(Received June 21, 1999; accepted August 25, 2000)

Abstract—We evaluated olfactory attraction of overwintered plum curculio (PC) adults, *Conotrachelus nenuphar*, to 16 individual volatile components of unripe plum odor in the laboratory using a still-air dual-choice bioassay system and in the field using baited cotton dental wicks attached to boll-weevil traps placed on the ground beneath the canopy of unsprayed apple trees. Two compounds, ethyl isovalerate and limonene, were significantly attractive in both laboratory bioassays and field experiments. In laboratory bioassays, as concentration was decreased across five orders of magnitude, a greater number of compounds elicited responses suggestive of attractancy (except at the lowest concentration). Even so, linalool, 2-hexanone, and 3-hydroxy-2-butanone were the only other compounds showing significant attractiveness in laboratory bioassays, but none of these (nor any other compounds) were significantly attractive in field assays. We suggest that the use of ethyl isovalerate and/or limonene as odor attractants offers potential to increase the efficacy of current traps for monitoring PCs immigrating into fruit orchards during spring.

Key Words—*Conotrachelus nenuphar*, attractants, host plant volatiles, monitoring

INTRODUCTION

Currently, no reliable monitoring device exists to detect initiation and amount of fruit injury by the plum curculio (PC), *Conotrachelus nenuphar* (Herbst) (Coleoptera: Curculionidae). This insect is a principal pest of stone and pome fruit in eastern and central North America (Racette et al., 1992) and one of the most destructive pests of peaches and plums in the southeastern United States (Yonce et al., 1995). Growers are forced to use the appearance of fresh egg-laying scars as a sign that PCs pose an imminent threat to fruit in orchards (Prokopy and Croft, 1994).

Various trap designs have been evaluated for monitoring PC adults. They include inverted polyethylene funnels hung beneath tree trunks to capture falling adults (Le Blanc et al., 1981), unbaited sticky-coated apples or plastic spheres hung from host tree branches (Yonce et al., 1995), pitfall traps placed beneath host trees (Yonce et al., 1995), unbaited cotton boll-weevil traps placed on vertical stakes between woods and commercial orchards (Yonce et al., 1995), and cotton boll-weevil traps baited with a component of male PC sex pheromone, grandisoic acid, and placed on cut ends of vertical host tree branches (Eller and Bartelt, 1996). Tall dark-colored unbaited pyramid traps capped with detachable conical boll weevil trap tops, developed originally as supernormal visual mimics of tree trunks for attracting host-seeking pecan weevils, *Curculio caryae* (Horn) (Tedders and Wood, 1994) also have been tested; these traps were placed on the ground in or adjacent to orchards (Prokopy and Wright, 1998; Prokopy et al., 1999). Of these candidates, only the last two methods showed any success, but even they captured small numbers of PCs.

Numerous species of weevils are attracted to host plant volatiles or specific compounds present in host plant volatiles, including the banana weevil, *Cosmopolites sordidus* (Germar) (Budenberg et al., 1993), the cabbage seed weevil, *Ceutorhynchus assimilis Payk.* (Evans and Allen-Williams, 1992, 1993; Bartlet et al., 1997; Smart and Blight, 1997), the pecan weevil, *Curculio caryae* (Horn) (Collins et al., 1997), the pea weevil, *Sitona lineatus* L. (Landon et al., 1997), and the red weevil, *Rhynchophorus ferrugineus* (Olivier) (Gunawardena et al., 1998).

PCs are attracted to host fruit odor over short distances in the laboratory (Butkewich and Prokopy, 1993; Prokopy et al., 1995; Leskey and Prokopy, 2000), and in the field at distances up to 3 m (Butkewich and Prokopy, 1997). A potential method for improving trap efficacy for PCs is to deploy specific attractive compounds present in host plant volatiles in conjunction with a trap. This has been done with the cabbage seed weevil, for which water-bowl traps painted yellow and filled with detergent solution were baited with specific odor compounds from oilseed rape, *Brassica napus* (Smart and Blight, 1997). Although PCs are attracted to host fruit odor, it is not known which particular compounds

present in such odor could potentially be attractive to PCs and provide growers with a means of increasing trap efficacy over unbaited traps (Le Blanc et al., 1981; Yonce et al., 1995; Prokopy and Wright, 1998; Prokopy et al., 1999) or be used in combination with grandisoic acid (Eller and Bartelt, 1996).

Wild plum, *Prunus americana*, is the native host of PCs (Maier, 1990), suggesting that volatiles from cultivated plum potentially could be attractive. We identified 16 individual volatile compounds from odor of unripe host fruit of cultivated plum, *Prunus domestica*, and evaluated responses of PCs to these compounds in the laboratory both in 1998 and in 2000. We used a laboratory bioassay system designed to test PC responses to host fruit odor (Prokopy et al., 1995). During 1998, we also evaluated PC responses to these 16 compounds at a field site using baited boll weevil traps placed on the ground beneath the canopy of unsprayed apple trees.

METHODS AND MATERIALS

Immature Plum Volatiles. Unripe cultivated plums (var. Fellenburg) were gathered approximately two weeks after bloom from an unmanaged orchard at the Ohio Agricultural Research and Development Center. Forty plums were placed in an 8-dr (32 ml) vial, held on ice, and transported to the laboratory for volatile collections. Volatile analysis commenced within 10 min of collecting the fruit. The cap of the vial was outfitted with two rubber septa, which allowed the flow of compressed air into the vial and flow of volatile-laden air out to a trap. Prior to entering the sample vial, the high-purity compressed air was filtered through activated charcoal and humidified by bubbling through distilled water. Fruit volatiles were collected using a trapping device described previously by Phelan and Lin (1991). The device consisted of a 60-cm × 0.1-cm-ID nickel capillary trap packed with Tenax GC (60/80 mesh) and attached to a Hewlett-Packard 5890A gas chromatograph (GC) using a two-position six-port Valco valve (Houston, Texas). This setup allowed volatiles to be collected from the sample and then thermally desorbed at 200°C directly to the capillary GC column. Plum volatiles were collected for 30 min at 20 ml/min. The trap was purged with dry helium for 3 min, and then volatiles were desorbed for 2 min to a DB-1 (0.32 × 30 m, 5-μm film) capillary column. Components were eluted at 30–200°C at 10°C/min, followed by analysis using a HP 5970 Mass Selective Detector interfaced to the GC. Initial identifications were confirmed by comparison of retention times and mass spectra with authentic samples. Blank volatile collections using a clean empty vial were conducted each morning to isolate possible contaminants from the trapping system and GC. Following volatile collection, plums were placed immediately in hexane to permit extraction of possible additional compounds.

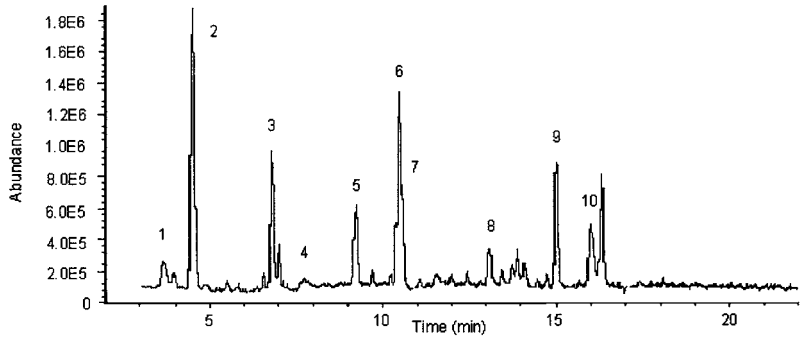

FIG. 1. Total ion chromatogram of natural plum volatiles collected on Tenax for 30 min at 20 ml/min from 40 immature plums (10 g total, avg. = 7.3 mm) at 2 weeks after bloom. Compound identity: **1**, 2-propanol (8 ng); **2**, ethyl acetate (119 ng); **3**, 3-hydroxy-2-butanone (56 ng); **4**, 2-pentanol (4 ng); **5**, ethyl butanoate (40 ng); **6 + 7**, trans-2-hexenal and ethyl isovalerate, respectively (71 ng); **8**, benzaldehyde (11 ng); **9**, limonene (51 ng); **10**, linalool (29 ng). Unmarked peaks were incompletely identified.

Ten compounds were identified from volatile emissions of field-collected plums (Figure 1). Six additional compounds not found in plum volatile profiles were identified from hexane extracts of plums: benzonitrile, 2-hexanol, 3-hexanol, 2-hexanone, 3-hexanone, and isopropyl acetate. All compounds identified from volatile emissions and from hexane extracts were evaluated as potential attractants for PCs in laboratory and field experiments. Compounds were purchased from Aldrich Chemical Company, Inc. (Milwaukee, Wisconsin). For laboratory bioassays, each compound was diluted in hexane (with the exception of 3-hydroxy-2-butanone, which was diluted in water) to yield five concentrations: 1.00, 0.10, 0.01, 0.001, and 0.0001%. For field experiments, all compounds were diluted in technical grade mineral oil to a 5.00% concentration; those compounds found to exhibit high levels of either attractancy or repellency were diluted again to a 0.50% concentration.

Laboratory Bioassay Procedures. All PCs used here were collected as overwintered adults in the field in late May or early June in 1998 and 2000 from populations present on unsprayed wild plum or apple trees in Hampshire County, Massachusetts. They were assumed to be approximately the same age but of unknown mating status. Within a few hours of collection from the field, PCs were segregated according to sex using criteria described by Thomson (1932). Adults were held for the duration of all experiments in wax-coated paper cups (473 ml) with clear plastic lids. No more than 60 individuals were held in any one cup. PCs were held under a photoregime of 16L : 8D to mimic long-day conditions in nature from late May to late June. Fresh food, either unsprayed

wild plum or apple fruit, was provided along with a wetted cotton wick as a water source. Although some herbivorous insects respond differently to host plant odors according to type of diet provided prior to assay, in preliminary laboratory experiments with PCs, we saw no difference in pattern of PC response to host fruit odors between individuals fed unsprayed apple or plum (Leskey and Prokopy, unpublished data).

A dual-choice still-air system of enclosed Petri dishes, described by Prokopy et al. (1995), was employed to test attractiveness of the 16 volatile components of plum odor. Tests were conducted at ~26°C, 65–80% relative humidity, at the beginning of scotophase of the 16L : 8D cycle, and were carried out from late May to late June in 1998 and 2000. Two pipette tips were attached over holes of the same diameter pierced in the lid of the Petri dish. These tips act as treatment tubes down which the volatiles can pass. A 75-μl aliquot of a solution containing a single compound was pipetted onto a 1-cm square of cotton wick placed next to one of the two pipette tips. A 75-μl aliquot of hexane (or water, in the case of 3-hydroxy-2-butanone) was used as a solvent control and pipetted onto a second cotton square placed next to the end of other pipette tip. During bioassay preparation, volatiles and controls were pipetted beneath a fume exhaust system to prevent cross-contamination between treatments and controls. Hexane-diluted compounds and controls were allowed to evaporate for approximately 4 min, and then each tube was covered with a transparent polystyrene cup. Water-diluted compounds and controls were covered immediately by cups. After cups were placed over both tubes, the bioassay became a closed system, allowing volatiles from the treatment wick to diffuse through the opening of the adjacent pipette tip, into the treatment tube, and then into the Petri dish chamber, presumably creating a concentration gradient of treatment odor that did not, however, exclude treatment odor from entering the control tube. PCs, chosen randomly from the available field-collected pool, were held in groups of 40 males or 40 females, starved for 24 hr, and chilled for 15–20 min in a cold room at 8–9°C just before use. Handling of PCs was kept to a minimum. A single PC was placed gently in the center of each bioassay dish. Each replicate, measuring response to a particular compound, consisted of 12 PCs tested singly in individual bioassay dishes held together on a tray. Dishes were then moved immediately to the testing room. PCs were fed immediately after the bioassay period (2 hr) had ended and were reused in subsequent bioassays no less than four days later.

To assess attractiveness of a particular compound, we used a response index (RI) developed by Phillips et al. (1993). A positive response to either the treatment (a particular compound) or control (corresponding solvent) was considered to have occurred when a PC crawled up the inner surface of one of the two tubes and entered a cup containing either the treatment or control within 2 hr. Few PCs (<3%) leave a treatment or control cup after entering it. PCs were allowed 2 hr to respond because it takes longer than 1 hr for the odor gradient and/or PC

response level to reach an asymptote; after 2 hr, little change in PC response level occurs (Prokopy et al., 1995). The RI was calculated by subtracting the number of PCs responding to the control (C) from the number responding to the treatment (T), dividing the amount by the total number of PCs tested, and multiplying by 100. Thus, $RI = ((T - C)/\text{total}) \times 100$; the greater the RI value, the more attractive the stimulus. We accept a RI value of 9 as the minimum for suggesting attractiveness and a RI value >40 as being highly attractive. This latter is based on the mean ± a single standard deviation unit (mean RI = 25.0 ± 16.0 SD, $N = 120$) obtained for responses to a standard attractive source: a hexane extract of McIntosh fruit collected one week after bloom, previously shown to be the most attractive phenological stage of apples (Leskey and Prokopy, 2000). Under this system, a RI value of −13 or greater can be considered as indicating repellency (according to the subtraction of two standard deviation units from the mean RI for our hexane standard). One replicate (involving assay of 12 PCs) was tested each day that bioassays were conducted. If the RI for the standard fell below a value of 9, data from that particular day were discarded. Discrimination of host odor by PCs is significantly and positively correlated with barometric pressure (Leskey 2000). On test days when barometric pressure was low, PCs did not discriminate well between standard and control. In addition to assessment using RI values, data were subjected to a one-tailed Wilcoxon signed rank test ($P < 0.05$). For each replicate of a particular compound, i.e. a tray of 12 Petri dishes, we subtracted the total number of PCs that entered control cups from the total number of PCs that entered treatment cups to obtain the difference between them and used this value to designate ranks among all replicates. Ranks were ultimately used to calculate the test statistic (Statistix, 1992). Those PCs that remained in the dishes were excluded from this analysis because they did not respond to either the treatment or control.

Field Assay Procedures. For each compound tested, a 150- or 15-μl aliquot of compound in neat solution was diluted to a 5.00 or 0.50% concentration, respectively, in mineral oil (3 ml total volume); 3 ml of mineral oil alone served as a control. Each treatment or control substance was applied to a 7.6-cm piece of cotton dental wick (Absorbal, Wheatridge, Colorado), which was then wrapped with aluminum foil, sealed at one end, and suspended horizontally by a wire attached to the base of a fountain-style boll weevil trap top capping an accompanying solid green boll weevil plastic trap base (Gemplers, Inc., Belleville, Wisconsin).

Release rates were determined by exposing five wrapped wicks (identical to those deployed in field assays) containing each compound at each concentration tested to open-air indoor conditions at 26–28°C for 96 hr and weighing each wick daily to determine milligrams of compound lost per day over the four-day period.

All compounds were evaluated simultaneously in a small unmanaged block

of apple trees of mixed cultivars, each about 3 m in canopy diameter. Grass beneath tree canopies was maintained at 5–10 cm throughout. One trap was placed at each cardinal point approximately 1 m away from the trunk beneath the canopy of an unsprayed apple tree, with the compound- or control-baited wick facing the trunk. For each tree, traps baited with the same compound were placed at north and south positions and control-baited traps at east and west positions (or the reverse orientations determined randomly). After 48 hr, PCs captured in the compound- and control-baited traps were counted, with totals from the two compound-baited traps combined into a single value and totals from the two control-baited traps combined into a single value, each value constituting one replicate. For the next replicate, trap location for each compound was rerandomized among trees, cardinal orientation of compound- and control-baited traps beneath trees was randomly assigned, and compound- and control-baited wicks were replaced.

In the first field experiment, each of the 16 compounds was evaluated in 12 replicates run consecutively over a 24-day period at a 5.00% concentration of each compound. In the second field experiment, the most and least attractive compounds from the first field experiment were tested again, at a 5.00% as well as a 0.50% concentration, with 10 replicates of each. Procedures were essentially the same as in the first field experiment except that each replicate lasted 24 rather than 48 hr.

To measure the attractiveness of a particular compound, a field response index was calculated by subtracting the number of PCs responding to the control (C) from the number responding to the treatment (T) [the particular compound], dividing by the total number of PCs captured in the treatment and control traps, and multiplying by 100. Thus, $RI = [(T-C)/(T+C)] \times 100$; the greater the RI, the more attractive the compound. To analyze the extent of response to traps baited with a particular compound compared to corresponding control traps, data were subjected to a one-tailed Wilcoxon signed rank test ($P \leq 0.05$). For each replicate of a particular compound, we subtracted the total number of PCs that entered control-baited traps from the total number of PCs that entered treatment-baited traps to obtain the difference between them and used this value to designate ranks among all replicates. Ranks were ultimately used to calculate the test statistic (Statistix, 1992).

RESULTS

Laboratory Assays. There were no significant differences between males and females in response to compounds at any of the five concentrations tested. Therefore, results were combined across sex to increase statistical power. For compounds at 1.00% concentration (Table 1), an RI suggesting attraction ($RI >$

[b] Treatments and controls are significantly different from each other at $P \leq 0.05$ according a one-tailed Wilcoxon signed rank test.

9) was recorded for ethyl butyrate ($RI = 14.6$), while RIs suggesting repellency ($RI < -13$) were recorded for benzaldehyde, benzonitrile, 3-hexanone, 3-hydroxy-2-butanone, linalool, and *trans*-2-hexenal. The positive response to ethyl butyrate was not significant, whereas there was a significantly greater response to control over treatment for the latter six compounds plus isopropyl acetate, indicating that PCs were likely repelled at 1.00% concentration. At 0.10% concentration, responses suggesting attraction were recorded for ethyl isovalerate ($RI = 12.5$), 2-pentanol ($RI = 12.5$), and 2-hexanone ($RI = 10.4$), with response to ethyl isovalerate being significantly greater than to control (Table 2). RIs suggesting repellency were recorded for benzaldehyde and *trans*-2-hexenal, just as at the 1.00% concentration, with significantly greater response to control over treatment for each (Table 2). At 0.01% concentration, responses suggesting attraction were recorded for ethyl isovalerate ($RI = 23.6$), limonene ($RI = 18.1$), ethyl acetate ($RI = 12.5$), linalool ($RI = 12.5$), and benzonitrile ($RI = 11.7$), with responses to treatments of ethyl isovalerate, limonene and linalool being significantly greater than to controls (Table 3). A RI suggesting repellency was recorded for 3-hydroxy-2-butanone as was also the case at 1.00% concentration;

responses to controls of 3-hexanone, 3-hydroxy-2-butanone, and *trans*-2-hexenal were significantly greater than to treatments. For compounds at 0.001% concentration, RIs suggesting attraction were recorded for 2-hexanol (*RI* = 13.3), 3-hexanol (*RI* = 13.3), 2-hexanone (*RI* = 13.3), 3-hydroxy-2-butanone (*RI* = 23.3), linalool (*RI* = 11.7), and *trans*-2-hexenal (*RI* = 10.0), with responses to treatments of 2-hexanone and 3-hydroxy-2-butanone being significantly greater than to controls (Table 4). RIs suggesting repellency were recorded for benzaldehyde, benzonitrile, and isopropyl acetate with significantly greater responses to controls of benzonitrile and isopropyl acetate (Table 4). At 0.0001% concentration, no responses suggesting attraction were recorded and only isopropyl acetate elicited a response indicating repellency, with response to control being significantly greater than to treatment (Table 5).

Field Assays. In the first field experiment, the highest positive RIs were recorded for responses to traps baited with ethyl isovalerate (*RI* = 71.4), limonene (*RI* = 37.5), benzonitrile (*RI* = 33), and 3-hydroxy-2-butanone (*RI* = 26.3), with responses to ethyl isovalerate and limonene being significantly greater than to controls (Table 6). Negative RIs, indicative of more PCs caught in control-baited

[b] Treatments and controls are significantly different from each other at $P \leq 0.05$ according to a one-tailed Wilcoxon signed rank test.

traps than compound-baited traps, were recorded for 2-hexanol, 3-hexanol, 2-hexanone, 3-hexanone, isopropyl acetate, 2-pentanol, and 2-propanol, with significantly greater responses to control-baited traps than to traps baited with 3-hexanol or 3-hexanone. In the second field experiment, highest positive RIs were recorded for responses to limonene ($RI = 100$) and ethyl isovalerate ($RI = 80$) at 5.00% concentration, with response to each compound being significantly greater than to control. A lesser degree of positive response (none significant) occurred to both of these compounds at the 0.50% concentration and to 3-hexanol at either concentration (Table 7).

DISCUSSION

Two compounds, ethyl isovalerate and limonene, were significantly more attractive than controls in both laboratory bioassays and field experiments (Tables 2, 3, 6, and 7). In laboratory bioassays, as the concentration of compound was decreased successively from 1.00% to 0.001%, a successively greater number of compounds elicited a response suggestive of attractancy ($RI > 9$),

[b] Treatment and controls are significantly different from each other at $P \leq 0.05$ according to a one-tailed Wilcoxon signed rank test.

including significantly greater response to treatment over control for linalool at 0.01% (Table 3) and 2-hexanone and 3-hydroxy-2-butanone at 0.001% (Table 4). Benzaldehyde, benzonitrile, 3-hydroxy-2-butanone, linalool, and *trans*-2-hexenal were significantly less attractive than controls in laboratory bioassays at 1.00% (Table 1) but yielded positive RIs (although not significantly positive responses) in the field (Table 6). In contrast, the green leaf volatiles 2-hexanol and 2-hexanone showed RI values suggesting attractancy in laboratory assays at 0.001% (Table 4) but showed negative RIs in field assays (Table 6).

Ethyl isovalerate and limonene were the only compounds tested here that yielded positive and significant responses from PCs in both laboratory bioassays (Tables 2 and 3) and field experiments (Tables 6 and 7). Volatiles from host plant odors can be used in conjunction with traps to markedly increase trap efficacy, as has been shown in the case of butyl hexanoate (a component of apple odor) that enhances attraction of apple maggot flies, *Rhagoletis pomonella* (Walsh), to fruit-mimicking red sphere traps (Reissig et al., 1982; Duan and Prokopy, 1992; Reynolds and Prokopy, 1997). Addition of ethyl isovalerate and limonene to traps may provide growers with a means to increase trap efficacy over cur-

rent unbaited PC traps (Le Blanc et al., 1981; Yonce et al., 1995; Prokopy and Wright, 1998; Prokopy et al., 1999). In combination with grandisoic acid, an attractive component of the male-produced aggregation pheromone (Eller and Bartelt, 1996), these fruit volatiles could be even more useful in enhancing trap efficacy, such as in the case of traps for the palmetto weevil, *Rhynchophorus cruentatus* Fabricius (Giblin-Davis et al., 1994) and the West Indian sugarcane weevil, *Metamasius hemipterus sericeus* (Olivier) (Giblin-Davis et al., 1996), where combinations of host plant tissue or host plant volatile compounds plus synthetic pheromones were deployed.

Green leaf volatiles including, most importantly, certain 6-carbon alcohols and aldehydes, result from metabolism of lipids and are produced by many green plants (Bernays and Chapman, 1994). Chemotactic responses by herbivorous insects to these compounds are considered to be a generalized mechanism of host plant recognition (Metcalf and Metcalf, 1992). In our field experiment, a negative RI was recorded for PC responses to 2-hexanol, 3-hexanol, 2-hexanone, and 3-hexanone with significantly greater responses to control-baited traps for 3-hexanol and 3-hexanone (Table 6). Perhaps at the concentrations tested, PCs

[a] Each replicate consisted of captures by two compound-baited and two control-baited traps placed on the ground beneath the canopy of an unsprayed apple tree for 48 hr.
[b] Treatments and controls are significantly different from each other at $P \leq 0.05$ according to a one-tailed Wilcoxon signed rank test.

perceived these volatiles to be from a nonhost green plant and thus avoided them. Similarly, traps baited with the green leaf volatiles 1-hexanol, (*E*)-2-hexen-1-ol, (*Z*)-2-hexen-1-ol, and (*Z*)-3-hexen-1-ol alone or in combination resulted in reduced trap catches of the striped ambrosia beetle, *Trypodendron lineatum* (Olivier), in forests of Douglas fir trees in British Columbia, indicating that these beetles may use these compounds as cues to avoid nonhost angiosperm logs in their search for host coniferous logs (Borden et al., 1997). On the other hand, unlike *T. lineatum*, PCs could be attracted to broad-spectrum green leaf volatile compounds, but at lower concentrations. For example, male PCs were attracted to a 5-mg dose of a known green leaf volatile, (*Z*)-3-hexen-1-ol, in an olfactometer in significantly greater numbers than to higher doses of this compound or to a control (Cormier et al., 1998). Similarly, attractive response was recorded for PCs to 3-hexanol at 0.001% concentration but not to this green leaf volatile at higher concentrations in our laboratory bioassays (Tables 1–4).

Insect response to a particular volatile compound can be markedly influenced by the concentration of that compound. For example, the boll weevil,

Anthonomus grandis Boheman, was repelled at the highest concentration and attracted at lower concentrations of β-bisabolol, the major volatile of cotton, evaluated in laboratory experiments in a moving air olfactometer (Dickens, 1986). The concentrations of 1.00% and 0.10% for most compounds tested in our laboratory bioassays were probably too high to elicit an attractive response from a PC in the confined space of a Petri dish chamber and over the short distance between odor source and release point of the PC. However, concentrations were not high enough to anesthetize or immobilize PCs as can be done by holding PCs at cold temperatures. When immobilized, PCs exhibit retracted antennae and legs. We conducted extensive observations of PCs in Petri dishes at these higher concentrations and observed that PCs appeared to be alert (erect antennae and nonretracted legs) during experiments. More importantly, as concentration was decreased to as low at 0.001%, a greater number of compounds elicited responses, suggesting attraction of PCs in our laboratory bioassays. For example, both linalool and 3-hydroxy-2-butanone were significantly less attractive than controls at 1.00% but were significantly more attractive than controls at 0.01% and 0.001%, respectively (Tables 1, 3, and 4), and *trans*-2-hexenal was significantly less attractive than control at 1.00% but elicited a response suggesting attraction at 0.001% (Tables 1 and 4). Thus, concentration of a particular compound appears to have been an important factor influencing PC responsiveness in our laboratory bioassays.

The concentration of a particular compound (or amount released) and the context in which it is evaluated likely have strong effects on the nature of PC responsiveness. As already mentioned, we found that benzaldehyde, benzonitrile, 3-hydroxy-2-butanone, linalool, and *trans*-2-hexenal were significantly less

attractive than controls in laboratory bioassays at 1.00% concentration (Table 1), but yielded positive RIs in the field at 5.00% concentration (Table 6). Laboratory bioassays evaluated PC responses in enclosed chambers over short distances, whereas field assays involved PC responses over longer distances in natural surroundings. The reverse was true for cabbage seed weevils; these weevils were attracted to (*Z*)-3-hexen-1-ol in a linear track olfactometer in laboratory experiments (Bartlet et al., 1997), but in the field, this compound had no effect on trap captures during weevil colonization of crop fields or was slightly depressive to trap captures during dispersal from crop fields (Smart and Blight, 1997). Similarly, male Mediterranean fruit flies, *Ceratitis capitata* (Weidemann), were attracted to limonene, α-terpineol, linalool, and geranyl acetate in laboratory cages and in wind tunnels, but not in the field (Howse and Knapp, 1996). Perhaps PCs, cabbage seed weevils, and male Mediterranean fruit flies express attraction to certain compounds under certain conditions, but do not do so under other conditions because of greater/lesser concentration of compound and/or the context in which a compound is offered. The still-air dual-choice bioassay system used here is a relatively simple method for simultaneously rapid screening of PC response to a large number of compounds, but this method can not be recommended for gaining deeper insight into the true nature of PC behavior during orientation toward or away from compounds of differing concentration.

This study provides the first evidence for PC attraction to specific compounds present in host plant odor, namely ethyl isovalerate and limonene. However, both of these compounds, as well as other compounds tested, might be more attractive at concentrations or release rates different from those used here, or when in combination. Although ethyl isovalerate and limonene significantly increased trap captures under the conditions tested here, further tests are needed to optimize formulation, release rate, type of trap used in association with compound deployment, and positioning of compounds on traps. The indication here of PC attraction to these compounds increases the potential for creating a reliable monitoring device for this important tree fruit pest.

Acknowledgments—We thank Max Prokopy, Keri Tallman, Anthony Minalga, Susan Nixson, Margaret Young, Brian Hogg, Jonathan Black, Stephen Lavallee, Anthea Yannopoulos, Amanda Ross, and E. Fidelma Boyd for their technical assistance. Anne Averill, Juan Rull, and two anonymous reviewers provided helpful comments to an earlier version of this manuscript. These studies were supported by USDA Hatch funding, the New England Tree Fruit Growers Association, and a University Fellowship to T. C. Leskey from the University of Massachusetts at Amherst.

PLANT GROWTH INHIBITORY ACTIVITY OF L-CANAVANINE AND ITS MODE OF ACTION

NAOKO NAKAJIMA,* SYUNTARO HIRADATE, and YOSHIHARU FUJII

National Institute of Agro-Environmental Sciences
3-1-1 Kan-nondai
Tsukuba, Ibaraki 305-8604, Japan

(Received April 3, 2000; accepted August 26, 2000)

Abstract—L-Canavanine is a nonprotein amino acid contained in jack bean [*Canavalia ensiformis* (L.) DC] and shows a plant inhibitory effect. The inhibitory effect was determined by an immersion test and a microdrop test that employed rice seedlings. L-Canavanine inhibited elongation of the second leaf sheath of rice seedlings more than other natural bioactive substances, such as salicylic acid and cinnamic acid. The modified microdrop test revealed that the mode of action of L-canavanine had no relation to gibberellin synthesis. In the microdrop test, the inhibitory effect of L-canavanine was decreased by simultaneous addition of L-arginine, an analog of L-canavanine. Free amino acid analysis of rice shoots clearly showed that L-canavanine induced an unusual accumulation of L-arginine. However, accumulation of L-arginine did not cause the inhibitory effect on plant growth. These results suggest that the mechanism of inhibition of L-canavanine is closely related to the inhibition of arginine metabolism.

Key Words—L-Canavanine, nonprotein amino acid, plant growth inhibitor, mode of action.

INTRODUCTION

Some chemicals contained in plants have protective functions against insects, microorganisms, and plants. They are variable in their chemical structures and modes of action (Einhellig, 1995b). Some of them may be useful as agricultural chemicals. Many insecticides and fungicides come from natural plants (Benner,

1996). On the other hand, few natural plant compounds are used as commercial herbicides because they do not show strong and long-term effects like synthetic herbicides (Benner, 1996). However, it should be possible to reduce the amount of synthetic herbicide applied by using natural products or allelopathic plants or microorganisms that produce those products (Einhellig, 1995a).

L-Canavanine (Figure 1) is a nonprotein amino acid found in legumes such as jack bean [*Canavalia ensiformis* (L.) DC.] (Turner and Harbone, 1967). Jack bean has been shown to inhibit growth of some other plants (Shibuya, 1994), and L-canavanine is referred to as an allelochemical of jack bean (Shibuya, 1994). In this study, the plant inhibitory activity of L-canavanine was determined and compared with other bioactive substances derived from plants. The mode of action of L-canavanine was investigated.

METHODS AND MATERIALS

Comparison of Activity on Elongation Growth. The immersion test (Murakami, 1973) and the microdrop test (Murakami, 1968) were modified as follows.

In the immersion test, 1 ml of 0.5% (w/v) agar medium containing 0.5 mM of the test compound was poured into a glass vial (30 mm ID × 60 mm long). After solidification, five rice seeds (*Oryza sativa* L. cv. Nipponbare) germinated for two days at 30°C were planted on the agar medium in the vial and incubated for five days at 30°C under continuous irradiation with fluorescent lamps (50 μmol/m^2/sec). The length of the second leaf sheath of treated seedlings was measured and compared with that of controls (untreated seedlings).

In the microdrop test, a vial (30 mm ID × 60 mm long) was filled with 30

ml of 0.5% (w/v) agar medium, and five germinated rice seeds (*Oryza sativa* L. cv. Nipponbare) were planted on the medium after solidification. The vial was incubated at 30°C for two days under continuous irradiation with fluorescent lamps (50 μmol/m^2/sec). Test solution (1 μl) was applied on the cross-point of a coleoptile and the first leaf of a seedling by using a microsyringe. After four days, the length of the second leaf sheath was measured. A test solution was prepared by dissolving each test compound in 50% (v/v) aqueous acetone (5 mM). The lighting was changed by covering with one or two layers of black cheesecloth to shade and improve the sensitivity of this method. One or two layers of black cheesecloth decreased light intensity to 20 and 12 μmol/m^2/sec, respectively.

Influence of Gibberellin on Activity. The microdrop test described above was further modified to clarify the relation of the inhibitory effect of allelochemicals with gibberellin synthesis. In this method, rice seedlings grown in the presence of GA_3 were used. To optimize the concentration of GA_3 in agar medium, germinated seeds were placed on medium containing 0, 0.5, 1.0, 1.5, 2.0, 2.5, or 3.0 μM GA_3 and incubated for six days at 30°C under continuous irradiation with fluorescent lamps (50 μmol/m^2/sec). After incubation, the length of the second leaf sheath was measured and the appropriate concentration of GA_3 was determined. Rice seedlings grown under the above conditions were examined for allelochemicals. After application of the test solution, the vial was incubated under the same conditions described above, and length of the second leaf sheath of the seedling was measured after four days.

Effect of L-Arginine on Growth Inhibition Induced by L-Canavanine. In the microdrop test, 0 or 5 nmol/plant of L-canavanine was applied to the coleoptile and the first leaf of a rice seedling, and after drying at room temperature for 1 hr, 0, 25, or 50 nmol/plant of L-arginine was added. After four days of incubation at 30°C, the length of the second leaf sheath of the seedling was measured.

Analysis of Free Amino Acids and Determination of Ammonia. The shoots of rice (0.5–1.0 g) were homogenized in 80% ethanol at 4°C and extracted at 80°C for 20 min. The supernatant was collected by centrifugation at 2000*g* for 10 min. The extraction was repeated twice. Supernatants were combined and evaporated at 40°C under vacuum conditions. They were dissolved in water and washed with ethyl ether to remove pigments. The water fraction was reevaporated and dissolved into 1.5 ml of 0.02 N HCl and analyzed with an amino acid analyzer (Hitachi L-8500) to determine amino acids and ammonia.

Chemicals. GA_3, L-mimosine [α-amino-3-hydroxy-4-oxo-1(4H)-pyridinepropanoic acid], protocatechuic acid (3,4-dihydroxybenzoic acid), cinnamic acid (3-phenyl-2-propenoic acid), oxalic acid (ethanedioic acid) and salicylic acid (2-hydroxybenzoic acid) were obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Paclobutrazol [(2*RS*,3*RS*)-1-(4-chlorophenyl)-4,4-dimethyl-2-(1H-1,2,4-triazol-1-yl)pentan-3-ol] was obtained from Zeneka

K. K. Agrochemicals (Tokyo, Japan). Vanillic acid (4-hydroxy-3-methoxybenzoic acid) and salicylhydroxamic acid (*N*,2-dihydroxybenzamide) were obtained from Aldrich Chemical Company, Inc. (Milwaukee, Wisconsin USA). Hydroquinone (1,4-benzenediol), arbutin (4-hydroxyphenyl-β-D-glucopyranoside), L-canavanine {*O*-[(aminoiminomethyl)amino] homoserine}, L-DOPA [3-(3,4-dihydroxyphenyl)alanine], and syringic acid (3,5-dimethoxy-4-hydroxybenzoic acid) were obtained from Nacalai Tesque Inc. (Kyoto, Japan). Synthetic abscisic acid (ABA) {[*S*-(*Z*,*E*)]-5-(1-hydroxy-2,6,6-trimethyl-4-oxo-2-cyclohexen-1-yl)-3-methyl-2,4-pentadienoic acid}, coumarin (2H-1-benzopyran-2-one), and sinapic acid (3,5-dimethoxy-4-hydroxycinnamic acid) were obtained from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan). A new plant growth inhibitor found in *Duranta repens*, durantanin II, was purified by the method reported by Hiradate et al. (1999).

RESULTS

To evaluate the sensitivity of the bioassay methods for determining inhibitory activity, paclobutrazol, an inhibitor of gibberellin synthesis, was selected as a reference compound. In the immersion test, the inhibitory effect of 1 μM paclobutrazol was detected (Figure 2).

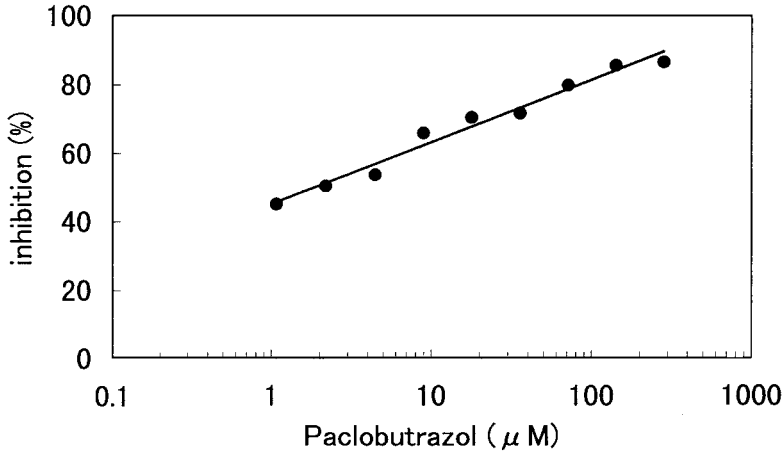

FIG. 2. Effect of paclobutrazol on elongation growth of the second leaf sheath of rice seedlings (immersion test). Germinated seeds were planted on 1 ml of 0.5% agar containing an appropriate concentration of paclobutrazol. Inhibition (%) was calculated as 100 − [(treated/control) × 100].

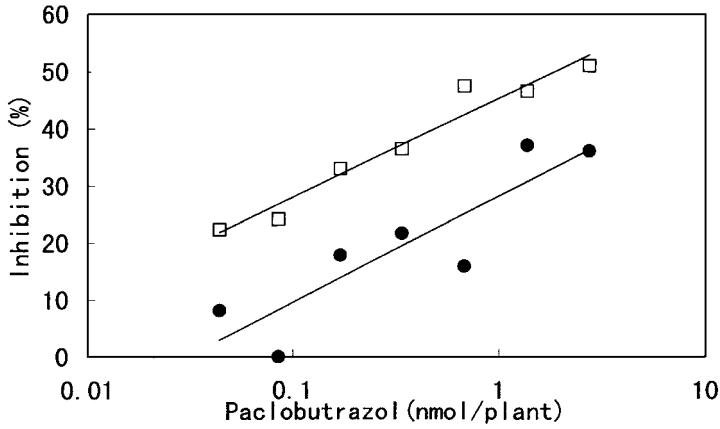

FIG. 3. Effect of irradiance condition on the growth inhibition activity of paclobutrazol on the second leaf sheath of rice (microdrop test). Inhibition (%) was calculated as 100 − [(treated/control) × 100]. ●: 50 μmol/m^2/sec, □: 20 μmol/m^2/sec.

For the microdrop test, the effect of light irradiance on the inhibitory effect of paclobutrazol was studied to optimize sensitivity of this test. Paclobutrazol showed higher inhibitory activity under 20 μmol/m^2/sec of irradiance than under 50 μmol/m^2/sec (Figure 3). The low irradiance condition of 12 μmol/m^2/sec was almost at the same level as that under 20 μmol/m^2/sec (data not shown). In this study, an irradiance condition of 20 μmol/m^2/sec was used.

The immersion test detected strong inhibitory effects of coumarin, L-canavanine, L-mimosine, and a triterpenoid saponin, durantanin II (Figure 4). The microdrop test showed specific strong inhibitory activity of L-canavanine (Figure 5).

The microdrop test was modified to detect inhibitory effects on gibberellin synthesis. Elongation of the second leaf sheath is promoted when the rice seedling is grown in GA_3-containing medium. The rate of the GA_3-induced promotion of elongation became constant when the concentration of GA_3 was higher than 1 μM (data not shown). Paclobutrazol, a gibberellin synthesis inhibitor, inhibited elongation of the second leaf sheaths of rice seedlings grown with no GA_3 in the medium, but not when they were grown in 1 μM GA_3 medium (Figure 6a). On the other hand, ABA, which inhibits gibberellin-induced plant growth, inhibited elongation of the second leaf sheaths of the rice seedlings grown in 1 μM GA_3 medium as well as in medium with no GA_3 (Figure 6b). L-Canavanine had the same effect as ABA (Figure 6c).

When 25 and 50 nmol/plant of L-arginine was applied after application of L-canavanine, the inhibitory effect of L-canavanine was removed in proportion

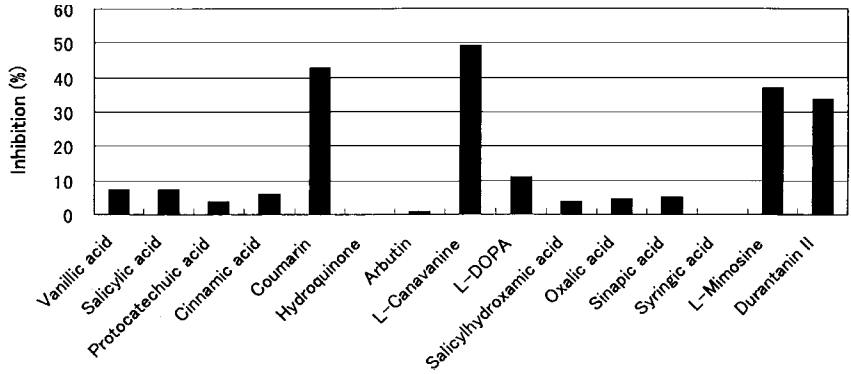

FIG. 4. Effect of allelochemicals on the elongation growth of the second leaf sheath of rice seedlings (immersion test). Five germinated seeds were planted on 1 ml of 0.5% agar each containing 0.5 mM of chemical. Inhibition (%) was calculated as 100 − [(treated/control) × 100].

to the concentration of L-arginine (Table 1). On the other hand, application of L-arginine alone had no effects on the elongation growth (Table 1).

Table 2 shows that almost all amino acids were increased by application of 5 nmol/plant of L-canavanine. L-Arginine content was increased (698% of control), but it was not significant. Application of 5 nmol/plant of L-canavanine and 50 nmol/plant of L-arginine significantly increased the contents of alanine (266% of control) and L-arginine (2885% of control). On the other hand, application of

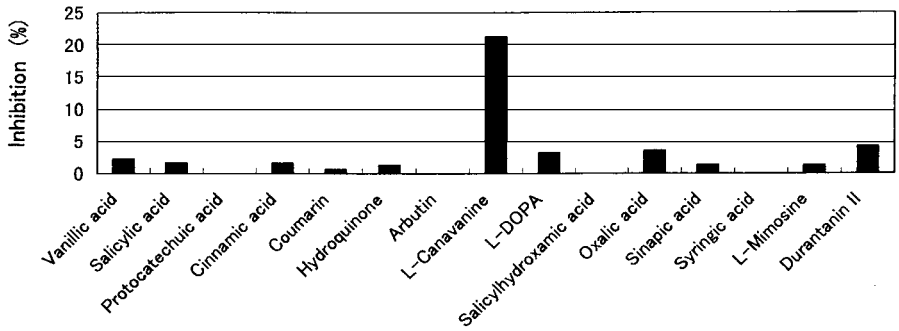

FIG. 5. Effect of allelochemicals on the elongation growth of the second leaf sheath of rice seedlings (microdrop test). One microliter of 5 mM of each test solution (5 nmol) was applied onto the cross point of the coleoptile and the first leaf of a rice seedling by using a microsyringe. Inhibition (%) was calculated as 100 − [(treated/control) × 100].

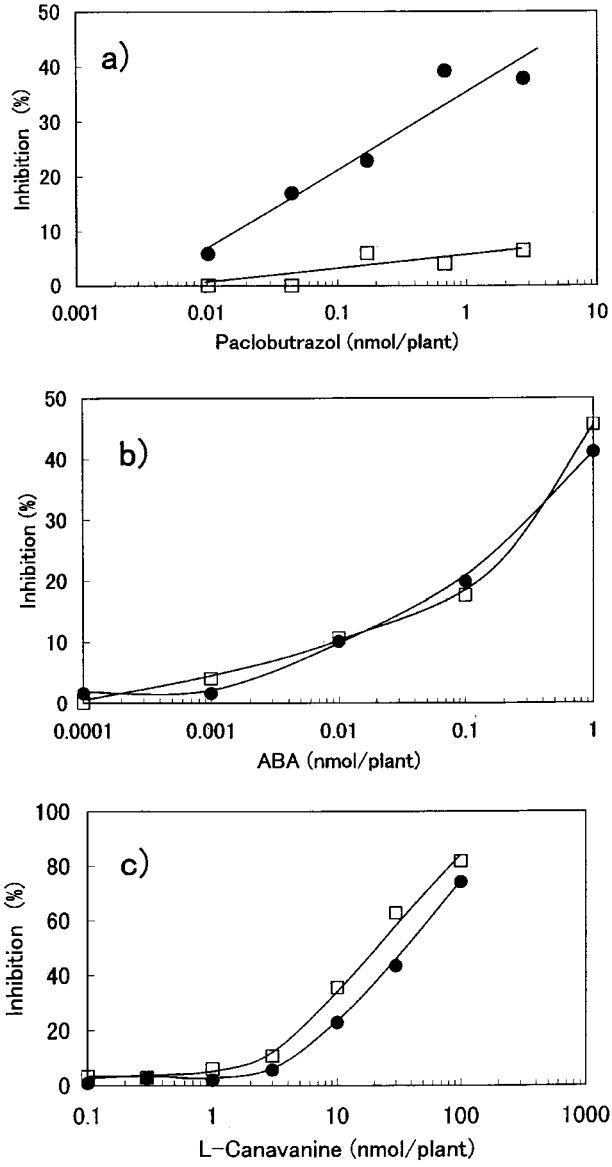

FIG. 6. Effect of 1 μM GA_3 in agar medium on elongation growth of the second leaf sheath of rice seedlings as influenced by (a) paclobutrazol, (b) ABA, and (c) L-canavanine in microdrop test. Inhibition (%) was calculated as 100 − [(treated/control) × 100]. ●: 0 μM GA_3, □: 1 μM GA_3.

TABLE 1. EFFECT OF TREATMENT OF L-CANAVANINE AND L-ARGININE ON LENGTH OF SECOND LEAF SHEATH OF RICE SEEDLINGS IN MICRODROP TEST[a]

Treatment (nmol/plant)		Length of second leaf sheath (mm)
L-canavanine	L-arginine	
0	0	37.2 ± 1.7
0	25	37.4 ± 1.9
0	50	36.9 ± 2.6
5	0	30.0 ± 2.4[b]
5	25	32.1 ± 2.4[b,c]
5	50	35.1 ± 2.9[b,c]

[a] Values are the means with SD ($N = 24$).
[b] Significant difference from treatment of 0 nmol/plant L-canavanine and 0 nmol/plant L-arginine by t test ($P < 0.01$).
[c] Significant difference from treatment of 5 nmol/plant L-canavanine and 0 nmol/plant L-arginine by t test ($P < 0.01$).

50 nmol/plant of L-arginine did not significantly increase arginine content. After four days of treatment (Table 3), glutamic acid and alanine was increased in comparison with controls by application of L-canavanine. The content of L-arginine was reduced to 124% of control. In application of L-canavanine and L-arginine, the contents of glutamic acid, alanine, and L-arginine increased. Glutamic acid also increased by application of L-arginine. Application of L-canavanine and L-arginine had no effect on ammonia content at two and four days after treatment (data not shown).

DISCUSSION

In this study, effects of an allelochemical candidate, L-canavanine, on elongation growth of a plant was investigated in comparison with other bioactive substances derived from plants by using microdrop and immersion tests. In these tests, paclobutrazol, an inhibitor of gibberellin synthesis (Hedden and Graebe, 1985), was used as a reference inhibitor. In the immersion test, inhibitory activity of 1 μM paclobutrazol was seen (Figure 2). To improve the sensitivity of the microdrop test, experimental lighting conditions were optimized prior to the test. Gawaronska et al. (1995) reported that low irradiance promoted gibberellin synthesis and elongation growth of pea seedlings (*Pisum sativum*). Figure 2 shows that the inhibitory activity was more significant under low irradiance (20 μmol/m^2/sec) than under high irradiance (50 μmol/m^2/sec). Acceleration of elongation increases the sensitivity to detect inhibitory effects. By using these tests, inhibitory effects of L-canavanine and the other bioactive substances on elongation growth were compared.

[b] Percentage of control.

In the immersion test, L-canavanine, coumarin, L-mimosine, and durantanin II showed inhibitory effects on elongation of the second leaf sheaths of rice seedlings (Figure 4). In the microdrop test, L-canavanine showed the strongest inhibitory effects, but most of the phenolic acids such as vanillic acid and cinnamic acid had only weak activity (Figure 5). Among the tested compounds, L-canavanine was the strongest plant growth inhibitor.

One mechanism of inhibition of plant elongation is gibberellin synthesis inhibition. It is well-known that most commercial growth retardants inhibit synthesis of gibberellin (Kamiya, 1991). Because L-canavanine inhibited elongation and had growth-retarding activity, the inhibition of gibberellin synthesis is a candidate for the inhibitory mechanism. In order to clarify the mode of action, a bioassay for detecting inhibitory effects of gibberellin synthesis was developed. The microdrop test was modified to detect this inhibitory mechanism. In this method, rice seedlings were grown in the agar medium containing GA_3, resulting in recovery from gibberellin synthesis inhibition. Therefore, it should be possible to distinguish between inhibition of gibberellin synthesis and the other mechanisms by applying this test. The concentration of GA_3 in the agar medium was adjusted to 1 μM, because the gibberellin-induced elongation growth of the second leaf sheath became constant at a GA_3 concentration of more than 1 μM (data not shown). Paclobutrazol and ABA were used as reference substances to evaluate the effectiveness of the test. Paclobutrazol, which is an inhibitor of gibberellin synthesis (Hedden and Graebe, 1985), inhibited elongation of rice seedlings only when grown in the absence of GA_3 (Figure 6a). This is because paclobutrazol specifically inhibits gibberellin synthesis and decreases the concentration of gibberellin in rice seedlings. Paclobutrazol, however, barely inhibited elongation of rice seedlings grown in the presence of 1 μM GA_3. This is because GA_3 was supplied to the rice seedlings from the medium and paclobutrazol was not effective in lowering the concentration of gibberellin in the plants (Figure 6a). On the other hand, ABA is not an inhibitor of gibberellin synthesis, but an inhibitor of elongation growth of plants. ABA showed inhibitory activity on elongation of rice seedlings in the presence of GA_3 as well as in absence of GA_3 (Figure 6b). Accordingly, in this bioassay done in the presence of GA_3, an inhibitor of gibberellin synthesis shows no inhibitory effects, but other inhibitors with other mechanisms may show inhibitory activity. L-Canavanine showed a similar inhibitory effect to ABA on elongation of rice seedlings in the presence and absence of 1 μM of GA_3 (Figure 6c). This result suggests that the mechanism of inhibition by L-canavanine is not that of a gibberellin synthesis inhibition.

L-Canavanine is a nonprotein amino acid, and its structure is similar to L-arginine (Figure 1). Therefore, L-canavanine is likely to have some effect on the metabolism of arginine and the other related amino acids in plants. Simultaneous application of L-arginine significantly reduced the inhibitory effect of L-canavanine (Table 1). This suggests that the mode of action of L-canavanine

may be closely related to the metabolism of L-arginine. From the free amino acid analysis of rice shoots, it was clear that the L-canavanine increased L-arginine content after two days of treatment when both were applied (Table 2). This can be attributed to the application of exogenous L-arginine. However, in the treatment with only L-arginine, the accumulation of L-arginine was less. Therefore, we concluded that L-canavanine inhibited the metabolism of L-arginine in plants, resulting in its accumulation. This phenomenon is interesting because disturbance of amino acid metabolism is one of the important mechanisms of commercial herbicides, such as sulfonylurea derivatives or glyphosate. It may be that the inhibition of L-arginine metabolism is related to the growth inhibitory effect of L-canavanine. The accumulation of L-arginine seemingly would not cause the growth inhibitory effect, because the accumulation occurred more remarkably as rice seedlings recovered from the inhibitory effect of L-canavanine by application of L-arginine. After four days of treatment, this tendency was less, and amino acid contents including L-arginine changed similar to controls (Table 3). Except for L-arginine, treatment of L-canavanine only increased alanine after two days of treatment, and glutamic acid after four days of treatment. These amino acids derive from biosynthetic processes of L-arginine. Therefore, they may be affected by inhibition of L-arginine metabolism. In contrast, L-canavanine had no relation to the ammonia contents, indicating the inhibitory effect of L-canavanine was not due to ammonia accumulation. Thus, a deficiency of some of the compounds derived from L-arginine may be responsible for the growth inhibitory effect of L-canavanine.

As an analog of L-arginine, L-canavanine can be esterified with tRNA (Mitra and Mehler, 1967). Rosenthal (1991) reported that L-canavanine was incorporated into proteins of insects instead of L-arginine. Incorporation of L-canavanine into proteins alters the conformation and disrupts the function of the proteins. Production of proteins containing L-canavanine affects developmental processes and contributes significantly to expression of canavanine's potent antimetabolic properties in insects (Rosenthal, 1991). In this study, L-canavanine seemed to inhibit the metabolism of L-arginine in plants. Further study is needed in order to clarify whether or not L-canavanine is incorporated into proteins in plants.

Abstract—Electrophysiological and behavioral responses of the ladybird parasitoid *Dinocampus coccinellae* to volatiles from the seven-spot ladybird, *Coccinella septempunctata*, were investigated to identify semiochemicals involved in host location. Coupled gas chromatography–electroantennography (GC-EAG) with *D. coccinellae* located a small peak of prominent activity in an extract of volatiles from adult *C. septempunctata*. The active compound was identified by coupled GC-mass spectrometry and by comparison with an authentic sample as the free-base alkaloid precoccinelline, which forms part of the toxic defense of this ladybird. Behavioral studies in an olfactometer showed that *D. coccinellae* was significantly attracted to the volatile extract and also to the alkaloid. Myrrhine, a stereoisomer of precoccinelline found in low amounts in *C. septempunctata* and in other ladybird species, was shown to be electrophysiologically active and significantly attractive. Perception of ladybird alkaloids by *D. coccinellae* is a rare example of toxicants acting as aerially transmitted cues for interactions between the third and fourth trophic levels.

Key Words—Seven-spot ladybird, *Coccinella septempunctata*, Coleoptera, Coccinellidae, electroantennogram, behavior, *Dinocampus coccinellae*, Hymenoptera, Braconidae, alkaloid, precoccinelline, myrrhine, hippodamine, volatile, semiochemical.

INTRODUCTION

Ladybird beetles or ladybugs (Coleoptera: Coccinellidae) are important predators contributing to the natural control of pest aphid populations. However, they are themselves attacked by a range of natural enemies (Majerus, 1994). General predation on ladybirds by vertebrates such as birds is largely prevented by highly toxic alkaloids contained in a reflex bleed released when the ladybird is attacked. The effectiveness of this chemical defense is enhanced by the associated bright warning (aposematic) coloration and corelease of characteristic volatile compounds, e.g., 2-isopropyl-3-methoxypyrazine, which serves as a protective allomone and also as an aggregation pheromone (Al Abassi et al., 1998). The wasp *Dinocampus coccinellae* Schrank (Hymenoptera: Braconidae) is the main parasitoid of a number of ladybird species and can cause substantial reductions in populations of the seven-spot ladybird, *Coccinella septempunctata* L. (Majerus, 1994; Triltsch, 1996). There is a close association with the host, involving oviposition by *D. coccinellae* into the adult ladybird body and subsequent larval development, which indicates a tolerance by the wasp to the toxic alkaloids. Furthermore, *D. coccinellae* is known to utilize a combination of visual and olfactory cues in short-range host location (Orr et al., 1992). Since the associated semiochemicals may provide a means of reducing the impact of *D. coccinellae* on populations of *C. septempunctata* currently being exploited in biological control programs, the antennal and behavioral responses of *D. coccinellae* to volatiles associated with *C. septempunctata* were investigated using coupled gas chromatography–electroantennography (GC-EAG) and olfactometer studies. Our hypothesis was that *D. coccinellae* would exploit 2-isopropyl-3-methoxypyrazine as a kairomone in host location, since this compound had previously been identified as an aggregation pheromone for adult *C. septempunctata* (Al Abassi et al., 1998).

METHODS AND MATERIALS

Insects. *C. septempunctata* adults were collected during July–August from the grounds of IACR-Rothamsted, Hertfordshire, U.K., and kept in ventilated polyethylene boxes at 20°C, with the aphid *Acyrthosiphon pisum* as a food source, prior to vacuum distillation. *D. coccinellae* for electrophysiological studies were obtained from parasitized *C. septempunctata* adults; they were maintained under the same conditions as the ladybirds and kept in Petri dishes lined with moist filter paper and provided with a mixture of honey and water. Parasitoids less than 3 days old were used. For olfactometer studies, parasitized *C. septempunctata* adults were sent by air mail to Sweden and emerging *D. coccinellae* were provided with a diet of whey-cheese (Mild Mesost) and water. Parasitoids more than 1 day old were used.

Isolation of Volatiles. Adult *C. septempunctata* (ca. 1000, not sexed) were cooled with liquid nitrogen and extracted with freshly distilled chloroform (2 × 200 ml) for 24 hr (48 hr in total) at 25°C. The combined extracts were dried using anhydrous magnesium sulfate, filtered, and evaporated to ca. 5 ml. Volatiles were distilled under vacuum (0.03 torr) for 21 hr at 25°C as described previously (Pickett and Griffiths, 1980), and the distillate concentrated under a stream of nitrogen to 100 μl (10 ladybird equivalents/μl) and stored in a tightly capped microvial at −20°C.

Gas Chromatography (GC). The vacuum distilled volatiles were analyzed on a Hewlett-Packard 5890A gas chromatograph equipped with a cold on-column injector, a flame ionization detector (FID), and a 50-m × 0.32-mm-ID HP-1 bonded-phase fused-silica capillary column. The oven temperature was maintained at 40°C for 2 min and then programmed at 10°/min to 250°C. The carrier gas was hydrogen.

Electrophysiology. Electroantennogram (EAG) recordings from recently emerged *D. coccinellae* were made using Ag–AgCl glass electrodes filled with saline solution [composition as in Maddrell (1969) but without glucose]. The insect was anesthetized by chilling and an antenna was excised and suspended between the two electrodes. The tip of the terminal process of the antenna was removed to ensure a good contact. The signals were passed through a high-impedance amplifier (UN-06, Syntech) and analyzed using a customized software package (Syntech).

Stimulus Delivery. The delivery system, which employed a filter paper in a disposable Pasteur pipet cartridge, has been described previously (Wadhams et al., 1982). The stimulus (2-sec duration) was delivered into a purified airstream (1 liter/min) flowing continuously over the preparation. Samples (10 μl) of the standard solutions of test compounds were applied to filter paper strips, and the solvent was allowed to evaporate (30 sec) before the paper strip was placed in the cartridge. The control stimulus was hexane (10 μl). Fresh cartridges were prepared immediately prior to each stimulation. Five individual *D. coccinellae* were used.

Coupled Gas Chromatography–Electroantennography (GC-EAG). The coupled GC-electrophysiology system, in which the effluent from the GC column is simultaneously directed to the antennal preparation and the GC detector, has been described previously (Wadhams, 1990). Separation of the vacuum distillate volatiles was achieved on an AI 93 GC equipped with a cold on-column injector and an FID. Two columns were used, a 50-m × 0.32-mm-ID HP-1 column and a 30-m × 0.32-mm-ID HP-Wax column. For the HP-1 column, the oven temperature was maintained at 40°C for 2 min and then programmed at 5°/min to 100°C and then at 10°/min to 250°C. For the HP-Wax column, the oven temperature was maintained at 40°C for 1 min and then programmed at 10°/min to 220°C. The carrier gas was hydrogen. The outputs from the EAG amplifier

and the FID were monitored simultaneously and analyzed using the software package.

Coupled Gas Chromatography–Mass Spectrometry (GC-MS). A capillary GC column (50 m × 0.32 mm ID HP-1) fitted with an on-column injector was directly coupled to a mass spectrometer (VG Autospec, Fisons Instruments). Ionization was by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min and then programmed at 5°/min to 250°C. Tentative identification by GC-MS was confirmed by peak enhancement with authentic samples (Pickett, 1990).

Chemicals. 2-Isopropyl-3-methoxypyrazine (97%) was purchased from the Aldrich Chemical Company (Gillingham, United Kingdom). Coccinelline, i.e., the *N*-oxide of precoccinelline, the major toxic component of the reflex bleed of adult *C. septempunctata*, was isolated by acid–base extraction of a chloroform extract (extraction method as above, from ca. 900 adults), followed by liquid chromatography over neutral alumina (BDH, Brockmann Grade 1), eluting with chloroform and 99 : 1 chloroform–methanol (Pasteels et al., 1973). Precoccinelline (59 mg, 93% pure by GC) was obtained by catalytic hydrogenation [Adams' catalyst (PtO_2), methanol, 25°C] of coccinelline (80 mg) (Tursch et al., 1971). Myrrhine (10 mg, 90% pure by GC) was prepared from coccinelline (40 mg) via the Polonovski reaction (Tursch et al., 1975). Precoccinelline and myrrhine were then further purified (>99% by GC) by repeated liquid chromatography over neutral alumina (BDH, Brockmann grade 1), using 99 : 1 chloroform–methanol as the eluant. For all alkaloids, identity was confirmed by comparison of the IR, MS, ^{1}H NMR, and ^{13}C NMR spectra with literature values (Mueller et al., 1984; Lebrun et al., 1999). A sample of hippodamine (5 mg, >99% by GC) was provided by Professor D. Daloze (see Acknowledgments). Solutions for electrophysiological studies (10^{-5}–10^{-8} g/10 μl) were prepared in redistilled hexane, and for behavioral studies (10^{-6} g/μl) in redistilled diethyl ether.

Olfactometry. Behavioral assays using parthenogenetic *D. coccinellae* adults were carried out in a two-way Perspex olfactometer as described previously (Al Abassi et al., 1998). This comprised a weak airstream being directed towards the center of the olfactometer from two drawn-out arms to which volatile sources were applied at the inlets. For each experiment, one *D. coccinellae* was introduced into the center of the chamber and its position noted every 2 min for 20 min. Each experiment was replicated 8–10 times and the results analysed by paired *t* test; the number of visits into the treatment arm was compared with visits to the control arm. If the insect did not move between observations, the experiment was terminated and the data discarded. Stimuli comprised: (a) a single intact *C. septempunctata* adult; (b) the vacuum distillation extract, applied in a 0.5-μl microcap (i.e., 5 ladybird equivalents); (c) the test compounds (Figure 1) 2-isopropyl-3-methoxypyrazine (I), precoccinelline (II), myrrhine (III), and

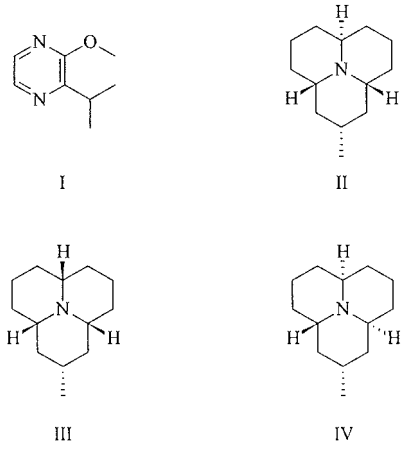

FIG. 1. Structures of compounds I–IV.

hippodamine (IV), diluted to $10^{-6}/\mu$l and applied individually in 0.5 μl microcaps, giving a stimulus approximately equivalent to the level of II found in the ladybird vacuum distillate.

RESULTS

In the olfactometer, adult *D. coccinellae* were not significantly attracted to a single intact *C. septempunctata* adult but showed strong attraction to the vacuum distillation extract (5 ladybird equivalents) (Table 1). Coupled GC-EAG of this extract with *D. coccinellae*, using nonpolar (HP-1) and polar (HP-Wax) capillary columns, showed that 2-isopropyl-3-methoxypyrazine had no electrophysiological activity (I, Figure 2). However, a small peak with a long retention time on both columns was associated with prominent electrophysiological activity (II, Figure 2). This compound was tentatively identified by coupled GC-MS and comparison with published mass spectra (e.g., Tursch et al., 1975; Mueller et al., 1984) as a 2-methylperhydro-9b-azaphenylene alkaloid (M^+ 193, Figure 3). Peak enhancement on coinjection with an authentic sample confirmed the identity of the compound as the free-base precoccinelline (II), a known defense alkaloid of *C. septempunctata* having high toxicity. A minor component of the volatile extract also showed significant electrophysiological activity (III, Figures 2 and 4), and GC-MS analysis gave a spectrum virtually identical to that of II (M^+ 193), suggesting that this component was a diastereoisomer. Coinjection with an authentic sample confirmed the identity of this peak as the ladybird alkaloid myrrhine (III). EAG dose–response curves from *D. coccinellae* confirmed that the pyrazine I was not active, even at high concentrations, while

precoccinelline (II) and myrrhine (III), and the other known ladybird alkaloid hippodamine (IV), showed similarly high activities (Figure 5). In olfactometer assays, *D. coccinellae* was significantly attracted to the alkaloids II and III but not to the pyrazine I or the alkaloid IV (Table 1).

DISCUSSION

Although *D. coccinellae* is known to be attracted by *C. septempunctata* (Orr et al., 1992), in this study, single intact ladybirds did not elicit statistically significant attraction. However, in the search for electrophysiologically and behaviorally active material, the volatile sample obtained by extraction and vacuum distillation of *C. septempunctata* gave highly significant responses. This difference may be due to a concentration effect, but it is more likely that the initial extraction in chloroform accessed compounds normally released only on damage, i.e., in the reflex bleed produced during predator attack. *D. coccinellae* showed no EAG or behavioral responses to 2-isopropyl-3-methoxypyrazine (I), despite such activity being anticipated under the hypothesis initiating this study. Surprisingly, the electrophysiologically active components of the vacuum distillation extract were found to comprise the free-base alkaloids precoccinelline (II) and myrrhine (III). When tested at biologically appropriate levels in the olfactometer, both compounds were significantly attractive to *D. coccinellae* and thus confer the kairomonal activity of the *C. septempunctata* volatiles.

Precoccinelline (II), myrrhine (III), and hippodamine (IV) are natu-

rally occurring 2-methylperhydro-9b-azaphenylene alkaloids that appear to be restricted mainly to ladybirds; of the six possible diastereoisomers, only these three have so far been isolated (Daloze et al., 1994/5; King and Meinwald, 1996). They are also utilized in a similar defense role by cantharid beetles and some amphibious vertebrates (Moore and Brown, 1978; Daly et al., 1993). Their limited occurrence in nature and their importance in the family Coccinellidae suggest that, for a specialist parasitoid such as *D. coccinellae*, these compounds would be reliable indicators for locating suitable hosts (Vet et al., 1991). Contrary to expectations, *D. coccinellae* was not significantly attracted to hippodamine (IV), the free-base defense alkaloid produced by another host species, the convergent ladybird, *Hippodamia convergens* Guerin. However, it was attracted to myrrhine (III), the minor EAG active component in the *C. septempunctata* volatiles; this compound is the major defense alkaloid produced by the eighteen-spot ladybird, *Myrrha octodecimguttata* L., a species that *D. coccinellae* has not been observed to parasitize (Richerson, 1970; Hodek and Honek, 1996; Majerus, 1997). Although further behavioral and ecological studies are necessary to elucidate the issues involved, the identification of toxic alkaloids as volatile

kairomones for *D. coccinellae* will form the basis for such work in these laboratories and, it is hoped, elsewhere.

Seminal studies on the defensive chemistry of ladybirds suggested that, of the six possible diastereoisomers, precoccinelline (II) and hippodamine (IV) are unique to *C. septempunctata* and *H. convergens*, respectively (Pasteels et al., 1973), which implies stereochemical control in their biosynthesis. However, with the onset of more advanced analytical techniques, investigations have revealed that such control is not as effective as previously thought, with mixtures of II and IV being found in both species (Daloze et al., 1994/5), although the presence of myrrhine (III) in *C. septempunctata* was not reported. Moreover, hippodamine (IV) was not found in the study of *C. septempunctata* volatiles described here.

The chemical ecology of multitrophic interactions such as those between

plants, aphids and aphid parasitoids has been widely studied with a view to exploiting parasitoids in biological control of pest aphid populations (Wadhams et al., 1999). In contrast, the chemical ecology of interactions between plants, aphids, ladybirds, and their parasitoids has received relatively little attention. The results of this study demonstrate the role of volatile semiochemicals in mediating trophic interactions between the third and fourth levels and represent a rare example of toxicants to which an animal has adapted acting directly as volatile kairomones.

For the development of aphid control programs that involve manipulation of ladybirds, methods of manipulating their natural enemies may also be needed. The significant attraction of *D. coccinellae* to such specific cues as the ladybird alkaloids suggests that there is potential for development of control strategies for this particular natural enemy, thereby enhancing the beneficial role of ladybirds through increased populations. However, as host location is likely to involve a mixture of olfactory and visual cues (Orr et al., 1992), further studies are required to assess the significance of the latter in this process.

Acknowledgments—The authors thank Professor D. Daloze, University of Brussels, Belgium, for kindly providing the sample of hippodamine. IMPORTANCE OF PREDATOR DIET CUES IN RESPONSES OF LARVAL WOOD FROGS TO FISH AND INVERTEBRATE PREDATORS

DOUGLAS P. CHIVERS[1,*] and REEHAN S. MIRZA[1]

(Received May 30, 2000; accepted August 29, 2000)

Abstract—We examined the effects of predator diet on the antipredator responses of larval woodfrogs (*Rana sylvatica*). We found that tadpoles showed stronger responses to fish (*Perca flavescens*) that were fed tadpoles than those fed invertebrates. Similarly, we found that tadpoles responded more strongly to larval dragonflies (*Anax* spp.) fed tadpoles than to dragonflies fed invertebrates. The overall intensity of response of tadpoles to fish was much stronger than that to dragonflies. Predator diet effects are not ubiquitous in predator–prey systems. We discuss possible reasons why predator diet effects are seen in some, but not all, predator–prey systems.

Key Words—Predation, antipredator behavior, chemical cues, diet cues, amphibians, wood frogs, *Rana sylvatica*.

INTRODUCTION

A wide diversity of aquatic organisms use chemical cues to mediate predation risk (reviews in Chivers and Smith, 1998; Kats and Dill, 1998). Chemical cues are particularly important in aquatic environments when visual cues are limited, such as at night, in structurally complex habitats, or in areas of high turbidity (Smith, 1992). Aquatic media are well suited for chemical signals because a large number of compounds can dissolve in water, giving a large number of potential chemical signals to be detected (Kleerekoper, 1969; Hara, 1994).

Recently, a number of studies have begun to examine the importance of predator diet cues in the behavioral, morphological, and life historical responses of prey animals to predators. For example, Mathis and Smith (1993a) documented that predator-naïve fathead minnows (*Pimephales promelas*) do not exhibit antipredator behavior to chemical stimuli from predatory pike (*Esox lucius*) if the pike are fed swordtails (*Xiphophorus helleri*), but do respond if the pike are fed fathead minnows. In a similar behavioral study, Chivers et al. (1996) showed that larval damselflies (*Enallagma* spp.) exhibit antipredator behavior to cues of pike fed damselflies, but not cues of pike fed a different diet. Stabell and Lwin (1997) found that crucian carp (*Carassius carassius*) exhibit an adaptive change in body morphology in response to predators fed carp but not predators fed a different fish diet (arctic char, *Salvelinus alpinus*). Moreover, Crowl and Covich (1990) showed that snails (*Physella virgata*) exposed to cues of crayfish feeding on snails were significantly larger and older at the age of first reproduction and at death than snails that were exposed to crayfish that were not feeding on snails.

A few studies have examined the importance of predator diet cues for amphibian prey. For example, Petranka and Hayes (1998) did not observe any differences in the intensity of antipredator behavior of wood frog (*Rana sylvatica*) tadpoles to larval dragonflies (*Anax junius*) that were fed tadpoles versus those that were starved for two days. In contrast, Laurila et al. (1997) showed that tadpoles of the common frog (*Rana temporaria*) responded more strongly to cues of larval dragonflies (*Aeshna juncea*) fed tadpoles than dragonflies fed insects. Similarly, Wilson and Lefcort (1993) showed that tadpoles of the red-legged frog (*Rana aurora*) exhibit antipredator behavior in response to predatory newts (*Taricha granulosa*) fed tadpoles but not to newts fed insects.

Even though diet-dependent antipredator responses are common in aquatic systems, they are not ubiquitous (Petranka and Hayes, 1998; Bryer et al., 2000). Additional studies are needed to understand the importance of diet-dependent antipredator responses in most predator–prey systems, including those involving amphibians. The aim of the current study was to examine if the importance of predator diet were dependent on the type of predator to which the prey is exposed. We examined the responses of wood frog tadpoles to cues from their natural fish predators (perch, *Perca flavescens*) and invertebrate predators (larva dragonflies, *Anax* spp.) that were fed either wood frog tadpoles or a diet of invertebrates.

METHODS AND MATERIALS

We collected six wood frog egg masses from a wetland in Orono, Maine, in April 1998 and transported them to our laboratory at the University of Maine

for testing. Each of the six clutches was maintained in its own 37-liter glass aquarium. The clutches were kept on a 14L : 10D photoperiod at approximately 20°C. After the tadpoles hatched, they were fed ad libitum with ground alfalfa pellets and fish food. Tests began when the tadpoles reached Gosner stage 25 (Gosner, 1960).

We placed one tadpole from each of the six clutches into each of 80 5-liter plastic pails filled with fresh well water. Each pail had a line drawn on the bottom. The line passed through the center of the pail. Tadpoles were kept in the pails for two days before being tested. We recorded the number of times the tadpoles in each pail crossed the centerline for a period of 5 min before and 5 min after adding one of five chemical stimuli to the center of the pail. The stimuli included: (1) cues of fish fed invertebrates, (2) cues of fish fed wood frog tadpoles, (3) cues of larval dragonflies fed invertebrates, (4) cues of larval dragonflies fed wood frog tadpoles, and (5) a control of well water. In each trial 10 ml of stimulus was used. The order of testing was randomized between treatments.

Preparation of Test Stimuli

Fish Cues. A total of four perch (mean ± SD mass = 3.39 ± 0.47 g) were used to prepare the fish cues. Two perch were kept in each of two different 37-liter aquaria and fed ad libitum with either wood frog tadpoles or invertebrates (*Daphnia* and corixids). Twenty-four hours before trials began, we placed one tadpole-fed fish and one invertebrate-fed fish into separate glass jars that held 3 liters of water. The fish conditioned the water for 24 hr prior to the trials. Fish were not fed in the stimulus collection chambers.

Dragonfly Cues. We prepared the dragonfly cues in the same manner as the fish cues except that we used 10 dragonfly larvae to condition the dragonfly-fed tadpole water and 10 dragonfly larvae to condition the dragonfly-fed invertebrate water. The mean (± SD) mass of dragonflies was 0.36 ± 0.03 g. We used 10 dragonflies not one dragonfly because we wanted to match the dragonfly mass with the mass of fish that we used to prepare the stimulus.

For each trial we calculated the change in number of line crosses before versus after the addition of each chemical stimulus. We used a paired *t*-test to compare whether tadpoles changed their behavior after addition of the control stimulus. Given that we found no effect of disturbance related to the addition of the control cue ($t = 0.27$, $d.f. = 15$, $P = 0.791$), we completed a two-way ANOVA testing for effects of predator diet, predator type, and an interaction between predator diet and predator type. We used one-tailed tests because we predicted that tadpoles would decrease activity in response to chemical cues of predators and that the intensity of the response would be stronger if the predator was fed a diet that contained the prey (Kiesecker et al., 1996; Petranka and Hayes, 1998; Chivers and Smith, 1998).

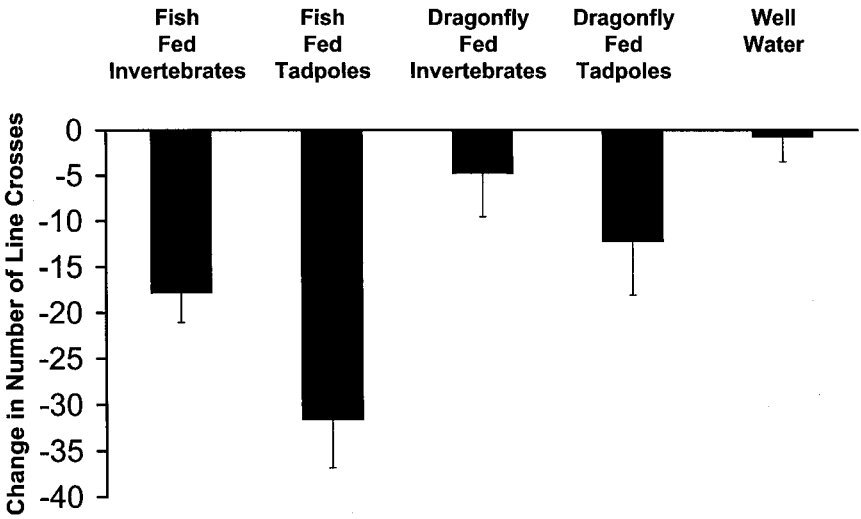

FIG. 1. Mean (+ SE) change in number of line crosses by groups of tadpoles exposed to various chemical cues.

RESULTS

Tadpoles showed a reduction in movement in response to all predator treatments (Figure 1). Our two-way ANOVA revealed that there was a significant effect of predator diet and a significant effect of predator type, but there was no interaction term (Table 1). The intensity of response of tadpoles to fish cues was more than double that of dragonflies.

DISCUSSION

The results of our study demonstrate that predator diet can dramatically influence the intensity of responses of wood frogs to cues of predators. These

TABLE 1. RESULTS OF TWO-WAY ANOVA FOR EFFECTS OF PREDATOR DIET AND PREDATOR TYPE ON ACTIVITY OF WOOD FROG TADPOLES

	F	*d.f.*	*P*
Predator diet	4.784	1	0.033
Predator type	11.081	1	0.001

results have important implications. Prey animals should exhibit antipredator responses to cues of predators that are a threat, but they should not waste valuable time and energy to respond to predators that are not a threat (Sih, 1987; Lima and Dill, 1990; Chivers and Smith, 1998).

Several studies have documented that tadpoles exhibit antipredator behavior when exposed to cues of fishes (e.g., Petranka et al., 1987; Kats et al., 1988; Stauffer and Semlitsch, 1993; Feminella and Hawkins, 1994). Some of these studies show that prior experience with fishes is not required for the prey to recognize and respond to the predator. Our results concur with these previous findings. We found that wood frog tadpoles with no prior experience with fishes exhibited antipredator behavior to chemical cues of the fish. Our study extends these findings because we found that the intensity of the response was increased when the fish were fed tadpoles as opposed to when the fish were fed invertebrate prey.

Tadpoles often respond to chemical cues of invertebrate predators even if the individual does not have experience with the predator. For example, Kiesecker et al. (1996) showed that tadpoles of the western toad (*Bufo boreas*), raised from eggs in the laboratory, exhibit responses to cues of backswimmers (*Notonecta* spp.) and giant waterbugs (*Lethocerus americanus*). Similarly, Petranka and Hayes (1998) found that predator-naïve wood frog tadpoles responded to chemical cues of dragonflies that were fed or starved for two days. In our experiment, we found that tadpoles decreased activity when exposed to either chemical cues of dragonflies fed invertebrates or dragonflies fed tadpoles.

We do not know which chemicals are responsible for eliciting the diet responses. In some predatory–prey systems, the prey animals respond to conspecific alarm pheromones in the diet of the predator (Mathis and Smith, 1993a,b). However, this is probably not the case in this system; wood frog tadpoles do not seem to possess a chemical alarm cue system (Petranka and Hayes, 1998).

We observed a significant difference in the intensity of responses to fish versus dragonfly predators. This difference could reflect that fish represent a much stronger threat than do dragonflies. Alternatively, the difference could be attributable to differences in the concentration of cues produced by the two types of predators. This is unlikely because we attempted to match the mass of dragonflies with that of fish.

A few previous studies have examined the effects of predator diet on antipredator responses of tadpoles. Petranka and Hayes (1998) failed to find differences in the way wood frog tadpoles responded to dragonflies that were fed tadpoles versus those that were starved. In contrast, Laurila et al. (1997) documented that tadpoles of the common frog responded with a more intense antipredator response to cues of dragonflies fed tadpoles than dragonflies fed insects. Wilson and Lefcort (1993) showed that tadpoles of the red-legged frogs exhibit antipredator behavior in response to predatory newts fed tadpoles but not

to newts fed insects. We found that wood frog tadpoles showed greater reductions in activity when exposed to both fish and dragonfly predators that were fed tadpoles as opposed to those fed invertebrates.

The fact that diet effects are seen in some predator–prey systems but not others is interesting and worth further investigation. Bryer et al. (2000) documented that slimy sculpins (*Cottus cognatus*) that were experienced with brook trout (*Salvelinus fontinalis*) exhibit antipredator behavior to chemical stimuli from trout regardless of the diet of the trout. They argue that brook trout are always a threat to slimy sculpins in this population and hence knowledge of the last meal eaten by the trout may provide little valuable information to the sculpin. This reasoning could explain why no diet effect was observed in this system. The same logic may apply to other predator–prey systems that have failed to find predator-diet effects. The fact that an effect of diet is observed when using one predator but not when using a different predator may be a consequence of differences in gut physiology of the predators. Some predators may be able to break down the chemicals that elicit the responses. Alternatively, if we see a diet effect when using one predator but not another, then this may indicate that the intensity of predation by one predator is less predictable than that of the other. If predators specialize on specific prey types during some times of the year, the actual threat posed by the predator is context dependent. Prey could use predator diet cues to respond more strongly to the predator only if predation on conspecifics was occurring. Additional studies are needed in order to elucidate why predator diet effects are seen in some, but not all, predator–prey systems.

(Received December 1, 1999; accepted August 30, 2000)

Abstract—The purpose of this work was to investigate whether ethylene is involved in the oxidative and defensive responses of barley to the aphids *Schizaphis graminum* (biotype C) and *Rhopalophum padi*. The effect of aphid infestation on ethylene production was measured in two barley cultivars (Frontera and Aramir) that differ in their susceptibility to aphids. Ethylene evolution was higher in plants infested for 16 hr than in plants infested for 4 hr in both cultivars. Under aphid infestation, the production of ethylene was higher in cv. Frontera than in Aramir, the more aphid susceptible cultivar. Ethylene production also increases with the degree of infestation. Maximum ethylene evolution was detected after 16 hr when plants were infested with 10 or more aphids. Comparing the two species of aphids, *Schizaphis graminum* induced more ethylene evolution than *Rhopalosiphum padi*. Infestation with *S. graminum* increased hydrogen peroxide content and total soluble peroxidase activity in cv. Frontera, with a maximum level of H_2O_2 observed after 20 min of infestation and the maximum in soluble peroxidase activity after 30 min of infestation. When noninfested barley seedlings from cv. Frontera were exposed to ethylene, an increase in hydrogen peroxide and in total peroxidase activity was detected at levels similar to those of infested plants

from cv. Frontera. When noninfested plants were treated with 40 ppm of ethylene, the maximum levels of H_2O_2 and soluble peroxidase activity were at 10 and 40 min, respectively. Ethylene also increased the activity of both cell-wall-bound peroxidases types (ionically and covalently bound), comparable with infestation. These results suggest that ethylene is involved in the oxidative responses of barley plants induced by infestation.

Key Words—*Hordeum vulgare*, *Schizaphis graminum*, *Rhopalosiphum padi*, Poaceae, greenbug, hydrogen peroxide.

INTRODUCTION

Ethylene regulates many physiological processes in plants (Mattoo and Suttle, 1991; Kende and Zeevart, 1997). Ethylene evolution is observed under many situations, including mechanical wounding, hypoxia, environmental pollution, and invasion by pathogens (Osborne, 1978; Boller, 1991; Anderson et al., 1993; Koiwa et al., 1997; Solano and Ecker, 1998). Ethylene induces defense responses in plants against pathogens (Van Loon, 1977) and pathogen resistance genes (PR genes) such as the PI genes, which encode proteinase inhibitors (Bol et al., 1990; Knogge, 1996; Koiwa et al., 1997). Ethylene induction and defense responses in *Nicotiana tobacco* can be elicited by xylanase from the fungus *Trichoderma viridis* (Anderson et al., 1993) or can be induced by jasmonic acid, which in turn is induced by abscissic acid (ABA) (Wasternack and Parthier, 1997; Koiwa et al., 1997). It has been reported that ethylene production is stimulated by a positive feedback loop with activation of ACC synthase (Chalutz et al., 1984; Kende and Zeevart, 1997). However, not all species of plants or cultivars respond to ethylene treatment (Bailey et al., 1993) and/or cell wall-digesting enzymes released by pathogens (Sharon et al., 1993; Knogge, 1996), suggesting specific requirements for ethylene and infection responses. In most plants, ethylene induces the synthesis of compounds that cross-link with cell wall polymers, thus reinforcing the cell wall structure and inhibiting the spread of the pathogen in plant tissues or reducing the injury caused by insect attack. For example, the lignification of Swede root is induced by ethylene (Rhodes and Wooltorton, 1973), possibly through the activation of PAL (Ecker and Davis, 1987) and peroxidases, which considerably reduce the pathogenicity (Ke and Saltveit, 1988; Ingham et al., 1998). In addition, tissues treated with ethylene accumulate cross-linking hydroxyproline-rich glycoproteins in cell walls (Esquerré-Tugayé et al., 1979; Fry, 1982; Cassab, 1998). Peroxidases are also involved in repair of cell walls because they catalyze the biosynthesis of lignin (Ingham et al., 1998; Cassab, 1998) and suberin (Espelie et al., 1986) and induce covalent linkage between lignin and other cell wall polymers (Iiyama, et al., 1994; Cassab et al., 1988; Cassab, 1998). In addition, ethylene induces the accumulation of some mRNAs,

such as those of PAL, coumarate CoA ligase, chalcone synthase, and transcripts of glycoproteins rich in hydroxyproline (Cassab et al., 1988).

Some barley cultivars are more resistant than others to aphid infestation because of morphological and/or biochemical characteristics (Corcuera, 1993). These characteristics can act as defensive barriers against the invader agent (Boller et al., 1983; Jackson and Taylor, 1996). Barley plants of cultivar Frontera are more tolerant to aphid infestation than cultivar Aramir (Casaretto and Corcuera, 1998).

The aphid species and its biotype may cause differences in the degree of damage caused by infestation of a particular wheat genotype (Anderson and Peters, 1994) or barley cultivar (Zúñiga et al., 1989). In barley the combination Frontera/*Schizaphis graminum* (biotype C) gives rise to less damage to the plant than the combination Aramir/*S. graminum* (biotype C). Both cultivars, Frontera and Aramir, are less damaged when they are infested by *Rhopalosiphum padi*. Therefore, the susceptibility or tolerance of a plant to aphid infestation will depend on the specific cultivar–biotype and cultivar–aphid species combinations (Dillwith et al., 1991; Anderson and Peters, 1994).

Aphids induce ethylene production in cereals (Dillwith et al., 1991; Miller et al., 1994; Anderson and Peters, 1994). Ethylene production induced by mechanical injury also influences morphological changes by increasing peroxidase activity (Depége et al., 1997; Ingham et al., 1998; Loukili et al., 1998). This phenomenon is called thigmomorphogenesis and has been observed in a wide variety of plants such as bean, tomatoes, *Bryonia dioica*, etc. (Depége et al., 1997; Loukili et al., 1998). Some aphids release cell wall-digesting enzymes, which could induce defensive responses in plants similar to those induced by pathogens (Runlin et al., 1999).

In this paper we postulate that ethylene is involved in the oxidative responses of barley induced by aphids. To test this hypothesis we examined: (1) ethylene evolution in two barley cultivars that differ in susceptibility to aphids; (2) the effect of infestation and ethylene on the synthesis of hydrogen peroxide; and (3) the effect of ethylene on the activity of soluble peroxidase and ionically and covalently bound peroxidases to the cell wall.

METHODS AND MATERIALS

Plants and Aphids. Two barley cultivars, Frontera and Aramir, which differ in their susceptibility to aphids (Casaretto and Corcuera, 1998), were used to study the effect of aphid infestation on plants. The aphids used in the assays were *Schizaphis graminum* (biotype C) and *Rhopalosiphum padi*. They were obtained from colonies maintained in the laboratory at temperatures of 28°C ± 2°C and under a photoperiod of 12L : 12D.

Ethylene Measurements. For ethylene production, infested and noninfested seedlings cultivated in little pots with vermiculite were placed in 1-liter bottles sealed with rubber caps. The accumulation of ethylene was measured by taking samples of air from the bottles with a syringe after 0, 1, 3, and 5 h. Samples of 1 ml were injected in a Shimadzu gas chromatograph equipped with a flame ionization detector (FID) using an alumina column. The temperature was 110°C for the column and 200°C for the FID detector. A standard of ethylene with a concentration of 77.2 ppb was used for calibration. Samples of air taken from a bottle without plants were used for controls. A control sample also was obtained from a bottle containing 20 aphids without plants. In each sample the fresh weight of the seedlings was used to express the ethylene production per kilogram of fresh weight. The values expressed in the results are the mean of three samples each obtained from independent bottles.

Hydrogen Peroxide and Peroxidase Activity Measurements. Nine-day-old barley plants (cv. Frontera) were incubated with 20 and 40 ppm of ethylene for a period of 6 hr. Samples were taken immediately after incubation (0 time) and at 5, 10, 15, 20, 25, 30, and 35 min after the end of the incubation period.

Extraction of Peroxidases. One gram of leaf tissue was ground in an ice-cold mortar using a pestle, and 10 ml of buffer phosphate (50 mmol/liter, pH 7) was added. The homogenate was centrifuged at 15,000*g* for 10 min. The supernatant was used as the cytosolic fraction and assayed for peroxidase activity. To extract proteins ionically bound to cell walls, the pellet from the previous extract was incubated in 1 mol/liter KCl at 4°C for 12 hr under constant agitation; this extract was centrifuged at 15,000*g* for 30 min. The proteins previously ionically bound to the cell wall were released into the supernatant. Peroxidases covalently bound to the cell walls were obtained by washing the pellet left from this last centrifugation 3 times with 1 mol/liter KCl. After the washes, the pellet was resuspended in 50 mmol/liter Na acetate, pH 5.0, with 2.5% pectinase (w/v), 0.65% cellulase (w/v), 2 mmol/liter benzamidine, and 1 mmol/liter peptain A and kept under agitation for 12 hr at 25°C. This extract was centrifuged at 15,000*g* for 30 min, and the covalently bound peroxidases were released into the supernatant.

Measurement of Peroxidase Activity. Peroxidase activity was measured against two substrates to determine whether the substrate would make a difference in the quantification of the enzyme activity. However, no differences in activity were found between the methods. In the first method (Chance and Maehly, 1955), guaiacol was used as substrate. The oxidation of guaiacol was measured by the increase in absorbance at 470 nm for 2 min. The assay contained 50 μl of 20 mmol/liter guaiacol, 2.9 ml phosphate buffer (pH 7.0), and 10 μl of enzyme extract. The reaction was started with 20 μl of 40 mmol/liter H_2O_2. An enzyme unit (EU) was defined as the amount of enzyme needed to oxidize 1 μmol of guaiacol per minute. In the second method (Cassab et al., 1988;

modified by Riquelme and Cardemil, 1993) the substrates were 0.1% *o*-fenilendiamine (*o*-PDA) and 0.012% H_2O_2 in 0.1 mol/liter Na citrate, pH 5. After 10 min of incubation of the enzyme extract with the substrates at 25°C, the oxidized *o*-PDA was measured at 450 nm. One enzyme unit (EU) was defined as the amount of enzyme which oxidizes 1 μmol/liter of *o*-PDA/min. No reaction was observed in the absence of H_2O_2. In both assays, peroxidase activities were expressed in EU per gram of dry weight.

Determination of Hydrogen Peroxide. H_2O_2 concentration was measured according to the method of Okuda et al. (1991). The reaction mixture contained 100 μl extract, 200 μl of 12.3 mmol/liter 3-(dimethylamino) benzoic acid in 0.4 mol/liter phosphate buffer (pH 6.5), 40 μliter of 3-methyl-2-benzothiazoline hydrazoline hydrazone, and 20 μl peroxidase (0.25 EU) in a total volume of 1 ml. The reaction was started by the addition of peroxidase at 25°C. The increase in absorbance at 590 nm was monitored in a double-beam spectrophotometer (Shimadzu UV-160).

Statistical Analysis of Data. Descriptive statistics (means, standard deviations and standard errors) were used to characterize the data on a plants basis. One-way ANOVA was used to determine the significance of differences of ethylene and aphid effects on plant hydrogen peroxide and peroxidase activity.

RESULTS

Ethylene Evolution from Two Infested Barley Cultivars. Barley plants (cv. Frontera and Aramir) 6, 9, or 12 days old were infested with *S. graminum*. Ethylene was measured after 0, 1, 3, and 5 hr of infestation and was expressed in parts per million per killigram of fresh weight. Ethylene evolution was higher for infested plants than noninfested plants and was also higher for older than younger plants (Table 1). In 6-day-old plants ethylene evolution values of Aramir and Frontera cultivars were not significantly different ($P \leq 0.05$). However, the ethylene production by 9- and 12-day-old plants was higher for cv. Frontera (the more resistant cultivar). Differences in ethylene production between cultivars increased in 12-day-old plants; cv. Frontera evolved almost twice as much ethylene as cv. Aramir after 3 and 5 hr of infestation ($P \leq 0.05$).

Twelve-day-old Aramir and Frontera plants were infested with different numbers of *S. graminum* nymphs. Evolution of ethylene increased as a function of the number of aphids per plant and as a function of infestation time (Figure 1). Maximum ethylene evolution was detected in both cultivars infested with 10 or more aphids for 16 hr. At this time, the levels of ethylene were 37% higher in cv. Frontera than in cv. Aramir.

Plants of cultivars Frontera and Aramir were infested each with 20 aphids of *S. graminum* or *R. padi*. Controls were noninfested plants. Ethylene level

[a] Plants were infested with 10 aphids 1 hr before initiated the ethylene measurements. Data on ethylene accumulation represent the mean of four samples (±SD). ND = non detectable.

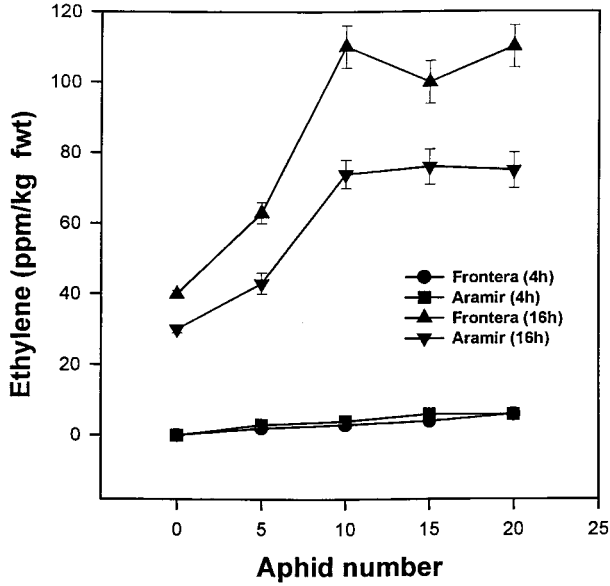

FIG. 1. Effect of aphid infestation on ethylene production in barley. Plants were infested with different numbers of *S. graminum*, one group during 4 hr and another during 16 hr. Each point represents the mean of three measurements (±SE); fwt = fresh weight).

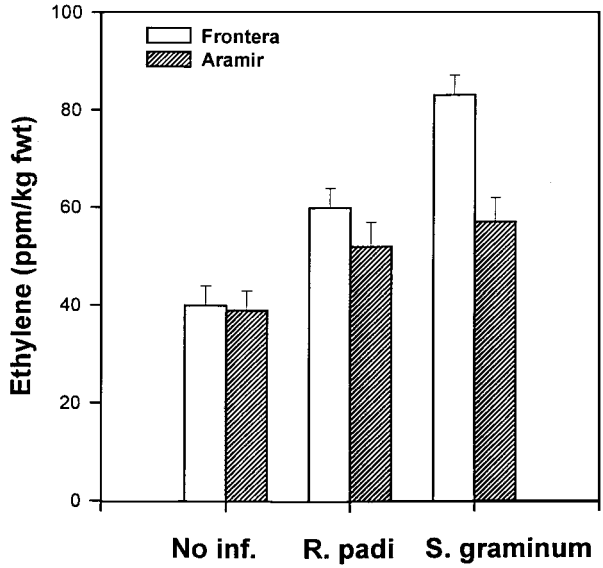

FIG. 2. Effect of two aphid species on ethylene production in barley plants. Plants of Frontera and Aramir cultivars 12 days old were infested with 20 aphids of *S. graminum* or of *R. padi* for 12 hr. Each point represents the mean of three measurements (±SE).

was measured after 12 hr of infestation (Figure 2). Production of ethylene in cv. Frontera plants infested with *S. graminum* was 53% higher with respect to controls and 29% higher than those infested with *R. padi*. In all assays with infested plants, cv. Frontera produced more ethylene than cv. Aramir ($P \leq 0.05$).

H_2O_2 Accumulation and Soluble Peroxidase Activity. H_2O_2 accumulation and soluble peroxidase activity were measured in 10-day-old plants of cv. Frontera infested with 20 aphids of *S. graminum* per plant. The aphids induced an increase in H_2O_2 accumulation with a transient maximum after 20 min of infestation (Figure 3) and was 41% higher than in noninfested plants. *S. graminum* also increased by 64% the soluble peroxidase activity with respect to control plants after 30 min of infestation (Figure 4).

In response to ethylene pulses of 20 and 40 ppm during 6 hr, H_2O_2 and soluble peroxidase activity in noninfested barley plants, cv. Frontera, increased to levels similar to those of plants infested with aphids (Figures 5 and 6). Levels of H_2O_2 were 53% higher in the plants treated with 40 ppm ethylene than in control plants reaching a maximum after 10 min of treatment. With 20 ppm, H_2O_2 accumulation was 43% higher in treated plants than in the controls. A maximum accumulation occurred after 15 minutes of treatment (Figure 5).

The maximum activity of soluble peroxidases occurred at 40 min with 40

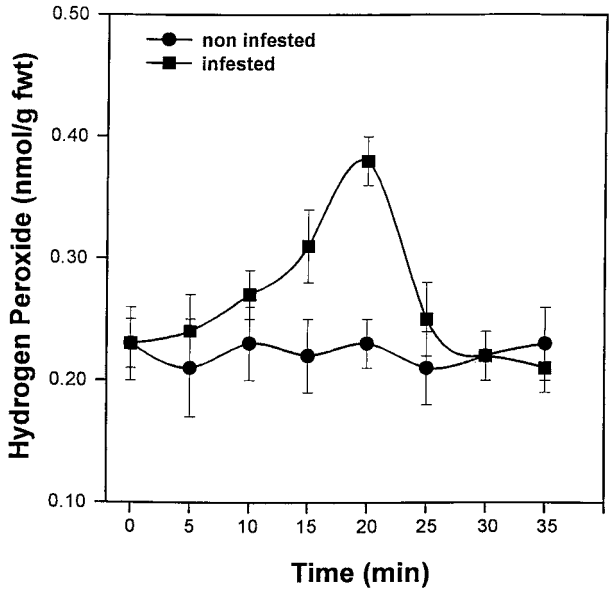

FIG. 3. Effect of aphid infestation on the accumulation of hydrogen peroxide in barley. Plants of Frontera cultivar 10 days old were infested with 20 aphids of *S. graminum* per plant for different periods of time. Each point represents the mean of three measurements (±SE).

ppm of ethylene treatment. However, the maximum activity occurred after 60 min when the treatment was 20 ppm of ethylene. With 40 ppm, soluble peroxidase activity was 53% higher in treated plants than in control ones. With 20 ppm the soluble peroxidase activity was 45% higher than in control plants ($P \leq 0.05$) (Figure 6).

Activity of both cell wall-bound peroxidases, those covalently and ionically bound, also increased under exposure of the plants to 40 ppm of ethylene. In the case of the ionically bound peroxidases, the level of activity was 40% higher than in the control plants after 20 hr of incubation. Covalently bound peroxidases were 24% higher than the control plants after 50 hr of incubation with ethylene (Figure 7).

DISCUSSION

Ethylene has been implicated in the response by plants to wounding (Osborne, 1978) and to pathogen attack (Ecker and Davis, 1987; Kende and Zeevart, 1997). Its biosynthesis is also promoted by many environmental stresses

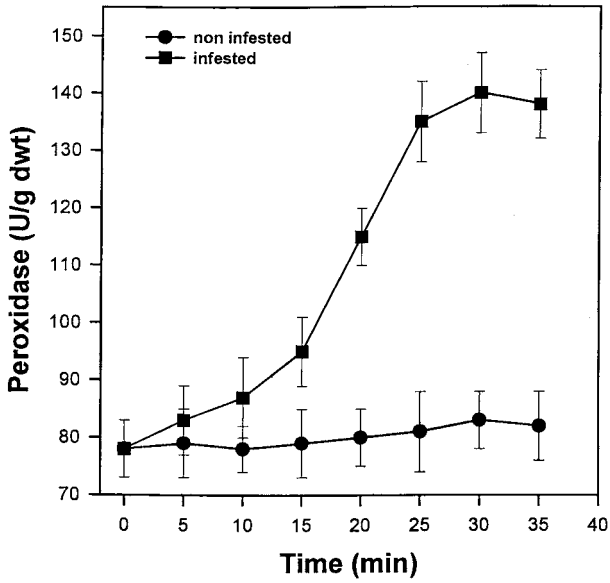

FIG. 4. Accumulation of soluble peroxidases in barley plants cv. Frontera infested with 20 aphids of *S. graminum* per plant for different periods of time. Each point represent the mean of three measurements (±SE).

(Kende and Zeevart, 1997). In pathogenesis, ethylene evolution is correlated with the induction of several PR genes (Dong, 1998). It is still unknown whether aphid infestation induces PR genes in barley as defensive mechanism. Results obtained in this work show that aphids induced more ethylene evolution in Frontera, a more resistant cultivar than Aramir, when infested by *S. graminum* (biotype C). Previous reports indicated that aphid infestation induced higher evolution of ethylene in susceptible than in resistant cultivars of alfalfa, wheat, and barley (Dillwith et al., 1991; Anderson and Peters, 1994; Miller et al., 1994). However, the physiological and molecular responses to infestation will depend on several factors such as plant cultivar, plant age, degree of infestation, aphid species and biotype, and infestation time. Anderson and Peters (1994) found that different combinations of wheat genotype–greenbug biotypes produced different amounts of ethylene.

In this work the infestation also induced an increase in the levels of hydrogen peroxide and peroxidase activity. Moreover, when the plants were subjected to ethylene, this hormone induced an increase in the hydrogen peroxide and in the peroxidase activity. Both hydrogen peroxide and peroxidases are related to the oxidative metabolism triggered by pathogenicity, stress conditions, and infes-

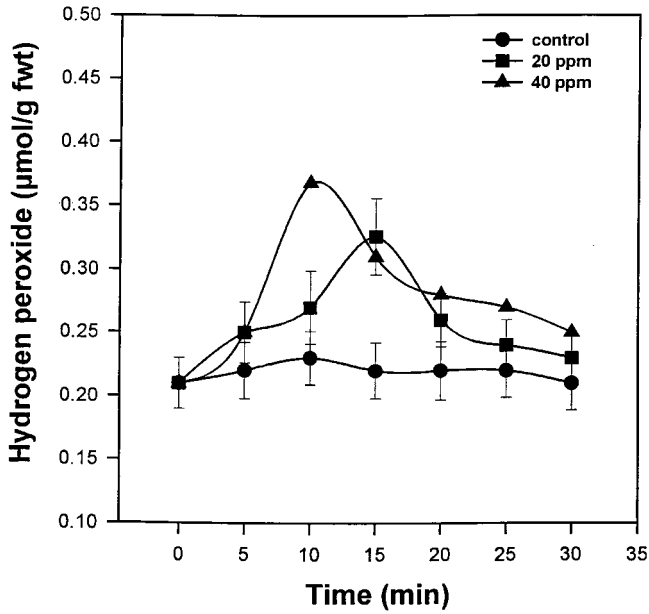

FIG. 5. Accumulation of hydrogen peroxide in cv. Frontera barley plants treated with 20 and 40 ppm of ethylene for 6 hr. After treatment, the hydrogen peroxide was measured at different periods of time. Each point represent the mean of three measurements (±SE).

tation, suggesting that in these cultivars ethylene may induce physiological and molecular responses related to aphid tolerance similar to those found in plant responses to pathogens (Wasternack and Parthier, 1997; Koiwa et al., 1997).

The time and intensity of plant defensive responses to a pathogen are crucial to determine if the infection can be prevented (Koiwa et al., 1997; Dong, 1998). In 12-day-old barley plants of both cultivars, ethylene production became significantly higher after 1 hr of infestation. This ethylene evolution was faster than that detected by Anderson and Peters (1994), suggesting that this initial ethylene evolution may be involved in the oxidative burst of barley plants. This burst may mediate defensive mechanisms against infestation, as has been found for pathogen-infested plants (Koiwa et al., 1997; Dong, 1998). Later production of ethylene by the infested plant may be related to the senescence process (Nakatsuka et al., 1998). Anderson and Peters (1995) found that AVG (2-aminoethoxyvinylglycine), an inhibitor of ethylene biosynthesis, did not reduce chlorophyll degradation or the lesions induced by infestation, indicating that ethylene may not be involved in the development of these symptoms.

The time of production of ethylene was similar in both cultivars of barley,

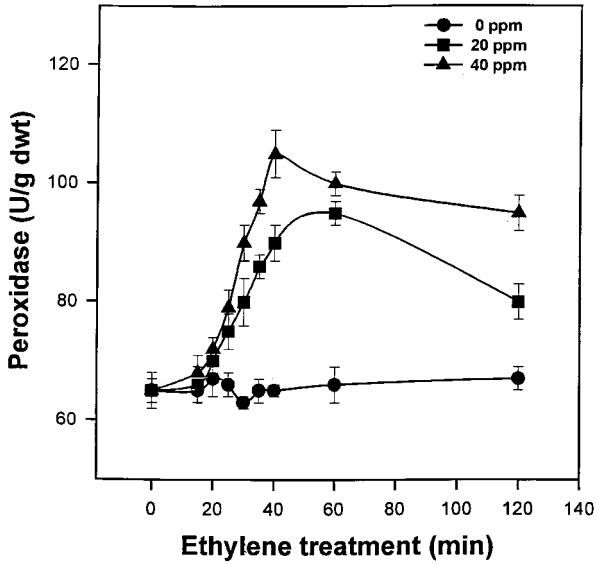

FIG. 6. Effect of ethylene on the activity of soluble peroxidases in barley plants cv. Frontera treated with 20 and 40 ppm of ethylene for 6 hr. After treatment, the peroxidase activity was determined at different periods of time. Each point represent the mean of three measurements (±SE).

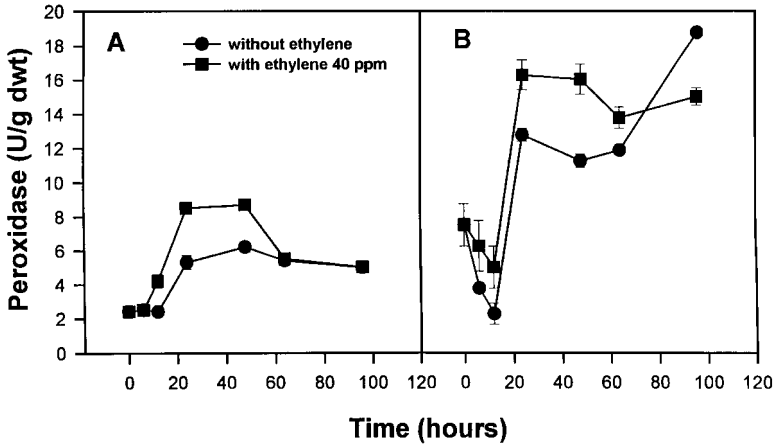

FIG. 7. Effect of ethylene on the activity of peroxidases ionically (A) and covalently bound (B) to the cell wall. The plants of cv. Frontera were treated with 40 ppm of ethylene for 6 hr. After treatment, the activity was measured at different periods of time. Each point represent the mean of three measurements (±SE).

although the levels were higher in cv. Frontera than in cv. Aramir. It seems, therefore, that in the two cultivars it was the magnitude of ethylene evolution, rather than the speed of the response that probably made the difference in their response to infestation.

In both cultivars during the first 4 hr of infestation, ethylene evolution increased slightly with the number of aphids. However, after 16 hr of infestation the level of ethylene evolution was clearly dependent upon the number of aphids per plant reaching a maximum when plants were infested with 10 aphids. This seems to indicate that in plants of this age the threshold of infestation to induce maximum ethylene production requires this number of aphids per plant.

S. graminum (biotype C) induced a higher level of ethylene evolution, indicating that this species was more aggressive in this barley cultivar than *R. padi* and produced more plant damage. This result is in agreement with previously published results, where the amount of chlorophyll loss was higher in barley plants infested with *S. graminum* (biotype C) than with *R. padi* (Casaretto and Corcuera, 1998).

In addition, aphids also induced accumulation of H_2O_2 and increased peroxidase activity. As occurs in the response to plants pathogens, the burst of H_2O_2 production by barley plants preceded the accumulation of soluble and cell wall peroxidases (Lamb and Dixon, 1997; Somssich and Hahlbrock, 1998). In infested barley plants, the maximum level of H_2O_2 was found about 10 min before the maximum accumulation of soluble peroxidase activity. However, in noninfested plants exposed to 40 ppm of ethylene the maximum level of H_2O_2 was reached after 10 min with a maximum induction of the peroxidase activity after 40 min. This suggests that the accumulation of soluble peroxidase activity is a consequence of the H_2O_2 burst and appears to indicate that the accumulation of H_2O_2 could be the beginning of a cascade of events that triggers physiological and molecular plant responses to prevent or minimize insect attack. This H_2O_2 may be produced in the cell wall or in the plasma membrane via a NADPH oxidase associated with this membrane, as has been reported in the case of pathogen attacks on plants (Somssich and Hahlbrock, 1998).

Plant cells produce H_2O_2 in response to both biotic and abiotic stress (Wojtaszek, 1997). H_2O_2 accumulation may be also implicated in the induction of defense genes (Wu et al., 1995). Therefore, the H_2O_2 production is a general response of plants to stress conditions and not specific to plants infested by aphids. While the exact biochemical reaction involved in the production of the H_2O_2 is still being studied, one may speculate that plants may use this compound not only as an inducer of the defensive cascade of metabolic events but rather as a defense mechanism itself (Lamb and Dixon, 1997). However, H_2O_2 can damage plant cells. The prevention of this damage would depend on the efficiency of the antioxidant systems. In plants, H_2O_2 is destroyed specifically by ascorbate peroxidase, and catalases (Asada, 1992; Mehlhorn et al., 1996; Foyer

et al., 1997). It is possible then that the Frontera cultivar has more antioxidant systems, thereby reducing the damage produced by the oxidants.

Infestation induced levels of H_2O_2 and peroxidases similar to those induced in plants by 40 ppm of ethylene, although, the production of H_2O_2 in plants exposed to ethylene was 10 min earlier than in the aphid infested ones. The increase in ethylene evolution induced by aphids is mediated by unknown events. One of them may be an increase in the level of abscissic acid (ABA), since ethylene and jasmonic acid synthesis seems to be mediated by ABA accumulation during pathogenicity (Peña-Cortés et al., 1995; Koiwa et al., 1997). ABA levels have been measured in extracts of infested barley leaves. No changes were found during the first 48 hr of infestation although, a substantial increase was found after 65 hr of infestation (Cabrera et al., 1994). Further research is needed to elucidate the possible role of ABA in ethylene induction in aphid infested barley leaves.

The ionically and covalently cell wall-bound peroxidase activities of barley seedlings increased more under ethylene treatment than in the control seedlings. The activity increase in the control samples was probably due to the experimental stressing conditions such that endogenous ethylene was produced by the seedlings placed in the sealed flasks. However, a small increase in cell wall-bound peroxidases could induce a rapid cell wall reinforcement by oxidative cross-linking and insolubilization of structural cell wall proteins. The extensin cell wall proteins are the best studied and identified. Being a family of proteins, extensins are also known as hydroxyproline-rich glycoproteins (HRGP) (Bradley et al., 1992; Cassab, 1998). Recently, in cotton cell cultures, a covalent linkage has been found between extensin and a pectin fraction, ramnogalacturan I (RG I), (Qi et al., 1995). The role of extensins still remains to be determined, but they probably facilitate cell wall lignification, acting as a primer for lignin deposition and lignin polymerization (Cassab, 1998; Loukili et al., 1998). Whether lignification of the cell walls in vascular bundles also occurs during infestation is unknown, but certainly it would make penetration of the aphid stylet more difficult.

It is interesting to note that the peroxide accumulation seems to occur before ethylene accumulation in infested plants. Thus, aphid attack may first induce H_2O_2 accumulation and H_2O_2 itself may be in part responsible for the induction of peroxidases and ethylene biosynthesis. However, it is not possible at this stage to know exactly the sequence of these events in the plant tissues. Ethylene, in turn, may induce expression of other genes involved in the reinforcement of plant cell walls (Esquerré-Tugayé et al., 1985).

(Received May 19, 2000; accepted August 30, 2000)

Abstract—The Dufour gland of *Nannotrigona testaceicornis* is a large, wide, pear-shaped sac. The gland secretion consists chiefly of the diterpene ester all-*trans*-geranylgeranyl acetate (64% of the total), together with a complex mixture of small amounts of cyclic ketals; mono-, sesqui-, and diterpene compounds; acetates; and other oxygenated compounds. Samples of *N. testaceicornis* collected at two sites in Brazil and one in México shared the same composition of their glands, suggesting that the species is uniform over this wide geographical area.

Key Words—Hymenoptera, Apidae, Meliponinae, exocrine secretion, geranylgeranyl acetate, terpene, oxidation products.

INTRODUCTION

An accessory gland of the poison apparatus, first described by Dufour (1834), is found in all aculeate Hymenoptera, which include bees, stinging wasps, and ants. It is a sac, surrounded by a single layer of secretory cells, with a duct which in bees opens into the sting chamber below the sting bulb. No common function has

0098-0331/01/0100-0069$19.50/0

been discovered for the Dufour gland in this wide range of insects (Hölldobler and Wilson, 1990). Among some solitary bees, according to Hefetz (1998), the Dufour gland contents are used to form a waterproof lining to the brood cells, e.g., in the ground-dwelling bees *Colletes thoracicus* and *Andrena haemorrhoa* (Hefetz, 1987), or to mark their nest entrances. In another ground-dwelling eusocial bee, *Lasioglossum* (*Euylaeus*) *malachurum*, Dufour gland secretion is probably used in nest-mate recognition.

The chemistry of the contents of the Dufour gland of solitary bees has already been studied in a number of species. In the Colletidae family, the secretion is dominated by saturated and unsaturated macrocyclic lactones as well as hydrocarbons (Hefetz et al., 1979; Albans et al., 1980; Cane, 1981). The Halictidae also contain macrocyclic lactones (Bergström, 1974; Hefetz, 1987), although Duffield et al. (1981) reported the presence of trace amounts of esters. The Dufour gland secretion of Andrenidae bees is composed of a variety of terpene hydrocarbons and terpene esters (Bergström and Tengö, 1974). In two Melittidae species, the Dufour gland secretion is composed of alkyl butanoates (Tengö and Bergström, 1976). Members of the Anthophoridae exhibited a variety of compounds: terpenoids (Batra and Hefetz, 1979), triglycerides (Norden et al., 1980), saturated and unsaturated hydrocarbons (Vinson et al., 1978). Francke et al. (1984), Williams et al. (1986) and Tengö et al. (1982) documented lactones, esters, hydrocarbons, spiroacetals, ketones, and alcohols in the Dufour gland of the Megachilidae.

Within the bees, social behavior is found chiefly in the family Apidae, and particularly in the subfamilies Meliponinae (stingless bees), Apinae (honeybees) and Bombinae (bumblebees). The Dufour gland of workers of *Apis mellifera* is very small, and although much is known about pheromones of honeybees, neither the chemical composition of the secretion nor its function is known. The Dufour glands of very few species of bumblebees have been studied. The secretions are dominated by straight-chain alkanes and alkenes from C_{21} to C_{31}, with some oxygenated compounds, terpenes, and fatty acids (Oldham et al., 1994a; Tengö et al., 1991). Again, the function is unknown.

In Meliponinae, de Lello (1976) described the single gland that opens at the end of the abdomen as homologous with the Dufour gland. The gland varies considerably in size and shape among species of stingless bees. In spite of the large number of species (about 500 and still increasing), no chemical studies of the Dufour gland secretion of Meliponinae have been made until now.

The genus *Nannotrigona* is found throughout southern México and Central and South America. It contains 10 recognized species (Camargo, 1990). The genus is of some importance because certain species of *Nannotrigona* are considered good pollinators for crops. *N. testaceicornis* (Lepeletier) (Apidae: Meliponinae) is used in Japan for the pollination of strawberries (Maeta et al., 1992). The cephalic secretion of this species has been shown to contain 2-methyl-6-

pentyl-3,4-dihydro-2H-pyran (Francke et al., 1985) (for structure, see Figure 3 below). According of Camargo (1990), *N. testaceicornis* is the only species of *Nannotrigona* found in Mexico.

The aim of this work was to learn something of the chemistry of the Dufour gland secretion of stingless bees. We have studied samples of *N. testaceicornis* collected in Brazil and Mexico, first, to see whether there was any variation in the composition of the secretion, since a single species with such a wide distribution might display geographical variations in its secretions. We have attempted to identify the material in the secretion as a preliminary to studying what might be its function.

METHODS AND MATERIALS

Samples of *N. testaceicornis* were collected at Rio Claro and Cosmopólis, two different regions in the state of São Paulo, Brazil, and in Union Juárez in the state of Chiapas, Mexico.

Scanning Electron Microscopy. The abdominal tergites of workers were carefully removed in a solution of cold 2% glutaraldehyde in sodium cacodylate buffer at pH 7.3, so as to expose the abdominal tissues for observation with a Topcon SM-510 scanning electron microscope. For this purpose, the opened abdomens were critical-point dried and coated with a 30-nm layer of gold.

Transmission Electron Microscopy. Worker bees were immobilized by cooling to 3°C, the Dufour glands were dissected and fixed in a solution of 2% glutaraldehyde in sodium cacodylate buffer (0.15 M), at pH 7.2. After 3 hr the glands were rinsed in cacodylate buffer (0.15 M), postfixed in 1% buffered osmium tetroxide for 2 hr and contrasted with uranyl acetate overnight. The material was dehydrated in an increasing series of alcohol and acetate solutions and embedded in Spurr's resin. Ultra thin sections were obtained with a Porter-Blum MT-2 Ultramicrotome, with glass and diamond knives, mounted on a grid, contrasted with lead citrate, and examined in a Zeiss transmission electron microscope.

Gland Dissection. Individual workers of *N. testaceicornis* were cooled in a refrigerator and dissected under distilled water. The Dufour gland was removed and carefully dropped into a thin-walled soda-glass tube (1.8 × 20 mm) previously sealed at one end, and the open end was then sealed in a micro-flame (Morgan, 1990).

Chemical Analysis. Gas chromatography–mass spectrometry was carried out with a Varian Star 3400 CX gas chromatograph linked to a Varian Saturn 4D mass spectrometer. The samples were analyzed using a fused silica column (30 m × 0.25 mm) coated with poly(5% diphenyl–95% dimethyl)siloxane. The oven was programmed from 50°C to 250°C at 15°C/min. The carrier gas was

helium. The injector port temperature was held at 200°C. The sample was heated in the injector to 200°C for 4 min before crushing the capillary, as described by Morgan and Wadhams (1972).

RESULTS

Dissection of worker abdomens of *N. testaceicornis* revealed a large sac at the end of the abdominal tip, which correspond to the Dufour gland (Figure 1). The reservoir opens into the cloacal chamber, from where the secretion may be deposited on the substratum by the tip of the abdomen. The Dufour glands of Meliponinae, like those of ants and other Hymenoptera, originate from the integument and are composed of class 1 cells according to Noirot and Quennedey (1974). The gland reservoir is lined with a single sheet of epidermal cells. Transmission electron microscopy revealed the fibrillar aspect of the procuticle, but

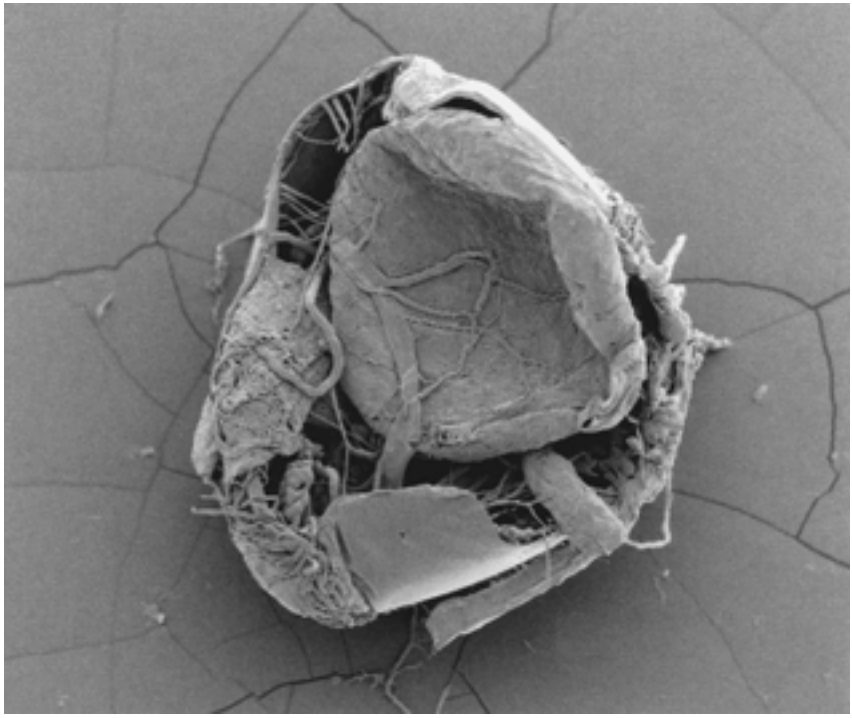

FIG. 1. Scanning electron micrograph of the partially dissected abdominal tip of *N. testaceicornis* (tergites removed) showing the size of the Dufour gland.

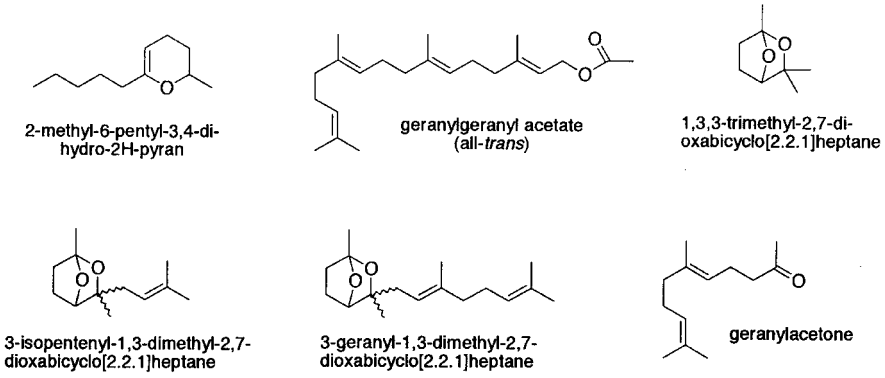

FIG. 2. Structures of some compounds discussed in the text.

contrary to what is found in the Dufour glands of other Meliponinae (Patricio, in preparation), the epicuticle is not smooth, but strongly crenellated. Since no cuticular pores were evident, the secretion from the internal vesicles may cross the cuticle by diffusion, as has been observed in some glands of termites (Quennedey, 1982). The vesiculated smooth endoplasmic reticulum is typical of pheromone-producing glands of invertebrates (Billen, 1987). Multilamellar bodies and storage vesicles are suggestive of intense cellular metabolism of these secretory cells. The epithelium of the glandular duct was composed of thin cells, indicating poor or no secretory activity.

The GC-MS analysis of the Dufour gland secretion of the three samples of *N. testaceicornis* showed that they had approximately the same composition, with the same major compounds and many minor components (Figure 2). Four individuals from each area were analyzed and their chromatograms compared. There was as much variation between individuals as there was between samples from different areas. We therefore concentrated on the identification of the first sample from Rio Claro. As learned from the microscopic examination, the gland forms a relatively large part of the abdominal organs and contains about 5 μg of secretion on average. The most notable feature of the composition was the relatively large amount of one component, all-*trans*-geranylgeranyl acetate (Figure 3), an acyclic diterpene ester (Table 1). There was a very small amount of the corresponding alcohol, *trans*-geranylgeraniol, and the corresponding lower homolog *trans*-farnesyl acetate. Retention times and mass spectra for these compounds were confirmed by comparison with authentic samples. Farnesyl acetate and geranylgeranyl acetate were prepared from acetyl chloride and the respective alcohols. Trace amounts of springene, the hydrocarbon corresponding to dehydrated geranylgeraniol were also seen (peak 30). There was also a set of oxidation products derived from geranylgeraniol (or its acetate), the simplest

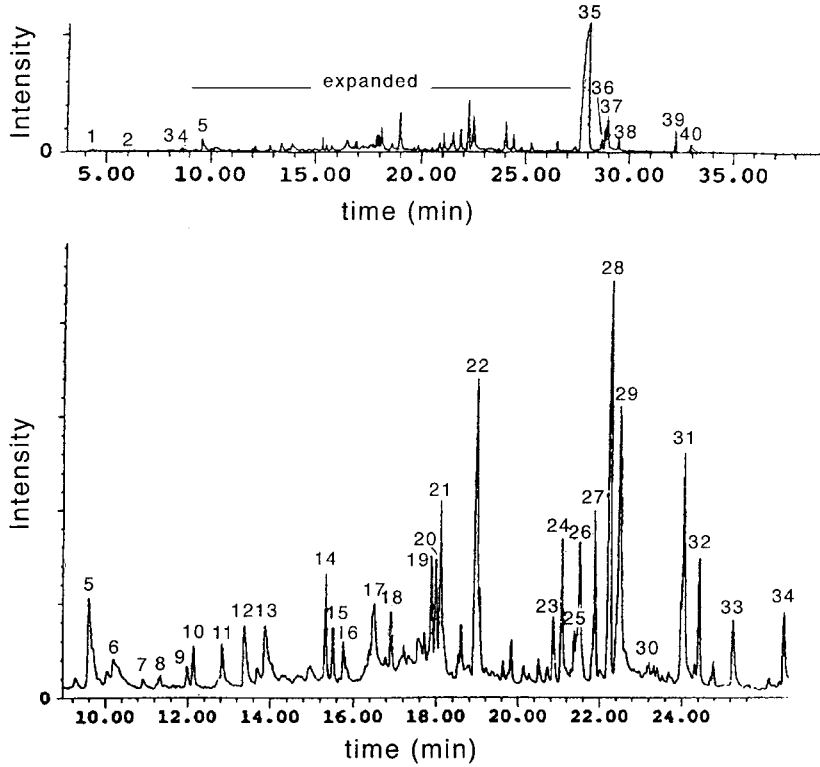

FIG. 3. Total ion current chromatogram of the Dufour gland secretion of *Nannotrigona testaceicornis*. Peak numbers refer to Table 1. The lower figure is an expansion of the region 10–25 minutes with many small peaks.

of these is 1,3,3-trimethyl-2,7-dioxabicyclo[2.2.1]heptane (Figure 3). The higher homologs can exist in two diastereomeric pairs, so two peaks are seen for each homolog of these compounds (peaks 14 and 15 and peaks 19 and 21; Figure 3). Identification of these compounds was provided by the work of Oldham et al. (1994b). Neral, geranial, geranylacetone, and the acetate esters were identified by comparison of their mass spectra and retention times with those of synthetic compounds. Farnesal was identified by comparison with the spectrum of material made earlier. As a sample was not available for retention time comparison, the isomer could not be identified with certainty, but was probably all-*trans*.

The second most abundant substance was identified as hexadecatrienal (M^+ 234). The double-bond positions were unknown, so the exact structure could not be identified, and no mass spectra were available for direct comparison. The next

Total amount (μg/gland)		4.8

[a] Peak numbers refer to Figure 2.
[b] Unconfirmed identification.

in quantity was peak 31 (Figure 3), identified as hexatrienyl acetate (M^+ 278), with the ions characteristic of a long-chain triunsaturated alkene, plus a strong ion at m/z 43 and a weak ion at m/z 61, characteristic of an acetate group. The next in quantity were tetradecyl acetate (peak 27) followed by geranylacetone (peak 17), which can also be regarded as an oxidation product of geranylgeraniol. The monoterpene aldehydes geranial and neral, together referred to as citral, comprised about 2.25% of the secretion. Peak 29 had a molecular mass two units greater than hexadecatrienal, and a mass spectrum very similar to that of peak 26. We deduce it is a hexadecadienal, but the difference in retention times should be much less if these two differ only in the presence of one double bond. Compound 4 is a structural isomer of compound 2. It has the same molecular mass (M^+ 142) and a similar mass spectrum [m/z 109 (5%), 100 (3), 82 (18), 72 (35), 71 (32), 67 (26), 57 (25), 43 (100)]. Its spectrum does not correspond to that of frontalin, which has the same mass and similar structure to compound 2. Compound 5 has a molecular mass of 138 and a mass spectrum close to that of geraniol. It must therefore be a 2,6-dimethyloctadiene or dihydroocimene, but we lack the synthetic standards to determine the double-bond positions. Compounds 9 and 10 are an isomeric pair of mass 140 ($C_{10}H_{16}O$), probably dimethylnonadienols, *cis* and *trans*, with a $(CH_3)_2COH$—because of the strong m/z 59 ion [m/z 140 (<5%), 110 (30), 95 (45), 69 (42), 59 (80), 43 (80% in compound, 100% in compound 10), 41 (100% in compound 9, 95% in compound 10)].

The component labeled 20 gave a mass spectrum with base peak of m/z 95, which resembles the mass spectrum of isoborneol, but the substance has a higher molecular weight than isoborneol. The structure of the unknown may be an isoborneol derivative with a long-chain alkyl substituent. Compounds 36, 37, and 38 are all geometric isomers of geranylgeranyl acetate. Their spectra are all similar to that of compound 35. They all differ from geranylgeraniol by having significantly strong ions at m/z 43, which is virtually absent in geranylgeraniol. The remaining 3.6% of the total consisted of seven unidentified terpenes (Table 1).

DISCUSSION

Unlike the tiny Dufour gland of honeybee workers, that of the stingless bee *N. testaceicornis* is a relatively large organ, filling the posterior part of the abdomen and containing micrograms of liquid secretion. The most important component by far is geranylgeranyl acetate. This compound has been found before in labial glands of males of several species of bumblebees (Kullenberg et al., 1973; Bergström et al., 1996; Bergman and Bergström, 1997), where it is used for territorial marking. The territorial marking pheromone from the male bee-wolf *Philanthus pulcher* (Hymenoptera, Sphecidae) contains a mixture of ethyl oleate and geranylgeranyl acetate as major components (McDaniel et al.,

1992). The Dufour gland of some species of *Formica* ants also contains geranylgeranyl acetate (Bergström and Löfqvist, 1973). All-*trans*-geranylgeranyl acetate and geranylgeraniol are components of the recruitment pheromone of the ponerine ant *Ectatomma ruidum* (Bestmann et al., 1995). The compounds have also been found in the female sex pheromone of click beetles (*Agriotes sputator*, *A. obscurus*, *Sinaptus*, and *Melanotus* species, Coleoptera, Elateridae) (Yatsynin et al., 1996) and even in a mammalian secretion, from the dorsal glands of the collared peccary, *Tayassu tajacu* (Mammalia, Tayassuidae) (Waterhouse et al., 1996). We have found geranylgeraniol in the Dufour glands of the Old World army ant *Aenictus rotundatus* and the isomer geranyllinalool in the Dufour glands of the New World army ant *Eciton burchelli* (Keegans et al., 1993).

Oldham et al. (1994b) found a series of bicyclic ketals accompanying geranylgeraniol, the principal component in the Dufour gland of the army ant *Aenictus rotundatus*. The simplest of these ketals is 1,3,3-trimethyl-2,7-dioxabicyclo[2.2.1]heptane (Figure 2). It was accompanied by higher homologs containing an isopentenyl or geranyl group (Figure 2). Two isomers were seen for each. We deduced that these compounds were oxidation products, either biochemical or atmospheric, of the geranylgeraniol. The same series of ketals has been observed in this work, always in very small quantity. 1,3,3-Trimethyl-2,7-dioxabicyclo[2.2.1]heptane was first identified in the aroma of Granny Smith apples (Stanley et al., 1986), and then identified in several species of ants of the subfamily Dolichodorinae (Tomalsky et al., 1987; Cox et al., 1989, see also Francke and Schröder, 1999). The complete series of homologs was recognized by Oldham et al. (1994b). Reexamination of the chromatograms from Keegans et al. (1993), Oldham et al. (1994b), and the present work shows that the first peak of each isomeric pair of homologs is the larger one. Study of molecular models indicates this must be the 3*S*,4*S*, 3*R*,4*R* enantiomeric pair. There are no reports of the presence of this substance in the secretion of bees that contain geranylgeraniol or its acetate. We also identified 6-methyl-5-hepten-2-one, geranylacetone, and farnesylacetone, the supposed biosynthetic precursors of these compounds, in *A. rotundatus* (Oldham et al., 1994b) and *E. burchelli* (Keegans et al., 1993), which adds support to the proposed structures and origins.

We found no differences in the analysis of the Dufour gland secretion of *N. testaceicornis* samples from Brazil and Mexico in the present study, although geographical variation is frequently encountered in other insect secretions with pheromonal activity. For example, the green stink bug, *Nezara viridula* has a worldwide distribution in the tropics and subtropics. The male pheromone includes various sesquiterpene compounds. Bugs from Brazil lack a sesquiterpene component that is present in populations from the southern United States and southern France, and sesquiterpene isomer ratios differ between French and North American bugs (Aldrich, 1988). In Lepidoptera, also, geographical variation of pheromone blends has been found. Hansson et al. (1990) found that

the sex pheromone of *Agrotis segetum* include three main components, (*Z*)-5-decenyl acetate, (*Z*)-9-dodeceyl acetate, and (*Z*)-9-tetradecenyl acetate. The ratio of these compounds in populations from Sweden, Britain, France, Armenia, and Bulgaria show marked differences. On the other hand, *Pectinophoroa gossipiella*, the pink bollworm, shows little variation among insects from California, Argentina, Brazil, China, Egypt, Mexico and Pakistan (Haynes and Baker, 1988).

Acknowledgments—We thank C. Mansfield, International Flavours and Fragrances Ltd., Suffolk, U.K., for the sample of geranylgeraniol; M.C. Guadalupe Nieto for helping with the scanning electron micrographs; and M.C. Manuel Rabanales for providing the *Nanotrigona* samples collected in México. This work was partly supported by CONACYT, México through a studentship to L.C.L.

(Received September 14, 2000; accepted August 30, 2000)

Abstract—CE_{145-66} is an improved early-maturing grain sorghum genotype, increasingly grown by farmers in the Sahelian part of Senegal. This genotype is known to have negative effects on the following groundnut crop, because of the release of allelopathic phenolic compounds into the soil. We have assessed the synthesis of phenolics in sorghum vegetative parts and the variations in synthesis between years and sites. Total phenols and phenolic acids in the aerial parts and roots of flowering sorghum plants from 52 farmers' fields at two sites (Sagnanème and Médina) in Senegal in 1996 and 1997 were measured. Thirty-eight soil samples, collected after the sorghum harvest, from sorghum rows and interrows also were analyzed for their phenolic content. Total phenols reached 1.1–1.5% of root dry weight and 1.1–2.2% of aerial parts dry weight, with little variation between sites, and large variability between years, presumably due to climatic conditions. Eight phenolic acids and three associated aldehydes were identified by HPLC, with *p*-hydroxybenzoic, *p*-coumaric, and ferulic acids the most abundant. Their totals reached 2.9–3.2 mg/g in 1996 and 2.6–2.8 mg/g in 1997 for the aerial part; and 3.3–3.6 mg/g in 1996 and 2.8–3.3 mg/g in 1997 for roots. In soils under sorghum rows, the mean water-soluble total phenols increased from 4.6 in 1997 to 6.7 μg/g in 1998 in Sagnanème, and from 3.8 in 1997 to 5 μg/g in 1998 in Médina. The concentrations of total phenols and phenolic acids were higher in rows than in interrows. All the phenolic monomers identified in vegetative parts were recovered in associated soil samples, with vanillic and *p*-hydroxybenzoic acids the most abundant. Finally, variability in plant phenolic content seemed more due to climatic than to cropping or soil factors,

as differences between years appear more important than differences between or within sites.

Key Words—Agricultural soils, allelopathy, phenolics, sorghum.

INTRODUCTION

Sorghum [*Sorghum bicolor* (L.) Moench] is a widely produced agricultural crop. Its aerial vegetative parts and seeds are used for many purposes. The vegetative parts are used for animal forage and rural construction, and sorghum grains is a basic food source for many. Grain sorghum is the second most important cereal crop grown under pluvial conditions in Senegal. $CE_{145\text{-}66}$ is an improved early-maturing grain sorghum genotype that is well adapted to the Sahelian zone (dryland) growing conditions in Senegal. Hence, more and more acreage is under cultivation in this part of the country.

Sorghum is also known to possess strong phytotoxic potential against weeds (Einhellig and Rasmussen, 1989; Weston, 1996), against itself (Guenzi and McCalla, 1962, 1966; Chopart and Nicou, 1973; Burgos-Leon et al., 1980), and against other crops (Chopart and Nicou, 1973; Delafond and Burgos-Leon, 1978; Burgos-Leon et al., 1980; Nicou, 1980; Ben-Hammouda et al., 1995). This toxicity is due to the production and release of phenolic compounds, including phenolic acids (Burgos-Leon et al., 1980; Ben-Hammouda et al., 1995) and sorgoleone (Einhellig and Souza, 1992; Einhellig et al., 1993; Weston et al., 1997, 1999). Sène et al. (2000) showed that phenolic acids left in the soil after a $CE_{145\text{-}66}$ crop affected the germination of groundnut. However, few studies have been done on phenolic metabolism and its variability in the vegetative parts of sorghum, and the release and decomposition of such compounds have never been studied under field conditions.

This study was done to enhance our knowledge of phenolic production by sorghum vegetative parts, and to establish the phenolic pattern of sorghum aerial parts and roots in agricultural conditions. A second aim was to compare patterns to those of associated soils, in order to assess the influence of this species on soil composition and subsequent fertility. Large sampling sets of plants (N = 52) and of soils (N = 38) were chosen directly in farmer's fields under natural conditions (wet season followed by a dry season) to take in account and estimate the variability of these compounds.

METHODS AND MATERIALS

Study Sites. Two sets of in situ measurements were made in farmers' fields (in 1996 and 1997) to examine the levels of phenolic compounds present in

sorghum aerial parts and roots. The fields were located at two sites in the central groundnut producing region of Senegal, at the villages of Sagnanème (latitude 14°N, longitude 16°15′W) and Médina (latitude 14°20′N, longitude 15°20′W). Twelve fields were monitored in Sagnanème and 15 in Médina in 1996, and 8 and 17, respectively, in 1997. The soils are ferralitic or ferruginous tropical, with 61–78% sand in the 0- to 10-cm layer. The crops were grown without fertilizer, herbicides, or additional irrigation, similar to the farmers' cultivation methods. Weeds were removed by hand.

Sampling Methods. Sorghum was sown by the farmers at the beginning of the rainy season, which lasts from July to October. A plot 25 × 25 m was marked out in each field on day 15 after emergence. These plots were divided into 25 subplots of 5 × 5 m; five of these subplots were randomly chosen for plant measurements and five others for soil measurements.

Ten flowering sorghum plants were collected from each subplot. Aerial parts and roots of the 10 plants were separated and pooled as a sample of aerial parts or a sample of roots. Samples were dried at 70°C for 96 hr and ground to a homogeneous powder. The five samples of ground aerial parts from each field were pooled and a 50-g sample was taken for phenol analysis. The root samples were treated similarly.

Soil samples were collected from the same fields (from five fields in Sagnanème and eight fields in Médina in 1997, but from all the fields in 1998) in June 1997 and April 1998 (during the dry seasons following the sorghum crop), from the prior sorghum rows and interrows. A total of three soil samples were taken from rows and three from interrows at 0–40 cm depth on each soil subplot. The samples (15) from previous sorghum rows at each field were mixed, and a 250-g sample was taken for phenol analysis. The samples taken from interrows were treated similarly. The soil was sampled before the beginning of the rainy season in 1997, but the rainy season started two weeks prior to soil sampling in 1998. The latter samples were taken after a total rainfall of 157 mm in Sagnanème and 91 mm in Médina. The 1997 and 1998 samples were air-dried for three months.

Plant Analysis. Dried ground roots or aerial parts (500 mg) were extracted twice (100 ml/75 ml) by refluxing with 70% (v/v) boiling ethanol for 20 min. The extracts were combined and evaporated under vacuum. The residues were dissolved in a standard volume of hot distilled water, and aliquots were taken for total phenol determination, with the Folin-Ciocalteau reagent and gallic acid as a standard. Results are expressed as milligrams of gallic acid equivalents.

Although most phenolic compounds are in the leaves as glycosides, the glycosidic bonds are rapidly cleaved at the beginning of senescence and the free phenolics accumulate in surface layers. Mild acidic hydrolysis was used to extract phenolic monomers from ground aerial parts. This type of hydrolysis also releases anthocyans from condensed tannins (proanthocyanidins) and allows quantification.

Dried, ground material (1000 mg roots or aerial parts) from each sample was hydrolyzed with 80 ml 2 M HCl (at 100°C, under O_2) for 40 min, and the resulting solutions were then extracted three times with diethyl ether. The residual aqueous extracts were filtered, and the anthocyan concentrations estimated by measuring at the wavelength of maximum absorbance. The organic extract was evaporated to dryness, and the residues were dissolved in ethanol and stored at −18°C until analyzed for phenolic acid content by HPLC.

Soil Analysis. Free (active) phenols were estimated in aqueous extracts to assess the extracellular persistence of phenolic compounds in humus. Water-soluble phenolic compounds were extracted for each sample by shaking approximately 100 g dry weight soil with 200 ml distilled water under N_2 for 14 hr at 10°C.

The solutions were filtered, and one aliquot was used to measure total phenols as above. About 500 ml of each water extract was then acidified with 2 M HCl and extracted three times with diethyl ether. The ether extracts were evaporated to dryness, and the resulting residues were dissolved in a known volume of ethanol and stored at −18°C.

Liquid Chromatography. The phenolic monomers were separated with a Waters 600 Controller, equipped with the diode array detector (Waters 996) and Millenium software. The samples (20 μl) were injected onto a column (250 × 4.6 mm) filled with μBondapak C_{18}, 10 μm, and eluted with a gradient of solvent A (0.5% acetic acid in distilled water) and solvent B (0.5% acetic acid in acetonitrile). The phenolic acids were separated by a linear gradient (flow rate 1.5 ml/min) from 0% to 20% B in 45 min, with 15 min of reequilibration between samples. They were further identified and quantified by comparing their UV spectra and retention times with those of standard compounds. About 90% of the products detected by chromatographic analysis from both plant and soil extracts were identified.

Statistical Analysis. Individual field results were not considered in this paper. Means across sites and across years were compared by the Mann Whitney *U* test. The Wilcoxon signed-ranks test for dependent variables was used to compare data from roots and aerial parts, and soil data from rows and interrows. Proportions (%) of individual phenolic acids were compared across years or sites by the binomial test.

RESULTS

Polyphenols in Aerial Parts of Sorghum. The total phenol concentrations estimated by the Folin-Ciocalteau reagent were 2.0–2.2% of the sorghum DW in aerial portions in 1996 at both sites, but only about half of this value in 1997 (Table 1). Some of these products were identified as phenolic monomers, and

[a] Total phenols are expressed in mg gallic acid equivalents/g dry weight; and the sum of all the identified phenolic acids in mg/g dry wt. Letters (a,b) indicate differences between years (Mann-Whitney test; $P < 0.05$). No differences (Mann-Whitney test; $P < 0.05$) were detected between sites except for total phenols in 1996 (α,β). No differences between phenolic acid relative weights (%) for 1996 and 1997 were detected by the binomial test. All values are mean ± SD.

their contribution to the amount of total phenols varied significantly, depending on the year. In 1996, they accounted for 14–15% at both sites and for 24% at both sites in 1997. Phenolic monomers included eight acids and two aldehydes, with some of them in very small amounts, including vanillin and syringic, protocatechuic, gentisic, and vanillic acids. *p*-Hydroxybenzoic acid, *p*-hydroxybenzaldehyde, *p*-coumaric and ferulic acids, and to a lesser extent, caffeic acid, were well represented. Their individual contributions to the total phenolic acids remained relatively stable across years and sites. These five acids accounted for 87–93% of the total acids. There was no difference between the two sites except for total phenols, which were more concentrated in aerial parts from Sagnanème in 1996 than in those from Médina. The lack of absorbance of the acidic extract at 500–600 nm indicated the absence of proanthocyanidins (condensed tannins) from aerial parts.

Sorghum Polyphenols in Roots. The roots also contained more total phenols at Sagnanème (1.6% dry wt) than at Médina (1.1%) in 1996 (Table 2). The concentration of phenolic acids in the roots was also higher at Sagnanème than at Médina in 1997. The proportion of phenolic acids in roots compared to the total phenol compounds varied between 24% and 27% (in 1997 and 1996, respectively). The patterns of phenolic monomers of the roots were the same as those of the aerial parts, except that the former contained less caffeic acid. *p*-Hydroxyben-

[a] Total phenols are expressed in mg gallic acid equivalents/g dry weight and the sum of all the identified phenolic acids in mg/g dry wt. Letters (a,b) indicate differences between years (Mann-Whitney test; $P < 0.05$). Differences between Sagnanème and Médina (Mann-Whitney test; $P < 0.05$) are indicated by Greek superscripts (for total phenols in 1996 and phenolic acids in 1997). Superscript letters (c,d) indicate differences between phenolic acid relative weights (%) in 1996 and 1997 (binomial test; $P < 0.05$). See values and mean ± SD.

zoic acid, *p*-hydroxybenzaldehyde, *p*-coumaric, and ferulic acids accounted for 91–94% of total phenolic acids. No proanthocyanidins were detected in sorghum roots.

Water-Soluble Compounds in Soil. As previous experiments (data not shown) have shown that amounts of water-soluble polyphenolics extracted from dried soils were inferior compared to frozen soil, this latter process was preferable. Unfortunately, due to field conditions, freezing of soil samples was not possible. For this reason, underestimation of concentrations was foreseeable in our study. As a result, data were analyzed by comparing sites or years rather than in terms of absolute concentration.

The total water-soluble phenols extracted from soils under sorghum rows increased from 4.6 in 1997 to 6.7 μg/g dry wt in 1998 (at Sagnanème), and from 3.8 in 1997 to 5.0 μg/g dry wt in 1998 at Médina (Table 3). Total phenols were more abundant under previous sorghum rows than under interrows in both years and at both sites (Table 3). In 1997, amounts under interrows were 89% of those under rows, and these proportions decreased to 34% and 38% in 1998, respectively, for Sagnanème and Médina. Phenolic acids also increased in concentrations from 1997 to 1998, with concentrations eightfold higher at Sagnanème and 18-fold higher at Médina (Table 3). Differences between rows and

[a] Total phenols are expressed in μg gallic acid equivalent/g dry wt and the sum of all the identified phenolic acids in ng/g dry wt. Letters (a and b) indicate differences between rows and interrows (Wilcoxon test; $P < 0.05$). Differences (Mann-Whitney test; $P = 0.05$) between 1997 and 1998 are indicated by Green letters (α, β). Letters (c and d) indicate differences between phenolic acid relative weights (%) in rows and interrows (binomial test; $P < 0.05$). All values are mean ± SD.

interrows were not significant in 1997, whereas in 1998, phenolic acid concentrations were four to six times higher in soils under sorghum rows than in soils from interrows.

The same phenolic acids found in the soils were all found in sorghum vegetative parts, except for syringaldehyde, which was found only in 1997 in Sagnanème soils. All 10 acids from sorghum vegetative parts were found in at least one soil, but their weight in total acids were very different. Protocatechuic, gentisic, caffeic, and ferulic acids were not found in any soils in 1997, including those from rows or interrows. *p*-Hydroxybenzoic acid, vanillic acid, and syringaldehyde accounted for 87–96% of the acids found in the soils in 1997, and for 65–83% of those found in 1998. *p*-Coumaric acid was more abundant in 1998 than in 1997, accounting for 7–15% of the total phenolic acids in 1998 and 0–2% in 1997.

DISCUSSION

Phenolic Metabolism in Sorghum Vegetative Parts. Although sorghum grain is a major source of condensed tannins (Gupta and Hashlam, 1978), tannins were not detected in the vegetative parts of sorghum tissues. Many of the total phenols extracted (15–30%) were in the form of phenolic monomers, although direct comparisons of these two parameters is difficult because of the relative Folin-Ciocalteau results (in gallic acid equivalents). Other phenolic compounds, including those that were detected by HPLC but not identified (one or two compounds in plant or soil extracts), require further analysis to provide a more complete view of sorghum phenolic metabolism.

Within one site and one year, relatively low variability was observed. Coefficients of variation (mean value) were, for total phenols, 14% in aerial parts and 15% in roots, and for phenolic acids 15% in both aerial parts and roots. Because these results were obtained with a large number of samples, they clearly indicate that the sorghum cultivar $CE_{145\text{-}66}$ contains higher concentrations of phenolics than other species, such as *Dennstaedtia punctilobula* leaves (0.4–1.2 mg/g equivalent tannic acid) (Dustin and Cooper-Driver, 1992), or *Triticum aestivum* roots (0.5 mg/g) and shoots (1.8 mg/g equivalent tyrosine) (Brown et al., 1984), or component parts of three other sorghum cultivars (leaves: 0.208–0.246, culms: 0.060–0.202, glumes: 0.120–0.193 mg/g, and roots: 0.166–0.215 mg/g equivalent acid ferulic) (Ben-Hammouda et al., 1995). The phenolic acid concentrations were also high in roots, where they reached one third of the total phenol concentration. Other genotypes contained (mg/g) 0.012–0.079 in glumes, 0.046–0.728 in leaves, 0.009–0.117 in culms, and 0.026–0.205 in roots (Ben-Hammouda et al., 1995). *Sorghum vulgare* had a total phenolic concentration of 0.421 mg/g in roots (Burgos-Leon et al., 1980). In contrast, Woodhead and Bernays (1978) found a higher phenolic acid level in sorghum leaves (5.4 mg/g). Burgos-Leon

et al. (1980) and Ben-Hammouda et al. (1995) found an allelopathic effect of these sorghum genotypes and species on other crops. The $CE_{145\text{-}66}$ genotype, with which phytotoxicity on groundnut germination has been shown, could be at least as allelopathic as those sorghum types. Sorghum sundangrass hybrid shoot tissues also have been reported to contain high levels of *p*-hydroxybenzoic acid and aldehydes that were well correlated with allelopathic potential of shoot tissues themselves (Weston et al., 1989). In our study, cinnamic phenolic monomers (*p*-coumaric, ferulic, and caffeic) were particularly abundant in $CE_{145\text{-}66}$. The phenolic acids identified in its vegetative parts were more varied than those previously found by the above authors in other sorghum varieties or species, probably because they were restrained by technical limits of detection. For instance, Woodhead and Bernays (1978) found no protocatechuic or syringic acids or vanillin in the sorghum genotype they studied, while Burgos-Leon et al. (1980) identified only *p*-coumaric, protocatechuic, and *o*-hydroxybenzoic acids. The other phenolic compounds they identified occurred at trace levels. More recently, Ben-Hammouda et al. (1995) found ferulic, *p*-coumaric, syringic, *p*-hydroxybenzoic, and vanillic acids.

