controls. Furthermore, the main male-specific component, methyl geranate, when tested as a single component at several doses, failed to elicit responses from females (20 μg, treatment 10 bugs, control 8 bugs, $P = 0.64$; 2 μg, treatment 5 bugs, control 5 bugs, $P = 1$; 0.2 μg, treatment

20 bugs, control 10 bugs, $P = 0.068$; χ^2 tests). Further tests with 0.2-μg doses of a three-component blend of (±)-methyl citronellate, methyl geranate, and (±)-methyl (*E*)-6-2,3-dihydrofarnesoate (0.5 : 100 : 2) resulted in attraction to the treatment versus a solvent control (treatment = 15, control = 3, $P = 0.0047$).

Field Bioassays. In the first field trial, 18 female *C. sayi* were observed on plants baited with the blend of male-specific *C. sayi* compounds versus a single bug on the control plants (ANOVA, $P = 0.057$). Although 10 male *C. sayi* were found on baited plants versus no males on control plants, the results were not significantly different [$P > 0.05$, multiresponse permutation procedure (MRPP)]. A second trial produced similar results, with more female bugs being collected on baited plants than on control plants (13 vs. 0, $P = 0.0044$, MRPP). No male bugs were found on either treatment or control plants in this bioassay.

A third bioassay testing the three-component blend versus the three possible two-component blends was indeterminate because the low numbers of bugs collected from baited plants precluded meaningful comparisons. However, a total of 18 females and 4 males were collected on plants baited with one of the four treatments, whereas no bugs of either sex were collected on control plants.

DISCUSSION

Reproductive Behavior. The close-range courtship of phytophagous stink bugs appears to follow characteristic steps, with all species examined to date exhibiting similar behaviors. These behaviors include a male approaching a female (over short distances), followed by antennation and head-butting of the female by the male, and end-to-end copulation (Fish and Alcock, 1973; Borges et al., 1987; Wang and Millar, 1997). The daily rhythms of reproductive activity also appear similar between species, with courtship and copulation being initiated primarily in the afternoon and evening [e.g., *Chlorochroa ligata* (Fish and Alcock, 1973); *Nezara viridula* (Harris and Todd, 1980); *Euschistus heros* (Borges et al., 1998a); *Thyanta pallidovirens* (Wang and Millar, 1997); *Acrosternum hilare* and *T. pallidovirens* (H. McBrien and J. Millar, unpublished data)]. Thus, late afternoon and evening were chosen as the optimum time to conduct both laboratory and field bioassays.

The pattern of *C. sayi* reproductive activity also coincided with the maximum production and release of pheromone by male bugs. However, the male-specific compounds were detected throughout the 24-hr monitoring periods, suggesting that the compounds were produced continuously, with only the production rate varied, or that the compounds were adsorbed on the cuticle, which then acted as a slow-release substrate. This pattern may have developed for several possible reasons. First, parasitoids of stink bugs use the male-produced compounds as kairomones (Aldrich, 1995), and timing peak production to the cooler parts of the

day with waning light levels may help male bugs avoid being parasitized (Harris and Todd, 1980). Second, because of the relatively long copulation times during which a copulating pair may be at greater risk of predation, peak production in the late afternoon and evening may be timed so that males and females find each other around dusk and then continue copulation under the cover of darkness. Third, peak pheromone production and mating activities may be timed for optimum temperature and humidity conditions. Mating activities in the heat of the day would increase the risk of desiccation, whereas cooler nighttime temperatures may hinder movement and activity.

Males transferred substantial weights of material to females during mating, with body weights of both sexes changing significantly after copulation. Weight changes occurred with both virgin and experienced insects, and mean duration of copulation was similar for virgin and experienced insects. Similar weight changes after mating occur with *T. pallidovirens* (Wang and Millar, 1997), and it has been documented that pentatomid females obtain nutrients from males, often in the form of large, nonfertilizing sperm (Schrader 1960; Mitchell and Mau, 1969; Mau and Mitchell, 1978; Kasule 1986). In *T. pallidovirens*, these materials resulted in enhanced egg production by females, increasing the reproductive output of both sexes (Wang and Millar, 1997). This increase in reproductive output should in turn encourage multiple copulations by both sexes, which is indeed a characteristic of pentatomid reproduction.

There are several possible explanations for male stink bugs being the pheromone-producing sex. For example, adult stink bugs are polyphagous and mobile, and it is known that they move into and out of habitats quickly. However, the details of the dynamics of these migrations are unknown, and it is possible that males are the pioneering sex in colonizing new habitats. Under such a scenario, males, upon finding a good habitat, might produce pheromone to attract females, with oviposition commencing within a day or so after copulation to the mutual benefit of both sexes.

Alternatively, stink bugs are attacked by a variety of parasitoids and predators, at least some of which use stink bug pheromones as kairomones to locate their prey (Aldrich, 1995). Because of the resultant risk, males may have evolved to be the pheromone producers, because a male that only survives long enough to mate once or a few times may still realize a large fraction of his potential reproductive output. Conversely, because females lay eggs at intervals throughout their adult lives, female reproductive output is maximized by longevity. Hence, the considerable risk of parasitization is primarily borne by the pheromone-producing males, for which longevity may be less important than attracting and copulating with females.

Male Specific Compounds. The male-specific compounds produced by *C. sayi* included three known terpenoid compounds, methyl geranate, methyl (*E*)-6-2,3-dihydrofarnesoate, and methyl citronellate. Methyl geranate and methyl citronellate have been identified frequently from the essential oils of plants, such as

species within *Lauraceae* (Ding et al., 1994). However, they are relatively uncommon in insects. Methyl geranate and analogs have been used as juvenile hormone mimics with the milkweed bug, *Oncopeltus fasciatus* (Brieger, 1971), to study structure–activity relationships. Methyl geranate was also collected from male Mediterranean fruit flies (*Ceratitis capitata* Wied.) (Flath et al., 1993), but because electroantennogram responses of female and male Medfly antennae to this compound were about the same, it was not considered to be a possible male pheromone (Jang et al., 1989). To our knowledge, methyl (*E*)-6-2,3-dihydrofarnesoate has not been found in nature and was originally synthesized as a possible treatment for liver disease (Yamatsu et al., 1981). Because of its structural similarity to insect juvenile hormones, this compound also has been used in the study of juvenile hormones (Campbell et al., 1998). However, a related compound, *trans*-2,3-dihydrofarnesol, found in labial glands from several species of bumblebees, may have a semiochemical role in scent marking of flight routes and possibly species recognition (Bergström et al., 1996).

Bioassays. Laboratory and field bioassays were complicated by the fact that females did not respond strongly to odors from conspecific males, to extracts from males, or to reconstructed blends of male specific compounds. Analogous problems have been reported during attempts to bioassay possible pheromone components for other phytophagous bug species. For example, two male-specific compounds, *trans*- and *cis*-(*Z*)-bisabolene epoxide, were first identified from the southern green stink bug, *Nezara viridula*, more than a decade ago (Aldrich et al., 1987; Baker et al., 1987), and blends of the two isomers are significantly more attractive to female bugs in laboratory bioassays than blank controls (Brézot et al., 1994). However, the attraction is comparatively weak. Furthermore, there has been only a single fragmentary report of field bioassays of the pheromone, despite the importance of this bug as a worldwide agricultural pest (Panizzi, 1997); only low numbers of bugs were attracted (Aldrich et al., 1993). Male-specific compounds also have been identified from a number of *Euschistus* spp. (Aldrich et al., 1991), but field bioassays resulted in collection of less than one bug per trap-day (Aldrich et al., 1991; Borges et al., 1998b). Laboratory bioassays with *Euschistus heros* (Borges et al., 1998a), *E. obscurus* (Borges and Aldrich, 1994), and *Piezodorus hybneri* (Leal et al., 1998) also demonstrated that attraction of female bugs to male volatiles or synthetic pheromone components was relatively weak, with less than 50% of the individuals tested being attracted to the test treatments.

We were able to demonstrate attraction of virgin female bugs to the odors from conspecific males, but not to aeration extracts from males, despite testing females from a number of cohorts on several occasions, using a variety of doses of extracts prepared from different cohorts of male bugs. There are several possible reasons for the failure of these bioassays. First, the crude extracts contained defensive chemicals in addition to the male-specific compounds, and these chemicals may have inhibited female responses. Second, the optimum dosage was not known,

and the production of male-specific compounds by the bugs was variable. Despite testing a number of different doses, there was no clear indication that any dose tested was attractive. The problem was compounded by the weak responses exhibited by females in the laboratory bioassays: even when the bioassay was working well, the best treatments were normally only two to three times as attractive as the controls.

Rather than spending further time on bioassays of crude extracts, the male-specific compounds were identified and synthesized to determine whether they had the expected biological activity. This approach allowed us to test doses varying by orders of magnitude and to standardize and reproduce blends over time. In the olfactometer bioassay, females exhibited attraction to the major male-specific compound and to the complete three-component blend of male-specific compounds. Further laboratory bioassays were not pursued because of declining populations of bugs in the colony.

Field Bioassays. Several reports indicate that many of the commonly used insect trap designs were not effective for phytophagous stink bugs and that bugs were frequently attracted to the vicinity of, but not into, traps (Aldrich et al., 1991; Sugie et al., 1996). In perhaps the most extreme example, James et al. (1996) caught no spined citrus bugs (*Biprorulus bibax*) in traps placed in citrus trees, but found that large numbers of bugs were attracted to trees containing traps. Consequently, instead of using traps of unknown efficacy, we decided to use a "trap plant" concept, in which the numbers of bugs on plants baited with pheromone lures or solvent controls would be counted. Before deploying bioassays, in a pilot experiment run to determine the optimum time to conduct bug counts, female bugs were not seen close to lures in the early morning when temperatures were still cool, nor were they seen in the upper half of the plants close to the lures during the heat of the day. The optimal period for attraction, in agreement with the laboratory studies and with previously reported data from other species, appeared to be late afternoon through to darkness. Consequently, field tests were evaluated from about 17:00 hr until dark.

Field test results followed the same general pattern as that seen in the laboratory, with weak attraction of adult female bugs to pheromone lures. Several other points also emerged. First, there were indications that lures also attract male bugs; the number of males on baited plants was always higher than the number near controls, in all tests run. However, there may be an alternate explanation for this apparent attraction; males searching for females may be attracted to or arrested on plants with females in response to cues associated with females. For example, males and females of several species of stink bugs are known to communicate over shorter distances by substrate-borne vibrational cues [*Nezara viridula* (Ota and Çokl, 1991), *N. antennata* (Konn et al., 1988), *N. viridula* and *Acrosternum hilare* (Çokl et al., 2001)]. Further studies will be required to determine whether males are indeed attracted to the synthetic male pheromone, or whether the

apparent attraction is actually arrestment or attraction in response to female-produced cues. There was no indication that the lures were attractive to immature bugs, as has been reported for at least one other stink bug species (Aldrich et al., 1987).

In total, the laboratory and field bioassay data provide strong evidence that one or more of the male-specific compounds are sex pheromone components. The relatively weak attraction of females to the pheromone suggests that other factors must also play a role in bringing the sexes together. For example, there is considerable evidence suggesting that sex attractant pheromones play a role in long-range attraction (Borges et al., 1987; Aldrich et al., 1987, 1991; James et al., 1994; Borges et al., 1998b). However, pheromones are probably not the only cues involved, because most phytophagous stink bugs are not strongly attracted into close proximity to pheromone sources or, at least, few phytophagous stink bugs have been caught in pheromone-baited traps (e.g., Aldrich et al., 1987, 1991; James et al., 1994). As described above, several reports suggest that at shorter ranges, stink bugs of both sexes may use vibrational signals transmitted through the substrate for intersexual communication (Ota and Çokl, 1991; Ryan and Walter, 1992). The possible effects of other sensory cues, such as visual signals, or cues associated with the host plants that may act in concert with insect-produced cues, remains to be investigated.

Because of the weak attraction to the male-produced compounds, and despite laboratory and field bioassay attempts extending over several years, it remains unclear whether the male-produced pheromone consists of the single component methyl geranate, or whether the true pheromone is actually a blend of methyl geranate and one or both of the minor male-specific components. Furthermore, all field bioassays to date have been carried out with racemic methyl dihydrofarnesoate and methyl citronellate, and it is entirely possible that the bugs may respond less well to the racemates than to the insect-produced enantiomers of these compounds. Efforts to address these questions are continuing, in parallel with efforts to develop an effective trap for this species.

(Received July 31, 2000; accepted February 9, 2001)

Abstract—The strawberry blossom weevil, *Anthonomus rubi*, is a major pest of strawberries in the United Kingdom and continental Europe. As part of a project to develop noninsecticidal control methods, the pheromone system of this species was investigated. Comparison of volatiles produced by field-collected, overwintering individuals of each sex led to identification of three male-specific compounds—(*Z*)- 2-(3,3-dimethylcyclohexylidene)ethanol, (*cis*)-1-methyl-2-(1-methylethenyl)cyclobutaneethanol, and 2-(1-methylethenyl)-5-methyl-4-hexen-1-ol (lavandulol)—in amounts of 6.1, 1.2, and 0.82 μg/day/male. The first two compounds are components of the aggregation pheromone of the boll weevil, *Anthonomus grandis*, grandlure II and grandlure I, respectively. Grandlure I was the (1*R*,2*S*)-(+) enantiomer and lavandulol was a single enantiomer, although the absolute configuration was not determined. Trace amounts of the other two grandlure components (*Z*)-(3,3-dimethylcyclohexylidene)acetaldehyde (grandlure III) and (*E*)-(3,3-dimethylcyclohexylidene)acetaldehyde (grandlure IV) were also detected. (*E*,*E*)-1-(1-Methylethyl)-4-methylene-8-methyl-2,7-cyclo-decadiene (germacrene-D), a known volatile from strawberry plants, *Fragaria ananassa*, was collected in increased amounts in the presence of pheromone-producing weevils. Male weevils only produced pheromone on *F. ananassa* and not on scented mayweed, *Matracaria recutita*, or cow parsley, *Anthriscus sylvestris*, although these are known food sources. In field trials using various combinations of synthetic grandlures I, II, III, and IV and lavandulol, significantly more weevils were caught in traps baited with blends containing grandlure I and II and lavandulol than in those baited with blends without lavandulol or unbaited controls. Addition of grandlure III and IV had no

0098-0331/01/0600-1203$19.50/0

significant effect on attractiveness. Horizontal sticky traps were found to be more effective than vertical sticky traps or standard boll weevil traps. In mid-season females predominated in the catches, but later more males than females were trapped.

Key Words—Strawberry blossom weevil, *Anthonomus rubi*, Curculionidae, Coleoptera, aggregation pheromone, Grandlure, lavandulol, germacrene-D.

INTRODUCTION

The strawberry blossom weevil, *Anthonomus rubi* Herbst (Coleoptera: Curculionidae), is a major pest of strawberry crops in the United Kingdom and Europe (Cross and Easterbrook, 1998; Hoffman, 1954; Popov, 1996) and is sometimes a pest of raspberry (Alford, 1984). The weevil is univoltine, and adults emerge in late April from overwintering sites of leaf litter and soil adjacent to strawberry fields (Fenouhlet, 1907; Jary, 1932). It feeds initially on strawberry foliage before mating commences at the onset of flower bud formation. Diapausal adults emerge six to eight weeks after oviposition. It feeds in and around the strawberry crop for about two weeks until leaving the crop for an overwintering site in late July/early August (Jary, 1932; Morris, 1977). Strawberry crop loss is a result of the oviposition behavior of the female, which involves deposition of a single egg in an unopened strawberry bud, followed by severing of the stalk below the bud (Jary, 1932; Alford, 1984). A single female lays up to 50 eggs and potential crop losses are great even at low population levels. Owing to the small size of the weevil and the nature of the damage, effects on the crop are often unnoticed until it is too late to take remedial action. Current control involves the routine use of broad-spectrum insecticides, e.g., chlorpyrifos, which is unsatisfactory due to high cost, environmental affects, and negative public perception. Thus, a more cost-effective, benign, and acceptable control method is desirable.

Extensive work has been carried out on identification of pheromones and their use within the Curculionidae (Bartelt, 1999), exemplified by the decades of research conducted on the boll weevil, *Anthonomus grandis* (Coleoptera: Curculionidae) (Hardee and Mitchell, 1997). Following identification of four components of the male aggregation pheromone of *A. grandis*, given the trivial name grandlure, (Tumlinson et al., 1969), pheromones of several weevil species have been identified. These include two from within the same subfamily as *A. grandis*, the pepper weevil *A. eugenii* (Eller et al., 1994) and the pecan weevil *Curculio caryae* (Hedin et al., 1996, 1997), both of which produce male aggregation pheromones incorporating Grandlure components.

Although there have been no reports of pheromonal attraction for *A. rubi*, the successful identifications from within the same genus encouraged a preliminary trapping study with this species, the results of which led to the investigation of the composition of the pheromone.

METHODS AND MATERIALS

Insect Material. In 1998, adult *A. rubi* were collected from strawberry plants, *Fragaria ananassa*, at Horticulture Research International, East Malling, West Malling, UK, during early April, the time of weevil emergence. As there was no report of sexual dimorphism within the species, these were sexed by placing a group of four or five weevils together in a Petri dish containing filter paper, and separating the pairs that displayed mounting behavior. Males and females were maintained in separate plastic propagators (36 × 22 × 16 cm; B&Q, Eastleigh, Hants, UK) at 20°C and 16L:8D. Insects were provided with *F. ananassa* flowers that were changed every three days.

In 1999, during the second week of March, deciduous tree leaf-litter was collected in transparent polyethylene bags from beneath and around conifer trees adjacent to strawberry fields at Boughton Monchelsea, Kent. These strawberry fields had contained a large population of weevils the previous summer, just prior to migration to overwintering sites. The litter was maintained at 20°C and emerging weevils were transferred to individual holding chambers (13 × 8 × 5 cm) containing *F. ananassa* plants.

During the first week of April 1999, a second collection of *A. rubi* was made at Boughton Monchelsea. These were weevils recently emerged from overwintering and found on cow parsley, *Anthriscus sylvestris.* This date preceded the onset of strawberry bud development. Weevils were kept in individual containers on *A. sylvestris.* A third batch of blossom weevils was collected in the first week of August from a strawberry farm at Doddington, Kent. These individuals were found feeding on scented mayweed, *Matracaria recutita.* When placed together they showed no sign of sexual behavior and were thus presumed to be the diapausal first generation adults.

Collection of Volatiles. For collection of emitted volatiles, natural or synthetic sources were placed in a glass chamber (10 cm long × 3 cm diam.). A diaphragm pump (Capex Mk II, Charles Austen, Weybridge, Surrey, UK) was used to draw air at 1 liter/min into the chamber through an activated charcoal filter (20 cm long × 2 cm diam., 6–18 mesh) and out through a collection filter containing Porapak Q (200 mg, 50–80 mesh, PhaseSep) held between plugs of silanized glass wool in a Pasteur pipet. The Porapak was purified by Soxhlet extraction with chloroform for 8 hr, and filters were washed well with dichloromethane immediately before use. Adsorbed volatiles were removed from the filters with dichloromethane (pesticide grade; 1 × 0.5 ml, 1 × 1 ml). For pheromone identification, volatiles were collected from one to three weevils on *F. ananassa* plants for 24 hr at 20°C with a 16L:8D cycle. Volatiles were also collected from weevils on *A. sylvestris* and *M. recutita.* Collections were also made from plants alone for comparison.

Gas Chromatography (GC). GC Analyses were conducted using Carlo Erba Mega Series 5300 instruments equipped with fused capillary columns (25 m ×

0.32 mm ID) coated with polar CPWax 52CB (Carbowax 20 M equivalent; Chrompack) or nonpolar CPSil 5CB (methyl silicone; Chrompack). The carrier gas was helium at 50 kPa, and the oven temperature was held at 50°C for 2 min then programmed at 6°C/min to 240°C. Injection was splitless (200°C) and detection was by flame ionization detection (FID, 240°C). Data was captured and processed using EzChrom 6.1 software. Retention indices (RI) were calculated relative to the retention times of straight-chain hydrocarbons. Collections of the natural pheromone were quantified approximately by coinjection with undecane (10 ng) and comparison of peak areas without consideration of response factors.

For determination of enantiomeric composition of chiral materials, analyses were done using a Varian 3700 gas chromatograph with cyclodextrin capillary, column (CP-Chirasil-Dexcb; 25 m × 0.32 mm ID; Chrompack). The carrier gas was helium at 100 kPa and the oven temperature was held at 125°C. Injection was in split mode (50 : 1), and data handling was as above. Retention time comparisons and coinjection of natural and synthetic samples were used for confirmation of absolute configuration.

Gas Chromatography-Mass Spectrometry Analysis (GC-MS). GC-MS analyses were carried out with a fused silica capillary column (25 m × 0.25 mm ID) coated with polar CPWax 52CB or nonpolar CPSil 5CB linked directly to a Finnigan 700 ion trap detector (ITD) operated in electron impact or chemical ionization (*iso*butane) mode. GC conditions were as above for these columns. Spectra were compared with those in the NBS/NIH/EPA library, the ITD terpenoid library (Adams 1989), and a library generated from samples analysed previously at NRI.

Chemicals. (±)-*cis*-1-Methyl-2-(1-methylethenyl)cyclobutaneethanol (grandlure I, purity 98%), (*Z*)-2-(3,3,-dimethylcyclohexylidene)ethanol (grandlure II, purity 99.5%), and (*E*)-2-(3,3,-dimethylcyclohexylidene)ethanol (purity 99.5%) were obtained from Bedoukian, Danbury, Connecticut. (*Z*)-2-(3,3-Dimethylcycloheylidene)acetaldehyde (grandlure III) and (*E*)-2-(3,3-dimethylcyclohexylidene) acetaldehyde (grandlure IV) were obtained as a mixture of grandlures I–IV in relative proportions of 3:3:1:1 from Plato Industries, Houston, Texas. (±)-2-(1-Methylethenyl)-5-methyl-4-hexen-1-ol (lavandulol, 95% purity) was obtained from Fluka. (−)-(7*S*)-1-(1-Methylethyl)-4-methylene-8-methyl-2,7-cyclodecadiene (germacrene-D) was the major component (approximately 20%) in ylang ylang oil (Holland and Barrett, Nuneaton, Warwickshire, UK) and was purified to 80% purity by flash chromatography on silica gel eluted with hexane. Racemic germacrene-D from *Solidago altissima* was provided by Prof. Yoo Tanabe of Kwansei Gakuin University Japan (Nishii et al., 1997). (1*R*,2*S*)-(+)-*cis*-1-Methyl-2-1(1-methylethenyl)cyclobutaneethanol [(+)-grandlure I] was a gift from Prof. Kenji Mori of Tokyo University in Japan (Mori and Fukamatsu, 1992).

Pheromone Dispensers. Pheromone blends (200 mg) were dispensed from sachets prepared by heat sealing white polyethylene layflat tubing (2.5 cm ×

2.5 cm × 120 μm thick; International Pheromone Systems Ltd., Wirral, UK). For laboratory studies, dispensers were maintained in a laboratory wind tunnel (27°C, 8 kph windspeed) and release rates were measured by periodic weighing and by trapping of volatiles emitted over 1 hr at 27°C as above. Volatile collections were analyzed by GC on the nonpolar CPSil 5CB column using 1-undecanol (5 μg) as internal standard.

In the first field trial, grandlure was formulated as a 3:3:1:1 blend of grandlures I–IV in red laminate squares1 (2.5 cm × 2.5 cm × 2 mm thick; Plato Industries).

Trapping Trials. Trapping trials were carried out in fields belonging to commercial strawberry growers in Doddington, Kent, and West Peckham, Kent, or on-station at HRI, East Malling, West Malling, Kent. Unless otherwise stated, traps were white corrugated plastic sheets (20 × 20 cm) coated with polybutene adhesive on both surfaces (Oecos Ltd., Kimpton, Herts, UK) positioned horizontally on top of a wooden stake (60 cm). During initial trials carried out in 1998, trapped weevils were observed to be escaping, and additional adhesive was used during 1999. Live weevils or synthetic lures were placed in pink hair-rollers (Tesco, Cheshurst, Herts, UK), capped at both ends with white, sterilin tube lids, and secured to the center of the upper surface of the trap with a nail into the supporting stake. Live weevils used as bait were provided with a cut strawberry flower, and the flower and any dead weevils were replaced every second day. Traps were positioned 6 m apart in a 5 × 5 Latin square (live baiting experiment) or randomized complete block design with three replicates at each of three sites (synthetic pheromone experiments).

In a comparison of trap designs, the above horizontal sticky trap was compared with the standard boll weevil trap from Plato Industries (Mitchell and Hardee, 1974a) and a vertical white sticky trap (20 × 20 cm; Oecos Ltd., Kimpton, Herts, UK) positioned 60 cm above ground level in a 3 × 3 Latin square design.

Weevils trapped during the 1999 trials were placed in hexane to remove excess glue and stored in 70% ethanol before random samples were sexed using the coxal thorn method (Balachowsky and Mesnil, 1935; Innocenzi et al., 2001).

Statistical Analysis. Total trap catches were transformed to $\log_{10}(x + 1)$ to normalize the variance. Two-way analysis of variance (ANOVA) was carried out to test for any treatment × location interaction. After one-way ANOVA on the transformed data, differences between means were tested for significance at the 5% level by the least significant differences (LSD) test.

RESULTS

Attractiveness of Male and Female Weevils. A preliminary trapping trial was done at Hillberry Farm, East Malling, UK, from 5 to May 19, 1998, comparing catches of weevils in traps baited with a male *A. rubi* weevil, female weevil,

F. ananassa plant only, grandlure dispenser, and *F. ananassa* plant, or unbaited control. Fifteen weevils were caught in the five replicates, all on traps baited with live males. The small numbers were possibly a reflection of the low population due to the grower's pest management regime, as well as the inability of the sticky trap to retain the weevils. During each survey, the recorded weevils were observed walking freely on the sticky traps.

Comparison of Volatiles from Male and Female Weevils. Gas chromatograms of volatiles collected from *A. rubi* in 1998 did not show any consistent differences between the sexes. However, in 1999, GC analyses of volatiles from individuals collected as overwintering adults revealed three components

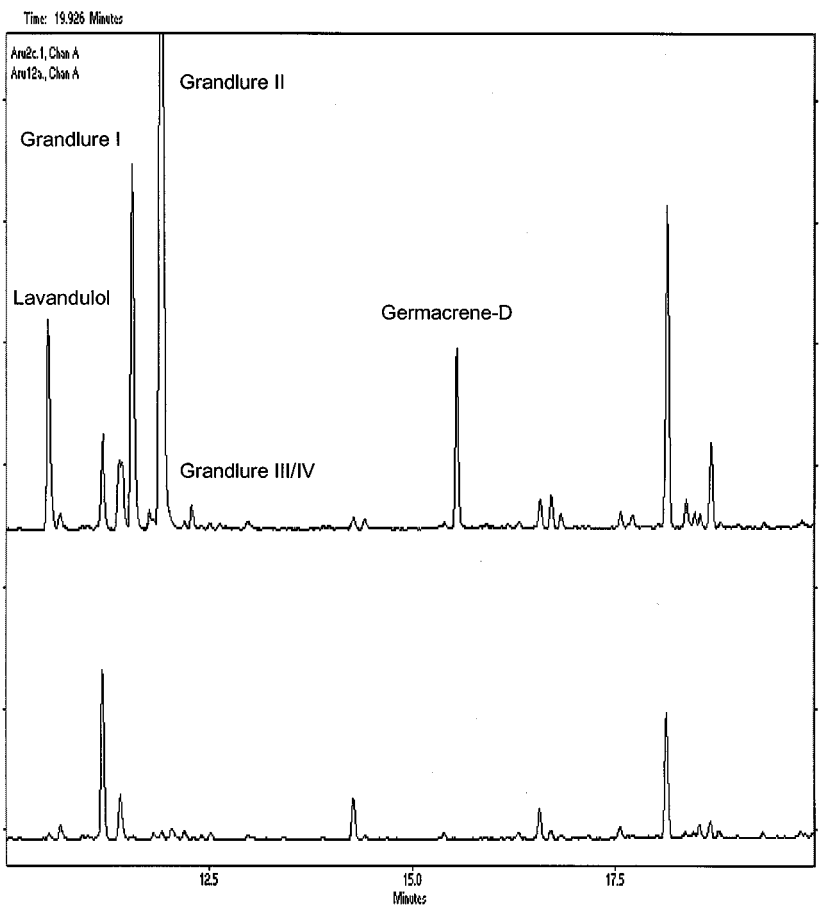

FIG. 1. Gas chromatograms (nonpolar CPSil 5CB column) of volatiles collected from male (upper) and female (lower) *A. rubi weevils.*

that were male-specific and another component found in relatively large amounts in male volatiles but only trace amounts in volatiles from females (Figure 1). Preliminary identifications were made by comparison of their EI mass spectra and library spectra and comparison of GC retention indices with published data. These preliminary identifications were confirmed by comparison of EI and CI mass spectra, retention indices on polar and nonpolar GC columns, and GC coinjection with the synthetic materials. The four components were found to be *cis*-1-methyl-2-(1-methylethenyl)cyclobutaneethanol (grandlure I), (*Z*)-2-(3,3-dimethyl-cyclohexylidene)ethanol (grandlure II), lavandulol, and germacrene-D (Figure 2), the latter being present in both male and female volatiles. These were produced in mean quantities per male weevil per day of 1.2, 6.1, 0.82 and 0.72 μg ($N = 8$), for grandlure I, grandlure II, lavandulol, and germacrene-D, respectively.

Further examination of GC-MS analyses of volatiles from male *A. rubi* showed the presence of trace amounts of the *E* isomer of grandlure II (approximately 1% of the *Z* isomer by GC-MS analysis), and also both (*Z*)-(3,3-dimethyl-cyclohexylidene)acetaldehyde (grandlure III) and (*E*)-(3,3-dimethylcyclohexylidene)acetaldehyde (grandlure IV) ($\leq$1% as compared with the (*Z*)-grandlure II by GC-MS) (Figure 2). The retention indices (RI) of the compounds identified on both polar and nonpolar GC columns are shown in Table 1. The *trans* isomer of grandlure I, fragranol (Bohlmann et al., 1973), was not available for comparison, but Yamazaki et al. (1994) reported this to elute clearly before the *cis* isomer on a Carbowax GC column.

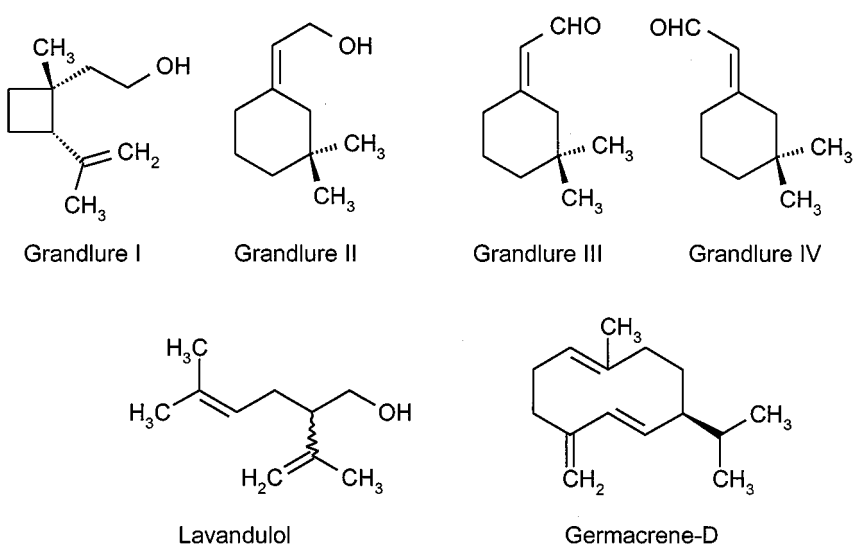

FIG. 2. Candidate pheromone components of male *A. rubi*.

TABLE 1. GC RETENTION INDICES (RI) OF PHEROMONE COMPONENTS

Chemical	RI	
	CPWax	CPSil
Grandlure I	1793	1190
(Z)-Grandlure II	1790	1203
(E)-Grandlure II	1801	1203
Grandlure III	1690	1219
Grandlure IV	1704	1228
Lavandulol	1677	1149

GC analyses of the volatiles from male *A. rubi* weevils on a chiral cyclodextrin column that separated the enantiomers of grandlure I (12.26 and 13.39 min) and lavandulol (7.17 and 7.44 min) showed that the naturally produced compounds were single enantiomers. Grandlure I was the (1*R*,2*S*)-(+) enantiomer by comparison of retention times and coinjection with the synthetic compound (12.26 min). The natural lavandulol cochromatographed with the second eluting enantiomer, but the absolute configuration is unknown as authentic samples of the enantiomers were not available. Racemic germacrene-D obtained from *Solidago altissima* extract gave two peaks on the cyclodextrin column with retention times of 19.76 and 20.58 min for the (+) and (−) enantiomers, respectively. The compound produced by male *A. rubi* weevils had the (−) configuration by retention time comparisons and coinjection with the *Solidago altissima* extract and (−)-germacrene-D obtained from ylang ylang oil (Nishii et al., 1997).

Volatile Collections from Weevils on Different Hosts. Volatiles from individual weevils were collected in the presence of *F. ananassa*. These weevils were then maintained on *F. ananassa* for two weeks, after which volatiles were collected from the same weevils in the presence of *A. sylvestris.* Volatiles were also collected from the weevils collected from *A. sylvestris* in the field in the presence of *A. sylvestris* or *F. ananassa*, the two plants being randomly assigned. The weevils collected from *M. recutita* underwent the same process in the presence of either *M. recutita* or *F. ananassa*. Volatiles were also collected from all three plants alone and from *F. ananassa* subjected to multiple cuts with microscissors.

Analyses of the collected volatiles by GC-MS showed that male weevils produced the above chemicals only in the presence of *F. ananassa*, and not in the presence of *A. sylvestris.* In GC-MS analysis of volatiles from weevils collected in August in the presence of either *F. ananassa* or *M. recucita*, the pheromone components were not detected. Volatiles from intact or cut *F. ananassa* contained small amounts of germacrene-D.

Pheromone Dispensers. Release rates from the sealed polyethylene sachet dispensers containing single components were constant (zero order). At 27°C and

8 kph windspeeed, rates were 1.0, 1.5, and 3.5 mg/day for grandlure I, grandlure II and lavandulol, respectively, as measured by weight loss of duplicate sachets.

The composition of the blends released from sachets containing the mixtures of components used in field trapping trials were measured by trapping and analysis of volatiles emitted. The mixtures were grandlure I + II (20:80), grandlure I + II + III + IV (25:58:8.5:8.5), Grandlure I + II and (±)-lavandulol (17:66:17), grandlure I + II + III + IV and (±)-lavandulol (ratio 19:47:7:7:20). The results over 36 days with a 200-mg initial loading are shown in Figure 3.

As expected from their individual release rates, the grandlure I + II blend released the two components in relative amounts similar to those in the starting

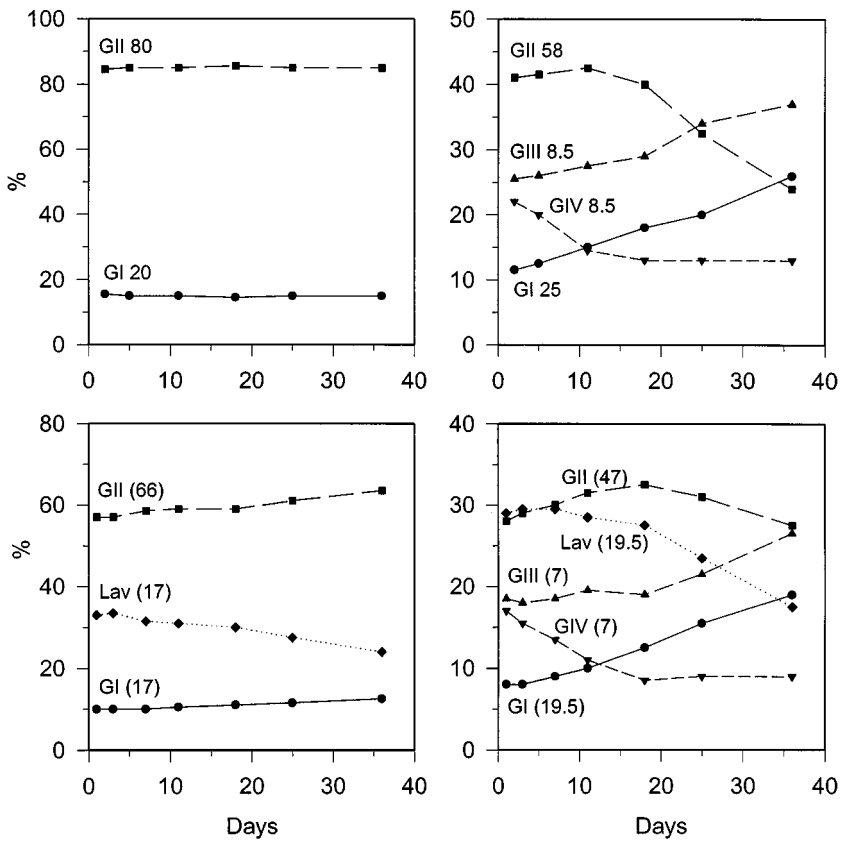

FIG. 3. Percentage composition of volatiles released from polyethylene sachet dispensers containing four different blends of synthetic pheromone components at 27°C and 8 kph windspeed. (GI = grandlure I; GII = grandlure II; GIII = grandlure III; GIV = grandlure IV; Lav = lavandulol; figures in parentheses are percentage in blend in sachet. Each sachet, replicated twice, contained 200 mg).

mixture, and this stayed constant during the period of measurement. With the three component grandlure I + II + lavandulol mixture, the lavandulol was released proportionately faster and the proportion of this component in the blend released declined.

The ratios of components released from the two mixtures containing the more volatile, and labile aldehyde components, grandlures III and IV, also deviated from the ratios in the starting mixture, especially in the presence of (±)-lavandulol. The blend released initially contained grandlures III and IV in higher relative proportions than in the blend in the sachet. However, whereas the proportion of grandlure III in the blend released increased during the study period, that of the *trans* isomer, grandlure IV, decreased over the first 20 days. This coincided with the appearance of additional GC peaks, suggesting some chemical transformation.

Trapping Trials. In 1999, attractiveness of the proposed pheromone components to *A. rubi* was evaluated in field trapping tests. A 3 × 5 randomized block design was set up at the three different sites using the four blends described above and a control, unbaited trap.

In the mid-season phase from mid-May to mid June 1999, the numbers of weevils caught in traps baited with blends of grandlure components alone (treatments B and D) were not significantly different from the numbers caught in unbaited traps (A) (Figure 4). Addition of (±)-lavandulol to either of these (treatments C

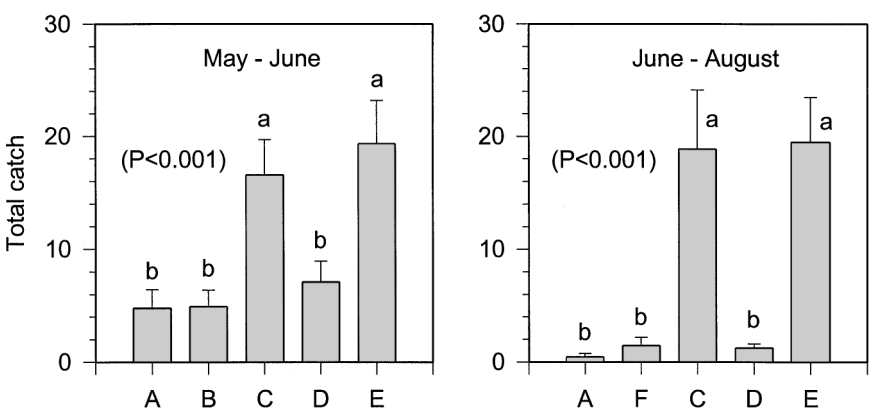

FIG. 4. Catches of *A. rubi* weevils in traps baited with different synthetic blends at three different sites, 1999 (three replicates at each site). Treatments in first experiment (40 days) were: A = control; B = grandlure I + II; C = Grandlure I, II, and (±)-lavandulol; D = Grandlure I, II, III + IV, E + Grandlure I, II, III, IV, and (±)-lavandulol; treatments in second experiment (34 days) were as previously except F = (±)-lavandulol. Standard error bars are shown for each treatment ($n = 9$); treatments with same letter above columns are not statistically different (LSD, $P = 0.05$); overall differences among treatments are shown in parantheses.

TABLE 2. CATCHES OF *A. rubi* WEEVILS IN THREE DIFFERENT TYPES OF TRAP[a]

Trap type	Total catch mean ± SE[b]
Horizontal sticky trap	15.5 ± 0.5 a
Vertical sticky trap	10.0 ± 2.0 b
Boll weevil trap	4.0 ± 0.0 c

[a] Lures contained grandlure I + grandlure II + grandlure III + grandlure IV + lavandulol; 3 replicates, May 23–July 25, 1999.
[b] Means followed by different letters are significantly different (data transformed to $\log_{10}(x + 1)$ followed by ANOVA and LSD test, $P = 0.05$).

and E) increased the catch ($P < 0.05$). Addition of grandlure III and IV had no significant effect on catches in the presence (E compared with C) or absence (D compared with B) of (±)-lavandulol.

Prior to the late-season phase from mid-June to early August, the lures were renewed, treatments rerandomized, and grandlure I + II (B) replaced by (±)-lavandulol (F) alone. Similar results were obtained with the two blends containing grandlure components and (±)-lavandulol (C, E) catching more weevils than the other treatments (Figure 4). Traps baited with grandlure I–IV (D) or (±)-lavandulol (F) did not catch more than unbaited traps (A).

The horizontal sticky trap was found to be the most effective trap design for trapping weevils when compared with a vertical sticky trap or the boll weevil trap (Table 2).

Sex of Weevils. Both male and female *A. rubi* were caught in sticky traps containing the attractive blends. However, the male to female ratio varied during the trapping period with females predominating in mid-season, but more males than females caught late season (Table 3).

TABLE 3. *A. Rubi* WEEVILS CAUGHT WITH SYNTHETIC LURES DURING TWO TRAPPING PERIODS[a]

	Catch [% (*N*)] [b]			
	May–June 1999		June–August 1999	
Sex	Lure A	Lure B	Lure A	Lure B
Male	36 (20)	40 (26)	75 (9)	80 (24)
Female	64 (36)	60 (39)	25 (3)	20 (6)

[a] Actual Numbers Sampled are in parentheses.
[b] Lure A: grandlure I + II + lavandulol (1:4:1); lure B: grandlure I + II + III + IV + lavandulol (19:47:7:7:20).

DISCUSSION

As with the three previously reported pheromones of weevil species in the subfamily Curculioninae (Tumlinson et al., 1969; Eller et al., 1994; Hedin et al., 1997), males of the strawberry blossom weevil, *A. rubi*, produce components of grandlure, the pheromone of the boll weevil, *A. grandis.* In addition to all four grandlure components, they also produce the acyclic monoterpene, lavandulol. Both grandlure I and lavandulol produced by males were found to be enantiomerically pure, although the absolute configuration of the latter has yet to be resolved. The grandlure I was shown to be the (1*R*,2*S*)-(+)- enantiomer as in *A. grandis*, where it has been shown that the opposite enantiomer is behaviorally inactive (Dickens and Mori, 1989). Trapping results with racemic materials showed that a minimum combination of grandlure I, grandlure II, and lavandulol was necessary to attract significant numbers of male and female *A. rubi.* Addition of small amounts of the aldehydes, grandlures III and IV, had no consistent significant effect on catches.

Germacrene-D was present in all headspace analyses incorporating strawberry plants, *F. ananassa.* This is a known component of *F. ananassa* volatiles (Hamilton-Kemp et al., 1990), but the amounts collected increased more than 10-fold in the presence of a pheromone-producing male. This increase may be due to production by the weevils or a plant response to feeding-induced damage. Although microscissor-damaged flowers and/or leaves did not produce elevated amounts of germacrene-D, this type of artificial approach to mimic insect-plant feeding has been shown to be unrepresentative (Loughrin et al., 1996; Dicke, 1999). Whether insect or plant produced, further investigation of germacrene-D is warranted because pheromone–host-plant synergism is widely reported (Landolt and Phillips, 1997) and the attractiveness of the pheromone is enhanced by host volatiles in many species of Curculionids (Dickens, 1989; Ridgway et al., 1990; Giblin-Davis et al., 1994, 1996; Cerda et al., 1999).

Volatile collections on the different host plants—strawberry and cow parsley, *A. sylvestris*—showed that males only produced the pheromone in the presence of *F. ananassa.* Observations in the laboratory and field confirmed that *A. sylvestris* is a food source. This suggests that male *A. rubi* may produce the pheromone from chemicals derived from the oviposition host-plant or that the male only signals when a suitable oviposition host has been located, the pheromone components being produced *de novo.* Pheromone biosynthesis in *A. grandis* is possible both from plant-derived precursors (Thompson and Mitlin, 1979) and by *de novo* synthesis (Mitlin and Hedin, 1974).

With *A. rubi*, the male/female mid-season response pattern to the pheromone mirrors that found for *A. grandis* (Hardee et al., 1970) and *A. eugenii* (Eller et al., 1994), in that catches during this mating and ovipositing period were dominated by females. However, late season catches were unlike the 1:1 sex ratio

reported in the American curculionids in that over 75% of the *A. rubi* catch was male. *A. rubi* produces one generation a year that is diapausal, and the late season catches were likely to include weevils in this physiological state. This is supported by concurrent collection of males and females that showed no mating behavior, and from which no pheromone components were collected. Villavaso and Earle (1974) and Mitchell and Hardee (1974b) reported that diapausal boll weevils were attracted to live, reproductive males and to the synthetic pheromone. Caution is necessary when relating the sex ratio of synthetic lure catches to the actual field sex ratio. Mitchell and Hardee (1974b), researching *A. grandis*, found synthetic lure/live-baited catches gave a different sex ratio to field-sampled collections.

Comparison of the three trap designs, white horizontal sticky, white vertical sticky, and boll weevil trap, showed that white horizontal sticky traps were more effective at trapping *A. rubi* weevils. This may in part be due to the weevil's attraction to white (unpublished results) and/or the ability of *A. rubi* to escape from the boll weevil traps, as reported by Eller et al. (1994) for *A. eugenii.* Over 95% of the weevils were trapped on the underside of the horizontal sticky surface, which suggests weevils fly to the vicinity of the pheromone source, then walk to it, and rarely fly directly onto it. This supports the hypothesis that flying is arrested on encountering high concentrations of aggregation pheromone (Dethier et al., 1960; Kennedy, 1977; Plarre and Vanderwel, 1999). Short-range pheromones (Hedin et al., 1979) as well as visual and acoustical cues may then take over. However, under laboratory conditions, *A. rubi* males mount all individuals encountered, regardless of sex, and the existence of a short-range, female-produced pheromone is considered to be unlikely.

Henson et al. (1976) studied the chemical stability of each grandlure component in isolation and found grandlures I and II to be stable, while grandlures III and IV formed several products, including the corresponding acids. In this work, the alcohols were stable in the absence of the aldehydes, but breakdown products were formed when they were mixed with the aldehydes. Mass spectral data suggested that the two predominant compounds were dehydration products of grandlures I and II, possibly catalysed by the acids formed from oxidation of grandlures III and IV.

The effect on trap catches of the individual lavandulol enantiomers and germacrene-D will be addressed in future studies, as will also optimizing of the component ratios and release rates of existing blends.

Acknowledgments—Thanks are due to Dr. Alan Cork for helpful comments regarding earlier drafts of the paper, Martin Ridout for advice on statistical methods, and to the growers Graham Cuthbert, Don Pascoe, and Harry Wooldridge who provided sites for the field trials. Professor Kenji Mori kindly provided a sample of (+)-grandlure I and Professor Yoo Tanabe generously supplied racemic germacrene-D. This project is funded by the Natural Resources Institute, University of Greenwich, and MAFF.

(Received October 5, 2000; accepted February 12, 2001)

Abstract—Abdominal defensive glands of both sexes of the Gulf fritillary butterfly, *Agraulis vanillae (Linnaeus) (Nymphalidae:Heliconiinae)* emit a pronounced odor when disturbed. We have identified 6-methyl-5-hepten-2-one; oleic, palmitic, and stearic esters of the corresponding alcohol 6-methyl-5-hepten-2-ol; hexadecyl acetate; 1,16-hexadecanediol diacetate; and 1,15-hexadecanediol diacetate in the glandular exudate. Since we have determined that free-flying birds or birds in a butterfly conservatory discriminate against *A. vanillae* as prey, we suggest that the constituents in the glands may play a defensive role against potential avian predators.

Key Words—*Agraulis vanillae*, defensive glands, 6-methyl-5-hepten-2-one, 6-methyl-5-hepten-2-ol esters, 1,15-hexadecanediol diacetate 1,16-hexadecanediol diacetate.

INTRODUCTION

The Gulf fritillary butterfly, *Agraulis vanillae* (Nymphalidae), was first described by Linnaeus (1758), who characterized it as a species whose brilliant coloration

*To whom correspondence should be addressed.

0098-0331/01/0600-1219$19.50/0

made it very conspicuous. *Agraulis* is the most primitive genus in the large neotropical subfamily Heliconiinae, a taxon that is famous for the development of mimicry theory utilizing both brightly colored unpalatable and palatable species of butterflies (Müller, 1886; Ross, 1995). This generally tropical butterfly is also unusual in its marked northern extension that reaches to Georgia, the Carolinas, and southern Missouri and Nebraska (Glassberg, 1999) in the United States (Emsley, 1965). The wing pattern is known for its striking contrast coloration with silver below the wings and triangles and polygons of alternating silver, yellow, red, and brown above. Tyrosine is responsible for the black and brown colors via melanin formation, while tryptophan forms the red, light brown, and tan portions via 3-hydroxykynurenine and ommochromes as shown by incorporation of these radiolabeled precursors (Nijhout and Koch, 1991).

Eltringham (1925) has discussed the observation of Müller (1886) on the emission of a "strong and nauseous smell" emanating from glands in the anal valvulae of the males and from a yellow gland extruded on the abdominal dorsum of the females of *A. vanillae.* Müller (1886) called this species the Maracuja butterfly because the larvae generally fed on the maracuja (*Passiflora edulis*, Passifloriaceae), also known as the passion flower, on which it does considerable damage. The odor of the exudate from the females was said to resemble that of phenylcarbylamine (phenylisocyanide) (Eltringham, 1925), but then again "not unpleasant" and "more complex than phenylcarbamylamine." We report below the chemical nature of some of the compounds in the exudates of male and female *A. vanillae.* The above workers all described the repellent functions of these odorous secretions, and we have made additional observations with predatory birds in view of the possible unpalatability of both females and males of *A. vanillae.*

METHODS AND MATERIALS

Extraction and Subsequent Survival. Eight males and five females were collected from a personal butterfly garden belonging to Ross (1999) in Baton Rouge, Louisiana on July 22, 1999. The butterflies were initially placed individually in glassine envelopes for temporary storage. After being brought inside, each butterfly was handheld with pressure exerted on the thorax and upper abdomen. The pressure forced extrusion of the glands, which were then punctured with a No.1 stainless steel insect pin. Squares of filter paper (7–8 mm) held with a watchmaker's pair of forceps were touched to the secretions for collection. The papers were then stored in small glass vials, three for the females and two for the males, each containing 1.0 ml of methyl alcohol. Separate pins were used for the males and females. Forceps were cleaned first with soap and water and then with methyl alcohol between sampling from males and females. Following extraction (milking), the butterflies were returned to their glassine envelopes, placed within lock-proof sandwich bags (males and females separate), and then stored in a refrigerator until

the following day. Milkings were done on four consecutive days; however, males produced virtually no secretions on days 3 and 4, whereas females continued to produce, albeit to a lesser degree, through day 4. By day 5, four of the males and one of the females had died and milkings were discontinued.

The remaining eight live individuals were returned to the garden. Surprisingly, after 15 min of resting in the summer sun, the butterflies began to fly, feebly at first, but in time, more naturally. Since the garden is full of flowers, including lantana, a favorite of *Agraulis*, most of the released butterflies began to feed. When checked 3 hr later, three males and three females were still present and flying about with no apparent difficulties. The following day only one male and two females were seen. The females were flying about a *Passiflora* vine attempting to oviposit, but the milking procedures had apparently damaged some critical component of their reproductive tracts since no deposition of eggs could be observed. Two females continued to remain within the garden for a total of four days.

Chemical Analysis. Mass spectra were run using an LKB 2091 mass spectrometer operating in the EI mode with a 15-m $\times$ 0.25-mm DB-1 column with 0.25-μm film thickness operating from 78 to 300°C at 8°C/min, with a helium flow rate of 10 ml/min. Samples (1 μl) of the extracts dissolved in methanol were injected at 250°C using a splitless injector.

Samples of 6-methyl-5-hepten-2-one and 6-methyl-5-hepten-2-ol were obtained from Aldrich (Milwaukee, Wisconsin). Hexadecyl acetate and 1,16-hexadecanediol diacetate were prepared by reacting equimolar amounts of the corresponding alcohols (Aldrich) with an excess of acetic anhydride in pyridine overnight. Evaporation of the excess reagents and solvent left the crude acetates that were used without further purification. The 1,2- and 2,3-hexadecanediol acetates were similarly prepared from samples of the diols prepared from the corresponding hydrocarbons in conjunction with elucidation of the structures of diols found in chicken uropygial glands (Haahti and Fales, 1967). 1,3-Hexadecanediol diacetate was similarly prepared by acetylation of the corresponding diol prepared by treating commercial tetradecanal from Fluka (Milwaukee, Wisconsin) with commercial vinylmagnesium bromide (Aldrich). The resulting crude 1-hexadecen-3-ol was treated with an excess of borane dimethylsulfide complex (Aldrich). The usual oxidative work-up with sodium hydroxide and hydrogen peroxide provided a sample of crude 1,3-hexadecanediol that was ca. 80% pure by gas chromatography.

1,15-Hexadecanediol diacetate was prepared by allowing an excess of 2.6 M methyllithium in ether (Aldrich) to react with 1 meq of ω-pentadecalactone (Aldrich) dissolved in 20 ml of hexane. After standing 10 min, dilute hydrochloric acid was added and the solution extracted with more ether. After drying with molecular sieves (3Å, Fluka), the extracts were evaporated and a solid residue obtained. This was easily recrystallized from 50% toluene in hexane, but NMR revealed it to be a mixture. A portion of the sample was then separated on 100-μm-thick silica gel thin layer chromatography plates (Aldrich) with 2% ethanol

in chloroform. Three zones with retention factors (R_f) 0.63, 0.28, and 0.20 were visualized with methyl red and their contents recovered by scraping and extraction with 10% ethanol in chloroform. The zone at $R_f = 0.63$ was found by MS to be recovered ω-pentadecalactone. The zone with $R_f = 0.28$ melted at 45–62°C and was found by GC-MS to be the desired 1-hexadecanol-15-one [*m/z* (%): 41(39), 43(100), 55(49), 67(14), 69(20), 71(29), 96(12), 180(3), 223(2), 226(1), 256(3, M^+)] contaminated with about 30% ethyl tetradecanoate, presumably from an impurity of that acid in the lactone. Reduction of the keto alcohol with sodium borohydride in ethanol overnight formed 1,15-hexadecanediol [*m/z* (%): 41(75), 43(60), 45(95), 55(100), 57(44), 67(40), 69(67), 71(28), 95(54), 96(41), 109(24), 111(25), 123(14), 124(15), 125(10), 137(8), 194(4), 196(6), 243(5), 258(0, M^+)], and acetylation with pyridine and acetic anhydride produced the diacetate, whose mass spectrum and retention times were identical with the unknown diol diacetate shown as peak 3 in Figure 2 below. The lower band of $R_f = 0.20$ was found to be the 2-methyl-1,15-hexadecanediol, mp 63–67°C, formed by secondary reaction of the methyl ketone with excess methyllithium [*m/z* (%): 69(100), 71(55), 81(34), 83(78), 95(40), 97(45), 109(23), 111(18), 123(10), 125(8), 168(4), 180(3), 196(10), 221(4), 224(4), 239(9), 257(13, M-CH_3), 272 (0, M^+)].

Predatory Birds vs. Gulf Fritillary. Potential avian predators in the presence of large populations of *A. vanillae* were observed in two situations. In the first, 50–70 butterflies were released weekly during 1996 into the "Butterflies in Flight" exhibit at the Audubon Zoological Garden, New Orleans, Louisiana (the releases were normal protocol for populating the conservatory). The exhibit included 60–70 free-flying birds, including aggressive insectivorous species such as red-rumped caciques [*Cacicus haemorrhous* (Icteridae)] and superb starlings [*Lamprotornis superbus* (Sturnidae)]. Avian predation on *A. vanillae* and other butterflies was monitored almost daily for nine months by G. N. Ross as well as by zoo employees and volunteers for approximately 60 hr, which included examination of the ground for detached wings.

Avian predation was also monitored in an outdoor butterfly garden ($\sim$350 m^2) in Baton Rouge, Louisiana, between 1997 and 1999 (Ross, 1999). *A. vanillae*, which utilizes *Passiflora incarnata* as a host plant (Ross 1996, 2000 b), was the most common butterfly species by a factor of at least 10-fold. A variety of known avian predators were present at all times in addition to a diversity of invertebrate species with well-known predatory propensities. Efforts were made to directly observe *A. vanillae* being utilized as a prey species or indirectly in terms of detached wings being present on the ground.

RESULTS

Abdominal Glands and Their Secretions. The female possesses a pair of posterior abdominal scent glands on the dorsum between abdominal segments 7

and 8. These glands are bright yellow in color, spherical in shape (1.9–2.4 mm in diameter), and appear spongy in texture. The paired structures are normally inverted. However, when a butterfly is captured or disturbed, the glands are quickly everted. Additionally, the dorsal membrane between abdominal segments 6 and 7 is partially extruded and appears bright yellow in color. If held within 15 cm, a strong, very sweet odor is easily detected. If a gland is punctured with a fine pin, a sizable quantity of bright yellow, clear fluid is emitted. This fluid has an acrid taste, dries rapidly, and retains its color. The odor is not detectable after the fluid dries.

The male possesses a pair of bilobed, spherical structures (glands) 1.4–1.8 mm in diameter within the valvae (claspers) of the abdominal tip. The structures appear as bright yellow swollen pads when the claspers are extended, which occurs with only the slightest provocation. The fragrance is more acrid and less sweet (more alcoholic) than that produced by the females. If a gland is punctured, a small amount (but less so than that of females) of clear yellowish fluid is released. The fluid has the same fragrance as that emitted by an unaltered male. The taste is acrid and similar to that of females, dries rapidly, and retains its color. The odor dissipates on drying

Chemical Analysis. In spite of the subtle differences in odor described above, samples of the fluid obtained from either male or female abdominal glands provided essentially the same gas chromatograms and mass spectral analyses. Figure 1 shows a chromatogram of the male exudate where the early-eluting peak (peak 1) was identified as 6-methyl-5-hepten-2-one via a search of the NIST-NIH-EPA database

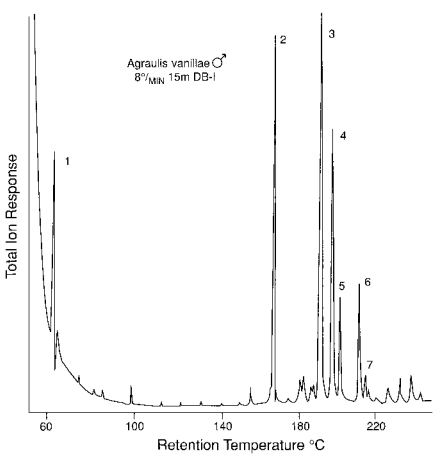

FIG. 1. Gas chromatogram of a methanol extract of male abdominal glands of *A. vanillae*: peak 1, 6-methyl-5-hepten-2-one; 2, hexadecyl acetate; 3, 1,15-pentadecanediol; 4, 1,16-hexadecanediol diacetate; 5, palmitoyl ester of 6-methyl-5-hepten-2-ol; 6, oleoyl ester of 6-methyl-5-hepten-2-ol; 7, stearoyl ester of 6-methyl-5-hepten-2-ol.

(NIST/NIH/EPA Mass Spectral Library, Standard Reference Data Program of the National Institute of Standards and Technology, Gaithersburg, Maryland) and by comparison of its mass spectrum and retention time with an authentic sample (Aldrich). Hexadecyl acetate (peak 2) was readily identified from its "acid plus one" peak at *m/z* 61 and its M-60 ion at *m/z* 224, and its presence also confirmed by comparison of its spectrum and retention time with an authentic sample. Peak 3 is discussed in detail below. Peak 4 was identified as 1,16-hexadecanediol diacetate through the database and by comparison with an authentic sample.

Mass spectra of peaks 5, 6, and 7 all closely resembled each other with abundant ions appearing at *m/z* 55, 69, 95, and 110 (Figure 2, peak 5). When searched in the database, these ions produced the spectrum of 5-[(1,5-dimethyl-4-hexenyl)oxy]-3-methyl-2-pentenoic acid ethyl ester where they were clearly due to the (1,5-dimethyl-4-hexenyl)oxy- moiety. This fragment corresponds to the alkoxy residue of 6-methyl-5-hepten-2-ol that is, in turn, the reduction product of the ketone found in peak 1. Peaks 5, 6, and 7 then represent homologous long-chain esters of that compound. Examination of minor peaks at higher mass identified these as palmitic acid (*m/z* 256), oleic acid (*m/z* 282), and stearic acids (*m/z* 284), respectively. To confirm the first of these assignments (peak 5), the palmitoyl ester was prepared from 6-methyl-5-hepten-2-ol (Aldrich) and palmitoyl chloride in pyridine. The product was indeed identical in retention time and mass spectrum with that obtained from the insect in peak 5. These compounds do not appear to have been encountered previously.

The mass spectrum of peak 3 resembled that of peak 4 (1,16-hexadecanediol diacetate) in many respects, including the loss of two molecules of acetic acid to form ions at *m/z* 222. However, peak 3 shows an ion at *m/z* 87 not seen in the 1,16-diol, and this suggests the linkage $CH_3CH = OAc^+$. In fact, one of us (H.M.F) earlier noted a series of 2,3-alkanediols in the uropygial glands of birds (Haahti and Fales, 1967), so 2,3-hexadecanediol diacetate was prepared from the diol synthesized in connection with that study. The 2,3-diol diacetate (Figure 2, bottom spectrum) did indeed show cleavage between the acetoxy groups producing ions at *m/z* 87 and *m/z* M-87 at 255, but its spectrum was not identical with that of peak 3. An isomeric ion $CH_2(OAc)CH_2^+$ of *m/z* 87 is theoretically available also from 1,3-hexadecanediol diacetate, so this compound was synthesized by the action of vinylmagnesium bromide on tetradecanal followed by hydroboration, oxidation, and acetylation. This compound (spectrum not shown) showed an abundant α-cleavage peak containing both acetate units at *m/z* 159 while the intensity at *m/z* 87 was only 8%, so it was also ruled out. By now it was clear that the two acetate units are more remotely located in the unknown. Based on the ion at *m/z* 87, as well as the presence in the extract of 1,16-hexadecanediol diacetate, we considered a likely candidate to be the 1,15-diol isomer. This diol was prepared by reacting commercially available ω-pentadecalactone (Aldrich) with methyllithium to form 1-hexadecanol-15-one

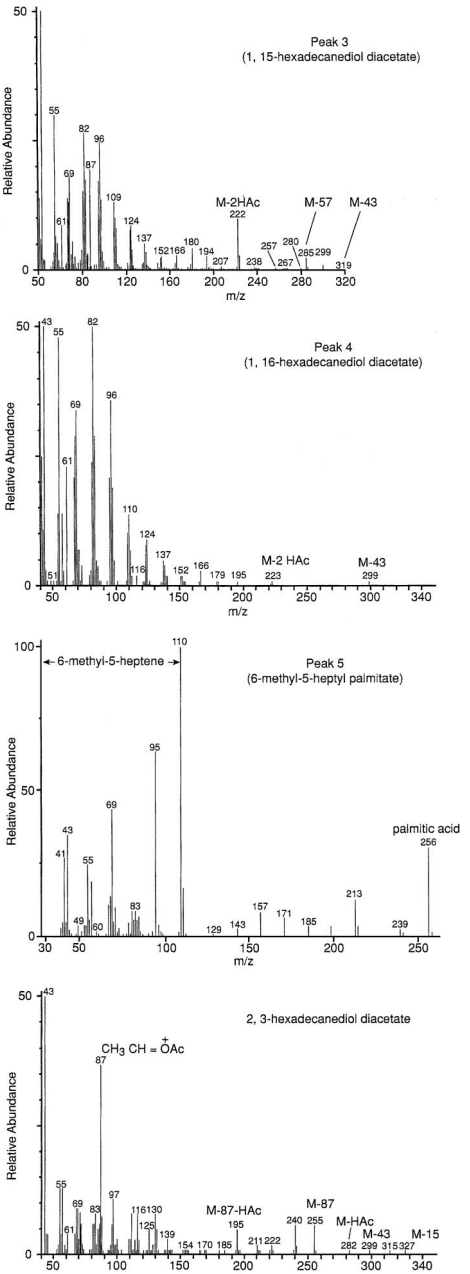

FIG. 2. Mass spectra of peaks 3, 4, and 5 in the gas chromatogram of the abdominal glands of *A. vanillae.* 2,3-Hexadecanediol acetate is presented for comparison to other diacetates (peaks 3 and 4).

(with much of the tertiary alcohol 2-methyl-2,15-pentadecanediol as by-product). Reduction of the ketone with sodium borohydride and acetylation with acetic anhydride gave the desired 1,15-pentadecanediol diacetate, which was indeed identical in retention time and mass spectrum with the compound represented by peak 3.

Predation on Agraulis vanillae. Predation on adults of *A. vanillae*, flying in a butterfly house, was never observed during the nine-month observation period. More than 400 butterflies were released into the exhibit building that also contained a population of free-flying insectivorous birds, including two species of aggressive predators; the superb starling and the red-rumped cacique. In addition, evidence of detached wings were never found on the ground. However, all species, other than the those belonging to the subfamily Heliconiinae, were eagerly attacked and eaten. (In time, many of the predatory birds had to be removed from the exhibit because they were decimating all nonheliconian butterflies.) Thus, in an enclosed environment, containing a significant population of predatory birds, adults of *A. vanillae* are discriminated against as prey items.

Similar results were obtained in an outdoor butterfly garden in which *A. vanillae* was the dominant butterfly species by a factor of at least 10. Different species of butterflies were observed to be fed upon by invertebrate predators that included spiders (Araneidae), assassin bugs (Reduviidae), dragonflies (Libellulidae), wasps (Vespidae), ambush bugs (Physmatidae), and praying mantids (Mantidae). Vertebrate predators included anole lizards and a variety of free-flying birds. Predation on butterfly species, especially *Phyciodes tharos* (Nymphalidae:Melitaeinae), *Hermeuptychia hermes* (Satyridae), and *Papilio polyxenes* (Papilionidae) was pronounced but was never observed with *A. vanillae.* In spite of its abundance, *A. vanillae* is obviously not a commonly utilized prey species and is avoided by both invertebrate and vertebrate predators.

DISCUSSION

The only truly volatile component found in both sexes in this study was 6-methyl-5-hepten-2-one, a well-known ant alarm pheromone and defensive allomone (Tomalski et al., 1987), and this compound may be objectionable to birds as well. Use of the volatile ketone as a solitary defensive compound by both cockroaches and beetles (unpublished data) clearly points to a similar role in adult *A. vanillae.* To us, the odor of this ketone, which can be detected easily when the butterfly is disturbed, does not recall the "phenylcarbamylamine" cited by Eltringham (1925), but, of course, this is a subjective evaluation.

The simultaneous occurrence of this compound in its alcohol form in the extract where it is conjugated to palmitic, oleic, and stearic acids may be significant. It is possible that this constitutes a method for its storage until required, whereupon it may be available via the sequential action of a lipase and oxidase from another

source or gland. The higher molecular weight diol diacetates may also be involved here by dissolution of the ketone, reducing its loss through evaporation. An alternative possibility for the diol diacetates, for which we have no evidence, is that they might have a function in the butterfly similar to that of the diols in the preen glands of fowl, i.e., by rendering their wing coverings water repellent (Haahti and Fales, 1967). However, extensive investigations on the Heliconiinae, implemented more than 100 years ago (Müller, 1886), emphasized that the secretions of the abdominal glands of these nymphalids clearly possessed a defensive function that afforded the butterflies considerable protection from predators. Although we cannot state unambiguously that the glandular components of *A. vanillae* are responsible for the apparent immunity of these butterflies from avian predation, we suspect that the compounds in this abdominal exudate may play an important role in defensive contexts. For example, we have observed that several ant species are effectively repelled by the defensive secretion of the cockroach *Neostylopyga rhombifolia* (unpublished data). This exudate is essentially pure 6-methyl-5-hepten-2-one. In addition to deterring these predatory invertebrates, we have also observed that the ketone-rich secretion of *N. rhombifolia* (Blattidae) effectively repels the American chameleon, *Anolis carolinensis*, a very aggressive vertebrate predator. These studies indicate that 6-methyl-5-hepten-2-one possesses deterrent properties against at least some invertebrate and vertebrate predators.

Our studies on the level of avian predation on free-flying *A. vanillae* clearly demonstrate that this eminently aposematic lepidopteran is virtually immune to the predatory activities of insectivorous birds. This was particularly striking in a butterfly conservatory where these lepidopterans shared their flying space with birds that fed readily on butterfly species other than *A. vanillae* (the same was true in the butterfly garden). Observations of *A. vanillae* versus birds in the butterfly exhibit indicated that birds took evasive action when they closed on the butterflies. It appears that these insects possess a powerful organoleptic shield that appears to insulate them from at least some avian and nonavian predators as well. Since the odor of 6-methyl-5-hepten-2-one can be detected in the presence of feeding *A. vanillae*, it is possible that the secretion of the abdominal glands may normally leak, thus enabling this aposematic species to advertise its presence freely through olfaction. Producing this ketone in sufficient quantity in order to be olfactorily aposematic may be possible if these butterflies are indeed generating its alcoholic precursor from the rich store of fatty acid esters of 6-methyl-5-hepten-2-ol. Additionally, it appears as if *A. vanillae* has morphological strategies that allow individuals to recover easily from an attack, another indicator that the species is protected.

The extraordinary tenacity of the individual butterflies that had been subjected to the milking procedures is probably yet another indication that *A. vanillae* is a protected species. Potential predators must learn which species to avoid, and learning requires sampling. Consequently it is in the best interest of a protected

prey to be able to survive an occasional attack and so most protected species have developed morphological strategies that bestow some degree of toughness (Ross, 2000a.).

Abstract—*Tetramorium bicarinatum* (Myrmicinae) is an ant species frequently found in tropical and subtropical areas, particularly in Africa, Southeast Asia (Japan), and South America (Brazil). The species is polygynous, reproduces by budding, and has sterile workers. Since the nests are widely distributed in a given area, the problem arises of territorial defense against conspecifics. Because not all ants defend territories, we assessed the defensive behavior of *T. bicarinatum* workers through intraspecific and interspecific aggressiveness tests. A detailed behavioral study of the interactions between workers from several different colonies of *T. bicarinatum* (originating from Japan and Brazil) showed that workers do not discriminate against conspecific nonnestmate individuals, but they are highly aggressive towards allospecifics (*Myrmica rubra*, Myrmicinae). The results suggest that each colony from this ant species possesses a similar colonial odor. Chemical analyses of the cuticular hydrocarbons of these species were made with gas chromatography coupled to mass spectrometry. Results showed that the different colonies of *T. bicarinatum* possess a common chemical profile mainly composed of straight-chain alkanes and alkenes, while *M. rubra* possess more methyl-branched alkanes. We suggest that methyl alkane cues play a determining role in colonial recognition and that these results could explain the underlaying basis of the lack of intraspecific aggressiveness in *T. bicarinatum.*

Key Words—Formicinae, intraspecific aggressiveness, cuticular hydrocarbon profile, *Tetramorium bicarinatum.*

INTRODUCTION

Nestmate recognition is a fundamental feature of social insect behavior and allows alien individuals to be rejected from the colony. The capacity to discriminate nestmates from nonnestmates prevents robbery, predation, and parasitism; enables the monopolization of resources in defended territories; and helps in eliminating neighboring competitors (Wilson, 1971).

Nestmate recognition is due to nonvolatile olfactory cues borne on each individual's cuticle, cues that are shared by all nestmates and vary among nests (Howse, 1975; Hölldobler and Michener, 1980; Howard, 1993; Lenoir et al., 1999). Among the cuticular lipids of ants that serve to prevent desiccation and regulate cuticular permeability (Hadley, 1980), hydrocarbons are dominant (Lahav et al., 1999; for reviews see Breed, 1998; Vander Meer and Morel, 1998; Lenoir et al., 1999). Several authors have hypothesized that some methyl-branched hydrocarbons could be involved in intracolonial recognition in ants (Bonavita-Cougourdan et al., 1987, 1990; Provost et al., 1992), and in social wasps (Dani et al., 1996; Gamboa et al., 1996).

Each colony member possesses its own cues (or labels) that are correlated with genotype (endogenous source) (for reviews see Hölldobler and Michener, 1980; Blum, 1987; Breed and Bennett, 1987; Vander Meer and Morel, 1998). These cues are influenced by exogenous sources from the physical and social environment, such as air, soil, food, nest materials, and colony structure (Carlin and Hölldobler, 1986; Gamboa et al., 1991). Examples in the literature of nestmate recognition stress the importance of exogenous sources in *Acromyrmex octospinosus* (Jutsum et al., 1979), endogenous sources in *Pseudomyrmex ferruginea* (Mintzer and Vinson, 1985), and a combination of both in *Solenopsis invicta* (Obin and Vander Meer, 1988). Thus, numerous combinations of endogenous and exogenous sources are possible as odor determinants constituting the specific chemical signature by which individuals recognize one another as members of the same colony (Vander Meer and Morel, 1998).

Each colony member also possesses a reference model of the chemical signature (or sensory template located in the brain or in the antennal receptor cells) encoding the labels that characterize nestmates. The acceptance or rejection of an individual can be explained by a decision rule, depending on the degree to which the chemical signature of the encountered individual and the reference model of its partner overlap. This rule can be used to determine appropriate subsequent behavior (Breed and Bennett, 1987; Errard and Hefetz, 1997). Moreover, since the odor is dynamic because of a constantly changing chemical environment as well as within-colony individual genetic variations, template plasticity must follow (Vander Meer et al., 1989). For example, in a monogynous species (where all the individuals of a colony are strongly related), the template must reflect the cue changes in order to permit, at any given time, the resident colony individuals

to exhibit aggressive behavior towards intruders such as conspecific, but nonnestmate individuals. In contrast, polygynous species often do not defend a territory and do not recognize conspecific nonnestmates as intruders (Vander Meer and Morel, 1998). Furthermore, Provost and Cerdan (1990) showed there is a correlation between the number of queens and the degree of closure of the colony. These authors showed that monogynous colonies of the ant *Messor barbarus* are more closed than colonies that have been made experimentally polygynous. Keller and Passera (1989) suggested in *Linepithema humile* that the presence of several queens in the same colony (polygynous species) may result in a less distinct colony odor (more variable genetic cues) and decreased intercolonial aggressiveness. This suggestion was confirmed by Morel et al. (1990), who have shown that in the fire ant *Solenopsis invicta* polygynous residents do not recognize monogynous or polygynous intruders as different; however, monogynous residents are aggressive towards both types of intruders. Thus, in this case, the cues for polygynous and monogynous intruders fit within the polygynous template. Vander Meer et al. (1989) reported a generalized cue/template model where environmental cues were expected to vary quantitatively and qualitatively, whereas heritable cues would vary only in the relative intensity of the compounds involved. Later, it was suggested (Vander Meer and Morel, 1998) that the difference between monogynous and polygynous nestmate recognition lies in the template, which in the latter case is broader and less distinct than that of their monogynous counterparts.

On the other hand, Provost et al. (1994) have shown that *Messor barbarus* workers belonging to monogynous colonies were able to discriminate between intruders from other monogynous colonies and those from polygynous ones. They observed that one set of hydrocarbons (*n*-alkanes, mono-, di-, and trimethyl alkanes) was characteristically associated with workers from monogynous colonies. It also emerged that another set of hydrocarbons could be said to characterize the digynous and trigynous colonies.

In the present study, we tested the intra- and interspecific defensive behaviors of the ant *Tetramorium bicarinatum* (Formicidae, Myrmicinae) to understand the mechanisms underlying its widespread success. *T. bicarinatum* is a species originating in Southeast Asia and is characterized as an accomplished tramp (Bolton, 1980). Its current biotope extends through all the tropical and subtropical areas, particularly in Africa, South America, and Japan, having been distributed throughout the world by humans (Bolton, 1980). This species has the following characteristics: it is polygynous (about 50 queens for 1200 workers), the sterile workers are small (3–3.5 mm), it reproduces by budding, and the nests are widely distributed over a given area (Bolton, 1980 and personal observations). *Myrmica rubra* (Formicidae, Myrmicinae), which is an allospecific intruder, is a polygynous and populous ant species (about 73 workers per queen and 1080 workers per colony) that is found in Europe, especially Northern Europe (Bernard, 1968).

In order to understand the basis of the discrimination process, we analyzed intraspecific and interspecific aggressiveness among different *T. bicarinatum* colonies and *M. rubra* colonies, and the cuticular hydrocarbon profiles of workers from each colony.

METHODS AND MATERIALS

Biological Material

The species studied, *T. bicarinatum* and *M. rubra*, were collected from different biotopes. Three colonies of *T. bicarinatum* were collected in Brazil: the Itabuna site (B1) is located 20 km from the Ilheus site (B2); both are 1000 km from the Crasto site (B3). Two colonies of *T. bicarinatum* were collected in Japan: the Kume site (J1) is an island 500 km from the Meijy site (J2). Two colonies of *M. rubra* were collected in France: the Gif-sur-Yvette site (F1) is 200 km from the Sainte Marie Dumont site (F2). The different *T. bicarinatum* colonies had 2–3 queens and 25–70 workers and brood, and the *M. rubra* colonies had 3–4 queens and 300–400 workers and brood (Table 1).

After collection, these mother colonies were reared in the laboratory in artificial plaster nests and maintained under standard conditions (23°C ± 2°C, 70% relative humidity, and a photoperiod of 10D : 14L). They were regularly fed with a honey–apple mixture and mealworms *ad libitum.*

Tolerance Tests

In order to analyze the degree of tolerance among individuals from the different colonies, we removed workers from the mother colonies. These ants were

marked with a color dot on the abdomen (one color for each colony), and nestmates were placed in the same experimental vial (Falcon, 15 ml, 12 × 1.5 cm). The different vials were placed in a neutral arena (35 × 25 cm) equidistant from a central source of food and opened. Twenty-four hours later we recorded the numbers and the identities of dead workers, alive and uninjured workers, and injured and fighting workers. We also recorded their respective localization in the different vials and in the arena as a function of their origin.

Intraspecific Intercolonial Tolerance Tests. For *T. bicarinatum*, three vials were placed in the arena, the first containing 50 workers from J1, the second 50 workers from B1, and the third 50 workers from B2.

For *M. rubra*, two vials were placed in the arena, the first containing 50 workers from F1 and the second 50 workers from F2.

Interspecific Tolerance Test. One vial contained 50 *M. rubra* workers from F1 and the second 50 *T. bicarinatum* workers from B1.

Aggressiveness Tests

For each confrontation, six workers were removed from the mother colonies. An individual marked with a color dot on the abdomen served as the test ant. It was confronted with five other individual nestmates or nonnestmates in a neutral arena (Petri dish 5 cm in diameter).

The different types of confrontations are shown (Table 2): intracolonial intraspecific confrontations or control encounters (confrontations with conspecific ants belonging to the same nest); intercolonial intraspecific confrontations (confrontations between conspecifics taken from Brazilian and Japanese colonies of *T. bicarinatum* and between French colonies of *M. rubra*; and interspecific

TABLE 2. DIFFERENT TYPES OF ENCOUNTERS[a]

[a] (See Table 1 for the origin of colonies). The colony origin of the test ant (marked) is in parenthesis.

confrontations (confrontation between *T. bicarinatum* from Brazil or Japan with *M. rubra* allospecific individuals).

For 3 min (until the first physical contact with the marked ant), we recorded the reaction of the ants towards the marked ant according to the following index of aggression: 1 = inspection and antennal contact, 2 = threat as indicated by mandibular opening, 3 = biting, 4 = biting with stridulations, 5 = curling the abdomen in stinging attempts, 6 = stinging. The frequency and duration of each behavioral component were recorded by using a microcomputer (Psion event recorder, Aware, Paris, France) and the overall aggressiveness (AI) exhibited in each encounter was calculated as follows (Errard and Hefetz, 1997):

$$AI = \frac{\sum_{i=1}^{n} AI_i * t_i}{T}$$

where AI_i represents the index of aggression, t_i the duration of each act, and T the total interaction time.

We conducted 15 replications for each type of encounter. Individuals were tested only once in a given encounter to avoid the possible effects of familiarization. The results were analyzed by using ANOVA (Statistica for Windows 95).

Chemical Analysis

For extractions, 10 workers from each colony of both species (*T. bicarinatum* and *M. rubra*) were killed by freezing. Each ant's cuticular compounds were extracted by immersion in 2 ml of pentane for 10 min, and the total pentane extract was drawn off and evaporated. Eicosane (n-C_{20}) was used as an internal standard. Extracts were redissolved in 50 μl of pentane, of which 2 μl were injected into a HP 5890 series II Plus gas chromatograph with a flame ionization detector equipped with a capillary column (Chrompack CPSIL 5 WCOT, 25 m $\times$ 0.25 mm ID). The injector was of the split-splitless type, and the injection was performed for 15 sec in splitless mode. The carrying gas was helium at 1 bar, and the temperature was programmed from 100°C to 280°C at 5°C/min. The chromatograph was coupled to a HP computer equipped with a HP 5890 Chemstation that provided the data.

Cuticular washes from each group of 50 *T. bicarinatum* workers were pooled and analyzed by GC-MS on a Varian 3300 linked to a nermag R10-10C quadrupole mass spectrometer. Spectra were recorded in electron ionization mode at 70 eV with a mass range of 40–540 atomic mass unit (amu). The samples were run on an AT-5 (Alltech) capillary column (30 m $\times$ 0.32 mm ID, 0.3-μm film thickness, Ross injector heated at 280°C) whose temperature was programmed from 120°C to 300°C at 8°C/min. The carrier gas was helium at 1 bar.

For *M. rubra* species, we used previous identifications of cuticular hydrocarbons (Bagnères and Morgan, 1991; Vienne, 1993).

The identified peaks were recorded, numbered, and used for chemical analysis. For each cuticular profile, the relative value of each with respect to the total was calculated and expressed as a percentage.

We used a hierarchical cluster analysis (Ward's method, Euclidean distance, Statistica for Windows 95) to estimate the similarity (or the divergence) of the chemical profiles of the different colonies. The statistical analysis was performed on 39 extracts (27 *T. bicarinatum* extracts: 5 J1, 5 J2, 6 B1, 6 B2, 5 B3, and 12 *M. rubra* extracts: 5 F1, 7 F2) and 68 peaks.

RESULTS

Tolerance Tests

In the intraspecific tests with *T. bicarinatum* workers taken from the three colonies, J1, B1, and B2, we observed that, after 24 hr in the same area, all workers were alive and none was injured (Table 3). A new distribution of the ants was observed, some of them having moved from their vials and changed places with nonnestmates. Workers from different mother colonies seemed to mix without any aggressive behavior.

The results of the intraspecific tests with *M. rubra* workers taken from the two colonies, F1 and F2, are also depicted in Table 3. After 24 hr, we observed numerous

TABLE 3. TOLERANCE TESTS[a]

Tolerance test	Vial number	Number and origin of live workers in each vial ($t = 0$)	Number, origin and localization of workers after 24 hr			
			Dead	Wounded outside	Fighting	Alive
T. bicarinatum	Vial 1	50 J1	0 J1	0 J1	0 J1	17 ± 2 J1 18 ± 2 B1 15 ± 3 B2
	Vial 2	50 B1	0 B1	0 B1	0 B1	20 ± 8 J1 23 ± 5 B1 11 ± 5 B2
	Vial 3	50 B2	0 B2	0 B2	0 B2	13 ± 4 J1 9 ± 5 B1 24 ± 2 B2

	Vial 2	50 F2	19 ± 7 F2	17 ± 8 F2	3 ± 2 F2	0 F2 8 ± 5 F1

[a] Tolerance test between *T. bicarinatum* workers taken from three different colonies: B1 and B2 (Brazil) and J1 (Japan) (mean $\pm$ SEM, $N = 3$) and between *M. rubra* workers taken from two different colonies: F1 and F2 (France) (mean $\pm$ SEM, $N = 3$).

dead individuals, while the majority of live workers were outside the vials. In these experiments, nonnestmates never cohabited peacefully, as was observed in the case of *T. bicarinatum* species.

In the interspecific tests, all *M. rubra* workers were killed by *T. bicarinatum* workers while all *T. bicarinatum* workers were uninjured and alive.

Aggressiveness Tests (Table 2)

In all control encounters (intracolonial confrontations), the interactions among nestmate individuals were not aggressive. Each individual recognized and tolerated its marked nestmates. Aggressiveness indices revealed that the control encounters in the seven different experiments were not significantly different ($F = 4.48$; dl 5,89; *NS*). It also seems that the color dot we marked the ants with did not affect the behavior of the other ants (visual cues) (Figure 1).

In all intercolonial, intraspecific confrontations (Figure 1), *T. bicarinatum* workers did not react aggressively towards nonnestmates ($AI = 0.57 \pm 0.03$). The encounters among the ants originating from Brazil ($AI = 0.46 \pm 0.04$) were not different from the control encounters ($F = 24.07$; dl 4,80; *NS*). In encounters involving ants originating from Japan, J1 workers from Kume island were not aggressive towards J2 workers ($AI = 0.87 \pm 0.09$), but the duration of antennal interactions increased relative to control encounters ($F = 46.47$; dl 2,192; $P < 0.001$) and the encounters between Brazilian populations ($F = 34.61$; dl 1,108; $P < 0.001$).

In contrast, *M. rubra* presented intraspecific intercolonial aggressiveness with some biting behaviors ($AI = 2.89 \pm 0.17$), more than that noted in all intraspecific *T. bicarinatum* encounters ($F = 432.93$; dl 1,253; $P < 0.001$) as depicted in Figure 2.

Interspecific confrontations between Brazilian or Japanese *T. bicarinatum* individuals towards *M. rubra* workers were more aggressive (much biting, $AI = 3.12 \pm 0.10$) than *M. rubra* workers towards *T. bicarinatum* workers ($AI = 1.74 \pm 0.11$, $F = 75.46$; dl 1,57; $P < 0.001$) (Figure 2).

Myrmica rubra workers seemed more aggressive in intraspecific encounters (threatening behaviors) than in interspecific encounters towards *T. bicarinatum* from Brazil or Japan, towards which they only exhibited longer antennations ($F = 30.70$; dl 1,58; $P < 0.001$). In contrast, *T. bicarinatum* workers were far more aggressive towards *M. rubra* workers than towards alien *T. bicarinatum* workers, which were ignored ($F = 636.68$; dl 1,252; $P < 0.001$).

Chromatogram Analysis

Each colony possesses a specific chemical profile: 32 compounds for *T. bicarinatum* from Kume (J1) and Meijy (J2); 31 compounds for *T. bicarinatum*

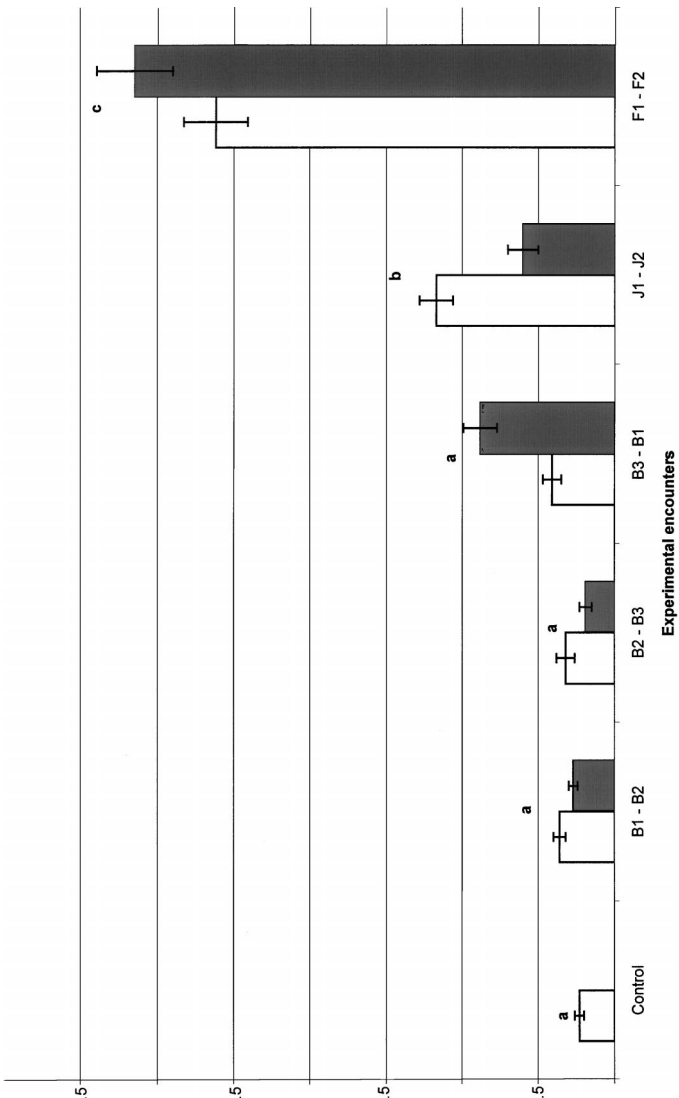

FIG. 1. Aggression of *T. bicarinatum* and *M. rubra* towards allocolonial intraspecific individuals according to the geographic area. *Tetramorium bicarinatum* encounters: B1–B2 (B1 towards B2 in white and B2 towards B1 in gray), and the *idem* for the other confrontations B2–B3, B1–B3, J1–J2. *Myrmica rubra* encounters: F1–F2 (F1 towards F2 in white and F2 toward F1 in gray). Different letters represent the groups, which differed significantly (ANOVA, $P < 0.001$, $N = 15$).

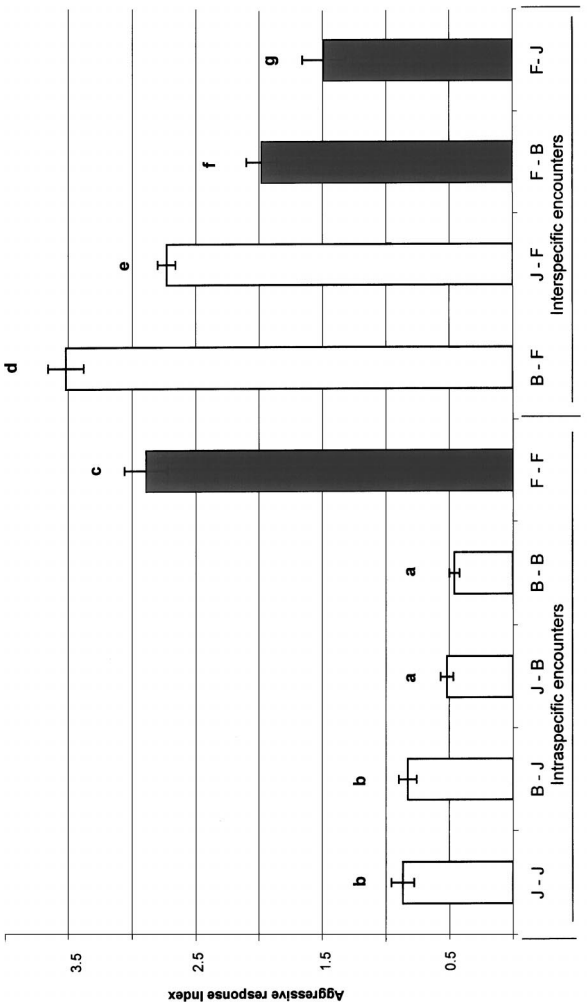

FIG. 2. Aggression of *T. bicarinatum* and *M. rubra* towards allocolonial conspecific individuals and towards allospecific individuals. Intraspecific encounters: J-J: intercolonial encounters between Japanese *T. bicarinatum* workers; B–J and J–.B: intercolonial encounters between Brazilian *T. bicarinatum* workers and Japanese *T. bicarinatum* workers and Brazilian *T. bicarinatum* workers; B–B. intercolonial encounters between Brazilian *T. bicarinatum* workers. F–F: intercolonial encounters between French *M. rubra*. Interspecific encounters: B–F and J–F (encounters between Brazilian and Japanese *T. bicarinatum* workers and *M. rubra* workers; F–B and F–J (encounters between *M. rubra* and Brazilian and Japanese *T. bicarinatum* workers. Different letters represent the groups, which differed significantly (ANOVA, $P < 0.001$, $N > 15$).

from Itabuna (B1), Ilheus (B2) and Crasto (B3); and 64 compounds for *M. rubra* from F1 and F2.

For *T. bicarinatum*, the most easily quantifiable hydrocarbons were (Table 4, Figure 3): 16 *n*-alkanes, (*n*-C_{13}–*n*-C_{15}, *n*-C_{17}, *n*-C_{19}–*n*-C_{30}), 18 mono- or di-alkenes

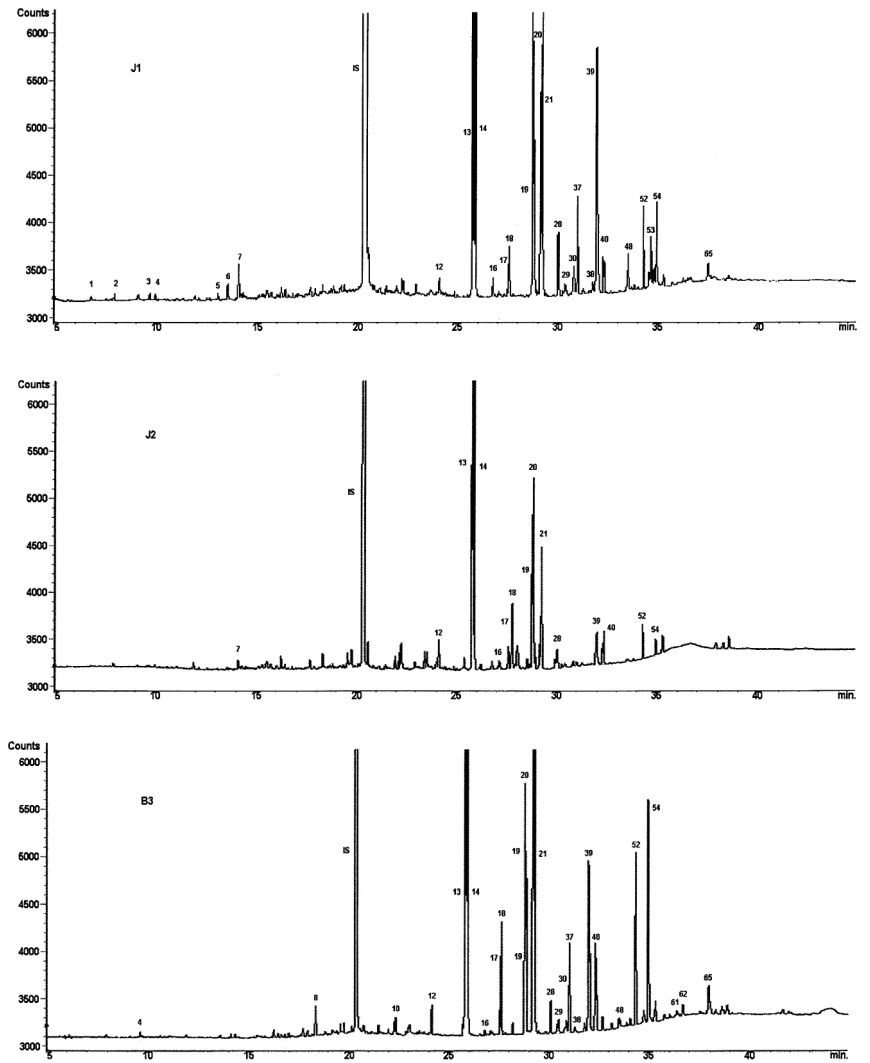

FIG. 3. Gas chromatograms of the cuticular hydrocarbon profiles of *T. bicarinatum* workers from colonies J1 (Kume, Japan), J2 (Meijy, Japan) and B3 (Crasto, Brazil).

[a](Me, DiMe, and TriMe correspond to methyl, dimethyl and trimethyl, respectively). Values indicate, for each compound, the mean relative percentage (± SEM) for a 10-min extraction with pentane (T indicates trace). Values are calculated for F1 workers ($N = 5$), F2 workers ($N = 7$), J1 workers ($N = 5$), J2 workers ($N = 5$), B1 workers ($N = 6$), B2 workers ($N = 6$), and B3 workers ($N = 5$).

(*n*-$C_{15:1}$, *n*-$C_{17:2}$, *n*-$C_{17:1}$, *n*-$C_{23:1}$, *n*-$C_{24:2}$, *n*-$C_{24:1}$, *n*-$C_{25:2}$, *n*-$C_{25:1}$, *n*-$C_{26:2}$, *n*-$C_{26:1}$, *n*-$C_{27:2}$, *n*-$C_{27:1}$, *n*-$C_{28:2}$, *n*-$C_{29:2}$, *n*-$C_{29:1}$, *n*-$C_{30:2}$, *n*-$C_{31:2}$, *n*-$C_{31:1}$), and one methyl-alkane (5Me-C_{27}). Twenty-eight compounds are common to the different colonies of *T. bicarinatum* but *n*-C_{13}, *n*-C_{14}, *n*-$C_{15:1}$, and *n*-$C_{17:2}$ were specific to the Japanese colonies (J1 and J2), and *n*-C_{19}, *n*-C_{20}, *n*-C_{21}, 5Me-C_{27} were specific to the Brazilian colonies (B1, B2, B3).

For *M. rubra* species, the most quantifiable hydrocarbons were: 8 *n*-alkanes (*n*-C_{23}–*n*-C_{30}), 3 *n*-alkenes (*n*-$C_{25:1}$, *n*-$C_{27:1}$, *n*-$C_{29:1}$), 40 mono-methyl alkanes, 10 di-methyl alkanes, and 2 trimethyl alkanes (Table 4).

The cuticular hydrocarbon composition of the ants studied was species specific. The profiles of the five different colonies of *T. bicarinatum* appear similar, and they differ from the *M. rubra* profiles (F1 and F2) that possess 39 monomethyl, 10 dimethyl, 2 trimethyl alkanes *M. rubra*-specific compounds.

Hierarchical Cluster Analysis (HCA)

The schematic representation of the clustering obtained with the HCA algorithm on the mean chemical data of each colony (Figure 4A) shows the nodes separating into three groups. The first node (68.02) separates *T. bicarinatum* colonies (J1, J2, B1, B2, B3) from *M. rubra* colonies (F1, F2), and the second (15.97), which divides Japanese *T. bicarinatum* colonies (J1, J2) from Brazilian *T. bicarinatum* colonies (B1, B2, B3), is situated at a less significant level. This cluster analysis reflects the proximity between Brazilian and Japanese colonies.

From the detailed clustering obtained with the HCA algorithm on individual *T. bicarinatum* data (Figure 4B), two groups emerged (first node = 74.23), a group including Brazilian individuals (B1, B2 and B3) and a second including Japanese individuals. The second node (49.78) separates Japanese individuals from Kume (J1) from those from Meijy (J2), while the third node (35.83) divides Brazilian individuals from Crasto (B3) from those from Itabuna (B1) and Ilheus (B2). This cluster analysis reflects the geographical proximity of B1 and B2, both collected in Bahia state.

DISCUSSION

The behavioral and chemical results of this study corroborate the hypothesis that recognition processes are based on the discrimination of colonial odor. Our results show that *T. bicarinatum* societies are open, in the sense intended by Le Masne (1952), because workers exhibit no aggressive behavior towards alien conspecifics. In fact, intraspecific confrontations never exceed antennation behaviors, and nonnestmate conspecifics mix peacefully with different partners that have

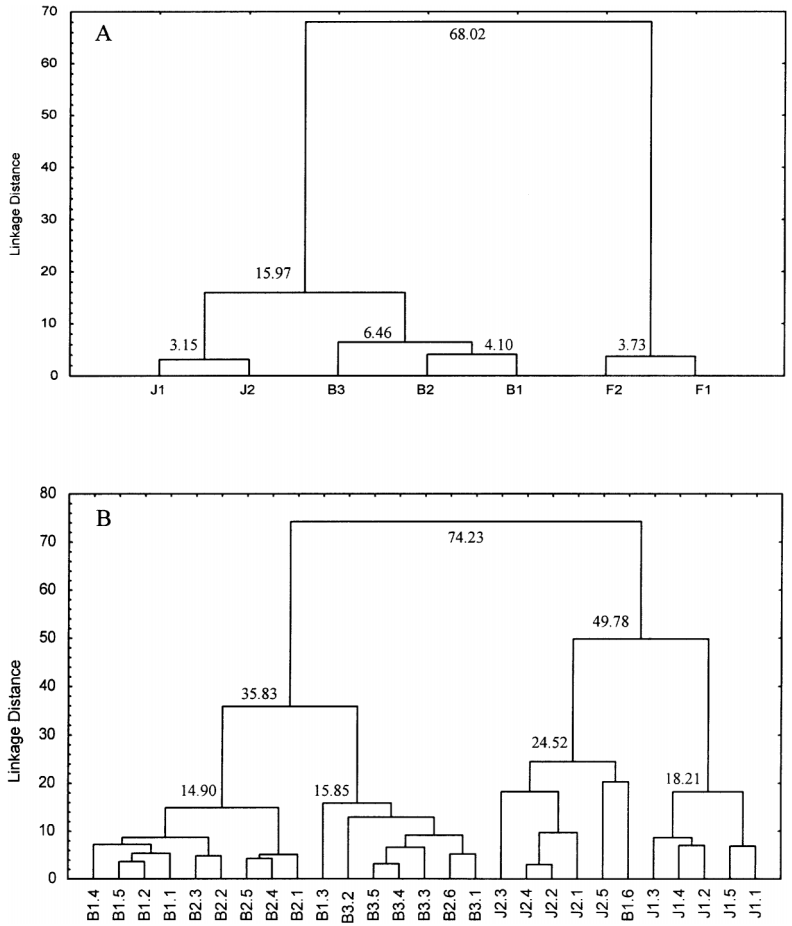

FIG. 4. Hierarchical cluster analysis (Ward's method, Euclidean distances) conducted on (A) the mean of the relative proportions of the 68 peaks of the workers cuticular profiles from the two colonies of *Myrmica rubra* (F1 and F2) and from the five colonies of *Tetramorium bicarinatum* from Japan (J1 and J2) and from Brazil (B1, B2 and B3); (B) the relative proportion of the 35 peaks in *T. bicarinatum* workers from Japan (J1: 1, 2, 3, 4, 5; J2: 1, 2, 3, 4, 5) and from Brazil (B1: 1, 2, 3, 4, 5, 6; B2: 1, 2, 3, 4, 5, 6; B3: 1, 2, 3, 4, 5).

numerous allogrooming and trophallaxis behaviors. In contrast, *M. rubra* societies appeared more discriminating in intraspecific confrontations that frequently ended in the death of individuals. *Myrmica rubra* interacted aggressively with conspecifics (coming from nests 200 km apart) through threatening and biting behaviors. These results confirm those by Cammaerts and Cammaerts (1984), who

showed that *M. rubra* alien queens are less accepted by workers, the more distant their nest.

Behavioral results demonstrating that *T. bicarinatum* workers do not act aggressively towards alien conspecifics support the observations by Provost and Cerdan (1990) on *Messor barbarus*, who showed that there was a positive correlation between the number of queens in a colony and its alien conspecific tolerance. Therefore, with high population levels (about 12,500 workers) and numerous queens (250–400 workers per queen) per colony, *T. bicarinatum* has the profile of a polygynous species, where there is no territorial defense and where alien conspecifics are not recognized as intruders (Vander Meer and Morel, 1998). In fact, the cuticular hydrocarbon profiles of *T. bicarinatum* from the different colonies reveal only a slight divergence, workers being tolerated and left alone by alien conspecific individuals. The longer antennal contacts observed in encounters involving Japanese workers from Kume Island are presumably due to the insularity of this colony. This has led to divergent cuticular hydrocarbon profiles. Similar results were observed by Dahbi and Lenoir (1998) in the ant *Cataglyphis iberica*. These authors showed that when workers were separated for three months (in groups with or without a queen), after regrouping, nestmate recognition remained unchanged but they observed longer mutual antennal contacts between previously separated workers without aggressive reactions. They concluded that this extension in antennal duration was probably due to the slight divergence observed in the cuticular chemical profiles of the workers during separation.

However, in spite of a lack of intraspecific aggressiveness, *T. bicarinatum* workers exhibit pronounced interspecific aggressiveness towards *M. rubra* workers. Since we have shown that the chemical cues of *T. bicarinatum* do not match the chemical cues of *M. rubra*, this suggests that *T. bicarinatum* workers are able to discriminate these chemical profile differences.

Since the cuticular profile of *M. rubra* is characterized by many branched alkanes (mono-, di-, and trimethyl alkanes), we suggest that colony recognition is strongly correlated to the composition of cuticular hydrocarbons, thus characterizing the chemical signature of *M. rubra*. This suggestion supports some previous studies. For example, several authors have shown that some methyl-branched hydrocarbons seem to be particularly involved in intracolonial recognition. In the social wasp *Polistes dominulus*, Dani et al. (1996) suggested that dimethyl-branched hydrocarbons seem to be important in distinguishing females according to their colony of origin. In *Polistes fuscatus*, behavioral and chemical analyses concluded that methyl-branched alkanes were relatively colony specific and that straight-chain alkanes were not (Gamboa et al., 1996). In the ant *Camponotus vagus*, Bonavita-Cougourdan et al. (1987) demonstrated that colony recognition was strongly correlated with the variation of relative proportions of dimethyl alkanes in different colonies. Provost et al. (1992) showed that in *Messor barbarus* the straight chain alkanes and certain dimethyl alkanes seem to be characteristic of the colony

signature. This, however, may not be the case for other ant genera. For example, the dimethyl alkanes present on the cuticular surface of several *Cataglyphis* ant species did not change drastically, showing that they do not have a communicative role, and, therefore, were not subjected to the presumed interspecific competition pressure (Dahbi et al., 1996).

Because these results suggest that branched hydrocarbons, particularly dimethyl alkanes, are important in distinguishing nestmates according to their colony, we hypothesize that the presence of these branched alkanes in the chemical signature of *M. rubra* could be implicated in discrimination by *T. bicarinatum.*

This hypothesis is reinforced by the results of encounters between *M. rubra* and *T. bicarinatum* that show that *M. rubra* workers discriminate conspecific alien individuals, while *T. bicarinatum* individuals induce only longer antennal contacts without any aggressive behaviors. As *T. bicarinatum* do not possess branched hydrocarbons, we suggest that *M. rubra* workers do not strongly attack *T. bicarinatum* workers because they do not recognize them as intruders. On the other hand, *M. rubra* discriminate alien conspecific workers whose chemical profile differed only quantitatively from their own.

Recently, it was experimentally demonstrated for the first time (Holway et al., 1998) that the lack of territoriality in the unicolonial Argentine ant (*Linepithema humile*) might account for their high population density. These authors demonstrated that a reduced intraspecific aggressiveness allows spatially separate colonies to fuse and achieve higher worker densities compared to colonies that exhibit intraspecific aggressiveness. They concluded that there is a relationship between reduced intraspecific aggressiveness and the concomitant abandonment of territorial behavior, unique to introduced populations of the Argentine ant, and that this contributes to the elevated population densities directly responsible for its widespread success as an invader. These authors proposed that the loss of intraspecific aggressiveness in this species might result either from the lack of stimuli due to the high degree of genetic relatedness among introduced colonies or from an innate loss of aggressiveness due to a break down in nestmate recognition.

We can surmise that *T. bicarinatum* species previously displayed intraspecific competition (possessing cuticular branched hydrocarbons like other Myrmicinae) and that this competitive ability has been lost during evolution, along with the branched alkanes. Two possible scenarios can be proposed. (1) The loss of intraspecific competition might have preceded the branched alkane loss. In this case, the chemicals have disappeared because they were not subjected to the presumed selective pressure. (2) The loss of branched alkanes might have preceded, leading to a lack of intraspecific competition, but with the alkanes being kept to prevent desiccation and regulate cuticular permeability. Whatever the case, *T. bicarinatum* has maintained the ability to discriminate cuticular branched hydrocarbons, as demonstrated by its aggressive behaviors towards *M. rubra* species.

Our study shows that *T. bicarinatum* workers exhibit a lack of territoriality against conspecifics over small and large spatial ranges (Brazilian and Japanese colonies). Moreover, in *T. bicarinatum*, the insignificant intraspecific aggressiveness seems to go along with strong interspecific competition, contributing to patterns of distribution and abundance in ant communities. In the same way, Human and Gordon (1999) showed that the aggressive behaviors of the Argentine ant may contribute to its competitive success against several native ants species, which tended to retreat more frequently. These behavioral characteristics of *T. bicarinatum* led us to confirm that this species is a highly successful tramp species (Bolton, 1980).

In his review, Passera (1994) concluded that tramp species are similar to polydomous ants with which they share the attributes of unicoloniality, colony reproduction by budding, or reduced nuptial flight, but that these attributes are more strongly expressed in tramp species. To these characteristics of polydomous species, tramp species add small size, monomorphism, and short queen longevity, so that finally only tramp species are truly domestic (dispersed throughout the world by human commerce and live in close association with humans), ensuring their ecological success.

Finally, if the lack of intraspecific aggressiveness is indeed due to the absence of branched alkanes, our results provide the chemical signature of an invasive species. This hypothetical additional character of tramp species could allow them to be better tolerated by other species, while remaining aggressive against all allospecific intruders, and could represent an important advantage for the invasive strategies these species are seen to deploy. If a lack of dimethyl alkanes contributes to the characteristics of a tramp species, surely other examples might also be available.

Acknowledgments—We are very grateful to Pierre Jaisson and Thibaut Monin for providing the ants. We would like to thank Alain Lenoir and Abraham Hefetz for proofreading the manuscript, and anonymous referees for constructive comments on this manuscript. We also thank Jerôme Orivel (Laboratoire d'Ethologie Expérimentale et Comparée, Université Paris Nord, F-93430 Villetaneuse) for the *M. rubra* GC analysis and Andrea Dejean for revising the English.

AVOIDANCE OF CONSPECIFIC INJURY-RELEASED CHEMICAL CUES BY FREE-RANGING *Gammarus lacustris* (CRUSTACEA: AMPHIPODA)

Abstract—Behavioral responses to chemical cues have been demonstrated for a range of aquatic animals. Injury-released chemical alarm cues from conspecifics are released when a prey's predator is actively foraging. Detection of these cues elicits antipredator behaviors that reduce the probability of predation. Amphipod crustaceans in the genus *Gammarus* are widespread denizens of ponds and streams. Antipredator responses by *Gammarus* to conspecific alarm cues, and subsequent reduction of predation risk, are known from experiments in the laboratory. Here, we verify laboratory findings by demonstrating an avoidance response to alarm cues using a field population of *G. lacustris.* We used small traps baited with sponge blocks containing either water (control) or injury-released cues from *Gammarus.* We repeated the experiment twice. In both experiments, significantly fewer *Gammarus* were captured in traps with alarm cue sponges than in traps with water sponges. Predatory leeches *Dina parva* were attracted to *Gammarus* traps in the first experiment but not the second experiment. In the second experiment, we measured the individual weight of captured amphipods. Two size classes were present; small (1–5 mg) and large (35–108 mg). Both sizes contributed to the avoidance response. Within the large size class, small individuals were significantly less responsive to the alarm cue than large individuals, implying that small adult *Gammarus* may have different cost/benefit decision criteria for risk assessment than large *Gammarus.*

Key Words—*Gammarus*, amphipod, crustacea, alarm cue, alarm signal, predator–prey, avoidance behavior, leech, *Dina parva.*

INTRODUCTION

Predator–prey interactions in aquatic environments are mediated, in part, by chemical cues released from various sources including disturbed and/or injured prey, and predators (Smith, 1992; Chivers and Smith, 1998; Kats and Dill, 1998; Tollrain and Havell, 1999; Wisenden 2000). Injury-released chemical alarm cues are released after a successful predatory attack and indicate imminent and proximate danger to conspecifics of the prey (see Chivers and Smith, 1998, for review). Aquatic taxa ranging from protozoa to amphibia use alarm cues to detect and avoid predators. Most of these studies have been conducted in the laboratory setting. While laboratory studies provide a carefully controlled environment in which to test specific hypotheses, the results lack the realism of the natural habitat. Field verification of laboratory findings is an important part of the scientific study of chemical ecology.

Amphipods in the genus *Gammarus* occur commonly in aquatic environments. They are small (<2 cm) detritivores that associate closely with the substratum and fall prey to a wide variety of predators. The substratum is often highly structured and water clarity often limited, reducing the reliability of visual information in assessing predation risk. *Gammarus* are well suited for the study of chemically mediated predator–prey interactions because they can be studied in the laboratory and in the field.

Laboratory populations of *Gammarus* show antipredator behavior in response to injury-released alarm cues of conspecifics (Williams and Moore, 1985; Mathis and Hoback, 1997; Wudkevich et al., 1997). In a laboratory study, latency to first capture by predatory green sunfish *Lepomis cyanellus* was significantly longer for *Gammarus* exposed to conspecific alarm cues than *Gammarus* exposed to water or heterospecific alarm cues (Wisenden et al., 1999).

It has not yet been established that free-living *Gammarus* respond with antipredator behavior to conspecific alarm cues in their natural habitat. We tested a field population of *Gammarus* for an avoidance response to alarm cues modeled after similar experiments on small fishes (e.g., Mathis and Smith, 1992; Chivers and Smith, 1994; Wisenden et al., 1995). Small sponge blocks soaked in water (control) or injury-released alarm cues of *Gammarus* were placed in small invertebrate traps. If field *Gammarus* avoid alarm cues, then we predicted that traps with alarm cues would catch fewer *Gammarus* than traps with water.

Recognition of conspecific alarm cues as indicators of risk generally occurs at a very early stage of development and requires no previous experience (Pfeiffer, 1963; Waldman, 1982; Magurran, 1989). However, there is some evidence from fishes that large individuals avoid alarm cues more effectively than small individuals (Mathis and Smith, 1992; Chivers and Smith, 1994; Chivers et al., 1995). Large, old individuals are more experienced than small, young individuals and may improve or acquire recognition of danger cues with age, particularly for responses to heterospecific alarm cues (Chivers et al., 1995). Alternatively, larger individuals

may be more vulnerable to predation and, thus, exhibit a lower response threshold than small individuals (Mathis and Hoback, 1997).