Total phenol concentration in the aerial plant parts was higher than in the roots in 1996 and 1997, but phenolic acid content in roots was equal to or higher than that in aerial parts. The relatively high concentrations of phenolic acids in roots compared to aerial parts is important for the management of farmers' cropping systems because aerial parts are completely removed from the fields for animal feed or other uses. Decomposing roots are thus likely to be the major source of phenolics and, hence, of allelopathic effects.

Variations Between Sites and Between Years. Comparisons of phenolic concentrations in roots and aerial parts between Sagnanème and Médina revealed small but sometimes significant differences. Environmental and agronomic factors likely explain this variability, including climate and soil fertility, since the same variety was grown at both sites. Médina has a drier climate (324 mm rainfall in 1996 and 403 mm in 1997), compared to Sagnanème (622 mm in 1996 and 932 mm in 1997). Soils are less fertile in Médina than in Sagnanème (Sène, 1999). The drop (by a factor of 2) in phenolic production in aerial parts between 1996 and 1997 could be due mainly to climatic factors (rainfall, radiation), which were very different in the 1996 and 1997 growing seasons. Rainfall was about 1.5 times greater in Sagnanème, and 1.25 times greater in Médina in 1997 than in 1996. As a moderate water deficit is believed to stimulate secondary metabolite synthesis (Horner, 1990; Koricheva et al., 1998), the water stress that occurred in 1996 could have resulted in increased phenolic production and then increased allelopathic potential. The between-sites and between-years differences were far greater for total phenols than for phenolic acids, and for aerial parts than for roots. Nevertheless the same pattern of acids has been found through years and sites, for both aerial and subterranean parts.

Phenolic Compounds in Soils. Although both plant biomass (Sène, 1999) and phenolic production were much lower in 1997 than in 1996, the highest concentration of phenolics in soils associated with sorghum occurred in 1998, rather than 1997. Total phenol concentrations in the soils that supported $CE_{145\text{-}66}$ were about 10- and 100-fold higher than those reported by Ben-Hammouda et al. (1995) from soils under diverse sorghum genotypes (70–200 ng/g). The patterns of phenolic acids found in the soils we assayed were the same as those identified in aerial parts and roots, confirming that sorghum is probably the main source of phenolic acids for its associated soils. The differences in the respective weights of these acids between plant and soil were due to biotransformations that occur during senescence, such as transformation of syringic acid to syringaldehyde, and the emergence of vanillic acid and vanillin following lignin breakdown. These phenolics therefore probably came mainly from sorghum root exudates or root decomposition, although leaching of aerial parts by rain prior to cropping is possible. It is likely that these phenolic acids remaining in soils after the sorghum crop had a negative impact on groundnut germination (Sène et al., 2000). Two of the major phenolic acids found in the soils (*p*-hydroxybenzoic and vanillic acid) were the same as those identified by Ben-Hammouda et al. (1995), which they found to be transmitted to the soil by root exudates, and which were reported by Rice and others to be active as phytoinhibitors (Rice, 1984; Weston et al., 1989). In the same way, synergistic inhibitory effects of vanillic and *p*-hydroxybenzoic acids (Einhellig and Rasmussen, 1978), or *p*-coumaric and ferulic acids (Einhellig et al., 1982) towards grain sorghum have been observed.

The amounts of total phenols and phenolic acids in the soil were lower in 1997, when samples were taken two weeks after the start of the rainy season, than in 1998. However, phenolics were more abundant in sorghum roots in 1996 than in 1997. Phenolics can be released from rotting roots and degraded by microorganisms (Paul et al., 1994). Burgos et al. (1980) found that *Aspergillus* spp. and *Enterobacter cloacae* quickly degraded sorghum phenolic acids in natural soils. It is likely that a great portion of the phenolics released in 1997 by the roots had been broken down, before sampling, by microbial activity following rainfall and soil imbibition. In contrast, the dry soils from 1998 were collected before the renewal of these activities. The large between-years differences in soil phenolic content might be attributed, therefore, to the differences in the sampling date and not necessarily to differences in the sorghum phenolic content. This would indicate that breakdown occurs rapidly in soil, thus leading to a decrease in phenolic compounds as soon as the rainfall season begins. This is also supported by the fact that *p*-hydroxybenzoic acid, vanillic acid, and their associated aldehydes, which were highly concentrated in the soils in 1997, are the least easily degraded phenolics in the soil (Morita, 1981; Maciack and Harms, 1986).

The total phenol contents of soil from previous sorghum rows were higher than in soil from interrows in 1997 and in 1998. The phenolic acid content of

soil samples from rows and interrows of previous sorghum were low and not significantly different in 1997, but in 1998, previous sorghum rows had four or five times higher concentrations of phenolic acids than interrows. A greater suppressive effect on succeeding crops would be expected in the prior sorghum rows than in interrows in farmers' fields, as shown by Sène et al. (2000) in certain fields. The spatial difference in the allelopathic potential of the soil from prior sorghum rows and interrows suggests that detrimental allelopathic effects from sorghum can be partly managed by cultural practices. For instance, sowing the succeeding crop in previous sorghum interrows may limit the residual allelopathic effect of sorghum; waiting for the beginning of rainy season before seeding is also a way to benefit from phenolic breakdown in the soil.

Finally, the same qualitative pattern of phenolic acids was found in vegetative parts of sorghum (var. $CE_{145\text{-}66}$) through a wide range of growing conditions, and variability in content seemed more due to climate than cropping or soil factors, as differences between years appear more important than differences between or within sites.

Acknowledgments—The field experiments were supported by the ISRA/USAID project "Natural Resource Based on Agricultural Research" (NRBAR). Plant and soil analyses were supported by the Département AGER, INA P-G, Paris. We thank Xavier Puthod for his work. The authors thank François Pellissier for help and advice and Owen Parkes for revising the English text.

(Received May 1, 2000; accepted August 30, 2000)

Abstract—The buffy-headed marmoset (*Callithrix flaviceps*) is apparently the only predispersal herbivore of the seeds of *Siparuna guianensis* at the Caratinga Biological Station in southeastern Brazil. Both the fruit receptacles and the frutioles (seeds) of *S. guianensis* are relatively rich in nutrients such as carbohydrates, proteins, and lipids, but the receptacles contain high concentrations of benzylisoquinoline alkaloids. The latter presumably act as a qualitative chemical defense, impeding the access of potential predators to the alkaloid-poor frutioles. However, on ripening, the receptacle splits open, exposing the frutioles, which enables *C. flaviceps* to avoid the plant's chemical defenses effectively. Taking care to avoid contact with the receptacle, the marmosets pluck out the frutioles and ingest the seeds. Qualitative and quantitative changes (in particular a significant reduction in daily ranging) in the marmosets' behavior during the period when *S. guianensis* frutioles were accessible indicate that this was a preferred plant resource. This is the first record of the consumption of *S. guianensis* seeds by callitrichine monkeys (which are not known to be systematic seed eaters), despite the fact that both are widely distributed in the Neotropics. It is thus possible that the

behavioral strategy observed here is a unique phenomenon resulting from a specific combination of factors, including the abundance of *S. guianensis* within the study area. The lack of other records may nevertheless be a result of insufficient sampling effort, in which case, the feeding strategies of callitrichines may have an important influence on the reproductive biology of *S. guianensis* in many areas.

Key Words—*Callithrix flaviceps*; *Siparuna guianensis*; Monimiaceae; chemical ecology; benzylisoquinoline alkaloids; seed eating; Brazilian Atlantic Forest.

INTRODUCTION

Marmosets (*Callithrix* spp., sensu Schneider and Rosenberger, 1996), the smallest-bodied extant simians (mean adult body weights 125–350 g), are widely distributed in the Neotropics south of the Amazon/Japurá river system and east of the Andes (Hershkovitz, 1977; Rylands et al., 1993). The key feature of marmoset ecology is a unique set of adaptations for the dietary exploitation of plant exudates, which these monkeys are able to obtain systematically by gouging the bark of gum-producing plants with their specialized lower anterior dentition (Coimbra-Filho and Mittermeier, 1976) and digest efficiently by fermentation in an enlarged cecum (Ferrari and Martins, 1992). Marmosets thus have access to an alternative to fruit as a source of carbohydrates that allows them to occupy, successfully, marginal and highly seasonal habitats in which most larger-bodied platyrrhines are rare or even absent.

Marmosets also exploit a variety of other plant resources, including fruit, nectar, and flowers, as well as fungi and both vertebrate and invertebrate prey (Stevenson and Rylands, 1988; Ferrari et al., 1996; Passamani, 1996; Veracini, 1997; Digby and Barreto, 1998). However, the systematic eating of seeds—as opposed to their incidental ingestion during fruit feeding—has not been recorded previously for either marmosets or other callitrichines (*Callimico*, *Leontopithecus*, and *Saguinus*), that are not specialized for gummivory. By contrast, seed eating is relatively common in medium-sized (body weight 2–4 kg) platyrrhines, the sakis and uakaris (Pitheciinae), and the capuchins (*Cebus* spp.). The former are specialized morphologically (Kinzey and Norconk, 1993) for this type of feeding behaviour, whereas capuchins rely more on their behavioral adaptability (e.g., Peres, 1991). This suggests that body size may be one important factor limiting seed-eating in callitrichines.

Chemical defense is one of the numerous mechanisms used by plants to deter mammalian herbivory, and the vast majority of deterrent substances are products of the secondary metabolism (Harborne, 1991). Most, if not all higher plants contain some kind of organic compound that is potentially toxic to animal browsers (Harborne and Turner, 1984). The feeding behavior of herbivores is

strongly influenced by secondary products, which determine the texture, taste, and flavor of plants (Luckner, 1990), and reinforce foraging strategies aimed at avoiding or minimizing their toxic effects (Leitão et al., 1999). In broad terms, plant chemical defenses can be seen as being either qualitative or quantitative. Quantitative defenses, such as essential oils, resins, and tannins, tend to reduce the ability of herbivores to digest or assimilate nutrients, whereas qualitative secondary compounds have a cumulative toxic effect (e.g., alkaloids, cyanogenic glycosides) (Luckner, 1990).

The present study focuses on the qualitative chemical defenses, in particular benzylisoquinoline alkaloids, of the Neotropical tree *Siparuna guianensis* (Monimiaceae) and their effects on the feeding behavior of buffy-headed marmosets (*Callithrix flaviceps*) in the Atlantic Forest of southeastern Brazil. The predispersal consumption of *S. guianensis* seeds by *C. flaviceps* appears to have been the result of a combination of specific factors, such as seed size, morphology, and chemical/nutrient composition, in addition to the relative abundance of the resource at the study site. While the evidence indicates that *S. guianensis* seeds were a preferred resource, the phytochemical analysis of *S. guianensis* fruit receptacles and frutioles presented here indicates that the fruit's qualitative chemical defenses dictated marmoset feeding behavior. The monkeys only ingested the lipid-rich frutioles when these were exposed by the splitting open of the mature fruits, which allowed them to avoid contact with the alkaloid defenses of the receptacles. This behavioral strategy may have a major impact on the reproductive cycle of *S. guianensis*, at least on a local scale.

METHODS AND MATERIALS

Study Site and Species

The present study took place in an area of secondary forest, dominated by *Anadenanthera peregrina* (Mimosoidae) trees, at the 880-ha Caratinga Biological Station (19°50′S 41°50′W) in Minas Gerais (Ferrari, 1991; Strier, 1992). A 50-m × 50-m trail grid was established within the study area to facilitate both the behavioral monitoring of study group members and the mapping of group movements.

The buffy-headed marmoset, *Callithrix flaviceps*, is endemic to the highland Atlantic forest of southeastern Brazil. Its geographic range, in eastern Minas Gerais and western Espírito Santo, is one of, if not the smallest of any marmoset species (Rylands et al., 1993). Like other Atlantic forest marmosets, *C. flaviceps* is a gummivore–faunivore, but (together with the closely related *Callithrix aurita*) exhibits characteristics such as relatively large home ranges (over 35 ha) that may be related to the comparatively harsh seasonal conditions it faces in the Serra da Mantiqueira mountain range (Ferrari et al., 1996).

FIG. 1. Split open fruit of *Siparuna guianensis* (1.0–1.5 cm) showing fruit receptacle with frutioles. (Photo by S. S. Ferrari.)

Siparuna guianensis (Figure 1) is found throughout most of tropical South America, northwards as far as Costa Rica (Duke, 1962). It is a monoecious shrub or tree that generally reaches a height of 5–10 m. The globose fruit receptacle is 1–1.5 cm in diameter, purple or red in color, and smells "strongly of lemon"

(Renner and Hausner, 1997). When ripe, the fruit receptacle splits open irregularly, revealing two to eight small frutioles (maximum dimension 0.5–0.8 cm), with a white, membranous epicarp (Pereira, 1991).

Behavioral Data

The behavior of a free-ranging *C. flaviceps* group, which contained 11–15 members, was monitored systematically between August 1985 and August 1986. Group members were fully habituated to the presence of human observers by the beginning of the study period. Quantitative behavioral data were collected using 1-min scan samples at 5-min intervals throughout the daily activity period (see Ferrari and Rylands, 1994) on 8–10 days each month.

During each scan, the initial behavior of each observed group member was assigned to one of five basic categories (forage, feed, travel, rest, miscellaneous) and, in the case of feeding records, food items being ingested were identified in relation to both the type of resource being exploited (i.e., fruit part, nectar, gum, etc.) and the taxon. Whenever possible, plant food sources were marked and mapped, and specimens were collected for identification.

The location of the group (central point of group dispersion) in relation to the trail grid was recorded in each scan, together with complementary information on group movements. These records were used to map group movements (daily path) and the occupation of 50-m × 50-m quadrats (day range), as defined by the trail grid.

Plant Material

Siparuna guianensis fruits were collected by José Rímoli at Caratinga Biological Station in February 1995. A voucher specimen is deposited in the herbarium of the Federal University of Minas Gerais (UFMG, Belo Horizonte, Minas Gerais, Brazil).

General Analytical Methods

^{1}H NMR spectra (CD_3OD or $CDCl_3$) were recorded on a Varian-Gemini 200 or 300 instrument. Mass spectra were recorded on a VG Autospec Mass Spectrometer (70 eV). GC-MS spectra were recorded with a Hewlett-Packard (HP) 5890 series II gas chromatograph, coupled to a MS HP mass selective detector 5972 equipped with a fused silica capillary (DB-1) column (30 m × 0.25 mm, 25-μm film thickness: Supelco, Inc.). Temperature programming was from 50°C to 270°C at 3°C/min, then maintained at 270°C for 20 min. Products were identified by comparison of their mass spectral fragmentation patterns with the National Bureau of Standards (NBS) Mass Spectra Data Base (Keller and

Milne, 1974) and mass spectra and GC retention times of standard compounds. UV spectra were obtained on a Hitashi 340 spectrometer and IR spectra on a Biorad FT-80 spectrophotometer. The HPLC apparatus comprised a Lachrom HPLC System (Merck) equipped with a D7000 interface, L-7100 pump, L-7450A diode array detector (DAD), and L-7612 solvent degasser. The injections were done manually with an injector valve (Rheodyne) equipped with a 20-μl sample loop. Data were analyzed in a Multi-Hauser Mixed Standard solution supported on a Pentium II 250-MHz (Compac) computer. A Lichrosorb RP-18 column (5 μm $\times$ 250 mm ID) N. 738342, coupled to a guard column Lichrocart 250-4 HPLC cartridge was employed. The sample elution was done with a mobile phase composed of (A) 0.2 M sodium perchlorate–60% perchloric acid (1000 : 0.2) and (B) acetonitrile, with a gradient elution of A and B changing from A : B 90 : 10 to 10 : 90 (linear gradient for 50 min); flow rate was 2.0 ml/min, monitoring was at 280 nm for peak identification.

Extraction and Isolation of Compounds

Five hundred grams of *S. guianensis* fruits were air dried and the frutioles were separated from the fruit receptacles. Each organ was ground and extracted continuously with hexane and MeOH at room temperature. The hexane and methanolic solutions were concentrated separately under reduced pressure, resulting in 15.2 g and 11.9 g of crude hexane extracts and 31.7 g and 73.27 g of crude methanolic extracts, from the frutioles and fruit receptacles, respectively. A portion of the methanolic extracts was suspended in MeOH–H_2O (9 : 1) and partitioned between hexane, dichloromethane, ethyl acetate, and butanol.

Fruit Receptacles

Part of the hexane extract (1.45 g) obtained from the partition of the methanolic extract was subjected to column chromatography over silica gel using a hexane–ethyl acetate gradient. A total of 50 fractions was collected. Fraction 5 was recrystalized from hexane to produce glucosyl sitosterol (3.5 mg) (Sakikabara et al., 1983).

The dichloromethane extract (2.1 g) was further separated into soluble portions of hexane (378 mg) and methanol (1401 mg). The hexane-soluble fraction was chromatographed over silica gel and eluted with AcOEt, with increasing amounts of MeOH, resulting in 86 fractions. Fractions 20–23 were further purified by washing with heated MeOH to afford nantenine (6.0 mg) (Guinaudeau et al., 1988).

The methanolic fraction of the dichloromethane extract was chromatographed over Si gel, eluted with AcOEt and MeOH. Three groups of eluates showed the presence of distinct spots on TLC. The AcOEt–MeOH 20%

(25.0 mg) eluate was purified twice by preparative TLC ($CHCl_3$–AcOEt–MeOH 2 : 3 : 0.5) to yield liriodenine (9.0 mg) (Guinaudeau et al., 1988). The AcOEt–MeOH 30% (40.0 mg) eluate was chromatographed over Sephadex LH-20 and eluted with MeOH 100%. Fractions 30–40 were combined and rechromatographed over the same resin to afford *N*-methyllaurotetanine (3.1 mg) (Guinaudeau et al., 1988). The third eluate (AcOEt–MeOH 40%) was rechromatographed over XAD-2 resin eluted successively with MeOH–AcOEt to give 100 fractions. Fractions A (MeOH, 10.0 mg) and B (AcOEt, 13.0 mg) were obtained from this column. Fraction A, by preparative TLC (10% $CHCl_3$/AcOEt plus 2% of NH_4OH), furnished norglaucine (3.3 mg) and asimilobine (3.3 mg) (Guinaudeau et al., 1988), while fraction B, by using the same procedure, furnished anonaine (3.5 mg) and nornantenine (2.7 mg) (Guinaudeau et al., 1988).

Analysis of Frutiole Fatty Acid Methyl Esters

The crude hexane extract was treated with MeOH–NaOH 70% for hydrolysis and the fatty acids were separated from the mixture through successive washes with ethyl ether, rendering 67.7% of fatty acid methyl esters following a derivation procedure using diazomethane. The organic phase was removed by syringe (30 μl) and analyzed within 80 min by GC-MS. The instrument and conditions are described above.

Detection of Frutiole Alkaloids and Flavonoids by HPLC

Each partition of the methanolic extract from the frutioles was analyzed by HPLC, as described above, for the qualitative identification of the alkaloids previously isolated in the fruit receptacles. The samples were diluted with methanol and analyzed within 50 min. The dichloromethane partition indicated the presence of an aporphinic alkaloid with a retention time of 10.5 min and equivalent area of 0.69%. The ethyl acetate partition showed three flavonoids with retention times of 8.0, 8.4, and 8.6 min, and equivalent areas of 5.55%, 4.9%, and 6.56%, respectively. The butanolic partition showed peaks corresponding to flavonoids, in 6.7, 6.9, and 7.3 min and 4.1%, 4.0%, and 7.7% of the equivalent area, respectively.

Nutritional Content of Siparuna guianensis *Frutioles and Fruit Receptacles*

Humidity and mineral residues were estimated after desiccation (at 105°C) and incineration (in a muffle, at 550°C), respectively, according to standard procedures (Pregnolato and Pregnolato, 1985). Lipid content was estimated after extraction with diethyl ether in a Soxhlet apparatus, according to standard procedures (Pregnolato and Pregnolato, 1985). Protein content was estimated using Jones's (1941) factor: protein = total nitrogen (N) × 6.25, using a semimicro-Kjeldahl method (Horowitz et al., 1984). Carbohydrate content was estimated by difference. The caloric value was calculated using conversion factors (9.0 for lipids, 4.0 for carbohydrates, and 4.0 for proteins), and the results are expressed in kilocalories per 100 g.

RESULTS

Phytochemical Analysis of Frutioles and Fruit Receptacles of Siparuna guianensis

The hexane-soluble fraction of the methanolic extract of fruit receptacles of *S. guianensis* contained no alkaloids. Glucosyl sitosterol was isolated from this fraction. Seven aporphine alkaloids were isolated from the dichloromethane partition of the methanolic extract from the fruit receptacles (Table 1), only one of which—liriodenine—was also found in the frutioles.

Phytochemical investigation of the dichloromethane partition of the methanolic extract of the frutioles, by contrast, exhibited a very low concentration of alkaloids. In addition to liriodenine, HPLC analysis of this fraction revealed traces of other aporphinic alkaloids, more polar than those found in the fruit receptacles. Examination of the ethyl acetate and butanolic partitions revealed the absence of alkaloids, but the presence of flavonoid derivatives (Table 1).

The hexane extract from the frutioles was subjected to saponification, which revealed four different fatty acid methyl esters after methylation (Table 2). Despite other differences in the composition of fruit receptacles and frutioles, their nutritional content was relatively similar (Table 3).

Behavior of C. flaviceps

The marmosets' diet consisted primarily of plant exudates, insects, and small vertebrates. Reproductive plant parts (RPPs) only made a significant con-

tribution to the study group's diet in the rainy season months of January and February, 1986, when they made up 64.7% and 52.7% of plant feeding records, respectively (the remainder being provided by gums). Apart from November, when fruit was the item consumed in 17.6% of plant-feeding records, RPPs contributed no more than 5% of records in any one month. This reflects the apparent lack of edible fruit within the study group's home range throughout most of the study period. Only 17% of 1329 trees marked for phenological monitoring produced fruit during the study period.

In January, the fruit of a single tree species (*Allophyllus* sp.) was consumed in 94.5% of the records of feeding on RPPs, while in February *Siparuna guianensis* provided 95.2% of the records. Both these relatively small tree species are characteristic of secondary forest and were exceptionally abundant in some parts of the group's home range. Approximately one third (32.3%) of the trees that bore fruit in the phenology sample were members of these two species.

When feeding on *Allophyllus* drupes, the marmosets consumed the sweet-tasting mesocarp surrounding the seed, which was occasionally swallowed—and defecated—intact. When feeding on *S. guianensis*, by contrast, the monkeys

ingested the seeds (frutioles) only, and ignored the fleshy receptacle. Feeding on *S. guianensis* began towards the end of January, when the ripe fruits began to split open, revealing frutioles embedded in the inner surface of the receptacle. The marmosets extracted the seeds with their mouths, apparently taking care not to touch the receptacle, and masticated them thoroughly prior to swallowing.

The seeds of *S. guianensis* constituted the single most important item (41.0% of feeding records) of the marmosets' diet in February. However, despite being a valuable source of lipids and protein (Table 3), the availability of *S. guianensis* seeds did not appear to modify significantly the foraging strategies of the study group members during February in comparison with neighboring months. The marmosets devoted a similar proportion (18.8%) of their activity time to foraging for animal prey compared with January (18.4%) and March (19.9%), the latter being a month of typically low fruit consumption. The net effect of the availability of *S. guianensis* seeds on the *C. flaviceps* diet was thus the same as that of *Allophyllus* drupes—a marked reduction in the consumption of exudates.

The principal behavioral change observed in February was a pronounced shift in ranging patterns. February was the only month in which group movements were concentrated in the southern half of the home range, within the zone of overlap with the ranges of neighboring groups. Some of the 50-m × 50-m quadrats in this area were visited eight or nine times during the 10 days of observation, whereas in other months (including July, for which the smallest monthly range was recorded), no quadrat was visited more than seven times. This shift in range use was clearly related to the distribution of *S. guianensis* within the study group's home range. Day ranging was also reduced significantly ($t = -1.77$, $P = 0.039$, one-tailed, $df = 123$) in February (mean daily path = 1052.5 ± 211.4 m, $N = 10$) in comparison with all other months (mean = 1247.6 ± 341.3 m, $N = 115$).

DISCUSSION

The exploitation of *S. guianensis* fruit by *C. flaviceps* at the Caratinga Biological Station is unusual for a number of reasons, not least because this is apparently the first record of systematic seed consumption by a callitrichine primate. In addition, the monkeys not only ignored the fruit receptacles, but actually avoided all contact with them, despite the fact that their nutritional composition was relatively similar to that of the seeds (frutioles), apart from some lipids that were more abundant in the seeds (Table 3). Saponification of this fraction revealed that palmitic and linoleic acids—common fatty acids—are the major lipid constituents (Table 2). Both frutioles and fruit receptacles were also potentially good sources of carbohydrates.

By contrast, a marked difference was found between frutioles and fruit

receptacles in terms of the content and composition of alkaloids. The fleshy receptacles contained seven different benzylisoquinoline alkaloids (Table 1), whereas the frutioles contained only one. These alkaloids, which have a variety of pharmacological effects (e.g., sedative, cytotoxic, hypotensive) on the central nervous system (Rios, 1989), appear to function as a qualitative defense against predispersal seed predation by impeding contact with the frutioles, one which is effective against all potential predators except *C. flaviceps*. It is interesting to note, in this context, that frutioles dropped on the ground were retrieved by foraging ants in a matter of seconds. The marmosets' exploitation of seeds exposed in ripe, split fruits was clearly an efficient strategy for the avoidance of chemical defenses. As *S. guianensis* fruits exhibited no external signs of ripeness, splitting may be an important behavioral cue, especially if immature seeds contain higher concentrations of alkaloids.

Plant toxins, like those of *S. guianensis*, are often bitter and can be detected easily by taste, allowing consumers to avoid the parts of the plant that contains it (Harborne and Turner, 1984). Apart from nutritional considerations, vertebrates select plant food species on the basis of taste and aroma (Harborne and Turner, 1984). Otherwise nutritious plants may thus be rejected not only because of the presence of noxious chemicals or toxins but also because of their disagreeable flavor, although this does not appear to be the case of *Siparuna guianensis*, which has a strong lemonlike scent.

In addition to their behavioral flexibility, the ability of *C. flaviceps* to exploit *S. guianensis* seeds would appear to be related to a number of other factors, such as the small body size of the marmosets. Tufted capuchins (*Cebus apella*) are also present at Caratinga, but apparently do not exploit *S. guianensis* seeds (J. Rímoli, personal communication). At least as adaptable behaviorally as marmosets, capuchins are much larger, with adult body weights of 2–4 kg. Exploitation of the small, piecemeal-ripening *S. guianensis* seeds may thus be energetically too inefficient for the capuchins. It is also possible that successful avoidance of the plant's chemical defenses depends on the small size of the seed gatherer.

What does remain unclear, however, is why the eating of *S. guianensis* seeds has not been reported in other callitrichines, despite the extensive data now available for this subfamily in terms of both species and study sites (e.g., Mittermeier et al., 1988; Rylands, 1993; Corrêa, 1995; Passamani, 1996; Veracini, 1997; Oliveira and Ferrari, 2000). Both *S. guianensis* and the Callitrichinae are widely distributed in the Neotropics, and most callitrichines exhibit a preference for disturbed or secondary habitats (Sussman and Kinzey, 1984). It is nevertheless possible that the present records were dependent on a unique or unusual combination of factors, such as the high density of *S. guianensis* at the Caratinga study site. An additional, intriguing possibility is that the behavior of *C. flaviceps* at Caratinga is a recent innovation that has yet to be transmitted "culturally"

to other populations, a situation encountered in some other nonhuman primates (e.g., Kawamura, 1965; Nishida and Uehara, 1980). Additional studies of *C. flaviceps* at other sites would help evaluate this possibility.

The changes observed in the behavior of the *C. flaviceps* study group during February 1986 indicate clearly that *S. guianensis* seeds were a preferred resource, reflecting both their abundance within the study area and their nutritional value. The significance of the reduction in daily ranging should not be underestimated, given the energetic constraints on these small-bodied primates (Goldizen et al., 1988; Ferrari, 1993). The marmosets' intensive predispersal exploitation of *S. guianensis* seeds may also have significant implications for the plant's reproductive biology at this site. It also remains to be seen how the herbivore–plant relationship (or lack thereof) influences reproductive processes in other *S. guianensis* populations.

Acknowledgments—Fieldwork on *C. flaviceps* was supported by the Brazilian National Research Council (CNPq), the Medical Research Council of Great Britain, the A. H. Schultz-Stiftung, London University Central Research Fund, the Boise Fund and the Leakey Trust. Laboratory work on the phytochemistry of *S. guianensis* was supported by CNPq. We would like to thank Bob Martin, Cida Lopes, and José Rímoli for their help with different stages of the fieldwork.

MANDIBULAR GLAND CHEMISTRY OF GRASS-CUTTING ANTS: SPECIES, CASTE, AND COLONY VARIATION

WILLIAM O. H. HUGHES,* PHILIP E. HOWSE, and DAVE GOULSON

Biodiversity and Ecology Division, School of Biological Sciences
University of Southampton
Bassett Crescent East, Southampton, SO16 7PX, U.K.

(Received February 14, 2000; accepted August 31, 2000)

Abstract—The compositions of the alarm pheromones of two species of grass-cutting ant, *Atta bisphaerica* and *A. capiguara*, were examined, and caste and colony variations quantified. The pheromones of *A. bisphaerica* and *A. capiguara* were remarkably similar and were composed of a complex mixture of volatiles in which 4-methyl-3-heptanone and 2-heptanone were the most abundant compounds. Small but consistent intraspecific differences were found between the worker castes and between individual colonies. The results support the view that alarm pheromones are rarely species specific. The possible importance of intercolony variation is discussed.

Key Words—Leaf-cutting ants, alarm, pheromone, caste, colony, *Atta bisphaerica*, *Atta capiguara*, mandibular gland, Formicidae.

INTRODUCTION

Alarm behavior is one of the most obvious behaviors of ants, but it is also one of the hardest to define because of the wide range of responses that it can involve. The chemistry of ant alarm pheromones is equally diverse, but compounds typically have a molecular weight of between 100 and 200 and have 5–10 carbon atoms (Wilson and Bossert, 1963). The range of possible molecular weights is related to the function of alarm pheromones. An alarm response is a rapid reaction and so requires compounds of high volatility and low molecular weight in order that they evaporate rapidly (Bossert and Wilson, 1963; Wilson and Bossert, 1963). Furthermore, there is less need for the specificity shown by other pheromones, such as trail or sex pheromones, and so large, complex

*To whom correspondence should be addressed.

molecules, which are energetically more expensive to produce, are unnecessary (Blum, 1969; Hölldobler and Wilson, 1990; Vander Meer and Alonso, 1998).

Leaf-cutting ants (Hymenoptera: Formicidae: Attini: *Atta* and *Acromyrmex*) are dominant herbivores in the neotropics (Hölldobler and Wilson, 1990). They can account for as much as 50% of the total herbivory in some areas (Blanton and Ewel, 1985) and are one of the most destructive pests in many of the regions where they occur (Weber, 1972; Cherrett, 1986). *Atta* colonies, in particular, can be extremely large, with worker populations that are highly polymorphic and polyethic. When alarmed, leaf-cutting ants exhibit an aggressive response (Wilson and Regnier, 1971) and release an alarm pheromone from their mandibular glands (Butenandt et al., 1969; Blum et al., 1968; Moser et al., 1968; Riley et al., 1974; Knapp, 1995).

A number of studies have examined the chemistry of this mandibular gland secretion. In the earliest work, Butenandt et al. (1959) identified citral as the main component in *Atta sexdens rubropilosa.* The presence of this compound gives the crushed heads of *A. sexdens* workers a characteristic lemon smell. Later, Moser et al. (1968) found 4-methyl-3-heptanone and 2-heptanone at a ratio of 4 : 1 to be the principal components in major workers of *A. texana.* These ketones were also identified at species-specific ratios in the alarm pheromones of six other species of *Atta*, including *A. bisphaerica* and *A. capiguara* (Blum et al., 1968). However, subsequent research by Schildknecht (1976) and Nascimento et al. (1993) has revealed the chemistry of the mandibular gland secretion to be far more complicated than these early studies suggested, and some 56 compounds have been identified to date in *Atta* alone. However, for only very few has any behavioral activity been demonstrated. Although Butenandt et al. (1959) described citral as being the alarm-stimulating compound in *A. sexdens rubropilosa*, all other studies have concluded that 4-methyl-3-heptanone is the most important releaser of alarm behavior in *Atta* (Blum et al., 1968; Moser et al., 1968; Riley et al., 1974; Knapp, 1995; Pow, 1996).

The composition of alarm pheromones can vary between castes of ants. This was first found to be the case in the African weaver ant, *Oecophylla longinoda*, in which the glands of minor workers lack three of the main compounds found in major workers (Bradshaw et al., 1979). Similar variation between castes has been found in *Atta sexdens rubropilosa.* Nascimento et al. (1993) analyzed the mandibular gland secretion of workers of this species and found that the extracts of large workers consisted of a complex mixture of compounds dominated by citral. The secretion of small workers was 89.5% 4-methyl-3-heptanone and neither of the isomers of citral were present. A similar pattern has been found in *Atta laevigata* with 4-methyl-3-heptanone again dominating the secretion of the smaller workers (Hernández et al., 1999).

Alarm pheromones also can vary between colonies. Bradshaw et al. (1979) found that the mandibular gland chemistry of colonies of *Oecophylla longinoda*

differed significantly between geographical localities and even between colonies from the same location. Cherix (1983) also found that the alarm pheromone of *Formica lugubris* differed both qualitatively and quantitatively between colonies at the same location. This aspect has not been examined in leaf-cutting ants. Most studies (e.g., Butenandt et al., 1959; Moser et al., 1968; Schildknecht, 1976; Nascimento et al., 1993; Hernández et al., 1999) have examined ants only from a single nest. However, Whitehouse and Jaffé (1995) found that workers of *A. laevigata* respond more aggressively to the crushed heads of nonnestmates than nestmates. This suggests not only that there are intercolony differences in the alarm pheromone, but also that these differences are detectable by the ants.

The alarm pheromone chemistry of *A. bisphaerica* and *A. capiguara* has not been examined since the early study by Blum et al. (1968). Furthermore, our knowledge of caste variation in the alarm pheromone of leaf-cutting ants remains limited and that of colony variation is nonexistent. Identification of the chemistry and variation in the alarm pheromone is essential to further studies on the alarm behavior of these species. The compositions, therefore, of the alarm pheromones of *A. bisphaerica* (Forel) and *A. capiguara* (Gonçalves) were examined. Compositions for the four worker castes of each species also were compared, and intercolony differences were quantified in *A. capiguara.* The behavioral activity elicited by the compounds will be examined elsewhere (Hughes et al., 2001).

METHODS AND MATERIALS

Sample Collection. Samples of the heads of both *Atta bisphaerica* and *A. capiguara* workers were collected between March and June 1998. For both species, 10 samples of each of the four worker castes were collected, based on the estimated head width of the ants. Minors were less than 1.4 mm head width, medias 1.5–2.0 mm, foragers 2.0–3.0 mm, and soldiers had head widths >3.0 mm. The minor and media worker samples contained the heads of 20 individuals, samples of foragers comprised 10 heads, while the soldier samples contained only a single head. The *A. bisphaerica* samples were collected from a single nest near Viçosa, Minas Gerais, Brazil. The nest from which the *A. capiguara* samples were collected was located near Capinópolis, Minas Gerais. In addition, 10 samples of the heads of *A. capiguara* foragers were collected from each of four nests located on the UNESP campus in Botucatu, São Paulo, Brazil.

Nascimento et al. (1993) found that the chemical composition of the mandibular glands of *A. sexdens rubropilosa* does not differ between ants on the foraging trails and those within the nest. To reduce the disturbance to the ants, therefore, they were collected from the trails. Ants were gently removed from the trails and immediately cooled, which prevented them from becoming alarmed. They were then transported to the laboratory where their heads were

removed and placed in glass vials containing 500 μl of dichloromethane solvent. The mandibular glands are probably the only source of volatile compounds in the heads of ants (Howse and Bradshaw, 1980), and both Nascimento et al. (1993) and Knapp (1995) have found that there is no difference in the volatiles contained in crushed heads and mandibular glands of *A. sexdens rubropilosa.* Only crushed heads were examined here. Once samples contained the required number of heads, the heads were crushed thoroughly with a glass rod. After 24 hr the extract was removed and stored between −20°C and −60°C until analysis.

Chemical Analysis. The sample extracts were analyzed by gas chromatography (GC) and gas chromatography–mass spectrometry (GC-MS). The gas chromatograph used was a Hewlett Packard 5890A with a flame ionization detector. The column was DB5, 30 m × 0.25 mm, with a film thickness of 0.25 μm. Nitrogen was used as the carrier gas. The temperature program was 40°C for 2 min, then increasing at 10°C/min, with a final temperature of 280°C for 30 min. Compounds were quantified with 5-methyl-3-heptanone (97%, Aldrich) as an internal standard.

To identify the compounds, a VG-Analytical 70-250SE mass spectrometer was used, coupled to a Hewlett-Packard 5790 gas chromatograph. The column was BP1, 25 m × 0.22 mm, with a film thickness of 0.25 μm. Helium was used as the carrier gas and the temperature program was 40°C for 3 min, increasing at 10°C/min to 75°C, then increasing at 20°C/min, and ending with 5 min at 300°C. The conditions were 70 eV electron impact (EI) ionization, and an ion chamber temperature of 200°C. Compounds were provisionally identified by examination of the fragmentation pattern of their mass spectrograms. This was then confirmed by comparing the results with library mass spectrograms and with the mass spectrograms of synthetic versions.

Statistical Analysis. The GC integrator produces peak areas for each compound that are dependent upon the amount of material in the sample. To avoid this, the areas of each peak are divided by the sum of areas of all the peaks in the sample. This results in proportional data that adds up to one. However, as the data are compositional, the peak proportions cannot be used for multivariate analysis. The data, therefore, were standardized by the formula proposed by Aitchison (1986):

$$Z_{ij} = \ln [Y_{ij}/g(Y_j)]$$

where Z_{ij} is the standardized area of peak i for ant j, Y_{ij} is the observed area of the peak, and $g(Y_j)$ is the geometric mean of the areas of all the peaks of ant j included in the analysis.

The standardized data were then examined by multivariate analysis of variance (MANOVA) to determine whether the groups differed in the abundances

of compounds present. Differences between the groups were examined further by a canonical discriminant analysis. In addition, a one-way univariate analysis of variance (ANOVA) also was carried out for each peak in each analysis. Only peaks that were abundant enough to be quantified in all of the samples being examined in a particular analysis (5–10 peaks) were included. This avoided the problem of large numbers of independent variables relative to the sample size resulting in significant discriminations being found where no actual groupings exist (Panel on Discriminant Analysis, Classification, and Clustering, 1989). As a small number of samples had evaporated during storage, the analysis was weighted for the number of replicates. Only the first two discriminant functions were considered to be important, because together these always accounted for at least 90% of the variance between groups. The discriminant scores for the functions were also used to predict group membership and thus to confirm the effectiveness of the functions in discriminating between the groups.

To quantify the similarity between the groups (castes, nests, etc.), Nei's distances were calculated (Nei, 1972; Ferguson, 1980). This technique provides an index of similarity between two groups from 1 (identical) to 0 (totally different). The formula used is:

$$I = \frac{\sum x_i y_i}{\sqrt{\left(\sum x_i^2 \sum y_i^2\right)}}$$

where I is Nei's coefficient of identity, x_i is the quantity of peak i for sample x, and y_i is the quantity of peak i in sample y. After converting the data into binary values (1 = present, 0 = absent), Nei's distances were calculated with Ochiai's resemblance coefficient. This takes the same value as the cosine coefficient (Nei's distance) when binary attribute data are used (Romesburg, 1989) and allowed the trace compounds to be included in the analysis.

RESULTS

A total of 41 peaks of high volatility occurred consistently in one or more groups. Of these, nine were identified with a high degree of confidence, including almost all of the most abundant peaks. Seven of these were ketones in the C_7 to C_9 range, and the others were nonanal and the monoterpene, limonene. A provisional identification was made for a further seven peaks.

Caste Differences in Composition. In both species, there was very little differences between the castes in the composition of volatiles in their mandibular glands, as represented by the extremely high Nei's values (Figure 1). Medias

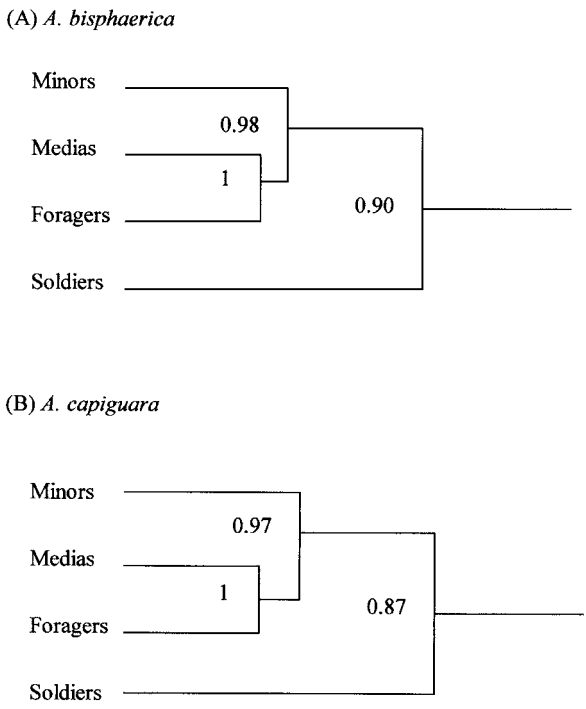

FIG. 1. Dendrograms based on Nei's distances as a measure of the degree of similarity between the composition of volatiles (presence/absence) in the extracts of the four castes (1 = identical, 0 = totally different).

and foragers contained the same compounds, and the composition of the minor worker samples was also very similar. Soldiers differed to a greater degree, and the castes differed in the proportions of the most abundant compounds (*A. bisphaerica:* $F_{40,100} = 4.66$, $P < 0.001$; *A. capiguara*; $F_{28,124} = 7.20$, $P < 0.001$) (Tables 1 and 2).

The discriminant analysis of the *A. bisphaerica* castes was based upon 10 peaks. Soldiers, and to a lesser extent minors, separated out from the other castes on function 1 (64% of the variance) (Figure 2). The function structure coefficients indicated that 4-methyl-3-heptanone contributed most to this variance. The ANOVA showed that the proportions of this ketone differed significantly between the castes ($F_{3,31} = 13.0$, $P < 0.001$), with the soldiers containing a lower proportion than the other castes (Table 1). Soldiers also had a higher proportion of 2-heptanone, although this was not significant ($F_{3,31} = 1.31$, $P = 0.29$), and they were the only caste to contain 2-nonanone and peak 29. Minor workers were distinguished from the other castes by function 2 of the discriminant anal-

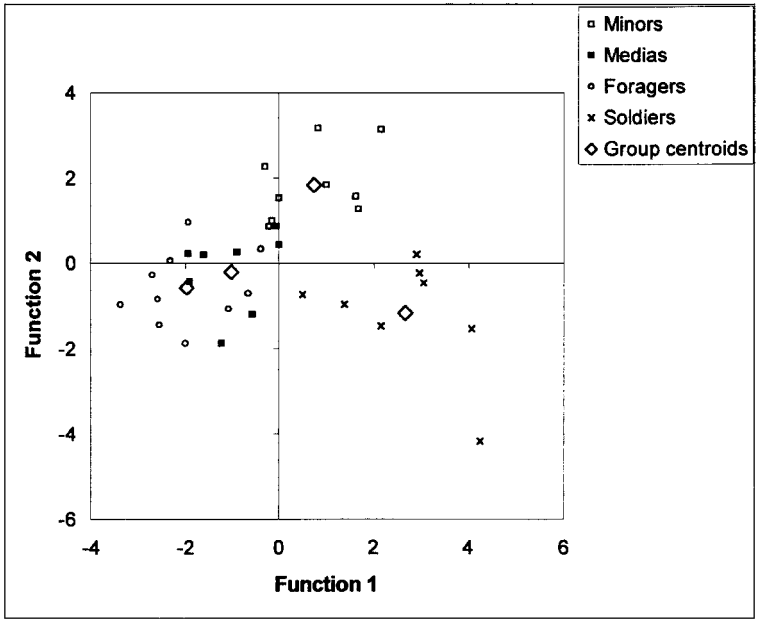

FIG. 2. Discriminant analysis of the four castes of *A. bisphaerica* [minors ($N = 9$), medias ($N = 8$), foragers ($N = 10$), and soldiers ($N = 8$)]. The proportions of 10 peaks were compared after standardization. Data points are the scores for each sample on functions 1 and 2 of the discriminant analysis, and the group centroids for each caste.

ysis (27% of variance) (Figure 2), which was mainly due to peak 3. This was higher in minors than in the other castes ($F_{3,31} = 5.30$, $P = 0.005$) (Table 1). Medias and foragers were not differentiated by either function (Figure 2), and their chemical profiles were virtually identical. The predicted classification based on the discriminant scores misclassified only 14% of samples (0/9 minors, 3/8 medias, 1/10 foragers, and 1/8 solliders).

Separation of the castes of *A. capiguara* by the discriminant analysis followed a similar pattern, with the analysis being based upon seven peaks. Both function 1 (55% of variance), and function 2 (36% of variance) separated soldiers and minors from the other two castes, with medias and foragers being very similar (Figure 3). Four peaks contributed to function 1. Peak 3 was higher ($F_{3,34} = 6.16$, $P = 0.002$), and 4-methyl-3-hexanone lower ($F_{3,34} = 3.99$, $P = 0.015$), in minors and soldiers compared with the other two castes (Table 2). There was also less 3-octanone in the soldiers samples ($F_{3,34} = 3.14$, $P = 0.038$), and the proportion of 4-methyl-3-heptanone decreased from minors to soldiers, although this was not significant ($F_{3,34} = 2.32$, $P = 0.093$). Function 2 was due

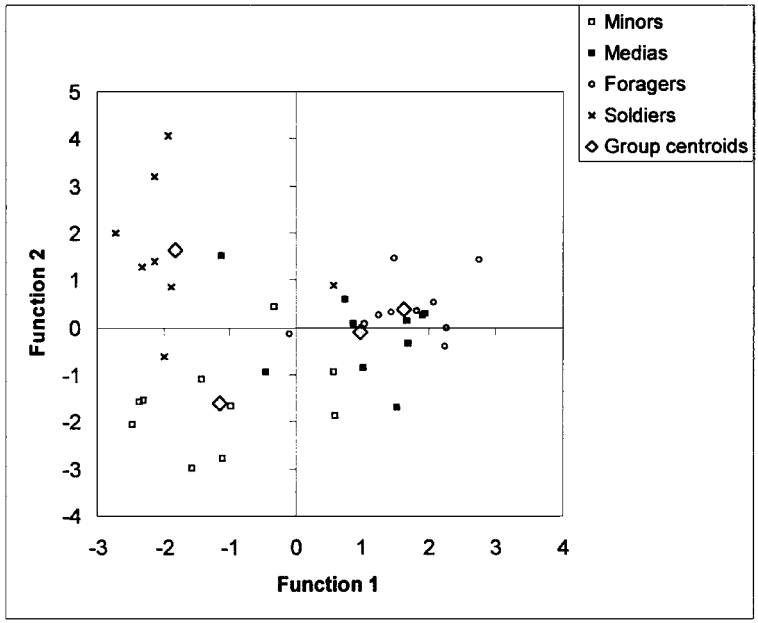

FIG. 3. Discriminant analysis of the four castes of *A. capiguara* [minors ($N = 10$), medias ($N = 10$), foragers ($N = 10$), and soldiers ($N = 8$)]. The proportions of seven peaks were compared after standardization. Data points are the scores for each sample on functions 1 and 2 of the discriminant analysis, and the group centroids for each caste.

mainly to 2-heptanone, although this did not differ between the castes ($F_{3,34} = 0.84$, $P = 0.481$). In addition, 2-octanone and 2-nonanone were found only in the soldiers (Table 2). Misclassification based on the discriminant scores was greater than with *A. bisphaerica*, with 26% being misclassified (2/10 minors, 4/10 medias, 2/10 foragers, 2/8 soldiers).

Species Differences in Composition. There was surprisingly little difference between *A. bisphaerica* and *A. capiguara* in the compounds present in their profiles (Nei's distance of 0.86), although they did differ in the proportions of the most abundant compounds ($F_{12,134} = 49.24$, $P < 0.001$). They were separated with a single function in the discriminant analysis, which used six peaks. This was contributed to mainly by 4-methyl-3-heptanone and 3-octanone. There was more 4-methyl-3-heptanone ($F_{1,71} = 28.44$, $P < 0.001$), and less 3-octanone ($F_{1,71} = 5.95$, $P = 0.017$) in *A. bisphaeric* (Tables 1 and 2). Overall, the proportion of 2-heptanone was also greater in *A. bisphaerica* ($F_{1,71} = 24.9$, $P < 0.001$), while there was more 4-methyl-3-hexanone ($F_{1,71} = 9.03$, $P = 0.004$) and peak 3 ($F_{1,71} = 44.5$, $P < 0.001$) in *A. capiguara.* Nonanal, peak 19, and peak 10

were found only in *A. bisphaerica*, and while 2-octanone was present in all the *A. bisphaerica* castes, it was found only in soldiers of *A. capiguara.* Prediction from the discriminant scores misclassified only 4.1% of the samples (3/35 *A. bisphaerica*, 0/38 *A. capiguara*).

Nest Differences in Composition. The nests at the Botucatu site differed from one another in the compounds present in their profiles (average Nei's distance of 0.76), and the proportions of the most abundant compounds also differed between the nests ($F_{12,124} = 9.85$, $P < 0.001$) (Table 3). In the discriminant analysis, with six peaks, nest B was clearly separated from the others on function 2 (26% of variance) (Figure 4). This was due mainly to 4-methyl-3-heptanone, of which there was more in nest B ($F_{3,33} = 19.84$, $P < 0.001$), and to 4-methyl-3-hexanone, of which there was less ($F_{3,33} = 12.33$, $P < 0.001$) (Table 3). 2-Heptanone was also more abundant in nests A, B, and C, than in nest D. All nests were separated by function 1 (73% of variance) (Figure 4). This was due to peak 7, which varied between an average of 18.1 ± 0.8% in nest D and only 1 ± 0.1% in nest A, with nests B and C being intermediate. The nests also differed considerably in the minor peaks that were present in their profiles (Table 3). Only 8.1% of samples were misclassified by predictions based on the discriminant scores (0/10 nest A, 2/9 nest B, 1/9 nest C, 0/9 nest D).

DISCUSSION

The volatile compounds identified in *A. bisphaerica* and *A. capiguara* were all within the 100–200 molecular weight range that is characteristic of alarm pheromone compounds (Wilson and Bossert, 1963). The main compounds were mostly methyl and ethyl ketones, which are the groups that dominate the alarm pheromones of myrmicine ants (Blum and Brand, 1972; Parry and Morgan, 1979). 4-Methyl-3-heptanone, 2-heptanone, 3-octanone, and 4-methyl-3-hexanone have previously been identified in the alarm pheromones of *Atta* (Schildknecht, 1976; Blum et al., 1968; Moser et al., 1968; Riley et al., 1974; Nascimento et al., 1993; Knapp, 1995; Hernández et al., 1999). In fact, 4-methyl-3-heptanone and 2-heptanone are extremely common alarm compounds and are found in a number of other ant species (Hölldobler and Wilson, 1990). The small quantities present of minor compounds prevented accurate mass spectrometry, and so their identity remains uncertain. However, at least some appeared to be low molecular weight aliphatic ketones and alcohols of the types commonly seen in the alarm pheromones of other leaf-cutting ants.

There were small but consistent differences between the castes in both species, although the profiles of medias and foragers were virtually indistinguishable. The similarity contrasts with studies on *A. sexdens rubropilosa* (Nascimento et al., 1993; Knapp, 1995) and *A. laevigata* (Hernández et al., 1999),

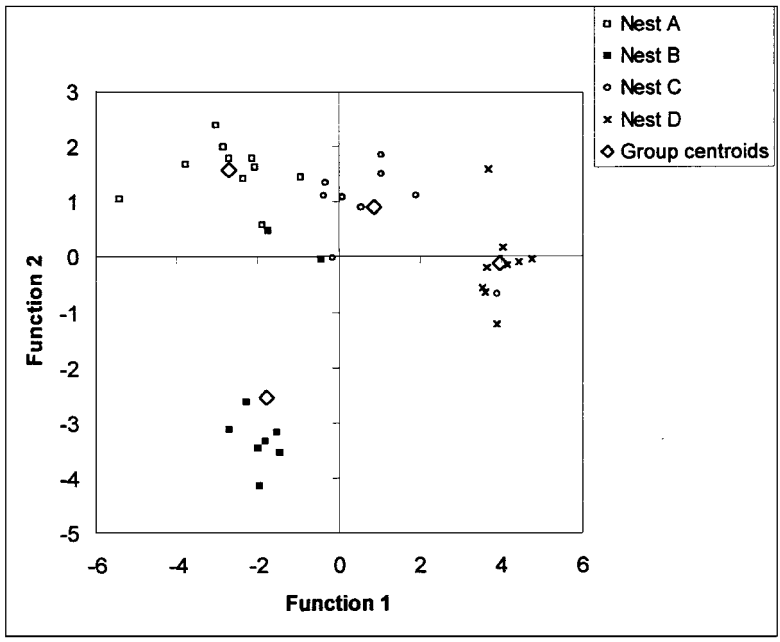

FIG. 4. Discriminant analysis of foragers from the four Botucatu nests of *A. capiguara* [nest A ($N = 10$), nest B ($N = 9$), nest C ($N = 9$), and nest D ($N = 9$)]. The proportions of six peaks were compared after standardization. Data points are the scores for each sample on functions 1 and 2 of the discriminant analysis, and the group centroids for each nest.

in which the alarm pheromone of the larger ants was a complex mixture of compounds while that of the smallest workers was almost pure 4-methyl-3-heptanone. Although the soldiers of both, *A. bisphaerica* and *A. capiguara* did have proportionally less 4-methyl-3-heptanone than the other castes, such a strong division between small and large workers was clearly not present in these species. In part, this may be ascribed to the size of the ants in the samples. Nascimento et al. (1993) and Hernández et al. (1999) reported that the alarm pheromones of ants <1.8 mm and <2.5 mm in head width, respectively, did not differ in composition. However, Knapp (1995) found that it was only the pheromones of workers with a head width of <1 mm that were dominated by 4-methyl-3-heptanone. The minors of *A. bisphaerica* and *A. capiguara* analyzed here had a head width of up to 1.4 mm, and so included individuals that were larger than the size range which Knapp (1995) found to be dominated by 4-methyl-3-heptanone. It would be interesting to examine in more detail the mandibular gland chemistry of the minor workers of *A. bisphaerica*,

A. capiguara, and indeed other species, to see if the caste differences described in *A. sexdens rubropilosa* and *A. laevigata* are a widespread phenomenon. The reason for caste variation is another area that deserves further research. Nascimento et al. (1993) and Bradshaw et al. (1979) have suggested that differences in chemical composition between castes may be due to living in different environments. However, individuals from every leaf-cutting ant worker caste may be found both inside and outside the nest, and no direct evidence for this theory has been found. The reason for caste variation, therefore, is still unclear.

There was also very little difference between *A. bisphaerica* and *A. capiguara* in the composition of the mandibular glands, although they could be consistently distinguished by the proportions of their major components. They were both very different from *A. sexdens rubropilosa*, and none of the larger molecular weight compounds, such as citral, were found. The most behavioral active compound in the alarm pheromone of *A. sexdens rubropilosa*, as well as *A. laevigata*, *A. cephalotes*, and *A. texana*, is 4-methyl-3-heptanone (Blum et al., 1968; Moser et al., 1968; Riley et al., 1974; Knapp, 1995; Pow, 1996). This was the most abundant compound in all the worker castes of both *A. bisphaerica* and *A. capiguara*, apart from the soldiers. It also has been identified in the mandibular glands of *A. colombica* and *A. robusta* (Blum et al., 1968). The lack of species specificity of alarm pheromones has been recognized by a number of authors (Wilson, 1965; Blum, 1969; Parry and Morgan, 1979; Vander Meer and Alonso, 1998). Unlike many other pheromones, discrimination between species is not essential to the function of alarm pheromones (Law and Regnier, 1971; Hölldobler and Wilson, 1990). Indeed, there could even be benefits to being able to recognize and respond to alarm pheromones produced by other species (Blum, 1969; Vander Meer and Alonso, 1998).

One explanation for the discrepancies between studies on the same species is colony-specific differences. Both the presence of minor compounds and the proportions of major compounds differ significantly among the nests of *A. capiguara.* In fact, the relatively high number of trace compounds that varied between colonies caused average Nei's distances between colonies to be lower than that between the two species. Similar intercolony differences in both the major and trace components have been found in weaver ants, *Oecophylla longinoda* (Bradshaw et al., 1975, 1979). Why colonies should differ to such a degree is unclear. Possibly the subtle differences in the composition of the alarm pheromone allow the recognition of nestmates (Howse, 1979; Bradshaw and Howse, 1984). Whitehouse and Jaffé (1995) have shown that the ability of leaf-cutting ants to distinguish between nestmates and nonnestmates is dependent upon a cue present in the head of the target ant. We present here the first evidence that the chemistry of leaf-cutting ant heads differs among colonies, supporting the hypothesis that alarm pheromones play an important role in nestmate recognition.

Acknowledgments—We are grateful to Malcolm Cherrett and John Bradshaw for comments on an earlier version of this work; to Evaldo Vilela, the Universidade Federal de Viçosa, Luiz Forti, and UNESP for providing supporting and facilities in Brazil; and to Kathy Ballard, John Langley, Dave Coreener, and the late Ian Stevens for technical assistance. (Received May 11, 2000; accepted September 1, 2000)

Abstract—Seven known phenolic acids implicated in wheat allelopathy were analyzed in a worldwide collection of 58 wheat accessions by gas chromatography and tandem mass spectrometry (GC-MS-MS). Chemical analysis showed that accessions differed significantly in the production of *p*-hydroxybenzoic, vanillic, syringic, *trans*-*p*-coumaric, *cis*-*p*-coumaric, *trans*-ferulic, and *cis*-ferulic acids in the shoots of 17-day-old wheat seedlings. The concentrations of *p*-hydroxybenzoic, vanillic, *cis*-*p*-coumaric, and *cis*-ferulic acids were normally distributed in the 58 accessions. A binormal distribution was found for syringic and *trans*-ferulic acids and a skewed normal distribution for *trans*-*p*-coumaric acid. The concentration of each compound also varied with phenolic acids. The relative abundance of each phenolic acid was ordered decreasingly as *trans*-ferulic, vanillic, *trans*-*p*-coumaric, *p*-hydroxybenzoic, syringic, *cis*-ferulic, and *cis*-*p*-coumaric acids. The concentration of total identified phenolic acids varied from 93.2 to 453.8 mg/kg in the shoots of 58 accessions. The content of each phenolic acid or group was highly associated with others in the shoots of wheat seedlings. Wheat accessions with high levels of total identified phenolic acids in the shoots are generally strongly allelopathic to the growth of annual ryegrass.

Key Words—Wheat, *Triticum aestivum* L., allelopathy, allelochemicals, phenolic acids, shoots, weed suppression.

INTRODUCTION

Phenolic compounds are among the most abundant groups of secondary metabolites in plants. Phenolics bear hydroxylated aromatic rings, and include simple phenols, phenolic acids, phenylpropanoids, coumarins, quinones, flavonoids, tannins, and other miscellaneous phenols (Harborne, 1980). They are known to be of significance in insect and disease resistance (Harborne, 1985) and in allelopathy (Inderjit, 1996). Many phenolic compounds are inhibitory to germinating seeds and growing plants (Rice, 1984). *p*-Hydroxybenzoic, vanillic, *p*-coumaric, syringic, and ferulic acids are the predominant phenolic acids identified as allelopathic agents in various natural and agroecosystems (Guenzi and McCalla, 1966; Blum et al., 1991; Chou et al., 1991; Ben-Hammouda et al., 1995).

Wheat (*Triticum aestivum* L.) possesses allelopathic potential for weed suppression. Aqueous extracts of straws were allelopathic to the germination and growth of a number of weed species (Steinsiek et al., 1982; Liebl and Worsham, 1983). Allelopathic ability of aqueous extracts differ significantly between cultivars (Guenzi et al., 1967; Wu et al., 1998). The allelopathic activity of wheat straws has been demonstrated under field conditions (Shilling et al., 1985). The results show that phytotoxins in wheat straws are water soluble and are prone to leach into the soil to influence the growth of weeds in the vicinity.

The chemical basis for the allelopathic potential of wheat straw has been investigated. Phenolic acids are a main category of allelochemicals implicated in wheat allelopathy with *p*-hydroxybenzoic, vanillic, *p*-coumaric, syringic, and ferulic acids being most frequently reported (Guenzi and McCalla, 1966; Lodhi et al., 1987). Ferulic and *p*-coumaric acids inhibit the radicle growth of radish (*Raphanus sativa*) at concentrations of 10^{-4}–10^{-3} M (Lodhi et al., 1987). Liebl and Worsham (1983) found that ferulic acid reduced germination and root length of *Ipomoea lacunosa*, *I. purpurea*, *Ambrosia artemisiifolia*, and *Sida spinosa*, at 5×10^{-3} M. Ferulic acid was further decarboxylated by a bacterium living on the carpels of *S. spinosa* seed to a more toxic styrene derivative 4-hydroxy-3-methoxystyrene (Shilling et al., 1985). Blum et al. (1991) reported that a mixture of phenolic acids similar to that obtained from the wheat soil under no-tillage systems reduced radicle and hypocotyl length of *Trifolium incarnatum.*

Although allelopathic activity varies considerably among accessions in a number of field crops, including wheat (Putnam and Duke, 1974; Fay and Duke, 1977; Spruell, 1984; Dilday et al., 1994; Wu et al., 1991a, 2000), little is known of the chemical basis for the varied activity. Several studies have screened a single active compound of plant tissues in a diverse crop collection in relation to plant natural defense against pests and diseases (Nicol et al., 1992; Lovett and Hoult, 1992), but screening for allelochemical content in plant tissues has been limited (Chou et al., 1991). Moreover, the allelopathic activity does not appear to be due to the effects of a single compound, but is more likely the result

of the combination and interaction of many allelochemicals (Einhellig, 1995). Simultaneous screening of multiple compounds responsible for weed suppression will be more informative.

Chemical analysis has shown that 39 wheat accessions differed significantly in total phenolic contents and that the allelopathic activity of wheat residues was highly associated with the total phenolic contents contained in each extract (Wu et al., 1998). The aim of the present study was to screen simultaneously seven known phenolic acids in the shoots of 17-day-old wheat seedlings in a diverse collection of 58 wheat accessions by gas chromatography and tandem mass spectrometry (GC-MS-MS).

METHODS AND MATERIALS

Wheat Growth. Based on previous experiments, a worldwide collection of 58 wheat accessions (*T. aestivum* L.) from the Australian Winter Cereals Collection was selected and grown according to the procedure described previously (Wu et al., 2000). Briefly, 12 pregerminated wheat seeds (surface-sterilized) of each accession were uniformly selected and aseptically sown on the agar surface with the embryo up, in three rows on one half of a glass beaker (500 ml) prefilled with 30 ml of 0.3% water agar. The beaker was wrapped with a piece of parafilm and placed in a controlled growth cabinet with a daily light/dark cycle of 13 hr/11 hr and a temperature cycle at 25°C/13°C. After the growth of seedlings for seven days, a piece of preautoclaved white paperboard was inserted across the center and down the middle of the beaker with the lower edge of the paperboard kept 1 cm above the agar surface. The beaker was again wrapped with parafilm and placed back in the growth cabinet for continuous growth of 10 more days.

Preparation of Shoot Extracts. The procedure previously described for the preparation of shoot extracts was used (Wu et al., 1999b). Briefly, shoots of 17-day-old seedlings were harvested for each accession and immediately freeze-dried. Then 0.100 g of shoots was cut into 2-mm lengths, ground into powder, macerated with 3 ml of 0.001 M HCl, sonicated at 5°C for 15 min, and centrifuged at 20,000 rpm and 10°C for 15 min. The supernatant was then collected and extracted three times with 10-ml portions of diethyl ether. The ether was evaporated under reduced pressure at 35°.

Derivatization and Quantitation. The derivatization and quantitation of samples were identical to those described previously (Wu et al., 1999b). Briefly, the silylation of shoot samples was accomplished by the addition of 1.0 ml of MSTFA (Alltech Australia) at 60°C for 30 min. The silylated samples were directly analyzed by GC-MS-MS. Each phenolic acid was identified and quantified by comparing retention time and product ion spectrum with that in the

user library created from the standard compound. Quantitative analysis was performed by the internal standard method (Wu et al., 1999b) and is reported in units of milligrams per kilogram of dry matter.

GC-MS-MS Analysis. GC-MS-MS analysis was carried out on a Varian 3400 CX gas chromatograph coupled with a Varian Saturn 2000 ion trap mass spectrometer. Parahydroxybenzoic acid (PHB), vanillic acid (VAN), syringic acid (SYR), paracoumaric acid (COU), ferulic acid (FER), and the internal standard (parachlorobenzoic acid) were obtained from Sigma-Aldrich Chemical Co. Silylated samples or standard compounds were introduced via a DB-5MS fused-silica capillary column of 30 m $\times$ 0.25 mm $\times$ 0.25 μm (J & W Scientific, Alltech Australia). The gas chromatographic and tandem mass spectrometric conditions for the analysis of wheat samples were identified to those reported previously (Wu et al., 1999b). Mass spectral scan time from m/z 50 to 450 was 1.0 sec (using three microscans). Nonresonant collision-induced dissociation (CID) was used for MS-MS. All samples were run in triplicate.

Data Analysis. All experimental data were subjected to analysis of variance with Genstat 5 (Release 3.2), and the treatment means were tested separately for least significant difference (LSD) at a 5% level of probability.

RESULTS

Variations in Levels of Phenolic Acids in Wheat Shoots. All 58 wheat accessions contained the seven phenolic acids, *p*-hydroxybenzoic, vanillic, syringic, *trans-p*-coumaric, *cis-p*-coumaric, *trans*-ferulic, and *cis*-ferulic acids analyzed in the shoots, and the concentrations of each phenolic acid differed significantly among accessions (Table 1, Figures 1–3). The content of *p*-hydroxybenzoic acid in shoots ranged from 9.8 to 49.3 mg/kg shoot dry weight, vanillic acid from 12.9 to 68.8 mg/kg, *cis-p*-coumaric acid from 0.8 to 11.2

TABLE 1. HIGHEST AND LOWEST CONCENTRATIONS OF PHENOLIC ACIDS IN WHEAT SHOOTS[a]

Phenolic acid	Lowest		Highest

trans-COU	Federation	11.4 ± 0.4	Sunstar	117.7 ± 4.8
trans-FER	Sunco	3.2 ± 0.2	Sunstar	149.3 ± 6.6

[a] Data presented as the means ± SD, mg/kg of dry matter.

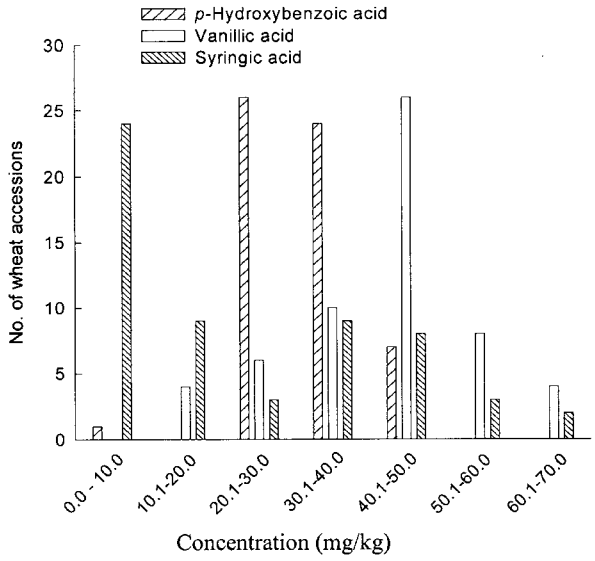

FIG. 1. Frequency distribution of the benzoic derivatives in 58 wheat accessions.

mg/kg, syringic acid from 1.9 to 61.5 mg/kg, *cis*-ferulic acid from 0.2 to 17.0 mg/kg, *trans*-*p*-coumaric acid from 11.4 to 1117.7 mg/kg, and *trans*-ferulic acid from 3.2 to 149.3 mg/kg.

Distribution of Phenolic Acids Among Wheat Accessions. The distribution of the level of each phenolic acid is presented in Figures 1–3. The levels of *p*-hydroxybenzoic and vanillic acids were normally distributed in the 58 wheat accessions, while a binormal distribution was found for the syringic acid (Figure 1). Only one accession produced *p*-hydroxybenzoic acid at a level less than 10.0 mg/kg, and seven accessions at a level of more than 40.0 mg/kg. Four accessions produced vanillic acid at less than 20.0 mg/kg and 12 accessions at more than 50.0 mg/kg; 24 accessions produced syringic acid at less than 10.0 mg/kg and 5 accessions at more than 50.0 mg/kg dry weight.

A skewed normal distribution was found for the *trans*-*p*-coumaric acid and a binormal distribution for the *trans*-ferulic acid (Figure 2). There were 10 accessions that produced a level of *trans*-ferulic acid at less than 25.0 mg/kg and six accessions at more than 130.0 mg/kg. Eleven accessions produced *trans*-*p*-coumaric acid at less than 25.0 mg/kg and six accessions at more than 55.0 mg/kg.

The levels of *cis*-*p*-coumaric and *cis*-ferulic acids were also normally distributed in the 58 wheat accessions (Figure 3). There was one accession that produced a level of *cis*-*p*-coumaric acid at less than 1.0 mg/kg and six acces-

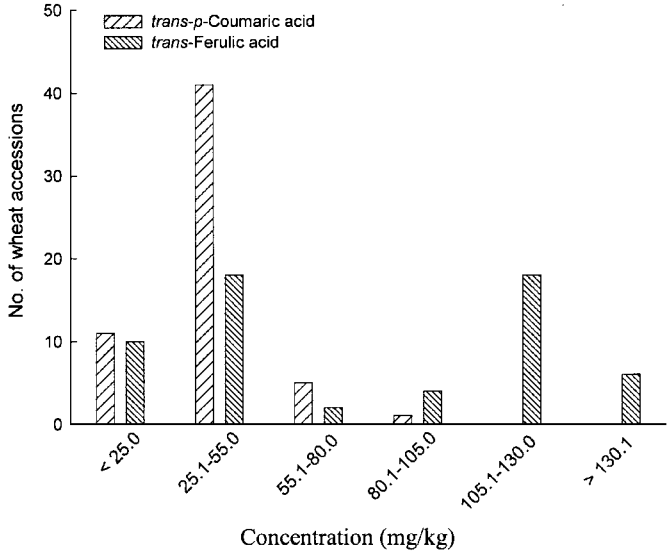

FIG. 2. Frequency distribution of the *trans*-cinnamic derivatives in 58 wheat accessions.

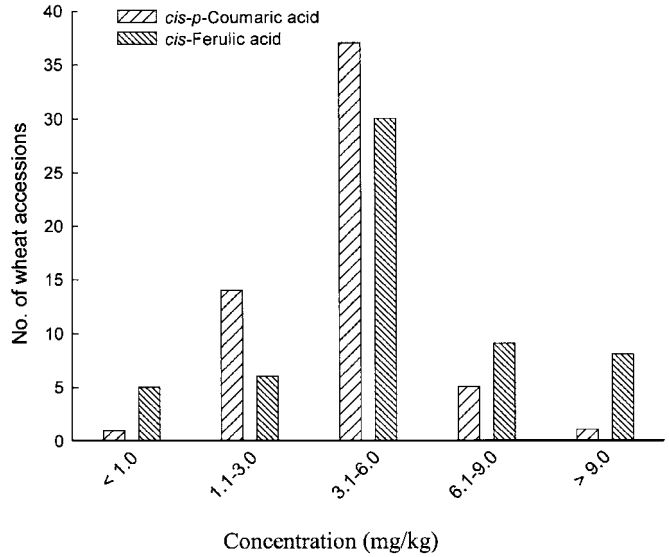

FIG. 3. Frequency distribution of the *cis*-cinnamic derivatives in 58 wheat accessions.

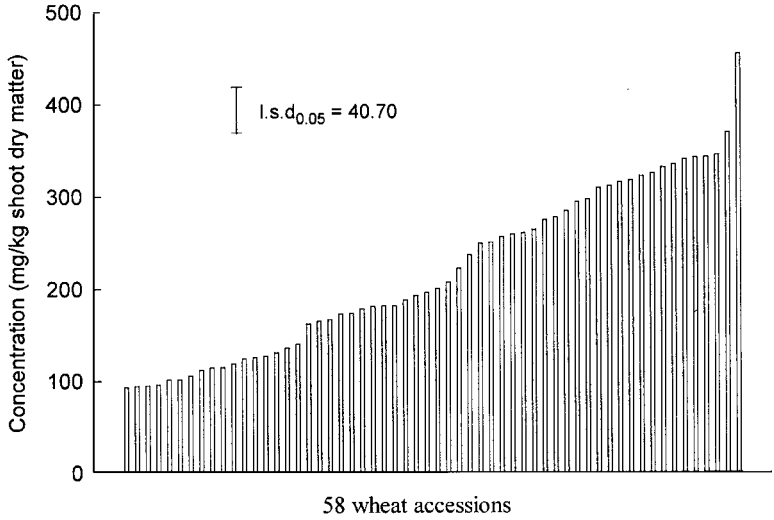

FIG. 4. Variation of total identified phenolic acids in wheat shoots.

sions at more than 6.0 mg/kg. Five accessions produced *cis*-ferulic acid at less than 1.0 mg/kg and 17 accessions at more than 6.0 mg/kg.

The concentration of total identified phenolic acids varied from 93.2 to 453.8 mg/kg in the shoots of 58 accessions (Figure 4). There were seven accessions that produced a level of total identified phenolic acids at less than 110.0 mg/kg: Emika, Canada 4125, Sunco, RAC 710, Hartog, Federation, and Eretria. Correspondingly, these accessions were often found to contain lower levels of individual phenolic acids in the shoot tissues. Eight accessions contained total identified phenolic acids at more than 330.0 mg/kg: Tasman, Bernina, Wattines, Insignia, Khapli, RAC 820, SST 6, and Sunstar. Correspondingly, higher concentrations of individual phenolic acids were often found in these accessions. Forty-three accessions produced total identified phenolic acids in a range of 110.0–330.0 mg/kg.

Different phenolic acids occurred in varied amounts in the shoots of the same accession. Of the seven phenolic acids analyzed, *trans*-ferulic acid was the most predominant with an average level of 74.1 ± 48.1 mg/kg in the shoots. The *cis* isomers of *p*-coumaric and ferulic acids were produced at the lowest level, occurring at 4.2 ± 1.6 and 5.2 ± 3.6 mg/kg, respectively. The following are listed in decreasing order of the concentration in the shoots of 17-day-old seedlings: *trans*-ferulic acid > vanillic acid (42.0 ± 12.1 mg/kg) > *trans*-*p*-coumaric acid (38.5 ± 18.3 mg/kg) > *p*-hydroxybenzoic acid (31.1 ± 7.3 mg/kg) > syringic acid (22.9 ± 18.2 mg/kg) > *cis*-ferulic acid > *cis*-*p*-coumaric acid.

[b] Significant correlation at $P < 0.05$.
[c] Significant correlation at $P < 0.01$.

Correlation Between Phenolic Acids in Wheat Shoots. The metabolism of many phenolic compounds is known to follow the shikimate pathway (Harborne, 1989). There were significant correlations between contents of phenolic acids in wheat shoots, except for *p*-hydroxybenzoic acid (Table 2). The content of *p*-hydrozybenzoic acid did not significantly correlate to that of vanilic, syringic, *cis*-ferulic, and *trans*-ferulic acids. After grouping the phenolic acids, it was found that there were significant correlations among benzoic acid derivatives, cinnamic acid derivatives total coumaric acid, and total ferulic acid (Table 3).

DISCUSSION

The contents of phenolic acids in wheat shoot tissues varied with accessions and compounds. *trans*-Ferulic acid was the predominant phenolic com-

pound identified. The abundance of *trans*-ferulic and *trans*-*p*-coumaric acids in wheat tissues has been reported previously. Salomonsson et al. (1978) found that *trans*-ferulic and *trans*-*p*-coumaric acids were the dominant acids in the aqueous alkaline extracts of barley, oat, wheat, rye, and rice straws, each at 510–3100 and 440–3100 mg/kg of straw, respectively. *cis*-*p*-Coumaric acid and *cis*-ferulic acid were at smaller levels of 130–530 and 100–560 mg/kg, respectively. Lodhi et al. (1987) found that ferulic and *p*-coumaric acids in the soil were present in higher concentrations than *p*-hydroxybenzoic, syringic, vanillic, and *p*-coumaric acids, and the amount of ferulic acid was higher than that of *p*-coumaric acid. However, Ben-Hammouda et al. (1995) reported that the concentrations of *p*-hydroxybenzoic, syringic, and vanillic acids in various sorghum plant parts were consistently higher than those of ferulic acid and *p*-coumaric acids, with ferulic acid being most frequently not detectable. It is seen, therefore, that the concentration of each phenolic acid varies greatly depending on biotic and abiotic factors, such as crop types and accessions, plant ages and parts, extraction methods, and the analytical techniques (EI-Basyouni and Towers, 1964; Guenzi and McCalla, 1996; Kaminsky and Muller, 1978; Lodhi et al., 1987; Ben-Hammouda et al., 1995).

Phenolic compounds have been implicated in residue allelopathy of a number of crops, including rice (Chou and Lin, 1976), sorghum (Ben-Hammouda et al., 1995), and wheat (Guenzi and McCalla, 1966; Salomonsson et al., 1978; Lodhi et al., 1987). The differential level of each phenolic acid identified in the present study could contribute in part to the variability of allelopathic potential of wheat accessions. Our research has shown that wheat seedling allelopathy on the growth of annual ryegrass (*Lolium rigidum* Gaud.) differed in a worldwide collection of 453 wheat accessions (Wu et al., 1999a). The eight accessions with the highest levels of total identified phenolic acids reported in the present study, with the exception of Insignia, which was only weakly allelopathic, were strongly allelopathic to the growth of *L. rigidum.* Similarly, the seven accessions with the lowest levels of total identified phenolics, with the exception of Sunco, in which an intermediate level of allelopathic potential was found, were weakly allelopathic to the growth of *L. rigidum.*

Allelochemicals present in plant shoot tissues may greatly contribute to residue allelopathy. Nevertheless, amounts of allelochemicals present in plant roots may be more critical to the actual exudation of such chemicals by the living roots into the growth environment. Exudation of allelochemicals is one of the processes whereby crops exert allelopathic activity. Further research is necessary to investigate the concentrations of phenolic acids in root tissues of wheat seedlings so that the allelochemical relationship between the contents of roots and shoots, and the involvement of root allelochemicals in wheat allelopathy can be determined.

Acknowledgments—This research is funded by both Charles Sturt University (CSU) and the Australian Cooperative Research Centre for Weed Management Systems. The authors are grateful for the gifts of wheat accessions from the Australian Winter Cereals Collection, and the provision of GC-MS-MS instrumentation from the Environmental and Analytical Laboratories at CSU.

(Received November 29, 2000; accepted September 2, 2000)

Abstract—The effect of cedrelanolide, the most abundant limonoid isolated from *Cedrela salvadorensis* (Meliaceae), was assayed as a plant-growth inhibitory compound against monocotyledonous and dicotyledonous seeds. This compound inhibited germination, seed respiration, and seedling dry weights of some plant species (*Lolium multiflorum*, var. Hercules, *Triticum vulgare*, var. Salamanca, *Physalis ixocarpa*, and *Trifolium alexandrinum*). Our results indicate that cedrelanolide interferes with monocot preemergence properties, mainly energy metabolism of the seeds at the level of respiration. In addition, the compound inhibits photophosphorylation, H^+ uptake, and noncyclic electron flow. This behavior might be responsible for its plant-growth inhibitory properties and its possible role as an allelopathic agent.

Key Words: *Cedrela salvadorensis*, cedrelanolide, Meliaceae, phytogrowth inhibition, seed respiration, Hill reaction inhibitor, limonoid, nortriterpenoid.

INTRODUCTION

Limonoids from the family Meliaceae are attracting considerable interest because of their insect antifeedant properties, with special focus on the ring-cleaved example, azadirachtin (Kraus, 1995). In contrast, less is known about the allelopathic activity of compounds in the azadirone, gedunin, mexicanolide, and sen-

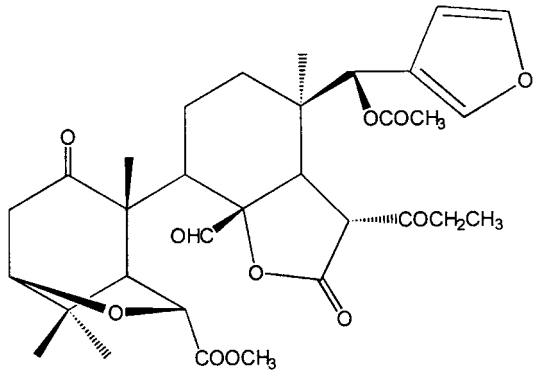

FIG. 1. Chemical structure of cedrelanolide.

danin classes. In a limited range of structures, they are also found in the families Rutaceae and Cneoraceae (Champagne et al., 1992). These natural products possess a wide range of biological activities including insect antifeedant activity (Isman et al., 1996; Mata R., 1996; Jiménez et al., 1997; Zhou et al., 1998; Veitch et al., 1999; Céspedes et al., 2000), plant-growth regulating properties (Céspedes et al., 1998, 1999a,b), medicinal effects in animals and humans (MacKinnon et al., 1997; Matsuda et al., 1998), and fungicidal (Govindachari et al., 1999; Weimin et al., 1998), bactericidal (Tada et al., 1999), and antiviral (Lowery et al., 1997) activities. Among the many limonoids isolated from these families, cedrelanolide (Figure 1) was found for the first time in *Cedrela salvadorensis* (Meliaceae), a Mexican specimen (Segura et al., 1994).

We found that some limonoids obtained from *Cedrela* species have different mechanisms of action on photosynthesis (Céspedes et al., 1998; Lotina-Hennsen et al., 1998). For example, gedunin and 7-oxo-7-deacetoxygedunin, isolated from *C. odorata* and *C. salvadorensis*, act as energy-transfer inhibitors interacting with CF_0 (Achnine et al., 1999) while odoratol has impairment effects on the donor side of photosystem II (Achnine et al., 1998). However, α-photogedunin and β-photogedunin isolated from *C. salvadorensis* and *C. ciliolata* (Syn *dugesii*) inhibit germination and respiration of monocot and dicot weed seeds, and the epimeric mixture partially inhibits photophosphorylation, H^+ uptake, and noncyclic electron flow (Céspedes et al., 1999a). In similar form, α- and β-photogedunin acetates inhibit seed germination, seedling growth, and seed respiration. In addition, these derivatives are Hill reaction inhibitors with two different targets of inhibition in the photosynthesis electron transport rate (Céspedes et al., 1998, 1999b).

The insecticidal behavior of cedrelanolide on *Ostrinia nubilalis*, the European corn borer, has been reported (Jiménez et al., 1997), as has the antifeedant

activity on *Spodoptera frugiperda* (Céspedes et al., 2000). Cedrelanolide may increase plant resistance to insect herbivores; however, its mode of action is unknown.

We are continuing investigations for biologically active limonoids with potential herbicidal properties (Lotina-Hennsen et al., 1998) and now report the phytotoxic properties of cedrelanolide on germination, root and shoot development, and respiration of seeds of two monocots (*Lolium multiflorum* and *Triticum vulgare*) and two dicots (*Physalis ixocarpa* and *Trifolium alexandrinum*). In addition to these inhibitory activities, the effects of this compound on the photosynthesis system are presented.

METHODS AND MATERIALS

Chemicals and Solvents. All reagents used were commercially available in either AR or chromatographic grade. Tricine, sorbitol, and methyl viologen (MV) were purchased from Sigma Chemical Co. Methanol, $CHCl_3$, CH_2Cl_2, KCl, $CuSO_4$, NH_4Cl, $MgCl_2$, pyridine, acetic anhydride, silica gel GF_{254} analytical chromatoplates, silica gel grade 60, 70–230, and 60 Å for column chromatography, hexane, and ethyl acetate were purchased from Merck.

Apparatus. ^1H NMR spectra were recorded at 300 and 500 MHz, and ^{13}C NMR spectra at 75 and 125 MHz, on Varian VXR-300S and VXR-500S spectrometers, respectively. Chemical shifts (parts per million) are related to $(CH_3)_4Si$ as internal reference. $CDCl_3$ and acetone-d_6 from Aldrich Chemical Co. were used as solvents. Coupling constants are quoted in hertz. IR spectra were obtained in KBr on Perkin-Elmer 283-B and FT-IR Nicolet Magna 750 spectrophotometers. Electron impact mass spectra were taken on a Jeol JMS-SX102A (70 eV). UV spectra were determined on a Shimadzu UV-160 spectrophotometer. Optical rotation was measured on a Jasco DIP-360 spectropolarimeter. Melting points were obtained on a Fisher-Johns hot-plate apparatus and are uncorrected. Electron transport and oxygen evolution were determined with a Clark-type electrode connected to YSI oxygraph model 5300.

Plant Material. The heartwood of *Cedrela salvadorensis* was collected in Morelia, State of Michoacán, in February 1997. A voucher has been deposited at the ethnobotanical collection of the National Herbarium (MEXU), Instituto de Biología, UNAM (Voucher: M. T. German and P. Tenorio No. 2.174. Register number: 800.193).

Isolation of Cedrelanolide. Cedrelanolide was obtained from a $CHCl_3$ extract of the stem bark of *C. salvadorensis* as colorless crystals (CH_2Cl_2–MeOH), mp = 280°, $[\alpha]_D^{20}$ – 10.24° (c 2.56, $CHCl_3$). The molecular formula $C_{32}H_{40}O_{11}$ was determined by mass spectrometry (HR-FAB-MS), *m/z* 601.2626 [M^++1], EI-MS, *m/z* (relative intensity) 541 (M^+–59, 1), 511 (1.4), 455 (25),

431 (20), 370 (50), 137 (100), 95 (41), 57 (37). Signals in the IR spectrum, in addition to the furan absorptions (1502 and 874 cm^{-1}), included strong carbonyl bands at 1790 (γ lactone), 1747 (ester), 1727 (aldehyde), and 1701 cm^{-1} (ketone). UV (EtOH) 208 nm. The shifts of ^{1}H NMR and ^{13}C NMR spectral data were identical with those published in the literature (Segura et al., 1994).

Seed Germination Bioassays. Monocot seeds of *Lolium multiflorum* (Poaceae) ryegrass var. Hercules were purchased from Barenbreig. *Triticum vulgare* (Graminae) wheat var. Salamanca, and two dicotyledons seeds—*Trifolium alexandrinum* (Leguminoseae) red clover var. Andino and *Physalis ixocarpa* (Solanaceae) green tomato—were purchased from Semillas Berentsen, S. A. de C. V. Celaya, Guanajuato, Mexico. Germination tests were run in triplicate with 100 *L. multiflorum* seeds, 40 *T. vulgare* seeds, 100 *T. alexandrinum* seeds, and 100 *P. ixocarpa* seeds for each concentration of sample for five days (three for germination and two for root and shoot growth). The number of seeds used for each experiment was selected so that an appreciable change in O_2 uptake could be detected by the oxygraph. The test seeds were held in the dark at 25°C in 9.0-cm Petri dishes containing an 8.5-cm sheet of Whatman No. 1 filter paper and 10.0 ml of test or control solution. The dishes were wrapped with Parafilm foil and incubated at 28°C in the dark. The number of germinated seeds was determined according to the criterion of 1 mm extrusion of the radicle. Germination rates were counted at 72 and 120 hr later for root and shoot growth measurements. Cedrelanolide was initially dissolved in methanol and diluted with water. The maximum final concentration of methanol was 0.1% and the same methanol concentration was used in the control solution. The pH of the solution was adjusted to 6.5 before the bioassay. Seeds were selected for uniformity of size, and damaged ones were discarded (Li et al., 1992).

Growth Bioassays. Coleoptyle or hypocotyle and root lengths for all germinated seeds were measured after 120 hr, in three replicates, after which the germinated plants were dried to constant weight at 40°C.

Seed Respiration. Seed respiration was measured polarographically as oxygen uptake during the germination process with a YSI oxygraph model 5300. The oxygen uptake, in the presence of different concentrations of cedrelanolide, was evaluated over 5 and 10 min, in a nonilluminated cell. The requirement for oxygen was plotted as a percentage of the control at 100%.

The data were analyzed by ANOVA ($P < 0.05$), and GI_{50}, RI_{50}, and I_{50} values for each activity were calculated by probit analysis on the basis of the percentage of inhibition obtained at each concentration of cedrelanolide. I_{50} is the concentration producing 50% inhibition, and GI_{50} is the concentration inhibiting 50% germination, and RI_{50} is the concentration that inhibits 50% of respiration.

Chloroplast Isolation and Chlorophyll Determination. Isolated chloroplasts were prepared from market spinach leaves (*Spinacia oleracea*) as previously reported (Mills et al., 1980; Saha et al., 1971; Jiménez et al., 1996) and the pellet

was resuspended, unless indicated, in a solution containing 400 mM sucrose, 5 mM $MgCl_2$, and 10 mM KCl buffered with 30 mM Na^+-tricine at pH 8.0. Chlorophyll concentration was determined according to Strain et al. (1971).

Measurement of Proton Uptake and ATP Synthesis. Proton uptake was measured as the rise in pH from 8.0 to 8.1 (Dilley, 1972). A combination microelectrode connected to a Corning potentiometer (model 12 Research pH-meter) with expanded scale and registered on a Gilson recorder was used. The reaction medium was 100 mM sorbitol, 5 mM $MgCl_2$, 10 mM KCl, and 1 mM Na^+-tricine at pH 8. ATP synthesis was measured titrimetrically according to the procedure of Dilley (1972), with 50 μM methyl viologen (MV) added as an electron acceptor for the Hill reaction.

Measurement of Electron Transport. Photosynthesis noncyclic electron transport rates from water to MV were monitored with a YSI (Yellow Spring Instrument) model 5300 oxygen monitor connected to a Clark-type electrode. The reaction medium was the same as that used in the H^+-uptake assay except for the tricine concentration (15 mM), and in the case of the uncoupled electron transport measurement 6 mM NH_4Cl was added. All reaction mixtures were illuminated with light from a projector lamp (GAF 2660) filtered through 5 cm of 1% $CuSO_4$ solution at 20°C (Calera et al., 1995; Van Gorkom and Gast, 1996).

RESULTS AND DISCUSSION

Seed Germination. Cedrelanolide inhibited seed germination for the four species tested (*L. multiflorum*, *T. vulgare*, *P. ixocarpa*, and *T. alexandrinum*) as concentration increased to 500 μM (Figure 2). The GI_{50} (concentration inhibiting 50% germination) values indicate that the monocot *L. multiflorum* is the most susceptible to cedrelanolide, with GI_{50} = 120.6 μM, and causing 100% at 300 μM (Table 1). The data suggest slow permeation of the compound through the seed membranes. In our test the preemergence assays were done before emergence of seeds, according to Hatfield and Karlen (1994) and Mohr and Schopfer (1995). These results suggest either that the oxygenated functions in the molecule play a role in inhibition because of lipophilicity or that the hydrophilicity of the oxygenated function of cedrelanolide (at physiological pH) makes it difficult for cedrelanolide to reach the target site.

Root and Shoot Elongation. Radicle and shoot development was partially inhibited by cedrelanolide. The monocots *T. vulgare* and *L. multiflorum* were more sensitive to cedrelanolide (I_{50} varying from 140 to 300 μM, Table 1) than were dicot seedlings (Figure 3), with the exception of *T. vulgare* roots, which were resistant to cedrelanolide inhibition (Figure 4).

Growth inhibition was concentration-dependent. As in germination, cedrelanolide had the least inhibitory effects on growth of *T. vulgare* (100%)

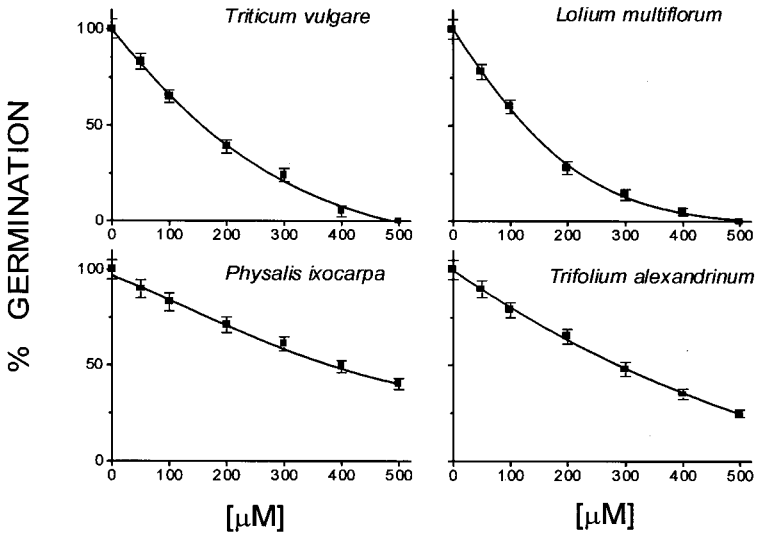

FIG. 2. Concentration-dependent inhibition of cedrelanolide on seed germination expressed as percent of control germination. Each value represents mean ± SE ($N = 5$) in error bars.

at 500 μM, and the least inhibitory effect on *L. multiflorum* at 300 μM. Here values indicate that the mechanisms of action of cedrelanolide may differ for growth and germination (Einhellig, 1986).

TABLE 1. EFFECT OF CEDRELANOLIDE ON SEED GROWTH (ELONGATION, GERMINATION, RESPIRATION, AND DRY WEIGHT)

	Cedrelanolide (μM)[a]				
	Elongation (EI_{50})		Germination	Respiration	Dry Weight
Species	Stems	Roots	(GI_{50})	(RI_{50})[b]	(DWI_{50})
T. vulgare	297.0	—	157.0	100	155.0
L. multiflorum	142.0	114.0	125.0	100	351.0
T. alexandrinum	452.0	393.0	289.0	400[c]	
P. ixocarpa	500.0	466.0	370.0	300	

[a] Means of three experiments. The EI_{50}, GI_{50}, RI_{50}, and DWI_{50} are the inhibitory concentrations that give 50% inhibition of seedling length (stem and roots), seed germination, respiration, and dry weight, respectively. Calculated by ANOVA ($P < 0.05$).
[b] Values giving 50% inhibition at 24 hr.
[c] Value at 30 hr.

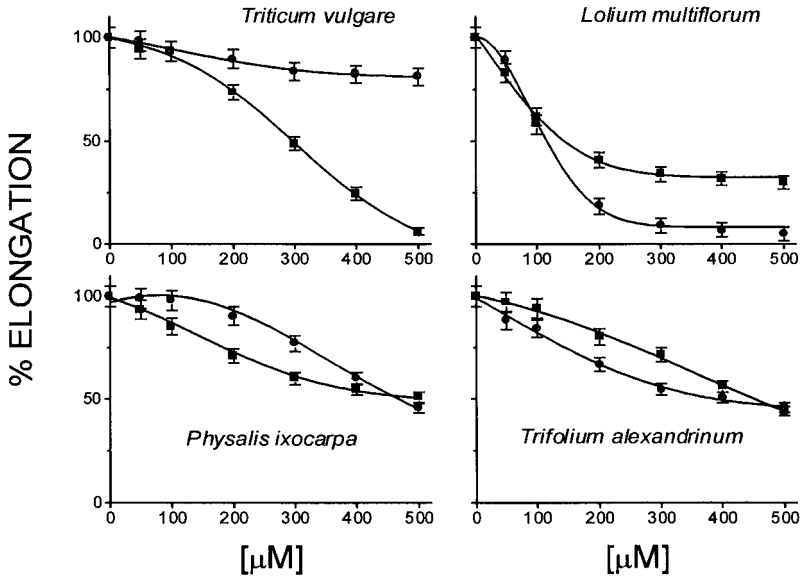

FIG. 3. Effects of solutions of cedrelanolide on seedling growth. (●, roots, ■, stems) of mono- and dicot seeds. Each value represents mean ± SE ($N = 5$) in error bars. The inhibition efficacy was expressed as a percentage of cedrelanolide activity inhibited compared with the control value (100%).

Dry Weight. In general, development of monocot species was more sensitive to cedrelanolide than dicot species. Dry weight of dicot species was not affected by cedrelanolide (Figure 4). Seedling biomass (dry weight) of monocots diminishes with concentration of cedrelanolide in similar form to germination.

Seed Respiration. Seed respiration was more sensitive to cedrelanolide than seed germination for all species tested. Inhibition of seed respiration by cedrelanolide was a function of time and concentration of the natural product. Thus, as incubation time or concentration increased, inhibition increased (Figure 5). The RI_{50} values (concentration inhibiting 50% respiration) show that monocot (*T. vulgare* and *L. multiflorum*) respiration was more sensitive to cedrelanolide than that of dicots (Table 2). These values suggest that cedrelanolide acts as an uncoupler to phosphorylation at low concentration, but at higher concentrations it either inhibits energy transduction or the respiration redox enzymes.

Effect of Cedrelanolide on ATP Formation, Proton Uptake, and Electron Transport Rate. To assess the effects of cedrelanolide on photosynthesis, we evaluated the effects on different photosynthetic reactions. The assay concentration ranged from 0 to 150 μM in 10 μM increments. Figure 6 shows that photosynthesis photophosphorylation from water to methyl viologen was inhibited by

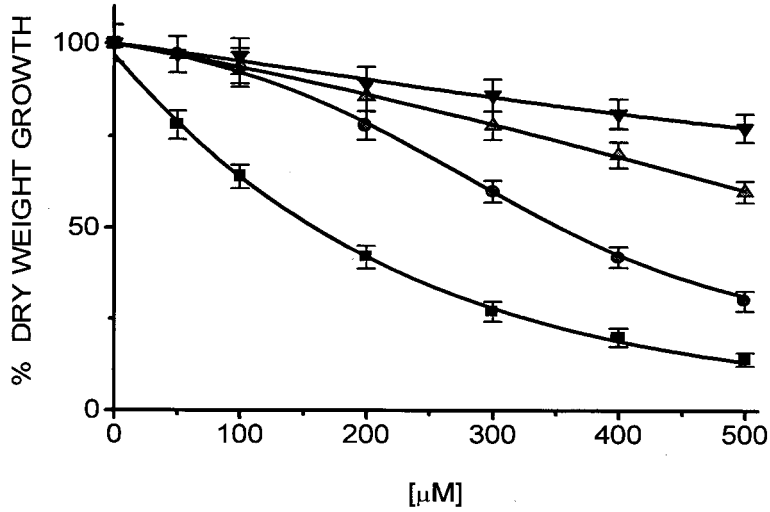

FIG. 4. Inhibition by solutions of cedrelanolide on dry weight of seedlings (■, *T. vulgare*; ●, *L. multiflorum*; ▲, *P. ixocarpa*; ▼, *T. alexandrinum*). Each value represents mean ± SE ($N = 5$) in error bars. The inhibition efficacy was expressed as a percentage of cedrelanolide activity inhibited compared with the control value (100%).

cedrelanolide at 100 μM with an IC_{50} of 29.5 μM (Table 2). In addition, Figure 6 shows that cedrelanolide inhibits proton uptake partially at 34.9 μM (IC_{50}) and completely at 100 μM. Based on Figure 7, we suggest that cedrelanolide inhibits the whole electron transport chain from water to MV at 60 μM, measured as oxygen uptake under photophosphorylating conditions. These effects are similar to that observed with the photogedunin acetate derivatives (Céspedes et al., 1998). The photogedunin acetates show these effects at concentrations of 10–30 μM, while cedrelanolide shows similar effects between 20 and 90 μM. According to pI_{50} values, cedrelanolide has similar potency as a Hill reaction inhibitor to some commercial herbicides that affect chloroplast electron flow. These results suggest that the presence of oxygenated functions significantly enhances the inhibitory potency of these compounds as electron transport inhibitors. Our group has demonstrated the effects of gedunin and 7-oxo-7-deacetoxygedunin (which are oxygenated limonoids) on the electron transport chain in the 300 and 400 μM range (Achnine et al., 1999). The pI_{50} values (Table 2) also indicate that this compound is a potent Hill reaction inhibitor, and its abundance in the plant *Cedrela salvadorensis* suggests a role as a defensive allelochemical.

Inhibition of germination, seed respiration, and radicle or shoot elongation by cedrelanolide was similar to effects of concentration ranges of phenolic acid derivatives, i.e., 100–1000 μM (Einhellig, 1986, 1995). Cedrelanolide

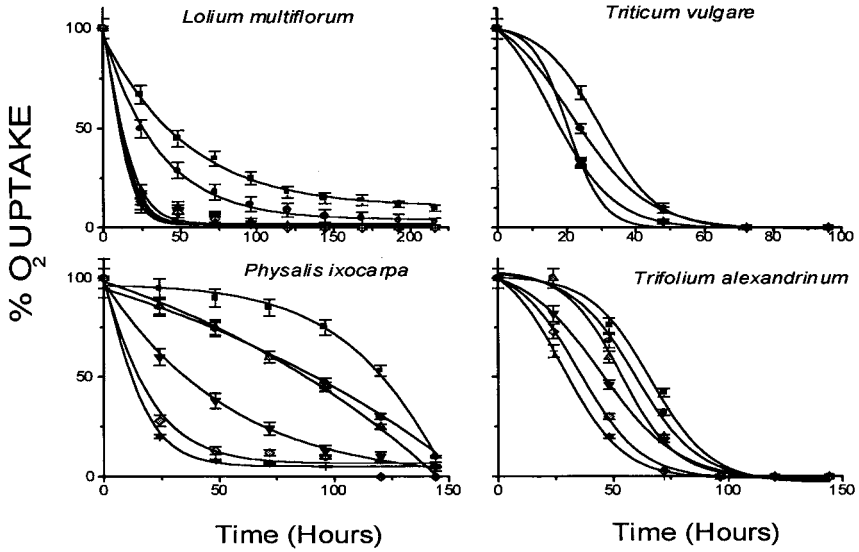

FIG. 5. Inhibition of respiration of *T. vulgare*, *L. multiflorum*, *P. ixocarpa*, and *T. alexandrinum* seeds by solutions of cedrelanolide, expressed as percent of O_2 uptake rate as a function of control seed respiration (■, 50 μM; ●, 100 μM; ▲, 200 μM; ▼, 300 μM; ♦, 400 μM; +, 500 μM. Each value represents mean ± SE ($N = 5$) in error bars.

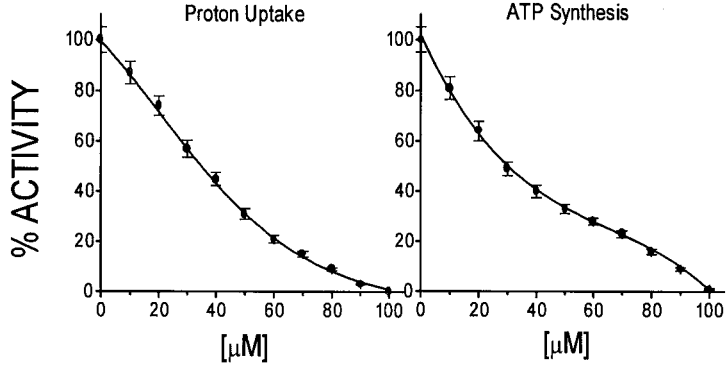

FIG. 6. Rate of ATP synthesis and proton uptake with increasing concentration of cedrelanolide in chloroplasts isolated from fresh spinach leaves. Each value represents mean ± SE ($N = 5$) in error bars. The inhibition efficacy was expressed as a percentage of cedrelanolide activity inhibited compared with the control value (100%). Control values for ATP synthesis and H^+ uptake were 350 and 280 μmol/mg chlorophyll/hr, respectively.

TABLE 2. EFFECT OF CEDRELANOLIDE (μM) ON PHOTOSYNTHESIS ELECTRON TRANSPORT RATE MEASUREMENTS IN INTACT FRESHLY LYSED SPINACH CHLOROPLASTS[a]

Activity	pI_{50}	IC_{50}
H^+-uptake	4.457	34.9
ATP synthesis	4.530	29.5
Basal	4.376	42.0
Uncoupled	4.468	34.0
Phosphorylating	4.610	24.5

[a] Means of three experiments. Values are expressed as the dose (μM concentration) that gives 50% inhibition. Calculated by ANOVA ($P < 0.05$).

inhibited respiration, germination, shoot and root elongation, and dry weight in a concentration-dependent manner. In general, radicle and shoot elongation were less sensitive to cedrelanolide inhibition than were germination and seed respiration (see I_{50}, Table 1).

Humilinolides A, B, C, and D (tetranortriterpenoids of the mexicanolide group) and the MeOH extract of the seeds from *Swietenia humilis* (Meliaceae), displayed marked phytoxicity towards radicle growth of *Amaranthus hyponcondriacus* and *Echinochloa crusgalli.* The IC_{50} of the extract was 275.95 and

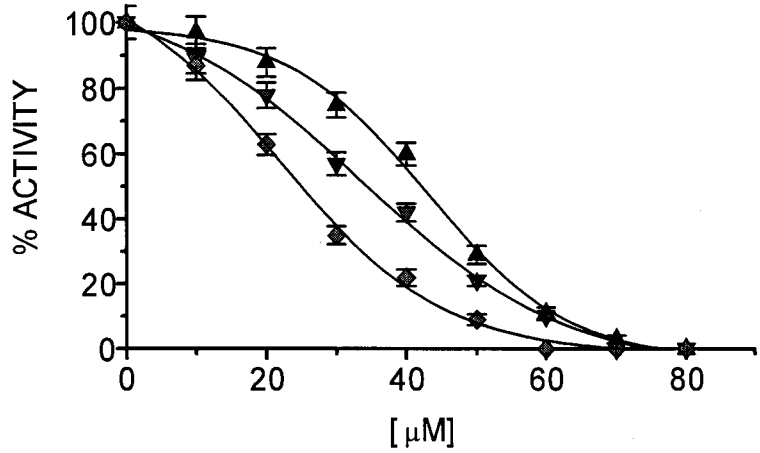

FIG. 7. Effects of cedrelanolide on electron transport rate (tridown, uncoupled; ♦, phosphorylating; and ▲, basal) in chloroplasts isolated from fresh spinach leaves. Control rate values (in μequiv e^-/hr/mg chlorophyll) are 300, 600, and 1050, respectively. Each value represents mean ± SE ($N = 5$) in error bars. The inhibition efficacy was expressed as a percentage of activity inhibited compared with the control value (100%).

171.54 ppm on radicle growth of *A. hyponcondriacus* and *E. crusgalli*, respectively. The humilinolides A and C showed the same effect at 99.06 and 163.0 ppm for *E. crusgalli*, respectively; and at 199.0 and 215.08 ppm for *A. hypocondriacus*, respectively. Humilinolides B and D were not inhibitory (Segura-Correa et al., 1993). These results show that cedrelanolide is a more potent inhibitor than the humilinolides to mono- and dicot seeds.

Achnine et al. (1999) investigated the effect of the limonoids gedunin, 7-oxogedunin, 7-deacetoxigedunin, and odoratol on photosystem I and photosystem II and reported that these natural products were inhibitory at different sites on the electron transport carrier of the photosynthesis process. However, the effect of other limonoids on seed germination, root and seedling growth, and seed respiration was unclear. Cedrelanolide is unique among limonoids reported to date (Segura et al., 1994) that should be biogenetically derived from a methylangolensate type of precusor. The unusual C-15 acyl group could be produced by an actyl transfer from a suitable ester, probably at C-30 (Taylor, 1979). A second modification would be the opening of the δ-lactone ring to give a free acid functionality at C-16 and the acyloxy group at C-17, and the C-16 acid could relactonize with a free hydroxyl group at C-8 to yield the γ-lactone portion.

This compound has certain similarities with sendanin and toosendanin and their derivatives (Isman et al., 1996; Schmutterer, 1995). We have recently reported that other limonoids cause different types of inhibition and characteristic effects on seed germination and respiration (Céspedes et al., 1998, 1999a,b). We know of no other reports of the effects of these kind of compounds on growth or germination.

INFLUENCE OF DEFOLIATION ON TOXIC ALKALOID CONCENTRATION AND ALKALOID POOLS IN TALL LARKSPUR

M. H. RALPHS* and D. R. GARDNER

USDA/ARS Poisonous Plant Laboratory
1150 E. 1400 North, Logan, Utah 84341

(Received May 1, 2000; accepted September 2, 2000)

Abstract—This study was replicated at two locations in the mountains of central Utah. In 1997, ten uniform plants of tall larkspur (*Delphinium barbeyi*) in the early bud stage (40 cm in height) were selected at each site and clipped at 5 cm above soil level. In 1998, one stalk from each plant was harvested on a weekly basis; in 1999, one stalk was harvested at four times during its phenological development. Toxic and total alkaloid concentrations were measured and alkaloid pools in the entire stalk were calculated. Clipping reduced stalk height to less than 50 cm in 1998 and 65 cm in 1999, compared to over 100 cm in unclipped control plants. Alkaloid concentration was similar to control plants, but toxic alkaloid pools were 70% lower than control plants, because of the reduction in biomass of the stalks. Clipping reduced subsequent vigor and the amount of toxic and total alkaloids in tall larkspur.

Key Words—Tall larkspur, *Delphinium barbeyi*, norditerpenoid alkaloids, defoliation, cattle poisoning.

INTRODUCTION

Larkspurs (*Delphinium* spp.) are an important group of poisonous plants on mountain rangelands. They are relatively palatable to all livestock (Pfister et al., 1988) but acutely toxic to cattle (Olsen, 1978), causing widespread deaths throughout the mountains in the western United States (Nielsen and Ralphs, 1988).

*To whom correspondence should be addressed. e-mail: mralphs@cc.usu.edu

0098-0331/01/0100-0151$19.50/0

The toxic compounds in larkspur are norditerpenoid alkaloids. Alkaloids containing the *N*-(methylsuccinimido)-anthranilic ester group (referred to as MSAL alkaloids) are the most toxic (Manners et al., 1995), with methyllycaconitine (MLA) being the most prominent toxic alkaloid. We have differentiated the class of toxic alkaloids (MSAL) in larkspurs from the other alkaloids (Gardner et al., 1997) and quantified them as a measure of potential toxicity to cattle (Ralphs et al., 1997).

Environmental stresses on tall larkspur (*D. barbeyi*) have little effect on toxic alkaloid levels. Light stress and photosynthesis inhibition (Ralphs et al., 1998a) and the herbicide glyphosate (Ralphs et al., 1998b) reduced the dry weight of the plants, thus increasing alkaloid concentration proportionately, but the absolute amount of alkaloids, or alkaloid pools, were not affected. Damage from the larkspur mirid (*Hopplomachus affiguratus*) actually reduced toxic alkaloid concentration (Ralphs et al., 1998c), rather than inducing alkaloid synthesis, as suggested by the plant defense theory (Tallamy and Raupp, 1991).

Laycock (1975) clipped Duncecap larkspur (*D. occidentale*) in the vegetative stage for two successive years and reported that the concentration of total alkaloids declined by 50%, compared with unclipped plants. If defoliation reduced the toxicity of larkspur, clipping or mowing larkspur patches might reduce the risk of poisoning cattle. However, the generalized plant defense theory (Rhoades, 1979, 1985) predicts that some plants induce synthesis of toxic defense compounds in response to defoliation as a self-defense mechanism. Sometimes the response is delayed to the next season's growth (Tuomi et al., 1990). This delayed resistance may be an active response induced by defoliation (Haukioja, 1980) or an indirect response resulting from nutrient stress (Tuomi et al., 1990; Bryant et al., 1993). The carbon/nutrient balance theory predicts that if either carbon or nitrogen limits growth, the other nutrient becomes excessive and can be shunted to defense compounds (Bryant et al., 1983). The objective of this study was to determine the effects of clipping tall larkspur on subsequent vigor, alkaloid concentration, and alkaloid pools.

METHODS AND MATERIALS

The study was replicated at two locations in the mountains of central Utah. The Ferron Reservoir site is 46 km west of Ferron at an elevation of 3150 m. It is in a subalpine zone and the vegetation consisted of scattered subalpine fir stands interspersed in the tall forb plant community dominated by tall larkspur, western cone flower (*Rudbeckia occidentalis*), sweet cicely (*Osmorhiza occidentalis*), and mountain brome (*Bromus carinatus*).

The Mt. Terrell site is 40 km east of Salina at 3230 m in the subalpine zone. Tall larkspur dominated the tall forb community with violet (*Viola purpurea*),

sedge (*Carex* spp.), and mountain brome as understory species. Both sites were fenced to prevent any grazing interference during the experiment.

Ten uniform plants (20–30 stalks/plant) were selected at each site and marked with an orange tent stake. The plants were clipped 5 cm above the soil on July 16, at Salina and July 17, 1997 at Ferron. The plants were in the early bud stage, prior to elongation of the inflorescence. In 1998, one stalk was harvested from each plant, on a weekly basis, to evaluate seasonal trends in toxic and total alkaloid responses to clipping the previous year. In 1999, one stalk was harvested in the late vegetative, early flower, late flower, and pod stages of development. The height of the stalk was measured when harvested. It was placed in an airtight plastic bag and immediately frozen on Dry Ice. The samples were freeze dried and then weighed to obtain dry weight. After grinding through a cyclone grinder, the alkaloids were extracted and analyzed by Fourier-transformed infrared spectroscopy (FTIR) (Gardner et al., 1997) to determine the concentration of the toxic MSAL alkaloids and total alkaloids. Alkaloid pools in each stalk were calculated by multiplying alkaloid concentration by the dry weight of the stalk (Ralphs et al., 2000). Pools are a better estimate of secondary compound synthesis because concentration can change by being diluted in a large plant, or concentrated in a small plant (Bryant et al., 1993).

The data were analyzed in two parts. The first analysis compared vigor measurements (number of stalks and dry weight per stalk) in the same plant when it was clipped in 1997 and at equivalent growth stages in 1998 and 1999. Data were analyzed in a random mixed analysis of variance in a split-plot design comparing locations and year, with plants within location as a random factor. The data were transformed by the log transformation prior to analysis, but actual means are presented. There was a location × year interaction ($P < 0.01$), so the model was reduced to a one-way analysis of variance comparing years within each location. Means were separated by least significance difference pairwise comparisons.

The second analysis compared seasonal trends of stalk height and alkaloid concentrations and pools between the plants that had been defoliated in 1997, and 10 undefoliated control plants at each location in 1998 and 1999. These variables were compared in a repeated measures mixed analysis of variance using compound symmetry covariance in a split plot design. Treatment (control, clipped), location, and year were the main effects, and plants within treatment and location was the factor repeated over weeks. The data were transformed by log transformation prior to analysis, but actual means are presented in the graphs.

RESULTS

Vigor. There was an initial difference in the number of stalks per plant between the two locations ($P < 0.001$). The Salina site had an average of 31

TABLE 1. VIGOR OF TALL LARKSPUR WHEN CLIPPED IN 1997 IN EARLY BUD STAGE AND RESPONSE IN 1998 AND 1999[a]

Location	Year	Plants (N)	Stalks/plant (N, mean ± SE)	Stalk weight (g, mean ± SE)
Ferron	1997	10	18 ± 2.3 a	5.3 ± 1.1 a
	1998	8	7 ± 1.4 b	1.8 ± 0.4 b
	1999	8	9 ± 3.4 b	2.2 ± 0.4 b
Salina	1997	10	31 ± 1.7 a	3.6 ± 0.3 a
	1998	9	16 ± 2.5 b	1.7 ± 0.2 b
	1999	8	32 ± 4.9 a	1.5 ± 0.1 b

[a] Means within locations not followed by the same letter differ ($P < 0.05$).

stalks/plant, compared with 18 stalks/plant at Ferron. Clipping greatly reduced the vigor of tall larkspur plants, in both number of stalks per plant and stalk weight (Table 1). The number of stalks per plant declined by 50% in 1998 and remained low in 1999 at Ferron. Stalks per plant increased, however, to pretreatment levels in 1999 at Salina. Stalk weight declined at both locations and remained low in both years.

Figure 1 illustrates the growth pattern of larkspur plants through the 1998 growing season. The control plants exceed 100 cm in height when mature. The plants clipped in 1997 reached a height of only 50 cm in 1998 and 65 cm in 1999 ($P < 0.001$).

Alkaloids. The concentrations of toxic and total alkaloids in defoliated plants were similar to the control plants and steadily declined through the growing season in both years (Figure 2). There was a year difference ($P < 0.001$) with both toxic and total alkaloids slightly lower in 1999.

There was considerable variability in concentration of toxic alkaloids in defoliated plants in 1998 (i.e., wide standard error bars; Figure 2). Some of the defoliated plants were severely stunted. Their stalks were small and spindly, and they remained in the vegetative stage throughout the growing season. In some but not all of these stunted plants, toxic and total alkaloids remained high throughout the growing season, in contrast with the other plants in which alkaloid concentrations declined with maturity. Perhaps the prolonged juvenile stage of the stunted plants accounted for the elevated and retained alkaloid concentrations.

The total amount of alkaloid in a stalk, or alkaloid pool, regardless of its size, was estimated by multiplying the dry weight of the stalk by its alkaloid concentration. Pools of both toxic and total alkaloids in clipped plants were only one third of the undefoliated control plants (Figure 3). Clipping suppressed both the growth and total amount of alkaloids in tall larkspur in the subsequent growing season.

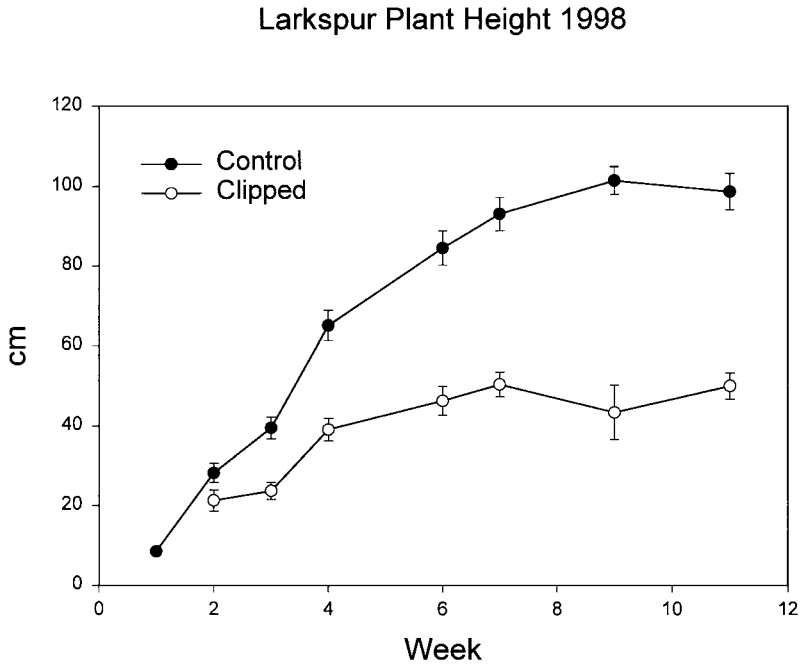

FIG. 1. Tall larkspur plant height through the 1998 growing season of undefoliated control plants and plants that were clipped in 1997.

DISCUSSION

Clipping tall larkspur in the early bud stage in 1997 greatly reduced the vigor of the same plants in 1998 and 1999. This agrees with the results of Laycock's (1975) experiments in which clipping duncecap larkspur in the early vegetative stage for two years was most detrimental to vigor when measured in the third year. Cronin (1971), however, reported that clipping tall larkspur at various frequencies during the growing season was not detrimental to the growth of the same plants the following year, but they failed to produce flowers. Vigor of other forbs in the tall forb community is also reduced by clipping: bluebell (*Mertensia arizonica* var. *leonardi*) (Laycock and Conrad, 1969), white polemonium (*Polemonium foliosissimum*) (McDonough and Laycock, 1975), Porter ligusticum (*Ligusticum porteri*), edible valeriam (*Valeriana edulis*), and Richardson geranium (*Geranium richardsoni*) (Julander, 1968).

Laycock (1975) further reported that the concentration of total alkaloids declined by 50% following two years of clipping. Earlier extraction methods for the titration analytical technique (Williams and Cronin, 1963) did not retrieve

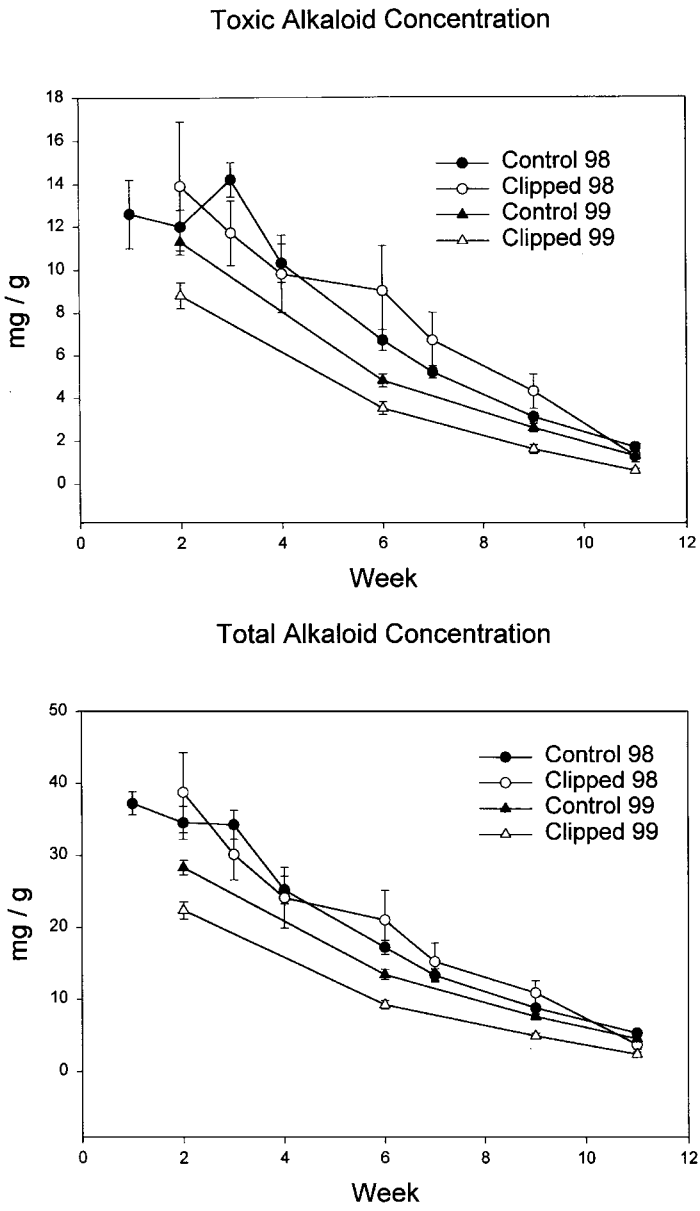

FIG. 2. Trends in toxic and total alkaloid concentration through the 1998 and 1999 growing season of control plants and plants that were clipped in 1997.

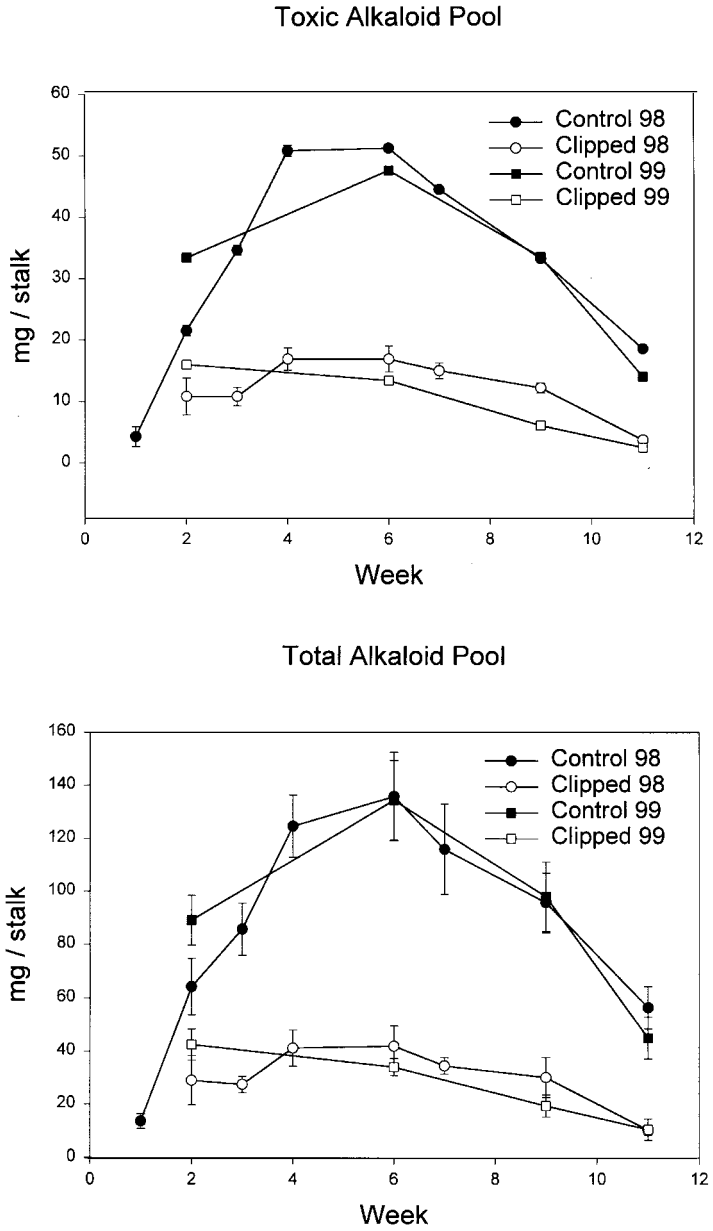

FIG. 3. Pools of toxic and total alkaloids in control plants and clipped plants in 1998 and 1999.

the toxic class of alkaloids (G. D. Manners, personal communication) and would subsequently underestimate the total alkaloid concentration. However, this does not explain the relative decline in total alkaloid concentration in Laycock's (1975) study and the lack of decline in alkaloid concentration in our study.

There was very little regrowth of clipped plants in 1997, and they were substantially smaller in 1998, both in height and stalk weight. Clearly their photosynthetic capacity was reduced. The carbon–nutrient balance theory (Bryant et al., 1983, 1992; Toumi et al., 1990) predicts that since carbon gain would be limited, nitrogen in excess of that used for growth could be used to increase synthesis of alkaloids. However, alkaloid synthesis apparently did not increase (alkaloid concentration was similar to controls and alkaloid pools were lower). In contrast, wild tobacco shifts its allocation of nitrogen to nicotine synthesis following clipping, at the expense of growth and reproduction (Ohnmeis and Baldwin, 1994; Baldwin et al., 1990).

Larkspur grows from buds on the crown of the tap root. These buds start to swell in the late summer and early fall, remain active and grow slowly beneath the snowpack over winter, and initiate rapid growth even before the snow melts in the spring (Kreps, 1969). Perhaps the removal of photosynthetic material during the 1997 growing season greatly restricted the energy flow to the crown and developing buds, resulting in the significant reduction in the number and vigor of stalks in 1998 and 1999.

Benn and May (1964) reported that alkaloids in *Delphinium brownii* are synthesized in roots and probably follow the mevalonate pathway of terpene biosynthesis or the recently proposed pathway starting from pyruvate and glyceraldehyde-3-phosphate (Lichtenthaler et al., 1997). Since energy and carbon were apparently limited in the roots of our clipped plants, alkaloid biogenesis may also have been limited.

Tall larkspur is not palatable to cattle in its early growth stages, but becomes palatable as it matures into the flower and pod reproductive stages (Pfister et al., 1997). Since clipping reduced the number and size of larkspur stalks, and prevented them from maturing into the reproductive stages, it may reduce the likelihood of cattle grazing clipped plants, as well as reducing the total larkspur biomass available to grazing animals. Alkaloid pools were also lower in the shorter stalks, although concentration of alkaloids remained unchanged. The reduced vigor of clipped plants may shift the competitive advantage to associated species in the plant community, which could further suppress larkspur growth. Thus, clipping may reduce the overall risk of poisoning in cattle.

(Received March 7, 2000; accepted September 3, 2000)

Abstract—The toxicological characteristics of dietary decomposed alder leaf litter against mosquito larvae were further investigated through enzymatic and chemical purification of a phenoliclike cell-wall fraction isolated from crude litter. The toxicity of the subfractions obtained was controlled by standard bioassays on third instars of *Aedes aegypti* chosen as a reference target species. Enzymatic hydrolyses of the cell-wall fraction were performed with caylase, pectolyase, esterase, and β-glycosidase, in order to release, respectively, cellulose material and phenolic compounds bound to lignins. These treatments did not affect the larvicidal activity and the phenolic activity of the cell-wall fraction. Chemical alkaline and acid hydrolyses were carried out to break ester and glycosidic bonds of the cell-wall fraction. Comparison of HPLC profiles of the hydrolysates from both toxic and nontoxic fractions did not reveal differences between the phenolic acids released. Aluminum chloride, known for its phenolic complexing activity, counteracted the larvicidal activity of the cell-wall fraction. Altogether, these results suggest the involvement of ligninlike compounds in the toxicity of dietary alder leaf litter against larval mosquitoes. The toxicity of this fraction, which was very sensitive to drastic and smooth oxidations, seemed to be associated with a strong oxidative potential. These results are discussed in relation to a possible mode of action of lignins in the plant–mosquito interactions.

Key Words—Alder leaf litter, larvicidal activity, ligninlike compounds, HPLC, bioassays, *Aedes aegypti*.

INTRODUCTION

Because of their various biological effects (reviewed in Appel, 1993), polyphenols are among the most important secondary compounds involved in plant–insect dietary interactions (Ali et al., 1999). Whereas the influence of polyphenols from green leaves on the ecotoxicology of terrestrial herbivorous insects has received much attention (Steinly and Berenbaum, 1985; Scriber et al., 1989), their dietary interaction with aquatic detritivorous Arthropoda is far less documented (Newman, 1991).

The ecotoxicological consequences of such an interaction are particularly important in mosquito breeding sites from Alpine hydrosystems (Rey et al., 1996). The polyphenols of decomposed leaf litter from riparian vegetation appear to be involved in the habitat segregation of larval Culicidae through their differential dietary toxicity (Rey et al., 1998a, 2000a). Such toxicity, mainly an interaction between alder [*Alnus glutinosa* (L.) Gaertn.] and larval *Aedes* taxa, appeared to be exerted against the midgut epithelium of the detritivorous larvae (Rey et al., 1999a; David et al., 2000a). The histopathological effects of dietary polyphenols observed in this target organ are stronger than those obtained with the bacterioinsecticide *Bacillus thuringiensis* var. *israelensis*, suggesting the possible use of those vegetable polyphenols in mosquito control (Rey et al., 1998b).

The detritivorous arthropodan fauna from Alpine mosquito breeding sites shows differential tolerance to those ingested polyphenols (Rey et al., 2000a). Different levels of cytochrome P-450 monooxygenase and esterase activity were associated with differential detoxifying capacities among species and ecotypes (Rey et al., 1999b, 2000b).

Preliminary toxicological characterization of the alder leaf litter indicated that the settling of the larvicidal effect required a 10-month decaying process in the mosquito breeding site, under complex seasonal biotic, climatic, and hydrologic factors (David et al., 2000b). The toxicity of the decomposed leaf litter seems to be intrinsic and associated with the high activity of insoluble phenolics of an extractible cell-wall fraction. Both toxicity and phenolic activity did not appear to be affected by a sequential extraction procedure with water, organic solvents, and a detergent (David et al., 2000b). At this stage of the purification procedure, this fraction included cellulose compounds (cellulose, hemicelluloses), pectic compounds, phenolic polymers of a lignin-type, and other insoluble polyphenols. Among those components, lignins, which are the most prominent polyphenols usually bound to plant cell-wall (Wallace and Fry, 1994), appear to be candidates for toxicity.

Further chemical transformation and fractionation of this cell-wall fraction are necessary to isolate the source of toxicity. For this purpose, we used gentle methods such as enzymatic hydrolyses (Faulds et al., 1999), or more drastic

methods such as alkaline and acid hydrolyses (Cvikrovà et al., 1993) before phenolic characterization and toxicological checking of the subfractions.

The toxicity of dietary vegetable phenolics is generally exerted on the midgut of herbivorous insects through oxidative mechanisms (reviewed by Summer and Felton, 1994). The sensitivity of the toxic cell-wall fraction to several chemical oxidants was tested in order to examine the involvement of oxidative stress in the larvicidal effects of the decomposed alder leaf litter.

METHODS AND MATERIALS

Plant and Insect Materials. The toxicity of decomposed alder leaf litter on larval mosquitoes was investigated on a purified cell-wall fraction extracted from crude 10-month-old litter. Samples were collected in August 1997 and 1998 in a woodland subjected to periodic flooding in the Rhône-Alpes region of France (Pautou and Girel, 2000), and they were deep-frozen until use. Extraction of the cell-wall fraction was performed according to the sequential fractionation procedure of Alibert et al. (1969), modified by David et al. (2000b), with water, absolute ethanol, acetone, and benzene, before Triton X-100 treatment. The cell-wall fraction was air-dried and stored at 4°C before subsequent enzymatic and chemical fractionation. Phenolic characterization and toxicity controls were performed on the subfractions.

A cell-wall fraction was extracted as above from samples of nontoxic 10-month-old litter for comparison of HPLC profiles of hydrolysates between toxic and nontoxic alder leaf litter. This nontoxic litter originated from a woodland near the site of collection of the toxic litter, but was subject to sparse flooding.

A. aegypti L. larvae, originating from a Bora-Bora strain raised in our laboratory (Rey et al., 1999b), were used as a standard for toxicity controls. This species was chosen because of its known sensitivity to crude alder leaf litter and cell-wall fraction (David et al., 2000a) and its continuous availability for experimentation.

Enzymatic Hydrolyses. Enzyme hydrolysis is helpful in the elucidation of the composition of the cell-wall fraction (Faulds et al., 1999). Information on the constituents of the cell-wall fraction involved in the toxicity factor may be provided by comparative larval toxicity controls of cell-wall fractions treated by differential enzyme hydrolysis. Several enzymes were used for this comparative toxicological analysis.

Caylase (caylase 345, Cayla S.A. Toulouse, France; a complex of extracellular enzymes with high cellulase and hemicellulase activities) and pectolyase (Sigma) were used separately or mixed together, in order to solubilize the polysaccharide and pectin compounds. In all cases, 100 mg of purified toxic cell-wall fraction, suspended in 20 ml of water adjusted to pH 5.5, was treated for 60 min at 36°C

with 200 mg and 20 mg of caylase and pectolyase, respectively. After filtration, the treated material was water rinsed and centrifuged (10,000*g* for 5 min) three times. Evaluation of the sugar quantity released in the supernatant, with glucose as a reference, was performed following the colorimetric method of Arnold (1965), by using the 3,5-dinitrosalicylic acid reagent. Absorbance was measured at 530 nm with a Perkin-Elmer 551 spectrophotometer.

β-Glycosidase (20 mg of 2.5 units/mg, Sigma) and esterase (30 μl of 4.16 units/ml, Sigma) were used to break down glycosidic and ester linkages, respectively. The procedure was identical to the above. For esterase, the pH was adjusted to 7.5 to obtain maximum enzymatic activity.

In all cases, toxicological checking and evaluation of total levels of phenolics (= phenolic activity) were performed on air-dried pellets. Total phenolics released after β-glycosidase and esterase digestion also were measured.

Alkaline and Acid Hydrolyses. For alkaline hydrolysis, 130 mg of purified toxic cell-wall fraction was treated with 30 ml 2 N NaOH under a nitrogen atmosphere for 2 hr at 20°C. After neutralization, the slurry was centrifuged at 20,000*g* for 10 min, and the pellet was rinsed with water and centrifuged as above.

For acid hydrolysis, 300 mg of purified toxic cell-wall fraction was treated with 20 ml N H_2SO_4 under agitation for 2 hr at 100°C. The neutralized slurry was filtered, water-rinsed, and centrifuged as mentioned above.

After hydrolysis, the resulting pellets were air-dried and stored at 4°C before determination of phenolic activity and larval toxicity control. The supernatants were evaporated to dryness, and the residue was dissolved in methanol to discard the sodium salts. The hydrolysates, solubilized in methanol, were chemically characterized through HPLC analysis.

HPLC Analysis. A reversed-phase system, including a Waters Spherisorb 5-μm ODS-2 column (250 × 4.6 mm ID; Alltech, Deerfield, Illinois) was used for the characterization of the phenolic acids released by acid/alkaline hydrolyses of the cell-wall fraction. The column was equipped with a 5-mm precolumn, a Dionex 4500i gradient pump, a Shimadzu SIL-9A autoinjector, a Shimadzu SPD 6A UV detector, and Shimadzu Workstation Class CR-10 integration software. The mobile phase consisted of ultrapure water with 1% orthophosphoric acid, and methanol (HPLC grade). The column was eluted with a 60-min water–methanol gradient at a flow rate of 0.5 ml/min. The gradient comprised 5 min isocratic 80 : 20, 40 min linear to 45 : 55, followed by 10 min linear to 80 : 20. Sample size was 150 μl and phenolic acids were detected at 280 and 320 nm.

The identification of phenolic acids eluted was performed by comparison with retention times of appropriate standards (gallic acid, ellagic acid, *p*-hydroxybenzoic acid, vanillic acid, *p*-coumaric acid, and ferulic acid) (Sigma). HPLC profile comparisons were made between toxic and nontoxic cell-wall frac-

tions in order to elucidate possible compounds released from the hydrolyzed cell-wall fraction that may be involved in the toxic factor.

Chemical Oxidations. Chemical oxidations were performed with aqueous solutions of $KMnO_4$ (0.02 N), $FeCl_3$–$FeK_3(CN)_6$ (1%, v/v) and NaOH (0.001 N to 0.2 N: see Figure 3 below). A 300-mg toxic cell-wall fraction was mixed in 30 ml of oxidative solutions for 2 hr under agitation at 20°C. Treated powders were water rinsed and centrifuged (10,000*g* for 5 min) three times, then air-dried before determination of phenolic activity and toxicity control.

Chelation with Aluminum Chloride. A purified toxic cell-wall fraction (10 mg) was suspended into 50 ml of 0.05% $AlCl_3$ aqueous solution at pH 7, and incubated 1 hr at 20°C.

Determination of Phenolic Activity. Determination of the phenolic compounds within the subfractions resulting from the enzymatic and chemical treatments was done in triplicate, with 5–10 mg (dry weight) of powder. Measurements were done with the colorimetric method by the Folin-Ciocalteau reagent and 20% Na_2CO_3, following the method of Marigo (1973) modified by David et al. (2000b), with gallic acid used as a standard. Absorbance was measured at 760 nm with a Perkin-Elmer 551 spectrophotometer.

Toxicity Controls. Toxicity of the subfractions obtained after the different enzyme activities and chemical treatments was checked with standard bioassays (WHO, 1981) on third-instar *A. aegypti*. Triplicate bioassays were conducted at 25°C, on samples including 20 specimens of the same size, in plastic vials containing 50-ml water suspensions of the different subfractions (10 mg/50 ml), with pH adjusted to 7.5. Controls were reared in tap water. Mortality was checked 2 hr after the beginning of the treatment. Results were corrected by Abbott's formula (Abbott, 1925).

RESULTS

Purification of Toxic Cell-Wall Fraction by Enzymatic Digestion. Enzymatic hydrolysis of the toxic cell-wall fraction with caylase and pectolyase alone or mixed together showed no obvious decrease of toxicity within this fraction (Table 1). Nevertheless, a significant amount of polysaccharide and pectin compounds were released by this treatment (representing 150, 30, and 210 μg glucose/mg for caylase, pectolyase, and both mixed together, respectively), indicating the efficiency of the treatments. The residual phenolic activity was not affected by these enzymatic digestions (Table 1).

These results suggest that the polysaccharidic compounds included in the cell-wall fraction and released by the enzyme activities may not be involved in the larvicidal effect. Moreover, the same relation previously mentioned by David et al. (2000b) between toxicity and total phenolic activity was observed here.

TABLE 1. EFFECTS OF ELIMINATION OF CELLULOSE AND PECTIN COMPOUNDS BY ENZYMATIC HYDROLYSIS ON TOXIC CELL-WALL FRACTION

Toxic cell-wall fraction	Toxicity (% mortality ± SE)	Residual phenolic activity (μg equiv gallic acid/mg powder)	Released sugars (μg glucose/mg powder)
Untreated	89 ± 6.6	36 ± 1.6	—
Treated with pectolyase	95 ± 5.4	31.2 ± 2.1	30 ± 5
Treated with caylase	94.8 ± 3.3	35.8 ± 2.4	150 ± 7.5
Treated with both pectolyase and caylase	84 ± 5.2	31.9 ± 0.9	210 ± 12

Hydrolysis of ester and glycosidic linkages within the cell-wall fraction, with esterase and β-glycosidase, released small amounts of phenolic compounds (1.4 and 3.2 μg equiv gallic acid/mg powder, respectively) (Table 2). There was no obvious decrease of toxicity within the subfractions obtained. Thus, the polysaccharidic compounds and phenolic acids linked to the insoluble cell-wall fraction did not seem to be involved in the larvicidal effect of the litter.

These results confirm our knowledge of the composition of the cell-wall fraction, showing that its main components involved in toxicity are supposed to be related to the ligninlike compounds. They constitute the main polyphenolic constituents remaining within the cell-wall fraction after enzymatic treatment.

Chemical Treatments. Both acid and alkaline hydrolysis of the toxic cell-wall fraction led to a strong loss of toxicity (Table 3). In the same way, an important decrease of phenolic activity within this fraction was observed after hydrolysis (i.e., from 48% for acid hydrolysis up to 55% for alkaline hydrolysis).

However, these drastic hydrolyses did not release any significant toxic compounds, as shown by the comparison of HPLC profiles of the supernatants resulting from hydrolyses of toxic versus nontoxic cell-wall fractions (Figure 1). In both cases, among the few solubilized compounds, four of them were identi-

TABLE 2. EFFECTS OF ELIMINATION OF CELL-WALL LINKED PHENOLIC COMPOUNDS BY ENZYMATIC HYDROLYSIS ON TOXIC CELL-WALL FRACTION

Toxic cell-wall fraction	Toxicity (% mortality ± SE)	Residual phenolic activity (μg equiv gallic acid/mg powder)	Released phenolic compounds (μg equiv gallic acid/mg powder)
Untreated	92.5 ± 3.6	37 ± 1.2	
Treated with β-glucosidase	99 ± 1.2	34.1 ± 1.6	1.4 ± 0.1
Treated with esterase	97.3 ± 3.3	33 ± 1.9	3.2 ± 0.2

TABLE 3. EFFECTS OF ACID AND ALKALINE HYDROLYSIS ON TOXIC CELL-WALL FRACTION

Toxic cell-wall fraction	Toxicity (% mortality ± SE)	Phenolic activity (μg equiv gallic acid/mg powder)
Untreated	98.5 ± 1.6	35.8 ± 1.2
Treated with H_2SO_4	2.5 ± 1.3	18.7 ± 2.6
Treated with NaOH	0	16.2 ± 4.2

fied by comparison with commercial compounds: gallic acid (R_t = 11.5 min), *p*-hydroxybenzoic acid (R_t = 26.7 min), vanillic acid (R_t = 29.8 min), and *p*-coumaric acid (R_t = 37 min). The most abundant compounds present in both profiles were *p*-hydroxybenzoic acid and gallic acid. None of them appeared to be more represented in the hydrolysate from the toxic cell-wall fraction than in that from the nontoxic one. There was no significant difference between alkaline (not shown) and acid (Figure 1) hydrolysis at both 280 (Figure 1) and 320 nm (not shown). HPLC results suggested that drastic hydrolyses did not solubilize any toxic component from the cell-wall fraction but may break them down or change their configuration into nontoxic forms. Thus, the phenolic compounds from the cell-wall fraction involved in the toxicity may be associated with the ligninlike compounds themselves rather than with the phenolic acids bound to lignins.

In the same way, strong chemical oxidations of purified toxic cell-wall fraction induced considerable decrease of both toxicity and phenolic activity (Figure 2). Nevertheless, in our experiment, $KMnO_4$ seemed to be more efficient than $FeCl_3$–$K_3(CN)_6$ among the oxidants used. Similar results were found after gentler oxidations with NaOH at low concentrations (Figure 3). These results indicated that the toxicity of the cell-wall fraction was rapidly canceled for NaOH concentrations under a threshold of 0.2 N and that a phenolic activity up to 15 μg equiv gallic acid/mg powder was necessary for a visible larvicidal effect.

The involvement of phenolic compounds within the toxic factor was also confirmed by treatment of the purified toxic cell-wall fraction with $AlCl_3$, known for its phenolic complexing activity. $AlCl_3$-treated samples only induced 1.5% of larval mortality, while untreated samples induced 97.5% of mortality, and $AlCl_3$ controls did not show any effect on larval survival (data not shown).

DISCUSSION

A preliminary characterization has associated the larvicidal properties of the decomposed alder leaf litter from Alpine mosquito breeding sites to an insoluble cell-wall fraction with a strong phenolic activity (David et al., 2000a). The current enzymatic and chemical purification of this cell-wall fraction revealed a

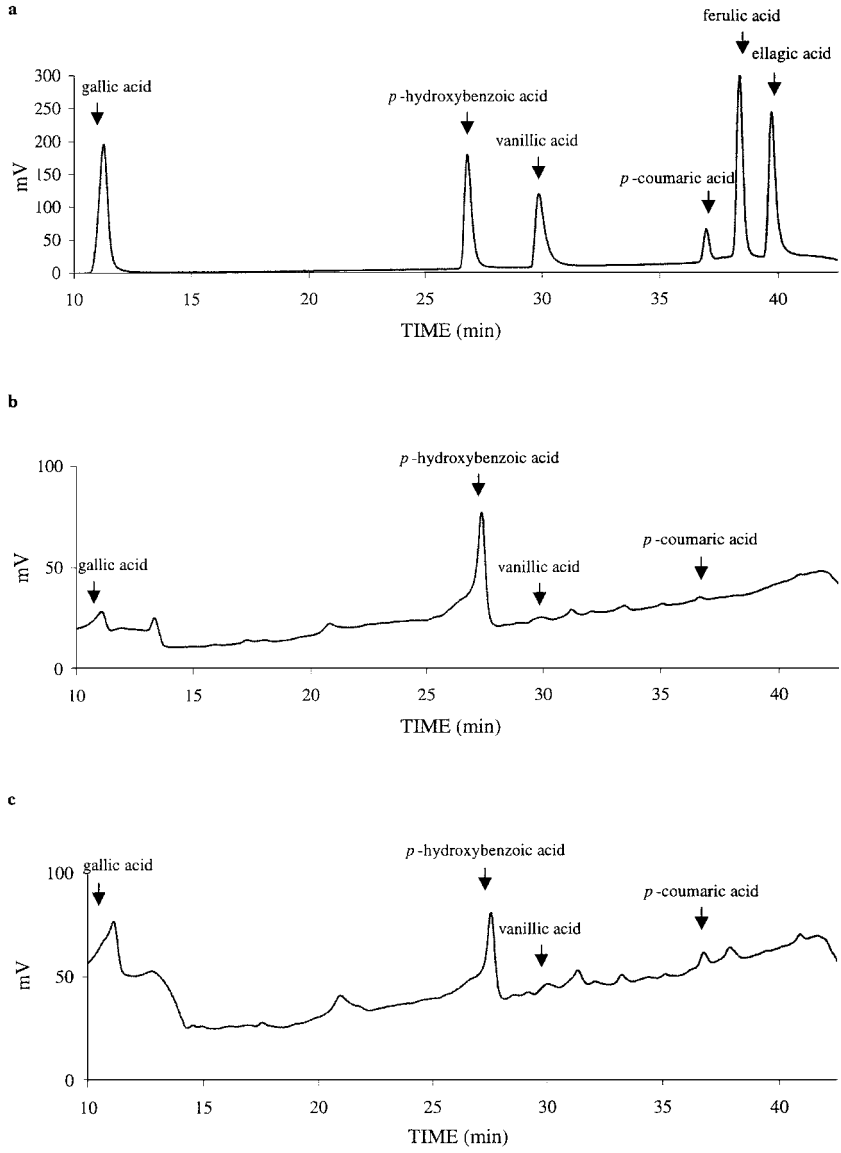

FIG. 1. Comparative HPLC profiles of standard compounds (a), toxic cell-wall fraction after drastic acid hydrolysis (b), and nontoxic cell-wall fraction after drastic acid hydrolysis (c). Extracts were run on reversed-phase HPLC, and phenolics were detected by absorbance at 280 nm. Peaks identified are indicated on the chromatogram.

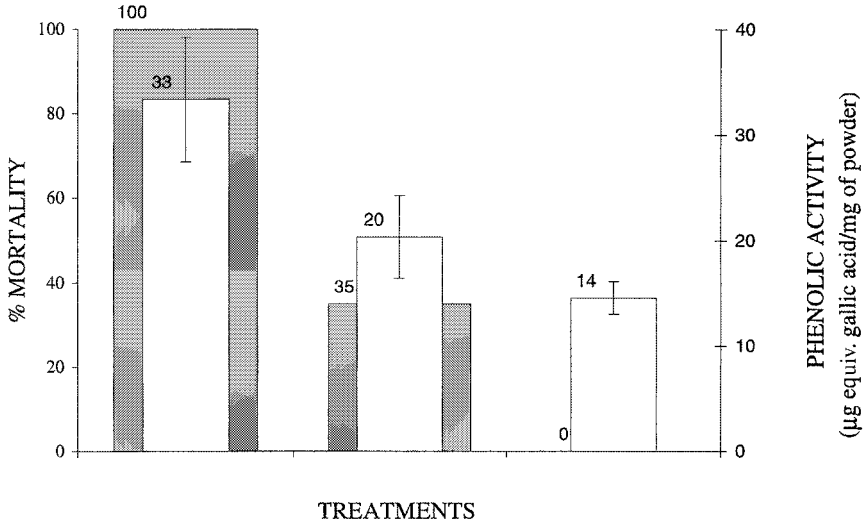

FIG. 2. Effects of chemical oxidation on toxicity (dark bars) and phenolic activity (white bars) of the cell-wall fraction.

toxic subfraction, including polyphenols, which may be characterized as lignin-like compounds. The sensitivity of the toxic fraction to both drastic and gentle oxidations suggested that the oxidation potential of these compounds within the larval midgut epithelium may be an important component of toxicity of alder leaf litter.