To investigate the effect of size on recognition of conspecific alarm cues we weighed captured *Gammarus.* We predicted that if aversion of alarm cue was acquired with age, or if cost/benefit decision criteria change with size, then large *Gammarus* would be caught in alarm cue traps in lower proportions than small *Gammarus.*

METHODS AND MATERIALS

Experiment 1. Alarm cue was prepared from adult *Gammarus lacustris* sampled from Erhard Pond in fall of 1997, located approximately 70 km SE of Moorhead, Minnesota, USA (46°30′N, 96°05′W). Erhard Pond does not contain any fish species. A stock solution of alarm cues was prepared be reducing 15 adult *Gammarus* (mean weight ± SE = 52.1 ± 1.6 mg, $N = 15$) to a fine pulp with mortar and pestle and diluting to a final volume of 37.5 ml with dechlorinated tap water. Small blocks of cellulose sponge (2 × 2 × 1.5 cm) each received 1.5 ml of the stock solution of alarm cues. This method of stimulus preparation is similar to the one successfully used by Wudkevich et al. (1997) and Wisenden et al. (1999). We thus prepared 15 sponges of *Gammarus* alarm cue and froze them at −20°C. Fifteen additional sponge blocks were soaked in 2.5 ml of dechlorinated tap water to control for the effect of sponge and water and then frozen at −20°C. Sponges were kept on ice during transport to the study site and remained frozen until used in the experiment to guard against any degradation of the cue.

We placed 30 invertebrate traps in Erhard Pond approximately 5 m apart along the shore, at a depth of about 0.5 m. The traps consisted of a 1-q (946-ml) wide-mouth Mason jar fitted snugly with a plastic funnel inserted into the jar opening with the apex of the funnel directed inward. The funnel was held in place by rubber bands attached to hooks on the outside of the funnel and the jar. Traps were laid on their side on the pond bottom. Inside each jar we placed a sponge soaked in either alarm cue or water. Traps were set in pairs (one control trap and one experimental trap simultaneously) at 5-min intervals, then pulled exactly 1 hr later at 5-min intervals in such a way that time in the water was held constant and equal among trap pairs and sponge types. Trap contents were stored and returned to the laboratory for counting.

Experiment 2. We repeated the experiment in spring 2000 at the same study site using similar methods. Adult *Gammarus* to be used for alarm stimulus were collected a few days prior to the field test and brought to the laboratory. Some of the adults were coupled in precopulatory amplexus. For each sponge (3.5 × 3 × 2 cm), we individually crushed a male–female pair (mean ± SE combined weight of each male–female pair = 176.9 ± 4.2 mg; $N = 17$) to a fine pulp with a mortar and pestle and diluted to a final volume of 10 ml with dechlorinated

water. Thus, stimulus strength in the second experiment was about four times stronger than in the first experiment. We prepared each of 17 sponges with 10 ml of alarm cue and another 17 sponges each with 10 ml of dechlorinated water (control). All sponge blocks were frozen at -20°C, and transported to the study site on ice to keep them frozen until needed.

Thirty-four traps were placed in the littoral zone within 1 m from the water's edge along the shoreline of Erhard Pond at approximately 5-m intervals. The traps used in the second experiment were commercial traps (MT3 minnow traps, Aquatic Ecosystems Inc.) and differed slightly from those used in the first experiment. The commercial traps consisted of 1-q (946-ml) wide-mouth Mason jars with inverted plastic funnels adapted to thread directly onto the jar mouth. The traps were laid on their side on the pond bottom as in the first experiment. Each trap contained one sponge block (control or alarm cue) and was set and retrieved in control–alarm pairs at 5-min intervals as for the first experiment. Time in the water was exactly 1 hr. Trap contents were returned to the laboratory to be counted and weighed to the nearest milligram. Large *Gammarus* were weighed individually. *Gammarus* <5 mg were too small to weigh individually. Small *Gammarus* for each trap were combined and weighed en masse to determine average weight.

Statistical Analysis. Statistical tests for avoidance behavior are one-tailed because we predicted a priori that *Gammarus* would avoid conspecific alarm cue. All other statistical tests are two-tailed.

RESULTS

Experiment 1. The median number (and 25th percentiles) of *Gammarus* per trap was 90 (50–117.5) and 40 (30–66.5) for control and alarm cue traps, respectively (Figure 1). Significantly more *Gammarus* were captured in control traps than alarm cue traps (Wilcoxon Mann Whitney test: $z = 1.95$, $P < 0.026$). These data are consistent with an avoidance response to conspecific alarm cues.

Leeches *Dina parva* entered traps with *Gammarus* alarm cue significantly more frequently than control traps (Figure 2). There was a median (and 25th percentiles) of 0 (0–1) and 2 (0.5–3) leeches in control and alarm cue traps, respectively (Wilcoxon Mann Whitney test: $z = 2.57$, $P = 0.025$). Five of 15 control traps caught at least one leech, whereas 11 of 15 alarm cue traps caught at least one leech (Figure 3). There was no correlation between number of *Gammarus* and number of leeches per trap for all traps combined ($R^2 = 0.0003$, $F = 0.007$, $P = 0.931$), within alarm cue traps ($R^2 = 0.0022$, $F = 0.029$, $P = 0.866$) or within control traps ($R^2 = 0.0007$, $F = 0.008$, $P = 0.927$).

Experiment 2. The median number (and 25th percentiles) of *Gammarus* per trap was 6 (5–9) and 3 (2–5) for control and alarm traps, respectively (Figure 4). Significantly more *Gammarus* were captured in control traps than in alarm cue traps (Wilcoxon Mann Whitney test: $z = 2.84$, $P = 0.002$). These data, collected

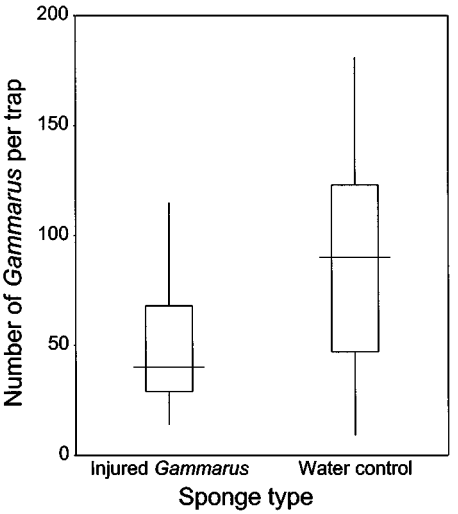

FIG. 1. Box and whisker plot of median, 25th percentiles, and range of number of *Gammarus* caught in the first experiment. Traps were baited with sponges containing either *Gammarus* injury-released alarm cues or water (control).

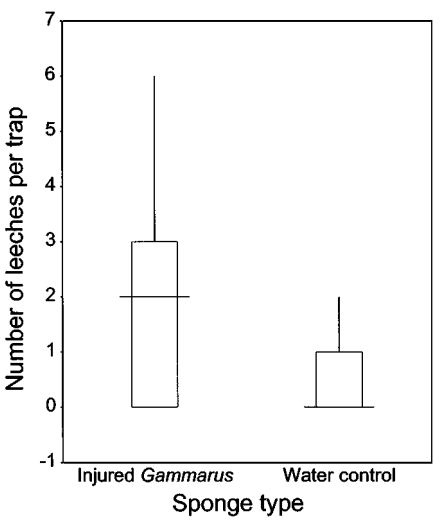

FIG. 2. Box and whisker plot of median, 25th percentiles, and range of the number of leeches caught in the first experiment. Traps were baited with sponges containing either *Gammarus* injury-released alarm cues or water (control).

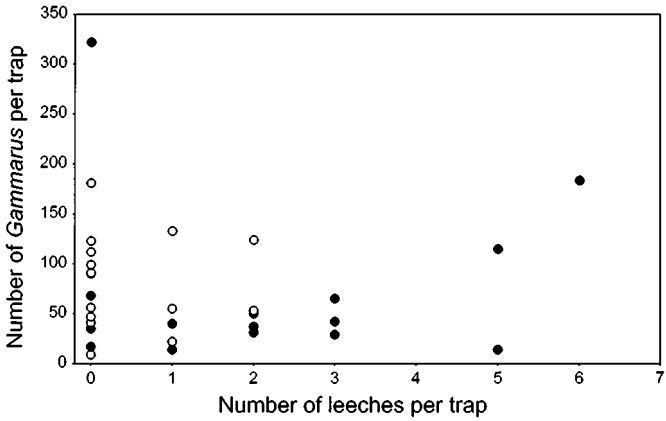

FIG. 3. Number of *Gammarus* per trap plotted against the number of leeches per trap in the first experiment. Open symbols, traps with water sponges; closed symbols, traps with alarm cue sponges.

at a different time of year and with slightly different gear and stimulus strength, corroborate data from the first experiment. Only four of 17 alarm cue traps and three of 17 control traps caught leeches. Because the majority of traps caught no leeches, the median (±25th percentiles) number of leeches entering both trap types was 0 (0–0) (Wilcoxon Mann Whitney test: $z = 1.29$, $P = 0.197$).

There were two distinct size classes in the catch (Figure 4). Small (1–5 mg) and large (35–108 mg) *Gammarus* both contributed to the overall avoidance response.

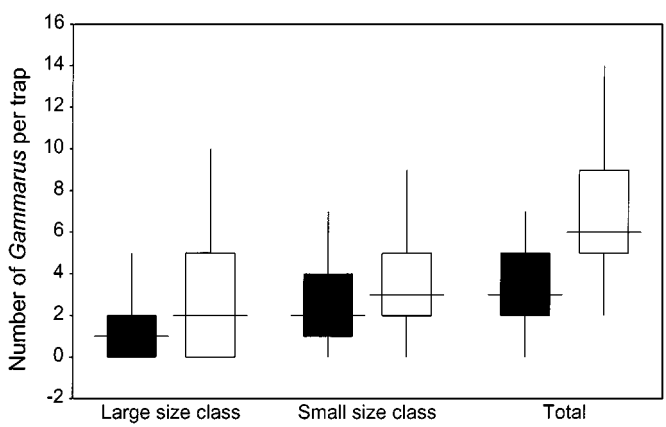

FIG. 4. Box and whisker plot of median, 25 percentiles and range of the number of *Gammarus* per trap in the second experiment. The large size class ($N = 72$) ranged from 32 to 108 mg, the small size class ($N = 104$) ranged from an average of 1 to 5 mg. Solid bars, alarm cue traps; open bars, control traps.

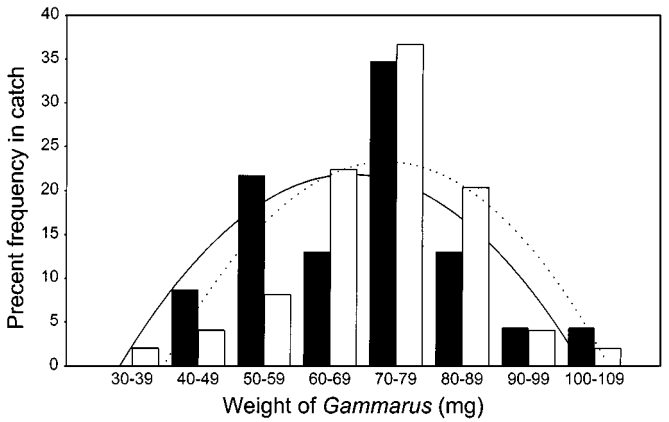

FIG. 5. Percent of the catch in each trap type in the second experiment represented by the large size class of *Gammarus* ranging from 32 to 108 mg. Fitted lines are second-order polynomial functions. Alarm cue traps, solid bars and solid line; control traps, open bars and dashed line.

However, the effect of alarm cue was not significant within the small size class (Wilcoxon Mann Whitney test: $z = 1.09$, $P = 0.276$) or (barely) the large size class (Wilcoxon Mann Whitney test: $z = 1.95$, $P = 0.051$) partly due to the low overall numbers of animals captured in the second experiment.

Within the large age class, small individuals did not avoid traps containing alarm cue as much as large individuals (Figure 5). We divided the size range of *Gammarus* into equal thirds creating small (32–57.3 mg) and large (82.7–108 mg) size categories with the adult size class. Small *Gammarus* represented 30.4% of the individuals caught in alarm cue traps, whereas small *Gammarus* represented only 10.2% of the catch in control traps ($\chi^2 = 4.44$, $P < 0.05$). Large *Gammarus* represented 17.4% and 20.4% of catches in alarm cue and control traps, respectively ($\chi^2 = 0.09$, $P > 0.9$). Similar analysis of length distribution of the small size class (<5 mg) was precluded by the low accuracy of weight measurements at the limit of the range of our electronic balance. We do not have individual weights for small *Gammarus.*

DISCUSSION

These data provide an important verification of laboratory findings. Field populations of *Gammarus lacustris* avoided injury-released conspecific alarm cues in two separate experiments at different times of year and by using slightly different methods. Chemical alarm cues serve as an important indicator of predation risk

for *Gammarus* in the field, and presumably antipredator behavioral responses such as avoidance behavior serve to decrease the probability of predation (Hews, 1988; Mathis and Smith, 1993; Wisenden et al., 1999).

Responses by very small *Gammarus* contributed to the overall avoidance response, suggesting that recognition of conspecific injury-released cues as indicators of predation risk is either innate or acquired at a very early stage of development. Innate responses to conspecific alarm cues are thought to be the case for various fish species (Pfeiffer, 1963; Waldman, 1982; Magurran, 1989), but to our knowledge this is the first such evidence for an aquatic arthropod.

Within the adult size class of *Gammarus*, small individuals were disproportionately represented in alarm cue traps. We do not interpret this to indicate acquired recognition of conspecific alarm cues over time and experience (cf. Chivers et al., 1995) because very small juvenile *Gammarus* responded to the alarm cue.

Large *Gammarus* may respond most strongly to conspecific alarm cues because they have a greater cost–benefit trade-off than small *Gammarus*. Large adult *Gammarus* are more responsive to risk of fish predation than small adult *Gammarus* (Mathis and Hoback, 1997). Although fish predators are absent from our study site, a variety of waterfowl use the site and presumably prey on *Gammarus*. Largex *Gammarus* would be easier to detect by tactile probing of the vegetation and provide more energy per unit of foraging time.

Alternatively, cost–benefit trade-offs in risk assessment could depend on foraging opportunities for individuals at varying levels of social hierarchy, competitive ability, or somatic resources. Trade-offs between risk and foraging are well known (e.g., Milinski and Heller, 1978; Milinski, 1985; Godin and Sproul, 1988; Lima and Dill, 1990). Hungry (Smith, 1981; Brown and Smith, 1996), and low condition (Wisenden, Rush, and Sargent unpublished) fish do not respond to conspecific alarm cues with an overt behavioral response. Small *Gammarus* may tolerate more predation risk while foraging because of subordinate status or weak competitive abilities. Social interactions, dominance hierarchies, and territorial behavior among *Gammarus* are not well understood with respect to risk avoidance.

Leeches are significant predators of *Gammarus* and detect prey by chemical and tactile means (Dahl and Greenberg, 1997; Dahl, 1998). Leeches were attracted to traps with injury-released *Gammarus* cues, leaving open the possibility that *Gammarus* avoided alarm cue traps because of the presence of leeches rather than recognition of alarm cues per se. However, there was no correlation between the number of leeches and the number of *Gammarus* caught per trap. Moreover, leeches were attracted to the *Gammarus* cue in the first experiment only, and not in the second experiment, where cue concentration was four times higher. Thus, *Gammarus* aversion to the alarm cue in the first experiment was likely attributable to the alarm cue and not leeches.

Ostariophysan fishes possess specialized epidermal cells that contain an alarm pheromone. This pheromone is released when the skin is damaged; it signals alarm

to conspecifics and also serves as an attractant to predators (Mathis et al., 1995). Attracting predators can benefit the individual sending the signal because secondary predators attempt piracy or cannibalism that afford the prey an opportunity for escape (Chivers et al., 1996). The predator attraction hypothesis is the only mechanism for the evolution of ostariophysan alarm substance cells to receive experimental support. Leech attraction to injury-released cues of *Gammarus* raises the possibility that a similar alarm signal/predator attractant cue may be released from injured *Gammarus.* Leeches do not engulf their prey. Presumably, there is the potential for large amounts of internal fluids from *Gammarus* to be released in the process of being consumed by a leech, inadvertently informing other *Gammarus* of predation risk, but also attracting other leeches. Although special glands or cells that may contain a specialized pheromone are not known for *Gammarus*, chemical deterrents are known to occur in a number of aquatic arthropods in the insect orders Coleoptera and Hemiptera (Scrimshaw and Kerfoot, 1987). Further study is required to determine if *Gammarus* possess specialized structures and the nature of competitive foraging among two or more leeches.

In addition to verifying laboratory results and revealing potential size-dependent behavioral decision criteria, these data establish a convenient field technique for further testing the role of chemical cues in mediating predator prey interactions in aquatic invertebrates. It is our hope that future work will be stimulated in this direction.

Acknowledgments—We thank the Kevin Brennan of the U.S. Fish and Wildlife Service for permission to use Erhard Pond as a study site for this project. Mac Butler and Kyle Zimmer kindly loaned us the traps used in the first experiment. Funding for this research was provided by Minnesota State University Moorhead.

(Received January 3, 2000; accepted January 30, 2001)

Abstract—In a study aimed at the chemical characterization of constituents of the ventral gland secretion of the male dwarf hamster, *Phodopus sungorus sungorus*, 48 compounds, including saturated alcohols, saturated and unsaturated ketones, saturated and unsaturated straight-chain carboxylic acids, iso- and anteisocarboxylic acids, 3-phenylpropanoic acid, hydroxyesters, 2-piperidone, and some steroids were identified in the secretion. The position of the double bonds in γ-icosadienyl-γ-butyrolactone and γ-henicosadienyl-γ-butyrolactone, and the position of methylbranching in seven C_{16}–C_{21} saturated ketones could not be established. Several constituents with typically steroidal mass spectra also remained unidentified. The female dwarf hamster's ventral gland either does not produce secretion or produced so little secretion that it was impossible to collect enough material for analysis.

Key Words—*Phodopus sungorus sungorus*, dwarf hamster, mammalian semiochemicals, mammalian pheromones, exocrine secretion, ventral gland secretion.

INTRODUCTION

The dwarf hamster, *Phodopus sungorus*, also known as the Djungarian striped or hairy-footed hamster, is a small rodent found on different types of steppes characterized by extreme temperature differences such as the dry steppes of Mongolia, Western Siberia, where air temperatures vary between $+30^{\circ}$C in summer and -40°C in winter (Heldmaier, 1975), and in the eastern parts of the Lake Baikal region (Pogosianz and Sokova, 1967), as well as on the steppes of Kazakhstan, Manchuria, and North China (Wynne-Edwards and Lisk, 1984). The dwarf hamster is unusually resistant to low temperatures (Veselofsky and Grundova, 1965). It was found (Heldmaier, 1975) that they tolerated severe cold stress, but were less able to withstand heat.

Phodopus belongs to the family Cricetinae, of which they are one of the smallest species with a body length between 67 and 102 mm (Flint, 1966). Two subspecies of the dwarf hamster are mentioned in the literature, namely *P. s. sungorus* (Pallas), which is found in the western regions of their habitat, and the eastern subspecies *P. s. campbelli* (Thomas). However, the majority of authors make no distinction between the subspecies. A few minor differences between the subspecies have been reported. *P. s. campbelli* is gregarious (Wynne-Edwards and Lisk, 1984), while *P. s. sungorus* appears to be more solitary (Reasner and Johnston, 1988). The seasonal pelage color change from dark grey in summer to white in winter is, for example, also quite pronounced in *P. s. sungorus* (Heldmaier, 1975).

Although their cold resistance is noteworthy, the most unusual characteristic of these hamsters is their highly photoperiodic nature. It seems that rather than hibernate, they have adapted strategies for survival of severe winter conditions by making use of the extreme seasonal changes in photoperiod, which are characteristic of their natural habitat. During short photoperiods ($\leq$8 hr of light), as experienced in the Siberian winter, a reduction in body weight occurs, pelage color changes dramatically, male testicle regression occurs and reproductive ability is diminished (Hoffmann, 1973), sexual development is slowed down (Brackmann, 1977; Yellon and Goldman, 1984), and a reduction in the ventral gland size is also observed (Sunderkötter et al., 1990).

According to Heisler (1984), the olfactory marking behavior in this hamster includes marking with feces, urine, and secretions from the ventral gland, as well as sand-bathing behavior, in which the animal rolls on its back, not necessarily only in sand. The marking behavior of both males and females in neutral areas, in areas where males had previously marked, and in areas where females had previously marked was investigated. The marking frequency was found to be low in both sexes and lower in females than in males. The hamsters were observed to mark the periphery of the test area more frequently than they marked in the nonperipheral areas, and while the males did not mark more frequently in an area that had already

been marked by a male, they did show an increased marking frequency in areas previously marked by females.

Feoktistova (1994) investigated the behavioral responses of adult, sexually experienced males of *P. sungorus* toward different olfactory cues, such as urine, bedding material, and integumentary skin gland secretions of conspecific males and diestrous females. Habituation studies showed that males were able to discriminate between the odors of males and females. The odors of urine, bedding material, and the secretion of the sacculi, located at the opening of the cheek pouches of conspecific males, elicited a high level of midventral gland marking, while the same odors of females resulted in anogenital marking. The low population density, nocturnal activity, and arid habitat of the dwarf hamster are expected to favor marking activity in these animals. *P. s. sungorus* has well developed glands, of which the ventral sebaceous gland (*glandula abdominales*) located along the axis body line before the genitals, is one of the most important. The gland becomes visible at an age of about 4 weeks, and it functions only during the reproductive period. The hamsters use the secretion of this gland for marking their home ranges.

In contrast to the large volume of literature on olfaction in other rodent species, no comprehensive chemical investigation of the constituents of the secretions of the dwarf hamster has so far been undertaken. The aim of the present study is to initiate chemical investigations into the nature of the exocrine secretions in hamsters, specifically in *P. s. sungorus*, in order to provide information that could lead to new avenues of investigation of chemical communication systems in hamsters. It is hoped, for example, that the compounds found in the secretions will generate ideas as to their possible origin and/or purpose, and will enable biologists to use them in behavioral studies. Using compounds present in the hamster secretions in research on rodent olfactory receptors and behavior, makes much more sense than using arbitrarily selected compounds totally unrelated to substances involved in the semiochemical communication of these animals.

METHODS AND MATERIALS

General. Dichloromethane (1 ml) (Merck, residue analysis grade), was concentrated to 10 μl, analyzed for impurities, and found to be pure enough for extraction of small quantities of semiochemicals. Syringes were cleaned with this solvent. Glassware used for the collection and extraction of samples was washed, rinsed with distilled water, heated in an annealing oven at 500°C for at least 30 min, and cooled immediately prior to use to remove all traces of adsorbed organic material.

Analytical Methods. Gas chromatographic analyses were carried out with a Carlo Erba 5300 gas chromatograph equipped with a flame ionization detector, Grob split-splitless injector, and glass columns manufactured by the Laboratory for Ecological Chemistry, University of Stellenbosch. Glass capillary columns, coated

with a 0.25-μm film of the apolar stationary phase PS-089-OH, which is a silanol-terminated 95% dimethyl–5%-diphenyl siloxane copolymer, were used throughout the study. Helium was used as carrier gas at a linear velocity of 28.6 cm/sec at 40°C. The detector and injector were used at 280°C and 220°C, respectively. Samples were injected in the split mode (split ratio 6 : 1) and an oven temperature of approximately 30°C. The oven was heated ballistically to 40°C and programmed at 2°/min from 40° to 260°C (hold). Gas chromatographic retention time comparison of the constituents of the secretion with the commercially available and synthesized reference compounds was done by coinjection of the reference compound and glandular extract to determine whether the component under investigation was enriched by the reference compound.

Quantitative gas chromatographic analyses were done with the same instrument and column, and data acquisition with Borwin Intuitive Chromatography Software (JMBS Developments, 38600 Fontaine, France) using hexadecanoic acid as external standard. Ventral gland secretion (4.8 mg) was collected, extracted with dichloromethane as described below, and the extract concentrated to 20 μl of which 1-μl quantities were injected for analysis.

A Carlo Erba QMD 1000 GC-MS system was used to record electron impact (EI) mass spectra (70 eV) employing the GC parameters specified above. The interface temperature was maintained at 250°C. The ion source temperature was 200°C, and the source pressure varied between *ca.* 2×10^{-5} torr at a column temperature of 40°C, decreasing to 1×10^{-5} torr towards the end of the temperature program at a column temperature of 260°C. A scan rate of 0.9 scan/sec, with an interval of 0.1 sec between scans, was employed. Chemical ionization (CI) mass spectra with methane as reactant gas were recorded on a Finnigan 4500 quadrupole GC-MS system. The interface temperature was 220°C, and spectra were recorded at 60 eV and at a source temperature of 150°C. Under these conditions the pressure in the source was approximately 7×10^{-5} torr. Spectra were recorded at a rate of 2 scans/sec. Accurate mass measurements of the synthetic compounds were done on an AMD 604 magnetic sector mass spectrometer. The spectra were recorded at an ionization potential of 70.7 eV and a source temperature of 192°C. The resolving power was 4000, and a scan rate of 1 scan/sec was used, with a recovery time of 0.5 sec. A sampling frequency of 100 kHz was used, and the source vacuum was 1.4×10^{-5} torr. In the case of samples introduced on the probe, the probe was heated from 20° to 350°C.

^{1}H and ^{13}C NMR spectra of synthesized compounds were obtained on a Varian VXR-300 spectrometer at 299.9 MHz and 75.42 MHz, respectively. The ^{13}C spectra were obtained by using a 45° pulse angle and a pulse repetition time of 0.8 sec. Chloroform-d_1 (Merck, 99.8% isotopic purity) was used as solvent and tetramethylsilane (TMS) as internal reference.

Determination of Double Bond Positions of Constituents. Dimethyl disulfide (DMDS) derivatives were prepared from the unsaturated constituents of

the secretion according to the procedure described by Vincenti et al. (1987). A dichloromethane extract of the secretion was concentrated in a Reacti-Vial using a slow stream of purified nitrogen. The residual material was dissolved in carbon disulfide (50 μl) and treated with an excess (5-μl) of a solution of iodine in ether (60 mg/ml) and 50 μl of dimethyl disulfide. The Reacti-Vial was sealed and the reaction mixture heated in an oven at 60°C for 40 hr; then the iodine was reduced with aqueous sodium thiosulfate solution (5%). Separation of the aqueous and organic layers was facilitated by centrifuging the reaction mixture at 3000 rpm. The organic layer was transferred to another vial and concentrated to 5 μl for GC-MS analysis.

Sample Collection and Preparation. Djungarian dwarf hamsters, *P. s. sungorus*, were bred from stock obtained from a breeding colony of the Zoological Institute at the University of Bonn. All adult animals were kept indoors in separate wire cages (36 × 25 × 23 cm) with an exercise wheel, except when males and females were put together for breeding purposes. The animals were kept at a constant temperature of 22°C in a laboratory free from artificial odors. To simulate summer conditions, the animals were exposed to natural light during daytime (Stellenbosch 33°50′ southern latitude) and, in addition, fluorescent lights were left switched on permanently resulting in a minimum light intensity of 200 lux during the nighttime. Each hamster was supplied with half a coconut shell that served as a hut into which it could withdraw into almost total darkness. To avoid contamination of the secretions with plant volatiles, shavings from old, dry poplar logs were provided for bedding material. When breeding, animals were also provided with cellulose tissues. All bedding and cellulose materials were renewed at weekly intervals. All hamsters were provided *ad libitum* with water and food containing sunflower seeds. Twice a week they were supplied with slices of apple, carrot, and lettuce. No problems were experienced with maintaining and breeding the hamsters under these conditions.

Teflon stoppers and lengths of stainless-steel wire (15 × 0.4 mm) were washed with detergent solution; rinsed with distilled water, methanol, and dichloromethane, and dried in an oven at 110°C. Using precleaned tweezers, the stainless-steel wires were inserted into the tapered end of the Teflon stoppers. The other ends of each of the wires were bent to form a small eyelet having a diameter of approximately 1 mm with which the secretion could be removed from the gland. Ventral gland secretion was collected individually from mature males in their summer state on a weekly basis. Although a hairless secretory area was clearly visible on females in this state, they did not produce enough substance for collection. The waxy secretion was collected by scooping it from the glandular area with a precleaned stainless-steel eyelet. The Teflon stoppers were inserted into the flared ends of small glass vials to provide an air-tight stopper for the vials The samples were stored at −20°C for future use.

For analysis, initially the collected secretion was scraped off the wire loop and transferred to a Reacti-Vial containing dichloromethane. However, a substantial

proportion of the sample was lost in this process. To minimize the loss of sample, the stainless steel eyelet containing the sample was therefore cut off and allowed to fall into a Reacti-Vial containing 30 μl of dichloromethane. The material was sonicated for 20 min, and then the light brown, turbid extract was centrifuged at 2500 rpm for 15 min in order to separate the extract into a clear dichloromethane extract and a turbid supernatant layer. The bottom layer was removed from underneath the supernatant layer with a 100-μl syringe and transferred to a clean Reacti-Vial in which the extract was concentrated in an inert atmosphere to a concentration suitable for GC and GC-MS analysis.

Reference Compounds. In addition to authentic commercially available reference compounds, the following compounds were synthesized for retention time and mass spectral comparison with constituents of the ventral secretion.

2-Heptadecanol (**17**); Figure 1 was prepared by $NaBH_4$ reduction of 2-heptadecanone. HR-MS: *m/z* $(M\text{-}H_2O)^+$ 238.267, calcd. for $C_{17}H_{34}$ 238.266. ^{13}C NMR ($CDCl_3$): $\delta = 68.20$ (d, C-2), 39.41 (t, C-3), 31.95 (t, C-15), 29.4–29.8 (t, C-6–C-14), 29.38 (t, C-5), 25.80 (t, C-4), 23.49 (q, C-1), 22.71 (t, C-16), 14.12 (q, C-17).

(*Z*)-6-Heptadecen-2-one, (*Z*)-8-heptadecen-2-one (**13**), (*Z*)-6-nonadecen-2-one, (*Z*)-8-nonadecen-2-one (**28**), (*Z*)-10-nonadecen-2-one, (*Z*)-12-nonadecen-2-one (**29**), and their *E* isomers were prepared by alkylation of ethyl acetoacetate with the appropriate (*E*)- and (*Z*)-alkenyl bromides, hydrolysis of the condensation product, and decarboxylation of the resulting β-ketoacid according to the following procedure described for the preparation of (*Z*)-8-nonadecen-2-one.

A solution of tetrabromomethane (41.5 mg, 0.125 mmol) in dry acetonitrile (230 μl) was added to a solution of (*Z*)-5-hexadecen-1-ol (30 mg, 0.125 mmol) (Pherobank, Wageningen, The Netherlands) and triphenylphosphine (32.8 mg, 0.125 mmol) in acetonitrile (230 μl) in a 3-ml Reacti-Vial at room temperature and the reaction mixture stirred magnetically at room temperature for 24 hr. The resulting bromide and traces of unchanged starting compounds were extracted with *n*-pentane from the acetonitrile by magnetically stirring the reaction mixture with the *n*-pentane (300 μl), centrifuging the mixture at 1000 rpm for a few minutes and removing the supernatant pentane layer with a 500-μl syringe. The extraction was repeated five times. The reaction product was purified by bulb-to-bulb distillation to give (*Z*)-1-bromohexadec-5-ene, 36 mg (95%) bp 102 (air bath)/7.5×10^{-4} mm Hg. The alkenyl bromide, containing less than 0.1% of the unchanged 5-hexadecen-1-ol as the only impurity (GC-MS), was used to alkylate ethyl acetoacetate. Ethyl acetoacetate (1.35 g, 10.4 mmol) was deprotonated by adding it to a solution of sodium ethoxide (10.4 mmol) in absolute ethanol (50 ml). The resulting anion was alkylated by magnetically stirring a sample (600 μl) of this solution in a 3-ml Reacti-Vial with (*Z*)-1-bromohexadec-5-ene (36 mg, 0.119 mmol) at 90°C for 11 hr during which time a precipitate of NaBr was formed. The ethanol was evaporated at room temperature by using a slow stream of purified

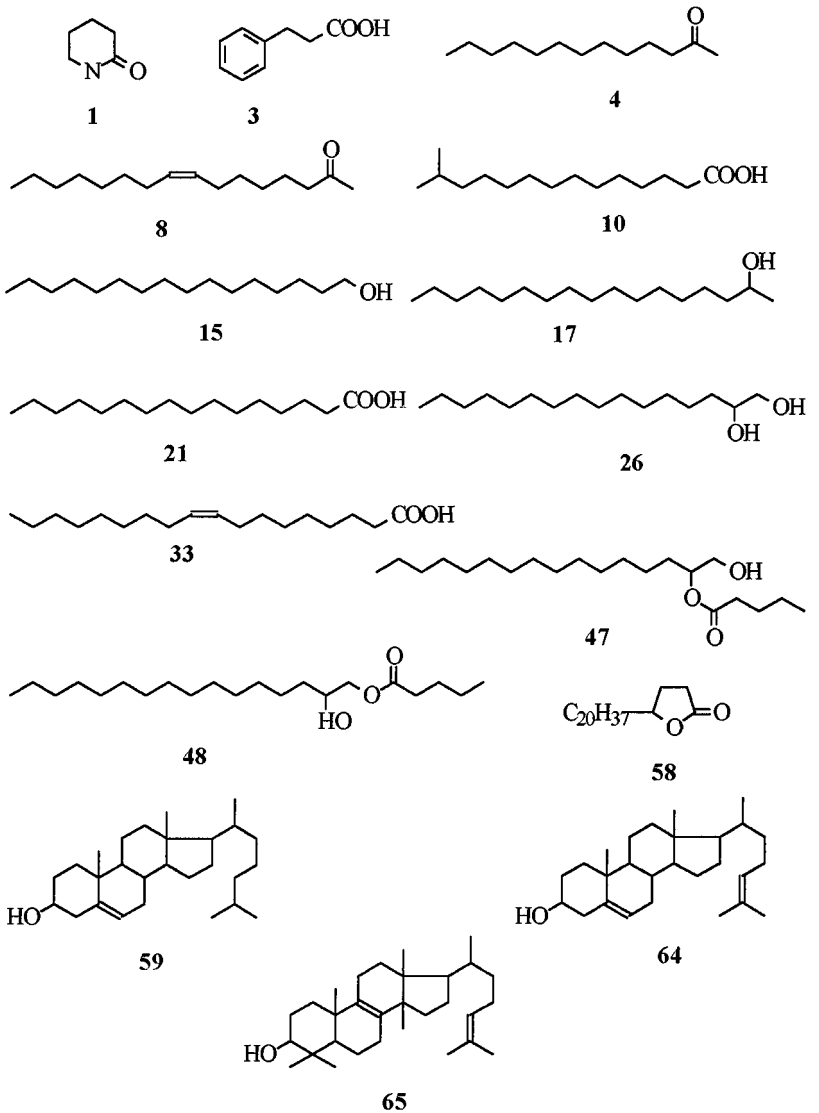

FIG. 1. Structures of representative examples of the compounds identified in the ventral secretion of the male dwarf hamster, *Phodopus sungorus sungorus.*

argon, after which the ethyl ester was hydrolyzed by stirring the residue in the Reacti-Vial with NaOH solution (1.5 M, 200 μl, 0.3 mmol) at room temperature for 24 hr. The unsaponified material and unchanged bromide were extracted twice with *n*-pentane (300 μl) by stirring the reaction product with the solvent, centrifuging the mixture at 1000 rpm, and removing the supernatant organic layer with a 500-μl syringe. The saponified material was acidified with H_2SO_4 (1.5 M) and the resulting ketoacid decarboxylated by heating the reaction mixture at 90°C until no further formation of gas bubbles in the Reacti-Vial (closed with a screw cap) could be observed. The organic material was extracted three times with *n*-pentane and washed free from H_2SO_4 with distilled water. Slow evaporation of the solvent gave (*Z*)-8-nonadecen-2-one (**28**) as a colorless oil (3.8 mg) containing 2.5% of the *E* isomer (GC-MS). ^{13}C NMR ($CDCl_3$): $\delta = 209.24$ (s, C-2), 130.22 (d, C-9), 129.48 (d, C-8), 43.78 (t, C-3), 31.93 (t, C-17), 29.85 (q, C-1), 29.77–28.83 (t, C-5, C-6, C-11–C-16) 27.25 (t, C-7)*, 27.03 (t, C-10)*, 23.79 (t, C-4), 22.69 (t, C-18), 14.11 (q, C-19) (* assignments interchangeable).

1-Hydroxyhexadec-2-yl pentanoate (**47**) and 2-Hydroxyhexadec-1-yl pentanoate (**48**) were prepared by the Al_2O_3-catalyzed reaction of 1,2-epoxyhexadecane with pentanoic acid as described by Burger et al. (1999a). The two isomers were formed in a ratio of 3 : 2. HR-MS (mixture of the two isomers): *m/z* M^+ 342.309, calcd. for $C_{21}H_{42}O_3$ 342.313. *Major component*: ^{13}C NMR ($CDCl_3$): $\delta = 174.37$(s, C-1), 75.50 (d, C-2′), 64.99 (t, C-1′), 34.30 (t, C-2), 31.95 (t, C-14′), 30.56 (t, C-3′), 29.4–29.7 (t, C-5′–C-13′), 27.16 (t, C-3), 25.33 (t, C-4′) 22.72 (t, C-15′), 22.28 (t, C-4), 14.13 (q, C-16′), 13.72 (q, C-5). *Minor component*: ^{13}C NMR ($CDCl_3$): $\delta = 174.05$ (s, C-1), 70.10 (d, C-2′), 68.58 (t, C-1′), 33.96 (t, C-2), 33.40 (t, C-3′), 31.95 (t, C-14′), 29.4–29.7 (t, C-5′–C-12′), 29.38 (t, C-13′), 27.05 (t, C-3), 25.39 (t, C-4′), 22.72 (t, C-15′), 22.28 (t, C-4), 14.13 (q, C-16′), 13.72 (q, C-5).

2-Piperidone (**1**). Cyclopentanone oxime was dried over phosphorus pentoxide and subjected to Beckmann rearrangement in concentrated H_2SO_4 to give 2-piperidone (δ-valerolactam) (Becker et al., 1973). HR-MS: *m/z* M^+ 99.066, calcd. for C_5H_9NO 99.068. ^{13}C NMR ($CDCl_3$): $\delta = 172.65$ (s, C-1), 42.20 (t, C-5), 31.51 (t, C-2), 22.28 (t, C-4), 20.88 (t, C-3).

RESULTS AND DISCUSSION

A typical total ion chromatogram of an extract of the ventral secretion of a male dwarf hamster is given in Figure 2 and the compounds identified in the secretion are listed in Table 1. Mass spectral data are given for only a few typical examples of the different compound classes present in the secretion, because the spectra of compounds within each class are quite similar and the spectral data of these typically long-chain compounds contain relatively little structural information. The structures of representative examples of each compound type are given

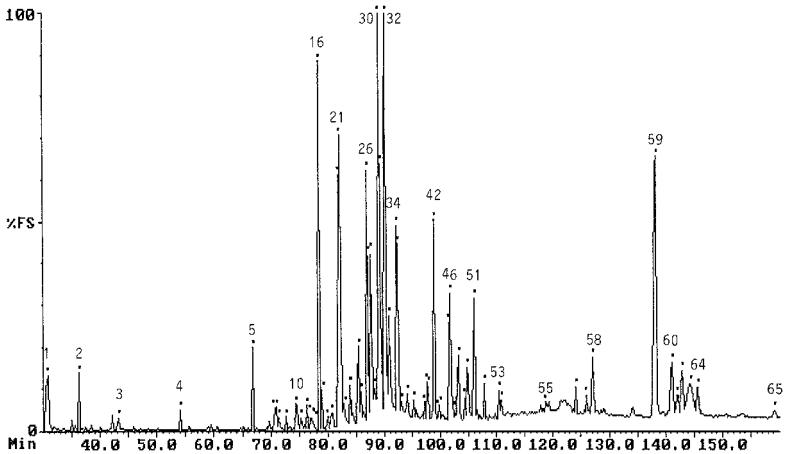

FIG. 2. Total ion chromatogram of an extract of the ventral secretion of a male dwarf hamster, *Phodopus sungorus sungorus.*

in Figure 1. Tentative identification of the constituents of the secretion was based on low-resolution EI mass spectra and CI mass spectral information obtained with methane as reactant gas. Final confirmation of many of the proposed structures was obtained by co-injection of an extract of the secretion with authentic synthetic material.

It is not possible to determine unequivocally the position of double bonds in unsaturated ketones from the low-resolution mass spectral data of their dimethyl disulfide (DMDS) adducts, because one CO and two CH_2 groups are isobaric, so that the DMDS derivative of one alken-2-one can give rise to two diagnostic ions with the same nominal masses (although having different accurate masses) as those from another isomeric DMDS derivative. Both the *E* and *Z* isomers of each of the pairs of alken-2-ones had therefore to be synthesized for retention-time comparison. There appeared to be two series of unsaturated ketones present in the secretion, one with the double bond in the 8 position and another one with the double bond equidistant from the methyl terminal end of the ketones. Although the position of the double bond of the unsaturated ketone **19** could not be determined, it is quite likely that it belongs to the first of these series and could therefore be (*Z*)-8-octadecen-2-one.

Although several presumably methyl-branched 2-alkanones having spectra similar to those of the unbranched ketones are present in the secretion, these compounds are present in such low concentrations that it was impossible to determine the position of the methyl branching from the available mass spectral data. The molecular masses of some of these ketones could be established from

TABLE 1. COMPOUNDS IDENTIFIED IN VENTRAL SECRETION OF DWARF HAMSTER

Peak (Figure 1)	Compound	EI Mass spectral data, *m/z* (%)	Quantity (ng/animal)

their $Cl(CH_4)$ mass spectra. The secretion contains unbranched as well as iso- and anteiso-branched fatty acids and it is, therefore, quite likely that most of the branched 2-alkanones could also be the iso ketones, while the unidentified ketone **36** could be 18-methyl-2-nondecanone. The retention-time increments observed

for the branched and unbranched carboxylic acids, for example, those between the C_{20} and C_{17} acids, correlate very well with the increments between the branched and unbranched ketones and therefore appear to confirm this assumption. Unfortunately, it was not possible to determine the position of the double bonds in the two γ-lactones **58** and **62**. As can be expected, their mass spectra do not contain the required structural information and their DMDS derivatives could not be found in the total ion chromatogram of a sample of the secretion subjected to DMDS derivatization, probably because the high masses of the derivatives precluded their elution from the capillary column.

According to its Cl(CH_4) mass spectrum, constituent **2** has a molecular mass of 166, and the compound apparently has an acetyl function. Its mass spectrum is similar to that of 1-acetylhydrindane, which also has a molecular mass of 166. However, the mass spectrum of this constituent has a prominent ion at *m/z* 109 (23%), which is relatively weak in the NBS library spectrum of 1-acetylhydrindane. Furthermore, the mass spectrum of the constituent **2** does not have an ion at *m/z* 148 which is present in the library spectrum. This constituent is, therefore, listed as unidentified in Table 1.

All of the constituents eluting in the high-molecular-weight range of the total ion chromatogram appear to be steroids. Some of these compounds remained unidentified in the present investigation and will be subjected to further scrutiny in future research on the dwarf hamster, because of their possible involvement in the chemical ecology of the animal.

Varying quantities of ventral secretion were collected from individual males. Table 1 contains quantitative data obtained from a rather large quantity (4.8 mg) of secretion collected from one male animal. These data are included merely to serve as a guideline for biologists planning behavioral studies on the dwarf hamster. The variation in the quantity of ventral secretion collected from individual animals, the probably incomplete extraction of, especially, the more polar compounds with a small volume of dichloromethane, and the fact that different samples of the secretion possibly contain different concentrations of moisture that is not detectable by FID are considered to be responsible for a larger factor of uncertainty than the use of an external standard and the unaccurate determination of the volume to which the sample was finally concentrated.

Carboxylic acids have been identified in many mammalian exocrine secretions. The longer-chain acids seem to be less common, especially in secretions investigated during the 1960s and 1970s, possibly because long-chain acids did not elute from some of the stationary phases and packed columns used during the earlier years of gas chromatography, or eluted as such broad peaks as to be almost undistinguishable from the baseline. Fatty acids were found in the anal sac secretions of many carnivores (Albone, 1984a) and in many other mammalian secretions. The preputial gland secretion of the musk rat, *Ondatra zibethica*, for example, contains a number of saturated, monounsaturated, and diunsaturated,

C_{12}–C_{20} fatty acids (Ritter et al., 1982). Fatty acids are also found in human vaginal secretions (Huggins and Preti, 1976) and in the interdigital secretion of the reindeer, *Rangifer tarandus* (Brundin et al., 1978). Many of the short-chain acids found in these secretions are iso- or anteiso-branched. 3-Phenylpropanoic acid **3** was identified, among others, in the anal sac secretion of the red fox, *Vulpes vulpes*, and the lion, *Panthera leo* (Albone and Eglinton, 1974), and in the urine of coyote, *Canis latrans* (Murphy et al., 1978).

Long-chain carboxylic acids (C_{15}–C_{25}) were found in the occipital secretion of the bactrian camel, *Camelus bactrianus*, together with some shorter-chain acids (Ayorinde et al., 1982). Long-chain fatty acids are particularly abundant in the interdigital secretions of bontebok, *Damaliscus dorcas dorcas*, and blesbok, *D. d. phillipsi*, containing the saturated unbranched C_6–C_8, C_{10}, C_{12}, C_{14}–C_{18}, and C_{20} fatty acids (Burger et al., 1999a). With the exception of the C_7, C_8, C_{10}, and C_{20} homologs, these acids are also present in the preorbital gland secretions of these two subspecies, which also contain the C_{19} acid (Burger et al., 1999b). The interdigital secretions of these two subspecies also contain oleic acid (*Z*9-C_{18}). The preorbital secretion of the grysbok, *Raphicerus melanotis*, contains the C_{14}–C_{18} and C_{20} fatty acids (Burger et al., 1996) and that of the steenbok, *R. campestris*, C_8, C_{10}, C_{12}, C_{14}–C_{16}, C_{18}, C_{20}, and unsaturated fatty acids (Burger et al., 1999c). Only the three C_{16}–C_{18} fatty acids are present in the preorbital secretion of the oribi, *Ourebia ourebi* (Mo et al., 1995) and the C_8, C_{10}, C_{12}, C_{14}–C_{16}, C_{18}, C_{20} fatty acids and several unsaturated analogs in the preorbital secretion of the grey duiker, *Sylvicapra grimmia* (Burger et al., 1990).

With a few exceptions, long-chain alcohols have not been found in many mammalian exocrine secretions. The identification of the C_{12}, C_{14}, C_{16}, and C_{18} alkanols in human vaginal secretions (Huggins and Preti, 1976) is one of these examples. Of the four long-chain C_{16}, C_{17}, C_{19}, and C_{21} alkanols (**15**, **17**, **31**, and **43**) present in the ventral secretion of the dwarf hamster, the C_{16} and C_{21} alkanols have been identified in the interdigital secretion of the bontebok and blesbok (Burger et al., 1999a), and the C_{16} alkanol in the preorbital secretion of the steenbok (Burger et al., 1999c), as well as in the tarsal volatiles of the reindeer, *Rangifer tarandus tarandus* (Andersson et al.,1975). Although the preorbital secretion of the grysbok contains at least 22 alkanols, alkenols, and alkadienols (Burger et al., 1996), the four alkanols found in the ventral secretion of the dwarf hamster are not among them.

Ketones are reasonably common in mammalian exocrine secretions, and Albone (1984b) has cited several examples of secretions containing a few short- to medium-chain ketones. Jemiolo et al. (1987) have found several saturated, unsaturated, and methyl-branched unsaturated ketones in the urine of the house mouse, *Mus musculus*. The ventral secretion of the dwarf hamster, however, seems to be unique in that it contains at least 25 alkan-2-ones and alken-2-ones from C_{13} to C_{23}. Only a few of the shorter-chain members of the group of ketones present in

the ventral secretion of the dwarf hamster were found in other animals, for example, 2-pentadecanone (**5**) and 2-heptadecanone (**16**) in the perineal secretion of the guinea pigs, *Cavia aperea* and *C. porcellus* (Wellington et al., 1979) and pentadecan-2-one in the dorsal secretion of the springbok, *Antidorcas marsupialis*, (Burger et al., 1981).

Unfortunately, the position of the double bonds in the two monounsaturated γ-lactones (**58** and **62**) could not be determined. One is immediately reminded of a similar compound, (*Z*)-6-dodecen-4-olide, that was identified as a component of the extract of the male tarsal hair tuft of the black-tailed deer, *Odocoileus hemionus columbianus* (Brownlee et al., 1969) and later shown to originate from the urine of the animal (Müller-Schwarze et al., 1978). The same compound was identified in the interdigital secretions of the bontebok and blesbok, secretions that also contain the δ-lactone, dodecan-5-olide (Burger et al., 1999a). The absolute configuration of this compound in the bontebok has not yet been established. Hexadecan-5-olide and its C_{17} and C_{18} homologs are present in the preorbital secretion of the bontebok and blesbok (Burger et al., 1999b). Dodecan-4-olide has been found in the occipital secretion of the bactrian camel (Ayorinde et al., 1982), the γ- and δ-lactones, pentan-4-olide, hexan-4-olide, and hexan-5-olide, have been identified in human urine (Zlatkis and Liebich, 1971); and the C_8–C_{12} γ-lactones in human skin lipids (Labows et al.,1979). The C_{15}–C_{18} and C_{20} alkan-4-olides and C_{16} alkan-5-olide were identified in the preorbital secretion of the grysbok (Burger et al., 1996) and the C_{16} and C_{18} alkan-4-olides in the preorbital secretion of the grey duiker (Burger et al., 1990).

Albone (1984c) discussed the possibility that 2-piperidone identified in the anal sac secretions of the dog, *Canis familiaris*, coyote, *C. latrans*, and mink, *Mustela vison*, could possibly be formed by the elimination of water from the precursor 5-aminovaleric acid that is formed by fermentation processes in the anal sac (Albone et al., 1976). 2-Piperidone has also been identified in human vaginal secretions (Huggins and Preti, 1976).

The ventral secretion of the dwarf hamster contains five long-chain hydroxyesters; **47**, **48**, **50**, **51**, and **54**. Although these hydroxyesters are not accompanied by long-chain epoxides in the ventral and other secretions, it is nevertheless accepted as a working hypothesis that they are formed through nucleophilic substitution of the corresponding epoxides by the corresponding carboxylic acids. The preorbital secretion of the grysbok contains 2-hydroxyoctadecan-1-yl acetate and 2-hydroxyicosan-1-yl acetate (Burger et al., 1996). The related steenbok's preorbital secretion contains 17 of these hydroxyesters, from 2-hydroxyheptadecan-1-yl acetate to 1-hydroxydocos-2-yl butanoate and 2-hydroxydocos-1-yl butanoate (Burger et al., 1999c), and the interdigital secretions of the bontebok and blesbok contain 12 hydroxyesters, from 2-hydroxyoctadecan-1-yl acetate to 2-hydroxydocosan-1-yl butanoate (Burger et al., 1999a). It is not clear whether these compounds have any semiochemical function because they are not very volatile.

Similarly it is not clear whether steroids such as the ubiquitous cholesterol, its derivative desmosterol, and lanosterol have a semiochemical function other than, possibly, serving as controlled-release carrier materials. Cholesterol and desmosterol have also been identified in the interdigital secretions of bontebok and blesbok (Burger et al., 1999a).

(Received January 3, 2000; accepted January 29, 2001)

Abstract—As a first step in a study of the role of the secretion of the supplementary sacculi (buccal secretion) of the dwarf hamster, *Phodopus sungorus sungorus*, almost complete chemical characterization of the secretion was achieved. The 35 compounds identified include carbon dioxide, hydrogen sulfide, a large number of carboxylic acids (representing the bulk of the organic volatile fraction of the secretion), phenol, 2-piperidone, indole, two long-chain hydroxyesters, cholestrol, desmosterol, and lanosterol. The position of the double bonds in γ-icosadienyl-γ-butyrolactone and γ-henicosadienyl-γ-butyrolactone could not be determined, and these two compounds remained only partially characterized. Large variations were found in the relative concentrations in which the short-chain carboxylic acids are present in the secretions of individual animals, and although this aspect was not investigated in sufficient detail in the present investigation, the difference in the carboxylic acid profiles of the secretions of individual animals could play a role in individual recognition in this animal.

Key Words—*Phodopus sungorus sungorus*, dwarf hamster, mammalian semiochemicals, mammalian pheromones, exocrine secretion, buccal gland secretion, supplementary sacculi.

*To whom correspondence should be addressed.

INTRODUCTION

Certain aspects of the biology of the dwarf hamster, *Phodopus sungorus sungorus*, were summarized in the previous article in the series on mammalian exocrine secretions (Burger et al., 2001). In addition to the ventral gland, both male and female dwarf hamsters produce a buccal secretion from the supplementary sacculi situated at the opening of their cheek pouches. Very little information is available on this subject. Functions attributed to this secretion include communication of information about sex, identity, female breeding condition, and even regulation of certain physiological functions in *P. s. campbelli* (Vasilieva and Feoktistova, 1994). These authors reported the results of a study on the role of the sacculi in the development of juveniles. It was found that surgical removal of the sacculi did not influence development of the pups when they could consume secretion from parents and littermates but that restriction or inability to consume secretion led to a significant increase in the pup mortality, with conditions such as nonspecific enterocolitis and disbacteriosis, and a significant delay in growth and reproductive development. An increase in adrenal gland weight occurred in such animals, and the effects of deprivation were found to be more pronounced in male pups.

The buccal secretion thus appears to play an important role in the survival and development of juvenile dwarf hamsters. Although polar involatile compounds could be responsible for at least some of the functions attributed to the secretion, it was decided to start with the investigation of the volatile organic fraction as a first step towards the complete chemical characterization of the secretion. We now report the identification of practically all its volatile organic constituents.

METHODS AND MATERIALS

General and Analytical Methods. The procedures and instrumentation used in the identification of the constituents of the buccal secretion of the hamster were described by Burger et al. (2001) in the previous paper in this series. In addition to the column coated with 95%-dimethyl–5%-diphenylsiloxane copolymer used for analysis of the ventral secretion of the male dwarf hamster, a glass capillary column (40 m $\times$ 0.3 mm) coated with 0.375 μm of OV-1701 was used for qualitative as well as quantitative analyses of the buccal secretion of male and female dwarf hamsters. The GC and GC-MS parameters used for analysis with the PS-089 column were also used for analyses on the OV-1701 column. These analyses were done on both columns using extracts of the buccal secretions of individual animals and the analyses were repeated using solventless sample introduction techniques. Small quantities of the secretion (*ca.* 0.2 mg) were, for example, introduced into the injector of the GC and the GC-MS instrument using a sample introduction

probe (Burger et al., 1990), and similar sample sizes were also introduced as a smear on the inside of a clean injector liner. When solventless sample introduction was used, the volatile material was cryotrapped on the column with dry ice. For quantitative analyses, the injector was operated in the splitless mode and the data acquisition and processing software specified in the previous paper in this series (Burger et al., 2001) were used.

Sample Collection and Preparation. The sticky, whitish secretion was collected separately from the supplementary sacculi of males and females in their summer state, i.e., with the day length exceeding 10 hr. Samples were collected on a weekly basis. Grasping a hamster firmly by the scruff of the neck caused the animal to open its mouth, and the waxy secretion was collected by scooping it from the glandular area with the device used for the collection of the animal's ventral secretion (Burger et al., 2001). The material was transferred from the wire loops to a Reacti-Vial containing dichloromethane using another piece of stainless-steel wire, after which the contents of the vial were thoroughly mixed using a thin glass rod. This caused the secretion to be spread out on the wall of the vial. The material in the vial was sonicated for 10 min, centrifuged for 15 min at 2500 rpm, and the dichloromethane extract containing the organic material transferred to a clean Reacti-Vial with a 100-μl syringe. The extract was concentrated in an inert atmosphere (Burger et al., 1999a) for GC and GC-MS analysis. Secretion intended for quantitative analyses was collected on a wire loop as described above. A small sample (*ca.* 0.2 mg) of the material was accurately weighed into a sample introduction probe (Burger et al., 1990) or a clean glass liner and immediately analyzed to avoid losing the more volatile constituents of the secretion. Hexadecanoic acid was used as external standard in the quantitative analyses.

Reference Compounds. Some of the compounds identified in the secretion are commercially available, while others were available from previous research projects. The following compounds were synthesized during the present study.

*3-Phenylpropanoic acid (**19**)*. Cinnamic acid (3.06 g, 20 mmol), dissolved in degassed methanol (25 ml), was hydrogenated at room temperature and atmospheric pressure in the presence of Pd on activated carbon (5%, 300 mg) until 1.02 equivalents of hydrogen had been taken up. The catalyst was filtered off and the methanol removed on a rotary evaporator. The product containing some residual catalyst was taken up in dichloromethane, the solution filtered through a layer of silica gel, and the solvent evaporated to give 3-phenylpropanoic acid (2.66g, 85.8%). ^{13}C NMR ($CDCl_3$): $\delta = 179.36$ (s, C-1), 140.14 (s, C-1′), 128.56 (d, C-3 and 5), 128.26 (d, C-2 and 6), 126.38 (d, C-4), 35.63 (t, C-2), 30.57 (t, C-3).

*2-Hydroxyoctadec-1-yl acetate (**31**)*. A mixture of the hydroxyester (**31**) and 1-hydroxyoctadec-1-yl acetate was synthesized by the Al_2O_3-catalyzed reaction of 1,2-epoxyoctadecane with acetic acid as described by Burger et al. (1999a). The title compound (**27**) and 1-hydroxyoctadec-1-yl acetate were formed in a ratio of 1 : 3 (GC-MS). HR-MS (mixture of the two isomers): m/z M^+ 255.262, calcd. for

$C_{20}H_{40}O_3$ 255.269. *Major component*: ^{13}C NMR ($CDCl_3$): $\delta = 171.48$ (s, C-1), 75.74 (d, C-2′), 64.82 (t, C-1′), 31.95 (t, C-16′), 30.51 (t, C-3′), 29.30–30.5 (t, C-5′– C-15′), 25.33 (t, C-4′), 22.71 (t, C-17′), 21.20 (q, C-2), 14.12 (q, C-18′). *Minor component* (**31**): ^{13}C NMR ($CDCl_3$): $\delta = 171.20$ (s, C-1), 69.99 (d, C-2′), 68.81 (t, C-1′), 33.37 (t, C-3′), 25.38 (t, C-4′) 29.30 (t, C-5′–C-15′), 31.95 (t,C-16′), 22.71 (t, C-17′), 20.89 (q, C-2), 14.12 (q, C-18′).

*2-Hydroxyicos-1-yl acetate (**32**)*. A mixture of the hydroxyester (**32**) and 1-hydroxyicos-2-yl acetate was prepared from 1,2-epoxyicosane as described above. The two isomers were present in the product in a ratio of 1 : 2 (GC-MS). HR-MS (mixture of the two isomers): *m/z* M^+ 356.332, calcd. for $C_{22}H_{44}O_3$ 356.329. *Major component:* ^{13}C NMR ($CDCl_3$): $\delta = 171.55$ (s, C-1), 75.75 (d, C-2′), 64.81 (t, C-1′), 31.95 (t, C-18′), 30.52 (t, C-3′), 29.3–30.5 (t, C-5′–C-17′), 25.33 (t, C-4′), 22.71 (t, C-19′), 21.22 (q, C-2), 14.13 (t, C-20′). *Minor component* (**32**): ^{13}C NMR ($CDCl_3$): $\delta = 171.27$ (s, C-1), 70.00 (d, C-2′), 68.80 (t, C-1′), 33.38 (t, C-3′), 31.95 (t, C-18′), 29.3–31.0 (t, C-5′–C-16′), 29.18 (t, C-17′), 25.39 (t, C-4′), 22.71 (t, C-19′), 20.90 (q, C-2), 14.13 (q, C-20′).

RESULTS AND DISCUSSION

A typical total ion chromatogram of an extract of the buccal secretion of a male dwarf hamster is given in Figure 1. Tentative identification of the constituents of the secretion was based on low-resolution mass spectral data, supported by information obtained by their chemical ionization mass spectra, generated with methane as reactant gas. Final confirmation of most of the proposed structures was obtained by coinjection of an extract of the secretion with authentic synthetic material.

Solventless sample introduction made it possible to identify even highly volatile constituents of the secretion such as carbon dioxide (which was to be expected in the material and is probably extracted from the animal's breath), hydrogen sulfide, and trimethylamine. The bulk of the volatile organic fraction of the secretion consists of short-chain carboxylic acids. These compounds together with the hydrogen sulfide and trimethyl amine are responsible for the unpleasant odor of the animal's breath.

A few diunsaturated compounds could not be fully characterized because dimethyl disulfide (DMDS) derivatization did not yield informative mass spectral data. This was probably due to the high molecular masses of the derivatives, which are expected to elute as flat peaks in the upper isothermal part of the chromatogram of the material subjected to DMDS derivatization. The interpretation of the mass spectra of long-chain hydroxyesters has been discussed by Burger et al. (1996). In the present study the identification of the hydroxyesters **31** and **32** was based

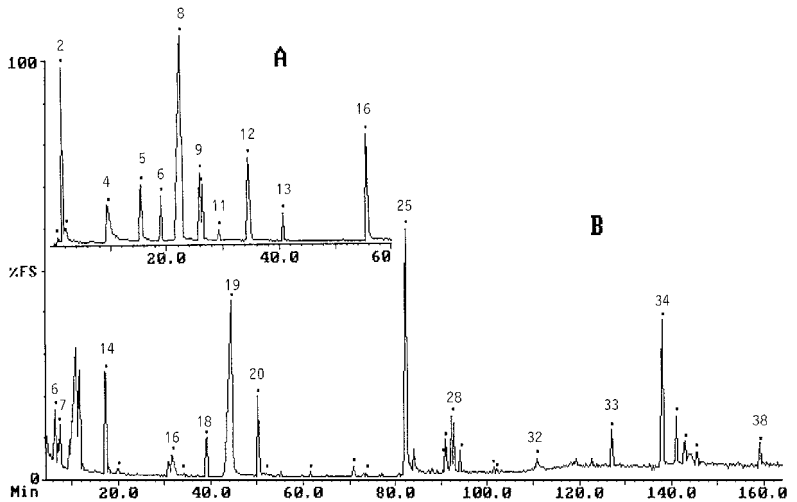

FIG. 1. Total ion chromatograms of the secretion of the supplementary sacculi (buccal secretion) of the dwarf hamster, *Phodopus sungorus sungorus*: (A) Analysis of unprocessed secretion on a relatively polar column (OV-1701) using solventless sample introduction; (B) Extract of the secretion analized on an apolar column (PS-089).

mainly on their coelution with the synthetic hydroxyesters because they are present in the secretion in such low concentrations that some of the less abundant ions were not visible in the high-molecular-weight range of their mass spectra. The two unsaturated γ-lactones, **33** and **36**, which are also present in the ventral secretion of the dwarf hamster (Burger et al., 2001), remained incompletely characterized in the present investigation. The compounds identified in the buccal secretion are listed in Table 1 together with information on the analytical techniques employed in their identification, and some quantitative data on the constituents present in male and female secretions. Several compounds identified in the animal's buccal secretion are also present in its ventral secretion. In addition to the structures of representative examples of these compounds given in the paper on the ventral secretion (Burger et al., 2001), the structures of some of the compounds that are not common to both secretions are given in Figure 2.

Typically about 1–4 mg of secretion could be collected from one animal, but some of the animals from our colony consistently produced almost no secretion. The quantitative determination of the volatile organic constituents of the secretion posed a problem because polar compounds such as the short-chain carboxylic acids were not quantitatively extracted with small quantities of dichloromethane from the mucoid material in which they are produced. The highly volatile constituents are lost during concentration of extracts when larger quantities of solvent are used.

TABLE 1. COMPOUNDS IDENTIFIED IN SUPPLEMENTARY SACCULI SECRETION (BUCCAL SECRETION) OF DWARF HAMSTER

Peak (Figure 1)	Compounds	EI Mass spectral data *m/z* (%)	Quantity (ng/animal)[a]	
			Male	Female
1	Carbon dioxide[b,c]	44(100), 28(7)	7	43
2	Hydrogen sulfide[b,c]	36(5), 35(3), 34(100), 33(38)	6	15
3	Trimethylamine[b,c]	59(46), 58(100), 57(8), 56(4), 43(5), 42(26), 41(5)	17	27
4	Ethanoic acid[b–d]	61(3), 60(100), 45(85), 43(92), 42(16)	569	682
5	Propanoic acid[b–d]	74(76), 73(5), 57(33), 55(19), 45(62)	30	376
6	2-Methylpropanoic acid[b–d]	88(7), 73(30), 55(8), 45(17), 43(100), 41(50)	65	163

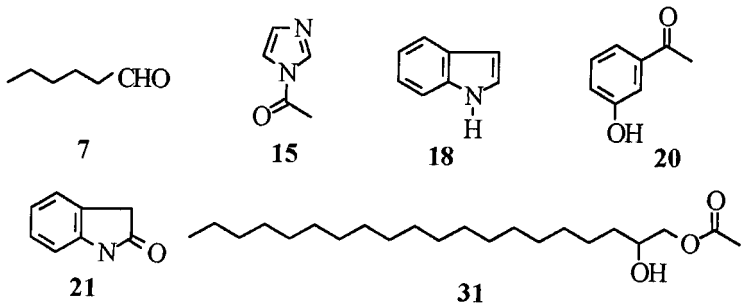

FIG. 2. Structures of some representative examples of the compounds identified in the buccal secretion of the dwarf hamster, *P. s. sungorus.*

Solventless sample introduction, on the other hand, discriminates to a certain extent against the heavy constituents of the secretion. Furthermore, the FID in GC analyses and the mass spectrometer in GC-MS analyses both have different quantitative responses to small and large molecules, while CO_2 and H_2S are not detected by FID. Ideally the volatile organic constituents present in the headspace gas of the secretion should be determined at temperatures corresponding to the hamster's body temperature in their summer and winter states. Furthermore, the extreme polarity differences between highly polar compounds such as ethanoic acid and the less polar long-chain constituents of the secretion, make it difficult to suggest an universal stationary phase for sample enrichment. Headspace analysis of the buccal secretion was not done in the present investigation. The quantitative data in Table 1 were obtained by combining the results of analyses using different capillary columns and sample introduction techniques in GC as well as GC-MS analyses. Although the quantitative results probably represent a relatively accurate picture of the quantitative composition of the secretion analyzed, the data are considered to be somewhat preliminary at this stage and are given merely as a guideline for biologists planning behavioral studies on the dwarf hamster. Nevertheless, the results do give quite a reliable picture of the ratio in which compounds within limited volatility ranges are present in the secretion. Some of the largest quantitative differences among the buccal secretions from individual animals were found among the short-chain carboxylic acids, and the role of these compounds in individual and sexual recognition in *P. sungorus* should be investigated in more detail.

The highly volatile compounds, carbon dioxide (**1**), hydrogen sulfide (**2**), and trimethylamine (**3**) were detected in the secretion because solventless sample introduction techniques were employed in GC and GC-MS analyses in addition to conventional analysis of extracts. These compounds are almost completely lost from an extract if the solvent has to be evaporated to concentrate an extract for analysis. The presence of carbon dioxide in the secretion is to be expected because it is

extracted from expired breath of the animal by the moisture-containing secretion. Hydrogen sulfide does not feature in reports on mammalian exocrine secretions, probably because it is not detected by FID. It will also not be registered in the total ion chromatogram if the mass spectra are scanned from a mass higher than *m/z* 34. Hydrogen sulfide, trimethylamine, and the short-chain fatty acids, of which almost all the unbranched, iso- and anteiso-branched members from C_2 to C_6 are present in the buccal secretion, are probably responsible for the obnoxious smell of the dwarf hamster's breath and the secretion. A mixture of similar volatile fatty acids has been identified in many mammalian secretions, such as, for example, the interdigital secretion of the reindeer (Brundin et al., 1978), the perineal scent gland of guinea pigs (Wellington et al., 1979), and human vaginal secretion (Huggins and Preti, 1976). The microbial production of trimethylamine, indole (**18**), other amines, organosulfur compounds, and fatty acids from amino acids in mammalian exocrine secretions has been reviewed and discussed by Albone (1984). The occurrence of long-chain saturated and unsaturated fatty acids, 2-piperidone (**16**), and 3-phenylpropanoic acid (**19**) in mammalian exocrine secretions was discussed briefly in the previous paper in this series (Burger et al., 2001).

Long-chain acetates are not common in mammalian secretions. Several have, however, been identified in the male abdominal scent gland of the jird, *Meriones tristrami* (Kagan et al., 1983), the preputial secretion of the mouse, *Mus musculus* (Spener et al., 1969), and the preorbital secretion of the male oribi, *Ourebia orebi* (Mo et al., 1995).

Phenol (**13**) and its derivatives, such as the three isomeric cresols, other alkyl-substituted phenols, and phenolic acids, are present in many mammalian secretions. Phenol and *p*-cresol were found in human vaginal secretions (Huggins and Preti, 1976); *p*-ethylphenol, *p*-propylphenol, and pyrocatechol in castoreum of the beaver, *Castor fiber*, (Lederer, 1946, 1949); phenol, *m*- and *p*-cresol, and *m*- and *p*-propylphenol in aged urine of some African Bovidae (Madubunyi et al., 1996); and phenol, *m*-cresol, *m*-ethylphenol, and *m*-propylphenol in the interdigital secretions of the bontebok, *Damaliscus dorcas dorcas*, and the blesbok, *D. d. phillipsi* (Burger et al., 1999a). The preorbital secretions of the antelope we have so far investigated do not contain phenols and phenolic compounds. As far as mammalian exocrine secretions are concerned, phenol and phenolic compounds are apparently found in glandular structures in which the conditions are favorable for survival of microorganisms and the accumulation of the secretions of the gland and/or the products of microbial activity.

Oxindole (**21**) as its steroid conjugate has been identified in the urine of children (Voeltler et al., 1971). Acetophenone has been identified in the urine of the red fox, *Vulpes vulpes* (Jorgenson et al., 1978), and *p*-hydroxyacetophenone in castoreum of the beaver (Lederer, 1946, 1949).

Hexanal (**7**) is a potent odor with a threshold value to the human nose slightly lower than that of limonene (Ohloff, 1978), which has been identified in human

breast milk (Stafford et al., 1976). It has also been found in interdigital and preorbital secretions of the bontebok, *Damaliscus dorcas dorcas* and blesbok, *D. d. phillipsi* (Burger et al., 1999a,b), and in the preorbital secretions of the steenbok, *Raphicerus campestris* (Burger et al., 1999c). In the interdigital secretions of the bontebok and blesbok, this aldehyde is accompanied by another nine saturated and unsaturated C_7-C_{10} aldehydes. The origin of aldehydes in mammalian secretions has not been established, but in addition to the possibility that they are produced by the exocrine glands of the mammals or by microbial action, short- to medium-chain aldehydes are also produced by the autoxidation of unsaturated lipids such as, for example, unsaturated triglycerides.

Unbranched short- to intermediate-chain alkanes have been identified in human effluvia (Ellin et al., 1974). The alkanes found in some mammalian exocrine secretions are mostly unbranched with intermediate to long chain lengths consisting of even as well as odd numbers of carbon atoms (Burger et al., 1990, 1999a–c). It has to be accepted that these compounds are produced by the glands or by microflora present in the glandular structures because there does not seem to be evidence that their presence can be ascribed to contamination of the secretions with, for example, petroleum products. The two γ-lactones (**33** and **36**) that are also present in the ventral secretion of the male dwarf hamster remained unidentified in this investigation. 2-Hydroxyicos-1-yl acetate (**32**) was also found in the male ventral secretion, but instead of 2-hydroxyoctadec-1-yl acetate (**31**), present in the buccal sectretion, the ventral secretion contains the 1-hydroxyhexadec-2-yl and 2-hydroxyhexadec-1-yl pentanoates and their hydroxyheptadecyl analoges. The presence of these γ-lactones, hydroxyesters, and the steroidal compounds cholesterol (**34**), desmosterol (**37**), and lanosterol (**38**) in the dwarf hamster was briefly referred to in the article on the ventral secretion of the animal (Burger et al., 2001).

EFFECTS OF GENOTYPE, NUTRIENT AVAILABILITY, AND DEFOLIATION ON ASPEN PHYTOCHEMISTRY AND INSECT PERFORMANCE

TOD L. OSIER* and RICHARD L. LINDROTH

Department of Entomology
University of Wisconsin—Madison
Madison, Wisconsin

(Received September 12, 2000; accepted March 7, 2001)

Abstract—Genetic and environmental variability, and their interactions, influence phytochemical composition and, in turn, herbivore performance. We evaluated the independent and interactive effects of plant genotype, nutrient availability, and defoliation on the foliar chemistry of quaking aspen (*Populus tremuloides*) and consequences for performance of gypsy moths (*Lymantria dispar*). Saplings of four genotypes were grown under two conditions of nutrient availability and subjected to three levels of artificial defoliation. Concentrations of all secondary and primary metabolites evaluated responded to at least one or more of the experimental treatments. Of the secondary metabolites, phenolic glycosides were affected strongly by genotype, less so by nutrient availability, and not induced by defoliation. Condensed tannins were strongly dependent upon genotype, soil nutrient availability, and their interaction, and, in contrast to phenolic glycosides, were induced by artificial defoliation. Of the primary metabolites, foliar nitrogen was affected by genotype and soil nutrient availability. Starch concentrations were affected by genotype, nutrient availability, defoliation and interactions among these factors. Foliar water content responded to genotype, nutrient availability, and defoliation, and the effect of nutrient availability depended on genotype. Herbivore performance on these plants was strongly influenced by plant genotype and soil nutrient availability, but much less so by defoliation. Although several of the compound types (condensed tannins, starch, and water) responded to defoliation, quantitative variation in these compounds did not contribute to substantive changes in herbivore performance. Rather, the primary source of variation in insect performance was due to plant genotype (phenolic glycoside levels), while nutrient availability (foliar nitrogen levels) was of secondary importance. These results suggest that genetic variation in aspen plays a major role in determining patterns of insect performance, whereas environmental variation, such as was tested, here is of negligible importance.

Key Words—Plant–insect interactions, genotypic variability, fertilization, defoliation, quaking aspen, *Populus tremuloides*, gypsy moth, *Lymantria dispar*, phenolic glycosides, condensed tannins.

INTRODUCTION

Quantitative variation in both primary and secondary plant chemistry is largely responsible for patterns of herbivore performance and distribution across available hosts (Krischik and Denno, 1983; Schultz, 1988; Bernays and Chapman, 1994; Berenbaum, 1995). Variation in phytochemistry is due to plant genotype, environment, and interactions between genotype and environment (Karban, 1992). Numerous studies have evaluated the independent effects of genotype (e.g., Foulds and Grime, 1972; Bowers and Stamp, 1992; Orians et al., 1993; Hwang and Lindroth, 1997; Rousi et al., 1997; Han and Lincoln, 1997) and environmental factors such as nutrient availability (e.g., Larsson et al., 1986; Bryant et al., 1987a,b; Björkman et al., 1991) and herbivore damage (e.g., Baldwin, 1988; Karban, 1993; Julkunen-Tiitto et al., 1995) on plant chemistry and plant–herbivore associations. However, the relative importance of, and interactions among, genetic and environmental factors remains poorly understood (Karban, 1992; Stiling and Rossi, 1996).

We used an experimental system including quaking (=trembling) aspen (*Populus tremuloides*) and the gypsy moth (*Lymantria dispar*) to test the effects of plant genotype, two environmental factors (nutrient availability and foliar damage), and their interactions on phytochemistry and herbivore performance. Quaking aspen is adapted to a variety of habitats (Mitton and Grant, 1996) and is the most widely distributed tree species in North America (Dickmann and Stuart, 1983). Quaking aspen has high genetic variability; variation can be observed for leaf and bark morphology, leaf phenology, and growth rate (Barnes, 1969; Dickmann and Stuart, 1983; Perala, 1990; Mitton and Grant, 1996). Moreover, clones vary in susceptibility to disease and herbivores (Barnes, 1969; Dickmann and Stuart, 1983; Perala, 1990). Across its range, quaking aspen is attacked by over 100 species of insects, a number of which are prone to population outbreaks (Perala, 1990). One such insect is the gypsy moth, which causes significant, but not uniform, defoliation to aspen during outbreaks in the Great Lakes region of the United States.

This system is well suited to studies of genotype $\times$ environment interactions because variation in aspen phytochemistry is known to have both genetic and environmental components (Lindroth and Hwang, 1996) and because induced responses have been documented for *Populus* species (Nef, 1988; Mattson and Palmer, 1988; Havill and Raffa, 1999). Variation in phytochemistry among clones has consistently been found to impact herbivores, and high concentrations of phenolic glycosides have strong and typically negative effects on herbivore development (Hemming and Lindroth, 1995; Hwang and Lindroth, 1997, 1998) and

fecundity (Osier et al., 2000). Although less well studied than genotypic effects, environmental factors also alter phytochemistry and herbivore performance on aspen. For example, availability of resources (nutrients, CO_2, light) affects aspen phytochemistry and herbivore performance (Bryant et al., 1987b; Lindroth et al., 1993; Kinney et al., 1997; Hemming and Lindroth, 1999; Agrell et al., 2000). Induced chemical responses in aspen are less well understood. Previous research has documented rapidly induced responses in secondary chemistry as a result of foliar damage. Responses have included slight increases in phenolic glycoside content (Lindroth and Kinney, 1998) and increases in condensed tannin (Clausen et al., 1989; Roth et al., 1998) and total phenolic (Mattson and Palmer, 1988) concentrations. The demonstrated impact of such induced chemical changes on insect performance, however, has been small (Lindroth and Kinney, 1998) to nonexistent (Roth et al., 1998). Varied responses among studies with aspen suggest that genetic or environmental factors may modulate the induction response.

METHODS AND MATERIALS

Experimental Design. The experiment was a completely randomized design with four aspen genotypes, two levels of soil nutrients, and three levels of defoliation. Each combination of aspen genotype, nutrient availability, and defoliation (24 treatment combinations) was replicated with four independent saplings in a fully factorial design (a total of 96 saplings).

Aspen Clonal Material, Propagation and Growth Conditions. The four experimental genotypes represent a range of low to high levels of constitutive resistance (Hwang and Lindroth, 1997, 1998). Responses of the genotypes to nutrient availability and damage were unknown. The genotypes originated from root material collected from several sites in south-central Wisconsin (Hwang and Lindroth, 1997). Genotypes A, B, C, and D correspond to Wau 1 (Waushara County), Dan 1 and 2 (Dane County), and Sau 3 (Sauk County), respectively, of Hwang and Lindroth (1997). Root material for use in this study was obtained from saplings maintained for several years in a common garden on the University of Wisconsin–Madison campus.

The four aspen genotypes were propagated from root cuttings (as in Hwang and Lindroth, 1997) in summer 1996. Suckers were planted in 1-liter pots and grown outside until leaf drop in autumn 1996. Saplings were bare-rooted and overwintered in moist peat moss at 4°C. In the spring of 1997, saplings were potted individually in 16-liter pots containing a 7:3 mixture of sand and local field soil (silt loam). To manipulate nutrient availability, Osmocote 8–9 month slow release fertilizer (18:6:12 N-P-K + micronutrients) was added at a rate of 3.5 g/liter to high-nutrient pots; low nutrient pots received no fertilizer. Saplings were watered and maintained throughout the summer of 1997. In the spring of

1998, high-nutrient plants were treated (top dressed) for a second time with the same dose of fertilizer as used previously.

Artificial Damage. Saplings were defoliated May 14, 1998, to coincide with the period when attack by outbreaking herbivores, such as young gypsy moth or forest tent caterpillars, would be expected. The goals of our simulated herbivore feeding were to remove leaf area to produce carbon stress (mimicking leaf area removed by feeding) and to maximize damage along the cut edge [assuming the cue for induction would come from the remaining damaged portion of the leaf (Mattson and Palmer, 1988)]. To accommodate both goals, leaves were cut across the mid-rib near the base of the leaf. This procedure removed 90% of the area of each leaf damaged, yet produced a long cut edge. Herbivore damage was simulated using hair-thinning shears, which produce a more ragged cut than regular shears. The damage treatment had three levels: 0, 25, and 75% of the leaves on a plant damaged. Within each branch, leaf plastochron index 1, 2, 3, or 4 was chosen randomly as the starting point. In the 25% damage treatment, every fourth leaf from the starting point was damaged, and in the 75% damage treatment, every fourth leaf from the starting point was skipped.

Although studies have shown that mechanically damaged foliage is not always of identical quality to herbivore-damaged foliage (Baldwin, 1990; Hartley and Lawton, 1991), we chose to artificially damage our saplings for several reasons. First, artificial damage can be inflicted more uniformly across genotype and nutrient treatments than can damage by free-feeding insects. For example, we knew from previous studies that the well-defended genotype used in this study (genotype D) is extremely unpalatable to herbivores (Hwang and Lindroth, 1997, 1998) and that it would not be possible to inflict a uniform amount of insect damage among the replicates of this genotype. Second, free-feeding insects would likely feed selectively on the best foliage, leaving the poorer foliage for insect bioassays and chemistry collections. Such experimental artifacts would falsely indicate induction. Finally, a recent study with hybrid poplar (Havill and Raffa, 1999) showed that artificial damage and damage from feeding herbivores generated foliage of statistically similar quality for gypsy moths. Moreover, it showed that genotypes that responded to any induction stimulus (artificial damage or gypsy moth damage) were likely to respond similarly to others, that is, no genotype $\times$ elicitor type interaction was found.

Rationale for Magnitude of Treatments Applied. For the test of genotypic variation, we chose genotypes that span the known range of resistance against foliar-feeding Lepidoptera such as the gypsy moth, forest tent caterpillar, big poplar sphinx moth, and Canadian tiger swallowtail. Thus, our aspen genotypes represented a range of low (genotype A), moderate (genotypes B and C), and high (genotype D) levels of phenolic glycosides (Hwang and Lindroth, 1997). Likewise, for our nutrient treatment we applied levels that span the range from very poor growth (our low nutrient level) to optimal growth without overfertilization (our

high nutrient level) (Hemming and Lindroth, 1999). The nutrient levels we used produced 2.5-fold variation in size after one year (based on an index of height $\times$ basal diameter^2). Foliage of low-nutrient plants was more yellow, although not chlorotic, when compared to the deep green foliage of high-nutrient plants (Osier, personal observation). For the defoliation experiment, we used levels that span the range of defoliation experienced by aspen in the field (control, minimal damage without substantial carbon stress, and severe damage) as recommended by Neuvonen and Haukioja (1985). *Populus* species can withstand 25% defoliation (our low level) with no growth inhibition, whereas $\geq$75% defoliation (our high level) results in carbon stress and growth loss (Hodson, 1981; Bassman et al., 1982; Reichenbacker et al., 1996).

Insect Bioassays. To match the phenology of the larvae and foliage of the experimental saplings, bioassays began on May 24 (approximately four weeks after budbreak and 10 days after defoliation). At this time, the foliage was of appropriate age and toughness (fully expanded and nearly fully mature) for fourth stadium gypsy moths. Fourth instars were used in bioassays because responses to phytochemistry of this developmental stage are representative of much of the larval developmental period (Lindroth and Bloomer, 1991; Hwang and Lindroth, 1997; Hemming and Lindroth, 1999). Due to quarantine restrictions, bioassays were conducted using excised foliage in Percival growth chambers within the University of Wisconsin Biotron. Growth chambers were maintained at a 15L:9D photoperiod and 25/10°C to simulate early summer conditions in Madison, Wisconsin (National Climatic Data Center).

Gypsy moth egg masses were provided by USDA-APHIS (Otis Air National Guard Base, Massachusetts). Egg masses were surface sterilized in a solution of 0.1% sodium hypochlorite with 1% Tween 80 (Sigma, St. Louis, Missouri) as a surfactant. All larvae were reared on aspen foliage known to contain low concentrations of plant secondary compounds until the end of the third stadium. Upon molting into the fourth stadium, larvae were assigned randomly among the treatments. To reduce the potential of bias due to loss of experimental cells, multiple larvae (subsamples) were reared on foliage from each of the four replicate saplings per treatment combination: three larvae were reared per sapling for genotypes A, B, and C, and six larvae per sapling for genotype D (more larvae were used per sapling for genotype D because of anticipated mortality due to high levels of constitutive resistance). Because the sapling served as the experimental unit, average performance of each group of larvae reared on foliage from a particular sapling was used for statistical analysis. To control for the effects of leaf age in insect bioassays and chemistry collections, we collected foliage from only the initial leaf flush (which comprises >95% of available leaves in the spring) and avoided new leaves at indeterminately growing shoot tips. Foliage was removed in a haphazard manner from the remaining undamaged foliage located on the upper third of each sapling. To maintain leaf turgor and freshness, floral waterpiks were

used and foliage was changed at least every three days; treatment of foliage in this way has been shown to maintain foliar concentrations of aspen compounds important for insect feeding (Lindroth, unpublished data).

Larvae for use in the bioassays were restricted to females because with the experimental design employed (relatively low replication and minimal subsampling), there was a high probability of losing experimental cells due to nonuniform distribution of gender across replicates (i.e., all males or females on a sapling). Gender of newly molted fourth-instar larvae was determined by use of known weight distributions from previous studies. This approach was highly successful, as $>95\%$ of the larvae used in the experiment were females. At the conclusion of each bioassay, gender was definitively determined by inspection of the genital pores of the fifth stadium larvae. Males were removed from the study.

Final larval mass, stadium duration, and consumption were recorded for the fourth stadium. Herbivore relative growth rate (RGR) and efficiency of conversion of ingested food to biomass (ECI) were calculated as in Waldbauer (1968). Calculation of relative growth rate was modified to use initial biomass rather than average biomass as the relative term (Farrar et al., 1989).

Chemical Analyses. Foliage was collected from experimental saplings on May 29, 1998, two weeks after defoliation and approximately midway through the insect bioassays. Fifteen leaves were collected per sapling by snipping leaves cleanly at the petioles; removing leaves in this way has been shown not to induce a response from the ramet (Mattson and Palmer, 1988). After removal, leaves were transported to the laboratory in plastic bags on ice, flash-frozen in liquid nitrogen, freeze-dried in a cooled specimen chamber (-10°C), ground through 40 mesh in a Wiley mill, and stored at -20°C until analysis. Treatment of aspen leaf material in this manner preserves labile compounds such as phenolic glycosides (Lindroth and Koss, 1996).

Percent water was determined gravimetrically, by the ratio of leaf dry mass to fresh mass. To measure nitrogen levels, Kjeldahl acid digestions were conducted using the method of Parkinson and Allen (1975), followed by nitrogen quantification using the micro-Nesslerization method of Lang (1958). Glycine *p*-toluene-sulfonic acid (5.665% nitrogen) was similarly digested and served as the standard. Condensed tannins were exhaustively extracted from leaf tissue in 70% acetone at 4°C (with 10 mM ascorbic acid as an antioxidant). To quantify condensed tannins in the extract, we used the butanol–HCl method of Porter et al. (1986). As the standard, we used condensed tannins purified from aspen by the method of Hagerman and Butler (1980). Concentrations of phenolic glycosides were determined by high performance thin-layer chromatography as described by Lindroth et al. (1993). Salicortin and tremulacin purified from aspen leaves served as standards. Starch was determined by the enzymatic method of Schoeneberger et al. (unpublished method).

Statistical Analyses. The effects of aspen genotype, soil nutrient availability, defoliation, and their interactions on aspen phytochemistry and insect performance data were analyzed using fixed-effects analysis of variance [PROC MIXED, Version 8 (SAS Institute, 1989)] with a completely randomized design. Critical α was 5% for this study. When subsampling was used (i.e., multiple insects reared per sapling), a mean was generated so that the unit of replication was the sapling ($N = 4$). We did not use analysis of covariance for the analysis of herbivore performance parameters, contrary to the recommendation of Raubenheimer and Simpson (1992). Because of the subsampled nature of this design, variation in initial larval weights among saplings was very low after generating means within saplings. Therefore, ANCOVA was not used, as specified by the model fitting guidelines of Littell et al. (1996).

To relate gypsy moth performance to quantitative variation in aspen phytochemistry, we used stepwise multiple regression [PROC REG, Version 8 (SAS Institute, 1989)]. Stepwise regression in SAS uses a combination of forward selection ($\alpha = 0.10$) and backward elimination ($\alpha = 0.10$) to fit a model. We used group means for each defoliation × genotype × nutrient combination ($N = 24$). To illustrate the relative proportion of variance explained by individual independent variables (phytochemicals), the contributions of individual coefficients of determination (partial R^2) to the total (R^2) are described when applicable. This is a valid approach in multiple regression when independent variables (phytochemical concentrations) in the model are not intercorrelated (Sokal and Rohlf, 1995). This was the case for the phytochemicals related with insect relative growth rate and final mass in this study (Table 1 and Table 3). To investigate relationships among phytochemicals and between constitutive and induced levels of plant secondary compounds, we used correlation analyses [PROC CORR, Version 8 (SAS Institute, 1989)].

TABLE 1. CORRELATION MATRIX OF RELATIONSHIPS AMONG ASPEN PHYTOCHEMICALS FROM 24 COMBINATIONS OF PLANT GENOTYPE, NUTRIENT AVAILABILITY, AND DEFOLIATION[a]

	Phenolic glycosides		Condensed tannins		Nitrogen		Starch	
	r	*P*	*r*	*P*	*r*	*P*	*r*	*P*

Water	−0.649	<0.001	−0.410	0.046	0.700	<0.001	0.164	0.442

[a] Pearson product–moment correlations are based on the mean values for each treatment.

RESULTS

Phytochemistry. Concentrations of both secondary and primary metabolites were universally affected by plant genotype and soil nutrient availability and in some cases were influenced by defoliation (Figures 1 and 2). Significant interactions among the factors were generally uncommon. Foliar concentrations of plant secondary metabolites (phenolic glycosides and condensed tannins) responded differently to the treatments (Figure 1). Phenolic glycoside concentrations were highly variable among genotypes and were slightly higher under conditions of high nutrient availability, but were unaffected by defoliation (Figure 1). Phenolic

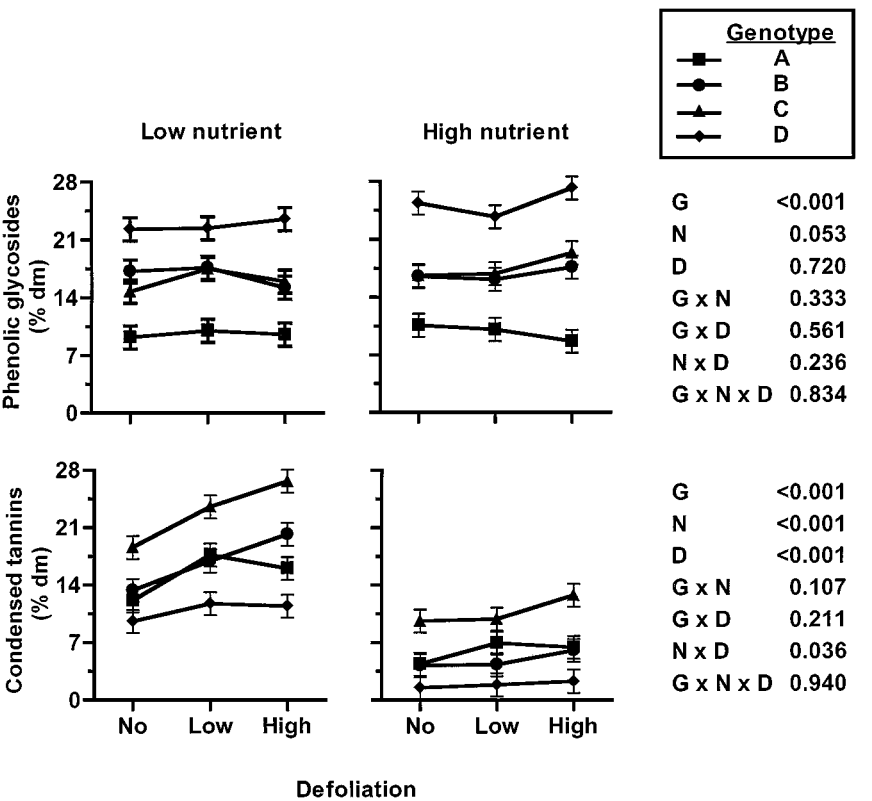

FIG. 1. Norm of reaction plots for phenolic glycoside and condensed tannin concentrations of aspen foliage in relation to nutrient availability and defoliation. *P* values indicate the results of three-way ANOVA: genotype (G) $df = 3$; nutrient availability (N) $df = 1$; defoliation (D) $df = 2$; G × N $df = 3$; G × D $df = 6$; N × D $df = 2$; G × N D $df = 6$. Each line represents a single aspen genotype. Vertical lines represent 1 standard error (calculated based on the pooled variance) of the mean.

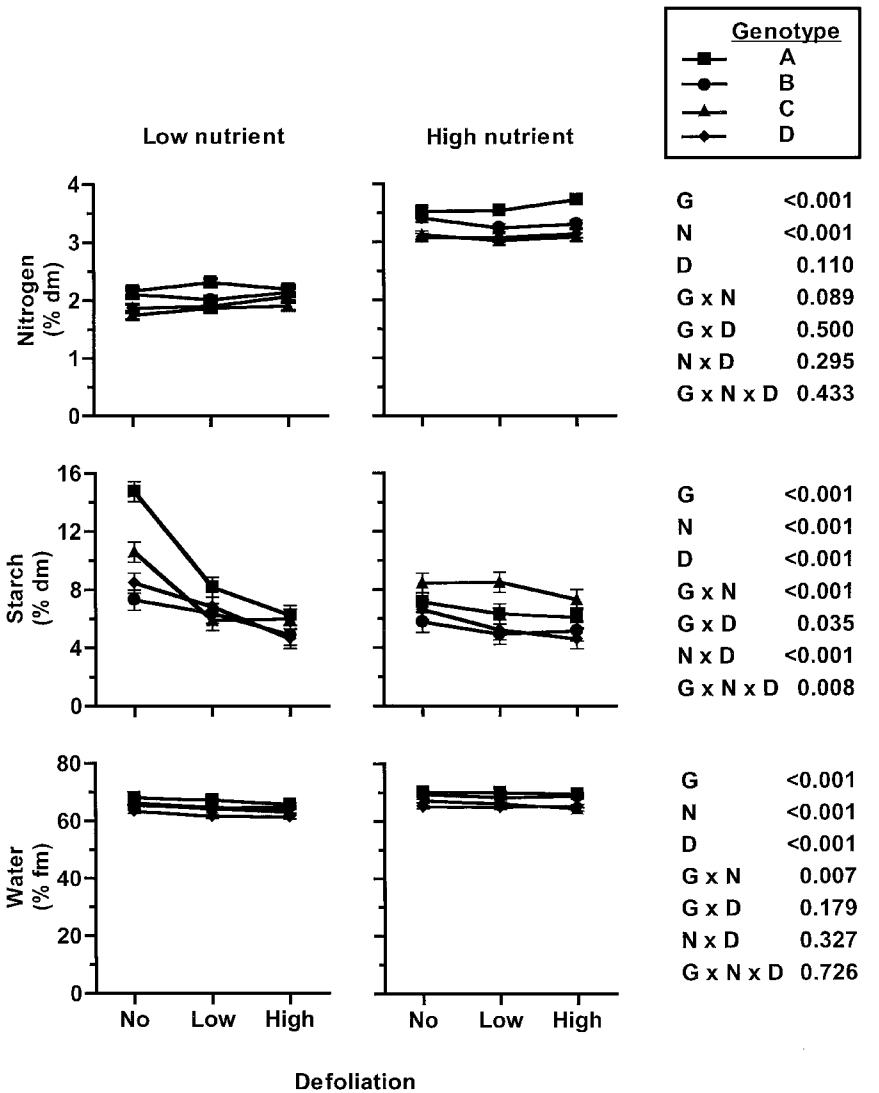

FIG. 2. Norm of reaction plots for foliar nitrogen, starch, and water concentrations of aspen foliage in relation to nutrient availability and defoliation. Format as in Figure 1.

glycoside concentrations were strongly dependent upon aspen genotype, which accounted for 93% of the variation explained (Figure 3). In contrast, concentrations of condensed tannins were strongly affected by all three treatments (Figure 1). Tannin concentrations averaged 1.8-fold higher under low nutrient availability and

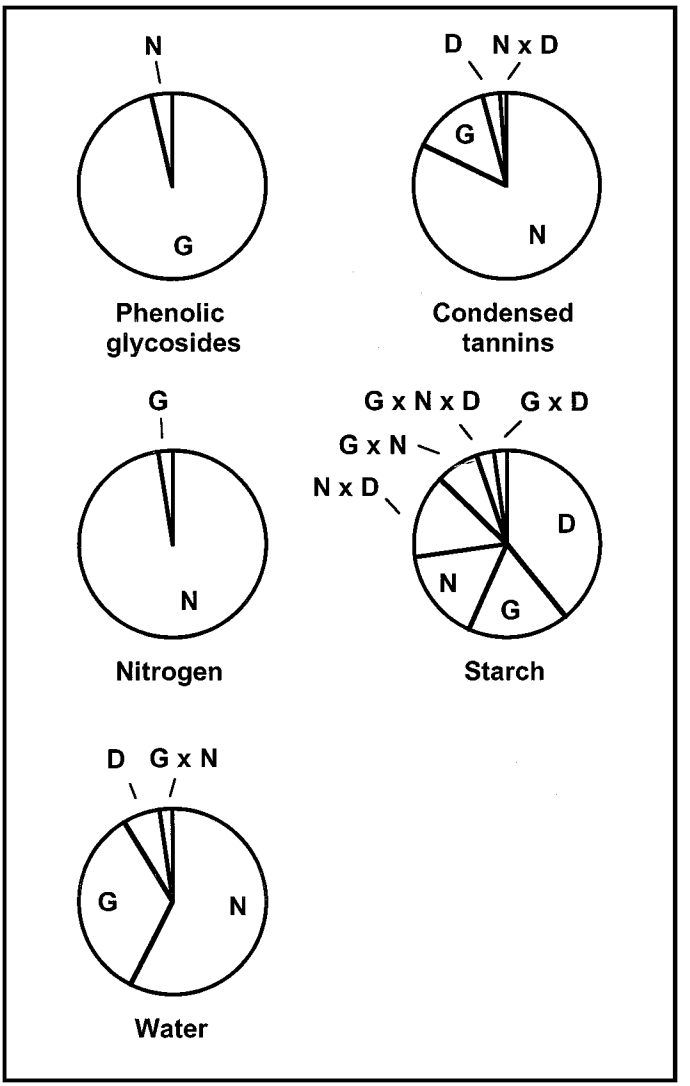

FIG. 3. Proportion of "explained variation" in relation to aspen genotype (G), nutrient availability (N), defoliation (D), and their interactions for phytochemical variables. For each variable, experimental treatments and interactions are ranked in decreasing order (clockwise from 12 o'clock) of the proportion of variation explained. Proportion of "explained variation" was calculated as: mean square for each treatment/total mean square explained. For the sake of clarity, only variation due to significant parameters is shown (in all cases variation due to nonsignificant factors was $<1\%$ of the total).

TABLE 2. CORRELATIONS BETWEEN INDUCED LEVELS OF CONDENSED TANNINS AND CONSTITUTIVE RESISTANCE (CONDENSED TANNINS, PHENOLIC GLYCOSIDES, OR THEIR COMBINATION) UNDER LOW AND HIGH NUTRIENT AVAILABILITY[a]

	Induced levels of tannins under the experimental treatments							
	Low damage, Low nutrient		Low damage, High nutrient		High damage, Low nutrient		High damage, High nutrient	
Constitutive levels	*r*	*P*	*r*	*P*	*r*	*P*	*r*	*P*
Condensed tannins	0.566	0.435	−0.132	0.867	0.914	0.086	0.973	0.027
Phenolic glycosides	0.968	0.032	−0.682	0.318	−0.311	0.689	−0.621	0.379
Combined	0.572	0.428	−0.826	0.174	0.328	0.672	−0.087	0.913

[a] Pearson product–moment correlations are based on a mean value per treatment ($N = 4$ clones).

were induced by defoliation. In addition, the effect of defoliation was influenced by nutrient availability; condensed tannins were more strongly induced under conditions of low nutrient availability. Soil nutrient availability accounted for the greatest amount of the variation (82%) among treatments, whereas plant genotype, defoliation, and the nutrient × defoliation interaction accounted for only 13, 3, and 1% of the variation, respectively (Figure 3). Under conditions of low damage, induced levels of condensed tannins related positively to phenolic glycosides (low nutrient availability) (Table 2). Under conditions of severe damage, however, induced levels of tannins related positively to constitutive levels of tannins (Table 2).

Similar to the secondary metabolites, patterns of responses of primary metabolites varied among the treatments (Figure 2). Foliar nitrogen was minimally variable among the genotypes and increased 1.4-fold with nutrient addition, but was not affected by defoliation (Figures 2 and 3). Foliar concentrations of starch were variable among genotypes and reduced by nutrient addition and defoliation. Although all factors interacted significantly, the magnitude of the defoliation effect was reduced dramatically by high nutrient availability for some genotypes (Figures 2 and 3). Concentrations of foliar water were significantly affected by plant genotype, soil nutrient availability, and defoliation, but the magnitude of variation in response to these treatments was small compared to that of the other phytochemicals measured (Figure 1).

Insect Performance. Plant genotype and nutrient availability affected all gypsy moth performance parameters, whereas defoliation affected only herbivore relative growth rate (Figures 4 and 5). Insect relative growth rate was strongly affected by aspen genotype, which accounted for the greatest proportion (78%) of the variation (Figures 4 and 6). Nutrient availability, although highly significant, had less of an effect on growth rate than did plant genotype (Figures 4 and 6). Larvae grew faster feeding on foliage from the high-nutrient treatment, and this effect depended upon plant genotype (Figure 4). Relative growth rates were weakly

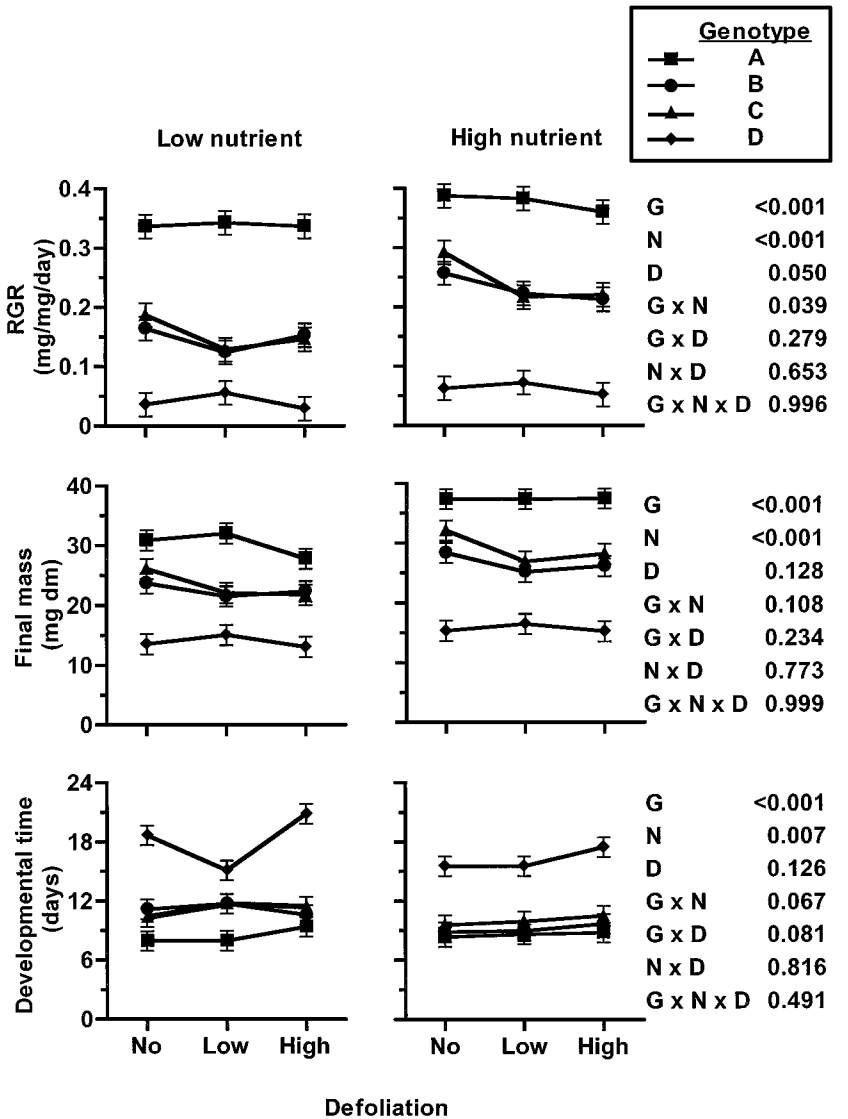

FIG. 4. Norm of reaction plots for gypsy moth relative growth rate, final mass, and developmental time in relation to nutrient availability and defoliation. Format as in Figure 1.

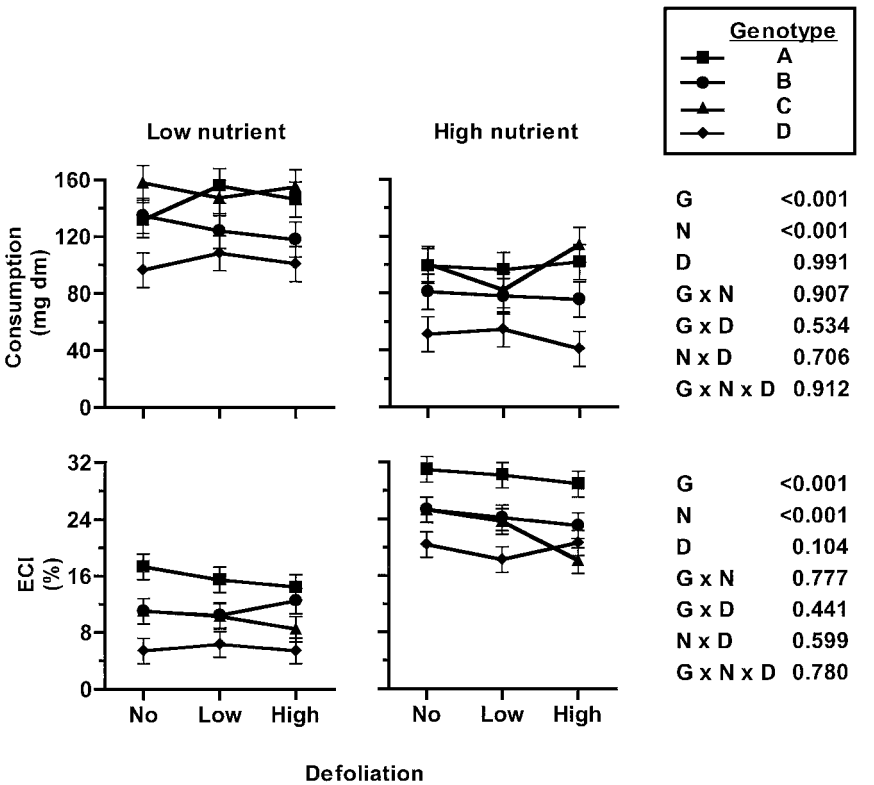

FIG. 5. Norm of reaction plots for gypsy moth consumption and utilization efficiency in relation to nutrient availability and defoliation. Format as in Figure 1.

affected by the defoliation treatments; insects feeding on defoliated plants grew more slowly than did those feeding on undamaged plants (Figure 4). Treatment effects on the dry mass of newly molted fifth-stadium larvae and on developmental time paralleled those of relative growth rate, except that a defoliation effect was not observed (Figures 4 and 6). Food consumption by larvae varied among the aspen genotypes and increased an average of 1.6-fold under low nutrient availability. Consumption was not, however, affected by defoliation treatment (Figures 5 and 6). Similarly, the efficiency of conversion of ingested food to biomass (ECI) was moderately affected by aspen genotype, enhanced by high nutrient availability, and unaffected by defoliation (Figures 5 and 6).

Relationship of Herbivore Performance to Phytochemistry. Stepwise regressions indicate that gypsy moth performance was related to concentrations of a number of phytochemicals; these correlations accounted for a large proportion of

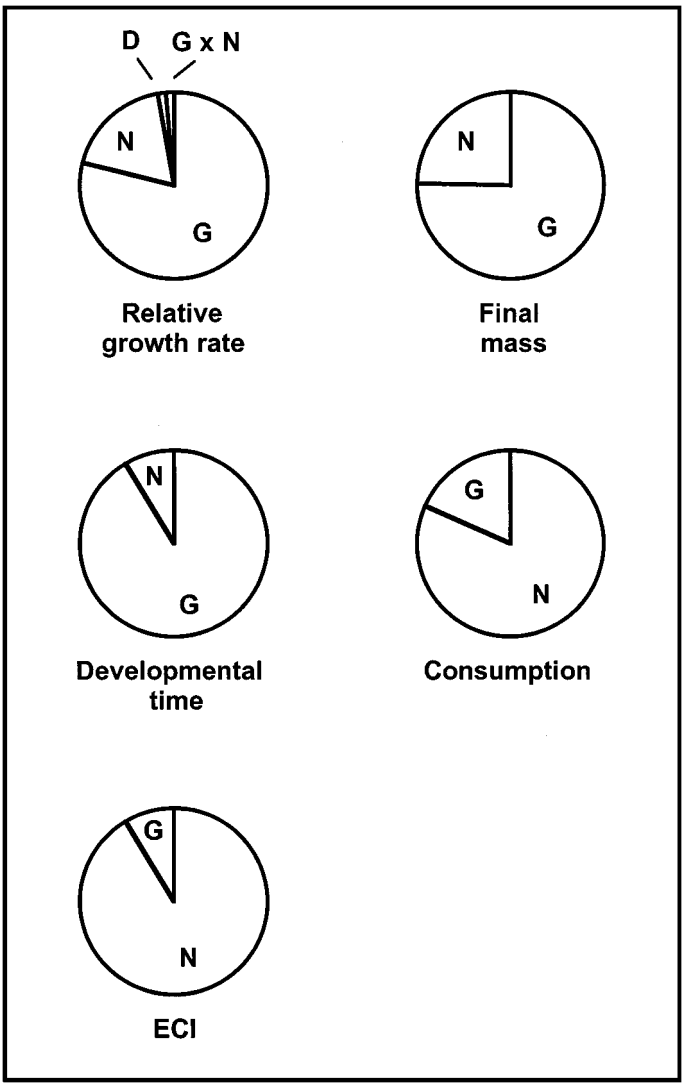

FIG. 6. Proportion of "explained variation" in relation to aspen genotype (G), nutrient availability (N), defoliation (D), and their interactions for insect performance variables. For each variable, experimental treatments and interactions are ranked in decreasing order (clockwise from 12 o'clock) of the proportion of variation explained. Proportion of "explained variation" was calculated as: mean square for each treatment/total mean square explained. For the sake of clarity, only variation due to significant parameters is shown (in all cases variation due to non-significant factors was $<1\%$ of the total).

TABLE 3. PHYTOCHEMICAL COMPONENTS ACCOUNTING FOR VARIATION IN GYPSY MOTH PERFORMANCE[a]

	Regression model			Partial regression components		
Parameter	Equation	R^2	P	Variable	R^2	P
Relative growth rate	$Y = 0.27 - 0.02(PG) + 0.07(N) + 0.01(S)$	0.957	<0.001	PG	0.818	<0.001
				N	0.128	<0.001
				S	0.012	0.030
Final dry mass	$Y = 33.34 - 1.19(PG) + 4.39(N)$	0.931	<0.001	PG	0.782	<0.001
				N	0.149	<0.001
Developmental time	$Y = 74.18 + 0.19(PG) - 0.97(W) - 0.18(CT)$	0.834	<0.001	PG	0.731	<0.001
				W	0.063	<0.020
				CT	0.040	<0.039
Consumption	$Y = 177.31 + 2.28(CT) - 2.70(PG) - 18.79(N)$	0.905	<0.001	CT	0.781	<0.001
				PG	0.083	0.002
				N	0.041	0.008
ECI	$Y = -92.10 + 7.59(N) + 1.35(W)$	0.964	<0.001	N	0.872	<0.001
				W	0.092	<0.001

Partial regression components for developmental time, consumption and ECI should be interpreted with caution due to intercorrelation of independent variables (see *Statistical Analyses* section).

[a] Stepwise multiple regressions, $\alpha = 0.10$ was used as the criterion for acceptance to, or rejection from, the model. CT = condensed tannins, N = nitrogen, PG = phenolic glycosides, S = starch, W = water.

the total variation in herbivore performance (Table 3). Relative growth rates were related negatively to foliar phenolic glycoside concentrations and positively to foliar nitrogen and starch concentrations (Table 3, Figure 7). Quantitative variation in these three types of compounds explained 96% of the among-treatment variation in relative growth rate (Table 3). Variation in phenolic glycoside concentrations explained a much greater proportion of the total variation in relative growth rate (82%) than did nitrogen (13%) or starch (1%). As was the case for relative growth rate, insect final mass was related negatively to phenolic glycoside concentrations and positively to nitrogen concentrations, explaining a total of 93% of variation (Table 3). Developmental time of gypsy moths was positively related to phenolic glycosides and negatively related to water and condensed tannin concentrations. These three foliar constituents accounted for a total of 83% of the variation in developmental time, and phenolic glycosides appeared most important (Table 3). Insect consumption was related positively to concentrations of condensed tannins and negatively to concentrations of phenolic glycosides and nitrogen. These three variables explained a total of 90% of the variation in insect consumption (Table 3). Two variables, nitrogen and water, explained 96% of the variation in insect growth efficiency (ECI; Table 3).

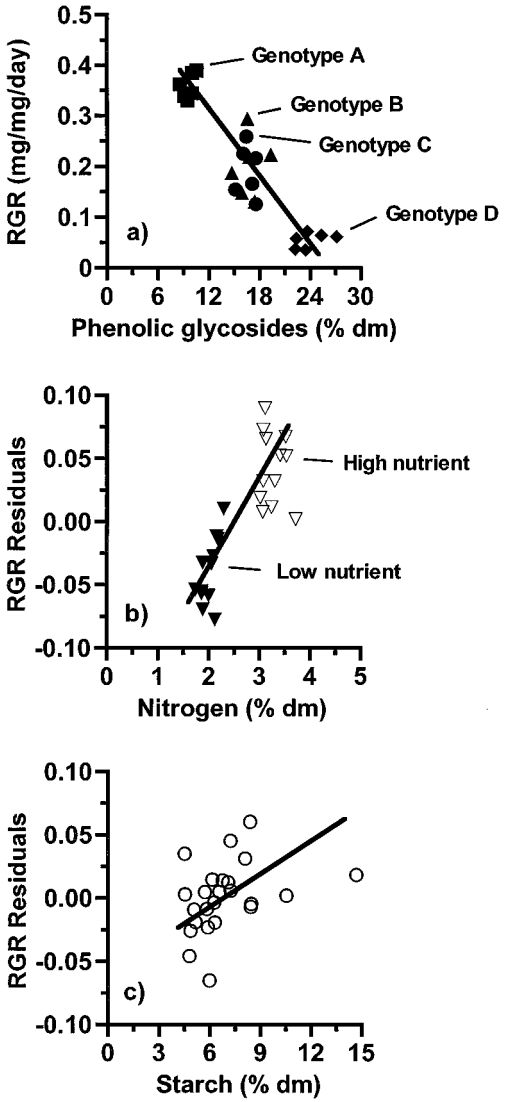

FIG. 7. Relationship of gypsy moth growth to concentrations of phytochemicals implicated as important by stepwise regression analyses. (a) The relationship of relative growth rate to phenolic glycoside concentrations; (b) the variation in relative growth rate unexplained by phenolic glycosides (residuals) plotted against foliar nitrogen concentrations; and (c) the variation in relative growth rate unexplained by both phenolic glycosides and nitrogen plotted against foliar starch concentrations.