Characterization of Ligninlike Compounds as Toxic Elements from Cell-Wall Fraction. All the toxicological results of our fractionation and HPLC design are congruent and suggest the involvement of ligninlike compounds in the toxicity of the cell-wall fraction from decomposed alder leaf litter.

Lignins are phenolic polymers (Lewis and Yamamoto, 1990) that are built by oxidative coupling of three major C_6–C_3 phenylpropanoid units together with amounts of C_6–C_1 units such as *p*-hydroxybenzoic acid, which may be linked via ester and ether bonds to the rest of the lignin molecule (Wallace and Fry, 1994). However, as lignins were insoluble, there is no analytical method currently available to directly characterize them, and we have used several indirect characterization traits.

Our enzymatic design for digestion of the cell-wall fraction with hydrolases, alone or mixed, which may have synergistic interactions (Faulds et al., 1999), led to a purified subfraction with a high phenolic content. This subfraction may correspond to a purified ligninlike fraction, according to Wallace and Fry (1994), in the phenolic content of the vegetable cell wall.

Lignins were present within the plant cell wall in covalent attachment to structural polysaccharides, and in ester linkages to phenolic acids (Wallace et al., 1991). Esterified phenolic acids were easily liberated from cell walls by 1 N NaOH at room temperature (Iiyama et al., 1990). Hydrolysis of these complexes may lead to ferulic, *p*-coumaric, vanillic, sinapic, and *p*-hydroxybenzoic acid (Wallace and Fry, 1994). As most of these compounds have been found in hydrolysates from the toxic cell-wall fraction without any larvicidal effect, this was another indication of the involvement of the lignin cores themselves in the toxicity factor, and not of the bound phenolic acids.

In the same way, oxidations released phenols from reactive sites of the lignin macromolecules, and the analysis of the oxidation products has been used as a relative measure of the total lignin concentration in plants or leaf litter (see references in Amelung et al., 1999). We successfully used the oxidation of the toxic subfraction by potassium permanganate (Gellerstedt, 1992), and, to a lesser extent, by $FeCl_3$–$FeK_3(CN)_6$ and dilute NaOH. In all cases, there was a correlation between degradative oxidation and loss of toxicity together with phenolic activity. Results were obvious when using serial doses of NaOH under the threshold of 0.2 N. In the same way, the ability of numerous structural groups of the phenolics from the subtoxic fraction to form complexes with metals, including $AlCl_3$ (Jurd, 1962), was another qualitative trait suggesting the involvement of lignins in the toxicity factor.

Possible Involvement of Ligninlike Compounds in Toxicity of Cell-Wall Fraction. The possible involvement of ligninlike compounds in the larvicidal properties of decomposed alder leaf litter was expected as lignins are known to be one of the predominant phenolic components in leaf litter (Molloy et al., 1977). As soon as the more labile components have been degraded, litter decomposition curves are dominated by lignins (Minderman, 1968). Lignins are among the most important defensive chemicals in plants, providing not only physical but also chemical defense against insects (Wainhouse et al., 1998). As suggested from an evolutionary standpoint, lignins and ligninlike compounds may have been originally defense-related (Boudet et al., 1996). Besides the well-known role of lignins in decreasing the digestibility of plant cell walls by phytophagous consumers indirectly through their deleterious effect on rumen flora (see references in Bennett and Wallsgrove, 1994), direct larvicidal properties of lignins were suggested for some xylophagous Coleoptera (Wainhouse et al., 1990). In a toxicological investigation of integumental lignin against Coleoptera larvae, antibiosis phenomena were observed by Stamopoulos (1988), who used artificial diet with lignin.

Toxicological Effect of Ligninlike Compounds in Larval Midgut. The ligninlike products currently characterized in the cell-wall fraction of decomposed alder leaf litter may act as toxic elements through their phenolic activity. This was strongly suggested by our preliminary data (David et al., 2000a,b) and our current fractionation experiments, both indicating a strict association between toxicity and phenolic activity. The loss of toxicity currently observed within the oxidized cell-wall fraction suggests a correlation between oxidative and toxic power.

The involvement of oxidative processes in litter toxicity is not surprising because, generally, oxidative activation is the most common biochemical mode of action of phenolics (Appel, 1993). Oxidation may be an important component of phenolic toxicity in mosquito larval gut, as also proposed for lepidopteran larvae (Barbehenn and Martin, 1994). The autooxidation of phenolics may result in the formation of superoxide radicals and other reactive oxygen species (see references in Summer and Felton, 1994), leading to a direct oxidative stress of the digestive system of actively feeding larvae. This process may be enhanced by the alkaline pH of the larval gut (Clements, 1992) or by oxidative enzymes such as peroxidases and polyphenol oxidases (Appel, 1993). When the oxidative stress exceeds the antioxidant resources of the midgut tissues, protein oxidation and lipid peroxidation could ensue. Such redox cycling may be directly related to the histopathological effects of the ingested leaf litter on the midgut epithelium (David et al., 2000a). The midgut epithelium seemed to be the privileged target for the deleterious effect of phenolics due to the high relative reactivity of free radicals and reactive oxygen species. The major damages may be observed on tissues close to the site where the oxidants are stored or synthesized.

Although the current analysis suggests the involvement of ligninlike compounds in the larvicidal effect of dietary alder leaf litter through a possible induction of an oxidative stress in the mosquito midgut, the origin and the exact constitution of the toxic ligninlike compounds during the decaying process of the leaf material in mosquito breeding sites need further investigation.

(Received November 3, 1999; accepted September 8, 2000)

Abstract—The labial gland of the French subterranean termite *Reticulitermes santonensis* De Feytaud contains a polar, heat-resistent, and persistent chemical signal that is released onto the food during food exploitation and stimulates feeding in nestmates. Separation of the labial gland secretion by thin-layer chromatography on cellulose plates revealed that the secretion contains components with reducing and amino groups. In feeding bioassays conducted on the cellulose plate after TLC, termites preferred the area between R_f 0.46 and 0.88 (biologically active zone) for feeding, indicating the location of the feeding-stimulating signal. Thirty-five synthetic chemicals with similar chemical properties as the feeding-stimulating signal were analyzed with TLC. None of them covered the biologically active zone. Therefore, all chemical classes tested, such as sugars, amino acids, and salts, are unlikely as possible sources for the signal structure. In feeding choice tests with synthetic chemicals, termites showed clear feeding preference only for sugarlike components with physiologically excessive concentrations of 10 mmol and 100 mmol. Amino acids induced only light feeding preference. The intensity of feeding stimulation by the natural signal from the labial gland as compared to synthetic phagostimulants is discussed.

Key Words—termites, labial gland, phagostimulants, thin-layer chromatography, sugars, amino acids.

INTRODUCTION

In termite societies communal tasks, such as food exploitation, involve large numbers of nestmates and are in many ways regulated by the secretions of exocrine glands. The paired labial glands play a major role. They are found in all termite species, located in the meso- and metathorax. Their histology and fine structure have been described for several termite species (e.g., Czolij and Slaytor, 1988; Billen et al., 1989; Costa-Leonardo and Cruz-Landim, 1991; Kaib and Ziesmann, 1992; Mednikova, 1996; Costa-Leonardo, 1997). The glandular ducts open into the oral cavity, and from there termites release the watery labial gland secretion onto the substrate.

The labial gland secretion is reported to have various species-specific functions in nest construction, including regulation of nest climate, defense, fungistatic action, and source of digestive enzymes (e.g., Noirot, 1969; Hewitt et al., 1971; Maschwitz and Tho, 1974; Martin and Martin, 1978; Grassé, 1982; Brian, 1983; Hogan et al., 1988; Olagbemiro et al., 1988; Veivers et al., 1982, 1991; Mednikova, 1991). The labial gland secretion also plays an important role during communal food exploitation, as recently documented for *Schedorhinotermes lamanianus* and *Reticulitermes santonensis* (Kaib and Ziesmann, 1992; Reinhard and Kaib, 1995; Reinhard et al., 1997). It contains a feeding-stimulating chemical signal released onto the food by termite workers while feeding. It stimulates additional workers to feed at the same site, resulting in a faster and more efficient exploitation of the food source. This feeding stimulating signal is polar, heat-resistant, and nonvolatile (Kaib and Ziesmann, 1992; Reinhard et al., 1997). However, further research is required for its chemical characterization.

Organization of termite feeding is of major economic interest, as it results in the destruction of the material they feed upon. The damage done by termites worldwide reaches several billion U.S. dollars per year (Lewis and Haverty, 1996). There has been extensive research on toxic food baits as a means of controlling termites (e.g., Esenther and Grey, 1968; Jones, 1984; Su, 1994; Peters and Fitzgerald, 1999), but only recently did it become clear that inducing termites to preferentially feed on the toxic bait is of critical importance to the viability of the baits. Therefore, bait additives acting as phagostimulants have been sought among chemicals of nutritional value such as sugars (Waller and Curtis, 1996) and amino acids (Mishra, 1992; Chen and Henderson, 1996). A natural phagostimulant, however, such as the signal found in the labial gland secretion of *S. lamanianus* and *R. santonensis* (Kaib and Ziesmann, 1992; Reinhard et al., 1997), could present a much more effective way to make toxic bait systems attractive to termites.

We investigated chemically the feeding stimulating signal from the labial gland secretion of *R. santonensis* with thin-layer chromatography (TLC) com-

bined with feeding bioassays. Furthermore, the phagostimulating effect of the signal was compared with the effect of an array of synthetic chemicals of similar chemical properties and possible nutritional value.

METHODS AND MATERIALS

Collection and Culture of Termites. A new colony of the subterranean termite *Reticulitermes santonensis* De Feytaud was collected in Ile d'Oleron, France, and kept in the laboratory under constant conditions of 25°C, 75% relative humidity. The colony was housed in a metal container (length × height × width: 150 × 50 × 100 cm) for several months with moist vermiculite as soil substrate and water source and pine wood as food. From the container the termites had access to a foraging arena via a silicone tube (5 mm ID). The foraging arena (10 × 10 cm and 5 mm high) had a sand-blasted glass plate as floor and was covered by a glass plate.

At a preliminary stage of the work, the experiments also were carried out with three older laboratory colonies of *R. santonensis* (reared for up to six years). We could not observe obvious colony-specific differences during the feeding bioassays and chemical analyses. Nevertheless, to avoid possible rearing-related artifacts, only the freshly collected field colony was used for the final experiments.

Preparation of Gland Extract and Synthetic Chemicals. Termite workers were killed by deep-freezing, fixed in a ventral position in paraffin, and covered with distilled water. The paired labial glands were removed through an incision in the thorax. Lots of 100 labial glands were simultaneously extracted in 100 μl distilled water for 12 hr at 4°C and then deep-frozen for 24 hr. Thereafter, the glands were removed from the extract and the extract again deep-frozen until tested. Thirty-five synthetic chemicals (see Table 2 below) were chosen according to physicochemical properties corresponding to the feeding stimulating signal from the labial gland (polar, heat-resistant, nonvolatile: Reinhard et al., 1997). Chemicals were dissolved in water or ethanol at concentrations of 100, 10, and 1 mmol.

Thin-Layer Chromatography. The labial gland extract and the synthetic chemicals were chromatographed on cellulose TLC plates of 10 × 10 cm (TLC aluminum sheets, cellulose F, layer thickness 0.1 mm, Merck). Labial gland extract (10 μl) and 100 mmol solutions of each of the synthetics were applied separately on TLC plates with a microcapillary. The plates were chromatographed at room temperature for 70 min with a mixture of 2-propanol, 25% ammonia solution, water, and saturated boric acid solution (6 : 2 : 1 : 1), pH 9. For detection of spots we used UV light (254 nm) was well as the reagents bromcresol green, aniline phthalate, and ninhydrin/collidine (Merck, 1970).

Bioassays on Feeding Stimulation. Termites are light sensitive, so all tests were made under red light illumination. Feeding behavior in termite workers can be recognized easily by the hypognathous head position and wriggling head movements while gnawing and tearing off food fibers. Feeding spots can also be recognized afterwards by marks or holes in the substrate due to removal of food particles by the termites. Frequencies and spatial distributions of workers that were feeding according to the behavior described above were recorded over time by video techniques (IR-sensitive Kappa camera) and subsequently analyzed. To determine feeding stimulation by labial gland components, 10 μl of the labial gland extract was applied as a 1-cm-long line on cellulose TLC plates (10 cm long $\times$ 3 cm wide) and chromatographed as described above. The TLC plate was then offered in the foraging arena for 1 hr. As control, a TLC plate chromatographed without extract was offered simultaneously. The spatial distribution of all termites feeding between the start and front line on the TLC plates during the 1-hr duration of the experiment was analyzed to determine preferred feeding zones. Termites displaying different behaviors, such as arresting or aggregating without actually feeding, were not considered. The bioassay was repeated 10 times.

For the feeding bioassay with synthetic chemicals, pieces of moist filter paper were used as described in Reinhard et al. (1997). Four indepenent tests were run simultaneously in the foraging arena. Each test consisted of two semicircles (2.5 cm diameter) of filter paper. One of the two semicircles was randomly chosen for application of 25 μl of a synthetic solution and moistened with water. The other semicircle was just moistened (control). For each test the distribution of the first 20 feeding termites on the two semicircles was determined. Termites arresting or aggregating without actually feeding as described above were not considered. Up to three concentrations per chemical were tested for feeding preference. Tests for each chemical and each concentration were replicated 20 times. Enzymes (not heat-resistant) and stearic acid (lower polarity) were not tested for feeding preference.

Data Analysis. The distribution of feeding termites on TLC plates was analyzed via the dispersion index (Elliott, 1979) and the R_f value of the biologically active zone determined. The sign-test was used to analyze the data of the semicircle bioassays.

RESULTS

Analysis of Labial Gland Extract. Thin-layer chromatography of labial gland extract of *R. santonensis* revealed two bands in the lower half of the plate visible under 254 nm UV light (Figure 1A). With bromcresol green (general reagent for organic components), aniline phthalate (reagent for reducing groups

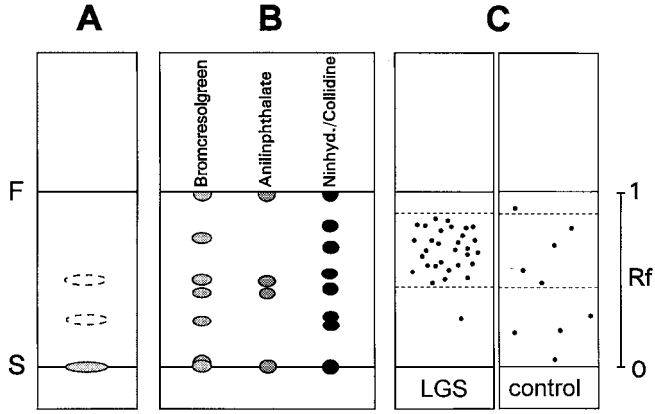

FIG. 1. Thin-layer chromatography of labial gland secretion (LGS) of *Reticulitermes santonensis* on cellulose plates. S: start line, F: front line. (A) Spots visible under UV 254 nm; (B) spots visible after detection with bromcresol green, aniline phthalate, and ninhydrin/collidine; (C) distribution of all termites (dots) feeding on a TLC plate within 1 hr of observation, left on LGS, right on control. Dotted lines: biologically active zone.

as in sugars), and ninhydrin/collidine (reagent for amino groups, amines, amino acids, and peptides) several further spots could be detected (Figure 1B). Consequently the labial gland secretion of *R. santonensis* contains components with reducing and/or amino groups.

When a TLC plate with chromatographed labial gland extract was offered to the termites, at least 95% of all termites showing feeding behavior were found between R_f 0.46 and 0.88 (Figure 1C, Table 1), leaving clear gnawing marks in the cellulose layer. Statistical analysis showed a difference from a random distribution at $P < 0.05$ for all 10 replicates. The feeding stimulating signal of the labial gland secretion must, therefore, be located in this area. In contrast, feeding termites were randomly distributed on the control plates (Figure 1C, Table 1), leaving gnawing marks all over the cellulose layer. Furthermore, more termites fed on the treated TLC plates (28.5 ± 5.6) within the 1-hr duration of the experiment compared to the control (2.7 ± 1.6, mean ± SD, $N = 10$, $P = 0.005$, Wilcoxon matched-pairs test).

Analysis of Synthetic Chemicals. Thirty-five synthetic chemicals with similar physicochemical properties to the feeding stimulating signal from the labial gland have been analyzed with TLC. Spot detection with bromcresol green showed that none of them covered the entire biologically active zone from R_f 0.46 to R_f 0.88 (Figure 2). Mono- and disaccharides were found only within the lower half of the active zone. Two of the sugar alcohols, amino sugars, methyl and phenyl sugars, as well as anhydrosugars/-sugar alcohols were located within or at least at the border

of the biologically active zone. Amino acids, peptides, enzymes, small carboxylic acids, and salts in general had much lower R_f values, while longer-chain carboxylic acids such as decanoic and stearic acid had higher ones.

The feeding choice tests on filter paper showed that few of the 31 chemicals tested had considerable feeding-stimulating effect, and this was only so at high concentrations (Table 2). A strong feeding-stimulating effect was found for sugars and methyl and phenyl sugars at a concentration of 100 mmol, and for glucose, sucrose, and cellobiose also at 10 mmol. Sugar acids, amino sugars, anhydrosugar, and amino acids showed some activity at 100 mmol. No significant feeding stimulation for any of the chemicals was recorded at 1 mmol (Table 2). Decanoic acid was repellent, and the termites fed more on the control. This repellency, though, is nonspecific and can be expected for various similarly volatile compounds such as ketones and alcohols.

[a] Abbreviations refer to Figure 2. +++: very strong feeding stimulation ($P < 0.001$), ++: strong feeding stimulation ($P < 0.01$), +: feeding stimulation ($P < 0.05$, +/−: tendency for feeding preference ($P = 0.05$–0.15), −: no feeding stimulation, −!: repellent, n.t.: not tested. P levels refer to original data of feeding choice assays: distribution of the first 20 feeding termites on two pieces of filter paper, treated vs. untreated, analyzed using the sign test, $N = 20$ per chemical and concentration.

DISCUSSION

The process of feeding and communal food exploitation in termites is strongly connected with their labial glands. Labial glands in the African dampwood termite *Schedorhinotermes lamanianus* and the French subterranean termite *Reticulitermes santonensis* contain a polar, heat-resistant, and nonvolatile chemical signal that stimulates feeding (Kaib and Ziesmann, 1992; Reinhard et al., 1997).

Analysis of the labial gland secretion of *R. santonensis* by TLC chromatography revealed the presence of numerous components. This corresponds with literature describing a variety of different compounds within the labial gland secretion of termites, such as proteins (digestive enzymes), lipids, mucopolysaccharides, and salts (Noirot, 1969; Veivers et al., 1982; Hogan et al., 1988; Mednikova, 1991; Tokuda et al., 1997; Watanabe et al., 1997).

The bioassay on TLC plates demonstrated that after chromatography the feeding-stimulating signal from the labial gland secretion is found in a large spot, spreading from R_f 0.46 to R_f 0.88. The fact that the termites respond to the labial gland secretion with feeding even after the separation of its constituents by TLC strongly indicates that the phagostimulant is a single component running as a streak in the TLC rather than a blend. The biologically active zone does not correspond to the spots detected in the labial gland secretion under UV 254 nm and after treatment with reagents or to any of the 35 reference chemicals analyzed. Therefore, it is unlikely that the feeding stimulating signal is found within the common chemical classes with appropriate physicochemical properties such as sugars, salts, amino acids, peptides, and carboxylic acids. Due to their low R_f value the digestive enzymes of the labial gland secretion can be excluded as a feeding-stimulating signal as well, confirming the findings of Reinhard et al. (1997). Detailed fractionation and GC-MS analyses of labial gland secretion are in progress to elucidate the molecular structure of the signal.

In feeding bioassays with cellulose TLC plates as food source, only very small numbers of termites could be induced to feed on the plates if these were untreated or had only synthetic chemicals applied to them. Cellulose TLC plates are therefore much less suitable as a food source for *R. santonensis*, compared to filter paper used in the former feeding bioassays (Reinhard et al., 1997). However, the feeding-stimulating signal of *R. santonensis* is powerful enough to make termites feed even on unsuitable food such as TLC plates. Considerable numbers of termites fed on plates treated with labial gland secretion. This confirms previous results with *R. santonensis*, where the termites could even be made to gnaw on a glass surface when labial gland secretion was applied (Reinhard et al., 1997).

The selected synthetic chemicals were much less effective as phagostimulants. A good feeding response in *R. santonensis* could only be induced on filter

paper and only with physiologically excessive concentrations of sugars and sugar derivatives. Amino acids proved to be only weak phagostimulants even in high concentrations.

The feeding stimulating activity of sugars has been shown earlier in *R. flavipes* and *R. virginicus* (Waller and Curtis, 1996), as well as in *Microtermes traegardhi* (Abushama and Kambal, 1976). Numerous other insect species react with increased feeding to artificial diets offering molar concentrations of diverse mono- and disaccharides (e.g., Ma and Jermy, 1976; Weibull, 1990; Schmidt and Friend, 1991; Allsopp, 1992; van der Meer et al., 1995). Our study shows considerable phagostimulatory activity of methyl and phenyl sugars, which has also been reported in a mosquito (Schmidt and Friend, 1991). The phagostimulatory effect of other sugar derivatives such as sugar acids, amino sugars, and the anhydrosugar are minor and likely to be due to the glucose component in them. Sugar alcohols had no effect on *R. santonensis* or on other insect species (Ma and Jermy, 1976; van der Meer et al., 1995).

The phagostimulant effect of amino acids on termites also has been shown for *Zootermopsis*, *Kalotermes*, and *Reticulitermes* species, as well as *Gnathamitermes tubiformans*, *Neotermes bosei*, and *Coptotermes formosanus* (Hungate, 1941; Spears and Ueckert, 1976; Mishra, 1992; Chen and Henderson, 1996). The feeding stimulation induced by amino acids differs between species, which might be due to the experimental setup used by the authors. Inconsistencies between results of feeding tests have been reported previously (Meehan and Wilde, 1989; Chen and Henderson, 1996). The phagostimulatory activity of amino acids also has been documented in other insect species (e.g., Sogawa, 1972; Viswanathan and Kalode, 1990; Allsopp, 1992). As in sugars, the increased feeding activity is likely to be due to the nutritional value of amino acids, which is especially relevant for termites. Generally, termite foods are low in nitrogen (Higashi et al., 1992) and termites are dependent on intestinal bacteria for nitrogen fixation (Breznak, 1975; Potrikus and Breznak, 1977; Ohkuma et al., 1996; Slaytor and Chappell, 1994). Because nitrogen is limited in naturally occurring termite food (Cowling and Merrill, 1966), nitrogen additives may increase food consumption.

Our results are consistent with the literature in which synthetic phagostimulants in termites are found among chemicals of nutritional value, such as sugars and amino acids. However, these compounds are only active in very high concentrations, as compared to the natural phagostimulant from the labial gland secretion of *R. santonensis*. Obviously this natural signal is much more effective, inducing feeding behavior at naturally low concentrations and even on substrates unsuitable as food sources (Reinhard et al., 1997). This indicates that once its chemical nature is identified, addition of the natural feeding-stimulating signal to a termite bait could increase food consumption and improve bait efficacy much more than the hitherto considered synthetic phagostimulants.

Acknowledgments—We are grateful to Dr. Michael Lacey, CSIRO Entomology, Australia, and Dr. Johannes Steidle, FU Berlin, Germany, for critical comments on an earlier draft of this paper. Dr. Monika Hilker, FU Berlin, Germany, provided laboratory facilities for the chemical analyses. Financial support was provided by a scholarship from the Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany.

(Received November 3, 1999; accepted September 8, 2000)

Abstract—The paired labial glands are located in all termite species in the thorax. During food exploitation workers of the French termite *Reticulitermes santonensis* and the African termite *Schedorhinotermes lamanianus* release the secretion of their labial glands directly onto the food. The secretion carries a water-soluble, heat-resistant, nonvolatile signal that stimulates gnawing and feeding and leads to aggregations of feeding workers. In a feeding bioassay, extracts of the labial glands of 11 termite species from five families all proved to have this feeding-stimulating effect both on *R. santonensis* and *S. lamanianus*. The heat resistance of the feeding-stimulating signal also could be shown for selected species from all termite families tested. A combined thin layer chromatography–feeding bioassay on cellulose TLC plates showed that after chromatography of labial gland secretion, the feeding-stimulating signal is located in all 11 species in the same area from R_f 0.46 to 0.88. An extract of labial glands of cockroaches stimulated feeding in *R. santonensis* and *S. lamanianus* as well, but was not active after heat treatment and after TLC. This points towards a general feeding-stimulating signal having evolved only in the labial gland secretion of termites.

Key Words—Termites, *Reticulitermes*, *Schedorhinotermes*, labial gland secretion, chemical signal, phagostimulant.

INTRODUCTION

The performance of labor in termite societies includes large numbers of nestmates, and its organization depends predominantly on chemical signals produced by various exocrine glands, such as the paired labial glands. These are located in the meso- and metathorax of all termite species, and the glandular ducts open into the oral cavity (Pasteels, 1965; Noirot, 1969; Billen et al., 1989; Costa-Leonardo and Cruz-Landim, 1991; Kaib and Ziesmann, 1992; Mednikova, 1996; Costa-Leonardo, 1997).

During communal food exploitation of termites, the labial gland secretion is released onto the food by feeding workers, as was recently demonstrated in the African termite *Schedorhinotermes lamanianus* and the French species *Reticulitermes santonensis* (Kaib and Ziesmann, 1992; Reinhard and Kaib, 1995; Reinhard et al., 1997a). It contains a chemical signal that stimulates additional workers to feed at the same site, thereby initiating clusters of feeding termites, aiding in efficient food exploitation. The feeding-stimulating signal was shown to be highly polar, heat-resistant, and nonvolatile in both *S. lamanianus* and *R. santonensis* (Kaib and Ziesmann, 1992; Reinhard et al., 1997a).

Both termite species belong to the same family, Rhinotermitidae, but they differ in many aspects of their biology, such as habitat, nesting habits, and foraging and recruitment strategies. While *S. lamanianus* is an arboreal termite that lives in humid forests of tropical Africa, *R. santonensis* occurs in a temperate zone of France in subterranean nests (Harris, 1968; Becker, 1970; Kaib and Brandl, 1992; Brandl et al., 1996). In *S. lamanianus* foraging is initiated by soldiers (Schedel and Kaib, 1987); in *R. santonensis*, in contrast, foraging is initiated by workers (Reinhard et al., 1997b). Nevertheless, both species form distinctive feeding clusters on the food source induced by release of the feeding-stimulating signal. This may indicate that feeding stimulation by the chemical signal from the labial glands is a general strategy for organization of communal food exploitation in termites.

Our work was undertaken to examine the existence of a non-species-specific feeding-stimulating signal in the labial gland secretion of termites. Using feeding bioassays with *R. santonensis* and *S. lamanianus* as test species, we investigated the labial gland secretions of 11 different termite species from five families, collected all over the world, as well as the labial gland secretion of one cockroach species for comparison.

METHODS AND MATERIALS

Collection and Culture of Termites. One colony of the subterranean termite *Reticulitermes santonensis* De Feytaud (Rhinotermitidae) was collected in

Ile d'Oléron, France, and kept in the laboratory under constant conditions of 25°C, 75% relative humidity. The colony was housed in a metal container with moist vermiculite as soil substrate and water source and pine wood as food. One carton nest of the termite *Schedorhinotermes lamanianus* Sjöstedt (Rhinotermitidae) was collected near a campsite at Shimba Hills National Reserve, Kwale District, Kenya, and kept in the laboratory under constant conditions of 28°C, 70–80% relative humidity, LD 12L : 12D h). The colony was housed in a plastic container, provided with water from a connected tank, and fed ab libitum with filter paper. From the containers the termites had access to foraging arenas via a silicone tube (5 mm ID). The foraging arenas (10 × 10 cm; height: *R. santonensis:* 0.5 cm; *S. lamanianus:* 2.5 cm) had a sand-blasted glass plate as floor and were covered by a glass plate.

Labial glands were obtained from workers of the above as well as the following termite species [reared at the Bundesanstalt für Materialforschung und -prüfung (BAM), Berlin, Germany]: *Kalotermes flavicollis* (Kalotermitidae, Mediterranean), *Mastotermes darwiniensis* (Mastotermitidae, Australia), *Hodotermes mossambicus* (Hodotermitidae, West Africa), *Zootermopsis angusticollis* (Hodotermitidae, North America), *Heterotermes indicola* (Rhinotermitidae, India), *Coptotermes formosanus* (Rhinotermitidae, Southeast Asia), and *Nasutitermes nigriceps* (Termitidae, Central America). *Macrotermes subhyalinus* (Termitidae, West Africa) was provided from a colony held at the University of Bern, Switzerland, and *Trinervitermes trinervoides* (Termitidae) was collected in the field near Grahamstown, South Africa. All termite species used are wood-eating, except *H. mossambicus*, *M. subhyalinus*, and *T. trinervoides*, which are grass-feeding. Cockroaches (*Periplaneta americana*) were provided by the Institut für Wasser-Boden-Luft-Hygiene (WABOLU), Berlin, Germany.

Earlier experiments (Reinhard and Kaib, 1995, 2001; Reinhard et al. 1997a) with other colonies of the same species did not show any intraspecific variation in individual feeding behavior or analyses of the labial gland secretion, as compared to the present work. Experiments were, therefore, carried out with only one colony of each species.

Preparation of Labial Gland Extracts. Labial gland extracts of termite workers and cockroaches were prepared as described in Reinhard and Kaib (2001). Ten labial glands per 100 μl water were extracted in the case of *R. santonensis*. As gland sizes differ species-specifically, lots of labial glands corresponding in volume to 10 labial glands of *R. santonensis* were pooled for gland extracts of the other species.

Bioassays on Feeding Stimulation. All tests were conducted in the foraging arenas and made under red light illumination. Frequencies and spatial distribution of workers that were displaying feeding behavior as defined in Reinhard and Kaib (2001) were recorded over time by video techniques (IR-sensitive CCD camera CF 15/2, Kappa) and subsequently analyzed.

Choice feeding tests were carried out both with *R. santonensis* and *S. lamanianus* on pieces of moist filter paper. In each test two semicircles (2.5 cm diameter) of filter paper were offered to the termites. On one of the two semicircles 25 μl of a labial gland extract was applied, the other semicircle was only moistened (control). For each test the distribution of the first 20 termites feeding on the two semicircles during the test duration of ca. 1 hr was determined. Tests were replicated 20 times. For the experiments on heat resistance, the labial gland extracts of *K. flavicollis*, *M. darwiniensis*, *H. mossambicus*, *R. santonensis*, *S. lamanianus*, and *M. subhyalinus* as selected representatives of the termite families as well as *P. americana* were chosen. The extracts were exposed for 15 min to 95°C in a waterbath before applying them to the semicircles of filter paper.

Feeding tests on thin-layer chromatography plates were carried out with *R. santonensis* only. Twenty-five microliters of labial gland extract each from the cockroach and the 11 termite species were applied separately as 1-cm-long lines on cellulose TLC plates and chromatographed as described in Reinhard and Kaib (2001). The TLC plates were then offered as food, and the spatial distribution of all termites feeding between start and front line on the TLC plates during the 1-hr duration of the experiment was analyzed. The bioassay was repeated five times for each labial gland extract.

Data Analysis. The sign test was used to analyze the data of the choice feeding tests on filter paper. The distribution of termites feeding on TLC plates was analyzed via the dispersion index (Elliott, 1979) and the R_f value of the preferred feeding zones determined.

RESULTS

Labial gland extracts of all 11 termite species and the cockroach had a strong feeding-stimulating effect both on *Reticulitermes santonensis* and *Schedorhinotermes lamanianus* (Figure 1). Neither *R. santonensis* nor *S. lamanianus* responded more strongly to their own labial gland secretion than to the secretions of the other species. Labial gland extracts of the three grass-feeding termite species had the same effect as extracts of the wood-feeding termite species.

After heat treatment of labial gland extracts of selected representatives of each family, only the termite secretions still had the same feeding-stimulating effect on *R. santonensis* and *S. lamanianus* (Table 1). Heat-treated labial gland extract of the cockroach species *Periplaneta americana* did not show any phagostimulatory effect.

When TLC plates with chromatographed labial gland extracts of the 11 termite species were offered to *R. santonensis*, the feeding termites showed a clumped distribution between R_f 0.46 and 0.88 for all extracts in all five replicates (Figure 2, Table 2). In contrast, feeding termites were randomly distributed

(C) Phylogenetic tree of tested species (Abe, 1987), no genetic distances presented.

on the TLC plates when cockroach labial gland secretion had been applied, leaving gnawing marks all over the cellulose layer.

DISCUSSION

The labial gland secretion of *Schedorhinotermes lamanianus* and *Reticulitermes santonensis* contains a feeding-stimulating chemical signal, inducing

[a] Distribution of the first 20 termites feeding on two semicircles of filter paper with and without 25μl LGS within 1 hr of observation (mean number per semicircle ± SD, $N = 20$, P as determined with sign test). For full names of species, see text and Figure 1.

clusters of feeding nestmates to form where applied (Kaib and Ziesmann, 1992; Reinhard et al., 1997a). The experiments presented here showed that labial gland secretion of various other termite species also induced the same feeding response in *R. santonensis* and *S. lamanianus*. The feeding-stimulating signal was heat-resistant in all termite labial gland secretions and was located within the same biologically active zone of R_f 0.46–0.88 after TLC separation. This corresponds to the zone determined as the location of the feeding-stimulating signal in *R. santonensis* after TLC (Reinhard and Kaib, 2001). These results strongly suggest that the feeding-stimulating signal from the labial glands in all termite species is of the same or very similar chemical composition, independent of phylogeny, geographical origin, or nesting or feeding habits.

This is supported by preliminary GC-MS analyses of termite labial gland secretions, which identified several metabolic compounds, common for *R. santonensis*, *S. lamanianus* (both Rhinotermitidae), *M. subhyalinus* (Termitidae), and *M. darwiniensis* (Mastotermitidae) (Reinhard, 1998; Ibarra, unpublished results). A variety of compounds are reported to be produced in the various cell types of termite labial glands (Noirot, 1969; Veivers et al., 1982; Hogan et al., 1988; Mednikova, 1991; Tokuda et al., 1997; Watanabe et al., 1997). It is quite possible

Dotted lines indicate biologically active zone. *P.a.: Periplaneta americana*, *K.f.: Kalotermes lavicollis*, *M.d.: Mastotermes darwiniensis*, *H.m.: Hodotermes mossambicus*, *Z.a.: Zootermopsis angusticollis*, *R.s.: Reticulitermes santonensis*, *H.i.: Heterotermes indicola*, *C.f.: Coptotermes formosanus*, *S.l.: Schedorhinotermes lamanianus*, *N.n.: Nasutitermes nigriceps*, *T.t.: Trinervitermes trinervoides*, and *M.s.: Macrotermes subhyalinus*.

that the chemicals extracted from the glands for the analyses are only partially the same as that deposited on the food by feeding workers. However, the fact that the termites respond to the labial gland extracts with feeding in the choice tests and even after the separation of its constituents by TLC supports the inference that the extracts do contain the relevant component(s). Further work on elucidation of the chemical structure of this general feeding-stimulating signal in termites is in progress.

The labial gland secretion of the cockroach, however, could not induce feeding after heat treatment or TLC separation. The observed feeding stimulation by untreated cockroach secretion can therefore not be caused by the persistent phagostimulant signal as found in termites. It must be due to other factors, for example, possibly digestive enzymes of the secretion (Slaytor, 1992) that metabolize the cellulose in the filter paper during the bioassay. Thus, the feeding-stimulating signal is not present in cockroaches, but was found in all 11 termite species, representing all termite families (except the rare Serritermitidae), coming from all continents, and including both xylophagous and harvester ter-

mites. Cockroaches are considered ancestral to termites (Krishna and Weesner, 1969/70; Terra, 1988; Kambhampati, 1995). Hence the feeding stimulant from the labial gland secretion must be an apomorphic character for the Isoptera that evolved during the rise of the whole order and is linked to the evolution of eusociality and the need to organize efficient communal exploitation of food sources. It is notable that this trait has been retained unchanged across the order.

The biological meaning of the signal lies in the formation of feeding clusters, rendering food exploitation more efficient. If several nestmates feed at the same spot, repeated application of saliva humidifies the food and repeated biting enhances the mechanical break-up of its surface. By concentrating feeding efforts, a termite colony can exploit a food source faster and more efficiently. The system of feeding clusters also guarantees that the released signal as well as other important compounds of the labial gland secretion, such as digestive enzymes (Martin and Martin, 1978; Veivers et al., 1982, 1991), are not lost, but again taken up by nestmates joining a group of feeding workers.

Feeding clusters can be observed easily in xylophagous termites such as *S. lamanianus*, which feed on clumped food sources (Kaib and Ziesmann, 1992). Other species, such as the harvester termites *H. mossambicus*, *T. trinervoides*, and *M. subhyalinus*, feed on dispersed food sources. They collect grass as a direct food source or even culture fungus on partly digested grass for food, respectively (Abe, 1987; Badertscher et al., 1983; Hewitt et al., 1990). Feeding clusters seem to be of little importance for them. However, preliminary observations have shown that even in harvester termites, several workers group to bite off pieces of longer grass stems (Reinhard, 1998). Furthermore, *H. mossambicus* workers preferred the spots on a grass stem where labial gland secretion had been applied before by another worker or artificially in a bioassay. Thus, even harvester termites employ the feeding-stimulating chemical signal for organization of communal food exploitation.

Although this is not required by definition (Nordlund and Lewis, 1976), it is generally acknowledged that many insect pheromones are rather species-specific. The existence of a non-species-specific phagostimulant in termites is remarkable. However, although the same feeding-stimulating signal may be used by sympatric species, a multitude of behaviors has evolved, preventing constant interspecific conflicts on common food sources. There are highly species-specific foraging and recruitment signals, specialized behavioral patterns and strategies, the use of soldier defense lines for delineating a given feeding area, and constructing physical barriers, such as galleries and cover sheets (e.g., Jander and Daumer, 1974; Howard et al., 1976; Kaib et al., 1982; Badertscher et al. 1983; Heidecker and Leuthold, 1984; Hall and Traniello, 1985; Traniello and Busher, 1985; Lys and Leuthold, 1987, 1991; Schedel and Kaib, 1987; Miura and Matsumoto, 1995; Reinhard, 1998). They ensure that several termite species may share common food sources without permanent conflicts. Furthermore, a com-

mon signal can even be of mutual advantage for rival colonies or species. Delaplane and La Fage (1989) reported that termites prefer timber that had previously been attacked by conspecifics, or even a different species, over sound wood. Termites recognize and accept food sources faster when previously used and thus marked with the common phagostimulatory signal.

Acknowledgments—We are grateful to Dr. Michael Lacey, CSIRO Entomology, Australia, and Dr. Johannes Steidle, FU Berlin, Germany, for critical comments on an earlier draft of this paper. Unpublished data by Fernando Ibarra, University of Hamburg, Germany, were part of a Master's thesis. Financial support was provided by a scholarship from the Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany.

(Received March 15, 2000; accepted October 9, 2000)

Abstract—Volatile components of *Pachycoris stallii* scent gland secretions and the bug's host plant, *Croton californicus*, were identified by gas chromatography and mass spectroscopy. The predominant compounds isolated from *C. californicus* fruit and leaves were β-myrcene and β-caryophyllene. Metathoracic gland secretions of *P. stallii* contained mostly (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, (*E*)-2-hexenyl acetate, and *n*-tridecane. In males, *n*-tridecane was present throughout the metathoracic gland, but in females this compound was found only in the median reservoir/accessory gland. (*E*)-2-Hexenal was present throughout the gland of female bugs, but in males was primarily present in the median reservoir/accessory gland. (*E*)-4-Oxo-2-hexenal and *n*-dodecane were isolated from the median reservoir/accessory gland of male and female bugs. Metathoracic glands were sexually monomorphic. Data from chemical analyses and anatomical observations suggest that dorsal abdominal glands of adults were apparently obsolescent. In nymphs, dorsal abdominal glands produced (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, *n*-dodecane, *n*-tridecane, and tetradecanal. The proportion of the predominant constituent, (*E*)-4-oxo-2-hexenal, decreased from 72% in the first instar to 47% in the fourth instar. Proportions of tetradecanal and *n*-tridecane were greater in the fourth instar than in the first instar. Observations of dissected glands indicated that median and posterior dorsal abdominal glands of all nymphal instars were more developed than anterior dorsal abdominal glands. Scanning electron micrography revealed the presence of polygonal microsculpturing on the integument surrounding the ostioles of metathoracic and dorsal abdominal glands. Chemical, anatomical,

and behavioral data indicated that *P. stallii* has a chemical defense system based on short-chain carbonyl compounds and that this system is directed against arthropods. The abundance of arthropod natural enemies apparently has forced *P. stallii* to maintain this defense system despite feeding on a toxic host plant.

Key Words—*Pachycoris stallii*, Pentatomoidea, Scutelleridae, allomone, *Croton californicus*, Euphorbiaceae, terpenoids, exocrine glands, aposematic, carbonyl defense.

INTRODUCTION

Heteroptera are well-known for their chemical defense systems (Aldrich, 1988). Heteropteran allomones are typically produced in and expelled from: (1) adult metathoracic glands located ventrally in the metathorax and with lateral ostia between the meso- and metathoracic legs, and (2) adult and nymphal dorsal abdominal glands arranged in a metameric series of up to four dorsally located glands on abdominal tergites III to VI (Staddon, 1979; Aldrich, 1988, 1995). The defensive secretions are usually mixtures of unbranched aliphatic compounds, most with carbon chains of C_6, C_8, and C_4, as well as some aromatic compounds (Staddon, 1979; Aldrich, 1995). These chemicals function as nonspecific toxins, irritants, and repellents, and are generally more effective against arthropods than birds or mammals (Eisner, 1970; Blum, 1981).

Aposematic heteropterans, like other apparent insects, have a high likelihood of discovery by natural enemies and are thus expected to be chemically well-defended (Pasteels et al., 1983). Aposematic bugs sometimes sequester compounds that are toxic to predators from host plants (Duffey and Scudder, 1972; Aldrich, 1988; Aldrich et al., 1996), or produce the typical allomones de novo or from simple precursors (Blum, 1981; Staddon et al., 1987; Krall et al., 1999). In many cases, sequestration of host toxins relaxes the selection pressure for production of typical exocrine gland secretions (Staddon et al., 1987; Aldrich, 1995; Aldrich et al., 1996).

Pachycoris stallii Uhler is an aposematic scutellerid bug of neotropical distribution. Adults are ca. 12 mm in length and are brown–black with 22 orange spots on the dorsum that sometimes coalesce. Nymphs are red with metallic blue–green markings on the abdomen, pronotum, head, and legs. *Pachycoris stallii* appears to be highly host specific to the euphorb *Croton californicus* Muell.-Arg. (Williams, unpublished observations), a perennial shrub that occurs in the southwestern United States and northwestern Mexico (Shreve and Wiggins, 1964). *Pachycoris stallii* is also a subsocial insect. Females oviposit on *C. californicus* leaves and guard the egg masses and first-instar nymphs from natural enemies (Williams, unpublished observations). With the exception of

first-instar nymphs that do not feed, all nymphal instars as well as adults feed on *C. californicus* seeds developing within capsular fruit. Early instar nymphs occur in aggregations on *C. californicus*. Field observations suggest that arthropods are the predominant natural enemies of *P. stallii* (Williams, unpublished observations). Like many Euphorbiaceae, *Croton* species produce an abundance of chemicals toxic and irritating to vertebrates (Upadhyay and Hecker, 1976; Chavez et al., 1982; Alexander et al., 1991). Phytochemicals in *C. californicus* apparently render it unpalatable, because herbivores, vertebrate and invertebrate alike, generally avoid it.

Pachycoris stallii is an aposematic insect that is relatively large and long-lived, apparently monophagous on a toxic host plant, and lives in aggregations in open habitat where it is attacked by other arthropods. Ecological theory predicts that such an insect should possess a fortified chemical defense system (Pasteels et al., 1983). The objectives of this study were to: (1) test the hypothesis that despite feeding on a toxic host plant that may confer protection against vertebrate predators, *P. stallii* maintains a potent exocrine gland defensive system directed at arthropods, and (2) describe the volatiles produced by *C. californicus*.

METHODS AND MATERIALS

Preparation of Chemical Extracts. Croton californicus and *P. stallii* were field-collected in Baja California, Mexico. Immediately after collection, three to seven *Croton* fruit or leaves were placed in a glass vial containing 1 ml ethyl acetate for 2 min, after which all plant tissue was removed and the vial was sealed.

Pachycoris stallii were held in plastic vials with several fresh *Croton* leaves until collection of secretions (<4 hr after collection). Metathoracic gland secretions were obtained from living bugs by two methods: dissection of whole glands and collection of rinsates from whole bugs. Whole glands were dissected in a paraffin-coated Petri dish with tap water and were separated into two groups: (1) median reservoirs with accessory glands (MR/AG) and (2) lateral reservoirs with secretory tubules (LR/ST). Excess water was drawn from the glands with tissue paper, after which the glands were placed in a glass vial with 0.5 ml ethyl acetate and macerated with a capillary tube. Whole-bug rinsates were collected by placing one to four adults of the same gender (females guarding egg masses, females not guarding egg masses, and males) into a glass vial with 1 ml ethyl acetate for 3 min, after which adults were removed. (Preliminary analyses indicated that dorsal abdominal glands of adult *P. stallii* produce only trace amounts of volatiles; thus, we attribute results from whole-bug rinses solely to metathoracic glands). Samples from one to six bugs were pooled for analysis.

Dorsal abdominal gland secretions were obtained from adults by dissection similar to that described for metathoracic glands. Anterior (tergites III–IV),

median (tergites IV–V), and posterior (tergites V–VI) dorsal abdominal glands were dissected separately. Samples from three to six bugs were pooled and stored in 0.5 ml ethyl acetate for analysis. Nymphal dorsal abdominal gland secretions were collected by placing 5–40 nymphs of the same instar in a glass vial with 1 ml ethyl acetate for 3 min, after which nymphs were removed. All extracts were held at −20°C until chemical analysis.

Chemical Analysis. Extracts were analyzed on a Hewlett-Packard 5890 gas chromatograph with a 15-m × 0.32-mm-ID column coated with 0.25 μm DB-5 film (J & W Scientific, Folsom, California) and equipped with a flame ionization detector. The injector temperature was 200°C and the detector temperature was 240°C. The temperature was held at 60°C for 1 min then increased at 10°C/min to 220°C and held for 4 min. Nitrogen (20 cm/sec) was used as the carrier gas.

Gas chromatographic–mass spectrometric (GC-MS) analyses were conducted on a Hewlett-Packard 5890 gas chromatograph and a 5970 mass spectrometer. Data were obtained by using a 25-m × 0.32-mm-ID column coated with 0.25 μm film of DB-5 MS (J & W Scientific). The injector temperature was 250°C and the detector temperature was 280°C. The column temperature was held at 60°C for 2 min, then programmed at 10°C/min to 230°C and held for 2 min. The helium flow rate was 28.7 cm/sec. Electron impact (EI) mass spectra were measured at 70 eV.

GC-MS data were analyzed on a Hewlett-Packard ChemStation by using a NBS mass spectral library. Compounds were identified by comparison of the obtained mass spectra to library spectra and spectra of known standards, and by matching the obtained chromatographic retention times to those of known standard compounds.

Gland Anatomy. Pachycoris stallii adults and all five nymphal instars were killed and preserved in 70% ethanol. These bugs were dissected and observed with a dissecting scope to obtain gross morphological descriptions of metathoracic and dorsal abdominal glands. Scanning electron microscopy was used to study the efferent systems of metathoracic and dorsal abdominal glands. Specimens killed in 70% ethanol were sonicated for 1 min to remove debris, then passed through a graded ethanol series for dehydration, after which they were critical-point dried with carbon dioxide. Specimens were then mounted on SEM stubs using conductive silver paint, and were ion sputter-coated with gold before viewing with a Philips 501 scanning electron microscope (3.6–7.2 kV).

Behavior of P. stallii. Field observations of *P. stallii* behavior aided interpretation of the chemical and anatomical data.

RESULTS

Plant Chemistry. GC-MS analysis showed that two compounds, β-myrcene and β-caryophyllene, were the major constituents in extracts of *C. californicus*

TABLE 1. COMPOUNDS PRESENT IN *Croton californicus*

Retention time (min)	Compound	Composition (%)[a]	
		Fruit	Leaves
6.19	3-thujene	2	3
7.21	β-pinene	2	0
7.32	β-myrcene	58	46
8.62	δ-terpinene	3	4
9.96	Unidentified	0	3
11.47	*n*-tridecane	2	5
14.63	β-caryophyllene	23	30
15.14	α-caryophyllene	3	0
15.47	Unidentified sesquiterpene	7	5

[a] Percentages based on total ion area.

(Table 1). Together these terpenoids comprised at least 75% of the volatile compounds identified in fruit and leaves. Small quantities of other terpenoids and an unbranched aliphatic compound were also identified.

Metathoracic Gland Chemistry. The predominant secretory components identified in rinsates of adult *P. stallii* were (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, (*E*)-2-hexenyl acetate, and *n*-tridecane (Table 2). Small quantities of unbranched aliphatic compounds were also present in rinsates of both genders. Aside from males having a greater proportion of (*E*)-2-hexenyl acetate than females, major differences in the relative proportions of chemical constituents were not observed between the genders (Table 2). In females, the most abundant constituents, in order of greatest proportion, were *n*-tridecane, (*E*)-2-hexenal, and (*E*)-4-oxo-2-hexenal. Together these compounds made up approximately 90% of the total volatiles collected from female metathoracic glands. In males, the most abundant constituents, in order of greatest proportion, were *n*-tridecane, (*E*)-2-hexenyl acetate, (*E*)-2-hexenal, and (*E*)-4-oxo-2-hexenal. These constituents comprised 96% of the total volatiles in male metathoracic glands. A possible explanation for the greater relative abundance of (*E*)-2-hexenyl acetate in male glands than in female glands may be that at the time the rinse was made some male bugs in the sample had not converted as much of the ester to the aldehyde as females had.

Results of chemical analyses of dissected metathoracic glands are presented in Table 3. Major differences were not observed in the chemical composition of metathoracic glands between females guarding egg masses and females not guarding egg masses. However, metathoracic gland secretions of males appeared to have a greater proportion of *n*-tridecane than was observed in females. In males, *n*-tridecane was present in MR/AG and LR/ST, but in females this compound was found only in MR/AG. (*E*)-2-Hexenal was present in both MR/AG

TABLE 2. COMPOUNDS PRESENT IN WHOLE-BUG RINSATES OF ADULT *Pachycoris stallii*

Retention time (min)	Compound	Composition (%)[a]		
		Female guarding egg mass	Female not guarding egg mass	Male
3.95	(*E*)-2-hexenal	32	36	20
5.85	(*E*)-4-oxo-2-hexenal	19	15	11
6.84	(*E*)-2-hexenyl acetate	4	trace	21
8.28	*n*-undecane	1	0	0
9.97	*n*-dodecane	4	3	2

and LR/ST of female bugs, but in males was primarily present in the MR/AG. (*E*)-4-Oxo-2-hexenal and *n*-dodecane were isolated from the MR/AG of male and female bugs.

Dorsal Abdominal Gland Chemistry. No volatiles were isolated from dorsal abdominal glands of adult female *P. stallii*. Adult males produced trace amounts of *n*-tridecane in the anterior and median dorsal abdominal glands, but no volatiles were isolated from posterior dorsal abdominal glands. Table 4 presents the volatile components identified from dorsal abdominal glands of first through fourth nymphal instar *P. stallii*. Rinsates of nymphs revealed the presence of (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, *n*-dodecane, *n*-tridecane, and tetradecanal. Of these compounds, (*E*)-4-oxo-2-hexenal comprised the greatest proportion of total constituents in the four nymphal instars tested (Table 4). The proportion of (*E*)-4-oxo-2-hexenal decreased from 72% in the first instar to 47% in the fourth instar. Tetradecanal and *n*-tridecane were present in similar proportions in all instars except the second, and relative proportions of both compounds were greater in the fourth instar than in the first instar.

Gland Anatomy. Metathoracic glands of *P. stallii* were sexually monomorphic. Median reservoirs were bright orange, while lateral reservoirs were translucent and without pigment. Microsculpturing of the integument was present surrounding the metathoracic gland ostia on the mesepisternum and metepisternum (Figure 1). Ostioles of adult anterior dorsal abdominal glands were of the type 1 (undivided ostiole) described by Remold (1962), while median and posterior ostioles were of a gradient between types 1 and 2 (divided ostiole). Adult dorsal abdominal glands were small and apparently obsolescent. These glands were mostly translucent, but with a bit of orange pigment. Anterior dorsal abdominal glands were divided half-glands and were spherical, while median and posterior

glands were undivided and elongate. All five nymphal instars possessed ostioles of a similar arrangement as adults (anterior, type 1; median and posterior, type 2) (Figure 2). Anterior dorsal abdominal glands of all nymphal instars resembled those of adults in relative size, shape, and color. Compared to the anterior glands, median and posterior dorsal abdominal glands of all nymphal instars were relatively well developed. These glands were elongate translucent swollen sacs, with some orange pigmentation. Scanning electron micrography showed the presence of a polygonal pattern of cuticular microsculpturing associated with the ostioles of dorsal abdominal glands (Figure 3).

DISCUSSION

The most prevalent compounds found in *C. californicus*, β-myrcene and β-caryophyllene, are terpenoids commonly found in higher plants. These compounds are known from several species of *Croton* (Neto et al., 1994; Menut et al., 1995). The function of β-myrcene and β-caryophyllene in *C. californicus* is not known, although they are present in the defensive secretions of some Heteroptera (Gough et al., 1985; Krall et al., 1997). *Pachycoris stallii* may use the relative ratios of these compounds to differentiate between structures on which to feed (fruit) and those for oviposition (leaves). The ratio of β-myrcene to β-caryophyllene in *C. californicus* fruit is 2.5 : 1, while in leaves it is 1.5 : 1. It is also possible that *P. stallii* uses other plant characteristics, such as minor chemical constituents or physical factors (e.g., shape and texture of plant structures), to recognize different plant structures. The presence of *n*-tridecane in fruit and leaves is probably the result of degradation of hydrocarbon components of cuticular waxes (Goodwin and Mercer, 1986).

Results of chemical analyses demonstrated that *P. stallii* employs a carbonyl-based scent gland chemistry [C_6 alkenal (*E*)-2-hexenal, the C_6 4-oxo-

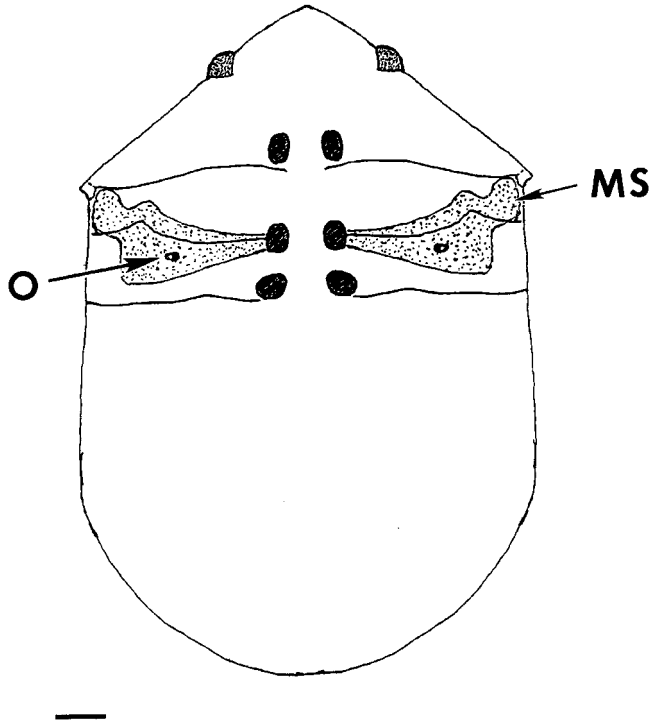

FIG. 1. Ventral view of *Pachycoris stallii* female showing the position of ostia (O) and microsculpturing (MS) on mesepisternum and metepisternum; scale bar = 1 mm.

2-alkenal (*E*)-4-oxo-2-hexenal, and the C_{13} alkane *n*-tridecane], which conforms to the general pattern for other Pentotomoidea (Staddon, 1979; Aldrich, 1988, 1995). As expected, the corresponding ester of (*E*)-2-hexenal, (*E*)-2-hexenyl acetate, was also present (Aldrich, 1988). Dorsal abdominal glands in adults were apparently obsolescent, while those of nymphs produced (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, *n*-dodecane, *n*-tridecane, and the C_{14} alkanal tetradecanal. With the exception of tetradecanal, these compounds are typical of those found in dorsal abdominal glands of Pentotomoidea. Anatomical data indicate that defensive secretions are produced in well-developed metathoracic or dorsal abdominal glands, and field observations indicated that the allomones are delivered via an efferent system that allows the concoction to be squirted (Williams, unpublished observations). Light and electron microscopy revealed the presence of microsculptured cuticle surrounding the ostia of these glands, presumably to aid in the accumulation and evaporation of the secretion (Staddon, 1979).

Current evidence on the cytological sources of the compounds produced

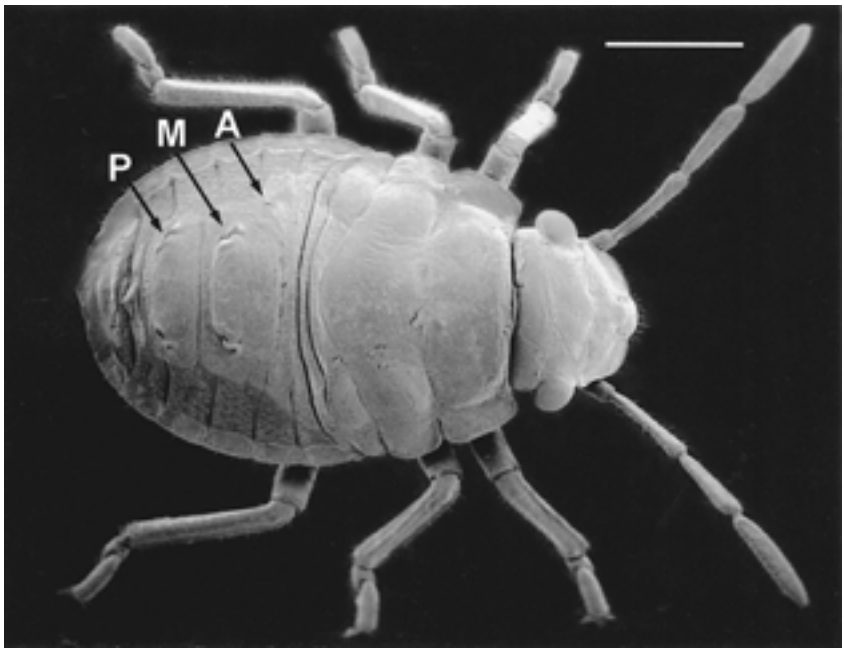

FIG. 2. Scanning electron micrograph of second-instar *Pachycoris stallii* showing arrangement of anterior (A), median (M), and posterior (P) dorsal abdominal gland ostia; scale bar = 1 mm, magnification 18×.

in the metathoracic glands indicates that esters are synthesized in the secretory tubules, and alkanals and related scent carbonyls are generally restricted to the median reservoir (Gilby and Waterhouse, 1967; Aldrich et al., 1978; Everton et al., 1979). Results of the present study conflicted somewhat with this trend. Analyses from dissected metathoracic glands suggest that (*E*)-2-hexenyl acetate is secreted in MR/AG, after which it is converted to (*E*)-2-hexenal, and possibly to (*E*)-4-oxo-2-hexenal, as in other Heteroptera (Staddon, 1979). Small quantities of esters produced in secretory tubules are usually found in the median reservoir (Staddon, 1979), but this does not explain the absence of the ester in the LR/ST extracts in *P. stallii*. It is possible that the bugs from which extracts were prepared had, upon being agitated prior to dissection, used all available (*E*)-2-hexenyl acetate to produce (*E*)-2-hexenal. As expected, (*E*)-2-hexenal was found in extracts of female MR/AG, but was also detected in extracts of LR/ST. This suggests that in *P. stallii* (*E*)-2-hexenal is formed in the lateral reservoir as well as the median reservoir. In male bugs, *n*-tridecane was present in extracts of MR/AG, as expected, but also in extracts of LR/ST, suggesting that *P. stallii* is

capable of producing *n*-tridecane in the secretory tubules and lateral and median reservoirs. Gilby and Waterhouse (1967) detected *n*-tridecane in the secretory tubules of *Nezara viridula* (L.).

Attributing biological significance to the differences between the chemical composition of allomones produced by *P. stallii* adults and nymphs is difficult in the absence of behavioral data. It is possible that the differences are not of great importance, as long as the chemical and physical characteristics of the mixtures result in an effective defense (Tschinkel, 1975). If this is true for *P. stallii*, then the differences may reflect different metabolic costs of synthesis between adults and nymphs. The differences observed may also reflect differences in natural enemies between nymphs and adults (Pasteels et al., 1982). Pasteels et al. (1983) suggested that such differences in composition might be a strategy to avoid counteradaptation by natural enemies. The above explanations may also apply to the observed changes in chemical composition of dorsal abdominal gland secretions between nymphal instars. Behavioral studies under field conditions will help elucidate the roles of scent gland secretions in different life stages of *P. stallii*.

Field observations supported the theoretical prediction that insects will utilize defensive secretions in a frugal manner and may use other defensive ploys before discharging allomones (Wallace and Blum, 1969; Whitman et al., 1990). The first line of defense for *P. stallii* is to run down stems away from the aggressor or drop to the leaf litter under the plant canopy (Williams, unpublished observations). Brooding females remain with their young and use behavioral defenses, such as kicking, towards an aggressor. These females were rarely induced to eject defensive secretions, possibly to avoid poisoning their offspring. Usually, bugs were induced to discharge allomones only after considerable physical contact, such as being pinched with forceps or after being handled. When bugs did discharge gland contents, they demonstrated the ability to squirt them toward an aggressor from a single ostiole, further suggesting that *P. stallii* uses allomones in a conservative manner.

The chemical nature of the scent glands of *P. stallii* suggests that this defensive system is directed at arthropods. The aliphatic aldehydes [e.g., (*E*)-2-hexenal], ketoaldehyde [(*E*)-4-oxo-2-hexenal], and *n*-alkanes (e.g., *n*-tridecane) produced by *P. stallii* are nonspecific irritants, toxins, or olfactory repellents of arthropods (Blum, 1981; Pasteels et al., 1983). Moreover, *n*-tridecane is believed to act as a surfactant and evaporatory retardant, as well as aid in the penetration of toxic aldehydes through an aggressor's cuticle (Staddon, 1979; Gunawardena and Herath, 1991). The nonspecific volatiles produced by *P. stallii* are known to deter ants (Blum, 1961; Wallace and Blum, 1969), and may also mimic alarm pheromones of ants, allowing bugs to escape (Blum, 1980). In the present study, field observations suggested that ants were the primary arthropod predators of *P. stallii*. *Dorymyrmex bicolor* Wheeler was commonly observed patrolling stems and leaves of *C. californicus*, as well as the soil surface, where they attacked nymphs and adults that fell to the soil and were immobilized by high surface temperatures. The ants were sometimes successful in driving brooding female bugs away from egg masses, after which eggs were consumed. Our results suggest that *P. stallii* is an aposematic heteropteran that, despite feeding on a host plant toxic to vertebrates, has maintained a potent exocrine defense system directed at arthropod predators.

Acknowledgments—Thanks are extended to the following individuals for taxonomic determinations: J. E. Eger, Jr. (*P. stallii*) and R. R. Snelling (*D. bicolor*). Technical assistance was provided by F. Bailey, R. N. Paul, and T. M. Roane, and J. R. Aldrich offered technical advice. We are also grateful to V. Manrique and anonymous reviewers for comments on the manuscript.

(Received March 13, 2000; accepted September 29, 2000)

Abstract—Antennally active, bark-derived, angiosperm volatiles were tested singly and in groups for their ability to disrupt the response of the Douglas-fir beetle (DFB), *Dendroctonus pseudotsugae*, to attractant-baited multiple-funnel traps. One compound, conophthorin, was active alone in reducing the response of beetles to the baited traps. Further experiments showed disruptive activity in two aliphatic green-leaf alcohols [1-hexanol and (*Z*)-3-hexen-1-ol], as well as guaiacol and benzyl alcohol, and three aliphatic aldehydes [nonanal, hexanal, and (*E*)-2-hexenal] but not in two aromatic aldehydes (benzaldehyde and salicylaldehyde). Every binary combination that included conophthorin or any two of the other groups, except aromatic aldehydes, significantly reduced the response of beetles to baited traps. Various ternary mixtures and the complete mixture of all the groups were generally the most effective treatments. These results provide evidence that DFBs recognize and avoid nonhosts while flying rather than landing on candidate hosts and testing them while in contact with the tree. Nonhost angiosperm bark volatiles may have practical utility on their own or in combination with the antiaggregation pheromone 3-methylcyclohex-3-en-1-one (MCH) to protect single trees, logs, or stands from attack by the DFB.

Key Words—Douglas-fir beetle, *Dendroctonus pseudotsugae*, Coleoptera, Scolytidae, nonhost volatiles, green-leaf volatiles, disruptant, 3-methylcyclohex-3-en-1-one, MCH.

INTRODUCTION

The Douglas-fir beetle (DFB), *Dendroctonus pseudotsugae* (Coleoptera: Scolytidae), is a destructive pest of Douglas fir, *Pseudotsuga menziesii*, forests throughout western North America. Its ability to breed in recently felled trees and slash allows populations to build up in areas of active logging or blown-down timber (Humphreys, 1995). In the first warm days of spring, brood beetles emerge and may mass attack and kill surrounding standing Douglas-fir trees (McMullen and Atkins, 1962). Prevention of DFB outbreaks in managed forests demands the prompt removal of slash following logging and sanitation logging to remove infested standing trees (Humphreys, 1995). However, these practices are not always convenient, feasible, or ecologically sensible. One alternative in the United States is to use the newly registered antiaggregation pheromone, 3-methylcyclohex-3-en-1-one (MCH) that has been shown to be efficacious in deterring beetle attack on susceptible timber (Ross et al., 1996). We hypothesized that supplements or alternatives to MCH might be found in the application of repellent nonhost angiosperm bark volatiles.

DFBs are highly host specific and do not attack angiosperm trees. A number of studies have shown that portions of nonhosts (Schroeder, 1992), as well as individual chemicals or blends of chemicals known to occur in angiosperm tissues (Dickens et al., 1992; Wilson et al., 1996; Borden et al., 1997, 1998; Byers et al., 1998; Deglow and Borden, 1998a,b; Poland et al., 1998; Poland and Haack, 1999; Huber et al., 1999), are active in reducing attraction of coniferophagous bark and ambrosia beetles to their aggregation pheromones or host kairomones. Coupled gas chromatographic-electroantennographic detection (GC-EAD) analyses have revealed a variety of nonhost angiosperm bark volatiles that elicit antennal responses in female DFBs (Huber et al., 2000). We report here the results of experiments testing these EAD-active compounds for their ability to deter the response of DFBs to traps baited with the attractant semiochemicals ethanol (Ross and Daterman, 1995), frontalin (Ross and Daterman, 1995) and 1-methylcyclohex-2-en-1-ol (MCOL) (Lindgren et al., 1992).

METHODS AND MATERIALS

Field trapping experiments were conducted approximately 18 km north of Lytton, British Columbia, Canada. The stand at the site was a mixture of mostly decadent Douglas fir, *Pseudotsuga menziesii*, and ponderosa pine, *Pinus ponderosa*, and much of the area had been recently logged. All experiments utilized 12-unit multiple funnel traps (Lindgren, 1983) (Phero Tech Inc., Delta, British Columbia) placed 15–20 m apart in a line along a logging road in randomized complete blocks. Release devices and rates for components used in attractive

baits (DFB lure), as well as synthetic nonhost volatiles that were tested for repellency, are given in Table 1. A small block of Vapona No-Pest Strip (Green Cross, Fisons Horticulture Inc., Mississauga, Ontario, Canada) was placed in each collecting cup so that captured predaceous beetles did not consume captured bark beetles.

Experiment 1 tested 20 EAD-active compounds individually for activity in reducing attraction of DFBs to attractant-baited traps. One other compound, conophthorin, was already known to be repellent to DFBs (Huber et al., 1999). The treatments were unbaited traps, traps baited with the three-component DFB lure (Table 1), or traps baited with the DFB lure plus either benzyl alcohol, benzaldehyde, 3-carene, decanal, guaiacol, heptanal, hexanal, 1-hexanol, 2-hexanone, 3-hexanone, (*E*)-2-hexenal, limonene, methyl salicylate, nonanal, octanoic acid, phenylacetaldehyde, α-pinene, β-pinene, salicylaldehyde, or toluene or a mixture of all of the above compounds in equal proportions (equal-ratio blend; Table 1). The experiment comprised 12 replicates carried out two or four replicates at a time between May 7–9, 7–12, 9–12, and 12–15, 1997, and with bait positions rerandomized between replicates.

Experiment 2 tested the effect of (*E*)-ocimene with three treatments: unbaited traps and traps baited with the DFB lure alone or with ocimene (72 *E*-isomer). Fifteen replicates were run simultaneously from April 24 to 29, 1998.

Experiments 3 and 4 tested three groups of synthetic nonhost compounds: (1) four green-leaf volatiles (GLVs) [hexanal, (*E*)-2-hexenal, 1-hexanol, and (*Z*)-3-hexen-1-ol]; (2) six volatiles (salicylaldehyde, conophthorin, guaiacol, nonanal, benzaldehyde, and benzyl alcohol) that each elicited antennal responses from ≥3 of the five scolytid species tested by Huber et al. (2000)[1]; and (3) seven volatiles [4-allylanisole, heptanal, (*E*)-2-heptenal, methyl salicylate, decanal, thymol methylether, and (*E*)-nerolidol] that elicited antennal responses from fewer than three of the five scolytid species. The six treatments in experiment 3 were: unbaited traps, traps baited with the DFB lure, and traps baited with the DFB lure plus the GLVs in group 1, the volatiles in group 2, the volatiles in group 3, or all the volatiles in groups 1–3. In experiment 4 the three groups of nonhost volatiles were tested in all three binary combinations and in the ternary combination with the following treatments: unbaited traps, traps baited with the DFB lure, traps baited with the DFB lure plus volatiles in groups 1 and 2, 1 and 3, 2 and 3, or 1–3. Fifteen replicates in each experiment were run from May 5 to 7, 1998 (experiment 3), and May 7–11, 1998 (experiment 4). Most of the volatiles in experiments 3 and 4 were tested as mixtures in common release devices (Table 1). No monoterpenes were included in experiments 3 and 4, as many such compounds are known to attractant various coniferophagous Scolytidae.

[1]Beetles tested in addition to the DFB were: *Dendroctonus ponderosae*, *D. rufipennis*, *Dryocoetes confusus*, and *Ips pini*.

TABLE 1. DESCRIPTION OF CHEMICALS AND RELEASE DEVICES UTILIZED IN TRAPPING EXPERIMENTS

Volatile category and compound[a]	Source	Purity (%)	Release device and experiment number	Release rate (mg/24 hr) and temperature
DFB lure				
Frontalin (racemic)	Phero Tech[b]	>99	0.4 ml PE[c] vial, closed (all experiments)	2.6 at 23°C
Ethanol	Phero Tech	95	40 cm Phero Tech pouch (all experiments)	40 at 20°C
MCOL	Phero Tech	98	Phero Tech bubblecap (all experiments)	2.0 at 20°C
Equal-ratio blend	Various		1.5 ml PP[c] vial, open (Exp. 1)	39 at 28°C
4-Allylanisole	Sigma[d]	98	15 ml PE bottle also containing heptanal, (*E*)-2-heptenal, methyl salicylate, decanal, and (*E*)-nerolidol (Exp. 3, 4)	3.8 at 25°C
Benzyl alcohol	Fisher[e]	98	1.5 ml PP vial, open (Exp. 1)	6 at 28°C
			15 ml Phero Tech bubblecap (Exp. 3–8)	1.3 at 20°C
Benzaldehyde	Fisher	>99	0.6 PP vial, open (Exp. 1)	15 at 28°C
			15 ml PE bottle also containing guaiacol, nonanal, and salicylaldehyde (Exp. 3, 4)	1.7 at 25°C
			Phero Tech flexlure (Exp. 5–10)	3.5 at 20°C
3-Carene	Sigma	90	0.6 ml PP vial, open (Exp. 1)	31 at 28°C
Conophthorin (racemic)	S.F.U.[f]	87	0.4 ml PE vial, closed (Exp. 3–10)	3.0 at 28°C
Decanal	Sigma	95	1.5 ml PP vial, open (Exp. 1)	11 at 28°C
			15 ml PE bottle also containing heptanal, (*E*)-2-heptenal, methyl salicylate, 4-allylanisole, and (*E*)-nerolidol (Exp. 3, 4)	2.5 at 25°C
Guaiacol	Sigma	>98	1.5 ml PP vial, open (Exp. 1)	19 at 28°C
			15 ml PE bottle also	1.9 at 25°C

All volatiles in experiments 5–10 were tested in separate release devices for each compound (Table 1). Experiments 5 and 6 tested the active synthetic compounds from experiments 3 and 4 in groups based on their chemical functionalities: (1) the bicyclic acetal, conophthorin, alone; (2) aldehydes [salicylaldehyde, benzaldehyde, hexanal, (*E*)-2-hexenal, and nonanal], and (3) alcohols and phenols [benzyl alcohol, (*Z*)-3-hexen-1-ol, 1-hexanol, and the phenol, guaiacol]. The treatments in both experiments included unbaited traps and traps baited with the DFB lure. In experiment 5 the other treatments were traps baited with the DFB lure plus the volatiles in groups 1, 2, 3, or 1–3. In experiment 6 the other treat-

ments were the DFB lure plus the volatiles in groups 1 and 2, 1 and 3, 2 and 3, or 1–3. Experiment 5 was run from April 24 to 26, 1999, and experiment 6 was run from April 26 to 30, 1999. Both had 15 replicates.

Experiment 7 tested the nonhost alcohols from experiments 5 and 6 in five treatments: unbaited traps, traps baited with the DFB lure and traps baited with the DFB lure plus aliphatic alcohols [1-hexanol and (*Z*)-3-hexen-1-ol], plus benzyl alcohol and guaiacol, or plus the aliphatic alcohols, benyl alcohol, and guaiacol all together. The experiment ran from May 14 to 22, 1999, with 17 replicates.

Experiment 8 tested the two groups of compounds from experiment 7 in binary combinations with each other and with conophthorin. The six treatments were: unbaited traps, traps with the DFB lure, and traps with the DFB lure plus aliphatic alcohols and benzyl alcohol plus guaiacol, aliphatic alcohols and conophthorin, benzyl alcohol plus guaiacol and conophthorin, or aliphatic alcohols, benzyl alcohol plus guaiacol and conophthorin all together. The experiment ran from May 22 to 24, 1999, with 15 replicates.

Experiment 9 tested the nonhost aldehydes from experiments 5 and 6 in five treatments: unbaited traps, traps baited with the DFB lure, and traps baited with the DFB lure plus either aromatic aldehydes [salicylaldehyde and benzaldehyde], aliphatic aldehydes [hexanal, (*E*)-2-hexenal, and nonanal], or both aldehyde groups together. The experiment ran from April 30–May 14, 1999, with 17 replicates.

Experiment 10 tested the aldehyde groups from experiment 9 in binary combinations with each other and with conophthorin. The six treatments were: unbaited traps, traps with the DFB lure, and traps with the DFB lure plus aromatic aldehydes and conophthorin, aliphatic aldehydes and conophthorin, aromatic and aliphatic aldehydes, or aromatic aldehydes, aliphatic aldehydes and conophthorin. The experiment ran from May 24 to 26, 1999, with 15 replicates.

Captured beetles were frozen until sexed and counted. Data were transformed by $\log_{10}(x + 1)$ (Zar, 1984) to meet the assumptions of homoscedasticity and normality and were analyzed by ANOVA followed by comparison of means by the Ryan-Einot-Gabriel-Welsch Multiple Q-test (REGWQ procedure) (SAS Institute Inc., 1988; Day and Quinn, 1989) by using SAS software (GLM procedure) (SAS Institute, Inc., 1988). In all cases $\alpha = 0.05$. Due to the large number of treatments, experiment 1 was best represented with descriptive statistics; no further statistical analysis was completed.

RESULTS

Of the 20 individual compounds tested in experiment 1, only 1-hexanol and benzyl alcohol appeared to weakly reduce attraction of DFBs to the attractant bait, a result similar to that obtained with the mixture of all compounds together (Figure 1). Some compounds appeared to enhance the attractiveness of the bait,

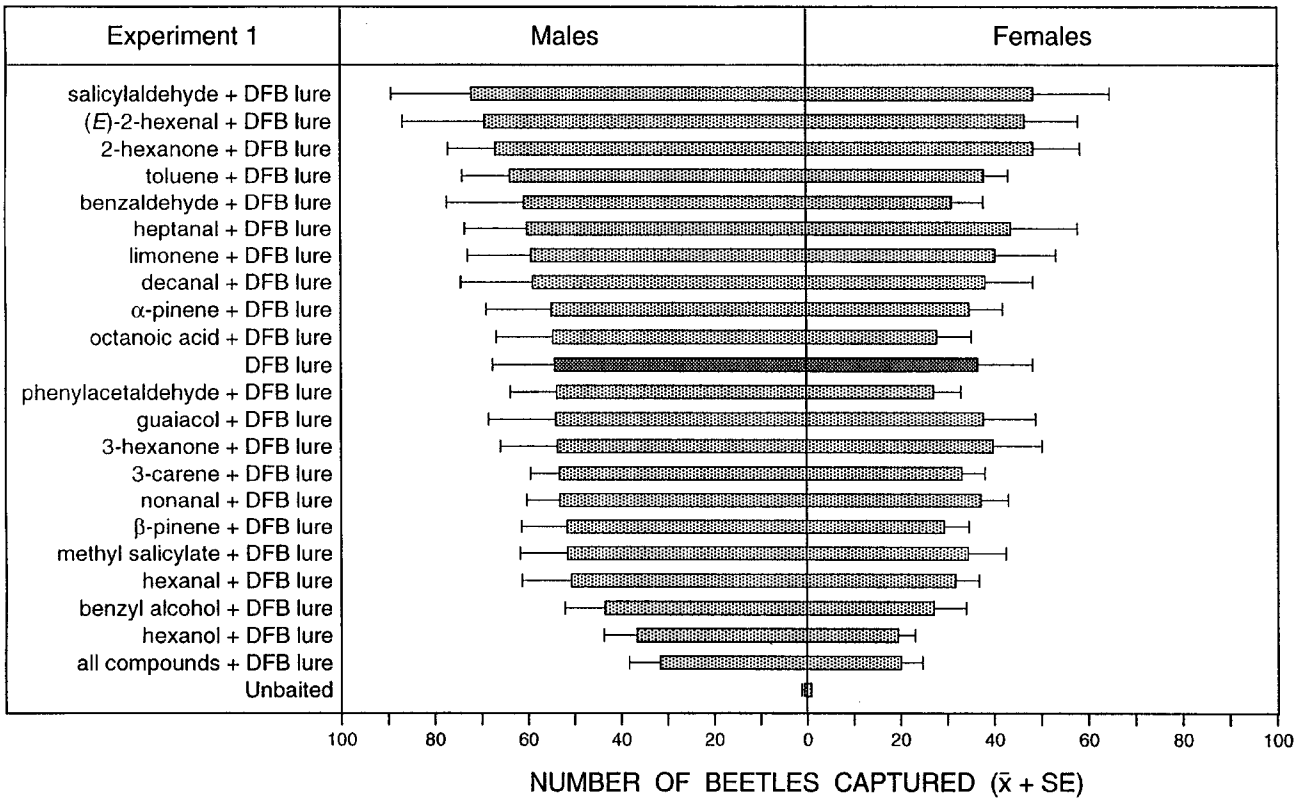

FIG. 1. Catches of *Dendroctonus pseudotsugae* in multiple-funnel traps baited with DFB lure alone or with single or combined nonhost bark volatiles in experiment 1, $N = 12$, May 7–15, 1997, near Lytton, British Columbia.

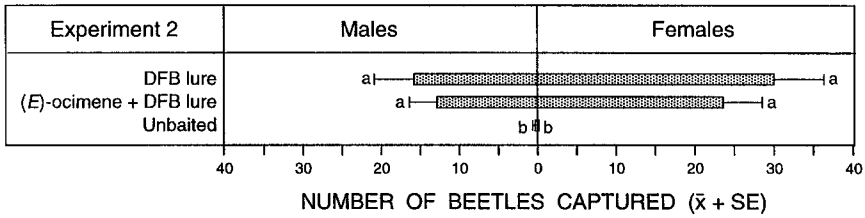

FIG. 2. Catches of *Dendroctonus pseudotsugae* in multiple-funnel traps baited with DFB lure alone or with ocimene [72% (*E*)-isomer] in experiment 2, $N = 15$, April 24–29, 1998, near Lytton, British Columbia. Bars for each sex with the same letter are not significantly different (Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$).

while most appeared to be benign. (*E*)-Ocimene did not significantly reduce the attraction of DFB to attractant-baited traps in experiment 2 (Figure 2).

In experiment 3, the GLVs reduced attraction of female DFBs, and the group of volatiles that elicited antennal responses from ≥3 scolytid species reduced attraction of both sexes (Figure 3). The combination of all three groups of compounds had the greatest disruptant effect, reducing catch to 13.5% and 11.2% of that in the attractant-baited control traps for males and females, respectively. Each of the binary combinations of the above groups tested in experiment 4 significantly reduced the attraction of both sexes of beetles to attractant-baited traps, as did the ternary blend, which reduced the total trap catch to 9.0% and 11.2% of the attractant-baited control traps in males and females, respectively (Figure 3).

Each treatment in experiment 5 reduced attraction of both sexes to attractant-baited traps, including conophthorin, which was active alone (Figure 4). The ternary combination of aldehydes, alcohols, and conophthorin was the most disruptive, reducing catch to 6.1% and 7.5% of that in attractant-baited control traps for males and females, respectively. Each of the binary combinations in experiment 6 reduced attraction of both sexes to attractant-baited traps (Figure 4). The ternary blend again resulted in the lowest trap catches, reducing trap catch to 7.4% and 4.1% of that in attractant-baited traps for males and females, respectively. Trap catch of female DFB was reduced to a level not significantly different from that in the unbaited control traps.

In experiment 7, benzyl alcohol plus guaiacol reduced the attraction of males to attractant-baited traps, and the aliphatic alcohols, 1-hexanol and (*Z*)-3-hexen-1-ol, reduced attraction of both sexes to attractant-baited traps (Figure 5). The treatment consisting of both groups reduced the catch to 23.4% and 24.9% of the attractant-baited control traps for males and females, respectively. Each of the two groups tested with conophthorin, and the two groups together reduced

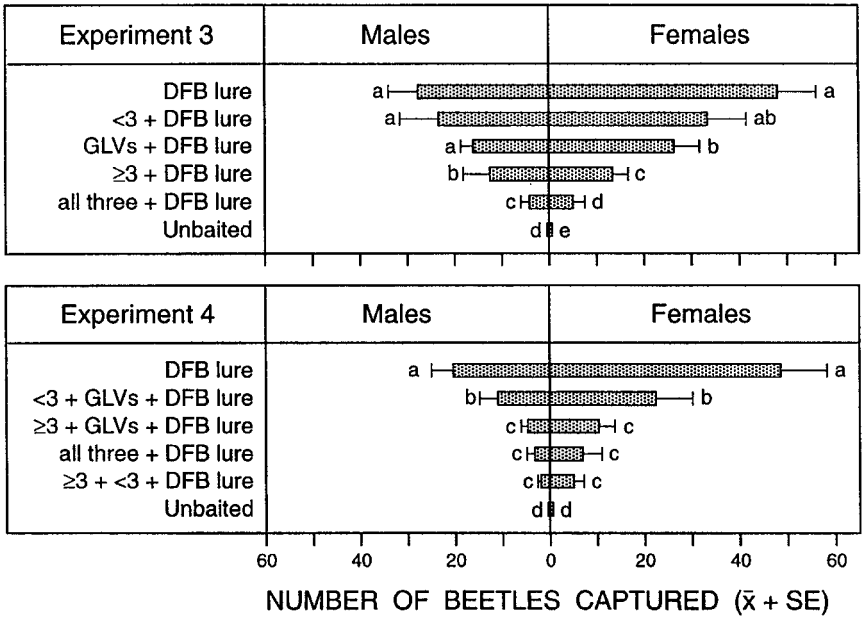

FIG. 3. Catches of *Dendroctonus pseudotsugae* in multiple-funnel traps baited with DFB lure alone or with three blends of nonhost compounds, tested singly in experiment 3 (top) and in binary and ternary combination in experiment 4 (bottom). The blends were green-leaf volatiles (GLVs), compounds eliciting antennal responses from at least three of five species of scolytids previously tested in electroantennogram studies (≥3), and compounds eliciting antennal responses from fewer than three of the five species tested (<3). Experiment 3, $N = 15$, May 5–7, 1998; experiment 4, $N = 15$, May 7–11, 1998, both near Lytton, British Columbia. Bars within each experiment and sex with the same letter are not significantly different (Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$).

attraction of both sexes to attractant-baited traps in experiment 8 and the blend of all compounds reduced trap catch to 29.4% and 21.8% of the attractant-baited control traps for males and females, respectively (Figure 5).

Only the aliphatic aldehydes, hexanal, (*E*)-2-hexenal, and nonanal, reduced attraction of both sexes of DFBs in experiment 9, reducing trap catch to 36.4% and 37.9% of that in attractant-baited control traps for males and females, respectively (Figure 6). The aromatic aldehyde treatment, salicylaldehyde and benzaldehyde, was inactive alone, but appeared to modify the disruptant effect of the aliphatic aldehydes when both groups were combined. Combining the two groups of aldehydes with each other or with conophthorin resulted in treatments that significantly reduced attraction of both sexes to attractant-baited traps in experiment 10 (Figure 6). The aliphatic aldehydes plus conophthorin reduced

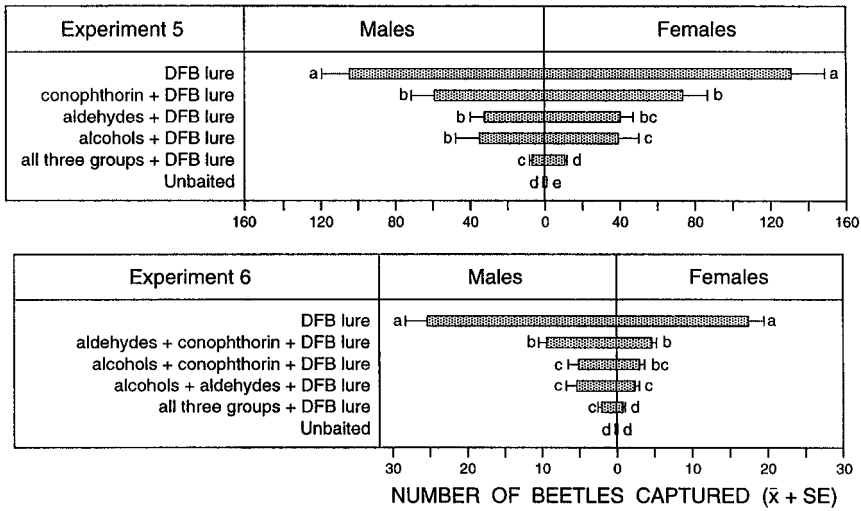

FIG. 4. Catches of *Dendroctonus pseudotsugae* in multiple-funnel traps baited with DFB lure alone or with the nonhost volatile, conophthorin, an aldehyde blend, and an alcohol blend tested singly in experiment 5 (top) and in binary and ternary combination in experiment 6 (bottom). Experiment 5, $N = 15$, April 24–26, 1999; experiment 6, $N = 15$, April 26–30, 1999, both near Lytton, British Columbia. Bars within each experiment and sex with the same letter are not significantly different (Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$).

the catch to 38.6% and 29.1% of that in the attractant-baited control traps for males and females, respectively.

DISCUSSION

We have shown that a variety of compounds known to be present in the bark of nonhost angiosperm trees strongly reduce attraction of DFBs to attractant semiochemicals. This is the first report of blends of angiosperm-derived compounds having such an effect on the DFB, and builds on the evidence of disruption caused by the known antiaggregation pheromone, MCH (Rudinsky et al., 1972; Ross et al., 1996) and the apparently ubiquitous spiroketal, conophthorin (Huber et al., 1999). Conophthorin is a known pheromone for other insects (Francke et al., 1978), including scolytids (Kohnle et al., 1992; Dallara et al., 1994; Pierce et al., 1995; Birgersson et al., 1995), but it is also found in *Acer*, *Betula*, *Populus*, and *Salix* spp. trees (Byers et al., 1998; Huber et al., 1999; R. Gries and C. Broberg, personal communication). It generally has a repellent or disruptive effect.

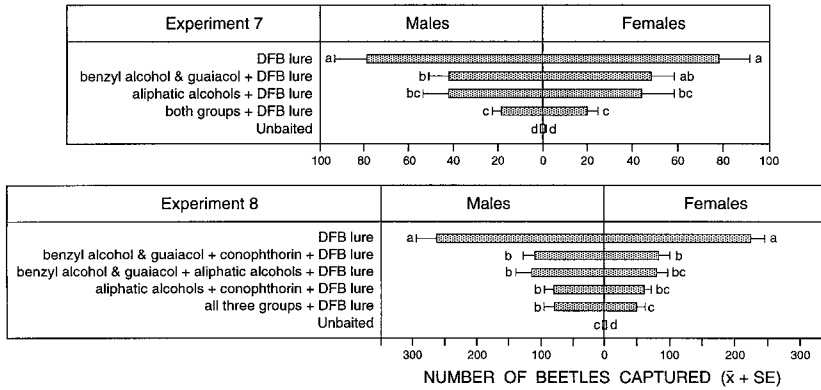

FIG. 5. Catches of *Dendroctonus pseudotsugae* in multiple-funnel traps baited with DFB lure alone or with blends of aliphatic alcohols or benzyl alcohol plus guaiacol tested singly in experiment 7 (top) and in binary and ternary combinations with each other and with conophthorin in experiment 8 (bottom). Experiment 7, $N = 17$, May 14–22, 1999; experiment 8, $N = 15$, May 22–24, 1999, both near Lytton, British Columbia. Bars within each experiment and sex with the same letter are not significantly different (Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$).

The monoterpene, (*E*)-ocimene, was tested alone in experiment 2 because it had not been included in the initial screening of compounds in experiment 1. It was not tested further, nor were any of the other monoterpenes, many of which are known to be common host conifer volatiles (Norin, 1996; Persson et al., 1996; Sjödin et al., 1996; Wang et al., 1997; Wibe et al., 1998). Although there is some possibility that (*E*)-ocimene or another monoterpene might augment the bioactivity of the most active nonhost volatiles in experiments 3–10, the strong disruptant effects that we obtained in this study are good evidence that the nonhost message can be obtained in the absence of these compounds. Additionally, several compounds tested in experiment 1 were not tested in further experiments, because additional GC-EAD and mass spectrometric data cast some doubt on their authenticity.

The only group of two or more of the EAD-active compounds tested in experiments 3–10 (Table 1) that did not reduce attraction of DFB to baited traps was the aromatic aldehyde group, salicylaldehyde and benzaldehyde (Figure 6). Different blends of compounds had similar disruptive effects, and the highest degree of disruption occurred when the largest number of compounds were grouped together, for example in experiments 5 and 6. This redundant and additive effect is similar to, but more complex than, that found by Borden et al. (1998) for the mountain pine beetle among 1-hexanol, benzyl alcohol, benzaldehyde, and nonanal.

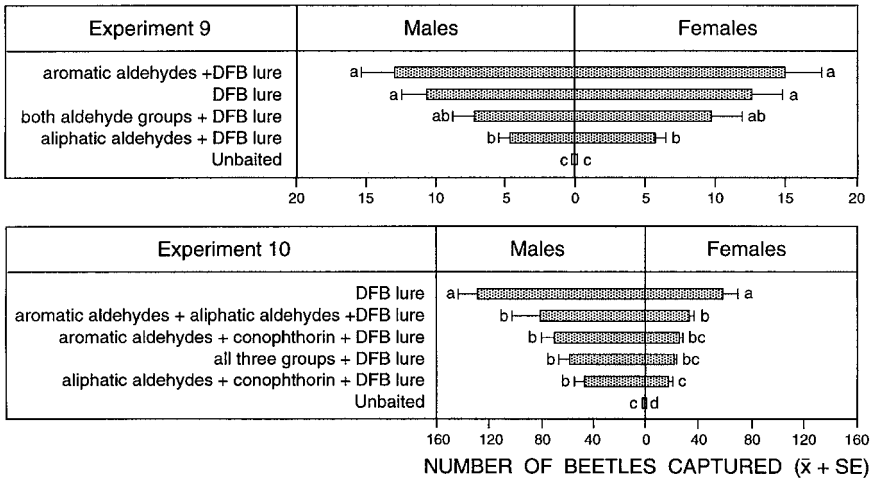

FIG. 6. Catches of *Dendroctonus pseudotsugae* in multiple-funnel traps baited with DFB lure alone or with blends of aliphatic or aromatic nonhost aldehydes tested singly in experiment 9 (top) and in binary and ternary combinations with each other and with conophthorin in experiment 10 (bottom). Experiment 9, $N = 17$, April 30–May 14, 1999; experiment 10, $N = 15$, May 24–26, 1999, both near Lytton, British Columbia. Bars within each experiment and sex with the same letter are not significantly different (Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$).

These effects are not always evident in studies of responses by conifer-ophagous bark beetles to angiosperm volatiles (e.g., Dickens et al., 1991; Byers et al., 1998). However, it is probable that testing of varied combinations of EAD-active nonhost volatiles would reveal such effects to be common in the conifer-ophagous Scolytidae. This is likely for two reasons. A beetle that was too sensitive to any one nonhost volatile would presumably be repelled from such a wide area that it could miss suitable hosts that grew in close proximity to nonhost angiosperm trees. The perception and avoidance of a number of compounds in an additive manner would require a foraging beetle to come fairly close to a nonhost tree before it was repelled. It has also been hypothesized (Borden et al., 1998) that the redundancy effect for nonhost angiosperm bark volatiles would allow a foraging coniferophagous bark beetle to perceive and avoid different blends of compounds that are indicative of a variety of nonhost angiosperm taxa.

Our results provide good evidence that the DFB is able to detect and avoid nonhost angiosperms while in flight rather than randomly landing on and testing individual trees, because most DFBs that attempt to land on a multiple-funnel trap are subsequently caught (D.P.W.H., personal observation). A reduction in

numbers of beetles captured when nonhost volatiles are added to attractive baits is then an indication of repellency, a result borne out by numerous other studies on coniferophagous Scolytidae (Dickens et al., 1992; Wilson et al., 1996; Borden et al., 1997, 1998; Byers et al., 1998; Deglow and Borden, 1998a,b; Poland et al., 1998; Poland and Haack, 1999; Huber et al., 1999). It is possible that the hypothesis of random landing by dispersing beetles on host and nonhost trees, followed by close-range acceptance or rejection while in contact with the tree (Moeck et al., 1981), applies only to some other species of coniferophagous Scolytidae, applies only for differentiation between host and nonhost gymnosperms, or is just a by-product of beetles landing for different reasons such as to wait out inclement weather or to rest.

Although the compounds tested in our experiments were based on antennal responses by female beetles, responses by both sexes were generally similar. This result is in opposition to the hypothesis that because females are required to make the initial decision regarding the suitability of a given tree, they would respond more strongly than males to nonhost volatiles. On the other hand, few beetles probably initiate an attack and female and male beetles entering a pheromone plume should be able to distinguish between host and nonhost trees in order to accurately locate a tree undergoing attack.

The strong disruptant effect of nonhost angiosperm bark volatiles suggests that, as for the mountain pine beetle (Wilson et al., 1996; Borden et al., 1998), they could be used alone or in conjunction with the antiaggregation pheromone, MCH, to protect fallen trees and susceptible standing timber from attack by the DFB.

(Received July 13, 2000; accepted October 1, 2000)

Abstract—Stereoselectively synthesized enantiomers of ethyl *cis*-5-iodo-*trans*-2-methylcyclohexane-1-carboxylate (ceralure B1), a potent lure for male Mediterranean fruit flies, were tested in the laboratory and the field against laboratory reared sterile flies. The (−)-ceralure B1 enantiomer was significantly more attractive than the (+)-ceralure B1 antipode. Dose–response studies of the above compounds demonstrated that (−)-ceralure B1 and to a lesser extent, racemic ceralure B1, captured consistently more male flies than trimedlure, the current male attractant used in detection programs. Longevity tests demonstrated that, over a three-week period, both (−)-ceralure B1 and racemic ceralure B1 caught significantly more flies than trimedlure. The synthesis of specific enantiomers of ceralure B1 shows great promise as a male attractant that could replace trimedlure for detection and delimitation in action programs aimed at this exotic pest.

Key Words—Mediterranean fruit fly, attractants, detection, male annihilation.

INTRODUCTION

The Mediterranean fruit fly (medfly), *Ceratitis capitata* (Wiedemann) is a serious pest of fruits and vegetables throughout many parts of the world. Except for the state of Hawaii, medfly is not established in the United States. If established, this pest would have a serious impact on US agriculture and the environment through increased costs for control and additional pesticide sprays. In addi-

0098-0331/01/0200-0235$19.50/0

tion, the regulatory quarantines by importing countries could severely restrict worldwide trade of US agricultural products (CDFA, 1994; Siebert and Cooper, 1995).

The establishment of this pest within the contiguous United States has been prevented through a vigorous detection, quarantine inspection, and eradication program. Monitoring and detection for the medfly using synthetic attractants is a key step in signaling the need for eradication. Each year states such as California, Florida, and Texas employ more than 100,000 traps in and around agricultural and urban areas to survey and detect possible introductions of medfly. For almost 40 years, trimedlure (TML), developed from an intensive US Department of Agriculture screening and testing program has been widely used as the "standard" synthetic male medfly attractant (Beroza et al., 1961). For commercial use, 2 g of trimedlure is formulated in a polymeric plug-type dispenser that provides controlled release of the attractant for up to eight weeks when deployed in Jackson traps (Leonhardt et al., 1987, 1989; Gilbert and Bingham, 1999).

Commercial trimedlure (TML) is an isomeric mixture of *tert*-butyl esters of 4- and 5-chloro-2-methylcyclohexane-1-carboxylate. Hence, trimedlure is a mixture of 16 possible regio- and stereoisomers. Of these, a single isomer (1*S*,2*S*,4*R*)-*tert*-butyl 4-chloro-2-methylcyclohexane-1-carboxylate (trimedlure-C enantiomer, henceforth referred to as (+)-trimedlure-C based on its optical rotation) was found to be the most attractive (McGovern et al., 1987; Doolittle et al., 1991; Heath et al., 1990). Furthermore, the optical antipode, (−)-trimedlure-C ((1*R*,2*R*,4*S*)-*tert*-butyl 4-chloro-2-methylcyclohexane-1-carboxylate) was shown to have very little biological activity.

McGovern co-workers investigated various halogen and ester analogs of trimedlure and found that ethyl 4- (and 5-) iodo-trans-2-methylcyclohexane-1-carboxylate (ceralure) was more potent and persistent than trimedlure (McGovern and Cunningham, 1988; DeMilo et al., 1994; Warthen et al., 1994). Like trimedlure, commercial ceralure is also a mixture of 16 regio- and stereoisomers. A field study designed to measure the relative attractiveness of the racemates, which were tediously separated by HPLC, demonstrated that racemic ethyl *cis*-5-iodo-*trans*-2-methylcyclohexane-1-carboxylate (ceralure B1) is most active (Warthen et al., 1994). Recently, a highly effective stereoselective synthesis that yields the two enantiomers of ceralure B1 on a multigram scale was developed (Raw and Jang, 2000).

For the current study, laboratory and field tests with released sterile flies on the island of Hawaii were carried out to compare the attractancy, dose–response, and initial persistence of the pure enantiomers as well as the racemic mixture. The purpose of this study was to evaluate the relative attractancy of the two nearly synthesized ceralure B1 enantiomers and to compare these to responses of commercially available trimedlure and ceralure.

METHODS AND MATERIALS

Test Compounds. Liquid trimedlure (UOP Chemicals, East Rutherford, New Jersey) (98% pure; density 1.02 g/ml) and ceralure (Agrisense/Biosys, Palo Alto, California) (98% pure; density 1.43 g/ml) were purchased from commercial sources. Ceralure was stored over a copper coil to prevent discoloration. The enantiomers of ceralure B1, ethyl (1*R*,2*R*,3*R*)-5-iodo-2-methylcyclohexane-1-carboxylate and ethyl (1*S*,2*S*,3*S*)-5-iodo-2-methylcyclohexane-1-carboxylate, henceforth referred to as (−)-ceralure B1 and (+)-ceralure B1, respectively, based on their optical rotations, were synthesized by using a unique nine-step process (Raw and Jang, 2000). This yielded each enantiomer on a multigram scale with high purity (97% ee) and an overall yield of 15%. Racemic ceralure B1 was synthesized via the same synthetic scheme utilized to synthesize the pure enantiomers of ceralure B1, with the exception of using racemic sigluric acid as starting material.

Insects. Sterilized medfly pupae were obtained from the USDA-ARS Pacific Basin Agricultural Research Center (PBARC) rearing facility in Honolulu, Hawaii. The flies were reared on an artificial diet (Tanaka et al., 1969) under standard mass rearing conditions and sterilized as pupae at a dose of 150 Gy two days before emergence. Flies were shipped by air to the PBARC laboratories in Hilo, HI, where 60–150 ml of pupae (both sexes) were placed either in small aluminum cubical screen cages (0.3 × 0.3 × 0.3 m) or in larger holding cages made from 57-liter (15-gallon) Rubbermaid "action packers" (Rubbermaid Inc., Khartoum, Sudan) modified by screened panels on the bottoms and sides of the units. The emerged flies were given water, sugar and hydrolyzed yeast protein. Flies were 2–9 days old when tested.

Rotating Olfactometer Test. Initial tests were conducted in a four-arm outdoor rotating olfactometer (3 × 3 × 2.5 m) as described in Jang et al. (1997). Neat compounds were diluted in reagent-grade acetone to give the following doses: 10, 1, 0.1, and 0.01 μg (in 100 μl acetone). The solutions were pipetted onto a 1.2-cm cotton wick inside of a Jackson trap containing a cardboard insert coated with stickem glue. One cubical aluminum cage of medflies (approximately 3600 flies of mixed sex) was released into the olfactometer. Temperature ranged from 20 to 24°C and relative humidity was 65–88%. Traps were allowed to slowly rotate within the olfactometer cage for 4 hr. At the end of the 4-hr test period, traps were removed and trapped flies were counted and recorded.

Open Field Test. All field tests were conducted by using Jackson traps with a 1.2-cm-long × 0.7-cm-diameter cotton wick that contained the test chemical (Harris et al., 1971). All tests were conducted with a randomized complete block design having five traps of each treatment in the block. The tests were replicated at least five times.

Dose–Response Tests. Traps were baited with (+)-ceralure B1, (−)-ceralure

B1, racemic ceralure B1, commercial trimedlure, commercial ceralure, or a blank (acetone) control. For each compound, the following doses were tested: 10, 1, 0.1, and 0.01 mg. Traps were placed in a macadamia nut orchard on the Island of Hawaii near the town of Hilo. Traps were separated by every other tree in every row (approximately 10 m between traps). Flies (approximately 6000/row) were then released by slowly walking between rows while allowing the flies to escape from the opened action packer. After 48 hr, traps were collected and brought back to the lab for analysis. Both males and females medflies were counted on the sticky inserts.

Longevity Tests. Preliminary tests to determine the effectiveness of the different chemical compounds over time were also carried out using sterile flies released in a macadamia nut orchard. In these tests, all compounds were applied to the cotton wick at a 10 mg dose. Traps were serviced weekly for three weeks. Inserts were changed each week and new flies were released, but the same cotton wicks were left in the field to age throughout the 3-week test period.

Data Analysis. Although male and female medflies were counted on the sticky inserts, the trap captures were overwhelmingly male biased. Thus, only data from male captures are included in the analysis. Data were subjected to analysis of variance (Proc GLM) and Tukey's honestly significant difference test for separation of mean values. Significant differences in response were determined at the $P < 0.05$ level. Data were not transformed prior to analysis. Statistical analysis was performed on SAS ver 6.12 (SAS Institute, Cary, North Carolina) with a PC. Values presented in the tables are means ±SEM.

RESULTS

In outdoor olfactometer cage tests, traps baited with (−)-ceralure B1 captured numerically more male medflies than did other traps at all concentrations. In comparison with commercial ceralure and the control, (−)-ceralure B1 produced significantly greater capture at the 10- and 1-μg mg dosages. At the 1-μg dosage, (−)-ceralure B1 was also different from racemic ceralure B1. There were no significant differences in trap captures among compounds at the 0.01-μg dosage (Table 1).

The field results comparing the relative attractancy of optically active ceralure B1 enantiomers, racemic ceralure B1, commercial trimedlure, and commercial ceralure at various doses are shown in Table 2. Traps baited with (−)-ceralure B1 captured significantly more male medflies than those baited with its (+)-ceralure B1 antipode. In addition, (−)-ceralure B1 and racemic ceralure B1 produced significantly higher capture than commercial trimedlure or ceralure at all dosages. In the course of these studies, it was noted that, at both the 10-mg and 1.0-mg doses of (−)-ceralure B1, trap saturation (overcrowding) was a

concern. Thus, the data at those concentrations may not be indicative of the relative attractiveness of (−)-ceralure B1 to the other attractants (e.g., trimedlure or commercial ceralure). At the 0.1-mg and 0.01-mg doses, trap saturation was not an issue. At these dosages, medfly capture by (−)-ceralure B1 outperformed, on average, commercial ceralure by 16-fold, and trimedlure by ninefold.

In longevity studies, all compounds were tested at the 10-mg dose. During the first week, both (−)-ceralure B1 and racemic ceralure B1 captured significantly more males than (+)-ceralure B1, commercial trimedlure, commercial ceralure, and control (Table 3). During the second week, captures at traps baited with (−)-ceralure B1 and racemic ceralure B1 were 20% and 30%, respectively, of the initial response before aging, whereas capture at traps baited with (+)-

ceralure B1, commercial trimedlure, and commercial ceralure, were not significantly greater than control. After two weeks, racemic ceralure B1 captured more males than any other compound, although the response was only 2% that of the initial response. By the third week of testing, all compounds were capturing few males flies.

DISCUSSION

In this study, we have evaluated the initial biological activity of a new stereoselectively synthesized enantiomer of the ceralure B1 isomer. The enantiopure (−)-ceralure B1 was more attractive to male medflies than either commercial ceralure (a mixture of 16 isomers), or commercial trimedlure (also a mixture of 16 isomers). This increase in relative attraction was not initially apparent from dose–response studies in the cage olfactometer (Table 1) but was clearly demonstrated in field tests at doses of 0.1–10 mg (Table 2). In addition, longevity tests with 10 mg showed greater capture in the field after two weeks compared to trimedlure or ceralure (Table 3).

From a practical perspective, these results clearly demonstrate that (−)-ceralure B1 and to a lesser extent, racemic ceralure B1, are significantly more potent medfly attractants than commercial trimedlure and ceralure. Capture by (−)-ceralure B1 outperformed the standard trimedlure used in survey and detection of medfly by as much as ninefold. Furthermore, the increased longevity of this compound, and hence the decreased volatility of this attractant compared to trimedlure, suggest that on a molecule-to-molecule basis, (−)-ceralure B1 should have even greater activity compared to trimedlure. Nevertheless, this conservative estimate demonstrates that the activity of (−)-ceralure B1 is greater than that reported for (+)-α-copaene (2–5 times more active than trimedlure) or even the

C isomer of trimedlure. To our knowledge (−)-ceralure B1 is the most potent medfly attractant thus far reported. Studies to demonstrate its effectiveness with wild fly populations have shown (−)-ceralure B1 to outperform trimedlure in the field (unpublished data). Further studies are currently in progress.

The increased effectiveness of (−)-ceralure B1 may justify the use of this attractant as a replacement of trimedlure, which is used annually in over 100,000 baited detection traps for monitoring infestations of the Mediterranean fruit fly in the United States. The effectiveness of (−)-ceralure B1 may have further implication for its potential use for male annihilation trapping of male medfly for control and eradication.

Abstract—Three Brassicaceae species, *Brassica napus* (low glucosinolate content), *Brassica nigra* (including sinigrin), and *Sinapis alba* (including sinalbin) were used as host plants for two aphid species: the generalist *Myzus persicae* and the specialist *Brevicoryne brassicae*. Each combination of aphid species and prey host plant was used to feed the polyphagous ladybird beetle, *Adalia bipunctata*. Experiments with Brassicaceae species including different amounts and kinds of glucosinolates (GLS) showed increased ladybird larval mortality at higher GLS concentrations. When reared on plants with higher GLS concentrations, the specialist aphid, *B. brassicae*, was found to be more toxic than *M. persicae*. Identification of GLS and related degradation products, mainly isothiocyanates (ITC), was investigated in the first two trophic levels, plant and aphid species, by high-performance liquid chromatography and gas chromatography–mass spectrometry, respectively. While only GLS were detected in *M. persicae* on each Brassicaceae species, high amounts of ITC were identified in *B. brassicae* samples (allyl-ITC and benzyl-ITC from *B. nigra* and *S. alba*, respectively) from all host plants. Biological effects of allelochemicals from plants on predators through aphid prey are discussed in relation to aphid species to emphasize the role of the crop plant in integrated pest management in terms of biological control efficacy.

Key Words—Allelochemical, glucosinolates, isothiocyanates, ladybird, aphid, toxicity, tritrophic interactions.

INTRODUCTION

Many Brassicaceae species are cultivated as oilseed, vegetable, or fallow plants. In 1997, cabbages (*Brassica oleracea* L.) represented 10.7% of the world vegetable production. More than 11% of plant oil was produced from rape, *Brassica napus* L. (FAO, 1995, 1997). Brassicaceae crops are known to biosynthesize glucosinolates (GLS) as secondary metabolites. Myrosinase, a thioglucosidase enzyme (EC 3.2.3.1.), was found in plants containing GLS but was also detected in insects, such as the cabbage aphid, *Brevicoryne brassicae* L. (MacGibbon and Allison, 1968; Francis, 1999a). In the plant, myrosinase is located in the cytoplasm whereas GLS are stored in vacuoles (Grob and Matile, 1979). Glucosinolate degradation is initiated when cell integrity is destroyed (Birch et al., 1990), leading to the production of nitriles, thiocyanates, oxazolidinethiones, and isothiocyanates (ITC). The latter compounds may act as infochemicals in plant–animal interactions (Lamb, 1989) and can also display toxic effects and constitute part of the plant's defense against fungal and insect infestation (Heaney and Fenwick, 1995). ITC may be repellent or attractant, depending on the insect. While Brassicaceae specialists are stimulated to feed and oviposit by these substances, generalist herbivores are generally deterred.

Chemical cues from plants or herbivores are essential in the effective localization of the host/prey habitat and the searching behavior of entomophagous insects (Sauls et al., 1979). *Adalia bipunctata* L. is known for its polyphagy towards many aphid species (Hodek, 1959) even if some of them can present negative effects on the ladybird development (Hodek and Honek, 1996). The herbivore aphids we studied were *M. persicae* and *B. brassicae*. The latter is a Brassicaceae specialist whereas the first one is a generalist (more than 400 host plants; Quaglia et al., 1993). Due to its high polyphagy, *M. persicae* is found on Brassicaceae plants and tolerates the GLS and their degradation products (Nault and Stayer, 1972).

Host plant suitability for aphids does not necessarily meet the aphidophagous predator needs (Hodek and Honek, 1996). Determination of tritrophic interactions includes both practical and theorical interests. Plant–aphid–predator relations have been little studied in integrated pest management programs and raise some questions: how do the third trophic level interactions evolve in the presence of allelochemicals constituting plant defenses? Is the impact of specific plant secondary metabolites similar on the biology of herbivores and entomophagous insects? What are the active allelochemicals in aphids—native GLS or their degradation products? Indeed, GLS break down by enzymatic degradation to release volatile by-products, including mainly isothiocyanates. Brassicaceae species used in these studies were chosen for their glucosinolate profiles: sinigrin and sinalbin are mainly present (around sixfold more than total GLS in rape) in *Brassica nigra* L. and *Sinapis alba* L., respectively, while low GLS

content rape variety includes several GLS in low concentrations. This work was carried out to determine the toxicity of the Brassicaceae secondary substances on an aphid predator and to identify accurately the chemical compounds involved.

METHODS AND MATERIALS

Plant and Insect Rearing. Broad beans (*Vicia faba* L.), black mustard (*Brassica nigra* L.), white mustard (*Sinapis alba* L.), and oilseed rape (*Brassica napus* L.) were grown in 10-cm-diameter plastic pots in three separate controlled environmental rooms at 20 ± 2°C temperature and 16L : 8D photoperiod. While beans were cultivated in pots containing a 1 : 1 mixture of perlite and vermiculite, Brassicaceae species were sown in 20-cm × 30-cm plastic trays containing ordinary compost and transplanted into plastic pots with the same compost when the plants had two true leaves.

Ladybirds, *Adalia bipunctata* L., *Acyrthosiphon pisum* (Harris), and *Myzus persicae* Sultzer had been reared in the laboratory for several years, whereas *Brevicoryne brassicae* L. was collected from a white mustard field in September 1998. While *A. pisum* was only reared on bean, the two other aphid species were mass reared on rape and white and black mustards. The Brassicaceae species were inoculated when they had five to six true leaves. Each plant species was cultivated in separate climate chambers.

For each combination of aphid species and host plant, 30 newly hatched larvae of *A. bipunctata* were isolated individually in 5-cm-diameter Petri dishes to avoid cannibalism and were kept at 20 ± 2° and 16L : 8D photoperiod. The larvae were collected from different egg clusters of the ladybird stock culture. Adults of the latter were reared in aerated plastic boxes (25 individuals per container) and fed every other day ad libitum with *A. pisum* reared on bean (optimal diet). Each experiment was repeated twice (a total of 60 individuals per beetle diet). Aphids stayed at least two weeks on their host plants before being removed from them and offered to the larvae ad libitum.

Biological Observations. Seven plant–prey combinations were tested in this work as ladybird diet: *M. persicae* reared either on *V. faba* (without GLS, considered as control), *B. napus*, *B. nigra*, or *S. alba* and *B. brassicae* reared either on *B. napus*, *B. nigra*, or *S. alba*. The Brassicaceae specialist aphid was not able to survive on bean.

After hatching, larvae were placed individually into 5-cm Petri dishes and observed every day to determine survival and appearance of nymphs until the pupal stage. Percent mortality at each development stage was analyzed by ANOVA after $\arcsin\sqrt{x}$ transformation (Dagnelie, 1973) and followed by mean comparisons by the Newman and Keuls method.

Glucosinolate Analysis. Glucosinolates were analyzed by high-perfor-

mance liquid chromatography (HPLC L-6200 and L-4000 UV detector, Merck-Hitachi) according to the ISO 9167-1 method, slightly modified. Plant, insect body, and honeydew samples were weighed and crushed in a hot methanol–water mixture (70 : 30 v/v). Glucosinolate enzymatic desulfatation was carried out on a DEAE column (Sephadex A-25) using commercial sulfatase. Desulfoglucosinolates were then analyzed by HPLC.

The *M. persicae* honeydew was collected on 20-cm × 20-cm glass plates placed just under the plants. After 48 hr of exposure, the plates were removed and rinsed with 10 ml of distilled water. To assess the occurrence of GLS in honeydew, samples were submitted to HPLC analysis as previously described. Sinigrin was used as the internal standard when *B. napus* and *S. alba* were involved whereas glucotropaeolin was added for *S. nigra* or aphid-related samples. Three replicates were considered for each analysis.

Glucosinolate Hydrolysis Product Analysis. White and black mustards contain high amounts of one major GLS (sinalbin and sinigrin, respectively), whereas the double zero variety of rape includes a mixture of low concentration GLS. We considered *B. nigra* and *S. alba* as two models, knowing that the low GLS content in rape would not allow easy detection of volatiles from aphids reared on it. That is why only aphids reared on both mustards were analyzed for the GLS hydrolysis products.

The volatile GLS metabolites from both aphid species (250 mg) reared on *B. nigra* were analyzed by use of a purge and trap unit (P&T Hewlett Packard) connected to a Hewlett Packard GC-MS system (HP5972 mass spectrometer coupled to a HP5890 series II gas chromatograph). Crushed samples were first maintained for 1 hr at 30 ± 0.2°C in thermostated glass tubes adapted to the P&T unit. They were purged with He at 4 ml/min for 11 min, the volatiles concentrated at room temperature on a Vocarb 3000, and finally desorbed by flash-heating to 250°C. The molecules of interest were automatically transferred to the GC-MS through a split-splitless injector at 250°C (splitless mode). They were separated on a HP5-MS (5% phenyl-dimethylpolysiloxane) column (30 m × 0.25 mm, *df* = 1 μm). The temperature program was from 40°C (1 min hold) to 180°C at 6°C/min then to 280°C at 15°C/min. MS spectra were obtained in the EI mode at 70 eV (scanned mass range from 30 to 300 amu). Analytes were identified on the basis of their retention times and by interpretation of MS fragmentation patterns. The recorded spectra were finally compared to those of the Wiley 238.L spectral library.

Nonvolatile GLS degradation products from both aphid species (samples each of ~250 mg) reared on *S. alba* were extracted with 500 μl pure diethyl ether for 12 hr. Solutions were injected as such in the splitless injector using the aforementioned GC-MS conditions. Quantification was performed by GLC with exactly the same chromatographic parameters on a Hewlett Packard (HP6890) apparatus equipped with a flame ionization detector maintained at

250°C. Two hundred micrograms of phenethyl-ITC was used as internal standard. The response factor was fixed to 1. The measurement of allyl-ITC was not performed due to its high volatility and the potential losses which could occur during crushing and transfer of the samples to the P&T system.

RESULTS

Ladybird Mortality. When total mortality was considered (Figure 1), significant differences were observed according to the aphid species ($F = 60.46$, $P < 0.001$). There was no difference in ladybird mortality when fed with *M. persicae* reared on the three Brassicaceae species and broad bean used as control ($F = 0.87$, $P = 0.494$). When *B. brassicae* was used as ladybird prey, highly significant differences in total mortality were observed depending on the host plant ($F = 447.97$, $P < 0.001$). Mortality of ladybirds fed *B. brassicae* reared on *B. napus* was lower than when they were fed aphids from *B. nigra* or *S. alba* ($q = 0.141$; $P < 0.01$). However, mortality rates on both mustard species reared aphids were not different ($q = 0.097$; $P > 0.05$).

Mortality of each larval stage of *A. bipunctata* fed a combination of aphid species and host plant was assessed (Figures 2a and b). Change of *M. persicae*

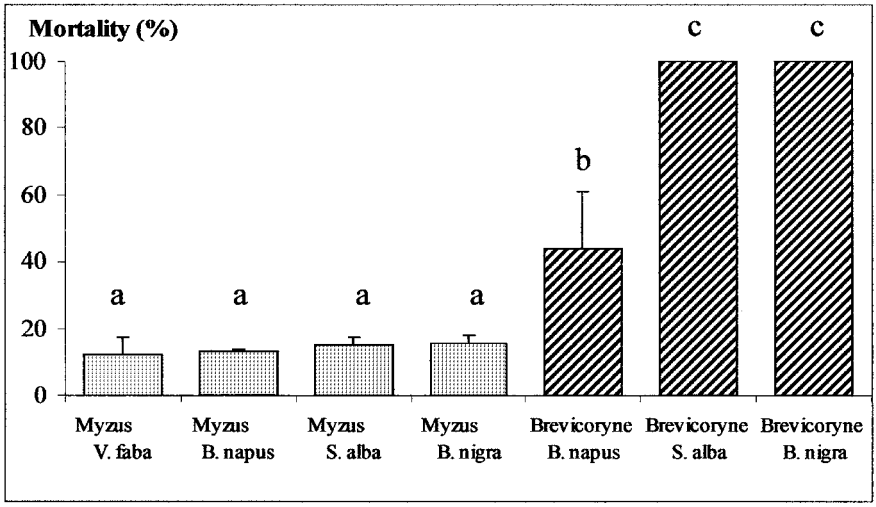

FIG. 1. Total mortality rates of *Adalia bipunctata* fed with different combinations of host plant and aphid species ($N = 60$). Error bars represent standard deviation from the mean and letters indicate significant differences at $P = 0.05$.

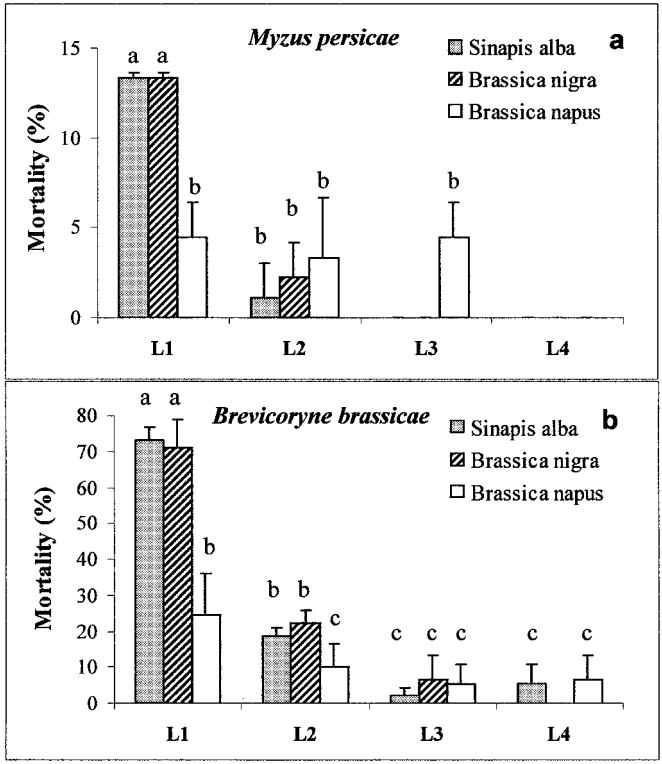

FIG. 2. Effect of aphid prey and host plant on larval mortality rates of *Adalia bipunctata* fed with *Myzus persicae* (a) and *Brevicoryne brassicae* (b) reared on *Brassica napus*, *Brassica nigra*, or *Sinapis alba* ($N = 60$ for each one). Error bars represent standard deviation from the mean and letters indicate significant differences at $P = 0.05$.

host plant displayed difference of mortality rates for first and third larval stages ($F = 40.41$ and $P < 0.001$; $F = 65.65$ and $P < 0.001$, respectively). Whether *B. napus* host plant induced lower mortality than the two mustard species ($q = 0.094$ and $P < 0.01$ for both mean tests), no difference was observed between the two latter plants ($q = 0.064$ and $P > 0.05$). Ladybird mortality rates observed for the three *M. persicae* host plants at the second larval stage were not different ($F = 0.60$ and $P = 0.579$).

A change of *B. brassicae* host plant induced a significant difference in mortality rates at the first and second larval stages ($F = 27.42$ and $P = 0.001$; $F = 5.16$ and $P = 0.048$, respectively). Mortality rates of *A. bipunctata* fed *B. brassicae* reared on both mustard species were higher than when fed aphids reared on rape ($q = 0.354$ and $P < 0.01$; $q = 0.132$ and $P < 0.05$ for first and second

TABLE 1. GLUCOSINOLATE CONTENTS IN PLANT AND APHID SPECIES[a]

Glucosinolate	Host plant leaf	*Myzus persicae*		*Brevicoryne brassicae* total aphid
		Total aphid	Honeydew

Sinigrin	8.45 ± 0.54	1.75 ± 0.39	1.92 ± 0.17	132.88 ± 17.12
Sinalbin	0.23 ± 0.04	<0.01	ND	4.89 ± 0.37
4-OH-Glucobrassicin	0.79 ± 0.03	<0.01	<0.01	8.32 ± 1.72
Progoitrin	0.07 ± 0.01	1.58 ± 0.48	<0.01	2.21 ± 0.41
Total	9.54 ± 0.42	2.33 ± 0.46	1.92 ± 0.17	148.20 ± 15.03

[a] Values are in μmol. g^{-1}FW. GLS amounts of *M. persicae* honeydew (in μmol) were determined from the glass plate rinsing solution. ND = glucosinolates were not detected.

larval stages, respectively). No difference was observed between aphids reared on *B. nigra* or *S. alba* ($q = 0.243$ and $P > 0.05$). *B. brassicae* host plant did not induce differences in mortality rates of third and fourth larval stage ladybirds ($F = 0.26$ and $P = 0.779$; $F = 1.88$ and $P = 0.232$, respectively).

Glucosinolate Analysis. The glucosinolates found in aphid samples and in host plant leaves are presented in Table 1 and 2. Small quantities of glucobrassicin, brassicanapin, and glucoraphanin were detected in both aphid species reared on the low-GLS-content rape. Larger quantities of sinalbin and sinigrin were found in aphid samples collected on *S. alba* and *B. nigra*, respectively. Larger differences in GLS content were observed between the aphid species. Higher GLS amounts were found in *B. brassicae* than in *M. persicae* samples. Complementary analysis of honeydew from the latter reared on each Brassicaceae species revealed traces of sinalbin and sinigrin in *S. alba* and *B. nigra*, respectively (Table 1). Honeydew production by *B. brassicae* was so small that analysis was not possible.

Glucosinolate Hydrolysis Product Analysis. Regardless of the host plant

TABLE 2. GLUCOSINOLATES FOUND IN HOST PLANT AND APHID SPECIES ANALYZED

Common name	Glucosinolate side chain
Sinigrin	allyl
Sinalbin	*p*-hydroxybenzyl
4-OH-glucobrassicin	4-OH-3-indolylmethyl
Progoitrin	2-OH-3-butenyl
Brassicanapin	4-pentenyl
Gluconasturtin	2-phenylethyl
Glucoraphanin	4-methylsulfinylbutyl
Glucobrassicin	3-indolylmethyl

(*B. napus*, *B. nigra*, and *S. alba*), the GC-MS chromatograms of volatiles from *M. persicae* only displayed β-farnesene, a well known aphid alarm pheromone (Pickett et al., 1992). No glucosinolate degradation product was detected for *M. persicae* (Table 3). *B. brassicae* samples displayed substantial amounts of ITC(s) and nitrile(s) according to the GLS present in the aphid host plant (Table 3). Allyl-ITC and allylnitrile were found in aphids reared on *B. nigra*, which biosynthesizes sinigrin. Analyses of aphids collected on *S. alba*, which contains sinalbin (4-hydroxybenzyl-GLS) by the purge-and-trap method, did not reveal the occurrence of ITC. As no peak was detected by this method, the unsuccessful recovery of 4-hydroxybenzyl-ITC was attributed to its low volatility. Diethyl ether extraction was then undertaken. Diethyl ether extracts of *B. brassicae* reared on *S. alba* had two peaks: benzyl-ITC and benzyl-nitrile. The occurrence of benzyl-ITC was surprising as this compound is characteristic of glucotropaeolin (benzyl-glucosinolate) degradation. Further analysis was carried out to be sure that this was not an analytical artifact. Commercial thioglucosidase was added to an aqueous

TABLE 3. VOLATILE CONSTITUENT ANALYSIS OF *Brevicoryne brassicae* AND *Myzus persicae* EXTRACTS BY GC-MS (TOTAL ION CURRENT)[a]

Aphid and host plant species	GLS hydrolysis products	Others
Brevicoryne brassicae		
On *Sinapis alba*	Benzyl-ITC (R_t = 22.87)	
	Benzylnitrile (R_t = 17.27)	
On *Brassica nigra*	Allyl-ITC (R_t = 10.53)	
	Allylnitrile (R_t = 4.70)	
Myzus persicae		
On *Sinapis alba*		β-farnesene (R_t = 24.60)
On *Brassica nigra*		β-farnesene (R_t = 24.63)

[a] Names of identified compounds are followed by their retention time (R_t).

solution of sinalbin (purified from *S. alba*; 2 mg/ml); 4-hydroxy benzyl-ITC was identified by GC-MS. This result indicates that sinalbin metabolism in *B. brassicae* is more complex than suspected. We hypothesize that the loss of an hydroxy group is linked to the insect extract and not to the analytical method. This observation needs further investigation.

Quantitative evaluation of the benzyl-ITC production from specialist aphids was assessed and revealed a constant ITC/associated nitrile ratio (5.59 ± 0.37; benzyl-ITC/benzonitrile) for all replicates. The benzyl-ITC that was produced from the *B. brassicae* samples was 3.0 ± 0.2 μmol/g fresh material ($N = 4$ replicates).

DISCUSSION

In association with visual cues, chemical composition plays an important role in host plant location by herbivorous insects (Prokopy and Owens, 1983). Fraenkel (1959) suggested that secondary plant metabolites were directly involved in food searching by insects. The impact of allelochemicals is not limited to the second trophic level, interactions are observed when entomophagous insects use synomones emitted by plants as cues for prey location. Volatile chemical cues employed by natural enemies may originate from the plant upon which the host is feeding, the host itself, other organisms associated with the host, or chemicals released as a result of interactions between the host and its food plant (Lewis and Martin, 1990). Release of herbivore-induced plant volatiles that act as reliable and detectable host location cues for parasitoids and predators has previously been demonstrated for several tritrophic systems (Dicke et al., 1990; Turlings et al., 1990).

The chemical traces of aphids, even in the absence of insects themselves, induce changes in ladybird oviposition behavior (Carter and Dixon, 1984). In this work, GLS were found in the honeydew of *M. persicae* reared on the three Brassicaceae host plants Weber et al. (1986) detected 3.6–28.7 μmol/g (dry weight) of GLS in the peach-potato aphid depending on the rape variety (low or high GLS content). Isothiocyanates and nitriles were detected by GC-MS in *B. brassicae* infesting either *B. nigra* or *S. alba*. The presence of benzyl-ITC was quite surprising; 4-hydroxy benzyl-ITC, the normal product of sinalbin degradation was not found. Loss of the hydroxy group seems to be due to the *B. brassicae* enzymatic extract but needs to be more extensively studied from a biochemical point of view. Benzyl-ITC, a typical glucotropaeolin degradation product, is toxic to some insects (Bartlet and Mikolajczak, 1989). These molecules emitted by the Brassicaceae specialist aphid could be used as infochemicals by entomophagous insects. Assays on the *B. brassicae* parasitoid *Diaeretiella rapae* demonstrated the role of volatiles from aphids as kairomones. Indeed,

they responded to odors of infested cabbage leaves or aphids alone but not plants uninfested by aphids, suggesting an innate odor preference for crucifer-feeding aphids (Reed et al., 1995). If Brassicaceae pest natural enemies use these infochemicals for their own benefit, generalist predators could use the ITC produced by *B. brassicae* as allomones to avoid this aphid species. When two aphid species were offered to *A. bipunctata* (*M. persicae* and *B. brassicae* or the latter and *A. pisum*), the generalist predator first consumed the other, then the Brassicaceae specialist species (Francis, personal communication). This rejection is directly linked to the food suitability represented by the aphid species (Hodek and Honek, 1996). No ladybird was able to reach the adult stage when fed with the specialist aphid reared on both mustard species. When prey was collected from rape, twofold lighter adults emerged (compared to control food, *M. persicae* on bean) and no reproduction was observed (Francis, 1999b).

Isothiocyanates, GLS degradation compounds, stimulate olfactory receptors of generalist herbivores such as *Aphis fabae*. Both pentenyl- and butyl-ITC are repellent to this aphid species (Isaacs et al., 1993). Alkenyl-ITCs are characteristic defensive chemicals of Brassicaceae. Chemical precursors that break down to release ITC have shown biological activity against pathogens and insect pests of Brassicaceae (Lamb, 1989; Dawson et al., 1993). The higher toxicity of *B. brassicae* prey to generalist predators can be objectively explained by the presence of these ITC compounds. Indeed, allyl-ITC and methyl-ITC are toxic to *A. bipunctata* (0.189 ppm $< LD_{50} <$ 0.308 ppm and 0.218 ppm $< LD_{50} <$ 0.551 ppm, respectively) after a 24-hr exposure (Francis et al., 1999). Moreover, myrosinase, the enzyme that catalyzes GLS degradation, was detected in *B. brassicae* but not in *M. persicae* (Francis, 1999a). ITC or nitriles were not found in the latter species reared on Brassicaceae species. Only intact GLS were observed in this aphid species reared on mustards or rape (0.47–2.33 μmol/g fresh aphid weight). On the other hand, high amounts of GLS were found in *B. brassicae* reared on both mustard species while lower allelochemical levels were observed on rape (25–30 times less). Weber et al. (1986) detected more than 60 μmol/g (when expressed on a fresh weight basis) of GLS in *B. brassicae* reared on high GLS content rapes.

Glucosinolates are known to display biological properties towards insects. While they are oviposition stimulants or phagostimulants (Hicks, 1974; Reed et al., 1989; Traynier and Truscott, 1991) for many Brassicaceae herbivore specialists, they also serve as repellents for most generalist crop pests (Blau et al., 1978; Erickson and Feeny, 1974). Foliar concentrations of GLS found in both mustard species were much higher than in rape (around sixfold more) and were in accordance with the results of Hopkins et al. (1998). Total GLS content in white mustard leaves were 50–70 μmol/g of dry weight, which corresponded to a concentration of 10–15 μmol/g GLS when expressed in fresh weight. Whereas 12.5 μmol/g (in dry weight) of total GLS was found in 00 rape leaves, more than

60 μmol/g was detected in a high-GLS variety of rape (Weber et al., 1986). Similar GLS concentrations (expressed in fresh weight), were reported in this study. Variations in GLS contents of cultivated species were tested to obtain resistant varieties of plant against herbivores. *Sinapis alba*, containing high amounts of sinalbin, was shown to be less susceptible to damage by insect pests than *B. napus* with low GLS content. The specialist aphid, *B. brassicae*, was found mainly on young tissues containing the highest total GLS levels, while the generalist aphid, *M. persicae*, was found predominantly on older plant parts (Hopkins et al., 1998). According to these authors, aphid distribution is directly linked to GLS concentration in plant.

Other secondary plant compounds are toxic to nonspecialist herbivores and to natural enemies of herbivores. Toxicity of *Aphis sambuci* seemed to be assumed by the passage of the glycoside sambunigrin from the plant *Sambuscus nigra* into the aphid. Several other species of aphids also seem to be poisonous to coccinellids, including *A. bipunctata*, and are rejected by ladybirds due to presence of allelochemicals, including *Macrosiphum aconitum* feeding on *Aconitum* (including aconitin), *Aphis nerii* infesting oleanders (including oleandrin and neriin), and *Aphis jacobaeae* feeding on *Senecio* sp. (including pyrrolizidine alkaloids) (Hodek and Honek, 1996).

Allelochemicals from plants are partly responsible for host specificity of herbivorous insects (Schoonhoven, 1981). As specialized organisms, insects developed many defense strategies. Their responses towards secondary metabolites vary considerably. Some insects have evolved adaptations to resist these allelochemicals, including stocking them as defense substances against natural enemies (Harborne, 1993). Others evolved biochemical systems to metabolize and assimilate secondary plant substances. Detoxification mechanisms can contribute to neutralizing the toxic potential of some compounds (Yu, 1984; Yu and Hsu, 1993). These adaptations range from chemical modification of toxin, its transformation into a nontoxic conjugated compound, or its sequestration. Allyl- and benzyl-ITC were metabolized by glutathione *S*-transferase (GST) from two lepidopterous generalist species (*Spodoptera frugiperda* and *Trichoplusa ni*), but no activity was detected with the specialist *Anticarsia gemmatalis* (Wadleigh and Yu, 1988). While the generalist aphid *M. persicae* displayed induction of the GST system when reared on Brassicaceae species (*S. alba*, *B. nigra*, *B. napus*), induction was not observed in the *B. brassicae* specialist herbivore whatever the host plant (Francis, 1999a).

Adaptation of the aphid predator, *A. bipunctata*, to crucifer allelochemicals is facilitated by induction of GST (Francis, 1999a). Indeed, the increase of GST activity was linked to the plant GLS levels predominantly with *B. brassicae* aphid. We hypothesize that the latter accumulates the plant secondary substances, constituting an aphid defense against their natural predators. More than the volatile emission as chemical cues, this phenomenon of bioaccumulation of

high GLS amounts in prey would imply an aphid limited consumption by entomophagous insects.

In conclusion, studies on integrated pest management must include both herbivore and plant trophic levels to determine the plant allelochemical impact on the third trophic level, the beneficial entomophagous insects. To obtain effective biological control, determination of the involved aphid species is not sufficient. Semiochemicals from plants, directly or through herbivore prey, must be taken into account as a potential toxin or reliable infochemical in relation to the efficacy of pest control by natural enemies. Effectiveness of biological control by coccinellids is influenced by many factors, among them the host plant species of the pest. If natural enemies attack a wide variety of herbivores that occur on the same host species, information from the plant may become very important (Vet and Dicke, 1992). The use of generalist predators is not always a general solution to control aphid infestations. This work confirms the need for a case-by-case consideration when setting an integrated pest management program, including chemical ecology approaches.

(Received November 15, 1999; accepted September 30, 2000)

Abstract—9,10-Dihydrophenanthrenes and phenanthrenes, mimics of natural compounds with strong antialgal activity, have been synthesized through cross-coupling by zerovalent Ni of 1-(2-iodo-5-methoxy)-phenylethanol or 2-iodo-5-methoxyacetophenone with iodoxylenes. The synthetic compounds had a hydroxyl or a methoxyl group at C-2 and two methyls in the C ring. Assays on the green alga *Selenastrum capricornutum* showed that all the compounds, except 2-methoxy-5,7-dimethylphenanthrene, caused strong inhibition of algal growth at 10^{-4} M. 2-Hydroxy-7,8-dimethyl-9,10-dihydrophenanthrene and 2-methoxy-5,6-dimethylphenanthrene fully inhibited growth at 10^{-5} M.

Key Words—*Juncus effusus*, phenanthrenes, 9,10-dihydrophenanthrenes, cross-coupling algicides, *Selenastrum capricornutum*.

INTRODUCTION

We reported in a previous paper (DellaGreca et al., 2000) the synthesis of 9,10-dihydrophenanthrenes 1a–1l and phenanthrenes 2a–2l, mimics of natural com-

*To whom correspondence should be addressed.

pounds isolated from the wetland plant, *Jancus effusus* (DellaGreca et al., 1992, 1993, 1995a,b, 1997). The compounds have the common feature of a hydroxyl or a methoxyl group at the C-2 position of the A ring, while a methyl group is located at different positions of the C ring. Synthesis was based on cross-coupling of 1-(2-iodo-5-methoxy)-phenylethanol (**3**) with the three isomeric iodotoluenes. The compounds, except 7-methyl-2-methoxyphenanthrene (**2g**), showed strong antialgal activity in assays of the freshwater green alga *Selenastrum capricornutum* at 10^{-4} M concentration. Most of them also retained strong activity at 10^{-5} M.

In pursuing the study of the structure–activity relationship, we have now synthesized all the isomeric phenanthrenes and 9,10-dihydrophenanthrenes with a hydroxyl or a methoxyl at C-2 bearing two methyls in the C ring. The synthesis was based on the cross-coupling of iodoarenes by zerovalent nickel (Semmelhack et al., 1981).

METHODS AND MATERIALS

Chemicals. 3-Iodo-4-methylbenzoic acid and iodobenzenes were obtained commercially (Aldrich). 1-(2-Iodo-5-methoxy)-phenylethanol (**3**) was prepared as reported by DellaGreca et al. (2000).

General Experimental Procedures. NMR spectra were recorded at 400 MHz for ^{1}H and 100 MHz for ^{13}C on a Bruker AC 400 spectrometer in $CDCl_3$ solutions. One-bond and long-range H-C COSY experiments were performed with the XHCORR microprogram with delays corresponding to $J_{C,H}$ = 160 Hz and 8 Hz, respectively. HPLC was performed on a Varian Vista 5500 with a UV detector.

*Synthesis of 2-Hydroxy-6,7-dimethyl-9,10-dihydrophenanthrene (**1t**), 2-Hydroxy-7,8-dimethyl-9,10-dihydrophenanthrene (**1x**), 2-Hydroxy-6,7-dimethylphenanthrene (**2t**), and 2-Hydroxy-7,8-dimethylphenanthrene (**2x**).* To a 50-ml three-necked flask, zinc dust (392 mg, 6 mmol washed with 2 N HCl, H_2O, EtOH, Me_2CO, Et_2O, and dried in an oven at 120°C), $NiCl_2$ (784 mg, 6 mmol), PPh_3 (6.3 g, 24 mmol), and dry DMF (10 ml) were added. The mixture was warmed at 40°C under N_2 and stirred for 1 hr. A solution of **3** (834 mg, 3 mmol) and iodo-3,4-dimethylbenzene (696 mg, 3 mmol) in dry DMF (5 ml) was added at once, and the reaction mixture was kept at 40°C for 6 hr. Then 2 N NH_4OH was added and the mixture was extracted with Et_2O. After evaporation the residue was chromatographed on silica gel (benzene–Et_2O 19 : 1) to afford biphenyl **5b** (360 mg, 1.4 mmol, 47%): ^{1}H NMR δ 7.21 (1H, d, J = 2.3 Hz, H-3), 6.84 (1H, dd, J = 2.3 and 8.4 Hz, H-5), 7.15 (1H, d, J = 8.4 Hz, H-6), 7.05 (1H, d, J = 2.3 Hz, H-2′), 7.16 (1H, d, J = 8.5 Hz, H-5′), 7.01 (1H, dd, J = 2.3 and 8.5 Hz, H-6′), 5.00 (1H, q, J = 6.4 Hz, H-7), 1.39 (3H, d, J = 6.4 Hz, H-8), 3.86 (3H, s, OMe), 2.30 (3H, s, Me), 2.31 (3H, s, Me).

To a solution of **5b** (360 mg, 1.4 mmol) in dry xylene (1 ml), I_2 (20 mg, 0.08 mol) was added and the mixture was kept at 140°C for 6 hr. Addition of 10% aq $NaHSO_3$ and extraction with Et_2O gave a residue that was chromatographed on silica gel (hexane) to give **6b** (265 mg, 1.1 mmol, 80%): ^{1}H NMR δ 7.24 (1H, d, J = 2.2 Hz, H-3), 6.94 (1H, dd, J = 2.2 and 8.4 Hz, H-5), 7.19 (1H, d, J = 8.4 Hz, H-6), 7.21 (1H, d, J = 2.4 Hz, H-2′), 7.28 (1H, d, J = 8.4 Hz, H-5′), 7.16 (1H, dd, J = 2.4 and 8.5 Hz, H-6′), 6.76 (1H, dd, J = 10.5 and 17.6 Hz, H-7), 5.24 (1H, dd, J = 1.8 and 10.5 Hz, H-8), 5.75 (1H, dd, J = 1.8 and 17.6 Hz, H-8), 3.91 (3H, s, OMe), 2.37 (6H, s, Me).

A sample of **6b** (130 mg, 0.55 mmol) in dry benzene (6.5 ml) in a Pyrex flask was irradiated under an air atmosphere with a 450-W Hanovia lamp at room temperature for 30 min with magnetic stirring to give a mixture of **2s** and **2w** (63 mg, 0.30 mmol, 54%) along with unreacted **6b** (52 mg). **2s** and **2w** were separated by HPLC-NH_2 (hexane–isopropyl ether 98.5 : 1.5) **2s** (28 mg) had: ^{1}H NMR δ 7.22–7.36 (2H, m, H-1 and H-3), 8.60 (1H, d, J = 9.1 Hz, H-4), 8.36 (1H, s, H-5), 7.63 (1H, s, H-8), 7.63 (1H, d, J = 7.4 Hz, H-9), 7.48 (1H, d, J = 7.4 Hz, H-10), 3.97 (3H, s, OMe), 2.55 (3H, s, Me), 2.49 (3H, s, Me); ^{13}C NMR δ 117.0 (C-1), 157.2 (C-2), 108.9 (C-3), 124.6 (C-4), 122.8 (C-5), 134.9 (C-6), 133.8 (C-7), 129.5 (C-8), 125.8 (C-9), 127.3 (C-10), 132.6 (C-1a), 125.9 (C-4a), 127.9 (C-5a), 133.9 (C-8a) 55.6 (OMe), 20.8 (Me), 22.9 (Me). Compound **2w** (27 mg) had: ^{1}H NMR δ 7.22–7.36 (2H, m, H-1 and H-3), 8.62 (1H, d, J = 9.3 Hz, H-4), 8.39 (1H, d, J = 9.3 Hz, H-5), 7.71 (1H, d, J = 9.3 Hz, H-6), 8.02 (1H, d, J = 8.4 Hz, H-9), 7.57 (1H, d, J = 8.4 Hz, H-10), 3.98 (3H, s, OMe), 2.55 (3H, s, Me), 2.83 (3H, s, Me); ^{13}C NMR δ 117.3 (C-1), 157.3 (C-2), 108.5 (C-3), 124.3 (C-4), 120.0 (C-5), 128.9 (C-6), 133.9 (C-7), 136.1 (C-8), 123.8 (C-9), 126.4 (C-10), 132.7 (C-1a), 126.6 (C-4a), 128.1 (C-5a), 129.8 (C-8a), 55.6 (OMe), 20.1 (Me), 21.0 (Me).

To a solution of **2s** (26 mg, 0.12 mmol) in dry CH_2Cl_2 (1.5 ml) cooled at −70°C, BBr_3 (100 μl) was added. Addition of 1 N $NaHCO_3$ after 3 hr and extraction with $CHCl_3$ gave a residue that was purified by preparative TLC (hexane–Et_2O 1 : 1) to give **2t** (18 mg, 0.08 mmol, 70%): ^{1}H NMR δ 7.21 (1H, d, J = 2.1 Hz, H-1), 7.19 (1H, dd, J = 2, 1 and 9.2 Hz, H-3), 8.56 (1H, d, J = 9.2 Hz, H-4), 8.34 (1H, s, H-5), 7.60 (1H, s, H-8), 7.62 (1H, d, J = 7.4 Hz, H-9), 7.46 (1H, d, J = 7.4 Hz, H-10), 2.52 (3H, s, Me), 2.45 (3H, s, Me); ^{13}C NMR δ 116.6 (C-1), 153.8 (C-2), 111.7 (C-3), 124.9 (C-4), 122.7 (C-5), 135.0 (C-6), 133.8 (C-7), 129.5 (C-8), 125.4 (C-9), 127.5 (C-10), 132.7 (C-1a), 125.8 (C-4a), 128.0 (C-5a), 133.5 (C-8a) 20.8 (Me), 21.1 (Me).

To a solution of **2w** (25 mg, 0.12 mmol) in dry CH_2Cl_2 (1.5 ml) cooled at −70°C, BBr_3 (100 μl) was added. Addition of 1 N $NaHCO_3$ after 3 hr and extraction with $CHCl_3$ gave a residue that was purified by preparative TLC (hexane–Et_2O 1 : 1) to give **2x** (17 mg, 0.09 mmol, 70%): ^{1}H NMR δ 7.21 (1H, d, J = 2.3 Hz, H-1), 7.19 (1H, dd J = 2.3 and 9.2 Hz), 8.58 (1H, d, J = 9.2 Hz,

H-4), 8.37 (1H, d, J = 9.3 Hz, H-5), 7.70 (1H, d, J = 9.3 Hz, H-6), 8.00 (1H, d, J = 8.4 Hz, H-9), 7.52 (1H, d, J = 8.4 Hz, H-10), 2.52 (3H, s, Me), 2.65 (3H, s, Me); ^{13}C NMR δ 116.9 (C-1), 154.0 (C-2), 112.0 (C-3), 124.6 (C-4), 119.9 (C-5), 128.9 (C-6), 133.9 (C-7), 136.2 (C-8), 124.0 (C-9), 126.1 (C-10), 133.1 (C-1a), 126.4 (C-4a), 128.1 (C-5a), 129.8 (C-8a), 20.1 (Me), 20.8 (Me).

To an EtOH solution (4.8 ml) of **2s** (26 mg, 0.12 mmol), $NaBH_4$ (0.3 mmol) and Et_3N (1.2 mmol) were added. The reaction mixture was irradiated for 2.5 hr with a Hanovia 450-W lamp and then HCl 10% was added. $CHCl_3$ extraction gave a crude product, which was chromatographed by preparative TLC (hexane–benzene 9 : 1) to give **1s** (13 mg, 0.06 mmol, 50%): ^{1}H NMR δ 6.72 (1H, d, J = 2.3 Hz, H-1), 6.88 (1H, dd, J = 2.3 and 8.4 Hz, H-3), 7.72 (1H, d, J = 8.2 Hz, H-4), 7.03 (1H, s, H-5), 7.49 (1H, s, H-8), 2.83 (4H, brs, H-9 and H-10), 3.85 (3H, s, OMe) 2.33 (3H, s, Me), 2.28 (3H, s, Me); ^{13}C NMR δ 112.2 (C-1), 159.1 (C-2), 113.5 (C-3), 124.5 (C-4), 124.3 (C-5), 134.9 (C-6), 134.9 (C-7), 129.4 (C-8), 28.6 (C-9), 29.8 (C-10), 137.9 (C-1a), 127.9 (C-4a), 138.9 (C-5a), 132.0 (C-8a), 55.3 (OMe), 19.7 (Me), 19.4 (Me).

BBr_3 (50 μl) treatment of **1s** (10 mg, 0.05 mmol) in dry CH_2Cl_2 (1 ml) at -70°C for 3 hr gave **1t** (7 mg, 0.03 mmol): ^{1}H NMR δ 6.74 (1H, d, J = 2.2 Hz, H-1), 6.78 (1H, dd, J = 2.2 and 8.4 Hz, H-3), 7.63 (2H, d, J = 8.4 Hz, H-4), 7.03 (1H, s, H-5), 7.47 (1H, s, H-8), 2.81 (4H, brs, H-9 and H-10), 2.32 (3H, s, Me), 2.28 (3H, s, Me); ^{13}C NMR δ 113.7 (C-1), 154.1 (C-2), 114.9 (C-3), 124.8 (C-4), 124.3 (C-5), 135.0 (C-6), 135.0 (C-7), 129.4 (C-8), 28.5 (C-9), 29.5 (C-10), 137.8 (C-1a), 127.7 (C-4a), 139.2 (C-5a), 132.0 (C-8a), 19.7 (Me), 19.4 (Me).

Photoreduction of **2w** (25 mg, 0.12 mmol), as described for **2s**, gave **1w** (11 mg, 0.06 mmol, 50%): ^{1}H NMR δ 6.79 (1H, d, J = 2.4 Hz, H-1), 6.84 (1H, dd, J = 2.4 and 8.5 Hz, H-3), 7.66 (1H, d, J = 8.5 Hz, H-4), 7.49 (1H, d, J = 8.1 Hz, H-5), 7.09 (1H, d, J = 8.1 Hz, H-6), 2.85 (4H, brs, H-9 and H-10), 3.84 (3H, s, OMe) 2.34 (3H, s, Me), 2.26 (3H, s, Me); ^{13}C NMR δ 112.3 (C-1), 158.6 (C-2), 113.0 (C-3), 125.0 (C-4), 120.6 (C-5), 128.1 (C-6), 134.9 (C-7), 134.8 (C-8), 25.3 (C-9), 29.4 (C-10), 135.1 (C-1a), 128.1 (C-4a), 138.6 (C-5a), 132.2 (C-8a), 55.3 (OMe), 15.4 (Me), 20.8 (Me).