To highlight how variation in phytochemical concentrations related to experimental treatments and likely determined patterns of herbivore performance, we present a series of figures illustrating results of the regression analyses for a single performance parameter (Figure 7). Insect relative growth rate was strongly and negatively related to phenolic glycoside concentrations. Variation in phenolic glycoside concentrations (along the *x* axis) is largely associated with aspen genotype (Figure 7a). A plot of the residuals (unexplained variation) from the first regression analysis versus nitrogen concentrations reveals a strong positive relationship (Figure 7b). Data points along the *x* axis are no longer grouped by genotype, but by nutrient availability, suggesting that soil nutrient availability is driving much of the variation in nitrogen concentrations. Finally, the remaining residuals are weakly and positively related to starch concentrations (Figure 7c). Variation in starch was affected by all treatments and their interactions, so position along the *x* axis is not clearly dominated by one or a combination of these.

DISCUSSION

Phytochemistry. Plant genotype, soil nutrient availability, and defoliation treatments affected phytochemical concentrations, although the magnitude and direction of responses to these treatments differed among chemical constituents. Aspen genotype was responsible for most of the variation in phenolic glycoside concentrations, while nutrient availability had a secondary effect. Nutrient addition resulted in a slight, but significant, increase in concentrations of phenolic glycosides. Such a response is not consistent with the predictions of the carbon–nutrient balance hypothesis (Bryant et al., 1983), growth–differentiation balance hypothesis (Herms and Mattson, 1992), or the protein competition model of phenolic allocation (Jones and Hartley, 1999). That phenolic glycosides responded positively to nutrient addition was unexpected given that in previous studies concentrations either responded as would be predicted (Hemming and Lindroth, 1999) or not at all (Kinney et al., 1997).

Condensed tannins responded most strongly to the nutrient treatment and were less influenced by plant genotype, defoliation, and the defoliation by nutrient interaction. As predicted by the carbon–nutrient balance hypothesis (Bryant et al., 1983), the growth–differentiation balance hypothesis (Herms and Mattson, 1992), and the protein competition model (Jones and Hartley, 1999), concentrations of condensed tannins were markedly lower under conditions of high nutrient availability. The short-term induction response of condensed tannins in our saplings is consistent with that of other studies using quaking aspen (Roth et al., 1998; Lindroth and Kinney, 1998). Furthermore, the induction response was ameliorated by the addition of nutrients. Such a pattern suggests a passive response due to altered carbon–nutrient balance, as demonstrated by Hunter and Schultz (1995)

for *Quercus prinus*, rather than an active defensive response on the part of the plant. Although the responses of tannins to nutrient addition accord with the predictions of the carbon–nutrient balance hypothesis, other phytochemical evidence suggests that the induction response is indeed an active response by the plant to defoliation, rather than a passive response driven by nutrient loss due to defoliation. The defoliated saplings appear to be under carbon (rather than nutrient) stress, indicated by the very low starch concentrations in these plants (as compared to undefoliated plants). The low carbon–nutrient ratios in the defoliated plants would predict low levels of tannins, rather than the dramatic increases observed.

The overall weak response of phenolic glycosides to environmental factors (both nutrient availability and defoliation) is consistent with other studies of aspen and is a striking contrast to the strong response of condensed tannins (Lindroth et al., 1993; Kinney and Lindroth, 1997; Roth et al., 1998; Hemming and Lindroth, 1999; Agrell et al., 2000). Although differences in environmental plasticity between phenolic glycosides and condensed tannins were striking, different suites of compounds within a plant can behave differently in response to environmental variability (Koricheva et al., 1998; Keinänen et al., 1999).

Although physiological responses to environmental conditions are important in determining allocation to phenolic glycosides and condensed tannins, allocation was found be largely genetically determined. The question arises as to what factors contribute to the maintenance, at the population level, of polymorphisms in concentrations of these secondary compounds. Polymorphisms in defensive allocation are likely driven, in part, by costs of production and storage (sensu Herms and Mattson, 1992). This appears to be the case with phenolic glycosides in quaking aspen, which are produced at a cost to growth (Osier and Lindroth, unpublished data). For condensed tannins, however, no ecological cost of production has been observed.

Trade-offs between constitutive defense and inducibility are considered as evidence that defenses are costly, although few such relationships have been demonstrated (Karban and Baldwin, 1997). In contrast to predictions, we found positive relationships between damage-induced changes in condensed tannins and constitutive levels of secondary metabolites under several nutrient–defoliation regimes. This is especially true for plants that were severely defoliated, as plants that had the highest constitutive levels of tannins also exhibited the strongest induced response. Our results differ from two other studies that reported negative correlations between induced and constitutive levels of phenolics in poplars. Mattson and Palmer (1988) reported a negative relationship between induced and constitutive levels of total phenolics in aspen clones with high levels of total phenolics, although a strong negative relationship was not observed across the entire range of genotypes used in that study. Nef (1988) found a negative relationship between induced and constitutive levels of total phenolics for three poplar hybrids. Both of these studies suggest that a negative relationship between induced and constitutive resistance

should be expected in aspen, but our results are strongly contradictory. One difference between our work and that of other researchers is that previous studies relied upon the method of Folin and Denis (1912), which measures not only "total phenolics," but also other compounds (e.g., reducing sugars) not quantified in our study.

Foliar nitrogen varied primarily in response to nutrient availability. Responses accorded well with predictions of the carbon–nutrient balance hypothesis (Bryant et al., 1983), as has been shown previously for aspen (Kinney and Lindroth, 1997; Hemming and Lindroth, 1999). Also similar to previous work (Hwang and Lindroth, 1997, 1998; Osier et al., 2000), foliar nitrogen varied among genotypes, although not dramatically so. Foliar starch concentrations decreased as a result of both nutrient addition and defoliation, as predicted by the carbon–nutrient balance hypothesis (Bryant et al., 1983; Tuomi et al., 1988). Moreover, the effect of defoliation was dependent upon nutrient availability; plants stressed by low nutrient availability experienced the greatest decrease in starch concentrations. Foliar water concentration was affected by plant genotype, soil nutrient availability, defoliation, and the interaction of genotype and nutrient availability. Although foliar water is important for herbivores (Scriber and Slansky, 1981), the variation in this study was small and unlikely to affect herbivore performance.

Herbivore Performance. Gypsy moth relative growth rates were most strongly affected by aspen genotype, less so by nutrient availability, and only minimally by defoliation and the interaction of genotype and nutrient availability. That plant genotype had a large effect on relative growth rates was not surprising, given that differences among aspen genotypes have been found to have similar effects in previous studies (Hemming and Lindroth, 1995; Hwang and Lindroth, 1997, 1998; Osier et al., 2000). Although the effect of genotype was expected to be strong, its magnitude far exceeded that of the environmental treatments. As expected, insects performed better on fertilized plants. The pattern for herbivore final dry mass and developmental time closely followed the pattern for herbivore relative growth rate, except there was no defoliation main effect and the effect of soil nutrient availability did not depend upon genotype.

Phenolic glycoside concentrations were implicated as the primary determinant of host quality; insects feeding on foliage from saplings containing high concentrations of phenolic glycosides took longer to develop and attained a lower final mass, as has been found previously (Hemming and Lindroth, 1995; Hwang and Lindroth, 1997, 1998; Osier et al., 2000). Studies in which purified phenolic glycosides were added to either foliage or artificial diet confirm the role of phenolic glycosides in altering host quality (Lindroth and Hemming, 1990; Hemming and Lindroth, 1995). In addition to phenolic glycosides, variation in nitrogen concentrations (due primarily to nutrient treatment) provided explanatory power for herbivore growth rate and final mass. This result is not surprising given the variation in nitrogen levels observed and that such variation is an important

determinant of insect performance (Mattson, 1980; Scriber and Slansky, 1981; Slansky, 1993).

Food consumption by gypsy moths was most dramatically influenced by nutrient availability. As is commonly observed (Mattson, 1980), larvae fed in a compensatory manner on the poorer quality foliage in the low-nutrient treatment. Although little evidence exists for aspen condensed tannins functioning as feeding deterrents or toxins to insects (Lindroth and Hwang, 1996), high concentrations of these compounds may have diluted nutrients and led to compensatory feeding. This response has been found previously (Osier et al., 2000) for condensed tannins in aspen and is similar to the response of insects to indigestible dietary components such as cellulose (Slansky, 1993). Larvae fed less on foliage containing high levels of phenolic glycosides and nitrogen, likely due to their feeding deterrent and nutritive properties, respectively. Although less important than nutrient availability, the magnitude of the genotype effect on consumption was similar to that observed previously for insects reared on aspen (Hwang and Lindroth, 1997, 1998). Insects fed foliage grown under low nutrient availability were much less efficient in converting food to body mass than were insects fed foliage from high-nutrient plants. As expected, the larvae were most efficient at converting ingested food to biomass when foliage contained high concentrations of nitrogen and water (Mattson, 1980; Scriber and Slansky, 1981; Slansky, 1993). Surprisingly, and in contrast to earlier research (Hwang and Lindroth, 1997), phenolic glycosides were not implicated as determinants of gypsy moth growth efficiency in this study. The absence of relationships may, in part, be a statistical artifact. Foliar water concentrations related strongly and negatively to those of phenolic glycosides (Table 1), and water may have served as a proxy for phenolic glycosides in the regression model.

The lack of a substantial damage-induced change in food quality was surprising given the importance of induced responses in many other systems (Karban and Baldwin, 1997). Absence of an effective induction response may explain why aspen forests are susceptible to outbreaks of spring-feeding insects such as gypsy moths, forest tent caterpillars (*Malacosoma disstria*), and large aspen tortrix (*Choristoneura conflictana*). Even though the defoliation treatment did not appear to markedly affect gypsy moth performance, we note that the aspen saplings did respond with a rapid induction of condensed tannins. This response may confer resistance against other types of enemies such as browsing mammals or pathogens at the site of wounding. Additionally, the possibility exists that extended duration of defoliation or repeated defoliation may alter the induction response observed (Karban and Baldwin, 1997). Other unpublished work with aspen, however, suggests that repeated defoliation (D. Parry, personal communication) or defoliation in the previous year (Osier and Lindroth, unpublished data) produces responses similar to those in this study.

Relative Importance of Plant Genotype and Environment. Results from other studies that compare the relative roles of plant genotype and environmental

conditions have implicated either genotype (Abrahamson et al., 1988; Hakulinen et al., 1995; Horner and Abrahamson, 1999) or environment (Orians and Fritz, 1996; Rossi and Stiling, 1998) as primary causes of variation important for herbivores. Studies with *Salix sericea* (another member of the Salicaceae) found results very different than ours; genotype was of relatively little importance compared to soil nutrient availability in determining the abundance of a suite of herbivores in the field (Orians and Fritz, 1996). Employing an experimental design similar to ours, a study with *Betula pendula* determined that fertilization explained most of the variation in insect performance and plant genotype explained less (Mutikainen et al., 2000). As with our study, however, defoliation (a delayed induced response) was relatively unimportant for insect feeding.

In addition to highlighting the importance of plant genotypic variation, our study revealed few interactions between genotype and environment for phytochemicals important for insect herbivores. The paucity of interactions between genotype and environment in our study is not surprising, given that such interactions have rarely been found to play a major role in other systems (Houle and Simard, 1996; Stiling and Rossi, 1996; but see also Horner and Abrahamson, 1999).

Because the relative strength of each treatment applied is important when attempting to rank treatment types, we endeavored to apply levels of each treatment that were biologically realistic and of comparable strength to the other treatments (see Methods and Materials). Even when environmental treatments were pushed nearly to extremes, environment and genotype $\times$ environment interactions were markedly less important than genotype in this study. Our results suggest that patterns of insect performance among aspen clones in the field are likely due to genetic variability rather than to environmental heterogeneity in nutrient availability or defoliation.

Acknowledgments—This research was supported by USDA NRI Competitive Grant 95-37302-1810 and UW Hatch Project 3931 to R.L.L. We thank Michelle Arnold, Brian Kopper, Sarah Wood, and Patrick Koss for technical assistance. Lynn Hummel and Laura Van Slyke provided invaluable assistance at the Walnut Street greenhouses. Thanks to Jen Klug for comments on the manuscript, Rick Nordheim for statistical advice, and Gary Bernon for providing gypsy moth eggs.

IMPORTANCE OF BACTERIAL DECOMPOSITION AND CARRION SUBSTRATE TO FORAGING BROWN TREESNAKES

S. M. JOJOLA-ELVERUM, J. A. SHIVIK, and L. CLARK*

United States Department of Agriculture
Animal and Plant Health Inspection Service, Wildlife Services

(Received October 12, 2000; accepted March 6, 2001)

Abstract—Brown treesnakes are an invasive species to the island of Guam that have caused extensive ecological and economic damage. Efforts to control the snake population have included trapping using live mouse lures, but for logistical and economic reasons a synthetic lure is needed. When searching for live food, brown treesnakes use both visual and odor cues. However, when searching for carrion, odor cues are sufficient. Attempts to develop synthetic lures based on chemical reconstruction of the complex carrion odor have not succeeded. We provide evidence that a microbial–substrate interaction is important for bait take by brown treesnakes. Microbial cultures taken from mouse carrion indicate that *Enterobacter agglomerans* is the predominant bacterium, and field tests suggest that this organism may be important to odor production that attracts brown treesnakes. This information may prove useful in the development of microbial-based biological reactors that could be formulated to produce a continuous stream of odor of sufficient complexity so as to be attractive to foraging snakes.

Key Words—Bacteria, bait, *Boiga irregularis*, brown treesnake, carcass, carrion, decomposition, *Enterobacter agglomerans*, lure, odor, rot

INTRODUCTION

The brown treesnake (*Boiga irregularis*) was accidentally introduced to Guam in the 1940s or early 1950s (Savidge, 1987; Rodda et al., 1992). Since then the island's snake population has increased dramatically, at times reaching densities of 50–100 snakes/ha (Rodda et al., 1992). The ecological and economic effect of the

* To whom correspondence should be addressed.

0098-0331/01/0700-1315$19.50/0

snake has been devastating, ranging from power outages to extirpation of avifauna and herpetofauna (Savidge, 1984, 1987; Fritts et al., 1987; Conry, 1988; Engbring and Fritts, 1988; Rodda and Fritz, 1992a). Guam's importance as a shipping hub makes the spread of brown treesnakes from Guam a threat to other sensitive Pacific Island ecosystems (e.g., Fritts, 1988). As part of a containment policy, the U.S. Department of Agriculture employs a variety of methods to reduce the likelihood that brown treesnakes will be exported inadvertently from Guam. These methods include trapping, search dogs, and hand removal of snakes from fences during spotlight searches (U.S. Department of Agriculture, 1996).

Trapping is a highly effective method for removing snakes from an area (Rodda and Fritts, 1992b; U.S. Department of Agriculture, 1996; Engeman et al., 1998). However, since live mice are used as lures, this method involves substantial logistical effort in field and laboratory maintenance, which in turn limits the number of traps that can be employed, especially for large-scale operations (Fritts et al., 1989; Shivik and Clark, 1999a). As a consequence, considerable research effort has been invested in searching for artificial lures that would reduce reliance on live mice, and hence reduce the labor needed to carry out an effective control operation using traps.

For live prey, brown treesnakes attend to both visual and olfactory cues (Chiszar et al., 1988, 1993, 1997a; Fritts et al., 1989; Shivik, 1998; Shivik and Clark, 1999a). Presentation of a combination of cues from these modalities is necessary to produce the most intense investigatory and foraging behavior in brown treesnakes (Chiszar et al., 1997b; Shivik, 1998; Lindberg et al., 2000). Somewhat surprisingly, brown treesnakes also actively forage for carrion in the field, and the carrion's effectiveness for capture is only slightly less than that seen for live mice (Shivik, 1998; Shivik and Clark, 1997, 1999a,b; Shivik et al., 2000). However, most notable was the observation that chemosensory cues were predominantly critical to brown treesnakes when foraging for carrion. Thus, the potential for the synthesis of an inanimate chemical lure exists. Unfortunately, attempts to reconstruct an effective chemical lure based on the chemical analysis of mouse carrion has proved difficult and ineffective because of the chemical complexity of the carrion odor and the snakes' lack of a reaction to imperfect chemosensory cues (Clark, 1997; Shivik, 1998; Shivik and Clark, 1999a). In this study, we set out to better understand the source and nature of the attractive odor of carrion that would be helpful in the development of a bioreactor that would generate salient odors. Because the odor of carrion decomposition is largely a result of a substrate–bacterial interaction, we hypothesized that the most attractive odors to brown treesnakes would be generated from the surface of mice. We reasoned that knowledge about the appropriate nutrient substrate and the bacteria responsible for decomposition would be helpful in guiding us to construct biological (microbial) reactors.

METHODS AND MATERIALS

We conducted experiments in the Conventional Weapons Storage Area on Andersen Air Base near Tarague and Haputo beaches, Guam, in May and June 2000. The disappearance of dead neonatal mice (DNM) from PVC tubes (i.e., bait take) was used as an index of acceptance of carrion by snakes. Analysis of over 1000 hr of video tape indicates that brown treesnakes are almost exclusively the sole vertebrate responsible for the disappearance of baits (Clark, personal observation).

Prior to an experiment PVC tubes (10.1 × 30.5 cm) were cleaned with mild chlorine bleach solution (1:100 chlorine–water) and rinsed with water. Patches of vegetation where PVC tubes were placed were systematically divided by a grid of roads. These patches of vegetation were approximately 6–12 ha, depending upon the spacing of roads (Savarie et al., 2001). Following cleansing, PVC tubes were suspended from strings at heights of 1.5–2 m in shrubs and trees and linearly placed along the forest edge adjacent to roads at 20-m intervals. When multiple transects were set out on the same day, the minimum distance between transects was 50 m, separated by road. Previous studies showed that the probability of snakes traveling this or longer distances in a given night was low (Savarie et al., 2001), hence transects could be considered independent experimental units.

Each transect consisted of $k \cdot r$ PVC tubes, where k was the number of treatment levels and r was the number of blocks within a transect. The number of blocks within transects was constant across all experiments ($r = 10$). The k treatment levels were randomly ordered within each block, r, such that each of the treatment levels was represented once within each block. We used transect as the statistical experimental unit. For each treatment level, k, the dependent variable was calculated as the proportion of baits missing, i.e., the number of baits missing divided by $r = 10$. Thus, the number of replicates for comparisons among treatment levels, k, for any given experiment corresponded to the number of transects, N.

Our experiments addressed three broad biological questions. In the first set of experiments we evaluated how the stage of decomposition of dead mice affected bait take by snakes. In a second set of experiments we evaluated how different parts of decomposing mice influenced bait take by snakes. In a third set of experiments we evaluated whether microbial degradation of carrion affected bait take by snakes.

Set 1

Experiment 1: Importance of Decomposition of Carrion for Lure Attractiveness. The objective of this experiment was to determine the attractiveness of fresh (<24 hr old) whole dead neonatal mice relative to 1-day old (24–48 hr) whole dead neonatal mice. In the latter case, the mice were aged under natural conditions.

Subsequently, both sets of mice were placed in the field. This experiment consisted of two treatment levels ($k = 2$) with $r = 10$ blocks per transect ($N = 4$), for a total of 20 PVC tubes per transect ($k \cdot r$). PVC tubes were checked for presence or absence of baits after 24 hr. Following the experiment, we removed, cleaned, and placed PVC tubes in a new, isolated edge of forest in preparation for monitoring the next transect in the experiment. Patterns of bait take were analyzed using a *t* test, where treatment was the between-measures factor and the proportion of baits taken was the response variable (StatSoft, 1994).

Set 2

Experiment 2: Whole vs. Reconstituted Mouse Lures. The objective of this experiment was to determine whether the modification of carrion was important for the attractiveness of the lure. This experiment consisted of two treatment levels ($k = 2$) with $r = 10$ blocks per transect ($N = 7$), for a total of 20 PVC tubes per transect ($k \cdot r$). For one treatment level we ground whole dead neonatal mice ($N = 10$) in a blender and rolled the ground meat and fur into balls (DMG). The second treatment level, the control, consisted of unaltered whole dead neonatal mice (DNM) ($N = 10$). PVC tubes were checked for presence or absence of baits after 24 and 48 hr. Placement, scoring, and cleaning of PVC tubes were similar to experiment 1. Bait take was analyzed using a two-way repeated-measures analysis of variance, where treatment was the between-measures factor, day was the within-measures (i.e., repeated) effect, and the proportional cumulative bait take was the response metric (Winer 1971, p. 520). Tukey's HSD test was used to determine the post-hoc differences among means for the main effect, and simple orthogonal contrasts were used to compare group means for the interaction term (StatSoft, 1994).

Experiment 3: Attractiveness of Mouse Parts and Tofu-wrapped Pelts. Grinding and combining mouse parts substantially reduced the attractiveness of baits to foraging brown treesnakes (experiment 2). Therefore, the objective of this experiment was to determine whether dissected, intact mouse parts were attractive baits. To separate pelts from carcasses (C), we thawed dead neonatal mice and carefully skinned them using dissecting scissors. We removed pelts at the wrist, ankle, tail bone, and rostrum; then wrapped the pelt around a piece of tofu (P_{tof}). The tofu served as a moisture source in the field to prevent the pelt from desiccating. All three bait types (C, P_{tof}, DNM) were placed into separate plastic cups, sealed, and kept cold until transported to the field. The methods for bait placement, assigning treatment levels within transects, monitoring PVC tubes, and analysis were identical to those described in experiment 2. This experiment consisted of three treatment levels ($k = 3$) with $r = 10$ blocks per transect ($N = 6$), for a total of 30 PVC tubes per transect ($k \cdot r$).

Experiment 4: Attractiveness of Mouse Parts and Cotton-wrapped Pelts. The objective of this experiment was to determine the attractiveness of pelts with moistened cotton as a moisture source (P_{cot}) and pelts without a moisture source (P) relative to DNM. The methods for bait placement, assigning treatment levels within transects, monitoring PVC tubes, and analysis were identical to those described above. This experiment consisted of three treatment levels ($k = 3$) with $r = 10$ blocks per transect ($N = 5$), for a total of 30 PVC tubes per transect ($k \cdot r$).

Set 3

Experiment 5: Attractiveness of Baits Treated with Alcohol. Because we found that pelts were taken at the same rate as DNM and that skinned carcasses were taken at lower rates (experiment 3), we limited further testing on the source of the lure odor cue to pelts in comparison to DNM. In this set of experiments, we treated pelts in one of two ways, working under the hypothesis that surface bacteria may be responsible for generating the odors to which snakes were attracted. In the first series of tests, pelts were prepared as described in experiment 3. No special treatment was afforded to nontreated pelts wrapped around tofu (P_{nt}). A second set of pelts (P_{alc}) was treated using alcohol. Briefly, pelts and tofu were separately soaked in 70% ethyl alcohol for 5 min prior to being wrapped together. Treated baits were placed in disinfected plastic cups, sealed for transport to the field, then placed into PVC tubes sprayed with 70% ethyl alcohol. PVC tubes and baits were again sprayed after bait placement to ensure a sanitary local environment, after which natural conditions were allowed to prevail. The methods for bait placement, assigning treatment levels within transects, monitoring PVC tubes, and analysis were identical to those described in experiment 2. This experiment consisted of three treatment levels ($k = 3$) with $r = 10$ blocks per transect ($N = 6$), for a total of 30 PVC tubes per transect ($k \cdot r$).

Experiment 6: Attractiveness of Baits Treated with Bleach. In a second set of experiments, we treated pelts with a commercial chlorine bleach (7:3, P_{chl}) and repeated the above experiment. The methods for bait placement, assigning treatment levels within transects, monitoring PVC tubes, and analysis were identical to those described above. This experiment consisted of three treatment levels ($k = 3$) with $r = 10$ blocks per transect ($N = 6$), for a total of 30 PVC tubes per transect ($k \cdot r$).

We carried out two types of field laboratory microbial assays to evaluate the efficacy of the chemical treatment technique and to provide a presumptive identification of the primary bacteria cultured from the surface of mouse pelts. In the lab, we placed newly prepared baits (P_{alc}, P_{chl}, P_{nt}, DNM; $N = 10$ per treatment type) onto nutrient agar plates and incubated the baits at 35°C for 24 and 48 hr, scoring the plates for presence of bacterial growth. From the field, a sample of

these same bait types was removed after the second day's evaluation, taken to the laboratory, placed on nutrient agar, incubated, and checked for bacterial growth as above. The rationale for this second evaluation was to determine if uneaten baits were more or less likely to foster bacterial growth. Finally, we streaked nutrient agar plates with swabs taken directly from the surface of DNM. Colonies of bacteria were isolated and tested for presumptive identification using Enterotube II and Oxi/Ferm tubes (BBL, Becton Dickinson).

Experiment 7: Attractiveness of Denatured Baits. The objective of this experiment was to determine the attractiveness of P_{nt}, of pelts that were boiled (P_b), and of intact DNM that were boiled (DNM_b) relative to DNM. Whole DNM and pelts were boiled for approximately 20 min to remove surface bacteria. As in previous experiments pelts were wrapped around tofu that served as a moisture source. This experiment served mainly as a pilot study for future experimentation and was one in which we assessed a nonchemical avenue of treatment while acknowledging the change in the nature of the proteins. Thus, only a single transect was used with $N = 10$ baits per treatment level (DNM, DNM_b, P_{nt}, P_b; 40 PVC tubes). The methods for bait placement, assigning treatment levels within the transect, and monitoring PVC tubes were identical to experiment 2. Comparison of treatments to DNM was done using a binomial test.

RESULTS

Set 1

Experiment 1: Importance of Carrion Decomposition for Lure Attractiveness. Carrion decomposed for two days was more attractive to brown treesnakes. There was a 90% increase in the rate at which 2-day-old whole mouse carrion was removed from PVC tubes relative to 1-day-old mouse carrion (Figure 1).

Set 2

Experiment 2: Whole vs. Reconstituted Mouse Lures. Whole mouse carrion was more attractive as a bait than reconstituted ground mouse (Figure 2A). DMG was 20% as attractive to brown treesnakes as DNM. As a function of decomposition over two days (Figure 2B), there was little increase in attractiveness for DMG, and a large increase in attractiveness for DNM.

Experiment 3: Attractiveness of Mouse Parts and Tofu-wrapped Pelts. Snakes removed whole dead mice and mouse parts from PVC tubes at different rates (Figure 3A). The cumulative proportional bait take of skinned carcasses was 49% lower than that observed for whole dead mice. However, the cumulative bait take of whole dead mice and pelts was similar. The bait take of pelts and skinned carcasses also was similar. The day effect, where the biological substrate presumably

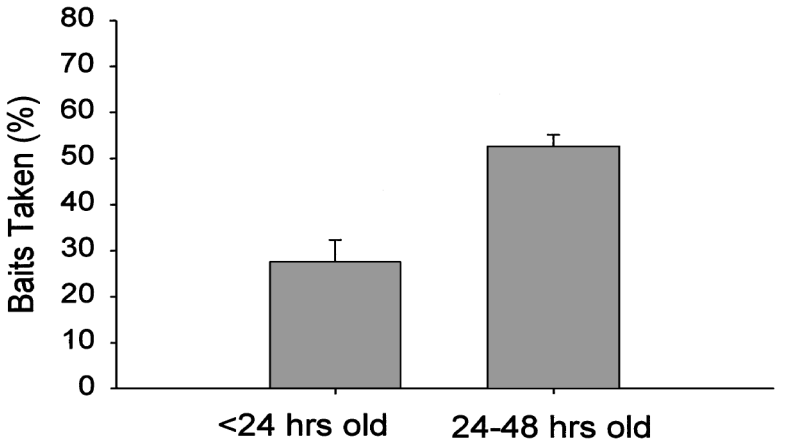

FIG. 1. Bait take (mean ± SEM) by brown treesnakes on Guam in experiment 1 for whole dead neonatal mice as a function of bait decomposition ($t = 21.429$, $df = 6$, $P = 0.004$). Percentage estimates were calculated using transect as the experimental unit ($N = 4$) with 10 observations per bait type per transect.

becomes more decomposed on day 2 vs. day 1, indicated that bait take varied as a function of time over two days for the treatments (Figure 3B). On the first day all bait types had similar rates of take. However, by the second day the cumulative bait take was much higher for the whole dead mouse relative to skinned carcasses. Bait take for pelts on the second day was intermediate between carcasses and whole dead mice. These observations suggest that the second-day effect is partly a function of changes taking place on the surface of the mouse, i.e., skin.

Experiment 4: Attractiveness of Mouse Parts and Cotton-wrapped Pelts. Bait take was the same for all bait types (Figure 4A). Bait take did not vary across days as a function of treatment (Figure 4B). Thus, bait take was not substantially affected by the presence or absence of the moisture source, at least for the time frame of these experiments.

Set 3

Experiment 5: Attractiveness of Baits Treated with Alcohol. Alcohol treatment diminished the attractiveness of pelts (Figure 5A). The cumulative bait take for alcohol-treated pelts was 50% lower relative to whole dead mice. The cumulative bait take for whole dead mice and nontreated pelts and that of nontreated and treated pelts were similar. The magnitude of the day effect was lowest for the alcohol-treated pelts and was proportionally similar for the whole dead mouse and nontreated pelts (Figure 5B). These observations suggest that treating the bait's

Percentage estimates were calculated using transect as the experimental unit ($N = 6$) with 10 observations per bait type per transect.

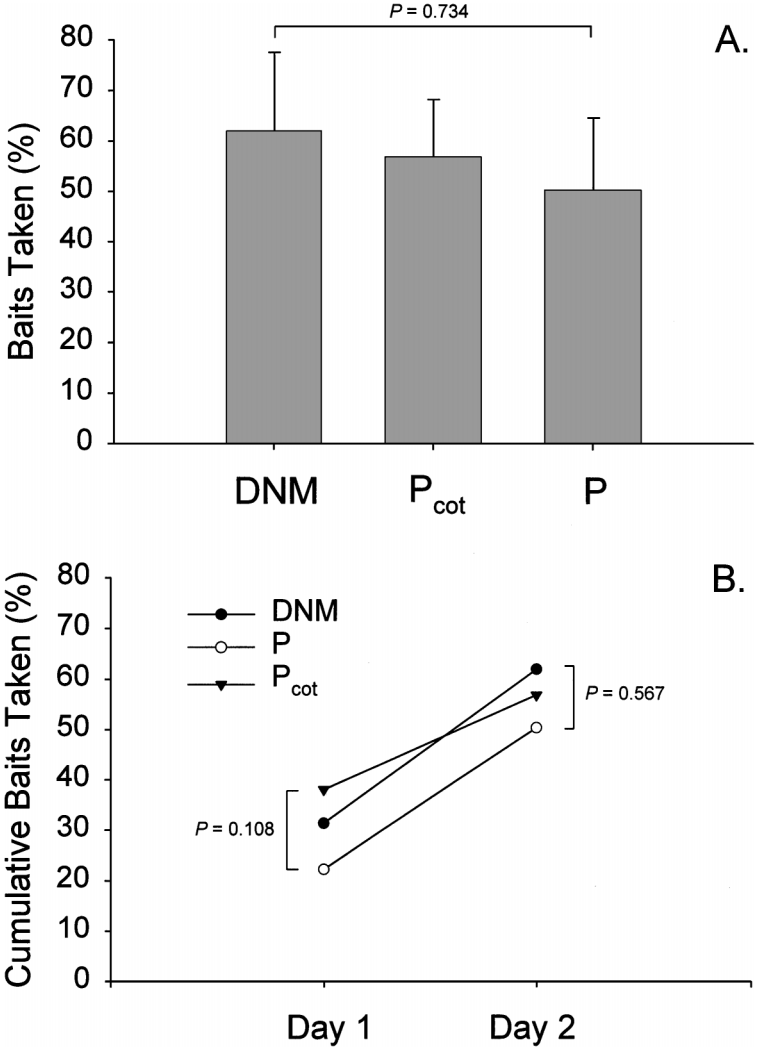

FIG. 4. (A) Bait take (mean ± SEM) by brown treesnakes on Guam in experiment 4 for whole dead neonatal mice (DNM), mouse pelts wrapped around moistened cotton (P_{cot}), and mouse pelts (P) ($F = 0.416$, $df = 2,12$, $P = 0.669$). (B) Profiles for the cumulative mean (±SEM) bait take of DNM, P_{cot}, and P baits as a function of time ($F = 0.375$, $df = 2,12$, $P = 0.695$). Percentage estimates were calculated using transect as the experimental unit ($N = 5$) with 10 observations per bait type per transect.

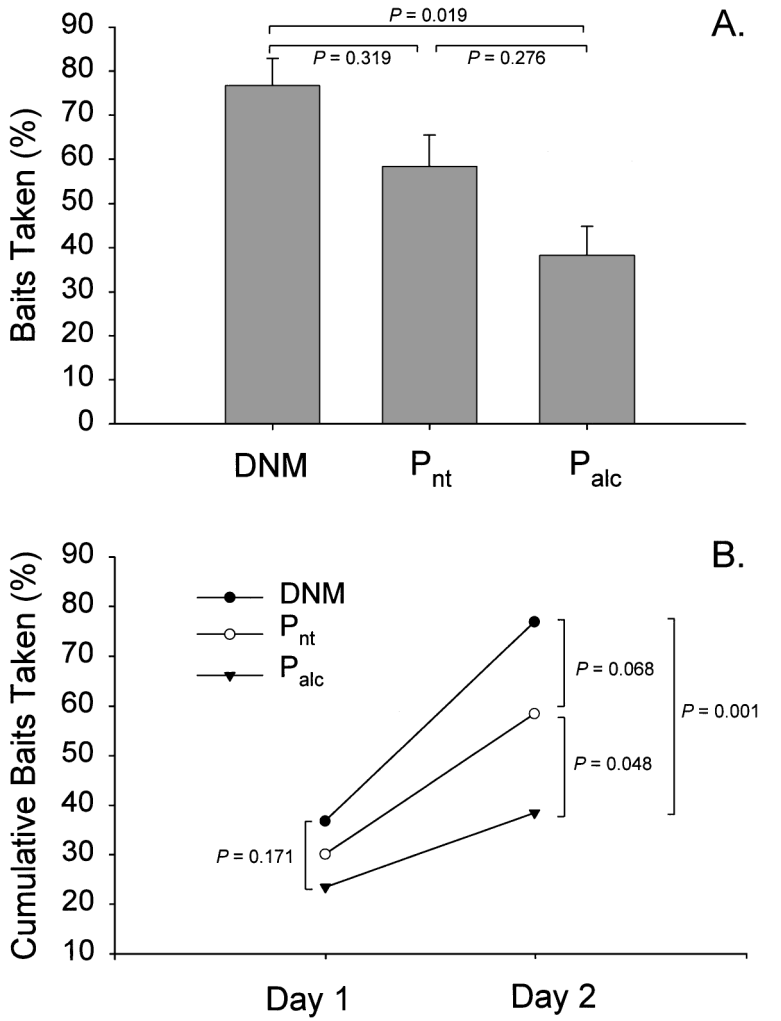

FIG. 5. (A) Bait take (mean ± SEM) by brown treesnakes on Guam in experiment 5 for whole dead neonatal mice (DNM), nontreated mouse pelts wrapped around tofu (P_{nt}), and alcohol-treated mouse pelts wrapped around tofu (P_{alc}) ($F = 4.807$, $df = 2,15$, $P = 0.024$). Tofu was used to preserve moisture content of pelts. Tukey's HSD comparisons and associated probability values are indicated by horizontal lines. (B) Profiles for the cumulative mean (±SEM) bait take of DNM, P_{nt}, and P_{alc} baits as a function of time ($F = 4.643$, $df = 2,15$, $P = 0.027$). Simple orthogonal planned contrasts and their associated probabilities are indicated by vertical lines. Percentage estimates were calculated using transect as the experimental unit ($N = 6$) with 10 observations per bait type per transect.

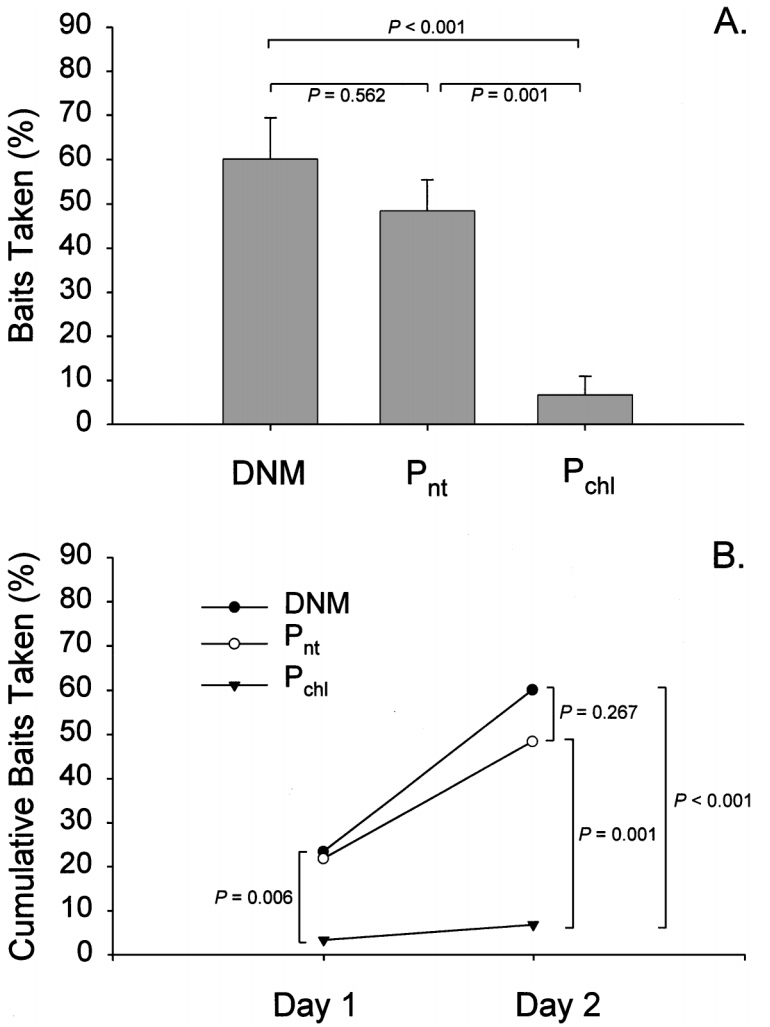

FIG. 6. (A) Bait take (mean ± SEM) by brown treesnakes on Guam in experiment 6 for whole dead neonatal mice (DNM), nontreated mouse pelts wrapped around tofu (P_{nt}), and bleach-treated mouse pelts wrapped around tofu (P_{chl}) ($F = 18.727$, $df = 2,15$, $P < 0.001$). Tofu was used to preserve moisture content of pelts. Tukey's HSD comparisons and associated probability values are indicated by horizontal lines. (B) Profiles for the cumulative mean (±SEM) bait take of DNM, P_{nt}, and P_{chl} baits as a function of time ($F = 4.877$, $df = 2,15$, $P = 0.023$). Simple orthogonal planned contrasts and their associated probabilities are indicated by vertical lines. Percentage estimates were calculated using transect as the experimental unit ($N = 6$) with 10 observations per bait type per transect.

surface decreases the attractiveness of the bait, either by chemical extraction of critical volatiles or by the antimicrobial effects of the alcohol wash.

Experiment 6: Attractiveness of Baits Treated with Bleach. Treatment of pelts with bleach strongly decreased the attractiveness of the bait (Figure 6A). Pelts treated with bleach were taken at 11% of the rate of whole dead mice, and at 14% of the rate of nontreated pelts. This strong main treatment effect held across days (Figure 6B). The source of the strong interaction effect was owing to the proportional cumulative increase in bait take for the whole dead mouse and non-treated pelts in contrast to the lack of increase in bait take for the bleach treated pelts. These observations indicate that bleach treatment exerted a stronger negative effect on bait take than an alcohol wash and that this action either by chemical extraction or antimicrobial properties eliminated important cues for foraging brown treesnakes that originated from the surface of the baits.

Both alcohol and bleach treatments of the pelts decreased microbial growth (Table 1). However, treatment with alcohol apparently did not eliminate all colony forming units because there was noticeable bacterial growth on agar plates after 48 hr. Bleach was a more effective disinfectant because none of the cultures showed evidence of any colony forming units for up to six days, after which some cultures showed signs of fungal growth.

From the field, a sample of unconsumed baits left in PVC tubes after two to three days was taken back to the laboratory and placed onto nutrient agar plates and incubated for 24 hr. All samples of whole dead mice and non-chemically-treated pelts yielded substantial bacterial growth after 24 hr of incubation (Table 1). The alcohol- and bleach-treated baits did not yield appreciable microbial growth after incubation. Of course, the microbial contamination of baits that were consumed is

TABLE 1. POSITIVE CULTURES FOR BAIT TREATMENTS PREPARED FOR BROWN TREE SNAKES ON GUAM IN MAY AND JUNE 2000

Treatment	Laboratory assays[a]		Field recovery assays at 24 hr[b]
	24 hr	48 hr	
DNM	10	10	10
P_{nt}	10	10	10

P_{chl}	0[d]	0[d]	0[d]
Control[c]	0[d]	0[d]	0[d]

[a] The number of agar plates out of 10 that showed signs of microbial growth. Freshly prepared baits were placed on nutrient agar cultures and checked at 24- and 48-hr intervals.
[b] The number of agar plates out of 10 that showed signs of microbial growth for bait treatments recovered from the field after >72 hr and checked after 24 hr of incubation on a nutrient agar culture plate.
[c] The negative control consisted of nutrient agar plate.
[d] Within-column comparisons of treatments to DNM ($P < 0.05$, binomial test).

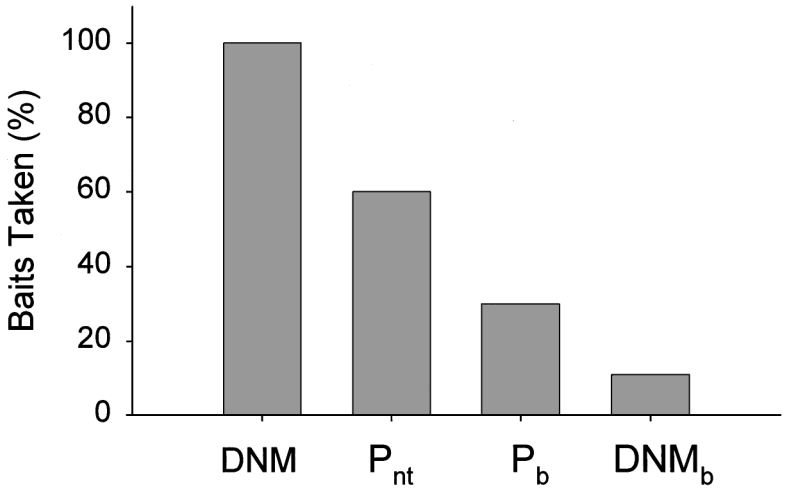

FIG. 7. Bait take by brown treesnakes on Guam for a single transect in experiment 7 for whole dead neonatal mice (DNM), nontreated mouse pelts wrapped around tofu (P_{nt}), boiled mouse pelts wrapped around tofu (P_b), and boiled whole mice (DNM_b). Tofu was used to preserve moisture content of pelts. Estimates were based on 10 observations per treatment type for this single transect. All treatments (P_{nt}, P_b, DNM_b) were different from DNM ($P < 0.05$, binomial test).

unknown. However, when the bait take rates of alcohol- and bleach-treated baits are considered in the context of the laboratory microbial culture experiments, the bait take rates are concordant with the degree of microbial contamination. That is to say, there is sufficient inferential evidence to suggest that the rate of bait take is dependent on the degree of microbial growth on the surface of the bait. Isolates from the cultures indicate that the predominant bacterial growth originating from the surface of dead mice is *Enterobacter agglomerans*.

Experiment 7: Attractiveness of Denatured Baits. Treating the mouse substrate by boiling also affects the attractiveness of baits (Figure 7), although there may also be effects owing to the general denaturation of the mouse parts.

DISCUSSION

Future effective snake control programs on Guam will use both traps and toxic bait delivery. For traps, the current lure used is a live mouse contained within a cage inside the trap. Such traps are reasonably effective in depopulating modest areas of brown treesnakes (Engeman et al., 1998). One drawback with this method of control is the expense and effort of maintaining live mouse colonies in the lab

and maintaining the live mouse lures in the field (Clark et al., unpublished results). The use of toxic baits also can be effective at depopulating modest areas of forest of snakes. Savarie et al. (2001) employed whole dead neonatal mice laced with acetaminophen as the lure/bait-toxicant delivery system in achieving near zero survivorship of snakes in 6-ha experimental plots. Despite this success there still is a need to develop a lure/bait system that does not rely on the killing of mice.

The successful artificial lure/bait system must provide snakes with long-distance cues that act to attract the snake to the vicinity of the substrate and short-distance cues that will promote ingestion. These cues are not necessarily the same (Clark and Kimball, unpublished results). The difficulty in constructing artificial lure and bait systems has been the uncertainty of what these cues might be. Presentation of simple chemical components of mouse carrion have yielded variable, but generally poor, success as attractants (Shivik and Clark, 1999a; Clark and Kimball, unpublished results). Even reconstruction of mouse carrion odor based on chemical analysis of the volatiles produced during rotting have failed to successfully attract snakes (Shivik, 1998). Clearly, brown treesnakes, despite their anecdotal reputation for eating anything, are quite discriminating foragers. One possible solution in the development of a realistic mimic of complex carrion odor is to develop a system that includes the odor-producing agents and the appropriate nutrient substrate for those agents. This study is a critical first step in that process.

Throughout the experiments we found a concordance between factors relating to microbial decomposition of the mouse and the rate at which baits were taken by snakes: baits left in the field for two days were taken at higher rates, and chemically treated (alcohol or bleach) baits were taken at lower rates. These chemicals act as disinfectants, but they may also act as extractive solvents, removing critical volatiles. While we infer that the critical attractive volatiles are products of microbial metabolism, and our experimental evidence is consistent with this view, these chemicals may also have removed critical volatiles by extraction. Experiments using antibiotics to suppress bacterial growth would be useful in determining which hypothesis is responsible for the taking of baits by snakes. It is unlikely that chemical treatment resulted in residues that acted as repellents to snakes. The positive controls, DNM, were in PVC tubes that were cleansed with bleach, and taking of bait was consistently higher in those treatments.

We also found that the nature of the bait substrate was important. Mouse carcasses without skin and reconstituted ground-up mice were not good baits. Whole mice and pelts were good baits. These observations make sense in the context of the cues a foraging brown treesnake is likely to encounter. Typically, the initial odors generated from carrion will be the result of aerobic decomposition of the surface of the animal. Thus, snakes should be more attentive to these types of cues.

Future development of artificial lure/bait systems may include the cell culture of mouse skin as the nutrient substrate that could be embedded into agar blocks

and inoculated with appropriate bacteria. We suggest *Enterobacter agglomerans* as an initial odor-producing agent, because it is the dominant bacterium isolated from mouse skin, although other bacteria could contribute to the complex odor of carrion. These bioreactor systems could potentially act both as lure and bait systems. Such systems would greatly reduce the need for large numbers of live and dead mice for snake control, thus making progress toward the goal of using artificial lure/bait systems to achieve effective snake control. Future work in our laboratory is directed at addressing these issues.

Acknowledgments—We thank K. G. Dyer for assistance in the field. We appreciate the continued efforts and help from H. Hirsh and others at Andersen Air Force Base, Guam. Comments from R. L. Bruggers, E. Campbell, M. W. Fall, T. H. Fritts, G. H. Rodda, M. E. Tobin, and D. S. Vice were helpful. This research was conducted with funds provided to the National Wildlife Research Center by the U.S. Department of Defense under Legacy Project Number DO822, "Field Evaluation of Chemical Methods for Brown Treesnake Management," and the sustained support of the Legacy Program is greatly appreciated. All experiments were performed in compliance with Institutional Animal Care and Use Guidelines.

Abstract—Red-backed salamanders, *Plethodon cinereus*, show a variety of alarm responses to chemical cues from eastern garter snakes, *Thamnophis sirtalis*. We measured the foraging activity of red-backed salamanders exposed to water soiled by a garter snake (fed *P. cinereus*) or to unsoiled water. Salamanders exposed to snake-soiled water showed less foraging activity than salamanders exposed to unsoiled water; therefore, predators could have nonlethal effects on salamander populations. Our results also show additional factors influenced salamander foraging activity. Salamander foraging activity and responsiveness to chemical cues do not appear to have been affected by sex or food deprivation. Salamander foraging activity does appear to have been influenced by activity biorhythms. Foraging activity of animals in both treatments showed a bimodal periodicity that is consistent with natural activity patterns controlled by internal biorhythms. Exposure to snake-soiled water significantly reduced foraging activity during periods of peak foraging activity, but had a subtler effect on foraging activity during natural lulls in activity. We suggest that both activity biorhythms and exposure to chemical cues are important factors affecting salamander foraging behavior.

Key Words—Biorhythm, chemical cues, *Plethodon cinereus*, foraging, salamander.

INTRODUCTION

Animals can significantly reduce predation risk by responding to alarm cues in the environment. Many animals show a variety of behavioral responses to chemical

alarm cues or predator chemical cues, including avoidance of, or reduced activity within, areas that contain cues (Kats and Dill, 1998). Although there are clear benefits to behavioral responses to predator cues, there can also be costs (Lima, 1998). For example, avoiding particular habitats or reducing foraging activity can compromise an animal's foraging success (reviewed by Lima, 1998; Lima and Dill, 1990). Understanding the potential costs of prey responses to predator cues is important because those costs determine the "nonlethal" effects of predators on prey populations (Laurila and Kujasalo, 1999; Laurila et al., 1998; Relyea, 2000; Relyea and Werner, 1999; see also review by Lima, 1998) and whole communities (Peacor and Werner, 2000; Persson, 1999; Turner, 1997; Turner and Mittelbach, 1990; Werner and Anholt, 1996). Lima (1998) suggests that the nonlethal effects of predators on prey populations might be less conspicuous, but far more important, than direct predation, and therefore, require increased attention.

Terrestrial salamanders within the genus *Plethodon* show several defensive responses to a variety of chemical cues that include combinations of predator-specific chemical cues and chemical alarm cues from conspecifics. Independent sources of chemical cues include the damaged tissues of conspecifics (Chivers et al., 1997), and chemicals released by predators such as the ring-necked snake (*Diadophus punctatus*) (Cupp, 1994) and the eastern garter snake (*Thamnophis sirtalis*) (Madison et al., 1999a,b; McDarby et al., 1999). Under certain conditions, salamanders only respond to combinations of predator chemical cues and chemical alarm cues. For example, *P. cinereus* responses to chemical cues from snakes depend on the time of day and the diet of the snake (Madison et al., 1999a,b; Murray and Jenkins, 1999). *P. cinereus* respond to chemical cues from snakes fed *P. cinereus* throughout the evening, but *P. cinereus* stop responding to the chemical cues of snakes fed alternative prey shortly after dusk (Madison et al., 1999b; Madison, Maerz, and Sullivan, unpublished data). *Plethodon* show variable responses to exposure to alarm chemical cues including avoiding substrates that contain the cues (Chivers et al., 1997; Cupp, 1994; Madison et al., 1999a,b; McDarby et al., 1999; Murray and Jenkins, 1999), changing their activity level (Madison et al., 1999a), or delaying emergence from refugia (Sullivan, Maerz, and Madison; unpublished data). Whether there are costs associated with these responses has not been addressed.

We investigated whether exposure to chemical cues from an eastern garter snake, *T. sirtalis*, would affect the foraging behavior of adult *P. cinereus*. *P. cinereus* foraging success is positively correlated with activity level outside retreats (Fraser, 1976; Jaeger, 1978, 1980, 1990). For fish and larval amphibians, activity level is positively correlated with predation risk (Godin and Smith, 1988; Skelly, 1994), so they generally reduce activity in response to alarm cues (Kats and Dill, 1998). *Plethodon* predators such as *T. sirtalis* and *D. punctatus* are more likely to attack a moving salamander (Maerz, personal observation), and terrestrial salamanders use immobility as their primary response to encounters with predators (Arnold, 1982;

Dodd, 1989; Ducey and Brodie, 1983). Therefore, we predicted that *P. cinereus* will reduce foraging activity when exposed to snake-soiled water. We also predicted that those salamanders exposed to snake-soiled water would pursue prey from shorter distances.

METHODS AND MATERIALS

Collection of Snake Odor. We collected adult *T. sirtalis* (∼400 mm snout–posterior vent length) from a mixed deciduous forest in Broome County, New York. We housed the snakes in individual 38-liter aquaria and fed them earthworms (*Lumbricus* sp.) twice weekly. We fasted an adult snake for 10 days prior to the start of trials, and then fed the snake two adult male *P. cinereus*. After the snake had eaten the salamanders, we transferred the snake to a clean 38-liter aquarium lined with dry paper towels. A second 38-liter aquarium lined with dry paper towels was set up for the unsoiled water (control). After four days, we removed the snake from the first aquarium, transferred the paper towels from each aquarium to individual plastic jars, and added 400 ml of distilled water to each jar 12 hr prior to the first set of trials. Jars were kept sealed between trials to reduce exposure to air and slow any potential aging of the sample. In order to reduce stimulus variation, the same solution was used for all trials. Prior research shows that *P. cinereus* responses are the same to chemical cues from different *T. sirtalis* provided those snakes are fed the same diet (Madison et al., 1999b); therefore, the results of our study, which uses chemical cues from a single snake, can be generalized to *P. cinereus* responses to other *T. sirtalis*.

Collection and Maintenance of Salamanders. We collected 24 adult male and 24 adult female *P. cinereus* from the State University of New York Nature Preserve, Broome County, New York. Salamanders were housed individually in 30-cm × 16-cm clear plastic boxes lined with 5 cm of moist soil and covered with a glass lid. We maintained salamanders in a controlled environment room at 17.5°C on a 12L:12D photoperiod, checked them every two days, moistened their soil as needed, and fed them five crickets (∼6 mm in length) weekly. After 60 days, we discontinued feeding and initiated trials.

Experimental Protocol. We could not test all 48 salamanders simultaneously, so we randomly assigned salamanders to consexual pairs for testing and subsequent statistical comparison. Within a pair, one salamander was randomly assigned to the snake-soiled water treatment and the other to the unsoiled water treatment. We tested partners sequentially on a preassigned trial date, randomizing the order of testing within each pair. Although not part of our initial design, pairs of salamanders were tested in blocks 4–6, 10–12, or 25–27 days after they were last fed. On the test day, we added 8 ml of the appropriate water treatment evenly across the soil surface of the salamander's box, and after allowing 2–3 min for the solution

to settle into the soil, we placed five 0.25-in. crickets in the box, covered the box with a glass lid, and videotaped the trial for 30 min. We conducted all trials during the dark portion of the photocycle with just enough incandescent light to record the trial with a 0.8 lux video camera.

P. cinereus foraging behavior is slow and deliberate. Salamanders usually orient toward prey from a resting position and then move toward prey in a series of discrete actions. Salamanders will often pause motionless between movements toward prey. From the videotapes, we measured the number of actions per minute and pursuit distance. "Actions" were defined as any single bout of continuous movement, which ranged from a reorientation of a salamander's head to several strides. We discriminated between "foraging actions" that were oriented toward a prey, and "nonforaging actions" that were oriented in all other directions. We defined pursuit as one or more actions culminating in a strike at prey, so pursuit distance was the interval between the salamander and its prey when pursuit began. Two independent observers scored all trials, and their scores were compared for consistency. A third observer reviewed any discrepancies between the scores of the two independent observers.

RESULTS

Only 18 of 24 salamander pairs could be included in our analyses. For four pairs, one or both salamanders managed to push into small crevices in the soil just prior to the application of treatment. Two other pairs were excluded because neither salamander moved during the entire 30-min observation period.

The proportion of salamanders exposed to snake-soiled water that attempted a strike was significantly less than that of salamanders exposed to unsoiled water (chi-square test: $\chi^2 = 6.78$, $df = 1$, $P = 0.009$). Half (9 of 18) the salamanders exposed to snake-soiled water struck at prey, while nearly all salamanders (17 of 18) exposed to unsoiled water struck at prey.

Overall, salamanders exposed to snake-soiled water made fewer foraging actions per minute than did their partners (Wilcoxon matched pairs test: $T = 12$, $N = 18$, $P = 0.001$; Figure 1). For different food-deprivation levels, foraging activity of unsoiled-water-exposed salamanders was greater within 4- to 6- and 10- to 12-day food-deprivation groups (Table 1). This trend was not significant for the 25- to 27-day group, but salamanders exposed to snake-soiled water showed reduced foraging activity compared to partners in four of six pairs.

The difference in pursuit distance between salamanders exposed to snake-soiled water (mean $\pm$ SE $= 6.52 \pm 1.52$ cm, $N = 8$) and their partners exposed to unsoiled water (mean $\pm$ SE $= 8.67 \pm 1.71$ cm, $N = 8$) was not different (Wilcoxon matched pairs test: $T = 12$, $N = 8$, $P = 0.401$). The power of this

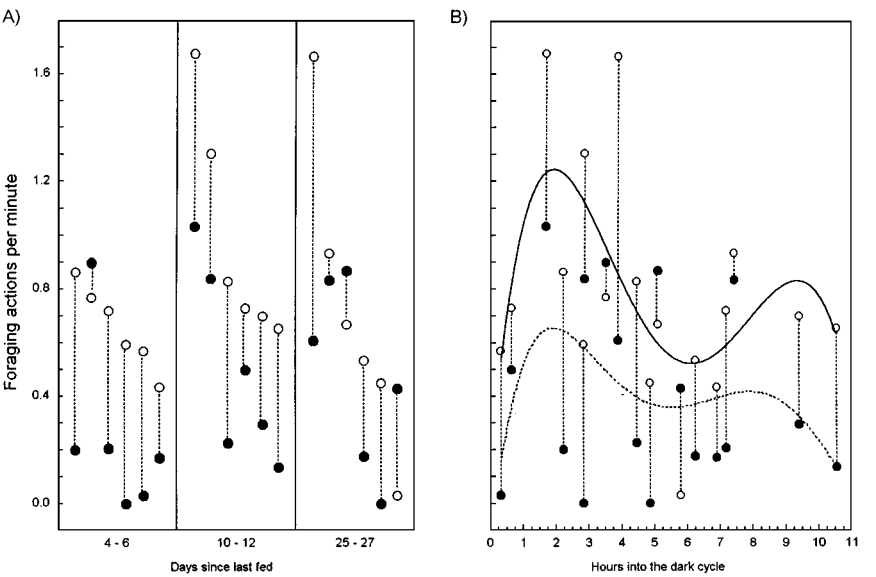

FIG. 1. Differences in the foraging activity rates of unsoiled water exposed (hollow circles) and snake-soiled water exposed (solid circles) *Plethodon cinereus*. Dashed lines connect symbols for partnered salamanders. (A) Data are arranged in descending order from most active salamander (exposed to unsoiled water) to least active within each food-deprivation group. Salamanders exposed to snake-soiled water had lower foraging activity rates than did their partners, and foraging activity rates of partnered salamanders were positively correlated. (B) Data are arranged according to the time within the dark phase when the trial was conducted. Curved lines are least-squares polynomial functions for salamanders exposed to unsoiled water (solid line) and salamanders exposed to snake-soiled water (stippled line).

comparison was weakened because a strike was a required component of pursuit; so only eight pairs were available for comparison. Overall, salamanders initiated pursuit within 18 cm of prey and only attempted a strike at prey within 2 cm.

Unexpectedly, foraging activity was positively correlated between partnered salamanders (Spearman rank correlation: $r_s = 0.663$, $N = 18$, $P = 0.003$; Figure 1A). Because salamanders were randomly partnered, this correlation suggests factors besides odor treatment influenced salamander foraging activity. Within odor treatments, male and female *P. cinereus* foraging activity was not different. Among the salamanders exposed to plain water, male foraging actions per minute (mean $\pm$ SE $= 0.82 \pm 0{:}12$, $N = 10$) were not different from female foraging activity (mean $\pm$ SE $= 0.74 \pm 0.16$, $N = 8$; Mann-Whitney U test, $U = 38.0$, $P = 0.859$). Likewise, among the salamanders exposed to snake-soiled water, male foraging actions per minute (mean $\pm$ SE $= 0.44 \pm 0.13$, $N = 10$) were not different from female foraging activity (mean $\pm$ SE $= 0.38 \pm 0.10$, $N = 8$; Mann-Whitney U test, $U = 39.5$, $P = 0.965$).

Within odor treatments, salamander foraging activity tended to increase in the high food-deprivation levels; however, some extremely high scores within those groups drove this trend and it was not significant (Table 1). Our sample sizes within food-deprivation levels were small, so the ability to detect a food-deprivation effect was limited. The positive correlation between foraging activity levels of partnered salamanders was apparent within food-deprivation levels (Figure 1A).

A least-squares polynomial curve of foraging activity as a function of the time period within the dark cycle showed bimodal foraging activity patterns in both treatment groups (Figure 1B). Salamanders in both odor treatments showed peaks in foraging activity 2 hr into the dark cycle and a smaller activity peak 10 hr into the dark cycle. Regardless of treatment, seven of the nine highest foraging activity levels were recorded 2–4 hr into the dark cycle.

DISCUSSION

Identifying potential costs associated with prey responses to alarm cues contributes to a more accurate understanding of the effects of predators on prey populations and whole communities (Lima, 1998; Persson, 1999). Even though prey responses to alarm cues might reduce predation rates, costs associated with those responses can negatively affect prey populations and alter the structure and function of whole communities. This study shows that red-backed salamander responses to chemical cues from a predator can compromise salamander foraging success. Salamanders exposed to snake-soiled water showed reduced foraging activity that resulted in most animals not attempting a strike at prey during our observation

period. Neotenic graybelly salamanders, *Eurycea multiplicata*, also reduce foraging activity and seldom attempt to capture prey when exposed to chemical cues from predatory fish (Whitham and Mathis, 2000). Reducing activity in response to alarm cues might reduce detection by visually oriented predators (Godin and Smith, 1988; Skelly, 1994), but could negatively affect salamander growth, development, and female fecundity (Bernardo, 1994; Fraser, 1980). Therefore, the potential for important nonlethal effects of predators should be incorporated into models of salamander ecology.

We do not know whether *P. cinereus* exposed to snake-soiled water failed to strike at prey because it is too conspicuous or because reduced pursuit activity results in fewer salamanders getting within strike range of prey. Regardless of treatment, salamanders generally initiated pursuit of prey from a distance of 6–8 cm and from as far as 18 cm, but needed to move within 2 cm to attempt a strike. Therefore, it is possible that reduced activity results in reduced encounters with prey at a sufficient distance to strike. Unlike the laboratory environment, the unconstrained movement of prey in the natural environment might further reduce prey encounter rates.

Our results on the effects of hunger on *P. cinereus* foraging activity are equivocal, but regardless of whether hunger affects salamander foraging activity, hunger did not appear to affect salamander responsiveness to chemical cues. It must be pointed out that all of the salamanders that we tested were deprived of food for at least four days therefore, it is likely that all were hungry to some degree. Thus, hunger did not diminish *P. cinereus* responsiveness to predator chemical cues, at least through 12 days of food deprivation. Other studies of larval anurans (Horat and Semlitsch, 1994) and neotenic adult salamanders (Whitham and Mathis, 2000) show that hunger does not diminish responsiveness to predator chemical cues even if hunger tends to increase foraging activity. In our study and the other studies of amphibians, food deprivation ranged from one to five days, and no level of food deprivation was sufficient to diminish responsiveness to predator chemical cues. Studies of other animals show interactions between the effects of hunger and exposure to predator chemical cues on foraging behavior with shorter periods of food deprivation. For example, one day of food deprivation is sufficient to increase foraging activity of three-spine sticklebacks, *Gasterosteus aculeatus* and override responsiveness to predator chemical cues (Godin and Crossman, 1994). We do not know why the effects of hunger on animal responsiveness to predator cues might differ between some amphibians and fish. Many amphibians, especially plethodontid salamanders, such as those tested in this study and by Whitham and Mathis (2000), have exceptionally high metabolic efficiencies that allow them to go for extended periods without food (Feder, 1983; Pough, 1983). High metabolic efficiency is a hallmark adaptation of amphibians and reptiles, enabling them to exploit highly variable environments where access to food can be limited frequently or for long periods.

We discovered *post hoc* that the foraging activity of partnered salamanders was positively correlated, which suggests additional influences on salamander foraging behavior independent of the effect of exposure to predator chemical cues. Because we randomly partnered salamanders, those additional factors that affected foraging activity must be conditions shared by partners. Partnered salamanders had three factors in common that might affect foraging behavior: sex, length of the food-deprivation period, and time within the dark cycle when the pair was tested. Maerz (2000) reported differences in foraging patterns between male and female *P. cinereus*, specifically that female salamanders tend to capture larger and sometimes more prey than male salamanders, and Dakin (1978) reported disproportionately high numbers of female *P. jordani* and *P. yonahlosse* during peak hours of salamander activity. However, in this study, we found no evidence of differences in foraging activity between male and female *P. cinereus*; so, sex was not a factor contributing to variation in foraging behavior among salamander pairs.

As discussed before, food deprivation did not appear to significantly affect salamander foraging activity and does not appear to account for the correlated behavior of partnered salamanders. Because of our small sample sizes within food-deprivation/odor treatment groups, we hesitate to conclude that food deprivation has no effect on *P. cinereus* foraging activity. However, Adler (1968) examined the effects of food deprivation on *P. glutinosus* activity, and although his study focused on internal activity biorhythms and not facultative adjustments to activity in the presence of prey, he reported that a month of food deprivation had no measurable affect on *P. glutinosus* activity patterns. Further, it was apparent that foraging activity was correlated between partnered salamanders even within food-deprivation groups.

We hypothesize that the positive correlation in activity level between partnered salamanders reflects internal biorhythm influences on activity. The activities of many animals are regulated by internal biorhythms that could operate independent of, or interact with, responses to chemical cues. In this study, those *P. cinereus* tested 2–4 hr into the dark cycle showed the highest foraging activity. Field studies show that when the environment is sufficiently moist, most *Plethodon* emerge from daytime retreats shortly after dusk to forage on the surface (Adler, 1968; Dakin, 1978). Salamander surface activity peaks 2–4 hr after dusk, declines late in the evening, and may peak again near dawn (Adler, 1968; Dakin, 1978). Adler (1968) suggested that increased rodent activity might account for the reduction in salamander surface activity in the middle of the night. Laboratory studies show that these daily activity patterns of *Plethodon* are regulated by an internal biorhythm tuned with extraoptic photoreceptors to the light–dark cycle (Adler, 1969, 1970). Biorhythmic regulation of activity persists at least 24 hr after the removal of photo cues (Adler, 1969).

Many studies consider the state of an animal, e.g., hunger level, when trying to understand an animal's response to stimuli, but most studies fail to factor in the

effects of biorhythms. In this study, exposure to predator chemical cues appears to reduce the amplitude of *P. cinereus* foraging activity, especially during periods of peak activity, but does not appear to affect the expression of temporal activity patterns. This suggests the need to consider biorhythms in the design of behavioral studies. Because exposure to chemical cues has a large effect on activity during activity peaks and a subtler effect on behavior during natural activity lulls, studies conducted during different times could produce different, potentially conflicting, results and lead to different conclusions about the effect of particular stimuli on an animal's behavior.

The interaction of behavioral biorhythms and chemical cues could be an important area of future research. Two key areas for research are: (1) how do behavioral biorhythms interact with facultative responses to environmental stimuli like chemical cues, and (2) are any responses to environmental cues under the control of biorhythms. We already know that *P. cinereus* responses to some chemical alarm cues show diel periodicity tied to the light–dark cycle (Madison et al., 1999a,b). Unlike *P. cinereus* responsiveness to the odors of snakes that fed on *P. cinereus*, which does not change throughout the diel cycle, *P. cinereus* responsiveness to the odors of snakes feeding on alternative prey varies depending on the time of day. *P. cinereus* respond the odors of *T. sirtalis* feeding on alternative prey during the day and for the first few hours after dusk, but stop responding late at night (Madison et al., 1999a,b; Madison, Maerz, and Sullivan, unpublished data). These temporal response patterns appear to be regulated by internal biorhythms tied to the diel cycle and are not directly affected by environmental cues such as light (Madison et al., 1999b). Circadian rhythmic control of responses to chemical cues has also been reported for *Drosophila* (Krishnan et al., 1999). Biorhythmic regulation of responses to predator cues should make prey responses more efficient. Predator activity or efficiency will vary depending on time of day and conditions, and prey can respond differently to the same cue depending on conditions.

CONCLUSIONS

This study shows that red-backed salamanders reduce foraging activity in response to exposure to chemical cues from a predator. Reduced foraging activity represents a cost associated with responses to chemical cues and suggests that predators could have nonlethal effects on terrestrial salamander populations. A positive correlation between the activity levels of randomly partnered salamanders exposed to different odor treatments indicated additional influences on salamander activity independent of odor treatment. Because activity patterns across the dark cycle were consistent with natural periodicity in foraging activity, which is under the control of internal biorhythms, we hypothesize that biorhythms and not sex or

hunger level affected salamander foraging activity. The effects of chemical cues on salamander foraging activity were strongest during natural peaks in salamander activity and subtler during natural lulls in foraging activity. Because biorhythms can affect both responses to chemical cues and other behaviors, such as foraging or mate search, and because independent rhythms could interact to produce different activity patterns under different contexts, studies of chemical cues should incorporate behavioral biorhythms into their design.

(Received December 1, 2000; accepted March 14, 2001)

Abstract—A predatory stink bug, *Eocanthecona furcellata*, died after feeding on *Milionia basalis* larvae. The compounds toxic to *E. furcellata* were isolated from the hemolymph of *M. basalis* larvae and identified as inumakilactone A, nagilactone C, and nagilactone C glucoside. The concentrations of inumakilactone A, nagilactone C, and nagilactone C glucoside in the hemolymph of the final instar larvae were 130, 50, and 770 μg/ml, respectively. Nagilactone C showed the highest insecticidal activity against second-instar nymphs of *E. furcellata*, while nagilactone C glucoside showed the lowest, one twentieth of that of nagilactone C. When mixed compounds were given at the same concentrations as those in hemolymph of *M. basalis*, all nymphs of *E. furcellata* died with in three days. Inumakilactone A and nagilactone C were found to be in the leaves of podocarp, *Podocarpus macrophyllus*, the only host plant of *M. basalis*, at concentrations of 13 and 175 μg/g fresh weight, respectively. However, no nagilactone C glucoside was detected in the leaves of this species. These results suggested that *M. basalis* may transform nagilactone C to its glucoside.

Key Words—Toxic compounds, defense substance, stink bug, *Eocanthecona furcellata*, geometrid moth, *Milionia basalis*, podocarp, *Podocarpus macrophyllus*, nagilactone, glucosides, inumakilactone, sequestration, transformation.

INTRODUCTION

The podocarp tree, *Podocarpus macrophyllus* (Podocarpaceae), is used as building material and as a street or garden tree in southern Japan because it is rarely infested by termites and insects (Saeki et al., 1970). *P. macrophyllus* was reported to

* e-mail: yasui@affrc.go.jp

0098-0331/01/0700-1345$19.50/0

contain substances toxic to some insect species (Ito and Kodama, 1976). However, the larvae of the geometrid moth, *Milionia basalis pryeri* Druce (Geometridae) have adapted to this plant and feed exclusively on it, with frequent outbreaks that cause considerable damage. Egg batches of the predatory stink bug, *Eocanthecona furcellata* (Wolff) (Heteroptera: Pentatomidae), have been observed on the leaves of *P. macrophyllus* (Wakamura, personal communication). *E. furcellata* is considered to be a predator of *M. basalis* because the stink bug attacks larvae of many species of Lepidoptera, Coleoptera, and Hymenoptera (Chu, 1975). However, a preliminary experiment showed that second-instar nymphs of *E. furcellata* died after attacking *M. basalis* larvae (Sakakibara, personal communication), suggesting that *M. basalis* larvae contain toxic compounds to protect themselves against predators.

In the present paper, we describe the isolation and identification of the toxic compounds in the hemolymph of *M. basalis* larvae against the predatory stink bug, *E. furcellata*, and the relationship between these isolated compounds and components in *P. macrophyllus*, the host plant of *M. basalis*.

METHODS AND MATERIALS

Insects. Larvae of the geometrid moth, *M. basalis*, were obtained from podocarp trees, *P. macrophyllus*, on Okinawa Island, Japan. The larvae were reared on the podocarp leaves in the laboratory. A laboratory colony of the predatory stink bug, *E. furcellata*, was maintained on frozen preserved larvae of the armyworm, *Pseudaletia separata*, which had been reared on an artificial diet, Insecta LF (Nihon Nousan Kogyo Co., Ltd., Japan). The second-instar nymphs of the bugs were starved for one day after ecdysis before conducting bioassays. All insects were reared at 25°C and 16L:8D photoperiod.

Collection of Hemolymph from M. basalis *Larvae.* *M. basalis* larvae (sixth instars) were kept in ice water for 15 min and then their prolegs were cut. Hemolymph was collected into 1.5-ml microtubes. The hemolymph was immediately heated and then kept at 60°C for 15 min to inactivate enzymes. The turbid hemolymph was then centrifuged, and the supernatant was separated and stored at −20°C until extraction.

Isolation of Toxic Compounds from Hemolymph of M. basalis *Larvae.* The hemolymph of *M. basalis* larvae (ca. 5 ml, sixth instars) was diluted with distilled water (5 ml) and extracted with hexane, ethyl acetate, and water-saturated 1-butanol (each 10 ml × 3), successively.

Bioassay. Test material was dissolved in methanol and applied (1 larva equivalent) to a piece of absorbent cotton (3 × 3 × 1 mm) on a sheet of parafilm (1 × 1 cm) that was placed on filter paper in a 5-cm plastic Petri dish. After the solvent evaporated, 25 μl of hemolymph of the silkworm, *Bombyx mori*, which

had been heated (60°C, 15 min) and centrifuged, was added to the cotton piece. Five second-instar nymphs of *E. furcellata* were released in the dish. To keep the test materials and insects from desiccation, a moistened cotton wick was placed on the inner side of the lid of the Petri dish. Whether the nymphs fed or not was judged from the excreta traces that remained on the filter paper disk. Mortality was checked after four days and evaluated as follows: −, less than 20%; +, ∼40%; ++, ∼80%; + + +, more than 80%. Each test was replicated at least three times.

Glycoside Hydrolysis. Hydrochloric acid (1 M, 0.05 ml) was added to the methanol solution of glycoside (0.5 mg/0.2 ml). The mixture was kept at 60°C for 14 hr, and then evaporated to dryness. Water was added to the residue, and the supernatant was separated and dried. Water (3 μl) was again added for the next trimethylsilylation.

Trimethylsilyl Derivatives of Carbohydrates. Carbohydrate in water solution (0.5 mg/5 μl) was mixed with TMSI-C (*N*-trimethylsilyl imidazole in pyridine, GL Sciences Inc.; 0.5 ml) in a sealed vial and kept at 60°C for 2hr. Authentic glucose, galactose, and sorbose were purchased from Wako Pure Chem. Industries, Ltd. Mannose, allose, and gulose were from Nakarai Chem. Ltd., Aldrich Chem. Co., and Sigma Chem. Co., respectively. Reaction mixture, 1 μl diluted 100-fold with pyridine, was directly injected into GC.

Isolation and Determination of Nagilactones from P. macrophyllus *Leaves. P. macrophyllus* leaves were steamed at 60°C for 15 min to inactivate enzymes in the leaves and then frozen. Freeze-dried powdered *P. macrophyllus* leaves were extracted with methanol for 1 night. After filtration, the methanol extract was evaporated. Distilled water was added to the residue and extracted thoroughly with hexane, ethyl acetate, and water-saturated 1-butanol, successively. The 1-butanol fraction was chromatographed on silica gel (ethyl acetate–methanol 10:1) and ODS silica gel (20% methanol). The crude inumakilactone A and nagilactone C were further purified by HPLC.

Equipment. A Shimadzu LC-10Avp system was used for HPLC. Separation was achieved with a Cosmosil-5C18-AR-II, 4.6 × 250 mm (Nacalai Tesque, Inc. Japan) column. The column temperature was 40°C. The eluting solvent was water–methanol (85:15). The flow rate was 1 ml/min. The UV detector was set at 210 for detection of inumakilactone A and at 254 and 300 nm for detection of nagilactones. NMR spectra were recorded with a Bruker ARX-400 (400 MHz) spectrometer, with pyridine-d_5 as a solvent. Mass spectra (FAB) were obtained with a Jeol JMS- SX102A spectrometer. Argon was used as a bombarding gas, (5×10^{-6} torr), FAB energy was set to 10 keV, and glycerol was used as a matrix. The gas chromatograph used was a Hewlett Packard (HP) 5890 II with a splitless capillary injector and a flame ionization detector. The column employed was DB-17HT (30 m × 0.25 mm I D × 0.15-μm film thickness; J&W Scientific); injection, 270°C; splitless time, 1.0 min; column oven temperature, 50°C for 1 min, programmed to increase up to 100°C at 20°C/min, and further increased to 270°C at 5°C/min,

and held at the final temperature for 5 min; carrier gas, helium at a column head pressure of 110 kPa. Within the GC peaks of hydrocarbons (C_{12}–C_{28}), those of C_{15}–C_{22} appeared at the same time intervals, that is, this condition was suitable for calculation of Kovát's retention time index.

Spectral Data. Data of compound **1** are: ^{1}H NMR (400 MHz); δ1.41 (3H, s, CH_3-20), 1.60 (3H, s, CH_3-18), 1.61 (3H, d, J = 6.2 Hz, CH_3-16), 2.18 (1H, d, 5.1, H-5), 3.56 (1H, dd, 6.0 and 4.2, H-2), 3.68 (1H, d, 4.1, H-1), 4.39 (1H, dq, 6.2 and 2.2, H-15), 4.69 (1H, dd, 5.9 and 5.1, H-3), 4.78 (1H, d, 8.5, H-14), 5.15 (2H, overlapping H-6 and H-7), 6.84 (1H, s, H-11). UV; λ_{max} 222 nm in methanol.

Data for compound **2** are: ^{1}H NMR (400 MHz); δ 1.22 (3H, d, J = 6.7 Hz, CH_3-16), 1.31 (3H, d, 6.7, CH_3-17), 1.59 (3H, s, CH_3-20), 1.89 (3H, s, CH_3-18), 2.14 (1H, d, 8.4, H-5), 3.45 (1H, m, H-15), 3.63 (1H, m, H-2), 3.65 (1H, d, 4.0, H-1), 4.04 (1H, m, 3-glc H-5′), 4.08 (1H, t, 8.3, 3-glc H-2′), 4.18 (1H, t, 9.1, 3-glc H-4′), 4.27 (1H, t, 8.8, 3-glc H-3′), 4.38 (1H, dd, 11.6 and 5.5, 3-glc H-6′), 4.58 (1H, dd, 11.7 and 1.7, 3-glc H-6′), 4.78 (1H, d, 5.8, H-3), 5.10 (1H, t, 8.1, H-6), 5.23 (1H, d, 7.7, 3-glc H-1′), 5.65 (1H, d, 8.0, H-7), 6.65 (1H, s, H-11). ^{13}C NMR (100 MHz); δ19.69 (C-20), 20.62 (C-16), 21.28 (C-17), 27.70 (C-18), 30.19 (C-15), 38.28 (C-10), 49.96 (C-4), 51.29 (C-5), 51.41 (C-2), 58.54 (C-1), 60.43 (C-7), 63.47 (3-glc6′), 72.00 (3-glc4′), 74.66 (C-6), 76.18 (3-glc2′), 77.58 (C-3), 78.75 (3-glc5′), 79.42 (3-glc3′), 108.19 (C-11), 108.26 (3-glc1′), 112.12 (C-8), 162.51 (C-12), 164.95 (C-14), 170.94 (C-9), 178.61 (C-19).

RESULTS

Isolation of Toxic Compounds from Hemolymph of M. basalis *Larvae.* Ethyl acetate, 1-butanol, and water extracts of the hemolymph showed toxic activity (mortality of more than 80%) to the nymphs of *E. furcellata.* Each extract was further fractionated to isolate the toxic compounds.

Identification of Toxic Compounds. Each isolated compound was identified by using the NMR, MS, UV spectra, and GC retention index system (Kováts, 1965). From the ethyl acetate extract of the hemolymph, compound **1** was isolated (Figure 1). The spectral data (NMR, UV) of compound **1** were identical to those of inumakilactone A, norditerpene dilactone, that was isolated from the podocarp tree, *P. macrophyllus* (Figure 1) (Ito et al., 1968).

From the 1-butanol extract, two compounds were found to have toxic activity against *E. furcellata.* Both compounds had the same UV spectra (λ_{max} 300 nm in methanol). Polar compound **2** was present in a large amount and showed a low toxicity, while the less polar compound **3** was present in a small amount and showed a high toxicity. UV spectra of **2** and **3** were very similar to that of nagilactone C, norditerpene dilactone, that was also isolated from the podocarp tree, *P. macrophyllus* (Hayashi et al., 1968; Ito and Kodama, 1976). The NMR

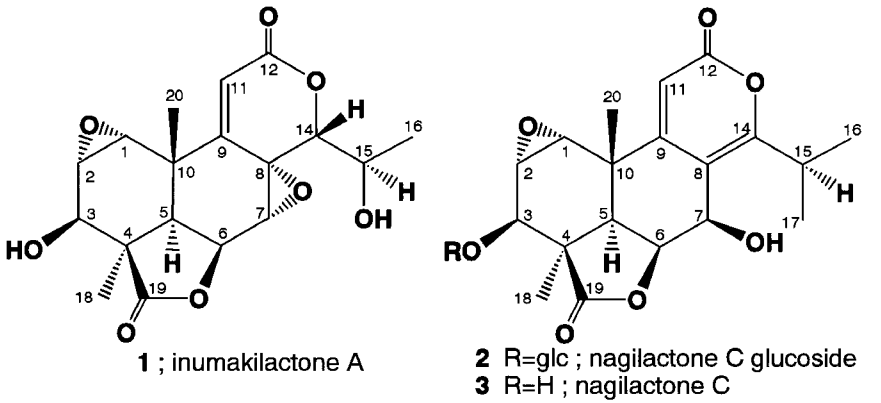

FIG. 1. Structures of toxic compounds **1**, **2**, and **3** isolated from hemolymph of *M. basalis*.

spectrum of **3** was identical with that of nagilactone C (Hayashi et al., 1968; Kubo and Ying, 1991) (Figure 1).

The mass peak (FAB) of compound **2** was observed at *m/z* 547 $(M+Na)^+$, which was higher by 162 mass units than that of nagilactone C, and indicated the presence of one additional mole of the glycosyl group in **2**. The ^1H and ^{13}C NMR spectra of **2** were very similar to those of nagilactone C (Hayashi et al., 1968; Kubo and Ying, 1991), except for the appearance of glycopyranosyl group signals. In addition, the signal at Me-18 in **2** (δ 1.89) shifted ca. 0.22 ppm upfield (nagilactone C; δ 2.11) and the carbon signal at C-3 in **2** (δ 77.58) shifted ca. 9.57 ppm downfield (nagilactone C; δ 68.01). Thus, the additional glycopyranosyl moiety appeared to link to the C-3 hydroxyl group.

In order to identify the unknown carbohydrate moiety in **2**, the GC retention index system (Kováts, 1965) was used. The data of FAB of 162 mass units difference between **2** and nagilactone C indicated that the molecular weight of the unknown carbohydrate moiety in **2** was 180. Therefore, some naturally occurring carbohydrates with the chemical formula of $C_6H_{12}O_6$ were used as standards. Each of the standard trimethylsilylated carbohydrate solutions (glucose, galactose, sorbose, mannose, allose, and gulose, 1 μl) as well as a solution of the hydrolyzed and trimethylsilylated compound **2** (1 μl) was injected into the GC together with the standard hydrocarbons in hexane solution 1 μl (C_{12}, C_{14}, C_{16}, C_{18}, C_{20}, C_{22}, C_{24}, C_{26}, and C_{28}, each 10 ng/μl). Retention indices were calculated. Since the retention index of the trimethylsilyl derivative of hydrolyzed compound **2** (peak 1: 1857, and peak 2: 1893; peak 1 and 2 were derived from α- and β-anomers during the trimethylsilylation of carbohydrates) agreed with that of glucose 5TMS (peak 1: 1858, and peak 2: 1893), the carbohydrate in **2** proved to be glucose. A signal at δ 5.23 (d, $J = 7.7$ Hz) was assigned to a glucosyl anomeric proton and the J value

suggested that the glycosidic bond had a β linkage. From the above evidence, **2** was identified as nagilactone C glucoside, 3-*O*-β-glucopyranoside of nagilactone C (Figure 1). Signals of ^{1}H and ^{13}C NMR spectra of **2** were all assigned by H-H cosy and HSQC spectra.

From the water extract of the hemolymph, the toxic fraction included nagilactone C glucoside (**2**) and nagilactone C (**3**), the same compounds as those of the 1-butanol extract.

*Quantification of Inumakilactone A (**1**), Nagilactone C glucoside (**2**), and Nagilactone C (**3**).* The concentrations of the three compounds in the hemolymph of *M. basalis* were calculated based on HPLC analysis, and found to be as high as 130, 770, and 50 μg/ml, respectively. The concentrations of **1** and **3** in the leaves of *P. macrophyllus* were 13 and 175 μg/g fresh weight, respectively.

*Relationship Among Concentrations of Compounds **1**, **2**, and **3** and* E. furcellata *Mortality.* When the test compound was applied to the absorbent cotton at concentrations of 1000, 200, 40, and 10 μg/ml each in silkworm hemolymph, the concentrations of inumakilactone A, nagilactone C glucoside, and nagilactone C, that showed 50% mortality of *E. furcellata*, were 260, 650, and 30 μg/ml, respectively (Figure 2A). Nagilactone C showed the highest insecticidal activity

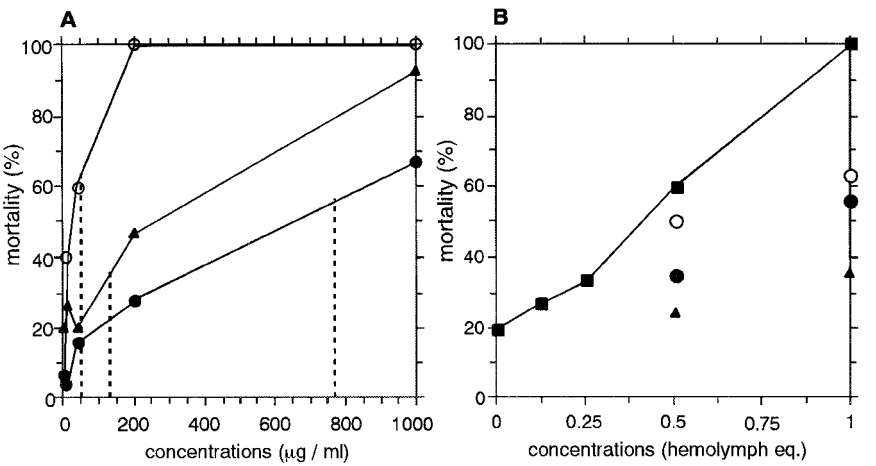

FIG. 2. Relationship between concentration of inumakilactone A, nagilactone C and nagilactone C glucoside and mortality of *E. furcellata*. (A) Test compound was applied at concentrations of 1000, 200, 40, and 10 μg/ml. Triangles: inumakilactone A, open circles: nagilactone C, closed circles: nagilactone C glucoside. Dotted lines indicate the contents of each compound in the hemolymph of *M. basalis* larvae. (B) Test compounds were applied at the same concentrations as hemolymph of *M. basalis*. Squares: three compounds mixed at the hemolymph of *M. basalis* equivalent, i.e., 1 eq mixture of inumakilactone A (130 μg/ml), nagilactone C (50 μg/ml), and nagilactone C glucoside (770 μg/ml); triangles: inumakilactone A, open circles: nagilactone C, closed circles: nagilactone C glucoside.

against *E. furcellata*, while nagilactone C glucoside showed the lowest, one twentieth of that of nagilactone C. When the three compounds mixed at the same concentrations as those in hemolymph of *M. basalis* larvae (**1**, 130; **2**, 770; and **3**, 50 μg/ml) were given to *E. furcellata*, none of the nymphs survived after three days (Figure 2B).

DISCUSSION

In this study, we identified that *M. basalis* larvae possess high concentrations of inumakilactone A (**1**), nagilactone C (**3**), and its glucoside (**2**) in the hemolymph as compounds toxic to *E. furcellata* (Figure 1). It has been reported that inumakilactone A and nagilactone C are contained in *P. macrophyllus*, the only host plant of *M. basalis* (Hayashi et al., 1968; Ito et al., 1968). Inumakilactone A shows antitermitic activity (Saeki et al., 1970), and nagilactone C is toxic to housefly larvae (Russell et al., 1972) and larvae of codling moth and light-brown apple moth (Singh et al., 1978, 1979). In the present study, inumakilactone A and nagilactone C were confirmed to be contained in the leaves of *P. macrophyllus* at concentrations of 13 and 175 μg/g fresh leaves, respectively. In *M. basalis* hemolymph, inumakilactone A, nagilactone C, and its glucoside were found to be at concentrations of 130, 50, and 770 μg/ml, respectively. Taking into account these results and the fact that no nagilactone C glucoside was detected in the leaves of *P. macrophyllus*, *M. basalis* is considered to sequester inumakilactone A and nagilactone C from the host plant and transform nagilactone C to its glucoside and store it. The conflict that the concentration of nagilactone C in the hemolymph is lower than that of the fresh leaves of *P. macrophyllus* can be explained by the likelihood of transformation of nagilactone C to its glucoside in *M. basalis* larvae. It is reported that larvae of the lycaenid butterfly, *Polyommatus icarus*, reared on inflorescences of *Coronilla varia* and *Medicago sativa* sequester host-plant derived flavonoids and glycosylated flavonoids (Wiesen et al., 1994). Wiesen et al. (1994) indicated that these flavonoids might be biotransformed to their glycosides by the insects or their gut flora. A similar transformation might occur in the case of *M. basalis*. Although it is uncertain, one of the reasons for transformation to glucoside form in *M. basalis* larvae may be to reduce the toxicity of nagilactone C for *M. basalis* itself (Figure 2A).

Inumakilactone A (**1**), nagilactone C (**3**), and its glucoside (**2**) in *M. basalis* hemolymph were contained at 130, 50, and 770 μg/ml, respectively. Each of these compounds showed insecticidal activity against *E. furcellata* at concentrations of 260, 30, and 650 μg/ml, respectively (50% mortality; Figure 2A). Furthermore, when the three compounds were given as a mixture at the same concentrations as in the hemolymph of *M. basalis* larvae, none of the *E. furcellata* nymphs survived. Thus, the concentrations of those compounds in the *M. basalis* hemolymph were

toxic enough to kill the *E. furcellata* nymphs. It is unclear whether the observed toxicity of *E. furcellata* larvae is due to postingestive effects, direct contact, or a combination of both. However, when *E. furcellata* larvae bloodsuck *M. basalis* larvae, they contact only at proboses, and other parts of the body and legs seldom contact *M. basalis* larvae. In addition, from HPLC analysis of the skin extract, only trace amounts of nagilactones were detected. Taking into account the above results, the observed toxicity of the *E. furcellata* larvae is regarded to be due to only postingestive effects.

In this report, we focused on the toxicity of host-derived compounds sequestered in *M. basalis* larvae. Since *M. basalis* larvae have an aposematic coloration, orange head and white–latticed black skin, the coloration may also play a part in the prey–predator interaction. Furthermore, other aspects, such as deterrence of the compounds, may contribute to the protection of *M. basalis* from predators. It has been reported that some of the defense substances directly toxic to predators have an unpalatable or deterrent nature (Nishida and Fukami, 1989; Nishida, 1994). For example, physiologically toxic grayanoid diterpenes that are sequestered from leaves of *Pieris japonica* by larvae of a geometrid moth, *Arichanna gaschkevitchii*, have potent deterrent activity (Nishida, 1994). The generalist predatory stink bugs, *E. furcellata*, put their proboses into lepidopteran larvae in response to (*E*)-phytol, which is produced by larvae from chlorophyll in food plants (Yasuda, 1997, 1998). *E. furcellata* put their proboses into *M. basalis* larvae, but soon pulled back, although they repeated short-time sucking. They then died after three days under confined conditions. This suggests a deterrent nature for *E. furcellata*. The deterrent nature may also play a part in the protection of *M. basalis* from *E. furcellata* in fields. Further investigation is needed to determine whether toxic compounds identified in this study have deterrent activity to predators.

Acknowledgments—I am grateful to Dr. J. Arnason of the University of Ottawa, Dr. M. Hattori and Dr. S. Wakamura for critical reading of the manuscript and valuable comments, and Dr. S. Wakamura for GC operation. I also thank Dr. M. Sakakibara for giving me the idea for this study, and Drs. N. Arakaki, K. Yasuda, M. Sakakibara, and K. Kinjo of the Okinawa Prefectural Agricultural Experiment Station for kindly collecting the *Milionia basalis* larvae, Dr. T. Yasuda for providing *Eocanthecona furcellata*, and R. Murakami for measurement of NMR spectra.

(Received November 16, 1999; accepted March 8, 2001)

Abstract—We investigated whether volatiles produced by spider mite-damaged plants of four gerbera cultivars differ in attractiveness to *Phytoseiulus persimilis*, a specialist predator of spider mites, and how the mite-induced odor blends differ in chemical composition. The gerbera cultivars differed in resistance, as expressed in terms of spider mite intrinsic rate of population increase (r_m). In order of increasing resistance these were Sirtaki, Rondena, Fame, and Bianca. To correct for differences in damage inflicted on the cultivars, we developed a method to compare the attractiveness of the blends, based on the assumption that a larger amount of spider mite damage leads to higher attraction of *P. persimilis*. Spider mite-induced volatiles of cultivars Rondena and Bianca were preferred over those of cultivar Sirtaki. Spider mite-induced volatiles of cultivars Sirtaki and Fame did not differ in attractiveness to *P. persimilis*. Sirtaki plants had a lower relative production of terpenes than the other three cultivars. This was attributed to a low production of *cis*-α-bergamotene, *trans*-α-bergamotene, *trans*-β-bergamotene, and (*E*)-β-farnesene. The emission of (*E*)-β-ocimene and linalool was lower in Sirtaki and Fame leaves than in Bianca and Rondena. The importance of these chemical differences in the differential attraction of predatory mites is discussed.

INTRODUCTION

The predatory mite *Phytoseiulus persimilis* Athias-Henriot is a specialist predator of the spider mite *Tetranychus urticae* Koch, an important pest in greenhouses. Since the predators feed almost exclusively on spider mite species from the genus *Tetranychus* and are unable to survive on alternative food sources such as pollen or nectar (Sabelis, 1985), they rely on their ability to locate areas where prey is present.

Several species of host plants respond to damage by spider mites with the production of volatiles that attract *P. persimilis* (Sabelis and van de Baan, 1983; Sabelis et al., 1984; Dicke and Sabelis, 1988; Dicke et al., 1990a,b, 1998; Sabelis and van der Weel, 1994; Sabelis and Afman, 1994). *Phytoseiulus persimilis* uses these odors to find leaves with colonies of its prey. The predators do not leave a prey patch until all prey is exterminated. This is most likely the result of arrestment in response to volatiles from damaged plants (Sabelis and van der Meer, 1986; Sabelis and Afman, 1994). Arrestment of the predators in a prey patch has a major influence on the population growth of the predators and their prey (van Baalen and Sabelis, 1995). Therefore, the response of the predators to spider mite-induced volatiles is likely to be important for the success of spider mite control with *P. persimilis*.

Different species of plants show qualitative and quantitative differences in the production of spider mite-induced volatiles, and these blends differ in attractiveness to *P. persimilis*. Even cultivars of the same species may differ in production of volatiles and attractiveness (see Takabayashi and Dicke, 1996, and Dicke et al., 1998, for reviews). Cultivar differences also have been found in the composition or the attractiveness of blends of volatiles that are produced in response to damage by other herbivores (Loughrin et al., 1995, 1996; Souissi, 1999). The success of *P. persimilis* in localizing spider mite-infested leaves and the speed at which prey populations are exterminated may, therefore, depend on the plant species or cultivar.

Gerbera jamesonii Bolus is an ornamental crop of which a large number of cultivars are grown commercially. During the breeding process, cultivars are mainly selected for color and shape of the flowers. However, quite a number of other differences exist, such as leaf shape and texture, density of trichomes, and resistance to the spider mite *Tetranychus urticae* Koch (Süterlin and van Lenteren, 1997; Krips et al., 1998, 1999a). Possibly, gerbera cultivars with spider mite damage differ as well in the production of volatiles, and these volatile blends may differ in attractiveness. This may result in cultivar effects on the ability of *P. persimilis* to localize its prey and the speed at which a spider mite population is exterminated.

The aim of this study was to compare the composition of the blends of volatiles produced by spider mite damaged leaves of four gerbera cultivars and to determine

the attractiveness of these blends to *P. persimilis*. We tried to relate differences in blends to differences in attractiveness to *P. persimilis*. However, gerbera cultivars differ largely in resistance to *T. urticae* (Krips et al., 1998), which results in unequal consumption rates by the spider mites. Thus, placing a standardized number of spider mites on gerbera leaves for a standardized amount of time does not result in equal damage on all cultivars. Because of these differences in host plant resistance, we estimated the amount of spider mite damage on the leaves by counting the number of eggs produced by the infesting spider mites on each set of leaves used in the experiments. In this way, we had an indication of whether or not cultivar differences in volatile production or attractiveness could be explained by differences in damage by spider mites.

METHODS AND MATERIALS

Plant Material

Gerbera (*Gerbera jamesonii*) plants were obtained from the gerbera breeding companies Prego Rijsenhout bv and Terra Nigra bv. They were grown at 20–30°C, 50–70% relative humidity, and at least 16 hr of light per day in a greenhouse at Wageningen University, The Netherlands. High-pressure mercury lamps were switched on when the light intensity outside dropped below 150 W/m^2 and switched off when it increased above 250 W/m^2. Plants used for the experiments were 6–12 months old. The youngest fully unfolded leaves of the cultivars Bianca, Fame, Rondena, and Sirtaki were used. Sirtaki is most susceptible to spider mites, closely followed by Rondena, while Fame is more resistant, and Bianca is most resistant. The intrinsic rate of population increase (r_m) of *T. urticae* is 0.24/day on Sirtaki, 0.21/day on Rondena, 0.16/day on Fame, and 0.09/day on Bianca (Krips et al., 1998). The cultivars Fame, Sirtaki, and Rondena are related to each other (see pedigree in Figure 1). Cultivar Bianca is unrelated to the other three cultivars.

Spider Mites

Spider mites (*Tetranychus urticae*) were collected from a commercial gerbera greenhouse at Mijdrecht, The Netherlands, in the spring of 1994 and were subsequently reared on the gerbera cultivar Sirtaki. Plants with mites were kept at 20–30°C, 50–70% relative humidity, and at least 16 hr of light per day in a greenhouse at Wageningen University.

Predatory Mites

Predatory mites (*Phytoseiulus persimilis*) were originally obtained from Entocare CV, a commercial mass rearing company for biological control. In our

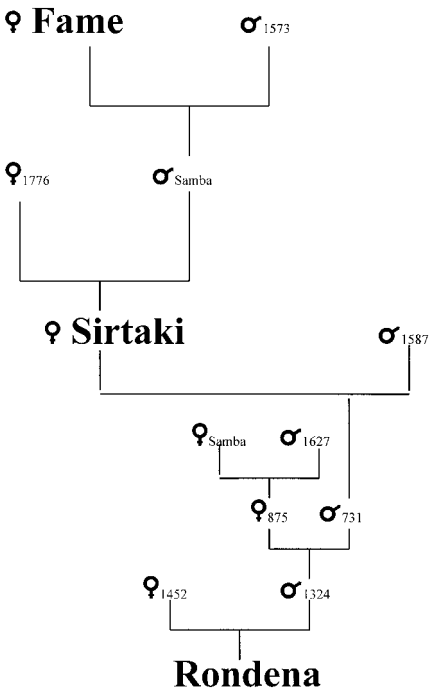

FIG. 1. Pedigree showing the relatedness of the gerbera cultivars Rondena, Fame and Sirtaki.

laboratory, they were reared on spider mites (*T. urticae*) on gerbera leaves of the cultivar Sirtaki. The predators were kept in Petri dishes of 9 cm diameter with an opening in the lid of 2.7 cm diameter, covered with fine-mesh gauze, and were offered pieces of leaves with spider mites three times a week. Once a week, five gravid female *P. persimilis* were transferred from each Petri dish to new ones. The Petri dishes were kept in a climate room at $23 \pm 2^{\circ}$C, $60 \pm 5\%$ relative humidity with a 16L:8D photoperiod.

Experiment 1: Preference of P. persimilis

Incubation of Leaves. We compared the attractiveness of the spider mite-induced volatiles of cultivar Sirtaki with those of cultivars Bianca, Fame, and Rondena. For each replicate, detached leaves of Sirtaki and one of the other cultivars were placed with their petioles in vials with tap water. The weight of the leaf samples was 30–70 g per cultivar, but was equal for both cultivars per replicate. Depending on the cultivar, 50–200 adult female spider mites were placed on each leaf, after which the leaves were incubated for seven days at $23 \pm 1^{\circ}$C, $60 \pm 5\%$

relative humidity, and a 16L:8D photoperiod. After seven days, we counted the number of eggs on the leaves as a measure of the spider mite damage inflicted. Approximately 20% of the leaf material ingested by spider mites is converted into eggs (Sabelis, 1981, p. 31), and at constant temperature and relative humidity, the number of eggs produced is directly related to the amount of ingested leaf material. Since we placed only adult female mites on the leaves, the leaves were not damaged by males. Eggs that were produced on the first day of incubation had, on some cultivars, developed into larvae during incubation. In these cases, the larvae were counted together with the eggs. Damage inflicted by these larvae was negligible compared to the damage inflicted by adult females (Sabelis, 1981).

Olfactometer Set-Up. Leaves of both cultivars were placed in separate jars that contained a small amount of water. The jars were connected to a Y-tube olfactometer, described in more detail by Takabayashi and Dicke (1992). Air with volatiles from spider mite-damaged leaves of one cultivar was led through one arm at 4 liters/min, and air from the other cultivar through the other arm at 4 liters/min. Air was extracted at the base of the olfactometer at 8 liters/min. In this way, two well-separated laminar airflows were generated in the olfactometer.

Bioassay. Adult female *P. persimilis*, from the culture on gerbera with spider mites, were starved for 3 hr and introduced individually into the olfactometer onto an iron wire running through the center of the olfactometer glass tube and parallel to the tube walls. Predators were placed at the base of the Y-tube and were allowed to choose between two olfactometer arms. The observation of a predator ended when it reached the far end of one of the olfactometer arms. Observations lasted for a maximum of 5 min per predator. Predators that had not reached the end of one of the olfactometer arms within this time were excluded from the statistical analysis. This happened in 44 cases out of a total number of 600 predators. For each replicate set of leaves, 20 predators were tested, and after every five predators, the connections of the odor sources to the two arms of the olfactometer were interchanged.

Statistical Analysis. For the statistical analysis, each olfactometer test with 20 predators and a separate set of leaves was used as a statistical unit. We used a generalized linear model (Crawley, 1993) for the number of predators choosing Sirtaki per replicate experiment with 20 predators. This model contained a binomial distribution with p for the proportion of predators choosing Sirtaki and a linear relationship between the logit of p and the amount of damage (=number of spider mite eggs) on each of two cultivars. This amount of damage is quantified by l_x, which is the logarithm of $x/(1-x)$, with x the fraction of eggs found on Sirtaki [eggs on Sirtaki/(eggs on Sirtaki + eggs on other cultivar)]. If $1_x > 0$, more eggs are found on Sirtaki than on the other cultivar, so we expect to find a higher rate of predators choosing for Sirtaki. If $1_x < 0$, more eggs are found on the other cultivar, and we expect a higher rate of predators to choose for the other cultivar.

We allowed the residual variance to be larger than prescribed by the binomial distribution through a multiplicative scale parameter. The main interest focused

on the probability p_0 of choosing Sirtaki at $1_x = 0$, i.e., with equal amount of damage on both gerbera cultivars. We tested the null hypothesis: $p_0 = 0.5$ versus the alternative $p_0 <> 0.5$. In other words, we tested whether the chance the predators chose for Sirtaki was 0.5 at an equal number of spider mite eggs on both cultivars. We further tested whether there is an effect of amount of damage on predator choice as follows: H_0: regression coefficient = 0 vs. H_1: regression coefficient >0. The model was fitted by using procedure GENMOD from the statistical program SAS version 6.12 (SAS Institute Inc., 1997).

We present results from analyses for the comparison of Sirtaki with each of the three other cultivars separately and from an overall analysis with all results combined, allowing for different success rates for different experimental setups, but with a common effect of amount of damage 1_x and a common overdispersion factor.

Experiment 2: Chemical Composition of Blends of Volatiles

We incubated detached leaves of the four gerbera cultivars with adult female spider mites following the procedure described for experiment 1. The fresh weight of the leaf samples was 34.6 ± 1.96 ($N = 5$), 29.7 ± 3.30 ($N = 6$), 32.8 ± 1.12 ($N = 6$) and 33.3 ± 3.73 ($N = 4$) g (mean $\pm$ SD) for Bianca, Fame, Rondena, and Sirtaki, respectively. The number of leaves varied between 3 and 10 per sample. Two additional samples were taken from Sirtaki with a smaller total weight (15.7 and 23.3 g) because some of the leaves had wilted during incubation and were discarded. After seven days, we counted the eggs that were present on the leaves to determine the amount of damage.

The leaves were placed with their petioles in a 200-ml glass vial containing tap water. The vial was subsequently placed in a 5-liter glass jar. Air entered the jar through a glass tube that nearly reached the bottom of the jar. Before entering the jar, air was cleaned through silica gel, molecular sieves, and activated charcoal, following the procedure described by Mattiacci et al. (1994).

An airstream of 450 ml/min was generated, and air was purged through the system for 1 hr prior to collection of volatiles in order to remove all contaminants from the jar. Subsequently, a Pyrex glass tube (161×6.4 mm OD, 3 mm ID) containing 90 mg Tenax-TA was connected to the outlet of the system for 15 min (6.75 liter). The volatiles from the Tenax tubes were analyzed by GC-MS by using the Thermodesorption Cold Trap Unit as an inlet on the gas chromatograph (Mattiacci et al., 1994).

Headspace samples were taken in four batches between April 1997 and November 1998. For all samples of Bianca, Fame, and Sirtaki and one sample of Rondena, we used a Supelcowax 10 fused silica capillary column, 60 m $\times$ 0.25 mm ID, 0.25-μm film thickness, with helium as carrier gas at an initial linear velocity of 22 cm/sec. The oven temperature was raised from 40°C to 270°C

at 4°C/min. For the other Rondena samples, a Restek Rtx200 column was used, 60 m × 0.25 mm ID, 0.25-μm film thickness. The oven temperature was raised from 40°C to 250°C at 4°C/min. Compounds were identified by comparison of the mass spectra (Finnigan MAT 95 mass spectrometer, 70 eV EI ionization mode, scanning from mass 24 to 400 at 0.7 sec/decade) with those in the Wiley library and in the Wageningen Mass Spectral Database of Natural Products and by checking the retention index. One additional sample of Sirtaki was analyzed on a BP5 column and was used only to verify the identification of some sesquiterpenoids by comparison with the retention indices as described in Adams (1989) and Joulain and Koenig (1998). An approximate measure of the sensitivity of the GC-MS was obtained by regular quantification of the peak areas of a mixture of standard compounds. The sensitivity was variable among batches of samples and was approximately 0.26, 0.10, and 0.05 ng/peak area unit for the three batches.

RESULTS

Experiment 1: Preference of P. persimilis *for Volatiles of Gerbera Cultivars with Spider Mite Damage*

In Figure 2 three pairwise comparisons of the attractiveness of spider mite-induced volatiles from different cultivars are shown. Each point in Figure 2 represents a separate olfactometer test with 20 predators. For each set of leaves, we have estimated the amount of mite damage by counting the number of eggs present on the leaves. The fraction of eggs on Sirtaki [eggs on Sirtaki/(eggs on Sirtaki + eggs on other cultivar)] is plotted on the *x* axis and the fraction of predators that chose for the volatiles of Sirtaki [predators to Sirtaki/(predators to Sirtaki + predators to other cultivar)] is plotted on the *y* axis.

Our null hypothesis was that the choice of the predators for the volatiles of one of the cultivars is determined by the amount of damage on that cultivar, in comparison with the amount of damage on the other cultivar. If this hypothesis is correct, one would expect the predators to choose for the volatiles of the cultivar with the most damage. Hence, in absence of preference, we expect points in the left-lower quarter and right-upper quarter of the graphs. With a generalized linear model and a subsequent contrast, we tested whether the predators had equal preference for the volatiles from both cultivars when spider mite damage on both cultivars was equal.

In the comparison between cultivars Sirtaki and Rondena (Figure 2A), most dots fall within the lower-right quarter of the graph, which means that, although the leaves of Sirtaki were more severely damaged by spider mites, the predators in the Y-tube olfactometer chose the volatiles of the less-damaged Rondena leaves. This preference for the volatiles of Rondena leaves was significant ($P = 0.004$). In total, 63% of the 179 predators chose Rondena. A similar result was obtained

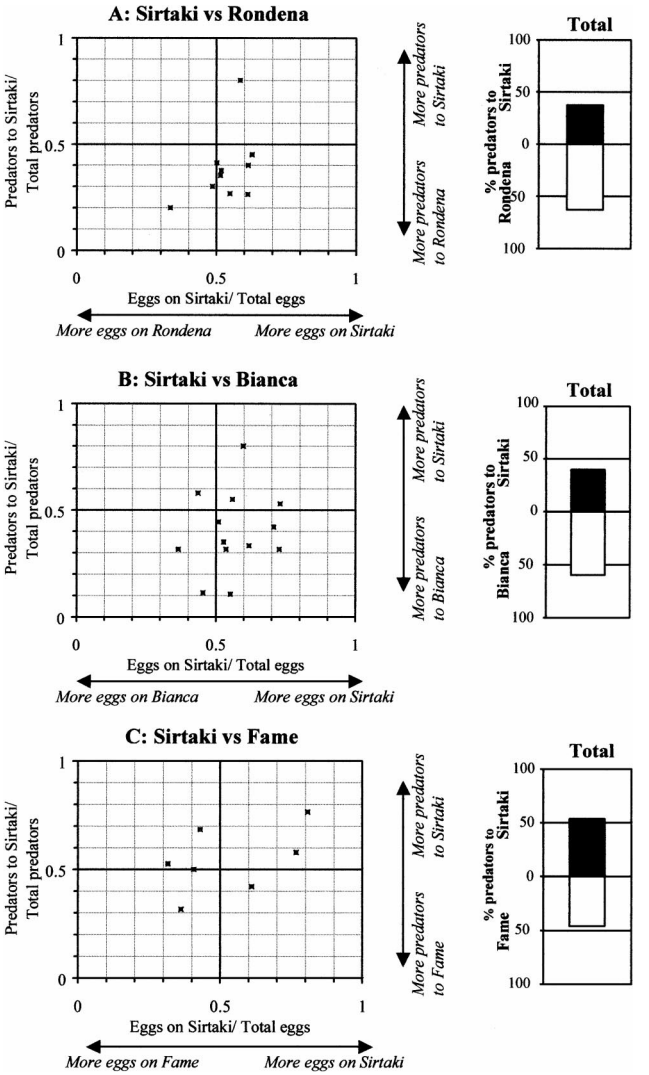

FIG. 2. Response of adult female *Phytoseiulus persimilis* to volatiles from leaves of gerbera cultivars infested by *Tetranychus urticae*. Each data point represents a Y-tube olfactometer test in which 20 adult female *P. persimilis* chose between volatiles from damaged leaves of two cultivars. The fraction of predators that chose for the spider mite-induced volatiles of either cultivar is plotted against the fraction of spider mite eggs (as a relative measure of damage) on the leaves of both odor sources. On the right of each graph, the pooled data for all replicates together is shown as the percentage of all predators that chose for each of the two cultivars.

in the comparison of Sirtaki and Bianca (Figure 2B). Although Sirtaki leaves had more damage than Bianca, there was no significant preference ($P = 0.08$). Of the 245 predators, 60% chose Bianca. When the predators were given a choice between spider mite-induced volatiles from Sirtaki and Fame, they did not show any preference ($P = 0.63$; Figure 2C). In total, 54% of the 132 predators chose Sirtaki.

If we perform a generalized linear model analysis on all data, we find the following results: a significant preference of the predators for Rondena volatiles over Sirtaki volatiles ($P = 0.01$), a significant preference for Bianca volatiles over Sirtaki volatiles ($P = 0.01$), and no significant preference for Sirtaki volatiles over Fame volatiles ($P = 0.70$). The amount of damage to Sirtaki, 1_x, showed a significant positive relationship with the rate of predators choosing Sirtaki ($P = 0.05$).

Experiment 2: Chemical Composition of Volatile Blends

The volatiles that are emitted by spider mite-damaged leaves of cultivars Bianca, Sirtaki, Fame, and Rondena are shown in Table 1. Since the total production of volatiles was variable, we calculated the relative production for each compound, based on the total amount of identified compounds. An approximation of the total production of volatiles by each cultivar is given in Table 1.

A large number of volatiles produced through different biosynthetic pathways is emitted by spider-mite-infested gerbera plants (Figures 3A and 3B). The major portions of the volatile blends consist of terpenoids (Figure 3A). Sirtaki produces the lowest relative amount of terpenoids, which is reflected in the highest relative production of aldehydes, ketones, acetates, nitrogenous compounds, and aromatic compounds (Figure 3B). Fame has a higher relative production of ketones and compounds that contain nitrogen than Bianca and Rondena, while Rondena produces more esters than the other two cultivars.

The compounds that represent more than 5% of the average total volatile blend of at least one cultivar are presented in Figure 4. The major compound is the homoterpene, 4,8-dimethyl-1,3(*E*),7-nonatriene, with a relative production that varies from 18% on Bianca to 26% on Sirtaki. Another homoterpene, 4,8, 12-trimethyl-1,3(*E*),7(*E*),11-tridecatetraene, has a relative production that varies from 6.7% on Bianca to 14% on Fame.

The most striking cultivar differences among the blends are found in the production of *cis*-α-bergamotene, *trans*-α-bergamotene, and *trans*-β-bergamotene. These three compounds each make up about 1% of the blend of Sirtaki, whereas they represent around 5%, 9%, and 4% of the blends of the other cultivars, respectively (Figure 4). The near absence of these compounds in the headspace of Sirtaki accounts to a large extent for the low total production of terpenoids by this cultivar. The production of the terpenoid (*E*)-β-ocimene is around 4% in Sirtaki and Fame, while it represents more than 8% in the blends of the other

[a] For each compound the percentage (mean ± SE) of the total amount of identified volatiles is given. Only compounds that represent at least 0.1% of the blend of one cultivar are presented. n.d. = not present in detectable levels in any of the samples of this cultivar.
[b] These unidentifiable compounds were present in many samples and are therefore not excluded from calculation of the total amount of volatiles.
[c] Based on the approximate sensitivity of the GCMS analysis per batch.
[d] Two samples with low total leaf weight of Sirtaki excluded.

two cultivars. Furthermore, (E)-β-farnesene is almost absent in the Sirtaki blend, whereas it represents 1.4–3.3% of the blends of the other cultivars (Table 1).

The relative production of (Z)-3-hexen-1-yl acetate, 2-butanone, and 2-methylbutanal-*O*-methyloxime is higher in Sirtaki than in the other three cultivars (Figure 4). Furthermore, Sirtaki has a higher production of 2-methylpropanenitrile and benzaldehyde (Table 1).