Demethylation by BBr_3 of **1w** (10 mg, 0.06 mmol) gave **1x** (6 mg, 0.04 mmol, 67%): ^{1}H NMR δ 6.72 (1H, d, J = 2.4 Hz, H-1), 6.77 (1H, dd, J = 2.4 and 8.5 Hz, H-3), 7.61 (1H, d, J = 8.5 Hz, H-4), 7.49 (1H, d, J = 8.1 Hz, H-5), 7.11 (1H, d, J = 8.1 Hz, H-6), 2.84 (4H, brs, H-9 and H-10), 2.36 (3H, s, Me), 2.28 (3H, s, Me); ^{13}C NMR δ 113.7 (C-1), 154.6 (C-2), 114.4 (C-3), 125.3 (C-4), 120.6 (C-5), 128.1 (C-6), 134.9 (C-7), 135.2 (C-8), 25.2 (C-9), 29.5 (C-10), 135.2 (C-1a), 128.4 (C-4a), 138.7 (C-5a), 132.3 (C-8a), 15.4 (Me), 20.8 (Me).

*Synthesis of 2-Hydroxy-6,8-dimethyl-9,10-dihydrophenanthrene (**1v**) and 2-Hydroxy-6,8-dimethylphenanthrene (**2v**).* A solution of **3** (3 mmol) and iodo-3,5-dimethylbenzene (3 mmol) in dry DMF (5 ml) was added to the mixture of the active nickel complex prepared as reported above. Work-up after 9 hr at 35°C

and chromatography on silica gel (benzene–Et_2O 19 : 1) gave biaryl **5a** (273 mg, 1.1 mmol, 37%): ^{1}H NMR δ 7.24 (1H, d, J = 2.2 Hz, H-3), 6.86 (1H, dd, J = 2.2 and 8.3 Hz, H-5), 7.08 (1H, d, J = 8.3 Hz, H-6), 6.92 (3H, d, J = 2.1 Hz, H-2′ and H-4′) 7.01 (1H, brs, H-6′), 5.01 (1H, q, J = 6.2 Hz, H-7), 1.41 (3H, d, J = 6.2 Hz, H-8), 3.86 (3H, s, OMe), 2.38 (6H, s, Me).

To a solution of **5a** (270 mg, 1.1 mmol) in dry xylene (1 ml), I_2 (20 mg, 0.08 mol) was added and the mixture was kept at 140°C for 6 hr. Work-up as for **6b** gave **6a** (212 mg, 0.88 mmol, 80%): ^{1}H NMR δ 7.30 (1H, d, J = 2.2 Hz, H-3), 6.98 (1H, dd, J = 2.2 and 8.4 Hz, H-5), 7.32 (1H, d, J = 8.4 Hz, H-6), 7.09 (2H, brs, H-2′ and H-6′), 7.18 (1H, brs, H-4′), 6.88 (1H, dd, J = 10.6 and 17.5 Hz, H-7), 5.32 (1H, dd, J = 1.8 and 10.6 Hz, H-8), 5.83 (1H, dd, J-1.8 and 17.5 Hz, H-8), 3.98 (3H, s, OMe), 2.49 (6H, s, Me).

Photocyclization of **6a** (100 mg, 0.4 mmol) in an Ar atmosphere for 1 hr gave 2-methoxy-6,8-dimethyl-9,10-dihydrophenanthrene (**1u**) (74 mg, 0.3 mmol, 75%): ^{1}H NMR δ 6.81 (1H, d, J = 2.4 Hz, H-1), 6.88 (1H, dd, J = 2.4 and 8.5 Hz, H-3), 7.71 (1H, d, J = 8.5 Hz, H-4), 6.95 (1H, d, J = 2.3 Hz, H-5), 7.41 (1H, d, J = 2.3 Hz, H-7), 2.82 (4H, brs, H-9 and H-10), 3.86 (3H, s, OMe) 2.37 (3H, s, Me), 2.33 (3H, s, Me); ^{13}C NMR δ 112.3 (C-1), 158.9 (C-2), 113.2 (C-3), 125.3 (C-4), 121.8 (C-5), 135.2 (C-6), 129.4 (C-7), 134.4 (C-8), 24.5 (C-9), 29.4 (C-10), 135.6 (C-1a), 128.0 (C-4a), 138.9 (C-5a), 132.0 (C-8a), 55.3 (OMe), 21.3 (Me), 19.7 (Me). BBr_3 demethylation of **1u** (30 mg, 0.18 mmol) gave **1v** (20 mg, 0.12 mmol, 68%): ^{1}H NMR δ 6.72 (1H, d, J = 2.5 Hz, H-1), 6.78 (1H, dd, J = 2.5 and 8.3 Hz, H-3), 7.64 (1H, d, J = 8.3 Hz, H-4), 6.93 (1H, d, J = 2.3 Hz, H-5), 7.41 (1H, d, J = 2.3 Hz, H-7), 2.80 (4H, brs, H-9 and H-10), 2.39 (3H, s, Me), 2.33 (3H, s, Me); ^{13}C NMR δ 113.7 (C-1), 154.7 (C-2), 114.6 (C-3), 125.4 (C-4), 121.6 (C-5), 135.1 (C-6), 129.4 (C-7), 134.8 (C-8), 24.3 (C-9), 29.1 (C-10), 135.5 (C-1a), 128.1 (C-4a), 139.2 (C-5a), 131.9 (C-8a), 21.2 (Me), 19.7 (Me).

Photocyclization of **6a** (100 mg, 0.4 mmol) in the presence of atmospheric oxygen gave **2u** (70 mg, 0.3 mmol, 75%): ^{1}H NMR δ 7.22–7.36 (2H, m, H-1 and H-3), 8.52 (1H, d, J = 9.2 Hz, H-4), 8.30 (1H, d, J = 1.9 Hz, H-5), 7.22 (1H, d, J = 1.9 Hz, H-7), 7.91 (1H, d, J = 7.4 Hz, H-9), 7.57 (1H, d, J = 7.4 Hz, H-10), 3.98 (3H, s, OMe), 2.72 (3H, s, Me), 2.52 (3H, s, Me); ^{13}C NMR δ 117.0 (C-1), 158.2 (C-2), 108.3 (C-3), 124.6 (C-4), 120.1 (C-5), 134.7 (C-6), 123.5 (C-7), 135.9 (C-8), 125.3 (C-9), 128.7 (C-10), 133.3 (C-1a), 124.8 (C-4a), 127.8 (C-5a), 130.7 (C-8a), 55.4 (OMe), 22.0 (Me), 19.8 (Me). Demethylation of **2u** (35 mg, 0.2 mmol) by BBr_3 gave **2v** (26 mg, 0.14 mmol, 70%): ^{1}H NMR δ 7.22–7.36 (2H, m, H-1 and H-3), 8.61 (1H, d, J = 9.2 Hz, H-4), 8.28 (1H, d, J = 1.9 Hz, H-5), 7.22 (1H, d, J = 1.9 Hz, H-7), 7.91 (1H, d, J = 7.4 Hz, H-9), 7.58 (1H, d, J = 7.4 Hz, H-10), 2.71 (3H, s, Me), 2.57 (3H, s, Me); ^{13}C NMR δ 117.1 (C-1), 153.0 (C-2), 111.5 (C-3), 124.9 (C-4), 120.2 (C-5), 134.9 (C-6), 123.5 (C-7), 136.0 (C-8), 125.3 (C-9), 128.7 (C-10), 133.7 (C-1a), 124.6 (C-4a), 127.8 (C-5a), 130.4 (C-8a), 22.2 (Me), 20.0 (Me).

*Synthesis of 2-Hydroxy-5,6-dimethyl-9,10-dihydrophenanthrene (**1n**) and 2-Hydroxy-5,6-dimethylphenanthrene (**2n**).* 2-Iodo-5-methoxyacetophenone (830 mg, 3 mmol), obtained by reaction of equimolar amounts of 3-methoxyacetophenone, I_2, CF_3COOAg, and iodo-2,3-dimethylbenzene (696 mg, 3 mmol) were added to a flask containing active Ni, prepared as described for **1t**. The reaction mixture was kept under N_2 at 40°C for 50 hr with magnetic stirring. Addition of 2 N NH_4OH and extraction with Et_2O gave crude **4c**, which was purified by silica gel column chromatography (hexane–Et_2O 19 : 1). Pure **4c** (300 mg, 1.3 mmol, 43%) gave the following data: ^{1}H NMR δ 7.20 (1H, d, J = 2.3 Hz, H-3), 6.97 (1H, dd, J = 2.3 and 8.3 Hz, H-5), 7.16 (1H, d, J = 8.3 Hz, H-6), 7.02–7.18 (3H, m, H-4′–H-6′), 3.89 (3H, s, OMe), 2.33 (3H, s, H-8), 2.04 (3H, s, Me), 1.92 (3H, s, Me). A pure sample of **4c** (200 mg), dissolved in MeOH (10 ml), was treated with $NaBH_4$ excess at 40°C for 20 min. The reaction mixture was added to 10% HCl and extracted with Et_2O. Preparative TLC (benzene–Et_2O, 47 : 3) gave pure **5c** (180 mg): ^{1}H NMR δ 7.18 (1H, d, J = 2.1 Hz, H-3), 6.97 (1H, dd, J = 2.1 and 8.4 Hz, H-5), 7.14 (1H, d, J = 8.4 Hz, H-6), 7.00–7.23 (3H, m H-4′–H-6′), 4.60 and 4.72 (1H, q, J = 6.2 Hz, H-7), 1.29 (3H, d, J = 6.2 Hz, H-8, 3.89 (3H, s, OMe), 2.01 and 1.96 (3H, s, Me), 2.36 (3H, s, Me).

To a solution of **5c** (180 mg, 0.7 mmol) in dry xylene (1 ml), I_2 (20 mg, 0.08 mol) was added, and the mixture was kept at 140°C for 6 hr. Work-up as for **6b** gave **6c** (143 mg, 0.6 mmol, 67%): ^{1}H NMR δ 6.90 (1H, dd, J = 2.3 and 8.3 Hz, H-5), 6.95–7.20 (5H, m), 6.41 (1H, dd, J = 11.0 and 17.1 Hz, H-7), 5.64 (1H, dd, J = 1.8 and 17.1 Hz, H-8), 5.11 (1H, dd, J = 1.8 and 11.0 Hz, H-8), 3.90 (3H, s, OMe), 2.35 (3H, s, Me), 1.98 (3H, s, Me). Photocyclization of **6c** (73 mg, 0.3 mmol) in an Ar atmosphere for 1 hr gave 2-methoxy-5,6-dimethyl-9,10-dihydrophenanthrene (**1m**) (55 mg, 0.2 mmol, 67%): ^{1}H NMR δ 6.86 (1H, d, J = 2.1 Hz, H-1), 6.84 (1H, dd, J = 2.1 and 8.5 Hz, H-3), 7.55 (1H, d, J = 8.5 Hz, H-4), 7.03 (2H, brs, H-7 and H-8), 2.73 (4H, brs, H-9 and H-10), 3.87 (3H, s, OMe) 2.50 (3H, s, Me), 2.35 (3H, s, Me); ^{13}C NMR δ 111.2 (C-1), 159.0 (C-2), 113.4 (C-3), 130.4 (C-4), 135.1 (C-5), 136.7 (C-6), 128.1 (C-7), 125.0 (C-8), 31.0 (C-9), 31.0 (C-10), 137.8 (C-1a), 128.2 (C-4a), 141.8 (C-5a), 132.8 (C-8a), 55.6 (OMe), 21.4 (Me), 19.4 (Me). BBr_3 demethylation of **1m** (45 mg, 0.17 mmol) gave **1n** (30 mg, 0.12 mmol, 66%): ^{1}H NMR δ 6.78 (1H, d, J = 2.4 Hz, H-1), 6.75 (1H, dd, J = 2.4 and 8.3 Hz, H-3), 7.48 (1H, d, J = 8.3 Hz, H-4), 7.03 (2H, brs, H-7 and H-8), 2.71 (4H, brs, H-9 and H-10), 2.49 (3H, s, Me), 2.35 (3H, s, Me); ^{13}C NMR δ 112.3 (C-1), 154.1 (C-2), 114.4 (C-3), 130.2 (C-4), 135.0 (C-5), 136.3 (C-6), 127.7 (C-7), 124.7 (C-8), 30.4 (C-9), 30.6 (C-10), 136.8 (C-1a), 127.9 (C-4a), 142.3 (C-5a), 132.6 (C-8a), 21.0 (Me), 19.0 (Me).

Photocyclization of **6c** (70 mg, 0.3 mmol) in the presence of atmospheric oxygen gave **2m** (50 mg, 0.18 mmol, 65%): ^{1}H NMR δ 7.28 (1H, d, J = 2.3 Hz, H-1), 7.21 (1H, dd, J = 2.3 and 9.2 Hz, H-3), 8.68 (1H, d, J = 9.2 Hz, H-4), 7.64 (1H, d, J = 8.7 Hz, H-7), 7.65 (1H, d, J = 8.7 Hz, H-8), 7.57 (1H, d, J = 7.9 Hz,

H-9), 7.38 (1H, d, J = 7.9 Hz, H-10), 3.98 (3H, s, OMe), 2.94 (3H, s, Me), 2.57 (3H, s, Me); ^{13}C NMR δ 114.8 (C-1), 157.4 (C-2), 108.8 (C-3), 129.8 (C-4), 135.4 (C-5), 136.4 (C-6), 128.2 (C-7), 125.8 (C-8), 128.0 (C-9), 126.3 (C-10), 132.6 (C-1a), 125.1 (C-4a), 129.7 (C-5a), 131.1 (C-8a), 55.4 (OMe), 22.0 (Me), 21.7 (Me). Demethylation of **2m** (50 mg, 0.18 mmol) by BBr_3 gave **2n** (30 mg, 0.12 mmol, 63%): ^{1}H NMR δ 7.27 (1H, d, J = 2.3 Hz, H-1), 7.15 (1H, dd, J = 2.3 and 9.2, H-3), 8.65 (1H, d, J = 9.2 Hz, H-4), 7.52 (1H, d, J = 8.6 Hz, H-7), 7.63 (1H, d, J = 8.6 Hz, H-8), 7.63 (1H, d, J = 7.9 Hz, H-9), 7.39 (1H, d, J = 7.9 Hz, H-10), 2.92 (3H, s, Me), 2.55 (3H, s, Me); ^{13}C NMR δ 114.4 (C-1), 153.1 (C-2), 111.7 (C-3), 130.0 (C-4), 135.3 (C-5), 136.5 (C-6), 128.3 (C-7), 126.1 (C-8), 127.9 (C-9), 125.2 (C-10), 132.4 (C-1a), 125.4 (C-4a), 129.8 (C-5a), 130.9 (C-8a), 21.8 (Me), 21.6 (Me).

*Synthesis of 2-Hydroxy-5,7-dimethyl-9,10-dihydrophenanthrene (**1p**) and 2-Hydroxy-5,7-dimethylphenanthrene (**2p**).* 2-Iodo-5-methoxyacetophenone (830 mg, 3 mmol) and iodo-2,3-dimethylbenzene (690 mg, 3 mmol) were cross coupled as described for **1n**. The reaction mixture was kept under N_2 at 40°C for 45 hr under magnetic stirring. Work-up gave **4d**, which was purified by column chromatography (hexane–Et_2O 9 : 1). Pure **4d** (350 mg, 1.5 mmol, 50%) gave the following data: ^{1}H NMR δ 7.00–7.11 (4H, m, H-3–H-6, H-5′), 7.19 (1H, d, J = 2.4 Hz, H-3′), 7.16 (1H, dd, J = 2.4 and 8.3 Hz, H-6′), 3.89 (3H, s, OMe), 2.37 (3H, s, H-8), 2.11 (3H, s, Me), 1.94 (3H, s, Me). $NaBH_4$ excess reduction of **4d** (300 mg, 1.3 mmol) gave crude **5d**, purified by preparative TLC (benzene–Et_2O 4 : 1). **5d** (270 mg, 1.1 mmol, 90%) had: ^{1}H NMR δ 7.20 (1H, d, J = 2.7 Hz, H-3), 6.85 (1H, dd, J = 2.7 and 8.4 Hz, H-5), 6.96–7.12 (4H, m, H-6, H-4′–H-6′), 4.61 and 4.75 (1H, q, J = 6.5 Hz, H-7), 1.30 and 1.32 (3H, d, J = 6.5 Hz, H-8), 3.89 (3H, s, OMe), 2.06 and 2.02 (3H, s, Me), 2.38 (3H, s, Me).

To a solution of **5d** (270 mg, 1.1 mmol) in dry xylene (1 ml), I_2 (30 mg, 0.14 mmol) was added and the mixture was kept at 140°C for 5 hr. Work-up as for **6b** gave **6d**, purified by preparative TLC (hexane), (217 mg, 0.9 mmol, 81%): ^{1}H NMR δ 7.19 (1H, d, J = 2.3 Hz, H-3), 6.88 (1H, dd, J = 2.3 and 8.6, H-5), 7.00–7.10 (4H, m, H-6, H-3′–H-6′), 6.42 (1H, dd, J = 11.0 and 17.1 Hz, H-7), 5.65 (1H, dd, J = 1.8 and 17.1 Hz, H-8), 5.10 (1H, dd, J = 1.8 and 11.0 Hz, H-8), 3.89 (3H, s, OMe), 2.38 (3H, s, Me), 2.03 (3H, s, Me).

Photocyclization of **6d** (100 mg, 0.4 mmol) in an Ar atmosphere for 1 hr gave 2-methoxy-5,6-dimethyl-9,10-dihydrophenanthrene (**1o**) (75 mg, 0.3 mmol, 75%): ^{1}H NMR δ 6.87 (1H, d, J = 2.1 Hz, H-1), 6.83 (1H, dd, J = 2.1 and 8.5 Hz, H-3), 7.61 (1H, d, J = 8.5 Hz, H-4), 7.02 (1H, brs, H-6), 6.95 (1H, brs, H-8), 2.74 (4H, brs, H-9 and H-10), 3.87 (3H, s, OMe) 2.59 (3H, s, Me), 2.34 (3H, s, Me); ^{13}C NMR δ 110.8 (C-1), 158.2 (C-2), 113.2 (C-3), 131.2 (C-4), 134.0 (C-5), 129.0 (C-6), 136.0 (C-7), 126.3 (C-8), 30.5 (C-9), 30.7 (C-10), 138.8 (C-1a), 127.9 (C-4a), 141.3 (C-5a), 131.4 (C-8a), 55.2 (OMe), 22.9 (Me), 20.9 (Me). BBr_3 demethylation of **1o** (45 mg, 0.17 mmol) gave **1p** (30 mg, 0.12 mmol,

66%): ^{1}H NMR δ 6.77 (1H, d, J = 2.4 Hz, H-1), 6.74 (1H, dd, J = 2.4 and 8.3 Hz, H-3), 7.52 (1H, d, J = 8.3 Hz, H-4), 6.99 (1H, brs, H-6), 6.93 (1H, brs, H-8), 2.71 (4H, brs, H-9 and H-10), 2.57 (3H, s, Me), 2.33 (3H, s, Me); ^{13}C NMR δ 1124 (C-1), 153.8 (C-2), 114.4 (C-3), 131.1 (C-4), 133.7 (C-5), 129.2 (C-6), 135.6 (C-7), 126.3 (C-8), 30.3 (C-9), 30.6 (C-10), 139.0 (C-1a), 127.9 (C-4a), 141.8 (C-5a), 131.1 (C-8a), 22.9 (Me), 20.9 (Me).

Photocyclization of **6c** (100 mg, 0.4 mmol) in the presence of atmospheric oxygen gave **2o** (73 mg, 0.3 mmol, 75%): ^{1}H NMR δ 7.22–7.38 (3H, m, H-1, H-3 and H-10), 8.89 (1H, d, J = 9.0 Hz, H-4), 7.67 (2H, s, H-6 and H-8), 7.64 (1H, d, J = 8.4 Hz, H-9), 4.00 (3H, s, OMe), 3.13 (3H, s, Me), 2.55 (3H, s, Me); ^{13}C NMR δ 115.5 (C-1), 157.1 (C-2), 109.3 (C-3), 134.6 (C-4), 134.9 (C-5), 128.5 (C-6), 134.6 (C-7), 127.3 (C-8), 128.2 (C-9), 126.8 (C-10), 133.0 (C-1a), 126.2 (C-4a), 128.1 (C-5a), 131.4 (C-8a), 55.4 (OMe), 27.3 (Me), 21.1 (Me). Demethylation of **2o** (36 mg, 0.2 mmol) by BBr_3 gave **2p** (27 mg, 0.14 mmol, 70%): ^{1}H NMR δ 7.26 (1H, d, J = 1.9 Hz, H-1), 7.21 (1H, dd, J = 1.9 and 9.2, H-3), 8.81 (1H, d, J = 9.2 Hz, H-4), 7.68 (2H, s, H-6 and H-8), 7.58 (1H, d, J = 8.4 Hz, H-9), 7.30 (1H, d, J = 8.4 Hz, H-10), 3.01 (3H, s, Me), 2.51 (3H, s, Me); ^{13}C NMR δ 115.2 (C-1), 152.9 (C-2), 112.1 (C-3), 132.9 (C-4), 134.9 (C-5), 128.6 (C-6), 134.5 (C-7), 127.2 (C-8), 128.1 (C-9), 126.0 (C-10), 133.1 (C-1a), 126.2 (C-4a), 127.5 (C-5a), 130.2 (C-8a), 27.2 (Me), 20.9 (Me).

*Synthesis of 2-Hydroxy-5,8-dimethyl-9,10-dihydrophenanthrene (**1r**) and 2-Hydroxy-5,8-dimethyl-phenanthrene (**2r**).* Equimolar amounts of methyl 3-iodo-4-methylbenzoate (830 mg, 3 mmol), obtained from 3-iodo-4-methylbenzoic acid by CH_2N_2 treatment in MeOH, and **3** (830 mg, 3 mmol) were added to the flask containing the active Ni complex. After 35 hr at 40°C in N_2 atmosphere, the reaction mixture was worked up as previously described and chromatography on a silica gel column (hexane–Et_2O, 7 : 3) gave diastereoisomeric biphenyls **5e** (245 mg, 1 mmol 34%): ^{1}H NMR δ 7.31 (1H, d, J = 2.3 Hz, H-3), 6.91 (1H, dd, J = 2.3 and 8.4 Hz, H-5), 7.08 (1H, d, J = 8.4 Hz, H-6), 7.31 (1H, d, J = 8.4 Hz, H-3′), 7.92 (1H, dd, J = 2.1 and 8.4 Hz, H-4′), 7.85 (1H, d, J = 2.1 Hz, H-6′), 4.51 and 4.69 (1H, q, J = 6.5 Hz, H-7), 1.26 and 1.28 (3H, d, J = 6.5 Hz, H-8), 3.87 (6H, s, OMe), 2.10 and 2.14 (3H, s, Me). Dehydration of **5e** (245 mg, 1 mmol) as reported gave **6e**, purified by silica gel column chromatography (hexane–Et_2O, 4 : 1) (205 mg, 0.8 mmol, 80%): ^{1}H NMR δ 7.20 (1H, d, J = 2.3 Hz, H-3), 6.89 (1H, dd, J = 2.3 and 8.4 Hz, H-5), 7.07 (1H, d, J = 8.4 Hz, H-6), 7.31 (1H, d, J = 8.4 Hz, H-3′), 7.99 (1H, dd, J = 2.1 and 8.4 Hz, H-4′), 7.81 (1H, d, J = 2.1 Hz, H-6′), 6.32 (1H, dd, J = 11.0 and 17.1 Hz, H-7), 5.68 (1H, dd, J = 1.8 and 17.1 Hz, H-8), 5.13 (1H, dd, J = 1.8 and 11.0 Hz, H-8), 3.89 (6H, s, OMe), 2.11 (3H, s, Me).

A pure sample of **6e** (200 mg, 0.8 mmol) in dry benzene (6.5 ml) in a Pyrex flask was irradiated under air atmosphere with a 450-W Hanovia lamp at room temperature for 5 hr with magnetic stirring to give **2y** (150 mg, 0.6 mmol,

75%): ^{1}H NMR δ 7.20–7.34 (2H, m, H-1 and H-3), 8.67 (1H, d, J = 8.7, H-4), 7.51 (1H, d, J = 8.5 Hz, H-6), 7.99 (1H, d, J = 8.5 Hz, H-7), 8.78 (1H, d, J = 8.0 Hz, H-9), 7.77 (1H, d, J = 8.0 Hz, H-10), 4.00 (6H, s, OMe), 3.16 (3H, s, Me). A sample of **2y** (115 mg, 0.6 mmol) dissolved in dry toluene (3 ml) was treated with Red-Al solution (3 mmol) for 2 hr. NaOH (2 N) was added and the crude product was extracted with Et_2O and chromatographed on silica gel (hexane–Et_2O 9 : 1) to give **2q** (90 mg, 0.45 mmol, 75%): ^{1}H NMR δ 7.22–7.38 (3H, m, H-1, H-3 and H-7), 8.87 (1H, d, J = 9.0 Hz, H-4), 7.40 (1H, d, J = 8.8 Hz, H-6), 8.00 (1H, d, J = 7.6 Hz, H-9), 7.58 (1H, d, J = 7.6 Hz, H-10), 4.00 (3H, s, OMe), 3.11 (3H, s, Me), 2.75 (3H, s, Me); ^{13}C NMR δ 115.3 (C-1), 157.2 (C-2), 108.7 (C-3), 130.7 (C-4), 134.8 (C-5), 129.2 (C-6), 127.2 (C-7), 134.3 (C-8), 124.0 (C-9), 126.4 (C-10), 132.7 (C-1a), 125.8 (C-4a), 128.5 (C-5a), 132.9 (C-8a), 55.3 (OMe), 274 (Me), 20.3 (Me). Demethylation of **2q** (40 mg, 0.2 mmol) by BBr_3 gave **2r** (35 mg, 0.18 mmol, 90%): ^{1}H NMR δ 7.28 (1H, d, J = 1.9 Hz, H-1), 7.18 (1H, dd, J = 1.9 and 9.2, H-3), 8.81 (1H, d, J = 9.2 Hz, H-4), 7.65 (1H, d, J = 8.5 Hz, H-6), 7.30 (1H, d, J = 8.5 Hz, H-7), 7.95 (1H, d, J = 7.7 Hz, H-9), 7.35 (1H, d, J = 7.7 Hz, H-10), 3.09 (3H, s, Me), 2.73 (3H, s, Me); ^{13}C NMR δ 115.1 (C-1), 153.1 (C-2), 111.7 (C-3), 130.8 (C-4), 134.8 (C-5), 129.6 (C-6), 126.5 (C-7), 134.8 (C-8), 124.3 (C-9), 126.0 (C-10), 132.5 (C-1a), 126.2 (C-4a), 128.1 (C-5a), 132.9 (C-8a), 27.4 (Me), 20.3 (Me).

A sample of **2q** (40 mg, 0.2 mmol) was photoreduced as reported for **2s** to give **1q** (30 mg, 0.15 mmol, 75%): ^{1}H NMR δ 6.85 (1H, d, J = 2.1 Hz, H-1), 6.83 (1H, dd, J = 2.1 and 8.5 Hz, H-3), 7.58 (1H, d, J = 8.5 Hz, H-4), 7.11 (1H, d, J = 8.1 Hz, H-6), 7.01 (1H, d, J = 8.1 Hz, H-7), 2.72 (4H, brs, H-9 and H-10), 3.87 (3H, s, OMe) 2.58 (3H, s, Me), 2.33 (3H, s, Me); ^{13}C NMR δ 110.7 (C-1), 158.1 (C-2), 112.7 (C-3), 129.5 (C-4), 134.3 (C-5), 129.5 (C-6), 127.9 (C-7), 131.3 (C-8), 26.0 (C-9), 30.0 (C-10), 137.4 (C-1a), 127.9 (C-4a), 141.4 (C-5a), 132.1 (C-8a), 55.2 (OMe), 22.9 (Me), 19.9 (Me). BBr_3 demethylation of **1q** (20 mg, 0.1 mmol) gave **1r** (15 mg, 0.09 mmol, 90%): ^{1}H NMR δ 6.76 (1H, d, J = 2.4 Hz, H-1), 6.74 (1H, dd, J = 2.4 and 8.3 Hz, H-3), 7.51 (1H, d, J = 8.3 Hz, H-4), 7.10 (1H, d, J = 8.1 Hz, H-6), 7.00 (1H, d, J = 8.1 Hz, H-7), 2.71 (4H, brs, H-9 and H-10), 2.57 (3H, s, Me), 2.34 (3H, s, Me); ^{13}C NMR δ 112.3 (C-1), 153.7 (C-2), 114.2 (C-3), 129.4 (C-4), 134.1 (C-5), 129.3 (C-6), 128.2 (C-7), 131.6 (C-8), 26.2 (C-9), 30.2 (C-10), 137.6 (C-1a), 127.9 (C-4a), 141.8 (C-5a), 132.2 (C-8a), 22.8 (Me), 20.1 (Me).

Bioassay. The strain UTEX 1648 *Selenastrum capricornutum* was maintained on Bold basal medium (BBM) solidified with agar 1.5% in continuous light at 23°C. Fresh axenic cultures for the experiments were grown in 100-ml cylinders on the same culture medium. For growth tests, the compounds were dissolved in acetone. Each soluion (20 μl) was added to test tubes containing 6 ml of inoculated medium, giving final concentrations of 10^{-4}, 5×10^{-5}, and 10^{-5} M. Controls containing only acetone also were tested. The test tubes were

incubated at 23°C on a shaking apparatus previously described (Aliotta et al., 1991). Total irradiation of 150 μE/sec/m^2 was provided by daylight fluorescent lamps (Philips TLD 30 w/55) from below the apparatus. The photoperiod was 16 hr light and 8 hr dark. Growth of cultures was followed daily, either by measuring the absorbance increase at 550 nm with a Bausch & Lomb Spectronic 20 colorimeter or by counting the cell numbers with a Thoma blood-counting chamber. The cell numbers of the initial inocula ranged from 10^6 to 1.5×10^6/ml, corresponding to 0.05–0.06 units of absorbance. Growth experiments were carried out in triplicate. To test statistical significance of results, one-way ANOVA was performed with $P = 0.05$. For each compound, a comparison among means was performed by Student-Newman-Keuls test (SNK), with $P = 0.05$. The statistical package SPSS was used.

The index of inhibition for compounds was calculated as $[1 - (X_a/Y_a)] \times 100$ (Blankley, 1973), where X_a is the growth rate of the alga in the presence of the compound tested and Y_a is the growth rate of the control.

RESULTS AND DISCUSSION

The basic formulas and substitutions of groups for the compounds synthesized are shown in Figure 1. 1-(2-Iodo-5-methoxy)-phenylethanol (**3**), synthesized as reported in the previous paper (DellaGreca et al., 1999), was used as a starting block in the synthesis of 6,7-, 6,8-, and 7,8-dimethyl compounds. In all the reactions, equimolar amounts of **3** and iodoxylene were added at once to the reaction mixture containing the active nickel complex generated in situ by action of dust zinc on $NiCl_2(PPh_3)_2$ (Tiecco et al., 1984). Coupling of **3** with iodo-3,4-dimetilbenzene gave biphenyl **5b**, which was converted into **6b** by dehydration with I_2 in dry xylene at 140°C. All attempts to obtain 2-methoxy-6,7-dimethyl-9,10-dihydrophenanthrene (**1s**) and 2-methoxy-7,8-dimethyl-9,10-dihydrophenanthrene (**1w**) by UV irradiation of **6b** in an Ar atmosphere (Padwa et al., 1977) failed, while photocyclization of **6b** by UV irradiation in an air atmosphere easily gave a mixture of 2-methoxy-6,7-dimethylphenanthrene (**2s**) and 2-methoxy-7,8-dimethylphenanthrene (**2w**), which were separated by HPLC-NH_2. Demethylation by BBr_3 in CH_2Cl_2 for 3 hr at −70°C converted **2s** and **2w** into 2-hydroxy-6,7-dimethylphenanthrene (**2t**) and 2-hydroxy-7,8-dimethylphenanthrene (**2x**).

2-Methoxy-6,7-dimethyl-9,10-dihydrophenanthrene (**1s**) and 2-methoxy-7,8-dimethyl-9,10-dihydrophenanthrene (**1w**) were obtained from **2s** and **2w** by photoreduction with $NaBH_4$ in EtOH and Et_3N and UV irradiation (Nien-chu et al., 1984). Subsequent demethylation as above reported gave 2-hydroxy-6,7-dimethyl-9,10-dihydrophenanthrene (**1t**) and 2-hydroxy-7,8-dimethyl-9,10-dihydrophenanthrene (**1x**).

FIG. 1. The basic structural skeletons of compounds synthesized, and the various groups that were substituted at the positions marked by R_1, R_2, R_3, and R_4.

Coupling of **3** with iodo-3,5-dimethylbenzene gave **5a**, which, through the styrene derivative **5b** was converted by UV irradiation into 2-methoxy-6,8-dimethyl-9,10-dihydrophenanthrene (**1u**) in an argon atmosphere and into 2-methoxy-6,8-dimethylphenanthrene (**2u**) in the presence of atmospheric oxygen. Demethylation of **1u** and **2u** afforded 2-hydroxy-6,8-dimethyl-9,10-dihydrophenanthrene (**1v**) and 2-hydroxy-6,8-dimethylphenanthrene (**2v**).

The synthesis of dimethyl compounds with a methyl at C-5 by cross-coupling of **3** with the right iodoxylene failed as the steric hindrance of

the methyl caused long reaction times, and in such conditions the primary process was replacement of iodine by alcoholic hydrogen. The same problem was overcome in the synthesis of 2-hydroxy-5-methyl-9,10-dihydrophenanthrene (**1d**) and 2-hydroxy-5-methylphenanthrene (**2d**) by cross-coupling ortho iodotoluene with 2-iodo-5-methoxyacetophenone. In the same way, the synthesis of 2-hydroxy-5,6-dimethyl-9,10-dihydrophenanthrene (**1n**), 2-hydroxy-5,7-dimethyl-9,10-dihydrophenanthrene (**1p**), 2-hydroxy-5,6-dimethylphenanthrene (**2n**), and 2-hydroxy-5,7-dimethylphenanthrene (**2p**) was performed. Couplings of 2-iodo-5-methoxyacetophenone with iodo-2,3-dimethylbenzene and iodo-2,4-dimethylbenzene gave ketones **4c** and **4d**, respectively. $NaBH_4$ reduction afforded carbinols **5c** and **5d**. These compounds, obtained as diastereoisomeric mixtures because free rotation of the rings about each other is hindered for the presence of the methyl at C-2′, were dehydrated directly to **6c** and **6d**. Photocyclization of **6c** in the absence and in the presence of atmospheric oxygen gave 2-methoxy-5,6-dimethyl-9,10-dihydrophenanthrene (**1m**) and 2-methoxy-5,6-dimethylphenanthrene (**2m**), respectively, which were converted into **1n** and **2n** by BBr_3 demethylation. Irradiation in both the conditions of **6d** gave 2-methoxy-5,7-dimethyl-9,10-dihydrophenanthrene (**1o**) and 2-methoxy-5,7-dimethylphenanthrene (**2o**), which were demethylated to **1p** and **2p**. All attempts to synthesize 2-hydroxy-5,8-dimethyl-9,10-dihydrophenanthrene (**1r**) and 2-hydroxy-5,8-dimethylphenanthrene (**2r**) this way failed because of very long reaction times in which no coupling between 2-iodo-5-methoxyacetophenone and iodo-2,5-dimethylbenzene was obtained.

Semmelhack (1981) observed an efficient coupling of aryl halides bearing aldehyde, ketone, ester, and nitrile groups. On this basis, **3** was cross-coupled with methyl 3-iodo-4-methylbenzoate to give the corresponding diastereoisomeric biaryls **5e** that were dehydrated to **6e**. Photocyclization of **6e** in both the reported conditions gave 9,10-dihydrophenanthrene (**1y**) and phenanthrene (**2y**), which were converted into 2-methoxy-5,8-dimethyl-9,10-dihydrophenanthrene (**1q**) and 2-methoxy-5,8-dimethylphenanthrene (**2q**) by sodium bis(2-methoxyethoxy)aluminum hydride. Final demethylation of **1q** and **2q** gave **1r** and **2r**.

The 9,10-dihydrophenanthrenes and phenanthrenes purified by HPLC were assayed on *Selenastrum capricornutum* at concentrations of 10^{-5}–10^{-4} M. The compounds were stable in the assay conditions and the results had statistical significance (Tables 1 and 2). All dimethyl-9,10-dihydrophenanthrenes cause full inhibition of algal growth at 10^{-4} M concentration and no differences were observed between the hydroxy and the methoxy derivatives. High activity is maintained at 5×10^{-5} M, while at 10^{-5} M only 2-methoxy-5,6-dimethyl-9,10-dihydrophenanthrene (**1m**), 2-methoxy-5,7-dimethyl-9,10-dihydrophenanthrene (**1o**), 2-methoxy-6,8-dimethyl-9,10-dihydrophenanthrene (**1u**), and 2-methoxy-7,8-dimethyl-9,10-dihydrophenan-threne (**1w**) are still active. These compounds

have a methyl at C-5 or at C-8, and when the other methyl is at C-7, 100% activity is observed. Except for 2-methoxy-5,7-dimethylphenanthrene (**2o**), all the dimethylphenanthrenes have high activity at 10^{-4} and 5×10^{-5} M concentrations with no differences among hydroxy and methoxy derivatives. At the lowest concentration, only 2-hydroxy-5,6-dimethylphenanthrene (**2n**), 2-hydroxy-5,7-dimethylphenanthrene (**2p**), 2-hydroxy-6,7-dimethylphenanthrene (**2t**), 2-hydroxy-6,8-dimethylphenanthrene (**2v**), and 2-hydroxy-7,8-dimethyl-phenanthrene (**2x**) are active, and **2n**, **2t**, and **2x** still cause full inhibition.

In conclusion, all the synthetic phenanthrenes and 9,10-dihydrophenanthrenes cause inhibition of algal growth in the examined concentration range. A comparison among monomethyl and dimethyl compounds shows that at the highest concentration the monomethyl derivatives are less active than the dimethyl derivatives, while at the lowest concentration the activity goes in the opposite direction.

(Received April 26, 2000; accepted October 4, 2000)

Abstract—Feeding by the aphid *Sipha flava* produces a reddish spot on mature leaves of *Sorghum halepense*. The present work is aimed at determining whether this plant response entails induced resistance against the aphid. Old and young leaves showed the same response to aphid feeding (reddish coloration). Water-stressed plants displayed a similar reddish coloration to aphid-infested plants. This was verified by evaluation of absorbance peaks of the respective leaf extracts. Aphid fecundity was reduced on previously infested (and hence reddish colored) leaves. However, aphid fecundity was not affected on water stressed plants. Furthermore, aphid survival was not different on artificial diets containing increasing concentrations of the reddish pigment. It is concluded that the reddish spot is correlated with, but is not itself responsible for, the observed induced resistance of *S. halepense* against *S. flava*.

Key Words—Induced responses, induced resistance, *Sipha flava*, *Sorghum halepense*, aphids, anthocyanins.

INTRODUCTION

Induced responses of plants to herbivory are frequently found in plant–insect interactions (Karban and Baldwin, 1997). When such responses have a negative effect on insect fitness, they are termed induced resistance (Karban and Baldwin, 1997). The magnitude of induced responses, and consequently of their effect on herbivores, may be affected by environmental conditions (Gianoli and Niemeyer,

* To whom correspondence should be addressed. e-mail: aletheia@abulafia.ciencias.uchile.cl

0098-0331/01/0200-0273$19.50/0

1996; Karban, 1987) as well as by the particular plant tissue that is attacked (Gianoli and Niemeyer, 1998; Gianoli, 1999).

Sipha flava (Forbes) is a cereal aphid that uses different cultivated and wild Poaceae (Young and Teetes, 1977; Breen and Teetes, 1986a; Blackman and Eastop, 1984). It has been recently reported in Chile, colonizing *Sorghum halepense* L. (Gonzáles et al., 1998), a common weed in cereal fields (Monaghan, 1979; McWhorther, 1989; Matthei, 1995). *S. flava* has a particular pattern of attack on host plants. Aphids initially colonize lower (older) leaves (Long and Hensley, 1972; Holman, 1974), producing a characteristic damage: a reddish spot appears on infested leaves (Breen and Teetes, 1986a, 1990; Webster, 1990). The spot spreads and eventually covers the entire leaf, accelerating its senescence (Breen and Teetes, 1986a; Webster, 1990). Aphids then move upward to colonize the next leaf. *S. flava* infestation may significantly decrease plant fitness. Thus, infested sorghum (*Sorghum bicolor* L.) plants show a reduction in biomass (Breen and Teetes, 1986b) and seed production (Breen and Teetes, 1986a). Likewise, aphid infestation reduces biomass of *S. halepense* plants (Gonzáles et al., unpublished).

The appearance of reddish coloration on tissues of sorghum plants, presumably involving anthocyanins, has also been related to the attack of the aphid *Schizaphis graminum* (Young and Teetes, 1977), to fungal infection (Nicholson et al., 1987), as well as to irradiation and low temperature (Shichijo et al., 1993, 1996). Moreover, the induction of anthocyanins by water stress is considered a widespread phenomenon in plants (Chalker-Scott, 1999).

The major aim of the present work is to determine whether the reddish coloration on leaves of *S. halepense* induced by feeding of *S. flava* is involved with the induced resistance. For this purpose, the fecundity of *S. flava* on previously infested (and hence reddish colored) and on uninfested leaves is compared. Given the particular pattern of occupation of plants of this aphid, these comparisons are performed on the natural site of attack, i.e., an old leaf, and on a young leaf. In addition, bioassays are conducted on artificial diets with different concentrations of plant extracts containing the reddish pigment. Complementary experiments evaluate aphid fecundity on plants where reddish coloration is induced by water stress. The qualitative similarity of the reddish coloration in water-stressed plants and in aphid-infested plants is assessed by their absorbance spectrum. Finally, some spatial and temporal characteristics of the induced response of *S. halepense* to *S. flava* infestation are addressed, and the effect on them of temperature and leaf age is evaluated.

METHODS AND MATERIALS

Organisms. Cultures of *S. flava* originally collected on *S. halepense* in the area of wheat fields in Santiago, Chile, were maintained on barley seedlings.

Seeds of *S. halepense* were collected in the same area. Aphids and *S. halepense* seedlings were kept in rooms at 20 ± 2°C and a 14L : 10D photoperiod. Aphids reproduce parthenogenetically under these conditions.

Leaf Age and Effect of Induced Response on Aphid Fecundity. Seedlings at the eight-leaf stage were infested with 15 adult aphids confined inside a clip cage attached to the leaf that bore the treatment. Two groups of infested plants were used: one received the aphid infestation on the third leaf (an old leaf); the other on the seventh leaf (a young leaf). Two groups of uninfested plants were used as controls, bearing empty clip cages on the respective leaves ($N = 15$ plants per treatment). Plants were then placed in growth chambers at constant temperature (20°C) and a 12L : 12D photoperiod. Aphids were removed after 24 hr of infestation, and plants were left for 92 hr, a time period after which a reddish spot appears on the infested leaves (data not shown). Immediately afterwards, aphid fecundity was evaluated in the four treatments (infested/uninfested; young/old leaf). An 8-day-old nymph was placed on the same leaves and on the same leaf part where clip cages were previously attached. Aphids were confined inside clip cages for eight days. At the end of this period, the number of nymphs produced was recorded. Data on aphid fecundity were analyzed by using a two-way ANOVA, with leaf age (young/old) and treatment (infested/uninfested) as main factors.

Bioassay and Extraction of Reddish Pigment. Aphid survival on artificial diets containing increasing concentrations of the reddish pigment, previously extracted from leaves of *S. halepense*, was evaluated. Ten aphids were confined in a vertically placed Plexiglas cylinder (3.0 cm high × 2.5 cm ID). A plastic net covered one end of the cylinder, and the other end was closed with a sachet made of two Parafilm M membranes. The sachet contained 200 μl of a sucrose solution (25% w/v, prepared in phosphate buffer pH 5.5) and the extract to be tested at concentrations of 0 (control) 0.4, 4, 10, 20, and 40 mg of reddish extract/ml of solution. The cylinders containing the aphids were kept at 20°C and in the dark for 48 hr. At the end of this period the number of aphids still alive was recorded. Five replicates were performed for each concentration of the extract tested.

The extract of the reddish pigment was obtained as follows. One hundred grams of leaves, which had been infested by aphids and showed the reddish coloration, were extracted for 24 hr at 4°C with 500 ml of HCl–MeOH (0.1% v/v) solution. The solution was vacuum concentrated to 100 ml, adjusted to pH 5 with $NaCO_3$, and maintained at −20°C for 5 hr. One milliliter of Me_2CO was then added and the suspension centrifuged for 20 min (−20°C, 20,000 rpm); the precipitate was discarded. Vacuum concentration was continued until the final reddish solid extract was obtained.

Aphid Fecundity on Plants Under Water Stress. Greenhouse observations indicated that plants under water stress develop a similar response to that

observed after aphid infestation, i.e., the appearance of a reddish spot. This led us to evaluate whether such a response could affect aphid fecundity, as previous aphid infestation did. Plants at the four-leaf stage were used in the experiment. A group of plants was deprived of watering for five days, whereas control plants were watered daily during that period ($N = 15$ per treatment, 20°C). At the end of the five-day period, aphid fecundity was measured exactly as in the first experiment (see above).

Comparison of Spectra of Reddish Spots of Plants Subjected to Aphid Infestation or Water Stress. To compare spectra, a 3-cm section was excised from a pigmented zone of a leaf (one per treatment). The leaf sections were extracted for 24 hr at 4°C in 5 ml of HCl–MeOH solution, as was described above (see procedure of extraction of the pigment). A Shimadzu UV–visible spectrophotometer (model UV-240) was used. The spectrum was evaluated at wavelengths of 400–700 nm.

Characterization of Induced Response. Experiments were conducted to determine the minimum duration of aphid infestation required to produce the induced response, the time until the appearance of the reddish spot, and its spatial extension. These evaluations were performed at 20°C and 28°C. *S. halepense* plants at the four-leaf stage were infested with 15 adults of *S. flava* inside a clip cage attached to the third leaf in the following treatments: 8, 10, 12, and 16 hr. At the end of the respective periods aphids were removed. Observations on the infested leaf were performed every 2 hr, and a positive response was considered when evidence of a reddish spot was apparent ($N = 10$ per treatment). In addition to this qualitative evaluation, the timing of the induced response, i.e., the time elapsed from the removal of aphids to the appearance of the spot, was recorded. The area of the reddish spot on leaves of plants of the same age, but infested during 24 hr, was assessed measuring its length (L) and width (W) and assuming a rectangular shape (Area = L × W). The percentage of leaf area covered by the spot was calculated after assessing the area of the whole leaf ($N = 10$). This was done by using image analysis software (Sigmascan). Evaluations with plants at the eight-leaf stage also were performed to determine the effect of leaf age on the timing of the induced response. The same protocol of aphid infestation (for 24 hr) was followed on the third leaf (an old leaf) and on the seventh leaf (a young leaf) ($N = 10$ for each treatment). Timing of the induced response was evaluated as described above.

RESULTS

Leaf Age and Induced Responses. The fecundity of *S. flava* was significantly reduced by previous aphid infestation on the leaf. Neither leaf age nor the interaction of factors had a significant effect on *S. flava* fecundity (Table 1).

TABLE 1. EFFECT OF LEAF AGE AND PREVIOUS INFESTATION OF *S. halepense* ON *S. flava* FECUNDITY

	Nymphs produced (*N*, mean ± SE)	
Leaf age	Control	Infested
Young	24.00 ± 2.20	20.36 ± 1.46
Old	21.55 ± 1.15	18.38 ± 1.44

	Analysis of variance			
Source	*df*	Mean square	*F* ratio	*P*
Leaf age (L)	1	61.98	1.80	NS[a]
Pre infestation (I)	1	146.40	4.25	<0.05
L × I	1	0.73	0.02	NS[a]
Error	47	34.40		

[a] NS = not significant ($P > 0.05$, two-way ANOVA test).

Bioassay of Reddish Pigment. The survival of *S. flava* was not significantly different on diets with increasing concentrations of the extract containing the reddish pigment ($F = 0.63$, $P > 0.05$, one-way ANOVA) (Table 2).

Aphid Fecundity on Water-Stressed Plants. The fecundity of *S. flava* (number of nymphs, mean ±SE) on *S. halepense* was not significantly different on plants under water stress (15.33 ± 1.3) and on control plants (18.45 ± 1.73; $t = 1.38$, $P > 0.1$).

Comparison of Spectra of Reddish Spots. The spectra of the reddish spot of plants under water stress and plants infested with *S. flava* showed a remarkable similarity in qualitative terms (Figure 1).

Characterization of Induced Response. The minimum duration of aphid

TABLE 2. SURVIVAL OF *S. flava* FEEDING ON ARTIFICIAL DIETS WITH DIFFERENT CONCENTRATIONS OF AN EXTRACT CONTAINING REDDISH PIGMENT

Extract conc. (mg/ml)	Survival (%, mean ± SE)[a]
0.0	78 ± 9.69
0.4	92 ± 5.83
4.0	88 ± 5.83
10.0	86 ± 4.00
20.0	90 ± 3.16
40.0	88 ± 5.83

[a] Means are not significantly different ($P > 0.05$, one-way ANOVA).

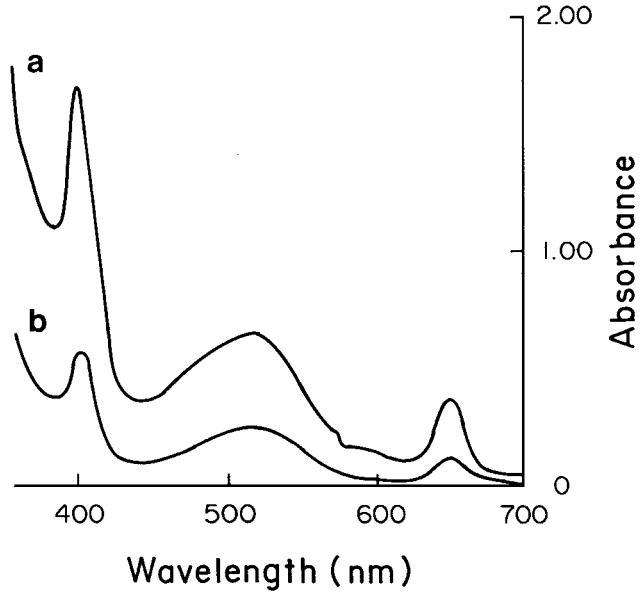

FIG. 1. Visible spectra of *S. halepense* leaf extracts showing reddish coloration caused by (a) infestation by *S. flava*, and (b) water stress.

infestation able to induce the reddish spot at 20°C was 16 hr, whereas at 28°C this time was reduced to 10 hr. After 16 hr of aphid infestation, the time (hours, mean ± SE) to the production of the reddish spot was similar ($t = 1.12$, $P > 0.1$) at 20°C (96.3 ± 1.02) and at 28°C (93.8 ± 1.05). The reddish spot was localized at 28°C, whereas it was spatially spread at 20°C ($t = 26.79$, $P < 0.001$) (Table 3). The reddish spot appeared on old leaves 92.4 ± 1.03 hr after the end of aphid infestation, whereas this time was significantly shorter on young leaves (72.15 ± 1.96 hr; $t = -8.43$, $P < 0.001$).

TABLE 3. CHARACTERISTICS OF THE RESPONSE (REDDISH SPOT) PRODUCED BY *S. halepense* AFTER *S. flava* FEEDING AT DIFFERENT TEMPERATURES

	20°C	28°C
Minimum time of infestation (hr)	16	10
Time to response (hr)	96.3 ± 0.02	100.3 ± 0.47
Leaf area covered by the spot (%)	37.61 ± 1.37	<1.0

DISCUSSION

Results showed a reduction in the fecundity of *S. flava* feeding on a previously infested leaf, which exhibited the reddish spot as induced response. The reddish spot, or another induced response correlated with it, could be the cause of the decrease in fecundity of the aphids. Negative effects on aphid fitness after infestation have been reported earlier (Cabrera et al., 1995; Gianoli, 1999; but see Formusoh et al., 1992). It has been shown that aphid infestation on other species of Poaceae may affect the nitrogen content of leaves (Dorschner et al., 1987) and change the concentration of secondary metabolites (Leszczynski, 1985; Gianoli and Niemeyer, 1997). The mechanism underlying the aphid-induced reddish spot in *S. halepense* is not clear at this point. Studies addressing the reddish spots on wheat plants caused by the aphid *S. graminum* have ascribed the leaf discoloration to an abnormal increase in volume of plastoglobuli, which in turn has a deleterious effect on chloroplasts producing chlorophyll loss (Ryan et al., 1990). Recent work involving sorghum and a nonpathogenic fungus suggests that anthocyanin accumulation is a consequence of the deactivation of related phytoalexins (3-deoxyanthocyanidins), which are induced immediately after fungal attack (Lo and Nicholson, 1998). It is considered that the induction of phytoalexins by microbial infections and by aphid feeding is very similar in nature, the common elicitors being oligosaccharides produced by plant cell wall degrading enzymes (Campbell and Dreyer, 1990).

Regardless of the particular mechanism involved in its production, the reddish spot in *S. halepense* is associated with induced resistance against *S. flava*. Thus, the plant response decreases aphid reproduction. The biological activity of anthocyanins against insects (Hedin et al., 1983), fungi (Schutt and Netzly, 1991), and bacteria (Stonecipher et al., 1993) has been demonstrated. In the present work, the negative effect on aphid fitness is achieved, but the infested leaf loses its photosynthetic capacity. This resembles hypersensitive responses found in other plant–insect systems (Fernándes, 1990), particularly those in which the insects have poor mobility, as is the case of *S. flava*.

Leaf age did not affect fitness of *S. flava*. This result is surprising given the usual difference in quality of leaves of different age for aphids (Merritt, 1996; Dixon, 1998) and the marked preference of *S. flava* for older leaves in the field (Long and Hensley, 1972; Gonzáles et al., unpublished). This suggests that ecological factors other than plant tissue quality may explain the within-plant distribution of the aphid (e.g., natural enemies) (Gonzáles et al., 2001). The interaction of aphid infestation and leaf age did not have a significant effect on aphid fecundity, which means that the occurrence of induced resistance was not related to leaf age. Two nonmutually exclusive explanations, from both sides of the insect–plant interaction, may be advanced. Thus, it may be thought that aphid feeding, and hence elicitation, is similar on usual (old leaves) and unusual (young

leaves) feeding substrates. Interestingly, differences in feeding behavior have been reported for aphids developing on young and mature leaves of the same host plant (Gabrys et al., 1997). From the side of the plant, the physiological events that take place following aphid feeding may not be different in young and old leaves. Similar results have been observed in aphid-infested wheat seedlings (Gianoli and Niemeyer, 1997).

The induction of anthocyanins by water stress is a common phenomenon (Chalker-Scott, 1999). In the present work, water stressed plants developed a response similar to that induced by aphid infestation, i.e., the appearance of a reddish spot on the leaves, which is likely to correspond to anthocyanin accumulation (Snyder and Nicholson, 1990; Shichijo et al., 1993, 1996; Chalker-Scott, 1999). Moreover, the reddish spot was shown to be qualitatively the same in terms of absorbance peaks for plants subjected to either treatment. Unlike aphid infestation, water stress did not produce a decrease in plant quality for aphids, suggesting that the induced resistance observed in *S. halepense* is specifically triggered by aphid attack. Thus, the reddish spot would be a symptom associated with induced resistance, but not a symptom of induced resistance itself. This is supported by the bioassay results that showed no deleterious effects of the reddish pigment on aphids. Interestingly, previous reports describe an increase in plant resistance conferred by anthocyanin induction (Snyder and Nicholson, 1990; Schutt and Netzly, 1991; Stonecipher et al., 1993). Caution is needed before ascribing a particular role to anthocyanin induction in insect–plant interactions.

Environmental variables affect the expression of both constitutive (Larsson et al., 1986) and induced (Coleman and Jones, 1991) levels of plant resistance. We evaluated some spatial and temporal aspects of the aphid-induced reddish spot under two different temperatures (20°C and 28°C). These evaluations are of interest because the main distribution of *S. flava* is in the tropics (Medina-Gaud et al., 1965; Smith and Cermeli, 1979), and hence the temperate climate of Chile could mediate or constrain some issues of the aphid–plant relationship. At 28°C, a shorter infestation time was needed to produce the reddish spots; they took slightly more time to appear, and were considerably smaller than at 20°C. The spots were notably more spread at 20°C, suggesting that the induced response may be constrained at higher temperatures. A similar pattern was found for aphid-infested wheat seedlings (Gianoli and Niemeyer, 1996). Provided that the spatial extension of the spot is correlated with the magnitude of its associated induced response (see above), these results suggest that *S. flava* would be favored at higher temperatures. This agrees with earlier findings of better performance of this aphid at 30°C than at lower temperatures (Starks and Mirkes, 1979).

Finally, young leaves reacted more readily than old leaves in terms of the appearance of the reddish spot. This result does not match the initial observation that the reduction in aphid fecundity did not vary with leaf age. Therefore, it

provides additional support to the main conclusion of this paper, i.e., that the reddish spot is correlated with, but is not itself, the induced response responsible for the observed induced resistance of *S. halepense* against *S. flava*.

Several lines of research are open after the preliminary findings of the present work. In terms of the plant, identifying the compound(s) responsible for the induced resistance and elucidating how the physiological mechanism of aphid resistance compares with that described for fungal infections need to be examined further. In terms of the insect, determining the factors that promote or constrain the pattern of distribution within the plant and relating this to the quality and responsiveness of the tissues should be studied. Other ecological factors, such as natural enemies (e.g., Gonzáles et al., 2001) and interspecific aphid competition (e.g., Gianoli, 2000) should not be overlooked given the fact that *S. flava* usually coexists with other aphid species (*Rhopalosiphum maidis*, *Schizaphis graminum*) on its host plants.

(Received July 5, 2000; accepted October 12, 2000)

Abstract—Termite mound soils eaten by chimpanzees of the Mahale Mountains and Gombe National Parks, Tanzania, have mineralogical and geochemical compositions similar to many soils eaten by higher primates, but release very low levels of either toxic or nutritional inorganic elements to solution at acid pH. Comparison with control (uneaten) soils from the same areas showed lower levels of carbon and nitrogen in the eaten soils,

a relationship confirmed by surface analysis. Surface analysis also revealed lower levels of iron on particle surfaces versus interiors, and higher levels of iron on ingested versus control soil particle surfaces. The soils can adsorb dietary toxins, present in the plant diet or those produced by microorganisms. Taking the toxic alkaloids quinine, atropine, sparteine, and lupanine as examples, it is evident that soils from Mahale have a very good adsorptive capacity. A new adaptive advantage of geophagy is proposed, based on the prevention of iron uptake. The behavior of the soils in vitro is consistent with the theory that geophagy has a therapeutic value for these chimpanzees.

Key Words—Adsorption, geophagy, health maintenance, iron, surface chemistry, termite mounds, XPS.

INTRODUCTION

Studies of soil consumption (geophagy) among nonhuman primates have focused on its potential value as a source of supplementary dietary minerals and as a vehicle for adsorption and hence removal of toxins with passage through the gut (Bolton et al., 1998; Muller et al., 1997; Mahaney et al., 1995; Izawa, 1993; Davies and Baillie, 1988; Fossey, 1974, 1983; Uehara, 1982; Oates, 1977, 1978; Hladik, 1977; Hladik and Gueguen, 1974). The possibility that geophagy is used by animals for seld-medication in disease and parasite infestation (as an adsorbent of harmful bacteria and toxins), as it is used by humans both traditionally (Johns, 1990) and in modern pharmaceuticals (Brouillard and Rateau, 1989), has also been suggested (Mahaney et al., 1996, 1997; Stambolic-Robb, 1997; Johns, 1990; Hladik and Gueguen, 1974).

Among higher primates, humans of many societies also have engaged in geophagy (Aufreiter et al., 1997; Johns and Duquette, 1991; Johns, 1990; Hunter, 1973; Laufer, 1930) for various reported reasons, e.g., to alleviate starvation in time of famine and to counter deficiencies of inorganic nutrients during pregnancy. A correlation was established between consumption of highly calcium-enriched termite-mount clay by pregnant women of various African ethnic groups and the absence of milk and other dairy products in their diet. Wiley and Katz (1998) found that soil consumption was absent in pasturalist societies with daily access to milk-producing livestock and used this to implicate geophagy soils as dietary calcium supplements. Geophagy has also been seen as a cultural tradition sponsored and/or advocated by religion. Clear reasons to justify the behavior are frequently unobtainable; possibly human geophagy was retained over evolutionary time due to survival benefits conferred by the behavior (Johns, 1990), and experimentation occurred with highly weathered natural earths in different environments (Mahaney, 1999).

Studies of geophagy soils from different geographical locations have shown that they are often similar in mineralogy and in chemical elemental content

(Browman and Gunderson, 1993). These similarities lead to the inference that soils of a particular chemical environment are selected for ingestion, from the mounds of termites of the subfamily Macrotermitinae. Reports of the ingestion of bioturbation (insect-selected) soils of termites or ants by primates are not unusual (Julliot and Sabatier, 1993; Aufreiter et al., 1997), and ants and termites themselves are often a source of food (Uehara, 1982; Watts, 1984). The chimpanzees of Mahale may be aware of key characteristics associated with termite mound soils. Uehara (1982) reported chimpanzees there sampling the soils of termite mounds through the year, apparently monitoring by taste the reproductive condition of the termites, for feeding on the termites.

The adaptive value of the soils is likely linked to their composition. Most of the analyzed soils have been found to contain a high proportion of $Al : Si = 1 : 1$ secondary clay minerals, with a lesser amount of $Al : Si = 2 : 1$ minerals, some quartz, and, often, high amounts of iron. The clay fraction of the soils is a physically and chemically active material that may absorb or adsorb (or conversely release) water, inorganic elements, or organic compounds to varying degrees, depending on the amounts of specific clay minerals and depending on variations of such conditions as pH. Many studies have considered a benefit of geophagy to be the adsorption of toxic organic components such as alkaloids in plant foods, as shown in vivo for parrots, by Gilardi et al. (1999), and for geese by Wink et al. (1993). Clay minerals are also capable of adsorbing bacterial or parasite-generated toxins (Said et al., 1980). This may be a key benefit of geophagy for the chimpanzees of the Mahale Mountains. Beneficial compounds or organisms could also be obtained from ingestion of the high-clay soils and provide sensory cues of smell and taste used by animals in choosing appropriate soils.

Behavioral research on chimpanzee groups in Mahale has been carried out since 1965 (Nishida, 1990). Investigation into the health and self-medicative behavior of chimpanzees at Mahale with a focus on plants has been carried out by one of the authors (M.A.H.) since 1985. Recently geophagy has also been studied with the objective of determining if this behavior can be considered another form of self-medication (Huffman, 1997). Early behavioral observations have shown that chimpanzees of Mahale sometimes consume termite mound soils during periods of gastrointestinal distress and when beset by intestinal parasites, and thus a preliminary reconnaissance was made of such soils in 1994 (Mahaney et al., 1996). A larger set of samples of eaten soils and uneaten control soils collected in 1995 (Mahaney et al., 1999) confirmed that the chimpanzees chose soils characterized both by combinations of halloysite and kaolinite, similar to those in formulations used by humans to reduce gastrointestinal afflictions, and by high concentrations of iron, for which a nutrient role was considered. Further observations showed that the chimpanzees frequently consume small quantities of these soils (~3 cc per feeding) (Figure 1).

FIG. 1. A chimpanzee of Mahale Mountains National Park, Tanzania, sampling termite mound soil. Photo by Michael Huffman.

Here, a new, larger set of samples of ingested termite mound earths from the Mahale sites was examined along with controls chosen at several meters' greater distance from the mounds than for collection of previous control samples. Additional analytical foci were placed on the potential of the soils to adsorb certain toxins and to release nutrients at acid pH and on an analysis of the soil particle surfaces. We also include information on two samples from the nearby Gombe

National Park research site where chimpanzees have similarly been observed engaging in geophagy. Results from a study of the microbiology of these soils by Ketch (1998) will be published separately. This paper concerns the chemistry, geochemistry, mineralogy, and adsorptive capacities of ingested soils, compared with control soils from the same areas, in order to isolate parameters that warrant further study.

METHODS AND MATERIALS

Behavioral Observations. Geophagy has been observed at Mahale and Gombe in both dry and rainy season months. In the course of ad libitum and focal-animal observations, the locations of chimpanzee geophagy were noted by researchers and field assistants at Mahale and Gombe. During the 15-day collection trip by Huffman in 1996, these sites were visited and collections made. No systematic observations covering all seasons have been made at Mahale, making systematic analysis of the seasonality of geophagy difficult. However, in 59 days of focal-animal observations made by Huffman in the 1991 rainy season, five incidences were recorded (Mahaney et al., 1996).

The Sites. The Mahale Mountains National Park is located on the eastern shore of Lake Tanganyika approximately 100 km south of the Gombe Stream National Park (6°S, 30°E; Figure 2). The climate of the area is influenced by north- and southeasterly (trade) winds. Local wind from the mountains has a drying effect, whereas wind from the lake brings moisture. The mountains range up to 2500 m asl, lake level is about 773 m asl. The underlying bedrock is primarily granite along with gneiss and schist (McConnell, 1950). Soils formed from this crystalline rock are relatively thin, stony, and porous (Collins and McGrew, 1988) with thin organic (Ah) horizons less than 18 cm thick. Soils were collected in mid-October 1996 over a period of five days during the end of the dry season at Mahale and during one day the same month at Gombe. Each termite mound was sampled by Huffman at those spots where chimpanzees were observed to consume the mound soil. All sites were located above ground at the top of a mound. Each control sample was collected approximately 4–6 m away from a mound, avoiding possible contamination down the slope of runoff mound material. Each sample came from the surrounding Ah horizons and had a darker tone than the mound soils.

Laboratory Analyses. Each sample was analyzed for water content and particle size of the <2 mm fraction. Water retention was determined by heating samples overnight at 110°C. The air-dried equivalent of 50 g oven dried soil was used to calculate the particle size. The sands (63–2000 μm) were separated by wet sieving. The silt and clay fractions were determined by pipet and hydrometer (Day, 1965). The particle size curves were drawn from the dry weight of sand and from density measurements made by hydrometer. Particle size distributions

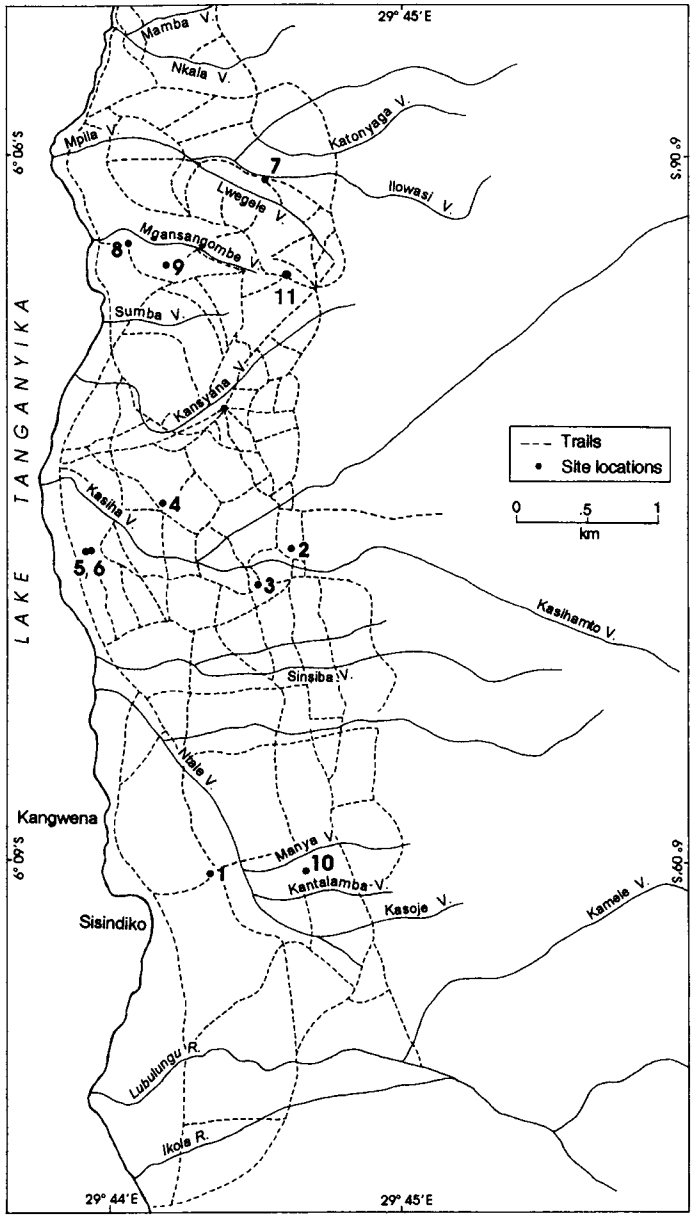

FIG. 2. Map showing the location of sample sites in Mahale Mountains National Park, Tanzania.

were analyzed as curves to determine the relative ratios of sand and silt to clay in each termite mound soil and each control soil.

Mineralogy was determined by X-ray diffraction (XRD) (Whittig, 1965). Major, minor, and trace elements were measured using instrumental neutron activation analysis (INAA). Five-hundred-milligram subsamples of the bulk materials were weighed into polyethylene vials and analyzed at the SLOWPOKE Reactor Facility of the University of Toronto, following procedures established by Hancock (1978, 1984). Two neutron irradiations and four counts were required to produce a database of 23 elements for each sample. Extracts of selected samples were prepared by shaking approximately 1 g of soil in 10 ml of pH 2.0 ammonium oxalate solution for 30 min, followed by gravity filtration through Whatman 42 ashless filter paper. The filtrates were allowed to stand for 48 hr to allow very fine particles to settle; approximately 1-ml volumes of the filtrates were weighed into polyethylene vials, which were then heat-sealed. The sealed samples were analyzed by INAA for short-lived, isotope-producing elements, and some selected samples were also analyzed for long-lived isotope-producing elements, following the procedures of Hancock (1978, 1984).

Selected soil samples were analyzed by scanning electron microscope (SEM) and energy dispersive spectrometry (EDS), including the light and heavy mineral fractions. For the light fraction, sands were randomly selected for analysis by SEM and EDS. All sands were analyzed for grain mineralogy and coatings that might reveal the chemistry of weathering products and coatings including clay minerals. The SEM-EDS analyses followed procedures outlined by Mahaney (1990) and Vortisch et al. (1987).

X-ray photoelectron spectroscopy (XPS) was used to analyze elements at the surface layers of individual particles of soil. The spectra were obtained on a Leybold MAX 200 XPS system based at the Institute for Biomaterials and Biomedical Engineering at the University of Toronto. Samples were prepared for XPS analysis by pressing the dried powdery <2-mm fraction of the soils onto adhesive copper tape, removing loose particles with light gas pressure, and mounting the tapes on a sample holder. Unmonochromatized Al K_α X-ray radiation was used as the excitation source. The source was run at 15 keV and 25 mA. Large-area analysis was performed (4×7 mm^2) to minimize collection time while maximizing signal. Relative atomic percentages were obtained from survey spectra (0–1000 eV, step size 800 meV) run in a low-resolution mode (pass energy = 192 eV). Details of the techniques are described in Sodhi et al. (1992). The data were normalized to unit transmission of the spectrometer by means of a routine provided by the manufacturer (Berresheim et al., 1991). The sensitivity factors (see Table 6 below) used to obtain these values were empirically derived by Leybold for the normalized spectra. Actual integration of the peaks was performed using Escatools (Surface Interface Inc., Mountainview, California). The surface specific nature of XPS limited depth analysis to 7–10 nm.

To measure the adsorptive capacity of soils, we employed the following design: About 500 mg of soil was added to 5 ml of water in 15-ml centrifugation tubes; 0.35 mmol of each of the alkaloids sparteine, lupanine, quinine, and atropine (adjusted to pH 6–7) were added. After 20 min of incubation, samples were vortexed and centrifuged for 20 min at 4000*g*. The separated supernatants were brought to pH 12 with 1 M KOH and subjected to solid–liquid extraction using ChemElute columns. Methylene chloride (3 × 15 ml) was used as eluent. The crude alkaloid extract obtained was analyzed by capillary gas–liquid chromatography, using a Carlo Erba gas chromatograph with a flame ionization detector (FID) and OV-1 (Ohio Valley) capillary column (15 m × 0.25 mm × 0.25 μm) (for details see Wink et al., 1993, 1995; Wink, 1993b). Authentic alkaloids were employed as external standards for quantification. Appropriate controls (samples with water and alkaloids) were used to define the amount of nonadsorbed alkaloids. All experiments were performed in triplicate.

RESULTS AND DISCUSSION

Particle Size. The data show little variation in sand + silt, but large variations in clay contents. Figure 3 shows results for ingested samples from sites in the Mahale Mountains. To read the data it is necessary to refer to the boundaries for sand (63–2000 μm), silt (2–63 μm) and clay (<2 μm). The *y* axis is cumulative, so the percentage at 4 phi is the sand and the percentage at 9 phi is the sand + silt. The percentage at 100 less 9 phi is the percent clay. The data for ingested soils show higher proportions of <2-μm material over control soils. There are clear textural differences between the ingested and control samples, showing that there is a preference for chimpanzees to select clay-rich material for ingestion.

Mineralogy. The X-ray diffraction data shown in Table 1 include both clay and primary minerals. Within the 1 : 1 group (Si : Al = 1 : 1), metahalloysite is predominant but is not confined to the ingested group. Kaolinite is dominant at site 3 and site 6 in moderate to abundant amounts and is present in eaten and control soils. Kaolinite and metahalloysite have similar chemistries (although metahalloysite has variable water content) and among the 1 : 1 sample group chimpanzees may be able to achieve the same benefit consuming both the control and ingested soils.

Within the 2 : 1 (Si : Al = 2 : 1) sample group, illite is present in both the ingested and control soils. Randomly interstratified illite–smectite is present in trace to moderate quantities in all sites; smectite is present in five sites including four where ingestion occurred. Smectite is often present in small amounts in geophagic soils and may have some value in geophagy, although the ingestion of Turkish soils high in smectite was shown in vivo in humans to pre-

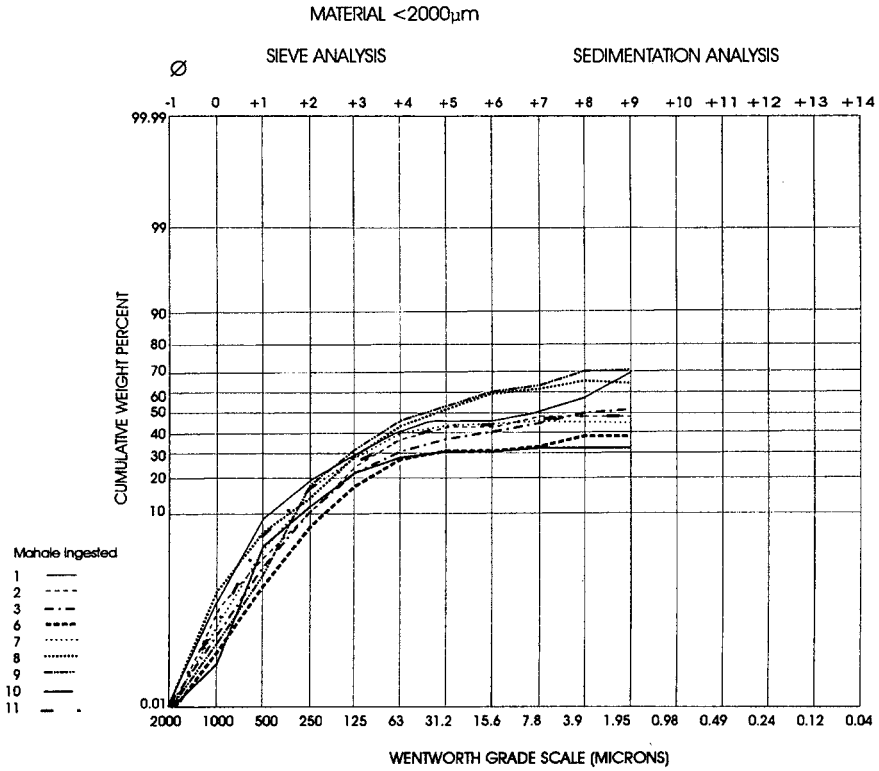

FIG. 3. Results for particle size analysis of soil samples ingested by chimpanzees.

vent uptake of Fe, whereas some soils of predominantly 1 : 1 clay mineral content, used by Native Americans, did not (Minnich et al., 1968). Vermiculite is absent in all soils; chlorite is also absent. Within the primary minerals, quartz, muscovite, orthoclase, biotite, and plagioclase feldspar are present in varying amounts. Quartz is somewhat more prevalent in the ingested samples. It is most abundant in weathered crystalline terrane and here may play a role in armoring the termite mound surface, by rain wash and surface hardening, against animal disturbance. With higher amounts of quartz, orthoclase and the micas are also seen to increase, indicating either younger soils (a sorting phenomenon) or a stronger granitic influence. Plagioclase occurred infrequently among the samples studied, and since it is generally one of the first minerals to weather by hydrolysis, this is not unexpected. Muscovite and its secondary cousins, on the other hand, are inert.

Metahalloysite and illite are common clay minerals in the Mahale soils. The

[a] The minerals identified include kaolinite (K), metahalloysite (MH), illite (I), illite-smectite (I-S), smectite (S), quartz (Q), orthoclase (O), mica (M), and plagioclase feldspar (P). Chlorite and vermiculite are not present even in trace quantities. Semiquantitative amounts of each mineral are given as trace (tr), small (X), moderate (XX) and abundant (XXX) quantities. E= eaten; C = control.

XRD traces show sharp, abundant reflections indicating a strong crystallinity and a mineralogy of a relatively high purity, similar to pharmaceutical clays marketed as digestive remedies. Data for sample 8E show that it contains somewhat more smectite than is common throughout the sample group. This profile is also similar to that from earth consumed by mountain gorillas in northwestern Rwanda (Mahaney et al., 1995). The chimpanzees do not always select soils with smectite present; the presence of chiefly kaolinite or metahalloysite is consistent.

Carbon and Nitrogen. The carbon and nitrogen contents (Table 2) of the control soils are consistently higher than those of eaten soils, as was also seen in the data from analysis of an earlier sample set from this area (Mahaney et al., 1999). This is probably a reflection of higher levels of organic matter in the surface soils of the area, as compared to the termite mounds that are derived from depths of up to 100 m. The lower levels of carbon and nitrogen of the termite mound soils are also seen in carbon values obtained for the XPS data (discussed below). This is likely due to the depth of acquisition as the insects build their mounds particle by soil particle from deep, wet soils. The resulting lower organic content may reflect lower levels of pathogens, a benefit of choos-

[a] Color follows Oyama and Takehara (1970). E = eaten; C = control.

ing termite mound material for ingestion over the surrounding soils, although the composition is very similar in many other respects.

Acidity. pH measurements of the soils (Table 2) show that the eaten soils have consistently higher pH than the control soils, as did the data from Mahale geophagy soils of 1995 (Mahaney et al., 1999). An antacid function has been proposed for geophagy in some monkeys (Poirier, 1970; Oates, 1978; Davies and Baillie, 1988) to maintain a higher pH in the forestomach. Although primates such as chimpanzees and humans do not maintain a forestomach bacterial flora, these soils may play an analogous role. While the lower pH of the control soils may be related to their higher organic content, the higher pH of the termite mound soils may also be due to termite activities in creation and maintenance of suitable conditions for the cultivation of fungal gardens.

Electrical Conductivity. The electrical conductivities of pairs of eaten and control soils (Table 2) do not show any clear trends. Intersite variability is far greater than intrasite variability, likely a reflection of differences between the eaten and control soils seen in data presented here.

Soil Color and Texture. Soil colors of the eaten and control soils range from yellow–red hues of 10YR 5/4, 5/6 (bright to dull yellowish brown) to stronger

yellow–red 7.5YR 4/4, 4/6 (brown, bright brown to orange) hues (Oyama and Takehara, 1970). Control samples, collected approximately 6–8 m away from a mound, came from the surrounding Ah (organic) or subsurface (nonorganic) horizons, giving a mix of 10YR and 7.5YR colors (Oyama and Takehara, 1970) that were sometimes lighter and sometimes darker than the eaten soils (Table 2). In five of six cases in Table 2, the control soils are slightly darker by one color value and two chroma, indicating a slightly higher amount of organic matter. This is likely due to greater amounts of humus in the control soil compared to the termite mound soil. Of the eight eaten soils analyzed, four have 7.5YR colors, indicating higher amounts of iron. The change in yellow–reddish hues from 10YR to 7.5YR reflects increasing redness, and most probably reflects the form and relative amount of iron in these soils, either as goethite (yellow hues) or hematite (more reddish hues). Soil textures are clay to sandy clay loam (Mahaney et al., 1999), apparent as observed on well-worn animal paths in the area (M. A. Huffman, unpublished results). There are no dominant soil structures in the samples studied, but occasionally subangular blocks are present, which must play a minor role in soil aeration. The termite soil ingested by chimpanzees is considerably richer in clay-size material than the nearby control soils, which are closer in texture to those described by Collins and McGrew (1988).

Scanning Electron Microscopy. Sands in the eaten samples were studied to elicit information on their mineral composition, weathered state, and the composition of coatings they carry. Most grains are coated either with clay minerals or Fe oxides (Figure 4A) suggesting they serve as a source of fine particles or oxides which might play a role in nutrition or self-medication, or alternatively in increasing the adsorption of molecules on the soils. (Figures 4B, 4D). Quartz, which is present in all the samples studied, is either fairly fresh (10% of the samples studied; Figure 4C) or coated to varying degrees with 50% etching, sometimes as in Figure 4E. The remaining 40% are well etched, as in Figure 4E. The data suggest that sands carry coatings that could provide chemical elements important in nutrition. Iron is so prevalent in the suite of samples studied that we first assumed it would be available for absorption. The clay mineral coating on Figure 4F supports the clay mineralogy, which shows a preponderance of 1 : 1 clay minerals including halloysite and kaolinite. When the soils are ingested, these clays, similar to pharmaceutical clays, would be exposed to the gut surfaces as coatings on these sand grains. Organiogenic forms seen on some of the sands from local termite mounds may be related to the presence of micro-organisms.

Geochemistry. Data from analyses of whole soils (Table 3) show that they contain high amounts of iron (>2–6%) in combination with high aluminum (approximately 10%). Potassium occurs at 1–3%. Calcium values are low, with only one site (1C) showing >2%. Sodium levels are also low, at <1%, except for sites 8 and 9, which contain about 1.7%. The essential trace elements cobalt and

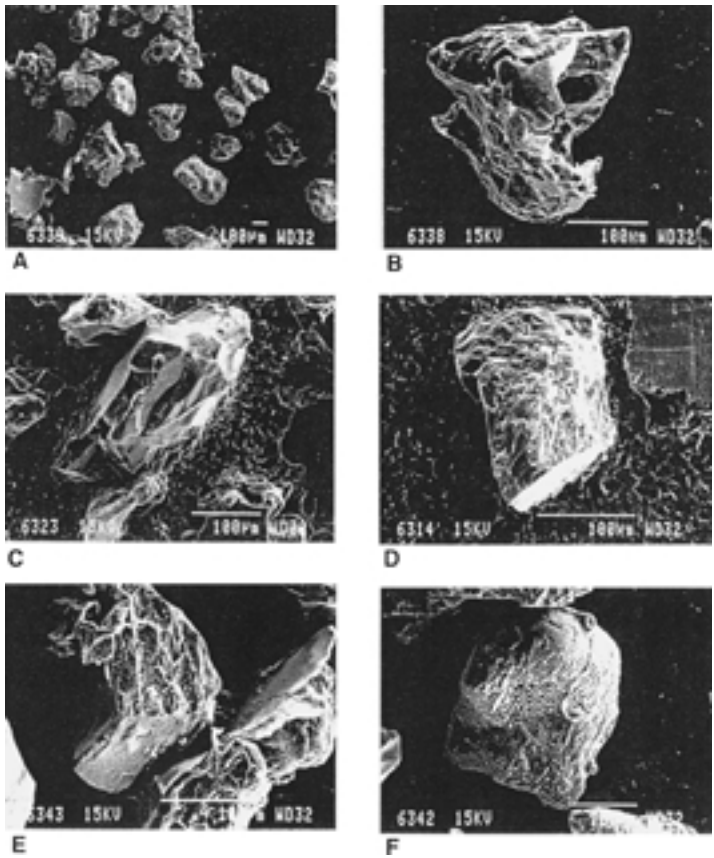

FIG. 4. Scanning electron microscopy from Mahale geophagy soils. (A) Group shot of mixed anhedral and euhedral grains of both lithic and mineral particles; most grains are coated with clay minerals or Fe oxides. Grain in center is enlarged in B. (B) Angular fragments from center of group. Flat, bent biotite mica on central surface, quartz above and amphibole (Fe, K, Mg, Al, Si) below. (C) Clean euhedral quartz showing polyhedral, grooved form with unworn, unetched surfaces—probably represents volcanic, pyroclastic particle. (D) Hornblende (Fe, Ca, Al, Si) showing compound morphology of etched, anhedral surfaces in contrast to cleavage-surface sides. Outcropping of amphibole cleavage on an anhedral surface form. (E) Quartz displaying a compound form with an organiogenic dendritic form on etched microstructural mineralic form, possibly a mineral other than quartz (calcite, feldspar or apatite), in contrast to fracture-surface sides. (F) Quartz displaying subround form, probably physically rounded. Etched clean upper surface is in sharp contrast to clay coating with Si : Al ratio of 1 : 1 indicating halloysite or kaolin group minerals. Linear and lobate-shaped clay ridges indicate downward movement of termite mount fluid on an overgrowth of possible crystalline, geopetal ornamentation.

chromium are present at measurable levels: cobalt is found in amounts of 2–13 μg/g and chromium at 10–20 μg/g, except for the Gombe site where roughly 100 μg/g was found. Several grams of soil are consumed daily.

Taking the north–south cline into consideration, calcium and manganese concentrations decrease in the sites from north to south, as does sodium (with some exceptions). Other chemical elements vary by up to a factor of 2 from site to site, indicating that we cannot use the whole data set as a coherent geochemical entity, but must restrict the geochemical evidence to a site-by-site (or microregion-to-microregion) basis. Electrical conductivity measurements (above) support this reservation.

In general, the levels of nutritionally important elements in these samples were similar to those reported by Hunter (1973) for soils consumed by humans in Africa. Hunter concluded they are a good source of mineral element supplementation. At Mahale, at each site for which we have both eaten and control material, the concentrations of most elements are highest in the eaten material. Enrichment of geophagy soils with essential elements has been noted previously. (Muller et al., 1997; Heymann and Hartmann, 1991; Mahaney et al., 1990; Davies and Baillie, 1988), and suggests that geophagy can be a strategy for obtaining mineral nutritional supplements. The presence of higher amounts of certain elements in soils is not, however, sufficient evidence of their availability for uptake, as shown below.

Acid Extractions. Acid extracts of the soils were prepared in order to simulate the dissolution of soil elements by the gastrointestinal tract. Although extraction using hydrochloric acid would have been a more realistic simulation of conditions in the stomach, the high chlorine levels thus produced would make analysis by INAA impossible for many elements. Thus, ammonium oxalate titrated to a pH of 1.99 was used to extract the soils. The elemental levels determined in these extracts are a measure of those available for absorption especially in the stomach. Changes of pH in the intestines may affect the element concentrations in solution at later points in passage of the soil through the digestive tract. Overall, low amounts of elements were found in the extracts. These levels were below those reported in a similar digestive experiment by Hunter (1973). The nutritionally important elements Ca, Co, Mn, Na, K, and V were determined in most of the samples analyzed. Cr, I, and Mg were below detection limits in many samples, although they were measured at site 10 (Tables 4 and 5).

Iron, an important nutritional element, although high in whole soils, was not detectable in extracts (Table 5). Aluminum, barium, and bromine, while generally not considered to be nutritionally important, may have some therapeutic effects and were present in most of the extracts tested. The enrichment, relative to control soils, of eaten samples with certain elements was not observed for these extracts. On the whole, the extracts contain only very low levels of inorganic nutrients, as shown by INAA. The results are not indicative of these soils as good sources of such nutrients.

XPS Analyses. We hoped to obtain information on the surface characteristics of the soil particles by assaying inorganic elements on the soil surfaces using XPS analysis. These surfaces, the interface of soil particles and their environment, would, when ingested, interact directly with the digestive tract and its contents. The soil particles in these samples are likely to consist of mineral grains

coated to varying degrees with clay minerals. The surfaces may thus represent the elemental composition of the clay minerals and molecules adsorbed onto the clay matrix, as well as some contribution from sharp or scraped-clean edges of hard mineral grain surfaces. The analytical technique allows for determination of all elements above a detection limit of about 1%. The results (Table 6) show that eight elements compose most of the soil particle surfaces.

Comparison with data from whole-soil analysis (Table 3) shows that Fe values, although relatively high (0.4–1.6%) in the surfaces, are more elevated in the interior of the particles. Although Fe is frequently found at high levels of several percent in soils ingested by primates, these soils do not seem to be good nutritional sources for the element, as Fe was not detectable in the extracts. However, without exception, the surfaces of the ingested soil particles were enriched with Fe compared to the controls. Whether iron plays a role in any physiological function of geophagy in this case is unknown, but charge relationships on the clay lattices could be altered by its presence, and hence adsorption properties of other molecules at these surfaces may be affected positively or negatively for different adsorbents. Fe may be present in a variety of forms in soils and clays, and further work would be useful to examine the form of iron in these soils which renders it unavailable for release at low pH. The interactions of iron in

aqueous media with clay surfaces are complex and alter the electrical properties of the clays (Henry et al., 1990), and the form of iron in these soils may play a role in their high adsorptive properties.

Magnesium was found to be enriched at the particle surfaces, relative to data for whole soil composition, but Ca was found at comparable levels in both the whole soils and at the soil particle surfaces, except in the Gombe samples, which were surface-enriched for Ca. Potassium was lower in the surfaces relative to whole-soil values. Aluminum was often slightly enriched, supporting the expectation that high-aluminum clay minerals coat the particles. Oxygen and silicon, however, were only measured by XPS. At all but one site, where both eaten and control samples were available, oxygen was found in higher concentrations in the eaten sample. This may be an indication of a higher oxide content and lower organic content in the eaten samples, as suggested by carbon concentration data for the whole soils (Table 2).

For each pair of samples, the carbon content was considerably higher in the controls, supporting the suggestion of Hladik and Gueguen (1974) that choosing insect-sorted soil reduces the ingestion of detrital organic material, including perhaps pathogens and parasites. The soil surfaces do not differ in carbon content between eaten and control samples except for the sample from Gombe, where the control soil is also enriched with carbon. Lower levels of carbon were found in the soil particle surface layers, compared to the whole soils. The surface carbon may include organic components or microorganisms peculiar to the chemistry of these soils and potentially beneficial to the chimpanzees. Organogenic forms on some surfaces were noted under SEM (see above).

Adsorption Capacity of Soils. Quinolizidine alkaloids (sparteine, lupanine), tropane alkaloids (atropine), and quinoline alkaloids (quinine) were employed as model compounds for toxic metabolites produced by plants (Wink, 1993a). The results, expressed as means ± SD, of triplicate analyses show that all the soil samples analyzed are capable of binding alkaloids, albeit to differing degrees (Table 7). Alkaloids remained unchanged in chemical terms, i.e., no degradation or conversion products were observed by GLC and GLC-MS. Soils from Mahale showed equally high adsorption rates for all four alkaloids. These binding properties are in general comparable to those of coal and charcoal, materials that are also used therapeutically to adsorb dietary and microbially produced toxins. However, usually the absolute capacities of soils were somewhat lower, depending on their chemical compositions. No differences were found between eaten and uneaten soils in most Mahale samples, an observation also made in earlier studies (Mahaney et al., 1999). However, in the Gombe samples, and in Mahale samples from sites 1 and 11, adsorption was lower in controls as compared to the eaten soils.

The chimpanzees of Mahale and Gombe National Parks eat soil with characteristic properties. Our results indicate certain features of the soils that should

be investigated further. One benefit of the ingestion of highly adsorptive high-clay soils has been considered to be the uptake by the soils of plant alkaloids and antinutrients ingested with a wild plant diet, shown to occur in vivo in birds (Wink et al., 1993; Gilardi et al., 1999), thereby preventing absorption of deleterious plant constituents via the gut. Such adsorptive properties are also known to be useful in preventing the absorption of bacterial toxins and in immobilizing and isolating pathogenic organisms in the gut by means of the adsorption of clay particles to surround the harmful organisms, to be eliminated with the feces (Said et al., 1980; Gardiner et al., 1993). Another possibility is the formation by clay particles of a mucoprotective barrier against intestinal pathogens, as shown in the lumen of *E. coli*-infected sections of rabbit ileum in vitro by Rateau et al. (1982). Knezevich (1998) cited low levels of diarrhea in geophagous rhesus macaques of Puerto Rico, in spite of high parasite loads, and thus geophagy may be a technique for tolerating the presence of some pathogens in the intestinal tract by blocking their action. Traditional human use of insect sorted soils in Zimbabwe for digestive upsets may be a parallel behavior to the use of termite mound soils by chimpanzees of Tanzania (Aufreiter et al., 1997). The mineral compositions of the Zimbabwean soils were comparable to that used in the pharmaceutical Kaopectate. However, such soils were reported to be recommended for collec-

tion from areas of the mound that had recently been disturbed by the insects. This suggests awareness of an influence on the soil resulting from insect contact, which could be the release of a functional compound or of beneficial microorganisms of insect origin applied as a remedy. Currie et al. (1999) demonstrated a mutualism between fungus-growing ants and a filamentous bacterium (an actinomycete) that produces antibiotics specific to a parasite of the insect-cultivated fungus. The ants studied by Currie et al. (1999) carry the bacterium on their ventral surfaces. The possibility that the chimpanzees ingesting termite mound soil are exploiting a similar insect-microbial relationship of termites is intriguing. Possibly some geophagy soils may also be a source of symbiotic organisms: Kortland (1984) pointed out the possible benefit to the health of zoo captives of a ciliate first observed and recognized by Reichenau (1920) as a potential symbiont of higher primates. The cellulose-digesting ciliate organisms, *Troglodytella abrasarti* and *T. gorillae*, were found attached to the mucous membranes of the cecum and large intestine, and although abundant in just-captured chimpanzees and gorillas, they disappeared soon from the gut of the captive animals, who also developed diarrhea in captivity. The source of these ciliates was not determined, and they were later dismissed as parasites, a conclusion disputed by Kortland (1984). These examples suggest the possibility of a relationship between intestinal microorganisms and the good health of higher primates that is maintained by geophagy. The soil is a possible source of beneficial gut microflora as well as of pathogens, and the gut flora of wild primates necessarily reflects their behavior and environment.

The role of geophagy among humans affected by iron depletion and anemia has long been a matter of debate. Geophagy in humans frequently has been associated with anemia and increased parasite loads, but it remains unclear whether geophagy of some soils is a causative factor or whether iron depletion or anemia may lead to geophagy. Geissler et al. (1997, 1998) found soils eaten by Kenyan children having a high prevalence of malnutrition to release iron at low pH sufficient to supplement their diet with 4.7 mg iron per day. They found, however, that there was more anemia and low serum ferritin among geophagous children, relative to those who did not eat soil. The soil eaten by chimpanzees of Tanzania did not release detectable iron at low pH. Iron depletion and anemia were associated with geophagy in Kenyan children (Geissler et al., 1998), whereas serum ferritin concentrations were found statistically to be dependent on geophagy, although no inference could be made on causality.

The possible prevention of iron absorption by geophagy of soils containing high iron concentrations may depend on the form of the iron. This has not been adequately investigated in geophagy studies but may help to predict the effect of iron on clay adsorptive and aggregation properties and on iron uptake or release by the clays. These are likely to be important in determining the consequences of geophagy. The effects of ingestion of several geophagy soils on iron uptake

in humans was tested by Minnich et al. (1968), who found that some soils, high in smectite, inhibited iron absorption while others, high in 1 : 1 clay minerals, did not. Iron may be associated with clay minerals in several forms. Ferric iron surface-complexed on mineral matter can be detrimental to health, in that it has been shown to play a role in increased lung inflammation related to inhalation of silicate dusts (Ghio et al., 1992), and silicate dusts can complex iron from biological sources. Structural iron, if in the form of Fe(III) on the other hand, may be reduced by soil bacteria to Fe(II). This reduction has also been shown to alter the swelling properties of smectites and also to affect particle and pore size (Gates et al., 1998). Acid may to some extent dissolve the edges of clay lattices and release such iron. Ferrous iron salts [Fe(II)] are readily absorbable, while ferric iron [Fe(III)], the rust-colored, oxidized form often found in reddish tropical and semitropical soils, is not considered bioavailable as a salt. However, it may be bioavailable but slowly released when complexed [for example, as in a polymaltose complex, as discussed in Tuomainen et al. (1999)]. The proportions of iron in different forms, the clay mineralogy of the soils, and the gut contents likely interact to confer particular properties on different soils when eaten. It is unknown if animals practicing geophagy can distinguish soils of different properties. The termite mound soils analyzed here, although shown to be high in iron, with slightly lower concentrations on the particle surfaces than the soil particle interiors (Tables 3 and 6) were found not to release detectable iron at low pH. The iron in these samples may be surface-complexed iron, with a limited availability for release from the clay, or it may be structural iron, since it was in a lower concentration at the surface of the soils particles. More extensive investigation would be necessary to clearly define the forms of iron present and the conditions for its bioavailability.

Minnich et al. (1968) described that high clay soils rich in iron and in smectites are habitually snacked on by women in Turkey, and they showed that their ingestion prevents iron uptake by the gut. The practice was associated with the occurrence of anemia among the women. The Turkish soils were also high in smectite. The termite mound soils of western Tanzania, however, contain significant amounts of illite and smectite–illite, 2 : 1 clay minerals comparable to smectite. Although they are rich in iron, they do not release it as low pH. The possible prevention of absorption of significant amounts of iron may have benefits for higher primates afflicted with pathogens: a wide spectrum of bacteria and fungi pathogenic to humans thrive in the presence of iron. Individuals with hyperferremia are more susceptible to pathogens: children with sickle cell disease commonly die of bacterial infection related to iron overload (Weinberg, 1974). Release of iron by the destruction of red blood cells in sickle cell anemia and thalassemia, and from the destruction of liver cells in malaria, increases susceptibility to pathogens as well as being damaging in its own right. Populations of humans practicing geophagy overlap with populations suffering from these

diseases, and it would be valuable to determine whether ingestion of high clay soils may be helpful in this respect.

Episodes of rapid absorption of iron, such as may be obtained from modern mineral supplements, may temporarily saturate the body's system for trapping free radical chemical species, leading to higher rates of lipid peroxidation (Tuomainen et al., 1999). Clay slows the movement of food through the gut. If very low levels of iron were continually released from some clays as they slowly move through the gastrointestinal tract, some iron could be provided for absorption, but the occurrence of peaks of iron absorption could be prevented. The already high concentration of iron in the soils may lend the soils particular, possibly useful aggregative and adsorptive properties, but, depending on its form, may also be a safety factor in limiting the rate of iron uptake by the gut.

However, an increased oxidative capacity in red blood cells has also been suggested to be beneficial in suppressing malarial infection. The Hausa of northern Nigeria, among whom geophagy is common (Wiley and Katz, 1998), utilize a variety of plants with antimalarial properties in their diet. The efficacy of these plants is related to rendering erythrocytes more sensitive to oxidative damage (Etkin and Ross, 1983). Excess oxidation is controlled by the erythrocyte by catalase, an enzyme that uses ferric iron as a cofactor. Sufficient iron in this case is therefore also necessary in controlling excessive oxidation.

In relation to the chimpanzees of Mahale and Gombe, the relationship between pathogenicity of *Entamoeba histolytica* and serum iron in humans, described by Meerovitch (1982), is particularly suggestive. Dysentery due to *E. histolytica* is more severe on an iron-rich diet, while cultures such as the Masai show a much lower incidence of this disease. Meerovitch (1982) related this to their drinking of milk, which supplies lactoferrin and transferrin, to compete with the bacteria for iron uptake in the gut. If adsorbent clay-rich soil also acts to take up iron in the gut, thereby inhibiting the pathogenicity of such bacteria, it would have considerable value in a semitropical environment.

Observations of ingestion of termite mound soils by chimpanzees apparently suffering from intestinal parasites and gastrointestinal symptoms were the impetus to this study (Mahaney et al., 1996, 1999), and ingestion of these soils may represent for the chimpanzees a means to limit the virulence of dysentery. Meerovitch (1982) noted that a high-starch diet, such as in herbivores, promotes the encystment of *E. histolytica*, so that such individuals may have high rates of infection, but high iron must be available for pathogenicity and virulence to rise. A change to meat diets would therefore promote virulent dysentery in such populations. Iron deficiency in human infants and young children is, however, associated with (negative) changes in cognitive function (Pollitt, 1993), and maintenance by geophagy of low iron stores to control pathogens may bring developmental risks. If humans use geophagy at a cost to cognitive abilities in order obtain resistance to endemic pathogens, geophagy is less likely

to have been part of the human behavioral repertoire throughout the course of evolution. The survival of geophagy as a prevalent behavior among pregnant women of nonindustrial cultures argues for its adaptive value (Geissler et al., 1999). We suggest that an adaptive benefit of geophagy of some soils is restriction or control of iron uptake, which helps to limit deleterious effects of some pathogens present in semitropical environments. An important area of investigation in understanding the effects of geophagy would be the routine application of methods that characterize iron chemistry and bioavailability in relation to clay mineralogy in geophagy soils and determination of the effects of iron speciation on clay aggregative behavior, on bioavailability of inorganics including iron, on microbial populations in the soil and in the gastrointestinal tract of geophagous creatures, and on adsorption of organic molecules onto the soils in physiological conditions.

In this context, the results of our analyses of termite mound soils eaten by wild chimpanzees of Mahale and Gombe are consistent with several mechanisms by which ingestion of high-clay soils help in maintaining health in a semitropical environment. In general, geophagy can be described as use of specific soil types, having particular clay components, which form in semitropical environments, as agents for the possible transfer of functional microorganisms and of molecules between the environment and the animals of that environment. They filter toxins and influence the movement of inorganic elements among plants, microorganisms, intestinal parasites, and the digestive tracts of animals.

Some geophagy soils have been shown to release significant amounts of nutrient elements at physiological pHs and are thought to contribute supplementary elements to the diet. It is unknown if geophagy soils with differing properties can be distinguished by sensory means. Although cultural memory may help primates to choose a location for obtaining appropriate soils, the mineralogy and possibly the compounds adsorbed by the clay minerals may also be a basis for sensing which soils are suitable for ingestion among those available in a complex environment. In relation to the particle surfaces, behavioral observations included that the chimpanzees often sucked on the soils, "like hard candy" (M. A. Huffman, field observations) and thus they were wetted in the mouth with saliva and likely broken down into small pieces before swallowing. Adsorbed material on the surface could be released by this behavior, which could be due to liking the taste of the soils, possibly because of the taste of kaolin materials or the taste of organics left by termite activity or of microorganisms. Here, it may be associated with chimpanzees monitoring the mounds for the presence of termites (Uehara, 1982). Occasionally, the chimps were observed to chew the soils, which would expose fresh mineral surfaces to the gut environment. Kaolinite, a 1 : 1 mineral often in high abundance in geophagic soils, is said to have a characteristic odor (and hence taste), and primates have been observed sniffing at soils before ingestion or rejection (Bolton et al., 1998; Uehara, 1982). Local children

at Mahale have said that they eat termite mound soil or clay from the walls of their homes in the rainy season because of the good smell. Women of Kenya distinguished between soils on the basis of taste (Geissler et al., 1999). Animals experienced in geophagy may also recognize the smell and taste of appropriate soils depending on their composition.

In summary, termite mound soils eaten by wild chimpanzees of the Mahale Mountains are rich in clay, particularly 1 : 1 clay minerals, with significant amounts of 2 : 1 clay minerals present. Soils selected for geophagy are relatively high in pH as compared to surrounding (control) soils. They contain elevated iron, which may affect binding affinities for other molecules. They release markedly low levels of elements to solution at low pH, show a relatively high capacity to adsorb alkaloids such as are found in the plants forming the diet of wild chimpanzees, and have a lower organic content than surrounding surface soils. We have described the health benefits of ingesting these soils that are consistent with behavioral observations of the wild chimpanzees of Tanzania, which may be relevant to human populations practicing geophagy.

Acknowledgments—M.A.H. sincerely thanks the people and the government of Tanzania for their long-term cooperation and commitment to his research, in particular the Tanzanian National Scientific Research Council, Tanzanian National Parks, Serengeti Wildlife Research Institute, Mahale Mountains Wildlife Research Centre, and the University of Dar es Salaam. Our deepest gratitude goes to all of our colleagues and friends for their generous efforts. Without their advice, support and understanding, the foundations of this work would not have been made. M.A.H., in particular, sincerely thanks (in alphabetical order) D. A. Collins, J. Goodall, M. S. Kalunde, H. Kayumbo, K. Koshimizu, H. Ohigashi, and Y. Sugiyama. Technical advice and support was provided to M.A.H. by staff of the Louis Pasteur Center for Medical Research, Kyoto. Field research and termite soil collection was funded by the Plant Science Research Foundation-Kyoto University, the Wellcome Trust, U.K., and the University of Toronto to M.A.H. Thanks also go to L. A. Ketch and D. W. Malloch of the Botany Department, University of Toronto, for their criticism of the early manuscript.

PHENYLHEPTATRIYNE VARIATION IN *Bidens alba* VAR. *radiata* LEAVES

EMILY G. CANTONWINE and KELSEY R. DOWNUM*

Department of Biological Sciences
Florida International University
Miami, Florida 33199

(Received July 5, 2000; accepted October 13, 2000)

Abstract—Variation of phenylheptatriyne (PHT) in leaves of *Bidens alba* (Linn.) var. *radiata* (Shultz-Bip.) was investigated across its Florida range, throughout the year, and in response to the photoenvironment. A survey of PHT in *B. alba* leaves was done at 13 sites in Florida and three sites throughout the year. PHT concentrations differed among populations ($P < 0.001$), but little of the variation was explained by latitude ($R^2 = 0.024$) or longitude ($R^2 = 0.022$). Leaf concentrations of PHT fluctuated throughout the year ($P < 0.001$); they were highest in October and lowest in January and April. Experimental manipulations of light quality and quantity caused increased PHT accumulation when UV wavelengths were filtered out and decreased accumulation under low R/FR treatments. Low light levels did not significantly influence the concentration of PHT on a dry weight basis, but did decrease leaf biomass and PHT levels on a leaf area basis. The results suggest that PHT in *B. alba* leaves varies in nature and that light quality affects PHT biosynthesis in situ.

Key Words—Acetylenes, Asteraceae, *Bidens*, phenylheptatriyne, phytochemical variation, geographic variation, seasonal variation, photoenvironment, light, R/FR, UV radiation.

INTRODUCTION

Secondary compounds vary within plant species. Some of the variation may be genetic; however, Bryant et al. (1983) has proposed that much of the quantitative phytochemical variation within a species may result from the availability of resources for their production. For example, when carbon availability is

* To whom correspondence should be addressed.

0098-0331/01/0200-0313$19.50/0

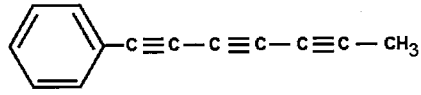
limited by low light, Bryant's hypothesis suggests that carbon would be allocated to growth (i.e., primary processes) rather than biosynthesis of secondary compounds—resulting in decreased production of defensive allelochemicals.

In addition to light quantity, light quality (i.e., wavelengths available) can also influence the levels of secondary compounds by activating enzymes (Tietjen and Materns, 1983) or genes coding for biosynthetic enzymes (Chappel and Hahlbrock, 1984; Lois et al., 1989; Schultze-Lefert et al., 1989). This is true for coumarins and flavonoids, both products of the shikimate pathway with known photomediated mechanisms (Beirer and Oertli, 1983; Hahlbrock and Scheel, 1989; Harborne, 1993).

Acetylenes are plant secondary metabolites derived from common fatty acids. There are about 1000 acetylenic compounds known from 18 plant families and the basidiomycetes (Bohlmann et al., 1973). They are common phytochemical constituents in such flowering plant families as the Asteraceae, Araliaceae, Companulaceae, Santalaceae, and Apiaceae. In many Asteraceae, acetylenes are characterized by conjugated systems of double and triple carbon bonds, often with cyclic or heterocyclic structures. Some acetylenes are toxic toward a variety of organisms that are detrimental to plants; many are phototoxic and require specific wavelengths of UV radiation for expression of their toxicity. Little is known regarding how acetylenes vary in nature or how environmental factors influence their biosynthesis or storage (Ichihara and Noda, 1977; Norton and Towers, 1985; Towers, 1984).

Phenylheptatriyne (1-phenylhepta-1,3,5-triyne, PHT) (Figure 1) is one such phototoxic acetylene that is activated by UV-A radiation (Wat et al., 1979, 1980; Weir et al., 1985). UV-excited PHT has been shown to degrade cellular membranes, resulting in broad-spectrum toxicity against competing organisms, including herbivorous insect larvae (Wat et al., 1981; Arnason et al., 1981), fungi (Bourque et al., 1985; Arnason et al., 1980), bacteria (Geissberger and Sequin, 1991; Towers et al., 1979; Wat et al., 1980; Rabe and Van Studen, 1997; Towers and Hudson, 1987), membrane-bound viruses (Hudson et al., 1986; Towers and Hudson, 1987), and other plants (Campbell et al., 1982).

PHT is found throughout *Bidens alba* var. *radiata* (Asteraceae), although the highest concentrations occur in leaves (Bourque et al., 1985). *B. alba* ranges



Phenylheptatriyne

FIG. 1. Chemical structure of PHT.

throughout Florida, the Caribbean islands, and the Gulf Coast of Mexico (Ballard, 1986) and is part of the *Bidens pilosa* (L.) complex (Ballard, 1986). This complex includes species that are invasive weeds in more than 40 countries (Holm et al., 1977). *B. alba* is used extensively as a food and medicine (e.g., Wat et al., 1980; Ugarte, 1997); much of the research on this complex recognizes PHT as a significant ecological and medicinal factor (Campbell et al., 1982; Meissner et al., 1986; Geissberger and Sequin, 1991; Wat et al., 1980).

This paper investigates the natural variation of PHT in *B. alba*, and explores the influence of photoenvironment on accumulation of this acetylenic compound in *B. alba* leaves.

METHODS AND MATERIALS

Protocol for Geographic and Seasonal Studies. Thirty plants were randomly sampled along a 50-m transect at 13 Florida sites between June 16 and 30, 1998 (Table 1). There was at least 150 km between sites to increase the likelihood of sampling from distinct populations. Plants growing in full sun environments were selected at each sample site. Because *B. alba* grows in disturbed habitats, sites were generally located along roadsides, parking lots, sidewalks, or empty lots. Sampled leaves were restricted to the second leaf from the top of a flowering shoot to minimize variation in PHT levels resulting from leaf position and/or developmental stage.

TABLE 1. PHT IN *B. alba* GROWING IN FLORIDA[a]

Site	Habitat description	Latitude (N)	Longitude (W)	PHT (mean ± SE)	
				nmol/mm^2	μmol/g^{-1}

R/FR normal		D
R/FR low		E

Three leaf discs were removed from leaves on site by using a hole punch. Individual discs measured 6.3 mm in diameter, resulting in a total area of 93.5 $mm^2/3$ discs. PHT was extracted by immersing the three leaf discs into 6 ml of methanol (MeOH) for 14 days. Preliminary studies to determine the stability of extracted PHT in MeOH revealed that PHT concentration remained constant for at least 60 days. Additional leaf discs (three per leaf) were collected and dried for dry weight determination. Seasonal variation in PHT levels was determined by sampling plants at three sites (sites 8, 9, and 12) in October, January, and April. Extracts were analyzed for PHT by high-pressure liquid chromatography (HPLC).

Photoenvironmental Experiments. Seeds were collected in Miami, Florida, surface sterilized with 0.05% sodium hypochlorite (Reddy and Singh, 1992), and germinated. Seedlings were randomly transplanted into 10.1 cm round pots after six days.

The experiment was set up in a partial factorial design with two levels for each of three light factors: quantity of total irradiation [high PPFD (photosynthetic photon flux density) versus low PPFD]; UV radiation (normal UV versus filtered UV), and R/FR (normal R/FR versus low R/FR) (Table 2). There were five treatments and five replications.

Five treatments were created by using energy films or plastics. Treatment A was an open control and had no film or plastic. Treatment B used a transparent plastic (4 mil thickness) that did not significantly alter transmitted light. This treatment served as a control for the plastic and film effects. Treatment C used a clear poly plastic (6 mil thickness) that filtered UV radiation without decreasing PPFD. Treatments D and E used energy films (3M Corp.) that filtered UV radiation and reduced PPFD by about 80%, but altered R/FR differently. Treatment D used a metal sputter-coated film (REAL20) that did not alter normal R/FR. Treatment E used a dye-impregnated film (NEARL20), which reduced R/FR to about 0.23 of normal. A LiCor LI-1800 spectroradiometer was used to quantify light treatments at the start of the experiment (Table 3).

Twenty-five enclosures ($59 \times 75 \times 54$ cm) were made from PVC pipe (2.5 cm) and set up in a Latin-square design. Energy films or plastics were taped

B	87.8	95.0	1.200
C	42.8	95.0	1.186
D	4.9	19.9	1.100
E	5.6	20.1	0.276

[a] Values are based on a single measurement (mean of three consecutive scans) made on October 15, 1998.

across the top of each enclosure with duct tape. The sides of the enclosures were left open because preliminary studies revealed that *B. alba* seedlings did not grow well when the enclosure sides were covered. Enclosures were tilted about 5 cm towards the south to allow for rain runoff. Nine pots were placed in 10.1-cm pot trays that rested on two cinder blocks underneath each treatment enclosure. This set-up gave plants approximately 8 hr of treated light each day.

All treatment enclosures had a minimum of eight plants. After two weeks, plants were treated with a soap spray (5 ml Dove liquid detergent in 896 g water) to eliminate aphids. Nearly all plants were infected with leaf-minors by the third week of the experiment. These insects were manually removed from affected leaves.

After four weeks, three leaf discs from the topmost leaf and the second leaf from the bottom (leaf 2) of each plant were extracted by soaking in 5 ml MeOH. Three additional leaf discs were dried to determine dry weight. Extracts were analyzed by HPLC after 14 days.

Quantification of PHT. PHT was extracted from fresh leaf material with HPLC grade MeOH. Extracts were filtered through Whatman No. 1 filter paper, diluted 1 : 1 with DI water, and partitioned against an equal volume of petroleum ether (PE; bp 30°C–60°C). PE was removed by rotary evaporation at 40°C, and the residue was dissolved in HPLC grade MeOH and stored at 4°C. Spectral analysis revealed that PHT was the predominant acetylenic component in *B. alba*, and it was easily identified by its unique UV absorption spectrum (Bohlmann et al., 1973).

PHT concentrations were determined by UV spectroscopy at 250 nm by using dilutions of PHT standard (ϵ = 148,000) (Bohlmann et al., 1973). Calibration curves were created to standardize PHT concentrations with HPLC peak area units. These were updated at the beginning and end of each study to ensure accurate calculations and were based on curves with $R^2 \geq 0.990$.

In all experiments, PHT was quantified by reverse-phase HPLC on a

Hewlett-Packard model 1090M chromatograph equipped with diode array detection. Separations were accomplished on Hypersil ODS microbore columns (Hewlett-Packard, 5 μm, 100 $\times$ 2.1 mm) with a 0.5 ml/min flow rate and a 40°C column temperature. A water–acetonitrile (H_2O/MeCN) solvent system was used to elute compounds from the column. The program was linear, increasing from 0% to 100% MeCN over 6.5 min, and remained at 100% MeCN for 0.5 min. Compound elution was monitored at 250 nm. All extracts were filtered through a 0.25-μm filter before HPLC injection. Injection volumes were 4 μl for geographic extracts and 7 μl for photoexperiment extracts.

Statistical Analysis. One-way analysis of variance (ANOVA) with site as main effect was used to compare leaf dry weight (DW) and two measures of PHT concentration, based on leaf area (PHT per square millimeter) and DW (PHT per gram). Means and standard errors for PHT per square millimeter, PHT per gram and DW were calculated by using descriptive statistics. Sites were distinguished into homogenous subsets with Tukey's post-hoc analysis. Correlation of PHT per square millimeter with DW for all sites combined, and for each site separately, was tested with a one-way ANOVA. Patterns for geographic influence were investigated with linear regression of PHT per gram by site location. Seasonal patterns were tested by using two-way ANOVA with site and month as the main effects.

Photoenvironmental data were separated into three subsets distinguished by light factor and analyzed independently. The influence of light quantity on leaf PHT was examined by using results from treatments C and D; UV and R/FR influence on leaf PHT levels were determined by using treatments B and C, and D and E, respectively. PHT per square millimeter, PHT per gram, and DW differences for light factor levels were tested with a one-way ANOVA, with light factor as main effect. Correlation between PHT per square millimeter and DW for each light factor was tested with one-way ANOVA. Statistical analyses were performed with SPSS base 9.0 (SPSS Software, Chicago, Illinois).

RESULTS

Data Sets. Three data sets are referred to in the results. Two of the data sets reflect different measures of PHT concentration—one based on leaf area (PHT per square millimeter), the other on leaf biomass (PHT per gram). The third data set, DW, refers to the dry weight of three leaf discs (grams per three discs) taken from the same leaf.

Geographic Variation in PHT and Dry Weight. Sites were restricted to open canopy locations, but they varied in geography and disturbed habitat type. Habitat descriptions, means and standard errors of PHT per square millimeter, PHT per gram, and DW for all sites are shown in Table 1.

TABLE 4. TUKEY'S POST-HOC ANALYSIS USING PHT PER GRAM TO DISTINGUISH HOMOGENEOUS SUBSETS OF SITES[a]

P	0.522	0.151	0.147	0.089	0.170

[a] Uses harmonic mean sample size = 30.000; $\alpha = 0.05$.

PHT per gram values differed between sites ($P < 0.001$). Post-hoc analysis distinguished sites into five subsets (Table 4). PHT per square millimeter and DW were also different between sites ($P < 0.001$). Longitude, from north to south, and latitude, from east to west, were not strongly correlated with PHT per gram ($R^2 < 0.024$), PHT per square millimeter ($R^2 < 0.033$), or DW ($R^2 < 0.029$).

Dry weights of three leaf discs ranged from 0.002 to 0.008 g (data not shown). The majority of samples were within 0.003–0.007 g, with sample sizes for these weights between 11 and 141 for all sites combined; there were only two samples for weights 0.002 g and 0.008 g. The correlation coefficient of DW and PHT per square millimeter for all sites combined was small ($R^2 = 0.070$). When sites were analyzed separately, two sites, 6 and 13, showed a significant correlation between PHT per square millimeter and DW ($P < 0.05$) with $R^2 = 0.382$ and 0.386, respectively. When 0.002 g and 0.008 g weights were excluded from analyses their significance was retracted. Other sites had a positive, negative, or no relationship between DW and PHT per square millimeter.

Seasonal Variation in PHT and Dry Weight. There were differences detected throughout the year for PHT per square millimeter ($P < 0.001$), DW ($P < 0.05$), and PHT per gram ($P < 0.001$), but they did not follow the same pattern. Variation across months is shown for PHT per square millimeter, PHT per gram, and DW (Figure 2). Plants sampled in June had higher PHT per square millimeter, PHT per gram, and DW than plants sampled in January and April. Those sampled in January and April were not significantly different from each

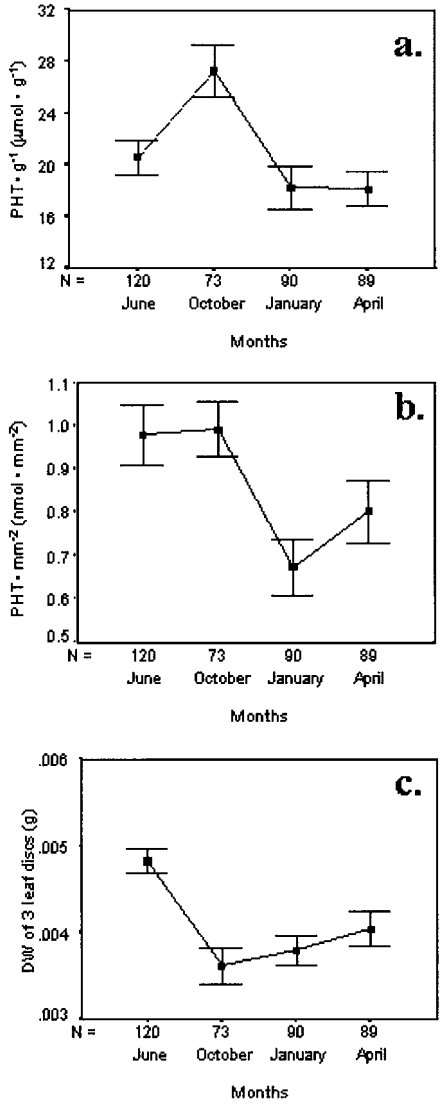

FIG. 2. Mean (± 95% CI) for PHT per gram (a), PHT per square millimeter (b), and DW (c) across months.

other for all analyses. Plants had more PHT per gram in October than plants from other months. DW was positively correlated with PHT per square millimeter ($P < 0.001$; $R^2 = 0.103$) throughout the year.

TABLE 5. INFLUENCE OF PHOTOENVIRONMENT ON PHT AND DRY WEIGHT IN *B. alba* BY LIGHT FACTOR AND LEAF POSITION

Light factor	Factor level	Leaf position	PHT (nmol/mm^2)	PHT (μmol g)	DW (g)
Quantity (intensity)	High	Top	0.81 ± 0.05	23.85 ± 1.46	0.003 ± 0.0002

			$P = 0.923$	$P = 0.923$	

[a] Denotes significance at $P \leq 0.05$.

Effects of Photoenvironment on PHT and Dry Weight. Light quantity affected PHT per square millimeter levels and dry weight. Low light decreased PHT per square millimeter and DW but did not affect PHT per gram. Selective removal of UV radiation resulted in significantly higher PHT per square millimeter for the topmost leaf and PHT per gram for leaf 2. The level of PHT per gram in the topmost leaf was lower under the low R/FR treatment than PPFD equivalent shade treatment (Table 5).

DW influenced PHT per square millimeter for leaves under the light quantity treatments ($P < 0.001$), with $R^2 = 0.224$ for the topmost leaf and $R^2 = 0.204$ for leaf 2, but had an insignificant influence for other light factors. The topmost leaf, the fourth or fifth leaf, had about three times more PHT per square millimeter than leaf 2 for plants included in the analyses, and about 1.5 times more for plants in the open control. Plants from the open control were not used in analyses because they grew differently from plants in the plastic and film treatments. They were significantly shorter and had no lower node branching, unlike plants from the other treatments. PHT levels from plants in the open control were not different from plastic control (UV+) for the top leaf, yet significantly higher for leaf 2.

DISCUSSION

Although there is no evidence that *B. alba* plants from the different sites in this study are reproductively isolated, the distances between sites (ca. 150 km) suggest that this may be enough to restrict gene flow. In addition, *B. alba* flowers do not self-pollinate (Ballard, 1986), increasing the possibility of divergent populations with distance. For these reasons, plants at the different sites were treated as distinct populations.

PHT per gram varied within and among populations throughout Florida. Almost none of the interpopulational variation of PHT per gram could be explained by latitude or longitude. Instead, concentrations were scattered throughout the state in no particular order. Although we restricted populations to open canopy locations, sites varied in soil type, water availability, and level of disturbance. Other environmental factors (i.e., nutrients and water) also influence the biosynthesis of secondary compounds (Gershenzon, 1984), but were not measured.

Foliar levels of PHT per square millimeter and leaf biomass (DW) also varied within and between populations, but PHT per square millimeter was not correlated with DW for most sites. This suggests that intra- and interpopulational variation of PHT per gram in leaves could be due to differences in allocation of resources to PHT biosynthesis over biomass.

Differences in PHT per gram from leaves sampled throughout the year were noted. PHT per gram was high in October followed by June, and low in January and April. Significantly higher PHT per gram in June and October may be a result of greater defense requirements during these months because of stronger herbivore pressure. An alternative hypothesis is that PHT per gram was high in late June and October because there was more carbon available for PHT synthesis (i.e., less was allocated to reproduction). Although *B. alba* flowers year round, there is evidence that closely related *B. pilosa* plants require at least 9 hr of low-light (night) to induce flowering (Kirszenzaft and Felippe, 1978). Day length is longest in late June and may have not been short enough by mid-October to stimulate intensive reproduction. In addition, *B. alba* appears to flower more in South Florida in the winter and spring (personal observation).

PHT per square millimeter and DW differed in leaves over the year. They were correlated in June, January and April, but not in October. October PHT per square millimeter was similar to June levels, but DW decreased. This resulted in the highest PHT per gram levels recorded in the study. The decrease in DW from October leaves without influencing PHT per square millimeter may be a mechanism to increase PHT per gram in response to October pressures by allocating carbon to PHT instead of biomass.

PHT per square millimeter levels were influenced by light quantity, but there was no difference for PHT per gram between light quantity treatments.

This was true in part because PHT per square millimeter and DW were correlated with each other. Because of this relationship, it appears as though PHT per square millimeter and DW were similarly influenced by low PPFD, suggesting that carbon may not have been assimilated into growth significantly more than PHT synthesis, which Bryant's model proposes. The correlation between PHT per square millimeter and DW suggests that PHT per square millimeter production might be linked to leaf tissue biomass rather than restricted by limited light.

Low R/FR decreased PHT per gram for the topmost leaf but did not affect leaf 2. The lack of response from leaf 2 may be due to minimized R/FR differences among treatments since lower leaves were shaded by top leaves and surrounding plants. The response of PHT per gram for the topmost leaf to low R/FR is similar to what has been shown for flavonoids. Flavonoid biosynthesis is induced by R and reversed by FR, resulting in less flavonoid biosynthesis when R/FR is low (Piringer and Heinze, 1954; Siegelman and Hendricks, 1957; Beggs and Wellmann, 1985). Therefore, low R/FR may inhibit PHT biosynthesis by a phytochrome-mediated mechanism similar to flavonoids. More research is needed to answer this question.

Decreased levels of UV radiation significantly increased PHT per square millimeter, for the topmost leaf and PHT per gram for leaf 2. UV apears to influence PHT levels in leaves, most likely affecting cuticular PHT, since epidermal leaf layers absorb most of the UV radiation reaching the leaf (Alenius et al., 1995). There are three possible modes of action that might explain these data. First, more PHT may have been photodegraded by higher levels of UV compared to filtered UV treatments. Photodegradation of PHT occurs when PHT is excited by UV (Marchant, 1987). Second, PHT accumulation may have increased in leaves in response to low UV levels to maintain defensive potential. Downum (1992) suggested that the high concentrations of acetylenes commonly found in roots may be a response to low UV occurrence. Third, low UV might allow plants to accumulate higher levels of PHT with less chance for autotoxicity (i.e., tissues might be able to store higher levels of these phototoxic components in the absence of the activating wavelengths of light). Little is known about polyacetylene autotoxicity, but plant cells are susceptible to UV-activated toxicity by PHT (Campbell et al., 1982). The last two hypotheses could be regulated by UV mechanisms. Additional research is needed to address these complex questions.

Does the photoenvironment explain the natural variation seen in geographic and seasonal studies? The variation detected within and among populations in geographic studies does not appear to be caused by light differences across geographic range. This is not surprising since the sampled populations were not that different in elevation or geography and probably did not vary a great deal in light quantity or quality. Some of the PHT per gram variation may be due to R/FR or UV effects from vegetative shading by neighbor plants.

PHT per square millimeter and DW detected in plants throughout the year

can be explained in part by seasonal fluctuations in light quantity for all months except for October. PPFD is highest in the summer and lowest in the winter (Lee and Downum, 1991). Plants in June, January, and April appear to respond to this variation much like the light quantity experiment—low PHT per square millimeter and DW when PPFD is low, and high PHT per square millimeter and DW when PPFD is high. However, plants sampled in October did not respond like plants from the other months suggesting that an alternative factor (i.e., increased herbivore pressures or flowering stage) may be a more likely explanation.

CONCLUSION

PHT concentrations in *B. alba* leaves are variable. There are significant concentration differences among populations, but the geographic location of sites does not explain much of the observed variation. Geographic variation, due to genetic or environmental differences, was not measured in this study. PHT concentrations in leaves were highest in the fall, and this suggests that the plants may need to defend themselves to the greatest extent during this season. Light quantity did not influence PHT concentrations in leaves, but did affect PHT levels and leaf biomass. Light quality influenced PHT concentrations in leaves and may be a regulatory factor in the biosynthesis of PHT. More research is necessary to demonstrate the effects of light quality factors on PHT biosynthesis.

Abstract—Phytohormones play critical roles in regulating plant responses to stress. We investigated the effects of salinity on abscisic acid (ABA), indole-3-acetic acid (IAA), salicylic acid (SA), and jasmonic acid (JA) in leaves, stalks, fruits, and seeds of *Iris hexagona*, a native wetland species. Using gas chromatography–mass spectroscopy with selected ion monitoring, our experiments demonstrated significant and different short- and long-term changes in iris phytohormones. ABA and JA generally increased and IAA and SA declined in response to salinity. We conclude that these phytohormones may have separate and interactive effects on how plants respond and adapt to stress in natural environments.

Key Words—Abscisic acid, *Iris hexagona*, jasmonic acid, indole-3-acetic acid, phytohormones, salicylic acid, salinity, stress.

INTRODUCTION

Increasing salinity from human disturbance and climate change is a critical problem worldwide because it has dramatic effects on plant physiology and performance (Levitt, 1980; Abbas et al., 1991; Brugnoli and Bjorkman, 1992; Morgan, 1984; Delesalle and Mazer, 1996; Morales et al., 1998). Salinity changes nutrient and water availability, lowers the quality of arable lands, and alters the structure of ecological communities. Salinity-induced osmotic stress, the physiological equivalent of drought stress, typically reduces growth and photosynthesis in plants (Pasternak, 1987). Stress can also arise from competition of sodium with nutritive ions, toxicity, and injury of cellular structures (Levitt, 1980). Because most studies have been performed with crop plants, we know little about salinity stress in natural plant populations, and we do not yet understand the role of salinity in the evolution of salt tolerance and plant speciation. Here we present

our research on plant growth regulators in a noncrop, glycophytic plant (*Iris hexagona*) exposed to salinity stress.

Plants produce proteins in response to abiotic (salinity, drought, temperature) and biotic (pathogens, herbivores) stress. Many of these proteins are induced by phytohormones such as abscisic acid (ABA) (Shinozaki et al., 1998; El-Enany, 2000; Jin et al., 2000), salicylic acid (SA) (Thaler et al., 1999; Hoyos and Zhang, 2000) and jasmonates (Chao et al., 1999; Thaler, 1999). The generic stress hormone ABA is up-regulated by salinity and induces genes involved in salt and osmotic alleviation (Serrano and Gaxiola, 1994). In cucumber leaves, salinity raised ABA levels, which subsequently increased cold and heat resistance of seedlings (Talanova and Titov, 1994). In the halophyte *Suaeda maritima*, ABA concentrations fluctuated in response to salinity (Clipson et al., 1988). ABA delayed the deleterious effect of NaCl and improved tolerance to ionic stress in tobacco callus culture (Eberhardt and Wegman, 1989) and in sorghum (Amzallag et al., 1990).

The observation that ABA accelerated adaptation of cultured tobacco cells to salt, but not to equivalent osmotic concentrations of sorbitol and polyethyleneglycol (LaRosa et al., 1985), suggests that ABA levels change more in response to salt than osmotic stress. Salt-induced ABA mediated the inhibition of leaf expansion and limited the accumulation of Na^+ and Cl^- in leaves, thus protecting bush beans from salt stress (Montero et al., 1997).

Jasmonic acid (JA) and its methyl ester, methyl jasmonate (JAMe), are naturally occurring regulators of plant development (Sembdner and Parthier, 1993). Elevated levels of JA can induce pathogen defense genes in soybean (Farmer et al., 1992; Creelman et al., 1992; Chao et al., 1999), reduce leaf abscission (Curtis, 1984), control the opening of rice florets (Zeng et al., 1999), and modulate salinity (Moons et al., 1997) and osmotic stress (Creelman and Mullet, 1995; Finch-Savage et al., 1996). Herbivory can increase JA production (Agrawal et al., 1999), which induces proteinase inhibitors (Farmer et al., 1992; Thaler et al., 1996; Thaler, 1999) and secondary compounds such as nicotine, a highly effective insecticide (Baldwin, 1994; Thaler et al., 1996; McCloud and Baldwin, 1997).

The induction of JA by wounding or pathogens is attributed to the release of fatty acids, by damaged cell membranes which then metabolize via lipoxygenase to JA (Sembdner and Parthier, 1993). Jasmonic acid and its derivatives also respond to salinity. For example, JAMe levels in rice roots increased significantly in 200 mM NaCl (Moons et al., 1997). Furthermore, pretreatment with JA diminished the inhibitory effect of high salt concentration on growth and photosynthesis of barley (Tsonev et al., 1998). Although JA has been linked with crop plant stress responses (Moons et al., 1997; Creelman and Mullet, 1995; Finch-Savage et al., 1996), there is no information about how salinity affects endogenous JA levels in natural plant populations.

Salicylic acid (SA) belongs to a diverse group of plant phenolics and is

associated with the chemical defense of plants against microbes and herbivores (Raskin, 1992; Thaler et al., 1999). It is widely distributed in monocot and dicot plants (Cleland and Ajami, 1974; Swain et al., 1985; Raskin et al., 1990). Plants are most likely to synthesize SA from cinnamic acid (Chadha and Brown, 1974), via phenylalanine–ammonialyase (PAL) activity. Increased endogenous SA levels coincide with accumulation of pathogen-induced proteins and elevated virus resistance in tobacco (Yalpani et al., 1993). Ethylene and various biotic and abiotic stresses such as salinity, chilling injury, and high temperature are known to increase PAL activity (Enyedi et al., 1992; Martinez-Tellez and Lafuente, 1997; Tomas-Barberan et al., 1997; Dunn et al., 1998), possibly contributing to enhanced SA levels.

SA has antagonistic effects on JA by preventing its accumulation in response to wounding. In flax SA inhibits transcription of allene oxide synthase (AOS), which mediates the conversion of lipoxygenase-derived fatty acid hydroperoxides to unstable allene epoxides and then to JA precursors (Harms et al., 1998). The wound-induced increase of leucine aminopeptidase (LapA) RNAs, which is up-regulated by ABA, JA, salinity, and water deficit, was inhibited by SA (Chao et al., 1999). SA also induces acidic pathogen-related (PR) genes and inhibits basic PR genes, whereas JA does the opposite (Niki et al., 1998). SA also reduced the synthesis of tomato proteinase inhibitors (Doares et al., 1995). Antagonistic interactions between SA and jasmonic acid affect the expression of PR protein genes in tomato (Thaler et al., 1999). Two drought-inducible genes in the drought-tolerant cowpea (*Vigna unguiculata*) were identified after treatment with high salinity and exogenous ABA. One of these genes was also expressed in response to heat stress, methyl jasmonate, and SA (Iuchi et al., 1996), suggesting that SA affects plant resistance to stress.

Indole-3-acetic acid (IAA) plays a major role on regulating plant growth. For example, it controls vascular tissue development, cell elongation, and apical dominance. IAA also responds to salinity in crop plants. There was a significant reduction in IAA levels in rice five days after exposure to NaCl (Nilsen and Orcutt, 1996) and salinity reduced IAA levels 75% in tomato roots (Dunlap and Binzel, 1996).

To our knowledge, this is the first investigation to link ecological responses and phytohormonal induction in natural plant populations under environmental salinity stress. The research is important because it can reveal the endogenous mechanisms that impart stress resistance and provide insight into the potential for native plants to adapt to environmental change.

METHODS AND MATERIALS

Plant Material. Iris hexagona Walter (Iridaceae) is a long-lived perennial that inhabits freshwater wetlands. Plants reproduce clonally via rhizomes and

sexually by fruits that contain up to 60 seeds. Although irises typically occur in fresh-water habitats, our populations are located in the saline soils (4–15 g/liter) of Marsh Island, a 33,000-ha salt marsh located off the coast of Louisiana, USA (92°W 29.5°N).

In March 1997, we collected a total of 300 rhizomes from 10 Marsh Island *I. hexagona* populations and planted them in a common garden in 30 Rubbermaid tubs (220 liters) filled with topsoil. The common garden was located at the Center for Ecology and Environmental Technology at the University of Louisiana at Lafayette. To investigate long-term effects of salinity stress, we randomly assigned tubs to low (LS, 15 mM), medium (MS, 50 mM), and high (HS, 100 mM) salinity treatments, consistent with levels in the natural *I. hexagona* habitat, and maintained the garden for 19 months. In this paper we report on the effects of the low and high salinity treatments.

Salinity Treatment. We established and sustained salinity levels in the common garden with Instant Ocean (Aquarium Systems, Inc., Mentor, Ohio), and monitored tubs weekly with an Orion 125 conductivity meter (Orion Research Inc., Beverly, Massachusetts). ABA, IAA, JA, and SA levels in leaves, seeds, seed pods, and flower stalks were determined at monthly intervals in 1998 and 1999. To investigate short-term responses to salinity we conducted a laboratory experiment and measured iris phytohormones 24 and 48 hr after exposure to 0, 100, 200, and 400 mM NaCl.

Extraction, Purification and Methylation of ABA, IAA, JA and SA. We collected samples on ice and either stored them in a −70°C freezer or extracted them immediately. About 1–2 g of tissue was weighed and ground into powder under liquid N_2. Then 200 ng of internal standards (D_2-ABA, [^{13}C] IAA, D_2-JA) and radioactive tracers—50,000 cpm of [^{3}H] ABA (53 Ci/mmol, Amersham Life Science), [^{3}H] IAA (27 Ci/mmol, Amersham Phamacia Biotech), [^{3}H] JA, 50 Ci/mmol, American Radiolabeled Chemicals Inc.) and 25,000 cpm of [^{14}C] SA (11.7 mCi/mmol, Sigma #S8644, carboxyl group labeled SA) were added and the samples extracted in 10 ml isopropanol overnight at 4°C. The supernatant was centrifuged (2500*g* for 5 min, 4°C), and collected in a 25-ml flask. Three additional extractions with 2 ml of 100% isopropanol were combined and reduced to the aqueous phase in a rotary evaporator and then diluted to ca. 20 ml with water and 0.5 ml of 0.1 M imidazole buffer (pH 8.0). The four components were prepurified using NH_2 columns (Alltech #211150). After priming the columns with methanol, 5% acetic acid, and water, the samples were applied, washed with hexane and methanol, and eluted with 75% methanol containing 0.3 N HCl, dried in a rotary evaporator, and taken up in 3×45 μl 36% MeOH. Then 100 μl of each sample was purified by HPLC (Dionex 500 equipped with a 50×4.6 mm ODS column, Phenomenex 00B-0351-E0) and eluted with 1% acetic acid in 36% MeOH (1 ml/min) for 19 min. The MeOH concentration was raised linearly to 50% within 7 min, and the column was isocratically eluted for

another 9 min. Under these conditions, the retention times for IAA, SA, ABA, and JA were 11, 16, 24, and 30 min, respectively. The two or three 1-ml fractions with the highest radioactivity of each compound were combined, dried in vacuo, methylated with 0.5 ml ethereal diazomethane, dried, and taken up in 50 μl of ethyl acetate. Since no deuterated standard was available for SA, 100 μl of ethyl acetate was used, and losses were determined by measuring the radioactivity of half of that amount. The cumulative losses during the purification resulted in efficiencies of 52–58% for ABA, 59–65% for IAA, 50–52% for JA, and 70–76% for SA.

Determination of ABA, IAA, JA and SA. Aliquots (1–2 μl) of the methylated ABA, IAA, JA, or SA samples were analyzed with an HP 6890 GC equipped with a HP 5973 mass selective detector using selected ion monitoring. Chromatography was carried out on a capillary column (15 m $\times$ 0.25 mm $\times$ 0.25 μm, J&W DB-1701) with helium as carrier gas (1.5 ml/min). For ABA and IAA the oven temperature started at 160°C and after 1 min was ramped to 280°C at 20°C/min. For JA analysis the initial temperature was 120°C, and it was raised at 20°C/min after 1 min. SA analysis started at 60°C for 1 min with a ramp of 20°C/min to 130°C and then 40°C/min to 280°C. Under these conditions, the retention times were 5.25, 4.0, 4.5, and 4.3 min for ABA, IAA, JA, and SA, respectively. The relative abundance of representative fragments for ABA (m/z 190/193), IAA (m/z 130/136), JA (m/z 151/153), and SA (m/z 120) was used for quantification. All analyses were performed in triplicate. The data were calculated as mean $\pm$ SE in micrograms per gram of dry weight (DW).

Statistical Analysis. We used full-factorial and repeated-measure analysis of variance to test the effects of salinity, time, and tissue type on ABA, IAA, JA, and SA concentrations [SAS PROC GLM Version 6 (SAS) Institute, 1994). Data were transformed when necessary to meet assumptions of normality and homogeneity of variance. To determine differences between individual groups, we conducted paired comparisons using Tukey-adjusted least-square means.

RESULTS

Short-Term Effects of Salinity on ABA, JA, IAA, and SA

In laboratory experiments, salinity had short-term effects on all four phytohormones examined (Figure 1). After about eight days, the leaves of plants exposed to 400 mM salt wilted and eventually died but lower salinities were tolerated. ABA content in leaves varied from 0.2 to 1.2 μg/g DW and increased in response to salinity concentration ($F_{3,16} = 24.41$, $P = 0.0001$) and duration of exposure ($F_{1,16} = 4.69$, $P = 0.046$). In paired comparisons, ABA significantly increased after 48 hr of exposure to 400 mM NaCl ($P = 0.0143$). Although 100–200 mM NaCl had a weaker short-term effect on ABA levels, there were

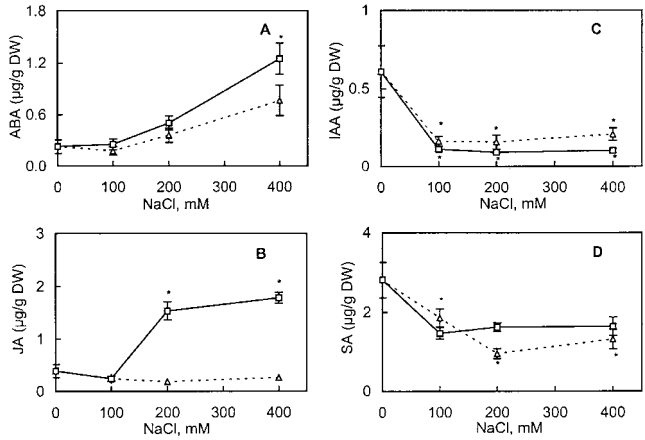

FIG. 1. Effect of 100, 200, and 400 mM NaCl on levels of ABA (A), JA (B), IAA (C) and SA (D) of *Iris hexagona* immature leaves after exposure for 24 (△) and 48 (□) hours. The bars represent standard errors. $^{*}P < 0.05$ as compared with controls (no added NaCl).

significant effects after long-term exposure in the field experiment.

In young leaves, JA content increased in response to salinity concentration ($F_{3,16} = 14.0$, $P = 0.0001$) and duration of exposure ($F_{1,16} = 77.6$ $P = 0.0001$) and ranged from 0.2 to almost 2 μg/g DW (Figure 1B). NaCl at 200 ($P = 0.0026$) and 400 ($P = 0.0008$) mM caused significant increases in JA content within 48 hr.

In contrast to ABA and JA, IAA content rapidly declined in young leaves exposed to salinity (Figure 1C) and was the most sensitive of all four phytohormones to the NaCl treatment ($F_{3,16} = 28.5$, $P = 0.0001$). Within 24 h of exposure to 100 mM NaCl, IAA levels fell from about 0.6 to <0.2 μg/g DW ($P = 0.0001$). The 24-hr IAA reductions were statistically similar to IAA levels after 48 hr of exposure.

Similar to IAA, SA levels in young leaves declined significantly in response to salinity ($F_{3,16} = 17.9$, $P = 0.0001$, Figure 1D). Within 24 hr after treatment with 200 mM NaCl, SA dropped from 2.8 to <1.7 μg/g DW ($P = 0.0001$). The SA reduction was strongest after 24 hr of exposure to 200 ($P = 0.0001$) and 400 mM NaCl ($P = 0.0002$).

Long-Term Effects of Salinity on Phytohormones

Abscisic Acid. In the common garden experiments, leaf ABA levels were greater in high salinity (HS, 100 mM) than low salinity (LS, 15 mM) plants over a six-month time period ($F_{1,4} = 37.7$, $P = 0.004$, Figure 2A). In both salinity

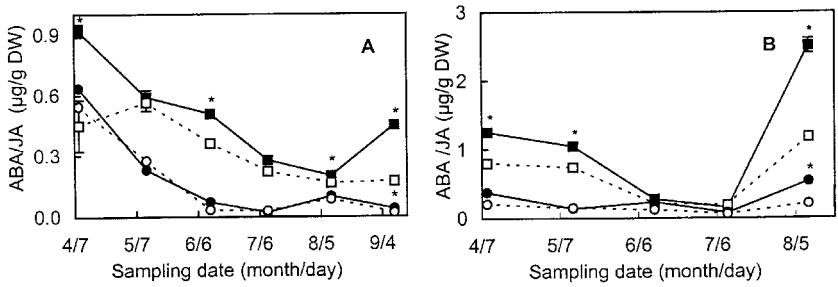

FIG. 2. Temporal change of ABA (squares) and JA (circles) levels in *Iris hexagona* leaves (A) and apex of flower stalks (B) exposed to 100 mM (HS, solid symbols) and ~15 mM (LS, open symbols) salinity. $^{*}P < 0.05$ in pairwise comparison between salinity treatment at the same time.

treatments, ABA levels decreased significantly from May through August, ($F_{1,5} = 37.1$, $P = 0.0001$), then rose significantly in the HS group in September ($P = 0.013$).

After anthesis (early April), the apical parts of HS stalks (Figure 2B) maintained significantly higher ABA levels than LS stalks in every month except June and July ($F_{1,4} = 209.5$, $P = 0.0001$). Towards the end of the growth season (August) ABA levels increased significantly in both LS and HS flower stalks, but the increase was much stronger in HS plants ($P = 0.004$), possibly due to impending abscission.

The ABA concentrations in developing immature flower stalks ranged from <1 to almost 2 μg/g DW (Figure 3A) and were significantly greater under high salinity ($F_{1,36} = 8.22$, $P = 0.0069$). The site of ABA production shifted during stalk development from the basal to the apical region ($F_{4,36} = 2.79$, $P = 0.041$), with the highest concentrations appearing in the central portion of 60-cm stalks ($P = 0.027$) and the apical portion of 90-cm stalks ($P = 0.037$).

The concentration of ABA was higher in developing seeds than pods (Figure 4A), regardless of salinity treatment ($F_{1,4} = 350.6$, $P = 0.0001$). ABA peaked between 20 and 40 days after anthesis ($F_{1,8} = 63.4$, $P = 0.002$) with concentrations of 10–17 μg/g DW. High-salinity seeds had higher ABA levels than low-salinity seeds ($F_{1,8} = 11.3$, $P = 0.01$). By day 60, seeds were fully developed and ABA concentrations had returned to their initial levels in both salinity treatments. The ABA in pods was low throughout seed development (<2 μg/g DW) and was not affected by salinity.

Jasmonic Acid. Salinity had no significant long-term effect on JA levels in the leaves of HS and LS plants (Figure 2A). Similar to the ABA profile, the JA levels decreased significantly early in the growth season from about 0.6 μg/g DW, to <0.1 μg/g DW ($F_{5,15} = 25.0$, $P = 0.001$) and then remained low. After

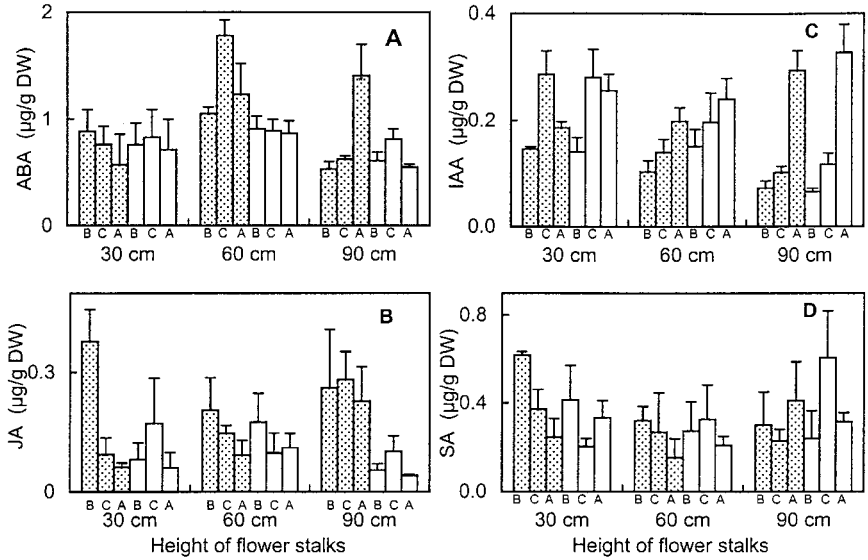

FIG. 3. Distribution of ABA (A), JA (B), IAA (C), and SA (D) in the flower stalks of *Iris hexagona* at different growth stages in the presence of 100 mM (HS, stippled) and ~15 mM (LS, open) salinity. The data are given for the base (B), center (C) and Apex (A) of young (30 cm), medium (60 cm) and mature (90 cm) stalks. $^{*}P < 0.05$ in pairwise comparison between salinity treatment at the same time.

anthesis (Figure 2B), salinity significantly increased JA content in the apical parts of flower stalks ($F_{1,4} = 10.8$, $P = 0.02$). Similar to ABA, JA concentrations rose significantly in HS stalks in August ($P = 0.004$).

Salinity had a significant positive effect on JA in developing stalks (Figure 3B). A higher JA content was measured in HS flower stalks than in LS stalks ($F_{1,36} = 9.43$, $P = 0.004$). In contrast, the JA levels did not vary significantly among the stages of development. On average, slightly more JA was produced in the basal stalk regions ($P = 0.048$), but 90-cm-long stalks showed a higher JA concentration in HS stalks.