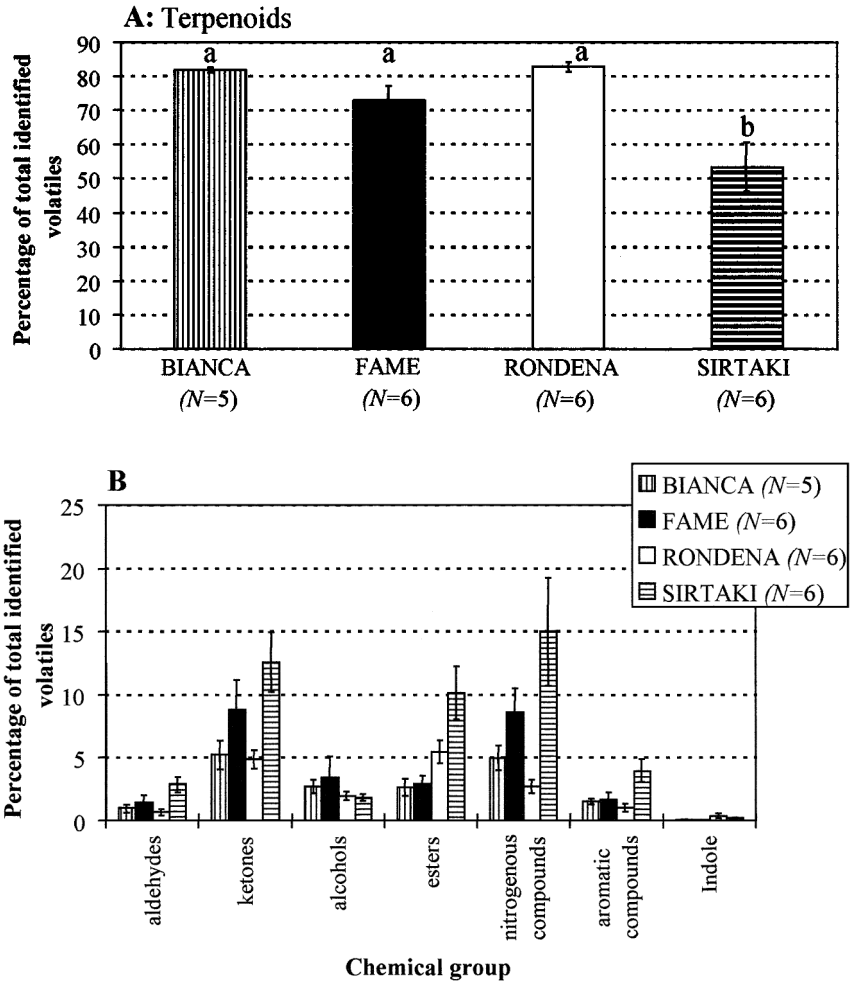

FIG. 3. Volatiles of four gerbera cultivars with *Tetranychus urticae* damage, divided into chemical groups: (A) percentage of terpenoids (different letters above bars indicate significant differences; ANOVA followed by LSD test, $\alpha = 0.05$). (B) percentages of the remaining groups. Vertical lines represent standard errors.

The total volatile production by Sirtaki was less than half the production rate of the other three cultivars (Table 1). The number of spider mite eggs found on this cultivar was also about half what was found on Fame and Rondena. Hence, the difference in total volatile production between Sirtaki as compared to Fame and Rondena can be explained by a difference in spider mite damage. However, the

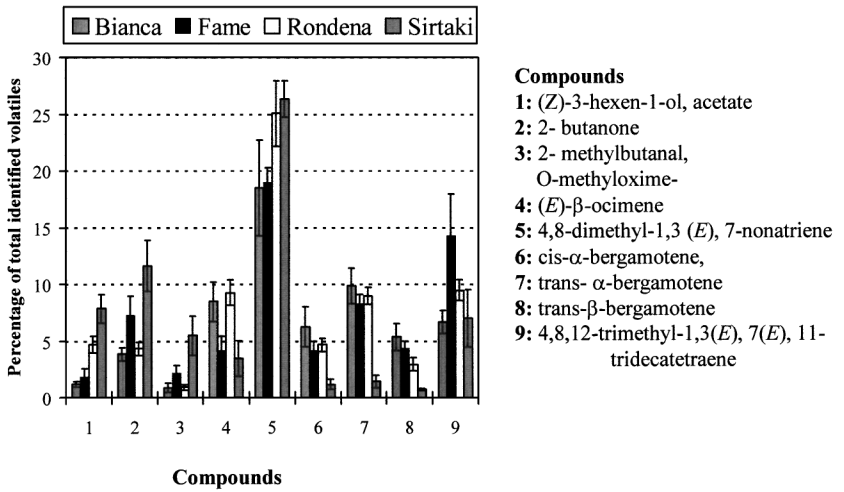

FIG. 4. Volatiles produced by leaves of four gerbera cultivars with damage of *Tetranychus urticae*. For each compound the average peak area divided by the total peak area of identified compounds is shown. Only compounds that represent at least 5% of the total volatile blend of a cultivar are presented. Vertical lines represent standard errors.

number of eggs on Sirtaki and Bianca is on the same order of magnitude, while the total production of volatiles of Sirtaki is less than half the production by Bianca. This difference in total production of volatiles, therefore, can not be explained by a difference in spider mite damage.

DISCUSSION

We have presented a method to compare the attractiveness of volatiles produced by spider mite-damaged leaves of four gerbera cultivars without ignoring differences in damage on the leaves as a result of differences in host plant resistance. We based our method on the assumption that attraction of *P. persimilis* is positively related to the amount of spider mite damage on gerbera leaves. We found a correlation between the amount of spider mite damage on the leaves and the attraction of *P. persimilis* towards the volatiles produced by these leaves. Previous studies showed that the response of *P. persimilis* to volatiles from spider mite-damaged bean leaves increases with the number of damaged leaves offered (Sabelis and van de Baan, 1983). Hence, the total amount of damaged leaf area is important for attraction of the predators. As the data in our paper demonstrate, however, the attractiveness of volatiles from spider mite-damaged leaves is also determined by the amount of damage per leaf.

The cultivars we investigated differ in resistance, as expressed in terms of spider mite intrinsic rate of population increase (r_m). In order of increasing resistance these were Sirtaki, Rondena, Fame, and Bianca, on which spider mite r_m is 0.24, 0.21, 0.16, and 0.09/day, respectively (Krips et al., 1998). *P. persimilis* has a preference for spider mite-induced Rondena and Bianca volatiles over those of Sirtaki, while no difference in attractiveness of Sirtaki and Fame volatiles was found. The predators that were used had been reared on spider mites on Sirtaki. The response of *P. persimilis* to spider mite-induced volatiles of a new host plant can be enhanced by experience (Takabayashi et al., 1994; Krips et al., 1999b). However, *P. persimilis* does not prefer the volatiles of Sirtaki over those of other cultivars. Hence, the differences in attractiveness can not be explained by rearing history or experience of the predators.

A low attractiveness of Sirtaki volatiles as compared with the volatiles of Rondena and Bianca may be the result of a lower production rate of volatiles by Sirtaki leaves, a different composition of the volatile blend, or a combination of the two. The results of the chemical analyses indicate that at equal damage, the total production of volatiles by Sirtaki leaves is lower than by Bianca leaves. However, this does not seem to be the case in the comparison between volatiles of Sirtaki leaves and Rondena leaves. Hence, the composition of the blend of volatiles appears to be important for the attractiveness to *P. persimilis*.

The blend of spider mite-damaged Sirtaki leaves consists of a lower relative amount of terpenes than the blends of the other three cultivars. Similarly, Loughrin et al. (1995) found that differences in volatile production of cotton cultivars were mainly based on differences in the production of terpenes. Several terpenes are known to attract *P. persimilis* (Dicke et al., 1990a). The low production of terpenes by gerbera cultivar Sirtaki in our studies is likely responsible for the low attractiveness of the blend for *P. persimilis*. The low production of terpenes by Sirtaki leaves was mainly due to the low production of *cis*-α-bergamotene, *trans*-α-bergamotene, *trans*-β-bergamotene, and (E)-β-farnesene. However, the low attractiveness of Sirtaki volatiles compared to those of Rondena and Bianca, can not be explained by the low production of these four terpenes because volatiles from Fame are equally attractive as volatiles from Sirtaki, although Fame has a much higher production of these compounds. On the other hand, the relative production of (E)-β-ocimene is lower in the blends of both Sirtaki and Fame than in those of Bianca and Rondena leaves. Interestingly, this compound is known to be attractive to *P. persimilis* when offered as an individual compound in a Y-tube olfactometer (Dicke et al., 1990a) and may, therefore, be partly responsible for the low attractiveness of Sirtaki volatiles in comparison to those of Rondena and Bianca.

Loughrin et al. (1996) found that cultivar differences of volatiles from undamaged apple leaves in attractiveness for the Japanese beetle *Popillia japonica* were correlated with the production of linalool. They also found indications that the

homoterpene, 4,8-dimethyl-1,3(*E*),7-nonatriene, played a role. Both compounds are attractive to *P. persimilis* (Dicke et al., 1990a). Our data indicate that the cultivar differences in attractiveness of gerbera volatiles may be related to differences in the production of linalool. The relatively unattractive Fame has the lowest production of linalool. The attractive Rondena leaves have the highest production rate. Sirtaki and Bianca have similar relative production rates of linalool, but Bianca had a total volatile production that was twice as high as the production by Sirtaki and, therefore, also produced twice as much linalool as Sirtaki.

The relative and absolute production of 4,8-dimethyl-1,3(*E*),7-nonatriene was equal in Sirtaki and Rondena, although the attractiveness of the blends differed. Furthermore, the attractive cultivar Bianca had a lower relative production of this compound than the unattractive cultivar Sirtaki. Therefore, the cultivar differences in attractiveness can not be explained by differences in the production of this homoterpene.

The relative production of 2-butanone, (*Z*)-3-hexen-1-yl-acetate, 2-methylpropane nitrile, and 2-methylpropanal-*O*-methyloxime is higher in the leaves of Sirtaki than in the leaves of the other three cultivars. (*Z*)-3-Hexen-1-yl-acetate is neither attractive nor repellent for *P. persimilis* (Dicke et al., 1990a), and the effect of the other compounds is not known. However, Takabayashi et al. (1994) found indications that two other oximes might be repellent to *P. persimilis*. Possibly, oximes play a role in the low attractiveness of the blend of Sirtaki leaves.

It has been hypothesized that plants that spend much of their resources on direct defense to herbivores may spend less on indirect defense by attracting natural enemies of the herbivores (Dicke, 1994, 1999). This raises the question whether there is a negative correlation between resistance to *T. urticae* and attraction of *P. persimilis*. The cultivars Sirtaki and Rondena are both highly susceptible to *T. urticae* (Krips et al., 1998). The volatiles of Rondena were more attractive to *P. persimilis* than the volatiles of Sirtaki. The cultivar Bianca is resistant to *T. urticae* (Krips et al., 1998), but the volatiles of this cultivar were more attractive to *P. persimilis* than the volatiles of the susceptible Sirtaki. Furthermore, the cultivar Fame is much more resistant than Sirtaki, while no difference in attractiveness of the volatiles of these two cultivars was found. Thus, no relation between direct and indirect defense of gerbera plants to *T. urticae* was found.

In conclusion, differences exist in the preference of *P. persimilis* for the blends of spider mite-damaged gerbera cultivars and the composition of these blends. The behavioral response of *P. persimilis* results in arrestment in a spider mite patch until all prey are exterminated. If only a slight fraction of the predators leaves the prey patch before all prey is exterminated, the prey population would reach much higher numbers and the moment at which all prey is eliminated by the predators would be postponed dramatically (van Baalen and Sabelis, 1995; Pels and Sabelis, 1999). If the less preferred volatile blends of Sirtaki and Fame result in a reduced arrestment of the predators on these cultivars, the success of biological control on

these cultivars will be much lower. However, it is possible that the production of volatiles by all four cultivars is above a threshold at which *P. persimilis* is arrested until prey extermination. Therefore, it will be necessary to investigate in future greenhouse studies whether the arrestment response of the predators is related to the preference of the predators for the volatile blends of certain cultivars and to the composition of these blends.

SINGLE AND BLENDED MAIZE VOLATILES AS ATTRACTANTS FOR DIABROTICITE CORN ROOTWORM BEETLES[1]

LESLIE HAMMACK*

USDA, ARS, Northern Grain Insects Research Laboratory
2923 Medary Avenue
Brookings, South Dakota 57006

(Received September 20, 2000; accepted March 13, 2001)

Abstract—Synthetic maize volatiles and analogs dispensed singly and blended were tested for attractiveness to western (WCR, *Diabrotica virgifera virgifera*) and northern corn rootworm beetles (NCR, *D. barberi*) in maize fields. Newly identified attractants included *syn*-benzaldoxime, especially for NCR, and β-caryophyllene for WCR females. (±)-Linalool was more effective than was (−)-linalool. Myrcene, (+)-β-pinene, and (−)-β-pinene were unattractive. Adding methyl salicylate to (±)-linalool, (+)-α-terpineol, or β-ionone appeared to synergistically increase capture of WCR females, but dispensing the terpenes in binary blends did not. Dose–response data for methyl salicylate, (±)-linalool, and a blend of both compounds confirmed the synergy. β-Caryophyllene, but not (−)-α-pinene, added to the latter blend produced a further synergistic increase in WCR female capture that did not vary with sesquiterpene dose from 1.0 to 100 mg. Indole addition to the same blend caused an increase in WCR female captures indicative of synergy, assuming that each did not individually lure different segments of the WCR female population. The green leaf volatiles *(Z)*-3-hexenyl acetate and (*Z*)-3-hexen-1-ol were unattractive alone and had no influence on efficacy of traps baited with 3.3 mg each of (±)-linalool, methyl salicylate, and β-caryophyllene. The latter mixture captured about half as many WCR females as did 10 mg of 4-methoxycinnamaldehyde, a potent WCR attractant standard. Substituting β-ionone for (±)-linalool yielded a ternary blend that captured more beetles than did the aldehyde and was unaffected by aldehyde addition. Olive oil, which has been used to sustain attractant volatilization, did not affect captures. The results show that the blending of maize volatiles has the

INTRODUCTION

Diabroticite rootworms (Coleoptera: Chrysomelidae) are major pests of maize, *Zea mays* L., in the United States, where most damage results from western (WCR) and northern (NCR) corn rootworms, *Diabrotica virgifera virgifera* LeConte and *D. barberi* Smith and Lawrence, respectively. The WCR was also recently introduced into Europe, where it is spreading and attaining pest status (Enserink, 1999). Principal rootworm management options are crop rotation and chemical insecticides. The latter account for nearly a fifth of the insecticides applied to U.S. field crops (Delvo, 1993). New management tools are needed to address pesticide-related environmental concerns and the emergence of corn rootworm populations adapted to resist insecticides (Meinke et al., 1998) or survive in maize rotated with another crop (Krysan, 1993; Stewart et al., 1995; Onstad et al., 1999). One promising approach is the exploitation of insect behavior-modifying chemicals. These include cucurbitacin feeding stimulants, currently under evaluation in area wide corn rootworm trials, and host plant kairomones or their analogs with odors attractive to adult diabroticite beetles (Levine and Oloumi-Sadeghi, 1991; Sutter and Lance, 1991; Metcalf and Lampman, 1997).

Because most crop damage from corn rootworms results from larval feeding, kairomones attracting adults could be most effectively used to monitor the potential for damaging larval populations in subsequent growing seasons or to interfere with reproduction by mass trapping or annihilation techniques. Unlike diabroticite sex pheromones, the kairomonal attractants, which apparently influence host seeking and selection, usually trap at least as many females as males, enhancing their potential as rootworm management tools (Quiring and Timmins, 1990).

Attraction of diabroticite beetles to host plant odors has been studied in considerable detail. Phytochemicals from Cucurbitaceae, the hypothesized ancestral hosts of diabroticite corn rootworms (Metcalf and Metcalf, 1992), have been most extensively studied (Metcalf and Lampman, 1997; Cossé and Baker, 1999); however, synthetic maize volatiles were examined in recent field trials (Hammack, 1996, 1997). Existing research stresses phenylpropanoids from cucurbits and terpenoids from maize, but diabroticite attractants show considerable chemical heterogeneity, and some, such as β-ionone, indole, 2-phenyl-1-ethanol, and phenylacetaldehyde, occur in both maize and squash blossoms (Flath et al., 1978; Buttery et al., 1980; Andersen, 1987; Andersen and Metcalf, 1987; Turlings et al., 1993). The green leaf

volatiles (GLVs), aliphatic six-carbon primary alcohols, aldehydes, and acetates that are ubiquitously distributed in the plant kingdom, also occur in both host groups, but have received little attention as corn rootworm attractants.

The chemical diversity of diabroticite attractants identified to date and their widespread distribution among plant families increase the likelihood that odorant blends are important for specificity and strength of adult host-finding responses. Although existing studies emphasize individual compounds, several blends of cucurbit blossom volatiles are known to produce a synergistic increase in capture of WCR, NCR, or southern corn rootworm, *D. undecimpunctata howardi* Barber (SCR). These blends include equal-weight mixtures of veratrol, indole, and phenylacetaldehyde (VIP) for SCR and 1,2,4-trimethoxybenzene, indole, and (*E*)-cinnamaldehyde (TIC) for all three species (Lampman and Metcalf, 1987). Indole was recently identified as a key synergist in both VIP and TIC mixtures and in combination with 4-methoxycinnamaldehyde, the most potent single-component attractant available for WCR and a possible contributor to cucurbit blossom aroma (Metcalf et al., 1995; Metcalf and Lampman, 1997). More limited evidence that lure efficacy can be increased by blending attractants has also been reported (Hammack, 1996; Metcalf and Lampman, 1997; Petroski and Hammack, 1998), including evidence for synergy between maize terpenoids.

Improved efficacy of corn rootworm kairomonal lures is desirable, at least for mass trapping and annihilation applications. This is because the kairomonal lures generally function least well, if at all, during maize silking, and intervention with these techniques would work best during or shortly after silking when females have emerged but not yet oviposited to any extent (Lance, 1993; Hesler et al., 1994; Hammack and Hesler, 1995).

The present study tested primarily maize terpenoids, GLVs, and blends of these chemicals for attractiveness to WCR and NCR beetles. The main goal was to assess the blending of individual attractants as a means of improving lure efficacy, emphasizing inclusion of maize headspace volatiles in test blends. Attention to blends also stimulated evaluation of the need for a previously used olive oil extender (Hammack, 1997) because of the possible existence of behaviorally active oil volatiles and the greater potential for interaction of any such volatiles with blended test components.

METHODS AND MATERIALS

Odorants. The structure and purity of the test compounds are shown in Figure 1. They were purchased from Fluka Chemical Co., Ronkonkoma, New York {(−)-linalool, β-caryophyllene [(-)-*trans*-caryophyllene], (+)-α-terpineol, (+)- and (−)-β-pinene}; Sigma, St. Louis, Missouri [(*Z*)-3-hexenyl acetate];

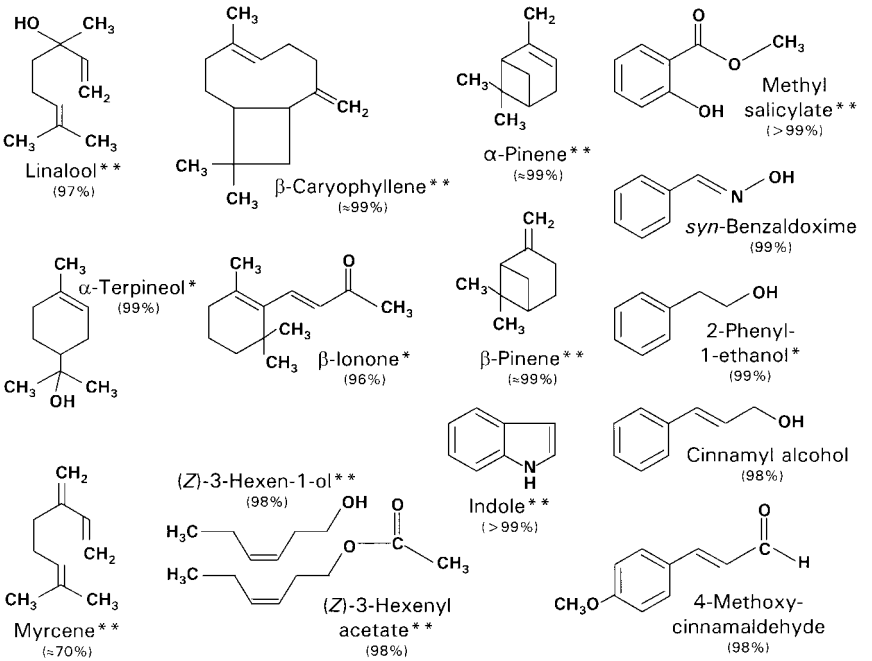

FIG. 1. Structure and purity (in parentheses) of test compounds. Single asterisks indicate maize volatiles (Flath et al., 1978). Double asterisks indicate those maize volatiles found in headspace analyses (see text for references).

Schweizerhall Inc., South Plainfield, New Jersey (4-methoxycinnamaldehyde); or Aldrich, Milwaukee, Wisconsin (all others).

Experiments. Ten field experiments were conducted between 1996 and 1999. One 1996 test examined the effect of omitting the olive oil extender on WCR and NCR responses to 2-phenyl-1-ethanol and to unbaited controls. This alcohol was used because it lures beetles of both species (Petroski and Hammack, 1998).

A second 1996 test screened single compounds for attractiveness. Four terpenoids (β-caryophyllene, linalool, myrcene, and β-pinene) were assayed because of their presence in maize headspace (Buttery and Ling, 1984; Light et al., 1993; Turlings et al., 1993; Takabayashi et al., 1995). *syn*-Benzaldoxime was tested because of its structural similarity with 2-phenyl-1-ethanol, a lure shared by maize and cucurbits, and with 2-phenyl-1-ethylamine, an effective NCR attractant not reported from host plants (Metcalf and Lampman, 1991; Petroski and Hammack, 1998). Cinnamyl alcohol was included as a reference standard for NCR, for lack of a maize headspace volatile highly attractive to this species. (±)-Linalool, previously

shown to lure primarily WCR (Hammack, 1997), served as a standard for WCR and was compared with (−)-linalool.

The remaining 1996 test screened for synergy among four maize volatiles known to individually attract primarily WCR: (±)-linalool, (+)-α-terpineol, β-ionone, and methyl salicylate (Lampman and Metcalf, 1988; Hammack, 1996, 1997). Screening was done by comparing responses to one-component, binary, and quaternary blends. The compounds were mixed in equal weights for convenience.

One of two 1997 tests yielded dose–response data for (±)-linalool, methyl salicylate, and an equal weight blend of both compounds to confirm synergy between them. Linalool was used for confirmation, rather than α-terpineol or β-ionone, because it is the only one of the three terpenes so far reported in maize headspace analyses (Buttery and Ling, 1984; Light et al., 1993; Takabayashi et al., 1995; Turlings et al., 1993).

The other 1997 test appraised synergy upon β-caryophyllene addition to the blend of (±)-linalool and methyl salicylate. This test was repeated twice, except that β-caryophyllene was replaced with one of two maize headspace volatiles: the attractant indole in 1998 and (−)-α-pinene in 1999. (−)-α-Pinene earlier showed evidence of slight attractiveness to WCR in one of two tests when dispensed by itself (Hammack, 1997).

The effect on beetle captures of altering the ratio of blend components was examined in 1998 by varying from 1 to 100 mg the amount of β-caryophyllene dispensed with 10 mg each of (±)-linalool and methyl salicylate. Another 1998 test evaluated attractiveness of two GLVs released by maize, (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate (Buttery and Ling, 1984; Light et al., 1993; Takabayashi et al., 1995; Turlings et al., 1993). The GLVs were dispensed individually and blended with 3.3 mg each of (±)-linalool, methyl salicylate, and β-caryophyllene. A final 1998 test aimed to enhance captures by replacing (±)-linalool with β-ionone in the ternary blend and to compare efficacy of the maize blends with that of 4-methoxycinnamaldehyde. The latter aldehyde was also dispensed in combination with the maize volatiles.

Bioassays. Cotton dental rolls (1 cm diam. 3.8 cm long) were used in all of the experiments to dispense the test odorants. Each roll was also treated in 1996 with 2.0 ml of olive oil in hexane (1:4 by volume) (Hammack, 1997), except for the test which compared attractiveness of 2-phenyl-1-ethanol dispensed with and without the extender. No extender was used after 1996. Odorant-treated dental rolls were attached for bioassay to yellow Pherocon AM (Trécé, Inc., Salinas, California) sticky traps as the traps were placed in grower maize fields in Brookings County, South Dakota. When multiple test compounds were to be dispensed from the same trap, each was applied to a half dental roll (1.9 cm long) that was separately affixed to the trap. The number of dental rolls and solvent volumes per trap (oil and hexane in 1996, acetone used to dissolve indole and 4-methoxycinnamaldehyde in 1998) were held constant within experiments. Control traps were identical to the treated

ones, except that no test odorant(s) was applied to the dental roll(s) affixed to the controls. Odorants were considered attractive if they captured significantly more beetles than did the control.

The experiments were all laid out in a randomized complete block design. Each consisted of eight blocks, except for six blocks in two 1996 tests: the test that examined effects of extender and the one that screened individual compounds for attractiveness. Traps were positioned at least 30 m from one another at ear height on maize plants, and crop phenology was determined during testing, as previously detailed (Hammack, 1996, 1997). Traps were left in the field for 48 hr, except for 96 hr when 2-phenyl-1-ethanol was dispensed with and without extender and 24 hr in the (−)-α-pinene test (for convenience). The species and sex of captured beetles were recorded once the traps were returned to the laboratory.

Odorant Interactions. Interactions were evaluated using dose–response data and ratios of interaction (ROI), where $ROI = [(A + B) + \text{Control}]/[(A) + (B)]$, A is the capture on a trap baited with odorant A, B is the capture on a trap baited with odorant B or blend B, and $A + B$ is the capture on a trap baited with both A and B (Hammack, 1996). Odorants were deemed to interact synergistically when the response to a blend exceeded that predicted from their individual dose–response curves (Barenbaum, 1989) and, in addition, the ROI value was greater than one (Hammack, 1996). If the first criterion was met but the $\text{ROI} = 1$, then synergy could still be occurring if the individual odorants were similarly affecting the same segment of the test population. Although such similar action was likely, it was not unequivocally proven in these field experiments.

Statistical Analyses. The SAS Institute (1989) statistical package was used for data analysis. To determine whether ROI values differed from 1, Student's *t* test for paired samples or Wilcoxon's signed rank test (*S* statistic) was used to test the null hypothesis of no difference between ROI numerator and denominator (PROC Univariate). Wilcoxon's test was used instead of the *t* test if the Shapiro-Wilk test for normality approached significance at $P \leq 0.1$ (PROC Univariate). Otherwise, data from each experiment were transformed $[\ln(x + 1)]$ to ensure homogeneity of variances and then examined by analysis of variance (PROC ANOVA). The Student-Newman-Keuls option was used to separate means after a significant ANOVA. The tables and figures show untransformed data. $P \leq 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Extender. Dose significantly influenced capture of both WCR and NCR on traps baited with 0–30 mg of 2-phenyl-1-ethanol, although WCR males were unaffected (Table 1). In contrast, treatment with the oil extender had no effect on captures of either sex or species nor did it interact with dose to alter captures (Table 1).

TABLE 1. CAPTURE OF CORN ROOTWORM ADULTS ON TRAPS BAITED WITH 2-PHENYL-1-ETHANOL ON DISPENSERS WITH AND WITHOUT OLIVE OIL[a]

2-Phenyl-1-ethanol dose (mg/trap)	Oil	Capture (mean ± SE)

Many extenders including olive and mineral oils have been used to sustain volatilization of candidate attractants from lure dispensers in field trials (Lampman and Metcalf, 1987; Petroski and Hammack, 1998; Cossé and Baker, 1999), although some, like olive oil, could release behaviorally active volatiles. The present study detected no effect of olive oil, either by itself or in combination with 2-phenyl-1-ethanol, on WCR or NCR captures. However, omission of the oil was still deemed desirable, at least in these short-term tests, because it precluded interaction with test compounds other than the alcohol and will facilitate future gravimetric measurement of attractant release rates.

Screening of Individual Terpenoids/Benzaldoxime. The screening of individual compounds (100 mg/trap) showed *syn*-benzaldoxime attractive to WCR females and to NCR of both sexes, while β-caryophyllene attracted only WCR females (Table 2). *syn*-Benzaldoxime captured more NCR than did the cinnamyl alcohol standard, considered a strong NCR attractant (Metcalf and Lampman, 1991), and as many WCR females as did (±)-linalool. β-Caryophyllene, in contrast, lured fewer WCR females than did the (±)-linalool standard. (−)-Linalool also proved less attractive than the racemic standard, especially to WCR but also to NCR females. Neither β-pinene stereoisomer nor myrcene was attractive (Table 2).

This is the first demonstration that syn-benzaldoxime and β-caryophyllene attract corn rootworm adults. Activity of the oxime may derive from a structural similarity with 2-phenyl-1-ethanol or 2-phenyl-1-ethylamine lures, or perhaps

TABLE 2. CAPTURE OF CORN ROOTWORM ADULTS ON TRAPS BAITED WITH CANDIDATE ATTRACTANTS[a]

[a] Test conducted September 9–11, 1996 ($N = 6$). Mean beetle count per corn plant ± SE on September 11 was 1.2 ± 0.2 WCR and 1.1 ± 0.2 NCR. Corn was in the dent stage (R5).
[b] Asterisks denote statistical significance at $P < 0.0001$, NS denotes $P > 0.05$ ($df = 8, 40$). Means within a column followed by the same letter do not differ by Student-Neuman-Keuls test, $P > 0.05$.

with phenylacetaldoxime, a common floral volatile (Kaiser, 1991). Oximes have not previously been reported as corn rootworm attractants and merit further study given the magnitude of WCR and especially NCR captures reported here.

β-Caryophyllene is released by a wide assortment of flowering plants (Knudsen et al., 1993; Borg-Karlson et al., 1994) and attracts insects other than WCR, including boll weevils (Minyard et al., 1969) and green lacewings (Flint et al., 1979). Like several other corn rootworm attractants, such as linalool and indole, β-caryophyllene is among volatiles released by maize in response to insect feeding (Turlings et al., 1993; Takabayashi et al., 1995). Its hydrocarbon structure renders β-caryophyllene an atypical attractant for diabroticite beetles. Several other maize terpenoid hydrocarbons, namely myrcene, β-pinene, and limonene (Light et al., 1993; Takabayashi et al., 1995), were tested here or earlier (Hammack, 1996), but failed to attract either WCR or NCR. (−)-α-Pinene, but not (+)-α-pinene, did attract WCR females in one of two earlier tests, although that response was only just detectable (Hammack, 1997) and not reproducible in the current study.

Unlike benzaldoxime, β-caryophyllene was a more effective WCR than NCR lure. Despite much overlap in the array of host compounds and analogs attractive to NCR and WCR beetles, response patterns of the two species are generally distinct (Hammack, 1996, 1997; Metcalf and Lampman, 1997; Petroski and Hammack, 1998). Distinct response patterns might be expected, as WCR and NCR likely

evolved their association with maize independently of one another and differ as adults in their reliance on maize for food (Branson and Krysan, 1981). Metcalf et al. (1998) considered the greater reliance of WCR on maize atypical of diabroticite adults, which as a group tend to feed on pollen from a variety of grasses and forbs, perhaps in response by some *Diabrotica* species to widely distributed floral volatiles shared with ancestral Cucurbitaceae.

The weaker response of both species to (−)- than to (±)-linalool implies that(+)-linalool, or a blend containing this enantiomer, is the more effective lure. The (+)-isomer was not, however, available for testing. Chirality is known to be important to WCR reacting to α-terpineol (Hammack, 1996), as well as to female cabbage looper moths and solitary bees, which both preferentially respond to (*S*)-(+)-linalool acting as a pheromone (Heath et al., 1992; Borg-Karlson et al., 1996).

Traps baited with effective lures usually attracted more females than males within each species, and the disparity between the sexes tended to be greater for WCR than NCR. These results agree with those of previous studies, where trap catch was examined by sex (see Hammack, 1997 for references and further discussion), except that NCR females do not always outnumber NCR males. Assuming attractant involvement in host seeking/selection, higher female captures likely relate to nutritional demands of oogenesis, which could be more stringent in the more fecund WCR than NCR (Naranjo and Sawyer, 1987). Captures would also reflect sex ratios in maize fields at testing. Female to male ratios could tend to rise in late season with earlier mortality of males due to protandry (Quiring and Timmins, 1990) or, in the case of NCR, which are more apt than WCR to move out of maize to feed on a variety of flowering forbs, with the migration of females back into maize to oviposit (Branson and Krysan, 1981).

Terpenoid and Methyl Salicylate Blends. When methyl salicylate and the three terpenes were assayed at 30 mg per component per trap, each binary blend captured significantly more WCR females than did its individual constituents only when the blend contained methyl salicylate (Figure 2). A significant increase occurred with mixing when methyl salicylate was added to (±)-linalool, (+)-α-terpineol, or β-ionone, but not when blends contained any two of the three terpenes. Mixing all four chemicals failed to increase the capture of WCR females beyond that achieved by mixing only methyl salicylate and β-ionone. The latter two were the least and most active, respectively, of the four single compounds (Figure 2). The other two, (±)-linalool and (+)-α-terpineol, showed an intermediate attractiveness. WCR males demonstrated significant, albeit weak, olfactory attraction only when treatments included β-ionone; however, none of the β-ionone blends was significantly better than β-ionone by itself (Figure 2). Only treatments containing (+)-α-terpineol or (±)-linalool attracted NCR in numbers significantly higher than control, although mean captures per trap failed to exceed 25 and showed no tendency to increase when chemicals were blended (data not shown).

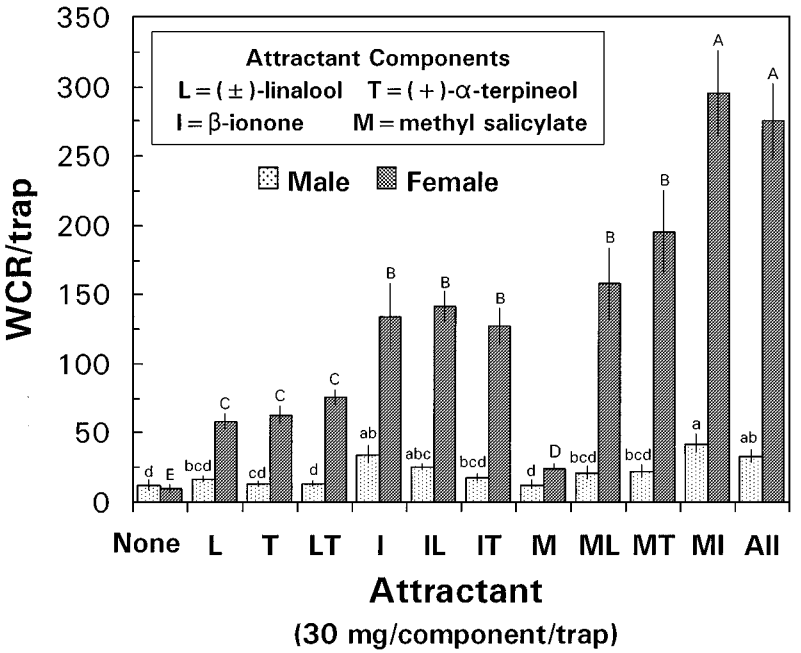

FIG. 2. Effect of blending (±)-linalool, (+)-α-terpineol, β-ionone, and methyl salicylate on WCR capture (mean ± SE, $N = 8$). Means within sexes topped by different letters differ at $P \leq 0.05$ by Student-Newman-Keuls test after ANOVA ($F = 66.62$ and 8.09 for females and males, respectively; $df = 11, 77$; $P < 0.0001$). On September 6, 1996 when the test ended, corn was dough to dent stage (R4–R5) and mean beetle count per plant ± SE was 0.9 ± 0.2 WCR and 1.2 ± 0.2 NCR.

Doses as low as 30 mg/trap (15 mg/chemical) of a 1:1 blend of (±)-linalool and methyl salicylate produced captures higher than those seen with as much as 120 mg of either compound by itself (Figure 3). ROI values calculated for WCR females reacting to the two chemicals, each chemical at doses of 7.5, 15, 30, or 60 mg dispensed from the same and separate traps, were very similar across doses, at 1.9 ± 0.2, 1.8 ± 0.3, 2.1 ± 0.5, or 1.9 ± 0.3 (mean ± SE), respectively. All four doses were, therefore, used to calculate a joint ROI of 1.9 ± 0.2, which differed from 1 ($S = 244$, $N = 32$, $P < 0.001$). Only the higher doses of the blend (60 and 120 mg) attracted NCR females, but the best mean capture (6.4 per trap) did not differ from that to any single component (data not shown). No odorant treatment attracted males of either species (data not shown).

The present tests clearly demonstrated a synergistic increase in capture of WCR females when methyl salicylate and linalool were dispensed from the same as compared with different traps, with observed captures at least 1.9 times those

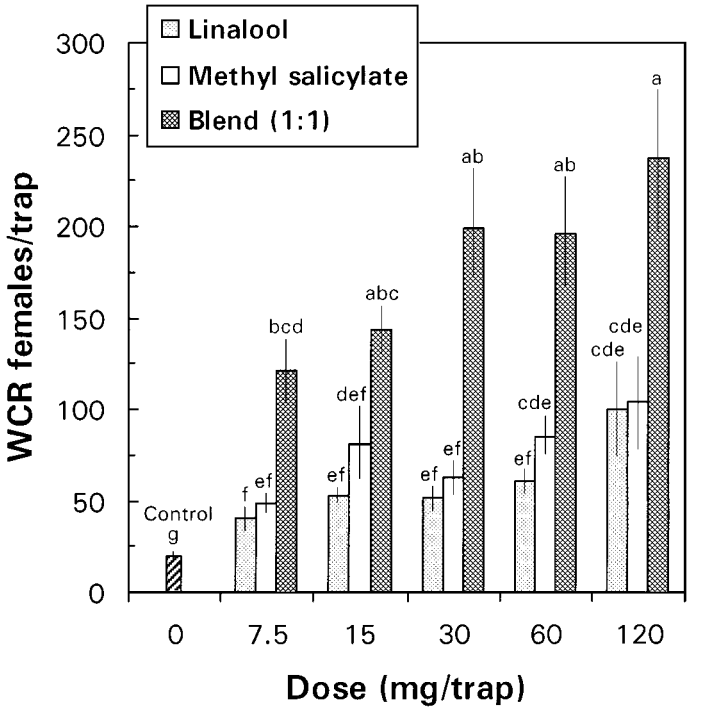

FIG. 3. Relationship between attractant dose and capture (mean ± SE, $N = 8$) of WCR females for (±)-linalool, methyl salicylate, and a 1:1 by weight blend of both. Means topped by different letters differ at $P \leq 0.05$ by Student-Newman-Keuls test after ANOVA ($F = 18.50$; $df = 15, 105$; $P < 0.0001$). On August 29, 1997, when the test ended, corn was dough stage (R4) and mean beetle count per plant ± SE was 1.4 ± 0.2 WCR and 0.9 ± 0.2 NCR.

expected had there been no synergy. The dose–response data showed that a rise of this magnitude would only be expected after about a 10-fold increase in dose of the individual compounds, assuming similar action of both odorants on the same segments of the field population.

Adding β-caryophyllene or indole, but not (−)-α-pinene, to a blend of (±)-linalool and methyl salicylate increased capture of WCR females above levels expected from simply increasing the dose of either the single compound or the binary blend (Figure 4). ROI values calculated in each series from captures on traps baited with 20 mg per component per trap were 2.5 ± 0.7, 1.1 ± 0.1, and 1.2 ± 0.3 for β-caryophyllene, indole, and (−)-α-pinene, respectively. Only the β-caryophyllene value differed significantly from 1 ($t = 2.36, N = 8, P = 0.05$; for (−)-$\alpha$-pinene, $t = 0.48, N = 8, P = 0.65$; for indole, $S = 5, N = 8, P = 0.55$).

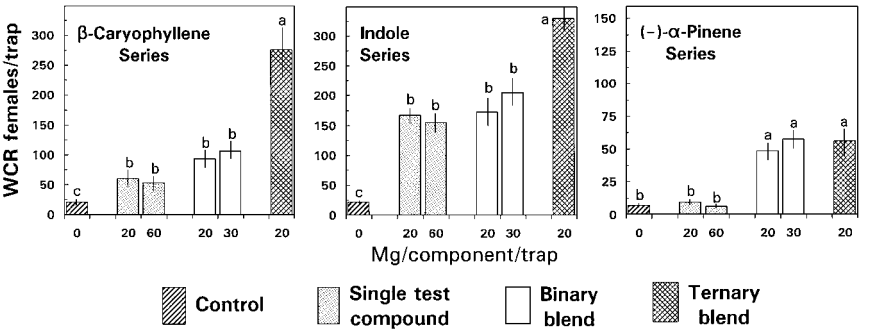

FIG. 4. Mean capture ± SE ($N = 8$) of WCR females with and without addition of β-caryophyllene, indole, or (−)-α-pinene to a 1:1 by weight blend of (±)-linalool and methyl salicylate (20 mg/component/trap for each ternary blend). Means in a series topped by different letters differ at $P \leq 0.05$ by Student-Newman-Keuls test after ANOVA ($F = 17.12$, 98.83, and 36.91, respectively; $df = 5, 35$; $P < 0.0001$). On August 28, 1997, and August 19, 1998, when the β-caryophyllene and indole series ended, respectively, corn was dough stage (R4) and mean beetle count per plant ± SE was 2.3 ± 0.3 WCR and 1.8 ± 0.2 NCR (1997) and 2.8 ± 0.4 WCR and 1.8 ± 0.3 NCR (1998). At the start of the (−)-α-pinene series on August 26, 1999, corn was dent stage (R5) and beetle counts were 1.3 ± 0.2 WCR and 1.0 ± 0.2 NCR.

Odorants lured WCR males just in the indole series, but responses were barely detectable and did not vary among olfactory treatments (data not shown). NCR reacted only to scents containing (±)-linalool, albeit in low numbers, and did not distinguish between binary and ternary blends (data not shown).

Thus, β-caryophyllene, which was only weakly attractive by itself, but not (−)-α-pinene, synergistically elevated female WCR captures when added to the linalool-methyl salicylate blend. Captures were again at least twice as high as expected without synergy. Indole addition to the binary blend produced a WCR response increase that was smaller than the three- to fivefold increase reported for its mixture with 4-methoxycinnamaldehyde or cucurbit volatiles (Metcalf et al., 1995). Indeed, the smaller increase could be explained without invoking synergy if indole and the binary blend were to attract different segments of the WCR female population. For example, one lure could attract females with immature ovaries seeking food and the other affect gravid females seeking oviposition sites. This hypothetical situation is perhaps less likely for WCR, which tend to oviposit where they feed, than for NCR, which feed on a variety of flowering forbs once maize silks dry and then return to maize to oviposit (Branson and Kryson, 1981).

Even 1.0 mg of β-caryophyllene added to 10 mg each of (±)-linalool and methyl salicylate increased captures of WCR females and yielded responses that were not lower than those obtained with additions up to 100 mg (Figure 5). WCR

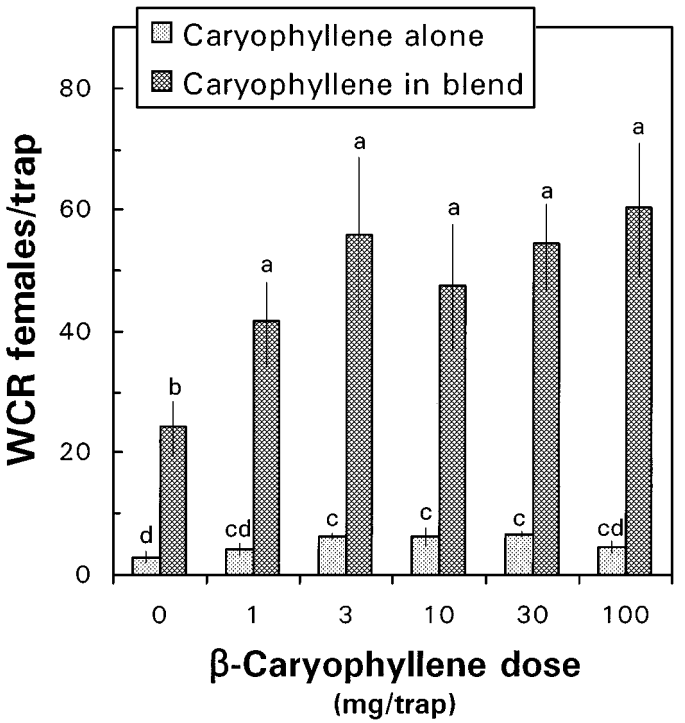

FIG. 5. Relationship between β-caryophyllene dose and capture (mean $\pm$ SE, $N = 8$) of WCR females upon caryophyllene addition to an attractant blend consisting of 10 mg each of (±)-linalool and methyl salicylate. Means topped by different letters differ at $P \leq 0.05$ by Student-Newman-Keuls test after a significant ANOVA ($F = 41.31$; $df = 11, 77$; $P < 0.0001$). On August 20, 1998, when the test ended, corn was dough to dent stage (R4–R5) and mean beetle count per plant $\pm$ SE was 1.8 ± 0.2 WCR and 3.1 ± 0.4 NCR.

males and NCR of both sexes failed to respond to any odorant treatment in numbers that were different from control (data not shown). Metcalf et al. (1995) also reported only a very gradual linear increase in efficacy as the dose of one member of a binary blend of floral volatiles attractive to WCR was increased over three orders of magnitude (varying dose of indole dispensed with 4-methoxycinnamaldehyde). Stronger dependence on attractant ratios might have been predicted (Loughrin et al., 1996) given the relatively specialized feeding habits of WCR adults (Krysan, 1993; Metcalf and Lampman, 1998) and the ubiquity of many WCR lures. A wider range of component test ratios and quantitative data on component release rates will ultimately be needed to critically evaluate component ratio effects on blend attractiveness.

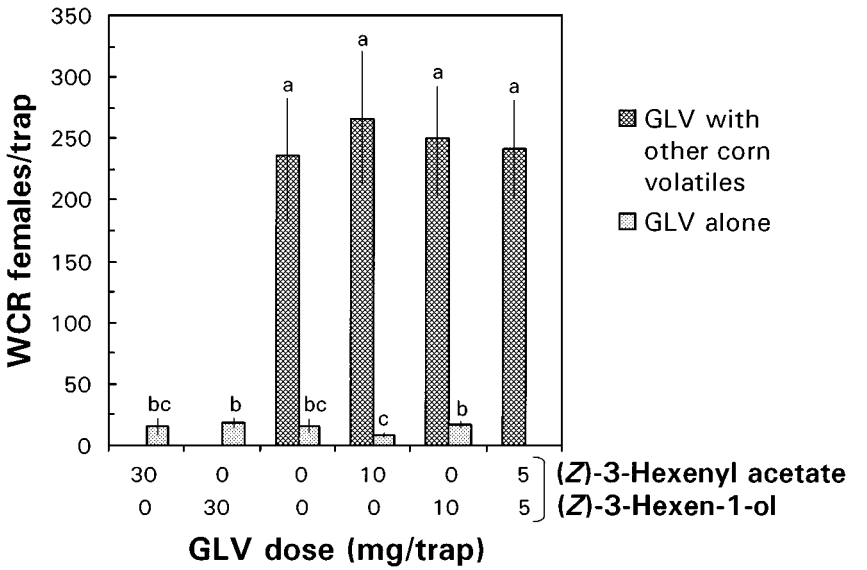

FIG. 6. Effect of the corn green leaf volatiles (GLVs), (*Z*)-3-hexenyl acetate and (*Z*)-3-hexen-1-ol, on WCR female captures (mean ± SE, $N = 8$) when the volatiles were dispensed singly and blended with other corn volatiles [3.3 mg/trap each of (±)-linalool, methyl salicylate, and β-caryophyllene]. Means topped by different letters differ at $P \leq 0.05$ by Student-Newman-Keuls test after a significant ANOVA ($F = 82.77$; $df = 8, 71$; $P < 0.0001$). On August 20, 1998, when the test ended, corn was dough to dent stage (R4–R5) and mean beetle count per plant ± SE was 3.6 ± 0.4 WCR and 1.8 ± 0.2 NCR.

Green Leaf Volatiles. Neither (*Z*)-3-hexenyl acetate nor (*Z*)-3-hexen-1-ol was attractive to WCR females when tested at 10 or 30 mg/trap (Figure 6), despite abundance of these GLVs in the headspace of maize leaves during plant tasseling and silking, when feeding conditions are optimal for corn rootworm adults (Krysan, 1993; Light et al., 1993). Moreover 10 mg of either volatile or a 1:1 (w/w) blend of both also did not affect captures when added to 3.3 mg each of (±)-linalool, methyl salicylate, and β-caryophyllene (Figure 6). Although GLVs attracting some insects can become inhibitory at higher doses, addition of the acetate and alcohol to the attractive blend of maize volatiles without effect argues against any such inhibition in the present tests. No olfactory treatment in this test significantly affected capture of WCR males or either NCR sex (data not shown).

Blend Efficacy/Enhancement. A blend of (±)-linalool, methyl salicylate, and β-caryophyllene (each at 3.3 mg/trap) captured fewer WCR of both sexes than did 10 mg of the 4-methoxycinnamaldehyde reference; however, substituting β-ionone for (±)-linalool yielded a ternary blend that was more attractive than was the

TABLE 3. CAPTURE OF CORN ROOTWORM ADULTS ON TRAPS BAITED WITH (±)-LINALOOL OR β-IONONE BLENDED WITH METHYL SALICYLATE AND β-CARYOPHYLLENE, COMPARED WITH 4-METHOXYCINNAMALDEHYDE STANDARDS[a]

[a] Test conducted August 12–14, 1998 ($N = 8$). Mean beetle count per corn plant ± SE on August 14 was 3.7 ± 0.5 WCR and 1.4 ± 0.2 NCR. Corn was in the milk to dough stage (R3–R4).

[b] (±)-Linalool or β-ionone (3.3 mg) blended with 3.3 mg each of methyl salicylate and β-caryophyllene for a total of 10 mg/trap.

[c] Asterisks denote statistical significance at $P < 0.0001$, NS denotes $P > 0.05$ ($df = 4, 28$). Means within a column followed by the same letter do not differ by Student-Neuman-Keuls test, $P > 0.05$.

aldehyde (Table 3). Addition of the aldehyde to the ternary blend containing β-ionone did not affect captures of either WCR sex. No odorant influenced NCR (Table 3).

SUMMARY AND CONCLUSIONS

This study identified two new attractants for corn rootworm adults: *syn*-benzaldoxime and β-caryophyllene. The oxime was notable for its strong attractiveness to NCR, whereas β-caryophyllene synergistically elevated captures of WCR females when blended with other maize headspace volatiles. Methyl salicylate showed a similar synergy when dispensed with one of several maize terpenoids. Indole also increased WCR captures in a manner suggesting synergy but to a lesser extent than reported for its interaction with cucurbit volatiles and their analogs. The results support the conclusion that olfactory synergism plays a key role in host finding by diabroticite corn rootworm adults, in agreement with studies of cucurbit-diabroticite interactions (Metcalf and Lampman, 1997), and demonstrate that the blending of maize volatiles has the potential to dramatically improve efficacy of corn rootworm lures with applications in pest management. Attaining full potential will likely entail adjustment of compound release rates to match natural conditions optimal for corn rootworm attraction, conditions not yet fully elucidated. Most chemical studies of maize volatiles have examined younger crop developmental stages than those preferred by corn rootworm adults or else used cut or macerated tissues, which may release qualitatively and quantitatively different blends than do intact or herbivore-damaged tissues (Buttery and Ling, 1984; Turlings et al., 1993; Takabayashi et al., 1995).

Acknowledgments—I thank Kent Howell and Vanderwal Farms, Inc., for generously permitting experimentation in their maize fields. Janet Fergen provided excellent technical assistance, aided by Sherri Brende, Jennifer Denkinger, Julie Marler, Mary Roduner, Holly Schultz, and Cara Wulf. Robert Bartelt (ARS, Peoria, Illinois), Astrid Eben (Instituto de Ecologia, A.C., Xalapa, Veracruz, Mexico), Wade French (ARS, Brookings), Julio Rojas (El Colegio de la Frontera Sur, Tapachula, Chiapas, Mexico), and two anonymous reviewers read an earlier version of the manuscript and provided many useful suggestions.

Abstract—The sex pheromone of the pea midge consists of 2-acetoxytridecane, (2*S*,11*S*)-diacetoxytridecane and (2*S*,12*S*)-diacetoxytridecane. The responses of male pea midges to the corresponding stereoisomers of (2*S*,11*S*)-diacetoxytridecane and (2*S*,12*S*)-diacetoxytridecane were tested in field trapping experiments and by electroantennographic recordings. When added at 20% of the pheromone component to the sex pheromone blend, the (2*S*,11*R*)- and (2*R*,11*S*)-stereoisomers of (2*S*,11*S*)-diacetoxytridecane, were shown to have a strong inhibitory effect on male attraction in the field. At the same dose, (2*R*,11*R*)-diacetoxytridecane, (2*R*,12*R*)-diacetoxytridecane, and *meso*-2,12-diacetoxytridecane, did not have a significant effect on male behavior. It was also shown that substitution of either (2*S*,11*S*)-diacetoxytridecane or (2*S*,12*S*)-diacetoxytridecane with the related stereoisomers reduced trap catches to the level of blank traps. The electroantennographic recordings showed similar dose–response curves for the pheromone components and the stereoisomers shown to have an inhibitory effect. It seems likely that male antennae have receptors for both

pheromone components and for inhibitory stereoisomers. Scanning electron microscopy and transmission electron microscopy of the antennae revealed three types of sensilla involved in chemoreception: sensilla circumfila, sensilla trichodea, and sensilla coeloconica. The sensilla circumfila and trichodea are both innervated by two sensory cells, whereas the sensilla coeloconica are innervated by four to five cells.

Key Words—*Contarinia pisi*, Cecidomyiidae, Diptera, sex pheromone, (2*S*,11*S*)-diacetoxytridecane, (2*S*,12*S*)-diacetoxytridecane, stereoisomers, inhibition, EAG recordings, antennal morphology.

INTRODUCTION

The pea midge, *Contarinia pisi* Winn. (Diptera: Cecidomyiidae), a serious pest of commercial peas in northern Europe (Wall et al., 1985; Pillon and Thieuleux, 1995), was the first species of the family Cecidomyiidae, gall midges, for which the full sex pheromone blend was identified (Hillbur et al., 1999, 2000). It consists of 2-acetoxytridecane, (2*S*,11*S*)-diacetoxytridecane, and (2*S*,12*S*)-diacetoxytridecane. All three compounds elicited a response from antennae of males when pheromone gland extract from females was analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) (Hillbur et al., 1999). The low concentration of 2-acetoxytridecane in gland extract prevented determination of its absolute configuration (Hillbur et al., 1999). However, in a wind tunnel bioassay a blend of racemic 2-acetoxytridecane, (2*S*,11*S*)-diacetoxytridecane, and (2*S*,12*S*)-diacetoxytridecane was as attractive to males as gland extract, indicating that if females produce only one enantiomer of 2-acetoxytridecane (*R* or *S*), the other one is not strongly inhibitory (Hillbur et al., 2000). A related compound, (2*S*)-(*E*)-10-tridecen-2-yl acetate, has been identified as a sex pheromone component in another gall midge, the Hessian fly, *Mayetiola destructor* (Foster et al., 1991). However, results from behavioral tests suggested that the complete Hessian fly sex pheromone contains one or more additional components (Harris and Foster, 1991, 1999). Recently, (2*S*,7*S*)-2,7-nonadienyl dibutyrate has been identified as sex pheromone of the orange wheat blossom midge, *Sitodiplosis mosellana* (Gries et al., 2000).

A general problem in gall midge pest management is to detect the often inconspicuous adults (Harris and Foster, 1999). Results from field trapping experiments with synthetic pea midge sex pheromone (Hillbur et al., 2000) showed that pheromone traps, as outlined by Wall et al. (1985), could be useful for monitoring of the emergence of adult pea midges. For this purpose, it would have been economically advantageous if the racemic mixtures of the diacetates instead of pure (2*S*,11*S*)- and (2*S*,12*S*)-diacetoxytridecane could be used as lures, since enantiopure compounds are far more costly to produce. However, traps baited with a blend of the racemates of all three compounds were not attractive to pea midge males

in the field, indicating that one or several of the stereoisomers not produced by the females are inhibitory (Hillbur et al., 2000). For the design of an economic chemical synthesis, the continued development of a monitoring system for the pea midge would benefit from a more detailed knowledge about requirements for stereochemical purity of the compounds, and specifically, which stereoisomers are inhibitory.

Thus, the aim of this study was to investigate the response of male pea midges to all stereoisomers of the female-produced sex pheromone components, (2*S*,11*S*)-diacetoxytridecane and (2*S*,12*S*)-diacetoxytridecane. Both behavioral responses in the field and electroantennographic (EAG) recordings were studied. Male responses to various doses of the synthetic sex pheromone blend in the field were also tested. In addition, the structures of the antennal sensilla were investigated by scanning electron microscopy and transmission electron microscopy.

METHODS AND MATERIALS

Insects. Soil containing cocoons with diapausing *C. pisi* larvae was collected near Chalons-sur-Marne in the Champagne district in France in August 1999. The soil was kept in cold storage at 6°C for approximately 5 months for completion of larval diapause. The cocoons were then separated from the soil with water using a sieving method (Doane et al., 1987), and the adults were allowed to emerge at 18L:6D photoregime, 25°C, and 70% relative humidity. Immediately upon emergence and before mating, males and females were separated and transferred to glass cages (28 × 28 × 33 cm) kept at 18L:6D photoregime, 15°C, and 75% relative humidity. Males used for electrophysiological recordings were one day old.

Chemicals. 2-Acetoxytridecane, racemic (2,11)-diacetoxytridecane, racemic (2,12)-diacetoxytridecane, and the stereoisomers of the diacetates were synthesized as described by Hillbur et al. (1999). The enantiomeric excess, ee, of the stereoisomers was at least 98%, as determined by chiral gas chromatography (Hillbur et al., 1999).

Electrophysiology. For electrophysiological recordings a Plexiglas holder with two wells connected to an amplifier by gold wire electrodes was used (JoAC, Lund, Sweden) (Zhang et al., 1997). Males were suspended between the wells by pressing the thorax, until fixed, into a slit in the well wall facing the 2-mm gap separating the wells. The head and antennae protruded into the gap. The tips of the antennae were then positioned in a small glass capillary, kept in place by dental wax in an equivalent slit in the opposite well. Finally, both wells and, by capillary force, the glass capillary were filled with Beadle-Ephrussi Ringer solution, thus providing contact. Antennal preparations were continuously exposed to a charcoal-filtered and humidified airstream (0.5 m/sec) through a glass tube (8 mm diam.). Stimuli

were delivered in 0.2-sec puffs at a flow rate of 10 ml/sec (stimulus controller, Syntech, Hilversum, The Netherlands), injected into the airstream 20 cm from the antenna. During dose–response recordings, all doses of one compound, starting with the lowest dose, were presented to the antenna before the next compound was tested. The order in which compounds were presented was varied between antennae. The test compounds (0.1, 1, 10, and 100 μg) in 10 μl of redistilled hexane (Labscan) were applied directly onto the glass in the tip of Pasteur pipets. The pipets were not used until 1 hr after compound application and were renewed after approximately 10 stimulations. Between tests, pipets were kept at -18°C. After every second test stimulus the response to a reference stimulus (10 μg of (2*S*,12*S*)-diacetoxytridecane on filter paper) was recorded. In order to correct EAG values for antennal fatigue, each test response was normalized by dividing it with the average response to the two adjacent reference stimuli. Antennal signals were amplified (JoAC) before they were recorded and analyzed with ElectroAntenno-Graphy software (Syntech).

Field Tests. Field tests were done in France between May 19 and 27, 2000, at three sites, Saint Pouange, Sompuis, and Songy, in the Champagne district. A parallel to one of the experiments was done at two sites in the UK (Market Weighton and Pocklington, Yorkshire) between June 11 and July 4, 2000. Sticky delta traps were placed in *C. pisi* emergence fields, i.e., in wheat fields after peas, 10–20 cm above ground. At each site, five replicates (only four in the UK) were placed along five well-separated transects. Within replicates traps were separated by 10 m. Trap positions were maintained unchanged during the experiment to avoid possible effects of contaminated vegetation. Dental cotton rolls (Celluron No. 2, Paul Hartmann S.A., France) cut in thirds were used as dispensers (Hillbur et al., 2000). Chemicals were applied to the dispensers as a hexane solution. Dispensers were not changed during the experimental period. In France, trap catches were counted and sticky inserts were changed daily. In the UK, catches were counted and inserts changed every three to four days.

In all experiments, a standard treatment, 10 μg (2*S*,11*S*)-diacetoxytridecane + 10 μg (2*S*,12*S*)-diacetoxytridecane + 10 μg 2-acetoxytridecane, and a blank, where the dispensers were not loaded with any chemicals, were used as reference traps. In the first experiment, two two-component blends, 10 μg (2*S*,11*S*)-diacetoxytridecane + 10 μg 2-acetoxytridecane and 10 μg (2*S*,12*S*)-diacetoxytridecane + 10 μg 2-acetoxytridecane, were tested (see also Figure 1, lower part). In the second experiment, three-component blends were tested where the two diacetates, (2*S*,11*S*)-diacetoxytridecane and (2*S*,12*S*)-diacetoxytridecane, had been substituted, one by one, by the other stereoisomers (Figure 2, lower part). A possible inhibitory effect of the stereoisomers was tested in a third experiment by addition of 2 μg of them, separately, to the standard blend (Figure 3a, lower part). In a continuation of this experiment, the dose of the stereoisomers proven to be

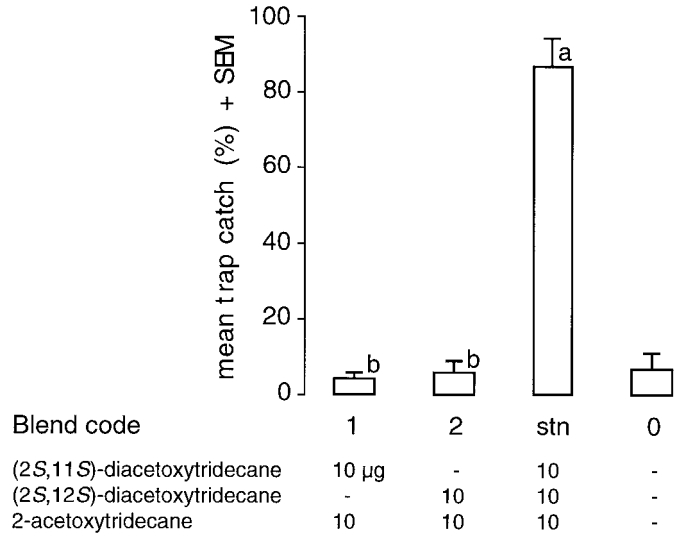

FIG. 1. Field captures of pea midge males in traps baited with the standard three-component blend and with two-component blends where one of the diacetates has been omitted. Treatments labeled with the same letter are not significantly different according to nonparametric Kruskal-Wallis analyses of variance, followed by paired Mann-Whitney *U* test with Bonferroni correction ($0.01 > P > 0.001$) (Systat, 1992).

inhibitory at 2 μg was lowered to 0.5 μg, whereas the dose of the stereoisomers that did not have any effect at 2 μg was raised to 10 μg (Figure 3b, lower part). Finally, a dose–response experiment compared traps baited with 1, 10, and 100 μg, respectively, of the standard three-component blend. This experiment was done both in France and in the UK.

Electron Microscopy. For transmission electron microscopy (TEM), antennae from both sexes were dipped for a few seconds in 70% ethanol to reduce surface tension: after this treatment they were rapidly transferred to 3% glutaraldehyde in 0.15 M cacodylate buffer and kept overnight. After dehydration in ethanol, the preparations were brought to Epon via propylene oxide. Polymerization was carried out at 60°C for 48 hr. The blocks were trimmed and the ultrathin sections on the grids were stained in uranyl acetate and lead citrate in an LKB Ultrostainer. The sections were examined in a Jeol 1200 EX transmission electron microscope operated at 60 kV. For scanning electron microscopy (SEM), preparations fixed and dehydrated as above were critical point dried, mounted on holders, and sputter-coated with gold–palladium 40:60. The preparations were studied in a Jeol T330 scanning electron microscope.

Treatments labeled with the same letter are not significantly different.

Statistics. The proportion of males caught by different treatments did not differ between sites, even if there was a large difference in population density. Therefore, to make sites comparable, the proportions within replicates, i.e. the number of males caught by one treatment in a replicate divided by the total number of males caught in that replicate, were used for statistical analyses. Differences were analyzed by nonparametric Kruskal-Wallis analyses of variance, followed by pairwise Mann-Whitney *U* test with Bonferroni correction (Systat, 1992). The number of replicates of the blank traps was lower than for the other treatments and, consequently, they were not included in the analysis. The dose–response curves obtained by EAG recordings were analyzed by two-way analysis of variance (ANOVA) followed by a Duncan's multiple-range test (Statistica, 1993).

FIG. 3. Field captures of pea midge males in traps baited with the standard three-component blend, 2-acetoxytridecane, (2*S*,11*S*)-diacetoxytridecane, and (2*S*,12*S*)-diacetoxytridecane (stn), in combination with: (a) 20% of each of the stereoisomers separately, and (b) 5% of the stereoisomers proven to be inhibitory at the 20% level and 100% of the stereoisomers that had no effect at the 20% level. Treatments labeled with the same letter are not significantly different.

RESULTS

The results from the field experiment with the two-component blends (1 and 2) showed that all three components are needed to attract male pea midges (Figure 1). Of the total number of males caught in this experiment, 87% were caught in traps baited with the three-component blend (stn) (Figure 1). Substitution of (2*S*,11*S*)-diacetoxytridecane and (2*S*,12*S*)-diacetoxytridecane with the corresponding stereoisomers (blends 3–7) reduced trap catches to the level of the blank trap (0) (Figure 2). Only the standard three-component blend (stn) caught significant numbers of midges (73%). Addition of 20% (2 μg) of stereoisomers to the standard blend (stn) showed that at this dose (2*R*,11*S*)-diacetoxytridecane (11) and (2*S*,11*R*)-diacetoxytridecane (12) have a strongly inhibitory effect on male attraction (Figure 3a). Both treatments reduced trap catches to the same level as the blank traps (0). Addition of (2*R*,12*R*)-diacetoxytridecane, *meso*-2,12-diacetoxytridecane, and (2*R*,11*R*)-diacetoxytridecane, to the standard three-component blend (blends 8, 9, and 10) did not affect male attraction. Catches in those traps did not differ significantly from the number of males caught with the standard blend (stn) (Figure 3a). A decrease in the dose of the inhibitory stereoisomers to 5% (blends 16 and 17) and an increase of the dose of the other stereoisomers to 100% (blends 13, 14, and 15) resulted in an overall decrease in differences in trap catches between treatments (Figure 3b). Only in traps where 5% (2*S*,11*R*)-diacetoxytridecane had been added to the standard blend (17) did catches differ significantly from those baited with the standard blend (stn) (Figure 3b).

In France, the dose–response experiment showed that 1 μg of the standard blend was the most attractive dose to males (Figure 4a). It attracted 60% of the males, whereas traps baited with 10 and 100 μg caught 24 and 16%, respectively (Figure 4a). In the UK, however, there were no significant differences in trap catches between the doses (Figure 4b). Population densities were higher in France than in the UK. The total number of males caught in traps baited with 1 μg of the standard blend was 13,200 in France (experimental period 8 days) and 5,100 in the UK (experimental period 23 days).

The male antennal response to the female-produced stereoisomers, (2*S*,11*S*)-diacetoxytridecane and (2*S*,12*S*)-diacetoxytridecane increased with an increasing dose of the stimuli (Figure 5). Similar dose–response curves were obtained for the inhibitory stereoisomers (2*R*,11*S*)-diacetoxytridecane and (2*S*,11*R*)-diacetoxytridecane, but the responses were slightly lower than to the pheromone compounds (Figure 5). Even lower responses were elicited by the behaviorally inactive stereoisomers, (2*R*,11*R*)-diacetoxytridecane, (2*R*,12*R*)-diacetoxytridecane, and *meso*-2,12-diacetoxytridecane (Figure 5). An analysis of variance showed that the factors compound and dose, as well as their interaction, had a significant effect (two-way ANOVA; factor 1: compound, $df = 160$, $F = 10.426$, $P < 0.001$, factor 2: dose, $df = 160$, $F = 16.296$, $P < 0.001$, compound $\times$ dose, $df = 160$, $F = 1.692$,

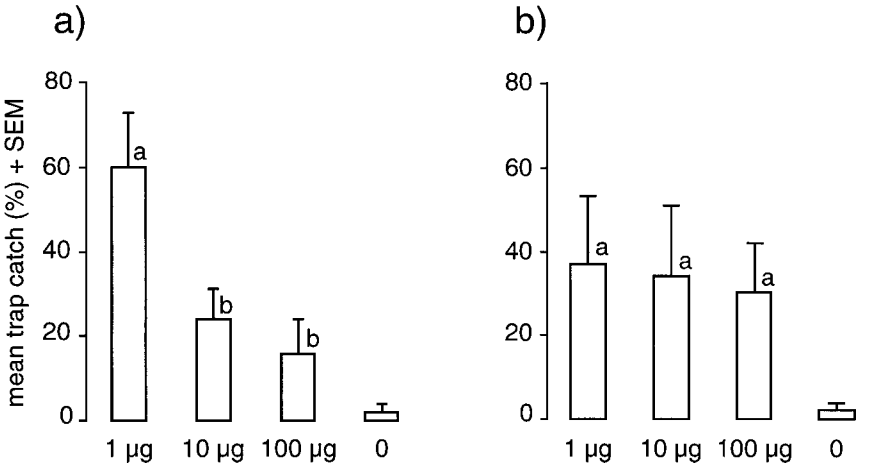

FIG. 4. Field captures of male pea midges in traps baited with different doses of the standard 3-component blend, 2-acetoxytridecane, (2*S*,11*S*)-diacetoxytridecane, and (2*S*,12*S*)-diacetoxytridecane (stn): (a) in France, and (b) in the UK. Treatments labeled with the same letter are not significantly different.

$P < 0.05$). The interaction term shows that there is a significant difference between the slopes of the dose–response curves.

The analyses of the structure of the antennae showed that antennae of males consist of 12 antennal segments (flagellomeres), in addition to the two basal segments, scapus and pedicellus. Each flagellomere is about 100 μm long and consists of two swollen nodes connected with a cylindrical portion (Figure 6). The sensilla are confined to the nodes, which are found in the proximal and middle portions of the flagellomeres. In the females, the 12 flagellomeres are cylindrical (40×25 μm) (Figure 7). In both sexes, small protrusions (microtricha) cover the surface of the flagellomeres (Figures 6 and 7). Three types of chemosensory sensilla are found on the antenna: compound sensilla with wall pores (s. circumfila), hairlike single sensilla with wall pores (s. trichodea), and double-walled sensilla (s. coeloconica). The circumfila have a peculiar shape and exhibit different structures in males and females. Long uninnervated bristles are also present among the antennal sensilla (Figures 6 and 7). These companion bristles have a shaft provided with small teeth.

In the males, there is one wreath of circumfila on each node. In each of these, there are about 10 forked sensilla that are joined apically. The circumfila are found close to a transverse row of companion hairs (Figure 6). Inside the antenna, two dendritic segments from sensory cells are enclosed within an enveloping cell, corresponding to the thecogen cell of other sensilla. At the distal part of the innermost enveloping cell, there is no dendritic sheath as in other

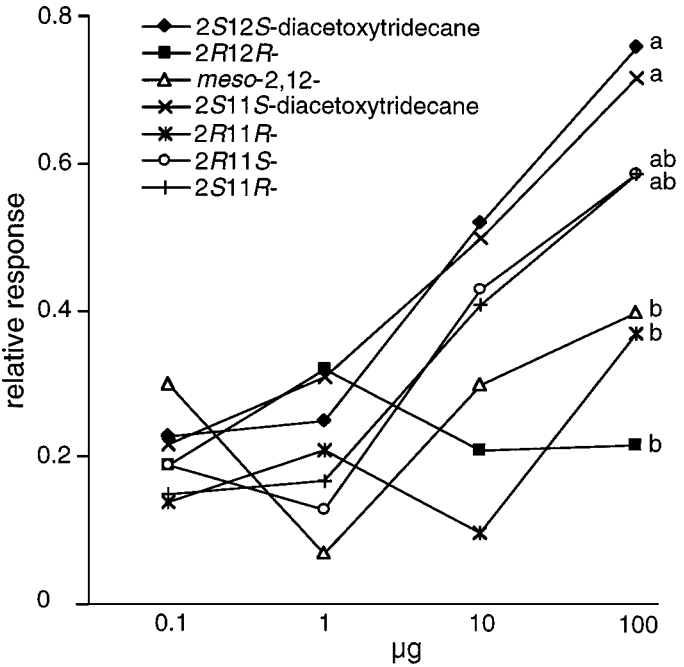

FIG. 5. Electroantennogram (EAG) responses from male pea midge antennae to different doses of the stereoisomers of (2,11)-diacetoxytridecane and (2,12)-diacetoxytridecane ($N = 6$). EAG values were corrected by relating the measured values to a standard measurement before and after the test compound. Dose–response curves followed by the same letter are not significantly different according to Duncan's multiple range test ($P < 0.05$) (Statistica, 1993).

insect sensilla (Figure 8). The transition zone between the inner and outer dendritic segments is situated about 5 μm below the base of the hair. Lymph cavities are lacking in this region. The basal part of the hair is invaded by the sensory cells and the enveloping cells that send protrusions into the hair (Figure 8). The basal part of the hair is about 2 μm long and has a smooth outer surface. Above this zone the two branches of the sensillum turn transversely until they are close to the companion hairs, which they accompany in a distal direction (Figure 9). The proximal curved parts of the branches have a transverse cuticular pattern, whereas the distal part has longitudinal furrows (Figure 9). The sensillar hair branches follow the companion hairs to their tips, and here the branches from two adjoining sensilla fuse (Figure 6). In the distal part of the circumfila there are one or two branches of the outer dendritic segments. The density of the pores is quite low in the males.

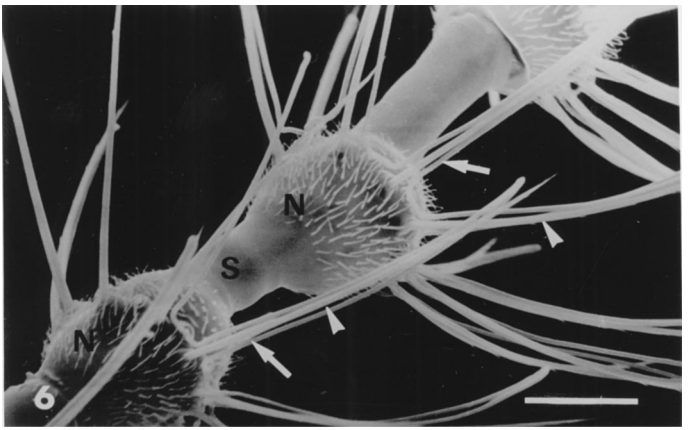

FIG. 6. Flagellomere from male consisting of two nodes (N), that are connected with portions of smaller diameter (S). On the nodes are sensilla circumfila (arrows) and companion hairs (arrowheads). Scale bar = 20 μm.

Sensilla circumfila in the females form two transverse loops connected with two axial connections (Figure 7). A large number, approximately 25–30, of sensilla form this continuous structure. The circumfila of the females also possess two sensory cells, and the other cellular arrangements below the antennal surface are similar to those of the male (Figure 8). The surface of the cirumfila in the females

FIG. 7. Flagellomere from female showing sensilla circumfila (asterisks), sensilla trichodea (arrows), and companion hairs (arrowheads). Scale bar = 20 μm.

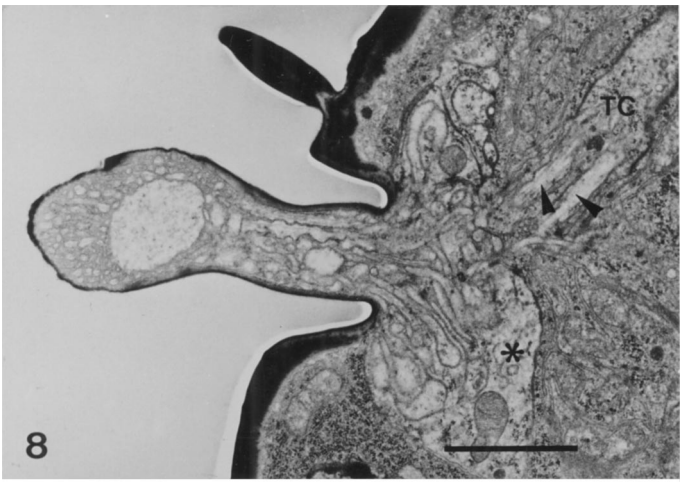

FIG. 8. Section through the base of a sensillum circumfilum in a male. The outer dendritic segments (arrowheads) are enclosed within the innermost enveloping cell (TC). Another enveloping cell (asterisk) has a more superficial position, sending processes into the base of the cuticular hair. Scale bar = 0.5 μm.

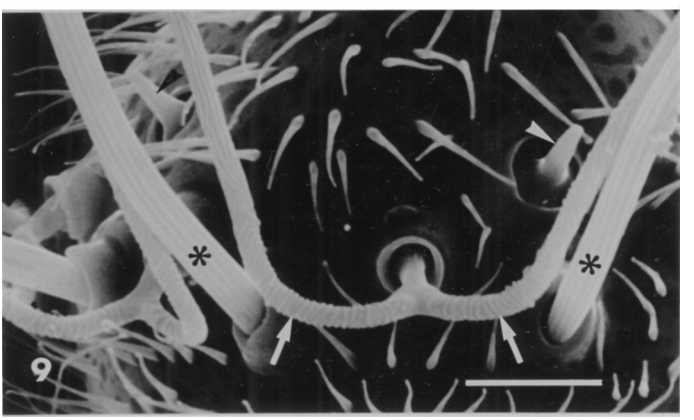

FIG. 9. The sensilla circumfila (arrows) are forked and the branches follow the companion hairs (asterisks). Sensilla coeloconica are indicated with arrowheads. Scale bar = 5 μm.

is smooth (Figure 7). The cuticle possesses a large number of small pores, which lack pore tubules. The outer dendritic segments branch profusely in the hairs.

The sensilla trichodea are found in relatively low numbers, about five on each flagellomere. They are innervated with two sensory cells, and the arrangement of the enveloping cells is similar to that of the circumfila, but the single wall-pore sensilla possess a dendritic sheath, which originates from the thecogen cell. Basally, the surface structure of the hair consists of longitudinal folds. Distally, there are transverse ridges. The dendritic outer segments branch moderately in the outer part of the hair. The pore density is lower than in the circumfila, and the pores lack tubules.

There are a few sensilla coeloconica on each flagellomere. They are innervated with four to five sensory cells, and they possess a dendritic sheath as well as inner and outer lymph cavities. The cuticular hair is short, 2 μm, and has apical slitlike pores.

DISCUSSION

In several species that use only one stereoisomer of a chiral compound as a sex pheromone component, the inhibitory effect of other stereoisomers on sex attraction forms a basis for reproductive isolation. This has been shown in species as diverse as scarab beetles (Leal, 1996), corn rootworms (Guss et al., 1985; Krysan et al., 1986), winter-flying geometrid moths (Szöcs et al., 1993), and bark beetles (e.g., Birch, 1984; Seybold, 1993). The ratio at which stereoisomers have an inhibitory effect varies between species. Leal (1996) suggested that in species where the chiral compound is just one constituent of a multicomponent pheromone blend the antagonistic effect of the antipode might be better tolerated, because species separation is then additionally supported by other compounds in the specific blend. Separation in time or space may also contribute to reproductive isolation between closely related species (e.g., Löfstedt et al., 1991; Szöcs et al., 1993).

It is not possible to say whether species separation is the reason for the inhibitory effect of (2*S*,11*R*)- and (2*R*,11*S*)-diacetoxytridecane observed in this study, because the inhibitory stereoisomers are not known to be pheromones of any related species. However, there are indications that the same or similar compounds are used as sex pheromone components within the Cecidomyiidae. The pea midge compounds and the compound identified for the Hessian fly are similar in structure, and, when tested in the field, the latter did not attract Hessian fly males but large numbers of males of another gall midge species (Harris and Foster, 1999). Moreover, all presently identified compounds within the family are chiral (Foster et al., 1991; Hillbur et al., 1999, Gries et al., 2000). Therefore, it seems reasonable to assume that the inhibitory effect of the stereoisomers (2*S*,11*R*)- and (2*R*,11*S*)-diacetoxytridecane observed in this study may be a mating barrier

between the pea midge and one or several related sympatric species. Furthermore, species specificity in the pheromone signal seems also to be maintained by the blend composition. Removal of either of the diacetates from the blend yielded trap catches comparable to those in the blank traps (Figure 1), as did removal of the third component, 2-acetoxytridecane (Hillbur et al., 2000).

The response at the antennal level can be discussed in view of both the behavioral and the electrophysiological data. The field experiments show that in order to attract pea midge males, neither of the diacetates can be substituted by the corresponding stereoisomers (Figure 2). The males must thus be able to distinguish (2*S*,11*S*)- and (2*S*,12*S*)-diacetoxytridecane from the other stereoisomers, which suggests that they have antennal receptors specifically tuned to these compounds. Evidence for enantiospecific pheromone receptor neurons has been reported in e.g. scarab beetles (Wojtasek et al., 1998). The strong inhibitory effect of (2*S*,11*R*)- and (2*R*,11*S*)-diacetoxytridecane on male attraction (Figure 3a) indicates that the antennae also have receptors specific for these antagonists. This is also supported by the EAG results, where similar dose-response curves were obtained from the pheromone components and the antagonists (Figure 5). The other stereoisomers do not seem to be of importance to male pea midges (Figures 3a,b and 5).

Earlier fine structural investigations of gall midge antennae have revealed five sensillum types involved in chemoreception: sensilla circumfila, sensilla trichodea, sensilla basiconica, sensilla coeloconica, and uniporous peg sensilla (Slifer and Sekhon, 1971; Solinas and Nuzzaci, 1987; Crook and Mordue (Luntz), 1999). Three of these, sensilla circumfila, sensilla trichodea, and sensilla coeloconica, were found on pea midge antennae. The circumfila are a unique type of sensilla found only in gall midges (Hallberg and Hansson, 1999). In the pea midge, the pronounced sexual dimorphism in the circumfila and their looped, surface-enlarging structure in the males indicate that they are important in the detection of female sex pheromones. This has also been suggested for the sorghum midge, *Contarinia sorghicola* (Slifer and Sekhon, 1971) and another gall midge, *Mycodiplosis erysiphes* (Solinas and Nuzzaci, 1987). In the blackcurrant leaf midge, *Dasineura tetensi*, however, sensilla circumfila are more elaborate in females than in males (Crook and Mordue (Luntz), 1999). Instead, sensilla trichodea, shown to be more common in males than in females in this species, were assumed to be more important in sex pheromone detection (Crook and Mordue (Luntz), 1999).

Transmission electron microscopy showed that in the pea midge both sensilla circumfila and sensilla trichodea possess two sensory cells. In view of the results of the present study, one would expect to find at least four receptor neurons associated with sex pheromone reception on male pea midge antennae, one for each of the pheromone components and at least one for the antagonists. Which of the sensillum types house these neurons and how they are organized remains to be investigated by single sensillum recordings. As pointed out by Baker

et al. (1998), cocompartmentalization within the same sensillum of receptors tuned to the pheromone components and receptors tuned to the antagonist should optimize both the spatial and temporal resolution ability of the male. Cocompartmentalization of pheromone and antagonist neurons is commonly found in Lepidoptera (e.g., Löfstedt et al., 1990; Cossé et al., 1998; Todd and Baker, 1999) and has also been shown in a diprionid sawfly (Hansson et al., 1991) and in scarab beetles (Wojtasek et al., 1998).

This study provides valuable information for the continued development of a pea midge monitoring system, both with regard to purity and amount of chemicals required. The results indicate that only (2*S*,11*S*)-diacetoxytridecane has to be of high stereoisomeric purity. The configuration of (2,12)-diacetoxytridecane, like that of 2-acetoxytridecane (Hillbur et al., 2000), does not seem to affect male behavior. For use in monitoring traps, the French results clearly show that the lowest dose, 1 μg, is the most attractive one (Figure 4a). The fact that no significant differences were seen between the doses in the UK (Figure 4b) could be explained by factors such as differences in temperature that would affect the emission rate of the compounds from the dispensers or the comparatively low population densities at the experimental sites in the UK. Adult pea midges have been shown to be highly aggregated in emergence fields (Wall et al., 1991). At low population densities, this could result in variable trap catches.

Acknowledgments—We thank E. Marling and R. Ward for technical assistance. J. Cheminon, D. Van de Veldes, B. Chazel, G. Abit, C. Baguet (France), A. Kitching, and R. Padgett (UK) are acknowledged for kindly letting us use their fields for experiments. We are also grateful to P. Witzgall for valuable suggestions regarding the field experiments, F. Schlyter and T. Meiners for statistical advice, and P. Anderson for comments on an earlier version of this manuscript. This work was supported by Carl Tryggers Stiftelse för Vetenskaplig Forskning, the Faculty of Landscape Planning and Horticulture, SLU, Sweden, Processors and Growers Research Organisation and the Horticultural Development Council, UK.

(Received December 20, 2000; accepted March 13, 2001)

Abstract—The sex attractant pheromone blend of *Hemileuca maia* (Lepidoptera: Saturniidae) from the vicinity of Baton Rouge, Louisiana, has been identified. The major component of the blend is (*E*10,*Z*12)-hexadeca-10,12-dienal (*E*10,*Z*12–16:Ald), in combination with the minor components (*E*10,*Z*12)-hexadeca-10,12-dien-1-ol (*E*10,*Z*12–16:OH), and (*E*10,*Z*12)-hexadeca-10,12-dien-1-yl acetate (*E*10,*Z*12–16:Ac). Ratios of the compounds in extracts of female pheromone glands varied around a mean of 100:7.4:6.3. None of the three components were attractive to male moths when tested as single components. Several other compounds were tentatively identified from female pheromone gland extracts, including *E*10,*E*12–16:Ald, *E*10,*E*12–16:OH, and *E*10,*E*12–16:Ac, but addition of these components, either alone or in combination, at biologically relevant rates, did not significantly increase the attractiveness of lures. The saturated analogs, hexadecanal, hexadecanol, and hexadecyl acetate, also were identified in gland extracts, but had no apparent effect as pheromone components.

Key Words—*Hemileuca maia*, (*E*10,*Z*12)-hexadecadienal, (*E*10,*E*12)-hexadecadienyl acetate, (*E*10,*Z*12)-hexadecadienol, sex pheromone.

INTRODUCTION

The buck moth, *Hemileuca maia* (Drury) (Lepidoptera: Saturniidae), is widely distributed throughout the eastern half of the United States (Tuskes et al., 1996).

0098-0331/01/0700-1409$19.50/0

It is an occasional defoliating pest of oaks, with localized outbreaks appearing sporadically and unpredictably (Martinat et al., 1997). The mature caterpillars are about 6.2 cm in length, and each body segment contains numerous tufts of compound urticating spines. When the caterpillars are handled or crushed, these spines break off in the skin, causing a severe burning sensation. Reddish welts may persist at the site of contact for weeks. Stinging also may produce anaphylactic shock reactions in sensitive individuals. During outbreaks, the larvae can be a severe nuisance and a health hazard, and the problem is exacerbated by the larval habit of wandering off the host plant. As colorfully described by Earle (1966), "Their presence greatly diminishes the joy of walking barefoot in the springtime." The problem can be severe enough that trees in public places are sprayed with insecticide during the spring caterpillar emergence in attempts to reduce populations in urban and suburban areas.

The basic biology and distribution of *H. maia* have been summarized (Earle, 1966; Tuskes et al., 1996; Martinat et al., 1997). Eggs are laid in late fall in rings around oak twigs, and hatch the following spring. The early instars are gregarious and exhibit processionary behavior, whereas later instars are solitary. In the southern United States, pupation occurs in late May to early June, and pupae go through a summer diapause before emerging in late November to early December. The adult moths are diurnal and are easily seen because of their distinct black and white markings and their size.

Earle (1966) reported that caged virgin female moths attracted numerous male moths with a sex attractant pheromone, but to date, there has been no further investigation of the pheromone components. As part of a continuing study of sex pheromones of the North American Saturniidae, we report here the identification and field testing of the female-produced sex pheromone blend of *H. maia*.

METHODS AND MATERIALS

Insects. Late-instar caterpillars, which feed primarily on live oak, *Quercus virginianus* (Mill), were collected at Burden Research Plantation, Baton Rouge, Louisiana, in late May and early June of 1995–1997. In the laboratory, the caterpillars were held in screen-covered 160-liter plastic containers at 27°C and 65% relative humidity. Fresh-cut oak foliage was placed in the containers daily until pupation. The larvae pupated in the 3 to 5-cm layer of vermiculite covering the bottom of the container. Approximately 150 pupae were collected from the vermiculite in September and October, sexed by using dimorphic genital characters, and sent to University of California, Riverside. Upon arrival, the sexed pupae were held separately in 4-liter paper cans with screen lids and damp vermiculite until the moths emerged. Additional humidity was provided by moistening paper towels and placing them on the screen lid, with a sheet of clear plastic draped over the lid

to maintain high humidity. Upon emergence, males were allowed to expand and dry their wings before being placed in labeled glassine envelopes, then in sealed plastic bags with a damp towel, and held in a refrigerator (10–15°C) until needed for electroantennographic studies. Females were allowed to expand their wings and usually began to call within 1–2 hr of emergence inside the paper can, where they were allowed to remain until excision and extraction of the sex pheromone glands.

Extraction of Sex Pheromone Glands. Female sex pheromone glands were removed from virgin calling females (1–2 days old) by extruding the gland by applying gentle pressure to the tip of the abdomen and removing the everted gland and terminal abdominal segments with microscissors. The excised glands from individuals, or from several females combined, were placed into a 0.25-ml conical glass vial insert containing approximately 30 μl pentane. Care was taken to remove as much of the meconium as possible with clean Kimwipes to minimize contamination of the extract. The glands were extracted for 20 min, then the extract was transferred to a clean insert and concentrated by passive evaporation as needed. If not used immediately, extracts were stored at −20°C.

Gas Chromatography. Gas chromatography (GC) analyses were conducted in splitless mode with Hewlett-Packard 5890A or 5890 Series II gas chromatographs (H-P, Palo Alto, California), that used helium carrier gas. Columns and programs used to analyze extracts included: DB-1701 (30 m × 0.32 mm ID, 0.25 μm film, J&W Scientific, Folsom California; 100°C/0 min, 15°C/min to 275°C, hold 60 min), DB-5 (30 m × 0.32 mm ID, 0.25 μm film, 100°C/0 min, 10 or 15°C/min to 275°C, hold 30 min), and DB-WAX (30 m × 0.32 mm ID, 0.25 μm film, 100°C/0 min, 15°C/min to 250°C, hold 20 min).

Coupled Gas Chromatography–electroantennography (GC-EAD). Aliquots of female extracts and synthetic standards were analyzed by coupled GC-EAD with an H-P 5890 series II GC, with either DB-1701 or DB-5 columns operated under the conditions described above. Details of the set-up and operation of the system, and the preparation of the moth antennae for GC-EAD analyses, have been described previously (McElfresh and Millar, 1999a–d).

Coupled Gas Chromatography–mass spectrometry. Electron impact (EI) mass spectra (70 eV) were taken with an H-P 6890 gas chromatograph interfaced to an H-P 5973 mass selective detector. An HP5-MS column (30 m × 0.25 mm ID) was used in splitless mode, programmed from 50°C at 1 min, 10°/min to 250°C, hold 20 min, injector 275°C, transfer line 280°C. Compounds in the insect extract (an aliquot of a composite sample from five females) were identified by comparison of retention times and mass spectra with those of synthetic standards (see below).

Approximately 2 female equivalents (FE) of a composite extract of five females obtained in July 1997 were concentrated under a gentle stream of N_2, then taken up in 20 μl CH_2Cl_2 and treated with 2.5 μl of a solution of

4-methyl-1,2,4-triazoline-3,5-dione (MTAD, 1.2 mg/ml; Aldrich Chemical, Milwaukee, Wisconsin) (Young et al., 1990; McElfresh and Millar, 1999a). The resulting faint pink solution was concentrated to <5 μl, and a 1-μl aliquot was analyzed by GC-MS, by using an injector temp of 300°C, a temperature program of 100°C/0 min, 15°/min to 300°C, hold 20 min, and a solvent delay time of 8 min. Identifications were confirmed by analyses of adducts prepared in identical fashion from synthetic pheromone standards.

Synthesis of Pheromone Components. Standards used in chromatographic work and for making lures for field trials were synthesized and purified as described in McElfresh and Millar (1999a). All compounds used in field trials were a minimum of 98% chemically and isomerically pure. GC standards of all four 10,12–16:Ac isomers also were obtained from Darwin Reed, Plant Biotechnology Institute, National Research Council of Canada, Saskatoon, Saskatchewan, Canada.

Field Trials. Lures consisted of 11-mm red rubber septa (Wheaton Scientific, Millville, New Jersey), individually labeled with a treatment number and loaded with heptane solutions (100 μl) of test blends, plus 2 drops of 10 mg/ml butylated hydroxytoluene (BHT) in heptane as an antioxidant. Once the treatment solutions had soaked into the septa, the lures were stored in 20-ml glass screw-cap vials for transport. Lures were stored in a freezer or an ice-chest when not in use, except during shipping. A particular set of lures was not used for >11 days.

Field trials with blends of synthetic pheromone components were conducted in December of 1995–1998. Most field trials were conducted at the Burden Research Plantation, Baton Rouge, Louisiana, in a mixed hardwood forest bordered by open fields. Pherocon 1C traps (Trécé Inc., Salinas, California) were used, placed on the ground at least 30 m apart. In 1997, two replications of a trial were conducted in New Orleans, Louisiana, and these traps were placed approx. 1 m off the ground in two separate locations. Treatments were usually tested in three to four replicate blocks spaced 100–270 m apart. Blocks consisted of six to nine treatments, including a trap baited with a solvent-treated control. Each block was counted a minimum of three and a maximum of eight times. Trap bottoms were changed as necessary, as they became covered with accumulations of moth scales. Trap counts were conducted before 09:00 hr or after 15:00 hr when flight had ceased, and traps were rerandomized after each count. All moths were removed from the traps at each count.

Data Analysis. To eliminate the day factor, which was irrelevant for our purposes, the daily counts for each treatment in a given block were pooled. This sum was then transformed ($\sqrt{x} + 0.5$) prior to conducting a two-way ANOVA followed by a Student-Neuman-Keuls (SNK) test to separate means when appropriate (SAS Institute, 1996). Treatments that failed to capture any moths were not included in the ANOVA because of their lack of variance.

RESULTS

Analysis of Female Pheromone Gland Extracts. Analyses of gland extracts by coupled GC-EAD demonstrated that male moth antennae responded to at least six components in the extracts (Figure 1). These compounds, and several others present in the extracts, were identified by GC and GC-MS, and the identifications were confirmed by comparison of retention times on at least two capillary GC columns of differing polarities and of mass spectra with those of standards.

The mass spectrum of the component eliciting the largest antennal response (Figure 1, peak **2**) was consistent with that of a conjugated 16-carbon diene aldehyde, with a comparatively strong molecular ion (*m*/*z* 236, 19% of base peak at *m*/*z* 67), with a possible molecular formula $C_{16}H_{28}O$. The relatively large size of the molecular ion, coupled with a retention time considerably longer than that of a hexadecanal standard, provided support for a conjugated diene being present somewhere in the structure, as did a set of ions at *m*/*z* 67, 81, 95, 109, and 123. Comparison of the mass spectrum and retention time with those of a standard of *E*10,*Z*12–16:Ald provided an exact match. The position of the diene was corroborated by formation of the Diels-Alder adduct with the powerful dienophile 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) (Young et al., 1990; McElfresh and Millar, 1999a). The adduct gave a molecular ion as expected at *m*/*z* 349 (9%) and

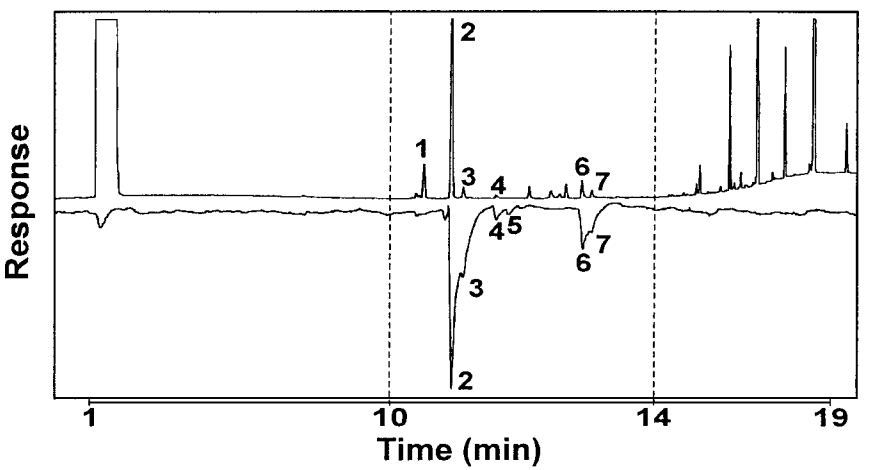

FIG. 1. Coupled gas chromatogram–electroantennogram of male *H. maia* antenna stimulated by a female pheromone gland extract. Column: DB-5 (30 m × 0.32 mm ID, 0.25-μm film, temperature program 100°C/0 min, 10°C/min to 275°C for 30 min). Identifications of peaks: 1, 16:Ald; 2, *E*10,*Z*12–16:Ald; 3, *E*10,*E*12–16:Ald; 4, *E*10,*Z*12–16:OH; 5, *E*10,*E*12–16:OH; 6, *E*10,*Z*12–16:Ac; and 7, *E*10,*E*12–16:Ac.

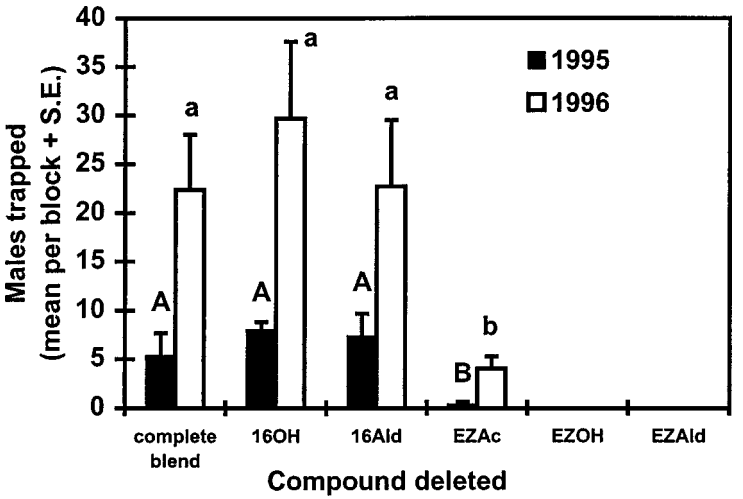

FIG. 2. Trap catches of male *Hemileuca maia* in field trials near Baton Rouge, Louisiana, December 12–15, 1995, and December 7–13, 1996, testing a five-component blend that mimicked the ratios found in a pheromone gland extract from females versus four-component blends with single compounds deleted. The complete blend consisted of: *E*10,*Z*12–16:Ald, *E*10,*Z*12–16:OH, *E*10,*Z*12–16:Ac, 16:Ald, and 16:OH (100:8:4:35:21 μg/septum, respectively). Total number of moths trapped = 63 in 1995 (solid bars), and 236 in 1996 (open bars). Significant differences among treatments are indicated by different letters surmounting the bars (1995, capital letters, 1996, lowercase letters; SNK test, $\alpha = 0.05$). Two-way ANOVA for blend effect in 1995, $F = 9.30$, $df = 3, 6$, $P = 0.0113$; for block effect. $F = 3.75$, $df = 2, 6$, $P = 0.0879$. Two-way ANOVA for blend effect in 1996, $F = 18.64$, $df = 3, 6$, $P = 0.0019$; for block effect, $F = 19.71$, $df = 2, 6$, $P = 0.0023$.

strong peaks at *m*/*z* 208 (100%) and 306 (48%) from cleavage of the alkyl chains in the three and six positions of the adduct, unequivocally demonstrating that the diene in the original structure was in the 10,12 position. The geometry of the diene was corroborated by comparison of retention times on four GC columns with those of synthetic standards of all four 10,12–16:Ald isomers. Only the *E*10,*Z*12–16:Ald isomer matched the insect-produced compound on all four columns.

A minor component of the extract (peak **3**, Figure 1) eluting shortly after the main component also elicited a strong EAD response from male antennae, seen as a shoulder on the main peak. The mass spectrum of this component was similar to that of the main component, *E*10,*Z*12–16:Ald, and these data, in conjunction with retention time matches with a standard on four columns, confirmed the minor component to be *E*10,*E*12–16:Ald.

Two later-eluting minor components (peaks **6** and **7**, Figure 1) eliciting medium intensity responses from male moth antennae were identified as *E*10,*Z*12–

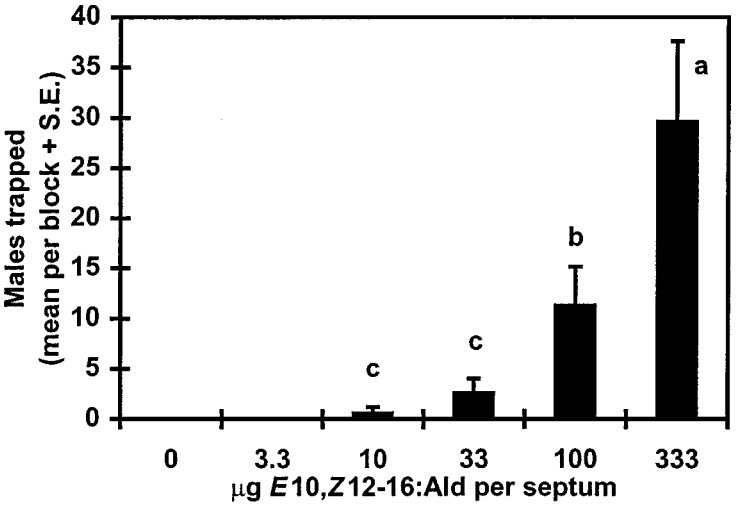

FIG. 3. Trap catches of male *Hemileuca maia* in field trials testing lures with various doses of *E*10,*Z*12–16:Ald, with *E*10,*Z*12–16:OH and *E*10,*Z*12–16:Ac held constant at 2.6 and 1.3 μg/septum, respectively. Trial conducted December 12–17, 1996; total number of moths trapped = 133. Treatments with different letters are significantly different (SNK, $\alpha = 0.05$). Two-way ANOVA for *E*10,*Z*12–16:Ald dose effect, $F = 34.72$, $df = 3, 6$, $P = 0.0003$; for block effect, $F = 11.91$, $df = 2, 6$, $P = 0.0082$.

and *E*10,*E*12–16:Ac, respectively. The mass spectra of both were similar, although only a partial spectrum of the later-eluting compound, present in smaller amount, was obtained. The mass spectrum of the more abundant compound was characterized by a molecular ion at *m*/*z* 280 (16%; possible molecular formula $C_{18}H_{32}O_2$), and a small but distinct fragment at *m*/*z* 220 (2%, loss of acetic acid). The relatively large size of the molecular ion, coupled with retention time somewhat longer than that of a hexadecyl acetate standard, supported the presence of a conjugated diene rather than two isolated double bonds. Comparison with a database spectrum of *E*10,*Z*12–16:Ac (NIST/EPA/NIH Mass Spectral Database, 1992) also resulted in a close match. The diene position was confirmed by GC-MS analysis of the MTAD adduct, with the adducts showing diagnostic fragments at *m*/*z* 350 (38%) and *m*/*z* 208 (100%) from cleavages of the alkyl groups attached to the 3 and 6 positions of the six-membered ring of the adduct, definitively placing the conjugated diene in the parent molecule at the 10,12 position. Determination of the double bond stereochemistries was made by comparison of retention times of the insect-produced compound with those of authentic standards on four GC columns as described above. Only the *E*10,*Z*12–16:Ac isomer matched the retention time of the insect-produced compound on all four columns.

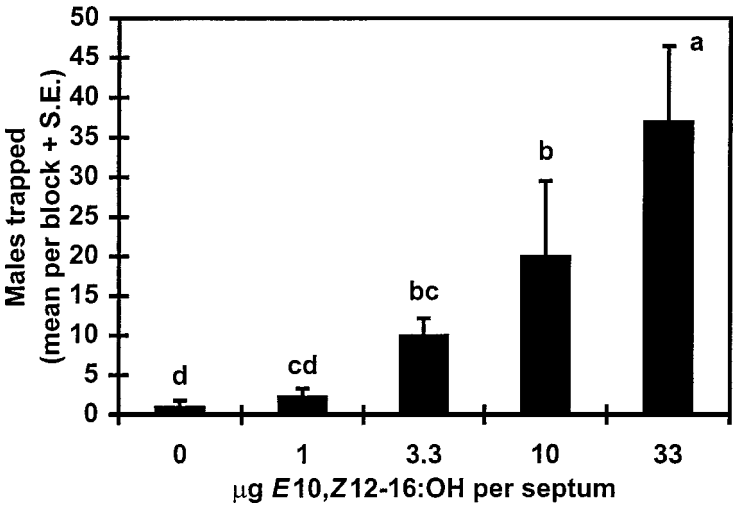

FIG. 4. Trap catches of male *Hemileuca maia* in field trials testing lures with various doses of *E*10,*Z*12–16:OH, with *E*10,*Z*12–16:Ald and *E*10,*Z*12–16:Ac held constant at 100 and 4 μg/septum, respectively. Trial conducted December 7–20, 1997; total number of moths trapped = 211. Treatments with different letters are significantly different (SNK, $\alpha = 0.05$). Two-way ANOVA for *E*10,*Z*12–16:OH dose effect, $F = 15.78$, $df = 4, 8$, $P = 0.0007$; for block effect, $F = 8.70$, $df = 2, 8$, $P = 0.0098$.

The partial mass spectrum of the less abundant of the two compounds (peak 6, Figure 1) did not exhibit a molecular ion or the weaker *m/z* 220 ion, but the fragmentation pattern in the lower mass ranges, and particularly the characteristic *m/z* 67, 81, 95 ion pattern, was similar to that of the *E*10,*Z*12–16:Ac. This partial mass spectrum, in conjunction with retention time matches on four columns with those of a standard, and the fact that an *E*10,*E*12–16:Ac standard elicits strong signals from male moth antennae, strongly supports the identification of this compound as *E*10,*E*12–16:Ac.

Two further minor components (peaks **4** and **5**, Figure 1) that elicited small responses from male antennae were tentatively identified as *E*10,*Z*12– and *E*10, *E*12–16:OH, respectively. Because of the trace amounts present in the extracts, mass spectra could not be obtained. Nevertheless, retention time matches with standards on several columns, elicitation of responses from male antennae with standards, and the fact that the corresponding aldehydes and acetates are present in the extracts renders these identifications virtually certain.

In addition to these six components, a number of other compounds were identified in extracts from pheromone glands from females, including hexadecanal (peak **1**, Figure 1), docosane, tricosane, tetracosane, and hexacosane, all

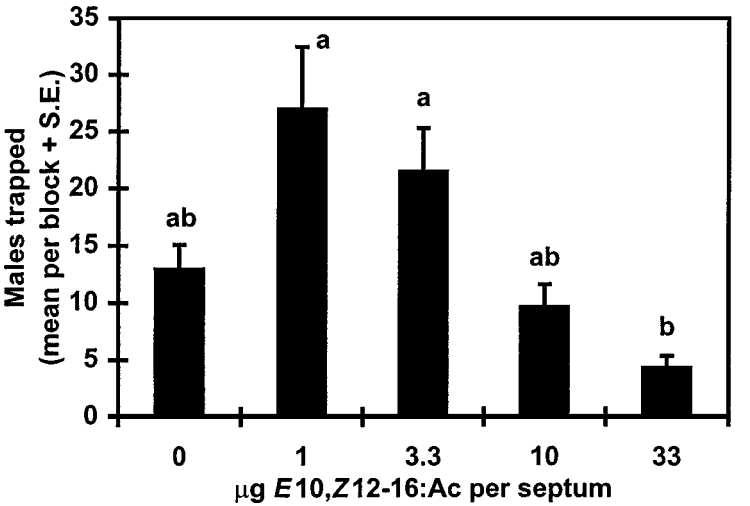

FIG. 5. Trap catches of male *Hemileuca maia* in field trials testing lures with various doses of *E*10,*Z*12–16:Ac, with *E*10,*Z*12–16:Ald and *E*10,*Z*12–16:OH held constant at 100 and 10 μg/septum, respectively. Trial conducted December 7–20, 1997, total number of moths trapped = 205. Treatments with different letters are significantly different (SNK, $\alpha = 0.05$). Two-way ANOVA for *E*10,*Z*12–16:Ac dose effect, $F = 6.44$, $df = 4, 7$, $P = 0.0169$; for block effect, $F = 0.86$, $df = 2, 7$, $P = 0.4649$. (Note: The 3.3 dose was lost or stolen from block 2 and could not be included in the analysis).

tentatively identified from mass spectra and mass spectral matches with database spectra. Identifications were confirmed by comparison of retention time and mass spectral data with those of the corresponding standards on multiple GC columns. In addition, hexadecanol and hexadecyl acetate were tentatively identified in extracts by retention time match-ups with standards.

There was considerable variability among extracts in the amounts of compounds present. For example, of 34 extracts from individual females, only four extracts contained measurable amounts of compounds, with two extracts containing about 20 ng of the major component, *E*10,*Z*12–16:Ald, and a further two extracts containing about 10 ng each. In these four extracts, the ratio of *E*10,*Z*12–16:Ald to *E*10,*Z*12–16:OH to *E*10,*Z*12–16:Ac was $100{:}7.4 \pm 3.3{:}6.3 \pm 1.7$. The quantities of hexadecanal and hexadecanol were estimated as $23 \pm 9\%$ and $11 \pm 10\%$ of the major component, respectively. The amounts of the other components were too low to be quantified with any degree of accuracy.

Male antennal responses were also quantified, both with extracts and with standards, with responses being expressed as a percentage of the response to *E*10,*Z*12–16:Ald. The quantities of *E*10,*Z*12–16:OH and *E*10,*Z*12–16:Ac in

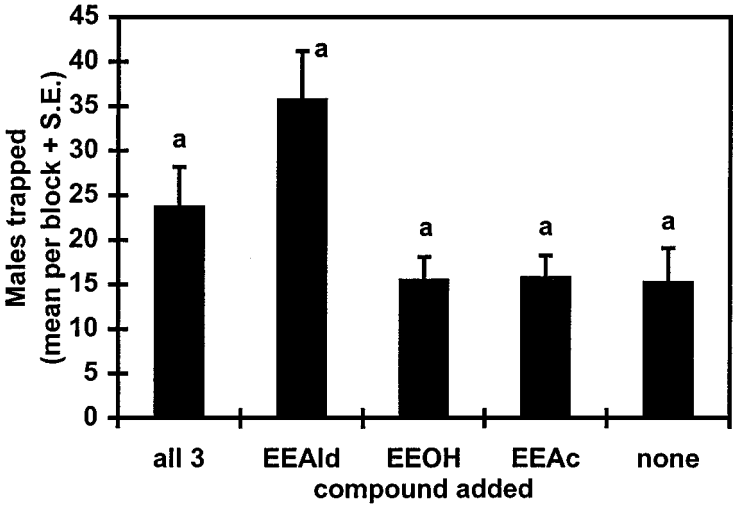

FIG. 6. Trap catches of male *Hemileuca maia* in field trials testing lures with a single dose of *E*10,*E*12–16:Ald, *E*10,*E*12–16:OH, and *E*10,*E*12–16:Ac, either as single components or as a combined mixture, at a dose of 10:2.5:1 μg/septum, respectively, added to the basic blend of *E*10,*Z*12–16:Ald, *E*10,*Z*12–16:OH, and *E*10,*Z*12–16:Ac (100:10:1 μg/septum, respectively). Trial conducted December 17–23, 1997; total number of moths trapped = 424. Treatments were not significantly different, despite a significant ANOVA (SNK, $\alpha = 0.05$). Two-way ANOVA for additive effect, $F = 3.63$, $df = 4, 12$, $P = 0.0369$; for block effect, $F = 1.51$, $df = 3, 12$, $P = 0.2619$.

extracts elicited responses of $17 \pm 7\%$ and $25 \pm 10\%$, respectively, when each of three male antennae were challenged with aliquots of four female extracts. Male antennae ($N = 5$), each challenged six times with mixtures of equal amounts of *E*10,*Z*12–16:Ald, *E*10,*Z*12–16:OH, and *E*10,*Z*12–16:Ac, gave mean responses of 100%, $41 \pm 11\%$, and $47 \pm 19\%$, respectively, indicating that the antennae were most highly tuned to *E*10,*Z*12–16:Ald.

Field Trials. The first field trial conducted in 1995 and repeated in 1996 tested the importance of individual components of a five-component blend mimicking the female blend (Figure 2). Four-component blends, in which either hexadecanol or hexadecanal had been dropped out, were as attractive as the full five-component mixture, indicating that these two components were not of significant importance to the attractiveness of the mixture. However, removal of *E*10,*Z*12–16:Ac from the blend resulted in a sharp drop in attraction of male moths, whereas blends missing either *E*10,*Z*12–16:Ald or *E*10,*Z*12–16:OH were completely unattractive, clearly indicating that these three compounds were critical components of the blends. The next field trial (Figure 3) tested blends of these three components,

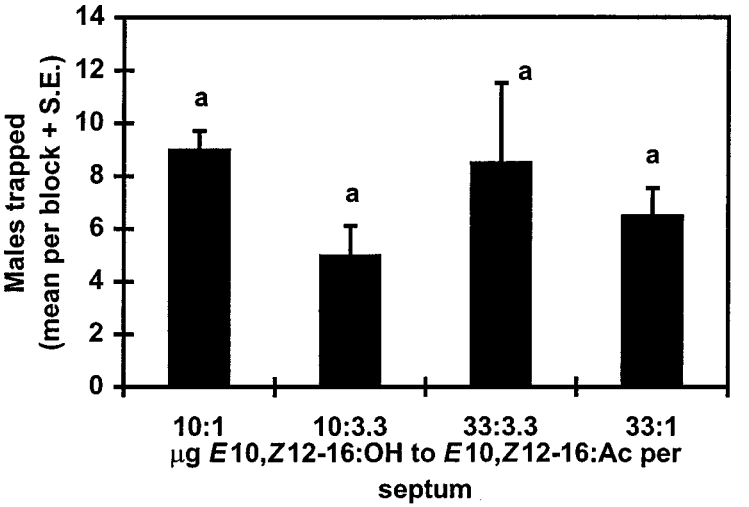

FIG. 7. Trap catches of male *Hemileuca maia* in field trials testing lures with varied amounts of different mixtures of $E10,Z12$–16:OH, and $E10,Z12$–16:Ac, with $E10,Z12$–16:Ald held constant at 100 μg/septum. Trial conducted December 17–23, 1997, total number of moths trapped = 113. Treatments were not significantly different (SNK, $\alpha = 0.05$). Two-way ANOVA for dose effect, $F = 1.06$, $df = 3, 9$, $P = 0.4115$; for block effect, $F = 1.67$, $df = 3, 9$, $P = 0.2426$.

with fixed amounts of $E10,Z12$–16:OH and $E10,Z12$–16:Ac (1.3 and 2.6 μg, respectively) and variable amounts of $E10,Z12$–16:Ald (0-333 μg). Trap captures increased with increasing amounts of $E10,Z12$–16:Ald, the major component of the pheromone. A third field trial (Figure 4) tested blends of the three components in which the amounts of $E10,Z12$–16:Ald and $E10,Z12$–16:Ac were held fixed at 100 and 4 μg, respectively, while the doses of $E10,Z12$–16:OH were varied from 0 to 33 μg (approximately 10 times higher ratio than found in gland extracts from females). Trap catches were directly proportional to the amount of $E10,Z12$–16:OH, with the highest dose used (33 μg) resulting in the largest trap catches. An analogous trial conducted the following year tested the effects of variable amounts of $E10,Z12$–16:Ac (0–33 μg), with fixed amounts of $E10,Z12$–16:Ald and $E10,Z12$–16:OH (100 and 10 μg/septum, respectively) . There were no significant differences in numbers of moths captured in traps baited with 0–10 μg of $E10,Z12$–16:Ac (Figure 5), whereas the highest dose of 33 μg resulted in significantly fewer moths caught than the optimal doses of 1 and 3.3 μg.