There were significant differences between seeds and pods in JA production ($F_{1,8} = 11.1$, $P = 0.01$, Figure 4B) and the pattern of production reversed over time. For example, seeds produced more JA than seed pods in the earliest time period ($P = 0.002$), but significantly less than seed pods in all but the final stage ($P = 0.0001$, 0.0004, 0.02, and 0.76, respectively). In further contrast with ABA, JA levels were highest on average in LS than HS tissue ($F_{1,8} = 7.3$, $P = 0.027$, Figure 4B). Time also affected JA production ($F_{5,4} = 58.2$, $P = 0.0008$). After 40 days, JA concentrations decreased from >1.0 to <0.15 μg/g DW in both salinity

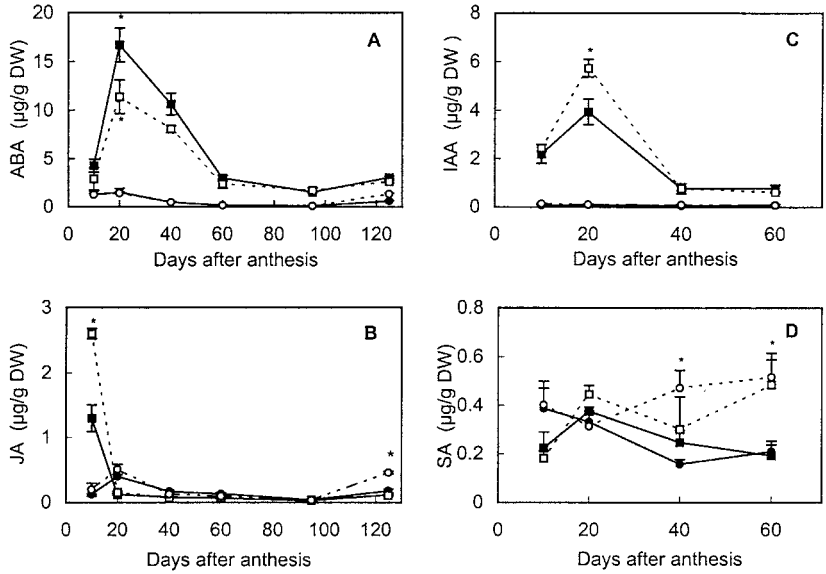

FIG. 4. Temporal change in ABA (A), JA (B), IAA (C), and SA (D) levels of seeds (squares) and pods (circles) of *Iris hexagona* growing in high (HS, 100 mM, solid symbols) and low (LS, ~15 mM, open symbols) salinity following anthesis. $^{*}P < 0.05$ in pairwise comparison between salinity treatment at the same time.

treatments and remained flat for the rest of the growth period, except for a small but significant late-season rise in LS pods ($F_{1,4} = 33.4$, $P = 0.0004$).

Indole-3-acetic Acid. Salinity caused a slight reduction of IAA in developing flower stalks ($F_{1,44} = 3.61$, $P = 0.064$), but tissue type ($F_{2,44} = 30.4$, $P = 0.0001$) and stalk height ($F_{2,44} = 5.31$, $P = 0.009$) had much stronger effects (Figure 3C). The IAA content of growing stalks ranged from <0.1 to 0.35 μg/g DW, and there was an increasing basipetal gradient in the 60-cm and 90-cm stalks of both LS and HS treatments.

Seeds produced significantly more IAA than pods ($F_{1,8} = 163.0$, $P = 0.0001$) and initial seed development was characterized by an increase in IAA ($F_{1,8} = 94.4$, $P = 0.0001$, Figure 4C). HS seeds produced significantly less IAA than LS seeds at 20 days after anthesis ($P = 0.018$) but did not differ thereafter. The IAA content of pods was low throughout seed development and unaffected by salinity.

The weak effect of salinity on IAA levels (Figure 3C) corresponds to the similarity in growth rates of HS and LS flower stalks (Figure 5). Growth rates varied from 3 to 6 cm/day and were most strongly affected by time ($F_{23,272} = 17.4$, $P = 0.0001$) and temperature ($R^2 = 0.4$, $P = 0.0001$).

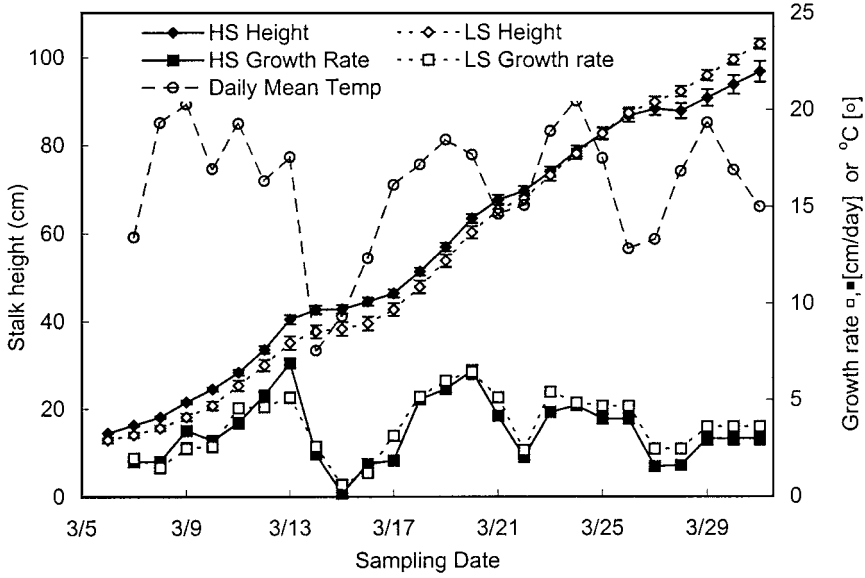

FIG. 5. The effect of salinity on the length and daily growth rate of *Iris hexagona* flower stalks prior to anthesis. Iris were grown in low (~15 mM) and high (100 mM) salinity. For the sake of comparison, the daily mean temperature during this time period is shown as well.

Salicylic Acid. SA ranged from 0.2 to 0.6 μg/g DW (Figure 3D) and salinity had no effect on the production of SA in developing flower stalks. There was a significant effect of stalk height on SA, with 30-cm and 90-cm stalks producing more SA on average than the 60-cm stalks ($F_{2,35} = 6.3$, $P = 0.005$). The SA levels did not develop into a consistent gradient within the stalks.

Salinity had an overall negative effect on SA production in seeds and pods ($F_{1,8} = 8.9$, $P = 0.02$, Figure 4D), and it was most pronounced 60 days after anthesis ($P = 0.006$). Similar to JA, there was a significant interaction between tissue type and time ($F_{3,8} = 7.5$, $P = 0.02$). The SA concentration in LS pods increased over time while that of the HS pods decreased. This interaction was caused primarily by a reversal in the pattern of SA production by seeds and pods 20 days after anthesis ($F_{1,8} = 14.9$, $P = 0.005$).

DISCUSSION

The response of plants to stress involves complex physiological and biochemical responses, including changes in the concentration and ratios of endoge-

nous phytohormones. This is the first study that examines the spatial and temporal fluctuations of four growth regulators in a noncrop plant in response to salinity. The data indicate that salinity has significant and differential effects on the four growth regulators: ABA and JA increase and IAA and SA decline in response to plant salinity stress.

ABA is a generic stress hormone that has multiple functions, including the induction of genes involved in osmotic stress protection (Serrano and Gaxiola, 1994). Our results showed that salinity increased ABA contents in both young and mature *I. hexagona* leaves (Figures 1 and 2). This is consistent with other plant species that increase ABA production in response to salinity (Talanova and Titov, 1994; Clipson et al., 1988; Moons et al., 1997; Montero et al., 1997). ABA concentrations fluctuated among different segments of the flower stalks and during different developmental stages (Figures 2–4), therefore no specific tissue or ontogenetic state can be identified as most responsive to salinity-elevated ABA levels. Generally, the central and apical portions of mature flower stalks contained the highest ABA levels (Figure 3), establishing a basipetal gradient. Therefore, these areas are likely sites of ABA biosynthesis.

The ABA content of seeds is especially important because it influences seed dormancy patterns (Baskin and Baskin, 1998; Skriver and Mundy, 1990). Our determination that the highest ABA concentrations occurred in immature seeds and declined with seed maturation (Figure 4) supports evidence that ABA inhibits germination (Skriver and Mundy, 1990; Baskin and Baskin, 1998). Therefore, the higher level of ABA in HS plants may result in delayed seed germination relative to LS plants.

There are several mechanisms by which elevated ABA could increase plant resistance to stress. ABA can improve water permeability (Glinka and Reinhold, 1971), and it induces late-embryogenesis abundant proteins (LEA), osmoprotectants, and osmolyte biosynthesis genes (Thomas and Bohnert, 1993; Zhu et al., 1997). An ABA-inducible group of proteins (e.g., dehydrins, LEA) are thought to protect cells from water deficit and freezing by stabilizing other proteins and membranes (Thomashow, 1999).

Salinity-induced ABA may affect the reproductive success of iris by influencing embryonic development and the duration of seed dormancy. This notion is supported by the observation that in iris, seed number and germination rate increased in seeds derived from salinity-stressed plants (unpublished data). In contrast to seeds, ABA levels in iris seed pods did not change in response to salinity (Figure 4), indicating that seeds are a major target and possibly site of ABA synthesis.

JA is a fundamental signaling molecule in all plants and has been identified in over 160 plant families (Sembdner and Parthier, 1993). The level of JA in plant tissues varies as a function of tissue type, development, and external stimuli. The highest levels of JA are typically found in flowers and reproduc-

tive tissues (Creelman and Mullet, 1995). JA is known to increase in response to mechanical wounding and water deficit (Creelman and Mullet, 1997), herbivory (Thaler et al., 1996, McCloud and Baldwin, 1997; Thaler et al., 1999), microbial cell wall elicitors (Blechert et al., 1995), the plant signaling peptide systemin (Bergey et al., 1996), and salinity (Tsonev et al., 1998).

Our analysis revealed significant effects of salinity on JA levels. The response is stronger in young leaves and flower stalks than in later stages of development (Figures 1 and 3). Because JA and ABA levels increase in vegetative structures (Figure 2A and B), these hormones may act synergistically in raising salinity tolerance. However, JA levels decline during seed development and were generally reduced in HS plants (Figure 4B). Alternatively, salinity-enhanced ABA levels may inhibit JA production in seeds by reducing the amount of linolenic acid, a precursor of JA biosynthesis (Creelman and Mullet, 1997).

Exogenous JA inhibits seed germination in *Brassica napus* and flax (Staswick and Lehman, 1999). Although we have no evidence that JA inhibits germination of iris seeds, immature LS seeds contain higher concentrations of JA (Figure 4B), and LS seeds germinate at a slower rate than seeds from HS plants (unpublished data). This hypothesis could be tested by external application of JA to seeds.

Salinity significantly reduced IAA levels in leaves and seeds (Figures 1C and 4C), consistent with observations in rice (Nilsen and Orcutt, 1996) and in tomato (Dunlap and Binzel, 1996). Reduced IAA levels may contribute to the reduced above-ground biomass observed in HS-grown iris (unpublished data). Lower IAA contents could also explain the greater number of aborted seeds in HS plants that was noticed during sample prparation. However, this may be compensated for by the increase in the total number of seeds in the HS plants (data not shown).

Significantly higher levels of IAA and zeatin riboside occurred in response to stress in *Rosmarinus officinalis L.*, a Mediterranean shrub that does not accumulate ABA when subjected to water stress (Lopez-Carbonell et al., 1996). Iris accumulated ABA and therefore the combined effect of elevated ABA and reduced IAA levels are likely to diminish growth. The similarity in growth rate and final length of Iris flower stalks from both salinity regimes (Figure 5), and the identical IAA content in developing stalks (Figure 3C) suggests that the transition to the generative growth phase (formation and development of flower stalks) is the most carefully controlled stage of iris ontogeny. The fluctuations of ABA and IAA in the generative tissue (Figure 4A and C) may be an important process for seed development in salinity-stressed plants. The salinity-reduced IAA levels could cause delayed acquisition of resources necessary for generative growth and seed development.

SA and its methyl acetate can inhibit the biosynthesis and activity of JA (Pena-Cortes et al., 1993; Harms et al., 1998), which is supported by the oppo-

site responses of Sa and JA in iris leaves, seeds, and pods (Figures 1B and D, 4B and D). A similar inverse relationship between SA and JA has been reported in *Arabidopsis* (Gupta et al., 2000), suggesting that the ratio of SA and JA may also indicate salinity stress. In our experiments, salinity caused a significant reduction of SA in young iris leaves, seeds, and pods (Figures 1D and 4D). However, there was no difference in SA levels in the LS and HS flower stalks (Figure 3D). Low-salinity seeds and pods had higher SA levels than HS reproductive tissues, and the difference increased with time (Figure 4D). The significant decrease in SA content in young iris leaves (Figure 1) and changed content in seeds and pods (Figure 4D) could have implications for the sensitivity to pathogens. Pathogens increase SA levels (Yalpani et al., 1993; Thaler et al., 1999), and a combined effect of salinity and pathogens would lead to a stronger defense response, ostensibly leading to greater resistance against pathogen attack of stressed plants. The same synergistic effects between salinity and SA possibly account for the induction of drought-inducible genes in cowpea (Iuchi et al., 1996).

We have demonstrated that salinity at levels experienced by natural populations profoundly affects four important iris growth regulators. The reduction of SA and IAA and the increase of ABA and JA in salinity-exposed plants suggest interactive phytohormone effects on plant growth and reproduction. Although iris vegetative biomass is substantially reduced by salinity, the seed number and germination success increased significantly (unpublished data). Our experiments indicate that phytohormones play critical roles in plant responses to salinity. Our data are consistent with the concept that hormonal responses in plants control the allocation to generative and vegetative performance, thereby increasing survival in and adaptation to stressful environments.

Acknowledgments—We are indebted to Ed Mouton and the Louisiana Department of Wildlife and Fisheries for invaluable biological and logistical support. We thank Peter Van Zandt and Mark Tobler for outstanding field and laboratory assistance. This research was supported by National Science Foundation grant DEB-96-32302 to SM and KHH, and by Sigma-Xi and University of Louisiana Graduate Student Organization grants to Y.W.

Abstract—The growth–differentiation balance hypothesis (GDB), which postulates a physiological trade-off between growth and differentiation (morphological and chemical), has been tested almost exclusively for carbon-based secondary metabolites. Little attention has been paid to N-based compounds. In this study we aimed to test the predictions of the GDB hypothesis under field conditions for growth and pyrrolizidine alkaloid (PA) formation in *Senecio vulgaris*. We conducted a reciprocal transplant experiment at two sites differing widely in their nutrient supply. These included a conventionally managed vineyard (V) and a strip of local wild flowers between crop fields, which was established to promote species diversity in agroecosystems (C). No fertilizer or pesticides are allowed in such ecological compensation areas. In C, we expected lower growth but higher PA formation than in V. Due to differentiated selection regimes in the two habitat types with regard to nutrient (nitrogen) availability in the soil, we also expected different N-allocation patterns for the genotypes of the two collection sites. Plants of V produced more biomass and were taller than the plants of C. The relatively poor nitrogen conditions in C favored an earlier differentiation towards generative organs. In plants of C, higher concentrations of PAs were found than in plants of V. There exists a close negative correlation between growth and PA formation, indicating a trade-off. The origin of the plant

material had only a little effect on PA formation. The observed phenotypic reaction of PA formation in *S. vulgaris* in the two habitats fits quite well the predictions of GDB theory. It is shown that this general response is overlaid by physiological factors leading to a pattern of PA accumulation, which is not readily predictable by nonmechanistic theories.

Key Words—Environment, growth, growth–differentiation balance hypothesis, phenotypic plasticity, pyrrolizidine alkaloids, secondary metabolism, *Senecio vulgaris*.

INTRODUCTION

It is widely accepted that phytochemicals play an important role in ecological interactions by, for example, protecting plants against herbivores and pathogens, providing specialized herbivores with ecological niches, or by modulating litter decomposition (for reviews see Rosenthal and Berenbaum, 1992; Harborne, 1993). Inversely, plant secondary metabolism is known to be influenced by environmental parameters. Since these are increasingly changed by human activities, it is important to understand the related phenotypic reactions or adjustments of secondary metabolism. Specifically, the increase of both CO_2 and nitrogen forms available to plants is a new and relevant issue to be investigated in this context (Heyworth et al., 1998).

Two basic concepts dealing with the phenotypic response of secondary metabolism to the above-mentioned parameters have been proposed. The carbon–nutrient balance hypothesis (CNB) (Bryant et al., 1983) postulates limited growth and reduced N-based phytochemicals, but favored accumulation of carbon-based secondary metabolites such as phenolics, terpenoids, and tannins when carbons dominate over nutrients (primarily nitrogen). An excess of nitrogen (over carbon) results in preferential allocation of nitrogen-based compounds such as alkaloids or cyanogens. Due to such imbalances, growth may remain suboptimal.

The growth–differentiation balance hypothesis (GDB) (Loomis, 1953; Herms and Mattson, 1992) centers on a physiological trade-off between growth and differentiation. Plant tissue grows either by division or expansion of cells, or differentiates chemically and/or morphologically. As both growth and differentiation are dependent on photosynthetic products, they are, in terms of metabolism, negatively correlated with each other, whereby differentiation is thought to include secondary metabolism. The hypothesis states that: when resource availability is low, both growth and differentiation are reduced; at intermediate resource levels differentiation is favored; and at high resource levels growth prevails.

Unfortunately the CNB and GDB hypotheses have been tested almost exclu-

sively for carbon-based secondary metabolites and little attention has been paid to N-based compounds. Nevertheless, the formation pattern of phenolics appears to be in accordance with both hypotheses. Elevated CO_2 led to an increase in the concentration of phenolic compounds, and their concentration was found to decrease after fertilization (e.g., Muzika, 1993; Gebauer et al., 1998; Peñuelas and Estiarte, 1998).

The majority of studies do not support either theory with regard to nitrogen-based secondary metabolites. For instance, *Nicotiana attenuata* is homeostatic in its patterns of nitrogen allocation to nicotine and to growth. Under laboratory conditions, an eightfold nitrogen supply had no effect on either the constitutive or methyljasmonate-induced nicotine accumulation when allometrically related to growth (Lynds and Baldwin, 1998). In *N. sylvestris*, nicotine accumulation continues during nitrogen stress (Baldwin et al., 1993). It was concluded that nitrogen allocation to nicotine is not dependent on nitrogen in excess of growth requirements (Baldwin et al., 1993; Ohnmeiss and Baldwin, 1994). For pyrrolizidine alkaloids (PAs) in *Senecio jacobaeae*, no negative relationship between growth and differentiation could be found (Vrieling and van Wijk, 1994). Deficiencies of mineral nutrients including N did not significantly alter PA concentrations in flower heads of *Senecio vulgaris* under growth chamber conditions (Brown and Molyneux, 1996). GDB theory is supported by the work of Höft et al. (1996) who found that nitrogen supply resulted in enhanced alkaloid accumulation in *Tabernaemontana pachysiphon* under greenhouse conditions. Moderate fertilization was more effective than abundant nitrogen supply.

The above-mentioned studies testing CNB and GDB hypotheses in view of nitrogen-based secondary metabolites were carried out under greenhouse or laboratory conditions and were not conclusive. It is essential to investigate these models under field conditions so that the plants are exposed to the entire array of physical factors. Clarifying the validity of these hypotheses also is important from a nature conservation view. The fulfilment of the GDB predictions in heavily fertilized soil, for instance, suggests a decrease of the allelochemical concentration in the plant body. This will influence not only plant survival but also the fitness of associated specialist insect herbivores (for reviews see Rosenthal and Berenbaum, 1992; Harborne, 1993).

In an agroecosystem of northern Switzerland, we examined GDB in *Senecio vulgaris* by choosing two habitats differing widely in their nutrient supply. These were a conventionally managed vineyard and a strip of local wild flowers between crop fields, which was established to promote species diversity in agroecosystems. No fertilizer or pesticides are allowed in such ecological compensation areas. The Swiss government financially subsidizes farmers for setting aside arable land for ecological purposes.

PA formation in the predominantly inbreeding *S. vulgaris* provides an excellent model to study phenotypic plasticity of PA formation and possible

effects on specialized herbivores. PAs are feeding deterrents for most herbivores (Hartmann, 1999) and are hepatotoxic to vertebrate (Mattocks, 1986) and mutagenic to insects (Frei et al., 1992). The use of PA by specialist insects is well documented (Boppré, 1995; Hartmann, 1999). Specialized insect herbivores such as *Arctia caja* and *Thyria jacobaea* (Lepidoptera: Arctiidae) (Hartmann and Witte, 1995), which were, among other species, associated with *S. vulgaris*, were favored. Both species are recorded in the study area and are on the red list of endangered species (Bundesamt für Naturschutz, 1998).

Sites of PA biosynthesis are the roots, where the key compound senecionine *N*-oxide is produced (Sander and Hartmann, 1989) and its formation is quantitatively controlled. Senecionine *N*-oxide is translocated to the above-ground plant parts (Hartmann et al., 1989) and subsequently subjected to chemical diversification specific to species and populations (von Borstel et al., 1989; Witte et al., 1992). The total amount of alkaloids is not changed by this diversification. Senecionine *N*-oxide and the transformation products are spatially mobile but do not underlie degradation (Hartmann and Dierich, 1998).

A reciprocal transplant experiment was carried out with seed material originating from a vineyard and an ecological compensation area, which were closely located and ecologically similar to the experimental sites. The first aim was to test the predictions of the GDB hypothesis under field conditions. In the compensation area we expected lower growth but higher PA formation than in the vineyard. Secondly, due to differential selection regimes in the two habitat types with regard to nitrogen availability in the soil, we also expected different N-allocation patterns among the genotypes of the two collection sites. Thirdly, we aimed to clarify whether plants growing in compensation areas with low N input may allocate higher levels of PAs and benefit specialized insect herbivores.

METHODS AND MATERIALS

Plant Material and Design of Field Trials. Achenes of *S. vulgaris* were randomly sampled in 1997 in the Klettgau region of northern Switzerland (Canton of Schaffhausen) in both a vineyard and an ecological compensation area ca. 5 km apart. Achenes from 10 individual plants per site were grown for one generation in the greenhouse at the University of Fribourg to reduce possible maternal effects. In April 1998, achenes from five individuals (maternal seed families) from each site were sown in seed trays containing nutrient-poor soil in the greenhouse. After 19 days, seedlings were planted into two field plots (1×3.5 m) located in an ecological compensation area (C) and in a vineyard (V), respectively. All vegetation was removed in these plots before planting the seedlings. Field plots were in close (200 m) to each other and located near where the original material had been collected. In each habitat, 10 individuals from each

seed family and from both origins (C and V) were randomly assigned to plant positions in a regular grid of 15 × 15 cm, resulting in 100 plants per site. In the vineyard trial it was necessary to replant, since all seedlings suffered from herbivory (most probably slugs) during the first night. Replanting resulted in a delay of 14 days for the whole experiment.

Harvesting and Determination of Growth Parameters. Above-ground biomass from each of three randomly selected plants from each family was harvested around midday at 18 and 37 days after planting, i.e., 37 days and 56 days after sowing. After determination of plant height, leaf numbers, and fresh weight, the material was dried at 70°C to measure the dry weight. At the second harvest, plants were dissected into vegetative (stem and leaves) and generative parts (flower heads).

Soil Nitrogen Analysis. At the second harvest, five soil samples were randomly collected from the upper 30 cm of soil and pooled to determine total mineralized nitrogen (N_{min}, NO_3, and NH_4). The analysis was carried out photometrically by Schweizer AG, (Laboratory of Soil Analytics and Environmental Technologies, Thun, Switzerland), according to the N_{min} method of Scharf (1977).

Extraction of PA. The method of Hartmann and Toppel (1987) was slightly modified: the dried and finely powdered plant material was extracted with 0.05 M H_2SO_4 (ca. 25–50 mg/ml) at room temperature for 1 hr by sonication. An aliquot of the extract was transferred into a 2-ml Eppendorf tube and centrifuged. Then, 500 μl of the supernatant was mixed with 300 mg freshly reground (in a mortar) zinc dust and vigorously shaken for 5 hr in order to reduce the PA N-oxides. After centrifugation, 400 μl of the extract was removed and the pH adjusted with concentrated ammonia to ca. 8.0, as estimated by dotting on an indicator stripe. The extract was applied onto a Kieselgur column (Extrelut, Merck, Darmstadt, Germany) in a Pasteur pipet, and after 5 min, elution was carried out with 6 ml CH_2Cl_2. After passive evaporation of the solvent at room temperature, the residue was dissolved in 400 μl methanol. In a few cases, where the plant sample weight was below the standard extraction measure, the volume parameters were adjusted. The purification procedure resulted in a loss of 16, 31, and 27% of retrorsine, seneciphylline, and senecionine, respectively, as determined by reference compounds. The presented values were adjusted accordingly.

HPLC. Separation of PA was performed on a Nucleosil 100-5 ODS (Stagroma) column (5 μm; 4.6 × 250 mm; precolumn 4 × 20 mm) with 50 mM KPi buffer (with 1% THF), pH 2.5 (buffer A) and MeOH (with 1% THF) (buffer B) at a total flow rate of 1 ml/min and by the following gradient (% B over A): 0 min (5), 0–14 min (10), 14–25 min (50), 25–26 min (5); and 26–35 min (5). Parameters were controlled by a Hewlett Packard liquid chromatography (model HP 1090) equipped with a diode array detector set at 216 nm. Peak identification was achieved by comparing UV spectrum and R_t of authentic standards (library

established under separating conditions). Quantification was made by standard curves (external standards). The R_ts (minutes) were as follows: retrorsine (20.5); seneciphylline (23.6); senecionine (26.6). The latter includes the *E* isomer integerrimine.

Statistical Analysis. A nested ANOVA design was adopted as a model with origin (site where mother plants had been collected), genotype (original seed family, individual plant) and environment (experimental site) as main factors. The effect of origin was tested against the genotype within origin, the origin × environment interaction against the genotype × environment interaction, and all other factors and interactions against the residual term.

RESULTS

Genetic Effects. Nested analysis of variance showed no significant effect of origin and origin × environment on both the plant growth and PA formation (Tables 1 and 2). Significant genotype effects on growth were detected for plant fresh and dry weight, plant height, and fruit fresh weight (Table 1). With regard to PA formation, the effects were low and, with the exception of PA concentration related to dry weight, not significant (Table 2). Genotype × environment effects were only found for plant height and for dry weight of flowers at the second harvest (Table 1) but not for PA formation (Table 2).

Environment Effects on Growth Parameters. After 37 days of development, no environmental effect could be observed on plant height, but dry weight differed significantly (Table 1). Plants of C had 51% higher dry weight than plants of V. At this developmental stage no reproductive organs were visible.

After 56 days of development, plants in V were significantly taller than plants in C and the fresh weight of plants of V was 70% higher than those of C (Figure 1). Generally, differences in dry weight were more prominent at the first harvest and differences in fresh weight at the second harvest (Table 1).

Fresh weight and dry weight of flower heads were significantly different (Table 1). Flowers of C had 60% more fresh weight (Figure 1) and 135% more dry weight than the flowers of V due to an advanced stage of differentiation at the same age in C. More than twice as many flower heads had developed in plants of C compared to plants of V (results not shown). The fresh and dry weights of an individual flower head, however, was higher in plants of V.

Plants of V were more succulent at both sampling dates. The dry–fresh weight ratios were higher in plants of C than of V.

Environment Effects on Alkaloid Formation. A highly significant environmenal effect on PA concentration was found when referred to the fresh weight (Table 2). At both harvest times, PA concentrations were about twice as high in plants of C than in plants of V (Figure 2). On a dry weight basis the PA

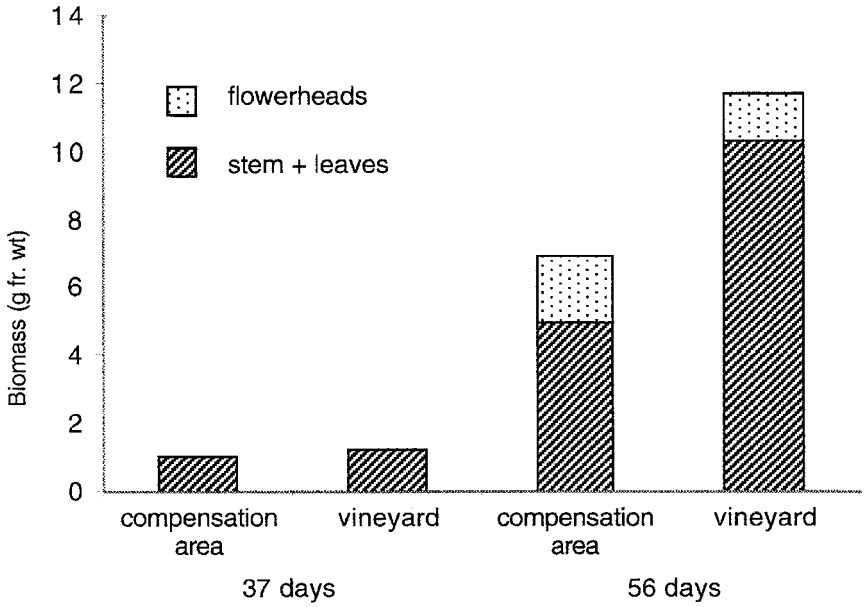

FIG. 1. Biomass (g fr. wt) of *Senecio vulgaris* at 37 days and 56 days of development.

concentrations were 15% and 24% (first and second harvest times, respectively) higher in plants of C than in plants of V. The effect was significant only after 56 days. Total PA content was higher in plants of C than in plants of V (about 70% after 37 days and about 12% after 56 days). The effect was significant only at the first harvest time.

At both sites, PA concentration decreased from the first to the second harvest by a factor of almost 2 (from 0.90 to 0.48 mg/g fresh wt in C and from 0.44 to 0.24 mg/g fresh wt. in V; Figure 2). No environmental effect on PA formation could be found in fruits (Table 2).

The main alkaloid compounds were seneciphylline and senecionine (including the *E* isomer integerrimine) in varying proportions. The portion of retrorsine was below 10%. Correlating with the habitat, no significant alkaloid pattern was found.

Soil Nitrogen. Mineral nitrogen of V was twice as high as of C (33 kg N_{min}/ha and 16 kg/N_{min}/ha, respectively). Compared to sites in the neighborhood, the soil nitrogen content of V was relatively low, because no fertilization was carried out during the experiment. The nitrogen content of C is within the range of sites nearby (Serena Rigamonti, personal communication).

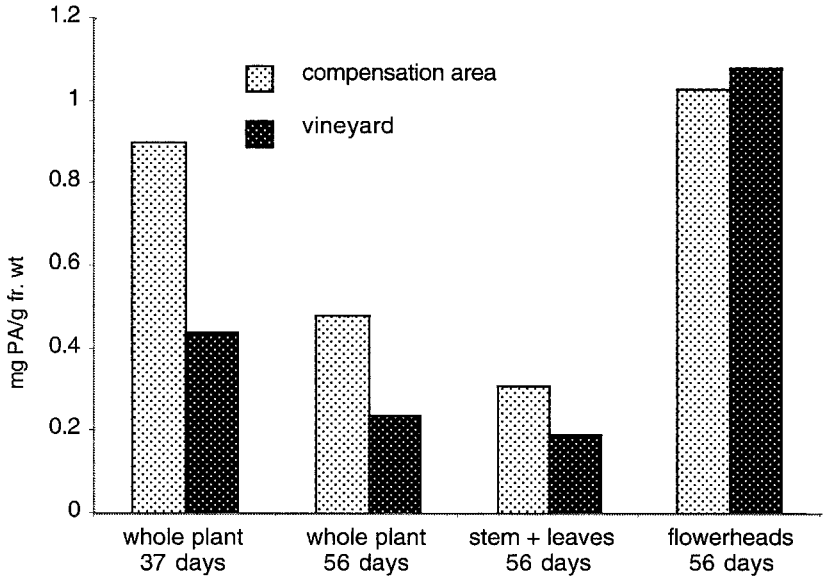

FIG. 2. Alkaloid concentration (mg PA/g fr. wt) in *Senecio vulgaris* at 37 days and 56 days of development.

DISCUSSION

In general, the observed results fit the GDB hypothesis (Loomis, 1953; Herms and Mattson, 1992) quite well. Plants of V with a larger soil nitrogen supply were oriented to growth whereas plants of C were oriented to differentiation. After 56 days, plants of V had a higher fresh weight, were taller, and had more leaves (result not shown) than plants of C. The number of flower heads, however, was twice as high in plants of C than in those of V. The relatively poor nitrogen conditions favored an earlier differentiation towards generative organs. After 37 days, the measured growth parameters (fresh and dry weight, height) did not yet demonstrate higher growth of V and dry weight was even lower in V.

PA formation also followed the GDB hypothesis: higher concentrations were found in plants of C than of V (Figure 2). In accordance with growth development, the difference is more pronounced after 56 days than after 37 days. There exists a significant negative correlation between log biomass and milligrams of PA per gram of biomass ($R^2 = 0.52$, $P < 0.001$ for fresh weight; $R^2 = 0.31$, $P < 0.001$ for dry weight) indicating a trade-off between growth and differentiation (Figure 3). Such a significant negative correlation was also found within each site (for fresh weight: V: $R^2 = 0.43$, $P < 0.001$; C: $R^2 = 0.23$, $P = 0.007$).

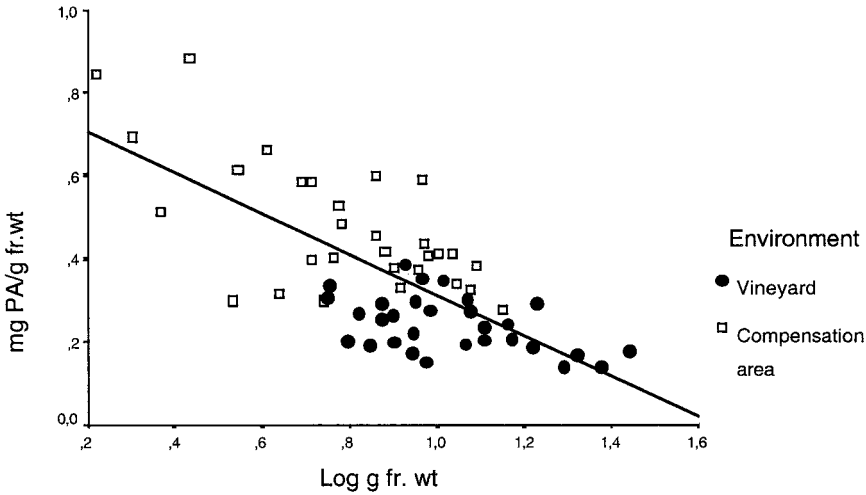

FIG. 3. Correlation between of log fresh weight and alkaloid formation at 56 days of development ($R^2 = 0.52$, $P < 0.001$).

The CNB hypothesis (Bryant et al., 1983) was not supported. Higher availability of nitrogen did not lead to an increased accumulation of PAs.

The fact that seed origin had no significant effect on the various growth and PA parameters assessed is not surprising. A recent plant molecular study carried out on these *S. vulgaris* populations suggests that ecological compensation areas were only recently colonized from adjacent corn fields, with a nitrogen status similar to the vineyard sites (Müller-Schärer and Fischer 2000). The significant genotype effects observed for some of the growth and PA variates indicate, however, genetic variation for these traits and, therefore, the potential for local adaptation.

PAs are synthesized in the roots. In organ cultures their formation is strictly linked to root growth and ceases when root growth stops (Hartmann et al., 1988; Sander and Hartmann, 1989). The shoot–root ratio in *S. vulgaris* correlates positively with the availability of soil nitrogen (Van der Kooij et al., 1998); therefore, plants of C might have a relatively better developed root system than plants of V. If the postulated link between root growth and PA formation exists under field conditions, increased PA formation in C could be an indirect consequence of a morphophysiological adaptation to low mineral nutrient conditions and not a reaction in the sense of the GDB hypothesis. A significant negative correlation between shoot–root ratio and PA concentration could be detected in experiments with seedlings of *S. vulgaris*. A similar trend, although not significant, was found in seedlings of *S. jacobaea*. In both species, a significant positive cor-

relation was found between root biomass and total PAs per seedling (Schaffner et al., unpublished manuscript). The relationship between root growth and PA formation should be further studied under field conditions.

Physiological and biochemical (Hartmann, 1999; Hartmann and Dierich, 1998; Hartmann and Zimmer, 1986) as well as genetic studies (Vrieling et al., 1993) indicate that two different sections of PA formation exist. The root, where biosynthesis of the key compound, senecionine N-oxide, occurs under highly constrained conditions, and the above-ground parts, where a large number of subsequent biosynthetic transformations and tissue- and development-specific accumulations take place. This study supports the model of Hartmann and Dierich (1998) also for an ecological factor. Nitrogen supply is a high constraint for the production of the total amount of PAs (relative to biomass) in the roots. The flexible translocation and allocation of PAs in the above-ground plant parts is independent of the production in the roots. Although alkaloid production relative to biomass was lower in V than in C, alkaloid content in the generative plant parts is equal in V and in C. In an ecological sense, it is reasonable that alkaloid accumulation in vulnerable and valuable plant organs as flowers and fruits are, within a certain range, independent of the supply. Therefore, although the phenotypic reaction of PA formation in *S. vulgaris* in the two sites fits quite well the predictions of GDB theory, the response in detail is overlaid by physiological factors leading to a pattern of PA accumulation, which in its details is hardly predictable by nonmechanistic theories.

The hypothesis that ecological compensation areas with low soil nitrogen may be beneficial to endangered insect specialists that sequester PAs has to be tested further. The results clearly show that PA concentration is higher in plants of C than V, which is in agreement with this hypothesis. The internal allocation pattern may compensate for this reduced production as the level of PA concentration in flowers was found to be independent of the soil nitrogen conditions. Therefore, only specialized insects consuming vegetative plant parts would be able to benefit from increased PA concentrations of ecological compensation sites.

(Received December 26, 1999; accepted October 12, 2000)

Abstract—Effects of 2-β-D-glucopyranosyloxy-4-hydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA-Glc) and DIMBOA-Glc *N-O*-methylated (HDMBOA-Glc), two compounds present in high concentration in maize, were tested on the aphid *Metopolophium dirhodum* reared on artificial diet. HDMBOA-Glc and DIMBOA-Glc decrease survival of adults with an LD_{50} of 1 mM and 5.6 mM, respectively, after 72 hr of feeding. These compounds also decrease the fecundity of the aphids at concentrations of 2 mM and 1 mM, respectively. At concentrations of 2 mM HDMBOA-Glc and 8 mM DIMBOA-Glc in the diet, the average lifetime fecundity of 10 females is near zero. Offspring mortality on diet with 2 mM DIMBOA-Glc is significantly higher than with the control diet. In contrast, HDMBOA-Glc has no effect on the survival of offspring. The possibility that these compounds protect Poaceae against aphids is discussed.

Key Words—Poaceae, maize, 1,4-benzoxazin-3-ones, hydroxamic acids, DIMBOA, aphids, *Metopolophium dirhodum*, artificial diet, plant resistance.

INTRODUCTION

Poaceae such as maize contain 1,4-benzoxazin-3-one derivatives in high quantity (0.2% fresh weight). These compounds belong to three classes—hydroxamates, lactams, and *N-O*-methylated derivatives—and are present in noninjured plants

*To whom correspondence should be addressed.

only as β-glucosides (Cambier et al., 1999). When plants are crushed, β-glucosidases transform glucosides into corresponding aglycones (Wahlroos and Virtanen, 1959).

Aglycone hydroxamic acids and mainly DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one) have been associated with resistance to insects such as *Ostrinia nubilalis* (Hübner) (Lepidoptera: Pyralidae) (Houseman et al., 1992) and *Diabrotica virgifera virgifera* (Leconte) (Coleoptera: Chrysomelidae) (Xie et al., 1990) and to several aphid species: *Rhopalosiphum maidis* (Fitch) (Long et al., 1977), *Metopolophium dirhodum* (Walker) (Argandona et al., 1980), *Schizaphis graminum* (Rondoni) (Corcuera et al., 1985), *Sitobion avenae* (Fabricius) (Thackray et al., 1990), *Rhopalosiphum padi* (L.) (Thackray et al., 1990), and *Diuraphis noxia* (Kurdjumov) (Mayoral et al., 1996). Argandona et al. (1980, 1981) found negative correlations between hydroxamic acid concentration in the plant and aphid infestation and distribution. The decrease of growth rate and intrinsic rate of increase (r_m) of the aphid populations with the increase of hydroxamic acid concentration also has been shown (Argandona et al., 1980; Thackray et al., 1990). Experiments with artificial diet have shown that DIMBOA is toxic and deterrent to aphids (Argandona et al., 1983). Givovich and Niemeyer (1995) have confirmed the feeding deterrent effect of this compound by electronic monitoring of aphid feeding.

A compound present in the phloem sap, the main nutrition site of aphids, can be both antixenotic (deterrent) and antibiotic. A compound present in the path followed by the aphid stylet during penetration of the plant can act only as a feeding deterrent.

DIMBOA is not detected in the phloem sap (Molyneux et al., 1990; Givovich et al., 1992, 1994; Caillaud and Niemeyer, 1996). Thus, this compound can not act as an antibiotic. Furthermore, we recently found that DIMBOA is not present in maize seedlings during an aphid attack (unpublished data). Indeed, DIMBOA-Glc and DIMBOA β-glucosidase are stored in different compartments (extravacuolar and vacuolar spaces, respectively) (Massardo et al., 1994). So, it is possible that during aphid nutrition, the β-glucosidase is not released from the vacuolar space (Dreyer and Campbell, 1987), and consequently, DIMBOA-Glc is not transformed into DIMBOA. However, this transformation undoubtedly occurs when a plant is crushed by insects such as *Ostrinia nubilalis* or *Diabrotica virgifera virgifera*. Therefore, we believe that DIMBOA is not the main resistance factor to aphids in maize seedlings.

On the contrary, the glucoside of DIMBOA and/or other compounds related to DIMBOA could potentially protect maize plants against aphids. Indeed, we have detected in the honeydew produced by *Metopolophium dirhodum* several glucosides of 1,4-benzoxazin-3-one derivatives, such as DIMBOA-Glc and HDMBOA-Glc (2-β-D-glucopyranosyloxy-4-hydroxy-4,7-dimethoxy-1,4-benzoxazin-3-one). These results suggest that DIMBOA-Glc and

HDMBOA-Glc are present in the phloem sap and are ingested by aphids. Furthermore, we have previously shown that these compounds are present in high concentrations in plants (Cambier et al., 2000). Finally, we have observed that plant resistance to *M. dirhodum* decreases when DIMBOA-Glc and HDMBOA-Glc concentrations decrease in aerial parts.

Some authors previously have reported the potential effects of DIMBOA-Glc on aphids reared on artificial diets. According to Corcuera et al. (1985), this compound at concentrations as low as 0.25 mM decreases the reproduction rate of *Schizaphis graminum*, and at a concentration of 4 mM causes the death of 50% of the nymphs after only 24 hr. Givovich and Niemeyer (1995) monitored the feeding behavior of five cereal aphids (*Rhopalosiphum maidis*, *Rhopalosiphum padi*, *Metopolophium dirhodum*, *Schizaphis graminum*, and *Sitobion avenae*) on artificial diet via electrical penetration graphs (EPG) and showed that all species were equally sensitive to the feeding deterrent effect of DIMBOA-Glc. Concerning HDMBOA-Glc, its effects on aphids reared on artificial diet have never been reported.

The purpose of our work is to determine effects of DIMBOA-Glc and HDMBOA-Glc on survival and fecundity of aphids *Metopolophium dirhodum* by using an artificial diet. The results will give us information on the potential roles of these compounds in the plant resistance to aphids.

MATERIALS AND METHODS

Isolation of Compounds. HDMBOA-Glc and DIMBOA-Glc were isolated from maize (Magda, Sesnord, and Aztec varieties) aged 3–5 days. Aerial parts of 500 plants were cut and placed immediately in 500 ml of boiling methanol for 30 min. After filtration, the green extract was evaporated under vacuum at 35°C to a volume of 50 ml. The extract was placed in a refrigerator for several days, filtered, and evaporated to dryness under vacuum at 35°C. The dried residue was dissolved in 15 ml water. Each sample was prepurified on a Sep-Pack C18 cartridge (Waters, Milford, Massachusetts).

The purification was accomplished by preparative HPLC. Samples were chromatographed with a Spectra System AS 3000 on a 10-mm × 25-cm microbore reverse phase C18 preparative column (10 μm, econosphere). A two-solvent system was used to generate the mobile phase: solvent A was 100% water, and solvent B was 100% methanol. Solvents were degassed and filtered. The flow rate was 4.7 ml/min. The mobile phase at the initiation of each run was an 8 : 2 ratio (A to B). After injection of 500 μl of sample, a 4-min linear gradient from 8 : 2 to 5 : 5 A/B was applied and held for another 16 min. Elution was monitored at 280 nm with a Spectra System UV 1000 wavelength detector. The mobile phase flow was connected to a fraction collector.

DIMBOA-Glc and HDMBOA-Glc were identified and quantified from their UV spectra. Purity was verified by mass spectrometry.

Feeding and Diet Composition. Aphids were fed from artificial diet placed between two layers of Parafilm M stretched over Petri dishes. The diet was a mixture of sucrose, amino acids, vitamins, and mineral salts, derived from that described by Auclair (1965).

Effects of DIMBOA-Glc and HDMBOA-Glc on Aphids. Individuals of *Metopolophium dirhodum* (Walker) were collected from naturally infested maize and wheat in Belgium and were reared on wheat seedlings grown in the laboratory at 22 ± 2°C with a 16L : 8D regime. Adults of unknown age were placed on the diets. One day later, nymphs 0–24 hr old were collected and placed on *Triticum aestivum* (Torfirda variety). After eight days in these conditions, nymphs had reached the adult stage. These apterous adults aged 0 ± 1 day were used in the experiments.

Four concentrations of DIMBOA-Glc (1, 2, 4, and 8 mM) and four concentrations of HDMBOA-Glc (0.25, 0.5, 1, and 2 mM) were separately added to the diet to give a range of concentrations similar to those found in aerial parts of maize seedlings. Control diets did not contain DIMBOA-Glc and HDMBOA-Glc. Ten Petri dishes were used with each concentration, and ten apterous adults of *M. dirhodum* aged 0 ± 1 day were placed in each dish. Every day, during a six-day period, survival and fecundity were noted, diet was renewed, and the offspring were discarded, except on the second day. On the second day, nymphs were collected in the order to determine effects of DIMBOA-Glc and HDMBOA-Glc on the offspring originating from these adults.

Impacts of DIMBOA-Glc and HDMBOA-Glc were determined as follows. One hundred nymphs aged 0 to 24 hr laid by adults in 10 Petri dishes containing 0, 1, and 2 mM of DIMBOA-Glc and 0, 0.25, 0.5, and 1 mM of HDMBOA-Glc were placed in other dishes and fed the same diet as the mother. Every day, for four days of experiments with HDMBOA-Glc and for five days with DIMBOA-Glc, survival of nymphs was determined and diet was renewed. Artificial diets containing 4 and 8 mM of DIMBOA-Glc and 2 mM of HDMBOA-Glc were not tested on the offspring because fecundity of adults was too low at these concentrations.

Statistical Analysis. On the third day of the experiment, concentration–mortality regressions were estimated by Probit analysis (Finney, 1971). Data from all bioassays were corrected for control mortality with Abbott's (1925) formula.

On the sixth day of the experiment, one-way analyses of variance (ANOVA) were performed on all aphid survival data (10 per concentration × 5 concentrations). Then, a Scheffé test allowed us to rank the means of the different concentrations and control. These analyses were performed on SAS software (SAS, 1985) for each compound.

Cumulative fecundity curves for each HDMBOA-Glc or DIMBOA-Glc concentration were established. Because of its logistical shape, a fitting by the DUD method (Doesn't Use Derivatives) (SAS, 1985) was performed according to the following equation:

$$y = c/1 + e^{z}$$

where $z = -(x-a)/b$, y represents the value of the cumulative fecundity at age x, a is the inflexion point, b is the inverse of the slope, and c is the plateau value. The equation represents the total number of offspring produced in one generation by an adult female. The DUD method allowed the calculation of a confidence interval for each parameter. We assumed that values were significantly different when confidence intervals did not overlap (Van Impe and Hance, 1993; Kennedy and Hance, 1995).

The number of nymphs laid by the 10 adult females present in each dish during one generation was also determined by this method. Nevertheless, in this case, the number depends on fecundity and survival of the females.

RESULTS

Effects of HDMBOA-Glc on Aphids. With diets containing HDMBOA-Glc, adult aphid survival was always lower ($\alpha = 0.05$) than with the control diet (Figure 1). Survival decreased with the increase in concentration. After six days, 97% of aphids fed on the diet containing 2 mM of HDMBOA-Glc were dead compared to only 18% on the control diet. Mortality seemed particularly high during the second and third days of the experiment and is similar to that observed when aphids are not fed.

LD_{50} and LD_{95} of HDMBOA-Glc on aphids after three days of feeding were 1 mM (limits: 0.8 to 1.1) and 3.8 mM, (limits: 3 to 5.5), respectively.

Concerning the cumulative fecundity per female (Figure 2), no significant difference was observed between the control and concentrations of 0.25, 0.5, and 1 mM of HDMBOA-Glc. A sharp decrease in fecundity was, nevertheless, observed for the 2 mM concentration. However, if we consider the global fecundity per replication (combining survival of the adult females and fecundity), and if we plot the plateau value in relation to HDMBOA-Glc concentration (Figure 3), we observe a strong linear relationship, $y = -52.7x + 114.1$ ($r^2 = -0.99$), stressing the importance of the combined effect (adult survival + fecundity) on the development of the next generation.

Surprisingly, nymphs laid by adult females reared on the artificial diet containing concentrations of HDMBOA-Glc at 0.25, 0.5, and 1 mM did not show any difference in mortality over the 4 days of their rearing.

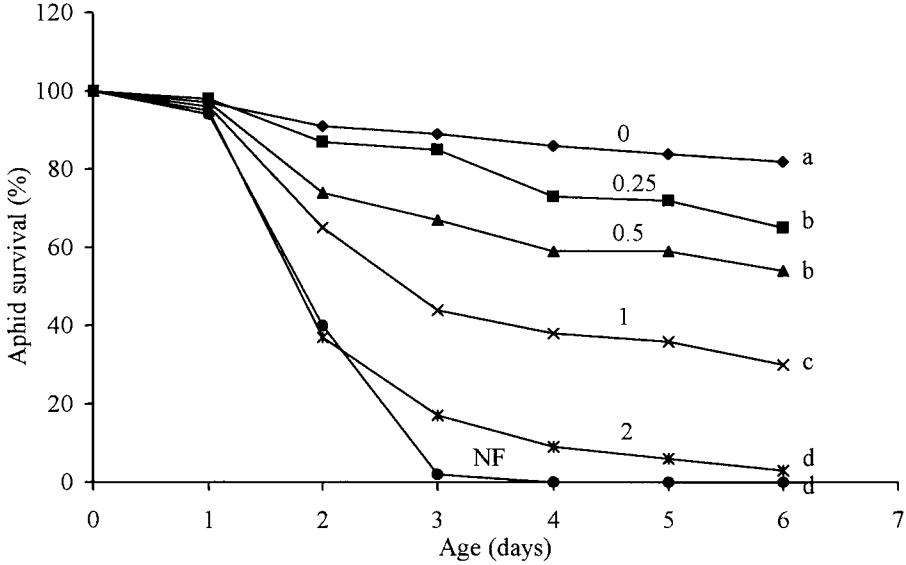

FIG. 1. Survival of *M. dirhodum* adults at different concentrations of HDMBOA-Glc. Numbers represent concentration (mM) in the diet. NF = not fed. On the sixth day of the experiment, significant differences of adult survival are indicated with different letters (Scheffé test; $\alpha = 0.05$).

Effects of DIMBOA-Glc on Aphids. On the sixth day, adult survival (Figure 4) on diets containing 0, 1, and 2 mM of DIMBOA-Glc is not significantly different from controls. Incorporation of higher concentrations of DIMBOA-Glc in the diet, 4 and 8 mM, decreased survival significantly ($\alpha = 0.05$). The LD_{50} and LD_{95} of DIMBOA-Glc on aphids after three days of feeding are 5.6 mM (limits: 5 to 6.5) and 18.6 mM, (limits 14 to 28.5), respectively.

Maxima of logistical curves representing the cumulative fecundity per female (Figure 5) are always significantly different ($\alpha = 0.05$) from control diets. However, no difference appears at concentrations of 1, 2, and 4 mM. At 8 mM concentration, fecundity is near zero. As with HDMBOA-Glc, we observed a linear relationship between the maximum of the logistical equation, c, and DIMBOA-Glc concentration (Figure 6). The equation is $y = -8.1x + 69.8$ ($r^2 = -0.98$).

Mortality of the offspring reared for five days on artificial diet with increasing concentrations of DIMBOA-Glc at 0, 1, and 2 mM was 3, 12, and 24%, respectively. Only the last concentration gave significantly higher mortality ($\alpha = 0.05$).

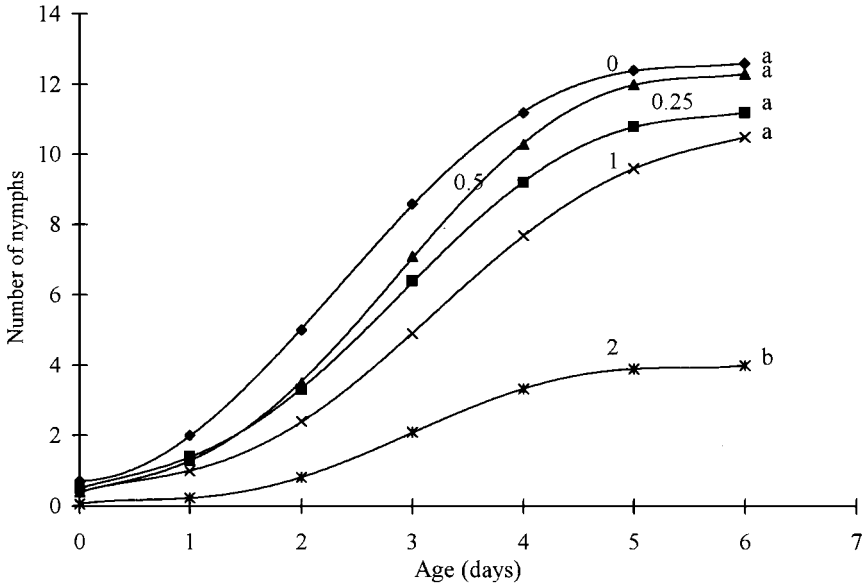

FIG. 2. Curves of cumulative fecundity per *M. dirhodum* female feeding on diets containing different concentrations of HDMBOA-Glc. Experimental points are adjusted to a logistical curve by the DUD method (see Materials and Methods). Number on the curve represents concentration (mM) in the diet. Different letters mean that plateau values, *c*, are significantly different.

DISCUSSION

Our results show that DIMBOA-Glc and HDMBOA-Glc have an important negative effect on survival and fecundity of *M. dirhodum* adults fed on artificial diet at concentrations similar to those found in maize aerial parts (Cambier et al., 2000). Global fecundity is low when DIMBOA-Glc and HDMBOA-Glc concentration in the diet is 8 mM and 2 mM, respectively. HDMBOA-Glc is more active than DIMBOA-Glc on aphid survival. Indeed, after three days of feeding, the LD_{50} and LD_{95} are, respectively, 5.6 and 4.9 times lower that these of DIMBOA-Glc.

Recently, Escobar et al. (1999) tested antifeeding and antibiotic effects of 25 compounds, including benzoxazinones, benzoxazolinones, and N-glyoxylamide derivatives towards the aphid *Sitobion avenae* in diet bioassays. Their results showed that these compounds increased the mortality at a concentration of 2 mM in the diet. Nevertheless, no glucosylated derivatives were tested. In this paper, we show that glucosides present in maize plants, such as HDMBOA-Glc, have

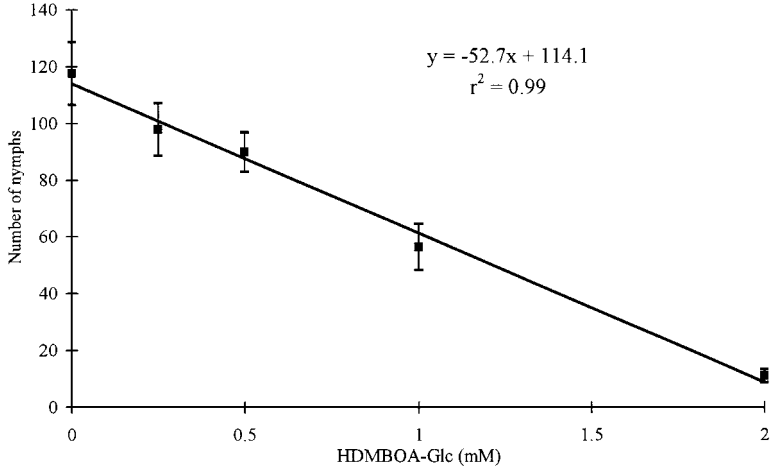

FIG. 3. Average fecundity of 10 *M. dirhodum* females during their life (maximum of the cumulative fecundity curve) that fed on diets containing different concentrations of HDMBOA-Glc. Vertical lines at data points show standard errors.

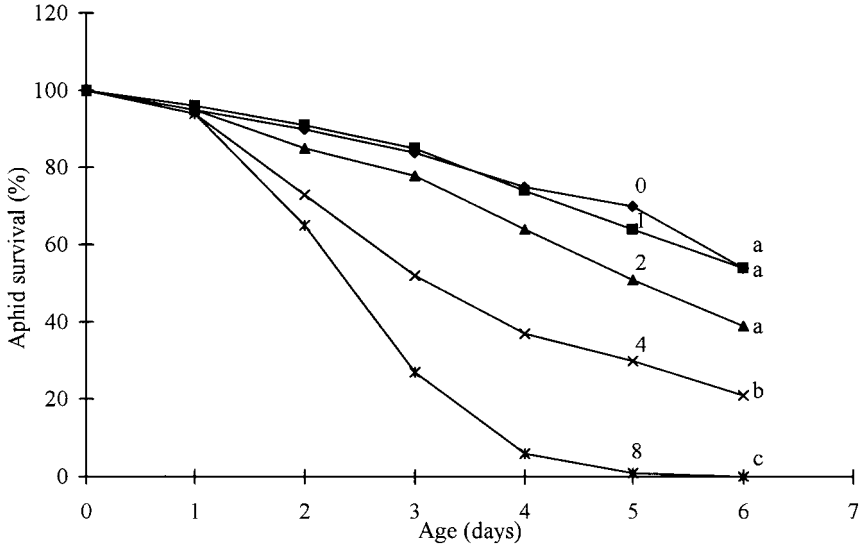

FIG. 4. Survival of *M. dirhodum* adults in the presence of different concentrations of DIMBOA-Glc. Numbers on the line represent concentration (mM) in the diet. On the sixth day of the experiment, significant differences of adult survival are indicated with different letters (Scheffé test; $\alpha = 0.05$).

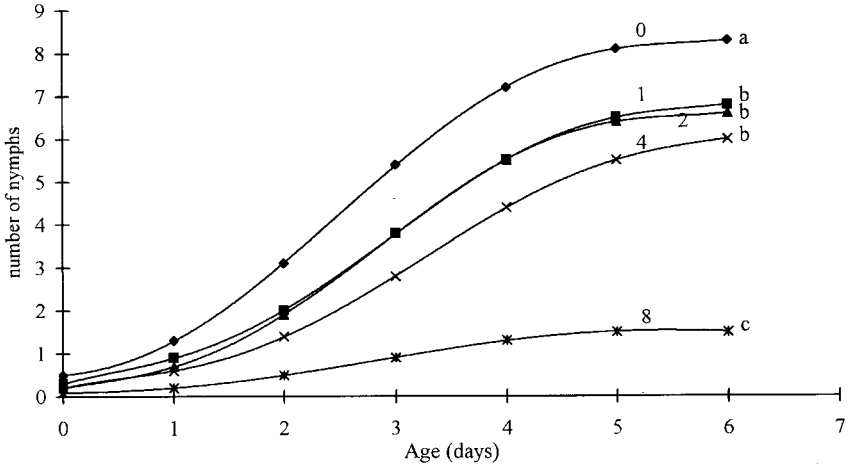

FIG. 5. Curves of cumulative fecundity per *M. dirhodum* female feeding on diets with different concentrations of DIMBOA-Glc. Experimental points are adjusted to a logistical curve by the DUD method (see Materials and Methods). Numbers on the curve represents concentration (mM) in the diet. Different letters mean that plateau values, *c*, are significantly different.

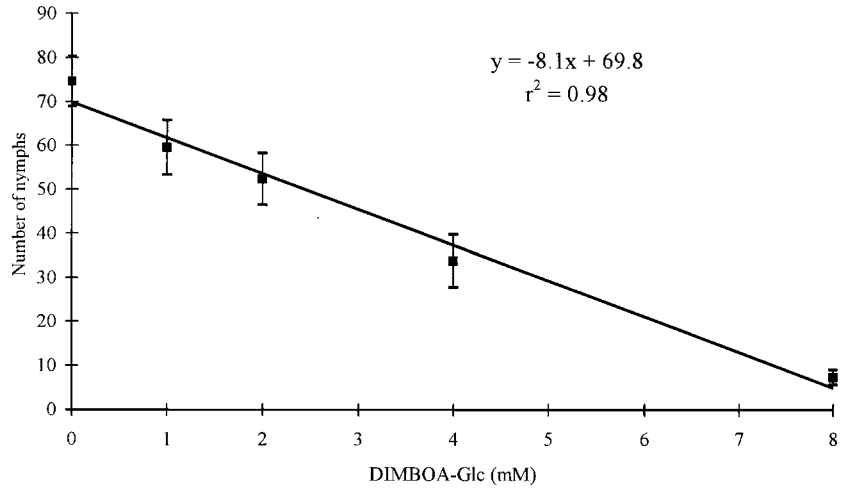

FIG. 6. Average fecundity of 10 *M. dirhodum* females during their life (maximum of the cumulative fecundity curve) that fed on diets containing different concentrations of DIMBOA-Glc. Vertical lines at data points show standard errors.

negative effects on aphids fed on artificial diets. Thus, in future investigations, it seems essential to study their roles in the plant resistance to aphids.

DIMBOA-Glc and HDMBOA-Glc appeared to act as strong feeding deterrents. Indeed, during the first three days, when aphids are fed on a diet containing these compounds, adult survival decreases so that it follows the same pattern as that observed when they are not fed. Furthermore, when concentrations of these compounds are high in the diet, fecundity of the adults is near zero, the quantity of honeydew released is low, and the number of wandering aphids is increased.

The survival of offspring laid by females fed on artificial diets containing HDMBOA-Glc seems not to be affected. The major reason is probably that the HDMBOA-Glc concentrations (0.25, 0.5, and 1 mM) were too low. A DIMBOA-Glc concentration of 2 mM weakly but significantly decreased survival of the offspring laid.

We have never been able to establish a *M. dirhodum* population on maize plants less than 15 days old. On these young plants, aphids wandered and starved after several days. Thus, maize seems to have developed an important defense mechanism against aphids at the more sensitive stage.

Concentrations of DIMBOA-Glc and HDMBOA-Glc are high in aerial parts of maize one day after seed germination. These concentrations are 13 mM and 1.5 mM, respectively (Cambier et al., 2000). Fourteen days later, they drop to 1.5 mM and 0.25 mM, respectively. Thus, concentrations decrease rapidly with plant age, and, we observe that populations of aphids begin to develop. Finally, as DIMBOA-Glc and HDMBOA-Glc are present in the phloem sap and probably in the vascular and mesophyll tissues (Argandona and Corcuera, 1985; Massardo et al., 1994), we suggest that the defense mechanism of the maize seedlings is due to the deterrent effect of these compounds.

Abstract—A role for inhibitors as regulators of seed dormancy in fire-dependent annuals and their nondormant (fire-independent) congeners was examined in the family Hydrophyllaceae. From seeds of the fire-dependent species, *Emmenanthe penduliflora*, *Phacelia minor*, *P. brachyloba*, and *P. grandiflora*, extracts were obtained that were found to be largely self-inhibitory and potent inhibitors of seed germination in nondormant congeners. Lower activity was detected in the fire-independent species, *P. tanacetifolia* and *P. campanularia*. The inhibitory activity was associated with the new sucrose ester, 6-*O*-linoleyl-α-D-glucopyranosyl-β-D-fructofuranoside.

Key Words—Chaparral, fire, germination inhibition, sucrose esters, Hydrophyllaceae, *Emmenanthe penduliflora*, *Phacelia brachyloba*, *Phacelia campanularia*, *Phacelia grandiflora*, *Phacelia minor*, *Phacelia tanacetifolia*.

INTRODUCTION

Fire is a dominant force in the ecology and evolution of plant communities in the California chaparral (Axelrod, 1958). The chaparral postfire environment is notable for the diversity of adaptive flora (Sweeney, 1956; Christensen and Muller, 1975) and in particular the rich complex of annual and short-lived woody species that are cued for germination by charred wood or smoke (e.g., Wicklow,

*To whom correspondence should be addressed.

0098-0331/01/0200-0371$19.50/0

1977; Keeley and Keeley, 1987). The life history of these "fire-recruiters" is one characterized by prolonged, deep seed dormancy in a soil seed bank, reliance on smoke for germination, and establishment and seed set in the first spring after a fire. In turn, these seeds recharge the persistent soil seed bank until the next fire and ensure the maintenance of the population over time.

Despite our understanding of the effects of fire on seed ecology and controls on germination behavior (Wicklow, 1977; Keeley et al., 1985; Keeley and Keeley, 1987; Keeley, 1992), considerably less is known about the mechanisms that maintain or enforce the prolonged, deep seed dormancy. Sweeney (1956) suggested that physical mechanisms controlled dormancy and germination in fire-recruiters. Structures adjacent to the embryo (*Phacelia*, *Allophyllum*, *Eucrypta*) or seed coat (*Camissonia*), or the selective permeability of the seed coat to water and solutes (*Emmenanthe*, *Antirrhinum*, *Chaenactis*) and the changes therein following exposure to smoke confirm a role for (morpho-) physiological dormancy (Quick, 1943, 1947; Egerton-Warburton, 1998, and unpublished data). However, physiological dormancy is often linked to the presence of germination inhibitors (Baskin and Baskin, 1998), and embryo coverings can either contain or prevent the leaching of inhibitors (Bewley and Black, 1982). To date, a role for endogenous inhibitors in maintaining seed dormancy in fire-recruiters is unknown. In this paper, we report for the first time the nature and chemical identity of a biologically active compound, the sucrose ester 6-*O*-linoleyl-α-D-glucopyranosyl-β-D-fructofuranoside, in seeds of the fire-recruiters, *Emmenanthe penduliflora*, *Phacelia minor*, and *P. brachyloba* (family Hydrophyllaceae), and its potential role in the regulation of dormancy and germination.

METHODS AND MATERIALS

Seed Materials. We assayed for inhibitors in seed of the fire-dependent species, *Emmenanthe penduliflora* Benth., *Phacelia minor* (Harvey) Thell., *P. brachyloba* (Benth.) A. Gray, and *P. grandiflora* (Benth.) A. Gray. All these species display a requirement for smoke-stimulated germination: dormant seed demonstrates 0–2% germination in comparison to >75% germination following exposure to smoke. Comparisons of inhibitory activity were made with seed of nondormant (fire-independent) congeners, *P. tanacetifolia* Benth. and *P. campanularia* A. Gray. Seeds of these species germinated readily in deionized water (mean germination >95%). Seeds of each species were collected from recently burned sites in southern California (fresh), obtained from the Rancho Santa Ana Botanic Garden (RSABG) Seed Collection (stored), or from commercial sources as follows: *E. penduliflora* (N = 3 accessions from recently burned sites and RSABG accession 19174), *P. minor* (N = 4, RSABG 16375, 16268), *P. brachyloba* (N = 3, RSABG 19141, 15943), and *P. grandiflora* (N = 2, RSABG 16851),

P. tanacetifolia (S&S Seeds, CA), and *P. campanularia* (Seeds of the Southwest, NM, RSABG 17578).

Extraction of Germination Inhibitors. Aliquots of seed of an individual species, each 0.5 g, were ground under liquid nitrogen to a fine powder and then steeped in 5 ml 90% EtOH for 24 hr at 18°C. The resultant slurry was pulse centrifuged to pellet the solids, after which the supernatant was removed and evaporated to complete dryness under a stream of compressed N_2. The pellet was resuspended in 5 ml of deionized water and steeped for a further 24 hr. The slurry was again centrifuged and then the aqueous portion removed and dried under N_2. Dry extracts were stored at −20°C until required for analysis and bioassays. All species and accessions were extracted in triplicate on at least three different occasions.

Analytical Methods. For TLC, precoated AL SIL G/UV (Whatman) plates were used and the compounds were detected by spraying with 0.5% thymol in 5% H_2SO_4–ethanol. ^1H and ^{13}C NMR spectra were obtained for d_4-MeOH solutions by using a Bruker ARX-500 instrument operating at 500.1 (^1H) and 125.8 MHz (^{13}C). Mass spectrometry was carried out with a VG Autospec Mass Spectrometer (70 eV) in the Fast Atom Bombardment mode with *m*-nitrobenzylalcohol as the matrix.

Seed Germination Bioassays Conditions. Individual extracts were used in bioassays without further purification since ^1H and ^{13}C NMR analyses demonstrated that extracts were fundamentally composed of a single sucrose ester (e.g., *P. brachyloba*), and all efforts to purify the extracts resulted in rapid hydrolysis of them. Dried extracts for testing were dissolved in 200 mM KH_2PO_4 buffer (pH 7.1) and pipetted into 6-cm-diameter Petri dishes containing two Whatman No. 1 filter papers. Filter papers were prerinsed with methanol, then rinsed in deionized water and air dried to remove any substances that could influence germination (Peterson and Harrison, 1991). Each species and sample was tested by using a final concentration of 25 mg dry weight seed per milliliter of buffer. Clean, intact bioassay seed of *P. tanacetifolia* or smoke-treated *E. penduliflora* (described below) were then placed in the prepared dishes and incubated for 48 hr at 18–20°C under a photoperiod of 14L : 10D. Petri dishes containing buffer only were used as controls. Each species and extract was tested at least three times. On each occasion, three replicates containing 50 seeds per dish were used to test the inhibition response. Germination was scored as positive if the length of the radicle was at least as long as the seed. Differences in the number of seeds germinating following incubation in ethanolic or aqueous extracts were analyzed with a *t* test (Zar, 1984). Germination of the bioassay species after incubation was analyzed first by using a χ^2 test among extracts and then between bioassay species (*E. penduliflora*, *P. tanacetifolia*) for each test species extract by using a *t* test. Germination data were also converted to a response index (*RI*) (Williamson and Richardson, 1988), where *RI* was calculated as: if $T > C$, then $RI = 1 - C/T$

and if $T < C$, then $RI = T/C - 1$. The term T is the germination response following incubation in the extract, and C is the percentage germination in the control (buffer). RI ranges from -1 to $+1$, where -1 indicates complete inhibition and $+1$ indicates stimulation of germination.

Concentration Effects. The degree of germination inhibition and ID_{50} (the inhibitory dose for 50% of the seeds tested) were evaluated by using a graded concentration curve with extracts ranging from 0 to 10 mg/ml of the bioactive compound, a sucrose ester. The relationship between the amount of sucrose ester in solution and germination inhibition or radicle length was analyzed with correlation and regression of the line of best fit (Zar, 1984).

Leaching Versus Deactivation of Inhibitors. The potency of endogenous inhibitors during germination and the potential for leaching of compounds during this period was evaluated in *E. penduliflora*. Batches of *E. penduliflora* seed (RSABG 19174) were soaked for 24 hr in Regen 2000 (dilution 1 : 1000 in deionized water), a commercially available smoke extract. Half of the seed batch was dry blotted on KimWipes, placed in Petri dishes containing Whatman No. 1 filter papers moistened with deionized water, and germinated at 18°C and a photoperiod of 14L : 10D. Up to 88% of smoke-water treated *E. penduliflora* germinated within 10 days of commencing imbibition. For that reason, we sampled seeds and germinants every two days for their inhibitor status during this period. The remaining seeds were soaked in deionized water (1 : 2, seeds–water), and subsamples of leachate were removed for bioassay every second day to coincide with the germination profile. Data were analyzed with a two-way analysis of variance for time (days) and extract source (leachate, germinant).

RESULTS

Aqueous and ethanolic extracts of seeds from all fire-dependent species were equally efficacious inhibitors of germination. We detected no significant difference ($P > 0.05$) in germination of *P. tanacetifolia* seed incubated in either extract; both sources consistently resulted in no germination. For that reason, the data reported here represent the results of combined germination responses to both extractions.

Seeds of nondormant (fire-independent) species, *P. tanacetifolia* and *P. campanularia*, exhibited little inhibitory activity (Table 1). In contrast, extracts from seeds of the fire-dependent species, *E. penduliflora*, *P. minor*, *P. brachyloba*, and *P. grandiflora*, were potent inhibitors of germination on both fire-dependent (*E. penduliflora*) and -independent bioassay species (*P. tanacetifolia*) (χ^2, $P < 0.05$). In both test species, extracts from all *Phacelia* species resulted in total inhibition of germination. The strongly negative RI values also reflect inhibition of germination. Extracts of *E. penduliflora* also inhibited the germination of *P. tanaceti-*

folia. However, a small proportion of the *E. penduliflora* bioassay seedlot germinated in the presence of the *E. penduliflora* extract. Such findings indicate that bioactive compounds are not totally self-inhibitory and, possibly, that the embryo is less sensitive to its own inhibitors than those of other species. The inhibitory effect was also readily reversible; the transfer of seeds of bioassay species to dishes containing deionized water resulted in 80–100% germination.

The degree of germination inhibition was directly correlated with the amount of bioactive compound in solution (line of best fit, polynomial $r = 0.964$, $P < 0.05$; Figure 1). Sucrose linoleate was identified as a bioactive compound in seed extracts (see below), and the sucrose ester demonstrated an ID_{50} of 3.4 mg/ml solution (Figure 1). An increasing concentration of sucrose ester in solution also resulted in a proportionate reduction in the elongation of the radicle

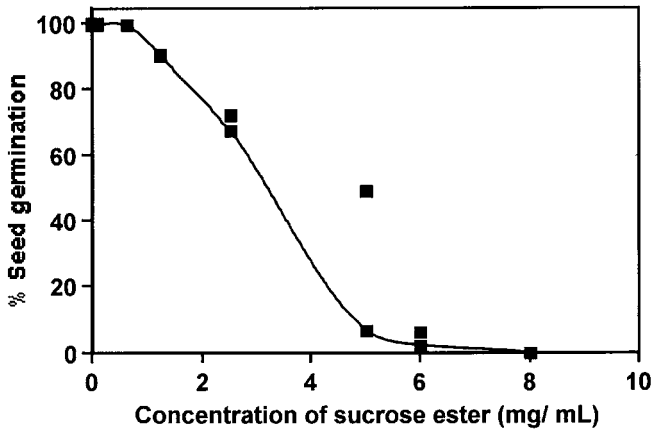

FIG. 1. Percentage germination of *P. tanacetifolia* seeds in response to increasing concentrations of sucrose linoleate extracted from seed of *E. penduliflora*.

(linear $r = 0.979$, $P < 0.05$; Figure 2), brown discoloration and curling of the radicle, and the loss of root hairs.

Inhibitory compounds were not leached from *E. penduliflora* seeds during germination (Figure 3), as bioassay of leachates gave 98–100% germination throughout the germination period. In contrast, inhibitors were detected within *E. penduliflora* seeds until germinants emerged, as indicated by the significant

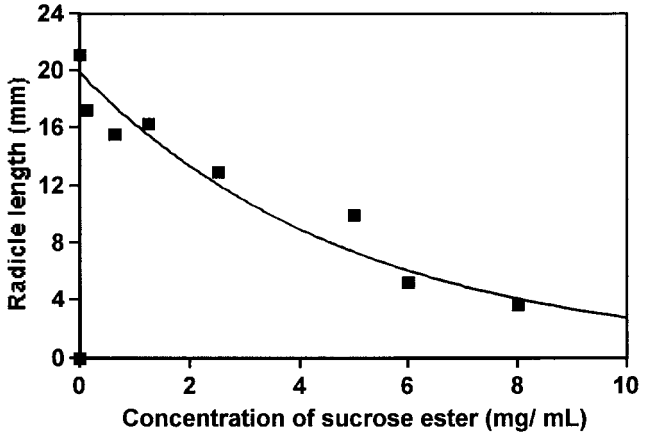

FIG. 2. Mean radicle length of *P. tanacetifolia* germinants following incubation in increasing concentrations of sucrose linoleate from *E. penduliflora* seed.

increase ($P < 0.05$) in bioassay germination at 10 days postimbibition (to 74%). These data indicate that release from inhibition was associated with deactivation, and not leaching, of the inhibitory compound(s). In addition, the absence of bioactive compounds in leachate reduces the potential for their role in allelopathic activity.

The extract from *P. brachyloba* appeared from thin-layer chromatography (TLC) to contain essentially a single compound as an amorphous solid. The proton and carbon NMR spectra indicated the presence of an unsaturated fatty acid residue that was identified as a linoleyl group by comparison with the spectra of linoleic acid (Pouchert and Behnke, 1976). However, a signal at δ_C 174.7 in the ^{13}C NMR spectrum indicated the presence of an ester, the free acid showed a signal for the carboxylic acid carbon at δ_C 180.1. The other signals in the NMR spectra of the compound suggested that the remainder of the molecule was a disaccharide (signals for 12 carbons in the region δ_C 61–106 (Table 2). Support for this conclusion came from FAB/MS measurements. The mass spectrum showed peaks at m/z 603 ($[M-H]^+$; 13%), 758 ($[M+matrix+H]^+$; 17%) and 263 (linoleyl ion, 18%) (see, for example, FAB mass spectra of sucrose esters) (de Koster et al., 1993). Detailed analysis of the NMR spectra provided evidence for the nature of the disaccharide unit as sucrose. Importantly, signals for three methyleneoxy carbons (δ_C 64.1, 63.4, 62.2, all triplets) and two acetal carbons (δ_C 105.3, 93.6, singlets) were of diagnostic significance. The location of the fatty acid residue at C-6 of the glucose unit was deduced as follows. The chemical shift and multiplicity (δ 4.35, J 3.9, 12.0 Hz; 4.17, J 6.0, 12.0 Hz) of the methyleneoxy protons of the esterifying alcohol indicated that the ester group was at C-6 or C-6′. It has been noted that the presence of an ester group at C-6′ results in shielding of the C-5′ from δ 82–84 to δ 78–79 (Matzusaki et al., 1992; Miyase et al.,

1999; Ohya et al., 1994). Since **1** shows C-5′ at δ 83.8, the ester group must be located at C-6. Finally, comparison of the NMR spectra of sucrose linoleate (**1**) with those of the model compound sibiricose A_3 (**2**) (Miyase et al., 1999) shows close correspondence, supporting the structure proposed.

Similar examination of the extracts from *P. minor* and *E. penduliflora* revealed the presence of **1** as the major compound, although traces of other sucrose esters varying in the nature of the fatty acid could be detected.

Given the structure of the compound (**1**; Figure 4) and the observation that inhibition was readily reversible by transferring seed to deionized water, it is tempting to suggest that the most likely mechanism of deactivation is hydrolysis of the ester resulting in the formation of free sucrose and fatty acid in solution.

DISCUSSION

Sucrose esters have been shown to be inhibitors of seed germination in the Solanaceae, (Matsuzaki et al., 1988) and Caryophyllaceae (Peterson et al., 1998). We have now shown that sucrose linoleate constitutes a potent inhibitor to seed germination in *Phacelia* and *Emmenanthe* of the family Hydrophyllaceae. Notably, we detected significant differences in the yield of the sucrose ester

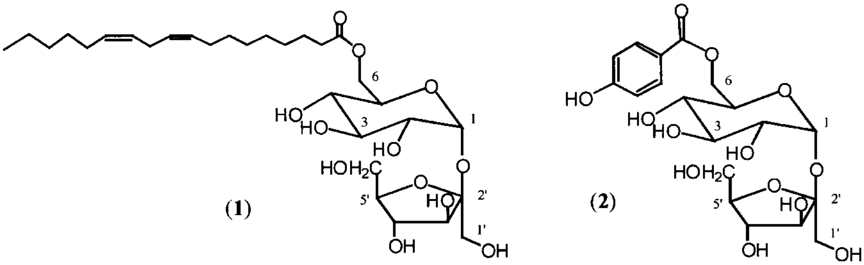

FIG. 4. Structure of sucrose linoleate (**1**) and the model compound, sibiricose A_3 (**2**).

among species based on life history traits (fire-dependent versus -independent). These findings denote, firstly, a familial similarity in the underlying biochemical pathways in these, and possibly other members, of the family Hydrophyllaceae, and secondly, that the sucrose ester concentration was a causal factor in maintaining dormancy or inhibiting germination in fire-recruiters. We infer that the sucrose ester regulates seed germination since other inhibitors, such as abscisic acid, benzoic acid, coumarin, lactones, or cinnamic acids, were not detected in extracts of *Emmenanthe* or *Phacelia* seed (Bewley and Black, 1982; Hillhorst, 1995).

Differences in germination strategies, in this instance sucrose ester yield, among related species may arise either on the basis of genetic differentiation or adaptation to environmental effects. Because sucrose linoleate occurred among phylogenetically related species, it is possible that the biosynthetic cascade for sucrose ester synthesis already exists. Accordingly, the up-scaling of this proximate signal and the production of sucrose esters in fire-recruiters may represent adaptation to the environment, including the maternal environment during development, because they contribute to the regulation of germination (Westoby, 1981).

Apart from the direct inhibition of germination, there are two mechanisms by which sucrose linoleate may contribute to the control of dormancy in Hydrophyllaceae and, in turn, prolong longevity of the soil seed bank. Sucrose esters may exhibit selective insecticidal properties (Puterka and Severson, 1995; Neal et al., 1994; Chortyk et al., 1996, 1997) and antibacterial and antimicrobial properties (Marshall and Bullerman, 1986; Holley et al., 1987; Chortyk et al., 1993). Such properties may limit seed herbivory or the deterioration of seed via the action of soil microbes, respectively.

Sucrose linoleate also may be closely associated with biochemical processes within the seed. Both the hydrophilic (sucrose) and lipophilic (fatty acid) nature of sucrose esters may control seed and cellular moisture; the sucrose moiety retains inherent seed moisture, while the lipophilic group repels the uptake of

water and, in turn, limits imbibition. Sucrose esters also slow cellular respiration and delay ripening, thus prolonging longevity (Bauchot et al., 1995). In addition, sucrose esters have strong emulsifying properties and have been associated with the prevention of thermal decomposition of proteins during either heating or cooling (Jandacek and Webb, 1978; Katsuragi, 1997); these properties are relevant to seed survival during fire, hot summers, and cool winters in the cismontane chaparral. Such mechanistic and functional traits may explain, at least in part, seed dormancy and seed bank persistence in fire-dependent Hydrophyllaceae.

Whether sucrose esters are explicitly linked to dormancy is a key question. Selection rarely acts on specific individual traits in isolation, but instead often on suites of traits in a correlated manner (Roff, 1992). In this context, dormancy in fire-recruiters may be a two-step process that comprises (morpho-) physiological and biochemical mechanisms operating in concert. Firstly, seed coat impermeability may regulate water and gas exchange (Egerton-Warburton, 1998), and secondly, sucrose esters (biochemical) may inhibit germination, reduce respiration, limit total seed moisture, and possibly enhance viability in the dormant phase (this study). Accordingly, we suggest that seed germination involves breaking both (morpho-) physiological and biochemical barriers in a temporal sequence. The exposure of seeds to smoke results in an increase in seed coat permeability and the uptake of water (Egerton-Warburton, 1998); in turn, imbibition may promote hydrolysis of the sucrose ester.

Acknowledgments—We thank David Reznick for assistance with seed collecting, Michael Wall at Rancho Santa Ana Botanic Garden for kindly providing many of the seed accessions used in the study, S&S Seeds for donation of *Phacelia tanacetifolia* seed, Sam Crace of Forest Flavors Inc. for the gift of Regen2000, and William Thomson for generous use of laboratory facilities.

Abstract—Twenty compounds identified in vulpia (*Vulpia myuros*) residues as allelochemicals were individually and collectively tested for biological activity. Each exhibited characteristic allelochemical behavior toward the test plant, i.e., inhibition at high concentrations and stimulation or no effect at low concentrations, but individual activities varied. Allelopathins present in large quantities, such as syringic, vanillic, and succinic acids, possessed low activity, while those present in small quantities, such as catechol and hydrocinnamic acid, possessed strong inhibitory activity. The concept of a phytotoxic strength index was developed for quantifying the biological properties of each individual allelopathin in a concise, comprehensive, and meaningful format. The individual contribution of each allelopathin, assessed by comparing the phytotoxic strength index to the overall toxicity of vulpia residues, was variable according to structure and was influenced by its relative proportion in the residue. The majority of compounds possessed low or medium biological activity and contributed most of the vulpia phytotoxicity, while compounds with high biological activity were in the minority and only present at low concentration. Artificial mixtures of these pure allelochemicals also produced phytotoxicity. There were additive/synergistic effects evident in the properties of these mixtures. One such mixture, formulated from allelochemicals found in the same proportions as occur in vulpia extract, produced stronger activity than another formulated from the same set of compounds but in equal proportions. These results suggest that the exploration of the relative composition of a cluster of allelopathins may be more important than simply focusing on the identification of one or two compounds with strong biological activity and that synergism is fundamental to the understanding of allelopathy.

INTRODUCTION

To identify and quantify compounds contained in plant residues is part of the process of discovering agents of allelopathy. Plants contain thousands of natural products, but not all are implicated as being allelopathic (Bell and Charlwood, 1980; Rice, 1984). Plant allelopathins may be released, either as metabolites or derivatives, into the environment by such processes as volatilization, root exudation, leaching, or residue decomposition and are thereby available to exert their allelopathic effect upon other plants (Putnam and Tang, 1986).

Conclusive establishment of an allelopathic interaction is often a complicated issue, as the biological activities of putative allelopathins are governed by a number of different factors. Such matters as individual chemical structure (Williams and Hoagland, 1982; Einhellig, 1989); antagonistic, additive, sequential, or synergistic effects (Inderjit and Mallik, 1997; Blum et al., 1999); and various biotic factors (Grime, 1979; Blum, 1995; Harborne, 1997) all impact upon observed activity. While various criteria have been proposed for the demonstration of allelopathy (Fuerst and Putnam, 1983; Willis, 1985; Blum et al., 1999), the full implementation of these criteria is in reality extremely difficult to achieve and may perhaps be unrealizable (Blum et al., 1999). Although it is expected that donor-plant allelopathins carried through soil will undergo various abiotic and biotic processes before making contact with the roots of receptor plants, their ultimate effect is to inhibit the growth or functions of that receptor. In this study, we have adopted an achievable demonstration of allelopathy that first identifies the compounds released from *V. myuros* residues, and then follows with bioassay tests of individual compound activity, determination of activity threshold concentrations, and the testing of various compound combinations for additive or synergistic effects (Rice, 1985; Putnam and Tang, 1986).

The weed *Vulpia myuros* is known to have characteristics that make it unattractive to livestock, as well as competitive against crop and pasture plants, so that our investigation was conducted not only to obtain a better understanding of its allelopathic fundamentals, but also to help develop strategies to better manage the vulpia weed problem of southern Australia at a practical ecosystem level. In our second publication on vulpia allelopathy (An et al., 2000), the main compounds released from vulpia residues were identified and quantified. The specific aims of this study were to test the biological activities of the previously isolated compounds (both individually and collectively) and to quantify their individual activities as well as the specific contributions of each to the overall phytotoxicity of their mixture.

METHODS AND MATERIALS

Of the 21 compounds previously identified in residues of vulpia (An et al., 2000), only 20 were used in this study, as hydroferulic acid was not available.

Bioassay Procedure

Preparation of Authentic Compound Solutions. A concentration series of 1, 10, 100, 250, 500, 750, and 1000 ppm was made for each of the 20 identified compounds (Table 1) by using commercially obtained authentic substances. 250

[a] Mix 1: 20 compounds mixed in equal proportions.
[b] Mix 2: 20 compounds mixed in the proportions found in vulpia ether fraction.

ml of 1000 ppm stock solution was first prepared for each compound by dissolving 0.25 g standard in a minimal volume of methanol and adding the remainder as distilled water to 250 ml. Each stock solution was then diluted to the required concentrations in 100-ml volumetric flasks. The same concentration series was also prepared for mixtures of these 20 compounds. Two kinds of 20-compound mixtures were prepared for the bioassay. The first was made by combining each of the compounds in equal proportions (mix 1). The second (mix 2 in Table 1) was made by combining each compound in a proportion equal to that determined to be present in the vulpia ether fraction (An et al., 2000).

Bioassay. The bioassay procedures developed previously (An et al., 1997a) were employed to test the biological activity of identified compounds using wheat as the indicator species. Fifteen pregerminated wheat (*Triticum aestivum* L. cv. Vulcan) seeds were placed in each Petri dish lined with filter paper. Five milliliters of compound solution was added. Control treatments received 5 ml of distilled water instead of compound solution. After 48 hr, the lengths (millimeters) of the longest seminal root and coleoptile were measured. The average length of radicle/coleoptile per Petri dish was used for statistical analysis. The bioassay was arranged in a randomized complete block design with three replicates.

Data Analyses

Seedling Elongation. The average radicle/coleoptile length per Petri dish was used for statistical analyses. The method of whole-range assessment developed by An et al. (1997b) was employed. The approach was to calculate the inhibition area between test plant response of the control (i.e., 100%) over the whole range of compound concentrations on the x axis, and the phytotoxicity curve on the test plant, as generated by these compound concentrations (Figure 1). Thus:

$$\text{inhibition area} = \int_{C_T}^{1000} [100 - f(C)]dC$$

where C is the compound concentration in ppm, and C_T is the threshold concentration for inhibition in the test plant. The computation of the area was done with MicroOrigin software. Biological activity across the whole range of concentrations was then calculated based on "inhibition index," which was defined as the percentage of the maximum area inhibited. Thus:

$$\text{inhibition index} = (\text{inhibition area}/\text{total area}) \times 100,$$

where the total area is defined as $\int_0^{1000} 100\ dC$

I_{50} Value and Threshold Concentrations. In addition to the inhibition index

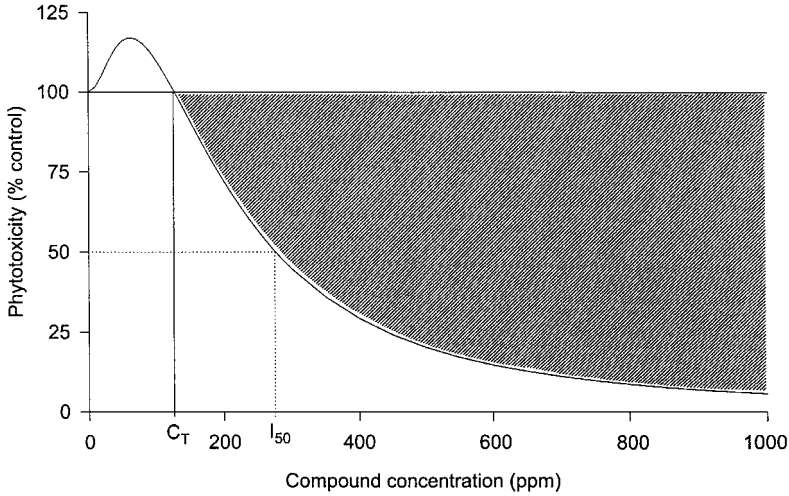

FIG. 1. Diagrammatic representation of seedling response to compound concentrations. The shaded section represents the inhibition area of the test plant by compound concentrations. C_T—the threshold concentration for causing inhibition; I_{50}—the concentration causing 50% of inhibition in the test plant.

values, the I_{50} value and the threshold concentrations at which a compound started to cause inhibition were also considered as important components for comprehensive assessment of a compound's biological activity. The I_{50} values (concentration required to cause 50% inhibition in the test plant) for coleoptile and root inhibition, respectively, were determined for each compound from the equation of best fit, the criterion for best fit being $r > 0.95$, which was significant at $P = 0.01$. Some compounds did not cause 50% inhibition over the range of compound concentrations tested. The I_{50} for those compounds was recorded as >1000 ppm. The inhibition threshold concentrations were those concentrations of the compound treatments at which coleoptile and root inhibition of the test plant were just recordable.

Overall Assessment. All parameters described, including inhibition index values of radicle/coleoptile lengths, threshold concentrations, and I_{50} values, were combined into a concise format to evaluate the overall biological activity of the compounds identified. All data were transformed to reduce the effect of differences in units and values among groups and to provide a homogeneous form for further analysis. Data from the threshold concentrations of inhibition were first transformed by subtraction from 500, while data from I_{50} were transformed by subtraction from 1000. Other group data remained intact. The standard deviation within each group was calculated. All data within each group were

divided by the standard deviation value for that group. All data in the six groups underwent an analysis of variance with MicroStat software, and the outcomes, as an average of six values for each compound, were displayed as a columnar list of integrated compound biological activity values from small to large. This concise-format value was defined as the phytotoxic strength index and gave a relative indication of biological activity for a given compound. A large index value means that a compound has strong biological activity, while a small value implies weak or no activity. Subsequently, all compounds were partitioned into groups based on the LSD value determined, that is, the value of the first compound in one group was significantly different from that of the first one in the group below (Table 2). Compounds in two adjacent groups are not necessarily all significantly different from each other, as overlap may occur.

TABLE 2. PHYTOTOXIC STRENGTH OF IDENTIFIED ALLELOCHEMICALS AS MEASURED BY OVERALL ASSESSMENT

Chemical name	Phytotoxic strength index	Biological activity	Average inhibition (% control)

Hydrocinnamic acid	3.72			

RESULTS

Individual Compounds

All 20 compounds tested exerted significant biological activities over the range of test concentrations (Figure 2). Typical allelochemical behavior was observed on the test plant, i.e., inhibition at high concentrations, stimulation or no effect at low concentrations. In terms of seedling inhibition, all compounds caused greater inhibition on root elongation than on coleoptile length. Threshold concentrations for both root and coleoptile inhibition were between 1 and 500 ppm. I_{50} levels for root inhibition were lower than for coleoptile inhibition. This indicated that the compounds had a greater effect upon plant roots than upon coleoptiles. The biological activities among compounds were not equal. Large differences in biological activity were evident among these 20 compounds, the active extent being dependent on the individual structure rather than on the compound class (Table 2). Generally, measured parameters (Table 1) were consistent with the strength of biological activities, even though some exceptions occurred. By combining all parameters considered, the compounds were partitioned into three groups in terms of the strength of their biological activity: strong, medium, and weak (Table 2). Since the phytotoxic strength for a specific compound is not a constant, but is related to the test plant species, the plant process, and the environmental conditions (Einhellig, 1986), only a relative concept was adopted here.

Most of the compounds tested fell either within the weak (40% of total) or medium (35% of total) classification, with only 25% being considered as strong. The amounts of compounds contained in the vulpia residue were not positively

Succinic acid	12.77	1.35
3-(4-Hydroxyphenyl) propanoic acid	12.87	2.50
Vanillic acid	19.51	2.04

[a] Calculation = $(C_i / \sum C_i) \times 100$, i = catechol, . . . , vannilic acid; C = phytotoxic strength index of individual compound multiplied by the mass of each compound in mix 2.
[b] As computed for Table 2.

correlated with their phytotoxic strength. Hydrocinnamic acid and catechol were found only in trace levels in the vulpia residue, but both exhibited strong phytotoxic activity. The quantity-dominant compounds such as vanillic, succinic, syringic, and the 3-(4-hydroxyphenyl)propanoic acids (but not salicylic acid) were found in weak and medium strength groups. This later led to the use of the phytotoxic strength index (Table 3) to evaluate the relative contribution of each compound to plant growth inhibition.

Combinations of Compounds

The combination of 20 compounds, whether mixed in equal portions by weight (mix 1) or in proportions reflecting the composition in vulpia residues (mix 2), exhibited appreciable biological activity. The general behavior of the mixtures was similar to that of individual compounds, i.e., inhibition occurred at high concentration and stimulation at low concentration, but there were additive and synergistic effects.

Those mixture concentrations at which each compound had a concentration below its own inhibition threshold still caused significant inhibition (Table 1, Figure 2). Mix 1 concentrations of 669 ppm and 407 ppm suppressed 50% of coleoptile and radicle lengths, respectively. Each compound was represented at a level of 33.5 ppm and 20.4 ppm, respectively, at which none of the compounds caused 50% inhibition on its own. Average I_{50} values for coleoptile inhibition were 960.4 ppm for the weak strength group, 724.0 ppm for the medium group, and 399.4 ppm for the strong group. Average I_{50} values for root inhibition were 610, 338, and 180 ppm for the above three groups, respectively. The threshold concentrations for mix 1 were 250 and 100 ppm for coleoptile and root inhibition, respectively. The concentrations of each compound contained in those two particular formulations of mix 1 were 12.5 ppm and 5.0 ppm, respectively, far below the inhibition threshold concentration for individuals in the majority of cases.

The significant inhibition of both root and coleoptile by the 750 ppm mix 1, containing 37.5 ppm of each compound, was equivalent to the average effects of the single compounds in the weak and medium strength groups at 1000 ppm and equaled the average for the individual compounds of the strong group at the 750 ppm level. None of the individual compounds exhibited significant inhibition at a concentration near 37.5 ppm.

The combination of these 20 allelochemicals in their natural weight proportions (i.e., mix 2) had biological activity similar to mix 1, except that it was stronger. In Table 2, mix 2 was classed within the strong group, while mix 1 was in the medium group. The stronger biological activity of mix 2 than of mix 1 indicated an enhanced effect among the compounds. No attempt was made to separate additive from synergistic effects. Mix 2 reflected a composition of compounds more likely to occur in the field. An attempt, by using the phytotoxic strength index, was made to evaluate the relative contribution of each allelochemical in mix 2 to the root phytotoxicity it caused (Table 3). Like their biological activities and levels present in the vulpia residues, the relative contributions of individual compounds to the overall phytotoxicity varied greatly. Vanillic, salicylic, succinic, syringic, and 3-(4-hydroxyphenyl)propanoic acids contributed most to the vulpia toxicity (more than 60% of total contributions), while hydroquinone, coniferyl alcohol, catechol, 3,4-dimethoxyphenol, and hydrocinnamic acid contributed little (Table 3).

DISCUSSION

All identified compounds exerted biological activity. Their phytotoxic strength was influenced by their concentrations as well as individual structure. The compounds were not equally inhibitory, and an overall assessment of

six significant parameters measured for each divided the 20 compounds into three groups: strong, medium, and weak phytotoxicity. Hydrocinnamic, salicylic, benzoic, 2-hydroxy-3-phenylpropanoic acids, and catechol possessed the greatest phytotoxicity; and coniferyl alcohol, protocatechuic, hydroquinone, 3,4-dimethoxyphenol, *p*-hydroxybenzoic, syringic, hydrocaffeic, and succinic acids the weakest; the rest were of an intermediate level.

Williams and Hoagland (1982) separated 12 phenolic compounds into four groups: very active, active, slightly active, and nonactive, based upon visual observations. Five of these chemicals appear in the list of 21 compounds found in the vulpia residue. The activity order reported for these five is consistent with the data presented here. Salicylic acid was reported as having markedly higher toxicity, while protocatechuic acid exhibited minimal activity (Einhellig, 1989).

The combination of the 20 allelochemicals resulted in an additive or synergistic effect. The inhibition threshold of mixtures was below most individual inhibition thresholds. It has been accepted in the literature that allelopathic interference often results from the combined effects of several different compounds (Rasmussen and Einhellig, 1977; Blum et al., 1985; Einhellig, 1987; Inderjit and Mallik, 1997). In a field situation where the amount of an allelochemical is often found to be well below the concentration for inhibition in a bioassay, such a concurrent interaction of allelochemicals may well be the explanation for the observed allelopathic phenomenon. The inhibition produced by the mixture of 20 allelochemicals combined in the same proportion found in the vulpia residue (mix 2) was compared with the inhibition produced by the crude ether fraction (An et al., 2000) by using as comparator the root inhibition area. The range of concentrations of 0–180 ppm for mix 2 was equivalent to the range of 0–1000 ppm for the crude ether fraction.

The result showed that the inhibition by mix 2 accounted for about 65% of the original inhibition produced by the whole ether fraction. Although the two bioassays were not conducted at the same time, they provide an indication that some compounds other than the chosen 20 allelochemicals identified are involved in the allelopathic interference by the vulpia residue. Indeed, GC-MS methylation analysis (An, 1995) identified about 25 compounds. If considering those additional compounds and the fact that syringic and hydroferulic acids were quantity-dominant compounds in the vulpia residue composition, the further inclusion of hydroferulic acid, with or without those additional compounds, in the mixtures for biological activity tests, would certainly increase the accountability of the allelochemical mixture for overall vulpia toxicity.

The concept of a phytotoxic strength index was developed for characterizing biological properties of allelochemicals and for quantifying their individual behaviors in a concise, comprehensive, and meaningful format. With such a single value index, the biological characteristics of 20 compounds were clearly distinguished. Even though the index was only adopted here for relative pur-

poses, its application went beyond the original context. For example, the index was used for assessing the relative contributions of each individual compound to the overall vulpia phytotoxicity. It was revealed that the relative phytotoxic contribution of an individual compound is largely correlated with its concentration. Even though hydrocinnamic acid and catechol had high phytotoxicity, their effects were greatly diminished by their trace levels in the vulpia residues; whereas the weak or medium toxicities of vanillic, syringic, and succinic acids were compensated for by their higher concentrations. The composition of allelochemicals in vulpia residues was dominated by the compounds that have only a low or medium phytotoxic strength but contribute most to the overall phytotoxicity, while a minority of compounds have high phytotoxic strength but are present only at trace levels. The more that allelochemicals are assessed for their phytotoxic strength index in a collective context, the more useful and meaningful the index will become, and contribute more to the understanding and application of allelopathy.

The combination of allelochemicals in equal proportions (mix 1) yielded less inhibition than the combination of allelochemicals in their natural proportions, even though the contribution to the mix of some compounds with high phytotoxicity had increased. This indicates that the composition of a natural allelochemical mixture is a more complex matter than the simple additive effect of 20 compounds. The synergistic effect is often far more profound than the mere additive effect. The contribution of each individual compound to the whole matrix of allelochemicals would be affected not only by its individual phytotoxic strength and the concentration present, but also most likely by the mixture's natural composition. This suggests that exploration of the composition of a cluster of allelochemicals may be more important than concentrating on the identification of one or two allelochemicals with strong biological activity. The relative composition of allelopathic mixtures in nature is fundamental to our understanding of allelopathy.

(Received October 11, 1999; accepted July 30, 2000)

Abstract—The behavior and dynamics of 20 identified allelochemicals in vulpia residues were both collectively and individually monitored, and their kinetic phytotoxicity was assessed. The total content of the identified allelochemicals in decaying vulpia residues increased from 0.31 to 1.24 mg/g dry residue over a 21-day decomposition period, while the total phenolic content increased from 1.86 to 2.16 mg/g dry residue. This corresponded to a phytotoxicity increase from 42% to 82% of radical inhibition. Allelochemicals changed in composition and quantity over the duration of the residue decomposition. Addition of soil to the residues reduced the total allelochemical contents extracted and altered the dynamic pattern. In the same period, the total content of allelochemicals declined from 0.061 to 0.046 mg/g residue + soil, with the total phenolics reduced from 0.20 to 0.11 mg/g residue + soil, corresponding to a radical length increase from 53% to 109% of control. Only 14 of the identified allelochemicals were detected in the mix of soil and residues, in contrast to 20 present in the residues alone. The implications of these findings are discussed.

Key Words—Phytotoxicity, allelopathy, allelochemical(s), vulpia, phenolic compounds, dynamics, plant residues.

INTRODUCTION

The monitoring of allelochemical dynamics in the environment is one necessary step for establishing conclusive proof of allelopathy (Putnam and Tang, 1986;

*To whom correspondence should be addressed. e-mail address: man@csu.edu.au

0098-0331/01/0200-0395$19.50/0

Dalton, 1999). Once allelochemicals are released into the environment, they are immediately subject to various physicochemical and biological processes, and they may be detoxified or toxified by soil organisms and/or may serve as a carbon skeleton for the production of new toxins by organisms in the soil (Blum et al., 1999). The composition and quantity of allelochemicals may vary substantially over time or with changed environmental conditions (Shindo and Kuwatsuka, 1977; Wójcik-Wojtkowiak et al., 1990; Dalton, 1999; Okumura et al., 1999). Phenolic acids, well-known potential allelochemicals, are readily converted from one structure to another with different phytotoxicities (e.g., ferulic acid to vanillic acid) by soil-borne microbes (Blum, 1998). For example, the content of *p*-hydroxybenzoic acid increased simultaneously with a rapid decrease in *p*-coumaric acid during the incubation of rice straw (Shindo and Kuwatsuka, 1975a,b). Phytotoxicity dynamics during residue decomposition has been well documented (Patrick et al., 1963; Chou and Lin, 1976; Mason-Sedun and Jessop, 1988). In general, decaying plant residues exhibit the most severe inhibition at the early stages of decomposition. As decomposition proceeds, the phytotoxicity declines. Only stimulation is evident at the later stages of decomposition (Mason-Sedun and Jessop, 1988; An et al., 1996a). Concentration changes of allelochemicals from decomposing plant residues have been shown to be related to phytotoxicity dynamics (Chou and Patrick, 1976; Tang and Waiss, 1978). An et al. (1996a) also theoretically demonstrated such a correlation from the viewpoint of mathematical modeling. However, little information is available on allelochemical dynamics during residue decomposition, either individually or collectively. Such matters as peak concentration, background concentration levels, shifts in composition, and the duration of peak concentration are largely unknown.

We have shown that the phytotoxicity of an aqueous extract of vulpia residues increased as decomposition proceeded, reached a maximum after 60 days of decomposition, and gradually diminished thereafter (An et al., 1997). Addition of soil to vulpia residues alleviated its allelopathic potential (An et al., 1993). Twenty-one compounds were identified and quantified in those vulpia residues (An et al., 2000), and their biological activity, characteristics, and individual contributions to overall phytotoxicity were subsequently assessed (An et al., 2001).

The objectives of this study were to elucidate the behavior of the identified allelochemicals during the decaying process of vulpia residues under various conditions, to monitor their quantity changes both collectively and individually, to gain insight into the allelochemical kinetics, and to clarify the correlation between phytotoxicity and allelochemical dynamics.

METHODS AND MATERIALS

Vulpia Residues and Soil. Material was obtained from pure mature stands of *V. myuros.* The residue material was cut 1.0 cm above the soil surface by hand,

oven dried at 40°C for 72 hr, and stored in dry conditions until commencement of the analysis.

About 1000 g soil was obtained from the top 10 cm layer of a vulpia-free field from the Charles Sturt University farm in Wagga Wagga, Australia. The soil was dried at 40°C, crushed, and passed through a 2-mm sieve.

Experimental Design and Decomposition Samples. Three treatment series were undertaken: residue alone, soil alone, and a mixture of residue with soil (residue + soil). Six decomposition periods, 1, 3, 7, 10, 14, and 21 days, for each treatment were used. For the residue alone treatment, 25 g dried vulpia residues, ground in a Wiley mill (1-mm mesh), were placed in a 500-ml glass jar with a lid, and 75 ml distilled water were added and mixed well. For the soil alone treatment, 25 g soil was placed in a 500-ml glass jar, and 7.5 ml distilled water was added to reach the field capacity of the soil. All samples were incubated in the dark at 20°C and allowed to decompose for the time period mentioned above. The air in the jar was exchanged through three 2-mm-diameter holes in the lid. The moisture content of the samples was kept constant by daily weighing the jars and supplementing the evaporated water loss.

Preparation of Aqueous Extracts. Aqueous extracts were obtained by adding 340, 290, and 350 ml distilled water to each sample of residue alone, soil alone, and residue + soil treatments, respectively, stirring for 10 min, and allowing them to settle for 5 min. The mixtures were decanted, filtered, squeezed through one layer of cheesecloth, centrifuged for 40 min at 3900 rpm, and then filtered through one layer of Whatman No. 1 filter paper. The volume of aqueous extract recovered from each of the three treatments was similar, about 270 ml. Each extract was partitioned into two lots and subjected to bioassay and chemical analysis, respectively.

Bioassay for Testing Phytotoxicity. The bioassay was carried out in 9-cm plastic Petri dishes lined with one piece of Whatman No. 1 filter paper. Fifteen germinated wheat (*Triticum aestivum* cv. Vulcan) seeds, radical length 3–5 mm, were transplanted in each dish, and 5 ml of sample extract was added. Control treatments received 5 ml of distilled water. The dishes were placed in an incubator, in the dark, at 24°C. After 48 hr, the lengths (millimeters) of the longest seminal root and coleoptile were measured. The average length per Petri dish was used for statistical analysis. The bioassay was arranged in a randomized complete block design with three replicates.

Extraction and Separation of Allelochemicals. Acetone (750 ml) was added to 250 ml of the aqueous extract from each treatment. The mixture was stirred at slow speed overnight at room temperature. Proteins and lipids in the supernatant were precipitated and filtered by vacuum filtration through two layers of Whatman Nos. 4, 1, and 42 filter papers. The precipitate was discarded. The acetone was removed from the extract by rotary evaporation below 40°C. The clear aqueous extract was sequentially partitioned twice with 500 ml hexane,

then five times with 300 ml diethyl ether. The hexane fraction was discarded, and the diethyl ether fraction was dried with Na_2SO_4, concentrated to dryness and weighed.

Determination of Total Phenolics. After evaporation of acetone from the above aqueous extracts, 30 ml sample extract was taken for estimating total phenolic contents by colorimetric procedures that used Folin-Ciocalteau phenol reagent (Sigma-Aldrich Australia) (Lowe, 1993).

For the soil alone treatment, 10 ml of extract were placed in test tubes, and then 3 ml 20% Na_2CO_3 solution (w/v) was added to each tube, followed by 1 ml Folin-Ciocalteau reagent. The solutions were mixed well and allowed to stand for 1 hr at room temperature (20–25°C); the absorbance was read at 750 nm in a spectrophotometer against a distilled water blank. For the residue alone, the sample was replaced by 0.5 ml extract and 9.5 ml distilled water. For residue + soil, the sample comprised 5 ml extract and 5 ml distilled water. The total phenolic substances in aqueous extracts were calculated from the calibration curve prepared from solutions of 1, 2.5, 5, 7.5, and 10 μg/ml vanillic acid and were reported as micrograms vanillic acid equivalents per milliliter of extract.

Qualitative and Quantitative Determination of Allelochemicals. The 21 allelochemicals identified before (An et al., 2000) were targeted in three experimental treatments through the decomposition period. The sample preparation and GC-MS analyses were the same as previously described (An et al., 2000). All samples were first subject to silylation and then analyzed by using a Hewlett-Packard 5890 series II gas chromatograph coupled with a VG Trio-2 mass spectrometer. Target compounds in samples were identified by comparison with GC retention times and MS of reference compounds. Quantitation was done by an internal standard method with multiple-point calibration curves. All samples were run in triplicate.

RESULTS

Phytotoxicity of Decomposing Vulpia Residues

With treatment of residue alone, all aqueous extracts exerted a strong inhibition on the test plant, with 42–82% radical length being inhibited (Figure 1a). The decomposition of residue accelerated the development of phytotoxicity. After one day of decomposition, the residue extract caused 42% inhibition of root length, and 11% of coleoptile length. As decomposition proceeded, phytotoxicity steadily increased and reached its maximum at day 21, and inhibition on root and coleoptile length of wheat increased to 82% and 72%, respectively (Figure 1a and b).

Addition of soil to residue altered the residue phytotoxicity pattern (Figure 1). The aqueous extracts from the mixture of residue + soil only exhibited

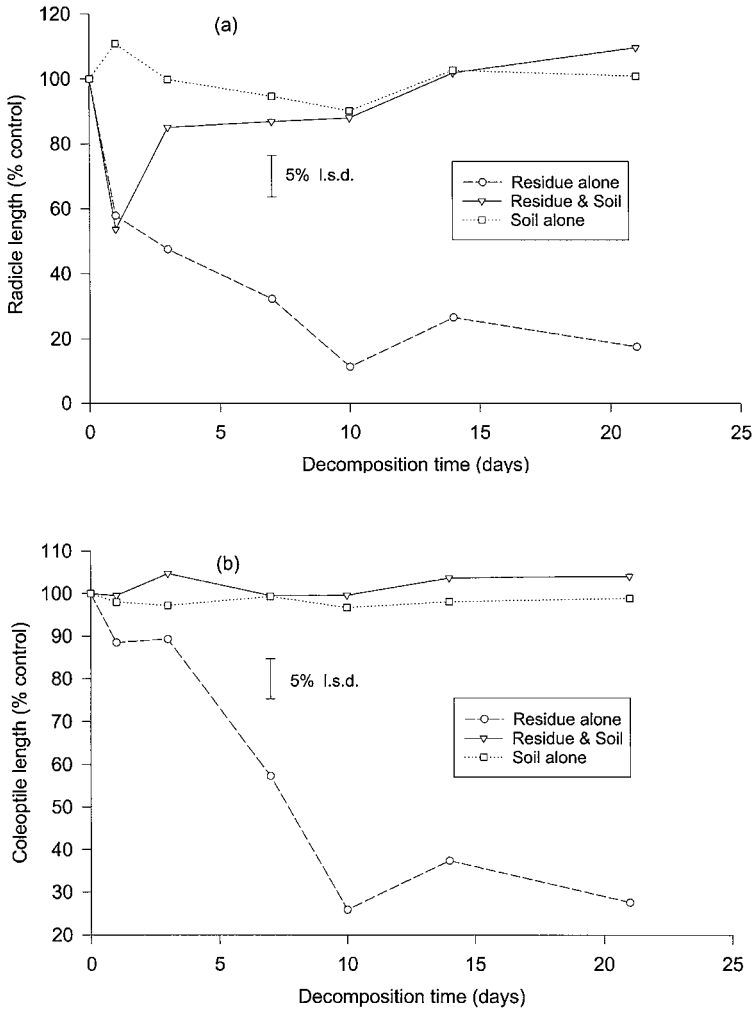

FIG. 1. Phytotoxicity dynamics of three experimental treatments as measured by seedling length of test plants (wheat cv. Vulcan): (a) measured by radicle length; (b) measured by coleoptile length.

severe phytotoxic effects on root length of wheat at an early stage of decomposition, i.e., at day 1 it inhibited up to 45% of radical length. As decomposition time increased, phytotoxicity rapidly decreased. By day 14 of decomposition, the phytotoxicity completely disappeared. At day 21, radical growth was actually stimulated. The coleoptile responses were no different from the control over

the whole decomposition period. The treatment of soil alone showed no effects on wheat growth, and only fluctuated around the control responses.

Total Phenolic Contents and Phytotoxicity

Total phenolic contents in residue alone were the highest among the three treatments, and steadily increased as the decomposition proceeded (Figure 2). Over a 21-day period, the total phenolics in aqueous extracts increased from 137 to 159 ppm, which accounted for 0.19% and 0.22% residue dry weight, respectively. The soil alone had the lowest phenolic contents. Its concentrations fluctuated between 1.2 and 6.1 ppm, which only accounted for 0.001 and 0.007% soil dry weight. The dynamics of total phenolics in residue + soil was different from both the residue-alone and soil-alone treatments. Addition of soil to residue reduced total phenolics, as well as changed their pattern compared to the residue alone. The total phenolic contents of residue + soil ranged from 15.0 to 44.3 ppm, about 10-fold decrease compared to the residue alone.

The phytotoxicity of all treatments was closely related to their corresponding total phenolic contents (Figures 3 and 4). The 42% radical inhibition in residue alone corresponded to a 137 ppm total phenolic content, while 15 ppm total phenolic content in residue + soil corresponded to a radical length increase of 110% control. Total phenolics in soil alone varied between 1.0 and 6.0 ppm, while the corresponding phytotoxicity only fluctuated around the control

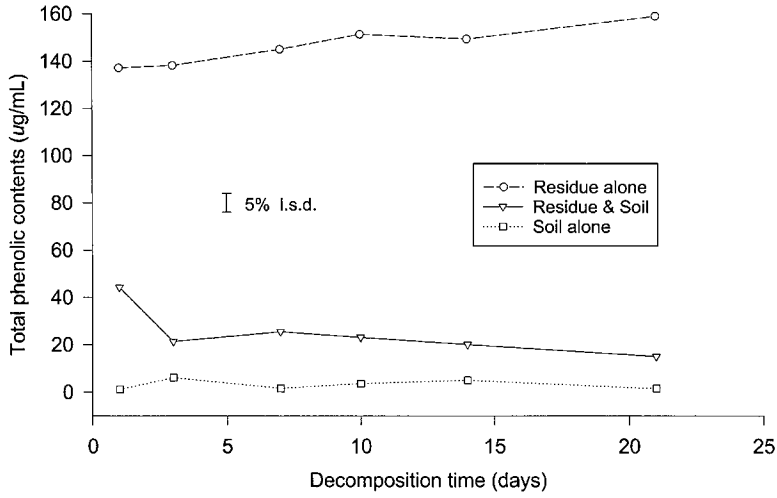

FIG. 2. Dynamics of total phenolic contents in three experimental treatments.

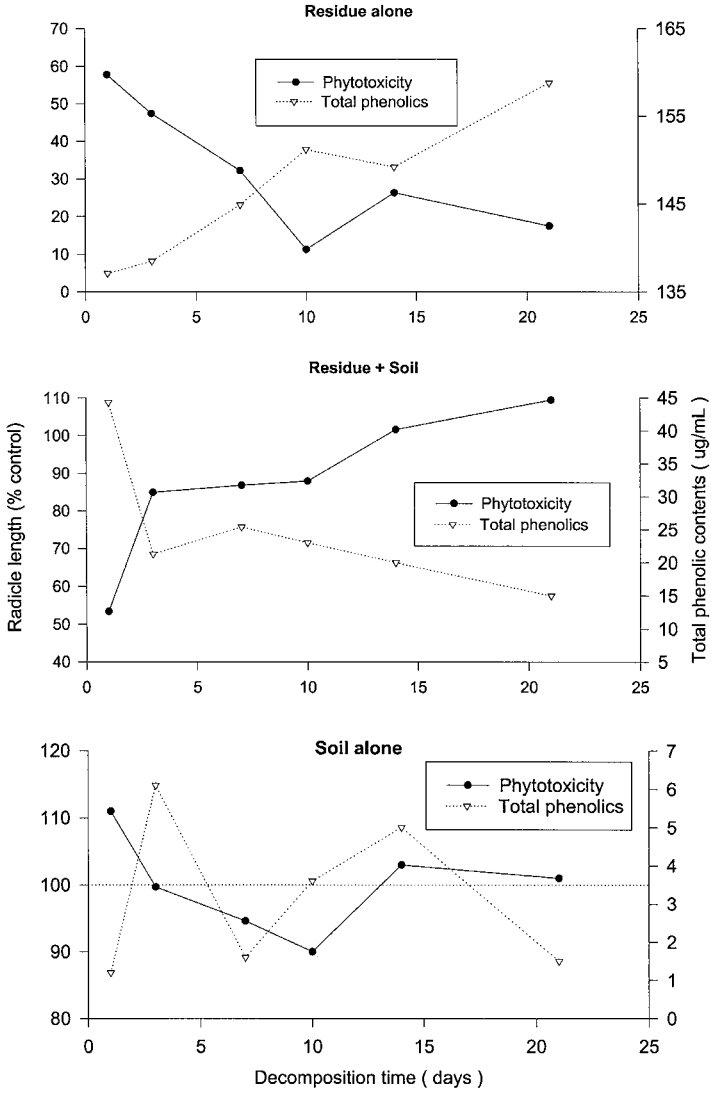

FIG. 3. Phytotoxicity dynamics of three experimental treatments with the corresponding dynamics of their total phenolic contents.

responses. In general, high total phenolic contents in aqueous extracts corresponded to severe inhibition, while low contents were associated with much less inhibition or no inhibition, even stimulation.

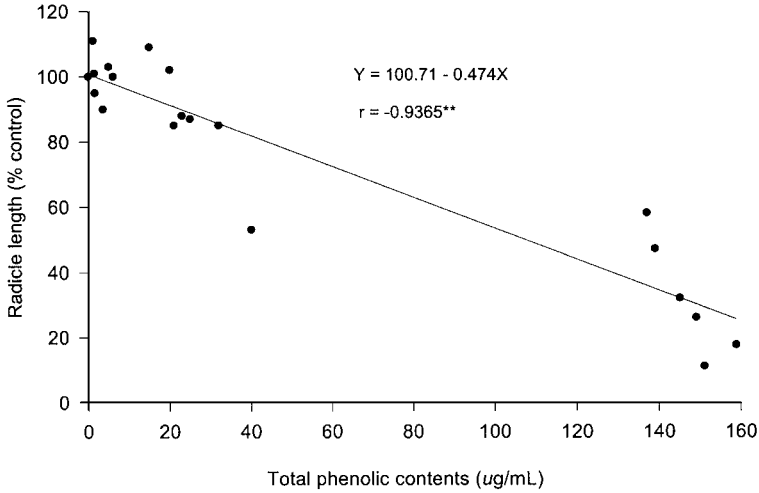

FIG. 4. The correlation between phytotoxicity of aqueous extracts of three treatments and their total phenolic contents.

Dynamics of Composition and Quantity of Allelochemicals

Residue. Among the 21 allelochemicals monitored, all except pyrogallol were detected. However, their presence and quantities were varied considerably, depending on individual compounds as well as the decomposition process (Table 1). Hydrocaffeic and *p*-hydroxybenzenepropanoic acids appeared as the decomposition proceeded, whereas the appearance of hydroquinone, salicylic, and gentisic acids fluctuated over the course of decomposition. The quantities of compounds, such as benzoic acid, succinic acid, catechol, 3,4-dimethoxyphenol, salicylic acid, α-hydroxybenzenepropanoic acid, *p*-hydroxybenzenepropanoic, syringic, and hydroferulic acids, were generally increased in the course of decomposition. With compounds such as *p*-hydroxybenzoic, vanillic, *p*-coumaric, and ferulic acids, their quantities were initially high, but decreased from day 7 to day 14 of decomposition, then increased at day 21. Other compounds, such as hydroquinone, coniferyl alcohol, hydrocinnamic, *p*-hydroxyphenylacetic, gentisic, protocatechuic, and hydrocaffeic acids remained relatively constant over the decomposition period.

The sum of the allelochemicals generally increased over the decomposition period, from 306 to 1236 μg/g residue, which accounted for 0.03% and 0.12% residue weight, respectively, and accounted for 16% and 57% total phenolic contents. The dynamic pattern was similar to that of total phenolics.

Resiue + Soil. Compared to the 20 allelochemicals detected in the residue-alone treatment, only 14 were detected in the residue + soil. The appearance of

Hydrocaffeic acid			7.85	8.80	10.09	8.95
Ferulic acid	54.81	54.24	10.83	10.22	18.50	55.01

these 14 allelochemicals varied with decomposition time and with the individual compound (Table 2). Catechol, salicylic, *p*-hydroxybenzenepropanoic, vanillic, syringic, and *p*-coumaric acids were only detectable in some stage of the whole decomposition process. Hydroferulic acid was only present at day 1 of decomposition, thereafter only syringic acid was detectable. The number of allelochemicals in the composition varied with the decomposition time. At day 1, 14 allelochemicals were detected, but the number decreased afterwards. The quantities of compounds such as benzoic acid, succinic, *p*-hydroxybenzoic, vanillic, and *p*-coumaric acids decreased as the decomposition proceeded, while others remained relatively constant.

In general, even though the quantities of total allelochemicals were slightly higher at an early stage of decomposition, they basically remained constant. In contrast with the residue alone, the total quantities of allelochemicals declined, reduction ranging from 83 to 97% over the decomposition period. However, their proportions to total phenolic content increased as the decomposition proceeded, similar to the residue alone treatment.

Soil. The results were the same as for the residue + soil treatment. Only 14

[a] Syringic and Hydroferulic acids.

allelochemicals were detected, but salicylic acid in the residue + soil was substituted by protocatechuic acid. The appearance of all compounds except *p*-hydroxyphenylacetic, ferulic, hydrocinnamic acids, catechol, and succinic acid, fluctuated over the decomposition period (Table 3), as did the total quantities. The decomposition period did not affect allelochemical contents in the soil. The allelochemical levels in the soil were low, about 1.2–10.1 μg/g dry soil, accounting for only 0.0001–0.0010% dry weight, significantly lower than both the residue and the residue + soil treatments.

DISCUSSION

Phytotoxicity dynamics varied with the experimental treatments. Residue alone showed a steady increase in phytotoxicity as the decomposition proceeded. Soil alone did not show any significant stimulation or inhibition over the whole decomposition period, while the addition of soil to residue, i.e., residue + soil, significantly alleviated the phytotoxicity of vulpia residue. This is consistent with previous findings (An et al., 1993, 1997). Considering that the phytotoxicity of vulpia residues declined after 60 days of decomposition (An et al., 1997), the alleviation of residue phytotoxicity by soil may be attributable to an alteration in

the dynamic pattern of toxin development, driven by biotic and abiotic processes in soil (Bhowmik and Doll, 1979, 1984; Weston and Putnam, 1986; Blum et al., 1999). It may be that as the ratio of soil to residues increases, such an alteration of phytotoxicity pattern would not be obvious. Nevertheless, the finding that residue + soil still exerted strong inhibition at an early stage of the decomposition strongly indicated the existence of such a pattern change. This was certainly important in applying the findings to field practice. For example, a management strategy that used cultivation and then the delay of sowing for about three weeks avoided the peak inhibitory period from vulpia residues but took advantage of the noninhibitory period later, and thereby allowed successful pasture establishment, which had failed earlier owing to heavy infestation by vulpia (An et al., 1996b).

The results of the allelochemical dynamics agreed with the phytotoxicity kinetics, confirming the strong correlation expected between the phytotoxicity of residue extracts and their total phenolic contents. There exists a significant linear correlation ($r^2 = 0.99^{**}$) between vulpia extract concentrations and their total phenolic contents and between vulpia extract concentrations and their phytotoxicity (An, 1995). A causal relationship between these allelochemicals and phytotoxicity has been previously documented (Lovett and Ryuntyu, 1992; An et al., 1993). The present results further enhance the proposition that the identified phenolic compounds were the responsible agents for vulpia phytotoxicity.

The data presented here show that the behavior of individual allelochemicals and the composition of allelochemicals are different, depending on the

degree of residue decomposition. In the residue alone treatment, even though the sum of individual allelochemicals generally increased over time, compounds such as protocatechuic and hydrocinnamic acids kept relatively constant levels, while compounds such as ferulic and vanillic acids showed an increase, a decrease, and then another increase. The appearance of hydroquinone and salicylic acid fluctuated, and hydrocaffeic acid only appeared after seven days of decomposition. Such behavior of phenolic compounds was also observed by Wójcik-Wojtkowiak et al. (1990) and Shindo and Kuwatsuka (1975b) in rye and rice residues, respectively. Chou and Patrick (1976) reported that the concentration of toxins from corn residues reached a maximum at 15–25 days of decomposition and declined thereafter. As it is known that allelopathic effects are often the result of synergistic activity by a cluster of allelochemicals and that synergistic effects are dependent upon the composition of allelochemicals, a better understanding of such compositional changes may be required for effective field application of allelopathy.

The decomposition period had no effect on the phenolic content in the soil-alone treatment. This may indicate that soil itself contained a certain level of phenolic compounds that was not high enough to have effects upon plants and that these phenolics were at an equilibrium level among microbes and various environmental factors such as moisture and temperature. Phenolic acids, such as *p*-hydroxybenzoic, vanillic, *p*-coumaric, and ferulic, have been commonly found in soil: their quantities varied, depending upon plant species growing on the soil, soil type, and extraction method (Dalton, 1999). In the soil alone treatment, allelochemical quantities ranged between 1 and 10 μg/g soil. Biological tests in our previous paper (An et al., 2001) have shown that the activity threshold concentrations of those individual allelochemicals present in soil averaged 150 ppm, but with respect to an artificial 20-compound mixture, the average was only about 9 ppm. In the present study, only 14 compounds were detected in the soil treatment, and the average threshold concentration of those individuals in this mix would be likely greater than 9 ppm, far higher than their actual levels present in the soil. This may explain why the soil alone did not have any effect on test plants.

With the residue + soil treatment, low levels of allelochemicals, as well as fewer allelochemicals, were found. The dynamics pattern of allelochemicals from vulpia residues was altered by the incorporation of soil. In terms of the behavior of individual allelochemicals, it was similar to the residue-alone treatment. The persistence of most compounds was not changed, but their levels decreased over the decaying process. Allelochemicals are subject to various biotic and abiotic processes that reduce their concentrations and availability after their release into the soil. Such processes include utilization by soil-borne microorganisms (Blum and Shafer, 1988; Blum et al., 1998, 1999), sorption by soil organic matter (Makino et al., 1996) and clay minerals (Huang et al., 1977),

polymerization (Wang et al., 1986), chemical transformation into other toxic or nontoxic compounds (Blum, 1998; Okumura et al., 1999), and the degree of contact with plant roots (Blum et al., 1999).

To exert allelopathic effects on target plants, allelochemicals, after release into the environment, need to persist in the soil, undergo biotic and abiotic processes, and reach sufficient concentration for effect. The production, transformation, and destruction of phytotoxic compounds from decaying plant residues occur simultaneously in the soil (Blum, et al., 1999). The effective quantity is the difference between the amount produced and the amount inactivated. Thus, retention and the effective quantity of allelochemicals in soil and their ultimate allelopathic effects will vary, depending upon the relative rates of addition of allelochemicals to the environment, their decomposition or inactivation, the soil properties, and physicochemical conditions. Data from residue + soil showed that the addition of residue to soil increased phytotoxin production in the soil, even though allelochemicals were adsorbed, decomposed, inactivated, and/or polymerized to some extent by the soil. The levels of allelochemicals produced were generally discounted in soil, but sufficient concentration for inhibition still occurred for a short time, as evidenced by the severe phytotoxicity at an early stage of decomposition. In reality, such short-term inhibition could affect a susceptible organism's ability to compete with a nonsusceptible organism (Rice, 1984). As the decomposition period was prolonged, the amount of allelochemical inactivation could not be balanced by new production. Phytotoxin levels soon declined to plant-tolerant levels, which were compatible with the levels in soil. This was reflected in phytotoxic terms as no significant detrimental effects on test plants.

DESCRIBING PHYTOTOXIC EFFECTS ON CUMULATIVE GERMINATION

L. S. DIAS

Departamento de Biologia, Centro de Ecologia Aplicada
Universidade de Évora
Ap. 94, 7002-554 Évora, Portugal

(Received January 26, 2000; accepted October 7, 2000)

Abstract—Phytotoxic studies strongly depend on evaluation of germination responses, which implies the need for adequate procedures to account for distinct aspects of the germinative process. For this, indices, comparisons among treatments at various times, and model fitting have been proposed. The objective of this work is to compare the three approaches and select the one providing the greatest insight and precision. Speed of germination, speed of accumulated germination, the coefficient of the rate of germination, comparisons at each determination time, including final germination, and the parameters of the Weibull function were examined. The Weibull function proved the best approach to describe the germination process, providing not only the same type of information about the speed of germination, with greater precision, but also additional information about the initiation and shape of the germination response curve.

Key Words—Allelopathy, *Cistus ladanifer*, germination, indices, phenolics, phytotoxicity, *Trifolium subterraneum*, Weibull function.

INTRODUCTION

Allelopathic and phytotoxic studies often involve the assessment of chemical effects on germination, requiring adequate description of the germinative process in addition to data on final germination alone. Attempts to describe germination responses in phytotoxic studies include the use of indices such as the speed of accumulated germination (Einhellig et al., 1982), coefficient of the rate of germination (Dias, 1991), and speed of germination (Wardle et al., 1996), the fit of Richard's function (Lehle and Putnam, 1982), or the test of differences in cumulative germination separately for each time of counts (An et al., 1996).

More recently, Chiapusio et al. (1997) compared four indices and compar-

0098-0331/01/0200-0411$19.50/0

isons between the control and treatments at each time of counts for their ability to test physiological hypotheses in allelopathic studies. The indices were: (1) total germination (G_T) expressed as proportion or percentage, by far the most commonly used germination descriptor; (2) speed of germination (S), usually known as Maguire's (1962) speed of germination; (3) speed of accumulated germination (AS), which can be traced back to Kendrick and Frankland (1969) and Bouton et al. (1976); and (4) coefficient of the rate of germination (CRG), presented by Kotowski (1926), its reciprocal being in use for more than a century (Edwards, 1934).

The results suggest that data interpretation depends on the index, that all indices fail to reflect adequately all allelochemical effects on germination, and that single comparisons between control and treatments at each time would be more appropriate (Chiapusio et al., 1997).

The option for comparisons between the control and treatments at each time germinated seeds were counted (observation time) raises a number of practical and theoretical questions. First, if different phytotoxic studies are to be compared, some kind of standard should be accepted for the observation time. This is a practical objection that raises questions as to the definition of observation time, its adequacy for different species, and the possibility that data interpretation might depend upon observation time; in fact, if different time intervals are chosen, different patterns of effects could emerge, as a close look at the report of Chiapusio et al. (1997) of *p*-hydroxybenzoic acid effects suggests. Finally, there is the more theoretical question of the real meaning, physiological or allelopathic, of making comparisons at 6-hr intervals or any other equally or unequally spaced interval.

An alternative approach would consider the whole process of germination, with observation time depending primarily on the species used. Therefore, observation time would provide point estimates, meaningless per se, allowing the fit of a general model that should be flexible enough to accommodate the widest possible range of germination patterns and with parameters meaningful in terms of germination. Additionally, it would be advantageous to separate the end of the process, expressed by total germination, from the path taken to attain it.

A number of models have been proposed to describe and compare germination, including orthogonal polynomials (Goodchild and Walker, 1971), cumulative normal distributions (Janssen, 1973), logistic functions (Schimpf et al., 1977; Hsu et al., 1984), gamma distributions (Thornley, 1977), Richard's function (Lehle and Putnam, 1982), and Weibull function (Bonner and Dell, 1976; Brown, 1987). Objections to many can be found in Brown and Mayer (1988), and include the failure of orthogonal polynomials to asymptote, the sensitivity to late-germinating seeds in gamma distributions, and the unreasonable assumption of symmetry in normal and logistic functions. In addition, when these and other models were compared in the same set of data by Brown and Mayer (1988), the

Weibull function (Weibull, 1951) proved the most suitable on theoretical and practical grounds (better fit and less sensitivity to initial estimates), accommodating a wide range of germination patterns (Brown, 1987).

The three-term Weibull function can be expressed by

$$Y = 1 - \exp - \{[(X - l)/k]^c\}$$

where Y is the cumulative proportion of germinated seeds at time X, l is a location parameter estimating the latest time at which the germination is zero, k is a scale parameter with $l + k$ estimating the time at which the germination is 0.63, and c is a shape parameter that evaluates the symmetry of the distribution ($3.26 \leq c \leq 3.60$ showing symmetry, $c < 3.26$ positive, $c > 3.60$ negative asymmetry).

Therefore, the objectives of the present study were to compare the adequacy of the Weibull function to reflect phytotoxic effects on germination with comparisons between cumulative germination at each observation time and the indices examined by Chiapusio et al. (1997). The experimental procedure involved testing the effects on germination of complete and phenolics-removed water extracts of vegetative shoot tops of *Cistus ladanifer* L., a spontaneous, aromatic shrub, known for its allelopathic activity (Dias et al., 1999). No attempt was made to fully consider the single or combined contribution of osmotic pressure or pH to the effects of water extracts.

METHODS AND MATERIALS

Materials. Shoot tops of *C. ladanifer* were collected near Évora (southern Portugal) in early summer. Cuttings included up to 50 mm of lignified stem, but only the three upper nodes were used. Seeds of subterranean clover (*Trifolium subterraneum* L. cv. Clare) were provided by the Estação Nacional de Melhoramento de Plantas.

Extract Preparation. Intact shoot tops were soaked in distilled water for 24 hr at 35°C, continuous light, filtered through Whatman No. 1 paper, and the extract adjusted to a concentration of 50 mg/ml (fresh weight volume). Phenolics were not quantified but their occurrence was ascertained by using Folin-Ciocalteau reagent (E. Merck). Half of the extract was repeatedly treated with Polyclar AT (BDH Chemicals, Ltd.), stirred for 15 min at room temperature, and filtered through Whatman No. 1 paper until no reaction with Folin-Ciocalteau reagent was detected by spectrophotometry. Both extracts were centrifuged for 30 min at 5200g, and the supernatant was used. Osmotic pressure and pH of the treatments, control included, were determined with a semimicroosmometer (Knauer type M) and a pH-meter (Metrohm E-520).

Germination Bioassay. Four replicated 10-cm Petri dishes were fitted with

Whatman No. 1 paper, sown with 25 seeds of subterranean clover, and wetted with 5 ml of the appropriate extract. The control was prepared similarly with distilled water. Seeds were incubated under a 20°C/30°C, 16/8-hr cycle, continuous dark, and were considered germinated if the radicle was at least as long as the greater dimension of the seed (Rietveld, 1975). Germinated seeds were regularly counted and discarded for eight days.

Germination Indices and Modeling. The selected indices, S, AS, and CRG, were calculated from the original data. For each observation time, cumulative germination (G_D) was expressed as proportion of sown seeds. The three-parameter Weibull function was fitted by least squares nonlinear regression with the Marquardt method, with data expressed as the cumulative proportion of seeds that actually germinated. Estimates of l were accepted only when their values were between the last time without and the first with observed germination. The same applies for k, considering that $l+k$ estimates the number of days at which the proportion of seeds that actually germinated is 0.63.

Statistical Analysis. Comparison of indices, G_D, and Weibull's parameters were made with a comparison-wise error rate of 0.05 by two-tailed Student's t or Mann-Whitney U tests.

RESULTS AND DISCUSSION

Results are summarized in Table 1. According to them, osmotic pressure and pH relevance can not be completely discarded, implying that, as usually happens in this type of study, the phytotoxic interpretation may include effects other than those of the biological activity of chemicals present in the extracts.

Nevertheless, the same information is obtained from the three indices S, AS, and CRG, namely that the complete extract and phenolics-removed extract differ from the control but not from each other. Because of the higher values of the indices in the control, water extracts of *C. ladanifer* reduce the speed at which germination develops, and because no differences were found between the extracts, that reduction can be attributed to the nonphenolic fraction.

When observation times are examined, there is a clear inhibition of germination associated with the two extracts at days 1.9 and 2.7, the intensity strongly decreasing from day 1.9 to day 2.7. At day 3.6, conclusions are prevented by the lack of "transitivity" (Chew, 1976), i.e., the complete extract and the control are the same, the complete extract and the phenolics-removed extract are also the same, but the control and the phenolics-removed extract are different. Results are clear again at days 4.7 and 7.7 ($=G_T$), when no significant differences were found among the control, complete extract, and phenolics-removed extract. Therefore, no effects of water extracts of *C. ladanifer* on final germination of subterranean clover were found. As detected by the three indices, both

[a] OP is expressed as mosmol/kg, S and AS as number of germinated seeds per day, CRG as day^{-1}, G_D as proportion, l and k as day. In the same line, means with different letters are significantly different at $P = 0.05$ ($N = 4$, except for Weibull parameters of control, where $N = 3$).

treatments significantly delayed germination, an effect that had disappeared by day 4.7 and should, as before, be attributed to the nonphenolic fraction of the extracts.

With the exception of one replicate of the control, the Weibull function could always be fitted, with the coefficient of determination ranging between 0.751 and 0.999 (average of 0.960).

No significant differences in l were found among the treatments and the control, suggesting that the ability of subterranean clover seeds to start germination is not affected by either the phenolic or nonphenolic fraction.

Conversely, significant differences in k were found between the control and extracts, but not between extracts. Thus, after the onset of the process, the rate of germination ($1/k$) is equally reduced by the complete and phenolics-removed extract (Figure 1). The nonphenolic fraction might be responsible for this effect, since no differences were found between extracts.

The same conclusion resulted when indices and single comparisons were examined. Modeling the germination process by the Weibull function, however, allows a more precise estimate of this delay, which can be expressed by the time needed to attain 0.5 of final germination (G_{50}). In this case, G_{50} is 1.395 days in the control, 2.724 days in the phenolics-removed extract, and 3.012 days in

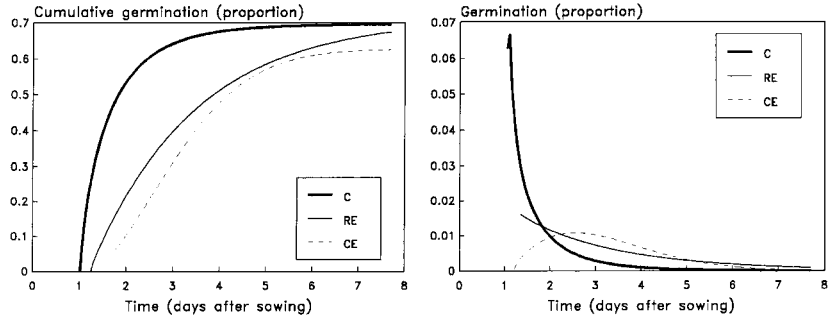

FIG. 1. Cumulative and noncumulative germination of subterranean clover in the control (C), phenolics-removed (RE), and complete (CE) extract, expected from fitted Weibull functions.

the complete extract if the start of the experiment is considered, or 0.375, 1.500, and 1.840 days, respectively, if the beginning of the germination, evaluated by l, is considered.

Finally, the shape of the germination is expressed by c. Given the mean value of the control, the germination of subterranean clover is clearly positively asymmetric with a pronounced tail to the right, as can be seen in Figure 1. This would be expected in such a species. The same occurs with the complete and phenolics-removed treatments. However, no differences were found between the control and phenolics-removed extract, with both differing from the complete extract. This implies that the strong asymmetry of the frequency distribution of germinated seeds over time is reduced by phenolic compounds extracted from *C. ladanifer*, but is insensitive to the nonphenolic fraction.

CONCLUSIONS

According to the data, (1) total germination and (2) time needed for its start are not affected by extracts; (3) the rate at which the germination proceeds from then on is equally reduced by the extracts, with the nonphenolic fraction being the cause; while (4) a less asymmetric distribution of germinated seeds is to be found when phenolic compounds of *C. ladanifer* are tested in addition to the nonphenolic fraction.

Conclusion 1 can only be obtained from single comparisons of final germination, which should always be considered in addition to Weibull modeling. Conclusion 3 can be obtained from indices, comparisons at determination times, or Weibull modeling, with the later allowing a greater precision. Finally, conclusions 2 and 4 only emerge when the Weibull function is fitted to the data,

providing a more complete and insightful picture of phytotoxic effects on germination.

Therefore, the use of the Weibull function appears to be a better approach to describe and analyze germination processes in phytotoxic studies, compared to cumulative germination at each observation time or the use of common indices.

Acknowledgments—I thank Gertrudes Mariano (Departamento de Biologia, Universidade de Évora) for technical assistance, Manuel Barradas (Director of Estação Nacional de Melhoramento de Plantas) for seed provision, and Alexandra S. Dias (Departamento de Biologia, Universidade de Évora) and two anonymous reviewers for comments on the manuscript.

(Received July 6, 2000; accepted October 31, 2000)

Abstract—We analyzed the flight of the rose chafer *Macrodactylus subspinosus* (F.) (Melolonthinae: Scarabaeidae) and the Japanese beetle *Popillia japonica* Newman (Rutelinae: Scarabaeidae) in a wind tunnel with controlled humidity, temperature, light, and airflow. The data indicate that an optimum combination of light and temperature dramatically improves their response to lures. Both species took off upwind, oriented to, and contacted the odor source well (40–60%) when light intensity was >50% of a clear day, temperature was 26–27°C, and relative humidity was 65–75%.

Key Words—Coleoptera, Scarabaeidae, Melolonthinae, *Macrodactylus subspinosus*, Rutelinae, *Popillia japonica*, wind-tunnel flight, semiochemicals.

INTRODUCTION

The most discriminating bioassays for characterizing semiochemicals are those that utilize the entire natural response and restrict the animal as little as possible (Miller and Roelofs, 1978; Baker and Cardé, 1984). "Because the responses made in-flight are so highly integrated, bioassays utilizing flight in wind are probably the most discriminating in pheromone research" (Baker and Linn, 1984). The wind tunnel has proven an invaluable tool in the identification of attractants for many insect species.

Attempts to conduct wind-tunnel bioassays with Scarabaeidae, such as the Japanese beetle, *Popillia japonica* Newman, and the rose chafer, *Macrodacty-*

lus subspinosus (F.) have met with limited success. This difficulty is evident in the fact that most sex pheromones and other attractants for scarabs have been developed using olfactometers or field tests. Although field-testing is important, it is most efficiently used as the ultimate test of the efficacy or accuracy of the synthetic blend. The advantages of using a wind tunnel over field studies in the initial stages of identification include greater control of variables that modulate response, higher discriminating power, and the ability to conduct experiments throughout the year or during inclement weather (Baker and Linn, 1984).

M. subspinosus is attracted to an equal blend of α-ionone, (*E*)-2-nonenol, hexanoic acid, pentanoic acid, and octyl butyrate (Williams et al., 1993). *P. japonica* is attracted to a 3 : 7 : 3 blend of 2-phenylethyl propionate, eugenol, and geraniol (PEG) (Ladd and McGovern, 1980). The sex attractant pheromone of *P. japonica* is (*R*,*Z*)-5-dec-1-enyloxacyclopentan-2-one (Tumlinson et al., 1977). In the field, traps baited with these compounds will catch large numbers of individuals in a short time (Williams et al., 1990; Klein et al., 1981), but in the laboratory, it is difficult to elicit upwind flight to either of these blends (Klein, Linn, and Robbins personal communication). Leal (1995, 1998) has successfully flown the scarab, *Anomala daimiana*, in a wind tunnel (Leal, 1995) and has demonstrated that it is possible to overcome the lack of a discriminating bioassay by using his "short-cut" techniques, but agrees that "one of the main barriers in the task of identifying sex pheromones from scarab beetles is the lack of a uniform and consistent bioassay" (Leal, 1995). Successful indoor wind-tunnel experiments with the green June beetle, *Continis nitida*, (Domek et al., 1990) have suggested that increased light intensity may be important. In their experiments, the wind tunnel was lit with sixteen 40-W cool white fluorescent tubes.

Scarabs include some of the world's most significant insect pests (Vittum et al., 1999), but pesticidal control of scarabs has been inconsistent since the loss of cyclodiene insecticides (Facundo et al., 1994). Cost-effective and discriminating laboratory bioassays would speed development of behavior-modifying chemicals as economically viable alternatives for control.

METHODS AND MATERIALS

Insects. M. subspinosus adults were obtained from field traps in Castalia, Ohio (41°22′52″N, 82°49′23″W) baited with the aforementioned five-component blend on June 5, 1999. The location was a sandy field of mainly tall fescue, *Festuca arundinacea*; orchard grass, *Dactylis glomerata*; and several Asteraceae members. *P. japonica* adults were obtained from field traps in Wooster, Ohio (40°46′47″N, 81°55′12″W) baited with PEG lure and the sex pheromone on June 22, 1999. *M. subspinosus* were kept cool and transported from the field in a plastic drink cooler. They were stored in said container near a window at

room temperature until needed and fed sections of musk thistle (*Carduus nutans*) collected from the Castalia site. *P. japonica* were also transported and stored in this manner, but were fed store-bought sliced red delicious apples. Beetles were stored up to five days before use in assays.

Chemicals. The equal five-component blend used in trials with *M. subspinosus* consisted of α-ionone and (*E*)-2-nonenol (Bedoukian Research Inc., Danbury, Connecticut); hexanoic and pentanoic acid (Aldrich Chemical Co., Milwaukee, Wisconsin); and octyl butyrate (Penta Manufacturing, Livingston, New Jersey). Neat PEG lure was obtained from Michael G. Klein, USDA-ARS, Japanese Beetle Laboratory, Wooster, Ohio.

Wind Tunnel. The flight chamber was a 50-cm × 50-cm × 200-cm pine frame painted gray. It had heat-shrink plastic windows and eight aluminum mixing screens mounted over the upwind end of the tunnel to reduce turbulence. Airflow was created with a window fan placed upwind of the mixing screens. Airspeed was measured by timing the flight of a pulse of wood smoke and maintained at 30 cm/sec for all experiments by varying the distance between the fan and the mixing screens.

The wind tunnel was housed in a 3.2-m × 2.4-m × 2.1-m high environmental chamber (Conviron model BDW80) that contained 16 metal halide lamps (MH) (General Electric, Multi-Vapor, MV-400), 16 high-pressure sodium (HPS) lamps (General Electric, Lucalox, LU-400), two 200-W incandescent bulbs (IB), chrome walls, and humidity and temperature controls. The light from all the lamps passed through a Plexiglas ceiling. In *M. subspinosus* trials, the temperature and relative humidity were constant at 26°C and 75% ± 5 ($\overline{X} \pm s$), respectively. Four light levels were used: 10 (2 IB), 480 (6 MH, 6 HPS, and 2 IB), 800 (10 MH, 10 HPS, and 2 IB), and 1260 μmol photons/sec/m^2 (16 MH, 16 HPS, and 2 IB). We used a fixed, factorial design in trials with *P. japonica* to test interactions between light and temperature. Relative humidity was maintained at 66% ± 7 ($\overline{X} \pm s$). Light levels were as above (with the omission of level 480) and crossed with the following four temperatures: 21, 24, 27, and 30°C. Light intensity was measured with a Li-Cor Quantum sensor, which measured photosynthetically active radiation (PAR, 400–700 nm), and a Li-Cor (LI-185B) display. The spectral quality of the light was also measured with a Li-Cor scanning spectroradiometer (model LI-1800), which measured radiation from 300 to 1100 nm at 2-nm intervals.

Experimental Protocol. Experiments were conducted in a randomized complete block with blocking over time. In both experiments, treatments within a block were presented randomly over time. *M. subspinosus* experiments were conducted in five blocks over one day (June 6, 1999) between 14:00 and 21:00 hours. *P. japonica* experiments were conducted in three blocks with one block conducted per day between 12:00 and 22:00 hr (June 23–25, 1999). The peak activity of *P. japonica* and *M. subspinosus* is between 13:00 and 15:00 hr (Lacey

et al., 1994) and 10:00 and 14:00 hr (Heath, unpublished), respectively. In all experiments, we conducted 10 trials per treatment replication and recorded the proportion responding.

Beetles were removed from their storage cage and transferred to 4.5-cm × 3.5-cm diam. cylindrical screen acclimation cages. They were then allowed to acclimate in the environmental chamber under treatment conditions for at least 5 min before trials. Each beetle was coerced to crawl from the acclimation cages onto a rolled section of screening and held about 15 cm into the end of the wind tunnel and at the same height as the chemical source (25 cm). Beetles were tested individually and given up to 1 min to respond. Three responses were recorded: take-off upwind, orientation to the odor plume (locking on), and source contact. Orientation was observed as a directed, relatively slow, flight upwind with very little horizontal casting. This response contrasted with seemingly random flight upwind often colliding with the wind-tunnel walls, which was scored only as take-off upwind. As in Facundo et al. (1994), those that took flight but did not contact the source were given a maximum of three chances within the 1-min period. The most complete response was recorded. Lures were placed 20 cm downwind of the mixing screens and at a height of 25 cm in glass vials near a crumpled white paper towel (flower mimic). The *M. subspinosus* five-component lure was presented at 10 mg/ml in ethanol and *P. japonica* PEG lure was presented at 100 mg/ml in ethanol. We did not determine the sex in *M. subspinosus* trials and to reduce variability only used males in *P. japonica* trials.

Statistical Procedures. Take-off upwind, orientation to the odor plume, and source contact were analyzed first with an ANOVA and then with polynomial contrasts using SYSTAT (Wilkinson et al., 1989). *M. subspinosus* source contact proportions were arcsin ($p^{1/2}$) transformed, and the transformed data met assumptions of homogeneity of variance and normality of errors. *P. japonica* source contact proportions met assumptions of homogeneity of variance and normality of errors without transformation. In both experiments, adults were used only once and chosen from a random section of the holding container.

RESULTS

Light intensity inside the wind tunnel was marginally reduced by the plastic windows, but the light quality (that is, the proportion of radiant energy devoted to each wavelength) was nearly unchanged. Likewise, among the three highest levels of light, the quality did not differ. However, the lowest level (10 μmol photons/sec/m^2) differed both in quality and quantity (Figure 1), since only the incandescent bulbs were used.

In both species, positive photoaxis was more obvious at the lower light levels. When light levels were increased, they reduced their flight toward the

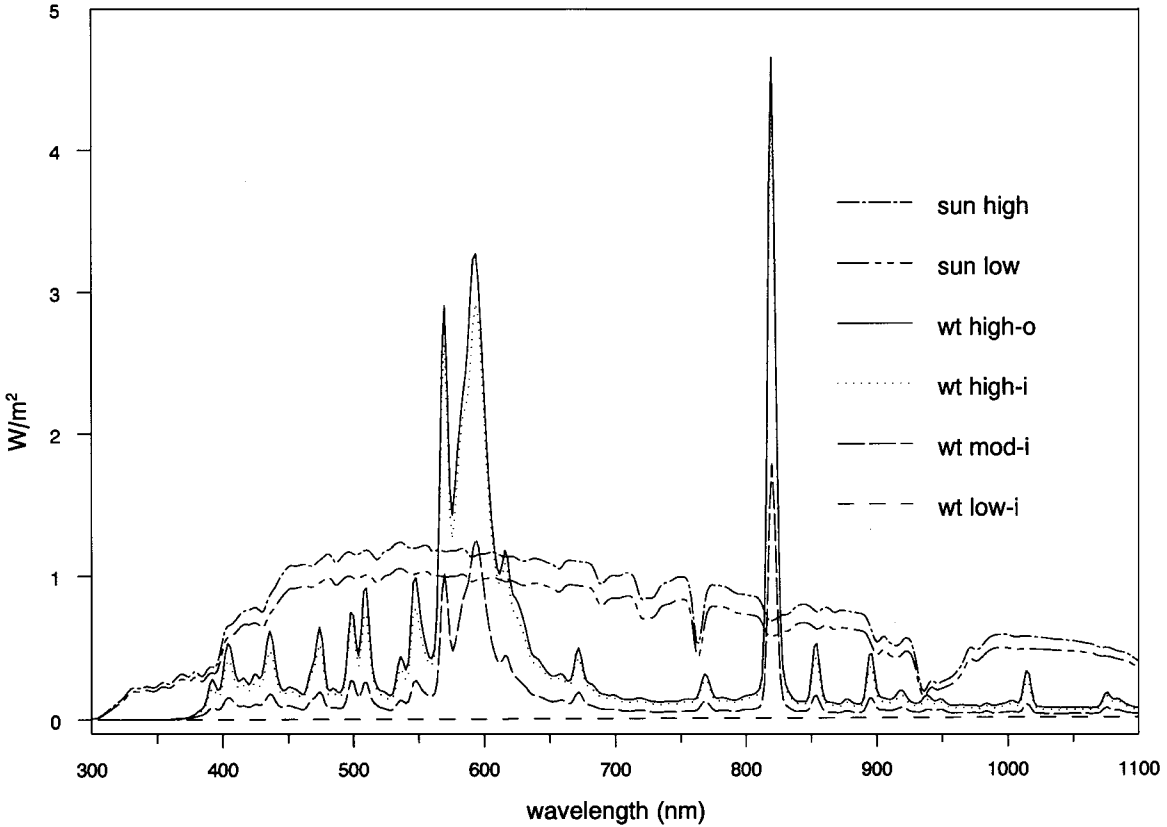

FIG. 1. Spectral quality of light used in the current experiments compared to that of natural light in Peoria, Illinois, in September. "Sun high" and "sun low" are at 12:36 hr and 11:36 hr, respectively; "wt high," "wt mod," and "wt low" in the legend refer to the 1260-, 480- and 10-μmol/sec/m^2 light levels, respectively. The suffixes refer to the location of the spectroradiometer sensor, which was either inside (-i) the wind tunnel or outside (-o) to illustrate the filtering effects of the wind-tunnel windows on light quality and quantity. Note that the "wt low-i" line runs close to the *x*-axis.

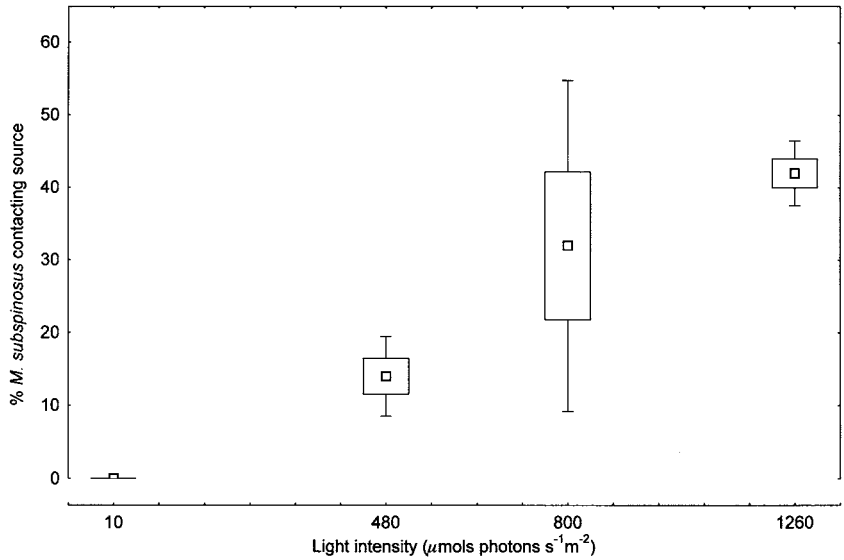

FIG. 2. Percentage of *M. subspinosus* adults contacting the source often ($N = 5$) with respect to light intensity (PAR, 400–700 nm). Mean, ±1 standard error, and ±1 standard deviation are represented by the point, box, and whiskers, respectively.

wind-tunnel ceiling after take-off and began orienting to the odor plume more readily. Details for the take-off-upwind and orientation-to-the-plume responses have been omitted for simplicity, but the profiles were generally very similar to those of the source-contact response analyzed below and presented in Figures 2 and 3.

In trials with *M. subspinosus*, the effect of light intensity on source contact was significant ($F = 13.6$; $df = 3, 12$; $P < 0.001$), but there was no significant block (time) effect. As light intensity increased, the ability of *M. subspinosus* adults to contact the odor source also increased linearly (Figure 2) (first-order polynomial contrast, $F = 39.0$; $df = 1, 12$; $P < 0.001$). Higher order (second and third) polynomial coefficients were not significantly different from zero.

In trials with *P. japonica*, the main effects of blocking ($F = 6.3$; $df = 2, 22$; $P = 0.007$), light intensity ($F = 26.5$; $df = 2, 22$; $P < 0.001$), and temperature ($F = 5.9$; $df = 3, 22$; $P = 0.004$) were all significant. However, there was a significant interaction between light and temperature ($F = 6.5$; $df = 6, 22$; $P < 0.001$, Figure 3). For instance, at 27 and 30°C, the highest light intensity inhibited response (only second-order contrasts were significant; 27°C: $F = 17.1$, $df = 1, 4$, $P = 0.014$; 30°C: $F = 28.0$, $df = 1, 4$, $P = 0.006$); but at 21 and 24°C, the effect of light was positive (only first-order contrasts were significant; 21°C: $F = 8.6$, *df*

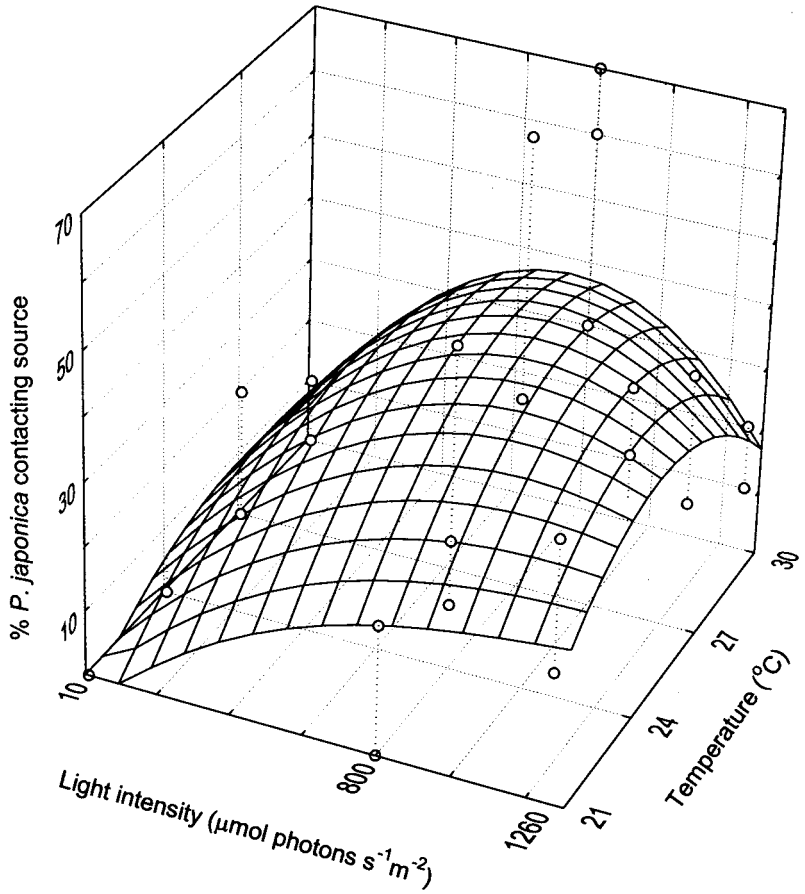

FIG. 3. Response surface and raw data for the percentage of 10 *P. japonica* males contacting the odor source with respect to light intensity (PAR, 400–700 nm) and temperature. Note several points are identical and thus overlapped ($N = 3$).

= 1, 4, $P = 0.043$; 24°C: $F = 17.2$, $df = 1, 4$, $P = 0.014$). Temperature × light polynomial contrasts revealed that increased temperature inhibited response at the highest light level (second-order contrast, $F = 8.7$, $df = 1, 6$, $P = 0.026$; first- and third-order contrasts were not significant). At the second light level, the effect of temperature on source contacts increased linearly (first-order contrast, $F = 22.9$, $df = 1, 6$, $P = 0.003$; higher-order contrasts were not significant). At the first light level, increasing the temperature did not significantly increase the response (all order contrasts were not significant).

DISCUSSION

We submit that identification of diurnal scarab semiochemicals has been slowed by the lack of a discriminating long-range laboratory bioassay. This deficiency is evident in the relatively large percentage of studies conducted under field conditions. These data suggest that the lack of high light intensities in past attempts with wind tunnels may have contributed to the failure to obtain a discriminating response. Lacey et al. (1994) found that *P. japonica* are most active in the field when wind speed is moderate and light intensity and temperature are maximized. Most wind-tunnel studies with beetles have used light intensities <80 μmol photons/sec/m^2 (Visser, 1976; Salom and McLean, 1990; Zhang et al., 1994; Prokopy et al., 1995; Evans and Allen-Williams, 1998) and only one (Domek et al., 1990) has used higher light intensities on scarabs. The light intensities in the current study were 10 times higher than in most studies and the data indicate that this is necessary to obtain a quantifiable response in these scarabs.

In trials with *P. japonica*, the response was inhibited at higher levels of temperature and light (Figure 3). Given that the quantity of stimulus presented was comparable to natural levels, the inhibition is likely due to differences in light quality. Figure 1 shows qualitative differences between sunlight and our artificial lighting with respect to wavelength. Although the total radiation, even at our highest level, was lower than a sunny day in September, the yellow–orange band at ca. 600 nm and the near-infrared band at ca. 825 nm were considerably higher than natural light (Figure 1). These qualitative differences could have their effect in a number of ways, of which spectral sensitivity is the most likely. The spectral sensitivity of *P. japonica* may be such that higher-than-natural levels of yellow–orange light may be inhibitory even when the total radiation is less than would occur naturally. *Liocola brevitarsis* (Scarabaeidae) are sensitive to light below 600 nm (Lin and Wu, 1991); if *P. japonica* possesses similar sensitivities, the high levels at 600 nm may inhibit them. Since beetles were stored in a relatively dark container prior to bioassays, their eyes would have been dark-adapted. This could have increased their sensitivity and thus indirectly decreased their threshold of inhibition.

The evolutionary advantage of flying to plant compounds only when the light levels are high is not obvious. However, Furutani and Arita (1990) have illustrated that total carbohydrate content of leaves is linked to light intensity and to Chinese rose beetle (Scarabaeidae) feeding preference. Furthermore, Wardlaw (1990) indicated that production and translocation of carbohydrates in plants varies diurnally. In this scenario, beetles that respond to plant volatiles when light intensity is high would increase their probability of finding plants high in carbohydrates. Further, if sight is important in recognizing hosts or mates, they may gain visual acuity with additional light. Further studies should consider whether

the effect exists for pheromones, which portion of the electromagnetic spectrum is responsible (i.e., UV, visible light, or infrared), where the modulating radiation is received, where in the nervous system the impulse is integrated to modulate behavior, and what benefit beetles gain from flying only when light levels are high.

These results have implications for conducting laboratory bioassays with other beetle families. Prystupa et al. (1988) conducted wind-tunnel studies with *Diabrotica* spp. in a greenhouse; results were more discriminating those those of an earlier experiment carried out in the laboratory (Dobson and Teal, 1987). However, Guss et al. (1982) report failed orientation experiments with *Diabrotica* in greenhouse studies. Since glass effectively filters out most infrared radiation (Lazzari and Nunez, 1989), it would be interesting to compare the greenhouse window materials in the aforementioned studies to gain insight into the importance of infrared radiation in modulating orientation. Bartelt and Zilkowski (1998) and Phelan and Lin (1991) have had considerable success flying nitidulids in wind tunnels, but the beetles often take several minutes to hours to respond (Zilkowski et al., 1999)—perhaps light is important.

Our finding that high light intensity dramatically increases diurnal scarab response to semiochemicals in a wind-tunnel bioassay should make future scarab semiochemical identifications faster and more cost-effective since workers will have the added advantage of a discriminating laboratory bioassay. It also highlights a potential model system for the study of how encoded olfactory information is modulated by other stimuli in the nervous system.

Acknowledgments—This project would not have been possible without the funding from the Ohio Grape Industry Committee. We thank Michael R. McGuire, USDA, Peoria, Illinois, for providing sunny day data, equipment, and assistance with the spectroradiometer measurements; Michael G. Klein, USDA-ARS, Japanese Beetle Laboratory, Wooster, Ohio, for providing the JB lures and helpful comments; and Jennifer L. Heath for assistance with the bioassays.

(Received March 8, 2000; accepted November 7, 2000)

Abstract—Recently, 7-methylheptadecane and 7,11-dimethylheptadecane have been reported as sex pheromone components of both spring hemlock looper (SHL), *Lambdina athasaria*, and pitch pine looper (PPL), *Lambdina pellucidaria*. Our objective was to test the hypothesis that SHL and PPL are reproductively isolated, in part, through species specificity in: (1) absolute configuration of pheromone components, (2) diel periodicity of pheromonal communication, and/or (3) seasonal flight period. In coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses of stereoselectively synthesized (7*S*)- and (7*R*)-7-methylheptadecane [7*S*; 7*R*]

as well as (7*S*,11*S*)-, (7*R*,11*R*)-, and (*meso*-7,11)-7,11-dimethylheptadecane [7*S*,11*S*; 7*R*,11*R*; *meso*-7,11], only 7*S* and *meso*-7,11 elicited responses by male SHL and PPL antennae. In field experiments, male SHL and PPL were attracted only to lures containing 7*S* plus *meso*-7,11. In hourly recordings of trap-captured males, SHL and PPL in their respective habitats were trapped between 24:00 and 03:00 hr. Capture of both SHL and PPL in pheromone-baited traps throughout June indicated overlapping seasonal flight periods. These findings of identical absolute configuration of pheromoal components, diel periodicity of pheromonal communication, and overlap of seasonal flight periods support synonymy of SHL and PPL. Finite taxonomic classification of PPL and SHL must await careful assessment of further criteria, such as morphometrics, molecular comparisons and ecological analyses.

Key Words—Geometridae, 7-methylheptadecane, 7,11-dimethylheptadecane, pheromone chirality, diel periodicity of pheromonal communication, seasonality of flight, reproductive isolating mechanisms, synonomy.

INTRODUCTION

The spring hemlock looper (SHL), *Lambdina athasaria*[7] (Walker), and pitch pine looper (PPL), *L. pellucidaria* (Grote and Robinson), have remarkably similar life histories (summarized in Duff, 1998). Although they prefer hemlock (SHL) and pine (PPL) forests, they are neither spatially nor temporally completely isolated. Both SHL and PPL overwinter as pupae in the forest duff. Adults begin to emerge in mid to late May and are present until the end of June or early July. With identical sex pheromone blends (7-methylheptadecane and 7,11-dimethylheptadecane) identified in both species (Gries et al., 1994; Maier et al., 1998), alternative mechanisms of reproductive isolation needed to be investigated. Here we tested the hypotheses that PPL and SHL are reproductively isolated, in part, through species specificity in: (1) absolute configuration of pheromone components; (2) diel periodicity of pheromonal communication; and/or (3) seasonal flight period.

METHODS AND MATERIALS

Syntheses. (7*S*)-7-Methylheptadecane, (7*R*)-7-methylheptadecane, (7*S*,11*S*)-7,11-dimehylheptadecane, (7*R*,11*R*)-7,11-dimethylheptadecane and (*meso*-7,11)-7,11-dimethylheptadecane, hereafter referred to as 7*S*, 7*R*, 7*S*,11*S*, 7*R*,11*R*, and *meso*-7,11 (Figure 1), were synthesized as previously described (Sheng,

[7] Univoltine *L. athasaria* investigated in this study is not to be confused with the bivoltine oak feeder, *L. fervidaria athasaria* (Walker), which is illustrated by Covell (1984). Larvae of *L. athasaria* considered here are restricted to eastern hemlock.

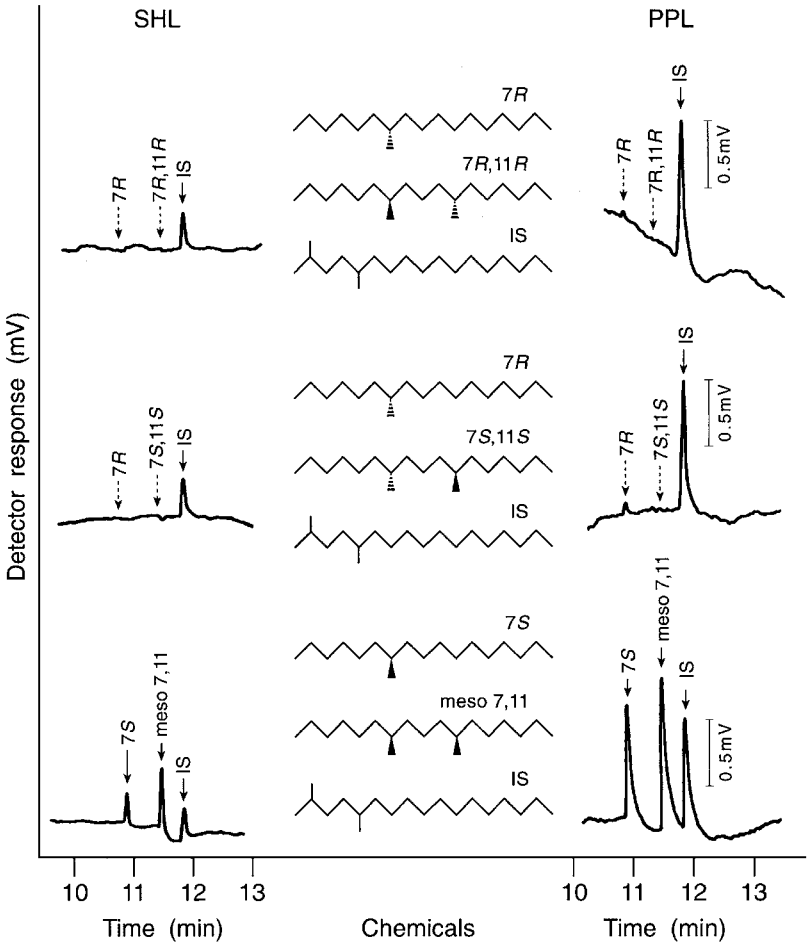

FIG. 1. Representative GC-EAD recordings from male spring hemlock looper (SHL) and from male pitch pine looper (PPL) antennae, responding to 1000 pg of 2,5-dimethylheptadecane [internal standard (IS)] and to 2 pg of optical isomers of pheromone components. Antennal recordings conducted in consecutive order (top to bottom), employing the same antenna. Flame ionization detector (FID) recordings omitted. Compound nomenclature: 7*R* = (7*R*)-7-methylheptadecane; 7*S* = (7*S*)-7-methylheptadecane; 7*R*,11*R* = (7*R*,11*R*)-7,11-dimethylheptadecane; 7*S*,11*S* = (7*S*,11*S*)-7,11-dimethylheptadecane; meso 7,11 = (*meso*-7,11)-7,11-dimethylheptadecane. Chromatography: Hewlett Packard 5890 equipped with a fused silica column (30 m × 0.25 mm ID) coated with DB-5 (J&W Scientific, Folsom, California); splitless injection, temperature of injection port and FID detector: 250°C; temperature program: 120° for 1 min, then 10°C/min to 280°C.

1996; Shirai, 1997; Shirai et al., 1999). Based on gas chromatographic analyses, all compounds used in field experiments were >94% chemically pure. Compounds were 99–100% enantiomerically pure as estimated by the enantiomeric excess (99.8–100%) of the starting material (enantiomers of methyl 3-hydroxy-2-methyl propanoate).

Laboratory Analyses. Adult male SHL and PPL were collected at night in Peoples State Forest, Barkhamsted, Litchfield County, Connecticut, and Myles Standish State Forest, Plymouth, Plymouth County, Massachusetts, respectively. Moths were cooled (8°C) overnight and couriered to Simon Fraser University the next day for coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses (Arn et al., 1975). Each antenna tested (four and five for male SHL and PPL, respectively) was subjected in the same order to three mixtures of candidate pheromone components at 2 pg each. Mixtures 1–3 contained 7*R* plus 7*R*,11*R*, 7*R* plus 7*S*,11*S*, and 7*S* plus *meso*-7,11, respectively. An internal standard, 1 ng of 2,5-dimethylheptadecane, was coinjected with each mixture, to monitor possible deterioration of antennal responses over the 30–40 min test period for each antenna.

Experimental Sites. Experiments with SHL and PPL were conducted at Peoples State Forest and Myles Standish State Forest, respectively. In Peoples State Forest 120 km inland, the transition-zone forest of gymno- and angiosperm trees forms a dense canopy with hemlock, *Tsuga canadensis* (L.) Carr., as the dominant species. The forest lies at 300 m in elevation and receives 306 mm of rain from June to August (Owenby and Ezell, 1992). The pine forest at Myles Standish State Forest exhibits an open forest canopy with pitch pine, *Pinus rigida* Miller, as the dominant species. Directly on the Atlantic coast, the pine forest experiences a moderate, ocean-influenced climate, with little summer rain and prolonged periods of drought (Schweitzer and Rawinski, 1988). More detailed characteristics about experimental sites and their locations are provided in Duff (1998).

General Design of Field Experiments. Experiments of identical or compatible design, conducted concurrently for both SHL and PPL (except experiment 7), were set up in randomized, complete blocks with traps and blocks at 15- to 20-m intervals. Green Unitraps (Phero Tech Inc., Delta, British Columbia, Canada) were suspended from *T. canadensis* (SHL) and *P. rigida* (PPL) at 1.5–2 m above ground and 2–5 m within the forest margin. Traps were baited with grey rubber septa (The West Company, Lionville, Pennsylvania) impregnated with stereoisomers of synthetic pheromone components in HPLC-grade hexane. Each trap contained a dichlorvos cube (Bio-Strip, Inc., Reno, Nevada) to kill captured males. Moths were removed and counted every two days.

Field Test of Optical Isomers of Pheromone Components. Experiment 1 (SHL) and experiment 2 (PPL) tested stereoisomeric 7,11 alone and in combination with either 7*S*, 7*R* or both. The 7*S* (experiment 3, SHL) or 7*S* plus 7*R*

(experiment 4, PPL) were tested alone and in binary and quaternary combinations with 7*S*,11*S*, 7*R*,11*R*, and *meso*-7,11. Experiment 5 (SHL) tested 7*S* alone and in binary combination with *meso*-7,11 and all possible ternary and quaternary combinations with 7*S*,11*S*, 7*R*,11*R*, and *meso*-7,11. Experiment 6 (PPL) was identical to experiment 5, but replaced 7*S* with 7*S* + 7*R*. Experiment 7 was conducted only with PPL and tested 7*S* plus *meso*-7,11 alone and in combination with 7*R* at three different ratios. Experiment 8 (SHL) and experiment 9 (PPL) tested 7*S* alone and in combination with *meso*-7,11 at three different ratios. Experiment 10 (SHL) and experiment 11 (PPL) tested *meso*-7,11 alone and in combination with 7*S* at three different ratios. Experiment 12 (SHL) and experiment 13 (PPL) tested 7*S* plus *meso*-7,11 at increasing doses.

Height-Dependent Trap Captures of Male SHL and PPL. For experiment 14 and 15, ten trees >200 m apart were selected at each experimental site. Unitraps baited with grey rubber septa impregnated with 50 μg 7*S* and 16 μg *meso*-7,11 were hung at 1.5, 3, and 5 m above ground in each tree. Captured male SHL (experiment 14) or PPL (experiment 15) were recorded two days after experiment initiation.

Diel Periodicity and Seasonality of Trap Captures. Experiments 16 and 17 recorded the diel periodicity of captures of male SHL and PPL, respectively. Ten trees >100 m apart were selected at each experimental site. One Unitrap baited with grey rubber septa impregnated with 50 μg 7*S* and 16 μg *meso*-7,11 was hung 1.5 m above ground and 2–5 m within the forest margin in each tree. Captured males were recorded hourly for 24 hr. Experiments 18 and 19 recorded seasonal flight periods of male SHL and PPL, respectively. Selection of trees and trap placement were the same as in experiments 16 and 17. Traps were baited with grey rubber septa impregnated with 50 μg racemic 7 and 16 μg stereoisomeric 7, 11. Captured males were removed and counted every two days from May 28, to June 24, 1997.

Statistical Analyses. Despite transformation, most trap catch data were not normally distributed and were therefore subjected to nonparametric analyses of variance by ranks (Friedman's test) followed by comparison of means (Bonferroni test) (Zar, 1984; SAS/STAT 1988 user guide, release 6.03 edition, SAS Institute, Cary, North Carolina).

RESULTS

In GC-EAD recordings, 7*S*, but not 7*R*, and *meso*-7,11, but not 7*S*,11*S* or 7*R*,11*R*, elicited responses from male SHL and PPL antennae (Figure 1). In field experiments 1 and 2, 7*S* in combination with stereoisomeric 7,11 attracted male SHL and PPL (Figure 2). For both species, 7*R* was inactive with 7,11, but doubled captures of male PPL when added to 7*S* plus 7,11 (Figure 2, experiment 2). For

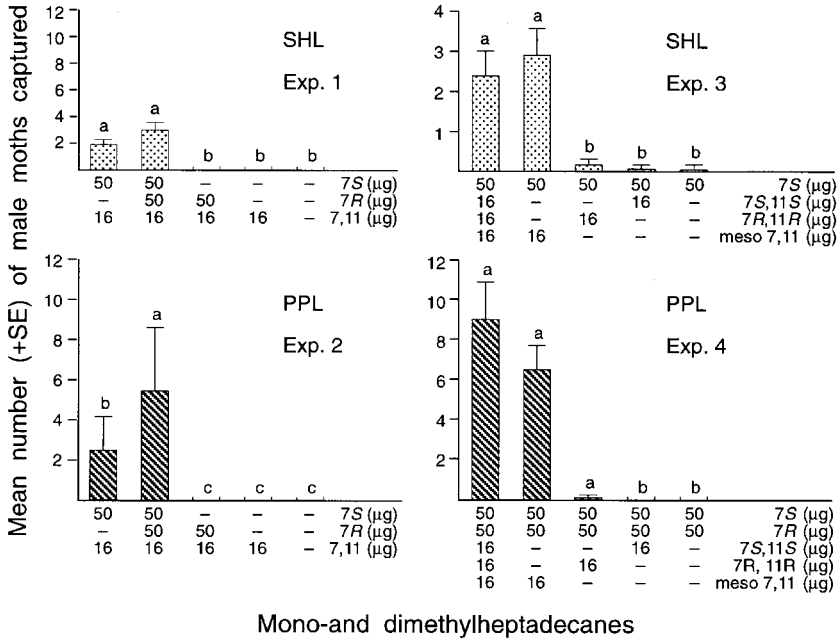

FIG. 2. Left: Captures of male spring hemlock loopers (SHL) (experiment 1; June 10–12, 1997; 10 replicates) and pitch pine loopers (PPL) (experiment 2; May 30–June 3, 1997; 10 replicates) in Unitraps baited with stereoisomeric dimethylheptadecane alone and in combination with 7*S*, 7*R*, or both. Right: Captures of male SHL (experiment 3; June 12–14, 1997; 10 replicates) and male PPL (experiment 4; June 3–5, 1997; 10 replicates) in Unitraps baited with 7*S* alone (SHL) or 7*S* plus 7*R* alone (PPL), and in binary and quaternary combinations with 7*S*,11*S*, 7*R*,11*R*, and *meso*-7,11. For each experiment, bars with the same letter are not significantly different, $P > 0.05$. Compound nomenclature as in Figure 1 legend. Note that when apparent behavioral activity of 7*R* in experiment 2 was retested in a subsequent experiment, it was inactive (Duff, 1998).

both SHL and PPL, the synergistic stereoisomer of 7,11 proved to be *meso*-7,11 (Figure 2, experiments 3, 4; Figure 3, experiments 5, 6); 7*S*,11*S* and 7*R*,11*R* were benign. Retesting 7*R* as a potential pheromone component for PPL in experiment 7 failed to disclose any behavioral activity associated with this compound (Duff, 1998). The blend of 7*S* plus *meso*-7,11 at a 50 : 16-µg ratio was more attractive to male SHL and PPL than blend ratios with reduced amounts of either *meso*-7,11 (Figure 4, experiments 8 and 9) or 7*S* (Figure 4, experiments 10 and 11). When 7*S* plus *meso*-7,11 were tested at five doses separated by orders of magnitude, only traps baited with the highest dose captured significant numbers of males (Figure 5, experiments 12 and 13).

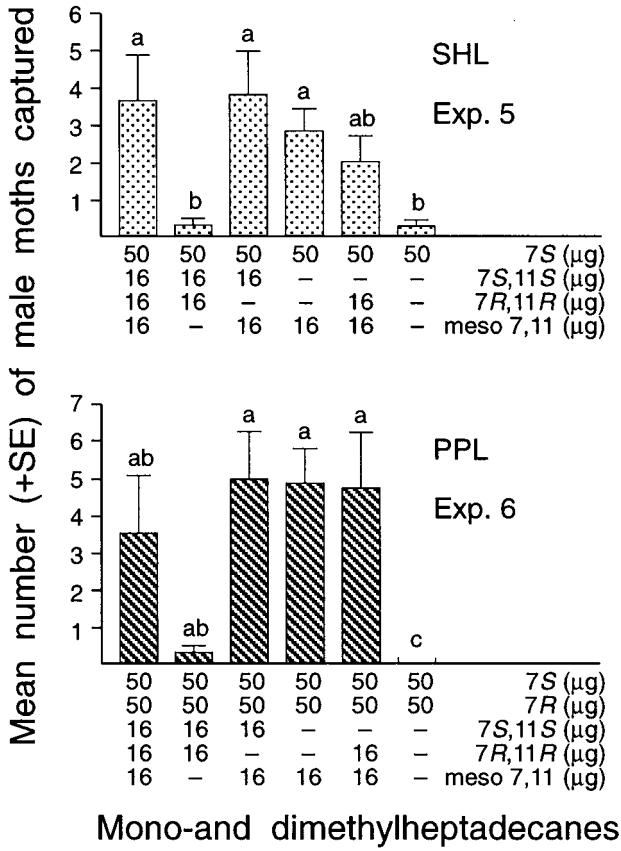

FIG. 3. Captures of male spring hemlock loopers (SHL) (experiment 5; June 14–16, 1997; 10 replicates) and male pitch pine loopers (PPL) (experiment 6; June 5–7, 1997; 10 replicates) in Unitraps baited with 7*S* alone (SHL) or 7*S* plus 7*R* alone (PPL), in binary combination with *meso*-7,11), and in all ternary and quaternary combinations with 7*S*,11*S*, 7*R*,11*R*, and *meso*-7,11. For each experiment, bars with the same letter are not significantly different, $P > 0.05$. Compound nomenclature as in Figure 1 legend.

Traps suspended at 1.5 m above ground captured significantly fewer male SHL than those at 5 m (Figure 6, experiment 14) and significantly fewer male PPL than those at 3 and 5 m (Figure 6, experiment 15). In hourly recordings of captured males, seven SHL and five PPL were captured between 24 : 00 hr and 0300 hr (Figure 6, experiments 16 and 17). The seasonal flight periods of SHL and PPL overlapped (Figure 6, experiments 18 and 19), but few SHL were captured until mid-June.

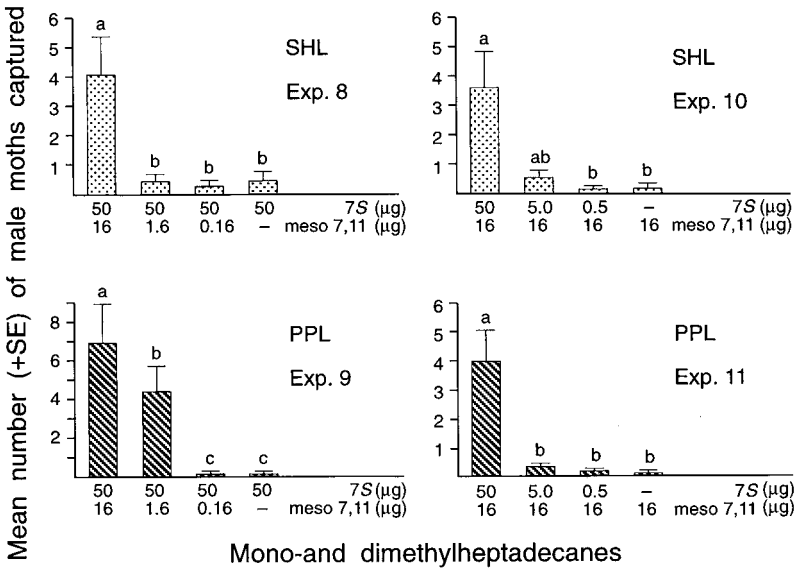

FIG. 4. Left: Captures of male spring hemlock loopers (SHL) (experiment 8; June 16–18, 1997; 10 replicates) and male pitch pine loopers (PPL) (experiment 9; June 11–13, 1997; 10 replicates) in Unitraps baited with 7*S* alone and in combination with (*meso*-7,11) at three different ratios. Right: Captures of male SHL (experiment 10; June 18–20, 1997; 10 replicates) and male PPL (experiment 11; June 13–15, 1997; 10 replicates) in Unitraps baited with *meso*-7,11 alone and in combination with 7*S* at three different ratios. For each experiment, bars with the same letter superscript are not significantly different, $P > 0.05$. Compound nomenclature as in Figure 1 legend.

DISCUSSION

Electrophysiological recordings (Figure 1) and field experiments (Figures 2–6) indicate that SHL and PPL lack specificity of their pheromone blends. Antennae from males of both species discriminated between optical isomers of pheromone components (mono- and dimethylheptadecanes), but invariably responded only to 7*S* and *meso*-7,11 (Figure 1). Attraction of male SHL and male PPL only to lures containing 7*S* + *meso*-7,11 (Figures 2–4) confirms enantio- and stereospecific recognition of pheromone components, and demonstrates that SHL and PPL use chiral pheromone components of identical absolute configuration. Because 7*R*, 7*S*,11*S*, or 7*R*,11*R* elicited neither antennal (Figure 1) nor behavioral responses (Figures 2–4), they can not be employed by female SHL or PPL to inhibit or reduce cross-attraction of heterospecific males. Moreover, different blend ratios of 7*S* + *meso*-7,11 had similar effects on captures of male

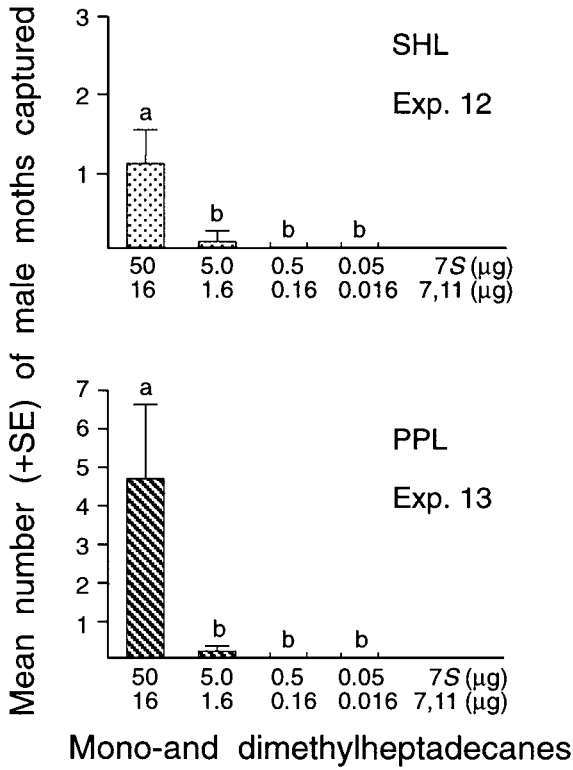

FIG. 5. Captures of male spring hemlock loopers (SHL) (experiment 12; June 20–22, 1997; 10 replicates) and male pitch pine loopers (PPL) (experiment 13; June 15–17, 1997; 10 replicates) in Unitraps baited with 7*S* + *meso*-7,11 at four different doses. For each experiment, bars with the same letter are not significantly different, $P > 0.05$. Compound nomenclature as in Figure 1 legend.

SHL and PPL (Figure 4, experiments 8–11), eliminating blend ratios as a means of pheromonal specificity.

Enantiospecific perception of pheromone components by males implies enantioselective biosyntheses by females. Confirmation that female SHL and PPL stereoselectively produce 7*S* and *meso*-7,11, however, must await development of a chiral GC column that separates optical isomers of methyl- and dimethylheptadecane.

With identical sex pheromones, SHL and PPL could maintain reproductive isolation through temporal (diel and/or seasonal) separation of sexual communication. Sympatric and coseasonal artichoke plume moths, *Platyptilia carduidactyla* (Riley) and *P. williamsii* (Grinnell), for example, use identical sex

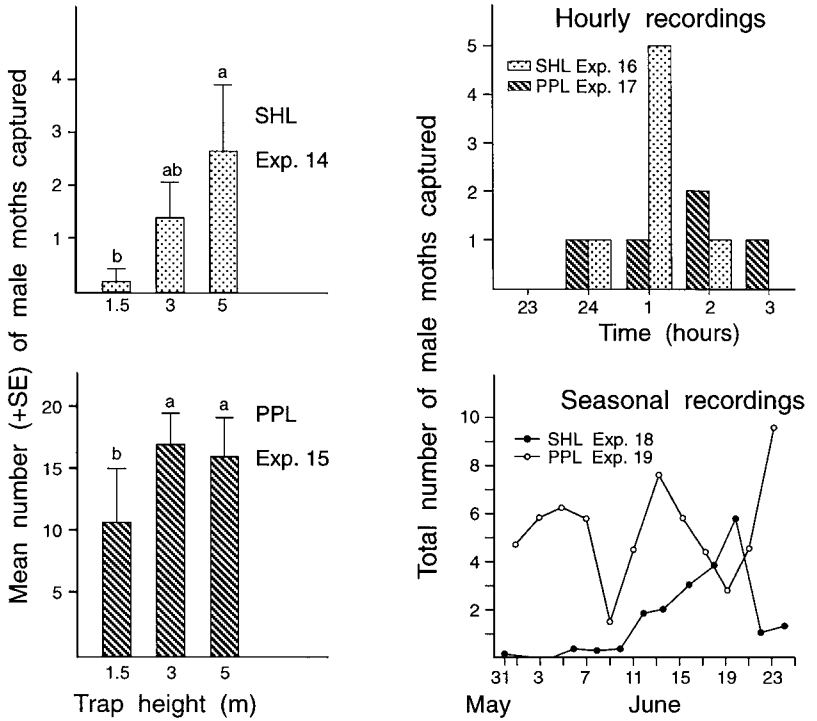

FIG. 6. Left: Captures of male spring hemlock loopers (SHL) (experiment 14; June 19–22, 1997; 10 replicates) and male pitch pine loopers (PPL) (experiment 15; June 17–21, 1997; 10 replicates) in Unitraps suspended from trees at 1.5, 3, and 5 m above ground and baited with 50 μg 7*S* plus 16 μg *meso*-7,11. For each experiment, bars with the same letter are not significantly different, $P > 0.05$. Top right: Hourly recordings of trap captured male SHL (experiment 16; June 19–22, 1997; 10 replicates) and male PPL (experiment 17; June 17–18, 1997; 10 replicates) in Unitraps baited with 50 μg 7*S* plus 16 μg *meso*-7,11. Bottom right: Seasonal recordings of trap captured male SHL (experiment 18; May 31–June 26, 1997; 10 replicates) and male PPL (experiment 19; May 31–June 26, 1997; 10 replicates) in Unitraps baited with enantiomeric 50 μg 7 and stereoisomeric 50 μg 7,11. Compound nomenclature as in Figure 1 legend.

pheromones but release them at different times of the night (Haynes and Birch, 1986). Diel periods of pheromone communication in SHL and PPL, in contrast, seem to overlap (Figure 6). Even though the seasonal flight period of SHL may commence ~7–10 days earlier than that of PPL (Maier and Lemmon, 1996), capture of male SHLs and PPLs in pheromone-baited traps throughout June (Figure 6) eliminates seasonality of flight as a reproductive isolating mechanism.

Spatial separation (between or within habitats) of sexual communication represents a third potential isolating mechanism. The SHL occurs in moist areas within forests of eastern hemlock. The PPL, in contrast, typically inhabits dry sandy areas with mainly pitch and other hard pines. While SHL and PPL are mostly allopatric in eastern North America (Maier and Lemmon, 1996), their habitats are not far apart and areas of sympatry may exist. Captures of male SHL and PPL mainly in traps suspended at 3 and 5 m (Figure 6) suggest that females of both species call in similar locations within the forest canopy, and that spatial separation of sexual communication would fail in coinhabited forests.

In summary, our study did not reveal discernible differences in the pheromone biology of PPL and SHL, supporting the contention that they should be synonymized (Zhang, 1994). Finite taxonomic classification of PPL and SHL, however, must await careful assessment of other criteria (Roelofs and Brown, 1982; Roelofs and Comeau, 1969), such as morphometrics, molecular comparisons, and ecological analyses.

Abstract—To identify potential hormonal pheromones of the round goby (*Neogobius melanostomus*), a species recently introduced to the Great Lakes, we used electro-olfactogram (EOG) recording to examine olfactory responsiveness to more than 100 steroids and prostaglandins. *Neogobius* detected free and conjugated 18-, 19- and 21-carbon steroids, but did not detect prostaglandins. EOG cross-adaptation, used to determine if *Neogobius* can discriminate the detected compounds at the sensory level, suggested that the detected steroids act on four classes of olfactory receptor mechanisms named (according to the most potent ligand for each): estrone, 17β-estradiol-3β-glucuronide, etiocholanolone, and dehydroepiandrosterone-3-sulfate. Although none of the detected steroids induced reproductive behaviors, exposure to steroids from three of the four receptor classes (estrone, 17β-estradiol-3β-glucuronide, or etiocholanolone) increased ventilation rate in males, whereas only etiocholanolone increased ventilation rate in females. Using the ventilation increase as a behavioral bioassay of steroid detection, behavioral cross-adaptation studies in males demonstrated that steroids discriminated at the sensory level are also discriminated behaviorally. These findings suggest the round goby may use steroids as putative pheromones.

Key Words—Round goby, *Neogobius melanostomus*, sex pheromones, steroid, electro-olfactogram, cross-adaptation, ventilation, sexual dimorphism.

INTRODUCTION

Water-borne steroids, prostaglandins, and their metabolites are potent stimulators of reproductive physiology and behavior in a number of fish species (Sorensen and Caprio, 1998; Sorensen and Stacey, 1999). Moreover, electro-olfactogram (EOG) recording studies (e.g., Sorensen et al., 1995), which seek evidence for hormonal pheromones by examining olfactory response to numerous steroid and prostaglandin compounds, indicate that these fish pheromones are widespread among freshwater fishes and are present in some euryhaline marine forms (Stacey and Cardwell, 1995, 1997). The majority of studies on fish hormonal pheromones have focused on ostariophysin species from the orders Cypriniformes, e.g., goldfish, *Carassius auratus* (Sorensen and Stacey, 1999); common carp, *Cyprinus carpio* (Irvine and Sorensen, 1993; Stacey et al., 1994a); tinfoil barb, *Puntius schwanenfeldi* (Cardwell et al., 1995); loach, *Misgurnus anguillicaudatus* (Kitamura et al., 1994), and Siluriformes, e.g., African catfish, *Clarias gariepinus* (van den Hurk and Resink, 1992), but there also is evidence for hormonal pheromones in several Salmoniformes, e.g., Atlantic salmon, *Salmo salar* (Waring and Moore, 1997); arctic char, *Salvelinus alpinus* (Sveinsson and Hara, 1995); brook trout, *Salvelinus fontinalis*, and brown trout, *Salmo trutta* (Essington and Sorensen, 1996). In contrast, with the exception of the pioneering work of Colombo et al. (1977, 1982) in the black goby (*Gobius jozo*), reports of pheromonal androgens in the urine of male yellowfin Baikal sculpins (*Cottocomephorus grewingki*) (Katsel et al., 1992), a brief description of EOG responsiveness to steroids in a cichlid (*Haplochromis burtoni*) (Robison et al., 1998), and indications that preovulatory Eurasian ruffe (*Gymnocephalus cernuus*) release a novel conjugated steroid with behavioral actions on males (Murphy et al., 2000), nothing is known of hormonal pheromone systems in perciform fishes, a diverse and ecologically important group both in freshwater and marine ecosystems.

In this study, we report the results of EOG and behavioral studies indicating the use of steroidal pheromones by the round goby, *Neogobius melanostomus*, a native of the Caspian and Black seas, which recently has been introduced to the Great Lakes in ship ballast (Crossman et al., 1992; Jude et al., 1992). The objectives of our study were twofold. First, we wished to increase the understanding of perciform pheromones by focusing on a species from a diverse and widely distributed perciform group (Family Gobiidae) that contains many marine taxa and that is suitable for laboratory-based reproductive studies (Moiseyeva and Rudenko, 1976). Second, we hoped that an understanding of hormonal pheromones of *Neogobius* might suggest methods for control of this species in the Great Lakes.

Spawning in *Neogobius* appears to be typical of many gobiids (Miller, 1984). Males migrate from deeper waters to spawning areas in the spring, estab-

lish territories prior to arrival of females, defend a nest site to which females are attracted for spawning, and care for single or multiple batches of eggs (Moiseyeva and Rudenko, 1976; MacInnis and Corkum, 2000). As with other male gobiids [e.g., *Bathygobius soporator* (Tavolga, 1956)], male round gobies use visual displays (coloration changes and posturing) and acoustical signals when courting females (Protosov et al., 1965; Moiseyeva and Rudenko, 1976). In particular, evidence that pheromones play important reproductive roles in other gobies (Tavolga, 1956) and that a conjugated steroid, 5β-androstan-3α-ol-17-one-3-glucuronide (etiocholanolone-glucuronide; ETIO-g), has pheromonal function in *G. jozo* (Colombo et al., 1980, 1982) suggested that, as in many other fish (Stacey and Cardwell, 1995, 1997; Sorensen and Stacey, 1999), EOG studies would be useful in determining if *Neogobius* detects hormonal pheromones.

The round goby has established thriving populations in all of the Great Lakes and might invade the Mississippi River drainage system, with potentially detrimental effects on many North American native fish species and ecosystems (Charlebois et al., 1997). Great Lakes *Neogobius* are of concern because there is evidence they have contributed to population declines of native mottled sculpin (*Cottus bairdi*) and other benthic fishes (Dubs and Corkum, 1996). Round gobies displace native benthic species from optimal spawning habitats, eat their eggs and young, and have a relatively high fecundity since they spawn a number of times in a season (Dubs and Corkum, 1996; Charlebois et al., 1997; MacInnis and Corkum, 2000). Additionally, because round gobies eat zebra mussels (*Dreissena polymorpha*), which can accumulate polychlorinated biphenyls and in turn are preyed upon by sport fish, they might facilitate introduction of toxins into Great Lakes food webs (Ray and Corkum, 1997). Understanding sex pheromones of the round goby could lead to techniques for population monitoring or disruption of spawning.

METHODS AND MATERIALS

Experimental Fish. Sexually mature *Neogobius* were collected between May and August, 1994–1996 by angling and bottom trawl from the St. Clair and Detroit Rivers (Windsor, Ontario, Canada), flown to Edmonton within three days of capture, and maintained in mixed-sex groups (four to six fish) under constant photoperiod (16L : 8D). Fish were held in 70-liter flow-through aquaria supplied with dechlorinated tap water that varied seasonally from 9 to 18°C. Aquaria contained gravel, an air stone, floating artificial plants, and clay flower pots and PVC pipes for shelter. A variety of live, frozen and flake food was provided ad libitum.

Fish were sexed by the shape of the urogenital papilla: the females have a broad, truncated tip with a large pore, and that of the male is long and slen-

der with a minute opening. Both males and females used in the EOG recording and behavior experiments were caught in Windsor in breeding condition. Most females had distended abdomens at capture and discharged eggs into aquaria within two weeks of captivity. Males kept in mixed sex groups periodically exhibited courtship behavior (color changes and territoriality), and occasionally fertilized eggs were found on the ceiling of the PVC tubes, indicating that holding conditions did not inhibit reproductive behavior. Only larger fish (>8 cm in length) were used in both EOG and behavior experiments. All experimental procedures involving fish were in accordance with Canadian Council of Animal Care guidelines.

Electro-olfactogram (EOG) Recording Technique. Sexually mature male and female *Neogobius* were tested for olfactory sensitivity to a variety of odors using EOG recording procedures similar to those described by Cardwell et al. (1995). Larger males and females (>8.0 cm in length) were chosen because it was too difficult to obtain a recording from smaller fish; the incurrent pore was too small for the size of electrodes used. Larger fish were sexually mature at the time of capture (see above) but may have undergone some gonadal recrudescence while maintained in the laboratory. Immediately prior to recording, fish were anesthetized by orally perfusing the gills with dechlorinated tap water containing 0.05% 2-phenoxyethanol (2-PE; Sigma, St. Louis, Missouri), wrapped in wet tissue and secured to a stand placed in an electrically grounded water bath. Fish were fitted with a polyethylene mouth tube that delivered aerated, dechlorinated water (containing 0.05% 2-PE) throughout the entire recording procedure. The temperature of the water bath and the anesthetic water (9–18°C) approximated that of the holding aquaria at the time of testing.

A glass capillary tube (70- to 120-μm tip diameter) filled with gelatin (8% in 0.6% NaCl) bridged Ag–AgCl electrodes filled with 3 M KCl to the olfactory tissue. The tip of the reference electrode was placed in the water bath. The odor delivery tube was positioned next to the excurrent pore of one naris, creating a reversed water flow (in the excurrent pore and out the incurrent pore); initial recordings failed to generate any EOG response if the odor tube was placed near the incurrent pore and the recording electrode was placed in the excurrent pore. In an attempt to facilitate recording, the naris was dissected to expose olfactory receptor cells. However, we were unable to obtain any measurable EOG response from the exposed naris; therefore the naris was left intact for all recordings.

Throughout a recording session (maximum duration of 3 hr), the naris was continuously perfused with dechlorinated tap water (background) until a computer-controlled solenoid switched the background solution to a test solution for 2 sec. The amplified signals (Grass P-18 DC amplifier) were digitized (National Instruments Lab-PC A/D converter), and the response was recorded for 10 sec from initiation of the odor pulse. After recording was completed, the gills were perfused with tap water without anesthetic until the fish began venti-

lating and could be returned to its aquarium. A number of fish were retested in a maximum of two additional EOG recording sessions (allowing at least one week between sessions), each of which was for a different cross-adaptation experiment (see EOG Cross-Adaptation below). There was no evidence that the EOG response was affected by prior recordings, insofar as response magnitudes remained equivalent on subsequent tests.

When an anesthetized fish had been mounted in the water bath for 30–45 min, recording began by determining olfactory response to 10^{-5} M L-alanine. If the response to L-alanine was greater than 3 mV (prestimulus voltage to peak stimulus voltage), testing with hormonal compounds was initiated. If the response was less than 3 mV, the recording electrode and/or odor tube were repositioned until a minimum 3-mV response was obtained or the recording was terminated and the fish recovered.

During the course of a recording, the sensitivity by 10^{-5} M L-alanine was monitored frequently to ensure the stability of the recording. As well, to determine if mechanical artifacts contributed to the EOG recording, the naris was exposed occasionally to 2-sec pulses of the same dechlorinated tap water (background water) that chronically irrigated the naris and was used for dilution of test odors (see Tested Odors below). Data (base to peak voltage differences) are presented as an absolute response in mV with response to background water (if any) subtracted. Sensory adaptation during recording was minimized by using a short exposure time (2 sec) and allowing 1–2 min between exposures to test solutions.

Tested Odors. The olfactory epithelium of *Neogobius* was exposed to 10^{-8} M solutions of eight prostaglandins (prostaglandins E_1, E_2, $F_{1\alpha}$, $F_{2\alpha}$, and $F_{3\alpha}$; 15-keto-prostaglandin E_2; 15-keto-prostaglandin $F_{2\alpha}$; 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$) and 114 steroids (Table 1) to determine compounds that consistently induced EOG response. Steroids and prostaglandins selected for testing included all those reported to be olfactory stimulants or to have pheromonal activity in other fish (Stacey and Cardwell, 1995; Sorensen and Stacey, 1999), as well as a number of related compounds, metabolites, and conjugates. Steroids and steroid conjugates were purchased from Sigma (St. Louis, Missouri) and Steraloids (Newport, Rhode Island) or received as gifts from Dr. A. P. Scott (Lowestoft), and Dr. J. G. D. Lambert (Utrecht). Prostaglandins were purchased from Cayman Chemical Company (Ann Arbor, Michigan). Because, in initial tests, prostaglandins failed to induce an EOG response in any fish, they will not be considered further in this section.

The 10^{-5} M L-alanine (Sigma, St. Louis, Missouri) used to monitor EOG recording preparations was prepared as a 10^{-2} M stock solution in double-distilled deionized water, stored in glass scintillation vials at 4°C and diluted in background water at the time of EOG recording. Olfactory response to 10^{-6} M L-alanine was also recorded, as this concentration was used in behavior tests.

TABLE 1. STEROIDS TESTED IN EOG RECORDING, GROUPED ACCORDING TO STRUCTURAL SIMILARITY AND INCLUDING ABBREVIATIONS

5α-Androstan (unconjugated): 5α-androstan-3,17-dione; 5α-androstan-3β-ol-17-one (epiandrosterone; EPIANDR); 5α-androstan-17β-ol-3-one.

5α-Androstan (conjugated): 5α-androstan-3β-ol-17-one-3β-glucuronide (epiandrosterone-glucuronide; EPIANDR-g); 5α-androstan-3α-ol-17-one-3α-SO_4 (androsterone-sulfate; ANDR-s).

5β-Androstan (unconjugated): 5β-androstan-3,17-dione (etiocholan-3,17-dione; ETIO-3,17-dione); 5β-androstan-3α-ol-17-one (etiocholanolone; ETIO); 5β-androstan-3β-ol-17-one.

5β-Androstan (conjugated): 5β-androstan-3α,17β-diol-3α-glucuronide; 5β-androstan-3α,17β-diol-17β-glucuronide; 5β-androstan-3α,11β-diol-17-one-3α-glucuronide (etiocholanolone-glucuronide; 11β-ETIO-g); 5β-androstan-3α-ol-17-one-3α-glucuronide (etiocholanolone-glucuronide; ETIO-g)

4-Androsten (unconjugated): 4-androsten-11β,17β-diol-3-one; 4-androsten-3,17-dione (androstenedione; AD); 4-androsten-11-keto-17β-ol-3-one (11-ketotestosterone); 4-androsten-11-keto-3,17-dione; 4-androsten-11α-ol-3,17-dione; 4-androsten-11β-ol-3,17-dione; 4-androsten-17α-ol-3-one; 4-androsten-17β-ol-3-one (testosterone; T).

4-Androstene (conjugated): 4-androsten-17β-ol-3-one-17β-glucuronide (testosterone glucuronide); 4-androsten-17β-ol-3-one-17β-SO_4 (testosterone sulfate).

5-Androsten (unconjugated): 5-androstene-3β,17β-diol; 5-androstene-3β-ol-17-one (dehydroepiandrosterone; DHEA).

5-Androsten (conjugated): 5-androstene-3β-ol-17-one-3β-glucuronide (dehydroepiandro sterone-glucuronide; DHEA-g); 5-androstene-3β-ol-17-one-3β-SO_4 (dehydroepiandrosterone-sulfate; DHEA-s).

Estratriens (unconjugated): 1,3,5(10)-estratrien-3α,17α-diol (17α-estradiol); 1,3,5 (10)-estratrien-3α,17β-diol (17β-estradiol; E2); 1,3,5 (10)-estratrien-3α-ol-17-one (estrone; E1); 1,3,5 (10)-estratrien-3α,16α,17β-triol (estriol; E3).

Estratriens (conjugated): 1,3,5 (10)-estratrien-3α,17β-diol-3α-glucuronide (17β-estradiol-3α-glucuronide; E2-3g); 1,3,5 (10)-estratrien-3α,17β-diol-17β-glucuronide (17β-estradiol-17β-glucuronide; E2-17g); 1,3,5 (10)-estratrien-3α,17β-diol-3α-SO_4; 1,3,5 (10)-estratrien-3α,17β-diol-17β-SO_4); 1,3,5 (10)-estratrien-3α,17β-diol-di-SO_4; 1,3,5 (10)-estratrien-3α-glucuronide-17β-SO_4; 1,3,5 (10)-estratrien-3α-SO_4-17β-glucuronide

Estrens (unconjugated): 4-estren-17β-ol-3-one

5α-Pregnan (unconjugated): 5α-pregnan-3,20-dione; 5α-pregnan-3β,17α-diol-20-one; 5α-pregnan-3β,20α-diol; 5α-pregnan-3β,20β-diol; 5α-pregnan-17,21-diol-3,20-dione; 5α-pregnan-17-α-ol-3,20-dione; 5α-pregnan-3β-ol-20-one; 5α-pregnan-3β,11β,17α,21-tetrol-20-one; 5α-pregnan-3α,17α,20β-triol; 5α-pregnan-3β,17α,20β-triol; 5α-pregnan-11β,17,21-triol-3,20-dione; 5α-pregnan-3α,17α,21-triol-20-one; 5α-pregnan-3β,17α,21-triol-20-one

5β-Pregnan (unconjugated): 5β-pregnan-3α,20β-diol (3α,20β-5βP); 5β-pregnan-3β,20β-diol; 5β-pregnan-17α,21-diol-3,20-dione (3β,20β-5βP); 5β-pregnan-3α,17α-diol-20-one (3α,17α-5βP); 5β-pregnan-3β,17α-diol-20-one; 5β-pregnan-3,20-dione (5βP); 5β-pregnan-17α-ol-3,20-dione; 5β-pregnan-3α,11β,17α,21-pentol; 5β-pregnan-3α,11β,17α,20β,21-pentol; 5β-pregnan-3α,17α,20α,21-tetrol; 5β-pregnan-3α,17α,20β,21-tetrol; 5β-pregnan-3α,11β,17α,21-tetrol-20-one; 5β-pregnan-3α,17α,20β,21-tetrol-11-one; 5β-pregnan-3α,17α,20α-triol; 5β-pregnan-3α,17α,20β-triol (3α,17α,20β-5βP); 5β-pregnan-3α,17α,21-triol-11,20-dione; 5β-pregnan-11β,17α,21-triol-3,20-dione; 5β-pregnan-3α,17α,21-triol-20-one; 5β-pregnan-3β,17α,21-triol-20-one

TABLE 1. CONTINUED

5β-Pregnan (conjugated): 5β-pregnan-3α,17α-diol-20-one-3α-glucuronide (3α,17α-5βP-3g)
4-Pregnen (unconjugated): 4-pregnen-11β,17α-diol-3,20-dione; 4-pregnen-11β,21-diol-3,20-dione; 4-pregnen-16α,17β-diol-3,20-dione; 4-pregnen-17α,21-diol-3,20-dione; 4-pregnen-17α,20α-diol-3-one; 4-pregnen-17α,20β-diol-3-one; 4-pregnen-20β,21-diol-3-one; 4-pregnen-17α,21-diol-3,11,20-trione; 4-pregnen-3,20-dione (progesterone); 4-pregnen-11α-ol-3,20-dione; 4-pregnen-11β-01,-3,20-dione; 4-pregnen-17α,-ol-3,20-dione; 4-pregnen-21-ol-3,20-dione; 4-pregnen-20α-ol-3-one; 4-pregnen-20β-ol-3-one; 4-pregnen-11β,17α,20β,21-tetrol-3-one; 4-pregnen-11β,17α,21-triol-3,20-dione; 4-pregnen-11β,17α,21-triol-3,20-dione (cortisol); 4-pregnen-14α,17β,21-triol-3,20-dione; 4-pregnen-17α,20β,21-triol-3,11-dione; 4-pregnen-17α,20α,21-triol-3-one; 4-pregnen-17α,20β,21-triol-3-one; 4-pregnen-3,11,20-trione
4-Pregnen (conjugated): 4-pregnen-11β,21-diol-3,20-dione-21-SO_4; 4-pregnen-17α,21-diol-3,20-dione-21-SO_4; 4-pregnen-17α,20β-diol-3-one-20β-glucuronide; 4-pregnen-17α,20α-diol-3-one-20α-SO_4; 4-pregnen-17α,20β-diol-3-one-20β-SO_4; 4-pregnen-21-ol-3,20-dione-21-glucuronide; 4-pregnen-20β-ol-3-one-20β-SO_4; 4-pregnen-11β,17α,21-triol-3,20-dione-21-glucuronide; 4-pregnen-11β,17α,21-triol-3,20-dione-21-SO_4; 4-pregnen-17α,20β,21-triol-3-one-21-SO_4; 4-pregnen-17α,20β-diol-3-one-20β-PO_4
5-Pregnen (unconjugated): 5-pregnen-3β,17α-diol-20-one; 5-pregnen-3β,21-diol-20-one; 5-pregnan-3β-ol-20-one (pregnenolone); 5-pregnen-3β,17α,21-triol; 5-pregnen-3β,17α,21-triol-20-one
5-Pregnen (conjugated): 5-pregnen-3β,21-diol-20-one-3β-SO_4; 5-pregnen-3β,21-diol-20-one-21-SO_4; 5-pregnen-3β-ol-20-one-3β-glucuronide; 5-pregnen-3β-ol-20-one-3β-SO_4

All other test odors were first prepared as 10^{-3} M stock solutions in 99% ethanol (free and sulfated steroids, prostaglandins) or 50 : 50 ethanol–water (glucuronated steroids), and stored at −20°C. Working solutions (10^{-6} M) were prepared in duplicate by diluting stock solutions in double-distilled, deionized water and stored in glass scintillation vials at 4°C. Test solutions were prepared immediately before recording by diluting appropriate amounts of the working solutions in 100 ml of background water (Cardwell et al., 1995). Ethanol control solutions were prepared in the same manner but contained no steroid or prostaglandin.

In initial recordings, five gobies (two males, three females) were exposed to 10^{-8} M test solutions of all the compounds listed above. Compounds that did not elicit a response from any fish were considered undetectable and were not tested again. A compound was considered detectable if, in more than one fish, it induced a voltage change greater than that induced by the background solution. Additionally, to ensure that a response to a compound was not due to contamination of the test solution, each detected steroid was tested on the same fish with a new test solution. Following these intial recordings, only detected steroids were used in further studies. After additional fish were tested with detectable steroids, male and female EOG responses to detected steroids were compared (*t*-test) (Wilkinson, 1994).

EOG Concentration–Response Studies. To compare olfactory potency of detected steroids, concentration–response relationships were determined for six detected steroids (estrone, E1; estradiol-3-glucuronide, E2-3g; etiocholan-3α-ol-17-one, ETIO; androsterone-sulfate, ANDR-s; dehydroepiandrosterone-sulfate, DHEA-s; dehydroepiandrosterone-glucuronide, DHEA-g) that, at 10^{-8} M, elicited consistent and large responses (greater than 20% of the response to 10^{-5} M L-alanine) and were thought likely to operate through separate olfactory receptor mechanisms. Criteria for determining compounds that may act through separate olfactory receptor mechanisms were arbitrary and based on studies in goldfish showing that 19- and 21-carbon steroids act through different receptor mechanisms and that some free and conjugated steroids also act through separate mechanisms (Sorensen et al., 1995). The concentration–response relationship of ETIO-g also was determined because, even though at 10^{-8} M it induced an EOG response less than 20% of that induced by 10^{-5} M L-alanine, it has been proposed to have pheromonal function in *G. jozo* (Colombo et al., 1980, 1982).

Concentration–response tests began at 10^{-12} M and increased by log molar increments to 10^{-8} M, with 10-min intervals between each exposure. Concentration–response tests for each selected steroid were performed on six fish (four females, two males). Response magnitudes (millivolts) were analyzed by ANOVA and Tukey multiple comparison test ($\alpha = 0.05$) (Wilkinson, 1994).

EOG Cross-Adaptation Studies. These studies compared the EOG response to a test compound before and during adaptation to an adapting compound, under the assumption that, if the EOG response to the test compound is unaffected by adaptation, it is acting through an olfactory receptor mechanism separate from that mediating response to the adapting compound (e.g., Caprio and Byrd, 1984; Sorensen et al., 1995). The design of the standard cross-adaptation procedure makes the assumption that a brief exposure to an odor will not influence EOG response to that odor when presented a short time later. However, interpretation of a cross-adaptation experiment will be confounded if a tested odor induces a smaller response on the second presentation, even in the absence of a tonically delivered adapting odor. The extent of this phenomenon in *Neogobius* was evaluated by a sequential exposure test.

Six fish (four females, two males) were exposed sequentially to 2-sec 10^{-8} M pulses of all steroids used for the cross-adaptation studies, and then retested with 2-sec 10^{-8} M pulses of the same steroids 30 min later: response magnitude to 10^{-5} L-alanine remained constant throughout. Differences between response magnitudes induced by the first and second exposures were analyzed by Wilcoxon matched-pairs test (Wilkinson, 1994). As well, for each steroid, the magnitude of the EOG response induced by the second exposure was converted to a percentage of the response induced by the first exposure (% IR = percentage of initial response), and the mean % IR used in analysis of the cross-adaptation experiment (see below). Steroids that failed to induce a second response in this

sequential exposure test were eliminated from all cross-adaptation studies (see Results).

Our cross-adaptation procedure was similar to that described by Sorensen et al. (1995). The naris first was exposed sequentially to 2-sec 10^{-8} M solutions of all of the detected compounds to establish initial preadaptation responses. Then, during adaptation to a 10^{-7} M solution of the adapting compound, the 10^{-8} M test steroids were administered again and in the same sequence. Test steroids were used at 10^{-8} M because many of them did not induce an EOG response at lower concentrations.

Five adapting steroids (E1, E2-3g, DHEA-g, ETIO, and DHEA-s) were chosen based on structure and detection threshold and on the results of preliminary cross-adaptation experiments (data not shown) that indicated which compounds operate through separate olfactory receptor mechanisms. Cross-adaptation experiments for each adapting steroid were conducted on six fish (four females, two males).

To monitor the quality of the EOG recording during the cross-adaptation procedure, the naris was exposed to 10^{-5} M L-alanine at the beginning and end of each cross-adaptation test, and after every fourth steroid exposure. As it was difficult to maintain a recording on *Neogobius* for the time required for a cross-adaptation experiment (>3 hr), only results of cross-adaptation tests in which L-alanine responses remained relatively stable throughout the recordings (approximately 50% of the tests) were used for analysis and presentation.

To reduce the potential for adaptation during the preadaptation testing, the compounds known to have the smallest response magnitudes were tested first. As well, compounds of similar structure were not tested in sequence to reduce the possibility of adaptation by sequential exposure to compounds that might operate through the same receptor mechanism. Some steroids that induced small responses at 10^{-8} M in initial testing (see Detected Odors in Results) failed to induce a response in the pretest of the cross-adaptation, and therefore, were not tested during the cross-adaptation phase.

Two liters of 10^{-7} M adapting steroid solution were prepared immediately before beginning cross-adaptation pretesting, held in a running bath of background water to maintain temperature, and used both to adapt the naris and to prepare dilutions of test steroids for cross-adaptation testing. Immediately following preadaptation application of 2-sec pulses of all the test steroids, the naris was exposed to the adapting steroid until the induced response reached a stable plateau (usually within 3 min) and then exposed to 2-sec pulses of the test steroids dissolved in adapting solution. The magnitude of the response induced during adaptation was converted to %IR and, for each steroid, the difference between %IR in cross-adaptation and %IR in the sequential exposure test was analyzed by Mann-Whitney *U* test.

Odor-Induced Ventilation Increase. Individual male or nonovulated female

gobies displayed no overt reproductive response to bolus addition of single detected steroids (final water concentration 10^{-8} M). However, a number of detected steroids did induce a transitory increase in ventilation frequency (opercular movements per minute) that formed the basis of a consistent and quantitative behavioral bioassay. Although the biological significance of odor-induced ventilation increases in *Neogobius* is unclear, the fact that in some benthic fish water flow through the naris changes in synchrony with ventilation (Nevitt, 1991) suggests increased ventilation might facilitate odor detection or processing.

Ventilation frequency was monitored in aerated 100-liter, flow-through test aquaria (90 cm long × 30 cm wide × 38 cm high) that were opaque on the ends and one side, with one side left clear for observation; a gravel substrate was provided and one PVC tube (12 cm length; 6 cm diameter) was placed with one end facing the observation side. Fish usually remained within the PVC tube, enabling ventilation frequency to be monitored readily. To minimize visual disturbance during observations, fish were observed through a small hole cut in an opaque cloth curtain that blocked the fish's view of the experimenter. Test odors and control solutions were injected into the test aquaria (at the water surface directly over the PVC tube) through silastic tubing fed through a hole in the cloth curtain and anchored to each aquarium. Injections of dye showed that an odor plume should reach the PVC tube within one min and disperse evenly throughout the aquarium within 3 min.

A single male or nonovulated female (>8 cm in length) was placed in each test aquarium at least five days before testing and exposed to different odors on consecutive days. On the morning of each test day, water flow was turned off 2 hr before an experiment, the fish was tested with only one odor, and water flow was resumed. In each test, a fish was observed for 12 min prior to odor addition (pre-exposure period), a test solution was then injected, and the fish was observed for an additional 24 min (test period). Ventilations were counted continuously for 1 min during every 3-min interval before and after addition of an odor, yielding 4 min of pre-exposure ventilation and 8 min of test ventilation. Six males and six females were tested with each odor.

Ventilation frequency of individual males and females was monitored in response to addition of ethanol vehicle (1 ml), eight steroids that induced an EOG response (E1, E2, E2-3g, ETIO, ETIO-g, DHEA-s, DHEA-g, and ANDR-s), one steroid that did not induce an EOG response (testosterone-glucuronide; T-g), and L-alanine. Steroid odors were tested either individually or in combinations by injecting either 100 μl or 1 ml of a 10^{-3} M steroid-ethanol solution to create 10^{-9} and 10^{-8} M concentrations after dispersal. L-Alanine (10 ml of a 10^{-2} M aqueous solution) was added to create a 10^{-6} M final concentration.

To determine if basal (pre-exposure) ventilation of males and females differed, pre-exposure ventilation frequencies of males and females were compared by unpaired *t*-test (Wilkinson, 1994), using for each fish the grand mean

of pre-exposure frequencies from all odor tests. Ventilation frequency differences between pre-exposure and test periods were analyzed separately by sex and odor, comparing the mean (per minute) frequency of the four pre-exposure samples and the mean of the frequencies observed during minutes 4 and 7 of the test period (Wilcoxon test) (Wilkinson, 1994). All ventilation data from the test period are presented as a percentage of the mean basal (pre-exposure) ventilation frequency.

Ventilation Concentration–Response Studies. Concentration–response relationships were examined for those steroids (E1, E2-3g, and ETIO) that increased ventilation frequency of male fish when tested at 10^{-8} M. The protocol was identical to that already described, except that the final concentrations in the test aquaria ranged from 10^{-12} M to 10^{-8} M and were prepared by diluting appropriate volumes of 10^{-3} M steroid solutions into 100 ml of double-distilled, deionized water, and then adding 1 ml of this solution to the test aquarium. Testing of each steroid began at 10^{-12} M, and increased in log molar increments on consecutive days. Six males were tested, all receiving the same treatment each day.

For each steroid, differences in test ventilation frequency due to odor concentration were analyzed by Friedman's nonparametric ANOVA (Wilkinson, 1994), using for each fish the increase in ventilation during the test period (mean of minutes 4 and 7 after odor addition). Dunnett's test (Zar, 1984) was used to determine threshold by comparing the response (mean of minutes 4 and 7 after odor addition) of the lowest concentration tested (10^{-12} M) to each of the higher concentrations.

Behavioral Cross-Adaptation Studies. Behavioral cross-adaptation using ventilation as the behavioral response was conducted to determine if *Neogobius* can behaviorally discriminate among steroids that might act through separate olfactory receptor mechanisms, as indicated by the results of our EOG cross-adaptation studies (see EOG Cross-Adaptation Studies in Results). Unlike EOG cross-adaptation, behavioral cross-adaptation did not involve addition of the test odor prior to applying the adapting odor, because there was no means for rapidly removing the test odor prior to applying the adapting odor. Thus, the purpose of the behavioral cross-adaptation experiment was to determine if adaptation eliminates the ventilatory response to the test steroid, rather than to compare responses to a test steroid prior to and during adaptation.

In behavioral cross-adaptation, a fish was observed for a 12-min pre-exposure period, immediately exposed to an adapting steroid (either 10^{-8} M E1 or ETIO), observed for a 24-min adapting period, immediately exposed to a test steroid (10^{-9} M), and observed for a further 24-min test period. Ventilation frequency was monitored continuously every third minute; six male fish were tested in each treatment group. The adapting steroid was expected to increase ventilation, whereas the test steroid was expected to increase ventilation only if it acts

through a different receptor mechanism than the adapting steroid (Murphy and Stacey, 1999).

Differences in ventilation frequencies in the pre-exposure, adapting, and test periods were analyzed by Friedman's nonparametric ANOVA (Wilkinson, 1994) and pairwise differences were analyzed by Dunnett's test (Zar, 1984) using mean frequencies for the pre-exposure period and for minutes 4 and 7 of the adapting and test periods.

RESULTS

Response to Test Odors. L-Alanine consistently induced an EOG response in *Neogobius* both at 10^{-5} M (Figure 1) and 10^{-6} M (mean ± SEM = 3.1 ± 0.6 mV; $N = 8$). Response magnitude to 10^{-5} M L-alanine was similar ($P > 0.05$; t test) in males and females (Figure 1). There were no significant mechanical artifacts in the EOG recordings, responses to background water being <0.1 mV in all cases. Neither the ethanol solvent in 10^{-8} M test solutions (up to 0.001%) nor any of the eight tested prostaglandins induced EOG responses in any fish. However, of 114 tested steroids (Table 1), 19 met the criterion of detection by inducing an EOG response >0.1 mV in more than one fish (Figure 1). Because there was no indication that EOG responses of males and females differed in magnitude (Figure 1), EOG results from both genders were pooled in concentration–response and cross-adaptation studies.

At a concentration of 10^{-8} M (the highest concentration tested), a diverse array of conjugated and unconjugated 18-, 19-, and 21-carbon steroids induced EOG responses; those induced by the 18-carbon steroids generally were the largest (Figure 1). The detected 19-carbon steroids form a diverse group, including the 4-androstene (AD), 5-androstene (DHEA-g, and DHEA-s), 5α-androstan (ANDR-s, and EPIANDR-g), and 5β-androstan (ETIO, ETIO-g, 11β-ETIO-g, and ETIO-3,17-DIONE) configurations. In contrast, all the detected 21-carbon steroids were variations and conjugates of the 5β-pregnan moiety.

EOG Concentration–Response Studies. All concentration–response profiles increased in magnitude with concentration once detection threshold was reached (Figure 2). Although it was clear that some fish responded to 10^{-11} M E1, E2-3g, ETIO, and ETIO-g, group responses to steroids were not significantly different ($P < 0.05$) than responses to background water until 10^{-9} M for E1, E2-3g, and ETIO, and 10^{-8} M for DHEA-g, ANDR-s, ETIO-g, and DHEA-s (Figure 2).

EOG Cross-Adaptation Studies. When steroids intended for use in the cross-adaptation studies were delivered as 2-sec 10^{-8} M pulses 30 min apart (sequential exposure study), there was a trend for many steroids to induce smaller EOG responses on the second presentation, although the reduction was significant ($P < 0.05$; Wilcoxon test) only for DHEA-g (Figure 3A). Although few

replicates were conducted, three of the 5β-pregnan compounds (5βP; 3α,20β-5βP; and 3β,20β-5βP) which induced small EOG responses in initial tests (Figure 1) did not induce EOG response when given the second time in the sequential exposure test, and therefore were omitted from subsequent cross-adaptation studies. For each of the remaining 16 detected steroids, the mean % IR during

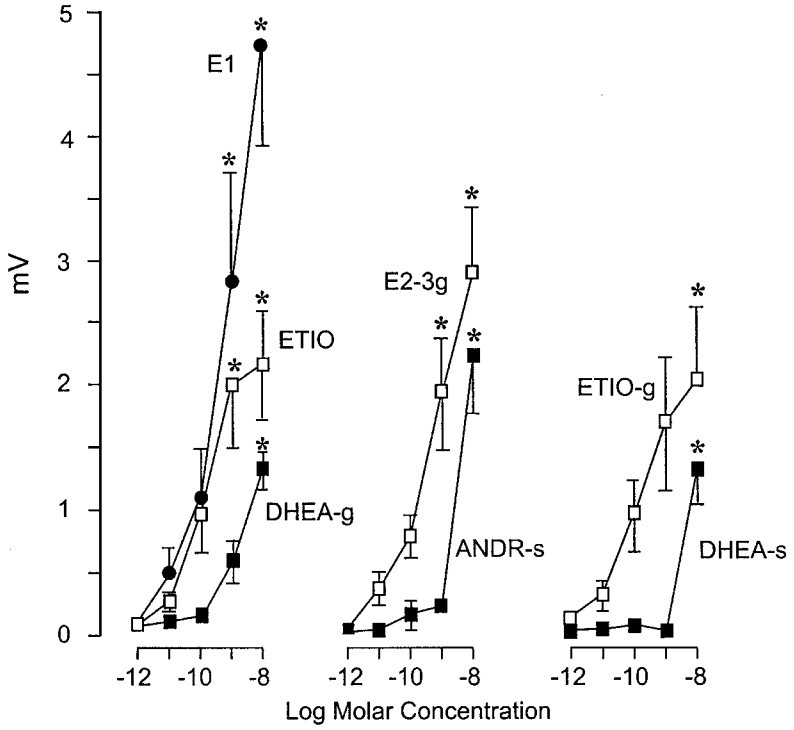

FIG. 2. Concentration response profiles (mean ± SE) for selected steroids. EOG responses expressed in millivolts. $N = 6$ for each steroid. *Response was significantly ($P < 0.05$) greater than response to background water.

the sequential exposure test (Figure 3A) was compared (Mann-Whitney *U* test) to the mean %IR during cross adaptation (Figure 3B–F).

Adaptation to 10^{-7} M ETIO significantly reduced EOG responses to 2-sec 10^{-8} M pulses of a diversity of 4-androsten (AD), 5α-androstan (ANDR-s), 5β-androstan (ETIO; ETIO-3,17-DIONE; and ETIO-g), and 5β-pregnan steroids (3α,17α-5βP; 3α,17α,20β-5βP; 3α,17α-5βP-g) (Figure 3B). Although adaptation to 10^{-7} M DHEA-s also significantly reduced response to ANDR-s (a 5α-androstan), it did not reduce responses to 5β-androstan steroids (e.g., ETIO, and ETIO-g) and produced a different pattern of adaptation of 5β-pregnan steroids than did adaptation to ETIO (Figure 3C).

In marked contrast to the pattern of adaptation to DHEA-s (Figure 3C), adaptation to DHEA-g (Figure 3D) did not affect responses to 5β-pregnanes, significantly reduced response to E2-3g and, rather than reducing response to ANDR-s, reduced response to its 3β isomer, EPIANDR-s (Figure 3D). This pat-

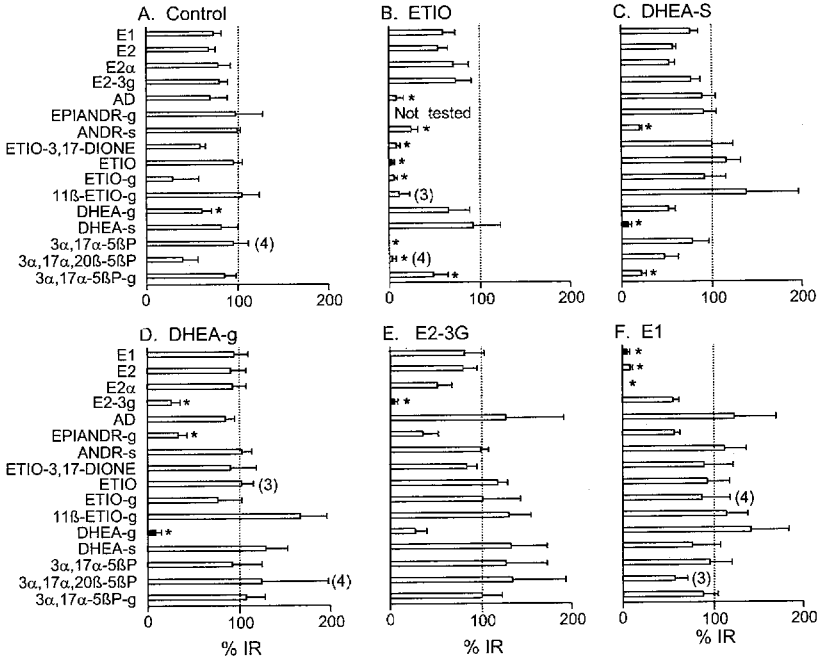

FIG. 3. EOG response to a 2-sec pulse of 10^{-8} M steroid expressed as percent of initial response (% IR) (mean + SE) to either (A) a 10^{-8} M of the same steroid delivered 30 min previously or during adaptation to (B) 10^{-7} M etiocholanolone (ETIO), (C) 10^{-7} M dehydroepiandrosterone sulfate (DHEA-s), (D) 10^{-7} M dehydroepiandrosterone-glucuronide (DHEA-g), (E) 10^{-7} M estradiol-glucuronide (E2-3g), or (F) 10^{-7} M estrone (E1). In B–F, response to adapting steroid indicated by solid bars. $N = 6$ except where indicated beside bars. See text and Table 1 for full names of steroids and text for calculation of % IR. *Response was reduced significantly ($P < 0.05$) by prior exposure (A) or by adaptation (B–F).

tern of adaptation to DHEA-g was similar to that seen during adaptation to E2-3g (Figure 3E), although in the latter case the apparent reductions in response to EPIANDR-s and DHEA-g were not significant.

Finally, adaptation to E1 significantly reduced responses only to the estratriene compounds E1, E2, and E2α (Figure 3F).

Although the results of our cross-adaptation studies (Figure 3) have not fully characterized the olfactory interactions of the steroids detected by *Neogobius*, they indicate the presence of at least four olfactory receptor mechanisms, which, for convenience, we term ETIO, DHEA-s, E2-3g, and E1.

Odor-Induced Ventilation Increase. *Neogobius* did not change their ventila-

tion rate in response to addition of 10^{-6} M L-alanine, the ethanol steroid solvent, 10^{-8} M T-g (a steroid that does not induce EOG response), or 10^{-8} M DHEA-s (a steroid that does induce EOG response) (Figures 4A and B and 5). In contrast, ventilation rate consistently increased in response to ETIO, E1, E2-3g, ANDR-s, and E2 (Figures 4C–E and 5).

Addition of ETIO increased ventilation in both male and female *Neogobius*, the response commencing within the first minute of steroid addition and persisting for approximately 10 min, after which ventilation quickly returned to basal rates (Figure 4C). Similar increases in ventilation were seen in both males and females in response to ETIO-g and ANDR-s (Figure 5), steroids in which EOG responses are significantly reduced during adaptation to ETIO (Figure 3B).

In contrast to the effect of ETIO, addition of E1 and E2-3g increased ventilation of males but not of females (Figure 4D, E). E2, for which EOG response is significantly reduced during adaptation to E1 (Figure 3F), also increased ventilation in males (Figure 5); the effect of E2 on ventilation was not examined in females. Addition of DHEA-g failed to affect ventilation, the apparent trend to increased ventilation being due to an increase in one fish of each sex (Figure 5).

Addition of a mixture of 10^{-9} M E1, E2-3g, ETIO, and DHEA-s induced a significant increase in ventilation, in which the magnitude (Figure 5) and duration (data not shown) were similar to those of its active components.

Behavioral Concentration–Response Studies. The threshold of the ventilation rate response was 10^{-10} M for ETIO and E1 and 10^{-9} M for E2-3g (Figure 6). Ventilation did not increase further at suprathreshold odor concentrations.

Behavioral Cross-Adaptation. In all four behavioral cross-adaptation experiments that used 10^{-8} M ETIO as the adapting steroid, male *Neogobius* significantly increased ventilation rate when exposed to the adapting odor (Figures 7 and 8A). During adaptation to ETIO, these males did not increase ventilation in response to addition of either 10^{-9} M ETIO or 10^{-9} M ANDR-s (Figures 7A and B and 8A), a steroid in which EOG response is significantly reduced by adaptation to ETIO (Figure 3B). In contrast, males adapted to ETIO significantly increased ventilation in response to addition of 10^{-9} M E1 and 10^{-9} M E2-3g (Figures 7C and D and 8A), steroids in which EOG response magnitude is not reduced by adaptation to ETIO (Figure 3B).

Similar results were obtained in behavioral cross-adaptation experiments that used 10^{-8} M E1 as the adapting steroid (Figure 8B): adapted males did not respond to E2, whose induced EOG response is significantly reduced by E1 adaptation (Figure 3F), but significantly increased ventilation rate in response to steroids (ETIO, E2-3g) whose induced EOG responses are unaffected by E1 adaptation (Figure 3F) (Murphy and Stacey, 1999).

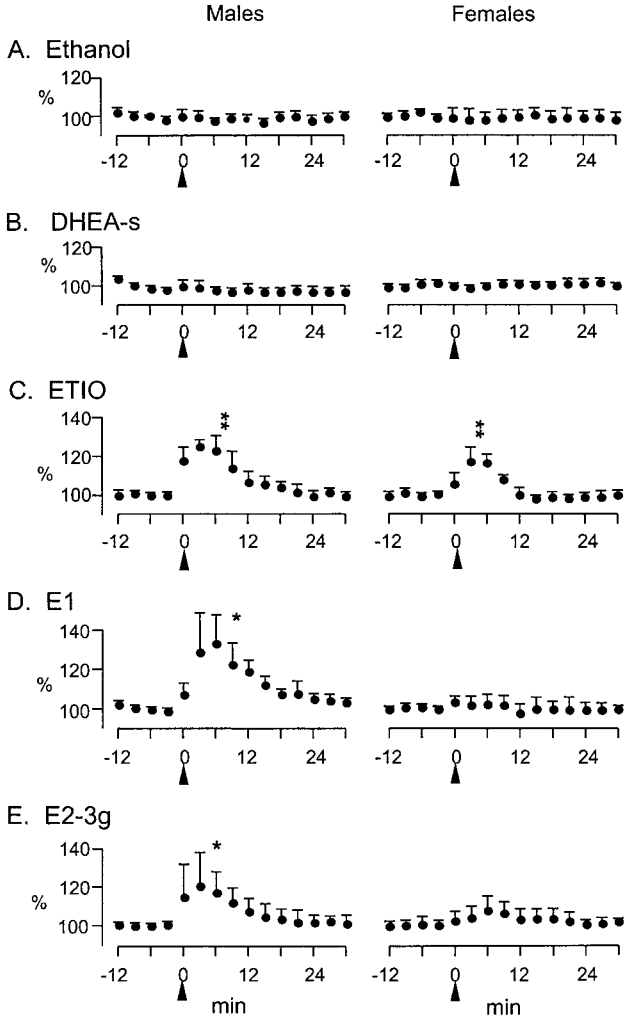

FIG. 4. Percent change in basal ventilation rate (mean + SE) of male and female gobies after addition (arrow) of (A) 1 ml ethanol or exposure to (B) 10^{-8} M DHEA-s, (C) 10^{-8} M ETIO, (D) 10^{-8} M E1, or (E) 10^{-8} M E2-3g. Ventilation rates following addition of test substances were calculated as a percentage of the basal ventilation rate (i.e., the mean ventilation rate in the 12 min preceding additions). $N = 6$ for all groups. Mean ventilation rate during minutes 4 and 7 following test substance addition is significantly different from the basal ventilation rate ($^{*}P < 0.05$; $^{**}P < 0.01$).

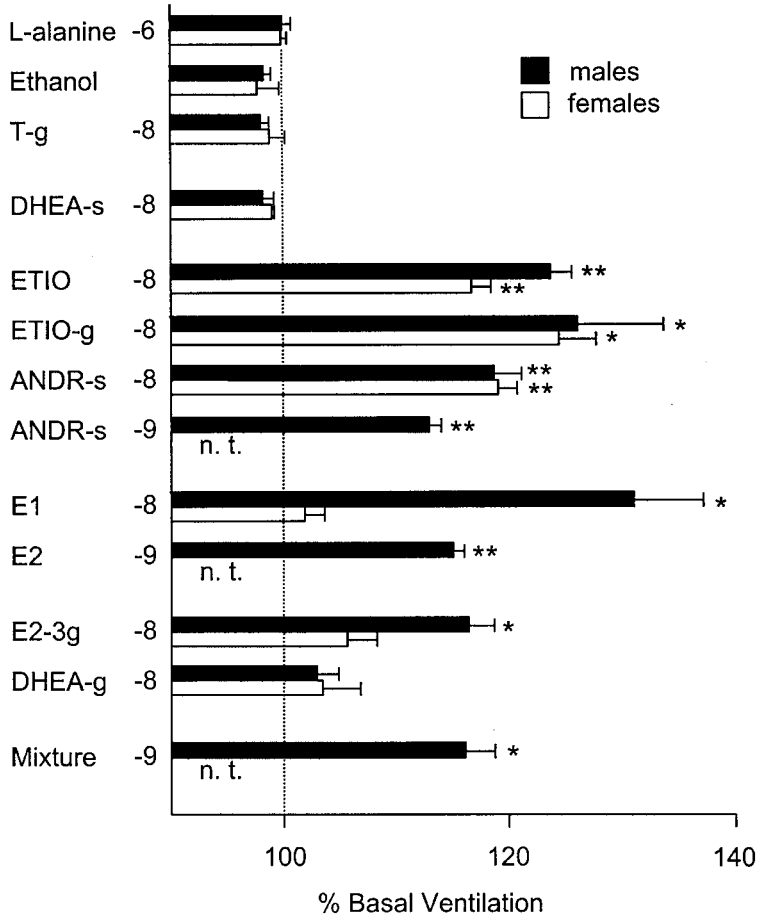

FIG. 5. Percent change in basal ventilation rate (mean + SE) of male and female gobies during minutes 4 and 7 after the addition of single test substances or a mixture consisting of four 10^{-9} M steroids (E1, E2-3g, ETIO, and DHEA-s). Ventilation responses to test substances were calculated as in Figure 4. See text and Table 1 for full names of steroids. $N = 6$ for all groups. n.t. = not tested in females. Mean ventilation rate after addition of a test substance is significantly different from basal ventilation rate ($^{*}P < 0.05$; $^{**}P < 0.01$).

DISCUSSION

The results of this study demonstrate that the round goby, *Neogobius melanostomus*, exhibits olfactory and behavioral responses to steroids, and thus may use released steroids as sex pheromones. The olfactory epithelium of *Neo-*

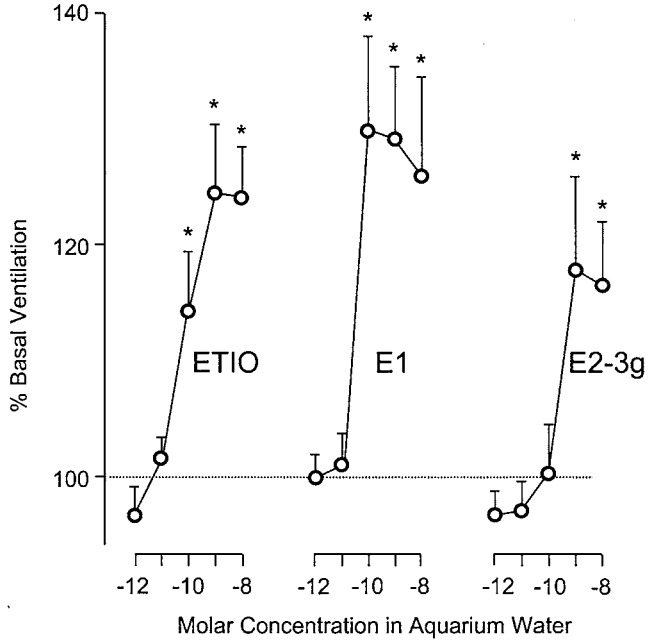

FIG. 6. Percent change in basal ventilation rate (mean + SE) of male gobies during the minutes 4 and 7 after exposure to ETIO, E1, and E2-3g. gobius exhibits EOG responses to a diverse array of steroids (Figure 1), but not to prostaglandins. These findings are consistent with the small number of EOG studies conducted in other perciform species that report a lack of olfactory responsiveness to a range of commercially available prostaglandins and responsiveness to a variety of steroidal compounds (Robison et al., 1998; Stacey et al., 1994b; Stacey and Cardwell, 1995, 1997; Murphy et al., 2000). Our EOG recording studies in *Neogobius* also indicate a lack of sexual dimorphism in detection of steroids (Figure 1). Although the precise reproductive status of the fish used in the recording (i.e., level of gonadal recrudescence) was not determined, other studies on fish report that gender and gonadal maturity have a very minor effect [common carp (Irvine and Sorensen, 1993)] or no effect at all [goldfish (Sorensen et al., 1995), tinfoil barb, *Puntius schwanenfeldi* (Cardwell et al., 1995)] on EOG detection and response magnitude of steroidal odors. By using ventilation increase as a behavioral bioassay, we also find that some detected steroids are perceived by *Neogobius* (Figure 4); unlike olfactory responses, however, behavioral responses to detected steroids is sexually dimorphic (Figure 5).

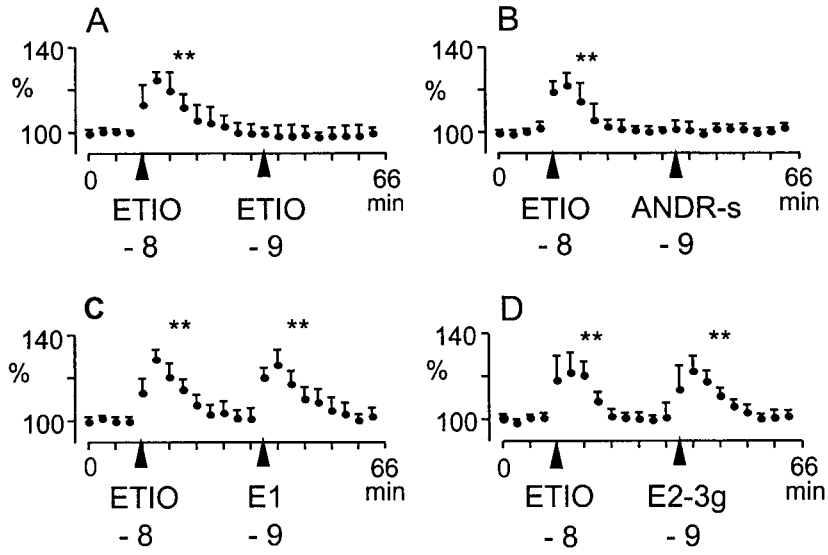

FIG. 7. Percent change in basal ventilation rate (mean + SE) of male gobies in behavioral cross-adaptation studies using 10^{-8} M ETIO (first arrow) as the adapting steroid and 10^{-9} M (A) ETIO, (B) ANDR-s, (C) E1, or (D) E2-3g (second arrow) as the test steroid. Ventilation responses to adapting and test substances were calculated as in Figure 4. $N = 6$ for all groups. **Mean ventilation rate after addition of an adapting or test steroid is significantly different from basal ventilation rate ($P < 0.01$).

Finally, our finding that ETIO-g induces olfactory and behavioral responses in *Neogobius* is consistent with biochemical and behavioral studies (Colombo et al., 1977, 1980, 1982) that indicate a pheromonal function for this steroid conjugate in the black goby, *G. jozo*.

Colombo et al. (1980) showed that ovulated female *G. jozo* are attracted to an ETIO-g source and often induced to oviposit in the absence of a male, whereas preovulatory females, or ovulated females that had completed oviposition, are not. In contrast, we observed no reproductive behavioral responses when isolated *Neogobius* or male–female pairs were exposed to ETIO-g or other detectable steroids (Murphy, 1998). Absence of reproductive behavior response in our studies could have been due to at least four factors. First, absence of female response to ETIO-g and related steroids was likely due to the fact that we were unable to obtain ovulated females for testing. Second, behavioral response to some steroid(s) might require the presence of nonolfactory cues that were not present in our test aquaria. Third, some detected steroids might induce only physiological responses. Fourth, although female *G. jozo* exhibit complex behavioral responses to ETIO-g alone, reproductive behavioral response in *Neogob-*

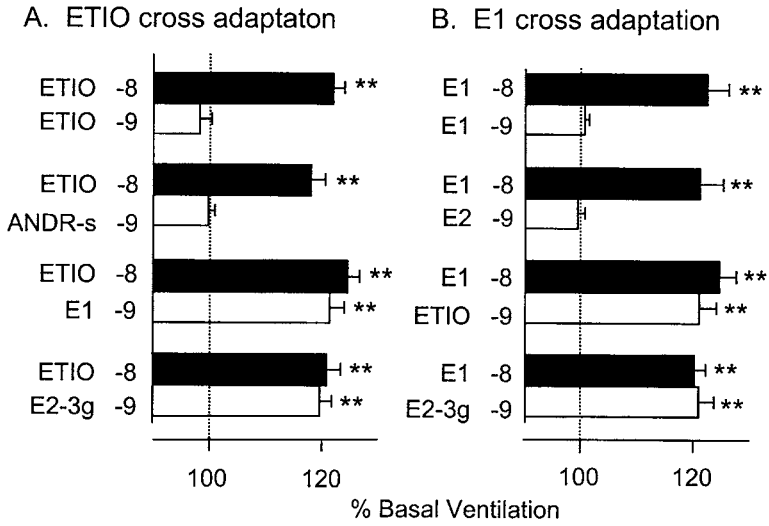

FIG. 8. Percent change in basal ventilation rate (mean + SE) of male gobies in behavioral cross-adaptation experiments using (A) 10^{-8} M ETIO and (B) 10^{-8} M E1 as the adapting steroids, as in Figure 7. Ventilation responses to adapting and test substances were calculated as in Figure 4. $N = 6$ for all groups. **Mean ventilation rate after addition of an adapting or test steroid is significantly different from basal ventilation rate ($P < 0.01$). Note (A) summarized from Murphy and Stacey (1999).

ius might require exposure to steroid mixtures. Nonetheless, we feel that the nature of the steroid-induced olfactory and ventilatory responses reported in this study provide evidence that steroidal compounds may function as reproductive pheromones in *Neogobius*.

Although the function of the ventilation responses to steroid odorants is not clear, the behavior may serve as a "sniffing" mechanism to facilitate odor detection by increasing water flow through the olfactory organ as has been proposed in flounder species (*Lepidopsetta bilineata* and *Platichthys stellatus*) (Nevitt, 1991). Ventilation rate increases may be analogous to tongue flicking observed in many lizard species in response to olfactory stimuli; an increase in the number of tongue flicks in response to novel odors is usually measured as an indication of odor detection in squamate reptiles (Cooper, 1994). Our ventilation rate bioassay requires further clarification on mode of action, as we have not ruled out other mechanisms of detection. For example, there is the small possibility that the steroids could be detected through the taste system or interact with gill processes. Despite these limitations, the ventilation rate measurements closely correspond to the olfactory measurements, and we predict that further investigation will show that this ventilation rate increase in response to steroids

is mediated by the olfactory system. Indeed, odor-induced ventilation could be a valuable behavioral bioassay for examining odor perception in other benthic fishes.

Our EOG cross-adaptation studies indicate that steroids detected by the olfactory organ of *Neogobius* (Figure 1) are discriminated by at least four proposed receptor mechanisms (E1, E2-g, ETIO, and DHEA-s); at least two compounds (ANDR-s and 3α,17α-5βP-g) appear to interact with two of these proposed receptor mechanisms (ETIO and DHEA-s) (Figure 3). Based on results of EOG concentration-response studies (Figure 2), we named the four proposed receptor classes after the most potent steroid odorants, assuming these to be likely natural ligands. However, the steroidal compounds released by *Neogobius* are not known.

Although our EOG and behavioral data indicate *Neogobius* possess multiple olfactory receptor mechanisms for steroidal compounds, using EOG cross-adaptation to link odorants with specific olfactory transduction processes (receptor mechanisms) can be problematic. For example, if olfactory receptors possess multiple binding sites for different odorants, an adapting odor that binds to one site could allosterically affect the binding properties of the other site(s), resulting in nonreciprocal cross-adaptation among compounds thought to share the same transduction mechanism (Caprio and Byrd, 1984). As well, if odorants possess more than one odotope (ligand–receptor binding site) (Shepherd, 1987), EOG cross-adaptation results will be complex. Interpretation of our cross-adaptation results also is confounded by the finding that even a brief (2-sec) pulse of steroid odor can reduce response to that odor when delivered 30 min later (Figure 3A). Therefore, due to the possibility that brief exposure to one compound reduces EOG response to all compounds detected via the same receptor mechanism, we maintained the same order of steroid exposure in our EOG cross-adaptation experiments and compared the reduction of test odorant response magnitude during adaptation to the reduction observed in the control (sequential exposure test; Figure 3A).

Despite these theoretical and practical problems inherent in EOG cross-adaptation studies, our interpretation of the cross-adaptation data is supported by results of the ventilation behavioral bioassays conducted with male *Neogobius*. Although males showed no behavioral response to one of the proposed steroid odorant classes (DHEA-s), they increased ventilation when exposed to the other three (E1, E2-3g, ETIO) (Figures 4 and 6), and did not respond to a steroid (T-g) that failed to induce an EOG response (Figure 5). Most importantly, ventilation responses of males clearly show they discriminate steroids that EOG cross-adaptation results indicate are detected by separate receptor mechanisms and do not discriminate steroids that appear to act through the same receptor mechanism (Figures 7 and 8).

Although behavioral assays have been used to examine discrimination of

amino acid odorants in channel catfish (*Ictalurus punctatus*) (Valentincic et al., 1994), the present study appears to be the first to demonstrate a clear relationship between peripheral (EOG) and central (behavioral) discrimination of steroid odorants. We expect that further behavioral cross-adaptation experiments using detected steroids not employed in this study will clarify the ability of *Neogobius* to discriminate steroid odorants.

Statistically, threshold ventilation response to ETIO and E1 (Figure 6) were lower (more sensitive) than threshold EOG responses (Figure 2); however, such a comparison likely has little biological significance. For example, given our small sample sizes for EOG concentration–response studies ($N = 6$), and the shapes of the concentration-response profiles (Figure 2), the statistical EOG thresholds appear to be conservative estimates of olfactory sensitivity. Moreover, the statistically greater sensitivity of ventilation responses to ETIO and E1 may simply have resulted from fish being exposed briefly to the injected steroid prior to its full dispersal throughout the test aquarium. The low detection thresholds to the steroids also suggest that the odors act through the olfactory system rather than the gustatory system (Sorensen and Caprio, 1998).

Unlike EOG responses to steroids (Figure 1), ventilation responses were clearly sexually dimorphic, males responding to three of the proposed steroid odorant types (E1, E2-3g, and ETIO) and females responding only to ETIO (Figure 4). Male androgenic steroid(s) appears to regulate this sexual dimorphism; females implanted with methyl-testosterone exhibit male-typical ventilation responses to E1 and E2-3g (Murphy and Stacey, unpublished results). The possible functional significance for this behavioral dimorphism is considered below.

Together, our EOG and behavioral data indicate the olfactory organ of *Neogobius* possesses at least four receptor mechanisms for steroid odorants. The proposed E1 receptor responded rather nonspecifically to unconjugated 18-carbon (C_{18}) steroids (E1, E2, and E2α), the nature of the oxygen group at C-17 apparently having little effect on olfactory potency. In contrast, addition of a hydroxyl group on C-16 (estriol; 1,3,5[10]-estratrien-3α,16α,17β-triol), or the addition of a glucuronide or sulfate group at C-3 or C-17 rendered the steroid undetectable by the proposed E1 receptor.

The proposed E2-3g receptor mechanism appears to interact with three seemingly diverse steroids (E2-3g, DHEA-g, and EPIANDR-g; Figure 3D,E). E2-3g and DHEA-g adapted each other, and both reduced the response to EPIANDR-g, although only the effect of DHEA-g adaptation on EPIANDR-g response was significant (Figure 3). Given the structure of the steroids adapted by ETIO (Figure 3B), it is expected that EPIANDR-g also interacts with the proposed ETIO receptor, although this was not examined. The structural requirements for ligands interacting with the proposed E2-3g receptor are unclear, given that it appears to interact with 5α-androstan (EPIANDR-g), 5-androstene

(DHEA-g), and estratriene (E2-3g) compounds. However, both a 5β- or planar glucuronide group at C-3 and an unconjugated oxygen group at C-17 appear important, because estratrienes without a C-3 glucuronide (E2), or with a C-3 sulfate (17β-estradiol-3-SO4) or C-17 glucuronide or sulfate (17β-estradiol-3-glucuronide-17β-SO_4), either did not induce EOG response (Table 1) or were unaffected by E2-3g adaptation (Figure 3). Unfortunately, no 5α-androstan-3α-glucuronides (e.g., androsterone-3α-glucuronide) were tested for interaction with the proposed E2-3g receptor, although ETIO-g, a 5β-androstan with a 3α-glucuronide, was detectable but unaffected by E2-3g adaptation (Figure 3E).

Given that E2-3g increased ventilation in male *Neogobius*, it is surprising that DHEA-g did not (Figure 5). The ineffectiveness of DHEA-g could have been due to the fact that it was a less potent olfactory stimulant than E2-3g (Figure 2). This seems unlikely, however, because ANDR-s, which appeared to be equipotent to DHEA-g in EOG concentration-response studies (Figure 2), increased ventilation when tested at a lower concentration than DHEA-g (Figure 5).

As males gobies are not reported to synthesize C_{18} steroids (Colombo et al., 1977; Asahina et al., 1989), we assume it is C_{18} steroids from females that normally interact with the proposed E1 and E2-3g receptors of males, either to signal that local females are vitellogenic, or to signal gender of females approaching the male's nest. The functional significance of separate receptors for conjugated and unconjugated C_{18} steroids is not known. However, studies on rainbow trout (*Oncorhynchus mykiss*) indicate that free steroids are preferentially released across the gills, whereas conjugates are released in the urine and feces (Vermeirssen and Scott, 1996). If this is the case with *Neogobius*, it is possible that E2-3g is released in concentrated urinary pulses and used by males to detect females at a distance, whereas E1 is released tonically at low concentration and used to identify females at the nest site.

The unconjugated C_{18} steroids detected by *Neogobius* are known to be detected by only a few species of the nonperciform fish (Orders Cypriniformes and Characiformes) that have been studied by EOG recording (Stacey et al., 1994b; Stacey and Cardwell, 1995, 1997). EOG studies indicate unconjugated C_{18} steroids are not detected by any of the small number of perciform species examined (Stacey et al., 1994b; Stacey and Cardwell, 1995, 1997; Robison et al., 1998; Murphy et al., 2000).

There is evidence that conjugated (glucuronated and sulfated) C_{18} steroids have pheromonal function in other species. C_{18} sulfates induce EOG responses in a number of characiform species (Stacey and Cardwell, 1995, 1997), and E2-3g and other glucuronated and sulfated forms induce EOG responses in a perciform, *Haplochromis burtoni* (Robison et al., 1998); however, there has been no attempt to determine pheromonal functions of the detected steroids in any of these species. Van den Hurk and Lambert (1983) proposed that male zebra fish (*Danio*

rerio) are attracted to females by a mixture of ovarian steroid glucuronides that contains 17β-estradiol-17β-glucuronide (E2-17g) and testosterone glucuronide (T-g). However, our EOG studies (Stacey and Cardwell, 1995, 1997), using the suite of steroids tested in *Neogobius*, indicate that zebra fish do not detect these steroid glucuronides, and instead detect one conjugated 4-pregnen compound (17,20β-P-20β-SO_4), which functions as a pheromone in goldfish (Sorensen et al., 1995). These EOG responses in zebra fish are consistent with studies of odor-induced olfactory bulb activity in zebra fish showing that prostaglandin $F_{2\alpha}$ and 17,20β-P-20β-SO_4 induce bulbar activity, whereas E2-17g and T-g do not (Friedrich and Korsching, 1998).

Structural requirements for ligands of the proposed DHEA-s receptor are not clear. A conjugate on C3 evidently is important, because DHEA did not induce an EOG response, but it appears the orientation of the conjugate is not critical, given that DHEA-s (a 5β- steroid) adapted the response to ANDR-s (a 5α- steroid; Figure 3C). Surprisingly, DHEA-s also adapted the EOG response to 3α,17α-5βP-3g. DHEA-s failed to increase ventilation in either sex and is reported to induce EOG response in only one other species, the cichlid *Haplochromis burtoni* (Robison et al., 1998).

The proposed ETIO receptor appears to be relatively nonspecific, since it interacted with a variety of C_{19} and C_{21} compounds, two of which (ANDR-s and 3α,17α-5βP-3g) also interacted with the proposed DHEA-s receptor (Figure 3B). However, the proposed ETIO receptor did exhibit specificity insofar as ETIO adaptation did not reduce EOG responses to 5-androsten compounds (DHEA-g, DHEA-g; Figure 3B) or to any steroids believed to interact with the proposed E2-3g and E1 receptors (Figure 3E,F). Both males and females increased ventilation when exposed to several steroids (ETIO, ETIO-g, and ANDR-s) that interact with the proposed ETIO receptor (Figure 5). Interaction of numerous 5β-reduced steroids with the proposed ETIO receptor is consistent with studies of *G. jozo* showing a preponderance of 5β-reduced products in in vitro incubations (Colombo et al., 1977). However, similar studies of the urohaze goby (*Glossogobius olivaceus*) indicate predominance of 5α-reduction in the testes and seminal vesicles (Asahina et al., 1989). Thus, interaction of the proposed ETIO receptor with a 5α-reduced steroid (ANDR-s) raises questions as to the nature of the natural ligands in *Neogobius*.

Olfactory and behavioral response to ETIO-g by the round goby is consistent with earlier work (Colombo et al., 1977, 1980, 1982) suggesting that this compound is released by male *G. jozo* to attract females and stimulate oviposition. However, given the number and variety of steroids interacting with the proposed ETIO receptor, it is likely that any pheromone acting through this receptor in *Neogobius* would be a mixture of C_{19} and C_{21} compounds. The fact that ETIO-g increases ventilation in both male and female *Neogobius* suggests that this and other steroids interacting with the proposed ETIO receptor induce repro-

ductive responses in both genders. It is possible that male *Neogobius* use ETIO to assess the proximity and reproductive status of neighboring males, whereas females use ETIO for mate search and mate selection, as is likely the case in *G. jozo* (Colombo et al., 1980).

In summary, this study of EOG and behavioral responses to steroidal compounds provides the most extensive data set on putative hormonal pheromones in any perciform species. Although the findings suggest that *Neogobius* has evolved a complex sex pheromone system, further research is required to determine the functions of the putative hormonal pheromones and the natural steroid odorants involved. Such research is warranted not only because *Neogobius* is a tractable species that could serve as a model for pheromone studies of paternal nest-guarding fishes, but also because further understanding might reveal pheromonal techniques to control the spread of this species in the Great Lakes and other North American aquatic ecosystems.

(Received July 23, 2000; accepted November 12, 2000)

Abstract—Volatiles from various life-stages of the bont ticks *Amblyomma variegatum* and *A. hebraeum* were collected by using solid-phase microfibers and charcoal traps. An octenol isomer was found to be a major constituent of most of the tick material sampled and was identified as 1-octen-3-ol by gas chromatography–mass spectrometry and by using antenna of the tsetse fly *Glossina brevipalpis* in gas chromatography-linked antennogram detection. Release of this compound increased during molt to adulthood and following mechanical disturbance of adult ticks. (*R*)-(−)-1-Octen-3-ol and racemate 1-octen-3-ol both induce an increase in upwind walk to the odor source from *A. variegatum* in an airstream on a servosphere. Volatiles from tick exuviae plus feces and from dead ticks also attracted *A. variegatum*, suggesting that 1-octen-3-ol may contribute to the aggregation response of *Amblyomma* spp. on such substrates. 2,6-Dichloroanisol and 2,5-dimethylpyrazine also were detected in volatiles from the ticks but induced no behavioral responses on the servosphere. The suspected tick pheromone component, 2,6-dichlorophenol, was detected from *A. variegatum* adults cut into pieces but had no effect on the behavior of *A. variegatum* on the servosphere at a range of doses.

Key Words—1-Octen-3-ol, ixodid tick, *Amblyomma variegatum*, tick attractant.

INTRODUCTION

Secretions from dermal glands of both prostriate and metastriate ticks have been widely reported (Lees, 1947; Balashov, 1972, 1983; Yoder et al., 1993a; Walker et al., 1996). Particular attention has been paid to the aggregation–attachment pheromone of some *Amblyomma* spp. (Gladney et al., 1974; Apps et al., 1988;

*To whom correspondence should be addressed. e-mail: Patrick.Guerin@zool.unine.ch

0098-0331/00/0300-0471$19.50/0

Diehl et al., 1991) and the suspected tick pheromone product 2,6-dichlorophenol (De Bruyne and Guerin, 1994). It is known that several metastriate ticks transiently release cuticular droplets in response to physical disturbance, for which a defensive role has been suggested. Yoder et al. (1993a) found that *Dermacentor andersoni*, *D. variabilis*, *A. americanum* and *A. maculatum* release a "pungent odor" associated with the appearance of droplets on the cuticle. Pavis et al. (1994) observed the release of droplets by *A. variegatum* after disturbance, and Walker et al. (1996) reported the release of droplets with a "sour, nut-like smell" from unfed and fed *Rhipicephalus appendiculatus* adults after handling. Behavioral tests with these exudates were carried out by Yoder et al. (1993b) on *D. variabilis* and by Pavis et al. (1994) on *A. variegatum*. Each demonstrated that the exudate gave significant protection to ticks for a day in a Petri dish assay against fire ant predation. It is likely that protection was afforded in these studies by nonvolatile components of the exudates and not by the transient odor associated with them upon release from the cuticle.

Here, we collected odor volatiles released by both resting and physically disturbed *Amblyomma variegatum* (Fabricius) and *A. hebraeum* (Koch) by using solid-phase microfibers and charcoal. The volatiles were analyzed by gas chromatography-linked mass spectrometry (GC-MS) and by gas chromatography-linked electroantennogram detection (GC-EAD). A servosphere apparatus was used to examine the behavioral responses of *A. variegatum* adults to the headspace of ticks, to 1-octen-3-ol and other volatiles identified.

METHODS AND MATERIALS

Ticks. The two tick species examined, *A. variegatum* and *A. hebraeum* (Acari, Ixodidae), have been reared at the Centre de Recherche Santé Animale S.A., Novartis, St. Aubin, Switzerland since 1981. All stages (immature and adult) are fed on the tails of Simmental calves at 22–24°C and kept under constant darkness during molt at 28°C/80–90% relative humidity. For our experiments, engorged females, unfed adults of both *A. variegatum* and *A. hebraeum*, and unfed nymphs of *A. variegatum* were maintained in a 10L : 10D cycle with 2-hr ramps of dawn and dusk at 19°C/90% relative humidity. *A. variegatum* adults of either sex, between 1 and 9-months old, were prepared for behavioral tests on the servosphere as in McMahon and Guerin (2000). Each tick was tested only once.

Odor Sampling with SPME. Two solid-phase microextraction (SPME) stationary phases (Supelco) were used: Carbowax/divinylbenzene (Carbowax/DVB), which can adsorb volatile alcohols, and Carboxen/polydimethylsiloxane (Carboxen/PDMS), which has an affinity for hydrocarbons after several hours with the analyte. The latter phase with its lower affinity for water is more suit-

able for sampling over biological material in humid environments. The fibers were preconditioned for 2 hr at 300°C in a N_2 stream.

Odor Sampling over Undisturbed Ticks. Volatiles from resting or dead ticks were sampled by using the Carboxen/PDMS fiber that was inserted without disturbing the resting ticks into a horizontally held glass tube (12 cm long, 2 cm diam.) containing 200 ticks and sealed at both ends with perforated plastic stoppers. The control consisted of placing a fiber in an empty glass tube within 50 cm of the test tube. The collection fibers were left to stand overnight. In this manner, volatiles from the following tick substrates were sampled: 9-month-old *A. variegatum* nymphs, 1- and 9-month-old *A. variegatum* adults, *A. variegatum* adults that had died in the previous two months, and 12-month-old *A. hebraeum* adults.

Odor Sampling over Manipulated Ticks. The Carbowax/DVB fiber was used to sample volatiles from disturbed unfed *A. variegatum* adults of both sexes by holding five unfed adults in a 2-ml vial and squeezing the ticks individually with forceps. The vial was sealed immediately with Parafilm, and a Carbowax/DVB fiber was inserted through the seal and held over the ticks for 1 hr. The sampling was repeated overnight. The control for this test was to hold the fibers above undisturbed ticks for the same time intervals. The Carbowax/DVB fiber also was used to collect volatiles from four *A. variegatum* females killed by freezing and immediately cut into four pieces.

Odor Sampling with Charcoal. Air was sucked with a membrane pump (200 ml/min) over groups of five gently shaken engorged *A. hebraeum* or *A. variegatum* females (<1 week after drop-off) held in a 500-ml gas-wash bottle. Volatiles from the ticks were trapped on a 5-mg charcoal trap held in a 60-mm long × 4-mm-diam. glass tube in the closed-loop stripping apparatus of Grob and Zürcher (1976). As water condensation can reduce the effectiveness of charcoal as an adsorbant, the charcoal trap was heated to 10°C above room temperature during odor entrainment. After collection of volatiles for 10 min, the flask was gently shaken again to induce the release of more droplets from the dermal glands, and odors were collected onto the charcoal trap for another 10 min. The charcoal trap was extracted with 12 μl dichloromethane, of which 2 μl were analyzed (below).

Volatiles from 9-month-old unfed *A. variegatum* adults were entrained onto a charcoal trap (above) from air (200 ml/min) passing over 200 ticks held in a 50-ml gas-wash bottle and shaken to induce release of volatiles from dermal glands. The odor collected was extracted with dichloromethane (as above).

Gas Chromatography-Linked Mass Spectrometry Analysis. The SPME fibers were withdrawn into the hollow needle of the holding syringe after odor sampling and reexposed for 1 min to desorb the trapped volatiles in a split/splitless injection port (injection temperature, 280°C) of a gas chromatograph (Hewlett-Packard 5890 GC) linked to a HP 5971A mass selective detector

(MSD). The analyte was swept from the injector port onto a DB-Wax high-resolution fused-silica capillary column (30 m long, 0.25 mm ID, 0.25-μm film thickness, J&W Scientific) with a precolumn (1 m deactivated fused silica). The column was connected via a 1-m deactivated fused-silica capillary (0.25 mm ID) to the MSD ionization chamber (temperature 160°C, ionization energy 70 eV). The MSD, in the EI mode, scanned for masses m/z 20–300. Helium was used as carrier gas at 50 kPa head pressure (but was set at a constant flow, 30 cm/sec for on-column injection of the charcoal trap extract, see above). Components of the desorbed material were identified by comparing the mass spectra of unknowns in the analyte with those of standards in a library of the HP Chemstation software and by matching retention times with synthetic equivalents.

Gas Chromatography-Linked Electroantennogram Detection. Tick volatiles were tested for the presence of 1-octen-3-ol by using the antenna of the tsetse fly *Glossina brevipalpis* in GC-linked electroantennogram detection (GC-EAD) (Arn et al., 1975). The antenna of *G. brevipalpis* is sensitive to subnanogram levels of this compound eluting from a GC column. Furthermore, by using the specific response of the antenna of *G. brevipalis* to 1-octen-3-ol (Ujváry et al., 2000), the product can be identified by its retention time and by comparing the response of the antenna to the analyte with that to a similar amount of the naturally occurring pure (*R*)-(−) isomer. This was achieved by comparing the ratio of the EAG to FID peak heights for the extract and natural (*R*-(−)-1-octen-3-ol.

The procedure for electroantennogram detection briefly described is as follows. Volatiles were delivered on-column to a Carlo Erba 5160 GC with a flame ionization detector (FID at 260°C). The extract or headspace was injected in splitless mode onto a 25-m fused-silica SE-54 column (Macherey-Nagel), 0.25 mm ID, 0.35-μm film thickness with H_2 as carrier gas (27 cm/sec). The column effluent was split (glass Y-splitter) so that 60% was directed to the FID and 40% to the electrophysiological preparation. The latter was swept by a conditioned airstream (see below) to the electrophysiological preparation from a heated transfer line (240°C) in the wall of the chromatograph in such a way that the column effluent was simultaneously monitored by the FID and fly antenna. The method of mounting the fly head for EAG recording was as in Guerin and Visser (1980). Briefly, the fly head was excised after momentarily anaesthetizing it with CO_2. A chloridized silver wire was placed in a drawn-out capillary (10-μm tip diameter) filled with 0.1% KCl that was inserted through the occipital opening reaching into the pediculus and served as the reference electrode. This preparation was then mounted under a microscope (WILD Kombistereo M3Z) where the antenna was bathed in a humidified airstream (90–100% relative humidity, 23 ± 2°C) flowing at 1 m/sec via a glass water-jacketed tube (6 mm ID) whose outlet was about 1 cm from the preparation. The unbroken tip of the recording electrode was brought into contact with the funiculus surface upon which the tip

broke. Funiculus surface contact was enough to record the EAG. Micromanipulators (Leitz) permitted accurate positioning of the preparation and recording electrode. The EAG signal was captured via a silver wire in the electrolyte-filled (0.1 M KCl) glass electrode connected to a high-impedance preamplifier and an AC/DC amplifier (UN-03, Syntech) and recorded on the hard disk of a PC with the FID signal via a 16-bit analog–digital IDAC card (Syntech) by using the GC-EAD software package (Syntech), and monitored simultaneously with an oscilloscope (Tektronix 5103).

G. brevipalpis antennae were employed in GC-EAD to test for the presence of 1-octen-3-ol in volatiles collected on charcoal from 9-month-old disturbed *A. variegatum* adults as described above. *G. brevipalpis* EAD responses also were used to monitor directly for the presence of 1-octen-3-ol in the air above tick material. For this, *A. variegatum* exuviae (0.3 g; 5 days after molt) from 150 individuals were placed in a closed 5-ml vial with a Teflon-coated rubber seal. One day later, 2 ml of air was withdrawn from this vial with a gas-tight syringe and injected on to the DB-Wax column in splitless mode (1 min). To facilitate the large-volume injection, the column head pressure was reduced manually for 5 sec during injection and then raised to 65 kPa. Analysis for the presence of 1-octen-3-ol over 10 unmolted *A. variegatum* ticks was carried out in the same manner. The influence of molting on the release of 1-octen-3-ol in the headspace was analyzed by sealing 10 unmolted *A. variegatum* ticks in a 5-ml vial as before. After two animals had molted, 2 ml of this headspace was withdrawn in the gas-tight syringe without disturbing the animals and injected in splitless mode as above. In addition, odor puffs from groups of five undisturbed and just disturbed *A. variegatum* adults were delivered to the antenna of *G. bevipalpis* from the barrels of 5-ml plastic syringes in which the ticks were held to test for electroantennogram responses (Steullet and Guerin, 1992).

Behavior. A locomotion compensator or servosphere (Kramer, 1976) was used to evaluate the behavioral responses of walking ticks to volatiles from tick material borne in an airstream (18 cm/sec, 70% relative humidity, 23–25°C) (McMahon and Guerin, 2000). Only the responses to *A. variegatum* adults were tested. Briefly, an animal is maintained at the apex of a Perspex sphere (50 cm diam.) to which the airstream is directed. Displacements of the sphere caused by the moving animal are monitored by pulse generators allowing the reconstruction of the tracks described by the arthropod (Kramer, 1976). This permits an evaluation of several parameters such as speed, angular velocity, the duration of the walk, and direction. The latter parameters can be used to calculate upwind (attractive) responses to volatiles. Two estimates of the upwind responses elicited by a treatment in the test period (1 min) compared to a control period of equal duration were employed in this study: (1) the percentage time spent walking in a cone 60° either side of due upwind, and (2) the change in "target vector" (Jones, 1977). The target vector provides an estimate of the efficiency with which a par-

ticular direction is followed. It is independent of the arbitrarily chosen upwind cone and is calculated by multiplying the cosine of the mean direction (∅) by the path straightness (circular statistics after Batschelet, 1981). Values for target vector range from −1 (downwind direction) to +1 (upwind direction).

Walks of the ticks also were monitored for a further minute (end-control period) following the withdrawal of test vapors to determine if they executed any off-responses. Such off-responses consist of the tick describing small circles, abruptly turning downwind, or both, within 10 sec of the loss of chemical. These behaviors never occur during control runs (McMahon and Guerin, 2000). Intertreatment comparisons of the proportion of ticks displaying such off-responses were carried out by using the Fischer exact test.

Tick Odors Tested on the Servosphere. Vapors from the following biological substrates were presented to walking *A. variegatum* adults on the servosphere from 500-ml gas-wash bottles (after McMahon and Guerin, 2000): (1) air at 150 ml/min swept over 200 dead *A. variegatum* adults, (2) air at 10 ml/min passed over 0.6 g of exuviae plus feces and of newly molted (<2 weeks) *A. variegatum* adults, (3) air at 75 ml/min over 20 unmolted *A. variegatum* adults, (4) air at 75 ml/min over 10 freshly molted *A. variegatum* adults (<48 hr after emergence), (5) air at 75 ml/min over five engorged *A. hebraeum* females, and (6) air at 75 ml/min over five engorged *A. variegatum* females. During experiments 5 and 6, the bottle containing engorged females was shaken gently after every two tests to provoke the release of more droplets from the dermal glands. The blank controls for the above experiments consisted of passing air through empty gas-wash bottles at the same flow rate as used in the tests.

Synthetic Volatiles Tested on the Servosphere. Vapors of the following compounds were delivered separately to *A. variegatum* adults on the servosphere from 500-ml gas-wash bottles at 150 ml/min (after McMahon and Guerin, 2000): 2,5-dimethyl pyrazine, 2,6-dichloroanisol (Aldrich; source doses 10 ng and 1 μg), 2,6-dichlorophenol (2,6-DCP, Supelco; source doses 100 fg to 10 ng in log steps), (*R*)-(−)-1-octen-3-ol (Robertet; source dose 10 ng); racemate 1-octen-3-ol (Merck; source dose 10 ng). All compounds were >97% pure as indicated by GC and were prepared in dichloromethane (Merck, analytical grade). The racemate was a 50 : 50 mixture of (*R*)-(−)-1-octen-3-ol and *S*)-(+)-1-octen-3-ol (separated on a 0.25-μm film of the chiral phase 6-TBDMS-2,3-diacetyl-β-cyclodextrin 100% in OV-1701 coated on a 30-m × 0.32-mm-ID capillary column with He as carrier gas).

RESULTS

Volatiles identified from A. hebraeum *and* A. variegatum. An octenol isomer matching the mass spectrum and retention time of racemate 1-octen-3-ol

was identified by GC-MSD over engorged *A. variegatum* (6 ng) and *A. hebraeum* females (0.2 ng) collected onto charcoal (Figure 1a, Table 1). This product also was identified in all the headspace samples of either species sampled with the Carboxen/PMDS fiber (Table 1) at levels between 0.2 and 2 ng. Furthermore, GC-MSD analysis of the volatiles over five unfed, undisturbed, and disturbed *A. variegatum* adults with the Carbowax/DVB fiber demonstrated that release of octenol (0.6 ng) was associated with squeezing *A. variegatum* (Figure 1b, Table 1). No octenol was detected after sampling the headspace for a further 13 hr, or in the headspace of the undisturbed control ticks with this SPME fiber.

The octenol isomer was identified as 1-octen-3-ol since it elicited the same response as the natural product from the antenna of *G. brevipalpis* in GC-EAD analysis of the vapors over disturbed unfed *A. variegatum* collected on charcoal (Figure 2). In the other GC-EAD analyses that used *G. brevipalpis* antennae, 1-octen-3-ol was the predominant chemical detected over freshly molted ticks at levels of 1 ng/tick. However, 1-octen-3-ol was not found over unmolted ticks or exuviae, the only tick headspace samples in which this compound was not detected. Direct stimulation of the *G. brevipalpis* antennae with volatiles from undisturbed and disturbed tisks held in syringes corroborated the GC-MSD and GC-EAD finding, i.e., the release of 1-octen-3-ol by ticks is enhanced by physical manipulation. Air passing over undisturbed ticks to the antenna failed to induce an EAG response, whereas the air over disturbed ticks caused a strong depolarization of the antennal receptors.

Other compounds, including short-chain aliphatic aldehydes and alcohols were recovered from both the charcoal trap extract and the SPME fibers in the vapors over engorged *A. variegatum* and *A. hebraeum* females. However, few of these volatiles were recovered in sufficient quantities to permit identification (the MSD has a detection limit for a full mass spectrum at ca. 0.1 ng). Apart from 1-octen-3-ol, only three compounds above the MSD threshold were identified over ticks (Table 1). 2,6-Dichlorophenol was detected only in the headspace of *A. variegatum* females cut into pieces (ca. 1 ng), and 2,6-dichloroanisol and 2,5-dimethyl pyrazine were identified only over 9-month-old or dead *A. variegatum* and *A. hebraeum* adults and, as such, may be degradation products. These three tick products had matching mass spectra and retention times with synthetic equivalents. Retrospective analysis for the presence of the major ion of each of these three compounds in the other tick headspace samples analyzed by GC-MSD failed to indicate the presence of any of these products at their respective retention times.

Behavior. Odors from tick material elicited behavioral responses in *A. variegatum* adults walking on the servosphere. Exuviae plus feces from freshly molted *A. variegatum* adults induced a significant increase in the time spent walking in the upwind cone ($P < 0.05$; Table 2). Volatiles of dead conspecifics attracted *A. variegatum* adults ($P < 0.01$; Table 2) and also induced a significant

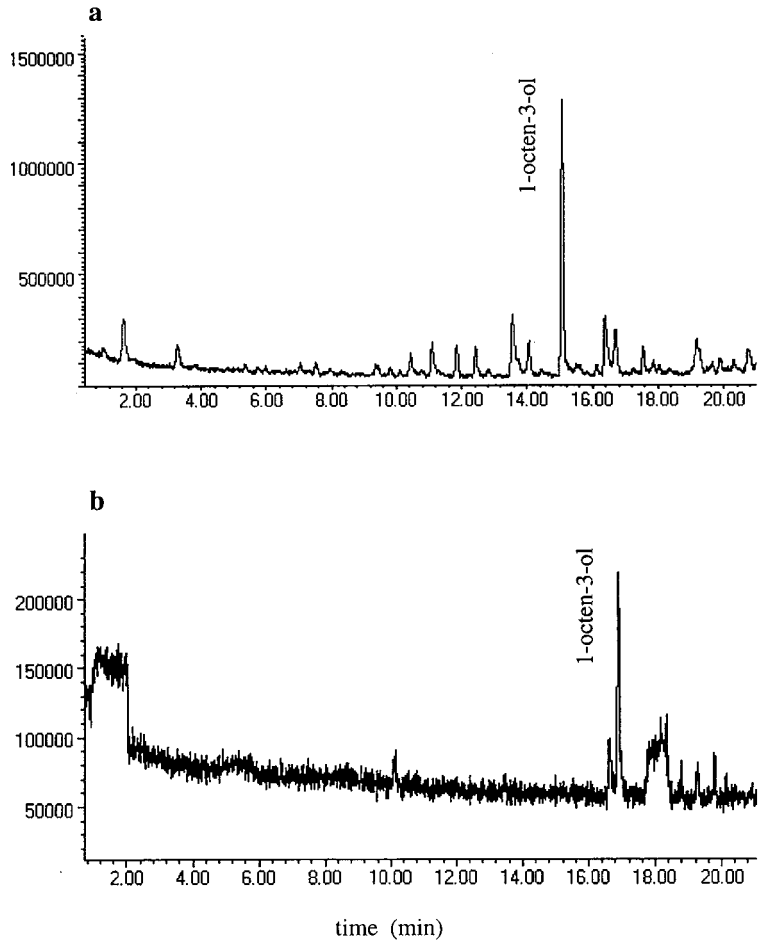

FIG. 1. Total ion chromatograms of volatiles collected over (a) disturbed engorged *Amblyomma variegatum* females by using a charcoal trap and (b) over unfed disturbed *A. variegatum* adults sampled by solid-phase microextraction with a Carbowax/divinylbenzene coated fiber (see text). Each 2-min interval (abscissa on the chromatogram) is equivalent to a 10°C rise in the oven temperature, starting at 40°C after 5 min. 1-Octen-3-ol predominates in both analyses occurring at a level of ca. 6 ng in a and ca. 0.6 ng in b in the 5–135°C elution temperature range presented. It was identified by matching the retention time and mass spectrum with a synthetic standard. The shift in the retention time of 1-octen-3-ol between the two chromatograms is due to a difference in column head pressure employed for the two analyses (on-column for the charcoal trap extract, splitless desorption for SPME fiber).

TABLE 1. COMPOUNDS IDENTIFIED IN HEADSPACE OVER *A. variegatum*

Compound	Identification by GC-MS			Identification by GC-EAD with *Glossina* antenna as detector	
	SPME		Charcoal entrainment	Direct headspace sampling	Charcoal entrainment
	Carboxen/PDMS	Carbowax/DVB			
1-Octen-3-ol	Disturbed adults Engorged females[a] Nymphs Dissected females Dead ticks Exuviae plus feces Undisturbed adults (1 month old)[a] Undisturbed adults (9 months old)[a]	Disturbed adults	Disturbed adults Engorged females[a]	Newly moulted adults	Disturbed adults
2,6-Dichlorophenol	Dissected females				
2,6-Dichloroanisol	Dead ticks Undisturbed adults (9 months old)[a]				
2,5-Dimethyl pyrazine	Dead ticks Undisturbed adults (9 months old)[a]				

[a]Compounds were also detected in the headspace of the same life stage of *A. hebraeum*.

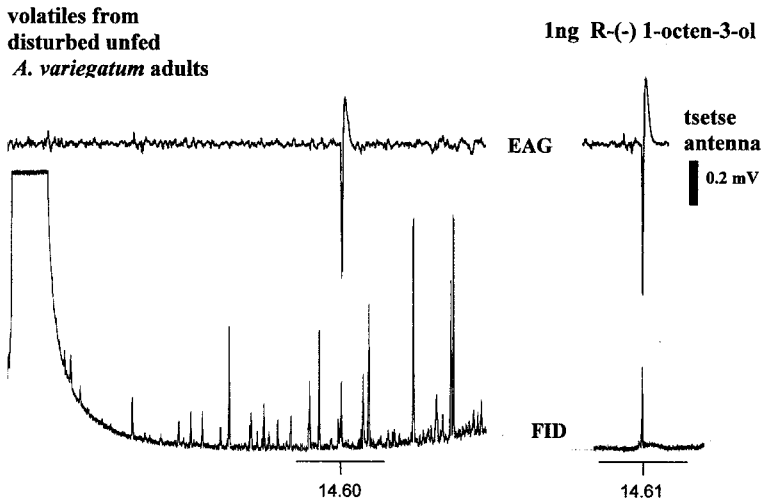

FIG. 2. Analysis of volatiles collected on a charcoal trap from disturbed unfed *Amblyomma variegatum* adults with the antenna of the tsetse fly, *Glossina brevipalpis*, as a biological detector in gas chromatography coupled electroantennogram detection (EAD). 1-Octen-3-ol eluted at 14.60 min. The amplitude of the EAG response (right) to 1 ng of (*R*)-(−)-1-octen-3-ol matched the response of a similar amount of the biologically active product in the extract. Several of the FID peaks are laboratory pollutants present in controls.

decrease in speed ($P < 0.01$). Odors from freshly cut females and unmolted and freshly molted *A. variegatum* adults did not attract conspecifics or influence their walking behavior. Odors from disturbed engorged *A. hebraeum* or *A. variegatum* adult females were unattractive, but *A. variegatum* responded to the odor of disturbed engorged *A. hebraeum* with a significant decrease in speed ($N = 14$; $P < 0.05$) and to disturbed engorged conspecifics with a decrease in angular velocity ($N = 24$; $P < 0.01$). No off-response occurred upon the withdrawal of tick odor.

The response to 1-octen-3-ol on the sphere was typified by an increase upwind walk (Figures 3 and 4) at a reduced speed and increased angular velocity. Both racemate 1-octen-3-ol and (*R*)-(−)-1-octen-3-ol attracted male and female *A. variegatum*. Nonetheless, (*R*)-(−)-1-octen-3-ol was a weaker attractant than any other treatment (Table 2), eliciting an increase in the walk in the upwind cone of just 8% and a moderate but insignificant increase in target vector. Although racemate 1-octen-3-ol was a strong attractant, evoking an increase in the walk in the upwind cone of 47%, no other differences in the behavior of the ticks were detected to these treatments. Furthermore, both 1-octen-3-ol

TABLE 2. UPWIND AND OFF-RESPONSES OF *A. variegatum* ADULTS ELICITED BY TICK ATTRACTANTS ON SERVOSPHERE[a]

Treatment (source dose)	*N*	% Change in time spent walking in upwind cone			Change in target vector			Off-responses	
		Median upwind response (interquartile range[b])	Wilcoxon signed rank test for a treatment (two-tailed *P* values)	Significance of change in duration of walk in upwind cone between treatments $P < 0.05$)	Median upwind response (interquartile range[b])	Wilcoxon signed rank test for a treatment (two-tailed *P* values)	Significance of change in target vector between treatments ($P < 0.05$)	Proportion of ticks showing an off-response	Significance of proportion of ticks showing off responses between treatments (Fisher exact test, two-tailed, $P < 0.05$)
Exuviae plus faeces (0.6 g)	18	11 (−1 to 31)	0.05	a	0.26 (−0.00 to 0.62)	0.01	a	1/18	b
Dead ticks (200)	13	21 (2–41)	0.01	a	0.23 (−0.05 to 0.64)	0.05	a	0/13	b
(*R*)-(−)-1-octen-3-ol (10 ng)	20	8 (−6 to 54)	0.05	ab	0.04 (−0.23 to 0.87)	0.23 (NS)	a	8/20	a
Racemate 1-octen-3-ol (10 ng)	21	47 (22–62)	0.001	b	0.71 (0.42 to 1.06)	0.001	b	13/20	a

[a] The index of the upwind response presented is the percentage difference in time spent walking in an upwind cone 60° either side of the air stream in the test period compared to the preceding control period. Intertreatment comparisons of the upwind responses were carried out by applying the Wilcoxon-Mann-Whitney test (two-tailed) to both the percentage change in the time spent walking in the upwind cone and to the change in target vector (values not shown) elicited by the treatments. Intertreatment comparisons of the proportion of off-responses induced by loss of stimulus were made with the Fisher Exact test (two-tailed). NS: Vapors of (*R*)-(−)-1-octen-3-ol did not elicit a significant change in target vector. Within a behavioral category, responses followed by the same letter are not significantly different.

[b] The interquartile range represents the 25 and 75 percentiles of the upwind response.

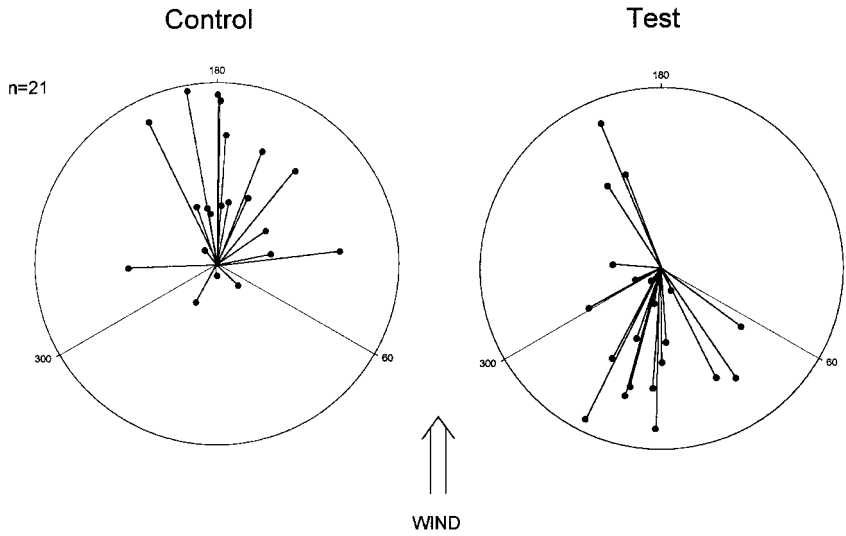

FIG. 3. Polar plot of the distribution of the mean direction (ϕ) of walks of *A. variegatum* adults ($N = 21$) on the servosphere during a 1-min control period followed by a 1-min test period where the same ticks were presented with vapors of a racemic mixture of 1-octen-3-ol (source dose 10 ng). The nearer the vector weighting (r) to the perimeter, the straighter the walk in that direction [circular statistics, after Batschelet (1981)]. Note the shift in mean walking directions in the presence of racemic 1-octen-3-ol.

samples elicited off responses (Table 2 and Figure 4) in 21 of a total of 41 *A. variegatum* adults tested, where the ticks reacted to the loss of the attractant either by describing small circles, abruptly turning downwind, or both in the 10 sec after loss of stimulus. This off-response was unique to 1-octen-3-ol. No such responses were observed for any other chemicals or tick volatiles presented to *A. variegatum* adults (Table 2).

The synthetic equivalents of the other products identified from ticks, i.e., vapors of 2,6-chloroanisol and 2,5-dimethyl pyrazine (source doses of 10 ng and 1 μg) presented separately to *A. variegatum* adults ($N = 15$, $N = 20$, respectively) failed to elicit any behavioral responses from *A. variegatum* on the servosphere, nor did 2,6-DCP have any effect on *A. variegatum* behavior on the servosphere in several tests spanning a source dose range with 10-fold increases from 100 fg to 10 ng ($N > 10$ for each dose).

DISCUSSION

1-Octen-3-ol is present in volatiles over various life-stages of both *A. variegatum* and *A. hebraeum*. Moreover, this compound attracts unfed *A. variegatum*

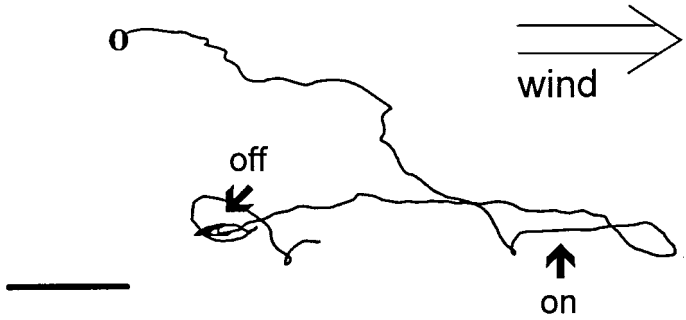

FIG. 4. Track described by an *Amblyomma variegatum* adult on the servosphere in response to vapors from racemate 1-octen-3-ol (source dose 10 ng). The track started (o) with the tick walking downwind (open arrow) in the control period. Note the off-response on loss of the attractant at odor off. The arrows on the track indicate odor on and odor off, and the bar beneath the track represents a displacement of 20 cm. Control, test, and end control periods of 1 min each.

adults on the servosphere. Whereas 1-octen-3-ol is a known semiochemical for hematophagous insects such as tsetse flies (Hall et al., 1984) and mosquitoes (Braverman et al., 1991), to our knowledge, this is the first report of 1-octen-3-ol being attractive to ticks. Although Norval et al. (1987) recorded activation of *A. hebraeum* in the field by odors of cattle and sheep, these authors recorded no such response to an open vial containing neat 1-octen-3-ol in the same study. Osterkamp et al. (1999) demonstrated that this compound enhanced the questing behavior of *Boophilus microplus*, albeit at the source dose of 3 μg compared to the 10-ng source dose used here. The level tested in this study is equivalent to about one twentieth that in bovid breath (Vale and Hall, 1985), and within the range of concentrations found attractive in wind-tunnel tests to the tsetse fly *Glossina morsitans morsitans* (Paynter and Brady, 1993) and the stable fly *Stomoxyes calcitrans* (Schofield and Brady, 1997).

The identity of the 1-octen-3-ol isomer released by the two *Amblyomma* tick species in our study is unknown. (*R*)-(−)-1-octen-3-ol predominates in bovid breath (Hall et al., 1984), probably arising from the enzymatic oxidation of linoleic acid (Tressl et al., 1982), but the racemate can arise from the nonenzymatic degration of this polyunsaturated fatty acid (Porter et al., 1980). In behavior, both 1-octen-3-ol samples tested elicited a similar proportion of off-responses upon withdrawal of the stimulus for *A. variegatum*, responses that were all but absent from the other treatments. Nonetheless, we found racemate 1-octen-3-ol to be a superior attractant to (*R*)-(−)-1-octen-3-ol, suggesting that the (*S*)-(+) isomer in the racemate might exert an independent effect. However, it is probably in the context of other as yet unidentified volatiles from ticks that

1-octen-3-ol exerts its effect. A difference in the efficacy of single compounds as attractants compared to the mixtures in which they are released has already been reported for this tick species (McMahon and Guerin, 2000).

The exact biological role of 1-octen-3-ol in the biology of *A. variegatum* and *A. hebraeum* remains to be determined. The greater amounts of 1-octen-3-ol recovered over disturbed ticks is consistent with reports such as that of Yoder et al. (1993b), wherein even bright light was sufficient to provoke the secretion of droplets by engorged *D. variabilis* females. Nonetheless, odors from tick material releasing relatively high amounts of 1-octen-3-ol in this study (newly molted ticks and engorged female *A. hebraeum* and *A. variegatum*) did not induce either attraction or repellency in *A. variegatum* adults on the servosphere. This suggests that ticks are either insensitive to the strong odor released or that some essential components of the odor did not reach the ticks on the servosphere. In contrast, attraction was recorded to samples emitting lower levels of volatiles, such as from dead ticks and exuviae plus feces. In the latter treatment, fecal volatiles are suggested as the potential source of the attractants, as 1-octen-3-ol was not detected over *A. variegatum* exuviae by using the sensitive electroantennogram detection method. The contribution of fecal attractants to "self-odor" in arthropods has long been recognized, particularly in aggregation. Ammonia has been implicated in the aggregation responses of arthropods, such as kissing bugs (Taneja and Guerin, 1997) and flour mites (Levinson et al., 1991) to their own feces, but fecal volatiles and odors released from the arthropods themselves may interact. Torto et al. (1996) demonstrated that phenols released from nymphal feces of the desert locust *Schistocerca gregaria* combined with several fatty acids and aldehydes released from nymphs themselves synergized the aggregation response. A similar role may exist for the several unidentified aldehydes present over engorged females (a particularly rich source of volatiles) in this study. Moreover, 1-octen-3-ol and several short chain aldehydes also are emitted by the host (Hall et al., 1984; Steullet and Guerin, 1994), and host volatiles attract *A. variegatum* (McMahon, 1999). It appears that ticks may be making parsimonious use of 1-octen-3-ol as a cue for aggregation with conspecifics and for host finding when in search of a blood meal.

Acknowledgments—This research was supported by the Swiss National Science Foundation (grants 31-37420.93 and 31-50658.97 entitled "Studies on the Chemical Ecology, Sensory Physiology and Behavior of Ticks"). We are indebted to the Hasselblad, Roche, and Sandoz Foundations, the Ciba-Geigy-Jubilaeums-Stiftung, and the Swiss Office for Education and Science for funding studies on tick sensory physiology and behavior at Neuchâtel. We thank Messrs P. Bula and J. Jonczy of Novartis Centre de Recherche Santé Animale S.A., Fribourg, Switzerland, for supplying us with ticks, and the International Atomic Energy Agency, Siebersdorf Laboratories, Austria, for supplying us with tsetse flies. We also thank Dr. D. Joulain, Robertet S. A., Grasse, France for the gift of (*R*)-(1)-1-octen-3-ol. The authors are grateful to Mainak Das for help with the behavioral tests. This paper is part of the PhD thesis submitted by C. McMahon at the University of Neuchâtel.

(Received January 18, 2000; accepted November 12, 2000)

Abstract—Cellulose triacetate was investigated as a chiral stationary phase for preparatively separating the enantiomers of lineatin, frontalin, *exo*-brevicomin, *endo*-brevicomin, verbenone, (*E*)-conophthorin, and grandisol. Tens of milligrams of both enantiomers were efficiently prepared in high percentage enantiomeric excess from one injection of each compound except grandisol. We prepared grandisyl acetate, benzoate, and 4-bromobenzoate to determine if derivatization of the free alcohol might improve separation. Of these, grandisyl 4-bromobenzoate provided the best separation but was still not very well resolved. Preparative separation of enantiomers on cellulose triacetate is a viable alternative to stereoselective synthesis when semiochemicals of very high enantiomeric purity are required for biological testing.

Key Words—Cellulose triacetate, preparative chiral liquid chromatography, lineatin, frontalin, *exo*-brevicomin, *endo*-brevicomin, verbenone, (*E*)-conophthorin, grandisol.

INTRODUCTION

When a pheromone component is chiral, the emitting organism often produces only one enantiomer or a specific blend of enantiomers and the receiving organism responds differently to each enantiomer. There are 10 categories for classifying the stereochemistry–bioactivity relationship, all with examples in nature (Mori, 1998). For instance, examples are known where either only one enantiomer is biologically active (Hoover et al., 2000), a specific blend of enantiomers is most active (Miller et al., 1996), or one enantiomer inhibits the other

* To whom correspondence should be addressed.