A further trial was conducted to determine the possible importance of the $E10$, $E12$–16:Ald, -OH, and -Ac isomers seen in the female gland extracts (Figure 6). Addition of any one of $E10,E12$–16:Ald, $E10,E12$–16:OH, or $E10,E12$–16:Ac,

or the mixture of all three (in ratios similar to those seen in pheromone gland extracts), to the three-component base mixture of *E*10,*Z*12–16:Ald, *E*10,*Z*12–16:OH, and *E*10,*Z*12–16:Ac (100:10:1) had no effect on the attractiveness of lures; all treatments attracted similar numbers of moths. A final trial tested different ratios of *E*10,*Z*12–16:OH to *E*10,*Z*12–16:Ac, with *E*10,*Z*12–16:Ald held constant at 100 μg/lure (Figure 7). There were no significant differences among treatments, indicating that the presence of the two components may be more important than their exact ratio, either in relation to each other or in relation to *E*10, *Z*12–16:Ald.

DISCUSSION

Pheromone components based on (*E*10,*Z*12)-hexadienyl compounds have now been identified in several species in the genus *Hemileuca* and two species in the sister genus *Coloradia* (McElfresh and Millar, 1999a–d; McElfresh et al., 2001). However, *E*10,*Z*12–16:Ald is the major component of the pheromone blend of *H. maia*, whereas *E*10,*Z*12–16:Ac constitutes the major component for the other species. As was found with the other species, a blend of the main component with at least one of the minor components (*E*10,*Z*12–16:OH) is crucial for attraction of male *H. maia*; blends must contain at least these two components to attract any male moths at all, and trap catches increased monotonically with increasing amounts of each of these compounds in blends, indicating their importance in the overall attractiveness. Surprisingly, the highest dose and ratio of *E*10,*Z*12–16:OH tested (33 μg, 33% of *E*10,*Z*12–16:Ald, the major component) was most attractive, even though this ratio is approximately 10 times the ratio found in the pheromone gland extracts.

The role of the third component, *E*10,*Z*12–16:Ac, is less clear. In one trial, (Figure 2), deletion of *E*10,*Z*12–16:Ac from the complete blend resulted in a significant decrease in attraction, whereas in a subsequent trial testing different ratios of *E*10,*Z*12–16:Ac to the other two components, lures containing no *E*10,*Z*12–16:Ac were as attractive as lures containing 1, 3.3, or 10 μg of *E*10,*Z*12–16:Ac. However, possible differences among treatments may have been obscured by the large variability in trap catches in that trial; lures containing 1 μg of *E*10,*Z*12–16:Ac caught almost twice as many moths as the lures without this compound, but the difference was not statistically significant. However, the highest dose of *E*10,*Z*12–16:Ac tested in this trial resulted in significantly fewer moths captured than the optimal doses (1–3.3 μg), clearly indicating that this compound can affect males' behavior.

Other minor components identified in female gland extracts, such as hexadecanal, hexadecanol, and the *E*10,*E*12–16:OH and -Ac isomers, do not appear to be crucial for the attraction of conspecific males; addition of these components in

biologically relevant amounts had no significant effect on trap captures. From the GC-EAD studies, it is clear that at least the latter two compounds are detected by male antennae, but their biological roles remain to be determined.

The possible role of *E*10,*E*12–16:Ald may warrant further investigation. Lures containing this compound, although not statistically different than the base blend without it, attracted more than twice as many male moths as the base blend. As in a previous trial, differences may have been obscured by the relatively small number of replicates and the relatively large standard errors. It is also clear that male moth antennae detect this compound because the EAD traces showed a distinct and reproducible peak (as a shoulder on the peak corresponding to the response to the main component, *E*10,*Z*12–16:Ald) in response to stimulation by this component of the pheromone gland extracts.

For practical purposes, the pheromone is already finding use in monitoring and control programs in those areas of the United States in which *H. maia* outbreaks result in nuisance and human health problems. For example, since 1997, the New Orleans Mosquito and Termite Control Board has used pheromone-baited traps to survey parks, oak-lined boulevards, and the city zoo area, with high trap catches alerting the Control Board to potential high larval populations the following spring.

Acknowledgments—We thank Darwin Reed for reference standards used in this study and Carol Adams for assistance with the statistical analyses. We also thank Stephen R. Sackett for assistance with field trials and placement of survey traps.

Abstract—We examined aggregative behavior of hatchlings of the desert locust *Schistocerca gregaria* emerging from solitaria egg pods that had been incubated in sand previously used for consecutive ovipositions by gregarious females. Hatchlings derived from such eggs were significantly more gregarious than those derived from pods laid in clean sand. The gregarizing effect of the sand-associated factor originating from 3, 5, or 10 ovipositions by gregarious females increased in a dose-dependent fashion. Washing the sand with organic solvents following such ovipositions, or flushing it with nitrogen gas, led to substantial loss of its gregarizing effect, showing that the active signal is volatile and of medium polarity. The gregarizing activity of the exposed sand correlated with the presence of C-8 unsaturated ketones, (*Z*)-6-octen-3-one and (*E*,*E*)-3,5-octadiene-2-one and its *E*,*Z* isomer, previously shown by us to form part of the releaser pheromone system that mediates group oviposition in *S. gregaria*. These ketones were present in relatively large amounts in the eggs obtained from egg pods of gregarious females and were also detected in the extracts of accessory glands of gregarious females, a candidate source of the gregarization factor. It is proposed that the pheromone is secreted at the onset of oviposition. This would account for its distribution predominantly within the eggs and surrounding sand at the site of oviposition. The study sheds new light on the pheromonal mechanism associated with transgenerational transmission of gregarious characters in crowded *S. gregaria* populations and provides yet another case in this insect of dual releaser and primer roles played by the same pheromone blend.

INTRODUCTION

Locusts are characterized by a pronounced ability to transform reversibly between two extreme phases, solitaria and gregaria, that differ in physiology, biochemistry, behavior, and morphology (Uvarov, 1966; Pener and Yerushalmi, 1998; Applebaum et al., 1997). Phase change is predicated on locust density, and crowding or uncrowding can lead to rapid (hours or days) changes in some of the phase-related traits, such as aggregation behavior (Roessingh and Simpson, 1994) and the production of mediating pheromones (Deng et al., 1996). Gregarious characters may spread horizontally through recruitment of solitary individuals into gregarizing groups (Njagi et al., 1996) and accrue across generations through the eggs (Pener, 1991; Islam et al., 1994a,b; Bouaïchi et al., 1995). Egg pods laid by gregarious females produce gregarious hatchlings, and those laid by solitary females produce solitary hatchlings (Pener, 1991; Islam et al., 1994a,b).

Recent studies on the desert locust, *Schistocerca gregaria*, have tried to elucidate the pheromonal mechanisms that underlie transgenerational transmission of gregarious characters. Two sets of pheromonal effects have been shown to operate. One is mediated by volatile signals that promote group oviposition behavior, thus ensuring spatial cohesiveness of the offspring. These include benzene derivatives, acetophenone and veratrole, associated with egg-froth (Saini et al., 1995; Rai et al., 1997), unsaturated ketones [(*Z*)-6-octene-2-one and (*E*,*E*)-3,5-octadien-2-one and its *E*,*Z*-isomer] secreted into the sand during oviposition (Torto et al., 1999), and a saturated aldehyde emitted by ovipositing females that attract other gravid females (Njagi et al., unpublished data). Since oviposition is generally a mixed-sex activity, the male-produced adult aggregation pheromone may also play a role (Saini et al., 1995).

The second pheromonal effect is mediated by a primer gregarizing factor associated with gregarious and gregarizing gravid females, including those that experience crowding at mating or oviposition (Islam et al., 1994a,b; Bouaïchi et al., 1995). McCaffery et al. (1998) considered the soil previously used by gregarious ovipositing females and foam plugs of egg pods as possible sources of the primer pheromone. A soil-borne factor was ruled out since egg pods of solitary females laid into sand previously used for oviposition by gregarious females gave hatchlings that were not different from solitary controls. On the other hand, there was significant evidence of gregarization in hatchlings derived from solitary eggs incubated with froth from egg pods laid by gregarious females. Saline aqueous extracts of the froth were similarly effective in inducing shifts towards the gregarious phase of hatchlings from solitary egg pods. Ultra-filtration at 3 kDa gave a filtrate that

essentially retained the activity of the original extract. The authors then concluded that the pheromone was a polar substance of low molecular weight (<3 kDa), released by the egg pod.

In our studies of soil-borne oviposition signals, the relevant compounds (C-8 unsaturated aliphatic ketones) were found to adhere strongly to dry soil and could only be desorbed under relatively high humidities (Torto et al., 1999). Interestingly, these compounds were also found in the eggs obtained from egg pods of gregarious females. This and the parsimonious functions of some of the desert locust pheromones as releaser and primer signals (Mahamat et al., 1993; Assad et al., 1997; Hassanali and Torto, 1999) led us to hypothesize that the ketones associated with soil used by gregarious females for oviposition might also function as the primer gregarization signal. The present study was undertaken to test this hypothesis. Since accessory glands of gregarious gravid females were recently implicated in the production, release, or activation of the primer factor (Hägele et al., 2000), we also examined extracts of the glands for the presence of the ketones.

METHODS AND MATERIALS

Insects

Desert locusts were reared under crowded (gregarious) or isolated (solitary) conditions as described by Ochieng-Odero et al. (1994). The stocks originated from egg pods supplied by the Desert Locust Control Organisation for Eastern Africa (DLCO-EA), Addis Ababa, Ethiopia, and have been periodically supplemented with collections from ICIPE Field station near Port Sudan. The insects were fed on fresh wheat seedlings, *Triticum* spp., and wheat bran.

Solitary-reared locusts had six nymphal instars, largely green in coloration; the sixth instar had an extra eye stripe. Adults of both sexes were greyish brown and had F/C ratios (length of posterior femur/maximum width of the head) >3.75, typical of solitary adults (Ochieng-Odero et al., 1994). Crowd-reared insects had five nymphal stages. Hoppers had black color patterns on a yellow background; immature adults were pink, while mature adults were bright yellow (males) or pale yellow on the head and pronotum (females). The F/C ratios of adults were <3.15, characteristic of gregarious locusts (Ochieng-Odero et al., 1994). In addition to morphometric and pigmentary differences, the two cultures differed markedly in pheromonal characteristics (Njagi et al., 1996; Torto et al., 1994, 1996).

Effect of Incubating Solitaria Egg Pods in Sand Exposed to Oviposition by Gregarious Females on Aggregation Behavior of Hatchlings

Preparation of Sand. Sand sieved through a wire mesh (2 mm^2 mesh size) was washed sequentially with hot water, methanol, acetone and dicholoromethane to

remove inorganic and organic contaminants and heat-sterilized at 205°C for 24 hr. After cooling to room temperature, it was moistened with distilled water to give a moisture content of ~15% (15 ml water to 100 g of sand) (Norris, 1968). The purity of the sand with respect to volatile contaminants was checked by aeration through activated charcoal and analyzing any trapped material by gas chromatography as described below. Standard aluminum oviposition cups (10 × 4 cm ID) were filled with the moistened sand and placed at the front of the false floor of standard aluminum locust rearing cages (50 × 50 × 50 cm) containing gregarious gravid females (Saini et al., 1995). After 24 hr, deposited egg pods were removed, the sand, thus exposed, was allowed to dry overnight in an aluminum tray in a temperature-controlled (30 ± 2°C) room. The sand was then sifted through a wire mesh (2 mm^2) to remove any remnants of debris of eggs and froth, and its moisture content restored to 15% by adding the appropriate amount of water.

Experimental Treatments of Solitaria Egg Pods. Egg pods from solitary females were transferred into oviposition cups with successively exposed sand prepared as described above or further treated, as outlined below: (i) exposed sand batches with 15% moisture in which gregarious females had previously laid successively 3, 5, or 10 egg pods, respectively; (ii) exposed sand batches as in (i) that were sequentially washed with methanol, acetone, and dichrolomethane, then spread out on a metal tray and left to dry at 30 ± 2°C for 24 hr, and remoistened to 15%; and (iii) exposed sand batches as in (i) that were flushed with gaseous nitrogen for 24 hr with the sand spread out thin in a glass chamber (24 cm long × 5 cm ID) to facilitate elution of volatile compounds, and then remoistened to 15%.

The following treatments served as controls: (iv) egg pods laid by solitary females in clean (unexposed), moistened sand; and (v) egg pods laid by gregarious females also in clean, moistened sand.

The egg pods thus prepared were then separately incubated at 30°C and 60–70% relative humidity. After seven days, they were checked repeatedly for hatching, and additional water was added to restore the moisture level in the sand, until hatching (12–15 days).

Behavioral Assays. Aggregation bioassays were conducted in a uniform ring-shaped aluminum arena with the floor divided into 18 equal segments (Ellis, 1953; Weisel et al., 1996). The diameter of the inner wall was 14.5 cm, the outer wall 29.0 cm, and the height 10 cm. The arena was covered by a glass plate and placed under an exhaust hood. The hood was fitted with two 60-cm diffused-light tubes (60 W) 40 cm above the glass plate to provide uniform illumination at the arena. The temperature of the room was maintained at 30 ± 2°C.

On hatching from oviposition cups, 12 neonate nymphs (<12 hr old) were released randomly into the bioassay arena and observed for 20 min. At the end of this period, the distribution of the insects (number of divisions that contained 0,1, 2, and ≥3 nymphs) was recorded. [Since groups of 4 and 5 in a given division on the arena were relatively rare, even for hatchlings that had emerged from crowd-reared

insects (see also Weisel et al., 1996), these were grouped into the ≥ 3 category]. The insects were then disturbed by tapping the glass top of the cage several times, after which they were allowed to settle before the next recording 20 min later. The procedure was repeated for 2 hr, which resulted in six readings per replicate. Each treatment was replicated five times, between which the arena was cleaned with detergent, rinsed with water and acetone, and dried in an oven at 100°C for 15 min. The level of aggregation was expressed in terms of the proportions of single insects and those that were in groups of ≥ 2 or ≥ 3. These were compared with a random theoretical distribution calculated from Poisson function (Sokal and Rohlf, 1981).

Analyses of Treated Sand and Eggs

Sands associated with the following three treatments were analyzed for the presence of volatiles (candidate primer pheromone): (i) cleaned, sterilized, and moistened sand (untreated control); (ii) sand in which gregarious locusts had oviposited for five successive times and moistened; and (iii) as in (ii), but flushed with nitrogen for 24 hr, and remoistened. Batches of sand from these treatments were put in glass chambers (10 cm long $\times$ 3.5 cm ID) and aerated as previously described (Torto et al., 1999). A charcoal-filtered airstream (106 ml/min) from a compressed air cylinder was passed over the sand for 24 hr in a room maintained at 30 ± 2°C. The effluent passed through activated charcoal (60 mg) contained in Pyrex glass tubes. The trapped volatiles were eluted with pure dicholomethane (2 ml, Aldrich Ltd., HPLC grade), each set pooled together, and stored at -15°C until analyzed. In addition, volatiles were also collected from eggs derived from five $\sim$1-day old egg pods that had been deposited in treatment (ii) above. The eggs were crushed in sterilized sand, moistened with water (to 15%), and volatiles collected as above.

For analyses, the volatiles were concentrated under a stream of nitrogen at 0°C to $\sim$100 μl. Five microliters of the extracts were analyzed by gas chromatography on a Hewlett-Packard (HP) 5890 Series II instrument equipped with a flame ionization detector (FID) and a HP capillary column (Carbowax 20 M, 50 m $\times$ 0.2 mm ID $\times$ 0.2 μm with nitrogen as the carrier at a flow rate of 0.35 ml/min (Torto et al., 1999). The oven was programmed as follows: 60°C (10 min) to 180°C at 5°C/min, 180°C (5 min) to 220°C at 10°C/min. Peaks were integrated by using a HP 3396 Series II integrator.

Analysis of Accessory Glands

Accessory glands (located at the anterior ends of the ovaries) were removed from crowd-reared (gregarious) gravid adult female locusts (40) and transferred into a vial containing saturated sodium chloride solution (10 ml). The suspension

was sonicated for 2 hr, dichloromethane or hexane (20 ml) added, and the mixture thoroughly shaken. The aqueous and organic layers were allowed to separate (2–3 min) and the organic layer collected. This was shaken with aqueous sodium hydroxide (20 ml, 5%) to remove the large amounts of C_1–C_{16} fatty acids present. The layers were allowed to separate (2–3 min), the organic phase collected and dried by passing through anhydrous sodium sulfate and then concentrated under a stream of nitrogen at 0°C to ~200 μl. Samples of the extracts (10 μl) were analyzed on a Hewlett-Packard (HP) 5890 Series II gas chromatograph and by GC-MS on a Fisons Instruments 8060 Series II chromatograph coupled to a Fisons Instruments VG Platform MS (EI, 70eV), employing the same chromatographic conditions as described above. A synthetic mixture of (*E*,*Z*) and (*E*,*E*)-3,5-octadien-2-one (donated by Professor T. C. Baker, Iowa State University, Ames, Iowa) allowed the confirmation of the identities of these ketones in the extracts of the accessory glands and contaminated sand.

Data Analyses

The behavioral data were subjected to analysis of variance (SAS Institute Inc.; Cary, North Carolina). Means were compared by the least significance (LSD) test.

RESULTS

Aggregation Assays. Aggregative behavior of newly hatched first-instar nymphs was influenced by the mother's phase state and by the type of sand surrounding the eggs. As expected, solitary mothers produced nonaggregative nymphs and gregarious mothers produced gregarious nymphs (Figure 1A, i and v). However, hatchlings derived from egg pods placed in sand contaminated by substances associated with gregarious egg pods were more gregarious (Figure 1A, ii–iv). On the other hand, when sands from gregarious pods were washed with organic solvents or flushed with streams of nitrogen, they lost their gregarizing activities (Figure 1B, ii–iv, and 1C, ii–iv, respectively).

The aggregation behavior of hatchlings from all treatments compared with those of solitary and gregarious controls is summarized in Figure 1D, where the proportion of single insects on the arena in different treatments is plotted against the proportion in groups of 2, 3, and higher. Pairs of insects were also included in the latter category in this plot, since solitary locusts avoid each other, and pairing constitutes an expression of grouping behavior (Ellis, 1963; Roessingh et al., 1993). The gregarizing effect of sand-associated factors originating from successive ovipositions by gregarious females is seen clearly to increase in a dose dependent fashion. Washing the sand with organic solvents or flushing it with nitrogen leads to loss or substantial decrease in the activity associated with the sand.

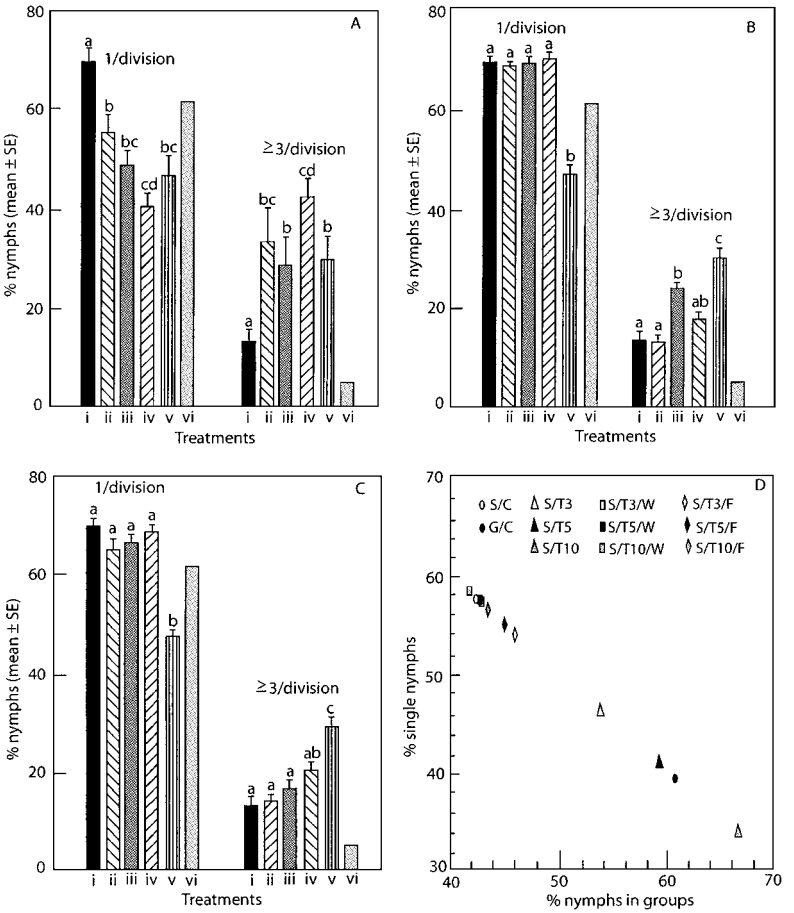

FIG. 1. Aggregation tendency of *S. gregaria* hatchlings from egg pods treated as follows: A, B, C i and v, untreated *solitaria* and *gregaria*, respectively; A ii, iii, and iv, solitaria egg pods incubated in sand exposed to 3,5, and 10 ovipositions by gregarious females, respectively; B ii, iii, and iv, solitaria egg pods incubated in sand exposed to 3, 5, and 10 ovipositions and then washed with organic solvents; C ii, iii, and iv, solitaria egg pods incubated in sand exposed to 3, 5, and 10 ovipositions and then flushed with nitrogen; A, B, C vi, represent values from Poisson function. D summarizes the results from all treatments: *solitaria* (S/C) and *gregaria* (G/C); S/T3, S/T5, and S/T10 represent hatchlings from *solitaria* egg pods exposed to sand contaminated by 3, 5, and 10 ovipositions, respectively; S/T3/W, S/T5/W, S/T10/W represent insects from *solitaria* egg pod from sand similarly contaminated but subsequently washed with solvents; and S/T3/F, S/T5/F, and S/T10/F represent insects from *solitaria* egg pods from contaminated sand but subsequently flushed with nitrogen. $N = 30$ for all data sets; bars in A, B, and C with the same letter are not significantly different at $P < 0.05$ (LSD test).

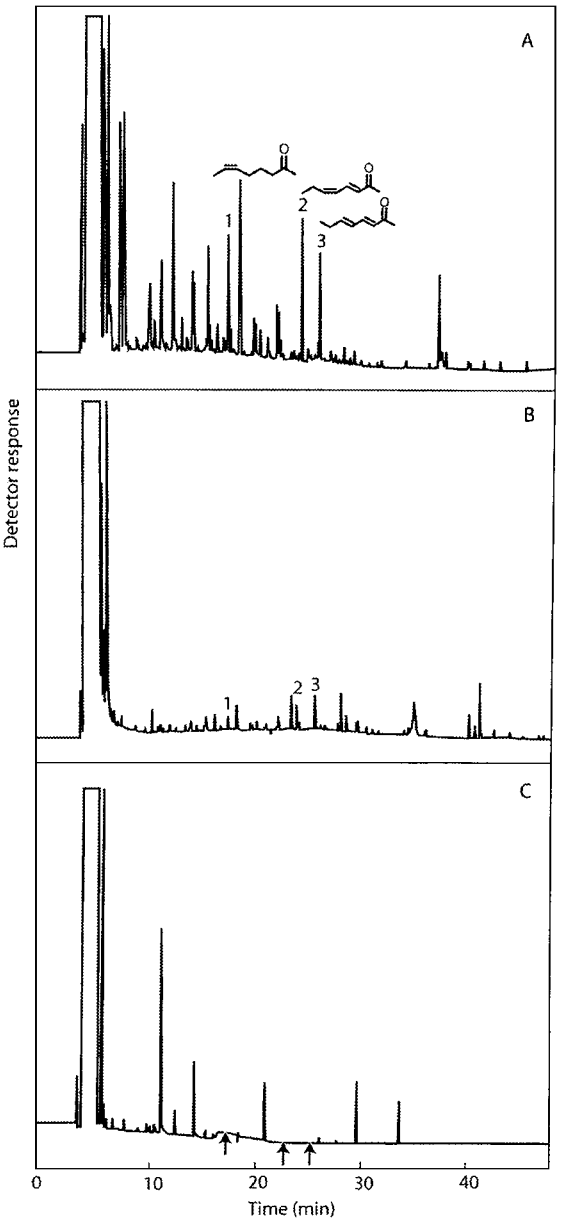

FIG. 2. Gas chromatograms of volatiles collected from (A) eggs from five egg pods crushed in clean sand, (B) sand into which five successive ovipositions by gregarious females had taken place, and (C) as (B) but after the sand had been flushed with nitrogen for 24 hr.

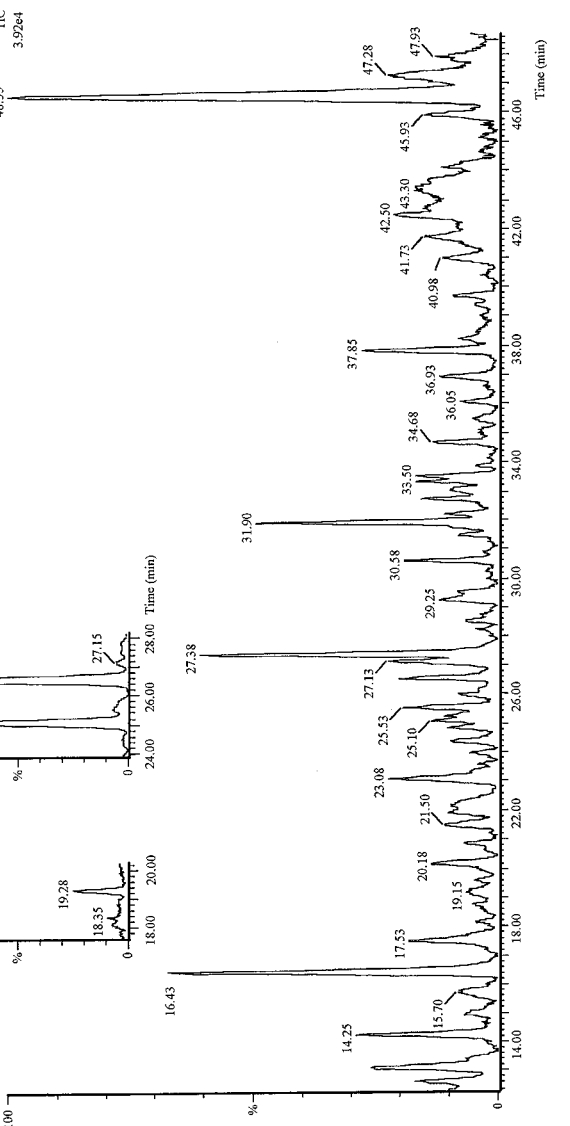

FIG. 3. Total ion MS chromatogram of an extract of accessory glands of *S. gregaria* females showing the presence of (*Z*)-6-octen-2-one ($R_t = 19.28$ min), (*E*,*Z*)-3,5-octadien-2-one ($R_t = 25.10$ min), and (*E*,*E*)-3,5-octadien-2-one ($R_t = 26.55$ min). Insets show single ion monitoring at m/z corresponding to the molecular ions of the compounds.

Analyses of Sand Batches and Eggs. Crushed eggs and sand in which five egg pods had been laid produced (*Z*)-6-octen-2-one and (*E*,*E*)-3,5-octadiene-2-one and its *E*,*Z* geometric isomer (Figure 2A, B). In contrast, these compounds were absent from sand aerated with nitrogen for 24 hr (Figure 2C).

Analysis of Accessory Gland Extracts. Figure 3 gives the total ion GC-MS chromatogram of the nonacidic fraction of accessory gland extracts. (*E*,*E*)-3,5-Octadiene-2-one and its *E*,*Z* geometrical isomer were relatively prominent, with mass spectra comparable to library data (NIST Registry, 1995) and to those of synthetic compounds. *E*,*Z*-isomer: *m*/*z* (%) at 95(100), 43(70), 81(55), 79(45), 124(34), 41(32), 53(28), 39(25), 109(15); *E*,*E*-isomer: 95(100), 81(70), 79(58), 124(50), 53(33), 43(32), 109(22), 65(18), 77(15). (*Z*)-6-Octene-2-one was present in lesser amounts and merged with another minor component. It was detected by single-ion monitoring at *m*/*z* 126, 108, 97, 58, 69, 55 and 43.

DISCUSSION

In a recent communication, we reported that crowd-reared *S. gregaria* oviposited preferentially in sand previously laid in by conspecifics relative to clean sand (Torto et al., 1999). Volatiles collected from sand previously exposed to gregarious egg pods also elicited a similar preference. Female responses toward batches of sand successively laid in by gravid females increased in a dose-dependent manner and correlated with the amounts of trapped volatiles from such batches. GC-EAD and GC-MS studies of the volatiles led to the identification of three EAG-active C_8 ketones, (*Z*)-6-octen-3-one and (*E*,*E*)-3,5-octadiene-2-one and its *E*,*Z* geometric isomer.

The results of the present study show that the aggregative behavior of hatchlings from solitary egg pods that were incubated in sand previously laid in by gregarious females represents a significant shift towards the gregarious phase (Figure 1A). This shift increases in a dose-dependent manner, as evidenced by increasing grouping behavior of hatchlings derived from egg pods incubated in sand batches that had been exposed to 3, 5, and 10 ovipositions, respectively, by gregarious females (Figure 1D). Washing the exposed sand with organic solvents or flushing it with nitrogen leads to loss of its gregarizing effect (Figure 1B,C), consistent with the relative polarity and volatility of the ketones. The presence of these compounds in relatively large amounts in the eggs of gregarious females (Figure 2) suggests that they serve an important function there. Moreover, their detection in the extracts of the accessory glands (Figure 3) is consistent with a recent study by Hägele et al. (2000) that demonstrated that the gregarizing factor probably originates from these glands.

How do we reconcile these findings with those of McCaffery et al. (1998), who found no significant activity in sand that had been exposed to oviposition by

gregarious locusts and who identified foam plugs as the source of the gregarizing factor in the egg pods? First, in our studies we have found that trapping by aeration of the ketones from exposed sand was dependent on the sand's moisture level; at low humidity, the ketones adhered strongly to sand (Torto et al., 1999). Thus, the failure by McCaffery et al. (1998) to observe any significant shift to the gregarious phase in hatchlings from solitaria egg pods that were incubated in exposed sand may have been due to insufficient moisture content of the sand used by these workers. Second, our analyses have shown substantially less ketones in froth plugs than in sand into which the gregaria oviposited (Torto et al., 1999). This is consistent with Szopa's (1981) finding that the accessory glands are not the primary source of the froth material, which appears to be produced mainly by the genital ducts (egg *calyces* and lateral oviducts). The ketone blend is probably secreted at the onset of oviposition, which would account for their relatively high titers in the eggs. The froth forming the plug likely picks up residual compounds, as it is later exuded from the oviduct.

The results of our experiments strongly implicate the C-8 ketones, previously identified as part of the releaser oviposition pheromone system of gregarious-phase desert locusts, as the principal primer signal responsible for maternal transfer of gregarious character and for predisposing solitaria eggs to produce gregarious hatchlings. However, other minor volatile components associated with sand and eggs may also contribute to the signal. The use of this relatively volatile set of compounds secreted during oviposition by crowded locusts would appear to be appropriate for its parsimonious functions. It can form an effective component of the oviposition attractant system of gregarious locusts, thus enhancing group oviposition and spatial cohesiveness of the resulting offspring (Saini et al., 1995; Rai et al., 1997; Torto et al., 1999). Since solitaria gravid females are also strongly attracted, the system also serves to recruit this phase of the insect into gregarizing groups, important during the early stages of phase transformation (Bashir et al., 2000). As a primer signal, we propose that the volatile nature of these substances would allow them to diffuse between the eggs and the surrounding soil and mix with similar vapors from neighboring oviposition sources to create a relatively homogeneous stimulus cloud at the communal oviposition site. This would promote a more uniform phase shift of the developing eggs at the site, the extent of shift being dependent on stimulus intensity. Further studies in the field and under controlled conditions are needed to explore the validity of these speculations.

In summary, the present study provides evidence of yet another case of pheromone parsimony in the desert locust. The blend of C-8 unsaturated ketones, probably produced in the accessory glands and secreted at onset of oviposition by crowded females, found earlier to be part of the oviposition attracting pheromone systems of the desert locust, is a strong candidate for the signal associated with maternal transfer of gregarious characters to the progeny. In our earlier studies, we showed that the nymphal and adult aggregation pheromones, respectively,

sequentially inhibit and accelerate the maturation of young gregarizing or gregarious adults, resulting in a more synchronous development of the insects (Richards and El Mangoury, 1968; Mahamat et al., 1993; Assad et al., 1997). The mechanisms by which these pheromones exert their primer effects remain to be elucidated. Studies with synthetic C-8 ketones of both the releaser and primer effects are in progress.

Abstract—The males of the decorator wasps *Eucerceris* have been observed to display abdomen-dragging behavior on plants surrounding their nest. It is thought that this applies a territorial-marking sex pheromone that serves to alert females to the males' territory for courtship and mating. The extracts of three species *E. rubripes*, *E. conata*, and *E. tricolor* have been analyzed by GC-MS. The gas chromatograms revealed the presence, in large quantities, of one common volatile compound in the male head extracts. By analogy with the closely related bee wolves *Philanthus*, we believe the pheromone is produced in the mandibular glands. Utilizing mass spectrometry, microreactions, FT-IR, and ^{1}H and ^{13}C NMR spectroscopy the structure of the pheromone was proposed to be (*Z*)-3-hexenyl 3-hydroxybutanoate, which was confirmed by synthesis. The absolute configuration of the chiral center was determined to be *R* for the three species by preparing the Mosher esters of the insect samples and comparing their GC retention times with a synthetic sample of known absolute configuration. In addition 2- and 3-hexenoic acid and some aromatic compounds were also found in varying quantities in both males and females along with hydrocarbons and fatty acids, although no species-specific profiles emerged.

Key Words—Mosher esters, absolute configuration, territorial marking sex pheromone, (*Z*)-3-hexenyl (*R*)-3-hydroxybutanoate, decorator wasp, *Eucerceris*.

INTRODUCTION

Eucerceris is a genus of digger wasps whose population is limited in distribution to North America (Scullen, 1968). These wasps, which we call decorator wasps because of their elaborate and decorative body sculpture and color patterns, build underground nests in sandy areas. They are members of the family Sphecidae within the subfamily Philanthinae (Alexander, 1992) and are closely related to the beewolves *Philanthus*. Both *Eucerceris* and *Philanthus* prey upon other insects which they sting into a state of paralysis and transport back to the nest. Multiple prey are then placed in cells, an egg is laid in each cell, and the female seals the cell. Development to adulthood is completed in the cell, with the prey consumed by the hatched larva.

Eucerceris and *Philanthus* also have a relatively unusual mating system among wasps and Hymenoptera in general (Thornhill and Alcock, 1983). Males of these species aggregate into groups, sometimes comprising leks, and establish territories on different plants. The males then display a walking behavior, during which they apply a pheromone by dragging their abdomen on the substrate. The pheromone is used for territorial marking and to attract receptive females to the territory (Alcock, 1975; Evans and O'Neill, 1985; O'Neill, 1983, 1992). Other males are also attracted to the territory and may try to usurp the established male's territory or mate with the approaching females.

The origin of this territorial marking pheromone is believed to be the mandibular glands, which has been confirmed by chemical analysis in several *Philanthus* species (Schmidt et al., 1985, 1990; McDaniel et al., 1987, 1992). The glandular secretion spreads from the mandibular glands to the brush of hairs present on the clypeus and from there is passed onto hairs arranged along the ventral part of the abdomen.

The purpose of this study was to identify and characterize the territorial-marking pheromones of four species of *Eucerceris: E. conata, E. montana, E. rubripes*, and *E. tricolor*. Males of *E. rubripes* and *E. tricolor* display the abdomen dragging behavior and aggressively defend their perches. Morphological examination of the males of all these species revealed the presence of rows of abdominal hairbrushes (Evans and O'Neill, 1985; Alcock, 1975).

METHODS AND MATERIALS

Biological Samples. Wasps were collected live, cooled on ice, and placed either intact or as heads and thorax–abdomens in dichloromethane (Burdick & Jackson, Muskegon, Michigan). Extracts (Table 1) were maintained at -25°C until analyzed. Wasps were obtained from the following locations, all within Cochise County, Arizona, U.S.A.: *Eucerceris conata*—5 km ESE of Willcox, September 2,

TABLE 1. EXTRACTS ANALYZED

Species	Male head	Male body	Female intact
Eucerceris conata	11	7	7
Eucerceris montana	5		
Eucerceris rubripes	5	5	1
Eucerceris tricolor	12		

1989; *E. montana*—7 km NW of Huachuca City, June 26, 1993; *E. rubripes*—7 km NNE of Tombstone, June 26, 1992; and *E. tricolor*—7 km NNE of Tombstone, June 26, 1993.

GC-MS Analysis. Generally gas chromatographic injections of 1 μl of a solution were performed in a splitless mode on a 5890 Hewlett Packard gas chromatograph coupled with a 5970B quadrupole mass spectrometer (70 eV electron impact ionization). The system was controlled by a 59970 ChemStation. For most samples a SGE/BPX5, 5% phenylpolyphenylenesiloxane was used (column: 12 m $\times$ 0.32 mm; 0.5 μm). The GC oven was programmed from an initial temperature of 40°C to a final temperature of 250°C heating at a rate of 10°C/min. Injection port and transfer line were set at 250°C and helium (1 ml/min) was used as carrier gas. Compounds were identified by comparison of their retention time and mass spectrum against synthetic standards.

Microreactions. Microhydrolysis of a sample was carried out using sodium hydroxide, following a similar procedure to one previously described (Pomonis et al., 1993), and the GC-MS of the resulting ether extract was recorded. Dimethyl-thiolation was carried out on the ester as previously described (Billen et al., 1986), but under an atmosphere of nitrogen, and the chromatogram and mass spectrum recorded.

Spectroscopic Measurements. FT-IR, spectroscopy was carried out on a Perkin Elmer Paragon 1000 FT-IR, and NMR spectra were recorded on a Bruker Avance DPX 300-MHz spectrometer. Samples were prepared for NMR by first passing the solution through a short silica column, eluting with deuterated chloroform, followed by repeated microdistillation of the dichloromethane solution gradually replacing the solvent with more deuterated chloroform.

Synthesis of (Z)-*3-Hexenyl* (R)-*3-hydroxybutyrate*. The compound was prepared using an adaptation of a method by Seebach et al. (1996). Sodium (*R*)-3-hydroxybutanoate (0.65 g, 6.2 mmol) in chloroform (9 ml) was added slowly to a stirred solution of (*Z*)-3-hexen-1-ol (0.85 g, 8.5 mmol), dicyclohexylcarbodiimide (DCC, 1.29 g, 6.2 mmol), 4-dimethylaminopyridine (DMAP, 1.13 g, 9.3 mmol), and 4-dimethylaminopyridine hydrochloride salt (1.96 g, 12.4 mmol) in chloroform (12 ml) under nitrogen. After 16 hr, the reaction mixture was filtered through cotton wool, washed with ether (20 ml), and evaporated on a rotary evaporator. The resulting residue was purified by flash chromatography (SiO_2, 7:3

petroleum ether–ethyl acetate) to give an oil, which by ^{1}H NMR was found to contain a mixture of the desired ester and (*Z*)-3-hexen-1-ol. Distillation under reduced pressure using a Kugelrohr apparatus (125–127°C, 0.2 mm Hg) gave the desired ester as an oil (0.45 g, 38.8% yield). FT-IR (CH_2Cl_2)/cm^{-1} 3449 (O-H), 1737 (C=O); ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.73 (3H, t, *J* 7.6, C$\underline{H}_3$-CH_2), 0.99 (3H, d, *J* 6.3, C$\underline{H}_3$-CH), 1.83 (2H, quintet, *J* 7.6, C$\underline{H}_2$-CH_3), 2.16 (2H, q, *J* 7.0, C$\underline{H}_2$-CH=C), 2.18 (1H, dd, *J* 8.4 and 16.5, C$\underline{H}_a$H$_b$-CO), 2.27 (1H, dd, *J* 3.7 and 16.5, CH$_a\underline{H}_b$-CO), 2.80 (1H, d, *J* 3.7, -O$\underline{H}$), 3.89 (2H, t, *J* 6.9, C$\underline{H}_2$-O), 3.90–4.30 (1H, m, C$\underline{H}$-OH), 5.07 (1H, ddt, *J* 1.4, 7.3 and 10.8, C$\underline{H}$=CH-CH_2), 5.26 (1H, ddt, *J* 1.4, 7.2 and 10.8, CH=C$\underline{H}$-CH_2); ^{13}C NMR (75 MHz, $CDCl_3$, off-resonance decoupled and DEPT) δ 14.23 ($\underline{C}H_3$-CH_2), 21.08 ($\underline{C}H_2$-CH_3), 22.30 ($\underline{C}H_3$-CH), 26.63 ($\underline{C}H_2$-CH=C), 42.67 ($\underline{C}H_2$-C=O), 64.08 ($\underline{C}$H-OH), 64.20 ($\underline{C}H_2$-O), 123.49 ($\underline{C}$H=CH-CH_2), 134.83 (CH=$\underline{C}$H-CH_2), 173.30 (O-$\underline{C}$=O).

Assignment of Absolute Configuration. (*Z*)-3-Hexenyl 3-hydroxybutyrate (insect sample or 1 mg, 0.95 μmol of synthetic samples) in chloroform (0.1 ml) was added slowly to a small vial containing a mixture of (*R*)-3-(3,3,3-trifluoro)-2-methoxy-2-phenylpropionic acid (9 mg, 3.9 μmol), DCC (10 mg, 4.8 μmol) and DMAP (1 crystal) in chloroform (0.1 ml). The reaction mixture was stirred for 16 h at room temperature. A gas chromatogram of the mixture was then recorded to ensure that all the (*Z*)-3-hexenyl 3-hydroxybutyrate had reacted. GC resolution of the resulting diastereoisomers was achieved using a Restek Stabilwax column with a polyethylene glycol phase (15 m $\times$ 0.32 mm; 0.25 μm) with the following temperature program: the injector port was set at 250°C, the initial temperature of the oven of 40°C was held for 3 min and then increased at 10°C/min to 250°C. The transfer line was at 250°C and helium was used as the carrier gas with a flow of 1 ml/min. Absolute configuration of the insect samples was established by comparison of retention times and co-injection with the synthetic (*Z*)-3-hexenyl (*R*)-3-hydroxybutyrate of known absolute configuration.

RESULTS

Male and female whole body extracts of *E. conata* and *E. rubripes* were analyzed by GC-MS and the resulting chromatograms compared (Table 2). For both species the main difference observed between the gas chromatograms was the presence of peak 7, which was found only in males. Both male and female body extracts contained similar mixtures of fatty acids and hydrocarbons (peaks 13 and above) plus 4-phenyl-3-hydroxybutan-2-one (peak 8) and its 2-hydroxy analog (peak 9).

GC-MS analysis was then undertaken on the male head extracts of all four species of *Eucerceris* (Table 2). It was found that head extracts of *E. conata*, *E. rubripes*, and *E. tricolor* contained the compounds giving rise to peak 7 in high

amounts, while the gas chromatograms of *E. montana* samples did not contain any peaks apart from those from fatty acids that could be identified on the polar column (data not shown). The abundance of the compounds giving rise to peak 7 in relation to the fatty acids and hydrocarbons in the male heads was greater than

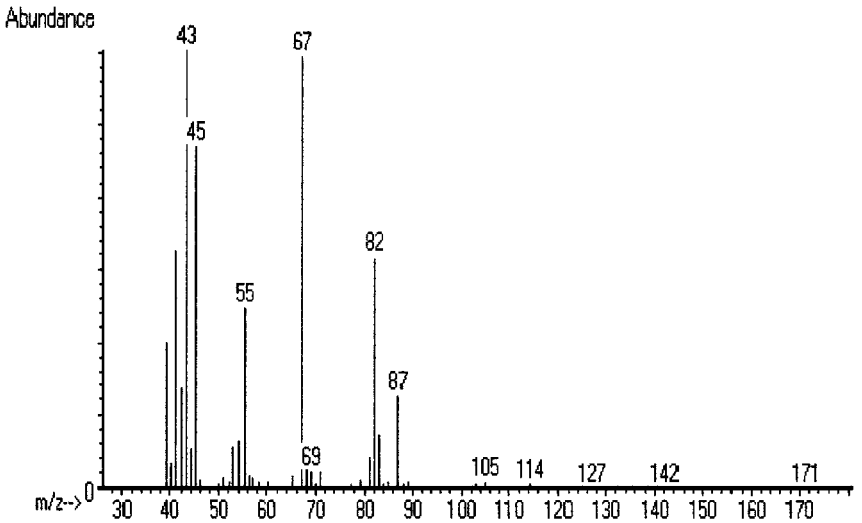

FIG. 1. Mass spectrum of (*Z*)-3-hexenyl (*R*)-3-hydroxybutanoate.

that found in the body extracts. There were also other minor compounds in the head extracts of all three species.

The mass spectrum corresponding to peak 7 had a base peak of 43, strong ions at 45, 55, 67, 82, and 87, no molecular ion and the highest ion at 171 (Figure 1). As we were unable to fully interpret the spectrum at the time we decided to undertake microreactions in order to elucidate the structure (Figure 2). Microhydrolysis under basic conditions followed by acidification and GC-MS of a hexane extract revealed the presence of an alcohol, (*Z*)-3-hexen-1-ol. Surprisingly no carboxylic acid could be found, suggesting it had either decomposed or it was soluble in the aqueous layer. The spectrum of the alcohol did explain the presence of the ion at 82 in the original spectrum resulting from alkyl–oxygen fission and also the 67 from further fragmentation. Methylthiolation using dimethyl disulfide (DMDS) followed by GC-MS confirmed the presence of only one double bond with a M^+ at 280 and two distinctive peaks at *m/z* 89 and 191 (Figure 2) resulting from cleavage adjacent to the methylthio groups.

The high concentration and purity of the compound corresponding to peak 7 in the *E. rubripes* head extract allowed FT-IR, ^{1}H NMR, and ^{13}C NMR spectra to be taken on the insect sample. FT-IR of the dichloromethane male head extract of *E. conata* revealed two strong absorptions at 3522 cm^{-1} and 1720 cm^{-1}, suggesting the presence of a hydroxyl group and an ester group. Substitution of the dichloromethane solvent for deuterated chloroform by careful microdistillation allowed a ^{1}H NMR spectrum of good quality to be acquired. This spectrum also

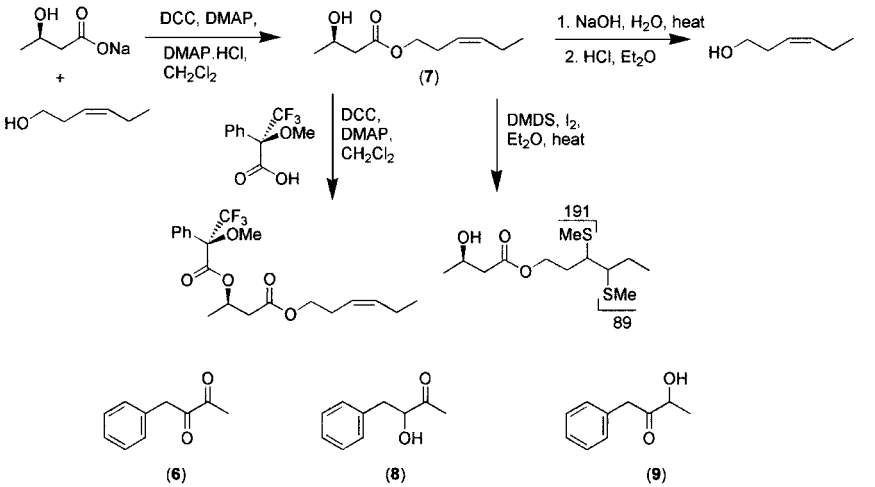

FIG. 2. Chemical procedures undertaken for the analysis and synthesis of (*Z*)-3-hexenyl (*R*)-3-hydroxybutanoate (7) and the structures of 4-phenylbutan-2,3-dione (6), 4-phenyl-3-hydroxybutan-2-one (8), and 4-phenyl-2-hydroxybutan-3-one (9).

confirmed the presence of a *Z* double bond ($J = 10.8$ Hz), and the signal at δ 3.8 ppm suggested a CH_2 adjacent to an oxygen. The ^{13}C NMR decoupled spectrum showed peaks at 123 and 135 ppm, which corresponded to the alkene carbons and an absorption at 173 ppm due to the ester carbonyl carbon. ^{13}C NMR DEPT spectra further confirmed the assignment of the structure. All of this evidence clearly pointed to the structure being (*Z*)-3-hexenyl 3-hydroxybutyrate. This was confirmed by coinjection onto the GC-MS of the natural extract with an authentic synthetic sample, which also had identical IR and NMR spectra.

The absolute configuration of the (*Z*)-3-hexenyl 3-hydroxybutyrate was determined by derivatization with (*R*)-Mosher acid (Dale et al., 1969) and comparison of the retention times of the resulting diastereomeric esters (Figure 3). Injection of the Mosher esters of the racemic mixture onto a 15-m Carbowax column showed two well-resolved peaks corresponding to the two diastereoisomers. Derivatization and analysis of the head extracts of *E. conata*, *E. rubripes*, and *E. tricolor* showed that these samples contained only one diastereoisomer. Preparation and derivatization of an enantiomerically pure sample of (*R*)-hydroxybutyric acid revealed that the absolute configuration of the (*Z*)-3-hexenyl 3-hydroxybutyrate in all of the *Eucerceris* samples was *R*.

A number of minor compounds were found within the *Eucerceris* extracts that belonged to four groups: aromatic ketones, unsaturated acids, acetates and hydrocarbons. Decomposition products of the ester, 3-hexenoic acid and 2-hexenoic acid, via plausible retroaldol, hydrolysis, oxidation, and isomerization reactions

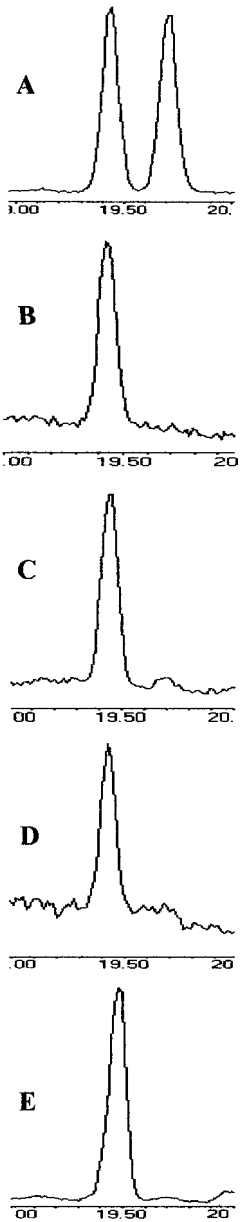

FIG. 3. Gas chromatograms of the Mosher esters of (*Z*)-3-hexenyl-3-hydroxybutanoate from: (A) a synthetic racemic sample, (B) *E. rubripes*, (C) *E. conata*, (D) *E. tricolor*, and (E) synthetic (*Z*)-3-hexenyl (*R*)-3-hydroxybutanoate.

were found to be among the minor compounds in *E. conata* and *E. tricolor* together with 3-hexenyl acetate in the latter species.

More interestingly were three related compounds that corresponded to peaks 6, 8, and 9. Peaks 8 and 9 had the same molecular ion M^+ 164 and a loss of 18 mass units suggesting they were isomeric alcohols and peak 6 had an M^+ of 162 suggesting that it was the corresponding ketone. GC-MS analysis followed by synthesis (Cocker and Grayson, 1975) confirmed their structures as 4-phenyl-3-hydroxybutan-2-one (8), its isomer 4-phenyl-2-hydroxybutan-3-one (9), and their oxidation product 4-phenylbutan-2,3-dione (6).

DISCUSSION

As the territorial marking sex pheromone is produced and released only by *Eucerceris* males and (*Z*)-3-hexenyl (*R*)-3-hydroxybutyrate is only found in extracts of males, then it is highly probable that this is the pheromone in *E. conata*, *E. rubripes*, and *E. tricolor*. We do not know why no other major components were detected, although there is a precedent for predominantly one compound from *Philanthus triangulum*, which contains 89% (*Z*)-11-eicosen-1-ol (Schmidt et al., 1990). We can only speculate that the lack of hydrocarbons or (*Z*)-3-hexenyl (*R*)-3-hydroxybutyrate in the chromatograms of *E. montana* is due to either decomposition of the sample or sampling at the wrong time of the season.

The chemical composition of the mandibular gland secretion of a number of species of *Philanthus*, a sister genus to *Eucerceris*, have been reported to consist of mixtures of long-chain alcohols, aldehydes, ketones and esters (Schmidt et al., 1985, 1990; McDaniel et al., 1987, 1992). In the five North American species of *Philanthus* previously studied, each was shown to have a species-specific blend of pheromones. It was suggested that as the species nest sympatrically in similar habitats, these pheromone blends help prevent species interbreeding. If (*Z*)-3-hexenyl (*R*)-3-hydroxybutyrate is the pheromone in all three congeneric species then this suggests that *Eucerceris* has evolved a different mechanism of species differentiation, possibly involving some of the minor compounds identified, even though our data are insufficient for us to distinguish between species. We also suspect that the minor aromatic compounds found in the male body and female extracts of *E. conata* and *E. rubripes* probably originate from a gland on the abdomen and are not cuticular compounds.

This is the first report of (*Z*)-3-hexenyl (*R*)-3-hydroxybutyrate being found in nature. Its odor was described by some as similar to that of old rose petals and its moderate volatility makes it highly suitable for an airborne pheromone that will degrade with time. (*R*)-3-Hydroxybutanoic acid is commonly found in microorganisms (Doi, 1990) and the compound itself and its dimer have been identified as the sex pheromones of the spider *Linyphia triangularis* (Schulz and Toft, 1993).

3-Hydroxy derivatives of other longer-chain acids have also been isolated from the leaf-cutting ant *Atta sexdens* (C_6, C_8, C_{10}) (Schildkneckt and Koob, 1971) and the mandibular glands of the bumble bee *Bombus terrestris* (C_6, C_8, C_{10}, C_{12}, C_{14}) (Hefetz et al., 1996). In the former the absolute configuration for the different 3-hydroxy acids varied; 3-hydroxydecanoic acid, the major compound was assigned the *S* configuration, whereas 3-hydroxytetradecanoic acid was racemic.

Methyl esters of the 3-hydroxy-substituted octanoic, decanoic, and dodecanoic acids have been found in the cephalic secretions of the solitary wasp *Campsocolia ciliata* (Borg-Karlson et al., 1987). Finally another similar ester to the one found in *Eucerceris*, (*Z*)-3-hexenyl (*R*)-2-hydroxy-3-methylbutanoate has been found to be the male produced aggregation pheromone of the assassin bug *Pristhesancus plagipennis* (James et al., 1994).

The finding that the highest concentrations of (*Z*)-3-hexenyl (*R*)-3-hydroxybutyrate are in the male head extracts suggests that, by analogy with *Philanthus*, the compound originates from the mandibular glands. Although accurate quantification was not possible at the time, what was most surprising were the considerable quantities of the ester present in *E. rubripes* head extracts. We found it remarkable that the extract of only seven heads was sufficient to take a ^{13}C NMR spectrum of good resolution with approximately 11,500 scans, suggesting there was over 1 mg of ester in that sample. Further studies are required in order to establish whether the wasps biosynthesize the compound themselves or sequester part or all of it from elsewhere.

(Received July 27, 2000; accepted March 14, 2001)

Abstract—Soldier defense secretions from samples of *Reticulitermes* collected in California, Nevada, Arizona, New Mexico, and Georgia were characterized and correlated with cuticular hydrocarbon phenotypes. Twenty-seven cuticular hydrocarbon phenotypes have been defined, and soldier defense secretion (SDS) phenotypes have been described for 25 of these. Forty-five terpenoid compounds were found, including monoterpenes, sesquiterpenes, and a few diterpenes. The monoterpenes include (−)-α-pinene, (−)-β-pinene, (−)-camphene, myrcene, (*Z*)- and (*E*)-ocimene, and (−)-limonene. The major sesquiterpenes produced are (+)-γ-cadinene, (+)-γ-cadinene aldehyde, (−)-germacrene A, germacrene B, γ-himachalene, and β-bisabolene. Some SDS phenotypes pair with more than one cuticular hydrocarbon phenotype; however, with two exceptions, each hydrocarbon phenotype is associated with only one SDS phenotype. These chemical characterizations lend support to the conclusion that there are numerous undescribed species of *Reticulitermes* in North America.

Key Words—*Reticulitermes*, Isoptera, Rhinotermitidae, subterranean termites, monoterpenes, sesquiterpenes, diterpenes, geranyl linalool, soldier defense secretions, cuticular hydrocarbons.

INTRODUCTION

We have been studying the foraging ecology of *Reticulitermes* (Isoptera: Rhinotermitidae) from sites in the western and southeastern United States, but have encountered difficulty identifying our collections to species in many locations. According to accepted biogeographical information, only one species, *R. hesperus* Banks, should be present at our California sites; *Reticulitermes* from New Mexico, Arizona, and Nevada should all be *R. tibialis* Banks; and the Georgia sites could be inhabited by the sympatric species *R. flavipes* (Kollar), *R. virginicus* Banks, and/or *R. hageni* Banks (Weesner, 1965, 1970; Haverty and Nelson, 1997; Haverty et al., 1996, 1999b,c, 2000).

The available keys to soldiers were unreliable in identifying many of our samples. For example, all California colonies keyed to *R. tibialis*, not *R. hesperus*, regardless of their geographic origin (Haverty and Nelson, 1997). Soldier samples from Georgia keyed to one of the three extant species that inhabit the southeastern United States (Haverty et al., 1996, 1999b). Alates rarely occur in foraging groups, thus seldom could be used for species determination. When alate specimens were present, however, species determination was often equivocal, especially for colonies determined to be *R. hageni* by soldier morphology. In short, determination of *Reticulitermes* species based on morphology can be uncertain. Because of this, we have routinely examined chemical characters as an aid in determining taxonomic identity.

Chemical characters, such as cuticular hydrocarbons and soldier defense secretions, have proven useful for distinguishing taxa of *Reticulitermes* (Bagnères et al., 1988, 1990, 1991; Baker et al., 1982; Clément and Bagnères, 1998; Clément et al., 1985, 1986; Haverty and Nelson, 1997; Haverty et al., 1996, 1999b; Howard et al., 1978, 1982b; Lange et al., 1989; Parton et al., 1981; Takematsu, 1999; Takematsu and Yamaoka, 1999; Zalkow et al., 1981). Cuticular hydrocarbon biosynthesis is largely genetically determined (Coyne et al., 1994; Kaib et al., 1991; Page et al., 1991), and the resultant mixture of compounds comprises a chemical "signature" enabling recognition at the species, colony, and individual levels, especially important in social insects (Bagnères et al., 1990, 1991; Clément and Bagnères, 1998; Howard, 1993; Howard et al., 1980, 1982a,b; Takahashi and Gassa, 1995). In fact, mimicry of the hydrocarbon signature allows termitophilous beetles to integrate peacefully into *Reticulitermes* colonies (Howard et al., 1980, 1982a). There is also evidence that when two termite species are artificially mixed, there will be some exchange of cuticular hydrocarbons, most likely by passive transfer (Vauchot et al., 1998).

Termite soldier defense secretions are synthesized *de novo* (Prestwich, 1979, 1984, 1988; Prestwich et al., 1981) and are used as weapons against intruders (Mill, 1983; Moore, 1974; Prestwich, 1979, 1983, 1984, 1988; Scheffrahn et al., 1983). Termite soldiers protect the colony against ants and vertebrate

predators, while workers are capable defenders in termite–termite conflicts (Thorne, 1982). Worker termites appear to be devoid of terpenoid compounds, so it is not likely that these chemicals are part of any colony signature (Clément and Bagnères, 1998). Although cuticular hydrocarbons and soldier terpenoid defense secretions probably have very different functions, both are nonetheless useful as taxonomic characters.

We analyzed cuticular hydrocarbons and soldier defense secretions from *Reticulitermes* collected at our experimental sites in California and Georgia, at various other sites in these states, and in Nevada, Arizona, and New Mexico. We report here the results of this chemotaxonomic study, and the complementary nature of these two sets of chemical characters.

METHODS AND MATERIALS

Insects. Termites were collected from monitoring stations at study sites in California and Georgia (Haverty and Nelson, 1997; Haverty et al., 1996, 1999b) or from infested wood in California, Georgia, Nevada, Arizona, and New Mexico (Haverty et al., 1999b) (Table 1). Termite workers were used for hydrocarbon analysis and soldiers from the same collection were used for terpene analysis.

Cuticular Hydrocarbons. Hydrocarbons were extracted from 100–200 dried workers and identified by gas chromatography–mass spectrometry (GC-MS) (Haverty et al., 1996; Page et al., 1997). Termite samples were sorted, separately for each state, on the basis of cuticular hydrocarbon composition and assigned to a hydrocarbon phenotype (Haverty and Nelson, 1997; Haverty et al., 1996, 1999b). Phenotypes are designated by the two-letter state abbreviation, followed by a letter, for example GA-A. Letters were assigned to phenotypes in the order they were discovered. There is no relationship between phenotypes from different states that have the same letter.

Soldier Defense Secretions (SDS). One to 10 soldiers from single collections were covered in *n*-pentane (ca. 200–600 μl) and held below -15°C until analysis. Monoterpenes, sesquiterpenes, and diterpenes extracted from soldiers were identified and quantified by GC-MS. Analysis was by splitless (0.7 min) injection on a 0.25 mm ID $\times$ 30 m 5% phenyl–95% methylpolysiloxane capillary column, helium carrier gas, temperature program 35°C (0.7 min isothermal) to 280°C at 6°C/min, with EI detection at 70 eV. Most compounds were identified by retention time and MS comparison with authentic materials or components of well-characterized essential oils run under identical conditions. In some cases, identification was by comparison with published GC-MS data only and considered tentative (compound name in parentheses). Unknowns were designated by apparent molecular weight and an identifying suffix letter.

Quantities of each terpenoid were calculated as a percentage of the total from integrated peak areas of the total-ion chromatograms without correction by

[a] Listed in descending order of abundance (see Tables 3–6 for specific quantities).

[b] Termites used for species identification were of the same hydrocarbon phenotype, but not necessarily from the same collection or locality as the samples used for soldier defense secretion analysis (Haverty and Nelson, 1997, Haverty et al., 1996, 1999b). Keys used for identification are from Weesner (1965) or Nutting (1990). Alate samples were collected along with other castes in wood or monitoring stations, otherwise noted as not available (NA).

response factors. Germacrene A, which gradually rearranges to β-elemene under GC conditions, appeared as a broad hump following the β-elemene peak. Its quantity was determined as the sum of the areas of the β-elemene peak plus the hump, minus the areas of the other peaks superimposed on the hump. Germacrene B behaved similarly (rearranging to γ-elemene) and was quantified by the same technique.

(+)-γ-Cadinene from pooled samples from various collections was purified by silica gel liquid chromatography and preparative GC as described elsewhere (Kim et al., 1994) and positively identified by diffuse-reflectance Fourier-transform infrared spectroscopy of ca. 50 μg of the neat material on powdered KBr in a microcup. Its optical rotation (α_D) was measured in hexane at 20°C.

The enantiomeric identity of a number of the monoterpenes and sesquiterpenes was determined by chiral GC. Conditions were: 10% permethylated β-cyclodextrin–90% OV-1701 capillary column, 0.25 mm ID × 30 m; 1°C/min program (0.5°C/min for β-elemene), 60°C–80°C for monoterpenes, 90°C–140°C for sesquiterpenes; splitless injection (0.7 min); flame-ionization detection; internal retention time reference standard was *n*-undecane for monoterpenes and *n*-tetradecane, *n*-pentadecane, and *n*-hexadecane for sesquiterpenes. Chiral analysis was done on one soldier collection from the hydrocarbon phenotype that was richest in the relevant terpene(s). Before analysis, oxygenated components were removed by passing the pentane solution through activated alumina. Enantiomer identification (indicated by sign of rotation in Tables 2–6 below) was by retention time comparison with authentic materials run under identical GC conditions. In the case of (−)-germacrene A, pooled samples were purified as for γ-cadinene, although under preparative GC conditions only β-elemene was recovered. This was then analyzed by chiral GC and compared to authentic (−)-β-elemene. The Kovats retention indices of the various sesquiterpene enantiomers are presented in Table 2.

RESULTS

Terpenoid Identification. γ-Cadinene and its aldehyde have often been reported from European and American *Reticulitermes* species, but there is some confusion in the literature as to the precise identity of these compounds. The original report (Zalkow et al., 1981) determined them to be the rare (+)-γ_1-cadinene [cadina-4(14),9-diene] and the corresponding C-15 aldehyde, but later literature from these and other authors variously report the hydrocarbon as "γ_1-cadinene" or just "γ-cadinene." We found the GC-MS data and IR spectrum of the hydrocarbon to be identical to that of authentic γ-cadinene [cadina-4,10(15)-diene], and the value of its optical rotation ($+100° \pm 10°$) was the same as that of the common enantiomer found in higher plants. Moreover, its retention time on the chiral GC

[a] 10% permethyl-β-cyclodextrin, 90% OV-1701, 0.25 mm ID × 30 m silica; temperature program 1°/min (β-elemene: 0.5°/min).
[b] Rearrangement product of (−)-germacrene A.

column was identical to that of authentic (+)-γ-cadinene. As for the aldehyde, the NMR data reported by Zalkow et al. (1981) are identical to those given in the literature for cadina-4,10(15)-dien-14-al (Kaiser and Lamparsky, 1983). Thus, these ubiquitous *Reticulitermes* sesquiterpenoids are shown to be (+)-γ-cadinene and its C-14 aldehyde (hereinafter called γ-cadinenal), rather than (+)-γ_1-cadinene and its C-15 aldehyde.

The CA-B collections had a sesquiterpene whose mass spectrum was nearly identical to germacrene A, but which had a slightly different GC retention time. It also did not rearrange to β-elemene as does germacrene A. This compound is tentatively identified as the *cis*-double bond isomer (*Z*,*E*)-germacrene A, also known as helminthogermacrene. It has been reported as the major SDS component in *Amitermes wheeleri* (Scheffrahn et al., 1986). In all examined cases (with the possible exception of β-elemene, the enantiomers of which were poorly resolved), the terpenoids were found to be optically pure (>90%). It is striking that except for (+)-γ-cadinene and its aldehyde, *Reticulitermes* sesquiterpenes are enantiomeric to those found in higher plants (Table 2), many having heretofore been reported only from fungi, liverworts, or marine organisms. This is further evidence that these termites are producing the SDS terpenoids *de novo* rather than sequestering them from ingested terpene-containing plants.

In this study, we identified 20 SDS terpenoids that have not yet been reported from termite soldiers of any family. The names of these compounds appear in bold face in Tables 3–6 below. In addition, we report nine unknowns that may also be

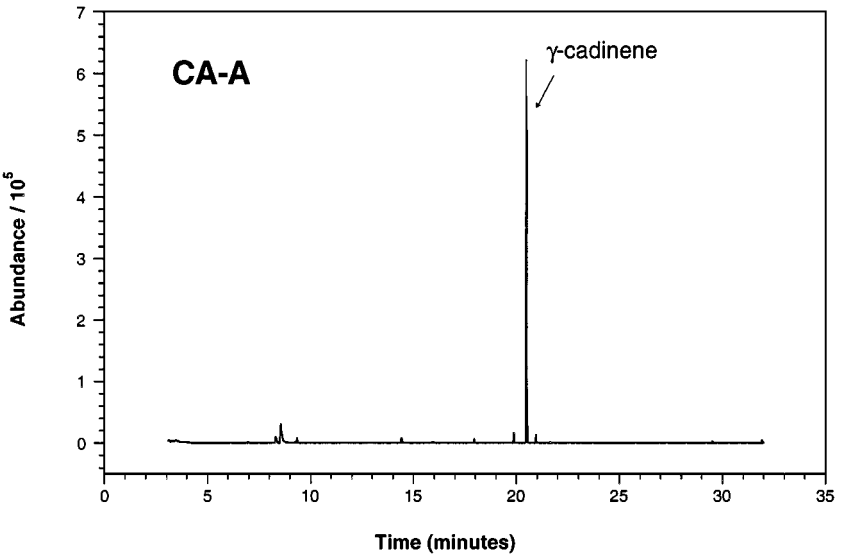

FIG. 1. Total ion chromatogram of defense secretions extracted from soldiers of cuticular hydrocarbon phenotype CA-A.

previously unreported. For brevity in the following discussion, signs of rotation will not be specified, although they are given in Tables 3–6 below.

Reticulitermes *from California.* So far we have characterized five cuticular hydrocarbon phenotypes of *Reticulitermes* in northern California: CA-A, CA-A′, CA-B, CA-C, and CA-D (Haverty and Nelson, 1997). CA-A′ is nearly identical to CA-A, distinguished only by the presence of two fairly abundant pentacosatrienes not found in CA-A, and it appears to be the most common phenotype (Haverty and Nelson, 1997).

Termite collections with cuticular hydrocarbon phenotypes CA-A or CA-A′ produce very similar SDS profiles: γ-cadinene predominates ($\geq$90.0%) (Table 3; Figure 1). A few compounds appear in small amounts ($\leq$2.0%) in some samples of CA-A that were not seen in CA-A′: myrcene, unknown (unk.) 204c, δ-cadinene, (E)-γ-bisabolene, and unk. 238a. CA-B samples produced α-himachalene (5.0%), γ-himachalene (13.4%), γ-humulene (1.2%), β-himachalene (4.9%), (Z,E)-germacrene A (6.8%), δ-amorphene (8.5%), γ-cadinene (39.6%), unk. 204e (1.4%), geranyl linalool (16.7%), and a few other minor components. The SDS mixtures of hydrocarbon phenotype CA-C contain predominantly germacrene A (92.8%), and small amounts of γ-cadinene (3.7%) and α-selinene (2.0%). α-Selinene (9.1%) was a larger component in CA-D, along with germacrene A (33.0%), γ-cadinene (17.4%), and geranyl linalool (38.0%) (Table 3).

[a] Terpenoids are listed in GC elution order. Terpenoids in bold type are newly reported for termite soldiers. Compound name in parentheses or brackets indicates identification is considered tentative. Unknowns are designated by apparent molecular weight and an identifying suffix letter.

[b] Values of 0.0 indicate the compound was detected, but at a level <0.05% of the total SDS.

[c] Values of 0.0 may indicate the compound was not detected, or detected at a level <0.05% of the total SDS.

[a] tr indicates a value <0.3%. All values except those for NV-B are means.

[b] Terpenoids are listed in GC elution order. Terpenoids in bold characters are newly reported for termite soldiers. Compound name in parentheses indicates identification is considered tentative. Unknowns are designated by apparent molecular weight and an identifying suffix letter.

Reticulitermes *from Nevada, New Mexico, and Arizona.* Collections in western Nevada provided us with another cuticular hydrocarbon phenotype, NV-A (Haverty et al., 1999b). The soldiers from these samples produced defense secretions consisting almost exclusively of geranyl linalool (99.7%) (Table 4). One sample with a cuticular hydrocarbon mixture qualitatively and quantitatively nearly identical to phenotype CA-B was also collected in Nevada near Pyramid Lake. However, the soldiers from this colony had a defense secretion comprised of 97.0% germacrene A, 1.2% germacrene B, and 1.0% β-selinene along with traces of myrcene, a composition more similar to soldiers of CA-C than of CA-B (Tables 3 and 4). This sample is referred to here as phenotype NV-B.

Currently, only one species of *Reticulitermes, R. tibialis,* is recognized from Arizona and New Mexico (Weesner, 1970). So far, five cuticular hydrocarbon phenotypes have been identified from this region: AZ-A, AZ-B, AZ-C, AZ-D, and NM-A (Haverty et al., 1999b). The terpene profiles for southwestern *Reticulitermes* sorted into four main SDS phenotypes. Hydrocarbon phenotypes AZ-A and AZ-B had similar terpene profiles, primarily comprised of γ-cadinene and geranyl linalool, although quantities were variable (Table 4). AZ-B generally had more γ-cadinenal (0.5–13.2%), than AZ-A (0–1.3%). Soldier defense secretions from hydrocarbon phenotype AZ-C showed evidence of geographic differences (Table 4; Figure 2). Phenotype AZ-C has only been collected from the Petran Montane Coniferous Forests biotic community zone in southcentral Arizona (Brown and Lowe, 1980; Haverty and Nelson, unpublished observations). Samples from the Mogollon (Interior) biogeographic province (Brown et al., 1979), from Prescott to Springerville, Arizona, had soldier defense secretions consisting mainly of myrcene (1.3–20.3%), (*Z*)- and (*E*)-ocimene (0–19.8%), β-bisabolene (17.8–57.3%), γ-cadinene (1.8–40.5%), and geranyl linalool (0–50.4%). These samples were summarized as one group, AZ-C(I), although they were quite variable. There was much less variability in SDS profiles from samples collected in the higher elevations of the Santa Catalina, Santa Rita, Chiricahua, and Pinaleno mountains of the Sonoran biogeographic province (Brown et al., 1979). Samples of this SDS phenotype, AZ-C(II), all produced $\geq$94.7% geranyl linalool. We have not yet collected live soldiers of AZ-D, thus, the defense secretion profile of this phenotype is unknown. Soldiers of hydrocarbon phenotype NM-A yielded almost exclusively geranyl linalool (99.8%) (Table 4).

Reticulitermes *from Georgia.* Fifteen different cuticular hydrocarbon phenotypes have been reported from Georgia: GA-A, GA-AB, GA-B, GA-C, GA-D, GA-E, GA-F, GA-G, GA-H, GA-I, GA-J, GA-K, GA-L, GA-M, and GA-N (Haverty et al., 1996, 1999b). Soldier defense secretions were characterized for all hydrocarbon phenotypes except for GA-B. Two SDS phenotypes were associated with GA-A. Phenotype GA-A(I) was distinguished by a large quantity of geranyl linalool (47.0–80.9%), while in the second phenotype, GA-A(II), this diterpene alcohol never exceeded 2.3% of the total (Table 5; Figure 3). Within

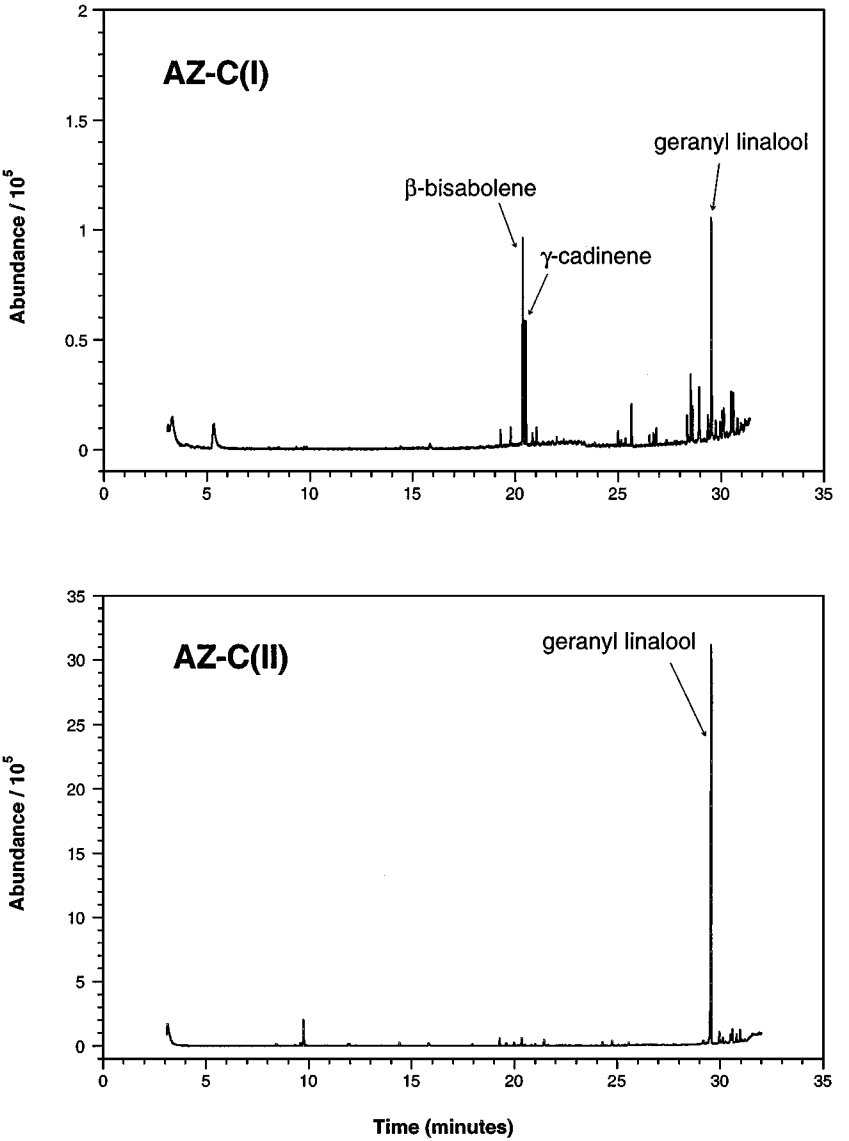

FIG. 2. Total ion chromatograms of defense secretions extracted from soldiers of cuticular hydrocarbon phenotype AZ-C.

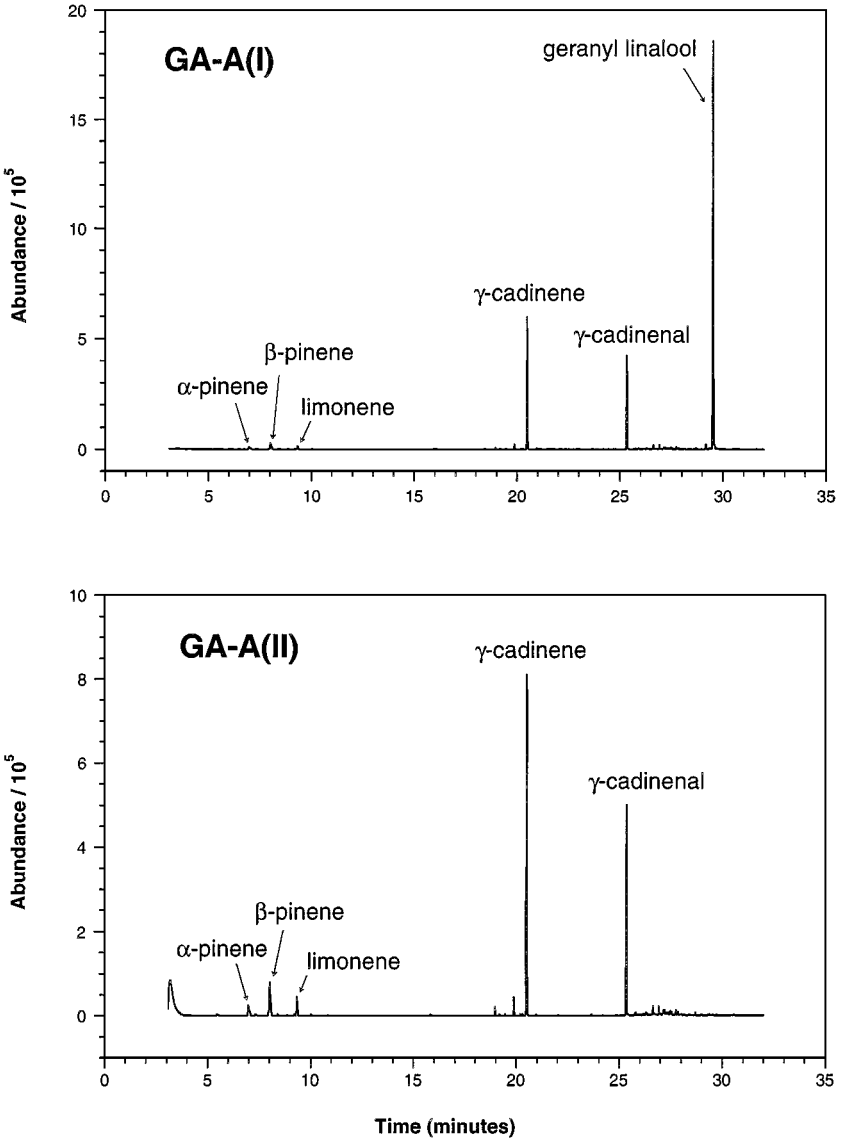

FIG. 3. Total ion chromatograms of defense secretions extracted from soldiers of cuticular hydrocarbon phenotype GA-A.

SDS phenotype GA-A(I), there was marked geographic variation in the amounts of the sesquiterpenes γ-cadinene and γ-cadinenal. Of the four samples making up this phenotype, the two from northern Georgia produced moderate amounts of γ-cadinene (10.7% and 20.4%) and γ-cadinenal (1.3% and 8.7%), while the two from Athens had trace amounts of γ-cadinene ($\leq$0.2%) and no detectable γ-cadinenal. These two sesquiterpenes were the major components for SDS phenotype GA-A(II); γ-cadinene averaged 56.3% of the total, and γ-cadinenal 17.2%. In both GA-A SDS phenotypes, with the exception of the two Athens samples, the ratio of γ-cadinene to its aldehyde was approximately 3:1 (Table 5). These phenotypes both contained monoterpenes (α-pinene, camphene, β-pinene, and limonene) in varying amounts (<0.1–15.9%) (Table 5). All of these GA-A samples keyed to *R. flavipes.*

Hydrocarbon phenotype GA-AB had only one SDS phenotype. This terpene type appeared to be intermediate between those produced by GA-A and GA-C in that it contained a significant monoterpene component, trace amounts of geranyl linalool, and roughly twice as much γ-cadinenal as γ-cadinene (Table 5; Figure 4). All GA-AB samples keyed to *R. flavipes.*

The SDS phenotype produced by GA-C soldiers contained no monoterpenes or geranyl linalool. The predominant components were γ-cadinene (averaging 20.1%) and γ-cadinenal (76.7%); the proportion of the latter was about three

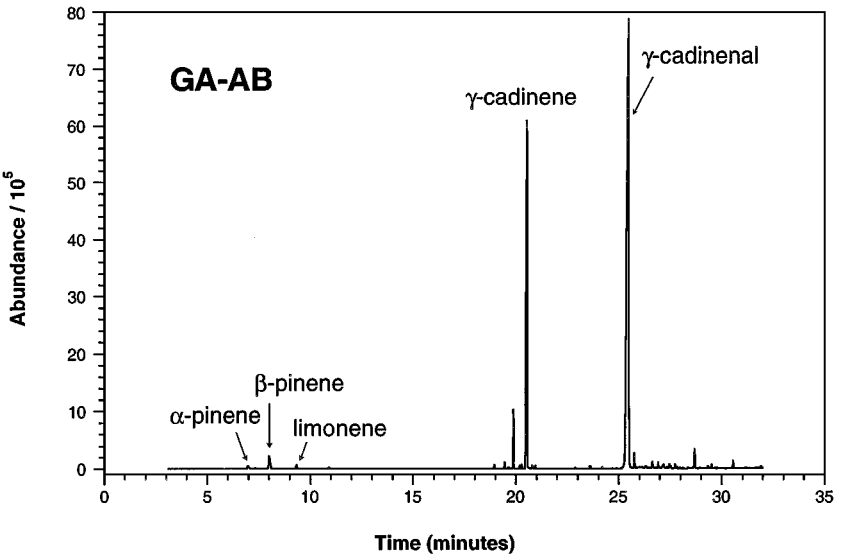

FIG. 4. Total ion chromatogram of defense secretions extracted from soldiers of cuticular hydrocarbon phenotype GA-AB.

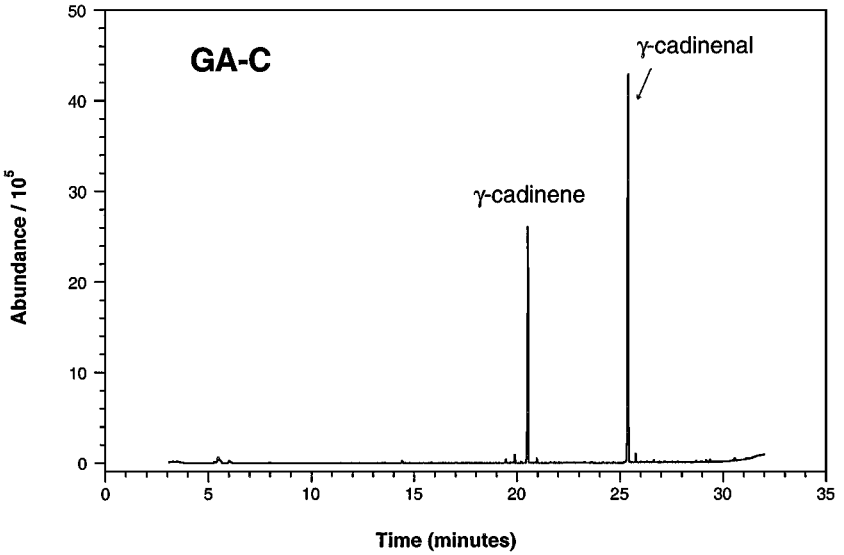

FIG. 5. Total ion chromatogram of defense secretions extracted from soldiers of cuticular hydrocarbon phenotype GA-C.

times that of the former, the opposite of SDS phenotypes produced by GA-A (Table 5; Figure 5). All GA-C samples keyed to *R. virginicus.*

Numerous hydrocarbon phenotypes, specifically those with a predominance of unsaturated hydrocarbon components (GA-D-I, -K to -N) produced nearly identical soldier defense secretions. This terpene mixture consisted primarily of γ-cadinene (79.1–100%) with only a trace of γ-cadinenal (Table 5; Figure 6). An unknown diterpene ($M_r = 272$, with a base peak of 257) was present in amounts ranging from $<0.1\%$ to 12.4%. All these samples keyed to *R. hageni* based on soldier morphology, although GA-D was the only phenotype that keyed to *R. hageni* based on alate morphology. Two of the cuticular hydrocarbon phenotypes, GA-E and GA-F, had alates that keyed to *R. virginicus* (Haverty et al., 1996). Alates were not available for the other phenotypes.

A single, distinct SDS phenotype was associated with hydrocarbon phenotype GA-J and was comprised primarily of germacrene A (50.8%) and germacrene B (39.9%) with lesser amounts of δ-elemene, farnesene, and geranyl linalool (Table 5). These samples all keyed to *R. hageni* based on soldiers.

DISCUSSION

Four SDS phenotypes paired with multiple hydrocarbon phenotypes: CA-C and NV-B produce nearly identical mixtures of soldier defense secretions; as do

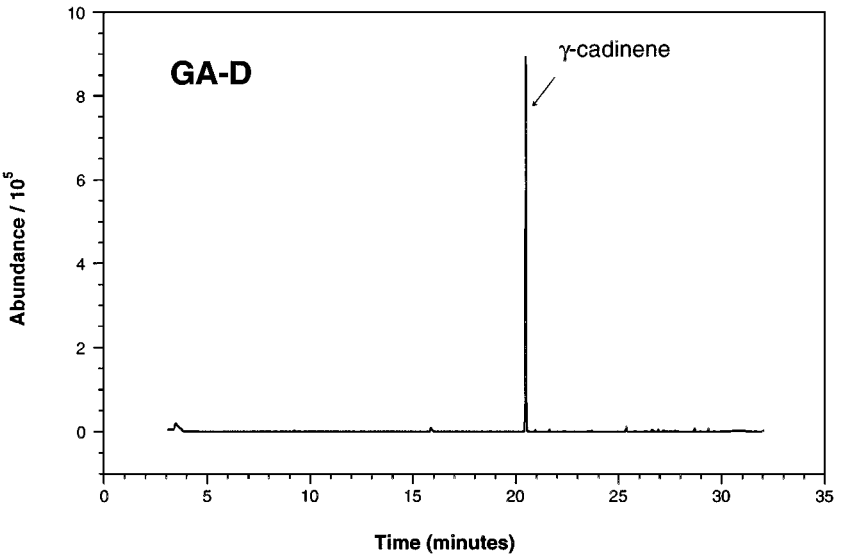

FIG. 6. Total ion chromatogram of defense secretions extracted from soldiers of cuticular hydrocarbon phenotype GA-D.

NV-A, NM-A, and some AZ-C samples; AZ-A and AZ-B; and GA-D-I, -K to -N (Table 6). Conversely, with the exception of AZ-C and GA-A, each hydrocarbon phenotype is correlated with only one SDS phenotype (Table 6).

The results from northern California consistently and repeatedly associate one hydrocarbon phenotype with one distinct soldier defense secretion phenotype (Table 3). We now consider CA-A and CA-A′ to be variations of one hydrocarbon phenotype, as we have recently seen samples from other locations in California that appear to be intermediate between the two (L. J. Nelson, unpublished observations). We believe there are at least four species of *Reticulitermes* represented by hydrocarbon phenotypes CA-A/CA-A′, CA-B, CA-C, and CA-D (Haverty and Nelson, 1997).

The cuticular hydrocarbon composition of the single sample of NV-B is nearly identical to that of CA-B, but we will designate it as a separate phenotype pending further sampling. There was virtually no overlap in terpene composition for these two hydrocarbon phenotypes (Tables 3, 4, and 6).

There are many similarities between NV-A and NM-A in both sets of chemical characters. They could quite possibly represent a single species that occurs in the Great Basin biogeographic province (Brown et al., 1979). AZ-A and AZ-B also likely represent a single taxon, based on their chemical phenotypes. These four phenotypes (NV-A, NM-A, AZ-A, and AZ-B) form a clade when subjected to

phylogenetic (PAUP) analysis based on cuticular hydrocarbons (Page et al., 2001), which may indicate a close taxonomic relationship. AZ-C is a distinct cuticular hydrocarbon phenotype, but exhibits some variability in SDS profiles (Tables 5 and 6; Figure 2). We feel confident that this is a separate species.

Sampling from Georgia has produced 15 cuticular hydrocarbon phenotypes and 6 SDS phenotypes. We consider GA-C (=*R. virginicus*) and GA-J (=undescribed species of *Reticulitermes*) to be distinct species, and we suggest GA-A, GA-AB, and GA-B are either separate taxa or represent intraspecific variation in *R. flavipes*. GA-AB has been found only on Sapelo Island off the Atlantic coast of Georgia, and nearby on the mainland (Chatham County). GA-B has been rarely found in Georgia, despite directed efforts to locate additional samples (Haverty et al., 1996, 1999b).

The remaining 10 hydrocarbon phenotypes from Georgia all possess the same terpene phenotype. Cuticular hydrocarbon phenotypes GA-D, GA-E, GA-F, GA-G, GA-H, GA-I, GA-K, GA-L, GA-M, and GA-N also have a common theme in their abundant production of certain olefins (Haverty et al., 1996, 1999b). Although some phenotypes appear to be restricted to certain geographic localities, they have all been seen from multiple collections. Variation in cuticular hydrocarbon composition due to the influence of seasonal or environmental effects has not been ruled out. However, when mitochondrial DNA genotypes of several colonies of *Reticulitermes* in Georgia were examined, samples with hydrocarbon phenotypes GA-I and GA-L (which were identified as *R. hageni* based on soldier morphology) formed a separate clade from phenotypes GA-D (identified as *R. hageni* by soldiers and alates) (Jenkins et al., 2000). Resolution of this taxonomic conundrum will require additional biological, chemical and genetic information.

The use of state designations for hydrocarbon phenotypes will undoubtedly be revised when we have sampled more widely and the phenotype distributions can be delineated more clearly. There are a few parallels in chemical characters when comparing collections from distant locations. For example, the hydrocarbon profiles of GA-A and GA-AB are qualitatively and quantitatively similar to CA-A/A′ (Haverty and Nelson, 1997; Haverty et al., 1996; Page et al., 2001), the main difference being the quantities of C_{33} methylalkanes present. Their terpene secretions are less similar, although the percent ranges of γ-cadinene and geranyl linalool overlap in some cases (Tables 3, 5, and 6). The hydrocarbon profile of the single sample of AZ-D appeared to be nearly identical to CA-A′. We were unable to collect soldiers from this colony, so the terpene profile remains unknown until more collections can be made in northwestern Arizona as well as other localities in the Great Basin Desert.

Termite collections that keyed to *R. hageni* by soldier morphology presented us with a wide array of hydrocarbon phenotypes (11), but with the exception of GA-J, all had the same SDS phenotype. This terpene phenotype is characterized by the abundance of γ-cadinene (averaging 95% of the total), as is the terpene

phenotype found in CA-A/A′ (Tables 3, 5, and 6; Figures 1 and 6). However, these 10 hydrocarbon phenotypes from Georgia are, as a group, qualitatively quite dissimilar in hydrocarbon components from phenotype CA-A/A′. The former have an abundance of olefins (>50% of total hydrocarbon) and the latter are characterized by a predominance of normal and methylbranched alkanes (Haverty and Nelson, 1997; Haverty et al., 1996, 1999b; Page et al., 2001).

No terpene compound was seen in every sample, although γ-cadinene and geranyl linalool were present in some amount in most phenotypes. The only phenotype with no detectable geranyl linalool was GA-C (Tables 5 and 6). γ-Cadinene was not detected in hydrocarbon phenotypes NV-A, NV-B, NM-A, or GA-J (Tables 4–6). Monoterpenes were seen in most phenotypes, in trace amounts, but were consistently present in cuticular hydrocarbon phenotypes GA-A and GA-AB (Tables 5 and 6).

Our results add to the body of knowledge already accumulated regarding the utility of these chemical characters for distinguishing taxa of North American *Reticulitermes*. Howard et al. (1978, 1982b) first reported the cuticular hydrocarbons of *R. flavipes* and *R. virginicus* collected near Gulfport, Mississippi. "γ_1-Cadinene" and "γ_1-cadinenal" were reported by Zalkow et al. (1981) as the major soldier cephalic secretion components of both *R. flavipes* and *R. virginicus* from Mississippi. Quantities were reported only for *R. flavipes*, and the two sesquiterpenes were present in nearly equal amounts. The identity of these sesquiterpenes is here revised to (+)-γ-cadinene and (+)-γ-cadinen-14-al. A few of our *R. flavipes* samples within groups GA-A(II) and GA-AB had comparable proportions to those reported by Zalkow et al. (1981), however, we found considerable variation in terpene composition within the three *R. flavipes* groups (Tables 5 and 6).

Clément et al. (1985) also examined frontal gland secretions and described four phenotypes of *Reticulitermes* in the southeastern United States: *R. flavipes* 1 and 2, *R. virginicus*, and *R. malletei*. Both *R. flavipes* phenotypes, Rf1 and Rf2, had γ-cadinene, geranyl linalool and small amounts of monoterpenes, but Rf1 also had γ-cadinenal. They also reported γ-cadinene and γ-cadinenal from *R. virginicus* and γ-cadinene alone in what is referred to as the species *R. malletei*. These would correspond to the SDS from our cuticular hydrocarbon phenotypes GA-C and GA-D-I, -K to -N, respectively (Haverty et al., 1996, 1999b). The hydrocarbon phenotype of *R. malletei* as reported in Bagnères (1989) is equivalent to our cuticular hydrocarbon phenotype GA-M (Haverty et al., 1999b).

Bagnères et al. (1990) documented the cuticular hydrocarbons and soldier cephalic secretions of *R. flavipes* in the southeastern United States and *R. santonensis* in France. The hydrocarbons of these two species were found to be qualitatively, but not quantitatively, identical. *R. flavipes* exhibited polymorphism in both sets of chemical characters, while *R. santonensis* did not. Three hydrocarbon phenotypes of *R. flavipes* were defined by multivariate analysis, two of which had unique

defensive secretion phenotypes (A and B), while the third was further divided into four defensive secretion phenotypes (C–F). Terpenes identified were α-pinene, β-pinene, limonene, γ-cadinene, cadinene aldehyde, and geranyl linalool. Phenotype A was defined as having the three monoterpenes and two sesquiterpenes, while B had only the two sesquiterpenes. Phenotype C exhibited all six compounds, D the two sesquiterpenes and geranyl linalool, while E and F had no γ-cadinene, only its aldehyde. Phenotype E also produced geranyl linalool, as did F, and F also had the three monoterpenes.

All but two of our samples identified as *R. flavipes* had γ-cadinene in quantities of at least 10.0% of the total. Those two samples, from Athens, Georgia, showed only traces of γ-cadinene and no γ-cadinenal, their profiles consisting mostly of geranyl linalool ($>$75.0%) and monoterpenes. As for *R. santonensis*, its terpene profile included the monoterpenes, geranyl linalool, and an unidentified sesquiterpene (Bagnères et al., 1990). γ-Cadinene and its aldehyde were absent. These authors suggest that *R. santonensis* and *R. flavipes* are the same species and that the lack of chemical variation in *R. santonensis* results from a founder event of a single colony of *R. flavipes* being successfully introduced to Europe from the United States (Bagnères et al., 1990).

The primary function of the various termite-produced terpenoid compounds has been attributed to their effectiveness in deterring predation by ants, either by toxicity or repellency (Zalkow et al., 1981; Baker et al., 1982; Mill, 1983; Scheffrahn et al., 1983; Clément et al., 1988; Lemaire et al., 1990). There is a strong indication of coevolution between termites and ants: where they are sympatric, the ants are less sensitive to the specific terpenoid compounds and where they are allopatric the ants are more sensitive (Zalkow, et al., 1981; Lemaire et al., 1990). Further behavioral studies are needed involving *Reticulitermes* species' defensive compounds and their effects on predators. Although an untested hypothesis, variation in SDS may reflect adaptation to the local ant fauna and could explain the presence of multiple SDS phenotypes of GA-A and AZ-C.

Howse and Bradshaw (1980) discussed the use of chemical data in ant and termite systematics and felt that the behavioral or ecological roles of the various chemicals should be known in order to be useful in this context. However, Prestwich (1983) suggested that the necessity of understanding the biological or ecological functions of the chemical characters is perhaps less important than knowing their biosynthetic relationships and that the phylogeny of the biosynthetic pathways reflects genetic drift or founder effects, rather than selective pressure. Brand (1978) stated that all available evidence, including chemical data, should be taken into account in describing a taxon and suggested that the biosynthetic homology of chemical characters provides a closer look at genetic relationships than does the similarity of morphological characters. Chemical variation certainly seems as likely to affect behavior as would variation in morphology. This suggests that chemical characters such as cuticular hydrocarbons and soldier defense

secretions are ideal tools for understanding the evolutionary relationships of the taxa in question, particularly so once the full elucidation of their biosynthesis has been achieved.

We believe, and have so stated, that existing keys to species of *Reticulitermes* are grossly inadequate and give a false sense of confidence in identifying species (Haverty and Nelson, 1997; Haverty et al., 1996, 1999b). Taxonomic assessments based on chemical characters and those based on morphological characters are not always in agreement. Takematsu and Yamaoka (1999) recently examined the cuticular hydrocarbons of six species of *Reticulitermes*, including three undescribed species, in Japan, Korea, and Taiwan. They observed nine different hydrocarbon phenotypes and recommended that four subspecies be elevated to species status. Takematsu (1999) then published a revision of *Reticulitermes* species in Japan, which included cuticular hydrocarbon data to supplement the more conventional characters used in taxonomy.

We agree that chemical characters have a place in the description of species. The more differences that exist to distinguish two groups of organisms, the greater the likelihood of their being separate species (Futuyma, 1998). Genetic studies of this genus will provide additional clarification. In studies of European *Reticulitermes*, variation in the composition of soldier frontal gland secretons has been correlated with differences in frequencies of esterase alleles (Clément, 1981; Parton et al., 1981). In future research we will attempt to match chemical characters with DNA sequences for all cuticular hydrocarbon phenotypes, building on previous work in this area (Jenkins et al., 1998, 1999, 2000). Agonistic behavior bioassays using *Reticulitermes* from northern California demonstrated a high degree of correlation between aggression and hydrocarbon phenotype (Haverty et al., 1999a). These chemotaxonomic studies have served to benefit our studies of ecology, behavior, and control of *Reticulitermes* (Getty et al., 1999a,b, 2000a,b; Haverty et al., 1999a,c, 2000). We hope further study will allow us to fully characterize these taxa.

ACKNOWLEDGMENTS

The authors thank Marion Page for his helpful review of this manuscript and Pierre Escoubas for inspiring us to pursue this line of research. Monica Townsend, Sherry Ridgeway, Anna Anisko, Gail Getty, Kirsten Copren, and Mechelle Cochran assisted in collecting and preparing many of the samples used in this study.

(Received September 22, 1999; accepted February 28, 2001)

Abstract—Pheromone communication systems have a reliable signal with a restricted window of amounts and ratios released and perceived. We propose a model based on a Gaussian response profile that allows a quantification of the response peak (location of optimum) and a measure of the peak width (response window). Interpreting the Gaussian curve, fitted by nonlinear regression (NLR), as a standard normal distribution, the peak location equals the mean (μ) and the window width equals $2\times$ the standard deviation (2σ). The NLR procedure can provide an objective measure for both peak location and width for a wide range of data sets. Four empirical data sets as well as 10 literature data sets were analyzed. The double-spined spruce engraver, *Ips duplicatus*, was field tested in four populations to find the optimum proportion for attraction to the two male aggregation pheromone components, ipsdienol (Id) and (*E*)-myrcenol

(EM), ranging from 0 to 100% of Id. Tests in Norway and the Czech Republic confirmed the preference of western populations for a blend between 50 and 90% Id. A population in Inner Mongolia showed a preference for traps with the 10 and 50% Id baits. The NLR fitted values for response peak and width (μ; 2σ) were: Norway 0.64, 0.73; Czech Republic 0.53, 0.73; NE China 0.77, 0.29; and Inner Mongolia 0.33, 0.50. The signal produced by Norwegian field-collected males had a narrower window width ($2\sigma = 0.12$). Males of the maize stem borer, *Chilo partellus*, were tested in a flight tunnel for their response to variation in the two major female sex pheromone gland components, (Z)-11-hexadecenal and the corresponding alcohol (OH). Variation of the alcohol in seven levels from 2 to 29% OH showed the highest male response for 17% OH. For all behavioral steps, the peak of male response was near $\mu = 0.14$, while the window width fell from $2\sigma = 0.5$ to 0.2 for eight sequential behavioral steps from take-off to copulation. Female production had a similar peak location ($\mu = 0.13$) but a narrower width, $2\sigma = 0.14$. Literature data from other moth species showed similar patterns, with a wider male response relative to the female production windows. Literature data on response to enantiomer ratios in a hymenopteran and to pheromone amounts in a dipteran were also described by our model. In a bark beetle population (*Ips pini*), with two hybridizing enantiomeric strains, the production peaks were narrower (0.1) than the response peaks (0.5). Thus, it in general, seems that in the pheromone systems analyzed, the width of the response window ($2\sigma = 0.1$ to 0.8) is larger than that of the production window ($2\sigma = 0.03$ to 0.14), irrespective of the sex of the sender.

Key Words—Response window, Gaussian curve, *Ips*, *Chilo*, individual variation, population variation, *Pectinophora*, *Argyrotaenia*, *Agrotis*, *Spodoptera*, *Neodiprion*, *Dacus*.

INTRODUCTION

The importance of ratios of pheromone components for optimum response and species specificity has long been appreciated for lepidopteran pheromone systems (Roelofs, 1978), and only more recently for coleopteran systems (Teale et al., 1991; Leal et al., 1994). The term "response window" was coined by Roelofs (1978) for a two-dimensional range of amounts (concentrations) and proportions of components evoking an optimum behavioral response, limited by a lower response threshold and an upper arrestment threshold. Later reviews (Löfstedt, 1990; Linn and Roelofs, 1994; Svensson, 1996b) and experimental papers (Linn et al., 1991; Svensson, 1996a) show the importance of variation in ratios for optimum response and the width of the response, determined by genetic (Löfstedt, 1990, 1993) and environmental (Svensson, 1996b and references therein) factors. However, the optimum of response has so far been determined by simply choosing the best experimental value or by visual interpolation between discrete values of the independent axis. The width of the response window has sometimes been set by visual inspection, but usually not quantified at all.

We propose a more analytical approach to quantify the optimal value of ratios of pheromone components. We will illustrate this by two examples. One is a bark beetle species, *Ips duplicatus*, which utilizes two male-produced monoterpene alcohol pheromone components attracting both sexes (aggregation pheromone) (Bakke, 1975; Byers et al., 1990; Schlyter et al., 1992). The other is a pyralid moth, *Chilo partellus*, which uses two female-produced major components, a monounsaturated aliphatic alcohol and aldehyde, attracting males only (sex pheromone) (Nesbitt et al., 1979; Beevor et al., 1990; Unnithan and Saxena, 1990).

We could not find any readily available method, except simple interpolation, to pinpoint the exact peak location and no objective method for defining the width of the response window. To this end, we developed a simple model, using the Gaussian or normal curve fitted by nonlinear regression. Our model gives the location and width of the optimum for field attraction in four different populations of *Ips duplicatus* and a comparison to male pheromone production. For the moth *Chilo partellus*, we quantified the decline in response window width with the sequence of male flight-tunnel behaviors and compared it to the variation of female production. Our method is then applied to a range of literature data on lepidopteran, coleopteran, and hymenopteran systems for proportions, including a hybrid population with two optima, and one example of response to amounts in a dipteran pheromone system.

METHODS AND MATERIALS

Rationale for the Model. We expected a maximum frequency of signaling to occur at a point (an optimum) on the independent axis. Thus, we seek a function, $g(x)$, to describe the signalling frequency, y, depending on x,

$$y = g(x) \tag{1}$$

Such a function shall measure both the location (position) of the peak on the x axis and the width of the peak. The signaling frequency profile includes both response and production. The response profile is typically measured in field experiments as number of trapped specimens for a continuous range of baits or in the laboratory as the frequency of responding individuals to a range of stimuli. In the same way we may measure production profile as frequency distributions (histogram) of individually analyzed calling insects. It is expected that a signal system should possess a peak of response or production, as well as two tails. For the sake of simplicity, we seek a symmetrical distribution function that is unimodal as well. In addition, a function describing such a profile must be convex near the peak and have two longer or shorter tails. For these reasons, neither the asymmetrical Poisson, F, or χ^2 distributions nor power functions like $g(x) = x^2$ without tails are suitable. The

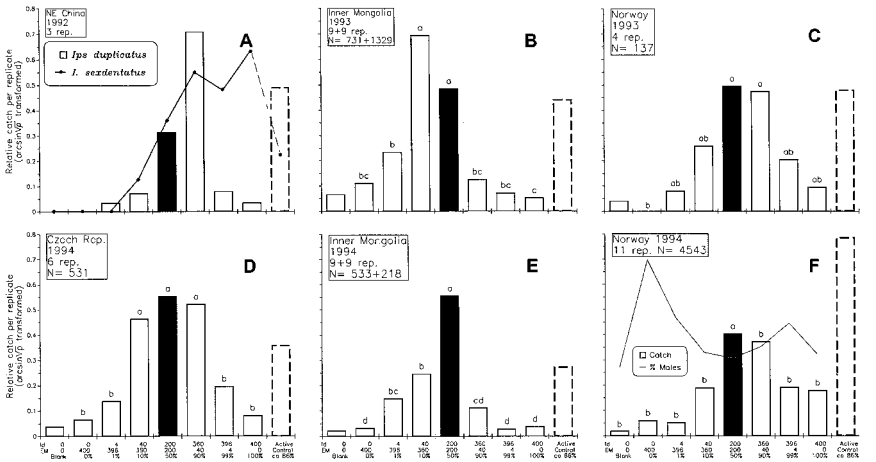

FIG. 1. Relative catches of *Ips duplicatus* in different experiments. Baits with 0–100% ipsdienol were released from wick dispensers containing solutions with varying ratios, but the same total amount. The relative amounts of each compound is given for each bait below the x axis. Active control is neat Id and EM in separate vials releasing about 86% Id at a dose of about 200 male equivalents (1 mg/day) (Schlyter et al., 1992). Bars with the same letter are not different by Duncan's multiple-range test ($\alpha = 0.05$). N is the total number beetles caught per experiment.

normal distribution and the t distribution have the desired properties. However, such functions are intrinsically nonlinear [cannot be linearized by a mathematical transformation (Norusis, 1994, p. 233; Sokal and Rohlf, 1995, p. 677)]. The Gaussian or normal curve was chosen for two reasons: (1) it was apparent from one data set (Figure 1A) that a response profile could be superficially close to such a curve; and (2) the normal curve and its parameters are well known to biologists as many characteristics in living organisms show such a distribution pattern and it makes statistical sense using it to describe a frequency distribution.

Equations for the Model. The formula for the well-known Gaussian or normal curve, with the two parameters for a population, μ, the mean or central moment of the population and σ, the theoretical population standard deviation (second moment) is;

$$g(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/2\sigma^2} \tag{2}$$

In an empirical sample, the estimated mean, $\bar{x}$, replaces μ, and similarly the standard deviation, SD, replaces σ. By analogy, we may interpret μ as the location of the optimum, or maximum response, of a response profile with a perfect bell shape.

The sample in this case is only the points defining the shape of the profile and the sample size, N, is 1. However, the sample size per se does not enter the equation (see formula above). (In a normal empirical sample, the sample size enters only when the uncertainty of the location of $\bar{x}$ must be estimated by the standard error of the mean ($\mathrm{SEM} = \mathrm{SD}/\sqrt{n}$) or by a confidence interval based on SEM and N, using the N dependent t distribution.)

For a production or response profile, we have used μ_p and σ_p, or μ_r and σ_r, for the two parameters estimated here by fitting the Gaussian curve. The subscripts p and r refers to production and response, repectively. The width of a response window we define in the simplest possible way as ranging from $\mu + 1\sigma_{p\,\mathrm{or}\,r}$ to $\mu - 1\sigma_{p\,\mathrm{or}\,r} = 2\sigma_{p\,\mathrm{or}\,r}$, which is equivalent to ca. 70% of a normal distribution. In addition, a scaling factor, f, was included to achieve a good fit in all cases, e.g. when the maxima were far from $x = 0.5$. Thus, the function fitted here included a factor to adjust the shape of the distribution for these more skewed and peaked data sets (with maxima close to $x = 0$ or 1), so that for describing a response or production profile the equation is:

$$g(x) = f\left[\frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/2\sigma^2}\right] \tag{3}$$

The factor f corresponds to a combination of the more commonly used measures of the third and fourth moments of a distribution; skewness and kurtosis (peakedness).

Parameter Estimation for the Model. Profiles were fitted by the unconstrained nonlinear regression procedure (NLR) of SPSS/PC+5.01 for DOS and SPSS for Windows 6.01 and 8.0 and SPSS for Macintosh 6.1.1. Direct comparison of program output showed that numerical results from the three platforms agreed exactly. Such NLR procedures are available in all other major statistical packages. Empirical data was fitted only to proportions of components, except for one literature set on amounts. In principle, any variable of the signal could be used, like emission of, or response to, component proportions or amounts. In most cases, proportions (p) were arcsin $\sqrt{p}$ transformed, and this was especially important for those cases with maxima close to $x = 0$ or 1. To retransform the estimate of $2\sigma_{p\,\mathrm{or}\,r}$ from the arcsin transformed scale, one has to use the relation, $2\sigma = (\mu + \sigma) - (\mu - \sigma)$, which on the retransformed (linear) scale becomes

$$2\sigma = \sin(\mu + \sigma)^2 - \sin(\mu - \sigma)^2 \tag{4}$$

As for any nonlinear regression procedure, the NLR procedure used here is iterative, and by using a model with improper starting values one might arrive at a local solution with a poor global fit. For this reason, it is mandatory to make plots of predicted values from the statistical fitting together with the experimental data. When data are less well behaved, either by having few points on the x axis in the region where the true peak is located or by having their maxima at extreme

x values (close to 0 or 1), the predicted curve may peak at a higher value than the empirical maximum response. This is not an error of fitting, but simply reflects that the true maximum resides between or outside the independent data points. Such fitted functions, seemingly artificial in relation to the data, may then generate new testable hypotheses. In the plots displayed here, we have scaled the raw data by dividing the response variable by the maximum empirical value. This makes fitted models comparable across data sets, but is not necessary for applying the model on a single set. Details of parameter estimates obtained are given in Tables 1–3.

Bark Beetle (Ips duplicatus) *Data.* The double-spined spruce engraver of Eurasia, *Ips duplicatus* (Sahlb.), occurs in the Paleartic from central Scandinavia, across eastern Europe to Siberia and NE China, and in the mountains of central Europe (Postner, 1974; Lekander et al., 1977; Pfeffer, 1995). It has recently become of concern as a forest pest in the lowlands of central Europe (Mrkva, 1994; Knízek and Zahradník, 1996). *I. duplicatus* usually occurs on trees that are under attack by *I. typographus*, where it occupies the top position of the tree trunk (Schlyter and Anderbrant, 1993). *I. duplicatus* has not been considered as a major pest (Postner, 1974), but recent outbreaks in Czech Republic (Knízek and Zahradník, 1996) and in Inner Mongolia (Zhang et al., 1995) as well as its status as a vector of phytopathogenic fungi (Krokene and Solheim, 1996), might alter its economic status. *I. duplicatus* has been known to respond to racemic ipsdienol (±)-2-methyl-6-methylene-2,7-octadien-4-ol (Bakke, 1975; Schlyter et al., 1987), but its pheromone includes also (*E*)-myrcenol, (2*E*)-2-methyl-6-methylene-2,7-octadien-1-ol (Byers et al., 1990). West palearctic (Norway/Sweden) *I. duplicatus* contains a blend of about 90:10 of ipsdienol–E-myrcenol (Id/EM) and a synthetic blend of these de novo produced components (Ivarsson et al., 1993) is highly competitive to natural pheromone emitted by unpaired males in spruce logs (Schlyter et al., 1992).

In spite of several qualitative tests (Bakke, 1975; Schlyter et al., 1987, 1992; Byers et al., 1990) and quantitative variations of the Id and EM combination (Schlyter et al., 1992), no test has varied the ratio of the two components, to find the bait with the optimum ratio for attraction in the field.

Field Response of Both Ips *Sexes*

Wick-Dispensers. For *Ips* trapping, we used a wick dispenser made of cotton yarn (Birgersson and Lejfalk, 1997) to deliver the two compounds. When releasing components of similar volatility, this dispenser delivers a range of proportion released without any accompanying change of total amount of released components. Compounds were dissolved in 4 ml octane as 1:100 (alcohols–octane) solutions in dark glass bottles, evaporating from a thin-walled Teflon tube-enclosed cotton wick yarn end (tube: 2.5 mm OD, 1.7 mm ID) at approximately 1 mg/day. Solutions

were prepared by making a concentrated stock solution of each compound and adding it in the required amounts to make up a 1% solution with a total of 40 mg of the two compounds combined in each vial (see *x* axis in Figure 1). The two components were ipsdienol, provided by Borregaard (Sarpsborg, Norway), and (*E*)-myrcenol, provided in 1992 by W. Francke (Organic Chemistry, University of Hamburg, Germany) and in 1993–1994 purchased from Phero Tech Inc. (Delta, British Columbia, Canada). Both compounds are monoterpene alcohols and have evaporation rates in the same range (Schlyter et al., 1992). A positive control consisted of a standard synthetic bait using polyethylene vials (Schlyter et al., 1992) releasing at total of ca. 1 mg/day of about 86% Id or about 200 male equivalents.

Study Areas and Traps. In Norway, trapping was done with a set of nine black nonsticky, standard Norwegian drainpipe traps (N79) as in an earlier test (Schlyter et al., 1992). The test sites were clear-cuts in a Norway spruce [*Picea abies* (L.) Karst.] forest from recent winter logging near Ås in SE Norway (Schlyter et al., 1992) in May–June in 1993 and, 1994. Traps were set up in a line and randomized using the same scheme in all sites.

In the Peoples Republic of China, black nonsticky, flight barrier (slot) traps (Theyson, Germany) were used in NE China 1992 and in Inner Mongolia 1993 and, 1994. In NE China, beetle response was tested in June 1993 in a recent clear-cut in a natural forest of *Larix gmelinii* L. with no prior record of *I. duplicatus*. The site used was near Xin-Lin (51°48′N, 125°38′E), ca. 150 km W of the Amur river in the Great Xingan Mountains. Nine traps were set up in a line ca. 30 m from the stand margin with 25 m between neighboring traps. Inner Mongolia beetles were sampled in 1993 and 1994 in a reserve of ca. 2000 ha of natural spruce forest [*Picea mongolica* (Wu, H.-Q.) Xu, formerly *P. koraiensis* Nakai or *P. meyeri* or *P. meyeri* var. *mongolica* Wu, as discussed by Xu (1994) and Liu (1994)] at Baiyinaobao (43°30′–36′N, 117°06′–16′E), Keshiketeng Qi (formerly Hexigten Qi) Inner Mongolia, China, which is situated in the grassland at the east edge of the Hunshandake desert, with a thick layer of sandy soil. Since the 1950s these stands, at the southwest margin of the natural distribution of *Picea mongolica* Xu, have been severely infested by sawflies and *I. duplicatus* (Liu, 1994; Zhang et al., 1995). The larger bark beetle competitor, *I. typographus*, has not been recorded here. In 1993 and 1994, two sets of nine traps were set up in small glades at the margin of the surrounding stand of dead trees killed by *I. duplicatus* the previous year. Traps were arranged in a curve in order to ensure a similar distance (ca. 15 m) to the insect source (the dead trees) for each trap. The distance between traps was ca. 8 m.

In the Czech Republic, black nonsticky, multifunnel traps (Lindgren trap, Phero Tech, Vancouver, British Columbia) were used in NE Moravia in Chuchelná near Opava (49°59′N, 18°8′E) in May 1994. The test site was a 1-year-old clear-cut in a monoculture of artificially planted Norway spruce forest (80 years old) at approximately 300 m above sea leavel. Since 1992, the largest European outbreak

of *I. duplicatus* has been recorded in this area (Knízek and Zahradník, 1996). Although most trees were attacked by *I. typographus*, many apparently healthy trees were killed by *I. duplicatus* alone.

Statistics. Number of replicates (trap rotations following a Latin-square randomization scheme) (Byers, 1991) and total catch for each study area and year are given in Figure 1. Statistical analysis of field trapping data from each replicate (trap rotation) was done by ANOVA, followed by Duncan's multiple-range test with SPSS/PC+ V5.01, on arcsin $\sqrt{p}$ transformed data to approach normality and homoscedasticity as judged by Barlett's and Cochran's C tests.

Ips *Male Aggregation Pheromone Production.* Collection of volatiles from individual unpaired wild males, freshly collected from Skotterud, Norway, established in host logs were made in the laboratory in Göteborg applying the method of Birgersson and Bergström (1989) as modified by Ivarsson (Ivarsson et al., 1993; Ivarsson and Birgersson, 1995). Logs of Norway spruce, *P. abies*, infested with *I. duplicatus* were collected outside Skotterud, Hedmark County, Norway. The beetles were reared out of the logs at 23°C and relative humidity 75% and stored in cooled containers (4°C) with moist paper. Prior to experiments, male beetles were allowed to fly in transparent boxes at 25°C, 85% relative humidity and 35,000 lx for 6 hr. Each beetle was put on a fresh *P. abies* bolt in a shallow predrilled hole (2.5 mm ID) and covered with a gelatin capsule (#00) fitting in the grooves, made with a cork borer (4 mm dram.), around the hole. As the beetles began to enter the bolt, the capsules were removed and the bolt placed in a climate chamber (75% relative humidity 23°C). During the first 20 hr, no collection of volatiles was made as the beetles excavated their nuptial chambers (Schlyter et al., 1992). After this time, Teflon tube columns (20 × 3 mm), filled with 35 mg Porapak Q (60–80 mesh, Supelco Inc, Belfonte, Pennsylvania) were placed outside each individual entrance hole (Birgersson and Bergström, 1989) and air at 20 ml/min was pumped through each column. After 3 hr of collecting, the columns were removed and eluted with 500 μl diethyl ether (p.a.; Fluka Chemie AG, Buchs, Switzerland) with 500 ng of quantification standard (heptyl acetate) added. The aeration extracts were concentrated to 100 μl prior to analysis. After aeration, the corresponding individual male hindgut extracts were done by the standard method (Birgersson et al., 1984; Schlyter et al., 1992; Ivarsson and Birgersson, 1995).

Analyses of the aeration extracts were performed by GC-MS on a Hewlett-Packard 5890II GC–Finnigan TSQ-700 quadrupole MS at 70 eV. The GC was fitted with a fused silica capillary column (45 m × 0.25 mm) coated with DB-Wax (PEG, $df = 0.25$ μm; J&W, Folsom, California). Helium was used as carrier gas at 25 cm/sec, and the temperature program was constant at 50°C for 5 min, 10°C/min to 230°C, held for 10 min. Injector and transfer line temperatures were 210°C and 230°C, respectively. The amounts of collected pheromone components [ipsdienol and (*E*)-myrcenol], were quantified against the added standard, and calculated based on a standard curve, covering 0.5–5000 ng. All extracts included here for

calculation of component proportions were above limit of quantification (LOQ) for both compounds.

Moth Chilo partellus *Data. Chilo* Zincken is a large genus in the Pyralidae family. The larvae of all *Chilo* spp. are stalk borers, several being serious pests on graminaceous crops (Moyhuddin, 1990). The sex pheromone of *C. partellus* has been studied as a tool for population monitoring and control methods. Nesbitt et al. (1979) established that the aldehyde, (*Z*)-11-hexadecenal (*Z*11–16:Ald) and the corresponding alcohol (*Z*)-11-hexadecen-1-ol (*Z*11–16:OH) were the major female sex pheromone gland constituents of virgin females of *C. partellus*, originating from India. Both major components are found in airborne volatiles from calling females (Nesbitt et al., 1979), suggesting a behavioral role for both components. However, when tested at several sites in Africa, the aldehyde alone or blends of the aldehyde and the alcohol were later found to be less effective in attracting male moths to traps (Beevor et al., 1990; Unnithan and Saxena, 1990, 1991), as well as in India (Seshu Reddy, personal communication). To test if both the major components previously identified were necessary, and, if so, to optimize the pheromone blend of *C. partellus*, we needed to test both the total dose of the two-component synthetic blend and the ratio between the two components. This was done by comparing the male pheromone response in a wind-tunnel bioassay to different pheromone blends. This approach also required a quantification of the individual female variation in the sex pheromone content, to compare the relationship between female production and male response.

Male Chilo *Flight Tunnel Response*

Insects. Chilo partellus moths were obtained from a laboratory culture established from field-collected material from Kenya and reared on a semisynthetic diet based on white beans. The culture was maintained in a climatic chamber (24°C, 80% relative humidity, 12-hr reversed scotophase), and was renewed regularly with field-collected material. The insects were sexed as pupae and kept separately under the same light and temperature regime. Males were collected every day and kept in humidified plastic boxes until use.

Pheromone Formulations. Chemicals, purchased from The Research Institute for Plant Protection, Wageningen, The Netherlands, were at least 98% pure with respect to geometrical and positional isomers. Stock solutions of each compound (1–50 μg/μl) were made up in hexane (Chemicon, redistilled p.a. quality). Blends of pheromone components to be tested were made by mixing various amounts of the stock solution and adding hexane to the desired concentration. All mixtures were checked before use, on a Hewlett Packard 5890 GC-FID equipped with a 30-m $\times$ 0.25-mm DB-1-coated fused silica capillary column (J & W, Folsom, California) to ensure purity.

Extracts of calling virgin females were made as described by Svensson (1996b). The female extracts and synthetic blends to be tested in the wind tunnel were applied to 1-cm^2 filter papers (Wratten 80) and the solvent was left to evaporate. This was done immediately before use. Filter papers with mixtures applied were used for only 15 min in the wind tunnel and then exchanged for new ones to ensure a relatively stable release rate.

Wind Tunnel Behavioral Tests. Wind-tunnel tests were performed in a $0.9 \times 0.9 \times 2.5$ m Plexiglas tunnel (Löfstedt et al., 1985) as described by Svensson (1996a). The environmental conditions were: 21–22°C, 50–60% relative humidity, 0.3 m/sec wind speed, light intensity 2 lux. The wind-tunnel tests took place 7–9 hr into the scotophase. The male insects were tested the first night after their eclosion and were conditioned at least 1 hr before testing. The physical wind-tunnel conditions were checked prior to every test. Vital single males were chosen from boxes containing emerged males and placed in glass tubes. The tube was sealed in both ends with a fine mesh until placed in the wind tunnel. The mesh was removed from one end and the tube held in the pheromone plume 200 cm downwind of the odor source. Males were given 1 min to respond. Males not responding during that time were discarded and recorded as nonresponders.

Three calling females, placed in a 12-cm-long $\times$ 28-mm-diam. glass tube, open in both ends, were used as a biological standard (the best possible stimuli) for every other treatment. All other treatments were run with the tester blinded with respect to the treatment tested. A mixture of 100 ng *Z*11–16:Ald and 30 ng *Z*11–16:OH applied on filter paper was used as the synthetic control in all tests unless otherwise described. By including both the best biological standard and a highly repeatable synthetic control, both the ultimate goal (attracting a virgin female) and the testing conditions (control of abiotic conditions) could be compared between different tests. All equipment, including all glassware that was used inside the wind tunnel, was heated over night between tests; metal stands for 12 hr 180°C, and glass tubes for 12 hr at 360°C, to prevent contamination. Eight behavioral steps were recorded (Table 3) and response expressed as percentage or proportion of tested males performing a behavior. Wind-tunnel data were analyzed by the method of adjusted significance levels of proportions (Ryan, 1960) for post hoc comparisons between treatments.

Dose–Response to Two-Component Synthetic Blend and Alcohol/Aldehyde. First, a dose–response study of the total amount at a fixed proportion was done. A two-component blend of *Z*11–16:Ald + *Z*11–16:OH (100 + 30 units of each, i.e., 23% alcohol of the total blend) applied on filter paper was made with the following doses: 1, 3, 10, 30, 300, 1000, and 3000 ng *Z*11–16:Ald, respectively. Each combination was tested on at least three different occasions, with calling females as controls. Secondly, different proportions of the two main components were tested at an optimal level of total amount. We added 2–40 ng *Z*11–16:OH to a fixed amount

of 100 ng *Z*11–16:Ald in an attempt to optimize the synthetic two-component blend. Seven different ratios of *Z*11–16:Ald and *Z*11–16:OH (from 100 + 2 to 100 + 40 units, or from 2 to 29% alcohol of total, Figure 3) were tested.

Female Chilo *Sex Pheromone Production*

Virgin females, in their second scotophase, were taken for extraction of pheromone components 9 hr into the scotophase and dissected. Single sex pheromone glands were extracted in 10 μl redistilled hexane (p.a. quality, Chemicon), with an internal standard of 10 ng (*Z*)-8-tridecenyl acetate, for 60 min. The extract was transferred to a 50-μl glass capillary, which was sealed immediately under an open flame. The capillaries were kept in a freezer until analysis. The analyses of individual female pheromone gland extracts were performed on a Hewlett Packard 5890 GC-FID. Gas chromatography parameters: 25 m $\times$ 0.25 mm DB-Wax column; temperature program: 70°C for 10 min, 70 to 230°C at 5°C/min, 230°C for 20 min. Hydrogen was used a carrier gas at 30 cm/sec.

RESULTS

Empirical Data

Field Response of Four Ips *Populations.* The first test in NE China in 1992 showed a marked preference by *I. duplicatus* for a high proportion of ipsdienol (% Id), close to 90% (90:10 Id/EM, Figure 1A). Overall catches were low due to a low population and allowed only three replicates. However, the validity of this small data set is shown by the unambiguous positive dose–response by the congener *I. sexdentatus* to an increase of Id up to and including 100% (Figure 1A). In contrast, *I. duplicatus* showed an optimum response, as the catches were lower at 99% Id and 100% Id baits than at the 90% Id, and this fitted well with the necessity of (*E*)-myrcenol as a synergist, as found in earlier tests in Norway (Byers et al., 1990; Schlyter et al., 1992). From the bell-shaped response profile it was obvious that the optimum was not located precisely at the treatment with the highest catch. The 90% Id bait had highest catch, but catches of the surrounding treatments were not symmetrically distributed around the 90% Id maximum (Figure 1A). Similar optima, situated between treatment values were observed later (Figure 1B–F).

In spite of few replicates due to cold weather, the test in Norway in 1993 showed a good response to 50% and 90% Id, as expected based on earlier results from this area (Schlyter et al., 1992) (Figure 1C). Data from Inner Mongolia in 1993 were quite surprising and almost a mirror image of those from NE China in 1992 and Norway in 1993. The best bait here was the 10% Id (10:90 Id/EM) followed by 50% Id (Figure 1B). These mirror-like results shed some doubt on

the reliability of bait preparation/labeling for China in 1993. Bait dispensers from China were not available for GC analysis, but three dispensers with pheromone solution left from Norway could be analyzed. GC results from these three baits showed no error in the Norway baits, proving the correctness of the solutions prepared, whereas the possibility of labeling errors for baits sent to China could not be disregarded.

The 1994 results from Inner Mongolia, Norway, and Czech Republic confirmed results of previous years (Figure 1D,1E). Inner Mongolia had the best catches for 50% Id followed by 10% Id, while Norway and Czech Republic had highest response to baits with $\geq$50% Id. The distribution of catch in Norway 1994 with ample replication, was very close to the results of the previous year (Figure 1C,F). The data from Inner Mongolia in 1994 were somewhat less extreme than data of the previous year, but both years had ample replication (Figure 1E). The results from Czech Republic had good catches with somewhat fewer replicates, and they were similar to the Norway data (Figure 1D). Sex ratios showed generally that the baits with the strongest attractivity had the lowest ratio of males. In other words, males—the pheromone-producing sex in *Ips*—had a wider response window than females, as shown for data from Norway in 1994 (Figure 1F).

Male Ips *Aggregation Pheromone Production.* In entrainments of emitted volatiles from field collected Norwegian males, there was a proportion (mean $\pm$ SD) of 86 $\pm$ 15% Id ($N = 30$). The same mean ratio of pheromone components was quantified from hindgut extracts: 85 $\pm$ 9% Id ($N = 27$). The frequency profile of the components emitted from males had a peak around 0.90 Id/(Id + EM), with a small left-tailed skewness (Figure 2). The absolute amounts quantified were higher in entrainments than in hindguts. For ipsdienol the amount in entrainments was 1800 $\pm$ 2100 ng with a range of 0–9600 ng ($N = 36$), while hindguts had only 300 $\pm$ 340 ng with a range of 0–1580 ng ($N = 32$).

Earlier data, based on batch analyses of males, agrees favorably with the present data, both from entrainments (85% Id, laboratory strain) and from hindgut extracts (82 and 86% Id, wild and laboratory strain) (Schlyter et al., 1992, 13–50 males per batch).

Chilo partellus *Dose–Response to Two-Component Synthetic Blend.* For all eight behavioral steps in the flight tunnel, the 100- or 300-ng doses gave the highest response. However, by post-hoc multiple range test there was no significant difference between baits with 30–1000 ng loading of the aldehyde for any of the eight steps (Figure 3A). The response pattern, e.g., doses that evoked the highest responses, became narrower and bell-shaped in the later behavioral steps (Figure 3A).

Chilo partellus *Dose–Response to Proportions of Alcohol–Aldehyde.* Seven different ratios of *Z*11–16:Ald and *Z*11–16:OH were tested for behavioral activity (Figure 3B). We found that an optimum synthetic blend of *Z*11–16:Ald and *Z*11–16:OH released a behavioral response as good as the corresponding amount

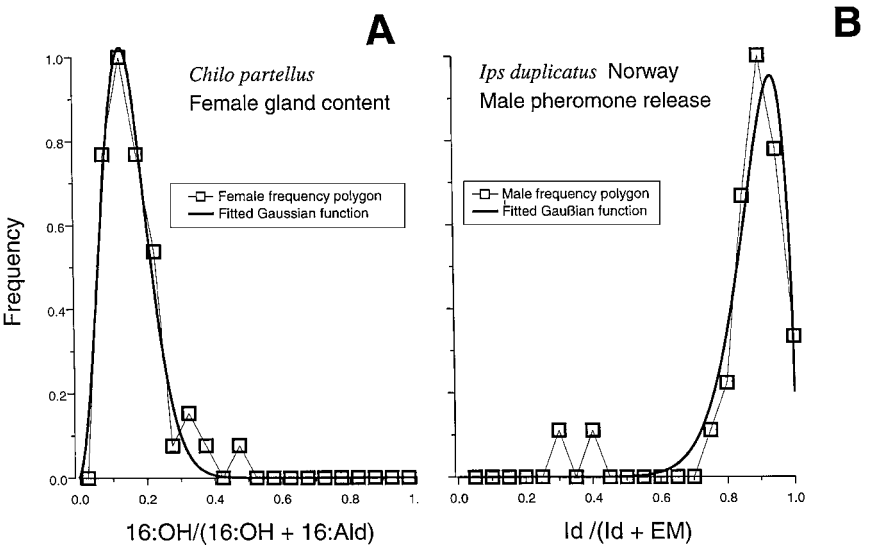

FIG. 2. Frequency distributions of production of pheromone component proportions (-□-) with overlaid estimated Gaussian curve (▬). Frequencies (*y* axes) were rescaled so that the bin with the highest frequency = 1. (**A**) Female pheromone production blends frequency profile of *Chilo partellus*, $N = 44$ females from a laboratory culture. See Table 3 for parameter estimates. (**B**) Male pheromone emission in *Ips duplicatus* from Norway, $N = 30$ wild collected males. For details of parameter estimates see Table 1.

of female gland extract. The male response to calling females was consistently around 90% in all tests ($N = 140$). However, calling females gave a slightly better response rate than synthetic baits at the later behavioral steps (Svensson et al., unpublished data). Both pheromone sources resulted in ca. 80% response at the 200-cm (source contact) behavioral step (Figure 3B). Response to the different ratios was apparently different, especially for the later behavioral steps (Figure 3B). The 17% OH treatment was the optimum, showing the highest response in all seven behavioral steps. However, by post hoc multiple-range test, usually only the 2% OH treatment was consistently different from the optimum (17% OH).

Female Chilo *Sex Pheromone Production.* Extracts of $N = 46$ *Chilo partellus* females showed that most female glands contained between 5% and 25% OH of the two main components, with a mean of ±SD 16.5% ± 8.9 (range 0–49%). However, there was a tail of the distribution of the production profile skewed towards higher values (Figure 2B). Some females had ≥30% alcohol component in their glands. By visual inspection, the male response profile (Figure 3B) seemed to have a somewhat wider window than that of the female production profile (Figure 2B). Gland extracts contained, on average, 74.2 ± 43.7 ng (11–202 ng) of the

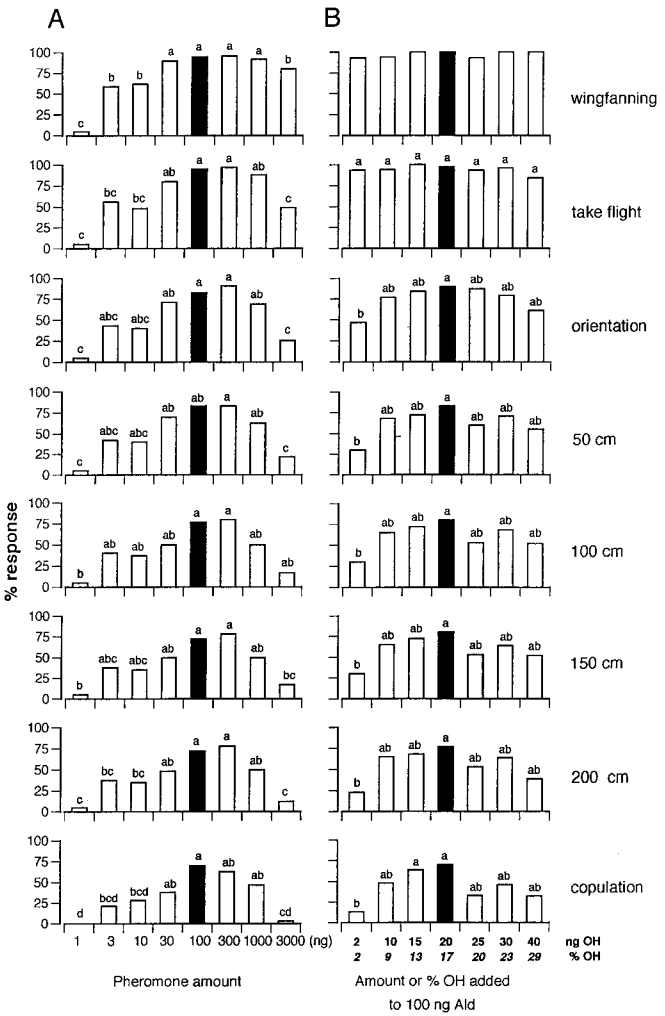

FIG. 3. Comparison of response frequency during different behavioral steps of male *Chilo partellus* in a wind tunnel to variation in total dose and proportions of components. Each combination was tested on at least three different occasions, with three calling females as controls. Bars with different letters are significantly different at $P < 0.05$, test of adjusted significance levels of proportions (Ryan, 1960). (A) Variation of total amount of the two-component mixture of Z11-16:Ald + Z11-16:OH (100:30) applied on filter paper, $N = 22$, 19, 24, 29, 31, 28, 28, and 22 for 1, 3, 10, 30, 300, 1000, and 3000 ng Z11–16:Ald, respectively. (B) Variation in proportion; different amounts of Z11–16:OH added to 100 ng Z11–16:Ald (100 + 2 to 100 + 40), comparable to 3 FE, and applied on filter paper, $N = 30$, 31, 25, 30, 15, 28, and 31 for 2, 10, 15, 20, 25, 30, and 40 ng OH, respectively.

major *Z*11–16:Ald component and 15.6 ± 13.7 ng (0–63 ng) of the minor *Z*11–16:OH component. The variation in amount of the aldehyde (CV % = 59), the main component, was thus somewhat lower than in amount of the alcohol (CV % = 88).

Model Parameter Estimation

Regression analyses for proportion (p) of pheromone components were generally more successful when arcsin $\sqrt{p}$ transformed $\bar{y}$ values were used than when the raw or linear y values were used (Tables 1 and 2). The arcsin $\sqrt{p}$ transformation of the independent axis was particularly valuable when empirical data was close to the extremes (0 or 1). The data on frequency of response or production (y axis) were rescaled so that the highest frequency was set at 1 for each data set, to facilitate comparisons between data sets. Plots of overlaid predicted values with the experimental data showed a subjectively pleasing fit in most cases (Figures 2, 3, and 6). Better estimates were obtained when using the mean of the response for each treatment ($\bar{y}$ values), rather than the raw data (e.g., Norway, 1994 data in Table 1).

Examples of plots with functions estimated from data that used the transformed x axis values but plotted on both the linear and transformed axis are given in Figure 4. On an arcsin $\sqrt{p}$ transformed independent axis (Figure 4A) both the data points and the profile obtained for response of *Ips duplicatus* in Norway, 1993 is more compliant with a Gaussian curve than when they are plotted on the linear (untransformed) x axis (Figure 4B). The fitted functions from other data sets for this species show the same change in shape (Figures 4C, D).

Iterations usually showed convergence in less than 100 iterations when using suitable starting values on good empirical material. In data sets with few values on the x axis or with a jagged profile, the convergence either took longer (>100 iterations) or sometimes arrived at local solutions giving globally impossible results. In some cases this was remedied by choosing starting values closer to those suggested by the raw data (e.g., *Agrotis segetum* males in Table 2). With the better empirical data sets, starting values were not at all important. This is normal for iterations of nonlinear regression systems in general (Norusis, 1994).

Ips duplicatus *Population Response and Male Production Models.* Fit to mean trap data estimates of Gaussian curves by NLR generally showed good correlation ($r^2 > 0.8$, Table 1); an example is the curve for Norway 1993 data shown in Figure 4A. The data from Norway 1993 and 1994 gave functions that looked similar (Figure 4C) and had fitted parameter estimates close to each other, although the better replicated data from 1994 had a somewhat better r^2 (0.98) than the 1993 data ($r^2 = 0.93$, Table 1). Especially for NE China 1992 data, the fitted Gaussian curve was narrower and the peak was much higher than the data points, but these x-axis points were based on only three replicates. Similarly, a somewhat higher absolute response value may be seen for Inner Mongolia 1993

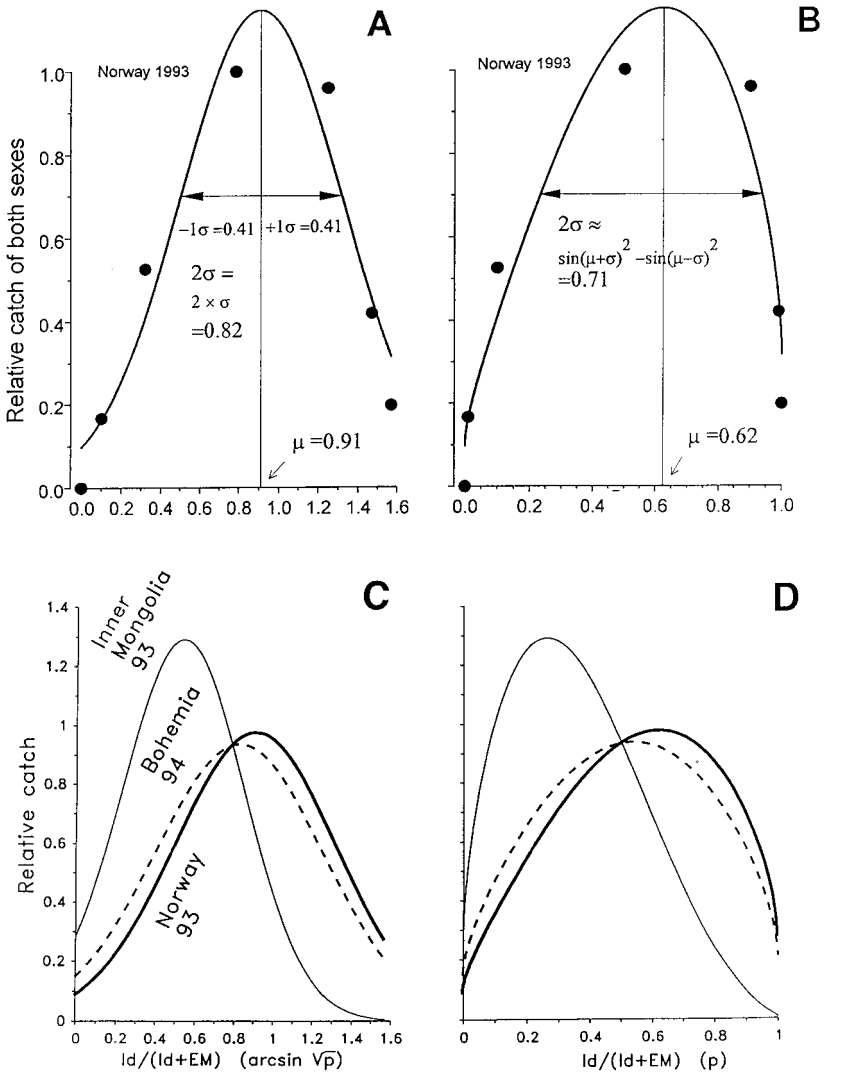

FIG. 4. Illustration of estimation on both transformed and untransformed independent axes by nonlinear regression (NLR) of Gaussian curve to relative catch profiles of *Ips duplicatus*. (**A**) The data set from Figure 1C with the fitted Gaussian curve; the x axis scaled as arcsin $\sqrt{p}$. (**B**) Same data and NLR curve as in A, but plotted on the x-axis scaled as p and with the formula for obtaining the window width on the untransformed scale. (**C**) Fitted Gaussian curves for selected data sets from Figure 1 with the x scale as arcsin $\sqrt{p}$. (**D**) As in C, but plotted on the x scale as p. Catch data (y axis) were rescaled so that the treatment with the highest catch = 1 for each data set. See Table 1 for parameter estimates.

data (Figure 4B). However, as the peaks of the fitted curves are between the data points, this is not an error in curve fitting. Instead, this means that the true maximum response is located between the fixed treatment values (x axis points for p values).

A summary of re-transformed estimates is shown below (number of trap rotations, N, in parenthesis):

NE China	1992	$\mu = 0.77$	$2\sigma = 0.29$	(3)
Inner Mongolia	1993	$\mu = 0.24$	$2\sigma = 0.42$	(9 + 9)
Inner Mongolia	1994	$\mu = 0.42$	$2\sigma = 0.59$	(9 + 9)
Norway	1993	$\mu = 0.62$	$2\sigma = 0.71$	(4)
Norway	1994	$\mu = 0.65$	$2\sigma = 0.75$	(11)
Czechia	1994	$\mu = 0.53$	$2\sigma = 0.79$	(6)

(For details of estimates see Table 1)

All data sets showed a peak of response (μ_r) located above 50% Id, except for the two sets from Inner Mongolia. The width of the response window ($2\sigma_r$) did not vary consistently with the location of the optimum. The number of replicates did not seem to influence window width, as the NE China 1992 sample with the fewest replicates ($N = 3$) had the lowest $2\sigma_r$, while the two Inner Mongolia samples with the largest number ($N = 18$) had intermediate values.

As an alternative way of separating the response from the different populations, cluster analysis was performed on the whole data set (Tóth et al., 1992), but with variable results. When including the active control, i.e., the earlier used 200 male equivalents bait (Schlyter et al., 1992), there was better resolution. However, in the cluster analysis, one may use five different methods for measurement of distances between clusters and four ways to combine cases into clusters, yielding $4 \times 5 = 20$ different plots. Of these, the cosine measurement together with average linkage combination of clusters methods gave a clustering result similar to the results obtained by our model.

Norway male beetles emitting pheromone (Figure 2) had a somewhat higher estimated peak location ($\mu_p = 0.94$ Id proportion) compared to the arithmetic mean of the sample, $\bar{x} = 86\%$ Id. This is due to the two values in the extreme left-hand tail of the male frequency polygon with a high EM content, influencing the $\bar{x}$, but not the Gaussian model production curve fitted by NLR (Figure 2). These data points were not included, as the model (equation 3) assumes and fits only a single, unimodal peak. To represent these two points would have required a model for two peaks or optima, as in equation 5. The estimated window width for production was $2\sigma_p = 0.14$, which was much smaller than that of Norway beetles responding (Figure 5), these having a window width of $2\sigma_r \approx 0.7$ both in 1993 and 1994 for their fitted response profiles (for details see Table 1).

Chilo partellus *Male Behavioral Steps and Female Production Models.* Male response width, when estimated by NLR, showed a marked decrease with the sequence of behavioral steps. The decreasing width of the response profile is plain to see when plotting the NLR estimated Gaussian curves for the sequential behavioral steps (Figure 5A). The overall fit of the regression was good (see Table 3 for details of parameter estimates), but the peak of the model response curve did not reach as high as 1.0, due to adjustment to the low values for the 20% OH treatment (Figure 3B and 5A). Quantification of the width of the response window with the progression of behavioral steps is shown in Figure 5B. The location of the peak did not change much after the two first behavioral steps (Figure 6B). After the first behavioral step, the continuous decline in response window width ($2\sigma_r$) with subsequent steps was highly significant ($r_S = -0.96$, $P = 0.0005$, $N = 7$). In contrast, the location of the peak response (μ_r), did not vary with behavioral step [$r_S = -0.14$, $P = 0.76$ (N.S), $N = 7$].

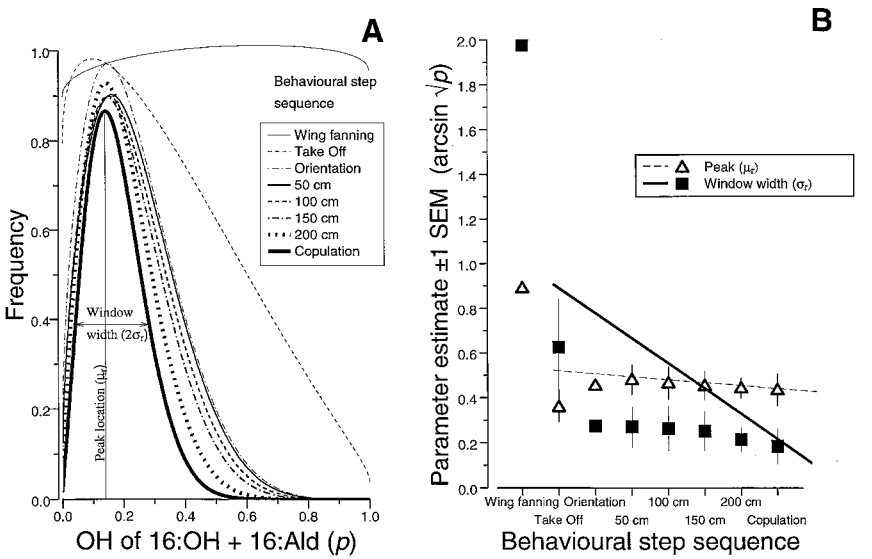

FIG. 5. Decrease in response width (σ) with behavioral steps sequence by male moths in flight tunnel. (**A**) Gaussian curve fitting by NLR to relative response frequencies of *Chilo partellus.* For raw data see Figure 3B and for details of parameter estimates see Table 3. (**B**) Decline in parameter values of μ_r (location of response peak) and σ_r (width of response profile) with the sequence of behavioral steps recorded. —) Regression for decline in response width, $P < 0.001$, $N = 7$, ----) Regression for change in peak location, $N = 7$, $p > 0.1$ NS. For both parameters the first point was omitted from analysis as their confidence intervals included zero (see Table 3).

The peaks of male response and female production were similar in their location ($\mu_p \approx 0.4$ on arcsin scale, Table 3). In contrast, the width of the female production window was somewhat smaller than that of the male response window, even at the last behavioral step. For the female gland content, the width was $2\sigma_p = 0.14$ compared to $2\sigma_r \approx 0.2$ for males in their two latest steps (Table 3).

DISCUSSION

Literature Data. The method for estimation of location and width of the response window developed here can be easily extended to other pheromone systems. Examples are given in Figure 6. Best fits are obtained with data that have a symmetrical profile and many values on the independent axis, such as those for *Pectinophora gossypiella* (Lepidoptera: Gelechiidae) (Linn and Roelofs, 1985) in Figure 6A. Highly asymmetrical profiles with few data points, such as that for *Spodoptera litura* (Lepidoptera: Noctuidae) (Tamaki, 1977), also can be fitted reasonably well (Figure 6B,C).

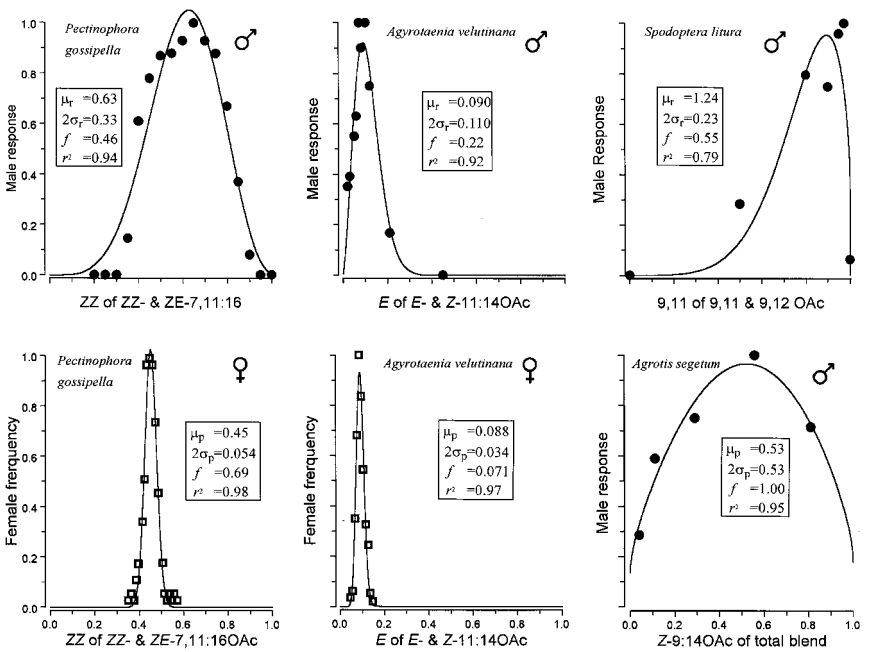

FIG. 6. Analysis of selected literature data on lepidopteran female sex pheromones; examples of Gaussian curve fitting by NLR to relative responses in males and production of females. For details of parameter estimates and references see Table 2.

Löfstedt (1990) plotted together the male response and female production of pheromone component ratios of *P. gossypiella* and *Argyrotaenia velutinana* and concluded that the male window of response was "relatively wider." Qualitatively, this conclusion seems reasonable when comparing Figure 6A vs. 6D and Figure 6B vs. 6E. Quantitatively, the $2\sigma_p$ for female production is 0.054 and 0.033, while the corresponding male window is more than twice as wide, having $2\sigma_r = 0.33$ and 0.11, for *P. gossypiella* and *Argyrotaenia velutinana*, respectively (Table 3).

Clearly, pheromone responses in other insect orders can also be analyzed as can responses to variation in amount of stimuli. Quantification of the response to variation in extreme enantiomer ratios in a sawfly is shown in Figure 7A. The variation in amount of pheromone in a fruit fly can be easily quantified by our method (Figure 7B).

The model may also be extended to analysis of data sets with a mixture of response profiles, where more than one peak of activity exists. A nice example of a sample with two optima for response and production is the *Ips pini* population in Princeton, British Columbia, Canada reported by Miller et al. (1996). This population seems to have two types of members belonging to one of two different signaling types, each producing and responding to ipsdienol of specific chirality, one with a peak near racemic (around 50/50) and one at high (+)-enantiomeric composition. A model for such a two-peak system can be expressed as the sum of two equations:

$$y = g_1(x) + g_2(x) = f_1\left[\frac{1}{\sigma_1\sqrt{2\pi}}e^{-(x-\mu_1)^2/2\sigma_1^2}\right] + f_2\left[\frac{1}{\sigma_2\sqrt{2\pi}}e^{-(x-\mu_2)^2/2\sigma_2^2}\right] \tag{5}$$

The two subfunctions, $g_1(x)$ and $g_2(x)$, are of the same form as equation (3) and their parameters are estimated by NLR in the same way. For the two-peaked model of this *I. pini* population sample, we assumed the width parameters to be the same, $\sigma_{p_1 \text{ or } r_1} = \sigma_{p_2 \text{ or } r_2}$, for the two response profiles in the population, while f, μ_p, and μ_r were allowed to vary. The fit to the raw frequencies of male production and population(s) response is good (Figure 8). In principle, the one-dimensional fitting along an x axis done here may be extended to a true two-dimensional response window, sensu Roelofs (1978), by fitting data on response to variation in both amount and proportion. Our present data sets do not allow this, as dose and proportion have not been independently varied over the whole parameter space.

Empirical Data. The wick dispensers for *Ips duplicatus* proved satisfactory over time, as they lasted for about 10 replicates (rotations) and with uniform release, as all baits went dry at approximately the same time. The optimum catch of the wick dispenser in Norway was similar to that of open PE vials used earlier (here active control) giving ≈200 ME (Schlyter et al., 1992). The traps used in the four different populations differed in their design and partly in their trapping principle.

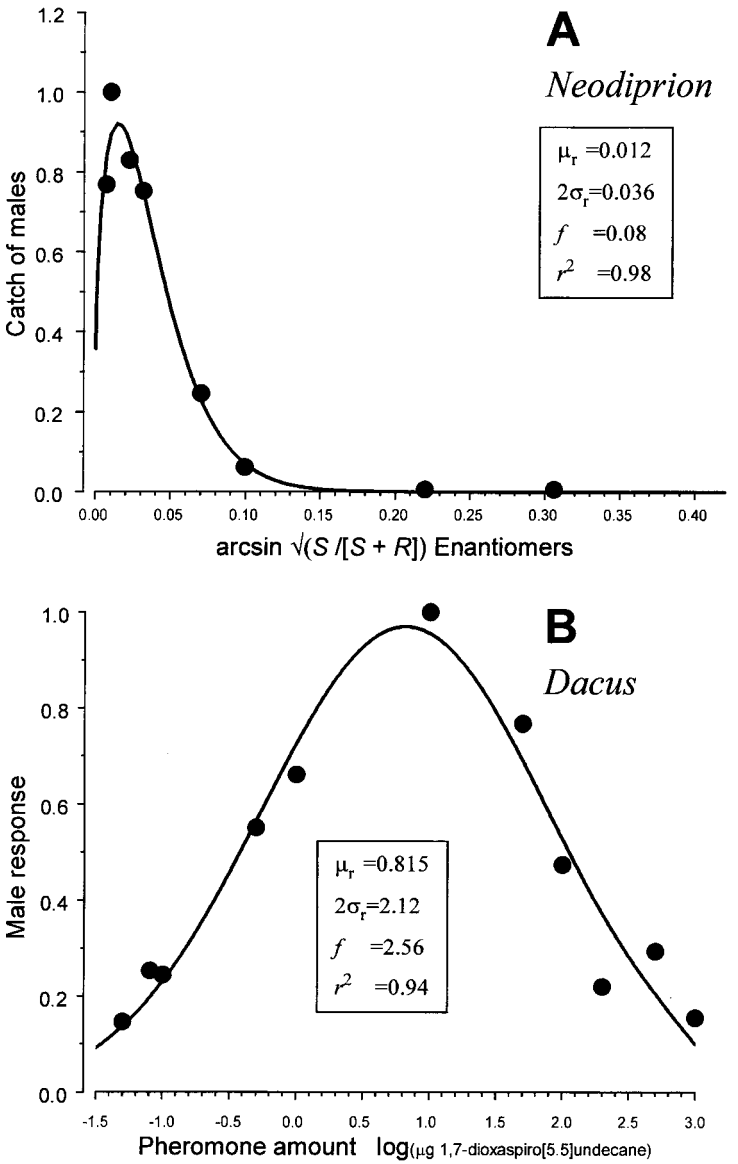

FIG. 7. Analysis of variation in attraction to extremely small proportion differences and to amounts of pheromone in two different insect orders. (**A**) Literature data of pine sawfly *Neodiprion sertifer* female sex pheromone; variation in proportion of diprionol enantiomers (Löfqvist, 1986). (**B**) Literature data of olive fruit fly *Dacus oleae*; variation in amount pheromone (Haniotakis and Pittara, 1994).

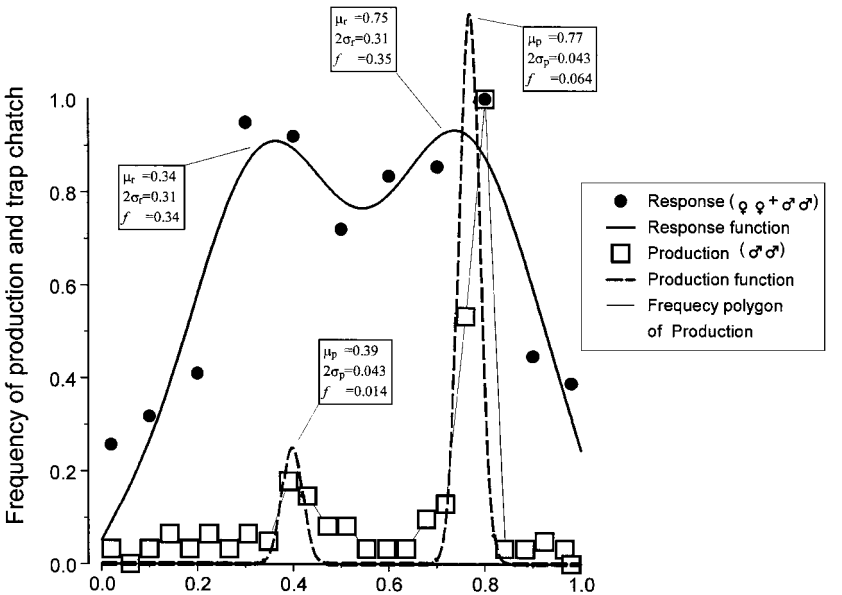

FIG. 8. Literature data of bark beetle *Ips pini* (Princeton, British Columbia, Canada) male aggregation pheromone; variation in proportion of (*R*)-(+)-ipsdienol enantiomer (Miller et al., 1996). Male enantiomer composition frequency profile (-□-) with double peaked Gaussian curve overlaid (**----**) and relative catches of both sexes at baits with varied enantiomer composition (●) with overlaid double peaked Gaussian curve (**—**). The type of equation fitted is equation 5, see Discussion.

While all provide a dark silhouette as a visual cue, the N79 model used in Norway in 1993 and 1994 requires beetles to both land and enter holes to get trapped. The Lindgren multifunnel trap (Czech Republic 1994) and the Theyson slot trap (China 1992–1994) are partly barrier traps in their function and require only that beetles orient close enough to the odor source to be intercepted and collected by a funnel or extended slot. A fraction of beetles probably still lands on the trap surfaces and later fall down to be trapped, but this has not been studied in detail. The similar sex ratios recorded in the whole material and the similarities between catches in Norway and Bohemia (Czech Republic) make it unlikely that trap design would have affected results. The most striking differences were in fact found between two localities in China using the same traps during the three years of study.

The results from the two years of sampling in Norway are almost identical in peak location and response width (window size). They also showed a very small cluster distance in the hierarchical cluster analysis. The two samples from Inner Mongolia differed somewhat in their location of optima but less in window width.

Correspondingly, the two Inner Mongolia data sets combined at larger cluster distance than the two Norway sets. The data sets that stand out from the others are the catches from Inner Mongolia in 1993 and 1994. Based on raw data showing the highest response for 50% and 10% Id baits, cluster analysis, and fitting of our model, this east Palearctic population seems to be unique. It should be noted that the geographic location of this population is 9° or about 1000 km west of the NE China locality of 1992. Thus, the Inner Mongolia population is not the population most distant from Europe, but it is biologically distinctive since it is isolated from other populations of *Ips duplicatus* and *Picea* (Zhang et al., 1995). Its host *Picea mongolica* Xu has been considered as a probably endemic taxon separate from both *P. koraiensis* and *P. meyeri* (Xu, 1981, 1994; Liu, 1994). In addition, both the bark beetle and the spruce tree live in a highly isolated environment in respect to the taiga, surrounded by grassland and on sandy soil. No *Ips typographus* could be detected by trapping with Pheropraxc pheromone dispenser in this area (Zhang, unpublished data). Therefore, the evolutionary direction of *I. duplicatus* population in Baiyinaobao, Inner Mongolia, together with its host tree, might have been genetically different from other populations, as in NE China and in Europe.

The analysis, or even accurate description, of differences in response to an array of several stimuli for different populations is not simple. Strictly speaking, this is a multivariate problem and cluster analysis is one possible method (Tóth et al., 1992). However, cluster analysis is a purely descriptive tool, and by using the many possible combinations of clustering techniques and distance measurements it is possible to get almost any dendrogram. We believe our method of fitting a Gaussian curve by NLR is more objective and quantitative, although it is still mainly descriptive. However, by use of the asymptotic SE (Table 1), it is possible to construct confidence intervals for the estimated parameters, as for any other standard univariate statistic. With our model, the several stimuli variables are reduced to one fitted function and the inherently more complex multivariate analysis types need not be evoked.

The variation of the proportion of the two major sex pheromone components of *C. partellus* was made in a fashion where the amount also was changed. The change in amount loaded on filter paper, however, was a minor one: the lowest dose was 100 μg and the highest 140 μg when ratio was changed (Figure 3B). The test of different total amount showed almost no difference between filter paper loads of 100 and 300 μg (Figure 3A). The two separate experiments gave the same result; unimodal pattern for both amount and ratio. This pattern is also seen in the other systems (Löfstedt, 1990).

Nesbitt et al. (1979) identified two major components in both female gland extracts and in female effluvia from *C. partellus*. However, they could only confirm a positive attraction effect for one of the components (*Z*11–16:Ald). Additions of the corresponding alcohol (*Z*11–16:OH) reduced the attraction. Our results

confirm the presence of these two major components in the gland extracts but, in contrast, indicate that both components are needed to achieve a high male response. The pheromone of *C. partellus* includes two major components; *Z*11–16:Ald and the corresponding alcohol *Z*11–16:OH, indicating a shared biosynthetic pathway.

The two pheromone components have also been identified in other *Chilo* species. *Z*11–16:OH is the major component of the sex pheromone of *C. infuscatellus* identified by Wu et al. (1984). A mixture of *Z*11–16:Ald and *Z*13–18:Ald was first identified as the female sex pheromone of the rice stem borer moth, *Chilo suppressalis* (Walker) (Nesbitt et al., 1975; Ohta et al., 1976). It was later shown that a synthetic two-component blend was less attractive in the field than live virgin females, although both components were shown to be essential for male attraction. A positional isomer of *Z*11–16:Ald, i.e., *Z*9–16:Ald, was later identified as a third pheromone component which drastically enhanced attractiveness to male moths in the field when combined with the two previously identified components (Tatsuki et al., 1983). However, in *C. partellus* we have no evidence that any of the minor gland constituents of the female have a positive effect on male pheromone attraction (Svensson et al., unpublished data).

Difference in Signaling Width of Production and Response

In most mating systems, the reproductive success of a male can be measured by the number of females he inseminates. In addition, the often strikingly male-biased operational sex ratio (OSR) in most insect species further rewards male reproductive strategies that lead to detection of as many females as possible (Emlen and Oring, 1977; Ims, 1988). In female-produced pheromone systems, the male detection propensity may be interpreted as the male response window. A male that is broadly tuned to female signals will probably have a greater chance of finding mates than a more finely tuned male, depending on female population variation. However, there may be a trade-off between the width of the male response window and his overall sensitivity (Svensson, 1996a), as well as a stabilizing or directional selection on male response if responding to sympatric species or different ecological races (Phelan, 1992). The differences in signaling width (2σ) between female pheromone production and male response in *C. partellus* seems to follow these predictions. The male response window is, however, not always much wider than the female production, as is the case in *Pectinophora gossypiella* (Figure 8). This may be explained by factors such as differences in the pheromone chemistry (*P. gossypiella* uses an easily controlled ratio between two isomers with the same vapor pressure) as well as differences in the OSR.

The aggregation pheromone systems in both *I. pini* (Figure 8) and *I. duplicatus* (Figures 1 and 2) show similar differences between production and response. The composition of pheromone components produced by males of both species is narrowly canalized ($2\sigma = 0.10$ and 0.14), whereas the response window by both

sexes in both *Ips* spp. is much wider ($2\sigma = 0.5$ and 0.3–0.8) (Table 1 and Figure 8). Schlyter and Birgersson (1989) quantified variation in amounts in samples of lepidopteran sex pheromones and in scolytid bark beetle aggregation pheromones. They found the coefficient of variation to be significantly higher in scolytid samples ($N = 9$) for the amounts of pheromone components than in moths ($N = 15$). This finding seems to contrast with the data on proportions of components quantified here. However, Schlyter and Birgersson (1989) did not find any difference between variation in proportions of components ($n_{\text{moths}} = 13$, $n_{\text{bark beetles}} = 6$) in samples from the two taxa. Thus, irrespective of the sex and taxa of the communicating insect, the responder seems be less precise than the sender. Interestingly, the absolute values estimated from both moths and bark beetles by our method were $2\sigma \leq 0.15$ for production but 0.3–0.8 for response. This fact may reflect both a common basic structure of constraints in these communication systems as well as the generality of our model.

A direct comparison of the descriptive and analytical power of our method is not possible as few authors have quantified widths of signaling windows, but our successful quantification of 26 profiles in 13 populations from 9 species indicates a rather wide usefulness.

Acknowledgments—We thank our colleagues in Lund and Alnarp for fruitful discussions of an early draft and Dr. A. El-Zayed for suggestions on a later draft, Mr. Erling Jirle for bark beetle breeding, and Ms. Eva Annerfeldt for field bait preparation. Dr. Marie Bengtsson supplied moth test solutions. We are grateful to Mr. Guang-Tian Liu (Baiyinaobao) and Mr. Dong Chu (Shenyang) for assistance in the field. Field work in China was partly supported by the Ministry of Forestry, Peoples Republic of China. We appreciate the financial support of the SAREC and NFR projects.

(Received June 12, 2000; accepted March 11, 2001)

Abstract—The response of plants to many phytochemicals changes from stimulatory to inhibitory as the concentration of the phytochemical increases. In this paper, a previous biological response model is extended to yield estimates of plant responses to changes in phytochemical concentrations in the case of density-dependent phytotoxicity. This requires a knowledge of plant densities, phytochemical concentrations in soil, and the relationship between the two. According to this model extension, inhibition is a probable outcome in density-dependent chemical interference, but phytotoxic effects may become stimulatory as plant density increases. In addition, low phytochemical concentrations in soil may cause an increase in the slope of the biomass–density relationship compared to the slope of control treatments. Experimental data from the literature support this model extension, and in several cases density-dependent chemical interference can be estimated mathematically.

Key Words—Chemical interference, phytotoxicity, competition, model, density, biological response, plant–plant interactions.

INTRODUCTION

To date, only a few methods have been described to distinguish the effects of chemical interference from those of resource competition (Lockerman and Putnam, 1981; Weidenhamer et al., 1989; Nilsson, 1994; Pellissier, 1995; Weidenhamer, 1996; Wu et al., 2000). The methods described are suitable only in certain situations. Growth experiments that utilize the density-dependent nature of phytotoxic effects can be used when the source of phytotoxins is independent of the activity of target plants

* e-mail: aki.sinkkonen@utu.fi

and phytotoxins are homogenously distributed in the environment (Weidenhamer et al., 1989; Thijs et al., 1994; Weidenhamer, 1996; Wu et al., 2000). Examples of such situations are monocultures under phytotoxic exposure or vegetation growing beneath allelopathic trees.

Weidenhamer et al. (1989) expressed the density-dependent nature of phytotoxic interactions as a graphic model (Figure 5 in Weidenhamer et al., 1989). In this model, the relationship between log mean plant weight and log plant density is linear if direct chemical interference does not exist. If chemical interference exists, the log-weight–log-density slope shifts downwards as plant density decreases or phytotoxin concentration increases in the substratum. In other words, the fewer individuals that share the toxins, the more their total response is affected. If the concentration is sufficiently high, growth may be completely inhibited at low plant densities. Weidenhamer et al. (1989) presented several data sets in support of their model, with varying target species, effective chemicals, harvest times, plant densities, and rates of phytotoxins.

Carballeira et al. (1988) modeled plant responses to varying allelochemical concentrations graphically. They proposed that the response is stimulatory at low concentrations, reaches a maximum at a certain concentration, becomes inhibitory as the concentration increases, and ends in total inhibition. An et al. (1993) presented the phenomenon as a mathematical model, based on enzyme kinetics. In this model, the biological response (P) to an allelochemical is the difference between biological responses to the stimulatory (S) and inhibitory (I) attributes of the allelochemical:

$$P_x = 100 + S_x - I_x \tag{1}$$

$$= 100 + \frac{S_m X^q}{(K_S)^q + X^q} - \frac{I_m X^q}{(K_I)^q + X^q} \tag{2}$$

in which 100 is the control (%), P_x is the biological response at concentration X, S_x is the stimulatory attribute at concentration X, S_m is the stimulatory response at saturating concentration, and K_S is the concentration at which $S = S_m/2$. The term q is a constant that controls the shape of the curve and is connected to the number of active sites per enzyme molecule for the substrate. I_x, I_m, and K_I are the respective parameters of the inhibitory attribute (An et al., 1993).

In this article, the biological response model of An et al. (1993) is combined with the density-dependent model of Weidenhamer et al. (1989). The resulting extension of the biological response model is applied to data presented by Hoffman and Lavy (1978), Andersen (1981), Weidenhamer et al. (1989), and Thijs et al. (1994). Finally, some practical and theoretical implications of the model extension are discussed.

METHODS AND MATERIALS

Description of Model Extension. It is hypothesized that the models of both Weidenhamer et al. (1989) and An et al. (1993) are applicable. The model of An et al. (1993) presents the biological response of plants to varying phytochemical concentrations. The density-dependent model by Weidenhamer et al. (1989) is based on the dilution of these phytochemical concentrations. Obviously, such dilution occurs when all plants try to take up the same phytochemicals at any plant density. When N plants compete for the same phytochemicals, any one of them cannot take up more than one Nth of those phytochemicals. If plants differ in size or activity, some of them may absorb more than others, but the mean exposure to phytochemicals does not change significantly when the model of Weidenhamer et al. (1989) is applicable (see Weidenhamer et al., 1989; Thijs et al., 1994; Wu et al., 2000). Thus, the phytochemical concentration X_i per plant at density i is a fraction (or multiple) of a known concentration X_0 per plant at a known number of individuals (N_0). As a result, there is a linear correlation

$$X_i = \frac{N_0 X_0}{N_i} \tag{3}$$

between the concentration at density 0 and the concentration at density i. X in equation 2 can therefore be replaced with X_i in equation 3:

$$P_{itot} = C_{itot} + \frac{S_m(N_0X_0/N_i)^q}{(K_S)^q + (N_0X_0/N_i)^q} - \frac{I_m(N_0X_0/N_i)^q}{(K_I)^q + (N_0X_0/N_i)^q} \tag{4}$$

Equation 4 computes the total response (P_{itot}) of treated plants compared to a control treatment (C_{itot}) at density i. Note that equation 2 is expressed in percentages, but equation 4 is not. Note also that the model of Weidenhamer et al. (1989) considers the responses of individual treated plants at a range of densities where total biomasses are constant ($= C_{0tot}$) in control treatments. Therefore, P_{itot} is divided by the plant number (N_i) at density i, giving the final model (Figure 1):

$$P_i = C_i + \frac{\frac{S_m(N_0X_0/N_i)^q}{(K_S)^q + (N_0X_0/N_i)^q} - \frac{I_m(N_0X_0/N_i)^q}{(K_I)^q + (N_0X_0/N_i)^q}}{N_i} \tag{5}$$

C_i is the response of an average control plant at density i. If total plant biomasses are C_{0tot} in control treatments, C_i is a fraction (or multiple) of C_{0tot}:

$$C_i = C_{0tot}/N_i \tag{6}$$

Note that if $S_x > I_x$, $P_i > C_i$, and if $N_i \to \infty$, $(P_i - C_i) \to 0$. Note also that if $X_{iSOIL} < X_{jSOIL}$, then $N_{P_i=C_i} < N_{P_j=C_j}$, where the subscript *SOIL* refers to phytochemical concentration in soil and $i > 0$. Equations 3 and 6 must be true only at

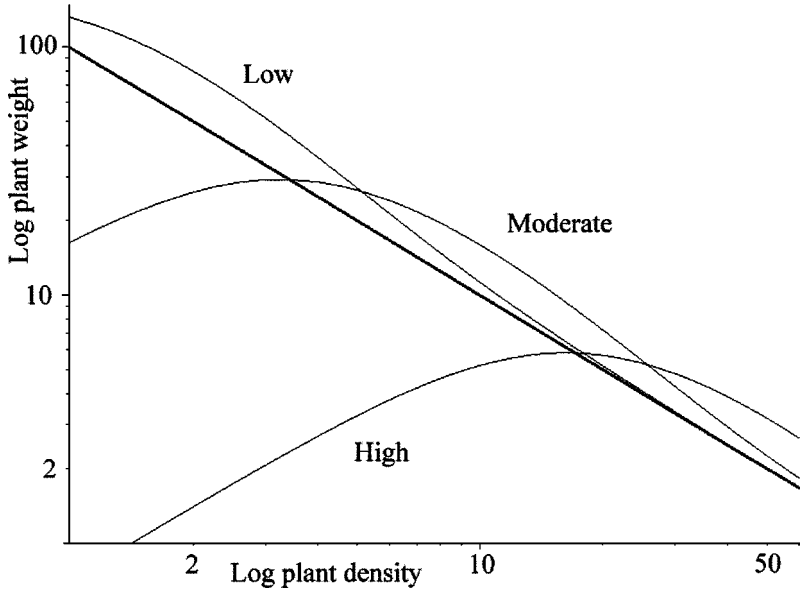

FIG. 1. Response of individual plants to plant density in arbitrary units at three phytotoxin concentrations. Straight line = nontreated controls. Default parameter values are $C_i = 100/N_i$, $N_0 = 1$, $q = 2$, $S_m = 100$, $I_m = 200$, $K_S = 5$ and $K_I = 30$. X_0 (low) = 20; X_0 (moderate) = 100; X_0 (high) = 500.

the densities and concentrations used. If $C_{itot} \neq C_{0tot}$, equation 6 may be redefined to suit the current situation.

Application of Model Extension. To examine the validity of the model, parameters were derived to suit data by Hoffman and Lavy (1978), Andersen (1981), Weidenhamer et al. (1989), and Thijs et al. (1994). Lagrangian interpolation and the Levenberg-Marquardt nonlinear regression were used to determine models for control treatments. The NLIN Procedure in SAS System for Windows Release 8 (SAS Institute Inc., Cary, North Carolina) was used to iterate all model parameters that minimized the difference between actual data values and the corresponding estimates of the used model. Finally, Pearson correlation coefficients were used to verify the accuracy of each model.

RESULTS

The effects of metribuzin residues on the yield of soybean (*Glycine max* L.) (Andersen, 1981) and the response of oat (*Avena sativa* L.) to atrazine (Hoffman and Lavy, 1978) have been parameterized (Figures 2 and 3). The lowest oat density

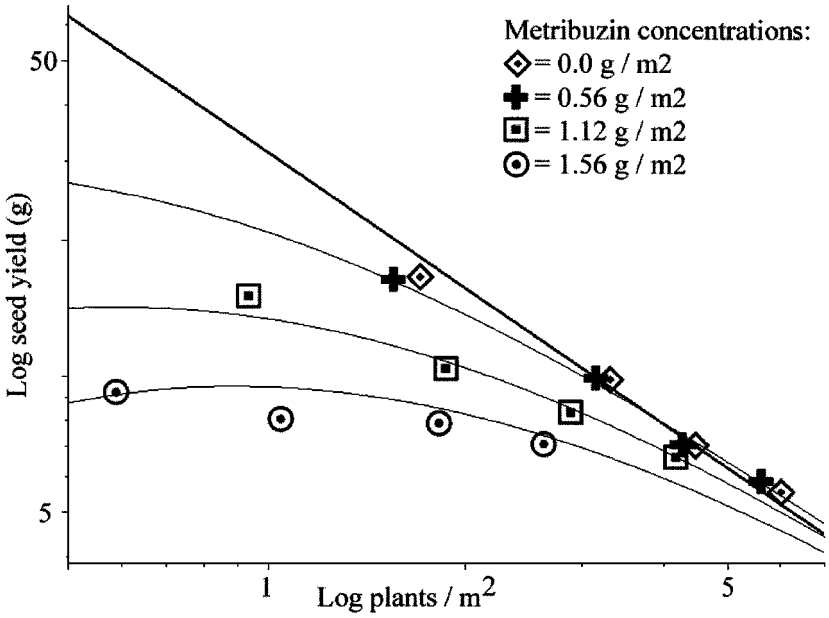

FIG. 2. Relationship of log plant density and log mean seed yield of individual soybean plants in the presence of residues of metribuzin. $C_i = 31.38/N_i . q = 1.11$, $S_m = 7.17$, $I_m = 40.35$, $K_S = 0.039$, $K_I = 0.73$, $N_0 = 1. r = 0.98$, $P < 0.001$. Values have been calculated from Andersen (1981).

(20 plants/pot) was excluded from analysis due to the exceptionally low dry weight of the control treatment (see Discussion).

Figure 4 shows the parameters modeled for soybean biomass at varying atrazine concentrations in a target-neighbor design by Thijs et al. (1994), where soybeans grew as neighbor plants and phytochemicals were added to the soil every other day. Competitive and chemical interference by the target plant, maize (*Zea mays* L.), decreased the suitability of the model extension at the lowest neighbor plant density, because the impact of the target plant increased as the number of neighbor plants decreased (see Niemeyer, 1988; Thijs et al., 1994). The lowest soybean density was, therefore, excluded from the analysis after many unsuccessful attempts ($P > 0.05$).

Figure 5 shows the parameters derived for shoot dry weights of bahiagrass (*Paspalum notatum* Fluegga) grown for five weeks in soil that had been treated with gallic acid and hydroquinone (Weidenhamer et al., 1989). It was not possible to calculate single parameters (see Discussion). Instead, the biomasses at different phytochemical concentrations of the substratum followed separate parameter values.

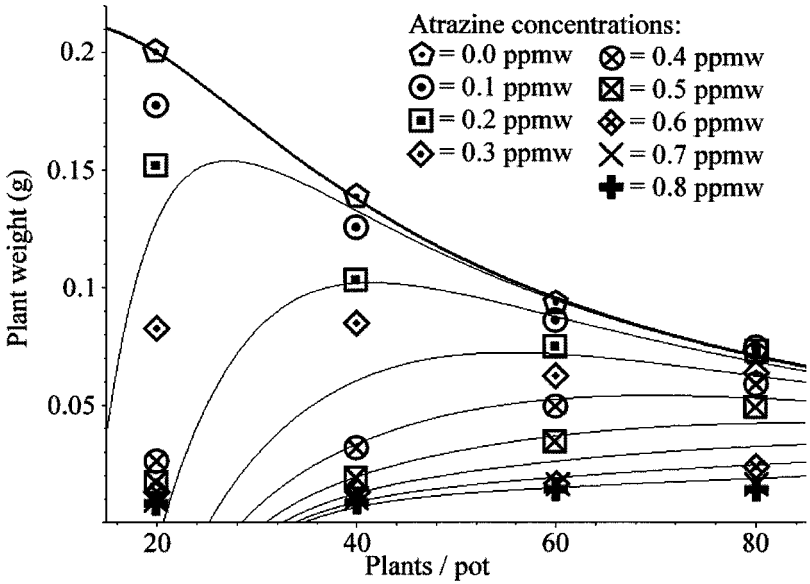

FIG. 3. Relationship of plant density and mean weight of individual oat plants grown in soil treated with atrazine. $C_i = 0.214 - 0.207^* e^{-196.16^* N_i^{-1.43}}$, $N_0 = 1, q = 3.21, S_m = 8.74$, $I_m = 14.2, K_S = 0.0065, K_I = 0.0067. r = 0.97, P < 0.001$. Values have been calculated from Hoffman and Lavy (1978).

DISCUSSION

Benefits of the Present Model. This extension of the model of An et al. (1993) is useful when estimating whether the response of plants to direct chemical interference can be distinguished from pure competition (Figures 2–5). In addition, this model extension attaches (both graphically and mathematically) growth-promoting interactions to the model of density-dependent phytotoxicity by Weidenhamer et al. (1989). They were aware of the possibility of growth- promoting chemical interference but did not include it in their graphic model. In density-dependent chemical interference, stimulatory effects do not necessarily differ greatly from the slope of control treatments at any plant density. The possibility of chemical interference should, therefore, be taken into consideration in cases where it may have been excluded previously.

This extension of the model of An et al. (1993) also has other benefits compared to the graphic model of Weidenhamer et al. (1989). The model extension does not require logarithmic conversion of the data. The best fit of the control treatments can be calculated with or without any conversion, and the result can be

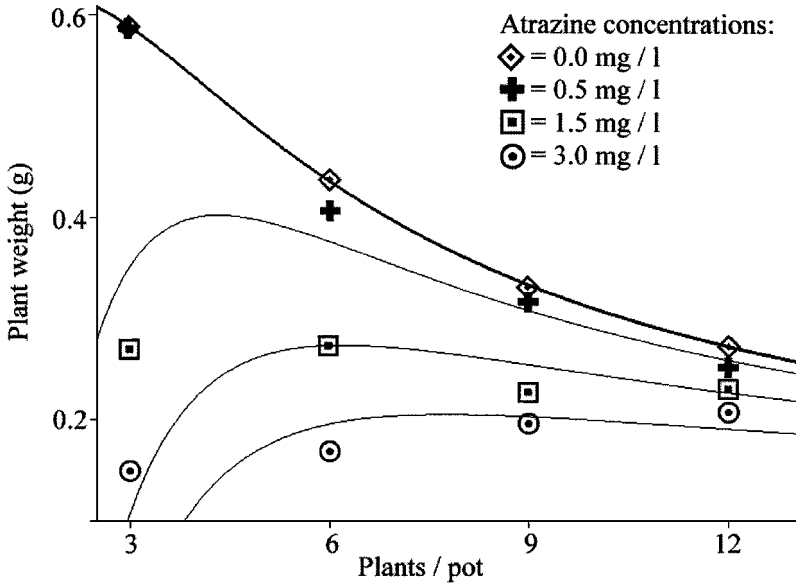

FIG. 4. Relationship of soybean density and individual soybean dry mass when corn was planted as target species and soil solution was treated with atrazine. $C_i = 0.627 - 0.525^* e^{-11.70^* N_i^{-1.37}}$. $N_0 = 1$, $q = 1.052$, $S_m = 4.545$, $I_m = 6.877$, $K_s = 0.143$, $K_I = 0.194$, $r = 0.98$, $P < 0.001$. Data from Thijs et al. (1994).

used as C_i in equation 5. If plants share most active chemicals at low densities, this model extension may not be limited to the densities of equal total plant biomasses in control treatments.

Limitations of the Present Model. Very high phytochemical concentrations and very low plant densities may not fit into this model extension. Plants may be so small or distances so great that phytochemicals cannot be diluted. Those conditions may create phytochemical-poor patches around plant roots that can be utilized with minor phytotoxic effects. A possible example of such conditions is the oat–atrazine bioassay by Hoffman and Lavy (1978). The dry matter of the control plants at the lowest density was two thirds that of the dry matter of control plants at other densities, and none of their treatments ended up in total growth inhibition (Figure 3). In addition, in that experiment, the seed number was approximated and no replacements of nongerminated seeds were made, which may negatively affect the accuracy of the parameters modeled.

The sensitivity of plants to phytochemicals may vary among treatments due to density-dependent stress (see Reigosa et al., 1999). The significance of such stress probably changes when the total dry matter of the treated plants has

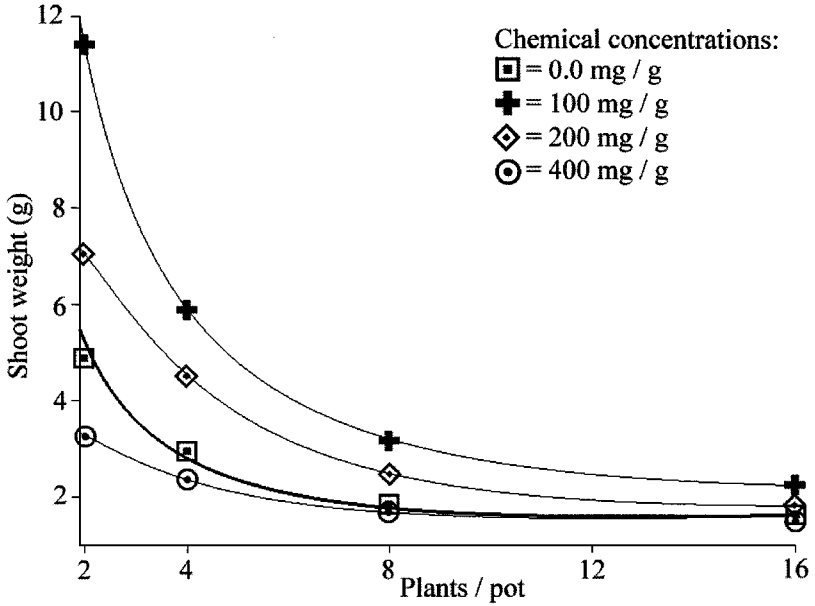

FIG. 5. Shoot dry weight of bahiagrass individuals grown in soil treated with gallic acid and hydroquinone. $C_i = 10.21/N_i + N_i/16.16$, $N_0 = 1$; ✚ : $q = 0.60$, $S_m = 32.91$, $I_m = 51.04$; $K_S = 1.16$ and $K_I = 42.80$; ◈ : $q = 1.51$, $S_m = 18.00$, $I_m = 33.79$; $K_S = 2.98$ and $K_I = 15.00$; ⊙ : $q = 1.15$, $S_m = 23.50$, $I_m = 39.55$; $K_S = 21.68$ and $K_I = 30.37$. $r = 1.00$, $P < 0.001$. Data from Weidenhamer et al. (1989).

reached its maximum. In accordance with that assumption, the lowest density could not be parameterized in the atrazine bioassay by Hoffman and Lavy (1978) (Figure 3), and the biomasses of the two lowest surviving plant densities possibly raised parametrized slopes in the metribuzin bioassay by Andersen (1981) (Figure 2).

The degradation of phytochemicals may also depend on the plant density or phytochemical concentration in the soil. For example, the quality of phytochemicals varied among treatments in the bahiagrass experiment by Weidenhamer et al. (1989). Hence, it was not surprising that common parameters could not be iterated for all three used phytochemical concentrations in that study. Instead, every concentration fit excellently in concentration-specific model parameters, as predicted by the present model (Figure 5). On the other hand, if the proportion of degraded phytochemicals was the same at all densities and concentrations used, and if the biological response of plants to phytochemicals was relatively linear at all occurring concentrations (see An et al., 1993), it should be possible to find common parameters for all treatments. The atrazine bioassay by Andersen (1981) may be

an example of such a situation, since single parameters were found even though atrazine probably degraded during the growing season (Figure 2).

When bioassays are conducted to study density-dependent chemical interference, it is essential to be aware of the other limitations of this model extension. Stimulatory effects may be slight due to intensive resource competition and other stress factors. More than one trend in the availability and activity of phytochemicals may be involved (see Gerig and Blum, 1991). In addition, the organisms studied may be autotoxic (Hall, 1989; Choesin and Boerner, 1991; Hedge and Miller, 1992). In general, as a consequence of any of these reasons, the results of a bioassay may not show parametrizable nonlinear weight–density slopes. In such cases, it may still be possible to determine graphically whether or not chemical interference is significant in a bioassay (see Weidenhamer et al., 1989) (Figure 1).

Implications of the Present Model. The case studies presented in this paper satisfy many of the assumptions of this model extension. When phytochemicals were added regularly, uniform parameters could be determined (Figure 4); when phytotoxins degraded nonlinearly, uniform parameters could not be found (Figure 5). Furthermore, changes in resource availability per plant affected the accuracy of the parameters modeled (Figure 3). However, bioassays designed to test this model extension are useful if we want to know whether or not the parameterization of a data set is actually due to the phytochemicals themselves. A time series of phytochemical concentrations in the soil may be a useful way to test the validity of this model in density-dependent growth experiments. If the assumptions of the model extension are true, uniform parameterization of randomly degrading phytochemical concentrations in the soil (with respect to original concentrations at different plant densities) will not be possible, but similarly degrading phytochemical concentrations may or may not be parameterized with single parameters depending on the linearity of the slope of plant responses to phytochemical concentrations (see An et al., 1993).

Based on the examples presented in this paper, the biological response model by An et al. (1993) is suited for modeling plant responses to density-dependent chemical interference. However, it may be possible to modify the model equations in some cases. First, equation 3 may be modified if an environmental factor, such as absorption of phytochemicals by soil particles or degradation of phytochemicals by soil microorganisms, alters the equation in a predictable way. Second, it may be possible to add a density-dependent stress factor to the model. This stress factor would change the power of stimulatory and inhibitory attributes at different plant densities. However, every modification must be based on empirical data showing a distinctive pattern that can be modeled.

One of the major problems in allelopathic studies has been the impossibility of estimating the role of rhizosphere microorganisms in allelopathic phenomena (Williamson and Weidenhamer, 1990; Inderjit and Dakshini 1995; Pellissier and Souto, 1999; Blum et al., 2000). In density-dependent chemical interference, the

phenomena observed may be affected by the quality, quantity, and patchiness of rhizosphere microorganisms, together with plant density, plant size, and phytochemical concentration. It is impossible to know whether this occurred in the examples presented in this paper. An appropriate method for testing the influence of soil microorganisms might be to measure the concentrations of potential phytochemicals in the soil as a time series in the presence and absence of rhizosphere bacteria and to compare this time series to parameterized plant responses in both situations.

Weidenhamer et al. (1989) speculated on the possible ecological implications of the density dependence of phytotoxic effects on the target species. Since stimulatory effects may exist regularly in the field, and since the balance between stimulation and inhibition depends on both plant density and the phytochemical concentration in the soil, the consequences of the effects of phytochemicals may perhaps be more diverse than has previously been assumed. The target species may, for instance, tend to evolve towards stimulation at higher phytochemical concentrations. In that case, however, the stimulatory effects will probably be weaker at low concentrations. Thus, the opposite of improved tolerance is also possible if plant densities are permanently high or phytochemical concentrations low. It may, therefore, be difficult to identify evolutionary adaptations to phytotoxicity without a detailed knowledge of the characteristics of every population and every chemical involved.

(Received September 20, 2000; accepted March 11, 2001)

Abstract—We examined 40 taxa from nine genera within the subfamily Mimosoideae; 29 (73%) from six genera produced carbon disulfide (CS_2). In addition, 19 of 40 taxa (48%) produced carbonyl sulfide (OCS). Of nine mimosoid taxa that produced CS_2, all possessed a djenkolic acid and a cysteine lyase. Of three mimosoid taxa that did not produce CS_2, two lacked a cysteine lyase and one lacked both a lyase and a djenkolic acid. Of 16 taxa from 14 genera from the other two subfamilies of the Fabaceae, the Caesalpinioideae and Papilionoideae, none produced CS_2. The results suggest that CS_2 production is common in the Mimosoideae and uncommon in the Caesalpinioideae and Papilionoideae and that plants in the Mimosoideae that do produce CS_2 must possess both a djenkolic acid and a cysteine lyase for this production to occur.

Key Words—Carbonyl sulfide, cysteine lyase, djenkolic acid, organic sulfide.

INTRODUCTION

The family Fabaceae consists of three subfamilies, the Caesalpinioideae, Mimosoideae, and Papilionoideae. When the roots of some plants in the Fabaceae are injured or wetted, they produce carbon disulfide (CS_2), a volatile, toxic, foul-smelling liquid (Haines et al., 1987, 1989; Hartel and Reeder, 1993; Feng and Hartel, 1996). Within the Mimosoideae, the presence of CS_2 has been reported in *Acacia pulchella* R. Br. (Whitfield et al., 1981), *Enterlobium cyclocarpum* (Jacq.) Griseb., *Leucaena multicapitula* Schery, *Mimosa pigra* L.,

Pithecellobium arboreum (L.) Urban [=*Cojoba aborea* (L.) Britton & Rose], *Pithecellobium catenatum* Donn. Sm., *Pithecellobium pedicellare* Ajillo, *Stryphnodendron excelsum* Harms (Haines et al., 1987, 1989), *Mimosa pudica* (L.) (Hartel and Reeder, 1993), and all known *Leucaena* spp. (Feng and Hartel, 1996). Within the Caesalpinioideae and Papilionoideae, the presence of CS_2 has been reported in *Gliricidia sepium* (Jacq.) Kunth ex. Walp. (Haines et al., 1987), *Medicago sativa* L., *Phaseolus* sp., and *Pisum* sp. (Westberg and Lamb, 1984). Thus, it appears that the presence of CS_2 is potentially common in the Fabaceae.

Our studies with the roots of the mimosoid species *M. pudica* suggest that CS_2 is produced through the hydrolysis of a djenkolic acid by a cysteine lyase (Piluk et al., 1998). Djenkolic acid [3,3′-methylenedithiobis(2-aminopropionic acid)] is a nonprotein, sulfur amino acid consisting of two cysteine molecules bound at the sulfhydryl groups by a C atom. With regards to djenkolic acid, many other mimosoid species contain djenkolic acid or its analogs, including *Acacia acapulcensis* Kunth (Evans et al., 1993), *Acacia farnesiana* (L.) Willd. (Gmelin et al., 1962), *Acacia georginae* F.M. Bailey (Ito and Fowden, 1972), *Acacia lemmonnii* Rose (Gmelin, 1959), *Acacia saficina* Lindley (Seneviratne and Fowden, 1968), *Acacia willardiana* Rose (Gmelin, 1959), *Albizia lophantha* (Willd.) Benth. [=*Paraserianthes lophantha* (Willd.) I. Nielsen subsp. *lophantha*] (Gmelin et al., 1957), *Desmanthus brachylobus* Benth. (von Krauss and Reinbothe, 1970), *Desmanthus chacoensis* Burkart (von Krauss and Reinbothe, 1970), *Desmanthus depressus* Hook & Berneby ex. Willd. (von Krauss and Reinbothe, 1970), *Desmanthus virgatus* (L.) Willd. (von Krauss and Reinbothe, 1970), *Dichrostachys glomerata* (Forsskal) (Gmelin et al., 1962), *Neptunia gracilis* Benth. (von Krauss and Reinbothe, 1970), *Piptadenia macrocarpa* Benth. (von Krauss and Reinbothe, 1970), and *Pithecellobium lobatum* Benth. (von Krauss and Reinbothe, 1970). With regards to a cysteine lyase, seeds (Gmelin et al., 1957) and roots (Schwimmer and Kjaer, 1962) of *Albizia lophantha* and the roots of *A. julibrissin* Durazz. (Mazelis and Fowden, 1973) and *Acacia farnesiana* (Mazelis and Creveling, 1975) possess *S*-alkyl cysteine *a-b* lyase (EC 4.4.1.6). It may be that production of CS_2 through the hydrolysis of a djenkolic acid by a cysteine lyase is the general mechanism for CS_2 production in the Fabaceae.

The objectives of this study were twofold: (1) to determine how common CS_2 production was in plant species within the Fabaceae, and (2) to determine from a select subset of CS_2-producing plants if this production was always associated with the presence of a djenkolic acid and a cysteine lyase. To do this, plants of 40 species from 9 genera within the subfamily Mimosoideae and 16 species from 14 genera in the subfamilies Caesalpinioideae and Papilionoideae were selected for testing. Because microorganisms can produce CS_2 (Kelly and Smith, 1990), all plants were grown gnotobiotically.

METHODS AND MATERIALS

For the taxa surveyed, seeds were obtained from Banco Latinoamericano de Semillas Forestales, Centro Agronomico Tropical de Investigacion y Ensenanza (CATIE); J. L. Hudson, Redwood City, California; GoldKist Farm and Garden, Athens, Georgia; Oxford Forestry Institute, Oxford, United Kingdom; Peter B. Dow Seed Company, Gisborne, New Zealand; Southern Regional Plant Introduction Station, Griffin, Georgia; Vaughan's Seed Company, Downers Grove, Illinois, and the seed collection at the University of Georgia. In addition, researchers collected seeds of various species for us from Costa Rica, Georgia (USA), Guatemala, India, and Senegal.

To increase germination rates, seeds possessing a thick seed coat (>0.5 mm) were scarified around their edges with fine sandpaper (220 grit) until the endosperm or cotyledon was just visible; areas adjacent to the hilum were not scarified. Seeds with thin and thick seed coats were surface-sterilized with 0.7 *M* NaOCl for 15 and 30 min, respectively and germinated on water agar (15 g agar per liter of distilled water) until the radicles emerged. Individual seedlings were aseptically transferred to gnotobiotic plant assemblies (Hartel et al., 1993) supplying both macro- (McClure and Israel, 1979) and micronutrients (Ahmed and Evans, 1960). Plants were grown under metal halide lights with an average light intensity of 550 μmol photons/m^2/sec. Average day/night temperatures on a 16L:8D cycle were 26 and 24°C, respectively.

Potential maximum production of CS_2 was quantified by using a sulfur-specific gas chromatograph calibrated against a CS_2 permeation standard as described by Piluk et al. (1998). The low limit of detection for CS_2 was 0.1 ng/ml. Some plant species also produced carbonyl sulfide (OCS), hydrogen sulfide (H_2S), methane thiol (CH_3SH), ethane thiol (CH_3CH_2SH), or a mixture of these gases. When detected, these compounds were also quantified against the appropriate permeation standard. The low limits of detection for OCS, H_2S, CH_3SH, and CH_3CH_2SH were 0.2, 0.2, 0.2 and, 0.5 ng/ml, respectively.

The presence of a cysteine lyase among a select group of CS_2-producing plants was determined as described by Piluk et al. (1998). The presence of a djenkolic acid among the same group of plants was determined using high-performance liquid chromatography with modifications of the methods of Bidlingmeyer et al. (1984) and Randle et al. (1995) as described in Piluk et al. (1998). *Mimosa pudica* was the positive control, and *Glycine max* (L.) Merr. and *Pisum sativum* L. Alaska were the nonmimosoid, non-CS_2-producing controls.

RESULTS

Of 40 taxa from nine genera within the subfamily Mimosoideae, 29 taxa (73%) from seven genera produced CS_2 from their roots (Table 1). In addition,

Dow Seed Company, Gisborne, New Zealand; 3, Southern Regional Plant Introduction Station, Griffin, Ga.; 4, Banco Latinoamericano de Semillas Forestales, Centro Agronomico Tropical de Investigacion y Ensenanza (CATIE); collected from: 5, Costa Rica; 6, Georgia (USA); 7, Guatemala; 8, Senegal; or 9, India.
[b] ND, none detected.
[c] Traces of hydrogen sulfide detected.
[d] Traces of methane thiol detected.
[e] Traces of ethane thiol detected.

18 of 40 (45%) taxa produced OCS from roots. No taxon produced OCS without also producing CS_2. Of three *Albizia* species, only *A. lophantha* produced CS_2 and OCS from roots. Of 24 *Acacia* taxa, 20 (84%) produced CS_2 from their roots and 12 (50%) also produced OCS. Roots of *Desmanthus virgatus* produced the highest amounts of both CS_2 and OCS. Only two species, *Desmanthus illinoensis* (Michaux) MacMillan ex. Robinson & Fern. and *D. velutinus* Scheele, produced CS_2 and OCS from shoot tissues (includes cotyledons), and these were detected in only trace amounts. Of the 29 mimosoid taxa that produced CS_2, individuals of 17 taxa (59%) produced CS_2 every time. In the remaining 12 taxa, CS_2 production was variable and at least one or more individual plants did not produce CS_2.

Hydrogen sulfide was also produced from the roots of *Acacia* x *giraffae* Willd. (2.4 ± 1.2 ng/mg dry root) and *Pithecellobium elegans* Ducke (3.1 ± 2.3 ng/mg dry root), and occasionally in the roots of *Acacia dealbata* (Link.), *Acacia farnesiana, Acacia nilotica* (L.) Willd. ex. Del., and *Desmanthus illinoensis*. The roots of some mimosoid taxa also produced trace amounts of methane thiol (*Acacia melanoxylon* R. Br. and *Acacia nilotica*) and ethane thiol (*Acacia caffra* (Thunb.) Willd. and *Acacia nilotica*). With the exception of *Acacia* x *giraffae* and *Pithecellobium elegans*, not every individual plant was positive for these trace gases.

Of 15 species from 14 genera in the subfamilies Caesalpinioideae and Papilionoideae, none produced CS_2 (data not shown). These were *Caesalpinia ferrea* C. Martius ex. Tul., *Cercidium microphyllum* (Torrey) Rose & I.M. Johnson, *Clianthus formosus* (G. Don) Ford & Vick, *Crotalaria longirostrata* Hook. & Arn., *Dalea purpurea* Vent., *Desmodium gangeticum* (L.) D.C., *Desmodium incanum* D.C., *Gledistia triacanthos* L.f. *inermis* (L.) C. Schneider, *Gliricidia sepium, Glycine max, Parkinsonia aculeata* L., *Pisum sativum* Alaska, *Schizolobium parahyba* (Vell. Conc.) S.F. Blake, *Sesbania formosa* (F. Muell.) N. Burb., and *Vigna acontifolia* (Jacq.) Marechal. Incidental, trace amounts of methane thiol were detected in the roots of some individuals of *S. parahyba*, and ethane thiol was detected in some individuals of *G. max* and *S. formosa*. As with some plants from the Mimosoideae, not every individual plant was positive for these trace gases.

Of nine mimosoid taxa that produced CS_2 from roots, all showed the presence of a cysteine lyase and a djenkolic acid (Table 2). Of three mimosoid species that did not produce CS_2, two lacked a cysteine lyase and one lacked both a lyase and a djenkolic acid. Neither of the two nonmimosoid, non-CS_2-producing species examined, *Glycine max* and *Pisum sativum* Alaska, possessed a cysteine lyase or a djenkolic acid.

DISCUSSION

This is the first report of CS_2 production from the roots of *Albizia, Desmanthus, Neptunia,* and *Schrankia* species, and additional reports of CS_2

TABLE 2. CS_2 PRODUCTION, PRESENCE OF DJENKOLIC ACID, AND CYSTEINE LYASE ACTIVITY DETECTED (+) OR NOT DETECTED (−) IN ROOTS OF PLANTS WITHIN SUBFAMILY MIMOSOIDEAE[a]

Subfamily (species)	CS_2	Djenkolic acid	Lyase activity
Mimosoideae			
Acacia elata	+	+	+
Acacia x *giraffae*	+	+	+
Acacia greggii	−	+	−
Albizia julibrissin	−	−	−
Albizia lophantha	+	+	+
Desmanthus virgatus	+	+	+
Leucaena cuspidata	+	+	+
Leuceana retusa	+	+	+
Mimosa pudica	+	+	+
Neptunia dimorphantha	+	+	+
Pithecellobium elegans	+	+	+
Prosopis alba	−	+	−
Papilionoideae			
Glycine max	−	−	−
Pisum sativum Alaska	−	−	−

[a] *Mimosa pudica* was the positive control, and *Glycine max* and *Pisum sativum* Alaska were the non-mimosoid, negative controls. Authority names are given in the text and Table 1.

production from two *Pithecellobium* and 20 *Acacia* species. Therefore, of ca. 65 genera in the subfamily Mimosoideae, eight of the 10 tested genera (for a total of 50 species) produce CS_2. As with some *Acacia*, *Pentaclethra*, and *Pithecellobium* species (Haines et al., 1987), some species within a genus did not produce CS_2 (e.g., *Albizia*). One species, *E. cyclocarpum*, previously described as a CS_2 producer (Haines et al., 1987), did not produce CS_2 when grown under gnotobiotic conditions.

Of 15 gnotobiotically grown taxa from the Caesalpinioideae and Papilionoideae, none produced CS_2. Although earlier reports described CS_2 production from *G. sepium* and *Pisum* sp. (Westberg and Lamb, 1984; Haines et al., 1987), we did not observe CS_2 production when these species were tested. Although this may be because of genetic variability, a more likely possibility is that the plants in these earlier studies were grown in nonsterile soil and the soil microorganisms produced the CS_2 (Kelly and Smith, 1990).

In addition to CS_2, many plants from the subfamily Mimosoideae also produced OCS. Carbonyl sulfide is toxic, although its toxicity is only half that of CS_2 (Peyton et al., 1978). With the exception of several *Leucaena* species (Feng and Hartel, 1996) and two *Desmanthus* species, all OCS production was in the roots.

The quantitative amounts of CS_2, OCS, and trace sulfides produced from gnotobiotic plants were consistent for some species and variable for others. Reasons

for this variability are unclear but may be because of genetic variability, the labile nature of many S-containing compounds (in which the intermediate products of an enzyme reaction can often lead to more than one end product; Cavallini et al., 1980), or the highly reactive nature of S-containing gases with various materials (Kuster and Goldan, 1987). In this study, it is unlikely that environmental conditions were responsible for the variability because conditions for sulfide production were optimal (Feng and Hartel, 1996).

Within the family Fabaceae, our results suggest that CS_2 production is common in the Mimosoideae and uncommon in the Caesalpinioideae and Papilionoideae. Within the Mimosoideae, the results show that both a djenkolic acid and a cysteine lyase were required for CS_2 production. This was shown for eight of the 11 previously untested species (i.e., *Acacia elata* A. Cunn. ex. Benth., *Acacia* x *giraffae*, *Albizia lophantha*, *Desmanthus virgatus*, *Leucaena cuspidata* Standley, *Leucaena retusa* Benth., *Neptunia dimorphantha* Domin, and *Pithecellobium elegans*). Of the remaining three mimosoid species, where a cysteine lyase or a djenkolic acid or both were absent, no CS_2 production occurred (i.e., *Acacia greggii* A. Gray, *Albizia julibrissin*, and *Prosopis alba* Griseb.).

The ecological role of CS_2 in plants in the Fabaceae is probably that of a deterrent to pathogens. Carbon disulfide is bacteriostatic (Bremner and Bundy, 1974; Hartel and Haines, 1992), fungicidal (Lewis and Papavizas, 1971; Banwart and Bremner, 1975; Filip and Roth, 1977), nematicidal (Guba, 1932), and insecticidal (Punj and Girish, 1969). Carbon disulfide produced by *M. pudica* decreases fungal colonization on the rhizoplane (Feng et al., 1998). It is also possible that plant-produced CS_2 affects soil ecological processes. Carbon disulfide is a potent inhibitor of nitrification (Bremner and Bundy, 1974; Ashworth et al., 1975; Hyman et al., 1990), and if a plant could produce sufficient CS_2 to inhibit nitrification, then this could be a N-conserving mechanism. The vast majority of soils have a net negative charge, thus, NH_4^+ does not leach through these soils as readily as NO_3^-. It would not be surprising if a djenkolic acid was indeed the parent compound for all plant-mediated CS_2 production in the Mimisoideae. Mimosoid legumes are well-known for containing nonprotein amino acids, and there is considerable evidence for their functional multiplicity in physical stress, insect deterrence, and phytotoxicity (e.g., Romeo, 1998).

Acknowledgments—We thank Mark Eiteman, Orla Finlay–Moore, and Robert Potter for their technical assistance. (Received November 2, 2000; accepted April 3, 2001)

Abstract—We tested two hypotheses: 1) that there is semiochemical-mediated attraction of male and female webbing clothes moth (WCM), *Tineola bisselliella* (Hum.) (Lepidoptera: Tineidae) to suitable larval habitat; and 2) that selection of optimal larval habitat has fitness consequences. In binary or ternary choice arena bioassay experiments that prevented WCM from contacting test stimuli, males and females were attracted to dried but untanned animal pelts (red squirrel, muskrat, beaver, coyote, red fox and bobcat) and preserved horseshoe crab but not to unprocessed sheep's wool, demonstrating semiochemical-based recognition of, and discrimination between, potential larval habitats. Selection of habitat has fitness consequences for ovipositing females, because significantly more male and female WCM completed development when the larval diet consisted of intact animal pelt (hide plus hair) rather than hide or hair alone. Equal attraction of male WCM to muskrat pelt volatiles in Porapak Q or solvent extracts of muskrat pelts indicated that volatile semiochemicals could be obtained by both methods.

Key Words—*Tineola bisselliella*, Lepidoptera, Tineidae, semiochemicals, larval-habitat location, host-habitat location, dietary requirements, fitness, larval development, untanned animal pelts, fur.

INTRODUCTION

Larvae of the webbing clothes moth (WCM), *Tineola bisselliella* (Hum.) (Lepidoptera: Tineidae), develop in temporary microhabitats not exposed to direct light, including sheltered nests (Woodroffe, 1953), animal lairs (Mallis, 1969;

*To whom correspondence should be addressed.

0098-0331/01/0800-1535$19.50/0

Hill, 1990), and dry carrion (Bornemissza, 1957). Like other scatophagous and necrophagous insects, adult WCM discriminate between and select a particular stage of temporary microhabitats (Bornemissza, 1957; Read, 1958; Stafford, 1971; Anderson and VanLaerhoven, 1996). For example, tineids such as WCM appear during the dry stage of carrion when only skin, hair, bones, and a little dry flesh remain (Bornemissza, 1957; Read, 1958; Stafford, 1971), whereas dipterans arrive quickly at and colonize fresh carrion (Rodriguez and Bass, 1983; Parker, 1970; Early and Goff, 1986; Anderson and VanLaerhoven, 1996; VanLaerhoven and Anderson, 1999).

In buildings, WCM larvae may feed year round on woollen textiles and other animal-based products, such as furs and carpets causing economic depreciation of goods disproportionate to the physical damage (Roth and Willis, 1952; Hinton, 1956; Mallis et al., 1959; Baker and Bry, 1982; Story, 1985). Depreciation caused by keratophagous insects including WCM approximates one billion dollars annually in the United States alone (Metcalf and Metcalf, 1994).

In optimal larval habitat and environmental conditions, female WCM may lay up to 250 eggs in 2 weeks. Larvae hatch in 3–7 days and develop through 5 instars (Titschak, 1922; Griswold, 1944). When feeding on raw animal pelts, they spin webbing tubes close to the hide to help maintain their water balance (Chauvin and Gueguen, 1978; Chauvin et al., 1981). Consuming first the base of the hair and surface of the hide, larvae ingest mainly soft keratin while avoiding sulphur-rich hard keratin in the distal shaft of the hair. This feeding habit leads to the debriding effect often seen in museum specimens. Under favorable conditions, larval and pupal development is complete after 3–5 weeks. In sub-optimal habitats like wool fabric, development may exceed 4 years because larvae may moult $\geq$40 times and repeatedly enter diapause (Titschak, 1922; Griswold 1944; Baker and Bry, 1982).

Previous studies suggested that tactile and contact chemoreceptive stimuli mediate selection of oviposition sites by females (Kan and Waku, 1985; Tranyier et al., 1994). Chemicals in eluents of acetone-washed raw sheep's wool and high concentrations of wool wax or vegetable oil deterred oviposition, whereas yeast or feces from larvae feeding on yeast-supplemented wool induced oviposition (Kan and Waku, 1985; Tranyier et al., 1994). Both of these studies were conducted in small Petri dishes (10 cm diam.), making it difficult to discern between tactile, contact chemoreceptive, and olfactory moieties of test stimuli.

We are engaged in a large study on sonic- and semiochemical-based communication in clothes moths. Herein we report long-range attraction *sensu* Kennedy[1] (1974) of male and female WCM to larval habitat, and differential development of larvae in habitats of different quality.

[1]An organism is attracted over long range if the distance to the stimulus exceeds a few body lengths of the organism.

METHODS AND MATERIALS

Experimental Insects

WCM adults were collected in the Natural History Museum of Simon Fraser University and placed in 1-l glass containers with mesh lids at 20–25°C, 40–70% R. H. and a 10L: 14D photoperiod. Larvae were provided with either freshly sheared untreated sheep's wool (courtesy of Anne Embra, Langley Spinners and Weavers Guild, Langley, B. C.) supplemented with brewer's yeast or with untanned animal pelts (Western Canada Fur Auctions, Vancouver, B. C.). These untanned pelts were from animals trapped and skinned during the 1996-1997 season. They were skinned, stretched, scraped of flesh and fat, air dried, and stored at ≤ -1°C before use. Every day, within 3 hr after dawn, adult WCM were collected and their sex determined through the presence of claspers and aedagus (male) or ovipositor (female).

Resource-Dependent Development of Larvae

Experiment 1 tested development of larvae on three resources: muskrat hair, muskrat hide with no hair, or muskrat hide with hair (intact pelt). Six each of these three resources (treatments) were kept separately for 18 months in 1-l glass containers with mesh lids at 25°C, 70% R. H. and a 10L:14D photoperiod. To obtain experimental insects, eggs were floated in 2% formaldehyde, rinsed three times with sterile water, and transferred with a brush to filter paper-lined Petri dishes. On hatching, 50 neonate larvae were transferred to each treatment container. Eclosed males and females were removed and recorded every day until no further moths were found for 14 consecutive days. Numbers of males and females per treatment were compared using the Kruskal Wallis test with Tukey type multiple comparisons ($\alpha = 0.05$) (Zar, 1984).

Capture of Habitat-Derived Semiochemicals

Dry, untanned pelts (150 cm^2) of eight vertebrate species, as well as formaldehyde-preserved dry horseshoe crab (Table 1), all potential habitats for WCM larvae, were placed in a cylindrical Pyrex^{TM} glass chamber. For one week, charcoal-filtered, humidified air was drawn at 2 l/min with a water-aspirator through the chamber and a glass column (14 cm $\times$ 13 mm O. D.) filled with Porapak Q (50–80 mesh, Waters Associates, Inc., Milford, MA). Volatiles were eluted from the Porapak Q with 5 ml of redistilled pentane. The eluent was concentrated to 2 ml by distillation in a 30 cm Dufton column, adjusting the volatile extract so that 2 μl equalled 5 pelt (or horseshoe crab)-min of volatile collection. Untanned pelts of muskrat (40 cm^2) were also extracted in dichloromethane (Cl_2CH_2) for 10 min. The supernatant was pipetted into vials, sealed, and refrigerated until used.

TABLE 1. SUMMARY OF EXPERIMENTS INVOLVING WEBBING CLOTHES MOTHS (*T. bisselliella*) AND STIMULI TESTED IN BINARY CHOICE ARENA BIOASSAY EXPS. 2–16

Exp.	No. of replicates	Sex	Mating status[a]	Test stimuli[b]
2	6	Female	Mated	Sheep's Wool
3	6	Female	Mated	Horseshoe Crab
4	10	Female	Mated	Red Squirrel
5	6	Female	Mated	Muskrat
6	6	Female	Mated	Beaver
7	6	Female	Mated	Coyote
8	6	Female	Mated	Red fox
9	6	Female	Mated	Bobcat
10	6	Female	Mated	Mink
11	6	Male	Unknown	Horseshoe Crab
12	6	Male	Unknown	Red Squirrel
13	6	Male	Unknown	Muskrat
14	6	Male	Unknown	Beaver
15	6	Male	Unknown	Coyote
16	6	Male	Unknown	Mink

[a] Mating status of males is unknown because 2 males had been confined with 1 female to ensure mating of females.

[b] *Sheep's Wool*, from domestic sheep sheared in spring 1995, stored for one year in polyethylene bag at room temperature; *Horseshoe crabs*, *Limulus polyphemus* L. (dry, formaldehyde-preserved); *Red squirrel*, *Tamiasciurus hudsonicus* (Erxleben), Peace River District, British Columbia, 20 dorsal and ventral samples cut from separate pelts; *Muskrat*, *Ondatra zibethica* (L.), Northwest Territories, 20 dorsal and ventral samples cut from separate pelts; *Beaver*, *Castor canadensis* Kuhl, Northwest Territories, 6 dorsal samples cut from 2 pelts; *Coyote*, *Canis latrans* Say, Northwest Territories, 6 ventral samples cut from 1 pelt; *Red fox*, *Vulpes fulva* (Desmarest), Peace River District, British Columbia, 6 ventral samples cut from 1 pelt: *Bobcat*, *Lynx rufus* (Schreber), Prince George District, British Columbia, 6 ventral samples cut from 1 pelt: *Mink*, *Mustela vison* Schreber, Vancouver Island, British Columbia, 12 dorsal and ventral samples cut from 3 pelts. All pelt samples originated from specimens trapped in winter 1996, and measured 150 cm^2. Control treatments consisted of cardboard or plastic models similar in size and shape to sheep's wool, horseshoe crab, or pelts.

Arena Bioassay Experiments

Tactic responses of WCM to untanned pelt samples or dry horseshoe crabs (Table 1) paired with cardboard or plastic model control stimuli in experiments 2–16 were assessed in a closed Plexiglas™ arena olfactometer (Figure 1). Bioassay experiments in moving air olfactometers proved unsuitable (see also Trematerra and Fontana, 1996). Stimuli were suspended 2 cm above the centre of Tanglefoot-coated disks kept 80 cm apart. Volatile extracts as test stimuli (Table 2, experiments 17–26) and solvent controls were pipetted on filter paper before being tested in two-choice (experiments 17–24) or three choice (experiments 25, 26) bioassays in the same arena olfactometer. Twenty-five male or 25 female moths per replicate were released from a Petri dish in the center of the arena after a 30-min

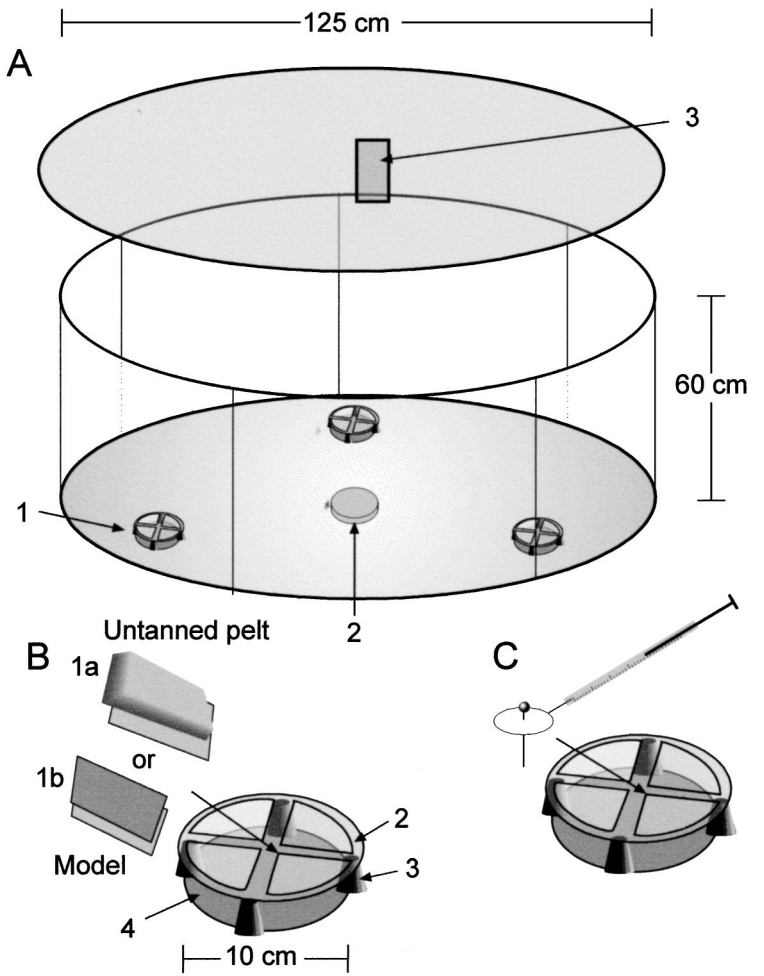

FIG. 1. Experimental design for ternary-choice arena bioassays. **A**: Plexiglas arena with capture device (1), Petri dish from which moths were released (2), and access port (3). For binary choice bioassays, one of the capture devices was replaced by the Petri dish (2) for release of moths. **B**: Capture device with animal pelt (150 cm^2) (1a, treatment) or cardboard model (1b, control) placed on a cardboard platform (2) suspended on rubber stoppers (3) (height 2.5 cm) above a Tanglefoot-coated cardboard disc (4) (10 cm diam.). **C**: Capture device with pin-supported filter paper impregnated with natural candidate semiochemicals in HPLC-grade solvent.

TABLE 2. SUMMARY OF EXPERIMENTS INVOLVING WEBBING CLOTHES MOTHS (*T. bisselliella*) AND STIMULI TESTED IN BINARY OR TERNARY CHOICE ARENA BIOASSAY EXPERIMENTS 17–26

Exp.	No. of replicates	Sex	Mating status	Experimental treatments[a]		
				Treatment 1		Treatment 2
17	10	Female	Mated	Volatiles of Horseshoe Crab		Pentane
18	10	Male	Unknown	Volatiles of Horseshoe Crab		Pentane
19	10	Female	Mated	Volatiles of Beaver Pelt		Pentane
20	10	Male	Unknown	Volatiles of Beaver Pelt		Pentane
21	10	Female	Mated	Volatiles of Red Squirrel Pelt		Pentane
22	10	Male	Unknown	Volatiles of Red Squirrel Pelt		Pentane
23	10	Female	Mated	Extract of Muskrat Pelt		Cl_2CH_2
24	10	Male	Unknown	Extract of Muskrat Pelt		Cl_2CH_2
				Treatment 1	Treatment 2	Treatment 3
25	10	Female	Mated	Extract of Muskrat Pelt	Volatiles of Muskrat Pelt	Both
26	10	Male	Unknown	Extract of Muskrat Pelt	Volatiles of Muskrat Pelt	Both

[a] In each replicate of experiments 17–24, treatment 1 received 75 horseshoe crab- or pelt-minutes of Porapak Q volatile extract; treatments 1 and 2 received the same amount of solvent ranging from 30–35 μl. In each replicate of experiments 25 and 26, treatment 1 received 10 μl (2%) of Cl_2CH_2 extract of muskrat pelt (150 cm^2) plus 30 μl of pentane, treatment 2 received 75 pelt minutes of Porapak Q volatile extract plus 10 μl of Cl_2CH_2.

acclimation period. After 12 hr, moths captured on the sticky disks were recorded as responders, whereas all other moths were collected from the arena and classed as non-responders. After completion of a replicate (a), every third replicate (b), and experiments (c), the interior surfaces of the arena olfactometer were wiped with a paper towel saturated with a Sparkleen^{TM}-solution (a, b, c), followed by hexane (b, c) and methanol (c); cleaned surfaces were allowed to dry and were ventilated for $\geq$ 7 hr (a, b) or $\geq$ 36 hr (c).

Experiments 2–16 (Table 1) tested the response of male and female WCM to potential larval habitats. Numbers of captured moths were analysed by the Wilcoxon's paired sample test for two choice experiments ($\alpha = 0.05$) and by the Kruskal Wallis test with Tukey type multiple comparisons for three choice experiments ($\alpha = 0.05$) (Zar, 1984).

RESULTS AND DISCUSSION

Most, fewer, and least adult WCM eclosed when larvae were reared on muskrat hide with hair, hide alone, and hair alone, respectively (Figure 2; experiment 1).

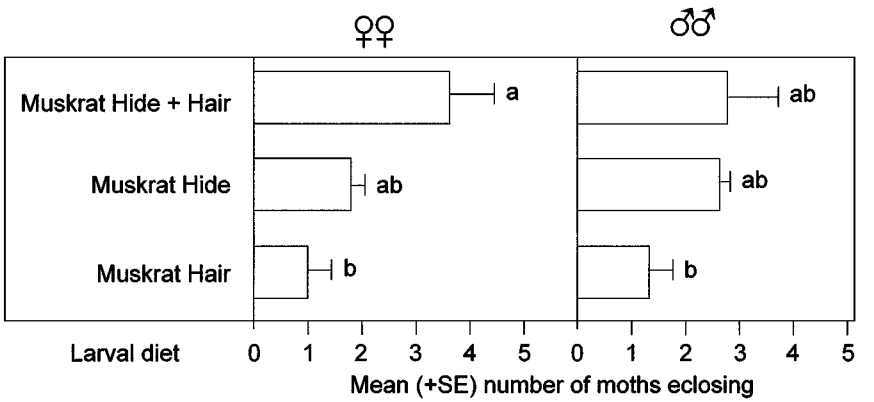

FIG. 2. Number of *T. bisselliella* completing development and emerging as adults when provided with different resources. Bars with different letters are significantly different [Kruskal Wallis test with Tukey type non-parametric multiple comparison ($P < 0.05$)].

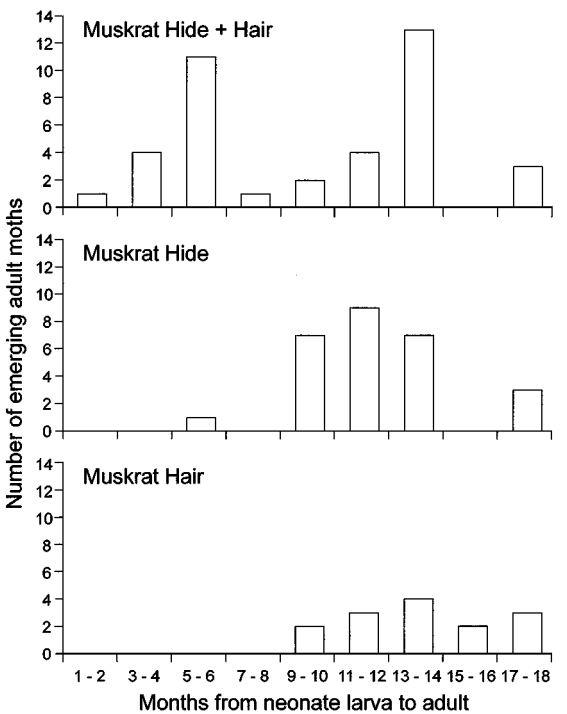

FIG. 3. Total number of *T. bisselliella* completing development and emerging as adults over time when provided with different resources.

Adult moths eclosed earlier and in greater numbers from muskrat hide with hair than from hide or hair alone, indicating that selection of suitable larval habitat has fitness consequences for ovipositing females (Figures 2, 3). Muskrat hide with hair met dietary requirements of developing larvae better than hair or hide alone. Although hair provides proteinous keratin for production of larval body mass (Cowell and McKay, 1937; Baker and Bry, 1982), hide-derived nutrients likely supplement the diet and facilitate development of larvae. B-complex vitamins and sterols essential for growth and development of insects are absent from clean animal hair (Fraenkel and Blewett, 1946) but present in vertebrate body fluids and cells (Mallis et al. 1959; Mallis et al., 1962). Untanned hide with glandular and cellular skin components contain these essential nutrients. WCM larvae ingesting these nutrients on the hide surface and soft keratin at the base of hair shafts cause the debriding effect seen on museum specimens.

The results of arena bioassay experiments provide evidence for long-range attraction[2] of both males and females to potential larval habitats. Female and male WCM were strongly attracted to preserved horseshoe crab (Figure 4; experiments 3 and 11) and pelt samples from red squirrel, muskrat, beaver, coyote, and mink (Figure 4; experiments 4–7, 10, 12–16). Females were also attracted to pelt samples from red fox and bobcat (Figure 4; experiments 8 and 9), but not to wool ($P > 0.05$) (Figure 4; experiment 2). This rejection of raw sheep's wool by female WCM even in the absence of alternative larval habitat is in agreement with Kan and Waku (1985) and Traynier et al. (1994), and supports the results of experiment 1 that hair alone is suboptimal for larval development. Wool or wool-fabric with proteinous keratin as the main constituent lack nicotinic acid, pantothenic acid, and sterols and are thus inadequate for larval development (Titschak, 1922; Griswold 1944; Fraenkel and Blewett, 1946; Mallis et al., 1959; Mallis et al., 1962; Baker and Bry, 1982).

Extracts of Porapak Q-captured volatiles from horseshoe crab, beaver, or red squirrel pelts were also highly attractive to both males and females (Figure 5; experiments 17–22), providing further evidence for olfactory recognition of larval habitat. Unlike females ($P > 0.05$), males preferred solvent extracts of muskrat pelt over solvent (Cl_2CH_2) alone (Figure 5; experiments 23 and 24), and Porapak Q-captured volatile extract plus solvent extract of muskrat pelt over either stimulus alone (Figure 5; experiments 25 and 26). Equal attraction of males to semiochemicals Porapak Q captured or solvent-extracted from muskrat pelt (Figure 5; experiments 25 and 26), suggested that essential attractants can be obtained by either method of volatile acquisition. Enhanced attraction of male WCM to Porapak Q plus solvent extracts from muskrat pelts (Figure 5; experiment 26) was likely

[2]The term long range attraction *sensu* Kennedy (1974) is applicable because webbing clothes moths (<0.8 cm in body length) were attracted to test stimuli positioned 2.5 cm above the sticky surface of the trap.