0098-0331/00/0300-0487$19.50/0

(Camacho et al., 1994). In some instances, closely related or sympatric species use the same pheromone components but vary the enantiomeric composition to distinguish each other (Leal, 1996). To fully understand these interactions, chemical ecologists need to investigate which enantiomer(s) the organism is producing and what behaviors the two enantiomers elicit in the receiving organism.

When chiral pheromones are first identified, the racemic form is usually synthesized (or purchased) to compare physical, chemical, and behavioral properties with the isolated pheromone. The next step is to investigate the stereochemistry of the pheromone component in the extract. Chirality can be assessed using chromatography on chiral stationary phases (Beesley and Scott, 1998) and other means, but to establish the absolute configuration, stereoselective synthesis is often necessary. To test the biological activity of each enantiomer, however, they both must be available in high enantiomeric purity in quantities suitable for bioassay or field testing that might involve two, often lengthy and difficult, chiral syntheses. Since the racemic form has already been made, and synthesis of the racemic form is usually much easier, the preparative separation of the enantiomers from the racemate can be a time- and labor-saving option.

We report here our investigations on the preparative chiral resolution of enantiomers of several pheromones that are difficult to obtain enantiomerically pure. We were initially only interested in separating the enantiomers of lineatin for field-testing, but this separation was so successful (Hoover et al., 2000; Lindgren et al., 2000) that we investigated other pheromones as well. We selected cellulose triacetate (CTA I) as the chiral stationary phase (CSP) for liquid chromatography for the following reasons: (1) it is available inexpensively in bulk; (2) it has high loading capacities because it is a pure chiral polymer, unlike most CSPs, which have a chiral compound bound to silica gel; (3) it has high chiral recognition; and (4) it is the most often used CSP for preparative separations, including a γ-lactone pheromone (Francotte and Lohmann, 1987) and a spiroacetal pheromone component with similarities to (*E*)-conophthorin (Isaksson et al., 1984). It is clearly the first CSP to try when attempting a preparative separation of enantiomers. The main drawback of this CSP is the slow kinetics of the adsorption–desorption process, which can broaden peaks and require very slow flow rates. A useful review is available of the various CSPs for preparative separation of enantiomers (Francotte and Junker-Buchheit, 1992). Free alcohols are often poorly resolved on CTA I, but esterification can improve resolution, depending on the acyl group (Francotte and Wolf, 1990). We prepared and tested grandisyl acetate, benzoate, and 4-bromobenzoate to possibly improve resolution.

METHODS AND MATERIALS

Racemic frontalin (1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane), verbenone (4,6,6-trimethylbicyclo[3.1.1]hept-3-en-2-one), the brevicomins (*exo*- and *endo*-

7-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1]octane), and lineatin (3,3,7-trimethyl-2,9-dioxatricyclo[3.3.1.$0^{4,7}$]nonane) were obtained from PheroTech Inc. (Delta, British Columbia, Canada). We obtained (±)-grandisol [*cis*-2-(1-methylethenyl)-1-methylcyclobutaneethanol] from Bedoukian Research Inc. (Danbury, Connecticut), and (±)-(*E*)-conophthorin [(*E*)-7-methyl-1,6-dioxaspiro[4.5]decane] was kindly provided by H. D. Pierce, Jr. (Simon Fraser University). Grandisyl acetate, benzoate, and 4-bromobenzoate were prepared by conventional esterification conditions with acetic anhydride or the corresponding acyl chloride in pyridine. The spectroscopic data for these esters were consistent with their expected structure.

A 2.5- × 100-cm water-jacketed glass column (Altex Scientific Inc., Berkeley, California) was slurry packed with approx. 200 g (dry wt) of cellulose triacetate (25–40 μm, EM Science, Gibbstown, New Jersey) previously swollen for 30 min in refluxing 10% water in ethanol. Both ends of the column had fixed bed supports each containing a porous Teflon filter (30–60 μm) backed by a woven Teflon defusing mesh. The column was connected to a Varian (Palo Alto, California) model 5000 liquid chromatograph with a 500-μl sample loop, and a Waters (Milford, Massachusetts) fraction collector. Injections of 50 mg of each analyte were made in ethanol unless stated otherwise. Freshly distilled anhydrous ethanol and purified water [Millipore (Bedford, Massachusetts) Alpha-Q Reagent Grade Water System] were used for the mobile phase, 10% water in ethanol unless stated otherwise. Shrinkage or swelling of the packed bed occurred when changing to different solvent systems that required the stationary phase to be added or removed as necessary. Previous work (Rimböck et al., 1985; Rizzi, 1989c; Isaksson et al., 1990; Bevan and Mutton, 1992) has shown that resolution improves dramatically at very low flow rates and that higher temperatures can increase column efficiency but often at the expense of resolution as retention and separation decrease. Therefore, we set the flow rate to 0.2 ml/min and ran separations at various column temperatures. Initial separations of lineatin at higher flow rates gave very broad peaks. Column back-pressure at 0.2 ml/min was less than 100 kPa.

Lacking a refractive index detector, an in-line polarimeter, or good chromophores for UV detection in most of the compounds, we followed each separation by gas chromatography. Fractions were collected every 30 min or 1 hr and analyzed to follow the elution of each enantiomer as shown in Figure 1. The critical fractions were usually located quickly by scent. Fractions and extracted peaks were analyzed by gas chromatography (Varian 3400 GC with Varian 8100 Autosampler, split, FID) with a J&W Scientific (Folsom, California) chiral capillary column (Cyclodex-B, 30 m × 0.25 mm ID × 0.25 μm, He carrier gas, injector and detector at 220°C, optimized pressures and column temperatures as noted in Table 1). Fractions were extracted with hexane before gas chromatography if the mobile phase contained more than 10% water. Otherwise, 1-μl samples of

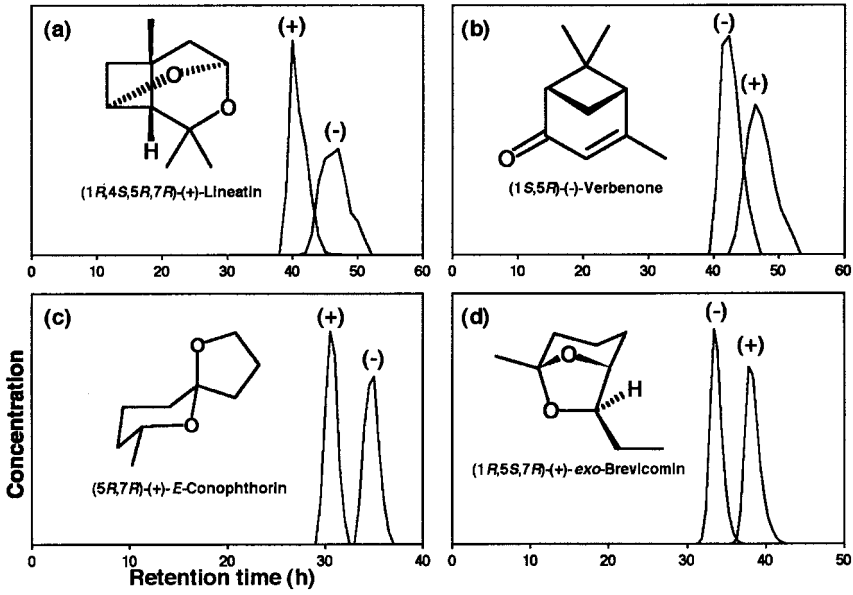

FIG. 1. Preparative resolutions of racemic pheromones on CTA I at specified temperatures. Mobile phase 10% water in ethanol and 50 mg of racemate injected unless otherwise specified: (a) 117 mg of (±)-lineatin, 50°C, absolute configuration from Kandil and Slessor (1985); (b) (±)-verbenone, 15°C, absolute configuration from Mori (1989); (c) (±)-(*E*)-conophthorin, 30°C, absolute configuration from Pierce et al. (1995); (d) (±)-*exo*-brevicomin, 15°C, absolute configuration from Mori (1989); (e) (±)-*endo*-brevicomin, 15°C, absolute configuration from Mori and Seu (1985); (f) (±)-frontalin, 30°C, absolute configuration from Mori (1975); (g) 100 mg of (±)-grandisol, mobile phase 40% water in ethanol, 30°C, absolute configuration from Mori (1989); (h) (±)-grandisyl 4-bromobenzoate, 10°C, sign of optical rotation refers to grandisol from the hydrolyzed ester.

each critical fraction were directly injected onto the chiral GC column. The enantiomers of grandisyl 4-bromobenzoate could not be resolved on the Cyclodex-B GC column, so fractions containing grandisyl 4-bromobenzoate were hydrolyzed for 1 hr at room temperature in 1 M ethanolic KOH, extracted into hexane, and then dried over anhydrous Na_2SO_4 before chiral-GC analysis of grandisol was completed.

To recover the enantiomerically enriched products, we combined fractions with similar enantiomeric purity and then diluted them with 3% aqueous $NaHCO_3$ so that two layers would form when extracted with 4 × 100 ml pentane (glass distilled). The combined pentane extract was dried over anhydrous Na_2SO_4, filtered, and rotary-evaporated. A Perkin Elmer (Wellesley, Massachusetts) Polarimeter 341 was used to determine the sign of optical rota-

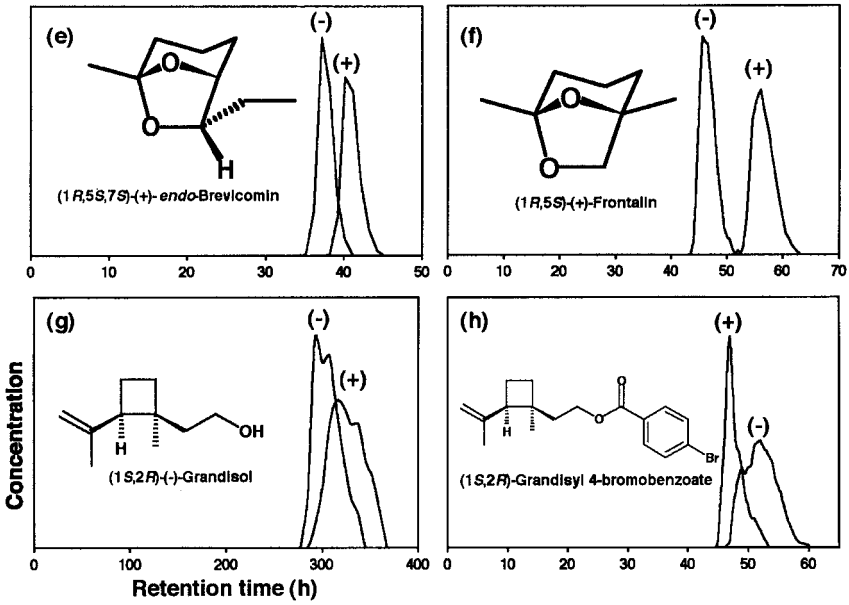

FIG. 1. Continued.

tion of the extracted peaks in pentane at 20°C and 589 nm (sodium D line). We checked the enantiomeric purity of the recovered enantiomers by chiral GC. The chemical purities of the extracted peaks were determined on a Hewlett-Packard

[b] Chiral GC column was temperature programmed as follows: 130°C for 1 min, then 0.5°C/min to 180°C. These peaks were broad and unresolved.

(Palo Alto, California) 5890 GC with a J&W DB-1 column (30 m × 0.25 mm ID × 0.25 μm, split, FID, head pressure 135 kPa He, injector and detector at 260°C, and column programmed 60°C for 1 min then 10°C/min to 260°C).

RESULTS

Most compounds were sufficiently resolved by preparative chiral liquid chromatography on CTA I to allow efficient preparation of both enantiomers in very high enantiomeric purity (Table 2 and Figure 1). Resolution approaching baseline separation was achieved for (*E*)-conophthorin, *exo*-brevicomin, and frontalin (Figures 1c, d, and f). The enantiomeric purity of both extracted peaks for these compounds exceeded 99.7% e.e. without discarding many overlapping, intermediate fractions. Each enantiomer was recovered in 50–80% yield, with the lowest yields for the enantiomers of (*E*)-conophthorin, which were easily lost during rotary evaporation. The enantiomers of lineatin, verbenone, and *endo*-brevicomin were not as well resolved (Figures 1a, b, and e) but recovery of enantiomers with high enantiomeric purity was still possible. As reported previously by Hoover et al. (2000), lineatin peaks were divided to yield two extracts of different % e.e. for each enantiomer. (+)-Lineatin was recovered with >99.98% e.e. in 34% yield and with 97.6% e.e. in 38% yield. (−)-Lineatin was recovered with 99.7% e.e. in 17% yield and 97.4% e.e. in 47% yield. For verbenone, we split the fractions where % e.e. = 0 and recovered the two peaks in 86 and 70% yield, both with 76% e.e. With some peak shaving, both peaks of *endo*-brevicomin were recovered in 60% yield, with >99.9 and 93% e.e. for the first and second peaks, respectively. However, with more severe peak shaving, higher enantiomeric purity is possible in reasonable yields.

The separation of grandisol was particularly difficult. The free alcohol could not be separated in 10% water in ethanol. Increasing the proportion of water in the mobile phase improved separation somewhat but dramatically increased retention (Figure 1g). By splitting the peaks where % e.e. = 0, these enantiomers were recovered with 43 and 42% e.e. in 81 and 89% yield for the first and second eluting peaks, respectively. Grandisyl acetate and grandisyl benzoate showed no signs of separating (Table 2). However, grandisyl 4-bromobenzoate run at 50°C and 10% water in ethanol showed a slight separation that improved when the column temperature was lowered to 10°C (Figure 1h). By splitting the peaks where % e.e. = 0, these enantiomers were recovered (after hydrolysis) with 54 and 61% e.e. for the first and second eluting peaks of grandisyl 4-bromobenzoate, respectively. Higher enantiomeric purity is possible by peak shaving, but this would decrease the yield. Enantiomeric purity can also be improved by rechromatographing an extracted peak with high, but not sufficient, enantiomeric purity. Unfortunately, less than 50% of the injected mass of this ester is grandisol,

[a] (+) and (−) refer to the sign of optical rotation of peak extracted from liquid chromatography.
[b] Resolution (R) = separation between peaks/(1.7 × average peak width at half height).
[c] Separation factor (α) = retention time_2/retention time_1.
[d] Sign of optical rotation refers to grandisol from the hydrolyzed ester.

and this method requires hydrolysis to recover the free grandisol. A more efficient separation is necessary to provide reasonable quantities of grandisol with higher enantiomeric purity. Grandisal, the corresponding aldehyde of grandisol, might resolve better on CTA I but is probably too unstable for such treatment (Webster et al., 1987).

The separation and extraction process did not introduce additional impurities, so the chemical purity of the extracted peaks was similar to the starting materials. Both commercial *exo*- and *endo*-brevicomin contained 5–10% of the other as an impurity. These compounds were partially resolved on CTA I (see Figures 1d and e), which resulted in some of the enantiomers becoming free from these impurities and thus chemical purity actually improved during enantiomeric separation.

We saw no change in the order of elution of enantiomers when changing

temperature and, for grandisol and its derivatives, mobile phase composition. The order of elution of enantiomers during chiral liquid chromatography did not correlate with elution during chiral gas chromatography, suggesting that the chiral selectivities of CTA I and Cyclodex-B were different.

Separation, retention, and peak widths increased with decreasing column temperature. However, the increase in separation compensated for increased peak widths as resolution also improved at lower column temperatures for all compounds tested. We preparatively separated lineatin at 50°C at the expense of some loss in resolution because retention times were faster and the second enantiomer tailed less than at lower temperatures, allowing faster throughput and resulting in smaller volumes to extract.

DISCUSSION

CTA I exhibits unique chromatographic properties. Separations are strongly temperature and flow-rate dependent, suggesting slow mass transfer. Many studies have shown that very slow flow rates provide the best resolution (Rimböck et al., 1985; Isaksson et al., 1990; Bevan and Mutton, 1992; Jacobson et al., 1993). Although 5–10% water in ethanol is the most common mobile phase, a range of mobile phases from water to cyclohexane has been used with CTA I. This CSP can be operated in either normal or reverse phase to allow separation of both polar and nonpolar racemates (Rizzi, 1989b,c; Francotte and Junker-Buchheit, 1992). The unusual and not completely understood separation mechanisms of CTA I makes prediction of success for particular racemates difficult (Rizzi, 1989a; Francotte and Wolf, 1990; Isaksson et al., 1990; Francotte and Junker-Buchheit, 1992). Most successful separations are with compounds that contain a ring close to the chiral center. Free alcohols often do not separate well on CTA I. However, simple esterification can improve the separation dramatically. Benzoates are particularly useful, with substitution in the *para* position having a strong influence on both retention and separation (Francotte and Wolf, 1990). With the large number of preparative separations already reported, CTA I appears to have broad applicability.

Although we did not investigate the loss of resolution at sample loads higher than the lineatin injection of 117 mg (Figure 1a), examples of much greater sample loads do appear in the literature (Francotte and Junker-Buchheit, 1992). For example, 2.47 g of (±)-γ-ethyl-γ-butyrolactone, the sex attractant pheromone of *Trogoderma* species, was separated on a 5- × 100-cm column (Francotte and Lohmann, 1987). Higher throughput can also be realized by injecting again before the previous injection has eluted. When resolution is not complete, yield versus the enantiomeric purity desired requires optimizing. By peak shaving, both enantiomers of all compounds tested here could be obtained in essentially

100% e.e., although yields for some compounds would be low. However, the intermediate fractions can be extracted and reinjected if the starting racemate is valuable.

The excellent separation achieved with spiroacetals, reported both here and by Isaksson et al. (1984), suggests that other spiroacetals of biological interest (Perron and Albizati, 1989; Moore et al., 1994; Weston et al., 1997) might be similarly resolved.

As was shown by Francotte and Wolf (1990), this method also can yield chiral building blocks or precursors to aid chiral synthesis if the final product is not resolvable. For example, derivatized chiral epoxy alcohols, which can be used to synthesize long chain epoxide-containing pheromones, are well separated on CTA I (E. Plettner, personal communication). However, milligram quantities of several epoxydiene pheromone components have also been separated directly on other CSPs (Qin et al., 1997). The separation of verbenone completed here also could provide, via reduction of the ketone, both enantiomers of the pheromones *cis*- and *trans*-verbenol in high enantiomeric purity. An acyclic pheromone, if it does not separate directly, could be prepared via a cyclic precursor. For example, a lactone that separates well on CTA I (Francotte and Lohmann, 1987) can be hydrolyzed to provide both enantiomers of an acyclic acid for further synthesis.

CONCLUSIONS

Using a readily achieved separation, we prepared excellent yields of both enantiomers of several pheromones in very high enantiomeric purity from the racemates significantly faster and less expensively than could be prepared by stereoselective synthesis. Under good conditions, hundreds of milligrams of racemic material can be completely separated into its enantiomers. Preparative chiral liquid chromatography with cellulose triacetate is a powerful alternative to stereoselective synthesis and should be considered when biological testing requires both enantiomers in very high enantiomeric purity.

(Received July 26, 2000; accepted November 8, 2000)

Abstract—Egg deposition of the elm leaf beetle *Xanthogaleruca luteola* causes the emission of volatiles from its food plant, *Ulmus minor*. These volatiles are exploited by the egg parasitoid, *Oomyzus gallerucae*, to locate its host. In contrast to other tritrophic systems, the release of volatiles is not induced by feeding but by egg deposition. Previous investigations showed that the release is systemic and can be triggered by jasmonic acid. Comparison of headspace analysis revealed similarities in the blend of volatiles emitted following egg deposition and feeding. The mixture consists of more than 40 compounds; most of the substances are terpenoids. Leaves next to those carrying eggs emit fewer compounds. When treated with jasmonic acid, leaves emit a blend that consists almost exclusively of terpenoids. Dichloromethane extracts of leaves treated with jasmonic acid were also investigated. After separation of extracts of jasmonate induced elm leaves on silica, we obtained a fraction of terpenoid hydrocarbons that was attractive to the parasitoids. This indicates that jasmonic acid stimulates the production of terpenoid hydrocarbons that convey information of egg deposition to the parasitoid.

Key Words—Egg parasitoid, synomones, plant defense, systemic induction, jasmonic acid, *Ulmus minor*, elm leaf beetle, *Oomyzus gallerucae*, sesquiterpenes.

INTRODUCTION

Plants respond to herbivory with the emission of volatiles that facilitate the ability of natural enemies of the herbivores to distinguish between infested and noninfested host plants (Dicke, 1994). Predators and parasitoids exploit compounds of different origin to locate their prey or their host (Dicke et al., 1990; Paré and Tumlinson, 1999; Mattiacci et al., 1995; Turlings et al., 1990). While some parasitoids are guided by green leaf volatiles (Du et al., 1998), others respond mainly to terpenoids (Turlings et al., 1993). They also have to cope with variations in the synomone blends. The total amount and composition of herbivore induced volatile emission depends on abiotic factors, such as light and water stress, and biotic factors, such as herbivore species and age, the plant species, the cultivar, and the age of leaves that have been fed on (Takabayashi et al., 1994). Nevertheless, parasitoids are able to distinguish between herbivory damage caused by a suitable host and nonhost insects. Generalists learn differences in odor composition and associate volatiles detected on the plant with host kairomones and visual cues (Vinson, 1985). The dependence of specialist parasitoids on specific herbivore-induced volatiles is more rigid. Foraging specialist parasitoids must express the highest degree of specificity in host recognition because a mistake in the final step of the host-location process would necessarily cause a loss of fitness. Release of herbivore-induced volatiles is also time dependent. Although some green leaf volatiles are emitted directly after feeding of herbivores, due to damage of leaf tissue, the major part of the components is synthesized de novo and emitted following a cascade of biochemical transformations (Paré and Tumlinson, 1997; Turlings et al., 1998).

Jasmonic acid is well known to act as a mediator of physiological changes in plants in response to herbivory. Exogenous addition of jasmonic acid or methyl jasmonate leads to an increase of defensive compounds (see, e.g., Baldwin et al., 1994; Baldwin and Preston, 1999; Farmer and Ryan, 1992; Miksch and Boland, 1996). Furthermore, it acts as a growth regulator and can promote senescence (Creelman and Mullet, 1997; Sembdner and Parthier, 1993). In the last decade, jasmonic acid was also shown to be involved in triggering the emission of plant volatiles in a wide variety of plants (Boland et al., 1995). Plant volatiles induced by herbivory were proved to attract predators and parasitoids of the herbivores in numerous systems (Dicke and Vet, 1999). Even though the substance pattern induced by jasmonic acid resembles the blend emitted after herbivory to a large degree in a studied case (Gols et al., 1999), predators also were shown to be able to differentiate between feeding and jasmonate-induced plants (Dicke et al., 1999). In the lima bean, the role of jasmonic acid in transforming the information of herbivory into the emission of sesquiterpene volatiles has been proved (Koch et al., 1999).

The elm leaf beetle, *Xanthogaleruca luteola* (Coleoptera, Chrysomelidae),

that feeds on the field elm (*Ulmus minor*) is attacked by the egg parasitoid *Oomyzus gallerucae* (Hymenoptera, Eulophidae). Prior to egg deposition, gravid elm leaf beetles gnaw a groove into the under-surface of a leaf. Into this groove they glue an egg mass of about 10–30 eggs by means of their oviduct secretion. After an induction period, the leaf emits volatiles that attract *Oomyzus gallerucae*. In contrast to the tritrophic systems mentioned above, emission of attractive volatiles from the elm is not caused by feeding but by egg deposition of the host (Meiners and Hilker, 1997). Previous investigations showed that the emission of volatiles is systemic (Meiners and Hilker, 1997, 2000). Plant parts located near leaves carrying eggs emit volatiles that attract parasitoids. It was further demonstrated that jasmonic acid renders elm leaves attractive to wasps (Meiners and Hilker, 2000).

In this work, we investigated the chemical composition of the odor emitted by differently treated elm leaves by using headspace techniques. Odor production induced by egg deposition, by jasmonic acid treatment, and by feeding damage was compared. We also analyzed the emission of volatiles of intact leaves next to leaves damaged by feeding or adjacent to leaves carrying eggs. In addition, extracts of jasmonic acid-treated leaves were fractionated in an effort to identify compounds responsible for parasitoid attraction.

METHODS AND MATERIALS

Plants and Insects. Elm twigs (*Ulmus minor*) from the lower part of a tree were cut from June to September in the botanic garden of the Freie Universität Berlin for headspace analysis or at Lake Ölper in Braunschweig for extracts. Twigs of the latter tree were also subject to headspace analysis after treatment with jasmonic acid. Adults and eggs of *X. luteola* were collected near Montpellier and Perpignan (southern France). All stages of *X. luteola* were kept at 20°C and 16L : 8D. Adults and larvae were fed elm leaves of *U. minor*. *O. gallerucae* emerging from elm leaf beetle eggs on *U. minor* were held at 10°C and 16L : 8D and fed diluted honey. Due to the availability of field elm leaves, only three generations of beetles and parasitoids were produced in the laboratory. Several days before testing they were transferred to 20°C conditions. Only experienced females with prior contact with host eggs were tested. These females encountered eggs two days prior to the experiment for a period of 24 hr (Meiners and Hilker, 1997).

Leaf Extracts. Freshly cut elm twigs with 10–20 leaves were placed in tap water containing 1 μmol/ml jasmonic acid and Tween 20 (Fluka, 0.05%). After 72 hr, elm leaves were ground under liquid nitrogen, and 100 ml of dichloromethane was added. The mixture was stirred overnight in a closed vial before the plant material was filtered off by using a chromatography column

filled with 10 g silica (Merck, mesh 70-230 ASTM). The filtrate was concentrated by distillation to a small volume. For control, freshly cut elm twigs with 10–20 leaves were kept in tap water and Tween 20 without jasmonic acid for 72 hr. The extraction of these so-called intact (control) leaves was conducted as described for the jasmonate-treated leaves. For fractionation, the extract was loaded onto a silica column (10.7 g, Merck, mesh 70-230 ASTM). After elution with 18 ml pentane, 9 ml of a solution containing sesquiterpenoids was obtained.

Headspace Samples. Headspace samples were taken 72 hr after starting the induction by closed-loop analysis. Samples were taken from: (1) an untreated elm twig kept in tap water for 72 hr, (2) an elm twig with 10–20 leaves without eggs that elm leaf beetles had fed on, (3) an elm twig with 10–20 leaves that carried 15–20 egg masses (i.e., about 1 egg mass per leaf), and (4) an elm twig with 10–20 leaves that was treated by jasmonic acid as described for the leaf samples.

Samples of systemically induced elm leaves were attained by placing an elm twig in a Plexiglas cylinder and dividing its lower part (15–20 leaves) from the upper part (15–20 leaves) by use of a partition plate (Meiners and Hilker, 2000). The lower part was offered to male elm leaf beetles or 15–20 egg masses were transferred onto its leaves. The twig was cut into two pieces, and the upper part was used for headspace sampling.

Sampling duration was 6 hr (Boland et al., 1984). The charcoal filters with 1 mg charcoal used were extracted with approximately 20 μl dichloromethane.

Chemicals. Jasmonic acid was synthesized by alkaline hydrolytic cleavage of methyl jasmonate (Baldwin et al., 1994). Its purity was checked by silylation with *N*-methyl-*N*-(trimethylsilyl)-trifluoroacetamide (MSTFA), followed by GC analysis. (*E*,*E*)-2,6-Dimethyl-3,5,7-octatrien-2-ol was prepared by reduction and rearrangement of ocimenone (van Dort et al., 1993). (*E*)-2,3-Epoxy-2,6-dimethyl-6,8-nonadiene was synthesized by oxidation of (*E*)-4,8-dimethyl-1,3,7-nonatriene with *m*-chlorperbenzoeic acid in dichloromethane (Kaiser, 1991).

Analysis. Samples were analyzed by GC-MS with a Hewlett Packard GC 6890 MSD 5973 with a split/splitless inlet, equipped with a 30-m HP5MS capillary column (0.25 mm ID, $d_f = 0.25$ μm). Some samples were analyzed by using a Gerstel KAS4 programmed temperature vaporization (PTV) inlet. Its heater was programmed from 50°C (0.1 min hold) to 280°C at 120°C/min. The oven temperature was programmed from 50°C (5 min hold) to 300°C at 5°C/min. Helium flow was adjusted to 1 ml/min in constant flow mode. The mass spectrometer was operated in 70 eV EI ionization mode. Compounds were identified by comparing mass spectra and retention indices with those of reference compounds or critical evaluated literature data (Joulain and König, 1998).

Bioassays. The effect of headspace samples and leaf extracts on the parasitoids was studied in a four-arm airflow olfactometer (for details see Vet et al., 1983; Meiners and Hilker, 1997, 2000). Odorless humidified air was presented

in three control fields to a female parasitoid, while the fourth field contained air that had passed the sample under investigation. The duration of stay of the parasitoids was observed over a period of 600 sec. The data were recorded with the help of the Noldus Observer program, version 3.0 (Wageningen, the Netherlands). The number of closed-loop samples tested was four each for the extracts of jasmonate treated and untreated leaves. The number of parasitoids was 20.

Statistical Analysis. Data were statistically evaluated by the Friedman test. Durations of stay in each of the four olfactometer fields were compared to each other by the Wilcox-Wilcoxon test (Bortz, 1993).

RESULTS

Analysis of Closed-Loop Extracts. Intact leaves emit only small amounts of volatiles consisting of terpenes (seven monoterpenes, a homomonoterpene, and seven sesquiterpenes). In one sample, no compound was detected at all.

Closed-loop extracts of elm leaves on which eggs were deposited and of leaves damaged by feeding contained more compounds. The emitted blends consisted mainly of terpenes, with (*E*,*E*)-α-farnesene, β-caryophyllene, and (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) as major compounds (Table 1, Figure 1). Aromatic compounds were emitted also from feeding-damaged and egg-laden leaves, but the monoterpenes identified in untreated leaves were detected only in minute amounts. Repeated samples showed a great variability in their quantitative composition. Terpenoids such as β-caryophyllene, (*E*,*E*)-α-farnesene, and (*E*)-2,3-epoxy-2,6-dimethyl-6,8-nonadiene (see Figure 2 for structures of various terpenoids identified), an oxidation product of DMNT previously only identified in the flower scent of *Selenicereus hamatus* (Kaiser, 1991), especially vary in their concentration. Considerable changes in the concentration of *cis*-jasmone and aromatic compounds such as methyl salicylate and esters of benzoic acid also were noted. No significant differences could be established between the two different treatments due to the variability of the samples.

(*Z*)-3-Hexenol and (*Z*)-3-hexenyl acetate are the main components emitted by leaves that were systemically induced by feeding on other leaves of the same twig. Leaves systemically induced by egg deposition produced terpenes with β-caryophyllene and (*E*)-4,8-dimethyl-1,3,7-nonatriene as main compounds (Figure 3). The headspace of the systemically oviposition-induced leaves contained several sesquiterpenes that were not detected in the two feeding induced samples.

The headspace of elm leaves induced by jasmonic acid consisted almost exclusively of terpenes (Figure 4). Again, the concentration of (*E*,*E*)-α-farnesene was quite variable in repeated samples. The homomonoterpenoid (*E*)-2,3-epoxy-2,6-dimethyl-6,8-nonadiene was identified in all samples examined.

[a] I, intact leaves, 3 samples; F, fed on by *X. luteola*, 7 samples; E, carrying eggs, 8 samples; SF, systemically induced by feeding, 2 samples; SE, systemically induced by egg deposition, 2 samples; J1, after treatment with jasmonic acid, 2 samples; J2, leaves from a different elm tree individual after treatment with jasmonic acid, 3 samples; M, molecular mass; b, base peak. Columns show results of single analyses. Relative proportions are indicated by numbers: 0, not detected; 1 < 0.1%; 2 < 0.2%; 3 < 0.5%; 4 < 2%; 5 < 5%; 6 > 5%.

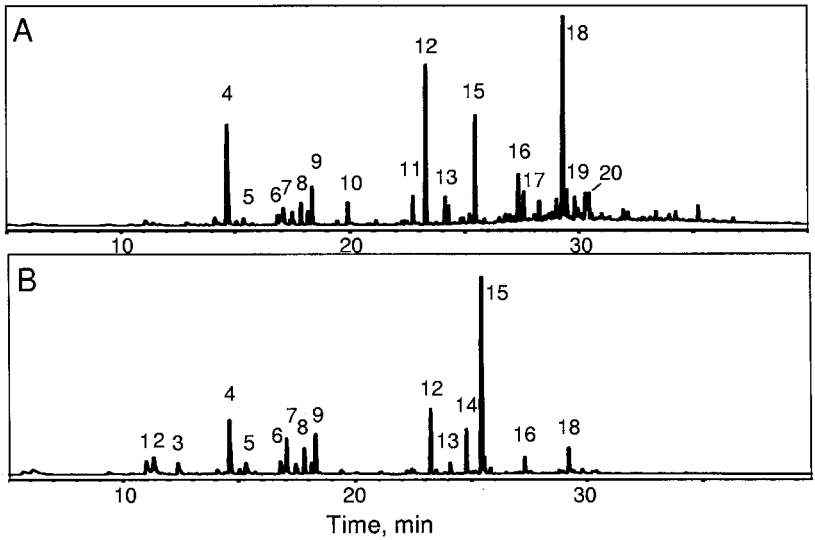

FIG. 1. Headspace analysis. Gas chromatograms of volatiles emitted from elm leaves after feeding (A) and egg deposition (B) of the elm leaf beetle. 1, (*Z*)-3-hexenyl acetate; 2, (*E*)-2-hexenyl acetate; 3, (*E*)-β-ocimene; 4, (*E*)-4,8-dimethyl-1,3,7-nonatriene; 5, phenylacetonitrile; 6, (*Z*)-3-hexenyl butanoate; 7, (*E*)-2-hexenyl butanoate; 8, (*E*)-2,3-epoxy-2,6-dimethyl-6,8-nonadiene; 9, (*E*)-2-hexenyl 2-methylbutanoate; 10, indole; 11, (*Z*)-jasmone; 12, β-caryophyllene; 13, α-humulene; 14, germacrene D; 15, (*E*,*E*)-α-farnesene; 16, oxygenated sesquiterpene, b = 159; 17, hexadecane; 18, oxygenated sesquiterpene, *M* = 220; 19, solvent impurity; 20, 2,6,10,14-tetramethylhexadecane; *b* = base peak; *M* = molecular mass.

The composition of volatiles induced with jasmonic acid also differs when comparing elm trees from different regions. The leaves of one elm tree investigated in Braunschweig produced large amounts of methyl salicylate after treatment with jasmonic acid; an elm tree in another location in Berlin lacked this ability, but emitted β-caryophyllene.

Analysis of Extracts. The composition of the extracts of jasmonate-induced and noninduced components showed some similarities. Again, the major group of compounds was terpenoids. Eight additional sesquiterpenes occurred in jasmonate-treated leaves compared to the extract of intact leaves. Chromatography on silica of the extract of jasmonate-induced leaves yielded a mixture of terpenoid hydrocarbons that was active in bioassays: (*E*,*E*)-α-farnesene, germacrene D, squalene, and other terpenoid hydrocarbons (Figure 5 and Table 2).

Attractiveness of Odor Blends from Closed-Loop Extracts. The closed-loop extracts of untreated leaves were not attractive (Friedman ANOVA $\chi^2 = 0.950$,

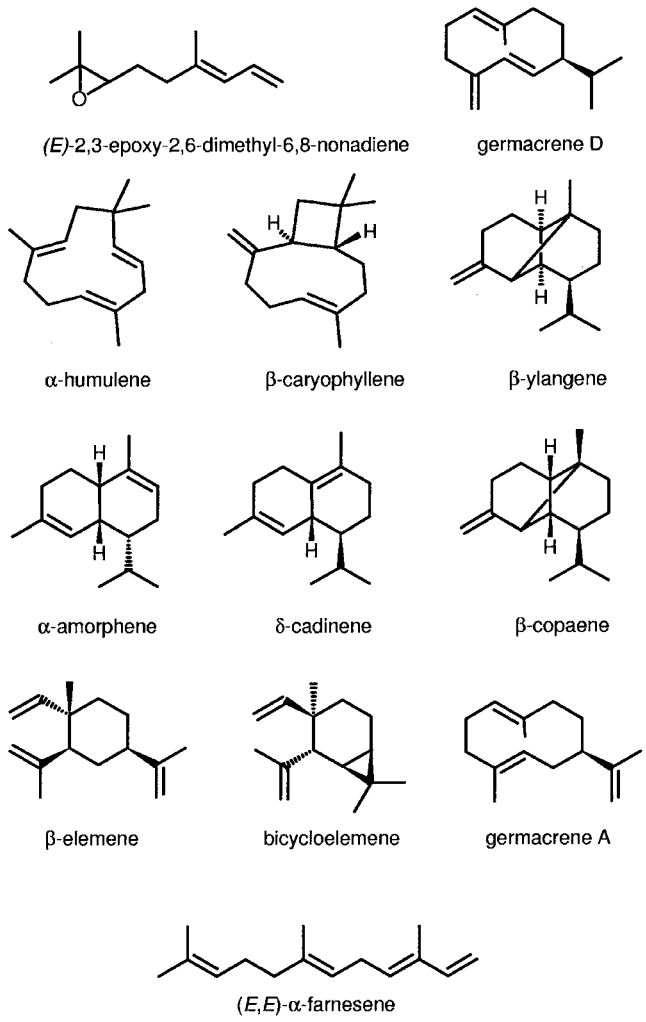

FIG. 2. Terpenoids identified or mentioned in text. Formulas show relative configurations only.

df = 3, ns; Figure 6a). The closed-loop extracts of jasmonic acid-treated leaves attracted the parasitoids in a four-arm olfactometer (Friedman ANOVA χ^2 = 18.588, *df* = 3, $P < 0.001$; Figure 6b). The odor of a fraction obtained by silica chromatography of an extract of jasmonate induced elm leaves also attracted the parasitoids (Friedman ANOVA χ^2 = 12.528, *df* = 3, $P < 0.01$. Figure 6c).

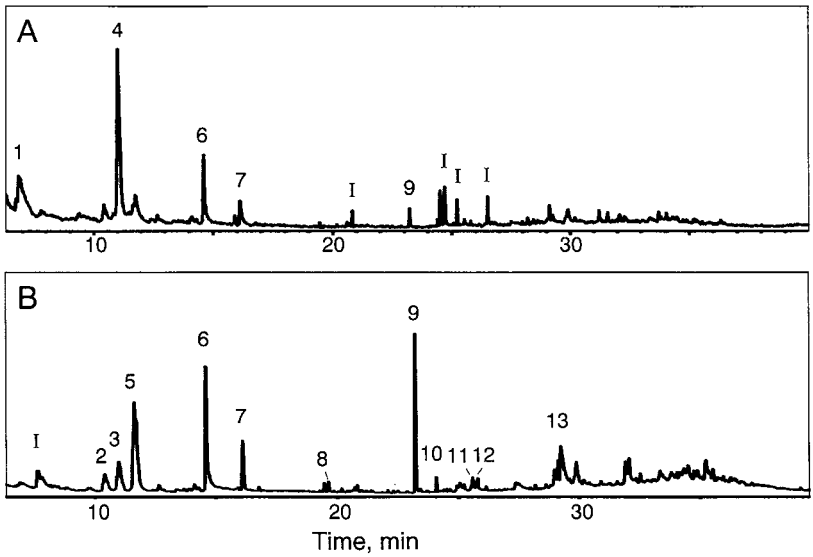

FIG. 3. Headspace analysis. Gas chromatograms of volatiles from leaves systemically induced by feeding (A) and by egg deposition (B) of the elm leaf beetle. Peaks: 1, (*Z*)-3-hexenol; 2, myrcene; 3, Δ^3-carene; 4, (*Z*)-3-hexenyl acetate; 5, limonene; 6, (*E*)-4,8-dimethyl-1,3,7-nonatriene; 7, borneol; 8, borneyl acetate; 9, β-caryophyllene; 10, α-humulene; 11, γ-cadinene; 12, δ-cadinene; 13, oxygenated sesquiterpene; M = 220; I, impurity; M = molecular mass.

DISCUSSION

Egg parasitoids can distinguish volatile profiles of elm leaves induced by egg deposition of the host from those elicited by feeding of the host. The way egg deposition evokes a plant response resembles processes following host feeding in other systems. The process is initiated by an elicitor and cannot be mimicked by simply wounding or feeding the leaves. The gnawing of a female elm leaf beetle prior to oviposition affects only the leaf surface and differs substantially from feeding (Meiners and Hilker, 2000). It cannot be excluded that the female also applies to the egg-associated elicitor an elicitor through the mouthparts when scratching the grooves for her eggs. The mechanical damage by this gnawing is minute, however, enabling no or only small amounts of saliva to contact the leaf. The mimicking of the gnawing by removing leaf surface tissue with a scalpel did not induce the emission of attractive volatiles (Meiners and Hilker, 2000) or of a substantial amount of green leaf volatiles (Meiners and Hilker, unpublished).

The elicitor was present in the oviduct secretion of *X. luteola*, which

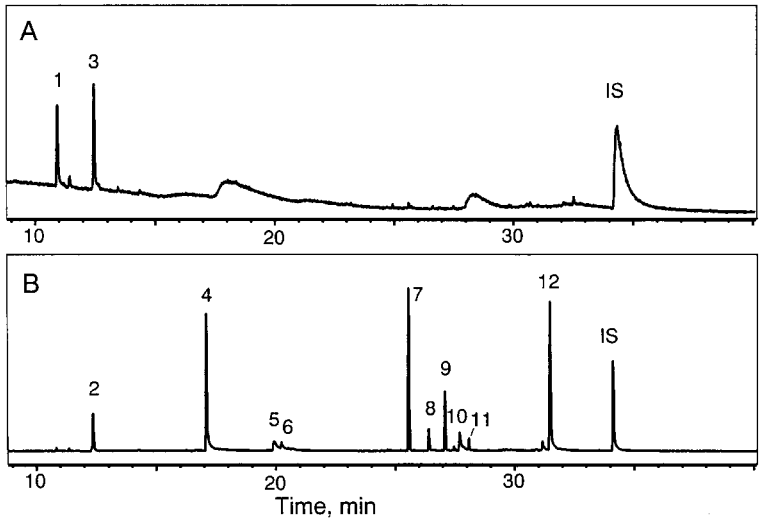

FIG. 4. Headspace analysis. Gas chromatograms of volatiles from jasmonic acid treated elm leaves (B) compared to untreated elm leaves (A). Peaks: 1, α-pinene; (2), (*E*)-β-ocimene; 3, β-pinene; 4, (*E*)-4,8-dimethyl-1,3,7-nonatriene; 5, (*E*,*E*)-2,6-dimethyl-3,5,7-octatrien-2-ol; 6, (*E*)-2,3-epoxy-2,6-dimethyl-6,8-nonadiene; 7, β-caryophyllene; 8, α-humulene; 9, germacrene D; 10, γ-cadinene; 11, δ-cadinene; 12, oxygenated sesquiterpene, M = 220; M = molecular mass; PTV inlet; oven programming was 40°C (5 min hold) to 300°C (5°C/min). Added reference compound was octadecane (10 μl/ml, IS).

attaches the eggs to the leaves (Meiners and Hilker, 2000). Elm leaves emit a complex mixture of compounds when eggs are deposited on them. Some of the components are derived from the lipoxygenase pathway (green leaf volatiles),

[a] Compounds identified in extracts from differently treated leaves extracts. I, intact leaves, 1 sample; J, leaves treated with jasmonic acid, 2 samples; A, attractive fraction containing sesquiterpenes, 1 sample; Columns show results of single analyses. Relative proportions are indicated by numbers: 0, not detected; 1 < 0.1%; 2 < 0.2%; 3 < 0.5%; 4 < 2%; 5 < 5%; 6 > 5%.

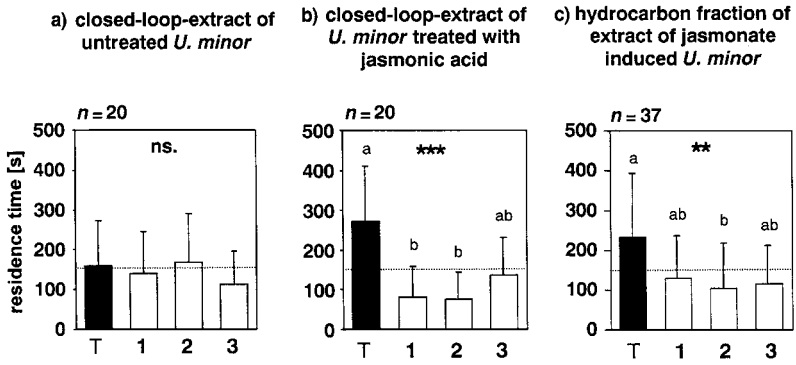

FIG. 6. Responses of females of the egg parasitoid *Oomyzus gallerucae* to volatiles from extracts of elm leaves. Mean values and standard deviations of residence times from females of *O. gallerucae* in test and control fields of a four-arm olfactometer. The observation period per female parasitoid was 600 sec, T = field with test odors; 1, 2, 3 = three field with control air. Treatments: (a) closed-loop extract of intact elm leaves; (b) closed-loop extract of intact elm leaves treated with jasmonic acid at a concentration of 1 μmol/ml; (c) hydrocarbon fraction of an extract of elm leaves treated with jasmonic acid at a concentration of 1 μmol/ml. Friedman test: $^{**}P < 0.01$. $^{***}P < 0.001$. Wilcox-Wilcoxon test: different letters indicate significant ($P < 0.05$) differences.

while most others are of terpenoid origin. A great number of components is found both in the volatile blend of leaves induced by egg deposition and by feeding. The main components are (*E*,*E*)-α-farnesene, β-caryophyllene, and germacrene D. The concentration of certain terpenoids, e.g., (*E*,*E*)-α-farnesene varies in leaves induced by egg deposition and by feeding. Additionally, there is variation in the concentration of these compounds in repeated experiments. Acetates, butyrates, and 2-methylbutyrates of the green leaf alcohols (*Z*)-3-hexenol and (*E*)-2-hexenol also contribute to the elm leaf odor. The overlap of compounds in the blend following egg deposition and herbivory can be attributed to the lack of necessity of plants that are under attack by a variety of herbivores to release highly specific synomones. As long as specialized parasitoids are among the species attracted, it is not necessarily beneficial for the plant to maximize the emission of volatiles in response to a certain herbivore (Turlings et al., 1995). Due to the variation in the composition of the emitted blends, we were not able to detect significant differences between bouquets induced by feeding or by egg deposition. Nevertheless, the herbivore might select only a few significant components of the whole mixture, or other compounds that eluded our analytical methods.

The induction of volatiles by egg deposition in the elm leaf is systemic, as described for herbivory (Meiners and Hilker, 2000; Dicke et al., 1992). Compar-

ing the volatiles emitted by leaves carrying eggs and adjacent egg-free leaves, the number of compounds emitted by the latter is lower. Green leaf esters and aromatic compounds are not emitted. This could be due to a dilution effect, because the signal that mediates egg deposition may be spread throughout the plant. Mechanical damage facilitates the liberation of compounds from the leaf tissue of plants (Paré and Tumlinson, 1998). With the exception of (*Z*)-3-hexenyl acetate, esters of green leaf alcohols are found only in small quantities in the blend of elm leaves systemically induced by feeding, but they are major components in the blend of damaged leaves.

Jasmonic acid renders intact elm leaves attractive to parasitoids (Meiners and Hilker, 2000). The odor composition caused by jasmonic acid treatment differs from the blend emitted from elm leaves with deposited eggs in regard to the absence of esters. It seems that compounds such as the green leaf volatiles and compounds derived from the shikimic acid pathway are not vital for parasitoids to detect the host plant.

The finding that induction with jasmonic acid leads to the formation of attractants for predators or parasitoids agrees with other studies (Gols et al., 1999). The effect of jasmonic acid on the production of terpenoids also could be demonstrated by comparing the dichloromethane extracts of noninduced and induced leaves, in which the number of sesquiterpenes is higher.

By separating apolar terpenoid hydrocarbons from more polar compounds with column chromatography on silica, we demonstrated that induction with jasmonic acid leads to the production of terpenoid hydrocarbons attracting the specialist parasitoid *Oomyzus gallerucae*. Removal of polar compounds, however, does not render the leaf extract unattractive. Both closed-loop extracts and the sesquiterpene fraction of the extract of jasmonic acid treated leaves attract parasitic wasps, although the concentration of the main components is different.

The importance of different terpenoids for parasitoid host location can be estimated by comparison of their occurrence in closed-loop extracts of leaves carrying eggs (Table 1, column E), jasmonate-induced leaves (Table 1, column J1), and the active fraction of jasmonate induced leaves (Table 2, column A). The least complex blend is found in the active fraction A, containing 12 compounds. The two sesquiterpenes, β-ylangene and bicycloelemene, were not detected in the eight analyses of the oviposition-induced leaves (Table 1, column E), while (*E*)-β-ocimene, β-elemene, and (*Z*,*E*)-α-farnesene were detected only once or twice. Thus, they might be less important for host location. The other volatile terpenoids, (*E*)-4,8-dimethyl-1,3,7-nonatriene, α-humulene, germacrene D, (*E*,*E*)-α-farnesene, and δ-cadinene might be involved, while β-copaene shows no clear trend. Some terpenoids, such as limonene, β-caryophyllene or α-amorphene are absent in the attractive fraction (Table 2, column A) and, therefore, seem to be inactive. In addition, the known instability of some sesquiterpenes, especially germacrenes, complicates the situation. Germacrene A, not detected

in any extract, is an unstable compound known to undergo Cope rearrangement to β-elemene at temperatures over 165°C, as normally encountered in the injection port of a GC (Teisseire, 1994). The same is true for bicycloelemene (rearrangement from bicyclogermacrene) (Garnero and Tabacchi, 1987). Germacrene D can rearrange to various compounds, preferably to δ-cadinene under treatment with silica, which was employed as medium in the fractionation of the leaf extract. Light can induce rearrangement to β-copaene, while heat above 190°C leads to its diastereomer β-ylangene as well as bicycloelemene (Garnero and Tabacchi, 1987; Bülow and König, 2000). In contrast, major rearrangement products such as the bourbonenes were not present. By use of a PTV injector, rearrangement processes are reduced (Garnero and Tabacchi, 1987). Comparison analyses performed with a PTV injector did not show significant differences compared to splitless injection. The rearrangements also can take place during biosynthesis of the sesquiterpenes, thus making it difficult to decide whether some of them are true naturally occurring components or artifacts. Many of the identified sesquiterpenes are biosynthetically related, for example, β-caryophyllene and α-humulene share the same precursor cation (Teisseire, 1994). In addition, germacrene A, or other sesquiterpenes even more susceptible to heat may be involved in the attraction. Furthermore, the specialist herbivore may be able to cope with changes in volatile composition.

Despite the similarity of the terpenoid blend elicited by jasmonate treatment and by egg deposition, it remains unclear whether the signal pathway proceeds via jasmonic acid. On the other hand, the absence of a variety of compounds may indicate that other mediators are involved. In the future, blocking experiments could confirm the role of jasmonic acid in the process of signal transaction.

Further insight into which terpenes are used by the parasitoid for host location will be obtained from electrophysiological studies. The activity of extracts obtained from jasmonic acid-induced leaves will provide access to larger amounts of volatiles relative to those from headspace techniques. Preparative chromatography will be performed to elucidate the function of single components in the behavior of *Oomyzus gallerucae*.

(Received March 1, 2000; accepted November 6, 2000)

Abstract—The novel naturally occurring 2-octanoylcyclohexane-1,3-dione **1** was isolated in its enol form from *P. guttiferum* (Araceae). Its chemical ecological relevance is discussed. There was mass spectral evidence for the presence of small amounts of the homologous 2-decanoyl and 2-dodecanoyl derivatives.

Key Words—Philodendron guttiferum, Araceae, 2-acylcyclohexane-1,3-diones, kairomone, ecological relevance.

INTRODUCTION

There are approximately 300 species of the genus *Philodendron* that are native to the tropical Americas and the West Indies. Several of these have been used in folk medicine for treatment of various ailments such as skin infections, boils, stomach disorders, and snake bites (Schultes and Raffauf, 1990). They have also been used as a contraceptive and a fish poison (Schultes and Raffauf, 1990). In particu-

lar, *Philodendron guttiferum* Kunth, (Araceae) is a "tree-loving" epiphytic species, common in the primary forest, that exudes a latex. It has been used in Ecuadorian traditional medicine as an antimicrobial agent. Our preliminary pharmacological tests of the crude extracts indicated moderate antiinflammatory, antiviral, and toxic properties. This, coupled with our observations of some interesting features in the ^{1}H NMR spectrum, prompted further investigation. The aim of our study was to isolate and characterize the biologically active compounds.

METHODS AND MATERIAL

Plant Material. P. guttiferum was collected in 1990 in the Provincia del Napo, Ecuador. A voucher specimen, F. G. 390, is kept in the Herbario Economico, Escuela Politecnica National, Quito.

General Procedures. The NMR spectra were recorded with a 270-MHz Jeol JNM EX-270/4000 instrument. Heteronuclear multiple quantum coherence (HMQC) and heteronuclear multiple bond correlation (HMBC) experiments were performed using a Varian VXR-400 NMR instrument. EI-MS and positive-ion FAB-MS (with glycerol as matrix) spectra were recorded with a Jeol JMS SX/SX102A instrument. Analytical TLC was performed with silica gel 60 F_{254} on precoated aluminum sheets. Preparative TLC was carried out on silica gel 60 $PF_{254+360}$-coated glass plates (20 × 20 × 0.25 and 0.50 mm; Merck, Darmstadt, Germany). UV light at 245 and 366 nm, and iodine chamber or spraying with vanillin–sulfuric acid were used to visualize compounds. MPLC was performed using Separo AB, MPLC equipment (Baeckström Separo AB, Lidingö, Sweden).

Extraction. The whole plant was dried at 40°C in the dark, in a ventilated hood, and ground. The material, 0.54 kg, was extracted at room temperature three times with light petroleum (40–60°C) with occasional stirring and filtered, followed by three extractions with methanol for seven days each time. The extracts were evaporated in vacuo to give 7.7 and 42.5 g of a gelatinous and oily material, respectively. The methanol extract was partitioned between ethyl acetate and water to give 13 g of an ethyl acetate soluble fraction. An insoluble residue of 1.5 g was discarded. The water phase was freeze-dried to give 27.4 g of a crude material, which mainly consisted of carbohydrates. It was not further investigated.

Isolation and Purification. The ethyl acetate fraction, 12.5 g, was subjected to Separo column chromatography on silica gel 60 (30 g) with gradient elution using hexane–CH_2Cl_2 and EtOAc–MeOH. From the nonpolar fractions, straight-chain hydrocarbons, fatty acids, and fatty acid methyl esters were isolated. At low solvent polarity 5 mg stigmasterol and 4 mg β-sitosterol were eluted and purified by preparative TLC using CH_2Cl_2 and $CHCl_3$–MeOH as eluents, respectively. They were identified by their ^{1}H NMR spectra and by comparison with authentic specimens.

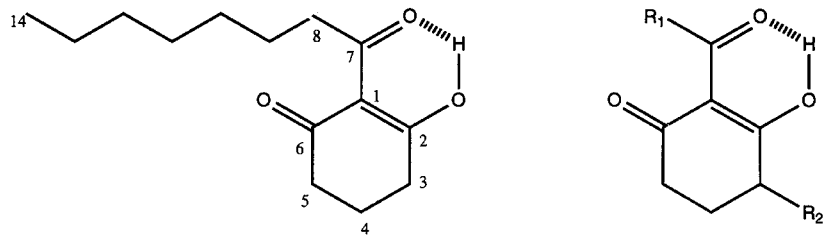
The novel naturally occurring compound **1** was eluted as an oil at a slightly higher eluent polarity and was purified by repeated MPLC and preparative TLC by using CH_2Cl_2 as eluent, 39 mg. ^{1}H NMR ($CDCl_3$), δ ppm: 0.89 (3H-14, t), 1.29 (8H-10-13, m), 1.59 (2H-9, quint), 1.98 (2H-4, quint), 2.47 (2H-3, t), 2.64 (2H-5, t), 2.97 (2H-8, t). ^{13}C NMR ($CDCl_3$), δ ppm: 14.09 (C-14), 19.07 (C-4), 22.60 (C-13), 24.60 (C-9), 29.09 (C-10), 29.34 (C-11), 31.72 (C-12), 33.21 (C-5), 38.69 (C-3), 40.50 (C-8), 112.85 (C-1), 194.68 (C-2), 198.36 (C-6), 206.09 (C-7). FAB-MS (positive mode) m/z (rel. int.): 239, $(M+1)^+$ ion, (98), 139 (18), 125 (13), 80 (28), 67 (35), 41 (55), corresponding to a molecular composition of $C_{14}H_{22}O_3$.

The mass spectra of the main chromatographic fractions containing **1** showed also small peaks at m/z 267 and m/z 295, $(M+1)^+$ ions and fragmentation peaks indicating the presence of the homologous compounds $C_{16}H_{26}O_3$ and $C_{18}H_{30}O_3$, **2**, $R_1 = (CH_2)_8CH_3$, $R_2 = H$ and $R_1 = (CH_2)_{10}CH_3$, $R_2 = H$, respectively. Inspection of the ^{1}H NMR spectrum of the crude petroleum ether extract showed that considerable amounts of metabolites of type **1** were present.

RESULTS AND DISCUSSION

The ^{1}H NMR spectrum of **1** showed only absorptions in the saturated aliphatic region, δ 2.97–0.89. The ^{13}C NMR spectrum was revealing in that it showed three C═O groups, C-2,6,7 but only one olfenic C-1 atom at δ 112.8, indicating an enolic fragment. This information, together with further HMBC experiments, led to the simple structure **1** for the component (Figure 1). The three strongly electron withdrawing acyl groups increase the acidity of the central H-1 atom sufficiently to transform the compound into its enol form, and **1** is consequently a chelating agent. Compound **1** has not been isolated previously from natural sources.

A literature search showed, however, that **1** was previously prepared by



1 **2**

FIG. 1. 2-Octanoylcyclohexane-1,3-dione and its dodecanoyl derivative. $R_1 = (CH_2)_{10}CH3$; $R_2 = H_X$.

chemical synthesis (Mudd, 1981) for the purpose of preparing model compounds for kairomones identified in the Mediterranean flour moth *Ephestia kuehniella* Zeller (Mudd, 1978, 1981, 1983) and other pyralid species (Corbet, 1971, 1973). Our ^{13}C assignments are in agreement with the literature (Mudd, 1981). The dodecanoyl derivatives **2**, $R_1 = (CH_2)_{10}CH_3$, $R_2 = H$ (Figure 1), has also been prepared by chemical synthesis (Oliver and Lusby, 1988).

Several insects secrete 2-acylcyclohexane-1,3-diones, **2**. R_1 is usually a saturated or unsaturated long chained alkyl group and R_2 is H or OH. Metabolites of this type are biologically active as insecticides and fungicides and affect the egg laying behavior and crowding in insects, hence controlling the population density (Corbet, 1971, 1973; Mudd et al., 1984). They act both as kairomones, attracting their predators, and allomones, of advantage to the host by regulating overcrowding. It is therefore conceivable that **1** in *P. guttiferum* acts as a protecting agent associated with the regulation of the number of feeding insects. It is not known whether these cyclic triketones are synthesized by the larva or are sequestered from the food. A compound related to **2**, $R_1 = (CH_2)_{10}Ph$, $R_2 = OH$, was isolated from Brazilian *Virola* and *Horsfeldia* species (Kato et al., 1992, and references therein). The possibility that the kairomones are sequestered from the food can not be excluded. A comprehensive review of the occurrence, biological effects, biogenesis, etc., of 2-acylcycloalkane-1,3-diones has recently been published (Rubinov et al., 1995).

Compounds **1** and **2** are biosynthetically closely related to the 2-acylresorcinols, which also have been found in the larval secretions, *Stephanitis* species (Oliver et al., 1985, 1990). These derivatives are reported to strongly inhibit PGH synthetase (Jurenka et al., 1989). A slightly different (folding of the polyketide chains in the biosynthesis leads to the 5-alkyl-1,3-resorcinols by decarboxylation. 5-Heptadecatri-8(*Z*),11(*Z*)-enylresorcinol was in fact isolated from *Philodendron scandens* (Reffstrup et al., 1982). Resorcinols were not observed in our extracts.

Since the ^1H NMR spectra of **1** and **2** are not particularly different from those of many fatty acids or hydrocarbons, always present in large quantities in plant extracts, the presence of minor amounts of this type compounds may occasionally have escaped detection in plants.

Acknowledgments—We are indebted to the Swedish Institute and the Egyptian government for fellowships to H.E. This work was supported by funds from the Swedish Council for Forestry and Agricultural Science and the Danish Natural Science Research Council. We wish to thank Dr. H. Balslev, Department of Botany, University of Aarhus, for identifying our plant material.

(Received July 31, 2000; accepted November 14, 2000)

Abstract—We examined the behavior of Formosan subterranean termites toward one of the components of vetiver grass oil, the roots of which manufacture insect repellents. We found nootkatone, a sesquiterpene ketone, isolated from vetiver oil is a strong repellent and toxicant to Formosan subterranean termites. The lowest effective concentration tested was 10 μg/g substrate. This is the first report of nootkatone being a repellent to insects.

Key Words—*Vetiveria zizanioides*, vetiver oil, sesquiterpenes, ketones.

INTRODUCTION

The Formosan subterranean termite is the most destructive termite species wherever it occurs in the world. These termites search for and find cellulose largely using chemical cues from the wood itself (Amburgey and Smythe, 1977; Reinhard et al., 1997), and they exhibit similar chemoresponses to a variety of chemicals. For example, trail-following behavior has been shown to naphthalene, a well-known insect toxicant (Chen et al., 1998b,c), 2-naphthalenemethanol (Henderson et al., 1996), and 2-phenoxyethanol, a component of some ballpoint inks (Chen et al., 1998a). Formosan subterranean termites live in a miasma of chemicals present in their nests, many of which appear to be plant derived (Chen et al., 1998b; Henderson et al., 1999). Our recent investigations have focused

*To whom correspondence should be addressed.

0098-0331/00/0300-0523$19.50/0

on natural plant extracts that may disrupt this insect's ability to recruit food sources.

Vetiver grass (*Vetiveria zizanioides*, Linn Nash), a fast-growing native plant of India, is a distant relative of maize, sorghum, sugarcane and lemongrass (National Research Council, 1993). The plant has been used in India for weaving mats, baskets, fans, sachets, and ornaments that have insect repellent properties. Clothes moths, head lice, and bedbugs are thought to be repelled by vetiver grass so fashioned (National Research Council, 1993). The Formosan subterranean termite, *Coptotermes formosanus* Shiraki, readily consumes sugarcane, causing agricultural damage to the crop in some countries (Chen and Henderson, 1996; National Research Council, 1993). Therefore, it was not readily apparent that termites would be repelled by components of vetiver grass. The compounds in vetiver oil that repel cockroaches and flies are believed to include α- and β-vetivone, khusimone, khusistone, zizanal, and epizizanal (Jain et al., 1982).

Preliminary studies using dried vetiver root in a sand substrate (1 : 10 ratio) indicated that Formosan subterranean termites were effectively repelled from tunneling to a food source (Henderson et al., unpublished data). Gas chromatographic and mass spectrometric analysis of vetiver oil separated on silica columns, along with behavioral bioassays, allowed us to identify nootkatone as a repellent to Formosan subterranean termites.

METHODS AND MATERIALS

Extraction of Vetiver Oil from Roots

We examined the extracts from the roots to determine which components of the oil were repellent. The roots of fresh Louisiana-grown vetiver grass *Vetiveria zizanioides* (provided by the Donald O. Heumann Greenhouse and Laboratory, Poydras, Louisiana) were cleaned, dried at room temperature, and ground with a blender. Vetiver oil was obtained by petroleum ether extraction of the dried roots. The components of vetiver oil were isolated by silica column (2.5 × 20 cm) and eluted with hexane and increasing amounts of methylene chloride. Five fractions were obtained by eluting with hexane–CH_2Cl_2: 80 : 20 for fraction 1, 70 : 30 for fraction 2, 60 : 40 for fraction 3; 40 : 60 for fraction 4, and 20 : 80 for fraction 5. Examination of sesquiterpenic ketones were visualized for their intrinsic fluorescence under UV light (Andersen, 1970) since they are potential insect repellents. The fractions detected by UV were further isolated by preparative TLC (Analtech, Newark, Delaware) using $CHCl_3$ as a mobile phase. The bands were visualized by charring the plate at 120°C after spraying with 50% sulfuric acid.

Gas chromatography–mass spectrometry (GC-MS) was performed on a Finnigan GCQ (Trace GC 2000 coupled with Polaris MSD). A silica capillary

MS column, DB-5MS (30 m × 0.25 mm × 0.25 μm; J&W Scientific, Folsom, California), was operated at 60°C for 1 min, increased to 150°C at 2.5°C/min held for 15 min at this temperature and increased to 260°C at 5°C/min, where is was finally held for 10 min. The injector port was operated in splitless mode at 250°C, and helium was used as carrier gas at 0.8 μ/min. The mass spectral detector (MSD) was set on full-scan mode (m/z 41–400). The authentic standard of nootkatone (crystalline, 97%) was purchased from Lancaster Synthesis Inc. (Windham, New Hampshire). Both α- and β-vetivone were kindly provided by Professor Ekkhard Winterfeldt (Institut für Organische Chemie, Technische Universität, Berlin).

Termite Bioassay

Experiment 1. A three-compartment plastic container (18 × 18 × 4 cm; Pioneer Packaging Co., North Dixon, Kentucky) was used for the termite bioassays. A small hole (0.5 cm diameter) was melted at the bottom of each of two inner walls, connecting the bioassay chamber compartments. For testing, 50 mg of nootkatone was dissolved in 10 ml ethanol as a stock solution. Five concentrations of nootkatone were placed into a sand substrate in the middle compartment of the biossay chamber: 0 (control), 10, 20, 100, and 200 μg/g sand. Four replicates were conducted for each concentration. For each concentration, 500 g of blasting sand was mixed with a series of dilutions of the stock solution (except for 0 μg/g) in 25 ml of ethanol in a glass pan and dried in a hood for 2 hr. The following day, 115 g of untreated blasting sand was added to one end of each compartment (home compartment), and 115 g of treated sand at one of five concentrations was added to the middle compartment. The 0-μg concentration was treated only with 25 ml of ethanol. Filter paper (Whatman No. 1, 2.3 cm diameter) was dried at 70°C for 3 hr and cooled to room temperature for 30 min before weighing. A weighed filter paper with 200 μl distilled water added was placed in the third compartment farthest from the introduction end. Ten milliliters of distilled water was added to the treated and untreated sand in the other compartments just prior to the introduction of termites. Fifty workers and five soldiers of Formosan subterranean termites from a large colony collected in Algiers, Louisiana, on November 18, 1997, were placed in the home compartment. The containers were covered with lids and kept in a dark incubator at 29°C. On day 16, each apparatus was dismantled, living termites were counted, and filter papers were cleaned, dried at 70°C for 3 hr, cooled for 30 min, and weighed. Consumption was calculated as the difference between the weight of filter paper before and after the 16-day incubation. The tunnels termites constructed in the sand were copied using a scanner for measurement of total tunnel lengths.

Experiment 2. The materials and methods were the same as described for

experiment 1, except: (a) the concentrations of nootkatone used to treat the sand in the middle compartment were slightly different; (b) observations of tunneling were recorded several times during the experiment; and (c) 50 g sand was placed in the third compartment under the filter paper disk and was moistened every two days with 0.3 ml of distilled water. For this experiment the concentrations of nootkatone were 0 (control), 5, 10, 20, 40, and 100 μg/g sand. Four replicates were performed for each concentration. Every two days all containers were checked for tunneling activity and the evaluating criterion was: 0 = termites on the surface (no tunneling); 1 = tunneling in the first chamber; 2 = tunneling in the first and in the middle (treated) chamber; 3 = tunneling in all chambers.

Statistical Analysis

For experiment 1, the differences among treatments in filter paper consumption, tunnel length, and percentage mortality were analyzed by ANOVA. For experiment 2, we used a nonparametric analysis of variance (Kruskal-Wallis ANOVA) in order to analyze trends in tunneling differences between days of observation. At the end of the experiment, differences among treatments were analyzed as in experiment 1. For both experiments, differences between treatments were analyzed by Tukey's studentized range test (HSD). Although percentage values were transformed to arc-sin of the square root for data analysis, nontransformed means are reported.

RESULTS

Identification of Nootkatone as Active Fraction from Vetiver Oil

Three fractions (3–5) contained autofluorescing bands detected by UV. Each fraction was further separated by preparative TCL with $CHCl_3$ as a mobile phase. In fraction 4, bands 1 and 2 autofluoresced, and were examined by GC-MS. Nootkatone was a major constituent of band 2 (Figure 1A). The chromatograph of authentic nootkatone is shown in Figure 1B. The nootkatone identification was verified by comparing the mass spectrum of its GC peak (Figure 2A) with authentic nootkatone (Figure 2B).

Termite Bioactivity of Nootkatone

Experiment 1. The mean consumption of filter paper decreased significantly in the presence of nootkatone; the decrease in consumption was concentration dependent (Table 1). Even at the lowest concentration tested (10 μg/g sand), nootkatone significantly decreased feeding as compared with the control. Little consumption of filter paper was found when concentrations of nootkatone were higher than 20 μg/g. Termite mortality increased as nootkatone concentrations

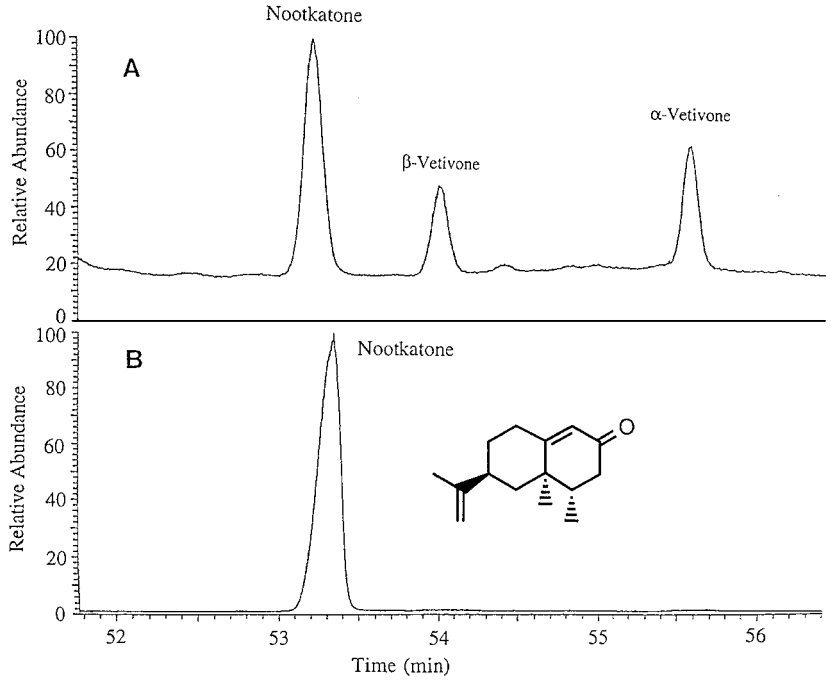

FIG. 1. Gas chromatography of band 2 (A) and the standard of nootkatone (B). The retention time of nootkatone in band 2 is 53.22 min (first peak) and in the standard is 53.35 min.

increased (Table 1). All concentrations of nootkatone had a significant impact on mortality when compared with the control. Ninety percent mortality or greater was observed in all chambers when nootkatone concentrations were ≥100 μg/g sand. The presence of nootkatone substantially decreased the tunneling activity even at the lowest concentration of 10 μg/g sand (Table 1). At higher concentrations of nootkatone (20 μg/g and higher), no tunneling was visible in the middle chamber.

Experiment 2. Units treated with different concentration of nootkatone showed significantly different levels of tunneling activity. On day two, significant differences were detected among treatments ($H = 20.47$, $df = 5$, $P = 0.001$, Kruskal-Wallis ANOVA); almost all groups treated with lowest concentrations were able to tunnel in the first and even in the middle (treated) chamber, while termites faced with the highest concentration remained on the surface. The same trend is confirmed on day 6 ($H = 17.39$, $df = 5$, $P = 0.0038$), where some termite groups (control and concentration 3) tunneled into the feeding chamber,

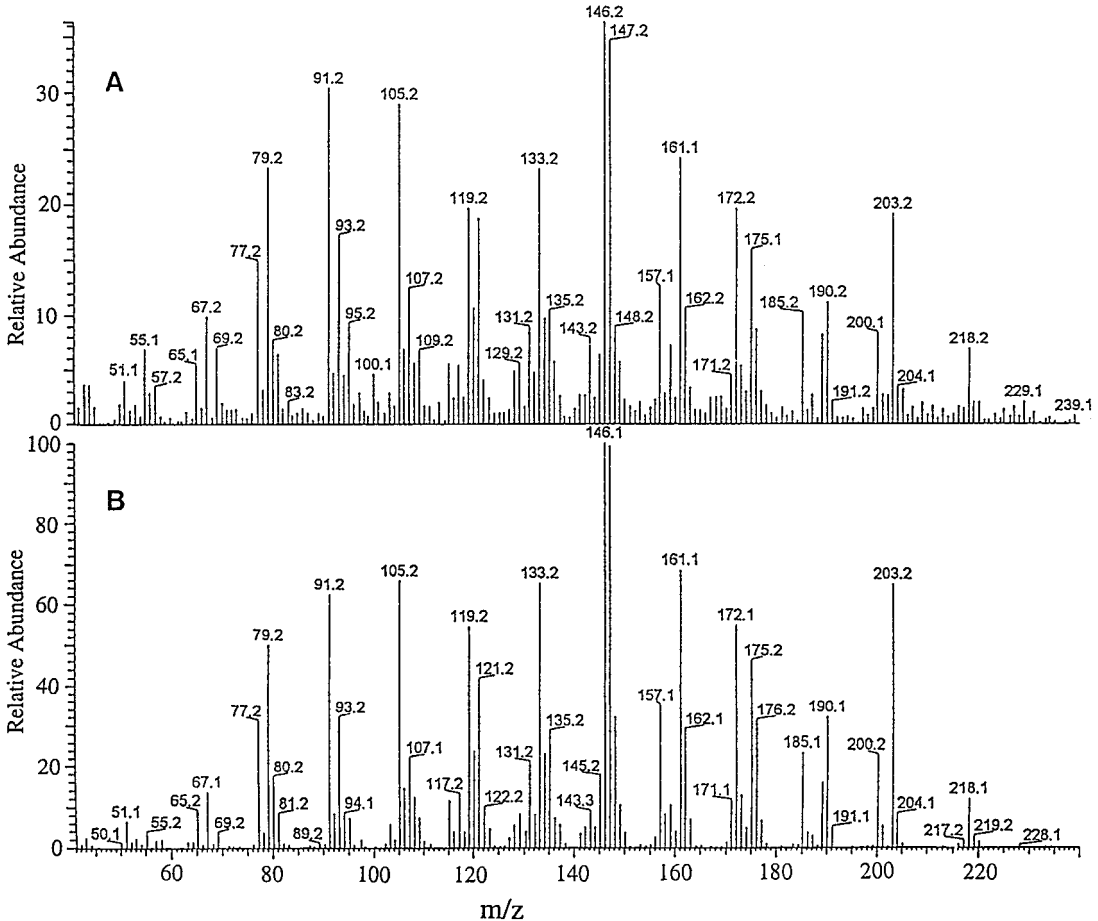

FIG. 2. Mass spectrum of the nootkatone peak in band 2 (A) and authentic nootkatone (B).

TABLE 1. MEAN (±SD) OF PAPER CONSUMPTION, PERCENT MORTALITY, AND TUNNELING LENGTH OF FORMOSAN SUBTERRANEAN TERMITE AFTER 16-DAY EXPOSURE (EXPERIMENT 1)[a]

Concentration of nootkatone (μg/g sand)	Weight loss of filter paper (mg)	Termite mortality (%)	Tunneling length (cm)
0	10.500 ± 2.867A	58.50 ± 8.72A	27.000 ± 6.072A
10	1.900 ± 0.641B	88.50 ± 10.12B	7.225 ± 2.155B
20	0.525 ± 0.709B	87.00 ± 18.22B	0.000 ± 0.000B
100	0.025 ± 0.050B	90.50 ± 11.72B	0.000 ± 0.000B
200	0.275 ± 0.050B	95.00 ± 8.718B	0.000 ± 0.000B

[a] Four replicates were included for each treatment. Means within a column followed by the same letter are not significantly different (ANOVA: $F = 9.39$, $df = 4$ and $P < 0.0005$ for paper consumption; $F = 4.22$, $df = 4$, $P < 0.0174$ for percentage mortality and $F = 43.1$, $df = 4$, $P < 0.0001$ for tunneling length.)

and on day 11 ($H = 14.52$, $df = 5$, $P = 0.0126$) (Table 2). As in experiment 1, significant differences were detected in filter paper consumption, where only the controls and groups treated with 20 and 40 μg/g sand of nootkatone could eat some filter paper. Differences were also detected in tunnel length: only the controls and units treated with the lowest concentration of nootkatone showed tunneling behavior. Due to high variability between units belonging to the same treatment group, no significant differences were detected on termite mortality.

TABLE 2. MEAN (±SD) OF PAPER CONSUMPTION, PERCENT MORTALITY, AND TUNNELING LENGTH OF FORMOSAN SUBTERRANEAN TERMITES AFTER 16-DAY EXPOSURE (EXPERIMENT 2)[a]

Concentration of nootkatone (μg/g sand)	Weight loss of filter paper (mg)	% termite mortality	Tunneling length (cm)
0	3.675 ± 3.500 A	27.727 ± 10.111 A	29.450 ± 8.065 A
5	0.150 ± 0.300 B	36.364 ± 7.120 A	24.975 ± 14.558 A
10	0.650 ± 1.300 AB	52.273 ± 45.281 A	11.000 ± 16.818 AB
20	0.300 ± 0.600 AB	48.182 ± 36.980 A	2.250 ± 2.872 B
40	0 ± 0B	39.091 ± 32.710 A	0 ± 0 B
100	0 ± 0B	58.636 ± 33.008 A	0 ± 0 B

[a] Four replicates were included for each treatment. Means within a column followed by the same letter are not significantly different (ANOVA: $F = 3.416$, $df = 5$, $P = 0.024$ for paper consumption; $F = 0.580$, $df = 5$, $P = 0.715$ for percentage mortality and $F = 7.215$, $df = 5$, $P = 0.0007$ for tunneling length.)

DISCUSSION

Vetiver oil is a complex essential oil containing several hundred individual compounds. Of them, 92 compounds have been characterized and can be divided into 33 esters, 36 sesquiterpenic hydrocarbons, 5 bi- and tricyclic sesquiterpenic alcohols, 9 ketones, 3 aldehydes, and 6 acids (Cazaussus et al., 1989). Nootkatone, 4,4a,5,6,7,8-hexahydro-6-isopropenyl-4,4a-dimethyl-2(3H)-naphthalone, is a mildly pungent sesquiterpene ketone found in the oil of Alaska yellow cedar, *Chamaecyparis nootkatensis* (Lamb) Spach (Erdtman and Hirose, 1962) and in a great number of citrus oils, especially oil from grapefruit, *Citrus pavadisi* Calli (MacLeod and Buigues, 1964). Nootkatone is widely used in the perfume and flavor industries, being essentially nontoxic to humans (National Research Council, 1993).

Our studies determined that nootkatone has potential as a termite repellent barrier. Considering tunneling behavior as a measurement of termite activity, these results confirmed that nootkatone effects termite vigor. Termites from colonies treated with lower concentrations of nootkatone were able to dig tunnels in the home and in the treated chamber, and this ability was negatively correlated with the concentration of nootkatone. Termites treated with the highest concentrations of nootkatone were not able to dig tunnels, even in the home chamber, possibly because of the nootkatone vapors acting as an inhibitor of termite mobility. We believe that a concentration of nootkatone bewteen 10 and 1000 μg/g, preferably between 10 and 200 μg/g, may be useful in repelling and killing termites. We are also evaluating nootkatone as a chemical that could be of value against termites in structural wood treatments or cellulose mulch applications (Henderson et al., unpublished data).

A barrier created by plants that manufacture a termite repellent could potentially provide long-lasting repellency. Vetiver grass is a fast growing plant with a huge spongy mass of roots. The roots grow to depths of 3 m, and with a little attention the plant could live for 50–60 years (National Research Council, 1993). Since the oil occurs primarily in the roots, a low-cost way to prevent invasion by subterranean termites and other insidious underground insects may be to plant a solid band of vetiver grass around a house. Recently, we found that some of the insect repellents found in the roots also occur in the soil surrounding the plant (Henderson et al., in preparation).

Vetiver oil is one of the most complex essential oils (Cazaussus et al., 1989). In addition to nootkatone, we also have found that vetiver oil itself and its major components α- and β-vetivone were powerful repellents and toxicants against Formosan subterranean termite (Zhu et al., in preparation). Jain et al. (1982) reported six substances in vetiver oil that have potent topical irritant activity on cockroaches and flies.

(Received April 26, 2000; accepted November 4, 2000)

Abstract—Slimy sculpins (*Cottus cognatus*) are small benthic fish that commonly co-occur with predatory fishes throughout most of their range in North America. In two laboratory experiments we examined the nature and extent of responses of slimy sculpins to chemosensory cues from predatory brook trout (*Salvelinus fontinalis*) and chemical alarm cues released by conspecific sculpins. Sculpins responded to three different classes of chemical stimuli: (1) cues of predatory brook trout, (2) damage-released alarm cues from conspecific sculpins, and (3) disturbance cues from conspecific sculpins. Sculpins did not distinguish between trout fed different diets; however, the presence of damage-released alarm cues did enhance the intensity of response to the predator chemicals. A histological analysis of the skin of sculpins revealed the presence of large sacciform cells that may act as the source of chemical alarm signals.

Key Words—Predation, chemical cues, alarm signals, disturbance cues, anti-predator behavior, sacciform cells.

INTRODUCTION

Predation is one of the most important selective forces shaping the behavior, morphology, and life-history characteristics of prey animals (Sih, 1987; Lima and Dill, 1990; Chivers and Smith, 1998). A fundamental way in which aquatic organisms assess predation risk is by using chemosensory information (Chivers and Smith, 1998; Kats and Dill, 1998). Under many circumstances chemical cues may be the best source of information available for prey to assess their risk. For example, chemical cues are probably of prime importance when high habitat complexity, low light levels, or high turbidity limit visual cues.

Prey animals assess predation risk using chemical cues from two sources. The first source, generally termed "predator chemicals" or alternatively "predator kairomones," is cues released directly from the predator (reviewed by Kats and Dill, 1998). The second source of chemicals is termed "alarm pheromones" or more generally "chemical alarm signals" (reviewed by Chivers and Smith, 1998). Alarm pheromones are chemicals released by conspecific prey animals when they detect or are captured by a predator. This class of chemicals is further categorized based on the point in the predation sequence upon which the chemical signal is released. Signals released by prey animals that are disturbed, but not injured, are referred to as disturbance signals. Those signals emitted by prey animals only following their capture by a predator are referred to as damage-released alarm signals. The classic Schreckstoff alarm system, characteristic of minnows and other ostariophysan fishes, is probably the best-known example of a damage-released alarm pheromone system. In this system, the pheromone is contained in specialized cells in the epidermis of the fishes (Smith, 1992; Chivers and Smith, 1998).

Damage-released chemical alarm systems are widespread in aquatic organisms. For example, there are estimated to be about 7000 species that possess the Schreckstoff alarm system (Smith, 1992). In addition, there are alarm systems in other groups of fishes (reviewed by Chivers and Smith, 1998), as well as in larval amphibians (Hews and Blaustein, 1985; Hews, 1988), gastropods (Appleton and Palmer, 1988), echinoderms (Lawrence, 1991), sea anemones (Howe and Sheike, 1975) insect larvae (Chivers et al., 1996; Huryn and Chivers, 1999) and crustaceans (Wudkevich et al., 1997; Hazlett, 1994).

Relatively little is known regarding the existence of disturbance signals in aquatic organisms. Disturbance signals are known in one species of crayfish (Hazlett, 1985, 1989), one species of hermit crab (Hazlett, 1990a), one species of larval frog (Kiesecker et al., 1999) and two species of fishes (Wisenden et al., 1995; Jordão and Volpato, 2000).

Antipredator responses to predator chemicals are common among a diversity of aquatic organisms, including fishes (reviewed by Kats and Dill, 1998). Several studies have documented that the presence and/or intensity of an

antipredator response of prey to predator chemicals is dependent upon the diet of the predator. In some cases, the prey animals will respond to the predator only when it is fed conspecifics of the prey (e.g., Mathis and Smith, 1993; Chivers et al., 1996). In other cases, the prey will respond to the predator regardless of the predator's diet, but the intensity of the response is stronger when the predator is fed conspecifics of the prey (Wilson and Lefcort, 1993).

We conducted a series of laboratory studies to examine chemosensory assessment of predation risk by slimy sculpins (*Cottus cognatus*). Slimy sculpins are small benthic fish that inhabit streams and lakes throughout much of northern North America. The sculpins used in our study were collected from streams in central Maine, where they co-occurred with predatory brook trout (*Salvelinus fontinalis*).

In our experiments we tested whether sculpins exhibited an antipredator response to either chemical cues from predatory brook trout, damage-released alarm cues from injured conspecifics, or cues of disturbed conspecifics. Additional experiments examined whether the diet of the brook trout influenced the intensity of the antipredator response of the sculpins and whether chemical alarm signals, presented simultaneously with cues of the predator, enhanced the intensity of the antipredator response. We also completed a histological examination of the skin of sculpins. The source of damage-released alarm pheromones of Ostariophysan fishes is large club cells in the epidermis (Smith, 1992). Similarly, the source of damage-released alarm cues of sculpins may be large sacciform cells in the epidermis (Hugie et al., 1991).

METHODS AND MATERIALS

Fish Collection and Maintenance

In the summer of 1998, we collected slimy sculpins from two adjoining streams in central Maine (Spruce Mountain Brook and White Brook, 69°12′W 45°29′N. Both streams contain brook trout. The fish were caught by backpack electrofishing and were transferred to our laboratory at the University of Maine. The fish were maintained in a 350-liter stream tank at 12–13°C on a 14L : 10D photoperiod. The stream tank was supplied with fresh well water at a rate of 1 liter/min. The fish were fed twice daily ad libitum with frozen brine shrimp (*Artemia salina*).

Brook trout were supplied by the Enfield State Fish Hatchery (Maine Department of Inland Fisheries and Wildlife). They were maintained in a 888-liter circular tank with the same temperature and photoperiod as the sculpins. As a standard diet, the trout were fed previously frozen brine shrimp and commercial trout (Corey Feed Mills). Specific experiments required us to change the diet of some trout (see experiment 2).

Skin Histology

Over the past two years we have made histological examinations of 19 sculpins. Immediately after they were killed, the tissue from the anterior dorsal region was excised and fixed in glutaraldehyde and osmium tetroxide using the microwave enhanced fixation method (Giberson and Demaree, 1995). The tissue was embedded in Epon-Aldarite and 1.5-μm-thick sections were made. We identified the sacciform cells by negative staining with periodic-Schiff's reagent and counterstaining with hemotoxylin.

Experiment 1: Responses of Sculpins to Alarm, Disturbance, and Predator Cues

Behavioural Assay. All experiments took place in a gravitational flow-through test apparatus (modified from Petranka et al., 1987). The testing apparatus consisted of two tiers of tanks. The lower test chambers were transparent plastic storage containers (35 × 50 × 17 cm), each of which had a thin layer of light-colored gravel that matched the substrate color of the stream where the fish were collected. The testing chambers each contained a centrally located shelter object consisting of one third of an overturned ceramic flower pot. Above each test tank there were two header tanks into which the stimuli were placed. The header tanks were nontransparent plastic storage containers (31 × 42 × 15 cm). Throughout the acclimation and testing periods, well water flowed from one of the stimulus tanks into the test chamber at a rate of approximately 1.5 liters/min.

Test fish were introduced to the test tank approximately 22 hr before they were tested. Each morning approximately 6 hr before the observations began, the test fish were each fed 1.5 ml of brine shrimp. The tests were conducted between 13:00 and 16:00 hr. Immediately before all trials, 20 ml of food-odor stimulus was added to the prestimulus tank. This was prepared by taking 1 ml of previously frozen brine shrimp and adding it to 75 ml of well water. After settling, the top layer was decanted and became the food-odor stimulus. Decanting ensured that no small pieces of food were present in the food-odor stimulus. We added 20 ml of food-odor stimulus because this was sufficient to encourage fish to move and explore the tank in search of food. All trials began 1 min after addition of the food-odor stimulus. For each trial we observed the behavior of sculpins for 10 min prior to the introduction of cues to the test tank. Cues were introduced by moving the inlet hose from one header tank to the other header tank that contained the appropriate stimulus. One minute after moving the inlet hose, we resumed recording the behavior of the sculpins for an additional 10-min poststimulus period. Moving the hose between the header tanks did not interrupt the water flow to the test tanks. Dye trials indicated that it took 45 sec for the stimulus water to reach the test tank after moving the inlet hose. The dye was evenly dispersed in the test tank within 1.5 min.

During the 10-min prestimulus and 10-min poststimulus periods, the following behaviors were recorded at 15-sec intervals: (1) number of short moves, (2) number of long moves and (3) shelter use. Short moves included all movements that were less than two body lengths. These are the most common types of sculpin movements. The fish made rapid "hops" along the substrate that ended in a rigid alert posture. Long moves included all movements that were greater than two body lengths. They typically occurred when the fish swam into the water column and glided back to the substrate.

Experimental Treatments and Preparation of Test Stimuli. In this experiment we exposed individual sculpin to chemical cues from: (1) predatory brook trout, (2) injured sculpins, (3) disturbed sculpins (chased with a model fish predator), with controls of (4) injured swordtails (*Xiphophorous helleri*), (5) undisturbed sculpins, and (6) a model fish predator. There were 20 replicates of each treatment. The order of treatments was randomized.

To prepare the brook trout stimulus we randomly removed a single brook trout from our holding tank of approximately 50 trout and placed it into the stimulus container 3 hr prior to the test. A sample of 14 stimulus trout had a mean (±SD) standard length of 129 ± 9 mm.

We used 1.5 cm^2 of sculpin skin to prepare the damage-released alarm cue for every two trials. This amount of skin is similar to that used in several other studies (reviewed by Chivers and Smith, 1998). A sculpin was humanely killed by pithing and decapitation. The skin was removed and separated as much as possible from the adhering muscle tissue and was homogenized in distilled water. The volume of the homogenate was brought up to 100 ml, strained through a fine mesh net, and divided into halves. This solution was added to the stimulus tank just before the beginning of the trial. This allowed the stimulus to disperse evenly in the stimulus tank before the trial.

In the disturbed sculpin treatment, five randomly selected sculpin were placed into the stimulus collecting tanks at 08:00 hr after being fed. All fish were chosen from a pool of previously tested sculpin. At the end of the prestimulus recording period, the sculpin were chased around the tank with a model fish predator. Care was taken to make sure that the sculpin were not accidentally hit during this procedure. They were chased for the entire 1-min interval between the pre- and poststimulus periods. The predatory fish model was a reinforced 6-inch soft fishing lure. We used five sender fish to produce the disturbance cue because sculpins frequently occur at high densities in the stream where they were collected.

In the undisturbed sculpin control treatment, five randomly selected sculpin were placed into the stimulus tanks at 08:00 hr after being fed. All fish were chosen from the same pool of fish used in the disturbed sculpin treatment. In this treatment, the sculpin were not chased around the tank with a model fish predator after the prestimulus period. Consequently, the only chemical cues were from undisturbed conspecifics.

To determine whether the fish model itself had any effect on sculpin behavior, we included a model-only control. Here the model was moved about the tank in the same manner as it was during the disturbed conspecific treatment. However, there were no sculpin present in the stimulus tank.

Stimuli from injured swordtails was prepared in the same manner as the stimuli from injured sculpins. We tested sculpins for a response to swordtails in order to control for a generalized response to injured fish skin. Swordtails were chosen because they are not closely related to sculpins nor do they co-occur with them. The swordtails were bought from a local commercial dealer as adults and maintained on Tetramin flake food.

Statistical Analyses. For each trial we calculated the difference in number of short moves and number of observations under the shelter between the pre- and post-stimulus periods. Long movements were rare and hence were dropped from the analysis. Positive values indicated increased movement and/or shelter use following addition of the stimulus; negative values indicate decreased activity and/or shelter use. Medians of each treatment were compared to the undisturbed sculpin control treatment using one-tailed Wilcoxon Mann-Whitney tests (Siegel and Castellan, 1988). The family-wise error rate was assessed and controlled using the modified Bonferroni test following Keppel (1982). The modified Bonferroni test specifies that corrections to the family-wise error rate be introduced only when the number of comparisons exceeds $k - 1$, where k is the number of treatments (Keppel, 1982). In this experiment, there was a total of six treatments. Since the analysis was restricted to five preplanned comparisons that were based on specific a priori predictions, the rejection probability (P) was set at 0.05 for each comparison (Keppel, 1982).

Experiment 2: Effects of Alarm Cues on Intensity of Sculpin Antipredator Responses

This experiment tested whether alarm cues in the diet of the trout had any influence on the antipredator responses of sculpin and whether chemical alarm signals presented simultaneously with cues of the predator enhanced the intensity of the anti-predator response. The sculpins used in this experiment were collected in November 1998 and were maintained as in experiment 1. The mean (±SD) standard length of sculpins used was 49.2 ± 5.1 mm. The trout used in this experiment were taken from those being held at our laboratory.

Four trout were housed in each of three 105-liter plastic aquaria, each of which had an air stone and was supplied with well water at a rate of 0.5 liters/min. Trout in the three containers were fed ad libitum every other day with brine shrimp, commercial trout pellets (a component of which is fishmeal), or pieces of freshly killed sculpin. The mean (±SD) standard length for the trout was 141 ± 7 mm, 143 ± 8 mm, and 146 ± 9 mm in the brine shrimp, trout, and

sculpin diet treatments, respectively. The fish were fed for at least seven days prior to being used as stimulus donors.

In this experiment, individual sculpins were exposed to one of the following five chemical treatments: (1) trout that had been fed sculpin, (2) trout that had been fed commercial trout pellets, (3) trout that had been fed brine shrimp, (4) trout fed on brine shrimp pluse 50 ml of injured sculpin cue (prepared as in experiment 1) or (5) 50 ml of distilled water. There were 20 replicates of each treatment. The order of the treatments was randomized.

The experimental protocol was nearly identical to experiment 1 except that observations were completed between 17:00 and 18:00 hr. All relative times remained constant between all experiments. As in the first experiment, we recorded the number of short moves and shelter use at 15-second intervals. However, we also recorded data on two additional response variables. In this experiment we recorded short moves only if they occurred out from under the shelter. During the first experiment, we observed that sculpins that moved to shelter often spent considerable time moving under the shelter. Movements under the shelter are probably not as risky as movements out of the shelter. We also recorded an index of total area of the tank used by the sculpins. We divided the total area of the tank (50×30 cm) into nine sections and summed the number of squares that the sculpins used before and after addition of the stimuli.

We employed the same generalized statistical approach as in experiment 1 except that we completed five preplanned comparisons. Because this experiment had five treatments, our rejection probability (P) was set at 0.04 for each comparison (Keppel, 1982).

RESULTS

Histology. We observed large sacciform cells in all 19 sculpins that we examined (Figure 1).

Experiment 1: Responses of Sculpins to Alarm, Disturbance, and Predator Cues. We observed that sculpins exhibited an antipredator response to chemical cues of brook trout, injured conspecifics, and disturbed conspecifics (Figure 2). However, there were some differences in the form of the response between treatments. In comparison to the undisturbed control treatment, sculpins responded to trout cues by decreasing their number of short moves ($U = 61.5$, $P < 0.001$), but they did not increase shelter use ($U = 175.5$, $P = 0.231$). Similarly, sculpins in the disturbed conspecific treatment decreased the number of short moves ($U = 137.5$, $P = 0.046$), but did not increase shelter use ($U = 193$, $P = 0.581$) when compared to the undisturbed controls. In response to cues of injured conspecifics, sculpins increased their shelter use ($U = 138.5$, $P = 0.034$) but did not decrease number of short moves ($U = 151$, $P = 0.092$) when compared to the undisturbed controls.

FIG. 1. Micrographs showing a sacciform cell of a slimy sculpin.

In relation to the undisturbed control treatment, sculpins did not increase shelter use or decrease the number of short movements in response to either the swordtail cues (shelter: $U = 159.5$, $P = 0.115$; movement: $U = 180.5$, $P = 0.299$) or the model (shelter: $U = 186.5$, $P = 0.652$; movement: $U = 186.5$, $P = 0.358$).

Experiment 2: Effects of Alarm Cues on Intensity of Sculpin Antipredator Responses. We observed that sculpins responded to chemical cues of brook trout regardless of the diet of the trout (Figure 3). In relation to the distilled water control, sculpins exposed to trout fed sculpins decreased movement ($U = 113.5$, $P = 0.007$), decreased area use ($U = 111$, $P = 0.004$), and increased shelter use ($U = 105$, $P = 0.004$). Similarly, sculpins exposed to trout fed commercial trout pellets decreased movement ($U = 108$, $P = 0.005$), decreased area use ($U = 107$, $P = 0.006$), and increased shelter use ($U = 127$, $P = 0.019$) in relation to the distilled water control.

Sculpins exposed to trout fed brine shrimp decreased movements ($U = 123$, $P = 0.014$), decreased area use ($U = 125.5$, $P = 0.013$) and increased shelter use ($U = 125.5$, $P = 0.016$) in relation to the distilled water control. In response to a combination of cues of trout fed brine shrimp plus cues of injured sculpins,

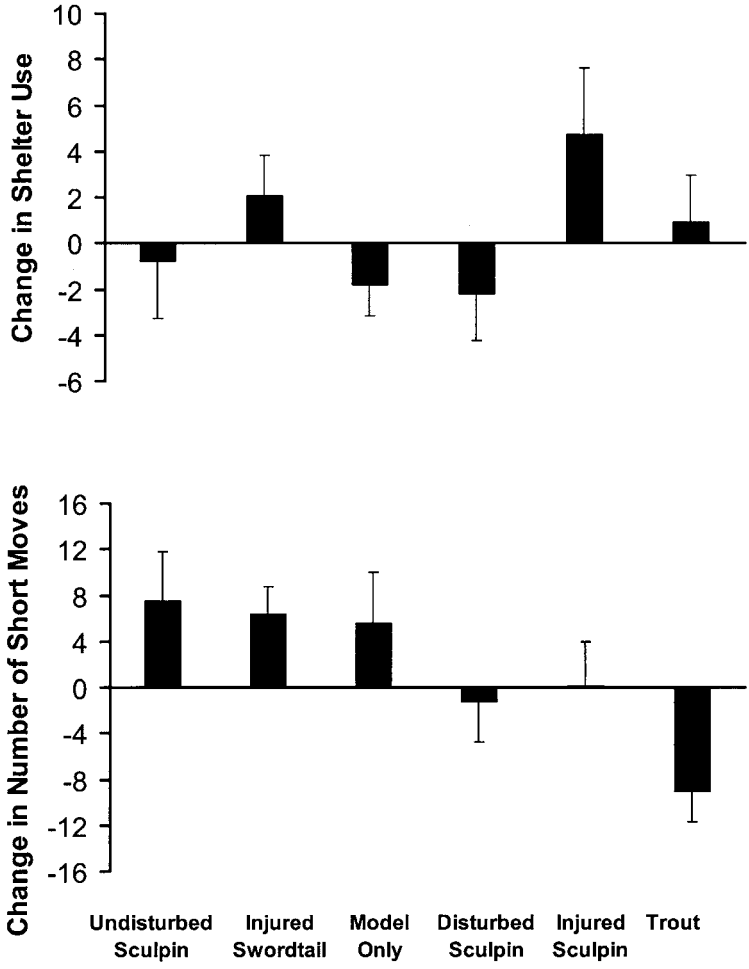

FIG. 2. Mean (±SE) change in shelter use and number of short moves by slimy sculpins following exposure to chemical cues. Treatments include: predatory brook trout, injured sculpins, and disturbed sculpins. Controls include: undisturbed sculpins, injured swordtails and a model fish predator.

sculpins decreased movements ($U = 93.5$, $P = 0.002$), decreased area use ($U = 78.5$, $P < 0.001$), and increased shelter use ($U = 100.5$, $P = 0.003$) in relation to the distilled water control. Even though sculpins responded to both cues of trout fed brine shrimp and cues of trout fed brine shrimp plus cues of injured sculpin, there was a difference in the intensity of response. Sculpins exposed to

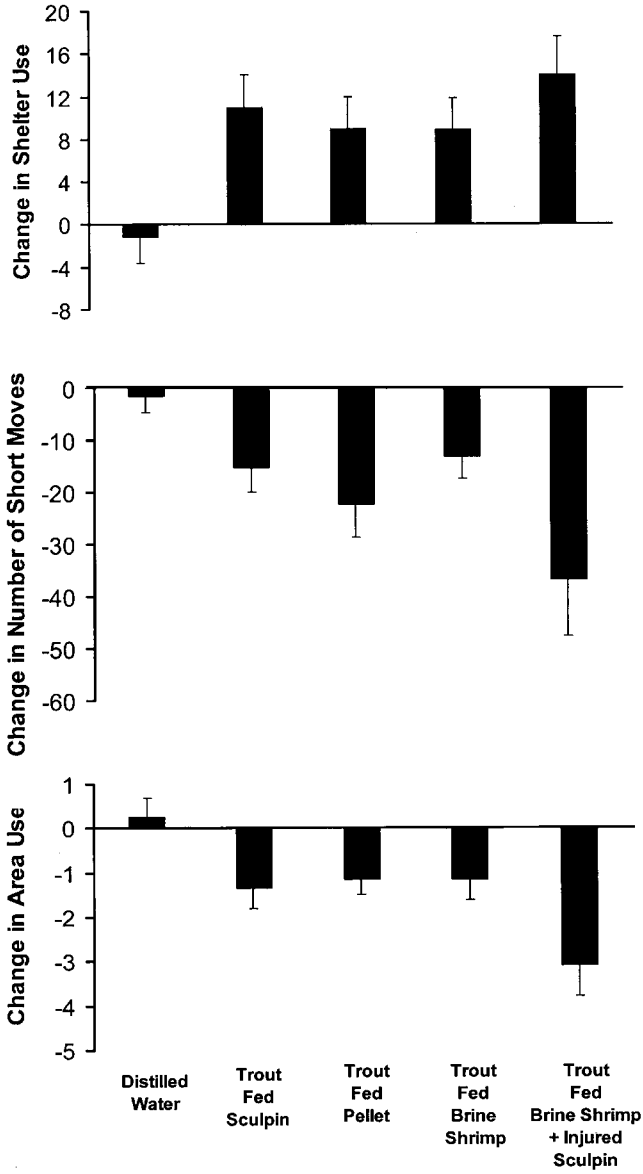

FIG. 3. Mean (±SE) change in shelter use, area use and number of short moves by slimy sculpins following exposure to chemical cues. Treatments include: brook trout fed sculpin, brook trout fed commercial pellets, brook trout fed brine shrimp, and brook trout fed brine shrimp + cues of injured sculpin. The control was distilled water.

cues of trout feeding on brine shrimp and alarm cues responded more strongly in terms of reducing area use than those exposed to cues of trout feeding on brine shrimp ($U = 132$, $P = 0.026$). There was no significant difference in the intensity of response when considering movement ($U = 150.5$, $P = 0.08$) or shelter use ($U = 167.5$, $P = 0.173$).

DISCUSSION

Our data provide evidence that slimy sculpins can assess predation risk by using a diversity of chemosensory information. In our original experiment, we documented that sculpins responded to three different classes of chemical stimuli: (1) predator chemicals, (2) damage-released alarm cues, and (3) cues of disturbed conspecifics. Additionally, we found that damage-released alarm cues enhanced the intensity of responses to predator chemicals.

The antipredator responses that we observed included reductions in activity and movement to shelter. Each of these responses would likely make the sculpins less visible to visually hunting predators such as brook trout.

Our data provide insights into the taxonomic distribution of damage-released alarm signals among members of the sculpin family (Family Cottidae). To date, five of approximately 300 species have been tested for responses to damage-released alarm cues. Neither *Cottus gobio* (Schutz, 1956) nor *Myxocephalus scorpius* (Pfeiffer, 1960) appear to respond to conspecific alarm pheromones, but *Oligocottus maculosus* (Hugie et al., 1991; Houtman and Dill, 1994), *Cottus perplexus* (Chivers et al., 2000), and *Cottus cognatus* (this study) do show responses. Additional studies are needed to elucidate taxonomic patterns of responses in this group. Specifically, we suggest that additional species in the genus *Cottus* be tested. Moreover, we suggest that *Cottus gobio* be re-examined.

The source of the damage-released signals of many fishes is thought to be specialized cells within the epidermis (reviewed by Smith, 1992). Club cells of ostariophysan fishes contain the Schreckstoff alarm signal. During the breeding season male minnows lose their club cells and simultaneously lose their ability to elicit a fright reaction in conspecifics (Smith, 1976). In other species of fishes that have been tested for an alarm response, many have been found to have similar large elonage vacuolated cells in their epidermis. However, there has been no extensive testing of most taxonomic groups for either behavioral responses or histology. In particular, the link between specialized epidermal cells and the fright reaction for fishes other than ostariophysans needs to be examined. Certain fishes outside the Superorder Ostariophysi have sacciform cells that are thought to be analogous to ostariophysan club cells. Darters have been shown to have both a fright reaction to damage-released pheromones and possess sacciform cells (Smith, 1979, 1982). Similarly, Hugie et al. (1991) showed that tidepool sculpin possess both sacciform cells and a fright reaction to cues of injured conspecifics. Our results concur with

the generalized patterns observed in these other fishes. We observed that slimy sculpins possessed both large sacciform cells and a response to damage-released alarm signals. We speculate that damage-released alarm cues are contained in the large sacciform cells; however, additional studies are needed.

Experiments testing for the presence of disturbance signals among fishes have only recently began. Wisenden et al. (1995) showed that Iowa darters (*Etheostoma exile*) exposed to a predator model released disturbance chemicals that caused an increase in vigilance in nearby conspecifics that could not see the predator model. Jordão and Volpato (2000) described similar results for the pacus (*Piaractus mesopotamicus*). Our results demonstrate that slimy sculpins exhibit an antipredator response to chemical stimuli from disturbed conspecifics. Several authors have speculated that the source of disturbance signals may be ammonia released from urine or across the gills during periods of increased activity (Hazlett, 1989, 1990b; Kiesecker et al., 1999). Kiesecker et al. (1999) showed that red-legged frog tadpoles release ammonia upon being disturbed by a predator. Conspecific tadpoles respond with antipredator behavior upon detecting a pulse of ammonia. Similar results are known for crayfish (Hazlett, 1990b). Additional studies are needed to determine whether ammonia is a component of disturbance signals in fishes.

Behavioral responses of prey animals to chemical stimuli from predators appears widespread, but such responses have not specifically been tested in sculpins (Kats and Dill, 1998). Ours is the first study to document that sculpins respond to chemical stimuli from predators. In our experiment, we observed that sculpins responded to brook trout regardless of the diet of the trout. Moreover, the intensity of response to the trout was similar regardless of the trout's recent diet. Some studies have documented that the diet of the predator influences the antipredator responses of prey animals. For example, Wilson and Lefcort (1993) showed that red-legged frog tadpoles respond more strongly to chemical stimuli from newts (*Taricha granulosa*) that have fed on tadpoles than newts that fed on invertebrates. Mathis and Smith (1993) showed that predator-naïve fathead minnows (*Pimephales promelas*) only respond to chemical stimuli from pike (*Esox lucius*) if the pike recently consumed minnows. In contrast, experienced minnows showed an antipredator response to chemicals from pike regardless of the pike's recent diet. The sculpins used in our study were wild-captured and hence experienced with brook trout. They responded to the trout regardless of its recent diet. This response makes good sense. Trout probably forage opportunistically on sculpins and hence are always a threat to them. A knowledge of the last meal eaten by the trout may provide little valuable information to the sculpin.

We found evidence that the presence of a damage-released alarm signal enhances the intensity of response to the predator. Scrimgeour et al. (1994) provided similar evidence for larval mayflies (*Baetis tricaudatus*). These results indicate that cues of the predator and alarm signals may compliment each other

to indicate a higher degree of threat than does either signal alone. The information received by the prey upon detecting predator chemicals is that there is a predator in the vicinity. When damage-released alarm cues are detected with predator chemicals, then the prey is aware of a predator that is actively hunting. The possibility exists that sculpins were not responding more intensely to the two cues because they compliment each other. Instead, the sculpins may have been responding to a quantitative difference in the amount of predation risk cue that they received. Additional experiments are needed to differentiate these possibilities.

Acknowledgments—We thank P. Altmann, J. Kobu, P. Lamothe, K. Mayer, and M. Puttlitz for their assistance. We also thank K. Edward and the Electron Microscopy Laboratory, University of Maine, for help and resources. Funding was provided by the University of Maine, the University of Saskatchewan, and NSERC of Canada. All experiments were completed in accordance with the University of Maine Institutional Animal Care and Use Committee Protocol #98-07-04.

Abstract—Protease inhibitors (PIs) are plant compounds that can inhibit proteases of mammal, insect, or pathogen origin and are frequently induced by mechanical wounding, insect feeding, or pathogen infection. *Nicotiana attenuata* is a species that induces nicotine, volatiles, and phenolics in response to damage. Here we examine the distribution of PIs in *N. attenuata* to determine if they are part of the induced response in this species and if this response is ontogenetically constrained. We found that *N. attenuata* shoot extracts inhibited trypsin (Tryp) and chymotrypsin (Chym) activities, while root extracts inhibited Tryp, Chym, and the bacterial protease subtilisin (Sub). The highest TrypPI levels were found at midday in the source-sink transition leaf, while older or younger leaves contained lower TrypPI levels and did not show significant diurnal fluctuations. Rosette plants, bolting plants, and flowering plants all contained TrypPIs in leaves, stems, and flowers, while seed capsules, seeds, and young seedlings did not contain any PIs. PIs in *N. attenuata* rosette plants were induced by *Manduca sexta* larval feeding, methyl jasmonate (MeJA) treatment, wounding, and application of *M. sexta* oral secretion and regurgitant. The response to MeJA application was stronger and longer lasting than to mechanical wounding. The direction and magnitude of the systemic response to mechanical wounding or larval damage depended on the age of the leaf that was damaged and the frequency of wounding. The systemic signal for TrypPI induction appears to follow source-sink relations in the plant and to be regulated by the octadecanoid pathway. Interestingly, by

the time plants reach the flowering stage, they had lost the ability to increase PI levels after MeJA treatment. We concluded that plant ontogeny constrains both constitutive and inducible PI production in *N. attenuata.*

Key Words—Induced responses, *Manduca sexta*, mechanical damage, methyl jasmonate, *Nicotiana attenuata*, octadecanoid pathway, ontogenetic constraints, protease inhibitors, source-sink relations.

INTRODUCTION

Protease inhibitors (PIs) are a class of compounds found in a wide range of plant families and are well studied for their activity as antiherbivore compounds (Ryan, 1990; Bode and Huber, 1992; Koiwa et al., 1997). Both in vitro experiments with insect gut extracts and *in planta* experiments with genetically transformed plants have shown that PIs can inhibit digestive enzymes and reduce growth of lepidopteran and coleopteran larvae (Johnson et al., 1989; McManus et al., 1994; Broadway, 1995; Heath et al., 1997). Additionally, some plants produce PIs that specifically inhibit proteases of pathogens (Geoffroy et al., 1990; Balandin et al., 1995). Many PIs have been found to be inducible after wounding, insect feeding, pathogen infection, or application of plant hormones, such as jasmonic acid (JA), abscisic acid (ABA), or ethylene (Peña-Cortes et al., 1988; Geoffroy et al., 1990; Farmer et al., 1992; Balandin et al., 1995; Koiwa et al., 1997).

Both constitutive and inducible PI levels in plants can be extremely variable, even within related plant species. Several types of PIs that differ in structure and activity are found within the genus *Nicotiana* alone. *N. tabacum*, for example, contains a PI that inhibits bacterial and fungal proteases and is a member of the potato PI-I family (Pot I) (Bode and Huber, 1992; Koiwa et al., 1997), and two PIs belonging to the potato PI-II family (Pot II) that inhibit trypsin (Tryp) and chymotrypsin (Chym) (Pearce et al., 1993; Balandin et al., 1995). *N. alata* and *N. plumbaginifolia* both produce PIs belonging to the Pot II family, which consist of a large precursor protein that is posttranslationally processed into smaller Tryp- or Chym-inhibiting subunits (Atkinson et al., 1993; Ausloos et al., 1995). Not all PIs are present constitutively (Fujita et al., 1993; Pearce et al., 1993; Balandin et al., 1995) and of those that are, not all are inducible (Hildmann et al., 1992; Botella et al., 1996).

The magnitude of PI induction may also vary depending on the amount of damage (Pearce et al., 1993; Alarcon and Malone, 1995), the type of herbivore that is feeding (Stout et al., 1998), or on the inducing agent that is applied (Botella et al., 1996). The induced PI response may be local and restricted to the treated leaves or organ (Jongsma et al., 1994; Balandin et al., 1995) or occur systemically throughout the plant (Pearce et al., 1993; Alarcon and Malone, 1995; Orians et al., 2000). Moreover, the ability of the plant to produce or induce PIs

may be age-dependent (Alarcon and Malone, 1995; Botella et al., 1996) or organ specific (Pearce et al., 1993; Ausloos et al., 1995), which suggests that in some plant species the expression of PIs is developmentally constrained. It is generally thought that this huge variation in types, distribution, and inducibility of PIs among plants is tightly linked with the ecological role of PIs in each species (Jongsma, 1995).

Nicotiana attenuata Torr. ex Watts (Solanaceae) is a native tobacco species that displays a remarkable array of inducible defenses in response to herbivores. Leaf damage and application of methyljasmonate (MeJA) significantly induce nicotine levels (Baldwin, 1999), volatile emissions (Halitschke et al., 2000; Kahl et al., 2000), and phenolic concentrations (M. Keinänen, personal communication) in this species. In addition to these defense compounds, it is likely that *N. attenuata* is also able to produce PIs. Closely related plant species, such as *N. tabacum* (Jongsma et al., 1994), *N. alata* (Heath et al., 1997), and *N. plumbaginafolia* (Ausloos et al., 1995), are known to produce several types of inducible PIs, all of which belong to the serine PIs (Koiwa et al., 1997). Hence, it may be expected that PIs are a significant part of the chemical changes causing increased resistance against herbivores after jasmonate treatment (Baldwin, 1998; van Dam et al., 2000).

Similar to other inducible defenses in native tobacco species, variations in induced PI patterns between and within *N. attenuata* plants may be developmentally constrained. For example, the systemic induction of both nicotine and volatiles in *Nicotiana* spp. depends on the developmental stage of the plant and the leaves. In *N. sylvestris*, a systemic increase in whole-plant nicotine is only elicited when old or mature leaves are wounded. This increase is due to increases in *de novo* nicotine synthesis. Once plants reach reproductive maturity at the elongating or flowering stage, they lose the ability to induce *de novo* nicotine production after damage (Ohnmeiss and Baldwin, 2000). The elicitation of systemic volatile emission in *N. attenuata* rosette plants is maximal when the second fully expanded leaf is damaged (Halitschke et al., 2000). Similar effects have been reported for systemic PI induction in poplar (Davis et al., 1991) and tomato (Orians et al., 2000), which suggests that plant ontogeny may account for some of the observed patterns in PI induction.

Here we show that *N. attenuata* contains different PIs in shoots and roots that can inhibit at least three different serine proteases. We found diurnal fluctuations in PI levels in the leaves of rosette plants, an increase in PI levels with development, and a decrease in PI inducibility in flowering plants. PIs in *N. attenuata* rosette plants can be induced by caterpillar feeding, MeJA application, wounding, and application of larval orval secretion and regurgitant, but the direction and magnitude of the systemic response depends on the age of the leaf that is damaged. We conclude that the systemic transport of the signal triggering PI induction follows source-sink relations in the plant and is at least partly regulated by the octadecanoid pathway.

METHODS AND MATERIALS

Plant Culture

Nicotiana attenuata Torr. ex Watts. (Solanaceae) seeds, from a bulk collection from several plants from a natural population in Utah (Baldwin, 1998), germinated and grew for two weeks in peat soil soaked in 50× diluted liquid smoke (House of Herbs, Passaic, New Jersey) to synchronize germination (Baldwin et al., 1994b). For hydroponic plants, seedlings were first transferred to communal hydroponic boxes filled with 0.292 g/liter. Peters Hydro Sol (Scotts Europe, Heerlen, The Netherlands), supplemented with 0.193 g/liter $Ca(NO_3)_2$, to synchronize growth and five days later to individual 1-liter containers filled with No-N solution, supplemented with 2 mmol/liter KNO_3 (Ohnmeiss and Baldwin, 1994). Unless otherwise indicated, hydroponic plants were used for experiments five to seven days after transfer to 1-liter containers. Soil-grown plants were transferred as seedlings to either 200 ml or 1-liter pots (depending on the duration of the experiment) filled with a peat-based substrate (TerraBril, Brill Substrate Co., Georgsdorf, Germany). Soil-grown plants were watered with demineralized water every other day. All plants were placed on tables in a growth room at 32°C/16-hr light, 27°C/8-hr dark, 65% relative humidity with 1000–1500 $\mu M/m^2/sec$ PAR at plant growing level.

Protease Inhibitor Extraction and Determination

Plant samples for PI analysis were weighed in an Eppendorf tube (~300 mg fresh wt), flash frozen in liquid N_2, ground with a pestle, and thawed on ice. If individual leaves were harvested, midribs were removed before weighing. After addition of 0.3 ml protein extraction buffer (Jongsma et al., 1994), the samples were vortexed and centifuged at 4°C for 20 min at 12,000*g*. The supernatant was transferred to a fresh Eppendorf tube and kept on ice until protein and PI analysis. Protein content of the samples was determined in triplicate using the method of Bradford (1976). PI activities were analyzed with the radial diffusion assay described by Jongsma et al. (1993, 1994), using either 42 nM bovine trypsin (Tryp; type III) (Fluka, Buchs, Switzerland), 42 nM bovine chymotrypsin (Chym; type II) (Sigma, St. Louis, Missouri) or 212 nM subtilisin Carlsbergh, (Sub; protease type VIII, bacteria) (Sigma) dissolved in agar. The active sites of all proteases were titrated to obtain the molar concentration of active enzyme before they were used for PI analysis (Jongsma et al., 1994). The detection limit of this method is ~0.2 μM PI (Jongsma et al., 1993). For TrypPI activities, a series of soybean Tryp inhibitor (STI) (Boehringer Mannheim, Mannheim, Germany) solutions were used to obtain a reference curve. To determine ChymPI and SubPI activities, we made reference extracts of *N. attenuata* plant material and determined their activity by titrating Chym or Sub with these extracts, using

benzoyl-tyrosine-*p*-nitroanilide (BTNA) (Bachem, Bubendorf, Switzerland) or *N*-acetyl-DL-phenylalanine-β naphthylester (APNE, Sigma) as substrate, respectively. Dilution series of these extracts with known ChymPI or SubPI activities were used to obtain a reference curve. PI activities are expressed as nanomoles per milligram of protein (Jongsma et al., 1994).

Types of PIs

In addition to the radial diffusion assay, we used spectrophotometric assays to test for the presence of inhibitors of five model target proteases belonging to the three different classes of proteases (serine, cysteine, and aspartic proteases) that have been described in the Solanaceae (Brzin et al., 1988; Mareš et al., 1989; Ryan, 1990). The inhibitory activity against Tryp, Chym, Sub (all serine proteases), papain (cysteine protease), and cathepsin D (aspartic protease) was measured in root, shoot, and seed extracts with assays that had an approximate detection limit of 0.02 μM. The TrypPI assay contained 4.6 pmol Tryp per well in 0.1 M Tris HC buffer with 10 mM $CaCl_2$, pH 7.6. After 15 min incubation at room temperature with inhibitor extract, 10 μl of a 50 mM benzoyl-argenine-*p*-nitroanilide (BANA) (Sigma) solution in dimethylsulfoxide (DMSO) was added to a final concentration of 2 mM BANA per well. After 30 min of incubation at 37°C the absorbance was measured at 405 nm. The ChymPI assay was performed similarly, but contained 11.8 pmol of Chym per well and was incubated for 1 hr at 37°C with 0.37 mM BTNA as substrate. SubPI activities were determined with 16.1 pmol Sub per well in 0.1 M Tris HCl containing 10 mM $CaCl_2$ and 0.05% Tween, APNE (0.48 mM) as substrate, and with an incubation time of 30 min at 37°C. Absorbance was measured at 520 nm immediately after adding 30 μl of a 1.6 mg/ml solution of Fast Blue (Fluka) in 0.1 M Tris HCl buffer, pH 7.6 Papain PI activity was measured similar to TrypPI activity, but in 0.1 M Na phosphate buffer, pH 6.0, containing 25 mM dithiothreitol, with papain (twice crystallized, Sigma) instead of trypsin and an incubation time of 1 hr at 37°C. PI assay with cathepsin D, isolated from bovine spleen (Fusek et al., 1992) was performed in Eppendorf tubes with 200 μl of preincubation mixture containing 25 pmol of cathepsin D and inhibitor extract. The pH of extract solutions was adjusted to 3.6 by adding 10 μl of 10% acetic acid per 100 μl extract solution. After 15 min of preincubation at room temperature, 1 ml of 2% hemoglobin in 0.1 M Na acetate buffer, pH 3.6, was added and incubation containued for 60 min at 37°C. The reaction was stopped by adding of 250 μl of 25% trichloracetic acid. The supernatant was collected by centrifugation (10 min at 10,000*g*) of the samples and its absorbance was measured at 280 nm.

Diurnal Fluctuations of PI Levels

Eighteen soil-grown rosette plants were selected two weeks after their transfer to 1-liter pots. On each plant, the leaf at node 0, defined as the leaf that is

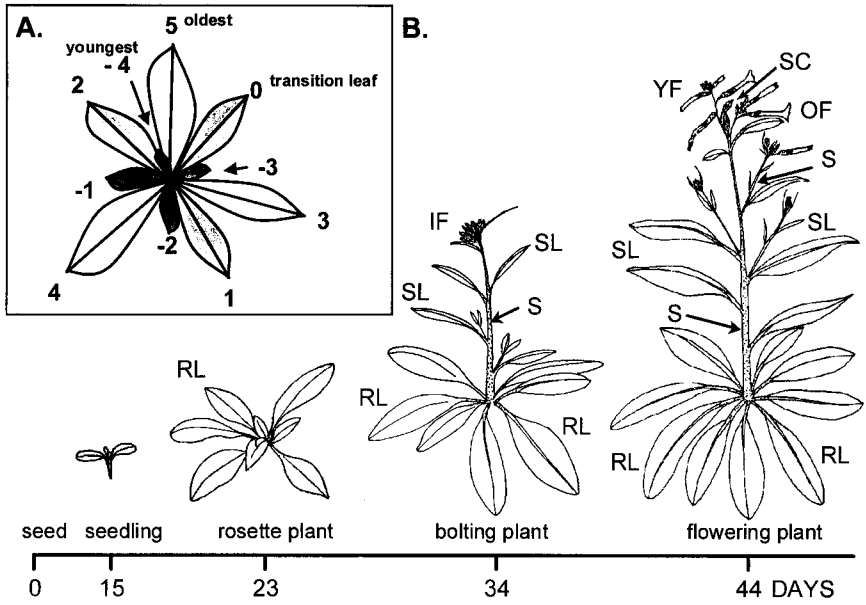

FIG. 1. (A) Numbering of the leaves at different phyllotaxic positions (nodes) on rosette plants of *N. attenuata* following Schittko et al. (2000). The leaf at node 0 has just completed the source-sink transition. (B) Schematic of the organs at different ontogenetic stages of *N. attenuata* plants. Time (in days) corresponds to the time line for the experiment measuring constitutive and induced PI activities in different developmental stages. RL = rosette leaves, SL = stem leaves, S = stems, IF = inflorescence, YF = young flower (unopened), OF = open flower, SC = seed capsules.

one phyllotaxic position younger than the first fully expanded leaf (Schittko et al., 2000) (Figure 1A) and the leaves at node 2 (older, fully expanded leaf) and node −2 (younger leaf) were labeled. The labeled leaves were harvested at 4-hr intervals (three plants per interval) during a 24-hr period to determine TrypPI activities.

Time Course of Induction

Plants were soil-grown as in the diurnal fluctuation experiment. On each plant, the leaf at node 0 was labeled and either damaged by removing a 2-mm strip perpendicular to the midrib with a scalpel each day (Jongsma et al., 1994), treated with 250 μg MeJA in lanolin (Baldwin, 1996), or left untreated. MeJA is deesterified to JA by plant esterases upon treatment and is a convenient way to introduce JA into plants. MeJA (Sigma) was close to its thermodynamic equilibrium (90.1% (1*R*,2*R*)-MeJA and 8.3% (1*R*,2*S*)-MeJA for the two naturally

occurring epimers. The labeled leaves were harvested at one, two, four, and eight days after the start of the experiment and extracted for TrypPI activities. Sampling took place at approx. 13:00 hr each harvest day (three plants per treatment per harvest). The plants whose labeled leaves were harvested were discarded. The TrypPI activities in the treated leaves were expressed relative to average activity of untreated leaves harvested at the same time.

Constitutive and Induced PI Activities in Different Developmental Stages

Minimal Seedling Size for PI Detection. Seeds were sown on day 0 and 14 days later, seedlings were transferred to 200-ml pots with soil. On days 18, 19, 20, and 21, a number of seedlings were excised with a scalpel at soil level to obtain 1–1.5 g fresh weight (FW) per sample (10, 6, 5, and 2 seedlings, respectively). The seedlings were extracted for TrypPI as above, with the addition of an extra concentration step in which proteins and PIs were precipitated with ice-cold, saturated $(NH_4)_2SO_4$ (Jongsma et al., 1994).

Developmental Changes. Seeds were sown as above (day 0). On day 15, seedlings were first transferred to communal hydroponic boxes to synchronize growth and five days later, to 2-liter pots filled with a high-N soil–Perlite mixture (van Dam and Baldwin, 1998). On day 23, three rosette plants (Figure 1B) were randomly selected to measure PI activities at the start of the experiment. Simultaneously, six plants were treated with 250 μg MeJA in 0.22 ml lanolin applied to two fully expanded leaves on each plant and three other plants were treated with 0.22 ml pure lanolin. On day 28, three MeJA-treated and three lanolin-treated rosettes were harvested by cutting of the shoot at the root–shoot interface. On day 35, three bolting plants (Figure 1B) were treated with MeJA, as above, and three other bolting plants were treated with pure lanolin. On day 39, we harvested the remaining three plants induced at the rosette stage on day 23, the three bolting plants induced on day 34, and the three bolting plants treated with lanolin on day 34. The entire shoot was cut off at the root–shoot interface and rosette leaves, stems, stem leaves, and inflorescences were separated (Figure 1B), weighed, and extracted for determination of TrypPI activity. On day 44, three flowering plants were treated with 250 μg MeJA on two rosette leaves and three other flowering plants were treated with pure lanolin. These plants were harvested on day 49 and separated into rosette leaves, stems, stem leaves, young unopened flowers, open flowers, and green seed capsules (Figure 1B). Additionally, we extracted three samples of seeds from the seed stock we used to grow the plants.

Local and Systemic Induction by MeJA Addition to Roots and Shoots

Nine hydroponically grown rosette plants were divided in groups of three and treated with either 250 μg MeJA in 0.02 ml lanolin paste on two fully expanded leaves (Baldwin, 1996), 250 μg MeJA as an aqueous solution to the

roots in the hydroponic solution (Lynds and Baldwin, 1998), or 0.02 ml pure lanolin paste to the shoot (control). Four days later, shoots and roots of the plants were harvested separately, flash frozen with liquid N_2, and ground with mortar and pestle. A 300-mg aliquot from each plant was extracted to determine TrypPI and ChymPI activities.

Local and Systemic Induction by Caterpillars

Six 2-day-old first instar *Manduca sexta* larvae (Carolina Scientific Supply Co, Burlington, North Carolina) were placed individually on the leaf at node 1 of six 2-week-old *N. attenuata* rosette plants. To prevent the larvae from moving to other leaves, leaves and larvae were enclosed in a 50-ml polystyrene container with a clear lid (Neupack Verpackungen, Hamburg, Germany). The petiole of the leaf was carefully slid through a slit in the side of the cup and the lids were perforated to allow for gas exchange and prevent condensation. Another six plants were fitted with similar cup over their node 1 leaf, but without a larva, to control for cup effects. Two days after the larvae had been placed on the plants, larvae and cups were removed from all plants and the damaged leaf at node 1, the leaf at node 3 (older than damaged leaf) and the leaf at node −1 (younger) of three control and three damaged plants were harvested. Before extraction, the leaves were photocopied on paper. The leaf area before feeding was estimated by cutting out the contour of the leaf as it was before damage and weighing the paper to the nearest 0.1 mg. Then the parts consumed by the larvae were cut out and the leaf copy was weighed again. The percentage leaf area consumed was calculated as [(mg before − mg after)/mg before] × 100%. The second group of three control and three damaged plants were harvested for TrypPI analysis four days after start of the experiment.

Local and Systemic Induction by Wounding at Different Leaf Positions

Twelve hydroponically grown plants in 1-liter pots were assigned randomly to one of four treatments (three plants each): (1) leaf at node 4 (older leaf) damaged, (2) leaf at node 0 (source-sink transition leaf) damaged, (3) leaf at node −4 damaged (younger leaf) damaged, or (4) no damage (control). The leaves were damaged daily by cutting off a 2-mm strip perpendicular to the midrib with a scalpel. Simultaneously with the first damage event, the plants were supplied with 1 mM KNO_3. Two days after the first damage event, the roots and the leaves at node 4, 0, and −4 were harvested on all plants for TrypPI and SubPI (roots only) analysis.

Local and Systemic Induction by Wounding or OS

Twenty hydroponically grown plants on 1-liter pots were assigned to the following treatments (four per treatment): (1) a single damage event and application of 15 μl water to the node 1 leaf; (2) as 1, but application of 15 μl undi-

luted, boiled, and filtered (0.45 μm filter pore size) *M. sexta* oral secretion and regurgitant (OS) (Schittko et al., 2000); (3) daily damage and daily application of 15 μl water; (4) as 3, but daily application of 15 μl *M. sexta* OS; and (5) control, leaf node 1 labeled at the start of the experiment but no damage treatment. Leaves were damaged by rolling a pattern wheel parallel to the midrib once on each side of the leaf, which created a standardized number of puncture wounds (Ohnmeiss and Baldwin, 1994). Water or OS was applied and rubbed in the leaf puncture wounds with a latex-gloved finger immediately after damage. Three days later, the damaged and treated leaves plus the leaves at node −1 were harvested to assess TrypPI activity.

Statistical Analysis

The data were analyzed using Statview (SAS Institute Inc., Cary, North Carolina) statistical software. Test values were calculated using type III SS and PI activity values were arcsine square root transformed before analysis. The PI levels of the time-course experiment and of the rosette plants in the different developmental stages experiment were analyzed by single ANOVA. Data sets with multiple dependent variables, such as PI levels in leaves and/or organs on the same plant, were analyzed by MANOVA. If the MANOVA produced a P value <0.05, it was followed by univariate ANOVAs for the individual effects and Fisher LSD post-hoc tests to detect significant differences between groups. Differences between treatment and organs in bolting and flowering plants in the developmental changes experiment were analyzed by separate ANOVAs with treatment and organ as main effects, because the data did not allow for MANOVA analysis due to lack of degrees of freedom. P values were corrected with the Bonferroni correction for multiple comparisons (Holm, 1979).

RESULTS

Types of PIs. All *N. attenuata* extracts exclusively contained serine PIs: we found TrypPI and ChymPI activity in the shoots and TrypPI, ChymPI, and SubPIs in the roots (Table 1). We detected neither PI activity directed against serine proteases in the seeds nor cysteine protease (papain) or aspartic protease (cathepsin D) inhibiting activity in any of the organs tested (Table 1). TrypPI activities in shoot extracts were consistently about four to five times higher than ChymPI activity in the same extract. Because TrypPI constituted the major part of the activity and was easier to detect, we used TrypPI as a proxy for total TrypPI and ChymPI activity in most of the following experiments.

Diurnal Fluctuations of PI Levels. The diurnal fluctuations in PI activity differed between leaves on different positions (MANOVA, $F_{15,28} = 2.05$, $P = 0.049$). TrypPI levels in the source-sink transition leaf (node 0) fluctuated sig-

TABLE 1. PRESENCE OF DIFFERENT TYPES OF CONSTITUTIVE PI ACTIVITIES IN ORGANS OF UNTREATED *N. attenuata* PLANTS MEASURED BY SPECTROPHOTOMETRIC METHODS[a]

Organ	TrypPI	ChymPI	SubPI	Papain PI	Cathepsin D PI
Roots	+	+	+	–	–
Shoots	+	+	–	–	–
Seeds	–	–	–	–	n.a.

[a] + = present, – = not detectable, n.a. = not analyzed.

nificantly during the day (ANOVA, $F_{5,12} = 3.767$, $P = 0.028$), being the highest in the middle of the light period and lowest at the end of the night (Figure 2A). Younger or older leaves had much lower PI levels during the daytime and showed no significant fluctuations (ANOVA, both $P > 0.1$). These data underscore the importance of controlling for diurnal and ontogenetic effects when quantifying PI dynamics.

Time Course of Induction. Both mechanical damage and application of 250 μg MeJA induced TrypPI levels locally in node 0 leaves above those measured in untreated controls (Figure 2B; ANOVA, treatment effect, $F_{1,15} = 57.113$, $P < 0.001$). TrypPI induction for both treatments was maximal after four days, but the effect of MeJA-application was signficantly stronger than that of damage (Figure 2B; treatment × harvest day effect, $F_{3,18} = 4.548$, $P = 0.0173$).

Constitutive and Induced PI Activities in Different Developmental Stages. Similar to seeds, very small seedlings do not contain detectable levels of TrypPI. We did not detect TrypPI activity until day 19 (six pooled seedlings, 1.0803 g FW). Seedlings harvested later, i.e., at day 20 and 21 also contained detectable TrypPI activities, and in subsequent experiments we only used plants that were 21 days old or older.

Rosette plants treated with MeJA had significantly higher TrypPI levels in their shoots than did untreated controls harvested at the same time or rosette plants harvested at the start of the experiment (Figure 3A; ANOVA, $F_{2,6} = 48.686$, $P < 0.001$). These MeJA-induced PI levls were lost in plants that were harvested 16 days later: bolting plants treated with MeJA as a rosette plant did not contain significantly higher PI levels than untreated bolting plants harvested at the same time (Figure 3B; Fisher LSD, $P = 0.41$). Bolting plants treated with MeJA five-days before harvest, however, contained significantly higher PI levels than did the other two groups (Figure 3B; ANOVA, treatment effect $F_{2,24} = 5.752$, $P = 0.009$, Fisher LSD comparisons with both other groups $P < 0.024$). Additionally, a significant difference in PI activity levels was found between organs on bolting plants (ANOVA, $F_{3,24} = 27.071$, $P < 0.001$), but the induced increase was similar in all organs (Figure 3B). Contrary to the patterns observed in younger plants, flowering plants that were treated with MeJA did not signifi-

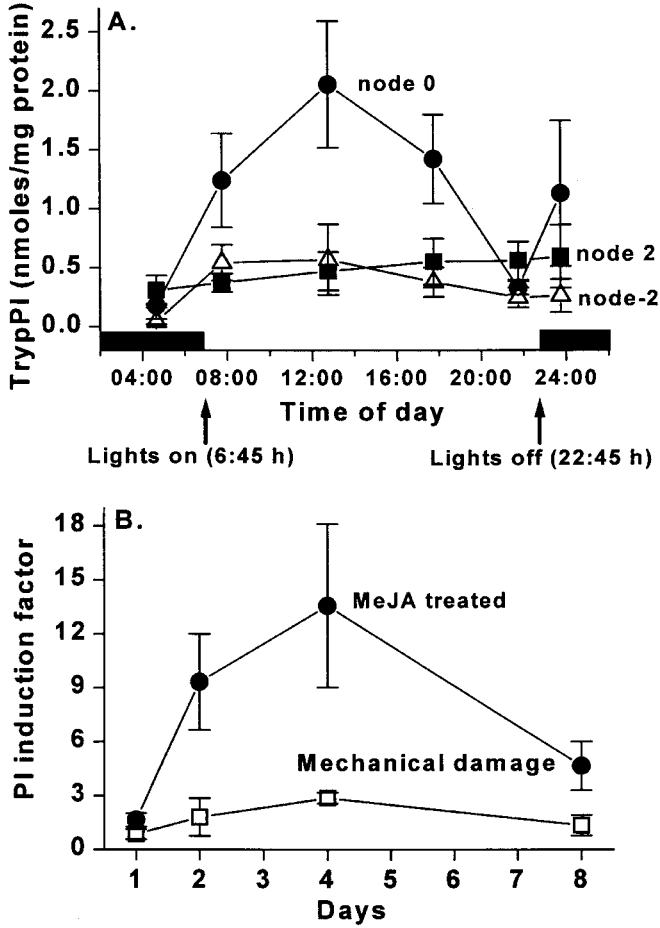

FIG. 2. (A) Diurnal fluctuations in TrypPI levels (mean ± SE, $N = 3$) in *N. attenuata* rosette plants in leaves at different phyllotaxic positions, harvested at 4-hr intervals. Circles: leaf at node 0 (source-sink transition leaf), triangles: leaves at node −2 (younger leaf), squares: leaf at node 2 (older leaf). (B) Relative increase of local TrypPI levels (means ± SE, $N = 3$) in time of the leaf at node 0 of *N. attenuata* rosette plants, after this leaf had been treated on day 0 with 250 μg MeJA or damaged daily by cutting with a scalpel. PI induction is expressed relative to the average PI level of node 0 leaves of untreated plants that were harvested at the same time intervals.

cantly increase TrypPI levels in any of their organs (Figure 3C; treatment effect $F_{1,24} = 0.741$, $P = 0.40$). Again, TrypPI levels differed significantly between organs ($F_{5,24} = 13.038$, $P < 0.001$). We did not detect any TrypPI activity in

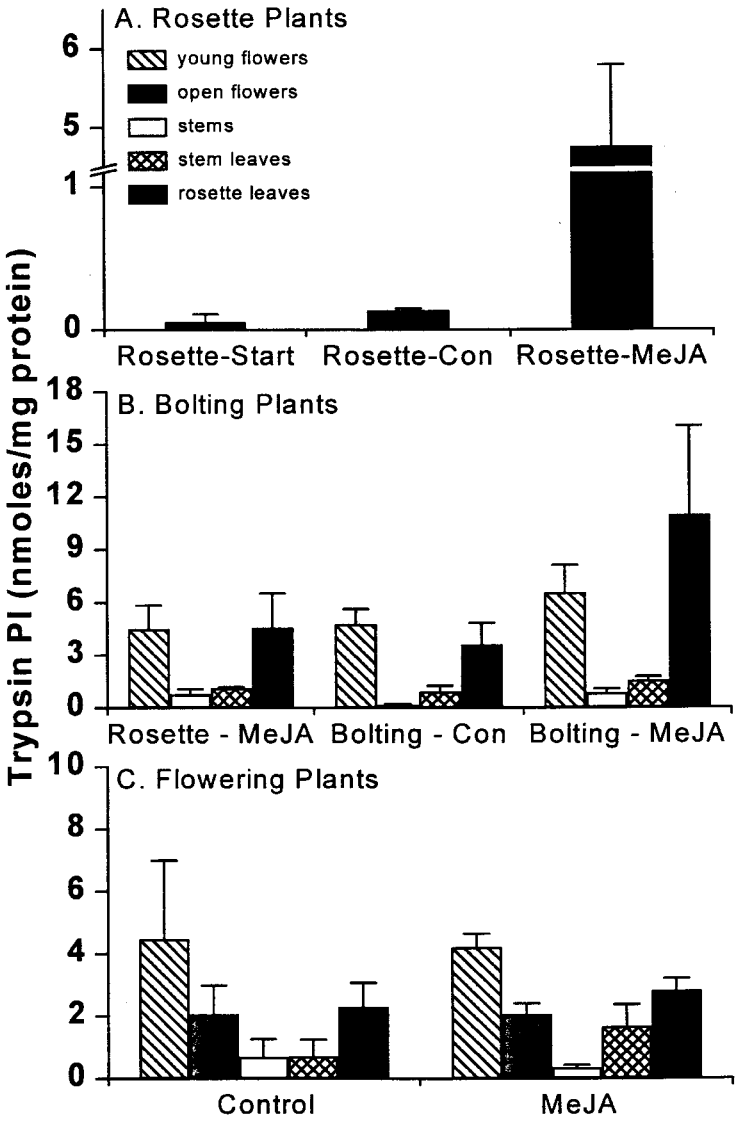

FIG. 3. TrypPI levels (mean ± SE, $N = 3$) in the different organs of control and MeJA-treated (250 μg/plant) *N. attenuata* plants in different developmental stages. (A) Rosette plants, harvested at day 23 (Start) or at day 28 (Con, MeJA). (B) Bolting plants, harvested on day 39, either treated with MeJA as rosette plants on day 23 (Rosette-MeJA), on day 34 when bolting (Bolting-MeJA) or treated with pure lanolin (Bolting-Con). (C) Flowering plants, treated with MeJA or pure lanolin (control) on day 44 and harvested on day 49.

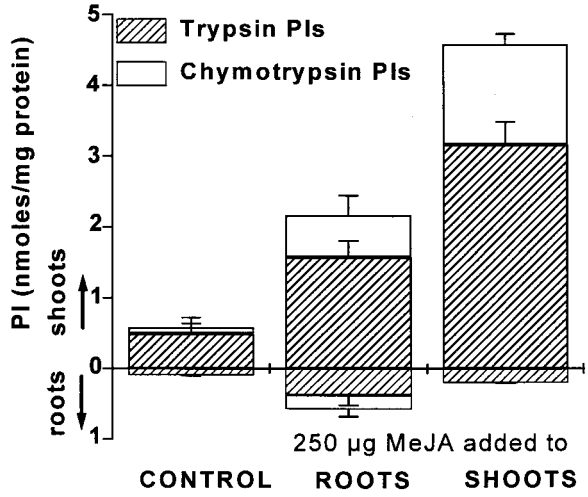

FIG. 4. Total PI activities, separated into TrypPI (hatched) and ChymPI (open) levels (mean ± SE, $N = 3$) in roots and shoots of hydroponically grown *N. attenuata* rosette plants two days after addition of MeJA to the roots or the shoots.

the seed capsules, which were still green at the time of harvest, nor in the seed samples (data not shown).

Local and Systemic Induction by MeJA Addition to Roots and Shoots. MeJA treatment significantly increased PI activities compared to those in control plants (Figure 4; MANOVA, treatment effect $F_{8,6} = 9.161$, $P = 0.0073$). Overall, leaf PI levels were significantly higher in the shoots than in the roots (Paired t test with Bonferroni correction for multiple comparisons, Tryp $t_8 = 5.121$, $P = 0.0018$, Chym, $t_8 = 3.482$, $P = 0.0083$). Although MeJA application also had a systemic effect, the strongest PI induction was in the treated organ (Figure 4). MeJA application to the roots induced total root PI activity levels to 6.0 times that of untreated roots, and leaf PI levels to 3.7 times that of control shoots (Figure 4, ROOT treatment). Leaf MeJA application, however, increased total leaf PI levels by a factor 8.2 and total root PI to only 2.1 times that of control plants (Figure 4, SHOOT treatment). Root ChymPI activity was only detectable in roots treated with MeJA and not in the roots of shoot-treated plants or control plants (Figure 4). SubPI levels in the roots did not significantly change in any of the MeJA treatments (data not shown).

Local and Systemic Induction by Caterpillars. On average, the *M. sexta* larvae consumed 13.2% (±3.7 SE) of the leaf they were confined to. This relatively small amount of damage significantly induced overall TrypPI activities in the plants they fed on (Figure 5, MANOVA treatment effect $F_{3,8} = 9.19$, P

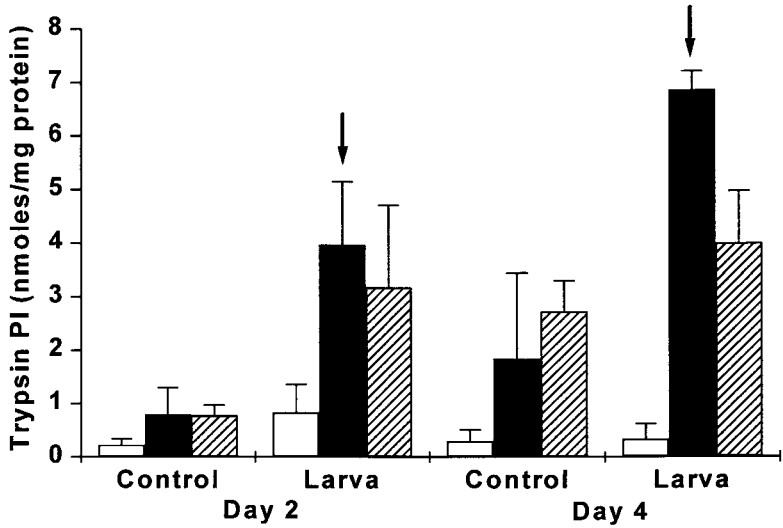

FIG. 5. TrypPI levels (mean ± SE, $N = 3$) after 2 and 4 days in leaves of *N. attenuata* rosette plants after 2 days of *M. sexta* larvae feeding on the leaf growing at node 1. Open bars: leaves at node 3 (older than damaged leaf), solid bars: leaves at node 1, hatched bars: leaves at node −1 (younger). Arrows identify the leaves that were damaged by the larvae.

= 0.012). The elevated PI levels were maintained for two days after the larvae had been removed (Figure 5, no significant treatment × day effect). Although the response was clearly systemic, the increase in PI activity was higher in damaged leaves and younger leaves than in older leaves (Figure 5). This indicates that the signal inducing PI activity levels is mainly transported acropetally within the shoot.

Local and Systemic Induction by Wounding at Different Leaf Positions. Mechanical damage significantly increased TrypPI levels in damaged shoots (Figure 6, MANOVA treatment effect $F_{9,15} = 2.845$, $P = 0.036$). There was both a local and a systemic effect, but within the shoot, systemic increased were detected only in leaves that were younger than the damaged leaf (Figure 6). For example, when node 0 leaves were damaged, TrypPI levels increased only in the damaged and younger leaves. When young leaves were damaged, none of the older leaves were significantly induced. This confirmed our previous observation that, within the shoots, the PI inducing signal is transported acropetally. Overall, the shoot response to damage on old leaves was the weakest (Figure 6). In the roots, however, both TrypPI and SubPI levels changed, although inversely, in response to damage (Figure 6, insert), but only TryPI levels did so significantly

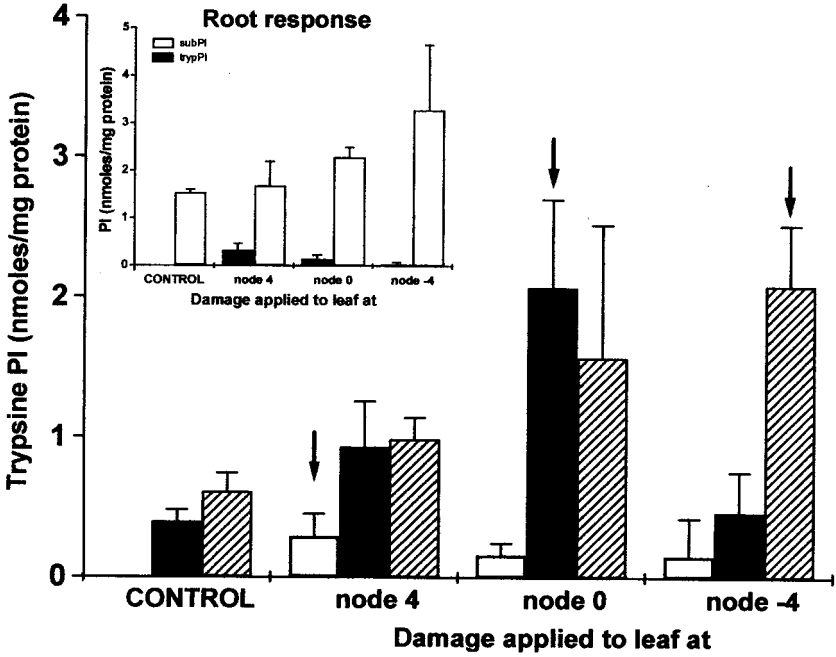

FIG. 6. TrypPI levels in shoots and TrypPI and SubPI levels (mean ± SE, $N = 3$) in roots (insert) of hydroponically grown *N. attenuata* rosette plants 2 days after the first damage. Different leaf positions were damaged daily with a scalpel. Open bars: leaf at node 4, solid bars: leaf at node 0, hatched bars: leaf at node −4. Arrows identify the leaf positions that were damaged in each group.

(ANOVA for TrypPI, treatment effect $P_{3,7} = 6.454$, $P = 0.02$). TrypPI levels were highest in roots of plants whose oldest leaves were damaged (Figure 6, insert). This indicates that in these plants some of the inducing signal was transported to the roots as well.

Local and Systemic Induction by Wounding and Regurgitant. Three days after the first treatment, TrypPI levels were significantly different between treatments (Figure 7, MANOVA $F_{8,28} = 3.111$, $P = 0.012$). The TrypPI levels in plants damaged once with or without application of OS were not significantly different from the control plants (Figure 7, Fisher LSD post-hoc test for both damaged and younger leaves, $P > 0.1$). Plants that were damaged repeatedly had significantly higher PI levels in the damaged leaves (Fisher LSD test on PI levels in damaged leaves, $P < 0.01$). Only when plants were repeatedly treated with OS were the PI levels in younger leaves higher than in those of the controls (Fisher LSD, $P = 0.0067$).

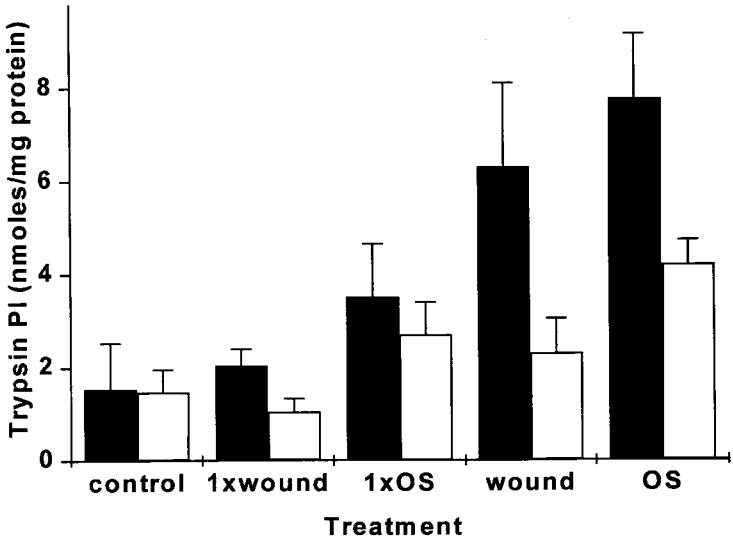

FIG. 7. TrypPI levels (mean ± SE, $N = 4$) of leaves on *N. attenuata* rosette plants 3 days after the first damage. 1 × wound = leaf at node 1 was damaged with a pattern wheel once on day 0 and 15 μl water was applied to the wound site, 1 × OS = same as 1 × wound plus 15 μl boiled and filtered *M. sexta* oral secretion and regurgitant (OS) was applied to the wound site, wound = leaf at node 1 was damaged and treated with 15 μl water daily for 3 days, OS = same as wound, but treated with 15 μl OS on the damaged site daily for 3 days. Solid bars: treated leaf (leaf at node 1), open bars: leaf at node −1 (younger).