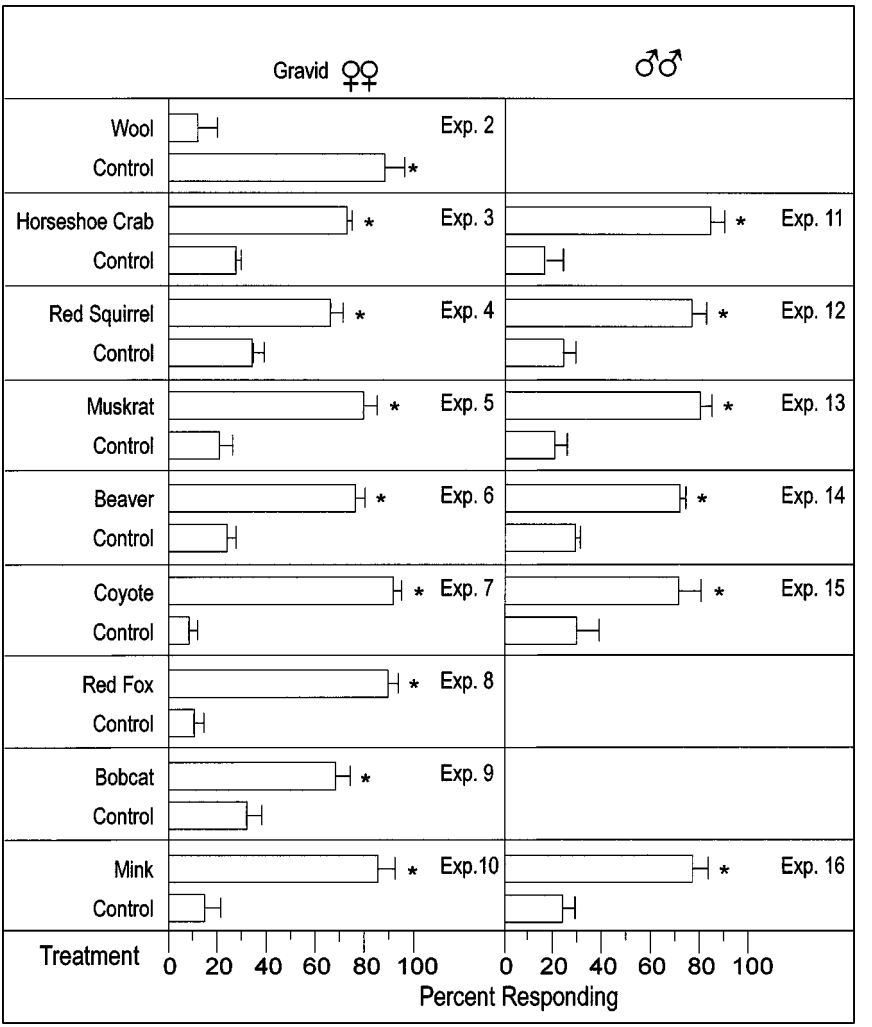

FIG. 4. Responses of adult *T. bisselliella* in binary choice arena bioassays to test stimuli (Table 1) in experiments 2–16. For each experiment, asterisks indicate a significant preference for a particular treatment [Wilcoxon paired-sample test ($P < 0.05$)]. Non-responders as follows: Exp. 2, 67 +/− 11%; Exp. 3, 31 +/− 3%; Exp. 4, 39 +/− 4%; Exp. 5, 39 +/− 7%; Exp. 6, 31 +/− 7%; Exp. 7, 28 +/− 5%; Exp. 8, 59 +/− 7%; Exp. 9, 55 +/− 9%; Exp. 10, 45 +/− 5%; Exp. 11, 27 +/− 10%; Exp. 12, 34 +/− 5%; Exp. 13, 50 +/− 9%; Exp. 14, 41 +/− 5%; Exp. 15, 50 +/− 13%; Exp. 16, 59 +/− 7%.

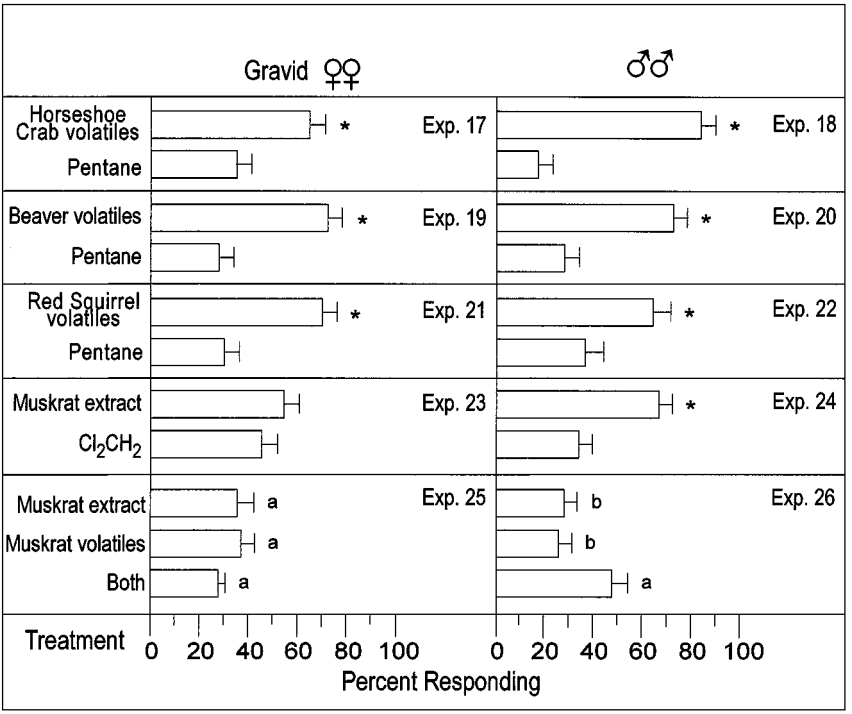

FIG. 5. Responses of adult *T. bisselliella* to test stimuli (Table 2) in binary choice arena bioassays (experiments 17–24) or ternary choice arena bioassays (experiments 25–26). For each of experiments 17–24, asterisks indicate a significant preference for a particular treatment [Wilcoxon paired-sample test ($P < 0.05$)]. For experiments 25 and 26, bars with different letters are significantly different [Kruskal Wallis test with Tukey type nonparametric multiple comparison ($P < 0.05$)]. Non-responders in experiments as follows: Exp. 17, 41 +/− 3%; Exp. 18, 27 +/− 8%; Exp. 19, 49 +/− 10%; Exp. 20, 52 +/− 6%; Exp. 21, 54 +/− 5%; Exp. 22, 39 +/− 6%; Exp. 23, 58 +/− 4%; Exp. 24, 27 +/− 5%; Exp. 25, 17 +/− 3%; Exp. 26, 12 +/− 3%.

due to increased quantities of semiochemicals, because GC-MS analyses failed to reveal any qualitative differences between these two sources of semiochemicals. Because Porapak Q-captured volatile extracts are void of fatty acids and are well suited for chromatographic analyses, they will be used to determine the identity of the semiochemicals that mediate attraction of male and female WCM to larval habitat.

Acknowledgments—We thank H. D. Pierce, Jr., for assistance in volatile collections, S. Halford, D. Baber and J. Moldenado for collecting and rearing *Tineola bisselliella*, and J. H. Borden and A. S. Harestad for review of the manuscript. This study was supported, in part, by an industrially oriented

research grant (IOR) from the Natural Sciences and Engineering Research Council of Canada (NSERC) with S.C. Johnson & Son, Inc. as the industrial partner, and by a Graduate Fellowship from Simon Fraser University to S. T.

(Received November 14, 2000; accepted April 2, 2001)

Abstract—Our objective was to identify the semiochemicals that mediate attraction of the webbing clothes moth (WCM), *Tineola bisselliella* (Lepidoptera: Tineidae), to suitable larval habitat. Coupled gas chromatographic-electroantennographic detection (GC-EAD) analyses of Porapak Q-captured bioactive volatiles from horseshoe crab, and dried but untanned vertebrate pelts revealed numerous EAD-active volatiles. These volatiles were identified by comparative GC-mass spectrometry and GC-EAD analyses of natural and synthetic compounds. A blend of 28 synthetic candidate semiochemicals attracted both male and female WCM. Experiments deleting various components determined that saturated aldehydes—but not unsaturated aldehydes, saturated hydrocarbons, saturated alcohols, or ketones—were essential for blend attractiveness. A blend of nonanal, the single most attractive aldehyde, in combination with geranylacetone was more attractive to WCM than the 28-component blend or dried, untanned animal pelt. Selection of larval habitat resides more with male than female WCM, as indicated by stronger EAD responses from male than female antennae to habitat-derived semiochemicals, and more selective and early response to habitat cues by males than females. Exploitation of nonanal and geranylacetone as resource-derived semiochemicals by both adult WCM and its larval parasitoid, *Apanteles carpatus*, is an example of convergent semiochemical parsimony.

Key Words—*Tineola bisselliella*, Lepidoptera, Tineidae, semiochemicals, larval-habitat location, host-habitat location, nonanal, geranylacetone, coupled gas chromatographic-electroantennographic detection, GC-EAD.

INTRODUCTION

Insects use short- and long-range, habitat-derived semiochemicals to locate larval or host habitat. Most such semiochemicals have been identified for phytophagous, predatory or parasitic insects (e.g., Borden, 1982; Vet, 1983; Lindroth et al., 1988; Lin and Phelan, 1991; Nottingham et al., 1991; Leal et al., 1994; Byers, 1995; Takács et al., 1997; Macias-Samano, 1998; DeLury et al., 1999). Very few have been determined for scavenging and detritus-feeding insects like the webbing clothes moth (WCM), *Tineola bisselliella* (Hum.) (Lepidoptera: Tineidae) (e.g., Wilson, 1940, Kan and Waku 1985; Detmers et al., 1992; Gerard et al., 1993; Tranyier et al., 1994). Long-range attraction (Kennedy, 1974) of WCM to larval habitat has been demonstrated (Takács et al., 2001). We report identification of the semiochemicals that mediate this attraction.

METHODS AND MATERIALS

Capture and Analyses of Habitat-derived Semiochemicals. Dried but untanned pelt (150 cm^2) of various vertebrates or dry, formaldehyde-preserved horseshoe crab, *Limulus polyphemus*, (Table 1) as potential larval habitat were aerated for one week in a cylindrical Pyrex^{TM} glass chamber or extracted with dichloromethane (Cl_2CH_2) (Takács et al., 2001). Five pelt-min of volatile collection equalled 2 μl of volatile extract. Aliquots (1 μl) of Porapak Q-captured volatiles or Cl_2CH_2 extracts were analyzed by coupled gas chromatographic-electroantennographic detection (GC-EAD) (Arn et al., 1975), employing a Hewlett Packard (HP) 5890A gas chromatograph equipped with a fused silica column (30 m $\times$ 0.25 or 0.32 mm ID) coated with DB-5, DB-210, or DB-23 (J & W Scientific, Folsom, CA). Full scan electron impact (EI) mass spectra of EAD-active compounds were obtained by coupled GC-mass spectrometry (MS), using a Varian Saturn II Ion Trap GC-MS and a HP 5985B GC-MS, respectively, each fitted with the DB-210 or DB-5 column referred to above.

Experimental Insects and Arena Bioassay Experiments. Wild WCM adults were collected and reared for bioassays as previously described (Takács et al., 2001). Tactic responses of WCM to test stimuli were assessed in a closed Plexiglas^{TM} arena (Takács et al., 2001). Twenty-five male or 25 female moths per replicate were released from a Petri dish in the center of the arena after a 30-min acclimatization period. After 12 hr, moths captured on the sticky disks associated with test stimuli were recorded as responders; all other moths were removed and classed as non-responders. Numbers of captured moths were analysed by the Wilcoxon's paired sample test ($\alpha = 0.05$) (Zar, 1984).

Treatments and test insects for 23 experiments are documented in Table 2. Experiments 1 and 2 tested captured volatiles from pelts of red squirrel, *Tamiasciurus*

hudsonicus, for attractiveness. Experiments 3–6 compared attractiveness of a complex blend of synthetic candidate semiochemicals (Table 1) with that of a solvent control (experiments 3, 4) or red squirrel pelt volatiles (experiments 5, 6). To determine essential semiochemicals, experiments 7–15 tested the complex synthetic blend versus blends lacking certain classes of organic chemicals (Byers, 1992). An attractive but less complex blend plus geranylacetone–the latter identified after completion of preceding experiments—was then tested versus the complex blend (experiment 16). Taking results of experiments 7–16 into account, experiments 17–21 tested various blends of (mainly) aldehydic candidates. Experiments 22 and 23 tested a 2-component synthetic blend (nonanal plus geranylacetone) versus an attractive natural pelt. In experiments 22 and 23, captures of moths in bait stations were recorded hourly for 12 hr and once again after 24 hours.

Capture and Quantitative Comparison of Natural and Synthetic Kairomones. In experiment 24, volatiles from the following sources (4 replicates) were captured for 24 hr on Porapak Q: 1) muskrat pelt as used in experiments 22 and 23; 2) filter paper impregnated with equivalent amounts of synthetic chemicals tested in experiments 22 and 23; and 3) filter paper. Aeration and extraction procedures were as described above. Aliquots of 1.5 pelt-min equivalents of Porapak Q-captured volatiles, with piperitone added as an internal standard, were subjected to GC analysis, employing a Hewlett Packard (HP) 5890A GC equipped with a fused silica column (30 m $\times$ 0.25 mm ID) coated with DB-5 (J & W Scientific). Mean proportions of nonanal and geranylacetone relative to the internal standard were compared with the Kruskal Wallis test ($\alpha = 0.05$) followed by a Tukey-type nonparametric test ($\alpha = 0.05$) (Zar, 1984).

RESULTS

GC-EAD analyses of volatiles from horseshoe crab and dried but untanned animal pelts including red squirrel, muskrat (*Ondatra zibethica*), beaver (*Castor canadensis*), coyote (*Canis latrans*), mink (*Mustela vison*), red fox (*Vulpes fulva*), and bobcat (*Lynx rufus*) revealed 32 EAD-active volatiles (Figures 1, 2; Table 1). Responses from male antennae were consistently stronger than those from female antennae (Figures 1, 2). Chemical structures were assigned to EAD-active compounds based on their comparable retention indices, EI mass spectra, and EAD activity with synthetic compounds.

Volatiles from red squirrel pelts and a blend of 28 synthetic candidate semiochemicals (SB1; Table 1) were highly and equally attractive to both sexes (Figure 3; experiments 1–6). Responses by females did not significantly differ between the complex blend (SB1) and blends lacking either unsaturated aldehydes (SB2), hydrocarbons (SB3), or alcohols (SB4), but males consistently preferred certain incomplete blends over SB1 (Figure 4; experiments 7–12). Both males and

23	Male	Unknown	SB14	Muskrat pelt

[a] For experiments with solvent controls, both treatments received the same amount of solvent ranging from 15–25 μl. For experiments 1, 2, 5, and 6, 75 pelt-min of Porapak Q captured volatiles from pelts of red squirrel were tested. In experiments 22 and 23, untanned muskrat pelt was 150 cm^2 in size.
[b] Chemical composition of synthetic blends as in Table 1.

females were more strongly attracted to SB1 than to a blend lacking all saturated aldehydes (SB5) (Figure 4; experiments 13, 14), and males were equally attracted to SB1 and to a blend of saturated aldehydes (SB6) (Figure 4; experiment 15). However, males preferred a blend of saturated aldehydes plus geranylacetone (SB7) over SB1 (Figure 4; experiment 16) and a blend of C8 to C14 aldehydes (SB8) over a blend of C14–C18 aldehydes (SB9) (Figure 5; experiment 17). Males also preferred nonanal at high dose (SB10) over a blend of aldehydes including nonanal (SB6) (Figure 5; experiment 18). Nonanal at low dose (SB11) was as attractive as the blend of nonanal plus higher homologues (SB6) or nonanal plus lower homologues (SB12) (Figure 5; experiments 19, 20). Finally, males preferred nonanal plus geranylacetone (SB13) over unsaturated aldehydes including nonanal (SB6) (Figure 5; experiment 21).

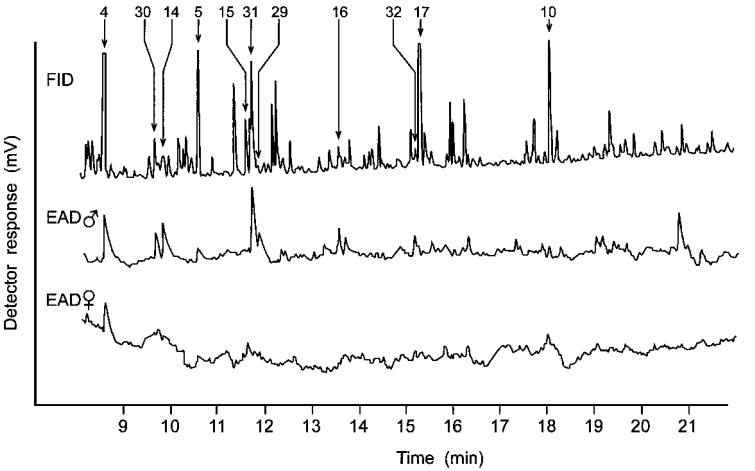

FIG. 1. Representative flame ionization detector (FID) and electroantennographic detector (EAD: ♂ or ♀ *T. bisselliella* antenna) responses to aliquots of 2.5 pelt-min equivalents of Porapak Q-collected volatiles from five museum specimens of horseshoe crab. Chromatography: Hewlett Packard 5890A equipped with DB-5 coated column; linear flow velocity of carrier gas: 35 cm/sec; injector and FID detector temperature: 240°C; temperature program: 1 min at 50°C, 20°C/min to 70°C then 7.5°C/min to 280°C. Numbers above FID peaks correspond to identified components in Table 1.

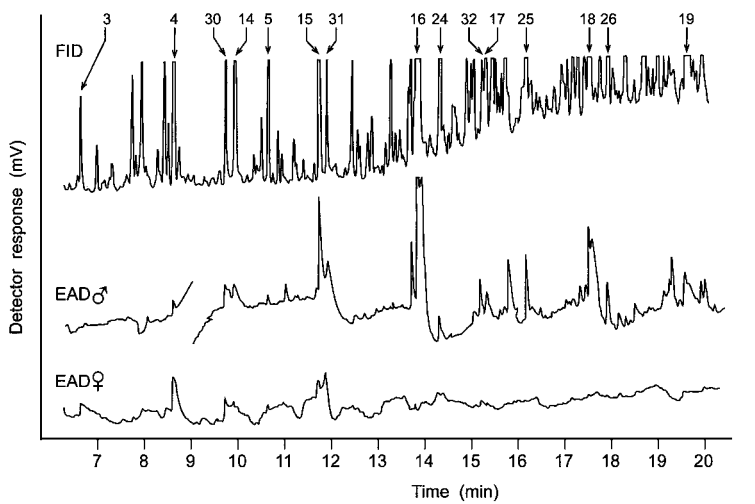

FIG. 2. Representative flame ionization detector (FID) and electroantennographic detector (EAD: ♂ or ♀ *T. bisselliella* antenna) responses to aliquots of 2.5 pelt-min equivalents of Porapak Q-collected volatiles from red squirrel pelt. Chromatography as in Figure 1. Numbers above FID peaks correspond to compounds in Table 1.

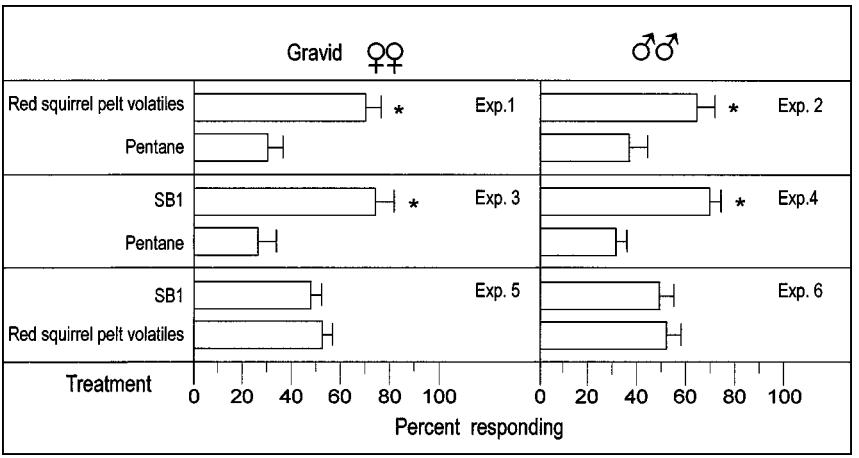

FIG. 3. Responses of adult *T. bisselliella* to test stimuli (Table 1) in binary choice arena bioassay experiments 1–6. For each experiment, asterisks indicate a significant preference for a particular treatment [Wilcoxon paired-sample test ($P < 0.05$)]. Nonresponders as follows: Exp. 1, 54 +/− 5%; Exp. 2, 39 +/− 6%; Exp. 3, 52 +/− 7%; Exp. 4, 42 +/− 8%; Exp. 5, 38 +/− 7%; Exp. 6, 33 +/− 5%.

Both females and males were more strongly attracted to the 2-component semiochemical blend of nonanal plus geranylacetone (SB14) than to natural muskrat pelt (Figure 5; experiments 22, 23). Males responded to test stimuli significantly earlier than did females (Figure 6).

When synthetic nonanal and geranylacetone released from filter paper, or natural nonanal and geranylacetone emanating from muskrat pelt, were captured on Porapak Q and quantified, amounts of nonanal were similar but more geranyl acetone was found emanating from muskrat pelt (Figure 7). This indicates that in experiments 22 and 23 nonanal and geranylacetone were released at quantities equivalent to, or less than those emanating from muskrat pelt, and that superior attractiveness of the synthetic blend was due to blend quality.

DISCUSSION

Our analyses show that nonanal and geranylacetone are key semiochemicals that mediate attraction of male and female WCM to larval habitat. The equal response of adult WCM to red squirrel pelt volatiles and a blend of 28 synthetic candidate semiochemicals (SB1) at equivalent quantities (Figure 3; experiments 5, 6), indicates that essential semiochemicals were present in SB1. Testing SB1 versus blends lacking unsaturated aldehydes (SB2), saturated hydrocarbons (SB3),

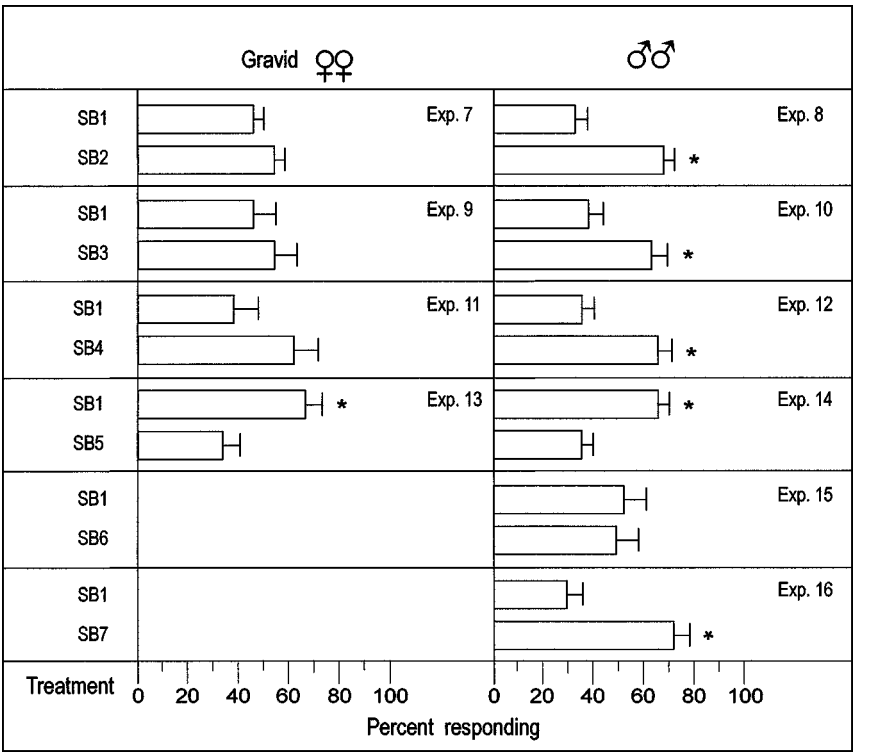

FIG. 4. Responses of adult *Tineola bisselliella* to test stimuli (Table 2) in binary choice arena bioassay experiments 7–16. For each experiment, asterisks indicate a significant preference for a particular treatment [Wilcoxon paired-sample test ($P < 0.05$)]. Non-responders as follows: Exp. 7, 52 +/− 6%; Exp. 8, 21 +/− 3%; Exp. 9, 52 +/− 8%; Exp. 10, 18 +/− 2%; Exp. 11, 58 +/− 9%; Exp. 12, 34 +/− 6%; Exp. 13, 26 +/− 8%; Exp. 14, 40 +/− 5%; Exp. 15, 42 +/− 8%; Exp. 16, 48 +/− 5%.

saturated alcohols (SB4), or saturated aldehydes (SB5) revealed that blend attractiveness required the presence of saturated aldehydes (Figure 4; experiments 7–14). The single most attractive aldehyde (nonanal) and attractiveness-enhancing geranylacetone were determined in bioassays with only males (Figure 4, experiments 15, 16; Figure 5, experiments 17–21), because males were generally more responsive and discriminating than females (Figure 4; experiments 7–14).

The prediction by a simulation model (Takács, unpublished data) that selection of larval habitat resides more with male than female WCM is supported by long-range attraction of males to larval habitat (Takács et al., 2001), and by our findings that: 1) habitat-derived stimuli elicited stronger responses by male than female antennae (Figures 1, 2); 2) males responded more selectively to habitat

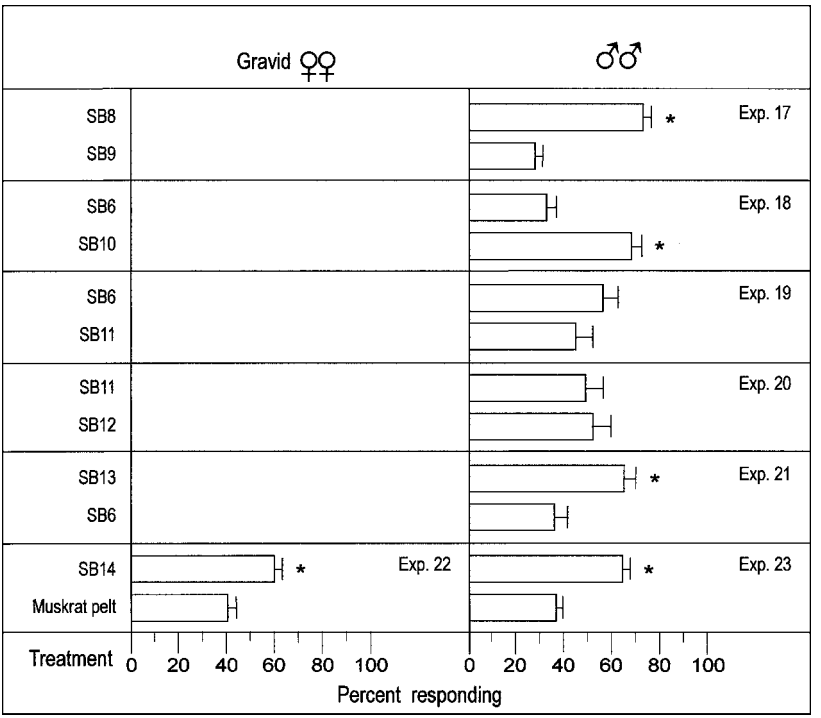

FIG. 5. Responses of adult *T. bisselliella* to test stimuli (Table 2) in binary choice arena bioassay experiments 17–23. For each experiment, asterisks indicate a significant preference for a particular treatment [Wilcoxon paired-sample test ($P < 0.05$)]. Non-responders as follows: Exp. 17, 37 +/− 5%; Exp. 18, 35 +/− 7%; Exp. 19, 50 +/− 6%; Exp. 20, 26 +/− 4%; Exp. 21, 41 +/− 7%; Exp. 22, 14 +/− 4%; Exp. 23, 13 +/− 5%.

cues (Figure 4, experiments 7–12); and 3) that males sought larval habitat earlier in the scotophase than females (Figure 6; experiments 22, 23). Habitat selection by males could enhance their potential mating success. It may place them at or near resources essential for resource-seeking females (Emlen and Oring, 1977).

The identification of nonanal and geranylacetone as key semiochemicals for both adult WCM (this study) and its larval parasitoid, *Apanteles carpatus* (Takács et al., 1997), provides an example of convergent semiochemical parsimony (Blum, 1996). Nonanal and geranylacetone obviously emanate from natural resources like dry carrion or untanned animal pelt in quantities (Figure 7) sufficient to serve both WCM and *A. carpatus* as habitat-derived cues.

Progressive colonization of temporary microhabitat by scatophagous and necrophagous insects seems to be associated with progressive changes in the composition of habitat-derived odorants (Bornemissza, 1957; Reed, 1958; Parker,

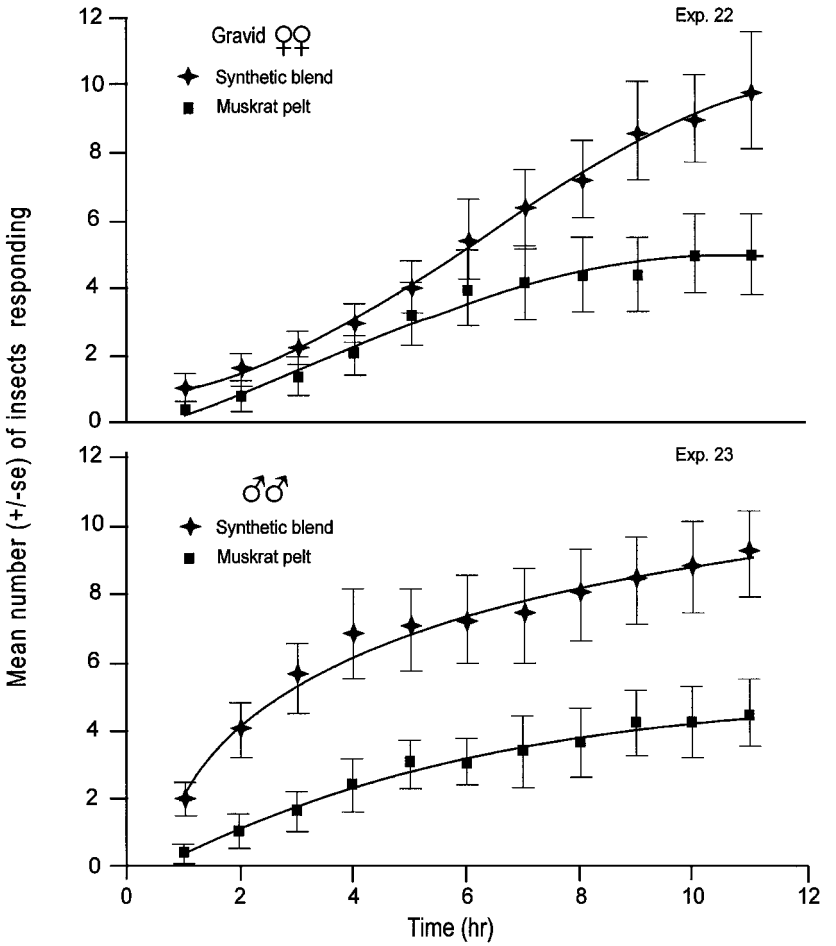

FIG. 6. Cumulative captures of adult *T. bisselliella* in binary choice arena bioassay experiments 22 and 23 on traps baited with a synthetic blend of nonanal plus geranylacetone (SB14, Table 1) or with dry, untanned muskrat pelt (150 cm^2). Experimental replicates commenced at the onset of the scotophase.

1970; Stafford, 1971; Rodriguez and Bass, 1983; Early and Goff, 1986; Anderson and VanLaerhoven, 1996; Takács et al., 1997; VanLaerhoven and Anderson, 1999). We hypothesize that respective odorants are characterized, in part, by their oxidative state, and that aldehydes predominate in the final dry stage of carrion. If true, female WCM may utilize the relative proportion of alcohols and aldehydes to assess suitability of larval habitat. Antennal response (Figures 1, 2) to, and behavioral deterrence by alcohols (Figure 4; experiments 11, 12) suggest that alcohols

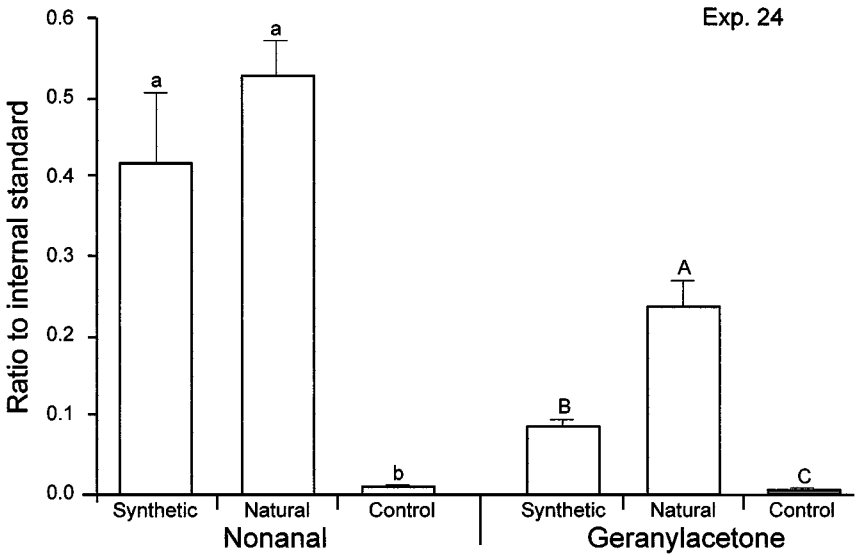

FIG. 7. Relative quantities of Porapak Q-captured synthetic and natural nonanal and geranylacetone disseminating from filter paper or muskrat pelt (150 cm^2). For each chemical, bars with different letters are significantly different [Kruskal Wallis test with Tukey-type non-parametric multiple comparison ($P < 0.05$)]. Note: Filter paper was provisioned with the equivalent amount of nonanal and geranylacetone that emanated from natural pelt during 24 hr of aeration in preceding studies.

signal sub-optimal larval habitat. Olfactory recognition of semiochemicals both from sub-optimal and optimal larval habitat by WCM may represent a fail-safe mechanism to select the microhabitat most suitable for larval development. Alternatively, a sub-optimal habitat at the time of oviposition may become optimal as the larvae develop.

Acknowledgments—We thank, H. D. Pierce, Jr. for assistance in volatile collections, S. Halford, D. Baber, J. Moldenado and L. Bertram for collecting and rearing *T. bisselliella*, Anne Embra from the Langley Spinners and Weavers Guild for supplying larval habitat, and J. H. Borden and A. S. Harestad for review of the manuscript. This study was supported, in part, by an industrially oriented research grant (IOR) from the Natural Sciences and Engineering Research Council of Canada (NSERC) with S. C. Johnson & Son, Inc. as the industrial partner, and by a Frank A. Linville Graduate Scholarship in Olfaction from Simon Fraser University to S. T.

(Received September 5, 2000; accepted April 7, 2001)

Abstract—Males of the European pine sawfly, *Neodiprion sertifer* Geoffr., were marked and released downwind from pheromone traps, baited with 100 μg of the sex pheromone (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecyl acetate. Males were released 5 m downwind from one trap, or downwind from five traps, 50 m or 200 m away. The average capture rates after 24 hr were 21.5%, 17.7% and 3.8%, respectively. The capture rate was highest at moderate wind speeds (1–2 m/sec) in the 50 m experiments, whereas it decreased above wind speeds of 1.5 m/sec in the 200 m experiments. With no precipitation and $>13.5^{\circ}$C during overcast, wind speed is presumably the most important climatic factor for *N. sertifer* males flying upwind to a pheromone source. Travel time, the elapsed time form take-off to landing on the trap, varied considerably, and the shortest recorded travel times were 1, 6 and 45 min for the 5, 50, and 200 m experiments, respectively. The trap efficiency *i.e.*, number of captured males per number of males that landed on the trap, was estimated at 52% in the 5 m experiments. The sampling range after 24 hr was calculated at approximately 400 m by regression analysis. The combination of the males' flight ability during upwind progress and their longevity (12 days), suggests a potentially large seasonal sampling range of the traps used in this study.

Key Words—Diprionidae, Hymenoptera, sampling range, mark-release-capture.

INTRODUCTION

Traps baited with species-specific pheromones are becoming common tools for monitoring insect pests, but the correspondence between catches and damage is often poor (Trumble, 1996; Lyytikäinen-Saarenmaa et al., 1999), partly because of an unknown sampling range of the trap. The sampling range is the maximum range from which insects can be shown to reach an attractive (odorant) source within a given time period (Wall and Perry, 1987). Another definition used for describing the action range of a pheromone trap is attraction range, the maximum distance over which insects can be shown to direct their movement to a source (Wall and Perry, 1987). The sampling range will increase with time until it levels off, whereas the attraction range is constant.

By performing well designed mark-release-capture experiments, one can determine how many insects are captured from different distances within a given time, and how fast the insects reach a trap. The influence of weather on trap catch can also be determined. Studies of this kind are rare, but should be useful when designing a monitoring program.

The European pine sawfly, *Neodiprion sertifer* Geoffr. (Hymenoptera: Diprionidae), is one of the most harmful defoliators of pines in Europe (Austaråa et al., 1987; Day and Leather, 1997). Many pine sawflies use sex pheromones for mate attraction (e.g., Anderbrant, 1999). On average, one *N. sertifer* female contains ca. 10 ng of the sex pheromone precursor, (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecanol (diprionol) (Wassgren et al., 1992). Males respond to the female-released pheromone (either acetate or propionate of the alcohol), both in electrophysiological recordings (Hansson et al., 1991) and in field trapping (Anderbrant et al., 1992a).

Östrand et al., 2000 showed that *N. sertifer* responded to synthetic pheromone 200 m away in the field; males directed their behavior, and also took off faster when stimulated by pheromone. Here, we report the capture rates of *N. sertifer* males released at various distances from pheromone traps, how weather affects capture rates, travel times of males flying upwind to a pheromone source, and the behavior of males landing on the pheromone trap.

METHODS AND MATERIAL

Study Site and Local Pine Sawfly Population. The study was performed in August and September, from 1996 to 1998, 35 km east of Lund, southernmost Sweden. To reduce the influence of native females, the experiments were carried out in a 210 × 210 m plot inside a 28 ha plantation of 2 to 3 m tall birch, *Betula pendula* Roth., bordered on the north and west by plantations of Scots pine, *Pinus sylvestris* L., 15 to 20 m tall. Small plots of larch, *Larix decidua* Mill., approximately 0.8 m tall, were present within the birch plantation.

To monitor the local population of *N. sertifer*, four Lund-I sticky traps (Anderbrant et al., 1989) were hung in a square, approximately 350 m from each corner of the experimental plot. Traps were baited with 100 μg of the attractive isomer, (2*S*,3*S*,7*S*)- 3,7-dimethyl-2-pentadecyl acetate (99% stereochemically pure), prepared at the Mid Sweden University (Högberg et al., 1990; Anderbrant et al., 1992a), and released from a cotton roll, Celluron® No. 2 (Paul Hartmann, S.A., France). Monitoring began at the end of July in 1996 and 1997, and baits were renewed every fortnight.

Insects. *Neodiprion sertifer* larvae were collected in June 1996 and 1997 near Valdemarsvik, Östergötland, Sweden, and in 1998, outside Filipstad, Värmland, Sweden. The larvae were reared in cardboard boxes, standing outdoors in a sun- and rain-protected area, and given water daily and pine twigs when needed. After having spun cocoons, males to be used in the experiments were separated from females.

During the first three release experiments in 1996, males were not marked because the four monitoring traps caught very few wild males. As the catches of wild *N. sertifer* males increased, we marked the males before release by painting a dot on the pronotum with a white instant marker (Edding 780, extra fine). In 1997, we also used silver and gold (PILOT, SC, extra fine). In 1998, the pronotum was divided into four fields. By painting one to three dots of seven different water-based and water-resistant colors, there were enough combinations for releasing individually marked males.

Males emerged indoors and, after marking, they were kept individually for $\leq$4 days at 4–8°C in plastic test tubes (i.d. 9.5 mm, 55 mm long) containing a piece of soft moistened paper and capped with perforated corks to allow for air exchange. On experimental days, males were kept in a cooling bag until release.

Longevity Study. The longevity of marked and unmarked males was determined in 1998. After emergence, the males were placed individually in plastic jars, 5 $\times$ 5 $\times$ 7 cm high, each containing a fresh pine shoot wrapped in moistened paper. The jars were put in plastic boxes, 22 $\times$ 30 $\times$ 12 cm, placed on wooden boards lying on the ground in the experimental plot. The plastic boxes were covered with a rain shelter. Two series each of 15 marked and 15 unmarked males were run, and the results were pooled. Living males were counted each day until all had died. The temperature inside the boxes was recorded throughout the study.

Experimental Design. Males were released 50 or 200 m downwind of five Lund-II pheromone traps (Anderbrant et al., 1989) (intertrap distance 25 m), or 5 m downwind of one trap (Östrand et al., 2000). At 50 m and 200 m, we used five traps to minimize the effect of shifts in wind direction. The traps were placed about 1.7 m above ground. New baits (100 μg) were used in each experiment; each bait released approximately 45 μg of the pheromone during the first day (calculated from Anderbrant et al., 1992b).

Males were released individually from open test tubes. In the first two experiments in 1996, up to 100 tubes were placed vertically in a test tube rack ($33 \times 12 \times 6$ cm) resting on a cardboard platform and attached to a wooden pole (ca. 1.7 m above ground). In the following experiments, the test tubes containing the males were opened and stacked horizontally in a plastic jar (i.d. 11 cm, 13 cm height) covered on the outside with black opaque plastic. Five holes (5 mm) were drilled in the lid around which a white cardboard platform (35×35 cm) was attached. After leaving the test tubes, the males moved towards the light coming through the holes in the lid. If >40 males were released, the test tubes were divided into two jars attached to one platform each and placed ca. 0.5 m from each other.

To avoid interference, pheromone sources were removed from the four monitoring traps before the experiments started. The prevailing wind direction was determined with a wind vane at 9 m above ground, and the platforms and the traps were re-positioned every experimental day so that males always were released downwind of the trap(s).

One or two observers stood behind the platforms and recorded which males took off. Another observer recorded incoming males in the traps. In the 5 m experiments, one person stood upwind of the trap and recorded the behavior of males landing on the trap. To allow behavioral observation of males as they entered these traps in 1997 (see Östrand et al., 2000), we used a sticky bottom with glue only in a central 4×4 cm square (below the dispenser). Males were observed until they took off again or became stuck on the glue. After 3–4 hr, we exchanged the bottom for one with glue on the entire surface during the remaining hours of the experiment. In 1998, we only used the regular bottoms fully coated with glue. Data from 1997 and 1998 on landing and take-off were coupled with observations in 1998 on trap efficiency to create a flow chart describing the sequence of behaviors during orientation and capture. Capture rates were based on the number of males that had left the take-off platform within 24 hr.

Because males seldom flew straight from the platform to the trap, and gusty wind transported them out of sight of the observer, it was impossible to measure the ground speed of orienting males. Instead, we calculated the elapsed time from take-off to landing = travel time. The exact time for landing could not be recorded when patrolling the five traps in the 50 m and 200 m experiments, and instead we present a range. The median of such ranges was used for statistical analysis of travel time. For instance the median travel time of a male reaching the trap within 6–9 min was 7.5 min.

Weather Recording. An automatic weather station was placed in the experimental plot. Air temperature and relative humidity were recorded at 2 m above ground with copper-constantan thermocouples with a 0.5 mm diameter and Hygromer® (Rotronic Bassersdorf, Switzerland), respectively. Incoming short wave radiation (335–2000 nm, Wm^{-2}) was measured 2 m above ground (Kipp and Zonen, Delft, The Netherlands). Wind speed and direction were recorded at

2 m and 9 m above ground with cup-wheel anemometers and wind vanes (R. M. Young, Traverse City, Michigan). Mostly, the sensors were scanned every 30 sec, and the data were stored as 30 min averages in a CR10 micro logger (Campbell Scientific, Logan, Utah). During the 5 m experiments and all experiments in 1998, the scanning interval was 2 sec, and averages were stored every second min.

In 1998, wind speed and direction, together with temperature, were recorded only at 2 m above ground. A copper-constantan thermocouple was used for recording the temperature in the plastic boxes during the longevity study. Wind speed recorded 2 m above ground was used in the capture-wind speed regression analysis.

Statistical Tests. The proportions of males of different age taking flight were compared with a *G*-test, and the longevity of marked and unmarked males was compared with Student's *t*-test (Sokal and Rohlf, 1995). Polynomial (second order) or linear regression analyses were used for evaluating the relationship between capture-wind speed (with and without temperature included), and capture-distance. Total capture rates were used in the statistical evaluations, except in the capture-distance regression, where captures were expressed per trap. Before regression analysis, the capture rates and distance were arcsin $\sqrt{}$ (proportion capture) and log transformed, respectively. The maximum sampling ranges were obtained by calculating the x-intercept at $y = 0$ for each of the three sampling times 1, 2.5, and 24 hr (Schlyter, 1992), and confidence intervals following Sokal and Rohlf, 1995.

RESULTS

Of 1961 males released on 28 days, 82.7% took off (range 62.1–96.6%) (Table 1). Take-off percentage was positively correlated with mean temperature during the first 3–5 hr of the experiments ($r^2 = 0.217$, $P = 0.01$, $N = 28$). The total catch in the two outermost traps in the 200 m experiments was higher than in the two innermost or the central trap, from left to right 7, 2, 5, 2, 7, whereas it was the opposite in the 50 m experiments: 13, 20, 28, 18, 7. From the release point, the angle of separation for the outermost traps was 64° and 32° in the 50 m and 200 m experiments, respectively.

Capture Rates. The capture rates after 24 hr in the 5, 50, and 200 m experiments were on average 21.5, 17.7, and 3.8%, respectively (Table 1). Captures varied with wind speed at all three distances. In the 50 m experiments, the recaptures were the highest at intermediate wind speeds, 1-2 m/s (Figure 1B). In the 200 m experiments, the captures decreased at wind speeds above 1.5 m/s (Figure 1C). In the 5 m experiment, which made use of only one trap, there was no significant relationship ($P > 0.2$ for linear and polynomial regressions) between capture and wind speed (Figure 1A). The recorded temperature varied from 13.4–25.4°C. In one instance, no males were captured when the temperature was low and the

[a] Capture figure after 2.5 hr.
[b] Excluding 6 Sep 97.
[c] Unmarked males released.

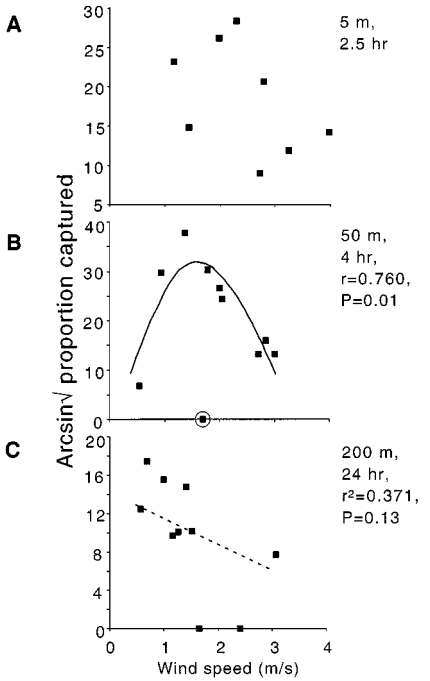

FIG. 1. Capture of male *N. sertifer* at different wind speeds when released at different distances from traps. Wind speed calculated from 30 min averages in the 50 and 200 m experiments, and 2 min averages in the 5 m experiments, except for the data on 24 Sept 97 when only 30 min averages were available. A. No significant relation. B. Encircled point is from 25 Sep 1996, when both temperature and incoming short wave radiation were low: 13.4°C and 172 W/m^2, respectively. Excluding this date, the data fit the bell-shaped function, $y = -10.8 + 48.1\,x - 13.9\,x^2$. C. $y = 14.3 - 2.5\,x$.

weather was cloudy (Table 1, Figure 1B). Otherwise, there was no relationship between capture and temperature, and the capture-wind speed regressions did not improve when temperature data were included.

Four and eight late-coming males were captured after the initial 24 hr of sampling in 1997 and 1998, respectively. Nine of these males were captured approximately 48 hr after release, and the remaining three males after 72 hr. Eight of these males were two days old, and one was five days old when captured.

Sampling Range. At all three distances, most males were recaptured within the first 3 hr of sampling (Figure 2). The calculated maximal distances at which a trap can be expected to catch males after 1, 2.5, and 24 hr of sampling were 190 m (95% confidence interval, 70–630 m), 290 m (C.I. 90–1250), and 396 m (C.I. 140–1600), respectively (Figure 2).

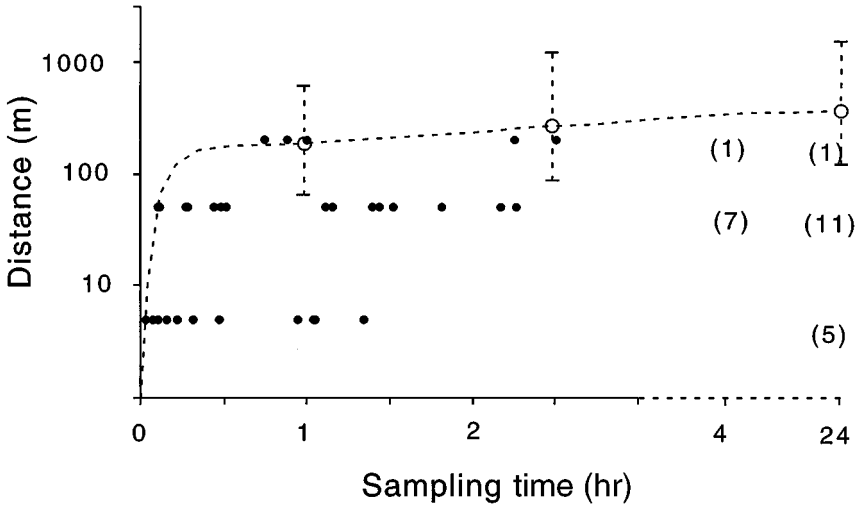

FIG. 2. Relationship between distance from pheromone traps and travel times of males caught in 1998 during the first 3 hr in the 5 m ($N = 12$), 50 m ($N = 16$), and 200 m ($N = 5$) experiments, respectively (black dots). Also shown (in parenthesis) are additional catches after 4 hr (not recorded in 5 m exp.) and 24 hr. Calculated maximal sampling distances (i.e., the expected sampling ranges of traps), with 95% confidence intervals, after 1 hr, 2.5 hr, and 24 hr of sampling are shown as open circles. The dashed line illustrates the theoretical relationship between time and sampling range.

Travel Time. When considering the distance, the time elapsed from take-off to landing was comparable for the fastest males at each of the three distances (Table 2); it took the sawflies 1 min or more to reach the trap in the 5 m experiment. Increasing the distance by a factor of 10 or 40, the shortest travel times increased to 6–10 min or 40–50 min, respectively (Table 2).

Males in the 50 m experiment in 1998 tended to reach the traps faster with increasing wind speed, $r^2 = 0.404$, $P = 0.065$, $N = 9$ (1 day old males with travel time $\leq$45 min, wind speed calculated from 2 min averages). Occasionally males landed in birch trees before reaching a trap, resulting in longer travel time.

Longevity and Effects of Age. Marked and unmarked *N. sertifer* males lived 11.4 ± 4.3, and 12.3 ± 5.2 days (mean $\pm$ SD), respectively, $t_{(58)} = 0.73$, $P > 0.05$, with a range of 2–25 days. The mean recorded temperature during the experiment was 13.6 ± 4.0°C, range 4.0–25.3°C, $N = 1344$, based on 30-min averages from 28 days.

Fewer males took off as age increased from 0 days (released the day they emerged) to 2 days; $G = 7.3$, $P < 0.05$, $N = 594$ in 1997, and $G = 8.2$, $P < 0.05$, $N = 639$ in 1998. There were no trends in the capture of males of different ages.

TABLE 2. TRAVEL TIMES (RANGES) FOR THE FIVE FASTEST MALES AT EACH OF THE THREE DISTANCES IN 1998. IN THE 200 M EXPERIMENTS, THE TRAVEL TIMES FOR ALL CAPTURED MALES THAT COULD BE IDENTIFIED ARE PRESENTED. THE AVERAGE WIND SPEED (RECORDED AT 2 M ABOVE GROUND) DURING EACH FLIGHT IS SHOWN TOGETHER WITH THE MALE'S AGE. ZERO DAY OLD MALES EMERGED ON THE SAME DAY THEY WERE RELEASED

5 m			50 m			200 m		
Travel time (min)	Wind speed (m/s)	Age (days)	Travel time (min)	Wind speed (m/s)	Age (days)	Travel time (min)	Wind speed (m/s)	Age (days)
0.8–3.0	0.8	0	≤6	3.2	1	39–50	1.3	1
1.4–3.0	1.3	4	≤7	3.2	1	44–62	1.7	1
1.0–3.0	2.5	0	9–17	1.8	0	51–68	1.9	0
1.7	1.1	0	9–19	1.9	0	139–170	1.3	1
3.1	1.2	0	≤17	2.8	1	194–205	1.2	1

In one of the 5 m experiments in 1998, 15.4 % of males aged 0 days were captured after 24 hr, and 19.4% of males aged 4 days were captured, $G = 0.2$, $P > 0.05$, $N = 57$. However, travel time to land on or in the trap for males aged 0 days was 10.2 ± 17.0 min ($N = 10$) faster, $t_{(16)} = 2.57$, $P < 0.05$, than the time of 42.7 ± 35.4 min ($N = 8$) for males aged 4 days.

Observations at the Trap. Most males took off into the wind and then flew in broad lateral turns of several meters in amplitude (side to side). When approaching a trap, males tended to fly straighter with lateral turns of a few decimeters. The flow scheme in Figure 3 shows the sequence of behaviors by males attracted to a trap based on observations at the traps and some assumptions. In the first 2.5 hr in the 5 m exp. in 1998, 52.2% of 23 males that landed on the trap were captured. In the first 2.5 hr in the 5 m exp. in 1997 and 1998, 87% (62/71) of 130 males landing on the roof took off again. In these experiments, one male visited a trap five times without getting caught. Of the males that landed elsewhere than on the sticky bottom of the trap, we assumed that the proportion captured later on the sticky trap bottom was equal to the proportion that took flight. By allowing for a maximum of five visits without getting caught and if 52.2% of the visiting males are trapped, we obtained by iteration that 39% of the males are permanently lost from the trap's attraction range in each round. These 39% represent the males that take-off from the trap, either directly from the roof or elsewhere from the trap, and are hereafter lost (27/69.5%). In the first visit, 30.5% of the males will be caught, of which 23% of them land directly on the sticky trap bottom (Figure 3). In the next four visits, 13.0, 5.5, 2.3 and 1.0% of the males from the initial visit will be caught.

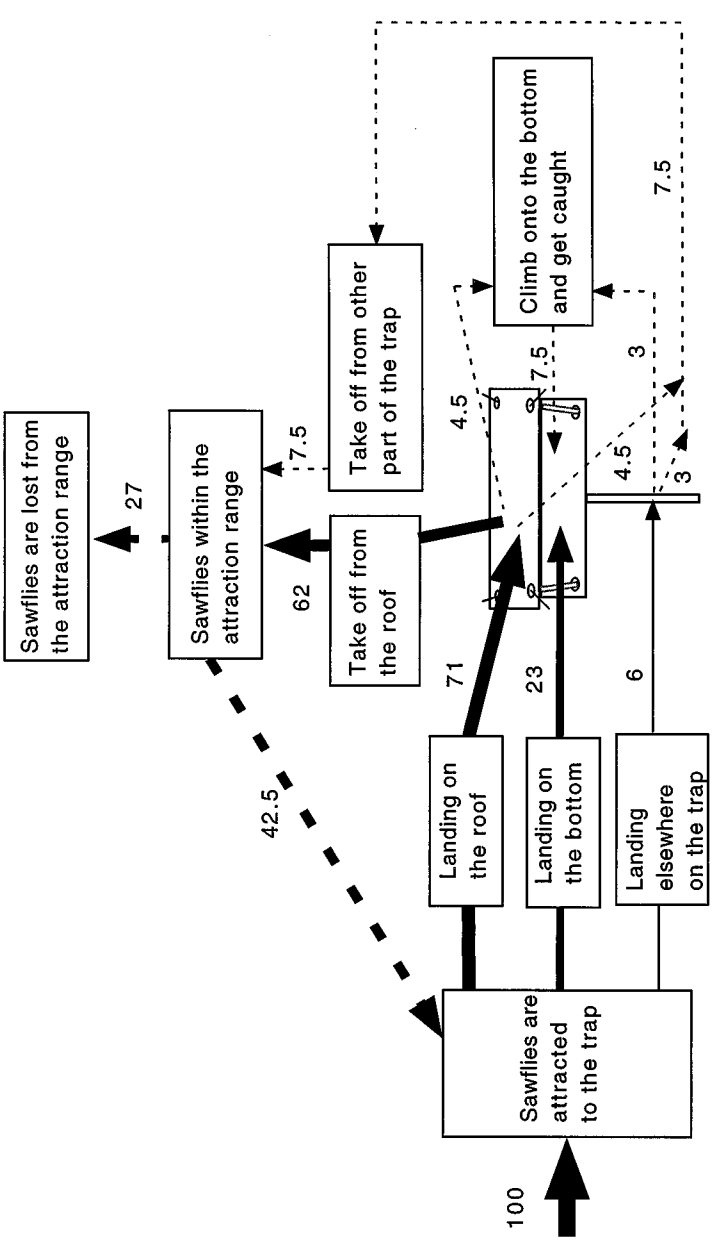

FIG. 3. Flow-scheme showing the capture of *N. sertifer* males landing on different parts of a pheromone trap. All figures in percentage, and at the start 100 males are attracted to the trap. Solid arrows are based on observations at the trap, and dashed arrows are based on assumptions. See text for more information.

DISCUSSION

Capture Rates and Sampling Range. Although a rough estimate, the 400 m sampling range, after 24 hr for the Lund-II traps baited with 100 μg of synthetic pheromone, is the first calculated sampling range of a trap for pine sawflies. The theoretical sampling range-time curve (Figure 2) will level off towards the maximum sampling range of a trap when sampling for longer than 24 hr, and will probably reach at least 500–600 m (Östrand and Anderbrant, unpublished data).

Captures in the 200 m experiments during the first 3.5–5 hr are similar to the 76% capture of the total capture of sweet potato weevils in the first 10.5 hr of a 27 hr period when *Cylas formicarius* (Summers) were released 10–1000 m from pheromone-baited traps (Sugimoto et al., 1994). Similarly, 90% of fall web worms, *Hyphantria cunea* (Drury), male were caught within 12 hr of a 60 hr sampling period (Zhang and Schlyter, 1996).

Wind Speed. As wind speed increases, a pheromone plume will elongate, making it easier for insects to locate the source, whereas a further increase in wind speed will decrease the maximum distance of pheromone detection due to greater dilution of the pheromone and higher turbulence intensities (Elkinton et al., 1987). At higher wind speeds, insects will have trouble flying upwind. Temperature will also affect the plume structure (Brady et al., 1995). Male *N. sertifer* became increasingly reluctant to wing fan and take-off as wind speed 2 m above ground increases from 1.5 to 4.0 m/s (Östrand et al., 2000). Therefore, the capture rate with increasing wind speed might be bell-shaped, as we observed in the 50 m experiments (Figure 1B). Such a pattern was not apparent at the other two distances. In contrast, Wedding et al. (1995) captured *N. sertifer* in increasing numbers as wind speed rose from 1 to 3 m/s, possibly because some males were released upwind and were transported toward the traps. There are, however, several indications from other studies for an optimal wind speed with regard to odorant source finding in insects (Nottingham, 1987; Aluja and Prokopy, 1992; Brady et al., 1995; Messing et al., 1997).

Travel Time. If the shortest recorded travel times are converted to 'travel speed,' we obtain ca. 5–10 m/min for the fastest *N. sertifer* males flying upwind. This speed is lower than the 20–30 m/min recorded for gypsy moths, *Lymantria dispar* L. (Elkinton et al., 1987) and 50–75 m/min for pea moths (Wall and Perry, 1987), both at wind speeds comparable to those in our study. However, the pea moths were released in a wheat field (Wall and Perry, 1987) and the gypsy moths in a pine plantation with little understorey vegetation (Elkinton et al., 1987), whereas the relatively dense birch plantation in our study allowed the pine sawflies to land in the birches on their way towards a trap. Among tsetse flies, *Glossina pallidipes* Aust., flying upwind at 5 m/s to an odorant source 75 m away, two cohorts were observed, those arriving directly and those making stops along the way (Griffiths

et al., 1995). The high wind speed in the 50 m experiments (Table 2), might have aided the sawflies to fly faster (or make fewer stops) than in the 200 m experiments.

Longevity and Effects from Age. Longevity in pine sawflies is temperature-dependent (Mallach, 1974). In Canada *N. sertifer* males lived on average 20 days at 18°C (range 4–32°C) and 25 days at 15°C (Lyons and Griffiths, 1962). In their 18°C treatment, an unexplainably longer longevity was recorded than the 11–12 day duration at 13.6 ± 4°C in our study. Male and female white pine sawflies, *Neodiprion pinetum* (Norton), lived 3–4 days at a constant temperature of 23°C (Rauf and Benjamin, 1980), whereas *Neodiprion fulviceps* Cresson lived only 2–3 days in the laboratory (Wagner et al., 1986). The combination of the males' flight ability during upwind progress and their longevity (12 days) suggest a potentially large sampling range of the Lund-I traps used in this study.

Moths often show a peak in response to pheromone at intermediate ages (McNeil, 1991 and references therein). However, although the amplitudes of EAG's recorded from *N. sertifer* increased until day 4 after emergence (Hansson et al., 1991), no trend could be seen in the capture of males of different ages in our study. In contrast, more 2 day old gypsy moth males were captured than 1 day old males (Elkinton and Cardé, 1980). In general, it seems as if the insect increases its sensitivity to the pheromone with increasing age, while the flight ability decreases (e.g., Haniotakis and Pittara, 1994; Shirai, 1998). In a short-lived species like *N. sertifer*, the 'optimal' age to locate a pheromone source is, therefore, about 1–2 days.

Observations at the Trap. The 52.2% catch efficiency obtained in this study is comparable with the highest proportions of pea moths captured by Lewis and Macaulay (1976) with different types of traps. In their study, there was no way of knowing if some moths returned and were caught later. In our study, males were marked, and many could be observed taking off several times before being trapped. The efficiency of the Lund-II trap may seem low, but it has the advantage of low catches when unbaited (Anderbrant et al., 1989). In a mark-release-capture experiment using the bark beetles *Ips typographus* L., Helland et al. (1984) recorded that some beetles were constantly lost from the close vicinity of a pheromone trap, and concluded that this was one explanation for pheromone traps having low catch efficiency.

Acknowledgments—We thank Karin Johnson, Johanna Skobe and Thomas Johansson for excellent technical assistance in the field, Christine Achberger, Marie Ekström and Kristina Blennow for running the weather station, Fredrik Schlyter and Neil J. Vickers for review of an earlier version of the manuscript, and Erik Hedenström and Hans-Erik Högberg for kindly providing the pheromone. The research was funded by the Swedish Council for Forestry and Agricultural Research, Stiftelsen Futura and the Commission of the European Communities, Agriculture and Fisheries (FAIR) specific RTD programme "Pine sawfly pheromones for sustainable management of European forests (PHERODIP)," CT 95-0339. The study does not necessarily reflect the Commission's views and in no way anticipates its future policy in this area.

DUAL CHEMICAL BARRIERS PROTECT A PLANT AGAINST DIFFERENT LARVAL STAGES OF AN INSECT

(Received February 23, 2001; accepted April 16, 2001)

Abstract—The host plants of the native American butterfly, *Pieris napi oleracea*, include most wild mustards. However, garlic mustard, *Alliaria petiolata*, a highly invasive weed that was introduced from Europe, appears to be protected from this insect. Although adults will oviposit on the plant, most larvae of *P. n. oleracea* do not survive on garlic mustard. We used feeding bioassays with different larval stages of the insect to monitor the isolation and identification of two bioactive constituents that could explain the natural resistance of this plant. A novel cyanopropenyl glycoside (**1**), alliarinoside, strongly inhibits feeding by first instars, while a flavone glycoside (**2**), isovitexin-6″-D-β-glucopyranoside, deters later instars from feeding. Interestingly, the first instars are insensitive to **2**, and the late instars are little affected by **1**. Furthermore, differential effects of dietary experience on insect responses suggest that **1** acts through a mechanism of post-ingestive inhibition, whereas **2** involves gustatory deterrence of feeding.

Key Words—Pieris, pieridae, crucifer, feeding deterrent, feeding inhibition, flavonoid, garlic mustard, Alliaria.

INTRODUCTION

Plants are chemically defended from insect herbivores by the presence of repellents, oviposition deterrents, feeding deterrents, and toxins. However, some herbivores inevitably adapt to these defenses and may eventually specialize by utilizing the "defensive compounds" to recognize their host plants (Ehrlich and Raven, 1964; Lindroth, 1988). In the Cruciferae (=Brassicaceae), glucosinolates and their

0098-0331/01/0800-1575$19.50/0

hydrolysis products act as a first line of defense against generalist insects, but some of these compounds have become signals for host finding and acceptance for many specialists (Feeny, 1977; Chew, 1988; Chew and Renwick, 1995). Some crucifers, however, produce additional compounds that protect them from specialists. For example, butterflies of the imported cabbageworm, *Pieris rapae* L. are deterred from ovipositing on *Erysimum cheiranthoides* and *Iberis amara* by the presence of cardenolides and cucurbitacin glycosides, respectively (Sachdev-Gupta et al., 1990; Huang et al., 1993). Larvae of this butterfly also are deterred from feeding on these plants by the same and similar compounds (Sachdev-Gupta et al., 1993a,b). The presence of such bioactive chemicals may have contributed to the rapid proliferation of many introduced plants in North America. For example, garlic mustard, *Alliaria petiolata*, a particularly invasive crucifer that was introduced from Europe late in the 19th century, is relatively free of herbivory (Nuzzo, 1993). The native butterflies, *Pieris napi oleracea* and *P. virginiensis*, oviposit on this plant, but their larvae usually do not survive (Bowden, 1971; Chew, 1981). In this study, experiments were conducted to examine the basis for the failure of *P. n. oleracea* larvae to develop on garlic mustard. Two chemicals responsible for inhibiting feeding were identified, and a unique system of selective resistance against different larval stages was discovered.

METHODS AND MATERIALS

Plants. Alliaria petiolata seedlings were obtained from various natural sites in the vicinity of Ithaca, New York, and transplanted into 10 cm cord pots of artificial soil (Cornell Mix A) in an air-conditioned greenhouse that was maintained at *ca* 25°C. Supplementary lighting was provided by 400-W multivapor high intensity discharge lamps.

Chemical Extraction. After 4-6 weeks, foliage from rosette plants was harvested and extracted with boiling ethanol for 5 min. The ethanolic extract was evaporated to dryness under reduced pressure, and lipids were removed by extracting with n-hexane. The defatted residue was dissolved in water and the aqueous solution was partitioned 3 times with 1-butanol. The combined butanol extract and the post-butanol water extract were concentrated under reduced pressure and dissolved in methanol/water mixtures for bioassays.

Insects. P. n. oleracea larvae for bioassays were from a colony started with insects that were collected by Dr. F. S. Chew (Tufts University) in Vermont and maintained in the laboratory at *ca*. 25°C. The colony was renewed or supplemented with field-collected butterflies on an annual basis. Oviposition occurred on cabbage plants in greenhouse cages, and the larvae were reared on cabbage (*Brassica oleracea* L var Golden Acre). Naïve neonates (no experience with a plant) were

obtained by allowing butterflies to oviposit on a strip of Parafilm that was wrapped around a beaker immediately below a cabbage leaf, on which butterflies made tarsal contact (Webb and Shelton, 1988).

Bioassays. Choice bioassays for feeding deterrent activity were conducted with early 4th instar larvae, using 1.5 cm diameter cabbage leaf discs as test substrate. Each side of test discs was treated with 20 μl of solution to provide a total of 0.1 gram leaf equivalents (gle) per disc, whereas pure solvent was applied to control discs. The tests were conducted in waxed paper ice cream cups (250 ml), each containing a paraffin wax layer at the bottom, which was covered with moist filter paper. Two treated and two control discs were arranged alternately in each cup and supported on insect pins. Four larvae were placed in the center of each cup, which was covered with a perforated plastic lid. After a period of 6 hr in the dark, the remaining area of each disc was measured with a LiCor-3100 area meter. The area consumed was obtained by subtracting the remaining area of each eaten disc from the average measurement of all discs that showed no signs of feeding. Feeding inhibition was expressed as a feeding deterrent index (FDI): $\mathrm{FDI} = 100 \times (\mathrm{C} - \mathrm{T})/(\mathrm{C} + \mathrm{T})$, where C is the area of control discs consumed and T is the area of treated discs consumed (Dimock et al., 1991). An FDI value of zero means that there is no preference, a positive value means that there is a preference for the control, and a negative value means a preference for the treatment. Subsequent bioassays with 2nd, 3rd, and 5th instars were conducted in the same manner. The time period for these assays was adjusted to allow for different consumption rates of the different instars. In each case, assays were terminated when approximately 50% of the control discs had been consumed.

For neonate assays, one treated and one control disc were pinned at the same height near the center of each cup so that they overlapped and larvae could readily move from one disc to the other. Five larvae were introduced to the overlapping area and the assays were continued for 24 hr, when measurable feeding had usually occurred. To determine the effects of diet on larval responses to the active compounds, eggs were allowed to hatch on a wheat germ diet (Bell et al., 1979) in styrofoam cups (250 ml), which were kept in an incubator at 27°C until the larvae at the different stages were used for assays.

Chemical Isolation. Semi-preparative HPLC was performed by using a C_{18} Bondex 10 (Phenomenex) column, 300 × 7.8 mm, at a flow rate of 2 ml/min. Subsequent analytical separation and isolation of pure compounds was accomplished by using a Luna C_{18} column, 250 × 4.6 mm (Phenomenex) at a flow rate of 1 ml/min. For both HPLC systems, a gradient of water and acetonitrile was used: CH_3CN 0% at time 0, 15% at 5 min, 30% at 25 min, and 10% at 30 min. The HPLC effluent was monitored by a diode array detector at 254 nm and at 218 nm.

RESULTS AND DISCUSSION

Previous studies have shown that water-soluble fractions from ethanolic extracts of *A. petiolata* foliage contain both oviposition stimulants and deterrents for *P. n. oleracea* butterflies, and the deterrent compounds could be extracted into butanol. Despite the presence of these unidentified deterrents, acceptance for oviposition could be attributed to the overwhelming effect of allylglucosinolate that is present as a stimulant (Huang et al., 1995). In this study, we tested for the presence of feeding inhibitors in similar extracts of rosette leaves of *A. petiolata*, before and after partitioning with 1-butanol. In choice bioassays with 4th instar larvae, we found that butanol extracts have strong antifeedant activity. Cabbage leaf discs treated with 0.1 gram leaf equivalents (gle) of the butanol extract were consumed by larvae significantly less than control discs that were treated with solvent alone (FDI $= 35.74 \pm 4.94$, $N = 10$). Reverse phase HPLC analysis of the butanol fraction using a water-acetonitrile gradient gave a chromatogram which showed 4 significant peaks (Figure 1). The UV-spectra corresponding to all but the first of these peaks were typical of flavonoids. Four major fractions (A–D), each of which included material associated with one major peak, were collected for bioassays. Feeding by 4th instar larvae of *P. n. oleracea* was deterred only by the fraction B (Figure 2a).

Additional bioassays with newly hatched larvae indicated that the total butanol extract of *A. petiolata* was even more inhibitory to neonates than to the 4th instars (mean FDI 54.6 vs 35.7, $N = 10$) . However, the fraction B, which was most inhibitory to 4th instars, was relatively inactive against neonates. Instead,

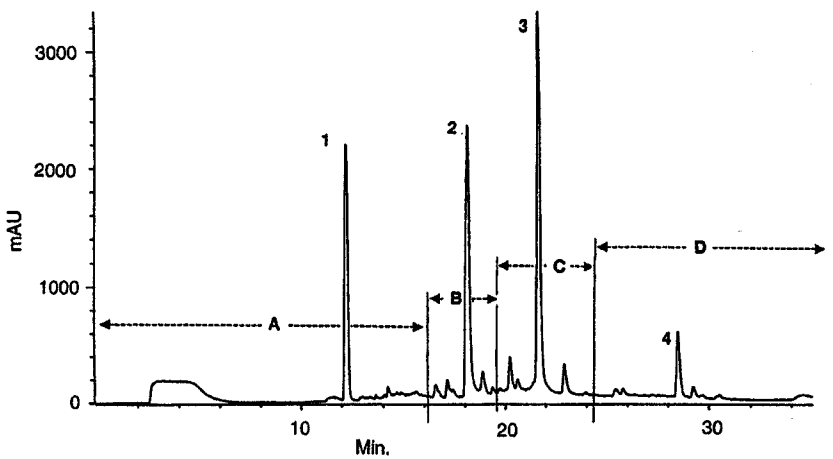

FIG. 1. High pressure liquid chromatogram of the 1-butanol fraction obtained from aqueous extract of *Alliaria petiolata*, with UV monitoring at 218 nm.

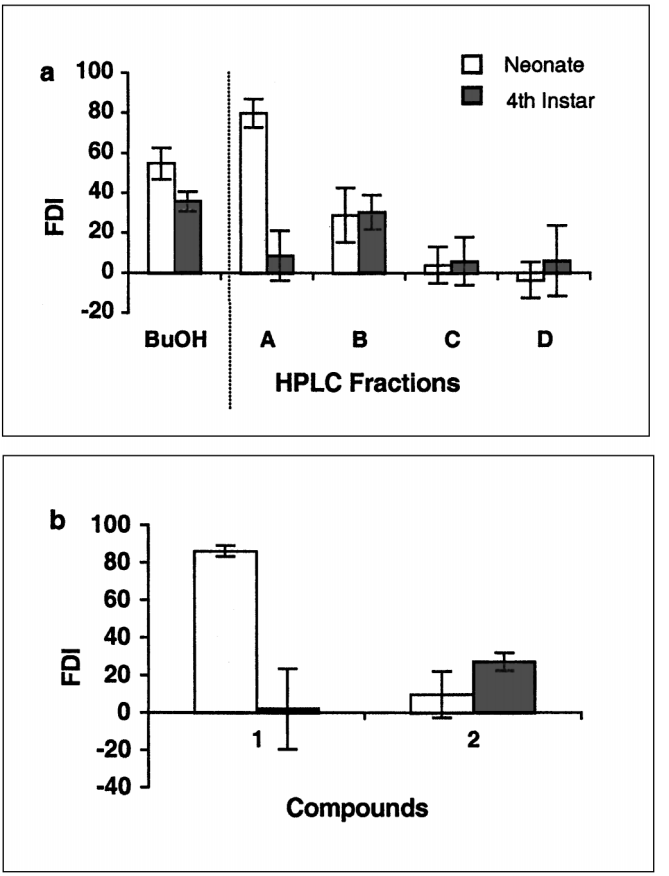

FIG. 2. Feeding inhibition (Feeding Deterrent Index, mean ± SE, $N = 10$) of neonate and 4th instar *P. napi oleracea* by **a**: total butanol extract (BuOH) and individual HPLC fractions, and **b**: compounds **1** and **2** isolated from these fractions by HPLC, at concentrations of 0.1 gram leaf equivalents/disc.

the fraction A that showed no activity against 4th instars was most inhibitory to neonates (Figure 2a). The major compound in each active fraction (**1** from A and **2** from B) was isolated by HPLC and tested for activity against both 1st and 4th instars. Compound **1** inhibited feeding by neonates, whereas compound **2** was active against the 4th instars (Figure 2b).

To determine the stage of development at which larval sensitivity changes from one compound to the other, we measured the responses of larvae to each compound at each stage in their development. Batches of larvae were reared from egg to 5th instar on cabbage or on wheat germ diet, and groups of larvae were

removed for assays at each stage. Previous work with *Pieris rapae* showed that larval responses to feeding deterrents can depend on dietary experience, and specific constituents of wheat germ are responsible for suppressing development of sensitivity to deterrents Huang and Renwick, 1995, 1997). Our experiments with *P. n. oleracea* now show that the larval response of this species to compound **1** is unaffected by diet, but sensitivity to the feeding inhibitor decreases steadily to zero by the time larvae molt to the 4th instar (Figure 3a). In contrast, the larval response to compound **2** is clearly dependent on diet. Larvae reared on wheat germ diet

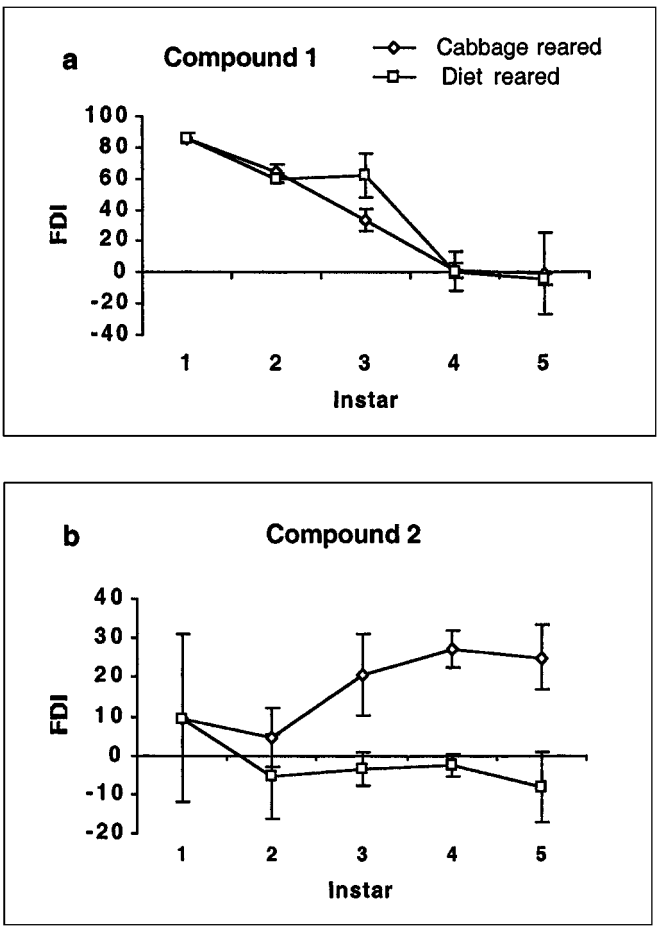

FIG. 3. Feeding inhibition by compounds **1** and **2** on different instars of cabbage-reared and wheat germ-reared larvae of *P. napi oleracea* (Feeding Deterrent Index, mean ± SE, $N = 10$).

remain insensitive to compound **2** throughout their development, whereas larvae feeding on cabbage develop sensitivity to reach a maximum during the last two instars (Figure 3b).

Compound **2** has been identified previously as a flavone glycoside, isovitexin 6"-*O*-β-D-glucopyranoside (Figure 4) (Haribal and Renwick, 1998). Compound **1** was collected by preparative HPLC of butanol extracts to provide mg quantities of material for spectral analysis, resulting in its identification as 4-β-D-pyranoglucosyloxyl-2(Z)-propene-1-nitrile (Haribal et al, 2001) (Figure 4).

Behavioral observations during bioassays provided clues about the mechanisms involved in the rejection of *A. petiolata* as a food plant. When neonate larvae were presented with a cabbage disc that was treated with a butanol extract of *A. petiolata* foliage or with isolated compound **1**, limited nibbling at the surface was observed, without any visible damage. However, some ingestion was evident from the green color visible in the larval gut, which is translucent at this stage. Similarly, when neonates were placed on the surface of a rosette leaf of *A. petiolata*, about one-quarter to one-third of the gut became green within a period of 4 hr, after which the larvae became motionless and made no further attempt to feed. In contrast, those 4th instars that rejected *A. petiolata* rosettes or cabbage discs treated with compound **2** made no attempt to feed or even to bite the plant tissue. (Note: the FDIs reflect combined data from larvae that fed to some extent and those that rejected treated discs outright). This observation would indicate that no ingestion

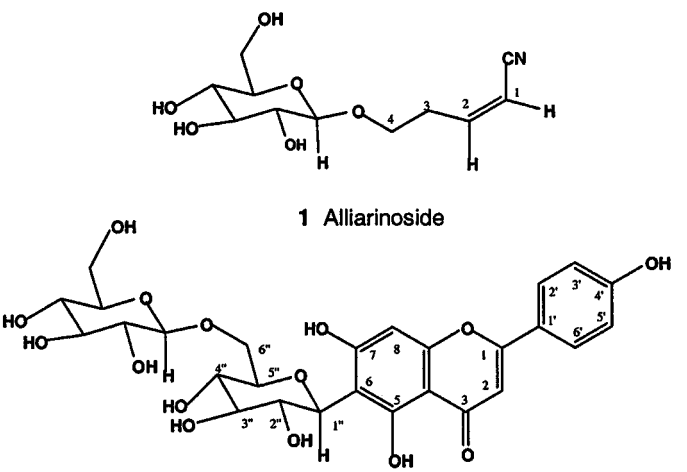

FIG. 4. Structures of compounds **1** and **2** identified as feeding inhibitors from *Alliaria petiolata.*

occurred before rejection by these individuals, whereas extensive palpation with the mouthparts would suggest that taste was involved in their rejection behavior (unpublished data).

Two distinct mechanisms appear to be involved in the resistance of garlic mustard to these pierid caterpillars. Compound **1** inhibits feeding by early instars through an apparent post-ingestive feedback mechanism (Frazier, 1991), whereas compound **2** acts as a direct feeding deterrent that is perceived by taste receptors on the mouthparts of late instars. To our knowledge, this is the first report of such selective barriers in a plant against different larval stages of an insect herbivore. The phenomenon of differential larval responses appears to be a result of simultaneous development of post-ingestive tolerance and taste sensitivity as the larvae feed and develop on their host plants.

Exploitation of garlic mustard as a potential host plant by *P. n. oleracea* is apparently thwarted by the presence of these two unrelated chemicals. Compound **1** effectively blocks feeding by first instars, so that any development of larvae from hatching eggs is unlikely. In addition, the potential migration of late instars from neighboring host plants is likely to fail as a result of the deterrent activity of compound **2**. Although it is clear that the response of such larvae to the deterrent will depend on their previous diet, experience on a preferred host such as cabbage is likely to result in relatively high sensitivity.

Subsequent studies have resulted in the identification of additional flavonoids in foliage of *A. petiolata*, but these do not appear to play a significant role in protecting the plant from *P. napi oleracea*. However, seasonal and population variation in content of the active constituents could potentially affect the susceptibility of garlic mustard to herbivory. (Haribal and Renwick, 2001).

SEASONAL AND POPULATION VARIATION IN FLAVONOID AND ALLIARINOSIDE CONTENT OF *Alliaria petiolata*

MEENA HARIBAL* and J. ALAN. A. RENWICK

Boyce Thompson Institute, Tower Road, Ithaca, NY 14853, USA

(Received December 19, 2000; accepted April 7, 2001)

Abstract—*Pieris napi oleracea*, an indigenous butterfly in North America, lays eggs on *Alliaria petiolata*, an invasive weed that was introduced from Europe. However, larval development on plants from different sources varies considerably. *A. petiolata* is a compulsive biennial, and its foliage is rich in apigenin flavonoids. We compared the chemistry of different vegetative forms from different populations in the vicinity of Ithaca, NY throughout the year. Significant differences occurred in the number of apigenin derivatives in different populations and vegetative forms, and seasonal variations in the amounts of these compounds were found. We have previously isolated two major compounds, alliarinoside [(2*Z*)-4-(β-D-glucopyranosyloxy)-2-butenenitrile] (**1**) and isovitexin-6-*O*″-β-D-glucoside (**3**), which negatively affect development of *P. napi oleracea* larvae. Comparative analyses of these compounds in two populations throughout the year showed that their concentrations reached maxima twice annually. Foliage is almost devoid of flavonoids in June-July. Thus, variation in the chemistry of the plant may account for observed variation in development rates and survival of the larvae. Several apigenin compounds were isolated and identified by spectral studies.

Key Words—*Alliaria petiolata*, *Pieris*, flavonoids, variation, seasonal, cyanoglucoside, Cruciferae.

INTRODUCTION

Alliaria petiolata, a native crucifer of Europe is quickly spreading in the eastern united states, replacing the native flora in various habitats. It was first reported on Long Island about 150 years ago, and is now distributed throughout many states from Maine to North Carolina in the south, and west to Wisconsin and Illinois (Nuzzo, 1993). Previously, a few C-glycosides were reported from *A. officinalis*

*To whom correspondence should be addressed. e-mail: mmh3@cornell.edu

(=*petiolata*) by Paris and Delaveau (1962). We have reported isovitexin 6″-*O*-β-D-glucopyranoside (3) from the foliage of *A. petiolata* as a compound that deters feeding by 4th instar larvae of *Pieris napi oleracea* (Harris), an indigenous butterfly of the north eastern USA (Haribal and Renwick, 1998). More recently, from aqueous extracts of *A. petiolata*, we identified (2*Z*)-4-(β-D-glucopyranosyloxy)-2-butenenitrile (alliarinoside) (**1**) as a feeding inhibitor/deterrent for first instar larvae (Haribal et al., 2001). However, field observations suggest that some populations of *P. napi oleracea* can survive on selected populations of *A. petiolata* (Chew, 1980; Courant et al., 1994; Chew et al., 1996). We have found considerable variation in alliarinoside and flavonoid content in different sources of the plant, and, in the present paper, we investigated variation in flavonoid content throughout the year, in different populations, and in different leaf forms to help explain observed variation in *P. napi oleracea* survival.

METHODS AND MATERIALS

Plant Material. To examine geographic differences, samples of *Alliaria petiolata* were collected from Tompkins County, in the neighborhood of Ithaca, NY, including Eastern Heights, Dryden Lake, and Salmon Creek areas. Additional samples were obtained from seeds collected in Massachusetts by F. S. Chew. Seedlings of these were grown in a greenhouse and in garden plots in June 1995. Both cauline and rosette leaves of the same plants were collected whenever available. Thirteen samples of rosette and 12 of cauline leaves randomly collected from each site (1-3 samples per site) were included for chemical analysis.

To monitor seasonal variation, the plants were studied throughout the year from Dryden Lake and Salmon Creek areas. Three samples of each leaf type were randomly collected every month (except in February and March, when only two samples were collected) from each location according to availability. Cauline leaves were present only from late May to July and rosette leaves were scarce in June and July.

Sample Preparation and HPLC Analyses. 0.25 g of fresh young leaf material were boiled in 5 ml of EtOH for 5 min and the resulting mixture was blended using a Tissue Tearor before dilution with water to 10 ml. After centrifugation, 6 ml of supernatant solution were evaporated to dryness and redissolved in 6 ml of water to give a concentration of 0.05 gram leaf equivalent (gle) per 2 ml. Suspended particles were removed by filtering through 4 μ nylon filters. Samples of 0.05 gle were directly injected onto the HPLC, fitted with a C_{18} RP column (C_{18} Bondex 5 μ, 300 $\times$ 7.0 mm, Phenomenex) using a water-acetonitrile gradient at a flow rate of 2 ml/min (0-5 min 0% acetonitrile; 25% acetonitrile at 40 min; 100% acetonitrile at 50 min), monitored by a Photodiode Array Detector at 218 and 254 nm.

Spectroscopic Methods. ^{1}H NMR spectra were recorded at 399.99 MHz, and ^{13}C NMR at 25.59 MHz in DMSO-d_6 or in acetone-d_6 unless otherwise stated, on a Varian instrument. ESI mass spectra were recorded on a Micromass (Manchester, UK) Quattro 1 instrument and the samples were introduced by a direct infusion method.

Quantification and Statistical Methods. The total absorption unit (AU) value was calculated as area under each peak (at 218 nm) to compare concentrations. Quantities of individual components of rosette leaves and cauline leaves from the same plant and from different plants in the same season were compared using the Student t-test. Mean values from the seasonal samples collected at Dryden Lake and Salmon Creek were also compared by the Student t-test. Only data for rosette leaves were used for this analysis.

RESULTS

The water-soluble fraction contained primarily highly polar compounds, including several flavonoid glycosides, which were indicated by their UV spectra obtained with the diode array detector. Eight chromatographic peaks, one corresponding to alliarinoside (**1**), and seven flavonoids, designated compounds **2–8** (Figure 1) with increasing retention time were analyzed. Considerable variation

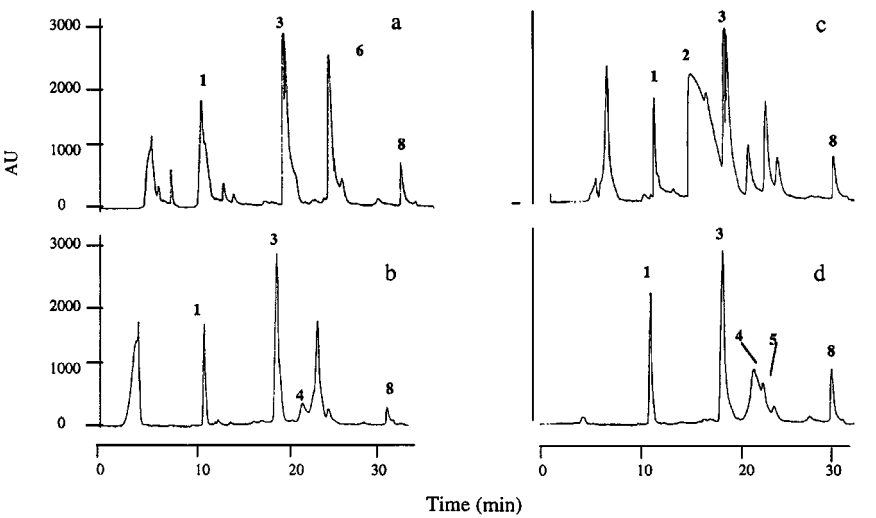

FIG. 1. HPLC chromatograms of extracts (0.05gle) of rosette leaves of *A. petiolata* from a) Eastern Heights, b) East Ithaca recreation way, c) Salmon Creek, d) from plants collected as seed in Massachusetts and grown in a greenhouse (UV absorptions monitored at 218 nm).

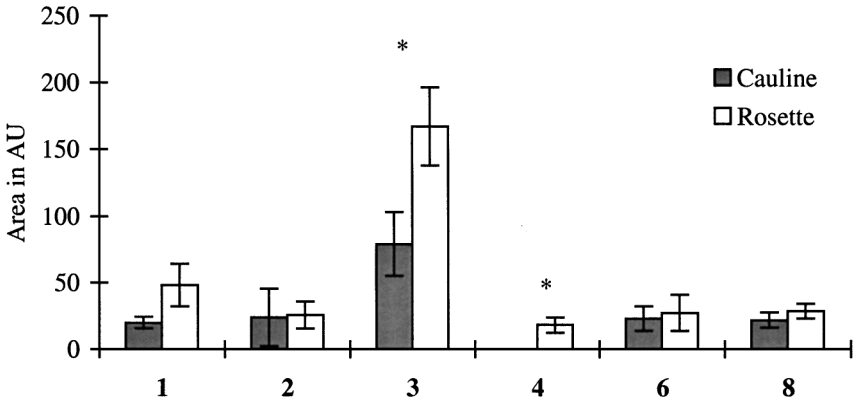

FIG. 2. Mean concentrations ± SE ($N = 13$ for rosette and $N = 12$ for cauline leaves) expressed in area ×1000 AU of alliarinoside (**1**) and flavonoids (**2–8**) in cauline and rosette leaves of *A. petiolata*. Integration values obtained based on absorption at 218 nm.

in flavonoid and in alliarinoside content (Figure 1 is a representative example of 4 samples) in the plants from different populations and in the different vegetative types of foliage (Figure 2) were found. Most flavonoids were flavones, but, in a few cases, kaempferol derivatives were detected. In some young leaves, anthocyanins were also present. Seven major flavonoids were detected. Most samples contained alliarinoside (**1**), flavonoids **2**, **3**, and **8**, at retention times of 10.8, 17.3, 19.5, and 32.5 min, respectively, at varying concentrations. The identification of compounds **1** and **3** has already been reported (Haribal and Renwick, 1998; Haribal et al., 2001). On the basis of its spectral data, compound **2** was identified as isoorientin-6″-*O*-*β*-D-glucopyranoside (Chulia and Mariottee, 1985). The ^{1}H NMR spectrum of **2** showed satellite peaks (at δ 5.00 and 4.66) for anomeric protons of hexose sugars, suggesting that a structural isomer of compound **2** was present at 5% of compound **2**. Other flavonoids **4**, **5**, **6** and **7** eluted at 21.6, 22.7, 23.7, and 29.0 min. Compound **6** has been identified as 6‴-*O*-sinapoyl-isovitexin-6″-*O*-*β*-D-glucopyranoside (Haribal et al., 1999). Compounds **4** and **5** were found to be isomers of **3** as shown by ESIMS ($[M + H]^+$ 595), but their fragmentation patterns were quite different. Since only small samples were available, no further structural analysis could be carried out. Peak **8** was found to represent a mixture of di-sinapoyl derivatives of an apigenin C-glycoside (MW 1008). Their complex ^{1}H NMR spectrum indicated that these may be structural isomers that have yet to be completely identified.

The rosette leaves contained higher concentrations of all compounds than did cauline leaves. The concentration of **1** in rosette leaves was not significantly different from that in the cauline leaves ($P = 0.064$), but levels of **3** (isovitexin 6″-*O*-*β*-D-glucopyranoside) were significantly higher ($P < 0.05$) (Figure 2). On

the basis of UV calibration curves, we estimated that the highest concentration of **3** in rosette leaves was 12–15 mg ($2.0–2.5\times10^{-5}$ mol) per gm fresh wt. Compound **4** was present in many populations of rosette leaves, but was absent from cauline leaves (Figure 2). The concentration of **1** could not be accurately assessed, since its highly hygroscopic nature made accurate weighing difficult.

The plants from the Dryden Lake area had fewer flavonoids than did those from Salmon Creek or from any other areas we investigated. Foliage from the Dryden Lake population contained **2**, **3** and **8**, as well as **7**, which was absent in the specimens from Salmon Creek (Figure 3). The plots of mean concentrations of flavonoids showed a bimodal temporal pattern in a given season for most of the compounds in both populations, but the patterns were not synchronized for the two populations. Flavonoid concentrations reached maxima around December–February and in May. Around June–July, when plants were senescing, most of the flavonoids were at low levels or undetectable. Only the flavonoid **8** was present throughout the year, and little temporal variation in its abundance occurred in the population from the Dryden Lake area (Figure 4). However, in the population from Salmon Creek, **8** reached higher concentrations when no other flavonoids were present. There were no differences in content of alliarinoside ($P = 0.41$, Student *t*-test) and isovitexin 6″-*O*-β-D-glucopyranoside ($P = 0.45$, Student *t*-test) (Figure 5) between the two the populations throughout the year, although these compounds reached maximal concentrations at different times. Also, **2** (Figure 6) was more abundant in the population from Salmon Creek area than in that from Dryden Lake area ($P < 0.0001$).

Integration values obtained for absorptions at 218 nm.

DISCUSSION

A. petiolata is a biennial (winter annual), which germinates in autumn and senesces by the following summer. It grows in different types of habitat, but prefers habitats that are in the shade of woods, along river edges, and along the roadside (Nuzzo, 1993). It is one of the first plants visible after snow-melt and it flowers by May, at which time trees and other plants are just beginning to leaf in our study area. Light, therefore, is not likely to be a direct cause of variation in individual flavonoids, although a higher total flavonoid content in May is probably related to light or day length. Plants from seeds collected in Massachusetts, when grown in greenhouse conditions, contained higher amounts of the isovitexin 6‴-*O*-sinapoyl-6″-*O*-β-D-glucopyranoside (**6**) than when grown in garden plot under natural conditions (unpublished results). Similarly, plants collected as seedlings from Eastern Heights in Ithaca produced more of **6** after cultivation in the greenhouse. Thus, **6** may be produced in response to greenhouse conditions, but a detailed investigation will be necessary to confirm this conclusion.

Several researchers have suggested that the structural diversity in flavonoid content of plants is due to genetic polymorphism and selective expression of different genes encoding for biosynthetic enzymes in response to different environmental stimuli (Chaves et al., 1993 and refs. therein). However, we did not attempt

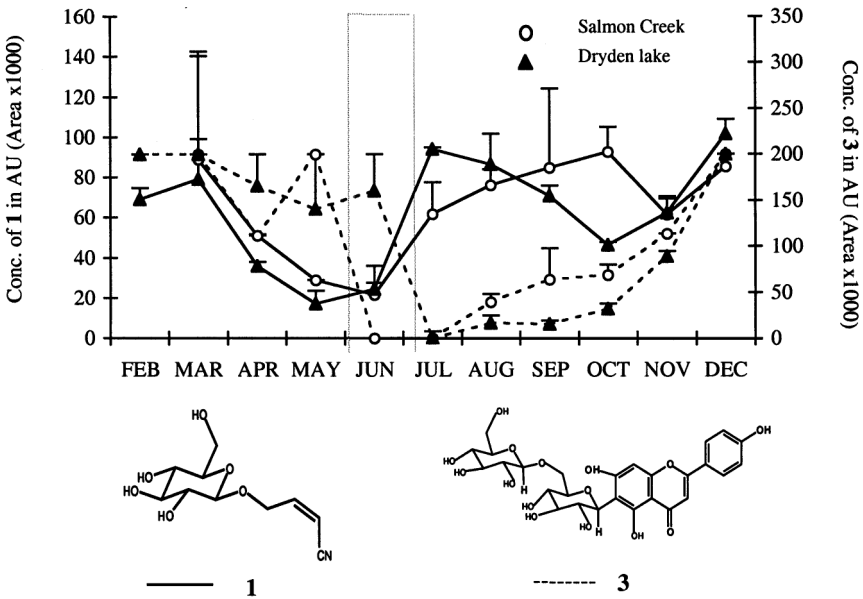

FIG. 5. Seasonal variation in concentrations expressed in area $\times 1000$ AU (values represent means $\pm$ SE for $N = 3$, except for Feb and Mar when only 2 replicates were collected) of **1** (alliarinoside) and **3** (isovitexin-6″-*O*-β-D-glucopyranoside) in extracts (0.05gle) of rosette leaves of *A. petiolata*. Integration values obtained based on absorption at 218 nm.

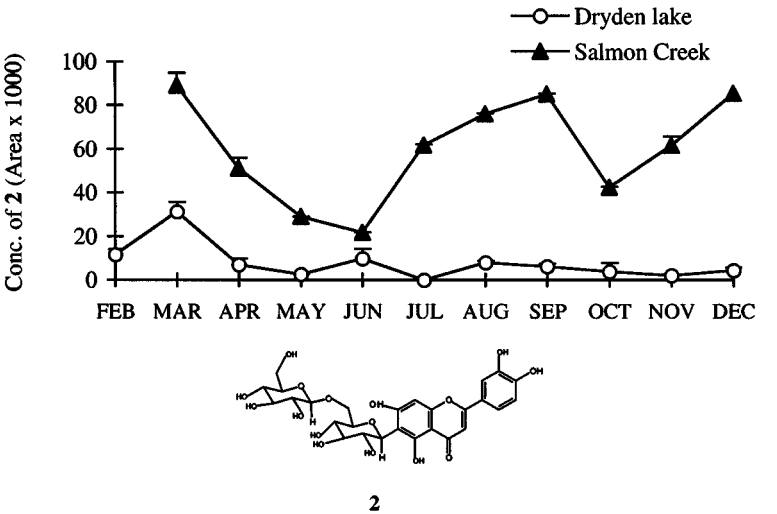
to confirm the role of genetics in the observed variation. The flavonoid content of plants is also known to vary quantitatively and qualitatively depending on growth stage, degree of senescence, season, and geographical location (Bohm et al., 1984; Chaves et al., 1993). Specific flavonoids are also produced in response to pathogens (Malhotra et al., 1996), wounding stress, herbivory, strong light, especially UV-B (Cuadra et al., 1997), and temperature stress (Chaves et al., 1997). Cooper-Driver et al. (1977) reported that variation in flavonoids in *Pteridium aquilinum* affects palatability to mammals and phytophagous insects such as the locust, *Schistocerca gregaria*.

A. petiolata appears to be relatively free of herbivory, except for limited slug feeding and damage by leaf miners. Flea beetles, major pests of most crucifers, generally avoid this plant (Nielsen et al., 1979). *P. napi oleracea* larvae cannot survive on *A. petiolata*, although the plant may be suitable for oviposition (Huang and Renwick, 1993). Alliarinoside inhibits feeding by neonate larvae, but later instar larvae are deterred by isovitexin 6"-*O*-β-D-glucopyranoside (Renwick et al., 2001). Szentesi (1991) and Chew et al. (1996) have shown that *P. rapae* and some populations of *P. napi* can survive on this plant. It seems likely that this occurs



2

FIG. 6. Seasonal variation in concentrations (expressed in area $\times 1000$ AU) (values represent means $\pm$ SE $N = 3$, except for Feb and Mar when only 2 replicates were collected) of **2** (isoorientine-6″-*O*-β-D-glucopyranoside) in Salmon Creek and Dryden Lake samples (0.05gle) of rosette leaves of *A. petiolata*. Integration values obtained for absorptions at 218 nm.

when levels of both alliarinoside and isovitexin 6″-*O*-β-D-glucopyranoside in the plant are below the threshold necessary for inhibition of feeding (Figure 5). When the flavonoid content is at its lowest level in June-July, the concentration of alliarinoside is at its highest (Figure 5), so that the plant has some protection mechanism at all times. Thus,variation in chemistry may explain the differential survival rates of *P. napi oleracea*, although variation in responses to these compounds by individual insects and populations may also play a role in the differential success of the species.

Acknowledgments—We wish to thank Dr. F. S. Chew for the sample of *Alliaria* seeds and for reviewing an earlier version of this manuscript. We also are grateful to Dr. A. Attygalle for running LC-MS of some of the flavonoids. This work was supported by NSF grant number DEB-9419797.

(Received November 28, 2000; accepted April 4, 2001)

Abstract—The food selection, growth, and fecundity of insect herbivores are largely dictated by the chemical composition and nutritive values of plant foliage. We studied the host-use efficiency of larvae of the generalist moth, *Operophtera brumata* (Lepidoptera: Geometridae) on three chemically divergent but nutritively similar willows (*Salix* spp.). The 4th instars were able to use the salicylate-free leaves of *S. phylicifolia* efficiently. Growth was slightly reduced on *S. pentandra*, which contained a moderate level of acetylated salicylates. The high concentration of salicylates found in the leaves of *S. myrsinifolia* seemed to provide efficient protection against non-specialized *O. brumata*. We also studied assimilation of nutrients and degradation of salicylates and other secondary compounds in the digestive tract of *O. brumata* larvae. Neither the assimilation of nitrogen nor of carbon were affected by secondary chemicals of ingested food. Salicylates were shown to be degraded to salicin and catechol, while further degradation of salicin to saligenin was rather slow. In an artificial diet experiment, we showed that two degradation products of salicylates, catechol and saligenin markedly reduced the growth of the larvae. Neither salicin nor chlorogenic acid affected larval growth. We conclude that salicylates reduced the growth of the generalist winter moth mainly by feeding deterrence caused by 6-hydroxy-2-cyclohexenone and catechol. Compared to the deleterious effects of salicylates the effects of other secondary compounds were minor.

Key Words—*Salix* spp., willow, phenolic glycosides, salicylates, *Operophtera brumata*, polyphagy, insect herbivory.

INTRODUCTION

Generalist insect herbivores are able to feed on a large number of different plant species. However, they are affected by variation in leaf quality: some species are clearly better hosts than others and many species are totally avoided. The differential suitability of plant species for generalist insects is based on structural and chemical defenses and on nutrient content of plant tissues. Because the majority of individuals in aboreal insect herbivore communities are generalists, effective defense against them may benefit plants by protecting them from severe defoliation, thus saving plant resources for growth and reproduction.

Operophtera brumata L. (Lep., Geometridae) is a typical polyphagous, spring-feeding leaf-defoliator of deciduous shrubs and trees, which may use numerous plant species belonging to several different genera as hosts. In eastern Fennoscandia, *Querqus robur* L. and *Prunus padus* L. are the primary hosts of the winter moth (Tikkanen, 2000). The chemistry of the leaves of these two hosts is, however, very dissimilar. The leaves of *P. padus* contain cyanogenic glycosides (Seigler, 1998) and a low level of tannins (Julkunen-Tiitto, personal communication), whereas the leaves of *Q. robur* are rich in tannic compounds (Feeny, 1968, 1970). During occasional outbreaks *O. brumata* can feed on many suboptimal host species including several willow species (*Salix* spp.) (Kirsten and Topp, 1991; Tikkanen et al., 1998, 1999, 2000). Since willows are common and abundant shrubs and trees in early successional deciduous forests in northern Europe (Hämet-Ahti et al., 1998; Skvortsov, 1999), where in many places the main hosts of *O. brumata* can be quite scarce, willows are potential alternative hosts of *O. brumata* (Tikkanen et al., 1998, 1999, 2000).

It is known that the palatability of different willow species to leaf-defoliators is largely determined by the chemical composition of the leaves. Salicylates deter feeding of many generalist insect herbivores (Tahvanainen et al., 1985; Lindroth et al., 1988; Lindroth and Peterson, 1988), but, can stimulate oviposition (Denno et al.,1990; Kolehmainen et al., 1994) and feeding of specialists (Matsuda and Matsuo, 1985; Smiley et al., 1985; Tahvanainen et al., 1985; Rank, 1992; Kolehmainen et al., 1995).

We studied the host use efficiency of a generalist moth, *O. brumata*, on three chemically different willow species; *Salix pentandra* (L.), *Salix phylicifolia* (L.) and *Salix myrsinifolia* (Salisb.). These species are common throughout Scandinavia (Hämet-Ahti et al., 1998; Skvortsov, 1999) and grow side by side on the banks of ditches, rivers, and other moist, disturbed habitats. However, the chemical composition and herbivore load of these willows are dissimilar. *Salix myrsinifolia* leaves contain a high level of non-acetylated salicylates (Julkunen-Tiitto, 1989; Rank et al., 1998) and a small number of generalist herbivores feed upon its leaves (Sipura, 1999, 2000). *Salix pentandra* contain a moderate level of acetylated salicylates (Rank et al., 1998; Julkunen-Tiitto, 1989), chlorogenic

acid and flavonoids (this study). Both *S. myrsinifolia* and *S. pentandra* are favored hosts for some specialized insect herbivores (Kolehmainen et al., 1994, 1995; Rank et al., 1998). *Salix phylicifolia* is practically devoid of salicylates but rich in flavonoids (Rank et al., 1998; Sipura et al., personal communication), and leaves of this mild tasting willow are readily eaten and sometimes heavily defoliated by generalist insect species (Tahvanainen et al., 1985; Sipura, 1999, 2000).

A potential defense compound may act in three ways: it may decrease the consumption, it may reduce assimilation efficiencies and digestion, and it may act as a toxin (Scriber and Slansky, 1981). Degradation of secondary chemicals generally increases the toxicity of compounds, e.g. cleavage of the sugar moiety from cyanogenic glycosides produces highly toxic HCN (Wink, 1997). Salicylates have been shown to be activated via degradation (Clausen et al., 1989). Degradation of salicortin, acetylsalicortin and tremulacin produce salicin and 6-hydroxy-2-cyclohexenone (6-HCH) which is oxidized further to catechol (Mattes et al., 1987; Clausen et al., 1989; Julkunen-Tiitto and Meier, 1992). Both 6-HCH and catechol are effective components of salicylates in their role of defending plants against herbivores (Clausen et al., 1989; Reichardt et al., 1990). Chlorogenic acid, which was found in considerable levels in the leaves of *S. myrsinifolia* and *S. pentandra* in our study, is shown to be oxidized to chlorogenoquinone by polyphenoloxidase (PPO) when leaf tissue is damaged and cell compartmentalization is ruptured (in Felton et al., 1989). PPOs (EC 1.14.18.1 or EC 1.10.3.2.) catalyze hydroxylation of monophenols and oxidation of diphenols to respective quinones (Mayer, 1987). Orthoquinones have strong oxidizing and alkylating activities and can bind to nucleophilic NH_2 and SH groups of aminoacids, peptides and proteins (Constabel, 1999), leading to reduction in the nutritive quality of foliage and in the growth of lepidopteran larvae (Felton et al., 1989)

The purpose of our study was to examine how the chemistry and nutritive status of the leaves of three chemically dissimilar willows affect feeding and growth of a generalist insect herbivore. More particularly, we wanted to find out how salicylates influence the growth of larvae: whether they act as antifeeding deterrents or whether they reduce the assimilation efficiency of nutrients. We analyzed the nitrogen and carbon content of the leaves of these willow species and the frass produced by larvae feeding on the same leaves. Furthermore, we studied the degradation of secondary chemicals, especially the degradation of salicylates, by analyzing the chemical content of the leaves and the frass. In addition, by rearing larvae on an artificial diet containing different potential defense compounds, we studied which of the secondary compounds reduced feeding and growth of larvae in the "real" leaf experiment. The ecological and evolutionary consequences of the interaction between chemically variable plant groups, such as willows, and the common polyphagous insect herbivore are discussed briefly.

METHODS AND MATERIALS

Plant Material. In mid-June 1999, leaves of *S. pentandra*, *S. myrsinifolia* and *S. phylicifolia* were collected from two-year-old clones from Siikalahti, in Parikkala, eastern Finland. These willow species were growing in mixed stands on the bank of an embankment road. Because the vegetation had been cut two years previously, all willow shrubs were of the same age. We randomly selected and marked 12 individual willow shrubs of each species.

Insects. The laboratory stock of larvae of *O. brumata* used in these experiments was reared on leaves of *P. padus* until the larvae reached the 4th instar. The population originated from 200 individuals collected in the summer of 1997 from a *P. padus* forest stand situated near Siikalahti.

Experimental Procedure of a "Real Leaf" Experiment. Fresh leaves were split into two parts, the main vein was removed and the leaf-halves were weighed. To obtain as homogeneous leaf material as possible, the first mature leaf counted from the shoot tip was always selected (a first fully expanded leaf). One leaf-half was offered to a single larva and the other was dried at room temperature and stored at -20°C until analyzed. Larvae feeding on *P. padus* were transferred on the leaves of the new host plants 10 h before the actual experiment, in order to rid the digestive system of these larvae of the remnants of *P. padus* leaves. After this pre-feeding period, the 4th instars were weighed and placed in petri dishes (one larvae/dish) with a new leaf-half. On the following day, new fresh leaf-halves were cut and offered to the larvae. These larvae were reared for 36 h at 16°C with an 18:6 L:D photoperiod. Thereafter, the larvae were weighed and allowed to continue feeding on fresh leaf halves for an additional 24 h to obtain enough frass for analyses. The frass and the remains of the leaf-halves were dried at room temperature and weighed. After drying, the frass was stored at -20°C until analyzed. The leaves of one individual willow were used for feeding two different larvae. The leaves used for feeding the first larva were analyzed for their secondary chemical content, and the leaves used for feeding the second larva, were analyzed for their nitrogen and carbon contents. Relative growth rates (RGRs), relative consumption rates (RCRs), apparent digestibility (AD), and water content of leaves were determined for the whole set of data.

Secondary Chemistry. Dried and frozen leaf samples were put into Falcon tubes containing 20 ml of cold methanol, and the samples were incubated for 15 min in an ice bath. After incubation, the samples were extracted 2×2 min with methanol ($20 + 10$ ml) using an Ultra-Turrax homogenizer (Janke & Kunkel, IKA Labortecnik, Staufen, Germany). The leaf extracts were filtered and evaporated to dryness in a vacuum evaporator. The residues were redissolved in 10 ml of methanol, and the samples were divided into 1 and 2 ml aliquots. The methanol was reduced to dryness with gaseous nitrogen and the samples were stored at -20°C until used for HPLC-analyses and butanol tests. The frass samples were

extracted by the same method except that 4 + 4 ml of methanol were used for extraction, and the samples were redissolved in 4 ml of methanol and divided into 0.5 ml, 1.0 ml and 1.8 ml aliquots.

The samples were analyzed by HPLC (Hewlett-Packard, Palo Alto, CA). The device, elution gradient, and conditions were as described by Julkunen-Tiitto et al. (1996). The compounds were identified by comparing their spectra and retention times to those of reference compounds. The compounds were quantified using the response factors of reference compounds. 2′-*O*-Acetylsalicin, diglucoside of salicin and an unknown salicin derivative were calculated using the response factor for salicin, a putative diacetylsalicortin found in *S. pentandra* leaves was calculated using the response factor for 2′-*O*-acetylsalicortin, and three salicortin derivatives of *S. myrsinifolia* were calculated using the response factor for salicortin. From the chromatogram of *S. pentandra*, we found six rather large peaks of some unknown flavonoids. The levels of these compounds were calculated using the response factor for quercetin. The levels of condensed tannins were determined from the methanol extracts by means of the butanol-HCl-test (Hagerman, 1995).

The unknown salicylates were tentatively identified by HPLC/API-ES mass spectrophotometry (HP 1100 Series LC/MSD, Hewlett-Packard, Palo Alto California) according to their molecular ion peaks. The substances were separated in an HP Hypersil ODS column (3 μm, 2.1 $\times$ 100 mm). The solvents were A: 1.5% THF and 0.25% acetic acid in dH_2O and B: 100% methanol. The elution gradient was the following: 0–5 min, 0% B; 5–10 min, 15% B; 10–20 min, 30% B; 20–30 min, 35% B; 30–40 min, 50% B; and 40–60 min, 100% B. The capillary for ES (electrospray ionization) was set to 3000 V, the nebulizer pressure was 35 psig, the temperature of the drying gas (N_2) was 350°C and the rate of flow was 12 l/min. The fragmentation voltage was 120 V, except for the fragmentation voltage for the diglucoside of salicin, which was 130 V.

Carbon and Nitrogen Analyzes. The carbon and nitrogen contents of the leaves and frass were analyzed with a CHN-analyzer (Elemental Analyzer—Mod. 1106, Carlo Erba Stumentazione). Acetanilide OAS (Elemental Microanalysis Limited) was used as the standard (C = 71.09%; H = 6.71%; N = 10.36%; O = 11.84%). The samples were analyzed in tin capsules, 6 $\times$ 4 mm D1006 (Elemental Microanalysis Limited). Three replicates were run from each leaf- and frass-sample. To check the condition of the analyzer, every 10th sample was a standard. If the deviation was too high, the analyzer was recalibrated and the samples were run again.

Experiment on Artificial Diet. We studied the effects of salicylates and chlorogenic acid on larval growth more closely in an experiment, where the 4th instars of *O. brumata* were reared on artificial diets with four different concentrations of chlorogenic acid, catechol, salicin, or saligenin. Since the isolation of salicortin and its derivatives is very laborious, we used their degradation products, catechol, salicin, and saligenin.

The highest concentration of defenses (90 μmol/g FW) used in this study was selected on the basis of an estimate of how much catechol and salicin and subsequently saligenin would be produced by a complete degradation of salicortin, the main salicylate of *S. myrsinifolia*, at the level observed in the leaves. The 2nd highest level was approximately the same as the concentrations of salicylates observed in the leaves of *S. pentandra*.

The artificial diet was produced according to the recipe of Goujet and Guilbort (Singh, 1985), with the exception that we used *S. phylicifolia* leaf powder instead of *P. padus* leaf powder and reduced the amount of agar from 5 g to 2 g (Agar bacterioloque type A, Biokar Diagnostic). Salicin (Sigma), saligenin (ICN Biomedicals Inc) and catechol (ICN Biomedicals Inc) were used at the concentrations of 0, 20, 45, and 90 μmol/g FW and chlorogenic acid (Aldrich Chemie Co, Carl Roth GmbH Co) at the concentrations of 0, 5, 20, and 45 μmol/g FW. A warm mixture of the artificial diet (2.5 ml) was poured into small petri dishes (3.5 cm) and allowed to solidify. The dishes were stored at $+4^{\circ}$C until used.

Larvae were placed in dishes on a normal artificial diet (no additional secondary metabolites) for 12 hr prior to the actual experiment. After this pre-feeding period ($+16^{\circ}$C), the larvae were weighed and transferred to experimental dishes, one larva to each dish. For every concentration of each substance studied, 10 replicate dishes were used. After 24 hours of rearing at $+16^{\circ}$C, the larvae were weighed again.

Calculation and Statistics. Relative growth rate (RGR), relative consumption rate (RCR), apparent digestibility (AD) (Waldbauer, 1968; Scriber and Slansky, 1981), water content of the leaves, and assimilation efficiencies of carbon and nitrogen were calculated by the following equations: RGR = mg biomass gained/mg initial biomass/d; RCR = mg eaten/mg initial biomass of larvae/d; AD = [(mg eaten—mg frass)/mg eaten] $*$ 100%; water content of leaves = (FW-DW/FW) $*$ 100%; assimilation efficiencies of carbon and nitrogen = [(μg ingested—μg in frass)/μg ingested] $*$ 100%. Fresh weight of the larvae was converted to dry weight by the equation: $DW = e^{(0.089 + 0.0392FW)}$. This equation is calculated from data on 57 5th instars of *O. brumata* weighing 15.5−62.8 mg ($r = 0.923$, $P < 0.001$). The larvae were dried for 24 hr at $+105^{\circ}$C and weighed again.

The differences in the levels of secondary compounds between the three willow species, were tested using a nonparametric Kruskal-Wallis test. The differences in RGR, RCR, AD, and water content as well as the differences in carbon and nitrogen contents and their assimilation efficiencies were tested using a one-way ANOVA followed by Tukey's test for multiple post hoc comparisons. The correlations of RGR with RCR, and AD and the water content of the leaves with RGR and RCR were tested by Pearson's correlation test. The correlations of the levels of secondary compounds, carbon and nitrogen content and their assimilation efficiency with RGR and RCR were also tested by Pearson's correlation test. Since the nitrogen and carbon contents were determined from leaf-halves that were different

from those used for secondary chemistry, these correlations were performed separately. Correlations were tested by including data from all three willow species and data within species. A sequential Bonferroni correction was used for evaluating correlations between secondary chemicals and RGR and RCR since they contained multiple comparisons (in whole data comparisons; $k = 8$ individual compounds, and within species comparisons; $k = 7$ individual compounds), which increases the experiment-wise rate of error (Rice, 1989). The results of the artificial diet experiment were analyzed by two-way ANOVA, but did not include chlorogenic acid since this was used at lower concentrations than the degradation products of the salicylates. The results for chlorogenic acid were tested separately using one-way ANOVA. A standard version of SPSS (1997) for Windows 8.0 (SPSS, Chicago) was used for all statistical tests.

RESULTS

Chemistry of Willow Leaves. As expected, the leaves of *S. phylicifolia, S. pentandra* and *S. myrsinifolia* were chemically very different (Tables 1–3). In these three willow species, the levels of chlorogenic acid, cinnamic acid, quercetin, myricetin, and luteolin derivatives and total salicylates, total flavonoids, and condensed tannins differed significantly ($P < 0.001$). *S. phylicifolia* (Table 1) contained a very high level of flavonoids, low levels of chlorogenic acids and condensed tannins, but no salicylates or cinnamic acid derivatives. *S. pentandra* (Table 2) contained moderate levels of salicylates, flavonoids, and chlorogenic acids and a low level of condensed tannins. *S. myrsinifolia* had a very high level of

TABLE 1. CONCENTRATIONS (MEAN ± SE) OF SECONDARY COMPOUNDS IN THE LEAVES OF *Salix phylicifolia* AND IN THE FRASS OF *O. brumata* LARVAE[a]

Compound	Concentration in leaves (mg/g DW)	Concentration in frass (mg/g DW)	Percent (%) degraded

[c] All flavonoids determined, nd = not determined.

salicylates, a low level of flavonoids, only a small fraction of condensed tannins, and a moderate level of chlorogenic acids (Table 3).

The main salicylates of *S. pentandra* (Table 2) were 2′-*O*-acetylsalicortin and its derivative, a putative diacetylsalicortin (531.2 *m/z* $[M + Na]^+$), which preliminarily is thought to contain two acetyl groups attached to a glucose moiety (Ruuhola et al., unpublished results). *S. pentandra* also contained low levels of salicin, 2′-*O*-acetylsalicin, and an unknown derivative of salicin (possibly an isomer of diglucoside of salicin). The main salicylate of *S. myrsinifolia* was salicortin. The leaves also contained salicin, diglucoside of salicin (471 *m/z* $[M + Na]^+$), and three derivatives of salicortin (Table 3). Salicortin derivative-1 (585.2 *m/z* $[M + Na]^+$) has provisionally been calculated to contain two 1-hydroxy-6-oxo-2-cyclohexen moieties (Tegelberg and Julkunen-Tiitto, 2001). Salicortin derivative-2 (871.2 *m/z* $[M + Na]^+$) is assumed to consist of two salicortin moieties (Julkunen-Tiitto and Sorsa, 2001). Salicortin derivative-3 was an isomer of salicortin derivative-2. As the main flavonoids, *S. phylicifolia* contained ampelopsin and its derivatives, but also quercetin, myricetin, luteolin derivatives, and one apigenin derivative (Table 1). In addition, *S. phylicifolia* contained (+)-catechin, which was absent from the leaves of *S. pentandra* and *S. myrsinifolia*. *S. pentandra* contained quercetin, myricetin

[b] All flavonoids determined, nd = not determined.

and kaemferol derivatives, one eridictyoyl derivative, and six unknown flavonoids (Table 2). The flavonoids of *S. myrsinifolia* consisted of quercetin and luteolin derivatives (Table 3).

Nutritive Values of Leaves and Assimilation Efficiencies of Carbon and Nitrogen. The leaves of the willow species differed significantly both in their digestibility (AD; $F_{2,29} = 3.495$, $P = 0.037$) and water content ($F_{2,29} = 3.587$, $P = 0.034$). The AD of the leaves of *S. myrsinifolia* was higher than the AD of the leaves of *S. phylicifolia* (Figure 1a). However, the differences in ADs between *S. myrsinifolia* and *S. pentandra* and between *S. pentandra* and *S. phylicifolia* were not significant. The water content of leaves tended to be higher in *S. myrsinifolia* than in *S. phylicifolia*; Tukey's HSD test, which is a conservative test, did not find the differences that were detected by ANOVA.

The nitrogen contents of the leaves of the different willow species did not differ significantly ($F_{2,29} = 1.337$, $P = 0.278$). By contrast, the carbon content of the leaves showed significant differences ($F_{2,29} = 6.421$, $P = 0.005$); the carbon content of *S. phylicifolia* leaves was significantly higher than that of *S. pentandra* leaves or *S. myrsinifolia* (Figure 1b). In spite of the lower AD of the *S. phylicifolia* leaves, the assimilation efficiency of nitrogen ($F_{2,29} = 1.225$, $P = 0.308$) or carbon ($F_{2,29} = 1.915$, $P = 0.166$) did not differ in larvae grown on different willows (Figure 1c).

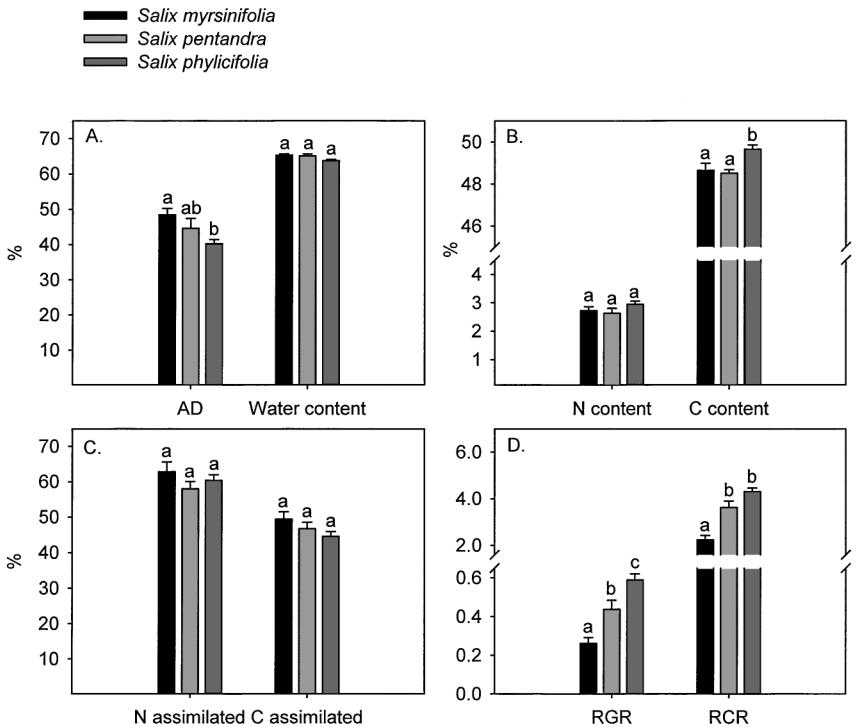

FIG. 1. AD and water (A), N and C (B) contents of the leaves of *S. pentandra*, *S. myrsinifolia* and *S. phylicifolia*. Assimilation efficiencies of N and C (C), RGR- and RCR-values of *O. brumata* larvae reared on these three willow species (D). The data were tested by one-way ANOVA followed by Tukey's HSD test for multiple comparisons (SPSS, 1997). Cases with statistically significant differences ($P < 0.05$) are identified by different letters.

Feeding and Growth of Larvae. The larvae of *O. brumata* grew at very different rates on different willows ($F_{2,59} = 19.56$, $P < 0,001$). The larvae grew best on *S. phylicifolia*, and the larval growth on this species was significantly faster than on *S. pentandra* (Figure 1d). The growth of larvae was slowest on the leaves of *S. myrsinifolia* (Figure 1d), and RGR differed significantly from that of larvae feeding on *S. phylicifolia* ($P < 0.001$) or *S. pentandra* ($P < 0.05$). The growth of larvae reared on *S. pentandra* was 25% slower and on *S. myrsinifolia* 60% slower than the growth of larvae on *S. phylicifolia*.

The consumption rates of the larvae differed on the three willows studied ($F_{2,59} = 24.17$, $P < 0.001$). The relative consumption rate (RCR) tended to be higher on *S. phylicifolia* than on *S. pentandra* ($P = 0.064$), and on *S. myrsinifolia* RCR was much lower than the RCR of larvae reared on *S. pentandra* or

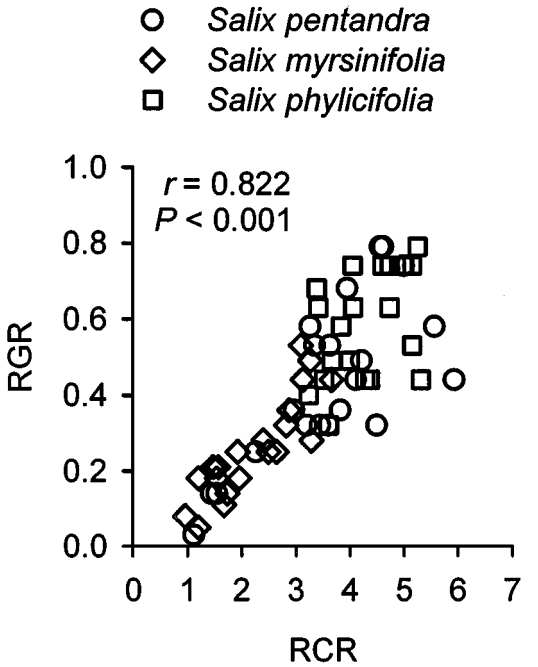

FIG. 2. Correlations between RGRs and RCRs. Comparisons were made with complete data including all three willows species (A), or within species; *S. pentandra* (B), *S. myrsinifolia* (C) and *S. phylicifolia* (D). Data were tested by Pearson's correlation test.

S. phylicifolia (Figure 1d). Furthermore, RCR and RGR correlated significantly and positively both within and between willow species (Figure 2).

Correlations between Leaf Characters and RGR and RCR. The levels of total salicylates and chlorogenic acid correlated strongly and negatively with larval growth and consumption (Figures 3a,b and 4a,b). In addition, the level of cinnamic acid correlated negatively with RGR and RCR (Figures 3c and 4c). By contrast, the level of myricetin derivatives and total flavonoids correlated positively with rate of consumption (Figures 4e and g). However, the correlation with growth rate was not significant (Figures 3e and g). The levels of quercetin and luteolin derivatives or condensed tannins did not correlate with RGR or RCR (Figures 3d,f,h and 4d,f,h). On the other hand, none of the concentrations of the secondary compounds correlated with RGR or RCR within species, although in *S. pentandra* the concentration of salicylates, chlorogenic acids, and condensed tannins tended to correlate negatively with RGR (data not shown).

When the correlation included all three willow species, digestibility of the leaves (AD) correlated negatively with RGR ($r = -0.335$, $P = 0.008$) and RCR

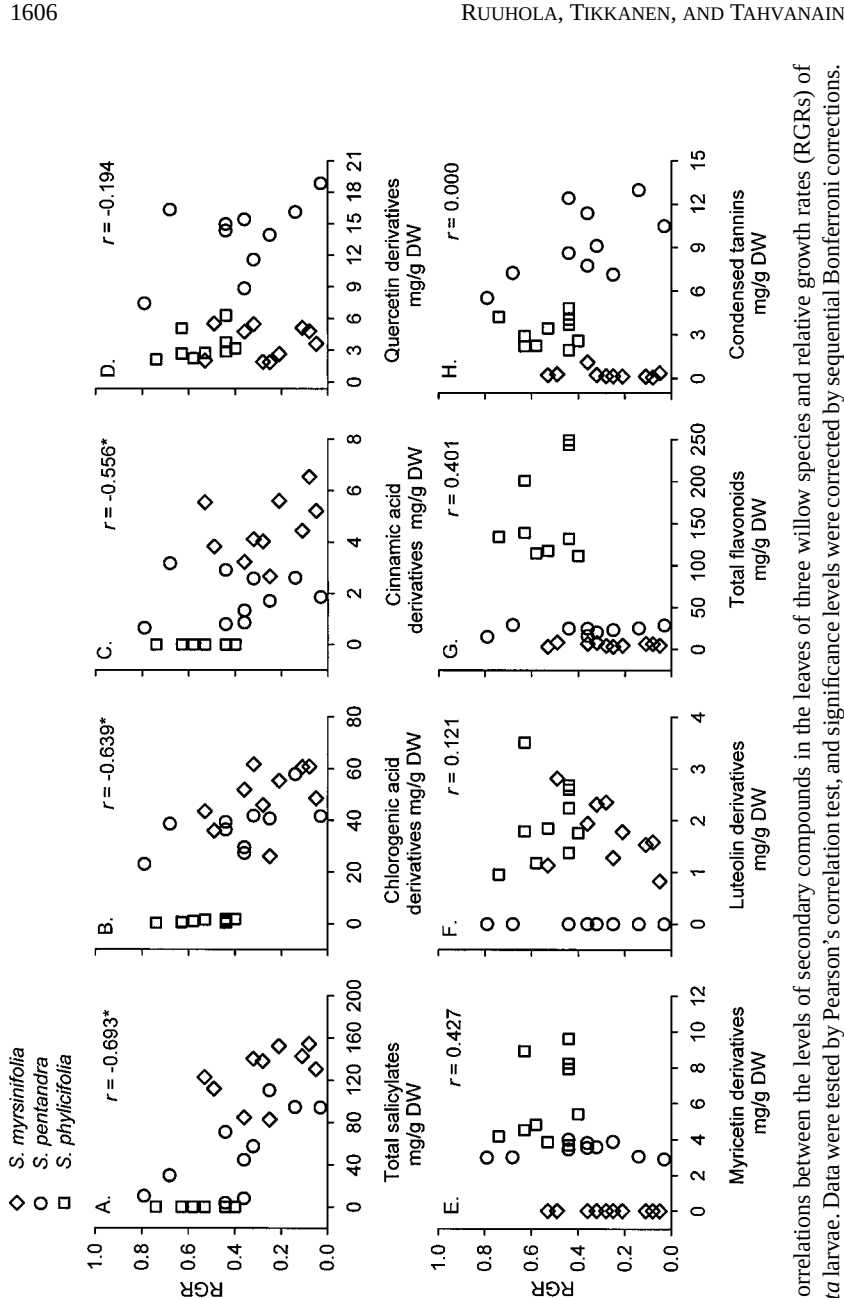

FIG. 3. Correlations between the levels of secondary compounds in the leaves of three willow species and relative growth rates (RGRs) of *O. brumata* larvae. Data were tested by Pearson's correlation test, and significance levels were corrected by sequential Bonferroni corrections. Statistically significant cases are marked by asterisks.

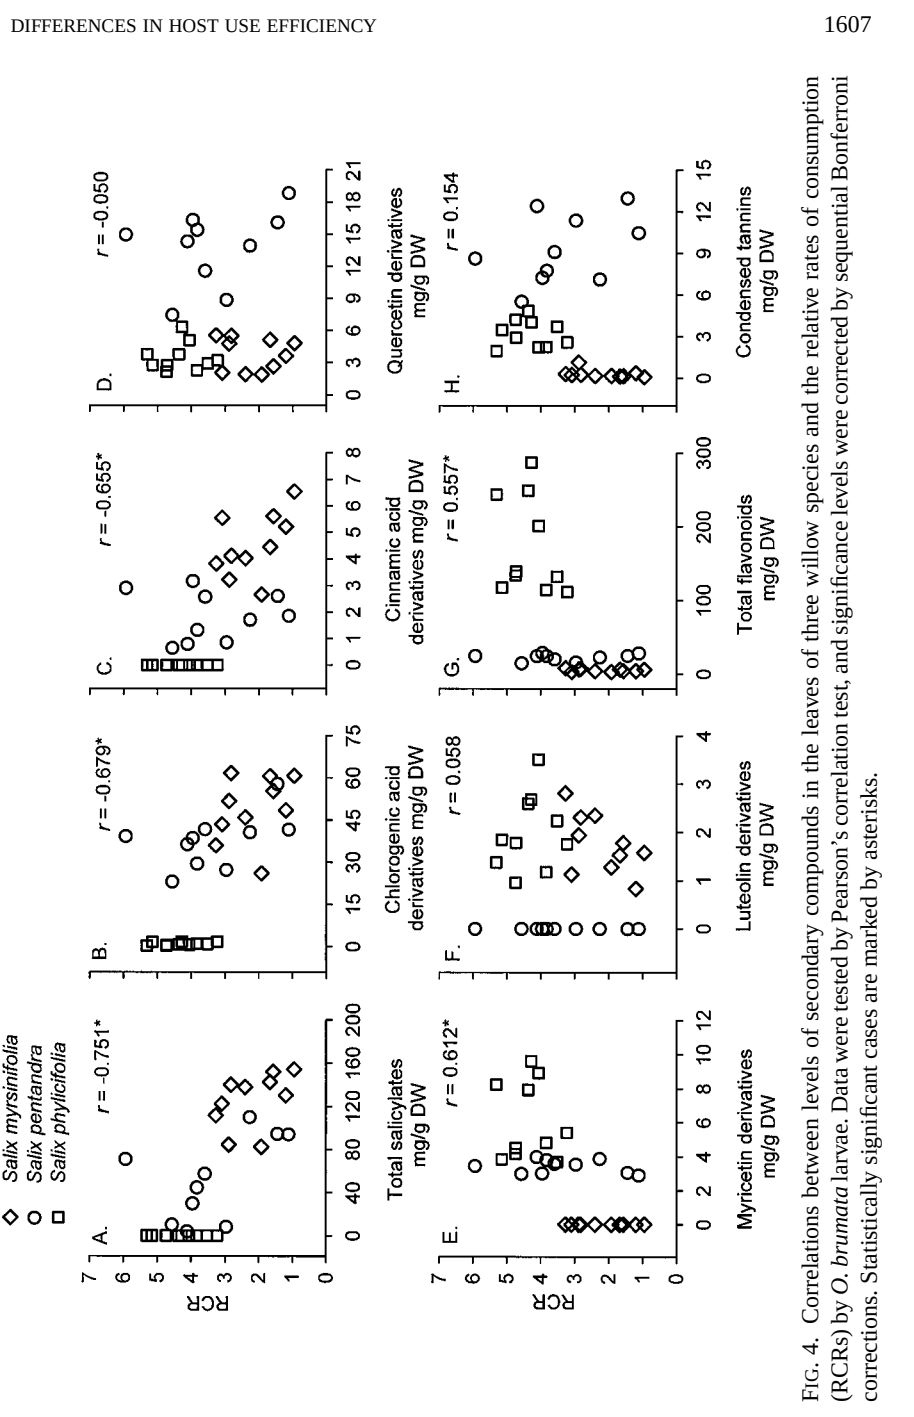

FIG. 4. Correlations between levels of secondary compounds in the leaves of three willow species and the relative rates of consumption (RCRs) by *O. brumata* larvae. Data were tested by Pearson's correlation test, and significance levels were corrected by sequential Bonferroni corrections. Statistically significant cases are marked by asterisks.

($r = -0.308$, $P = 0.015$). This is apparently due to the higher digestibility of *S. myrsinifolia* leaves as compared with *S. phylicifolia* leaves. Nevertheless, the quality of *S. myrsinifolia* leaves for *O. brumata* larvae was inferior, and the larvae grew very slowly. Neither the nitrogen nor the water content of leaves correlated with growth or consumption. The carbon content of leaves correlated significantly with RGR ($r = 0.366$, $P = 0.039$) but not with RCR ($r = 0.272$, $P = 0.132$).

Degradation of Secondary Compounds. In the digestive tract of larvae, labile salicortin, 2′-*O*-acetylsalicortin, and their derivatives were degraded completely to salicin, which was detected at high levels in the frass of larvae feeding on *S. myrsinifolia* and *S. pentandra* (Tables 2 and 3). Larvae feeding on *S. myrsinifolia* ingested on average 5.36 ± 0.57 μmol of salicortin, the main salicylate of this willow, and excreted 2.98 ± 0.31 μmol of salicin, which indicates that further metabolism of salicin was rather slow. Since we did not have separate response factors for all salicylates, we were not able to calculate the exact equimolar relationship between salicin and the other salicylates.

The frass of larvae feeding on *S. pentandra* (Table 2) contained catechol, which was not detected in the frass of larvae feeding on *S. myrsinifolia* leaves (Table 3). On the other hand, the frass of larvae reared on *S. myrsinifolia* contained

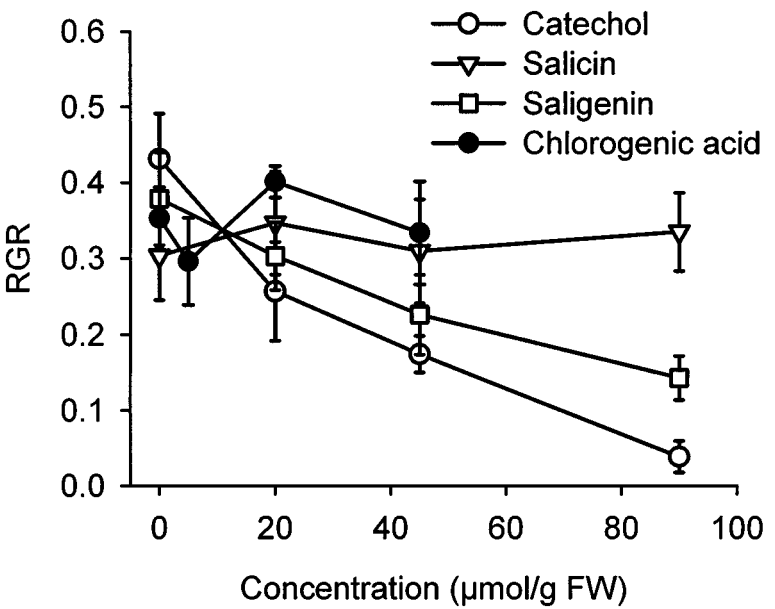

FIG. 5. Effects of increasing concentrations of catechol, saligenin, salicin, and chlorogenic acid on the relative growth rate (RGR, mean ± S.E.) of *O. brumata* larvae. $N = 10$ in each concentration of each compound.

TABLE 4. ANOVA TABLE OF THE FULL FACTORIAL ANALYSES FOR THE EFFECT OF CATECHOL, SALIGENIN AND SALICIN ON THE RELATIVE GROWTH RATE OF *O. brumata* LARVAE RAERED ON ARTIFICIAL DIET

Source of variance	*df*	MS	*F*	*P*
Model	11	0.064	4.324	<0.001
Compound	2	0.073	4.764	0.011
Concentration	3	0.110	7.180	<0.001
Compound × concentration	6	0.042	2.749	0.017

an unknown compound with a spectrum resembling that of cyclohexenone but with a longer retention time.

Chlorogenic acids, flavonoids, and cinnamic acids were degraded with different efficiencies depending on which willow species the larvae were reared on. Chlorogenic acid derivatives were degraded more efficiently on *S. myrsinifolia* than on *S. pentandra* and on *S. phylicifolia* (Tables 1–3), and cinnamic acid derivatives were degraded more efficiently on *S. myrsinifolia* than on *S. pentandra* (Tables 2 and 3). Quercetin derivatives, which were found in the leaves of all three willows, were totally absent from the frass of larvae feeding on *S. myrsinifolia* (Table 3), but in larvae feeding on *S. phylicifolia* or *S. pentandra*, quercetin derivatives were degraded 71.3% and 80.9%, respectively (Tables 1 and 2).

Growth of Larvae on Artificial Diets with Different Levels of Salicin, Saligenin, Catechol, or Chlorogenic Acid. Catechol and saligenin significantly reduced the growth rate of larvae, while salicin and chlorogenic acid did not (Figure 5). The differences between compounds and concentrations and their interactions were all significant (Table 4). With increasing levels of catechol and saligenin, the inhibition of RGR was almost linear (Figure 5).

Catechol added to an artificial diet mixture at concentrations of 20, 45, and 90 μmol/g FW resulted in 40%, 61%, and 91% reductions, respectively, in the growth of larvae. The addition of saligenin resulted in 21%, 40%, and 63% reductions, respectively, in the growth of the larvae. Thus, catechol was a more effective growth inhibitor than saligenin. We did not measure the feeding rates of the larvae, but it was clear that catechol acted as a strong feeding deterrent since larvae kept in dishes containing catechol ate very little, and at the highest concentration of catechol, larvae hardly touched the diet. This type of feeding inhibition was not detected with saligenin.

DISCUSSION

The growth and feeding of *O. brumata* larvae were retarded on both salicylate- and chlorogenic acid-rich willows, *S. myrsinifolia* and *S. pentandra*, when compared to the feeding and growth observed on the salicylate-free *S. phylicifolia*.

This retardation was obviously due to the unfavorable secondary chemistry of the leaves, since differences in the nutritive status, digestibility of leaves, and assimilation efficiencies of nitrogen and carbon cannot explain this retardation. There were no differences between *S. pentandra* and *S. phylicifolia* in water or nitrogen content or the digestibility of the leaves. Furthermore, *S. phylicifolia* leaves contained more carbon, less water, and had lower digestibility, indicating that the leaves of *S. phylicifolia* were tougher and probably contained more carbon based fibers and cellulose than did the leaves of *S. myrsinifolia*.

The strong correlation between leaf consumption and growth rate of larvae indicates that the differences between growth rates were explained by differential feeding rates of larvae reared on these three willows. In addition, the levels of the most abundant chemicals found in the leaves of *S. myrsinifolia* and *S. pentandra*, salicylates and chlorogenic acids, correlated markedly but negatively with both consumption and growth. This suggests that these compounds are potential antifeeding deterrents against *O. brumata*. Many reports have shown that salicylates act as feeding deterrents against generalist insect herbivores (Tahvanainen et al., 1985; Lindroth et al., 1988; Lindroth and Peterson, 1988); however, some reports show that chlorogenic acid slows down the growth of insect herbivores (e.g., Isman and Duffey, 1982; Felton et al., 1989; Felton and Duffey, 1991).

To clarify the question of whether the effective defensive compounds of *S. myrsinifolia* and *S. pentandra* were salicylates, chlorogenic acid, or both, we reared *O. brumata* larvae on an artificial diet. The diet contained chlorogenic acid and degradation products of salicylates in equimolar concentrations to the those observed in the leaves of *S. myrsinifolia* and *S. pentandra*. This experiment showed that the degradation products of salicylates, catechol, and saligenin, reduced the growth of *O. brumata*, while neither salicin nor chlorogenic acid significantly retarded the growth. Catechol, but not saligenin, clearly acted as a feeding deterrent. Similar results were observed by Clausen et al. (1989), who showed, that at the concentrations potentially found in the insect gut, 6-HCH and catechol significantly reduced pupal weight of *Choristoneura conflictana* (Lep.) reared on artificial diets. In addition, Lindroth and Peterson (1988) demonstrated that both salicortin and tremulacin reduced the growth of *Spodoptera eridania* (Lep.) larvae, primarily by decreasing consumption. Neither salicin nor chlorogenic acid had deleterious effects. In addition, their histopathological results showed that both salicortin and tremulacin acted as gut toxins, and they proposed that the active component was saligenin ester.

Our degradation pattern of salicylates does not conform to the model of Lindroth et al. (1988), who suggested that the degradation of salicortin and tremulacin begins with cleavage of the sugar moiety by β-glucosidase, and that the effective component in defense is cyclohexenone saligenin ester, which is detoxified by carboxyesterases. Instead, we propose that labile salicortin and 2′-*O*-acetylsalicortin and their derivatives are degraded first by foliar esterases or by

alkaline conditions to salicin and 6-HCH (see Mattes et al., 1987; Clausen et al., 1989; Julkunen-Tiitto and Meier, 1992). Salicin is then further degraded to saligenin by β-glucosidase activity (Julkunen-Tiitto and Meier, 1992). We propose that saligenin is a toxic agent of salicylates and may cause gut lesions such as those observed by Lindroth and Peterson (1988). β-Glucosidase has been shown to be ineffective in the degradation of acetylated salicylates. However, the cleavage of the acetyl moiety is achieved by esterases, although the reaction is slow (Julkunen-Tiitto and Meier, 1992). Thus, acetylation of salicylates may decrease their degradation rates in the digestive tract of insects and further decrease the toxicity of compounds. The oxidation of 6-HCH to catechol was obviously due to the alkaline condition of the midgut of *O. brumata* larvae. Catechol is a substrate of PPO (catechol oxidase; EC 1.10.3.2) and the *o*-quinone produced can bind to nucleophilic NH_2 and SH groups of amino acids and proteins (Constabel, 1999). 6-HCH is also an electrophile (Clausen et al., 1989), and thus, both catechol and 6-HCH are agents that may reduce the assimilation efficiencies of nutrients. In summary, salicylates may act in three ways: they are strong feeding deterrents, but they may also have toxic effects and reduce the assimilation of nutrients by precipitating essential amino acids and proteins. However, we emphasize that the observed growth retardation of *O. brumata* larvae was mainly a consequence of feeding deterrence.

One reason for the ineffectiveness of chlorogenic acid in retarding the growth of *O. brumata* larvae in our experiment could be the absence of active foliar PPOs in the artificial diet. However, the content of the midgut of *O. brumata* larvae is alkaline (Berenbaum, 1980), which should lead to auto-oxidation of chlorogenic acid (Felton et al., 1989). Felton and Duffey (1991) showed that chlorogenic acid added to an artificial diet decreased the growth of *Helicoverpa zea* (Lep.), but the effect was enhanced by the presence of plant peroxidases and H_2O_2. The age of the larvae may also affect their sensitivity to chlorogenic acid. For example, the growth of the 3rd and 5th instars of *Heliothis zea* (Lep.), was not affected by chlorogenic acid, while that of neonate larvae was inhibited (Isman and Duffey, 1982). Furthermore, we cannot rule out the possible synergistic effects of salicylates and chlorogenic acids.

The flavonoids, chlorogenic acid and cinnamic acid derivatives of three willow species were degraded at different rates. For example, the chlorogenic acid and quercetin derivatives that originated from *S. myrsinifolia* were decomposed more efficiently than those originating from *S. pentandra* or *S. phylicifolia*. One explanation for the dissimilar degradation efficiencies of these compounds could be the different levels of condensed tannins in the leaves of these willows; *S. myrsinifolia* had the lowest level of tannins. Tannins are able to bind proteins and thus inhibit enzymes (Goldstein and Spencer, 1985; Juntheikki and Julkunen-Tiitto, 2000). Goldstein and Spencer (1985) demonstrated that hydrolysis of the cyanogenic glycosides of *Carica papay* L. (Caricaceae) by specific β-glucosidases was inhibited

by the presence of tannins. On the other hand, the pH of the midgut of *O. brumata* is very alkaline: 9.2–9.5 (Berenbaum, 1980), and in such alkaline conditions tannin-protein complexes are thought to dissociate (Berenbaum, 1980; Zucker, 1983; Martin and Martin, 1984). It is also possible that the faster degradation rates of chlorogenic acid, cinnamic acid, and quercetin derivatives are due to the higher PPO activity of *S. myrsinifolia* leaves. We believe that secondary chemicals such as tannins may affect the degradation and thus the toxicity of other chemicals. However, we suggest that the flavonoids and the low levels of condensed tannins observed in this study did not have major negative or positive effects on larval growth when compared to the deleterious effects of salicylates.

It is intriguing to compare our results obtained with generalist *O. brumata* with the results of the experiment in which the growth of a highly specialized leaf beetle, *P. vitellinae*, was studied on the same set of willow species (Rank et al., 1998). The growth rates of *P. vitellinae* showed exactly the opposite pattern: the larvae grew fastest on salicylate-rich *S. myrsinifolia* and *S. pentandra*, and their growth was slowest on salicylate-poor *S. phylicifolia* (Rank et al., 1998). The larvae of *P. vitellinae* are assumed to utilize a glucose moiety released in the degradation of salicin as their energy source for growth (Pasteels et al., 1983; Rowell-Rahier and Pasteels, 1986). It is obvious that generalist larvae are not able to degrade salicin efficiently and utilize salicylates as an energy source.

Salicylate-rich *S. myrsinifolia* is a poor host candidate for *O. brumata*, at least in spring, when the salicylate levels are the highest (Julkunen-Tiitto, personal communication). On the contrary, a moderate level of acetylated salicylates found in the leaves of *S. pentandra* appeared not to be particularly deleterious, at least not for the 4th instars. Thus, both *S. pentandra* and *S. phylicifolia*, whose chemical compositions are, however, very dissimilar compared to the chemistry of the main hosts, *P. padus* and *Q. robur*, seem to be suitable alternative hosts for polyphagous *O. brumata*.

The ability of *O. brumata* to tolerate and to adapt to the use of hosts that are chemically so divergent and derived from different plant families is remarkable. One possible explanation for this tolerance might be found in the low β-glucosidase activity in the midgut of larvae. For example, the β-glucosidase activity observed in *Papilio glaucus canadiensis*, which is adapted to use salicylate-rich species as its host, was lower than the activity observed in *Papilio glaucus glaucus* which cannot tolerate salicylates (Lindroth, 1989). The slow further metabolism of salicin in the "real leaf" experiment and the ineffectiveness of salicin found in the artificial diet experiment support this hypothesis. In the first place, the ability to adapt to the use of chemically different hosts provides, the means for this moth to survive if dispersing neonate larvae do not succeed in settling on optimal hosts (Wint, 1983; Tikkanen, 2000). Secondly, the adaptability of *O. brumata* facilitates the opportunistic use of locally most abundant host plants (see Tikkanen, 2000).

In summary, high salicylate content of the leaves of some willow species, such as *S. myrsinifolia*, provides these plants with efficient chemical defense against many generalist insect herbivores. This resistance may significantly reduce the level of damage inflicted by generalist feeders (see Sipura, 2000) and may, in consequence, increase the overall fitness of these high salicylate willows. Plants with effective defenses may "escape" from herbivores, especially from generalist ones which are able to feed on other hosts and are not forced to take part in the "co-evolutionary arms race" (*sensu* Erlich and Raven, 1964). As a result, these plants may have more resources for competition or, if defensive chemicals are costly, they may adapt to a new life history strategy of lower growth and efficient defense (see Coley et al., 1985).

Acknowledgments—We thank the Punkaharju Forest Research Station of the Finnish Forest Research Institute for providing the facilities for the "real leaf" experiment, laboratory assistant Marja Noponen for guiding us in the use of the CHN-analyzer, Doc. Riitta Julkunen-Tiitto, Dr. Marja-Riitta Juntheikki and doctoral student Mika Sipura for their valuable comments on the manuscript. This work was supported by the Academy of Finland and the Foundation for Research of Natural Resources in Finland.

(Received October 9, 2000; accepted April 4, 2001)

Abstract—Repellency and toxicity of 8 essential oils (vetiver grass, cassia leaf, clove bud, cedarwood, *Eucalyptus globules*, *Eucalyptus citrodora*, lemongrass and geranium) were evaluated against the Formosan subterranean termite, *Coptotermes formosanus* Shiraki. Vetiver oil proved the most effective repellent because of its long-lasting activity. Clove bud was the most toxic, killing 100% of termites in 2 days at 50 μg/cm^2. The tunneling response of termites to vetiver oil also was examined. Vetiver oil decreased termite tunneling activity at concentrations as low as 5 μg/g sand. Tunneling and paper consumption were not observed when vetiver oil concentrations were higher than 25 μg/g sand. Bioactivity of the 8 oils against termites and chemical volatility were inversely associated. Listed in decreasing order of volatility, the major constituents of the 8 oils were: eucalyptol, citronellal, citral, citronellol, cinnamaldehyde, eugenol, thujopsene, and both α- and β- vetivone. Vetiver oil is a promising novel termiticide with reduced environmental impact for use against subterranean termites.

Key Words—*Coptotermes formosanus*, *Vetiveria zizanioides*, clove, repellents, toxicants, natural product chemistry, vetivone, nootkatone, eugenol.

INTRODUCTION

Essential oils are natural volatile substances found in a variety of odoriferous plants. When isolated from plants, essential oils are not usually extracted as chemically pure substances, but consist of mixtures of many compounds. Terpenes,

*To whom correspondence should be addressed.

0098-0331/01/0800-1617$19.50/0

organic compounds consisting of multiples of isoprene units are the dominant constituents of essential oils. Commercially, essential oils are used in four primary ways: as odorants in fragrances, as flavor enhancers in many food products, as pharmaceuticals, and as insecticides. Particular emphasis has been placed on their antimicrobial, antifugal, antitumor, and insecticidal actions (Franzios et al., 1997).

In recent years, essential oils have received much attention as potentially useful bioactive compounds against insects. Insecticidal activity of essential oils has been shown against cockroaches (Ahmad et al., 1995; Ngoh et al., 1998), mosquitoes (Watanabe et al., 1993), stored-product insects (Shaaya et al., 1991), ticks (Lwande et al., 1999) and house flies (Singh and Singh, 1991). Bultman et al. (1979) tested 42 tropical African woods and suggested that volatile allelochemicals from the wood might be one of the major factors for their natural resistance to *Coptotermes formosanus* Shiraki. Other studies confirmed that some essential oils, such as that extracted from cedarwood (Adams, 1991), *Litsea cubeba* (Lin and Yin, 1995a) and *Cinnamomum* spp. (Lin and Yin, 1995b), were naturally repellent to termites. Some essential oil components from resistant wood species also have been reported to be toxic to termites, including chamaecynone, an acetylenic terpenoid from *Chamaecyparis pisidera* D. Don (Saeki et al., 1973), 7-methyljuglone, a naphthoquinone from *Diospyros virginiana* L. (Carter et al., 1978), and torreyal from, *Torreya nucifera* Sieb. et Zucc., Kaya wood (Ikeda et al., 1978). A number of diverse terpenoids in essential oils, such as citronellal, citral, gernaniol and eugenol have repellent activity against the American cockroach (Ngoh et al., 1998) and the Formosan subterranean termite (Cornelius et al., 1997 and Sharma et al., 1994). Scheffrahn et al. (1988) isolated ferruginol, manool, and nezukol from bald cypress, *Taxodium distichum* L. wood, which acted principally as a feeding deterrent to *C. formosanus*. Nagnan and Clement (1990) reported on the topical toxicity of geranyllinalool to termites. Grace and Yamamoto (1994) found that Formosan subterranean termites avoided feeding on Alaskan yellow cedar. A major extractive in Alaskan yellow cedar is a sesquiterpene, nootkatone (Erdtman and Hirose, 1962). Recently, we found this chemical also was a component of vetiver grass oil and demonstrated it to have strong repelling activity against the Formosan subterranean termite (Zhu et al., 2001). In this study, the toxicity and repellency of 8 selected essential oils to the Formosan subterranean termite were evaluated and the volatility of their major compounds were compared by gas chromatography-mass spectrometry (GC-MS).

METHODS AND MATERIALS

Oils of vetiver (*Vetiveria zizanioides*, Haiti), cassia leaf (*Cinnamomum cassia*, Chinese), clove bud (*Eugenia caryophyllata*, Indonesia), cedarwood (*Juniperus virginiana*, Virginia), *Eucalyptus globulus*, *Eucalyptus citrodora*, lemongrass

(*Cymbopogon citrates*, East Indian) and geranium (*Geranium pelergonium graveolens*, Bourbon) were purchased from The Good Scents Company (TGSC, Oak Creek, WI). Cinnamaldehyde, thujopsene, eugenol, eucalyptol, citronellal, citral and citronellol were purchased from the Fluka Company (Milwaukee, WI). Vetivones (α- and β-) were kindly provided by Professor Ekkhard Winterfeldt (Institut für Organische Chemie, Technische Universität, Berlin).

Formosan subterranean termites were collected in a fallen Oak tree from New Orleans, Louisiana, and stored in a 250 liter container at 24-28°C in the laboratory. The mean weight of a worker termite (3^{rd} instar or older) was 1.2 ($\pm$0.01) mg.

Repellency Assay. The testing procedure was modified from Lewis et al. (1978). A Petri dish (5 cm in dia. and 1 cm high containing 20 ml air) was used for testing the toxicity and repellency of the essential oils against workers of the Formosan subterranean termite. Essential oils were dissolved in ethyl alcohol and prepared in a series of dilutions for testing. One ml of hot agar solution (1.5 g agar in 100 ml H_2O) was spread evenly in the bottom of each dish and allowed to cool. This ensured adequate moisture for the termites and helped to hold the sand in place that was layered above it. Blasting sand (fine, #4) was autoclaved for 30 min and oven-dried. The top half agar layer was covered with 1 g of treated sand and a piece of treated filter paper (Whatman #1; 0.5 cm $\times$ 1 cm). The other half was covered with 1 g of untreated sand and a piece of untreated filter paper (0.5 cm $\times$ 1 cm). Enough sand was used to cover the agar completely, but thin enough to not conceal the termites once introduced. Three concentrations of treated sand/filter paper were evaluated for each of the 8 oils tested (100 μg/g sand or 10 μg/cm^2, 250 μg/g sand or 25 μg/cm^2 and 500 μg/g sand or 50 μg/cm^2). There were 3 replicates for each oil at each concentration tested. Three replicates for the controls (untreated sand and filter paper) were set up. This experiment was repeated twice.

Ten worker termites were added to each Petri dish, and all Petri dishes were covered between observations to eliminate the light. Every 15 minutes for the first hour, termite activity was recorded by summing three scan samples (each reading taken within 3 seconds) in 5 minutes intervals per Petri dish on the number of termites observed on untreated sand/filter paper. After the first hour, termite activity was recorded each hour (three scans in 5 minute intervals) until 6 hr, then counted every 24 hours (three scans in 5 minute intervals) until four weeks. A Chi-Square test indicated that when 23 or more of the 30 termites (mean value of all replicates) were observed on the untreated sand, there was a significant difference in the repellency to termites between the oil-treated group and the control group ($x^2 = 4.59$, $df = 1$, $p = 0.032$) (Anonymous, 1998). Then, the oil was considered repellent. The oil was considered toxic if some or all termites behaved sluggishly, were moribund, or dead. When 29 of the 30 (mean value of all replicates) termites for a given concentration of a tested oil were either dead or moribund, the test was ended.

Tunneling Response, Consumption, and Mortality. Vetiver oil was further tested to evaluate its effect on tunneling response, paper consumption, and mortality of Formosan subterranean termite workers. Three-compartment plastic containers ($18 \times 8 \times 4$ cm) (Pioneer Packaging Co, North Dixon, KY) were used. A small opening (0.3 cm high and 5 cm long) was made at the bottom of each of the two inner walls to permit termite travel between the chamber compartments. Vetiver oil (50 mg) was dissolved in ethanol (10 ml) as the stock solution. Four concentrations (5, 10, 25, and 50 μg/g sand) and one control (0 μg/g sand) were prepared as follows: 500 g of blasting sand for each concentration was mixed with vetiver oil in 25 ml of ethanol containing 2.5 mg, 5 mg, 12.5 mg and 25 mg of vetiver oil in a glass pan and dried in a hood for two hours. The control was treated only with 25 ml ethanol. Then, 100 g of treated sand were added to the middle compartment of the bioassay chamber. One hundred grams of untreated blasting sand were added to one end of each compartment. Four replicates were set up for each treatment. Filter paper (Whatman #1; 2.3 cm dia.) that served as the food source was dried at 70°C for 3 hr and cooled to room temperature for 30 min before weighing. Filter paper and 50 g of untreated sand were placed in the third compartment farthest from the home compartment. Ten ml of distilled water were added to the sand in each compartment just prior to introduction of the termite. Fifty workers and 5 soldiers were placed in the home compartment. The containers were covered with lids and kept in a dark incubator at 25°C. On the 14th day, the experimental units were dismantled, living termites counted, and filter papers cleaned, dried at 70°C for 3 hr, cooled for 30 min, and weighed. The tunnels constructed along the bottom of the chambers in the sand were copied by a scanner for measurements of total tunnel length. A pre-measured string was placed over the curved tunnel paths viewed by the scanner for length measurements. Consumption was calculated as the difference between the weight of filter paper before and after testing. Tunneling response, paper consumption, and mortality of termites were analyzed by ANOVA (Anonymous, 1998). Tukey's studentized range test was used to compare the difference between treatments.

GC-MS Analysis. The major components of the 8 oils investigated were determined by GC-MS through identification of major peaks using the computer database with follow-up confirmation using authentic compounds. The percentage of the major component was calculated by integrating the peaks of the gas chromatographs for each essential oil. Gas chromatography-mass spectrometry (GC-MS) experiments were performed on a Finnigan's GCQ (Trace GC 2000 coupled with Polaris MSD). A silica capillary column DB-5ms (30 m $\times$ 0.25 mm $\times$ 0.25 μm, J&W Scientific, Folsom, CA) was used for separation of the chemicals. The carrier gas was helium (0.8 ml/min). The injection port temperature was at 250°C in splitless mode with 1 μl injection. The initial GC temperature was maintained at 60°C for 1 min, then increased to 150°C at 2.5°C/min and maintained for 15 min, then to 260°C at 5°C/min, and finally maintained at 260°C for 10 min.

The ion-trap mass selective detector was set in full scan mode from m/z 41 to 400.

RESULTS

Repellency. All of the essential oils exhibited some repellency at the lowest concentration tested, i.e., 10 μg/cm^2 (Table 1). Clove bud oil was the most toxic, causing mortality of over 50% at a concentration of 50 μg/ml air in 24 hours. Oil of *Eucalyptus globulus* had the least repellent activity. It lasted for only 4-5 hr at 10 μg/cm^2 and 12 hr at 50 μg/cm^2 and was not toxic. Oil of *Eucalyptus citriadora* was the second weakest repellent, with an effective period of 0.3-1 days. The effective period for lemongrass and geranium was 1-3 days at the concentration of 10 to 50 μg/cm^2. Oils of cedarwood and cassia leaf had better repellent effects. The repelling period was 3-6 days at the concentrations tested. Vetiver oil had the longest activity with a repelling period of 12-24 days.

Tunneling Response, Consumption, and Mortality. Mean consumption of filter paper was decreased as vetiver oil concentration increased ($F = 133.84$, $df = 4, 15$; $P < 0.0001$) (Table 2). Filter paper consumption was not observed when concentrations were $\geq$25 μg/g sand. Termite mortality was not different among

TABLE 1. COMPARISON OF EFFECTIVE PERIOD AND TOXICITY OF 8 ESSENTIAL OILS AGAINST WORKERS OF THE FORMOSAN SUBTERRANEAN TERMITE

Oil	Time beginning the effectiveness[a] (min)	Effective period (days)[b] oil concentration (μg/cm^2) on sand			Mortality
		10	25	50	
Vetiver	<15–60	12	17	24	*c*
Cassia leaf	<15–60	3	4	4	*c*
Clove bud	<15–60	3	30% dead in 2 days and 100% dead in 4 days	50% dead in 1 day and 100% dead in 2 days	yes

Geranium	<15–60	1	2	3	*c*

[a] The range of time included all three concentrations.
[b] Effective period defined as the time when 23 or more of the 30 termites (mean value of all replicates) were observed on the untreated sand. At that time, the oil was considered repellent (see Methods and Materials).
[c] Termites were gathered and sluggishly moved during the effective period.

TABLE 2. FILTER PAPER CONSUMPTION, PERCENT MORTALITY, AND LENGTH OF TUNNELING OF FORMOSAN SUBTERRANEAN TERMITES AFTER A 14-DAY EXPOSURE TO VETIVER OIL

Concentration of Vetiver oil (μg/g sand)	Consumption of filter paper (mg)[a]	% Termite mortality[a]	Tunneling length[a] (cm)
0	64.05 ± 6.85 a	13.50 ± 4.03 a	39.75 ± 3.18 a
5	15.80 ± 8.35 b	21.33 ± 2.08 a	27.87 ± 2.86 ab
10	8.65 ± 5.05 bc	13.00 ± 4.66 a	19.87 ± 4.52 b
25	0.0 ± 0.0 c	13.20 ± 3.78 a	0.00 ± 0.00 c
50	0.0 ± 0.0 c	15.50 ± 9.32 a	0.00 ± 0.00 c

[a]Means ± SE: Means with the same letter were not significantly different using Tukey's studentized range test.

the concentrations of vetiver oil tested ($F = 0.35$, $df = 4, 15$; $P = 0.840$). Vetiver oil decreased termite tunneling activity at concentrations as low as 10 μg/g sand ($F = 39.40$, $df = 4, 15$; $P < 0.0001$). Tunneling was not visible in the middle chamber when the concentration of vetiver oil was ≥ 25 μg/g sand (Table 2).

GC-MS Analysis. Cinnamaldehyde, vetivone, thujopsene, and monoterpenoids (citronellal, citronellol, eugenol, eucalyptol, and citral) were the major components of the tested essential oils (Table 3). Gas chromatography of these semiochemicals indicated that eucalyptol was retained the least (10.41 min), followed by citronellal (16.07 min), citral (20.41 min), citronellol (21.10 min), cinnamaldehyde (22.07 min), eugenol (26.18 min) and thujopsene (30.18 min) (Figure 1). Vetivone (α- and β-) eluted at 55.59 and 54 min., respectively. Therefore, the decreasing order of volatility was: eucalyptol > citronellal > citral ≥ citronellol > cinnamaldehyde > eugenol > thujopsene > α-, β- vetivone.

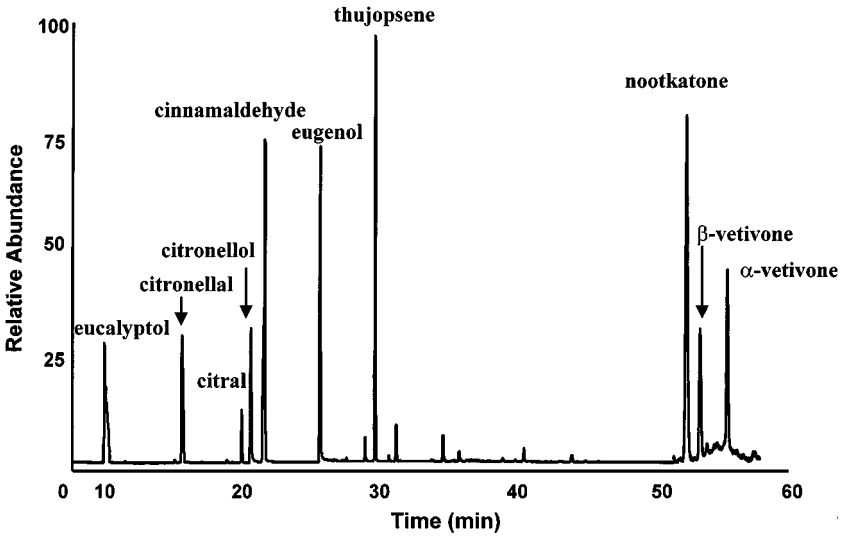

FIG. 1. Gas chromatography of a mixture of nine semiochemicals, those were determined as major components of the 8 essential oils studied.

DISCUSSION

Vetiver oil consists of a complex mixture of more than 300 compounds. Most of these substances belong to the sesquiterpene group of natural products. Among them, α- and β- vetivones are the major components in vetiver oil (St. Pfau and Plattner, 1939). Jain et al. (1982) reported that at least six compounds (α-, β-vetivone, khusimone, zizanal, epizizanal and (+)-(1S, 10R)-1,10-dimethylbicyclo [4,4,0]-dec-6-en- 3-one) were repellent to insects. Recently, we found three other vetiver oil compounds that were repellent to the Formosan subterranean termite including: nootkatone (Zhu et al., 2001), zizanol and bicyclovetivenol (Zhu et al., unpublished). From comparison of the repellent activities of the 8 essential oils (Table 1), we discovered that compound volatility was inversely proportional to repellent effectiveness. Vetivones (α- and β-) were the least volatile and the most effective repellents. The volatility of nootkatone is similar to α- and β- vetivone.

Although thujopsene, eugenol, cinnamaldehyde, citronellal, citral and citronellol have repelling activity against termites (Cornelius et al., 1997, Lin and Yin, 1995b, Adams, 1991), this activity only lasted for a short period of time. We believe that the long-lasting repelling activity of vetiver oil is based on its low volatility.

Essential oils or semiochemicals with low volatility may allow for a longer repelling period. Gas chromatography retention times of such chemicals may be

a useful parameter for developing effective and long-term repellents against the Formosan subterranean termite. Finding new termite-active compounds in essential oils is a direction we are now pursuing.

Acknowledgments—We are grateful to Drs. D.J. Boethel, D. Ring, and M. Stout for a review of this paper. This work was supported by a Specific Cooperative Agreement with the USDA-ARS in New Orleans. This project was approved for publication by the Louisiana State University Agriculture Center and Louisiana Agricultural Experiment Station as manuscript # 00-17-0401.

Zanthoxylum piperitum, AN ASIAN SPICE, INHIBITS FOOD INTAKE IN RATS

GISELA EPPLE,* BRUCE P. BRYANT, IGOR MEZINE, and STANLEY LEWIS

Monell Chemical Senses Center, 3500 Market St., Philadelphia PA 19104

(Received December 19, 2000; accepted April 4, 2001)

Abstract—We investigated the effects of a total extract from *Zanthoxylum piperitum* fruit, of the volatile components of extract, and of a non-volatile fraction containing the major alkylamides of *Zanthoxylum* (NVA) on food intake in rats. In Experiment 1, three groups (A, B, C) of mildly food deprived rats were given one hour long feeding trials during which they were offered choices between an oat-bran wafer paired with vegetable oil and a wafer paired with a *Zanthoxylum* preparation in vegetable oil. Trials were divided into three blocks of two tests each. During Blocks 1 and 3, two wafers coated with vegetable oil were offered to establish baseline consumption. During Block 2, Group A was given choices between wafers coated with oil and wafers coated with total extract. Group B was offered oil coated wafers and wafers coated with the NVA fraction. Group C received two oil coated wafers. One was served on top of a screened dish containing a sample of total extract. In this manner, the rats were exposed to volatile compounds emanating from the extract but could not contact the extract. The second wafer was served on top of a screened sample of oil. Results: In Blocks 1 and 3 trials, the rats fed indiscriminately from both wafers. During Block 2, total extract, the NVA fraction and the volatile compounds from extract all significantly reduced food consumption. In Experiment 2, habituation to the NVA fraction and to the volatile constituents of extract was examined in two additional groups (D, E), using the methods described above. Baseline consumption was tested in Blocks 1 and 3 by offering two oil coated wafers. During Block 2, group D was given 10 trials with oil coated and NVA-fraction coated wafers. Group E was given 10 trials with oil coated wafers paired with the volatile constituents of total extract and with those of oil. Results: Both groups failed to habituate to the *Zanthoxylum* stimuli. Wafers treated with the NVA fraction and wafers paired with the volatile constituents of extract were avoided throughout the 10 test days.

Key Words—Zanthoxylum, secondary plant metabolites, rats, feeding deterrents.

*To whom correspondence should be addressed.

INTRODUCTION

Many plant species produce secondary metabolites such as phenolics, alkaloids and terpenoids in defense against herbivores. These compounds may be toxic, interfere with metabolic processes when ingested, or may act as sensory irritants, causing some form of pain or irritation. Numerous studies have shown that mammalian herbivores avoid eating defended plant parts or, at least, reduce their consumption (Haslam, 1988; Harborne, 1991; McArthur et al., 1991; Palo and Robbins, 1991; Langenheim, 1994; Lawler et al., 1996). Because of this, the potential of secondary plant metabolites as feeding deterrents has received considerable attention as evidenced, for example, by a recent volume on repellents in wildlife management (Mason, 1997). Secondary metabolites, that cause irritation or pain are of particular interest in this respect since animals are unlikely to habituate to these sensations, while they often do so in response to olfactory and gustatory stimuli (Beauchamp, 1997). Thus, non-lethal feeding deterrents based on sensory irritants could be useful for managing herbivore damage in agricultural and forestry settings without danger of non-targeted toxicosis.

Recently, Bryant and Mezine (1999) studied the irritating properties of Szechuan pepper (*Zanthoxylum piperitum*, Rutaceae). This and several other species of *Zanthoxylum*, have been used for centuries as spices in Asian cuisine (Pfänder and Frohne, 1987; Bryant and Mezine, 1999), are employed in traditional Asian medicine (Shibata et al., 1999), and are used as insecticides and insect feeding deterrents (Jacobson and Crosby, 1971; Dube et al., 1990; Bower et al., 1993). Some species contain toxic compounds such as alkaloids, lignanes, furanocoumarin and 8-methoxypsoralen (Pfänder and Frohne, 1987).

In humans, fruits and other parts from *Zanthoxylum piperitum* are strong oral stimuli producing pronounced tingling and cooling sensations (Bryant and Mezine, 1999), which presumably account for its use as a condiment in some Asian cuisines. The extract from the fruit of *Zanthoxylum piperitum* is chemically complex (Yasuda et al., 1982; Pfänder and Frohne, 1987; Kashiwada et al., 1997; Bryant and Mezine, 1999). Many of its components are volatile. These include limonene, α-terpineol, linalool, citral, citronellal, cineol dipentene, and geraniol (Pfänder and Frohne, 1987). Many of these constituents, when delivered in vapor phase, produce ocular irritation in humans (Doty et al., 1978) and stimulate nasal trigeminal nerve fibers in the rat (Bryant and Silver, 2000). In addition to these compounds, a number of non-volatile alkylamides are present (Yasuda et al., 1982; Greger, 1984; Kashiwada et al., 1997).

At least one of the alkylamides, α-HO-sanshool, causes a strong tingling sensation, similar to a mild electric shock, as well as cooling, when applied to the human tongue (Bryant and Mezine, 1999). Using an animal model, the rat, Bryant and Mezine (1999) have shown that HO-α sanshool (2,6,8,10 dodecatetraenoic acid 2-hydroxypropyl amide), induces discharges in trigeminal sensory neurons.

Extracellular recordings from the lingual trigeminal nerve of the rat have shown that HO-α sanshool induces firing in tactile and cool sensitive neurons as well as sensitivity to innocuous stimuli in previously insensitive neurons (Bryant and Mezine, 1999). Moreover, assays of neuronal function that measured induced changes in intracellular calcium, using digital fluorescence imaging of cultured rat trigeminal neurons, showed that the majority of neurons that respond to HO-α sanshool does not belong to the major class of chemically sensitive pain receptive neurons, the polymodal nociceptors. These latter neurons are characterized by their sensitivity to capsaicin, the pungent compound in *Capsicum* peppers that induces heat and pain (Bryant, 1997).

The studies by Bryant and Mezine (1999) suggest that the oral sensations caused by Szechuan pepper depend, at least in part, on neurons other than the trigeminal polymodal nociceptors, which may mediate sensitivity to most irritants (Bryant, 1997). The effects on these neurons would suggest the induction of enhanced and novel oral sensitivity. Given these facts, it is worthwhile to evaluate the effects of *Zanthoxylum*-derived stimuli on food consumption and their potential as feeding deterrents for mammals. Because of the unique oral sensation that HO-α sanshool causes in humans, the alkylamides are of particular interest. The present paper describes studies on an omnivorous rodent, the laboratory rat. Studies with herbivorous rodents (guinea pig, voles) are in progress and will be reported in due course. Taken together, these studies might provide the basis for the development of feeding repellents that target a population of trigeminal neurons not targeted by currently known repellents.

METHODS AND MATERIALS

Preparation of Total Extract. Ripe fruit from *Zanthoxylum piperitum* was obtained from the Morris Arboretum of the University of Pennsylvania. Dried pericarps (5 kg) were extracted twice for 10 hours with ethylacetate (1:4; w : v). The combined extracts were evaporated *in vacuo* to produce a dark brown oil (440 g) that had a strong, characteristic odor for the human nose. We refer to this preparation as the "total extract". This extract constitutes 8.8% of the dry weight of the *Zanthoxylum* fruit.

Preparation of the Non-Volatile Fraction. A fraction containing only the non-volatile alkylamides was prepared. The total extract was re-extracted three times with 1.5 l of a methanol : water mixture (4:1). The upper water-methanol phases were combined and concentrated *in vacuo*. The resulting suspension was extracted four times with 200 ml of methylene chloride. The lower phases were combined, dried over anhydrous sodium sulfate and evaporated, yielding 170 g of a brown oil with a characteristic odor. This material was extracted five times with 100 ml of a mixture of hexane : ethyl acetate : ethanol (40:10:5). The upper organic phases

were filtered through a column (20 × 3 cm) packed with silica gel (40/63 mm, Davisil). Evaporation of the filtrate resulted in 120 g of brown oil with a weak characteristic odor.

The efficacy (>97%) of extraction of the alkylamides was confirmed at each step by analytical reverse-phase high performance liquid chromatography (HPLC). The material (3 × 40 g) was chromatographed using flash chromatography on a silica-gel (Merck 40/63 μ) packed column (50 × 4 cm) with 5% ethanol in hexane as mobile phase. Fractions were collected by volume and analyzed by high performance thin layer chromatography (HPTLC) [Kieselgel F_{254}. Merck; 10% EtOH in hexane]. Fractions containing hydroxy-alkylamides ($R_F = 0.5$) were combined and evaporated *in vacuo* to yield the total alkylamides (25 g) as a light-yellow odorless oil.

The final purification and removal of volatile impurities was achieved by reverse phase preparative HPLC (RP-HPLC). Conditions of RP-HPLC separation were as follows. Column: Zorbax C18 (Varian, Palo Alto) 10 mm, 250 × 22.4 mm; mobile phase: acetonitrile:methanol:water (27:38:35); flow 22 ml/min; sample size 200 mg in 0.5 ml of mobile phase. The eluent containing the hydroxy—alkylamides was concentrated *in vacuo* two times and the compounds were extracted using solid-phase extraction on C18 bonded silica gel (Sigma). Adsorbed compounds were eluted with ethanol, dried over anhydrous sodium sulfate and evaporated *in vacuo* to produce colorless crystals (yield 70%). We refer to this as the non-volatile alkylamide fraction (NVA fraction). The material is stable in ethanol solution (25 mg/ml) at -20°C under nitrogen for three months. For the human subject, the NVA fraction evokes oral sensations that are very similar to those caused by ripe *Zanthoxylum* fruit (Bryant and Epple, personal observation).

Preparation of Feeding Stimuli. For the feeding trials, total extract was diluted with Crisco vegetable oil to yield a 10% solution. In the remainder of the paper, we refer to this as "the extract". The NVA fraction was also diluted with vegetable oil. The concentration in oil was adjusted to be equivalent to the concentration of NVA in a 10% oily solution of total extract.

Subjects. Laboratory rats (*Rattus norvegicus*) who had never experienced *Zanthoxylum* before served as subjects. All animals were adults. The rats were individually housed in polypropylene rat boxes (40 × 20 × 20 cm). Food and water were available *ad libitum*, except during short periods of food deprivation prior to testing (see below).

Test Cages. For the purpose of testing the subjects were transferred to rat boxes identical to their home cages. The boxes contained aspen shavings and a water bottle, but no food. The test cages were oriented on a shelf so that their narrow sides (20 cm) faced the experimenter.

Feeding Experiments. Responses to extract from *Zanthoxylum*, to the NVA fraction, and to volatile compounds emanating from extract were examined by

comparing consumption of oat bran wafers treated with one of these stimuli to consumption of wafers treated with Crisco vegetable oil, the control stimulus. The amounts of wafer consumed during two-choice feeding trials lasting one hour were the dependent variables. All subjects had been habituated to wafers coated with vegetable oil prior to the experiments.

Wafers were prepared from 200 g of Quaker oat bran, 40 g of sugar, 5 ml of molasses, and 200 ml of water. From this mixture, 25 round wafers were cut to a size of 4.5 cm diameter and 5 mm thickness with a cutter. They were punctured with a small standardized tool in order to make them more adsorbent for stimulus fluids. Wafers were then air dried for 24 hr at room temperature. The dried wafers were hard enough so that the rats had to gnaw them rather than bite off large chunks. Wafers for the entire experiment were prepared at one time and were frozen until needed for testing. Immediately before the start of trials the thawed wafers were dipped into the experimental and control stimulus fluids for two minutes.

Stainless steel dishes (5 cm $\times$ 5 cm $\times$ 3 cm deep) were used to serve the wafers. Each dish was covered with a stainless steel lid that had a round hole in the center (diameter 3 cm). The wafers were fastened to the lids with wire, covering the hole so that the rats could not access the inside of the dish. This made it possible to offer oil-coated wafers in close proximity to volatile compounds emanating from extract placed inside the dish (see below).

The subjects were mildly food deprived before testing. All animals were removed from their home cages and placed in individual test cages six hours prior to each feeding trial. They remained without food for these six hours. The rats were then presented with two pre-weighed stimulus wafers and allowed to feed freely for one hour, after which the wafers were removed and the amounts of wafer consumed were determined.

During feeding trials the subjects were given choices between two dishes, each containing a wafer. The dishes were placed in the center of the front and back of the chamber against the cage walls. The front-back position of all stimuli was counterbalanced across subjects and across trials to compensate for possible front-back preferences during feeding.

Statistical Analysis. For each group of rats, significant differences between the amounts of food consumed from the control and the experimental wafers were analyzed by two-way analysis of variance (ANOVA) with repeated measures. Factors in this analysis were wafer-coating and block (see below). Tukey's HSD Method and ANOVA were used to identify *post hoc* differences.

Experiment 1. In this experiment the effects of extract, the NVA fraction and the volatile components of the extract on food consumption were examined. Three groups (A, B, and C) of eight rats (4 males, 4 females) each were used. Each group was given two-choice feeding trials twice a week for a total of six trials. The six trials were divided into three blocks of two trials each. To establish baseline

TABLE 1. SUMMARY OF STIMULUS PRESENTATIONS FOR GROUPS A–E

Group	Treatment Block 1	# of trials	Treatment Block 2	# of trials	Treatment Block 3	# of trials
A	oil vs oil	2	oil vs extract	2	oil vs oil	2
B	oil vs oil	2	oil vs NVA	2	oil vs oil	2
C	oil vs oil	2	oil vs extract volatiles	2	oil vs oil	2
D	oil vs oil	2	oil vs NVA	10	oil vs oil	2
E	oil vs oil	2	oil vs extract volatiles	10	oil vs oil	2

consumption, Block 1 for each group consisted of two trials offering a choice between oil-coated, but otherwise untreated wafers (Table 1).

During Block 2, each group of rats received a different experimental stimulus. For group A, the second block consisted of two trials offering choices between oil coated-wafers and wafers coated with *Zanthoxylum* extract. Group B was given two trials offering choices between oil-coated wafers and wafers coated with the NVA fraction. For group C, Block 2 consisted of two trials with choices between two oil-coated wafers. One wafer was fastened to the lid of a dish containing a disk of filter paper (5 cm diameter) with 200 μl oil, the second wafer was fastened to the lid of a dish containing a filter paper disk with 200 μl extract. The rats were exposed to the volatile compounds emanating from the oil and the extract, but could not contact the filter paper inside the dishes.

For all groups, Block 3 again consisted of choices between two oil-coated wafers. To avoid cross-contamination by volatile compounds emitted by the different *Zanthoxylum* stimuli, the three groups were tested consecutively in a well ventilated room (3.5 $\times$ 3.5 m) containing no other animals (Table 1).

For analysis, individual means of food consumption were calculated. The amounts consumed by each rat from the control wafer were averaged over the two trials representing a block and compared to the average amounts consumed from the experimental wafer. This was done to compensate for potential front-back preferences in feeding location. For trials using two oil coated wafers (Blocks 1 and 3), the amounts consumed in the front of the cage were averaged and compared to the amounts consumed in back of the cage.

Experiment 2. In this experiment, the question whether or not rats will habituate to *Zanthoxylum*, and after repeated exposure will increase consumption of wafers treated with the NVA fraction or with volatile components of the extract was examined.

Two groups (D and E) of *Zanthoxylum*-naive rats served as subjects. Group D contained seven rats (4 males, 3 females), Group E 10 rats (5 males, 5 females). Each group was given three blocks of 2-choice trials. During Block 1, baseline

consumption was established by testing the rats in each group on two different days with choices between two oil-coated wafers (Table 1).

During Block 2, habituation to the NVA fraction or to volatile components of extract was tested. Group D was offered choices between an oil-coated wafer and a NVA-coated wafer twice weekly for a total of 10 trials, i.e., for 5 weeks. Group E was given 10 trials during which choices between two oil-coated wafers were offered twice a week. One wafer was fastened to the lid of a dish containing a disk of filter paper (5 cm diameter) with 200 μl oil, the second one was fastened to the lid of a dish containing a filter paper disk with 200 μl extract. As in Experiment 1, the rats were exposed to the volatile components of the extract and oil, but could not contact the filter paper. During Block 3, the rats in both groups were again given two trials with a choice between two wafers coated with oil (Table 1). As in Experiment 1, both groups were tested consecutively in a well ventilated room.

To illustrate consumption over repeated trials, a preference ratio was calculated for each trial in Block 2 by dividing the amount consumed from the wafer treated with the NVA fraction or the volatile compounds from extract by the total amount consumed from both wafers. For Blocks 1 and 3, the amount consumed in the front of the cage was divided by the total amount eaten. A preference ratio of 0.5 reflects equal acceptance of both wafers offered during a trial.

RESULTS

Experiment 1. For each group of rats, ANOVA revealed differences in the amounts of food consumed from the two wafers available during choice tests, and an interaction between food consumption and Block (Group A: $F = 6.14$, $P = .016$, P for interaction $= .001$; Group B: $F = 19.94$, $P = < .001$, P for interaction $= .01$; Group C: $F = 13.5$, $P = .001$, P for interaction $= .003$). Figures 1–3 show mean amounts consumed from oil-coated control wafers and from wafers coated with the experimental stimuli during the three trial blocks. *Post hoc* comparison showed that during Blocks 1 and 3, animals in all groups consumed similar amounts of food from both dishes, each containing an oil-coated wafer.

During Block 2, Group A exhibited a very strong avoidance of wafers treated with extract (Figure 1). Post hoc analysis revealed that the animals consumed much less of the extract-treated than the oil-treated wafers ($F = 36.5$, $P < .001$). Group B consumed less from NVA-coated wafers than from control wafers ($F = 10.94$, $P = 0.005$) [Figure 2]. Group C avoided wafers presented over the vapors emanating from extract present in the dish below to a similar degree as Group A avoided extract-coated wafers ($F = 47.34$, $P < .001$) [Figure 3]. During Block 3, when given a choice between two oil-coated wavers again, animals in all groups fed indiscriminately from both wafers. Consumption during Block 3 was in the same range as that exhibited during the first block of trials.

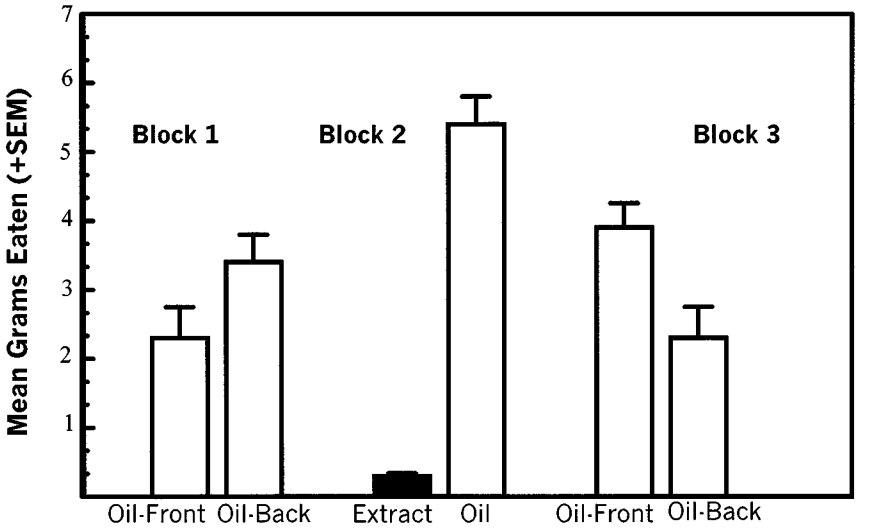

FIG. 1. Exp. 1. Amounts consumed by Group A from wafers coated with oil and wafers coated with extract during trial Blocks 1–3.

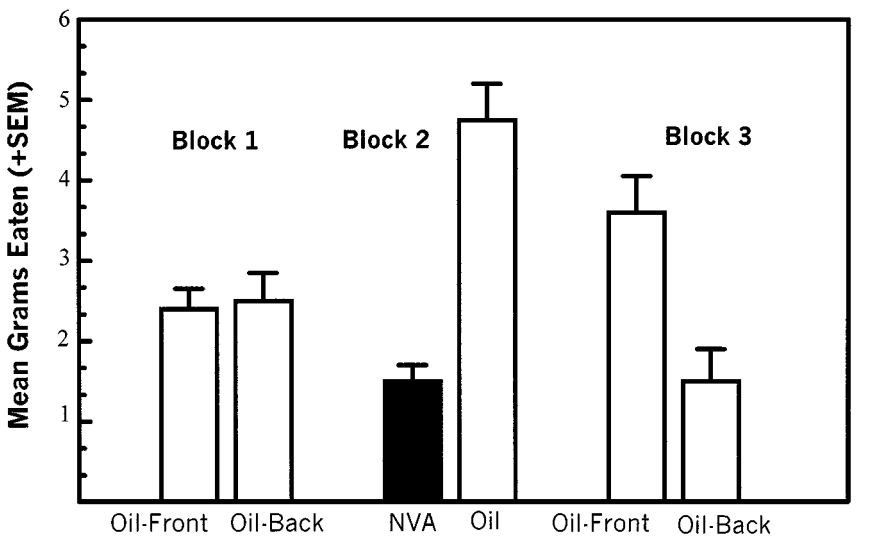

FIG. 2. Exp. 1. Amounts consumed by Group B from wafers coated with oil and wafers coated with the NVA fraction during trial Blocks 1–3.

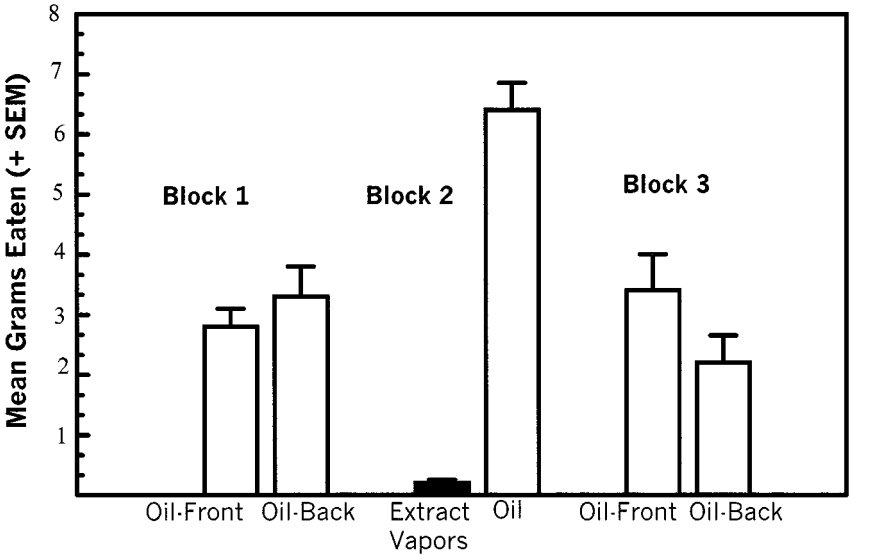

FIG. 3. Exp. 1. Amounts consumed by Group C from wafers served over a sample of oil and wafers served over a sample of extract during trial Blocks 1–3.

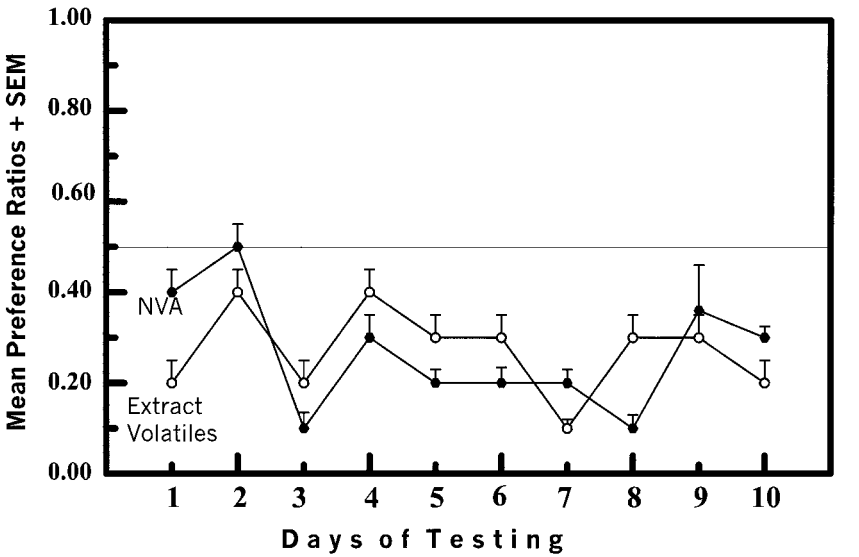

FIG. 4. Exp. 2. Daily preference ratios for trials offering choices between oil-coated wafers and wafers coated with the NVA fraction (Group D) and for trials offering choices between wafers served over a sample of oil and wafers served over a sample of total extract (Group E). The horizontal line marks the ratio of 0.5, reflecting a lack of preference.

For all trial blocks, the total amounts consumed from both dishes during choice tests were similar across blocks and between groups, suggesting that none of the stimuli reduced total intake (Group A: 5.9 ± .2 g; Group B: 5.8 ± .5 g; Group C: 6.0 ± .2 g).

Experiment 2. Figure 4 shows preference ratios obtained by Groups D and E over the 10 days of habituation testing. For both groups two-way ANOVA including trials in all blocks revealed differences in the amounts of food consumed from both dishes and an interaction between food consumption and trial days (Group D: $F = 16.83$, $P = < .001$, P for interaction $= < .001$; Group E: $F = 25.23$, $P = < .001$, P for interaction $= .02$). *Post hoc* 2-way ANOVA on the amounts of food consumed only during Block 2 trials showed an effect of wafer coating, but no interaction between wafer coating and days of testing (Group D: $F = 54.6$, $P = < .001$; Group E: $F = 42.3$, $P = < .001$). NVA coated wafers as well as wafers associated with vapors emanating from *Zanthoxylum* extract were avoided to a similar degree throughout the five weeks of testing. There were no differences in the amounts of food consumed from the two oil coated wafers in Blocks 1 and 3.

DISCUSSION

The results of the present study show that rats avoid food that has been treated with extract and fractions derived from the fruit of Szechuan pepper. In Experiment 1, rats strongly avoided the total extract, which is a complex mixture of volatile and non-volatile constituents (Bryant and Mezine, 1999; Kashiwada et al., 1997; Yasuda et al., 1982). Its volatile constituents alone, when present in close proximity to uncontaminated, palatable food, were as effective as the non-volatile constituents. Indeed, avoidance of wafers treated with the total extract may have largely been based on its volatile components.

Under the present trial conditions, where the rats had a choice between wafers coated with the experimental stimuli and with oil, none of the experimental stimuli affected the total amount of food consumed. They merely shifted consumption from wafers coated with experimental stimuli toward those coated with oil. Thus, *Zanthoxylum* compounds did not cause a generalized food aversion.

Figure 2 shows that the amount of food consumed from NVA treated wafers in Experiment 1 was higher than that consumed from wafers treated with extract and wafers served above a sample of extract. This does not necessarily indicate that the NVA fraction was less aversive to the rats than were extracts and extract vapors. As the result of the chromatographic process employed in its preparation, the NVA fraction does not contain volatile constituents. This was confirmed in behavioral studies with prairie voles. Choice tests, similar to those used in the present study, have shown that the voles avoided uncontaminated wafers associated

with volatile components of extract, but fed indiscriminately from wafers presented on top of dishes containing samples of NVA and wafers presented above samples of oil (Epple et al., unpublish data). Since NVA offers no volatile cues to its irritating effects, the rats probably needed to ingest at least some of the NVA coated wafer before perceiving its quality and responding with avoidance. In humans, there is a 1–2 minute latency between oral stimulation with NVA and the onset of oral irritation (Bryant and Mezine, 1999). In rats, there also is a 1–2 minute delay in the onset of trigeminal lingual nerve responses to oral stimulation with NVA (Bryant and Mezine, 1999). Therefore, in the present experiment, the rats may have ingested a relatively high amount of the treated wafers before they perceived the effect of NVA. The fact that there was no difference between the amounts of NVA treated wafer consumed on day 1 and day 2 of testing, or between preference ratios calculated for each day, also supports the assumption that the animals depended on oral stimulation to assess the aversive quality of NVA.

The results of Experiment 2 show that the avoidance of innocuous wafers associated with extract vapors and of wafers treated with the NVA fraction in Experiment 1 was not due to neophobia. Rats did not habituate to the volatile compounds emanating from *Zanthoxylum* extract or to the NVA fraction. Rather, they exhibited aversion over the entire 5 weeks of testing. Figure 4 shows that the rats tended to eat more of the NVA treated wafers on days 1 and 2 of testing than during the remainder of the trials. This might suggest that the animals learned to sample the wafers very carefully in order to detect the presence of NVA before proceeding to feed from a wafer. However, there was no significant decrease in consumption over time that would support such an assumption. *Post hoc* ANOVA on preference ratios did not reveal differences between days of testing.

It is interesting that the vapors emitted by the extract were so effective in reducing food consumption on a short term basis in Experiment 1, and remained effective in Experiment 2. On the first day of exposure to the volatile constituents of extract during Experiment 1, only one out of the eight rats consumed part of the wafer served on top of the dish containing extract. The remaining seven animals seemed not to have touched the food. Even when the rats were given a chance, during repeated presentation in Experiment 2, to discover that the wafers located above the extract samples were untainted, consumption remained reduced. The animals did not seem to habituate to these volatile compounds. This response is somewhat puzzling since the rats had plenty of opportunity to discover that the wafers were uncontaminated. It is conceivable that the persistant avoidance was not in response to compounds that only stimulated the olfactory system, but in response to irritation or pain mediated by the trigeminal system. Some volatile constituents of the extract are irritants for humans (Doty, 1978) and are known to stimulate nasal trigeminal nerve fibers in rats (Bryant and Silver, 2000). If the vapors emanating from the extract were concentrated enough to cause discomfort,

the rats would be unlikely to habituate to them, even if the food resources associated with the vapors would be more restricted than was the case in the present study. Experiments using anosmic rats and rats whose trigeminal A- and C-fibers have been desensitized with capsaicin could shed light on this question.

Some of the well documented avoidance responses of mammals to volatile constituents from plants may also be due to irritation rather that olfaction alone. Snowshoe hares (*Lepus americanus*) and Townsend voles (*Microtus townsendii*) avoid feeding from sources associated with the scent of pine oil extracted from pulp waste (Bell and Harestad, 1987). Snowshoe hares also avoid feeding on conifer seedlings to which odor dispensers with pinosylvin, a phenolic compound from Alaskan green alder (Clausen et al., 1986) have been attached (Sullivan et al., 1992). The scent of Siberian pine needle oil reduces food caching in pocket gophers (*Geomys bursarius, Thomomys talpoides*) [Epple et al., 1996, 1997]. Woodchucks (*Marmota monax*) avoid feeding on uncontaminated green pepper in the presence of volatile compounds from geranium oil and d-pulegone (Bean et al., 1997). The odors of crushed foliage from lodgepole pine (*Pinus contorta*) and Sitka spruce (*Picea sitchensis*), and of some of their monoterpene constituents, inhibit feeding in red deer calves (*Cervus alephs*) (Elliott and Loudon, 1987). Bell and Harestad (1987) have argued that the monoterpenes in essential oils from conifers have antimicrobial activity, which may interfere with digestive processes in cecal digestors and ruminants, and that such species avoid ingestion of defended conifer parts based on the characteristic odor of their essential oils.

Little seems to be known about which, if any, mammalian species exploit *Zanthoxylum* species as a food resource and what parts of the plants may be avoided. We were not able to find information on this question in the literature. *Zanthoxylum piperitum* trees at the Morris Arboretum, from which we obtained fruit for the present study, appear to be very well defended. The large white-tailed deer (*Odocoileus hemionus*) population at the Arboretum does not damage these trees, although heavy deer damage is incurred by many other trees and shrubs at this site. Intact ripe fruit does not emit an odor since its volatile compounds are encapsulated in oil glands in the pericarp. Any animal chewing the fruit, however, would immediately be exposed to its volatile and non-volatile components. The authors of this paper can attest to the fact that biting down on a single ripe fruit causes very unpleasant and long lasting oral sensations, which they are not eager to experience again. Thus, in summary it appears that the utility of some of the volatile and nonvolatile compounds of Szechuan pepper as feeding deterrents for mammals is worth exploring.

Acknowledgments—This research was supported in part by U.S. Department of Agriculture Cooperative Agreement #12-34-41-0040[CA] between the National Wildlife Research Center and Monell Chemical Senses Center and the Pennsylvania Department of Agriculture. ARE CHEMICAL ALARM CUES CONSERVED WITHIN SALMONID FISHES?

REEHAN S. MIRZA* and DOUGLAS P. CHIVERS

(Received January 26, 2001; accepted April 11, 2001)

Abstract—A wide diversity of fishes possess chemical alarm signalling systems. However, it is not known whether the specific chemicals that act as alarm signals are conserved within most taxonomic groups. In this study we tested whether cross-species responses to chemical alarm signals occurred within salmonid fishes. In separate laboratory experiments, we exposed brook charr (*Salvelinus fontinalis*), brown trout (*Salmo trutta*), and rainbow trout (*Oncorhynchus mykiss*) to chemical alarm signals from each of the three salmonid species and from swordtails (*Xiphophorus helleri*). In each case, the test species responded with appropriate antipredator behavior to all three salmonids alarm cues, but did not react to swordtail cues. These data suggest that chemical alarm cues are partially conserved within the Family Salmonidae. For each species tested, the intensity of the response was stronger to conspecific alarm cues, than to heterospecific alarm cues, indicating that salmonids could distinguish between chemical cues of conspecifics versus heterospecifics. These results suggest that the chemical(s) that act as the alarm cues may be: 1) identical and that there may be other chemical(s) that allow the test fish to distinguish between conspecifics and heterospecifics, or 2) that the cues that act as signals are not identical, but are similar enough to be recognized.

Key Words—Brook charr, rainbow trout, brown trout, alarm signals, antipredator behavior, Salmonidae.

INTRODUCTION

Chemical cues that serve as alarm signals have been reported in a wide variety of fishes. These chemical cues are released by prey upon detecting or being captured by a predator (Chivers and Smith, 1998). Chemical alarm signals function to 'warn'

*To whom correspondence should be addressed. email: mirza@skyway.usask.ca

0098-0331/01/0800-1641$19.50/0

nearby conspecifics of potential predators in the vicinity. Individuals warned by alarm signals may gain a survival benefit by avoiding the predator or by evading the predator during an encounter (Mathis and Smith, 1993a; Wisenden et al., 1999; Mirza and Chivers, unpublished data).

Chemical alarm signals may be particularly important when visual cues are limited, such as at night, in highly structured habitats or in areas of high turbidity (Smith, 1992). Furthermore, chemical signals function well in aquatic media because a large number of compounds can dissolve in water, giving a large number of potential chemical signals to be detected (Kleerekoper, 1969; Hara, 1994). Although controversy exists concerning the function of chemical alarm signals (Magurran et al., 1996; Smith, 1997; Brown and Godin, 1999), there exists considerable evidence for the antipredator function of alarm signals for both signal senders and receivers (Smith, 1992; Chivers and Smith, 1998). Thus, chemical signals provide reliable information to assess predation risk (Kats and Dill, 1998).

Chemical cues that are released when captured by a predator are referred to as damage-released alarm signals (Chivers and Smith, 1998). Damage-released alarm signals are found within a wide diversity of fishes and have been best characterized in the Superorder Ostariophysi (Schutz, 1956; Smith, 1992). Ostariophysans comprise 64% of all freshwater fishes, and includes minnows, suckers, loaches, characins, and catfishes (Nelson, 1994). Recently, other researchers have reported the presence of damage-released alarm signals in other groups of fishes, including gobies (Smith, 1989; Smith et al., 1991), poeciliids (Reed, 1969; García et al., 1992, Nordell, 1998; Brown and Godin, 1999; Mirza et al., unpublished data), sticklebacks (Mathis and Smith, 1993b; Brown and Godin, 1997), darters (Smith, 1979, 1982; Commens and Mathis, 1999), sculpins (Hugie et al., 1991, Chivers et al., 2000), cichlids (Wisenden and Sargent, 1997) and salmonids (Brown and Smith, 1997; Berejikian et al., 1999, Mirza and Chivers, 2000).

With the exception of research on Ostariophysan fishes, we know very little about the nature of chemicals that act as alarm signals for most species. The data of Schutz (1956) suggests that alarm signals are probably conserved within Ostariophysan fishes. He found that Ostariophysans responded to alarm signals from other Ostariophysans. Brown et al. (2000) recently showed that a nitrogen oxide functional group probably acts as the chief molecular trigger in the Ostariophysan alarm signalling system. The molecular trigger appears to be conserved within the Superorder. Whether or not alarm signals are conserved within other groups of fishes remains unknown. It is common for closely related species to show cross-species responses to alarm cues, however, it is unclear whether these cross-species responses occur because the species use the same chemical(s) in their signalling systems or whether the species have learned to recognize each other's alarm signals (Smith, 1982, Brown and Godin, 1997). Chivers and Smith (1994) and Chivers et al. (1995) have established that sympatric members of the same prey guild can learn to recognize each other's alarm signals.

In this study, we examined cross-species reactions to chemical alarm cues within the Family Salmonidae (Superorder Proacanthopterygii). In three separate laboratory experiments, we exposed brook charr (*Salvelinus fontinalis*), brown trout (*Salmo trutta*), and rainbow trout (*Oncorhynchus mykiss*) to chemical alarm cues from each of the three salmonids, plus chemical cues of swordtails (*Xiphophorus helleri*, Superorder Acanthopterygii). Swordtails represent a generalized injured fish cue since they are allopatric with all three salmonid species and phylogenetically distant from salmonids. Both rainbow trout and brook charr have been shown to possess chemical alarm signalling systems (Brown and Smith, 1997; Mirza and Chivers, 2000).

METHODS AND MATERIALS

Fish Maintenance. Juvenile brook charr, brown trout and rainbow trout were obtained from the provincial hatchery in Ft. Qu'Appelle, Saskatchewan, Canada in May of 2000. The three species of salmonids were kept in separate 350-L artificial stream tanks at 14°C on a 14 : 10 L : D photoperiod. Fresh dechlorinated water was introduced into each holding tank at a rate of 1 l/min. Fish were fed daily on a combination of commercial trout pellets and frozen brine shrimp, *Artemia* spp.

Brook Charr Responses to Alarm Cues. In this experiment, we exposed juvenile brook charr to one of four treatments: 1) brook charr skin extract, 2) brown trout skin extract, 3) rainbow trout skin extract or 4) swordtail skin extract. Each charr received only one of the four treatments, and the order of testing was randomized. A total of 90 charr were tested ($N = 20$ for each salmonid treatment, $N = 30$ for the swordtail treatment). Previous work had shown that brook charr do not respond to swordtail skin extract (Mirza and Chivers, 2000); however, the responses to swordtail skin extract were more variable than predicted, thus, we increased our sample size.

Each test chamber was set up as a gravity flow-through system (modified from Petranka et al., 1987). Water flowed into one of two 60 l header tanks, then spilled over into a 113 l test chamber (measuring 54 × 44 × 36 cm) and finally down the drain at a rate of 1 l/min. A single plastic tube ran into one of the two header tanks for introduction of chemical stimuli. Each test chamber was subdivided into two compartments by an opaque barrier with screen mesh at either end. The barrier was 12 cm from the long wall of the tank. This created an observation area of 54 × 32 × 36 cm. Behind the barrier, two small powerheads were used to create a circular flow in the tank. Each test chamber contained a single centrally located shelter object constructed from a ceramic tile (15 × 8 cm) with three glass legs (7 cm). A single plastic tube was situated at the right hand side of the chamber for introduction of food. A grid of 9 × 9 cm squares was constructed on the front of

the barrier to quantify movement of fish in the tank. A horizontal line divided the tank into upper and lower halves (Figure 1).

Skin extracts were obtained from donor fishes that were euthanized with a single blow to the head in accordance to guidelines set by the Canadian Council on Animal Care. For each set of trials, a fillet of skin was removed from both sides of each fish (approximately 2.5 cm^2) and placed in 50 ml of chilled glass-distilled water. Skin was homogenized and then filtered through filter floss, to remove the larger particles, then diluted in distilled water to make a final volume of 250 ml. Extracts were kept on ice and used approximately one hour after preparation. Each fish was exposed to a concentration of 0.5 cm^2 of skin. We used 4 brook charr (mean $\pm$ SD standard length $= 5.1 \pm 0.25$ cm), 4 brown trout (5.1 ± 0.26 cm), 4 rainbow trout (5.8 ± 0.26 cm) and 6 swordtails (4.5 ± 0.16 cm) as donors for skin extracts.

Fish were allowed to acclimate for 24 hr prior to trials. Each trial was 18 min in length and consisted of an 8-min pre- and 8-min post-stimulus period, with a 2-min stimulus introduction period between the pre- and post-stimulus periods. Dye trials indicated that it took approximately 1.5 min for the stimulus to enter the test chamber from the header tank. At the beginning of both the pre- and post stimuli periods, approximately 5 ml of thawed brine shrimp was introduced into the tank. The food was added to stimulate activity and would only remain in the water column for a few minutes. Charr were observed to forage predominantly in the water column, rather than pick food off the bottom. The water flow was switched over to the second header tank after the pre-stimulus period to allow introduction of the chemical stimulus.

During both the pre- and post-stimulus periods we recorded the number of line crosses, the amount of time spent under shelter, amount of time in the lower half of the tank (water-column position), number of feeding bites and latency to first feeding bite. A line cross was recorded when 75% of the fish's body crossed from one grid square to another. We also recorded whether the fish was motionless (stationary on the bottom or in the water column for a minimum of 30 sec). Changes between the pre-stimulus and post-stimulus periods were calculated and the difference in changes among treatments was analysed using a MANOVA followed by one-way ANOVAs on significant variables (Zar, 1996). Post hoc Tukey tests were used to determine which pairs of treatments differed for significant response variables. Frequency of motionlessness was compared using a *Chi*-square analysis. All statistics were calculated using SPSS 9.0.

Brown Trout Responses to Alarm Cues. In this experiment, we exposed brown trout to chemical alarm cues from each species of salmonid as well as swordtails. The experimental set-up procedures and statistical analysis were identical to that outlined for brook charr. There were 20 replicates of each treatment. Skin extracts were prepared from 4 juvenile brown trout (mean $\pm$ SD standard length $= 5.58 \pm 0.26$ cm), 4 brook charr (5.23 ± 0.17 cm), 4 rainbow trout (6.65 ± 0.31 cm) and 4 swordtails (4.55 ± 0.26 cm).

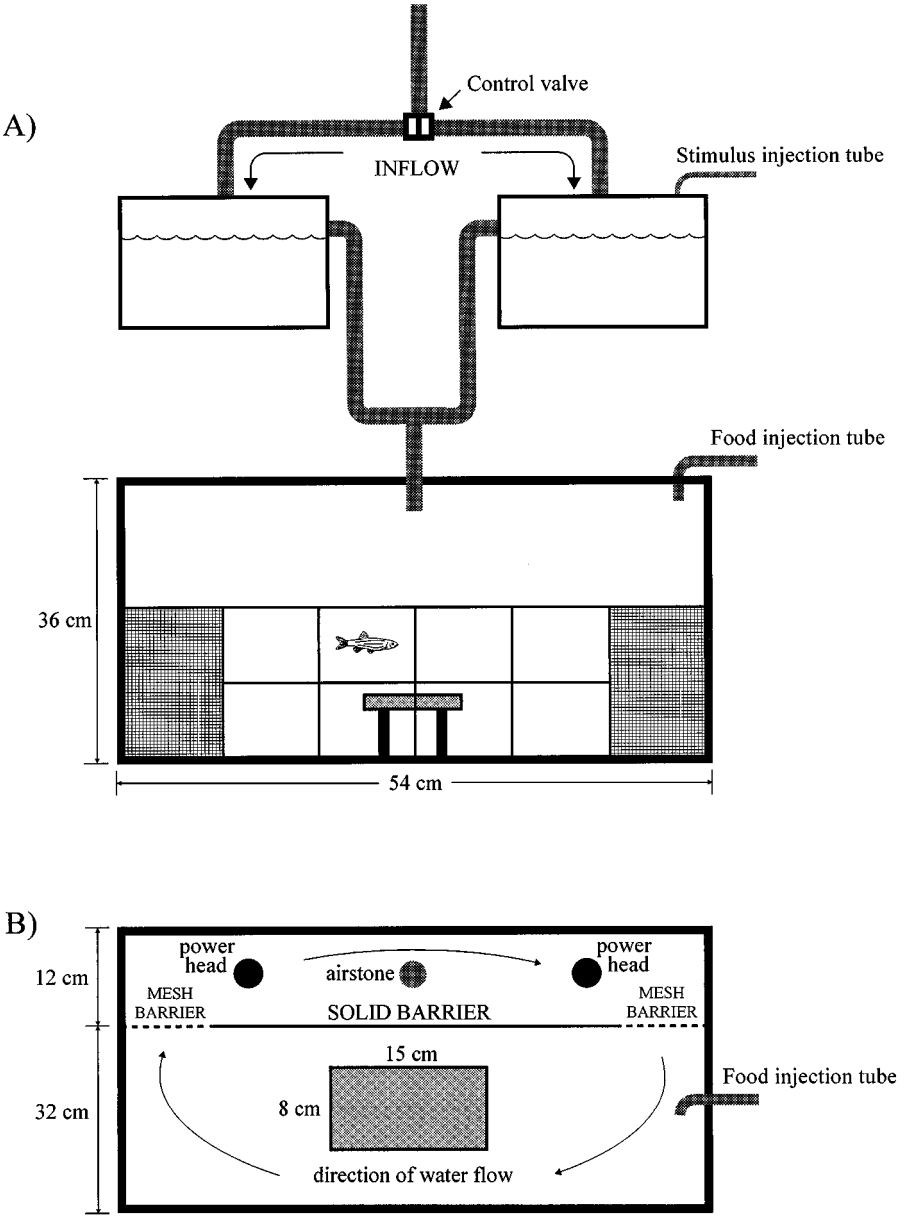

FIG. 1. Schematic diagram of the gravitational flow-through apparatus. A) front view, B) top view.

Rainbow Trout Responses to Alarm Cues. In this experiment, we exposed rainbow trout to chemical alarm cues from each species of salmonid as well as swordtails. The experimental set-up, procedures, and statistical analysis were identical to that outlined for brook charr. There were 20 replicates for each treatment. Skin extracts were prepared from 4 juvenile rainbow trout (mean $\pm$ SD standard length $= 7.60 \pm 0.29$ cm), 4 brook charr (5.83 ± 0.27 cm), 4 brown trout (6.57 ± 0.33 cm) and 4 swordtails (4.95 ± 0.39 cm).

RESULTS

Brook Charr Responses to Alarm Cues. MANOVA results reveal there was an overall difference among treatments (Table 1). Subsequent ANOVAs showed that there was a significant difference in changes in the number of line crosses, number of feeding strikes, and latency to first feeding strike, however, there were no significant differences among treatments for changes in position in the water column or shelter use (Table 1). Post hoc comparisons reveal that brook charr reduced activity more in response to all three salmonid skin extracts, than to swordtail skin. Moreover, there was less activity by brook charr exposed to brook charr extract than those exposed to brown trout extract (Figure 2). Brook charr reduced foraging in response to the salmonid extracts compared to swordtail skin extract, however, the only statistical difference was observed between rainbow trout skin extract and swordtail skin extract (Figure 2). The latency to first feeding strike was greater when brook charr were exposed to either conspecific or brown trout skin extract (Figure 2). However, there was no difference in response between swordtail and rainbow trout cues in terms of latency to first feeding strike.

TABLE 1. MANOVA AND ANOVA RESULTS FOR RESPONSES OF BROOK CHARR TO BROOK CHARR SKIN EXTRACT, RAINBOW TROUT SKIN EXTRACT, BROWN TROUT SKIN EXTRACT AND SWORDTAIL SKIN EXTRACT

Change in latency to first feeding strike	5.34	3,86	0.002

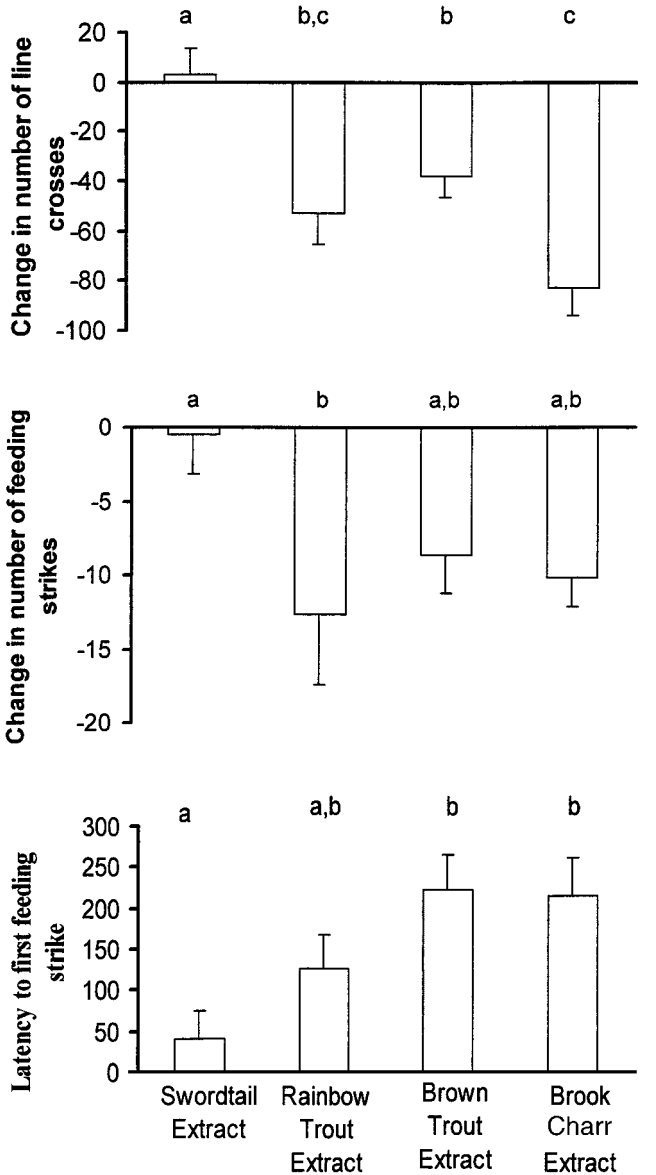

FIG. 2. Mean (+SE) change in number of line crosses, number of feeding strikes, and latency to first feeding strike for brook charr exposed to either brook charr skin extract, brown trout skin extract, rainbow trout skin extract, or swordtail skin extract. Different letters over bars denote significant differences at $P < 0.05$.

Brook charr were motionless in 12 out of 20 trials when exposed to brook charr skin extract compared to 6 out of 20 trials when exposed to brown trout skin extract, 1 out of 20 trials when exposed to rainbow trout skin extract, and 0 out of 30 trials when exposed to swordtail skin extract. Since no brook charr were motionless when exposed to swordtail skin extract, we excluded this data from the analysis to avoid having cells with frequencies of less than 5. We constructed a 2×2 contingency table comparing frequency of motionless to conspecific (brook charr) skin extract versus a combined heterospecific (brown trout and rainbow trout) skin extract. Brook charr were motionless more in response to conspecific skin extract than heterospecific skin extract ($X^2 = 11.13$, $df = 1$, $P = 0.001$).

Responses of Brown Trout to Alarm Cues. MANOVA revealed that there was an overall difference among treatments (Table 2). Subsequent ANOVAs showed that there was a difference in changes in the number of line crosses, number of feeding strikes, and latency to first feeding strike among treatments, however, there were no differences among treatments for changes in position in water column or shelter use (Table 2). Post hoc comparisons reveal that brown trout decreased activity more in response to all three salmonid skin extracts, than to swordtail skin extract. Moreover, there was less activity when brown trout were exposed to brown trout skin extract than to rainbow trout skin extract (Figure 3). Brown trout reduced the number of feeding strikes in response to all three trout skin extracts compared to swordtail skin extract (Figure 3). The latency to first feeding strike by brown trout was greater when exposed to brown trout skin extract compared to swordtail skin extract (Figure 3).

Brown trout were motionless in 13 out of 20 trials when exposed to brown trout skin extract compared to 5 out of 20 trials when exposed to brook charr skin extract, 8 out of 20 trials when exposed to rainbow trout skin extract, and 0 out of 20 when exposed to swordtail skin extract. Using the same basis for the *Chi*-square

analysis as in the brook charr experiment, we constructed a 2×2 contingency table comparing conspecific (brown trout) skin extract versus a combined heterospecific (brook charr and rainbow trout) skin extract. More trout were motionless when exposed to conspecific skin extract than heterospecific skin extract ($X^2 = 5.74$, $df = 1$, $P = 0.017$).

Responses of Rainbow Trout to Alarm Cues. MANOVA revealed that there was an overall difference among treatments (Table 3). Subsequent ANOVAs showed that there was a difference in changes in the number of line crosses, number of feeding strikes, and latency to first feeding strike among treatments, however, there were no differences among treatments for changes in position in the water column or shelter use (Table 3). Post hoc multiple comparisons reveal that rainbow trout decreased activity more in response to all three salmonid skin extracts, than swordtail skin extract. Moreover, there was less activity by rainbow trout exposed to conspecific skin extract than brook charr skin extract (Figure 4). Rainbow trout reduced the number of feeding strikes in response to all three salmonid skin extracts compared to swordtail skin extract (Figure 4). The latency to first feeding strike of rainbow trout was greater when exposed to rainbow trout skin and brown trout skin extract compared to swordtail skin extract (Figure 4). Moreover, rainbow trout responded more strongly to conspecific skin extract than to brook charr skin extract in terms of latency to first feeding. There was no difference between the swordtail and brook charr treatments in terms of latency to first feeding strike.

Rainbow trout were motionless in 13 out of 20 trials when exposed to rainbow trout skin extract compared to 10 out of 20 trials when exposed to brown trout skin extract, 4 out of 20 trials when exposed to brook charr skin, and 0 out of 20 trials when exposed to swordtail skin extract. We constructed a 2×2 contingency table comparing frequency of motionless of conspecific (rainbow trout) alarm cues to heterospecific (brook charr and brown trout) alarm cues. Motionless

behavior was exhibited more in response to conspecific alarm cues than heterospecific alarm cues ($X^2 = 4.85$, $df = 1$, $P = 0.028$).

DISCUSSION

The results of the present study and those of three recent studies (Brown and Smith, 1997, Berejikian et al., 1999; Mirza and Chivers, 2000) indicate that it is common for salmonid fishes use chemical alarm cues to mediate their risk of predation. Our results confirm previous studies showing alarm responses in rainbow trout (Brown and Smith, 1997) and brook charr (Mirza and Chivers, 2000). Moreover, we are the first to report the presence of a response to damage-released conspecific alarm cues in brown trout. Berejikian et al. (1999) demonstrated an alarm system in chinook salmon (*Oncorhynchus tshawytscha*). Each of the species tested to date has shown a clear response to damage-released alarm cues. Even though only 4 of 66 salmonids have been tested, the experiments have been completed on 3 different genera (*Salmo*, *Salvelinus* and *Oncorhynchus*). Consequently, we suggest that alarm systems are widespread among salmonid fishes. In each of our experiments, salmonids decreased activity and reduced foraging. By decreasing activity, salmonids can make themselves harder to detect by predators (Lima and Dill, 1990; Chivers and Smith, 1998).

Our study documents that each of the species of salmonids tested responds to each other's alarm cues, but does not respond to cues from injured swordtails. This is the first report of cross-species responses to alarm cues by salmonid fishes. Numerous other studies have tested for cross-species responses in other groups of fishes. For example, cross-species responses have been documented among gobies (Smith et al., 1991), darters (Smith, 1982, Commens and Mathis, 1999), stickleback (Mathis and Smith, 1993b; Brown and Godin, 1997), poeciliids (Mirza et al., unpublished data) and Ostariophysans (Schutz, 1956; Brown et. al., 2000).

Cross-species responses to alarm cues may reflect that the chemical(s) that serve as alarm cues are conserved within the taxonomic group. Brown et al. (2000) documented that a nitrogen oxide functional group is conserved as the chief molecular trigger of Ostariophysan alarm signals. If alarm cues are conserved in salmonids, we should observe cross-species responses even when the receivers have no experience with the cue (i.e., the first time the prey is exposed to the cue). If the alarm signals are not conserved, then we should not observe cross-species responses when the prey are first exposed to the cue. Even though cross-species responses are common in a variety of different fishes, researchers have not addressed whether the cues are conserved, because they have not ruled out the possibility that cross-species responses could be learned. Chivers and Smith (1994) and Chivers et al. (1995) have shown that species that are members of

the same prey guild (i.e., those species that occur in the same habitat and share predators) can learn to recognize each other's alarm cues.

In this study, we observed cross-species responses among salmonids that have no prior experience with each other. This indicates that the salmonid alarm cues are at least partially conserved. However, we also found evidence that each species could differentiate conspecific signals from those of heterospecifics. For all three species, we observed that test animals exhibited significantly more freezing and less movement in response to conspecific cues than to cues of heterospecifics. The fact that salmonids can recognize all heterospecific cues and also can distinguish between conspecifics and heterospecifics indicates that the chemical(s) that act as the alarm cue may be similar, but not identical. Alternatively, the chemical(s) that act as the alarm cue may be identical and there may be another chemical(s) present that allows the test fish to distinguish between conspecifics and heterospecifics. Additional work should address the nature of the chemicals that act as alarm cues in salmonid fishes.

Our results show that juvenile salmonids that detect chemical alarm cues released by other juvenile salmonids will obtain an antipredator advantage. They decrease activity and reduce foraging in response to cues of other injured heterospecifics. This type of cross-species reaction makes intuitive sense. If a particular predator were to capture a juvenile salmonid, then chances are the same predator would also be a threat to each of the other species. However, as the salmonids grow, they may come to occupy different ecological niches and have different predators. Whether adult salmonid fishes use alarm cues in the same manner as juveniles remain unknown. Further research should address this issue.

Acknowledgments—We would like to thank Jerry Banks and the Ft. Qu'Appelle hatchery for supplying the fishes for this study. This study was funded by grants to D. P. Chivers from NSERC of Canada and the University of Saskatchewan. The research described was approved by the University Committee on Animal Use and Supply at the University of Saskatchewan (Animal care protocol # 19920077).

ATTACK CONE AVOIDANCE DURING PREDATOR INSPECTION VISITS BY WILD FINESCALE DACE (*Phoxinus neogaeus*): THE EFFECTS OF PREDATOR DIET

Abstract—When confronted by potential predators, many prey fishes engage in predator inspection behavior. Previous authors have argued that by selectively avoiding the predator's head during an inspection visit (attack cone avoidance), individual inspectors may reduce their local risk of predation. In field trials, we investigated the effects of predator diet cues on the presence of 'attack cone avoidance' during predator inspection visits. Wild, free-ranging finescale dace (*Phoxinus neogaeus*) were exposed to the combined cues of a model predator and a distilled water control or the odor of a yellow perch (*Perca flavescens*) fed dace (with alarm pheromone), swordtail (*Xiphophorus helleri*) (lacking Ostariophysan alarm pheromone), or perch that were food deprived for four days. Finescale dace modified their predator inspection behavior following exposure to the odor of a perch fed dace (fewer dace present, reduced frequency of inspections, and an increased per capita inspection rate) compared to those exposed to the odor of a perch fed swordtails, perch that were food deprived, or a distilled water control. In addition, dace inspected the tail region more often only when the model predator was paired with the odor of a perch fed dace. In all other treatments, dace inspected the head region of the model predator more often. These data suggest that attack cone avoidance of inspecting prey fishes may be more likely to occur in high-risk situations, such as in the presence of conspecific alarm pheromones in the diet of potential predators.

Key Words—Predator inspection, Ostariophysan fishes, alarm pheromones, predator diet, anti-predator behavior.

INTRODUCTION

Predator inspection behavior, characterized by the saltatory approach towards and withdrawal from a potential predator, either alone or in groups (Dugatkin and Godin, 1992a; Pitcher, 1992), is a common phenomenon among many prey taxa, including fishes. Predator inspection is an inherently risky behavioral pattern, as it involves the approach towards a potentially risky predator. In order for this behavioral pattern to have evolved and be maintained within prey populations, there must be significant benefits associated with predator inspection.