DISCUSSION

Similar to what has been reported for other *Nicotiana* species, we found only inhibitors of serine proteases in *N. attenuata.* Preliminary results from affinity chromatography purification, followed by gel filtration and MALDITOF analysis indicate that the TrypPI/ChymPI activity from shoot extracts resides in a mixture of high and low MW proteins, the former weighing ~5.7 kDa (M. Horn and M. Mareš, unpublished results). This is similar to the structure of the Pot-II PI found in *N. alata.* This PI is synthesized as a 42-kDa precursor, which is proteolytically processed into five 6-kDa subunits, four of which inhibit Tryp and one Chym, and one, smaller, 5-kDa Chym-inhibiting unit (Atkinson et al., 1993; Heath et al., 1995; Lee et al., 1999). Our observation that the TrypPI activities were consistently 4–5 times higher than ChymPI activity in shoot extracts supports the proposition that the PIs in *N. attenuata* and *N. alata*, which belong to closely related sections within the genus *Nicotiana* (Goodspeed, 1954), share a

similar structure. The occurrence of similar types of PIs with different activities may provide broad-range plant resistance and possibly prevent herbivores from easily adapting their digestive enzymes and becoming resistant to plant defense (Broadway, 1995; Jongsma and Bolter, 1997).

Contrary to what has been found in *N. tabacum* (Geoffroy et al., 1990; Heitz et al., 1993), we did not find any Sub-inhibiting activity in shoots of *N. attenuata.* SubPI activity was found exclusively in the roots and was not significantly induced by either wounding or MeJA application. It is possible that SubPI activities increase specifically after pathogen infection (Geoffroy et al., 1990; Balandin et al., 1995) or elicitation by salicylic acid (SA) (Heitz et al., 1993). Affinity chromatography followed by gel filtration and SDS-PAGE revealed that the constitutive root SubPI consists of a 29-kDa protein that also inhibits Tryp (M. Horn and M. Mareš, unpublished results). It is generally thought that TrypPI/ChymPIs are targeted against insect or mammalian herbivores (Jongsma and Bolter, 1997), while SubPIs are considered defenses against pathogenic microorganisms (Geoffroy et al., 1990; Heitz et al., 1993). Given the abundance of microorganisms in the soil, the potential danger of attack by pathogens is much larger for roots than for shoots. This may explain our observation that *N. attenuata* contained relatively high constitutive SubPI in their roots.

We also found considerable variation in PI levels in time: within one photoperiod the PI level in source-sink transition leaves, growing at node 0, fluctuated dramatically. This variation suggests that PIs, in addition to being antiherbivore compounds, may be directly involved in the regulation of plant metabolism (Bode and Huber, 1992; Koiwa et al., 1997; Solomon et al., 1999).

On a larger time scale, PI levels in the plant changed during ontogeny. Seeds and very small seedlings did not contain any TrypPIs, while in rosette plants, PI levels increased with plant size. Within bolting and flowering plants, young, unopened flowers and rosette leaves had the highest PI levels. Apparently, these high PI levels in the flowers decrease after pollination, because open flowers contained lower PIs levels while seed capsules did not contain PIs at all. This is consistent with data on PI levels in reproductive organs of *N. plumbaginifolia* and *N. tabacum* (Pearce et al., 1993; Ausloos et al., 1995). In *N. plumbaginifolia*, PI levels were high in all floral parts, but dropped dramatically after pollination (Ausloos et al., 1995). No PI activity was found in the mature fruit or seeds of *N. tabacum* (Pearce et al., 1993; Ausloos et al., 1995). The high PI levels in the young flowers and flower parts may protect these valuable organs against herbivores and pathogens (Atkinson et al., 1993), while it was postulated that low PI level in mature fruits and seeds could facilitate seed dispersal by frugivores (Ausloos et al., 1995). In any case, the lack of PIs in the unripe fruits, seeds, and young seedlings of *N. attenuata* rules out a direct involvement in seed storage processes or germination (Koiwa et al., 1997).

TrypPI levels were locally and systemically induced by wounding, herbi-

vore feeding, and application of herbivore OS and MeJA, all of which are known to trigger the octadecanoid signaling pathway in plants (Koiwa et al., 1997). Alternatively, PI induction can also be enhanced (Fritig et al., 1998) or reduced (O'Donnell et al., 1996) by SA, which is involved in the systemic induction of pathogenesis-related proteins (Reymond and Farmer, 1998). Spray application of a 50 mM SA solution to shoots or of 1 mM SA to the roots, however, did not significantly change TrypPI levels in hydroponically grown *N. attenuata* plants (N. M. van Dam, unpublished results). These data indicate that for TrypPIs induction in *N. attenuata* JA may be the signal responsible for the systemic response: [^{14}C]JA tracer studies showed that JA applied to one fully expanded leaf is transported systemically throughout rosette plants (Zhang and Baldwin, 1997). Endogenous JA production increases with the number of wounds a leaf receives and results in proportional increases in whole-plant nicotine production (Baldwin et al., 1997). Similarly, we found that plants damaged daily with a pattern wheel had higher induced PI levels than plants subjected to a single damage event. The JA signaling pathway is also involved in systemic plant signaling after herbivore feeding. Application of *M. sexta* OS to *N. attenuata* leaves elicits both a localized JA burst (McCloud and Baldwin, 1997; Kahl et al., 2000) and a systemic signal that rapidly elicits JA amplification in leaf parts remote from the wound site (Schittko et al., 2000). In tomato plants JA is a specific systemic elicitor of both PI-I and PI-II mRNA transcription (Farmer et al., 1992). However, these results do not rule out that other signals, e.g., systemin-like molecules (Constabel et al., 1998), electrical signals (Wildon et al., 1992), ethylene (O'Donnell et al., 1996), or ABA (Peña-Cortes et al., 1988) may also be involved in systemic PI induction in *N. attenuata.*

Both local and systemic responses were influenced by induction treatment: TrypPI induction was stronger after MeJA treatment than after mechanical wounding. Replicated wounding, however, resulted in significantly higher local PI levels than a single wounding event, while additional application of *M. sexta* OS enhanced the systemic response. This indicates that the plant can discriminate between wounding and larval attack and possibly uses different signal pathways for local and systemic induction of PIs (Lightner et al., 1993; Koiwa et al., 1997; Reymond and Farmer, 1998). Application of *M. sexta* regurgitant also induces ethylene production in *N. attenuata* (Kahl et al., 2000), a plant hormone known to enhance the PI response to wounding (Heitz et al., 1993; O'Donnell et al., 1996) but to reduce the nicotine response (McCloud and Baldwin, 1997; Kahl et al., 2000). Such interactions between different signaling hormones may fine-tune the plant response towards specific attackers (Reymond and Farmer, 1998).

In contrast to induced increases in nicotine levels (Baldwin et al., 1994a), induction of TrypPI activity in *N. attenuata* is transient: 16 days after application of 250 μg MeJA, TrypPI levels were not different from those in untreated plants.

Possibly, PIs are metabolized to recycle valuable resources, e.g., N, that were used to construct them. This may be correlated with the resource costs of *de novo* production of PIs at induction, which may be even larger than the 6% of current N uptake invested in nicotine production (Baldwin et al., 1998). Similar to nicotine induction (Ohnmeiss and Baldwin, 2000), *de novo* PI induction is limited to the early stages of plant development: flowering plants treated with MeJA did not significantly increase local or systemic PI levels.

The within-plant pattern of systemic PI induction in *N. attenuata* rosette plants strongly suggests that the signal triggering remote PI induction follows source-sink relationships within the plant. When recently fully expanded, source leaves were damaged by herbivores or cutting, PI levels increased in all organs that receive photosynthetic products from these leaves, i.e., the younger leaves and, to a lesser extent, roots. If young sink leaves were damaged, PI levels increased only locally in this leaf and not in any other plant parts. Source-sink related induction patterns have been described in detail for PIs in poplar (Davis et al., 1991) and tomato (Orians et al., 2000). These results suggest that the systemic signal is transported in the phloem together with sucrose. Interestingly, damage to older leaves did not trigger such a strong systemic response in younger leaves as damage on younger source leaves, a pattern also reported from *N. tabacum* (Pearce et al., 1993). Possibly, these leaves export the majority of their photosynthetic products and systemic induction signals to the roots, which is consistent with the significantly larger TrypPI response in the roots when old leaves were damaged. Alternatively, older leaves may be less sensitive to leaf damage and produce less wound signal (Ohnmeiss and Baldwin, 2000).

PI induction is constrained by plant ontogeny, as has been described for the induction of nicotine (Ohnmeiss and Baldwin, 2000) and volatile emissions (Halitschke et al., 2000). *N. attenuata* is thus spatially and temporally limited in its ability to deploy certain defenses against herbivores. This ontogenetic constraint may be due to metabolic limitations: flowering plants preferentially allocate their resources to seed production and therefore may be physiologically prevented from allocating resources to functions that are not directly involved in fitness output, e.g., induced defense production. This may be an optimal strategy if leaf loss, e.g., to herbivores, in the flowering stage does not reduce lifetime seed output (Ohnmeiss and Baldwin, 2000). It remains a challenge to ecophysiologists to resolve the physiological and ecological significance of such ontogenetic constraints.

Acknowledgments—The authors thank M. Lim, G. Glawe, M. Ebbinghaus, and C. Müller for excellent technical assistance. N.M.D. thanks Dr. M. A. Jongsma and coworkers at CPRO-DLO in Wageningen, The Netherlands, for their hospitality and the private course in PI analysis. M.H. and M.M. were partially supported by grants GACR No. 522/00/1553 and GAAVCR No. IAA4055006. This research was supported by the Max Planck Society.

Abstract—Ectal mandibular glands of insects are exocrine glands localized in the anterior–lateral region of the head, close to the base of the mandibles. In social wasps, the gland is composed of secretory cells and a reservoir into which the secretion accumulates. At the time of emission the secretion flows onto a specialized cuticular area on the outside of the base of the mandibles. Secretion of *Polistes dominulus* is emitted only when wasps are greatly disturbed or in the presence of predators, and its function seems to be mainly defensive. Morphometric studies did not reveal any size differences between the glands of the queens and those of the workers. GC-MS analyses of the glands identified 32 compounds, mainly acids and aldehydes in the range C_2–C_{18}. The overall odor, caused by the mixture of aldehydes, is distinct. Workers do not respond strongly to the odor. The secretion probably serves as a warning signal to vertebrate predators.

Key Words—Ectal mandibular glands, colony defense, *Polistes dominulus*, social wasps, acids, aldehydes.

INTRODUCTION

Exocrine glands are found widely among social insects where they have various functions. Twenty-one different glands have been described in social bees, 39 in ants, 11 in termites, and 23 in social wasps (Billen and Morgan, 1998; Downing, 1991; Fortunato et al., 1998, 2000a; Jeanne, 1996; Landolt and Akre, 1979; Nedel, 1960). Some of these glands are common to all social Hymenoptera, even though their functions may vary across species, castes, or ages. Exocrine glands can produce a great variety of organic compounds, from low-molecular-weight substances to proteins. These glandular substances can be utilized as nest materials, in immature brood rearing, in the defense against predators or microorganisms, and, quite frequently, in chemical communication (pheromones and allomones). Despite this wide range of products, exocrine glands belong to only three structural types, described by Noirot and Quennedey (1974). Secretory cells possess a great functional plasticity and can produce very different secretions with slight variations in their morphology and ultrastructural organization.

Ectal mandibular glands are cephalic glands located in the anterior-lateral region of the head and are the only head glands in wasps that possess a reservoir (Landolt and Akre, 1979; Downing, 1991). This reservoir constitutes the largest part of the gland and is surrounded (although not completely) by secretory cells of type 3. The secretion produced is stored in the reservoir, and a sclerotized glandular duct connects the reservoir with the outside, opening directly at the base of the internal mandibular surface (Fortunato et al., 2000b). The location of the exit hole is consistent with the function that the secretion has in most species of aculeate social Hymenoptera. In honeybees, these glands are particularly developed in queens, where they produce sexual pheromones during the nuptial flight and, later, secrete a complex mixture of compounds that has a function in colony control. In worker bees, these glands are less well developed and the function of their secretion varies with the age of the individual (Free, 1987). In males the glands are quite reduced (Lensky et al., 1985) and their function is unknown.

In stingless bees (Meliponini), mandibular glands produce trail-following pheromones (Lindauer and Kerr, 1960), and in *Trigona* (*Oxytrigona*) a caustic secretion is released by biting (Michener, 1974). In ants, the secretions of these glands are often used as alarm or defensive pheromones (Buschinger and Maschwitz, 1984). In bumble-bees, they are the source of the secretion that males lay on various substrata during patrolling flights and serve to attract females to mating sites (Bergman and Bergström, 1997; Roubik, 1989).

Little information exists on the function of these glands in social wasps (Landolt and Akre, 1979). Downing and Jeanne (1983) suggested that the function in *Polistes fuscatus* was related to dominance hierarchy. A role in reproductive behavior is hypothesized for males of *P. major* (Wenzel, 1987) and of

some Stenogastrinae (Fortunato, personal observations). *Polistes dominulus* is a species widely distributed in southern Europe, North Africa, the Middle East, and part of Asia. Since 1980 it has also begun to colonize the United States (Cervo et al., 2000). It is characterized by an annual colony cycle (Turillazzi, 1980) with nests founded by one or more mated females in early spring (Pardi, 1942). The first individuals to emerge from these new nests are workers; reproductives begin to appear in late July and August. We report here morphological measurements of the ectal mandibular glands and chemical analysis of the secretion of *Polistes dominulus*, together with behavioral data demonstrating the function of the glands.

METHODS AND MATERIALS

Morphometric and Histological Measurements. For this study we used individuals from laboratory and field colonies from 1995 to 1998. Morphological measurements were made on intact glands dissected from wasps collected in the field. Profiles of glands were drawn with a *camera lucida* under a stereoscopic light microscope at 50× magnification, and glandular surfaces were measured with a computer by using the Java software program. Measurements were normalized by dividing by the head surface of the same animal. Measurements were recorded in pixels, since the size relative to the head, not the absolute metric measure, was required. Cells were counted after fixing glands in Pampl's solution, rehydrating for 10 min, and coloring for 10 min in Emallume followed by a toning in fresh water for 15 min. This dye stains nuclei brown-red and cytoplasm pink. Finally, glands were dipped in Vaseline and cells were separated with micro-needles on a slide, covered with a cover glass, and counted under a light microscope at 400× magnification.

Chemical Analyses. Chemical analyses were made at the CISM laboratory of the University of Florence and at the Chemical Ecology Group at Keele. At Florence mandibular glands were dissected in distilled water and their reservoirs squeezed to expel their contents. The secretion was particularly evident as it floated on water and could be collected by means of a micro-syringe and then directly injected into the gas chromatograph. GC-MS analyses were performed on a Saturn 2000 instrument (Varian, Walnut Creek, California), equipped with a fused silica capillary column (30 m × 0.25 mm coated with a 0.25-μm-thick film of 5% phenyl–95% dimethylsiloxane), with helium carrier gas at constant head pressure (6.7 psi). The oven temperature was initially 40°C for 4 min, then increased to 100°C at a rate of 20°C/min, then at 5°C/min to 300°C and maintained there for 4 min. The injector and transfer line temperatures were 250°C and 280°C, respectively. Injections were in splitless mode, with the ion trap mass spectrometer in EI mode, acquiring the mass range from m/z 40 to m/z 400, or

in positive CI mode, using acetonitrile as the reactant gas, acquiring the mass range from m/z 70 to m/z 400. Compound identification was by comparison with standard mass spectral data bases, and molecular masses obtained from the CI spectra.

For the analyses at Keele, glands were dissected in Italy and directly inserted in glass capillaries that were then scaled in a flame according to the method of Morgan (1990) and sent to England by mail. At Keele samples were analyzed on a Hewlett-Packard 5890 gas chromatograph directly coupled to a 5970B quadrupole mass spectrometer by using 70 eV electron impact ionization, with control by a HP 5972/5971 Chemstation. Individual glands were chromatographed on a 15-m × 0.32-mm-ID column (bonded polyethylene glycol stationary phase, 0.25-μm thickness, Stabilwax, Restek) with quartz glass injection liners (produced in the lab at Keele) with a plug of Restek silanized glass wool. Samples were injected in splitless mode (injection temperature 250°C) by crushing the capillary tubes immediately inside the injector port after insertion, as described by Maile et al. (1998), with helium as the carrier gas at a flow of 1 ml/min, and an oven temperature programmed to increase from 40°C (3 min) at 11°C/min to a maximum of 200°C. The split valve was closed before crushing the sample and reopened 45 sec later. Mass spectra were scanned from m/z 35 to m/z 550 with a scanning time of about 2.4 sec.

Compounds were identified by comparing their mass spectra with standard mass spectral data bases. The identity of the simple acids was confirmed by coinjection of synthetic standards (Sigma-Aldrich Co. Ltd., Gillingham, UK). As the chromatograms were characterized by many coeluting compounds, single ion monitoring at m/z 60 was used to recognize all the acids. Because the detector response for this wide range of compounds varies greatly, for quantification, calibration curves of six different concentrations of solutions of all the even-numbered acids from acetic to stearic acid were constructed. These calibration curves were used for quantification for compounds of appropriate chain lengths by comparison of peak areas.

Behavioral Observations. Colonies in various stages of development were used for behavioral observation both in the lab and in the field. The characteristic aromatic odor of the ectal mandibular gland secretion is easily detectable, and this made it possible for us to know when it was emitted. We relied on this property to study the factors involved in its emission with the evident limitations of such a type of test. Field nests were studied at sites in the countryside around Florence. Laboratory colonies were reared in glass cages (15 × 15 × 15 cm) with a ceiling of glass and steel mesh and supplied with water and food ab libitum.

To evaluate the possible alarm function of the secretion, the glands were dissected from individuals belonging to the same or to alien colonies under a stereoscopic light microscope and were presented to the colonies by using forceps. In a second experiment, (one to four) dissected glands were crushed on

25-mm^2 pieces of blotting paper and brought close to the colonies. As a control, clean blotting paper squares (or with other crushed body glands) were presented before and after the experiment. Video recordings were made in daylight with a Sony Handicam 8 mm with a macro lens, while night video recording was possible with an infrared micro-video camera and a portable lamp with IR filter.

RESULTS

Morphometric Analysis. Mandibular gland size relative to body size as measured by head area is given in Table 1. There was no significant difference between foundresses and workers or between dominant and surbordinate foundresses taken from six different postemergence colonies. The size of glands dissected from preemergence foundresses, from workers collected in July–August, and from males collected on nests in September was statistically different only for workers versus males. This last difference could probably be due to the young age of the males. The number of type three secretory cells in foundresses was, on average (±SD) 98.38, ±11.187 (N = 21, range 80–121).

Chemical Analysis of Secretion. The secretion was complex and variable from one individual to another, but in each was dominated by a series of aliphatic acids from C_2 to C_{18} (Figure 1), with relatively more of the even-numbered carbon atoms (Table 2). None of the acids were identified as being responsible for the characteristic odor of the freshly discharged secretion. Except for acetic and butyric acids, they have little or no odor. Small amounts of C_7–C_{12} aldehydes and some alcohols related to these acids were also present. Where identifiable,

TABLE 1. GLAND SIZE, RELATIVE TO HEAD SIZE, MEASURED AS COMPUTER PIXELS, COLLECTED FOR GROUPS OF *Polistes dominulus*[a]

Group	N	Gland size (pixels ± SD)	Significance
Foundresses[*b]	12	121.381 ± 26.873	
Workers[*b]	12	116.425 ± 32.114	Student's t, NS
Dominant foundresses[*,b]	6	112.852 ± 19.003	
Subordinate foundresses[*,b]	6	129.910 ± 32.451	Student's t, NS
Pre-emergent foundresses[†]	14	1502 ± 91.726	Statistically different only for males vs. workers, ANOVA, F = 3.625, df = 2 and 50, P = 0.0339, Fisher's test, P = 0.0113
Workers collected July-August[†]	23	1544 ± 65.564	
Males on nests, September[†]	16	1476 ± 88.745	

[a] Data marked with [†] were measured under different computer conditions from those marked with [*]. Data collected by the two different methods cannot be compared.
[b] Wasps were taken from six different postemergent colonies.

TABLE 2. MAJOR CHEMICAL COMPOUNDS DETECTED IN MANDIBULAR GLAND SECRETION OF WORKERS AND FOUNDRESSES OF *Polistes dominulus* COLONIES AND THOSE DETECTED AS TRACES (t)[a]

Compound	Peak	Mean secretion [ng, (min–max)]	% of total
Acetic acid	1	11.1 (1.7–30.4)	5.1

[a] The amount of each compound detected in a whole gland (ng) and the relative proportion of each compound (%) are given. Peak numbers refer to Figure 1.

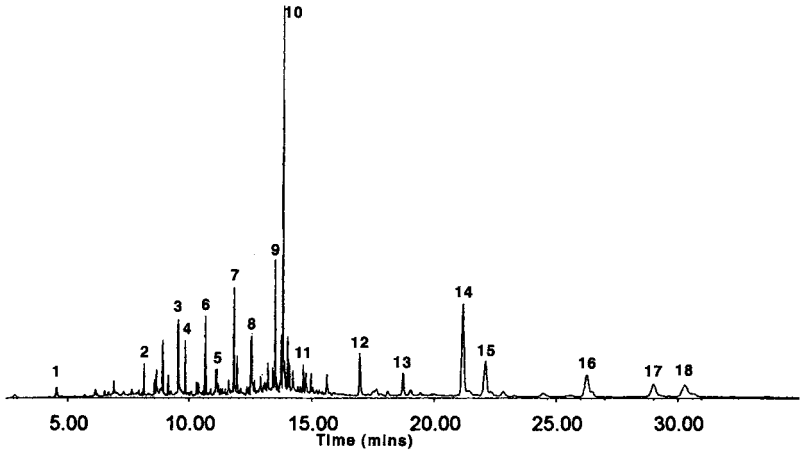

FIG. 1. Total ion chromatogram of the mandibular glands of a single worker of *Polistes dominulus*. The numbers correspond to those in Table 2.

these aldehydes are listed as traces in Table 1. The amounts of each component were in the low nanogram amounts, which made identification from the spectra difficult.

Behavior. Wasps release the secretion in a detectable quantity when isolated insects or colonies are greatly disturbed or attacked by a predator. Emission was perceived in 70 of 70 isolated females when they were trapped by their legs with forceps and in 50 of 50 colonies disturbed by the sudden approach of a hand or face to their cages. Individuals of any rank, caste, or sex can emit secretion at any moment of the colonial or life cycle (including hibernating females) both during the day or night. Emission occurs both from animals taken from nests or captured during foraging or mating flights.

Various factors can cause the emission of the secretion: capture, mechanical vibrations transmitted to the nest through the substrate, emission of CO_2 at the nest, presentation of possible predators to the colony (*Vespa crabro*), etc. Observations and video sequences showed that the approach of a predator to the nest first alerts the wasps, with raising of the wings and of the body. Rapid movements on the nests accompanied by mandible opening and wing beating follow, the latter producing an audible buzzing and circulation of air. The diffusion of the characteristic odor of the secretion, easily appreciated at this stage, is helped by the air disturbance by the wing beating. When the stimulus is particularly intense (this occurs especially after a flow of CO_2 over the nest) and at night, passage between all the various phases can be quite short. In the dark, wasps do not abandon the nest to attack, and this causes a cumulative higher release of secretion in the nest surroundings.

Wasps trapped by forceps and observed under a microscope are seen to open their mandibles to a maximum (more than 90°), uncover the basal internal surface (usually covered by the sides of the clypeus) and expose the specialized cuticular area with the glands opening (Fortunato et al., 2000b). In some cases, the emission of a little drop of secretion can be distinctly seen. Wasps can remain in this position for a few seconds to 1 min and can repeat the emission a number of times, even if the smell is less and less detectable.

After emission and when the colony is calm again, wasps begin intense and prolonged self-grooming.

Experiments on Possible Alarm Function of Secretion. In preliminary experiments, single mandibular glands were brought close to a colony on the tip of dissecting forceps. In no case was any particular alarm reaction observed from the wasps, and some of them only inspected and antennated the glands. In a second experiment, crushed glands on blotting paper were presented close to the colonies. The experiment was repeated on eight different colonies and in no case (0 of 8 trials) was any reaction observed different from the control. The same response occurred if mandibular glands were presented when crushed together with other glands (such as venom and salivary glands) (0 of 6 trials).

DISCUSSION

Morphometric analysis shows that there are no differences between dominant and subordinate females and between foundresses and workers of *P. dominulus* in the size of ectal mandibular glands. This is consistent with findings in *P. fuscatus* by Downing and Jeanne (1983), who measured the total size of the gland. However, this does not seem to be a good indicator of the actual functional activity of the glandular cells, as it is mainly determined by the size of the reservoir. On the other hand, it is known that glandular cells are particularly active in preemergence foundresses with respect to other phases of the seasonal cycle (Fortunato et al., 2000b). The preemergence phase is critical for *Polistes*, as nests are under heavy predation pressure (Yamane, 1996).

Chemical analysis of the secretion has identified a range of acids (Table 2), which are irritant and inclined to spread on insect cuticle. Many compounds that we identified have already been described as defensive secretions of other insects (Blum, 1981; Whitman et al., 1990). The characteristic odor of the fresh secretion is probably due to the mixture of aldehydes present but cannot be ascribed to any particular one. An interesting comparison can be made with the Nasonov secretion of *Apis mellifera*, which is produced in the glandular cells as a mixture of geraniol and nerol, which are oxidized enzymically to the corresponding aldehydes, and the aldehydes, on emission, are partly oxidized in the air to geranic and nerolic acids. The pheromone blend as detected is a mixture of alcohols, aldehydes, and acids (Pickett et al., 1981).

Wasps emit mandibular gland secretion only when a colony or a single animal is heavily disturbed; emission occurs at the end of a behavioral sequence that is typical of various social wasps (Starr, 1990). It can occur in any part of the day or of the colonial cycle. Rau reported a colony of *Polistes variatus* that, when disturbed, emitted a strong and sweetish odor easily detectable by the observer (Rau, 1939, page 37). There were no differences detectable between foundresses and workers in nest defense; while males seem to release the secretion only when captured. As our experiments indicate, the secretion does not possess an alarm function but, according to behavioral observations and to the characteristics of some of its compounds, it could be used as a defensive weapon. However, although this effect is still to be clarified, some hypotheses can be proposed. If the secretion is applied to an enemy body (other predatory insects) during a bite, it can act as an irritant; if it is vaporized in the air, it could act as an odorous warning mainly against vertebrate, macrosmatic, predators. The sting is efficient against predators only when it is used in contact with an aggressor. Wasps can prevent predators from approaching their colonies by attacking them in flight, but at night *Polistes* do not fly. A nocturnal predator such as a rat could get close enough to a nest to take advantage of the immature brood and to cause some damage to a nest before being repelled by the occupants. If stung by the wasps, the predators could connect the pain with the strong odor emitted by the insects during the defensive reaction and manage to avoid future possible unpleasant encounters. Thus, the odor (together with buzzing) would function in the dark the same way as the color and alarm movements act in the light. Experimental bioassays are necessary to confirm these hypotheses.

Acknowledgments—This work was supported by the European Commission through the Social Evolution network of the Universities of Aarhus, Firenze, Keele, Sheffield, Uppsala, Würzburg, and ETH Zürich, through the Training and Mobility of Researchers (TMR) program (contract ERBFMRXTC960072). Part of the research was also performed with funds from the Italian MURST (ex 60% and ex 40%). We thank Prof. Joan E. Strassmann and Dr. Rita Cervo who kindly revised an earlier version of this paper.

Abstract—Ant–plant mutualisms may provide indirect evidence for costs of antiherbivore defenses when plants demonstrate trade-offs between allocating resources and energy into ant attractants versus chemical defenses. We tested the hypothesis that ecological trade-offs in defenses are present in *Piper cenocladum*. This plant possesses two distinct defenses: food bodies that attract predatory ants that destory herbivore eggs and amides that deter herbivores. Previous studies have demonstrated that the food bodies in *P. cenocladum* are an effective defense because the ants deter herbivory by specialist herbivores. Amides in other *Piper* species have been shown to have toxic qualities, but we tested the additional hypothesis that these amides have an actual defensive function in *P. cenocladum*. To test for ecological trade-offs between the two putative defenses, fragments of *P. cenocladum* were examined for the presence of amides both when the plant was producing food bodies and when it was not producing food bodies. Plants with active ant colonies had redundant defenses, producing food bodies and high levels of amides at the same time, but we detected a trade-off in that they had significantly lower levels of amides than did plants with no ants. To test for the defensive value

of *P. cenocladum* amides, we used an ant bioassay and we examined herbivory results from previous experiments with plants that had variable levels of amides. These tests demonstrated that amides are deterrent to omnivorous ants, leaf cutting ants, and orthopterans. In contrast, the resident *Pheidole bicornis* ants are effective at deterring herbivory by specialist herbivores that oviposit eggs on the plant but not at deterring herbivory by nonresident omnivores. We concluded that although both amides and food body production appear to be costly, redundancy in defenses is necessary to avoid damage by a complex suit of herbivores.

Key Words—*Piper cenocladum*, ant plants, chemical defense, trade-offs, amides, herbivory, predation, Costa Rica, mutualism.

INTRODUCTION

Defenses against herbivores are assumed to be costly in terms of fitness-enhancing functions (Cates and Orians, 1975; Levin, 1976; Fox, 1981; Gould, 1983, 1988; Gershenzon, 1994; Sagers and Coley, 1995; Elle et al., 1999), but these costs are presumably outweighed by the benefits associated with lower levels of herbivory (Zangerl and Bazzaz, 1992; Simms, 1992). As a result of these costs, ecological and evolutionary defensive trade-offs are expected when resources are limited (Rehr et al., 1973; Simms, 1992). For example, a plant that invests heavily in trichomes as a defense should have low levels of chemical defenses compared to a similar species that has a low density of foliar trichomes or compared to an individual of the same species that has decreased its investment in trichome production. Such trade-offs can be difficult to detect (Simms, 1992), and some authors have even found that allocation of resources to multiple defenses is common in plants that need to defend against many different types of herbivores (e.g., Lindroth and Hwang, 1996).

While the presence of trade-offs is consistent with the hypothesis that defenses are costly, allocation of resources to multiple defenses, or redundancy in defenses (Romeo et al., 1996), does not imply absence of cost nor does it exclude the possibility of ecological trade-offs. Limited resources can still cause reduction of one redundant defense in response to an increase in another. Nevertheless, studies uncovering redundant defenses in ant–plant mutualisms have been used to argue that trade-offs between antiherbivore defenses do not occur and that the defenses are not costly because plants are able to allocate resources and energy into chemical defenses as well as ant attractants (biotic defenses). Steward and Keeler (1988) found that the mean number of different indole alkaloid compounds was not lower in species of *Ipomoea* that produce extrafloral nectaries compared to nonnectary plants; these results have been used as weak evidence that neither alkaloids nor nectaries are costly (Simms, 1992). Letourneau and Barbosa (1999) found that a mechanical defense (trichomes) in *Endospermum*

was induced both in the presence and absence of a biotic defense (ant defenders); this result implies that the mechanical defense is costly because it is induced (Baldwin, 1998), but that there is no trade-off between the mechanical and biotic defense. Janzen (1973) found that individuals of five *Cecropia* species found in areas without mutualistic *Azteca* ants did not produce mullerian bodies for these ants; he concluded that this biotic defense was metabolically expensive, but he did not examine the system for trade-offs with production of chemical defenses.

Only one study with ant–plant mutualisms has indicated that a trade-off may exist between biotic and chemical defenses, suggesting that both types of defenses are costly. Rehr et al. (1973) found that *Acacia* species without mutualistic *Pseudomyrmex* ants had leaves with cyanogenic glycosides, whereas a species with resident ants did not have cyanogenic glycosides. Furthermore, diets made from the nonant species adversely affected the feeding efficiency of *Prodenia eridania* (Noctuidae) larvae. These results have been used as evidence to support the hypothesis that there are costs associated with biotic defenses as well as chemical defenses (Simms, 1992). However, HCN did not affect the larvae in this study (Rehr et al., 1973), thus their conclusions rely on the assumption that the nonant *Acacias* contained an unidentified defensive compound that affects herbivores; it is equally plausible that nutritional factors other than plant defenses affected larval feeding efficiency.

We tested the general hypothesis of trade-offs in energy and resource allocation to competing defenses using an ant plant that facultatively produces food bodies in the presence of a specific ant species and that varies in levels of defensive secondary compounds. *Piper cenocladum* (Piperaceae) is an understory shrub that produces lipid- and amino acid-rich food bodies for a resident ant, *Pheidole bicornis* (Formicidae: Myrmicinae), which protects the plants from specialist herbivores (Letourneau, 1983). Plants in the Piperaceae commonly have high levels of secondary compounds that have antifeedant activities (reviewed by Parmar et al., 1997), and *P. cenocladum* has high levels of three amides that may be deterrent to herbivores (Dodson et al., 2000; Dyer and Letourneau, 1999a). We conducted a study to test the hypothesis that production of food bodies and secondary compounds is metabolically expensive so that high investment in one defense will lead to absence or lower levels of the other defense. Regardless of the presence of trade-offs, the fact remains that this plant species has redundancy in its antiherbivore defenses; thus we also tested the hypothesis that the multiple defenses are necessary because amides in *P. cenocladum* deter those consumers that are not deterred by ants: generalist herbivores and omnivores.

METHODS AND MATERIALS

Study System. Piper cenocladum is an understory shrub (usually less than 4 m tall) common in lowland wet forests in Costa Rica (Burger, 1971). The species

reproduces both vegetatively through layering (fallen shrubs root adventitiously) or fragmentation (petioles and twigs break off and root) and through seed (Gartner, 1989; Greig, 1993). The plant is commonly found as a shrub as well as a fragment (Gartner, 1989), and the biology of the two architectures can be very different (Dyer and Letourneau, 1999b). The leaves are large (most leaves fall within the range of 86–430 cm^2 when fully expanded) and long-lived (approximately 2 years), and opalescent food bodies are produced on the adaxial surface of sheathing leaf bases (petiolar cavities) when occupied by *Pheidole bicornis* ants.

The herbivores most commonly found feeding on *Piper* ant plants at our study site are specialist lepidopterans and coleopterans. Feeding damage from generalist herbivores, including leafcutter ants (Hymenoptera: Formicidae: *Atta cephalotes*) and orthopterans (Orthoptera: Tetigoniidae, Acrididae: *Microtylopteryx hebardi*, and Eumasticidae: *Homeomastax robertsi*) is occasionally found. The main herbivores that eat leaf tissue are geometrid moth larvae (Lepidoptera: Geometridae: *Cambogia* sp. and *Eois* sp.), skippers (Lepidoptera: Hesperiidae: *Quadrus cerealis*), saddleback caterpillars (Lepidoptera: Limacodidae), weevils (Coleoptera: Curculionidae: *Ambates* spp.), and at least 10 species of flea beetles (Coleoptera: Chrysomelidae: *Physimera* spp.) (Marquis, 1991; Dyer, Letourneau, and G. Gentry unpublished data).

Pheidole bicornis is a small, dimorphic species that occupies *Piper cenocladum*, harvests the food bodies produced by the plant, and removes insect eggs, some vines, and small phylloplane particles from the leaves (Risch et al., 1977; Letourneau, 1983, 1998). Production of food bodies by the plant is induced by an unknown compound produced by the ants (Dodson et al., unpublished data), and the food bodies are produced continually as a source of nutrition for the ants, in contrast to the occasional herbivores ants collect from the plant surface (Letourneau, unpublished data). Other species of *Pheidole* and other ants are occasionally found in the petiolar cavities of *P. cenocladum*, but they do not induce food body production by the plant.

The phytochemistry of the family Piperaceae and the genus *Piper* is well documented. Members of the genus *Piper* are known to produce alkaloids, aromatic hydrocarbons, oxygenated cyclohexanes, terpenes, chalcones, flavones, phenyl propenes, lignans, neolignans, and amides of a characteristic type sometimes referred to as *Piper* amides (reviewed by Parmar et al., 1997). These amides contain a phenyl moiety with a variable length carbon side chain (typically with at least one unsaturation) ending in a carbonyl carbon. The nitrogen-containing portion of the amide is derived from piperidine, pyrrole, or an isobutyl group and may contain an unsaturation and/or a carbonyl group. *Piper cenocladum* contains several amides at high concentrations (up to 0.58% dry weight): piplartine, 4′-desmethyl piplartine, and cenocladamide (Dodson et al., 2000). To our knowledge, none of the other *Piper* ant plants (*P. sagittifolium* C.DC., *P.*

obliquum Ruiz & Pavon, and *P. fimbriulatum* C.DC.) have been investigated for secondary compounds. A closely related species without ant mutualists, *Piper imperiale*, also contains high levels of amides (C. Dodson and J. Searcy, unpublished data). Many *Piper* amides that have been investigated for biological activity have been demonstrated to be insecticidal (Gbewonyo et al., 1993; Su and Horvat, 1981; Miyakado et al., 1989) or deterrent to leaf-cutting ants (Capron and Wiemer, 1996). One of the amides in *P. cenocladum*, piplartine, is known to be cytotoxic in vitro (Duh et al., 1990).

Study Site. Plant and insect collection areas were located at the La Selva Biological Station, Heredia Province, Costa Rica, located at 10°25′N, 84°05′W at ca. 100 m elevation on the Caribbean slope (Hartshorn and Hammel, 1994). The natural history of this lowland wet forest is described in great detail in McDade et al. (1994). We used plant fragments from previous experiments that had been established on a hectare of primary forest at about 1400 m on the Sendero Jaguar trail at La Selva. The soil at this site is the poorest of soil types where *P. cenocladum* grows at La Selva (Sollins et al., 1994), and the understory vegetation is similar to other primary and secondary forest areas where shrubs and fragments are found.

Quantification of Amides. We examined amides in experimental fragments. Plant samples were prepared as described in Dodson et al. (2000) and included 1-g replicate samples from individual plant fragments from La Selva. We harvested leaves from a two-year experimental study where fragments had been established in the forest (see Dyer and Letourneau, 1999a, for complete methods). The leaves were harvested from five samples of *P. cenocladum* fragments with ants (each sample included a homogenate of plants, with a mean of 4.4 plants per sample) and five samples of *P. cenocladum* fragments from that ants had been excluded (a mean of 3.8 plants per sample). We chose most recently expanded leaves that were similar in size and that had low levels of herbivory (<10%) and low epiphyll loads. Ant exclusion was accomplished by applying to the petioles one to two drops of dilute Diazinon insecticide (0.85 mg wettable powder per liter of distilled water) every two to three months for 1.8 years (see Dyer and Letourneau, 1999a for methods). Experiments examining the effects of these dilute insecticide applications indicated no measurable effects of the insecticides on plant biomass, herbivory, epiphyll cover, and other variables (Letourneau and Dyer, 1998; Letourneau, Dyer, and G. Vega, unpublished observations). When the plant fragments were harvested, mean number of ants per plant per sample was 4 ± 3 SE for the ant exclusion plants and 129 ± 56 SE for the unmanipulated ant plants. None of these 10 samples were manipulated in any other way (i.e., no fertilizer was added to the soil, light was not manipulated).

Leaves were dried at room temperature, ground, and extracted with 95% ethanol; the amides being isolated, as well as most putative *Piper* plant defenses, are stable at room temperature (Dodson et al., 2000; Parmar et al., 1997). The

crude extract residue was resuspended in 3 : 1 water–ethanol, which was then exhaustively extracted with chloroform and quantitatively analyzed by GC-MS using commercially available piperine as an internal standard at the 80 μg/ml level. Five point calibrations (50, 100, 200, 300, and 500 μg/ml) were prepared using synthetic piplartine (r^2 = 1.000) and synthetic 4′-desmethylpiplartine (r^2 = 0.999). Cenocladamide is unstable in solution, so its structural isomer, 4′-desmethylpiplartine was used as a standard, thus all concentrations we report for cenocladamide are estimates (Dodson et al., 2000).

We used multivariate analysis of variance (MANOVA) to examine the effects of ant exclusion on the concentrations of the three amides. We used profile analysis (*sensu* Tabachnick and Fidell, 1996) to detect any differences in responses of the three amides to the ant exclusion. The Wilks lambda statistic was used for all hypothesis tests.

Assays for Other Compounds. To examine the possibility of trade-offs between ant defense and other chemical defenses, we assayed for other common defensive compounds. TLC and GC-MS of all crude residues and ^{1}H NMR of the other fractions obtained in previously described chromatography (Dodson et al., 2000) were conducted to detect phenyl propanoids, aromatic hydrocarbons, oxygenated cyclohexanes, lignans, and neolignans in bulk samples of naturally occurring shrubs with and without ants. A separate sample of crude extract was screened for alkaloids (differential pH partitioning and TLC with iodoplatinic acid visualization).

Deterrence of Amides to Omnivores and Generalist Herbivores. Leaves from bulk shrub samples with high (1.36% dry weight) versus low (0.41% dry weight) levels of total amides were tested for palatability to insects using a bioassay with the giant tropical ant, *Paraponera clavata* (Formicidae: Ponerinae). The two distinct levels of amides were obtained by using naturally occurring shrubs without ants (high amides) and shrubs with ants (low amides). The *Paraponera* bioassay has successfully identified deterrent compounds in caterpillars and herbivore toxins in plants such as nicotine and solapalmatine in normal plant concentrations (Dyer, 1995, 1997; Dodson, Dyer, and G. Gentry, *unpublished data*). The bioassay only uncovers very deterrent compounds because the ants are less selective than other arthropods with respect to diet (Dyer, 1997), and extracts that deterred the ants were even more deterrent to wasps and bugs (Dyer, 1997). Complete methods for the bioassay are in Dyer (1995). Briefly, 15 g dry weight of each plant treatment (ants versus no ants) was extracted in 250 ml methanol. A 6.7% solution of this extract in 20% (by weight) sugar water and a control (6.7% methanol in 20% sugar water) were offered simultaneously to ants in 2.4-ml microcentrifuge tubes. Tubes were weighed before and after being exposed to foraging ants for 1 hr. A total of 150 extracts (each offered with a control tube) per plant treatment were offered to 15 colonies found between 2000 and 3200 m along the Sendero Tres Rios trail at La Selva. Adjusted consump-

tion differences (*sensu* Dyer, 1995) were calculated for each offering. This value compares consumption of extract versus control vials, adjusting for total consumption; for unpalatable extracts, a higher positive adjusted consumption difference indicates greater unpalatability. Mean adjusted consumption differences for the two plant treatments (high versus low amides) were compared using a t test ($N = 15$ colonies).

We conducted new analyses on folivory data from concurrent experiments (Dyer and Letourneau, 1999a,b) to test the hypothesis that *P. cenocladum* amides are deterrent to generalist herbivores. In one experiment (Dyer and Letourneau, 1999a,b) all leaves from 47 experimental plant fragments with ants and all leaves from 44 fragments from which ants had been removed were examined for damage from various orthopterans. This is the same experiment from which leaves were harvested from fragments for the chemical analysis. In a second experiment (Dyer and Letourneau, 1999b), all leaves from 40 shrubs with ants and all leaves from 37 shrubs from which ants had been excluded were examined for damage from *Atta cephalotes* and various orthopterans. We used chi-square statistics to test hypotheses of association between presence of ants and presence of herbivore damage.

RESULTS

Assays with the shrub samples for potential defenses other than amides were negative. TLC and GC-MS of all crude residues and ^{1}H NMR of the other fractions obtained in the previously described chromatography (Dodson et al.) indicates the absence of phenyl propanoids, aromatic hydrocarbons, oxygenated cyclohexanes, lignans, and neolignans. The screen for alkaloids was also negative.

Plant fragments from which ants were excluded had significantly higher concentrations of total amides (Table 1, $F_{1,8} = 8.3$, $P = 0.02$), and the profile analysis revealed that the magnitude of this increase did not differ between the three amides ($P > 0.05$ for all comparisons). For plant fragments maintained with insecticide applications to remove ant colonies, overall amide concentrations were 0.2 times greater than in plants with ants, which is a smaller difference than that reported for naturally occurring shrubs (3.3 times greater levels of amides in shrubs without ants) (Dodson et al., 2000). The overall levels of amides in fragments appear to be higher than those reported for naturally occurring shrubs (Dodson et al., 2000), but other differences between the fragments and shrubs were not controlled (i.e., many of the shrubs came from a different site).

The bioassays demonstrated that leaves from shrubs without ants were significantly more unpalatable than leaves from shrubs with ants. The mean adjusted

TABLE 1. CONCENTRATIONS OF *Piper* AMIDES IN *P. cenocladum* EXPERIMENTAL FRAGMENTS WITH AND WITHOUT *Pheidole bicornis* ANTS[a]

Compound	Concentration (% dry mass)	
	Ants present	Ants excluded
Piplartine	0.37	0.38
4′-desmethylpiplartine	0.39	0.43
Cenocladamide	0.64	0.93
Total amides	1.40	1.74

[a] Exclusion of ants was accomplished by applying dilute insecticide (Dyer and Letourneau, 1999a).

consumption difference was 0.055 for ant leaves and 0.266 for nonant leaves ($t_{28} = 2.8$, $P = 0.008$). Both of these values are relatively high, and the value for nonant leaves is not significantly different from plants with high levels of toxic compounds such as nicotine from cigarette tobacco (Dodson, Dyer, and G. Gentry, unpublished data).

Orthopteran damage was found on 18 of 91 *P. cenocladum* plants in the fragments experiment, and 78% (14) of these were plants with ants ($\chi^2_1 = 6.1$, $P = 0.01$). In the shrub experiment, orthopteran damage was found on 43 of 77 plants, and 27 (63%) of these were plants with ants ($\chi^2_1 = 4.6$, $P = 0.03$). Damage from the leaf cutting ant, *A. cephalotes*, is generally rare on *P. cenocladum*, but for the shrub experiment, 5 of 77 plants had ant damage, and all of these were plants with ants ($\chi^2_1 = 4.9$, $P = 0.03$).

DISCUSSION

A trade-off was evident between biotic and chemical defenses in experimental fragments of *P. cenocladum*. Overall levels of amides were higher when ants were either absent or at very low numbers in *P. cenocladum*. These experimental data corroborate correlational data that also demonstrated a defensive trade-off: naturally occurring shrubs without ants had 3.3 times higher concentrations of total amides than shrubs with ants (Dodson et al., 2000). Such a trade-off suggests that both biotic and chemical defenses are costly. If both defenses were low in material and energy costs, the plant would experience minimum tissue loss from herbivores by having both the ants and high levels of the amides, since it is likely that together they protect the plant against a broad range of different herbivores. Letourneau (1983; also see Letourneau and Dyer, 1998) has demonstrated that *Pheidole bicornis* ants cause lower lepidopteran folivory by removing eggs from the surface of the leaf. However, there is no evidence that these ants are able to decrease levels of herbivory by orthopterans and *Atta cephalotes*

(leaf cutting ants), since they are too small to deter such large herbivores. *Piper* amides could deter orthopteran herbivory by decreasing their feeding efficiency and deter *A. cephalotes* herbivory (Capron and Weimer, 1996) through some other mechanism such as antifungal properties.

Examination of leaves from previous experiments (Dyer and Letourneau, 1999a,b) corroborated the hypothesis that *P. cenocladum* amides are deterrent to generalist herbivores. Damage from leaf cutting ants and orthopterans was more common on plants with ants, and we have demonstrated that *P. cenocladum* shrubs and fragments with ants have lower levels of amides than those without ants. Furthermore, the bioassays demonstrate that plants without ants are more unpalatable than plants with ants. For the orthopteran data and the bioassay data, the plants were the same plants that we analyzed for amides, with ant-exclusion plants having higher levels of amides; thus, higher amide concentrations are present in plants that are avoided more by orthopterans and ants. However, orthopteran damage was still low when ants were present, and the levels of amides in ant-containing plants were still high enough to deter ants in the bioassay, so it is likely that plants are protected from generalists by amides whether or not they have ants—the protection is simply enhanced when the levels of amides increase. These results support recent hypotheses that stress that importance of redundancy in defenses when faced with a diverse herbivore assemblage (Romeo et al., 1996).

Since each mole of each amide contains a mole of nitrogen, the concentrations found in both our manipulated plants and the naturally occurring shrubs represent a considerable investment (Gershenzon, 1994) by these plants, which are nutrient limited (Dyer and Letourneau, 1999a). Results from other studies with *P. cenocladum* suggest that not only are amides costly, but they are more expensive to synthesize than food bodies. Plants grown in an experiment where all herbivores were excluded had a greater total biomass when ants were present and the plants were presumably producing lower levels of amides (Dyer and Letourneau, 1999a). *Piper* amides (Dodson et al., 2000) and food bodies (Risch and Rickson, 1981) both represent considerable investments of nitrogen and carbon, but it is possible that the costs of biosynthetic machinery, storage structures and enzymes, and overall investment of raw materials (reviewed by Gershenzon, 1994) for the amides is higher per plant than for the food bodies. One alternative mechanism for this result, that the ants provide nutrients to the plants in the form of nitrogenous wastes, has not been supported by experiments and field observations (Letourneau, 1983). It has not escaped our notice that other secondary metabolites may also increase when ants are excluded. We have eliminated this possibility for all probable candidates except the terpenes and flavanoids.

We cannot completely rule out the possibility that greater levels of herbivory on the ant-excluded plants induced increased levels of amides in those plants. However, the correlational results for shrubs (Dodson et al., 2000) only

included plants with low levels of herbivory (less than 10%) that had the same leaf size, levels of damage, and epiphyll load. For the fragments, which had lower levels of herbivory for ant versus nonant plants (Dyer and Letourneau, 1999a), the differences in amide concentrations were not as great as they were in the shrubs, which suggests that induction was not an important mechanism in our results. It is also possible that stressing the plants by adding insecticide to the petioles induced an increase in defensive compounds, but we have evidence that Diazinon has minimal physiological effects on *P. cenocladum* (Letourneau and Dyer, 1998; Dyer and Letourneau, 1999b), and we did not add insecticides to any of the shrub petioles.

Thus, in this ant–plant system, there appear to be trade-offs between investment in chemical defenses and ant attractants. Both shrubs and fragments utilize the two defenses and both exhibit the trade-off. Redundancy in defenses is also important to deter a diverse suite of herbivores, and the plant will invest in both defenses if possible.

Acknowledgments—This study was funded by NSF grant DEB-9318543 to D.K.L., faculty research grants from the UCSC Academic Senate and Social Sciences Division to D.K.L., and an NSF REU grant to D.K.L., L.A.D., and C.D.D. A portion of the study was funded by an Earthwatch grant and a National Geographic grant to L.A.D. We thank the Organization for Tropical Studies for use of their facilities and for valuable logistical help. Excellent technical assistance was provided by G. Vega, R. Krach, J. Sorensen, G. Gentry, J. Searcy, J. Jay, Z. Wright, and 12 Earthwatch volunteers. We are grateful to G. Gentry for comments that improved previous drafts of the manuscript.

Abstract—We investigated the effects of plant density on plant size, leaf total soluble protein content, and constitutive and wound-induced levels of proteinaceous trypsin inhibitors in pot-grown *Brassica napus* seedlings in two greenhouse studies. We manipulated plant density by varying the number of intraspecific neighbors surrounding a target plant in the center of each pot. In general, constitutive and induced levels of trypsin inhibitors were significantly reduced by competition in a density-dependent manner, to the extent that induction was greatly reduced or abolished in target plants surrounded by six neighbors. To investigate whether the effects of plant density on inhibitor production were mediated by nutrient availability, we manipulated the concentration of a complete fertilizer applied to target plants surrounded by six neighbors in two greenhouse studies. In general, constitutive and wound-induced levels of inhibitors in plants surrounded by six neighbors were increased by nutrient addition in a dose-dependent manner, such that wound-induction was completely restored in competing plants under conditions of high nutrient availability. Leaf total soluble protein content, measured only in the second trial of each experiment, was not affected by any of the treatments. The effects of plant density, nutrient addition, and wounding on inhibitor levels in all experiments were independent of their effecs on above-ground plant size at the time of wounding. Overall, our results suggest that decreasing nutrient availability mediates the density-dependent reductions in inhibitor levels in *B. napus* seedings.

INTRODUCTION

Induced defenses to enemy attack have been demonstrated in over 100 plant–herbivore and plant–pathogen systems and appear to be a form of adaptive phenotypic plasticity (Karban and Baldwin, 1997; Cipollini, 1998; Baldwin, 1999; Agrawal 1999). If defense production is costly to fitness in plants, phenotypic plasticity in defense production may have evolved as a cost-saving strategy that enables close phenotype–environment matching and maximizes plant fitness. However, many factors can constrain the induction of defense, potentially placing limits on the benefits of inducibility and preventing perfect phenotype-environment matching (DeWitt et al., 1998). For example, the degree of the induction of defense traits and/or biological resistance in plants can vary with such factors as plant size and age, type and timing of damage, and environmental conditions (Broadway and Missurelli, 1990; Karban; 1993; Baldwin and Schmelz, 1994; Jongsma et al., 1994; Alarcon and Malone, 1995; Gianoli and Niemeyer, 1996; Baldwin, 1999; Cipollini and Redman, 1999; Thaler et al., 1999).

Competition for limited resources is an important environmental factor known to influence many plant processes from the individual to the population and community level (Grace and Tilman, 1990). In terms of insect and disease resistance, some plant populations have been found to be more susceptible to insect attack or disease outbreaks when growing at high density (Colhoun, 1973; Burdon, 1987; Reader, 1992; but see Karban, 1993; Morrison, 1996). For example, we have found that interspecific competition with weeds increases herbivore damage and aphid numbers on *Brassica napus* plants in the field (D. Cipollini and J. Bergelson, unpublished data). This general phenomenon is thought to be partly explained by the presence of favorable microenvironmental conditions (e.g., high humidity, shelter from predators) and plant spatial distributions that facilitate the rapid build-up and spread of insects or disease inoculum among plants at high density (Colhoun, 1973; Reader, 1992). While these effects are undoubtedly important, plants may be unable to fully express constitutive and wound-induced defenses and/or biological resistance under resource-limiting conditions (like high density), thus contributing to their increased susceptibility to natural enemy attack (Clay, 1990). For example, Karban et al. (1989) showed that both reduced soil volume and increased plant density increasingly reduced the induction of biological resistance to mites and *Verticillium* fungi in pot-grown cotton. However, no measures of physiological or morphological defense traits were made in this study to address possible mechanisms.

Serine proteinase inhibitors are one class of constitutive and inducible defense found widely throughout the plant kingdom. Serine proteinase inhibitors (which are proteins) function by binding specifically with the protein binding site of proteinases (e.g., trypsin and chymotrypsin of insects and mammals), thereby competitively inhibiting their ability to bind and cleave proteins (see Koiwa et al., 1997, for review). Although their effectiveness as a defense against herbivores can vary by plant and herbivore species (Bolter and Jongsma, 1995; Broadway, 1995), proteinase inhibitors have been shown to reduce the growth and survival of many insects when present in artificial diets (e.g., Broadway and Duffey, 1986) and to reduce both insect feeding rate and performance when expressed in transgenic plants (e.g., Johnson et al., 1990; McManus et al., 1994). Moreover, the induction of serine proteinase inhibitors by wounding or insect attack, along with the induction of other defense proteins and compounds, is commonly associated with induced resistance to insects (Broadway et al., 1986; Thaler et al., 1996; Stout et al., 1998b).

We investigated some of the potential ecological constraints on the expression of a chemical defense by examining the effect of increasing plant density on constitutive and wound-induced levels of trypsin inhibitors in *Brassica napus* L. To investigate whether effects of plant density were mediated by nutrient availability, we examined the effects of increasing nutrient availability on constitutive and wound-induced levels of trypsin inhibitors in plants grown at high density. We also examined the extent to which variation in above-ground growth or total leaf soluble protein content explained the effects of plant density and nutrient availability on inhibitor production. We found that constitutive and local wound-induced levels of inhibitors were reduced by the presence of competitors in a density-dependent fashion and that nutrient addition could increasingly restore constitutive levels and wound-inducibility in plants grown at high density. Effects of plant density and nutrient availability on inhibitor production were independent of their effects on above-ground growth and were not associated with total leaf soluble protein content.

METHODS AND MATERIALS

Plant Growth. *Brassica napus* L. (Brassicacae) is a self-compatible annual plant that is grown commercially as an oilseed and forage crop that can occasionally escape cultivation and become naturalized in some environments (Duke, 1983; D. Cipollini, personal observation). We used an agronomic cultivar of *B. napus* (cv. Westar), commonly used in agroecological and physiological studies (e.g., Bodnaryk, 1992; Cipollini and Bergelson 2000), in our experiments. Plants were grown in ProMix BX potting soil from seed in 300 ml square pots (7 × 7 cm) in a greenhouse. To reduce genetic variation among replicate plants, we used

seeds gathered from one self-pollinated maternal plant that had been grown under greenhouse conditions very similar to those used in this experiment. Greenhouse photoperiod during experiments was controlled at 16L : 8D. Natural daylengths were extended as necessary with sodium vapor lamps, which were programmed to turn on whenever natural light levels dipped below 400 μmol photons/m^2/sec [photosynthetically active radiation (PAR)] during the 16-hr light period. Mean daytime irradiance during these experiments was ~1000 μmol photons/m^2/sec PAR. Temperatures averaged 26 ± 3°C during the light period and 21.5 ± 2°C during the dark period. Plants were watered daily with tap water and fertilized as indicated in each experiment. The first trial of each of our experiments was performed in the greenhouse at the University of Chicago (UC), while the second trial of each of our experiments was performed in the greenhouse at Wright State University (WSU). The major difference in conditions between the two trials was that daylengths were extended with cool-white fluroescent lighting at WSU, but other unknown differences certainly existed. Because of these differences, each trial was statistically analyzed separately to determine whether the pattern of responses to the treatments in each experiment would be similar under similar (but not identical) growing conditions.

Experiment 1: Effects of Plant Density on Growth and Trypsin Inhibitor Production. In this experiment, we manipulated plant density within pots around a target plant. This approach, termed the "target-neighbor" approach, has been commonly used to examine the competitive strength of individual plants under intra- or interspecific competition (Gibson et al., 1999). We grew target plants from seed in the center of each pot at four densities: (1) alone, (2) surrounded by two neighbors, (3) surrounded by four neighbors, or (4) surrounded by six neighbors. These pot densities correspond to field densities of ~15, 46, 75, and 105 plants/m^2, which are realistic for wild *Brassica* populations in the field (D. Cipollini, personal observation). Two to three seeds were sown at each position in each pot, and plants were selected for uniformity in size and thinned to the proper density and spacing three days after germination. Neighbors in each density treatment were spaced equidistant from the target plant and from each other. All plants in each pot were of the same age. Plants were fertilized once on day 7 following thinning with 50 ml of 200 ppm 15 : 16 : 17 N-P-K (plus micronutrients) soluble fertilizer (Peter's Peat-Lite Special).

Ten days after thinning, we randomly assigned half the target plants in each density treatment to be wounded. We wounded plants by crushing the distal one tenth of the first true leaf with sterilized needle-nosed pliers. Leaf crushing has been widely used in studies on the regulation of proteinase inhibitors in plants (e.g., Jongsma et al., 1994) and enables careful control of the amount and timing of damage applied to each leaf. We determined previously that this minimal amount of damage could effectively induce trypsin inhibitors in this cultivar of *B. napus* (Cipollini and Bergelson, 2000). The induction of trypsin inhibitor

activity in *Brassica oleraceae* (Broadway and Missurelli, 1990), and *Brassica rapa* (D. Cipollini, J. Busch, K. Stowe, E. Simms, and J. Bergelson, unpublished data) by this type of mechanical wounding closely simulates that produced in response to feeding by larval *Trichoplusia ni*. We expect that trypsin inhibitor induction by mechanical wounding simulates induction by natural herbivory in *B. napus* to a large degree, but the absence of herbivore saliva in mechanical wounds and the lack of spatially and temporally variable feeding patterns typical of herbivores certainly influences the degree to which this is true. Prior to wounding on day 10, we measured plant height and length of the first true leaf on all damaged and undamaged target plants. Three days following wounding, the first true leaves from wounded and unwounded target plants in each density treatment were harvested, placed individually in 1.7 ml microfuge tubes, and frozen immediately in liquid nitrogen. Thus, this study focused on locally induced, rather than systemically induced defenses. Leaf samples were stored at −20°C until analysis for trypsin inhibitor activity and soluble protein content as described below. Plants were grown in a completely randomized design on the greenhouse benches and randomly moved twice before wounding and once following wounding. Treatments were replicated 6–10 times.

We analyzed height and leaf length data taken on day 10 with a one-way ANOVA with density as the main effect. We analyzed trypsin inhibitor data with a two-way ANOVA with density (four levels), wounding (+ or −), and their interaction as effects in the model, with and without leaf length and plant height on day 10 as covariates. Because of unequal cell sample sizes, tests of significance were based on type III sums of squares. Data in all experiments were analyzed with SAS using the General Linear Models procedure (Release 6.12, SAS Institute Inc., Cary, North Carolina).

This entire experiment was repeated in a second trial, using five replicate plants per treatment combination. In addition to all of the measures above, total soluble protein content of the first true leaves (which required leaf weighing) was measured for each target seedling in the second trial, as described below. This was done to determine the relationship between trypsin inhibitor content (a soluble protein) and total soluble protein content in first true leaves. Growth and inhibitor data were analyzed separately for each trial. Total leaf protein data generated in the second trial were statistically analyzed in the same way as trypsin inhibitor data.

Experiment 2: Effects of Nutrient Availability on Growth and Trypsin Inhibitor Production. In this experiment, we manipulated nutrient availability to plants through additions of 15 : 16 : 17 N-P-K (plus micronutrients) soluble fertilizer to examine whether nutrient addition could ameliorate the effects of high plant density on inhibitor production. Target plants in each pot were grown surrounded by six neighbors, as described above. The soil used in this study contains a small amount of nutrients that can be depleted by plants in the absence of

additional fertilization, as evidenced by eventual growth limitation (D. Cipollini, personal observation). We fertilized plants 7 and 10 days after thinning with a 100-ml solution of fertilizer at one of the following four concentrations: 0, 50, 100, or 200 ppm. Ten days after thinning, we measured all target plants and wounded half of them in each nutrient treatment as described above. First true leaves were harvested from all target plants three days following wounding and stored until analysis of trypsin inhibitor activity and soluble protein content. Treatments were replicated 8–10 times.

We analyzed height and leaf length data taken on day 10 with a one-way ANOVA with nutrient availability (four levels) as the main effect. We analyzed trypsin inhibitor data with a two-way ANOVA with nutrient availability (four levels), wounding (+ or −), and their interaction as effects in the model, with and without leaf length and plant height on day 10 as covariates. Again, because of unequal cell sample sizes, tests of significance were based on type III sums of squares.

This experiment was also repeated a second time with five replicate plants per treatment combination. Total soluble protein contents of first true leaves were measured in addition to all of the other measures, and total leaf protein data were analyzed in the same way as inhibitor data. Data were analyzed separately for each trial.

Protein Extraction and Analysis of Trypsin Inhibitor Activity and Total Protein Content. To extract soluble proteins, we first ground individual leaf samples directly in the microfuge tubes without buffer, using a Teflon minipestle. A 0.150-ml aliquot of ice-cold 1 mM HCl (Broadway and Missurelli, 1990) was then placed in each tube, and the tubes were vortexed for 10 sec. Samples were then centrifuged as 12,000 *g* for 12 min in a microfuge cooled to 4°C. After centrifugation, the cleared supernatants were transferred into new tubes and used as the soluble protein extracts for both the trypsin inhibitor and total soluble protein content measurements. Extracts were kept on ice throughout the entire procedure and used immediately in chemical analyses.

We analyzed the trypsin inhibitor content of individual protein extracts using a radial diffusion assay through a trypsin-containing agar (Jongsma et al., 1993, 1994), as modified for *B. napus* in Cipollini and Bergelson (2000). In both trials, soluble protein contents of each extract were quantified in all experiments by the method of Bradford (1976), using the Bio-Rad protein dye reagent and bovine serum albumin as the standard. We expressed trypsin inhibitor content of each extract as micrograms of trypsin inhibitor/mg extract protein. This measure should be interpreted as the amount of trypsin inhibitor present per unit extractable soluble protein in a leaf. In the second trial of each density and nutrient experiment, we measured the fresh weight of leaf samples prior to protein extraction in order to determine total soluble protein content of leaf samples, which we expressed as mg total protein/g leaf fresh weight.

RESULTS

Effects of Density on Growth, Inhibitor Production, and Protein Content. In the first trial of this experiment (UC), we found that plant density affected both height ($F_{3,59} = 19.97$, $P < 0.001$), and length of the first true leaf ($F_{3,59} = 6.90$, $P < 0.001$) of 10-day-old *B. napus* seedlings. Height of plants in this experiment increased with increasing density, while leaf length decreased with increasing density (Figure 1A). In the second trial (WSU), plant density affected height ($F_{3,36} = 3.29$, $P = 0.0316$), and length of the first true leaf ($F_{3,36} = 4.68$, $P = 0.007$), in a similar pattern as in the first trial, although plants were slightly smaller overall (Figure 1B).

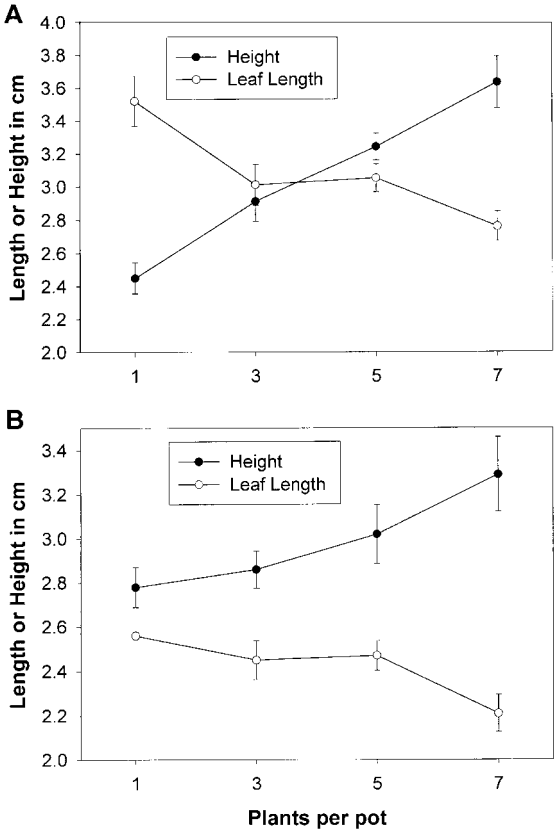

FIG. 1. Effects of plant density on plant height and length of the first true leaf in *B. napus* seedlings. In trial 1 (A), each point is the mean (±SE) of 6–10 plants; in trial 2 (B), each point is the mean (±SE) of 5 plants.

TABLE 1. UNIVARIATE ANOVA OF EFFECTS OF DENSITY, WOUNDING, AND THEIR INTERACTION ON TRYPSIN INHIBITOR LEVELS IN *B. napus* SEEDLINGS (TRIAL 1)

Source	*df*	MS	*F*	*P*

Wounding	1	223.48	25.0	<0.001
Density × wounding	3	41.342	4.62	0.006
Error	55	491.66		

In turn, we found that plant density, wounding, and their interaction all affected trypsin inhibitor levels in *B. napus* seedlings in either one or both trials (Tables 1 and 2). In unwounded plants, there was a density-dependent decline in constitutive trypsin inhibitor levels in the first trial (Figure 2A), that was not apparent in the second trial (Figure 2B). Wounding increased trypsin inhibitor levels in *B. napus* seedlings in both trials, as expected, but the degree of induction was dependent on plant density. In the first trial, inhibitor levels were induced by ~25% by wounding in plants grown alone, but the degree of induction declined with density to the extent that induction was completely abolished in plants surrounded by six neighbors (Figure 2A). Although (perhaps because) absolute levels of inhibitors were lower overall in the second trial, inhibitor levels were induced by ~170% by wounding in plants grown alone, but declined in a density-dependent fashion (i.e., significant wounding × density interaction), to the extent that inhibitor levels were induced by only ~80% in plants surrounded by six neighbors (Figure 2B).

In the second trial of this experiment, total soluble protein content of first true leaves was not affected by density ($F_{3,32} = 1.48$, $P = 0.239$), wounding ($F_{1,32} = 1.38$, $P = 0.249$), or their interaction ($F_{3,32} = 0.30$, $P = 0.823$) (data not shown).

We also found that effects of density and wounding on inhibitor production were largely independent of the effects of these factors on aboveground plant

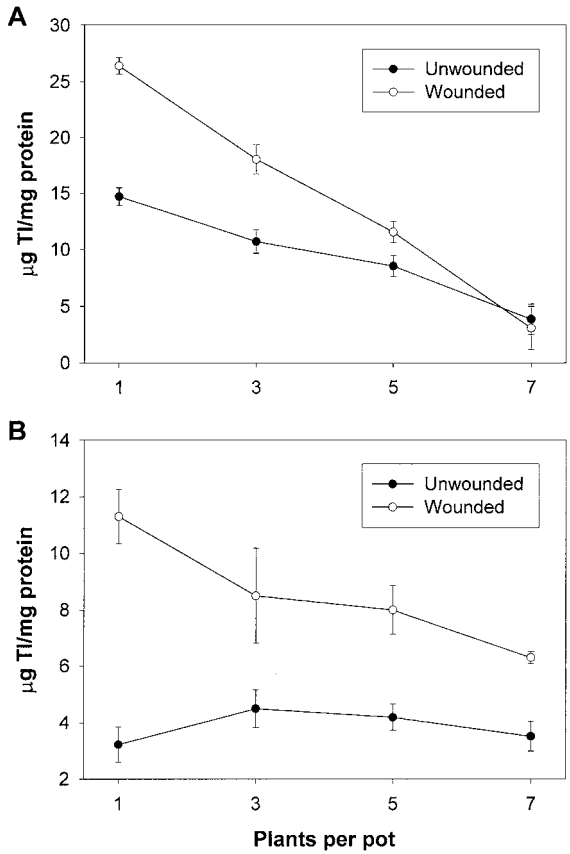

FIG. 2. Effects of plant density on constitutive and wound-induced TI activity in *B. napus* seedlings. In trial 1 (A) each point is the mean (±SE) of 6–10 plants; in trial 2 (B), each point is the mean (±SE) of 5 plants.

size in either trial. When either height or leaf length (on the day plants were wounded) were used as covariates in the ANOVA, significant effects of plant density, wounding, and their interaction on inhibitor levels were still apparent (data not shown).

Effects of Nutrient Availability on Growth and Inhibitor Production. In the first trial of this experiment, we found that nutrient availability had small but significant effects on height ($F_{3,68} = 2.83$, $P = 0.045$) and leaf length ($F_{3,68} = 16.51$, $P < 0.001$) of plants surrounded by six neighbors. Plants were shorter under no or low fertilization than at the highest fertilization level (Figure 3A). Leaves were slightly longer at the highest nutrient level than in all of the other

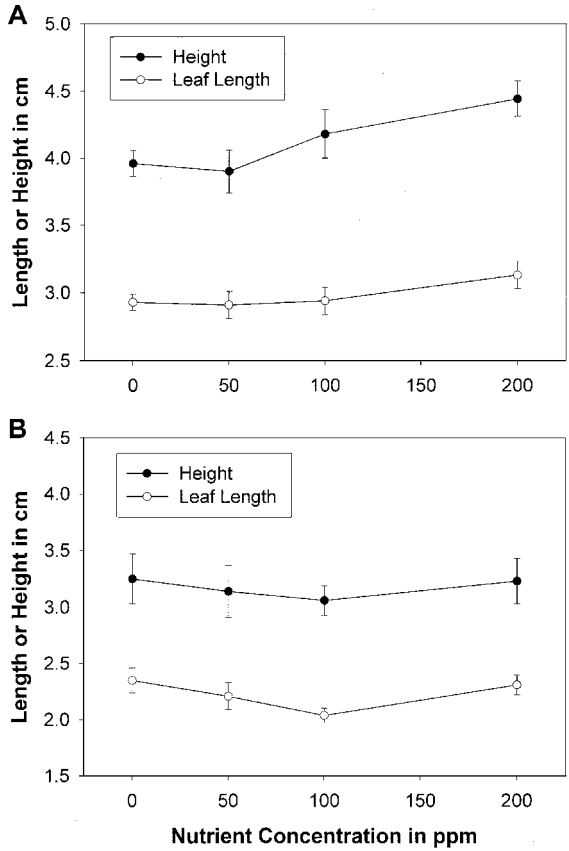

FIG. 3. Effects of nutrient availability on plant height and length of the first true leaf in *B. napus* seedlings grown at high density. In trial 1 (A), each point is the mean (±SE) of 8–10 plants; in trial (B), each point is the mean (±SE) of 5 plants.

treatments. In the second trial, nutrient availability had no effect on height ($F_{3,36} = 0.82$, $P = 0.492$) or leaf length ($F_{3,36} = 1.54$, $P = 0.224$) (Figure 3B), and plants were smaller than in trial 1 (Figure 3b).

In turn, we found that nutrient availability and wounding affected trypsin inhibitor levels in plants surrounded by six neighbors. In the first trial (Table 3), inhibitor levels increased with nutrient availability in a dose-dependent fashion and were higher in wounded plants (Figure 4A). In addition, the degree of induction of inhibitors by wounding was increased by nutrient availability in an additive fashion. While there was little or no induction at low nutrient availability, induction was completely restored by high nutrient availability to

TABLE 3. UNIVARIATE ANOVA OF EFFECTS OF NUTRIENT AVAILABILITY (NUTRIENT), WOUNDING, AND THEIR INTERACTION ON TRYPSIN INHIBITOR LEVELS IN HIGH-DENSITY GROWN *B. napus* SEEDLINGS (TRIAL 1)

Source	*df*	MS	*F*	*P*
Nutrient	3	124.44	10.4	<0.001

levels found in plants grown alone (Figure 4A). In the second trial (Table 4), inhibitor levels increased with nutrient availability in a dose-dependent fashion and were higher in wounded plants (Figure 4B). However, the degree of induction of inhibitors by wounding was increased interactively by nutrient availability. While inhibitors were induced by ~30% in unfertilized seedlings, inhibitors were induced by ~167% in fully-fertilized seedlings, a degree of induction nearly identical to that found in plants grown alone (Figure 4B).

In the second trial of this experiment, total soluble protein content of first true leaves was not affected by nutrient ($F_{3,32} = 0.34$, $P = 0.798$), wounding ($F_{1,32} = 0.001$, $P = 0.962$), or their interaction ($F_{3,32} = 1.17$, $P = 0.335$) (data not shown).

As above, we found that effects of nutrient availability on inhibitor production in this experiment were independent of the effects of these factors on aboveground plant size in either trial. When either height or leaf length on the day plants were wounded was used as the covariate in the ANOVA, significant effects of nutrient availability and wounding on inhibitor levels were still apparent (data not shown).

DISCUSSION

In this study, increased plant density and reduced nutrient availability were found to be important constraints on the constitutive and wound-induced expression of trypsin inhibitors in pot-grown *B. napus* seedlings. While wounding substantially induced inhibitors in plants either grown alone or at high density with ample fertilization, induction was either completely abolished or greatly reduced in plants grown at high density and low levels of fertilization. Constitutive levels of inhibitors were also low in competing plants without ample fertilization. Although plants were slightly smaller and levels of inhibitors were lower overall in the second trial of each of our experiments, the pattern of effects was largely the same as in the first trial. Our findings suggest that high density and/or reduced nutrient availability may be important ecological constraints on the abil-

ity of a plant to actively express chemical defenses to natural enemies. If this finding is also true in the field, it may lead to increased herbivore damage under such conditions. Furthermore, if the expression of chemical defenses is sensitive to environmental conditions, then not only the benefits, but also the costs of induced resistance in plants will likely vary across a range of environmental variation in the field (Baldwin, 1998; Baldwin et al., 1998). For example, Bergelson has shown that fitness costs of the constitutive expression of resistance in both wild lettuce (Bergelson, 1994b) and *Arabidopsis thaliana* (Bergelson 1994a) can vary with plant density and/or nutrient availability. Likewise, van Dam and Baldwin (1998) have shown that fitness costs of jasmonate-induced defense in tobacco are more apparent when induced plants compete with an uninduced neighbor. Baldwin and Hamilton (2000) have shown that such costs are associated with a reduced ability of jasmonate-induced plants to compete for nitrogen with uninduced neighbors. To more fully understand the range of costs and benefits of plant resistance, relevant environmental variables, such as competition, should be incorporated more often into studies on the regulation and ecological role of induced defenses.

In studies of the effects of environmental factors on the induction of defense, it is important to distinguish whether the environmental factors directly affect induction (e.g., through a resource-based constraint) or indirectly affect induction through modulation of plant size or developmental stage. This is particularly important when induction is developmentally regulated, as is true for the induction of trypsin inhibitors in *Brassica oleracea* (Broadway and Missurelli, 1990) and the induction of oxidative enzymes in tomato (Cipollini and Redman, 1999). Gianoli and Niemeyer (1996) have shown that increased temperature reduced the induction of defensive hydroxamic acids by aphid feeding in wheat. However, the effect of temperature on induction disappeared when its effect on plant growth rate was statistically controlled. In our experiment, significant effects of nutrient availability and plant density on inhibitor levels were independent of the effect of these factors on above-ground plant size at the time of wounding. When compared at a common size, increased plant density and reduced nutrient availability still constrained constitutive and induced inhibitor production. The relationship between inhibitor production and below ground growth is unknown, however. In turn, the effects of plant density, nutrient availability, and wounding on inhibitor levels were not associated with effects of these factors on leaf total soluble protein content, which were not significant. This finding is important in order to demonstrate that the environmental control of the constitutive or wound-induced production of inhibitors (which are soluble proteins) is not simply passively tied to total soluble protein production and that differences in inhibitor production among treatments are not an artifact of the manner in which we expressed inhibitor content (micrograms of trypsin inhibitors per milligram of extract protein).

The finding that plant density and nutrient availability could regulate inhibitor production independently from their effects on plant growth or total protein production suggests that inhibitor production is tuned to internal resource levels. Inhibitor induction in plants at high density and low nutrients levels may have been passively limited by resource availability. If this were the case, however, we would expect that total leaf soluble protein contents also would have been affected by high density or low nutrient levels, but they were not. On the other hand, if inhibitor production is costly to fitness, plants may have prioritized resources to important functions other than inhibitor production under conditions of resource stress (perhaps toward the synthesis of proteins that improve nutrient uptake) that may serve in some way to maximize growth or competitive ability. Indeed, inhibitor production was much more greatly affected by density or nutrient availability in our study than was above-ground growth. We do not know if reduced inhibitor production and declines in inducibility are the direct result of active suppression of inhibitor synthesis, the indirect result of resource limitation caused by allocation of resources to other functions, or the result of some other mechanism. If induced defense in plants is a form of adaptive phenotypic plasticity and is produced optimally, as has been suggested (Cipollini, 1998; Agrawal 1999; Baldwin, 1999), the suppression of allocation to induced defenses in certain environments to the benefit of growth could be an ecological cost-saving strategy with adaptive value. This possibility has rarely been considered, in part because the degree of wound induction of some defense compounds, such as furanocoumarins in parsnip (Zangerl and Berenbaum, 1994/95) and nicotine in *Nicotiana attenuata* (Lynds and Baldwin, 1998), can show little sensitivity to nutrient and/or light availability. In the only study we are aware of that investigated this possibility, Baldwin and Hamilton (2000) demonstrated that induction of nicotine synthesis in competing *Nicotiana sylvestris* plants with methyl jasmonate led to reduced fitness of plants grown with uninduced neighbors. To apparently minimize such costs, however, competing jasmonate-induced plants utilized a greater proportion of their acquired nitrogen in growth and reproduction than in nicotine synthesis relative to uninduced neighbors, which is consistent with the mechanism that we suggest is driving our findings. If defense cost savings under resource stress is the adaptive mechanism driving such results, it will be interesting and important to identify situations under which such cost savings ultimately translate into fitness benefits in the field.

While it is not known which nutrient may have been most limiting to inhibitor production in our experiments, proteinase inhibitors are nitrogen-rich proteins. Bolter et al. (1998) have shown that nitrogen deprivation severely reduced the wound induction of cysteine proteinase inhibitors in potato and tomato plants. In contrast, Stout et al. (1998a) have shown that nitrogen availability had little effect on the induction of chymotrypsin inhibitor activity in tomato, although inhibitor activity was not adjusted for extract protein con-

tent in their study. Unfortunately, the relationship between the effects of nitrogen availability on induced inhibitor levels and plant growth in either of these studies is not known. In our high-density treatments, plants exhibited a morphological response indicative of the shade avoidance syndrome (e.g., increased stem elongation at the expense of leaf area production) (Dudley and Schmitt, 1996; Cipollini and Schultz, 1999). While this suggests that light limitation may have partially mediated the results in our density experiments, it has been shown that plants can induce the shade avoidance response using light cues reflected from neighbors before significant light limitation occurs (Ballaré et al., 1990). Based on the relative lack of mutual shading among plants grown at high density in our study, we do not think that light was the primary limiting factor on inhibitor production in our experiment. Instead, because nutrient addition could increasingly restore constitutive and wound-induced levels of inhibitors in high density plants to levels found in plants grown alone, we believe that the effects of density on inhibitor production in our study were largely mediated by nutrient availability (and possibly nitrogen availability in particular). Nonetheless, increased light levels have been shown to increase serine proteinase inhibitor production in wounded tomato plants (Gustafson and Ryan, 1976), and light limitation would likely become more important as plants grow larger and the degree of mutual shading increases.

Regardless of the underlying physiological mechanisms, our results suggest that the ability of a brassicaceous plant to defend itself from natural enemy attack by using proteinase inhibitors (or other chemical defenses) may be severely constrained when plants are growing at high density and/or under conditions of low nutrients in the field, which could lead to increased herbivore damage. We recently found that weed competition can increase herbivore damage and aphid number on this cultivar of *B. napus* in the field (D. Cipollini and J. Bergelson, unpublished data), which may be related to dimished chemical defense production at high density. The ecological consequences of such findings may be compounded by the fact that plants are often less tolerant of leaf area removal when growing at high density or at low resource levels (Lee and Bazzaz, 1980; Lentz and Cipollini, 1998) and the fact that increased density can favor rapid herbivore and pathogen population growth through mechanisms unrelated to plant tissue quality (Reader, 1992). Moreover, our finding that plant density can profoundly influence the expression of a chemical defense is ecologically relevant to brassicaceaous plants in the field, which exhibit only short-distance seed dispersal, and thus often germinate and grow surrounded by a dense population of intraspecific neighbors (D. Cipollini, personal observation).

Because the effect of plant density on plant defensive chemistry has rarely been measured, it is not known the extent to which other classes of compounds, either in brassicaceous plants or in other plants, show the same lability as trypsin inhibitors in our study. For example, brassicaceous plants also rely to some

degree on a variety of glucosinolates for defense against natural enemies (Bodnaryk, 1992), but the effect of plant density on either constitutive or wound-induced glucosinolate levels has never been studied to our knowledge. Hjalten et al. (1994) have demonstrated that total phenolic concentration of birch seedlings declines with increasing plant density, but inducibility of phenolics was not examined in their study. In turn, although we can speculate on the ecological consequences of our findings in the greenhouse, the effect of plant density on induced biological resistance in the field has rarely been studied. In one study in which it has, however, induced resistance to leaf miners in wild cotton by early-season caterpillar damage tended to be more effective in plants grown at a reduced density relative to those grown at an endemic density (Karban, 1993). The ecological consequences of our findings at the biochemical level on the resistance of brassicaceous plants in the field are currently being investigated.

Acknowledgments—We thank Jennifer Olecziewski, Sylvia Woods, Jeremiah Busch, Sandra Suwanski, John Zdenek, and Ken Yliniemi for technical assistance. Suggestions by Tom Juenger, Kendra Cipollini, Jim Coleman, Colin Orians, and one anonymous reviewer substantially improved this manuscript. (Received May 31, 2000; accepted November 11, 2000)

Abstract—Eleven allelochemicals (ferulic acid, cinnamic acid, 4-hydroxybenzoic acid, hydroxycinnamic acid, methyl propionate, oxalic acid, methylmalonic acid, *p*-anisic acid, butyric acid, 3-hydroxybutyric acid, and azulene) were identified in the exudate of *Cistus ladanifer* L. We studied the effect of each on germination, cotyledon emergence, root length, and cotyledon length of *Rumex crispus*. Three groups were distinguished with respect to phytotoxic activity: compounds with low activity (ferulic acid, 4-hydroxybenzoic acid, oxalic acid, methylmalonic acid, *p*-anisic acid, hydroxybutyric acid, and azulene), with intermediate activity (cinnamic acid and hydroxycinnamic acid), and with high activity (methyl propionate and butyric acid). The effect of the interaction of the compounds was studied. When acting conjointly, all combinations tested produced a more negative effect on both germination and seedling growth than when acting alone. The interaction affected cotyledon emergence and root length more negatively than germination and cotyledon length. When hydroxycinnamic acid and cinnamic acid were added to these mixtures there was an enhancement in the phytotoxic activity, accentuating the effect of the other allelochemicals.

Key Words: Allelopathy, allelochemicals, phenolic compounds, *Cistus ladanifer*, *Rumex crispus*.

INTRODUCTION

Understanding the development, evolution, and structure of communities is a major objective of ecology. For plants, the questions are little understood.

Among the interactions, it has been suggested that allelopathy, defined as chemical plant–plant interaction whether positive or negative (Rice, 1984), is a major factor in regulating plant community structure (Smith and Martin, 1994). It could be regarded as a competitive phenomenon, and in habitats with limiting environmental conditions, there may be an enhancement of competition in general.

Cistus ladanifer is involved in the reduction of the richness and diversity of herbs in Mediterranean communities where it is present (Malato-Belíz et al., 1992). The cause may be responses to competition for nutrients, chemical interference, litterfall build-up, and penetration of light (Kuuluvaine, 1994). As we have shown in earlier work (Chaves and Escudero, 1997), the exudate of *Cistus ladanifer* leaves has phytotoxic activity that may be a cause of the reduction of herbs growing near this species.

Different types of secondary metabolites act as allelochemicals, among them phenols, terpenes, alkaloids, polyacetylenes, fatty acids, and steroids (Carballeira, 1980; Ballester et al., 1982; Kil and Yim, 1983; 1992; Wacker et al., 1990; Odén et al., 1992; Macías et al., 1993; Li et al., 1993; Gallardo et al., 1998). In many cases, compounds are found together in the growth medium, and their effect on plant development may be the sum of their interactions. Although there is little information on the interaction of phenols or other compounds as to how they affect germination and seedling growth, there is evidence that a mixture of phenols enhances their inhibitory action (Li et al., 1993).

The goal of the present work was to contribute to understanding the role of *Cistus ladanifer* in determining the structure of the communities it dominates. To this end, as we had shown previously that there are compounds in its exudate that act negatively on the germination and subsequent development of herbs (Chaves and Escudero, 1997), the next step was to determine the possible compounds that are involved in this process. In particular, we set out to demonstrate the potential of the identified compounds, determine the concentrations at which they are active, and understand the possible effects deriving from the interactions of the allelochemicals identified in the *Cistus ladanifer* exudate.

METHODS AND MATERIALS

Extraction of Exudate and Identification of Compounds

The exudate was extracted with chloroform. After evaporation, it was redissolved in hot methanol (10 ml/mg extract) (Vogt and Gülz, 1991), and the solution was stored at −20°C for 12 hr, thereby provoking the precipitation of methanol-insoluble compounds, mainly hydrocarbons and waxes. The soluble material was directly chromatographed on Sephadex LH-20 (12.5 g Sephadex LH-20 in a 25-cm-long × 1.5-cm-diam. column), with methanol as eluent. This procedure separates the flavonoids (Chaves et al., 1998) from the rest of the

compounds that are eluted first. It is this fraction that inhibits the germination of the herb species tested (Chaves and Escudero, 1997). On analysis by GC-MS, we identified the following compounds: ferulic acid (**1**), cinnamic acid (**2**), 4-hydroxybenzoic acid (**3**), hydroxycinnamic acid (**4**), methyl propionate (**5**), oxalic acid (**6**), methylmalonic acid (**7**), *p*-anisic acid (**8**), butyric acid (**9**), 3-hydroxybutyric acid (**10**), and azulene (**11**).

Germination Bioassay

Chemically pure reagents were obtained from Sigma Chemical Co. The species used to measure the effect of the compounds was *Rumex crispus* and was chosen because its seed germination and seedling growth are affected negatively when it is watered with the fraction of the exudate from which the compounds have been identified (Chaves and Escudero, 1997). *Rumex crispus* is found in the habitat of *Cistus ladanifer*. The seeds used for the bioassay were gathered in their natural habitat at the end of summer.

We placed 50 seeds (four replicates for a total of 200 seeds) in 9-cm-diam Petri dishes on Whatman No. 118 filter paper. The trial was initiated by adding 5 ml of the test solution or control (Milli Q water). The dishes were placed in a culture chamber with controlled temperature and lighting: 25°C constant temperature, and a 16L : 8D photoperiod. Every two days, 1 ml of the corresponding solutions (test or Milli Q water for the controls) was added to the dishes. Germinated seeds were counted daily (germination was when the seed coat had ruptured and the radicle had emerged). The experiment was continued for 10 days. We also counted cotyledon emergence, and at the end of the experiment measured the cotyledon length and root length of 10 seedlings from each dish (Jaderlund et al., 1996).

Several concentrations were tested for each compound, from the highest concentration of 1 mM down to that where we had observed no effect on any of the parameters. This lowest concentration depended on the compound: it was 0.5 mM for compounds **1**, **6**, **7**, **8**, **10**, and **11**; 0.1 mM for compounds **3** and **4**; 0.05 mM for **2**; and 0.001 mM for **5** and **9**.

The effect of the interaction of the compounds was studied by considering the action that each exerted separately, mixing those that acted negatively on germination, cotyledon emergence, root length, and cotyledon length, as well as a mixture of all compounds together. The seeds were watered with equimolar concentrations of 1 and 0.5 mM of the different mixtures. The following mixtures were tested:

Mixture 1: Compounds that inhibit root length when tested alone (**3**, **8**, **11**). Two solutions were prepared with equimolar concentrations of each of the compounds: 1 mM + 1 mM + 1 mM and 0.5 mM + 0.5 mM + 0.5 mM.

Mixture 2: Compounds of mixture 1 plus hydroxycinnamic acid. Two solu-

tions were prepared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

Mixture 3: Compounds of mixture 1 plus cinnamic acid. Two solutions were prepared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

Mixture 4: Compounds of mixture 1 plus hydroxycinnamic and cinnamic acids. Two solutions were prepared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

Mixture 5: Compounds that inhibit cotyledon length when tested alone (**1**, **3**, **6**, **7**, **8**, **10**). Two solutions were prepared with equimolar concentrations of each of the compounds at 1 mM and at 0.5 mM.

Mixture 6: Compounds of mixture 5 plus hydroxycinnamic acid. Two solutions were preared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

Mixture 7: Compounds of mixture 5 plus cinnamic acid. Two solutions were prepared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

Mixture 8: Compounds of mixture 5 plus hydroxycinnamic and cinnamic acids. Two solutions were prepared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

Mixture 9: Mixture of hydroxycinnamic and cinnamic acids. Two solutions were prepared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

Mixture 10: Mixture of all the compounds. Two solutions were prepared with equimolar concentrations of each of the compounds at 1 mM and 0.5 mM.

To eliminate effects of pH and osmotic potential, we measured these parameters for each solution. Osmotic pressure was measured with an HR-33T dewpoint microvoltmeter. The pH varied between 4.7 and 5.2 from one solution to another, and the osmotic potential was low in all solutions, varying between 0.2 and 0.5 bars. There were no significant differences in pH or osmotic pressure among solutions.

The results for germination, cotyledon emergence, inhibition of root length, and inhibition of cotyledon length are expressed as percentages of the control values. The significance level of comparisons among treatments was estimated by using the Mann-Whitney U test. Differences were taken as significant with $P < 0.05$.

RESULTS

Effect of Individual Allelochemicals on Germination, Cotyledon Emergence, and Seedling Growth. For each compound, the lowest concentration tested was

that at which there was no significant ($P > 0.05$) effect on the parameters being studied. Three groups were distinguished with respect to phytotoxic activity: compounds with low activity (**1**, **3**, **6**, **7**, **8**, **10**, and **11**); with intermediate activity (**2** and **4**); and with strong activity (**5** and **9**) (data not shown).

With respect to germination and cotyledon emergence, compounds **1**, **3**, **6**, **7**, **8**, **10**, and **11** showed no significant effect ($P > 0.05$). They affected seedling growth negatively, since they inhibited root length and cotyledon length ($P < 0.05$). Compounds **3**, **8**, and **11** inhibited root length at 1 mM concentration, and compound **11** at 0.5 mM. All compounds, with the exception of **11**, had a negative action on cotyledon length. The most effective were **1** and **6**, which had an inhibitory effect from 0.5 mM. (data not shown).

Compounds **2** and **4** were more active than the previous group. Compound **2** inhibited germination at 1 mM and cotyledon emergence was negatively affected by both: from 0.5 mM in the case of **2**, and only at 1 mM for **4**. For both allelochemicals, we observed an increase in the percentage inhibition of cotyledon emergence with concentration, but only **2** showed a significant positive correlation with concentration ($r^2 = 0.99$). (data not shown).

With respect to root length, compounds **4** and **2** were strong inhibitors at 1 mM, but the effect decreased at lower concentrations. For both compounds, the inhibition of root length was concentration-dependent ($r^2 = 0.98$ and $r^2 = 0.9$ for **4** and **2**, respectively). The cotyledon length was inhibited by **4** at only the highest concentration and down to 0.5 mM for **2**. There was also a concentration-dependent relationship in this case (data not shown).

Both of the most active compounds, **5** and **9**, completely inhibited germination down to 0.05 mM and had a strong effect at 0.01 mM. They were even more effective in inhibiting cotyledon emergence, being active down to 0.001 mM for **5** and 0.01 mM for **9** (data not shown).

The root length was inhibited by **5** at concentrations above 0.01 mM, and above 0.0001 mM for **9**. Likewise, cotyledon length was affected at above 0.001 mM for **9**, and 0.05 mM for **5** (data not shown).

Effect of Interactions of Allelochemicals on Rumex crispus *Germination and Seedling Growth.* The results given in Tables 1–4 (below) show the effect on germination of the conjoint action of the allelochemicals identified. All combinations tested produced a greater inhibition of seedling growth than when acting alone.

Mixture 1, made up of **3**, **8**, **11**, showed a negative effect (at 1 mM) on germination (Table 1), reducing germination by practically 60%. This effect disappeared at 0.5 mM. When hydroxycinnamic acid was added to this mixture, there was an enhancement of the inhibition, and this was enhanced further with the addition of cinnamic acid where the inhibitory action of the other compounds was augmented even at 0.5 mM.

Mixture 2, made up of compounds **1**, **3**, **6**, **7**, **8**, and **10**, non of which inhib-

ited germination individually, afected germination negatively when they acted jointly (Table 1). As in the previous case, the addition of hydroxycinnamic acid (**4**), enhanced the inhibitory action, reducing germination practically to zero.

Cotyledon emergence (Table 2) was strongly affected by the compounds acting conjointly. The interaction affected cotyledon emergence more negatively than germination. As with germination, the addition of cinnamic acid enhanced the effect, reducing cotyledon emergence practically to zero. At a lower concentration (0.5 mM), the effect was attenuated, except for the mixture of all the allelochemicals.

Root length and cotyledon length were affected differently. Root length was negatively affected by all mixtures (Table 3). At the 1 mM concentration, the reduction was so great that the seedlings were practically nonviable. The cotyledon length, however, as can be seen from Table 4, in those treatments where there was cotyledon emergence, was less negatively affected; mixture 1 (compounds **3**, **8**, and **11**, at 1 mM did not significantly affect this parameter. Hydroxycinnamic acid, when added to mixture 1, greatly enhanced the inhibitory activity (at 1 mM).

DISCUSSION

In earlier studies (Chaves and Escudero, 1997) we saw the allelopathic potential of the exudate secreted by *cistus ladanifer* leaves. In this work, we tried to understand this species' activity by determining the chemical nature of the compounds and by quantifying their phytotoxic activity. At least 11 compounds were found to possess activity, although at different levels of effectiveness. Two of them, methyl propionate and butyric acid, inhibited germination even at low concentrations. These compounds also are present in the exudate at low concentrations (Chaves et al., unpublished). The remaining compounds mostly affect seedling growth, inhibiting root length and cotyledon length. This effect may have equally negative consequences, since root growth is important for any species to become established under natural conditions.

The concentrations at which these compounds are effective are consistent with the findings of other workers (Kuiters, 1989; Li et al., 1993), who reported that some phenolic acids, such as cinnamic acid, have the same effect and activity on germination and seedling growth. The effective concentration is around 0.1–1 mM in inhibiting seedling growth or germination. Those authors found that

ferulic acid, however, inhibits germination at 1 mM, whereas in our experiment it inhibited seedling growth only, not germination. Blum and Rebbeck (1989) report that while ferulic acid inhibits root length, the roots are thicker, and they suggest that this compound may stimulate the initiation of secondary roots. We did not observe this phenomenon in our trials, nor any stimulatory effect on germination at low concentrations (Milborrow, 1984). The effect of these compounds has been shown to be species-dependent (Haugland and Brandsaeter, 1996), and this effect may be due to the difference in seed size, permeability, differential uptake, and metabolism.

Phenolic acids have been shown to inhibit the length of roots more than shoots (Li et al., 1993). We observed this phenomenon for cinnamic and hydroxycinnamic acids, with there also being a concentration-dependent relationship ($r^2 = 0.98$ and 0.92, respectively). This was not found to be the case, however, with ferulic and 4-hydroxybenzoic acids. Ferulic acid did not inhibit this parameter but did inhibit cotyledon length, and 4-hydroxybenzoic acid, while having an inhibitory effect, had more influence on cotyledon length. In contrast, azulene, which is not a phenolic, had a strong effect on root length but none on cotyledon length.

Compounds that have phytotoxic activity usually derive from various

sources, and it is a complicated task to determine their origin. Their effect, however, is determined by their conjoint action, and, as we found here, this action is more effective than when they act alone. Most previous reports of the interaction among phenols have not been subjected to rigorous examination. The present work has shown that a mixture of compounds, even of those with a weak negative effect, phytotoxic accentuates effects. This effect is enhanced when cinnamic and hydroxycinnamic acids are present. Li et al. (1993) have demonstrated synergy in the action of such phenolic acids as caffeic, ferulic, and cinnamic acids. This synergy implies that a high concentration is probably unnecessary for them to be active. Many of them have been identified in soils at low concentrations (Blum et al., 1989; Lyu et al., 1990; Lehman et al., 1994; Inderjit and Dakshini, 1991, 1992), and synergy may compensate for the low concentrations.

There is a growing understanding of the function and mode of action of these compounds. Neither pH nor osmotic pressure seem to be responsible for the observed negative effects (Rikala and Jozefek, 1990; Nilsson, 1992). Other theories are defended by Pandey (1994), Jaderlund et al. (1996), and Gallardo et al. (1998). For example, plants consume less water in the presence of such compounds, leading to root dysfunction, and the action of phenolic compounds

might be involved in lowering membrane integrity and disrupting enzymatic pathways.

Acknowledgments—The skilled assistance of Dr. J. Luis Rios (Instituto de la Grasa, CSIC, Sevilla, Spain) with the gas-mass spectroscopy measurements is gratefully acknowledged. We are grateful to the anonymous reviewer for contributing to the improvement of our manuscript.

Abstract—Of the aglycone flavonoids identified in the exudate of *cistus ladanifer*, two, the flavone apigenin-4′-(*O*)-methyl and the flavonol kaempferol-3,7-di(*O*)-methyl inhibit development of the seedlings of *Rumex crispus* at 0.5 and 1 mM. Additive effects were observed between the major flavonols of the exudate kaempferol-3-(*O*)-methyl and kaempferol-3,7-di-(*O*)-methyl in inhibiting the size of the cotyledons and delaying the germination and cotyledon emergence. The presence of apigenin-4′-(*O*)-methyl, kaempferol-3,7-di-(*O*)-methyl, and kaempferol-3-(*O*)-methyl was detected in the soils associated with *C. ladanifer* during the summer and autumn months. That these compounds are present in the soil and are not restricted to the leaves provides support for the hypothesis that *C. ladanifer* has allelopathic potential.

Key Words: Allelochemicals, allelopathic effect, phenolic compounds.

INTRODUCTION

C. ladanifer is a species that secretes an exudate rich in phenolics. The flavonoids show a marked qualitative and quantitative seasonal variation depending on factors such as moisture stress, ultraviolet radiation, and high temperatures (Chaves et al., 1993, 1997). The exudate becomes enriched in flavonoids during summer, when the flavonols (kaempferols) are more prevalent than the flavones (apigenins). Given the phytotoxicity of *C. ladanifer* that was demonstrated in earlier studies (Chaves and Escudero, 1997) and that some of the compounds responsible for the effect form part of the mixture of aglycone flavonoids extracted from its leaf exudate, the aim of the present study was to gain deeper knowledge of

* To whom correspondence should be addressed. e-mail: natchalo@unex.es

0098-0331/00/0300-0623$19.50/0

the potential allelopathic activity presented by this species. We set two objectives: (1) to determine which of the aglycone flavonoids identified in *C. ladanifer* exudate might be responsible for the phytotoxic effect that was demonstrated in earlier studies, by using *R. crispus* (an herb that is not found in the presence of *C. ladanifer*) as a test bed; and (2) to check for the presence of these compounds in the soil and determine at which times of ear they are present, to see whether the compounds may be able to exert their effect in their natural setting.

METHODS AND MATERIALS

Sample Collection. *C. ladanifer* leaves for flavonoid extraction were gathered in spring and summer (young leaves). Samples were taken in these two seasons because of the qualitative and quantitative seasonal variation in leaf flavonoid content (Chaves et al., 1993, 1997); a greater amount of flavones are extracted in spring, and flavonols in summer.

The *Rumex crispus* seeds used for the germination trials were collected at the end of the summer from meadows in its natural habitat. This species was chosen because its seed and seedling growth are affected negatively when they are watered with the fraction of exudate that contains flavonoids. (Chaves and Escudero, 1997).

After first having cleared the existing herb vegetation, soil samples were collected from the surface (less than 5 cm), this being the depth to which herb seeds are usually found. Each month, three soil samples were taken from beneath *C. ladanifer* plants, and another two samples as controls away from the influence of this plant. The sampling months were from April (when the secretion of flavonoids begins in the leaves) to November (when the secretion stabilizes).

Extraction of Flavonoids. The flavonoids identified in *C. ladanifer* (Chaves et al., 1998) are not commercially available and therefore were extracted from the exudate. The exudate was extracted with chloroform. For separation of the flavonoids, the extract was dissolved in hot methanol (10 ml/mg extract) (Vogt and Gülz, 1991), and the solution stored at −20°C for 12 hr, provoking the precipitation of methanol-insoluble compounds, mainly hydrocarbons and waxes. The flavonoid-containing supernatant was directly chromatographed on Sephadex LH-20 (12.5 g Sephadex LH-20) on a 25-cm-long × 1.5-cm-diam. column) with methanol as the eluent. With this procedure, the flaonoids are separated from the terpenoids and other phenolics that elute first. Three extracts were obtained, and these were subsequently analyzed by HPLC to determine the fraction containing the flavonoids.

Separation and Purification of Exudate Flavonoids by HPLC. The flavonoids were separated by using a semipreparative Nucleosil 5μ C-18 (250 × 10 mm) column and a water–methanol–acetonitrile–tetrahydrofurane

(56 : 16 : 6 : 22) solution at a flow rate of 1.75 ml/min. They were detected with a diode array at 350 nm wavelength. As the peak of each flavonoid was detected, it was collected in a separate tube. To eliminate any possible contamination from other compounds eluting close to the flavonoid being purified, the fraction was again separated by HPLC with a methanol–water (80 : 20) solvent at a 2.5 ml/min flow rate.

The flavonoids purified from the extract were: kaempferol-3-(*O*)-methyl (K3), kaempferol-3,7-di-(*O*)-methyl (K3,7), apigenin-4′-(*O*)-methyl (Ap4′) and apigenin-7-(*O*)-methyl (Ap7). Apigenin (Ap) was commercially available and was purchased from Aldrich-Quimica.

Extraction of Flavonoids from Soil. The soil samples were air-dried and stored in bags in darkness until analysis. Twenty-five grams of soil of each sample were extrated with 40 ml of methanol (Inderjit and Dakshini 1996b). The mixture was vortexed for 2 hr and then filtered through Whatman filter paper. The filtrate was evaporated and redissolved in 1 ml methanol.

HPLC Identification of Soil Flavonoids. The solution of soil extract was assayed by HPLC. Aliquots of 200 μl were injected into a Nucleosil 5μ C-18 (15 $\times$ 4.5 mm) analytical column with a water–methanol–acetonitle–tetrahydrofurane (56 : 16 : 6 : 22) solution at a flow rate of 0.7 ml/min. Flavonoids were detected with a diode array at a wavelength of 350 nm. The templates used to quantify the soil flavonoids were the purified flavonoids from the exudate.

Seed Germination. Rumex crispus seeds were watered with different concentrations of each of the flavonoids (Ap, Ap7, Ap4′, K3 and K3,7). The highest concentration was 1 mM and the lowest 0.1 mM (recommended effective concentration) (Williams and Hoagland, 1982; Li et al., 1993; Inderjit and Dakshini, 1995). We also performed experiments with the two major flavonoids, K3 and K3,7, together in order to analyze the interaction between these two flavonols. Measurements of pH were made to eliminate the possibility that these might influence observed trends. The pH of the extracts was 6.8 $\pm$ 0.2.

For each trial, 50 seeds (four replicates, 200 seeds in total) were placed in Petri dishes on Whatman No. 118 filter paper and to each dish, 5 ml of the corresponding extract was added. Control dishes were watered with Milli Q water. Dishes were placed in a culture chamber with controlled temperature and lighting: 16L : 8D at a constant temperature of 25°C. The corresponding solutions (extract or distilled water) were resupplied every two days. Germinated seeds were counted daily (germination being taken to have occurred when the testa had ruptured with the consequent appearance of the radicle). The experiment was continued for 10 days. Cotyledon emergence was also recorded, and cotyledon size (length) and root length were determined at the end of the experiment by measuring 10 seedlings (at random) for each dish (Jaderlund et al., 1996).

The results for root length inhibition and cotyledon size inhibition were expressed as percentages with respect to the controls:

$$\text{Root length inhibition (\%)} = \left(\frac{\text{root length with treatment}}{\text{root length control}} \right) \times 100$$

the lag in germination and cotyledon emergence was quantified by using the Weibull function (Brown and Mayer, 1988). The form of the fitted Weibull function is: $y = M\{1-\exp[-K(t-z)]^c\}$; where y is the cumulative germination at time t, and M, k, z, and c are empirically derived constants: M is the asymptote, k the rate of increase, z the lag in germination, and c is a shape parameter. The value of k, which represents the germination rate for each treatment, was estimated with this function. The significance level of comparisons between treatments was estimated by using the Mann-Whitney U test. Differences were taken as significant with $P < 0.05$.

RESULTS

Seedling Germination and Growth. The germination and cotyledon emergence percentages were not affected by any of the compounds ($P > 0.05$). The root length (Table 1), was significantly inhibited ($P < 0.05$) only by the 1 and 0.5 mM concentrations of Ap4′ and K3,7 and the K3/K3,7 mixture. In the case of K3,7, inhibition was concentration dependent ($r^2 = 0.99$). No concentration dependence was detected for Ap4′ or for the K3/K3,7 mixture. The K3,7 activity at 0.5 mM was comparable to that of the flavone.

TABLE 1. EFFECT OF DIFFERENT CONCENTRATIONS OF FLAVONOIDS ISOLATED FROM *C. ladanifer* EXUDATE ON *R. crispus* ROOT LENGTH AND COTYLEDON SIZE[a]

[b] Significantly different $P < 0.05$ from controls (Mann-Whitney U test).

With respect to cotyledon size (Table 1), there was no effect of any of the flavonoids alone, but the cotyledons were smaller when K3 and K3,7 acted together. The interaction between these two flavonols (which are the major flavonoids in *C. ladanifer* exudate) had different effects on root length and cotyledon size: their, joint action had a smaller effect on root length than did K3,7 alone, but was more effective in inhibiting cotyledon size ($P < 0.05$) than either flavonoid alone, where no inhibition was seen.

Delays in Germination and Cotyledon Emergence. Table 2 gives the rates of germination and cotyledon emergence for each flavonoid treatment. These indices quantify the effect on delaying germination and cotyledon emergence and are useful tools in understanding the degree to which development and the competitive possibilities of seedlings were affected. At 1 mM concentration, Ap4′ delayed germination and cotyledon emergence. The mixture of the two flavonols induced delay in germination rate at the 1 mM concentration and a notable delay in cotyledon emergence at 1 and 0.5 mM. Although the total germination percentage was unaffected, Ap4′ and K3/K3,7 had a clear effect on lengthening the time required for germination and cotyledon emergence.

Flavonoids in Soil. The flavonoids K3, K3,7, and Ap4′ were detected in the extract of soils associated with *C. ladanifer*. Table 3 lists the amounts of each flavonoid extracted from both the jaral soils and the control soils for each month of the sampling period.

One can see that in the controls (soils which were adjacent to the jaral) no

flavonoids were detected in any of the sampling months and also that the aglycone flavonoids secreted by the *C. ladanifer* leaves were the only three detected in the soil (Ap4′, K3, and K3,7).

No flavonoids were found in the *C. ladanifer* soils in the spring months (April and May), their presence began to be detectable in the summer (June). The greatest amounts were obtained from the September soil samples. One observes that there is great variability among sampling points (different soil samples) in a given month, and an even greater temporal variability: e.g., in June, K3 ranged between 1.3 and 9.6 mg/g dry wt $\times 10^{-5}$ and K3,7 between 4 and 79 mg/g dry wt $\times 10^{-5}$, and in September the ranges were from 5.3 to 24 mg/g dry wt $\times 10^{-5}$ for K3 and from 12 to 60 mg/g dry wt $\times 10^{-5}$ for K3,7. While this variability is patent, a common pattern is observed in the greater amount

of K3.7 for all sampling points in all months except July, when there was no K3,7 detected in any of the samples. It is noteworthy that Ap4′ was detected in only June and September, and then only in one sample, that which contained the greatest quantity of flavonoids. The amount of flavonoids declined considerably in October and November, being undetectable at some sampling sites.

The variability among sampling points and the temporal variation highlight the lack of homogeneity in the distribution of these compounds in the soil and the need for further work to determine their degradation and residence times. The results show that the presence of flavonoids with phytotoxic activity is not restricted to the leaves, but that they can also be detected in the soils, especially those with the greatest phytotoxic activity.

DISCUSSION

The present results provide evidence that the two flavonols (K3 and K3,7) and the flavone (Ap4′), the three aglycone flavonoids identified in the *C. ladanifer* exudate (Chaves et al., 1998), are those with the greatest phytotoxic activity. The activity is not directly related to inhibition of germination but is reflected in the effect on root length, cotyledon size, and the delay in rate of germination and of cotyledon emergence. A delay in germination rate and radicle growth will be important in the establishment of any species under natural conditions. The plant will have less opportunity to establish itself since it will be unable to take advantage of favorable conditions such as the first rains, and the roots may find it more difficult to penetrate the soil. This process is even more important in nutrient-poor ecosystems, such as those in which *C. ladanifer* grows, where competition is greater and the lack of nutrients may increase susceptibility to water deficit. The results are consistent with those of earlier studies, which have demonstrated the influence of other flavonoids on the size and development of roots and cotyledons (Inderjit and Dakshini, 1991, 1992, 1995) and the concentrations that are effective (1, 0.5, and 0.1 mM). The effect of the flavonoids on different physiological parameters is unclear and, therefore, so is the mode of action.

Trials performed by Jaderlund et al. (1996) suggest that the compounds that negatively affect germination and seedling development are water soluble and pass into the soil with the rain or the first stages of litter decomposition. The absorption and retention of allelochemicals in the soil has been documented (Huang et al., 1999), and therefore one must check for presence of these compounds there. The present work has demonstrated the presence of the flavonoids K3,7, K3, and Ap4′ in the soils of a jaral, mainly during the months when many species establish themselves. While it is essential to have data on the persistence and residence in soils in order to determine with precision the allelopathic activ-

ity of any given species, the presence and availability of these flavonoids in the soil, detected here for the first time, reaffirms the allelopathic likelihood of *C. ladanifer*.

In previous work, we have quantified the variation of these flavonoids in *C. ladanifer* leaves, as well as the factors that induce their synthesis (Chaves and Escudero, 1999; Chaves et al., 1993, 1997). We found a marked seasonal variation. The greatest flavonoid concentration in the leaf is in summer (specifically, in August). The route by which they enter the soil has not been established, but it could well be by rain (Inderjit and Dakshini, 1996a). This would explain the peak presence of K3 and K3,7 in September, since in the exudate, the greatest concentration is found in August: in this month, there may be up to 25 mg/g dry wt of flavonoids (Chaves et al., 1997) with these two flavonols representing about 70% of the total flavonoids. Although the summer is dry, often at the end of the season there are storms that may be sufficient to wash the flavonoids into the soil.

It is necessary to emphasize the variability in the amounts detected at different sampling points and different months. Studies by other authors (Inderjit and Dakshini, 1996b; Inderjit, 1998) have shown the variation in phenolic content of soils with respect to season and sampling site. For instance, phloroglucinol was found to vary from one site to another from 5×10^{-3} M to 10^{-6} M in the field (Inderjit and Dakshini, 1996b). It is no easy matter to determine the precise bioactive concentration of these compounds in soils under natural conditions, since they may decompose, be absorbed by seeds and roots, be leached, be fixed by other soil compounds, and be exposed to microbial activity (Dalton et al., 1983; Rice 1984; Blum and Shafer, 1988; Cheng, 1995). The concentration at which flavonoids are demonstrated to be active may possibly be greater than the concentration at which they are detected in the soil. A very high concentration in the soil is probably not needed for them to exert their allelopathic effect, however, since the compounds are continually being incorporated into the soil whenever it rains or leaves fall, an effect which may be even more important when the plant is a perennial such as *C. ladanifer*.

(Received August 16, 2000; accepted December 13, 2000)

Abstract—We investigated the hypothesis that wood-boring beetles in the genus *Monochamus* (Cerambycidae) utilize pheromones of sympatric bark beetles as host-finding kairomones. All nine bark beetle pheromones tested electrophysiologically were antenally active for both sexes of *M. scutellatus, M. clamator*, and *M. obtusus* from British Columbia. When field-tested with multiple-funnel traps (British Columbia) or cross-vane traps (Ontario), a blend composed of frontalin, ipsdienol, ipsenol, and MCH, in combination with a blend of host volatiles attracted significant numbers of *M. clamator, M. obtusus, M. notatus*, and *M. scutellatus* to baited traps. Traps baited with host volatiles in combination with a second blend composed of *endo*-brevicomin, *exo*-brevicomin, *cis*-verbenol, *trans*-verbenol, and verbenone caught no more beetles than unbaited traps or traps baited with the host blend alone. In British Columbia, traps baited with the first blend alone or both blends together captured more *M. scutellatus* and *M. clamator* than unbaited traps, demonstrating a response to bark beetle pheromones in the absence of host volatiles. These results suggest that *Monochamus* spp. are minimizing foraging costs by using the pheromones of sympatric bark beetles as kairomones.

Key Words—Coleoptera, Scolytidae, Cerambycidae, Buprestidae, *Monochamus*, chemical ecology, allelochemics, kairomones, coevolution.

INTRODUCTION

Most wood-boring insects reproduce in stressed, dying, or dead trees that are usually randomly distributed in space and time (Schroeder, 1992). The larvae feed under the bark in the phloem tissue, in the sapwood, and sometimes deep into the heartwood (Linsley, 1961), often boring long tunnels that weaken and degrade the wood and provide infection courts for wood-rotting fungi. Wood-boring beetles have caused economic losses as high as 30% in British Columbia log yards (Safranyik and Raske, 1970). A southern interior British Columbia mill, which converts 700,000 m^3 of coniferous timber into lumber annually, could expect annual degrade losses from all wood-borers to total US $1.8–4.8 million (Phero Tech Inc. 7572 Progress Way, RR#5, Delta, British Columbia. V4G 1E9, Canada. Damage Assessment of Woodborers in the Interior of British Columbia. Unpublished report. 1997). If these values were extrapolated to encompass all interior mills, annual losses would be US $293 million, $43.6 million of which would be attributable to large wood-borers. Wood-borers in the genus *Monochamus* are of particular economic significance, because in addition to causing significant physical damage (Parmelee, 1941; Gardiner, 1957, 1975), they are vectors of the pinewood nematode, *Bursaphelenchus xylophilus* (Vallentgoed, 1991).

Coniferophagous wood-borers use olfactory stimuli to locate hosts (Linsley, 1961), and many are attracted to host monoterpenes and ethanol (Chénier and Philogène, 1989). Consequently, commercial wood-borer baits consist of host monoterpenes (usually α-pinene) and ethanol to simulate the odor of a stressed or dying tree. Current understanding of the cues involved in host selection by wood-borers is incomplete.

There is considerable overlap in pheromone components among sympatric scolytid beetles (Borden, 1982), facilitating kairomonal responses by entomophagous insects to trees or logs infested by bark beetles of numerous species (Vité and Williamson, 1970; Dixon and Payne, 1979; Bedard et al., 1980; Bakke and Kvamme, 1981; Raffa and Klepzig, 1989). The association between bark beetles and wood-boring beetles has long been recognized but has only been formally tested twice (Billings and Cameron, 1984; Billings, 1985). A kairomonal response to bark beetle pheromones would be adaptive to host-seeking wood-boring beetles because it could aid them in locating suitable host material. Coniferophagous wood-borers in the families Cerambycidae and Buprestidae often attack the same hosts at the same time as conifer-infesting bark beetles (Dahlsten and Stephen, 1974; Stephen and Dahlsten, 1976; Dixon and Payne, 1979; Coulson et al., 1976, 1980).

Subcortical interactions between bark beetles and wood-boring beetles have been classified as competitive (Coulson et al., 1976, 1980; Schroeder and Weslein, 1994a,b) or commensal (Flamm et al., 1989). A decline in larval density or emergence of adult bark beetles was attributed primarily to competition between

cerambycid and bark beetle larvae. A kairomonal response to bark beetle pheromones would be even more adaptive to host-seeking wood-borers if bark beetle larvae represent a food resource for wood-borer larvae. Dodds et al. (2001) found that 74% of the six-spined ips, *Ips calligraphus*, larvae encountered by *Monochamus carolinensis* larvae in phloem sandwiches were attacked; 85% were killed, suggesting that cerambycid larvae may be facultative predators of bark beetle larvae. This result supports the earlier observation by Schenk and Benjamin (1969) that in Wisconsin "up to 50% of a brood in the egg and 1st instar was destroyed by cerambycid larvae; a single cerambycid larvae could reduce the available food supply by 3%." However, Flamm et al. (1989) found that foraging by *M. titillator* results in low mortality of the southern pine beetle *Dendroctonus frontalis*, because the larvae migrate to the outer bark before *M. titillator* foraging becomes significant. One possible explanation for the observed behavior is coevolution between *M. titillator* and *D. frontalis*, with larval *D. frontalis* migration to the outer bark being an adaptive response that would reduce mortality due to *M. titillator* predation.

Billings and Cameron (1984) and Billings (1985) found a kairomonal response by the southern pine sawyer, *Monochamus titillator*, to a blend of *Ips* spp. pheromones (ipsenol, ipsdienol, and *cis*-verbenol). In one study, there was a synergistic interaction between this stimulus and blends of *endo*-brevicomin and verbenone, or *endo*- plus *exo*-brevicomin with verbenone, all of which are pheromones of *D. frontalis* (Billings and Cameron, 1984). In the other study, this stimulus was synergized by loblolly pine, *Pinus taeda*, turpentine (Billings, 1985). Raffa (1991) reported an undisclosed number of *M. carolinensis* captured in ipsdienol-baited traps. Miller and Borden (1990) captured *Monochamus clamator* in increasing numbers as the combined release rates of ipsdienol and (−)-β-phellandrene increased.

There is considerable potential in exploiting bark beetle pheromones in wood-borer management, if they prove to be attractive to pest species. We report the results of experiments in British Columbia and Ontario demonstrating that certain bark beetle pheromones are attractive to *M. clamator, M. obtusus*, the white-spotted sawyer *Monochamus scutellatus*, and the northeastern sawyer *M. notatus.*

METHODS AND MATERIALS

Adult *M. clamator, M. scutellatus*, and *M. obtusus* were collected on emergence from caged bolts of lodgepole pine, *Pinus contorta* var. *latifolia*, and ponderosa pine, *P. ponderosa.* Coupled gas chromatographic–electroantenno graphic detection (GC-EAD) analyses were performed on the antennae of both male and female *M. clamator, M. scutellatus*, and *M. obtusus* with an HP 5890 gas chromatograph equipped with a fused silica column (DB-5, 30 m × 0.32 mm ID,

J&W Scientific, Folsom, California 95630-4714) (Gries, 1995). Authentic samples of nine candidate bark beetle pheromones (ipsenol, ipsdienol, MCH, frontalin, *cis*-verbenol, *trans*-verbenol, *exo*-brevicomin, *endo*-brevicomin, and verbenone) (Borden, 1985) were mixed in hexane solutions at concentrations of both 10 ng/μl and 100 ng/μl. These were analysed in 1-μl amounts by GC-EAD under splitless conditions with a temperature program of 60°C (1 min) then 10°C/min to 220°C. The analyses were repeated with a temperature program of 50°C for (1 min), then 10°C/min to 90°C and 4°C/min to 240°C to separate ispdienol and *trans*-verbenol.

Synthetic antennally active pheromones were arbitrarily partitioned into two blends: blend 1 consisting of ipsenol, ipsdienol, MCH, and frontalin and blend 2 consisting of *cis*- and *trans*-verbenol, *exo*- and *endo*-brevicomin, and verbenone (Table 1). These were tested in the field for behavioral activity with and without a host blend composed of ethanol and α-pinene (experiment 1) or ethanol with a synthetic host blend (Table 1) composed of 10.7% (−)-α-pinene, 0.4% (+)-α-pinene, 13.7% (−)-β-pinene, 7.3% myrcene, 1.5% 3-carene, 0.1% α-phellandrene, 63.7% (+)-β-phellandrene, 0.3% γ-terpinene, and 2.4% terpinolene (experiments 2 and 3) (Table 1). These proportions represent an average of those found in subalpine firs, *Abies lasiocarpa*, and Engelmann spruce, *Picea engelmannii.* Experiment 1 was run July 7–28, 1999 and had 24 replicates of five traps per replicate, with nine replicates set up in the Gorman Bros. Ltd. mill yard in Westbank, British Columbia, and 15 in the Weyerhaeuser Canada Ltd. mill yard in Okanagan Falls, British Columbia. Experiment 2 was run June 23–August 11, 1999 and had 10 replicates of five traps per replicate set up in a recently thinned white pine stand north of Thessalon, Ontario. The surrounding forest was predominately jack pine, *Pinus banksiana.* Experiment 3 was run July 19–August 14, 1999 and had eight replicates of five traps per replicate in the Slocan Forest Products Ltd., Tackama Division mill yard in Ft. Nelson, British Columbia. Experiment 4 was run June 29–July 31, 1999 and had 20 replicates with 10 each in Ainsworth Forest Products Ltd. mill yards in 100-Mile House and Chasm, British Columbia.

Experiments 1, 3, and 4 used 12-unit multiple-funnel traps (Lindgren, 1983) deployed in randomized complete blocks with traps $\geq$15 m apart. A small block of Vapona No-Pest Strip (Green Cross, Fisons Horticulture Inc., Mississauga, Ontario) was placed in each collecting cup to minimize predation and cannibalism. Traps were hung from aluminum poles such that the top funnel was ca. 1.5 m above ground. Experiment 2 used cross-vane traps with collection bins containing soapy water, deployed as above (de Groot and Nott, 2001).

The treatments for experiments 1–3 were: (1) unbaited control, (2) host blend alone, (3) host blend and pheromone blend 1, (4) host blend and pheromone blend 2, and (5) host blend and both pheromone blends. Treatments for experiment 4 were: (1) unbaited control, (2) pheromone blend 1, (3) pheromone blend 2, and (4)

both pheromone blends. Release devices and rates for all compounds are given in Table 1.

Captured beetles were collected weekly and frozen until they could be identified and sexed. *Monochamus* spp. were identified and sexed by using elytral, antennal, and sternite characters (Linsley and Chemsak, 1984). Voucher specimens for all species reported have been deposited at the Pacific Forestry Centre, Canadian Forest Service, Victoria, British Columbia.

Data for each sex were transformed by $\log_{10}(x + 1)$ to correct for nonnormality and heteroscedasticity (Zar, 1984), and analyzed by ANOVA (GLM) and the Ryan-Einot-Gabriel-Welsch (REGW) multiple-range test (Day and Quinn, 1989) with SAS Institute Inc. software (SAS Institute Inc., 1988). In all cases $\alpha = 0.05$.

RESULTS

As shown in a representative example from a female *M. scutellatus* antenna (Figure 1), all nine pheromones were detected by the antennae of both male and female *M. scutellatus, M. clamator*, and *M. obtusus*, with no differences by species or sex in the level of response.

In experiment 1, one or both sexes of *M. clamator* and *M. obtusus* were captured in higher numbers in traps baited with the host blend plus pheromone blend 1 than in traps baited with the host blend alone (Figure 2). Fewer *M. obtusus* of both sexes were captured in traps baited with the host blend plus both bark beetle pheromone blends. In no case were there significantly more beetles of either sex captured in traps baited with the host blend plus pheromone blend 2 than in either unbaited traps or traps baited with the host blend alone. Only male *M. obtusus* were more attracted to traps baited with the host blend than to the unbaited control traps.

In experiment 2, both sexes of *M. scutellatus* and *M. notatus* were captured in higher numbers in traps baited with the host blend plus pheromone blend 1. Both sexes of *M. scutellatus* and female *M. notatus* were captured in higher numbers in traps baited with the host blend plus both pheromone blends than in other traps (Figure 2). Similarly, both sexes of *M. scutellatus* and female *M. notatus* were captured in higher numbers in traps baited with the host blend plus pheromone blend 2 or the host blend alone than in unbaited traps. In experiment 3, both sexes of *M. scutellatus* were caught in higher numbers in all baited traps than in unbaited control traps.

In experiment 4, male and female *M. clamator* and *M. scutellatus* were captured in higher numbers in traps baited with pheromone blend 1 alone or combined with pheromone blend 2 than in unbaited traps or traps baited with pheromone blend 2 alone (Figure 3).

For experiments 1, 3, and 4 other wood-borer species were counted and sexed if $\geq$50 individuals were caught. Significant responses, all by beetles in the family

TABLE 1. COMPOUNDS AND THEIR SOURCE, CHEMICAL PURITY, RELEASE DEVICES, ENANTIOMERIC COMPOSITION, AND RELEASE CHARACTERISTICS OF SEMIOCHEMICALS TESTED IN FIELD EXPERIMENTS AS ATTRACTANTS FOR *Monochamus* SPP

Blend and compounds	Source[a]	Chemical purity (%)	Release device[b]	Enantiomeric composition (+:−)	Release rate (mg/24 hr)[c]
Pheromone blend 1					
Ipsenol	Phero Tech	98	bubble cap	50:50	0.24

[b] All release devices fom Phero Tech Inc. For the host blend, ethanol and all other compounds were released from separate sleeves. All other compounds were released fom separate devices.

[c] Release rates for ipsenol, ipsdienol, MCH, frontalin, *cis*- and *trans*-verbenol, *endo*- and *exo*-brevicomin, and verbenone were determined at 20–23°C by Phero Tech Inc. Rates for (−)-α-pinene, (+)-α-pinene, (−)-β-pinene, myrcene, 3-carene, (−) α-phellandrene, (−)-β-phellandrene, γ-terpinene, terpinolene, α-pinene, and ethanol were determined at 28–30°C at Simon Fraser University.

[d] Obtained from angelica seed oil (Liberty Natural Products). Enantiomeric determination after the field season revealed almost pure (+) enantiomer, the antipode of naturally occuring β-phellandrene in conifers.

[e] Standards not available. Unable to determine.

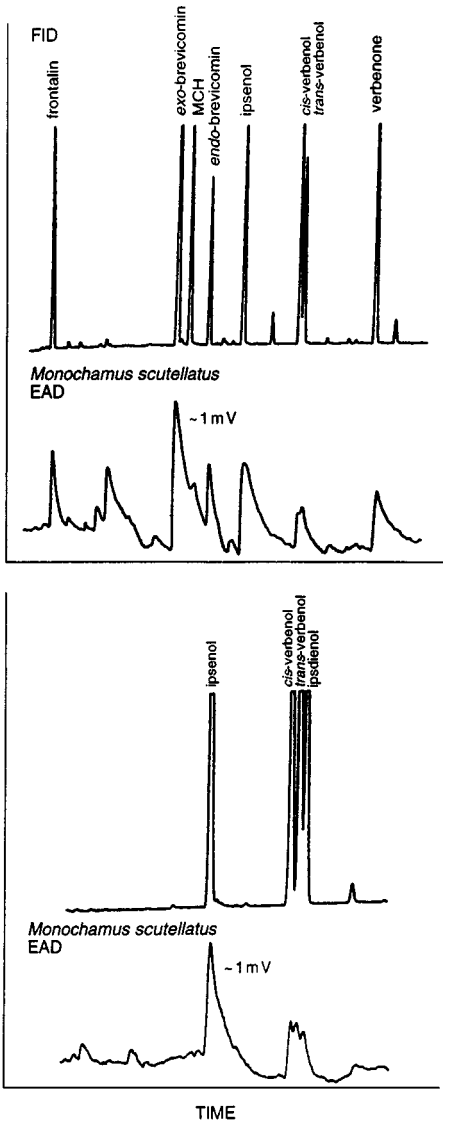

FIG. 1. Responses in GC-EAD analysis of female *M. scatellatas* antenna to nine bark beetle pheromones with a DB-5 column with a temperature program of 60°C (1 min), 10°C/min to 220°C (top), and a DB-5 column with a temperature program of 50°C (1 min), 10°C/min to 90°C, then 4°C/min to 240°C (bottom) to separate ipsdienol from *trans*-verbenol.

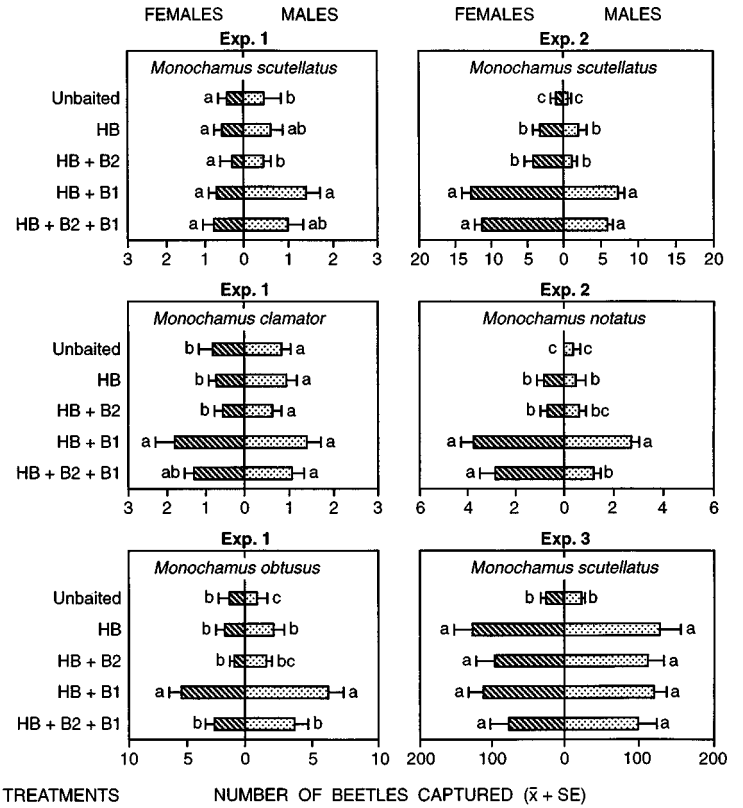

FIG. 2. Catches of four *Monochamus* spp. in experiments 1–3 in unbaited traps or in traps baited with a blend of host compounds alone (HB = host blend) or with pheromone blend 1 (B1), pheromone blend 2 (B2), or both blends together (Table 1). The host blend was composed of ethanol with α-pinene (experiment 1) or a complex blend of monoterpenes (experiments 2 and 3) (Table 1). Means within a species, experiment, and sex followed by the same letter are not significantly different, REGW test, $\alpha = 0.05$.

Buprestidae, were as follows: female *B. subornata* ($N = 89$) in experiment 1 captured in greater numbers in unbaited traps than in traps baited with the host blend and pheromone blend 2, with an intermediate level attracted to the host blend and host blend with pheromone blend 1 or pheromone blends 1 and 2; female *Chalcophora virginiensis* ($N = 158$) in experiment 4 captured in greater numbers in traps baited with pheromone blend 1 alone or with pheromone blend 2 than in other traps; male *Dicerca tenebrica* ($N = 482$) in experiment 4 captured in higher numbers in traps baited with either pheromone blend than in unbaited control traps, with an intermediate level attracted to both pheromone blends combined; female

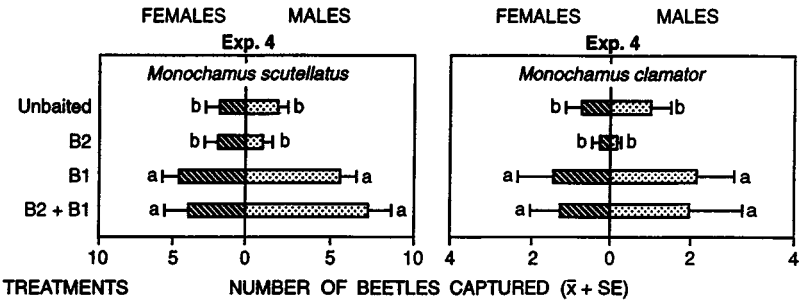

FIG. 3. Catches of *M. scutellatus* and *M. clamator* in experiment 4 in unbaited multiple-funnel traps or in traps baited with pheromone blend 1 (B1), pheromone blend 2 (B2), or both blends together. Means within a species and sex followed by the same letter are not significantly different, REGW test, $\alpha = 0.05$.

D. tenebrica ($N = 1288$) in experiment 4 captured in higher numbers in traps baited with blend 1 than in traps baited with both blends combined and unbaited traps, with an intermediate level attracted to blend 2; and female *Buprestis lyrata* ($N = 46$) in experiment 4 captured in higher numbers in traps baited with phero mone blend 2 than pheromone blend 1, with other treatments intermediate. Despite $\geq$50 beetles being captured, no significantly greater responses to baited over unbaited traps in any experiment were found for the following: *Xylotrechus longitarsus, X. undulatus*, *Asemum* spp., and *Arhopalus* spp. (all Cermabycidae), *Dicerca tenebrosa, B. nutalli, B. laeviventris, B. maculativentris,* and *Chrysobothris* spp. (all Buprestidae).

DISCUSSION

Our results demonstrate that *M. clamator, M. notatus, M. obtusus*, and *M. scutellatus* can perceive and are attracted by pheromones of sympatric bark beetles in combination with host volatiles. For two species, *M. scutellatus* and *M. clamator*, they also demonstrate that a response can occur to bark beetle pheromones in the absence of host volatiles, supporting the results of Billings and Cameron (1984), but not Billings (1985) for *M. titillator.*

These findings suggest that these *Monochamus* spp. use heterospecific pheromones as kairomones during host selection. The ability to respond to both sympatric bark beetle pheromones and host volatiles would minimize the energy spent in foraging to locate hosts, the exposure to predation or environmental extremes (Dahlsten, 1982), and the opportunity cost of time lost for other biologically important activities (Campbell, 1996) in both the presence and absence of mass-attacking primary and secondary bark beetles.

The occurrence of intraguild predation is well documented in many terrestrial and aquatic communities (Polis et al., 1989). Dodds et al. (2001) recently found that *M. carolinensis* is a facultative, intraguild predator of bark beetle larvae. We hypothesize that *M. clamator, M. notatus, M. obtusus,* and *M. scutellatus* are intraguild predators, and, thus, gain an additional adaptive advantage from being able to orient to bark beetle pheromones. Evolution of a kairomonal response by *Monochamus* spp. to the pheromones of numerous species of sympatric bark beetles would be facilitated by overlapping host ranges and similar larval requirements. The absence of one or both of these may explain why the majority of other wood-borers captured, mainly buprestids, did not respond to either the host or pheromone blends. If *Monochamus* spp. gain a significant adaptive advantage by preying on the larvae of bark beetles, they would inevitably be in competition with entomophagous insects that use the same compounds as kairomones (Borden, 1982).

In Ft. Nelson, population levels during experiment 3 were high, and it is possible that the high numbers of responding beetles obscured responses by *M. scutellatus* to different stimuli. Alternatively, the Ft. Nelson population of *M. scutellatus* may represent a behavioral ecotype that is associated with different bark beetles than those in southern British Columbia or Ontario.

The blends tested contained two antiaggregation pheromones: MCH and verbenone. Positive orientation toward sources of both aggregation and antiaggregation pheromones should be adaptive for *Monochamus* spp., as long as they indicate the presence of a suitable host. However, the lack of a response to pheromone blend 2 alone or combined with the host blend, as well as reduced responses by *M. obtusus* when it was combined with pheromone blend 1 in experiment 1, suggest that one or more of its components, possibly verbenone, could actually be repellent. The production of verbenone by microorganisms (Leufven et al., 1984; Hunt and Borden, 1990) after a host has been overcome by aggressive bark beetles may provide a signal to *Monochamus* spp. of hosts that are no longer acceptable. Verbenone might also be produced by microorganisms associated with larval wood-borers.

Kairomonal responses by *Monochamus* spp. may have practical application in pest management. If further research results in simplified and, thus, inexpensive kairomonal blends composed of both host volatiles and bark beetle pheromones, an improved trap (McIntosh et al., 2001; de Groot and Nott, 2001) baited with a more potent attractive lure might be used effectively in operational monitoring and mass-trapping programs. These in turn could lead to reduced degrade losses and (where pine-wilt disease occurs) curtailment of the spread or infection rate of the pine wood nematode.

ATTRACTION OF A LEAF BEETLE (*Oreina cacaliae*) TO DAMAGED HOST PLANTS

NICOLE M. KALBERER,*,[1] TED C. J. TURLINGS, and MARTINE RAHIER

Institute de Zoologie
Université de Neuchâtel
CH-2007 Neuchâtel, Switzerland

(Received September 1, 2000; accepted December 13, 2000)

Abstract—Early in spring, just after the snow melts, the leaf beetle *Oreina cacaliae* feeds on flowers of *Petasites paradoxus.* Later in spring they switch to their principle host plant *Adenostyles alliariae.* The attractiveness of short- and long-term damaged host plants was studied in a wind tunnel. The spring host *P. paradoxus* was more attractive to the beetles after it had been damaged overnight by conspecifics or artificially, but not when the plants were damaged half an hour before the wind-tunnel experiments. Contrary to *P. paradoxus,* the principle host plant, *A. alliariae* was more attractive shortly after an attack by conspecifics (half an hour before the experiment) compared to a undamaged plant, but lost its increased attractiveness when damaged overnight. The enhanced attraction of damaged plants was longer lasting in the spring host *P. paradoxus* than in the main host *A. alliariae.* Volatiles emitted by host plants were collected and gas chromatographic analyses of the odors collected showed qualitative and quantitative differences between damaged and undamaged plants. Among the volatiles recorded, green leaf volatiles and mono- and sesquiterpenes dominated. In overnight damaged *P. paradoxus* plants with an enhanced attractiveness, limonene was emitted in higher amounts. In freshly damaged *A. alliariae* leaves, more α-humulene and germacrene D were emitted compared to (*E,E*)-α-farnesene, whereas in the less attractive *A. alliariae* plants, more (*E,E*)-α-farnesene was emitted compared to α-humulene and germacrene D. In the field, the long lasting attraction of flowering *P. paradoxus* early in the season may facilitate mating in *O. cacaliae* after a successful overwintering.

Key Words—Olfaction, behavior, wind-tunnel, gaschromatography, Coleoptera, Chrysomelidae, *Oreina cacaliae.*

INTRODUCTION

Herbivory leads to plant injury and thus to enhanced emission of plant volatiles, which may in turn increase the attractiveness of these plants to beetles (Harari et al., 1994; Loughrin et al., 1995; Bolter et al., 1997). Host-derived volatiles can also interact with aggregation pheromones to produce synergized attraction, like that described in bark beetles, or they can be converted into pheromones, as in mountain pine beetles (Borden, 1984; Jones, 1985).

The alpine *Oreina cacaliae* (Coleoptera: Chrysomelidae) feed on two host plants at a field site in La Fouly (Val Ferret: Valais) in the Swiss Alps. In spring, just after the snow melts, the beetles feed on *Petasites paradoxus* (Asteraceae) in its flowering state. This is one of the first annual plants to occur at sun-exposed sites. Wind-tunnel experiments confirmed the attractiveness of *P. paradoxus* over a nonhost (*Tussilago farfara*) in the laboratory (Kalberer, 2000). Up to 80 individual *O. cacaliae* beetles can be found on a single flowering *P. paradoxus* plant in the field (Kalberer, personal observation). This observation led to the hypothesis that an aggregation pheromone might exist, that attracts beetles to an individual host plant. *O. cacaliae* beetles live for up to three years and generations overlap. Females are ready to copulate immediately after emergence in summer, whereas males do not mate until the following spring and summer (Rahier, unpublished results).

A second host plant, *Adenostyles alliariae* (Asteraceae), emerges three to four weeks after *P. paradoxus* and serves as summer host for the beetles. The leaves of *A. alliariae* contain pyrrolizidine alkaloids that are sequestered by *O. cacaliae* larvae and adults for their own defense (Ehmke et al., 1991; Dobler and Rowell-Rahier, 1994). *A. alliariae* has one single large leaf (0.2×0.3 m) in its vegetative state and occurs in patches. The leaves of adjacent plants are often overlapping, making it easy for *O. cacaliae* to walk from one plant to another. In the field, the beetles are much less aggregated on the *A. alliariae* leaves than on their spring host *P. paradoxus* (Kalberer, unpublished data). Quite often two and sometimes three beetles can be found on a single *A. alliariae* leaf, but their number rarely exceeds more than four (Kalberer, personal observation).

In relation to observations of aggregation in this beetle we tested (1) if an aggregation pheromone exists, (2) if plant injury changes the attractiveness of the host plants, and (3) if *O. cacaliae* reacts differently to short versus prolonged injury to *P. paradoxus* and *A. alliariae* plants. Different responses to already damaged *P. paradoxus* and *A. alliariae* may explain the observed differences in aggregation on these plants. Experiments to test ambulatory responses of beetles towards plant odors were conducted in a wind-tunnel. In addition, the volatiles emitted by undamaged and damaged host plants were collected, identified, and compared.

METHODS AND MATERIALS

The Insects. Adults of *O. cacaliae* were collected weekly from *P. paradoxus* in spring and from *A. alliariae* in summer, near La Fouly (Val Ferret: Valais) in the Swiss Alps. To prevent stress, beetles were transported to the laboratory in cooled containers. The beetles were maintained in glass jars in an incubator at a day temperature of 16°C and a night temperature of 12°C and a 16L: 8D light regime. Beetles were used within three days of collection in experiments and were sexed using sexual dimorphism of the tarsi (Lohse and Lucht, 1994).

The Plants. Plants used in the experiments were dug up weekly at or near the sites where beetles were collected and immediately transplanted into 15-cm-diameter ceramic pots. Potted plants were transported to the laboratory, where they were placed near a window and kept at room temperature until use. To obtain herbivore-damaged plants, 10 adult beetles (5 males and 5 females) were placed on *P. paradoxus* and *A. alliariae* plants and allowed to feed, either for half an hour before the experiment (short-term damage) or overnight beginning at 2000 hr, and the experiments were conducted during the next day (overnight damage). *A. alliariae* was also subject to another treatment in which five last-instar *O. cacaliae* larvae were allowed to feed on a plant for half an hour before the experiment (larval short-term damage). Both host plants were also subjected to an artificial injury treatment. Artificial injury to *P. paradoxus* was inflicted by a razor blade, with which two out of several dozen flowerheads were removed together with the edge of a basal leaf surrounding the floral stalk. In *A. alliariae*, artificial injury was administered by cutting two pieces (35 × 10 mm) from the edge of the leaf with a razor blade and punching a hole (14 mm diameter) in the middle of the leaf with a cork borer. Each plant was used once as an undamaged plant and once after being damaged in wind-tunnel experiments and for odor collection.

Wind-Tunnel. The Plexiglas wind-tunnel (0.6 × 0.6 × 1.8 m) was surrounded by a white tent to eliminate visual distraction for the beetles. Air was pulled through the tunnel at 0.1 m/sec with the use of a tubular duct fan (RR 125 C, Melios Ventilatoren AG, Urdorf, Switzerland) and was exhausted outside the room. A charcoal impregnated fabric cleaned the air at the tunnel entrance. Room temperature in the wind-tunnel facility was 22–23°C and humidity around 55% (for details see Kalberer, 2000).

Experimental Procedure. The assay was designed as a dual-choice test for walking beetles. Two differently treated potted plants were placed 0.3 m apart at the upwind end of the wind-tunnel. A glass plate (1.5 × 0.5 m) was placed horizontally in the wind-tunnel at a height adjusted such that air from the volatile-emitting, upper plant parts would pass over it. The distance between the point of beetle release on the glass plate and the plants was 1 m. The glass plate was cleaned with 70% ethanol after testing 10 beetles. Each plant combination was replicated four times with

20 beetles (10 females and 10 males) per replicate. Replication took place at intervals of at least one week with different plants and different beetles. The insects were deprived of food for at least 24 hr before being tested to promote their anemotactic response (Visser and Nielsen, 1977; Miller and Strickler, 1984). Glass jars with beetles were taken out of the incubator 30 min before an experiment and left near the wind tunnel to let the beetles acclimatize to the experimental conditions. Details on the behavior of the beetles in the wind tunnel are described in Kalberer (2000).

Wind-Tunnel Experiments Excluding Visual Cues. To exclude visual cues, the plants were not put in the wind-tunnel but placed outside the white curtain surrounding the wind tunnel. Compressed air, humidified and purified by a charcoal filter, entered a heat-sealed Nalophan cooking bag (Kalle Nalo, Wiesbaden, Germany) containing the potted plant. Teflon tubes led the air enriched with plant odors out of the cooking bag and into the wind tunnel through two holes at the upwind end of the wind-tunnel. The ends of the tubes were taped vertically to the upwind edge of the glass plate.

Pheromone Test. To test for pheromonal attraction, we placed either 10 overwintered males or 10 freshly emerged females in a large mesh metallic cage and released beetles of the opposite sex. To establish a dual-choice test, we had two cages, one with beetles and one empty. The experiments were conducted with 20 beetles and replicated four times.

Collection of Plant Volatiles. Volatiles were collected from potted plants inside a climate chamber at 15°C, 50–60% relative humidity, and 35,000 lux. The plants were placed inside odorless polyethylene terephthalate (PET) Nalophan cooking bags. One bag opening was sealed before use with a heat sealer (TEW Electric Heating Equipment Co. Ltd., type TISH-400), the other was tied around the plant stem with a plastic tie provided with the bags. Humidified and charcoal-filtered air entered the bag via a Teflon tube at a rate of 1000 ml/min. The Teflon tube was connected to the bags by a glass tube. The glass tube entered the PET bag and was introduced through a screw cap containing a Teflon-coated O-ring of the same diameter [6 mm; for details see Turlings et al. (1998)].

A volatile collection trap, consisting of a 10-cm-long × 6-mm-diameter glass tube containing 25 mg Super Q adsorbent (as described by Heath and Manukian, 1992), was attached to the PET bag in the same way as the inlet glass tube. Air was pulled through the collection trap in the bag via Tygon tubing at a rate of 800 ml/min (Turlings et al., 1998). Volatiles were collected for 4 hr, after which each trap was rinsed with 150 μl methylene chloride, and internal standards (400 ng *n*-octane and nonylacetate) were added before injection to a gas chromatograph (GC). Six collections per treatment were made.

Plant Volatile Analysis. Volatiles were analyzed with a Hewlett Packard 6890 GC equipped with an on-column injector and a flame ionization detector. Aliquots of 3 μl were injected onto a 30 m × 0.25 mm nonpolar column (EC1, film thickness) 0.25 μm, Alltech Associates), preceded by a 10-m × 0.25-mm deactivated

retention gap and a deactivated precolumn (30 cm × 0.53 mm, both Connex). Helium was used as the carrier gas at a flow rate of 24 cm/sec. The following temperature program was used: after a hold time of 3 min at 50°C, temperature was linearly increased at a rate of 8°C/min to 230°C and held for 9.5 min.

Data were collected and processed with ChemStation software (Hewlett-Packard). The main compounds were identified by GC-MS analysis on a Hewlett-Packard 5973 quadrupole-type mass selective detector (transfer line temp: 230°C, source temp: 230°C, quadrupole temp: 150°C, ionization potential: 70 eV, and scan range: 50 – 400 amu) coupled to the gas chromatograph described above. The compounds were identified by comparison of retention times to those of commercially available standards [nonene, α-phellandrene, limonene, linalool and *(E,E)*-α-farnesene] and by comparison of spectra to those of the Wiley and NIST libraries.

Behavioral Response to Collected Volatiles. This experiment was conducted to test whether the collected volatiles elicit a behavioral response in the beetles. Samples (50 μl each) containing the volatiles collected from healthy and artificially damaged *A. alliariae* plants, identical to the ones used for injection in the gas chromatograph, were offered on folded filter paper discs (90 mm diameter; Schleicher and Schuell, Dassel, Germany) placed on the glass plate at the upwind end of the wind-tunnel. No visual cues could help the beetles approach the odor source in the wind-tunnel.

Statistical Analysis. Odor preferences in the wind-tunnel were tested with a two-tailed binomial test, using the total number of beetles that made a choice for a particular odor ($\alpha = 0.05$) and pooling the data of the four replicates. To analyze the quantitative differences in the plant odors emitted by undamaged and damaged plants, we used an ANOVA followed by a Bonferroni-Dunn versus control (undamaged plant) post hoc test. Collected odor data were log (X + 1) transformed before analysis.

RESULTS

Choice Experiments

Damaged vs. Undamaged Petasites paradoxus: *Flowering State.* In choice experiments with flowering *P. paradoxus,* beetles showed a significant preference for plants damaged by overnight feeding beetles (Figure 1A, $P < 0.001$) and by artificial damage the previous evening (Figure 1B, $P < 0.01$) over undamaged plants. There was no difference in attractiveness between overnight damage caused by adult beetles and overnight artificial damage (Figure 1C, $P = 0.43$). Beetles were not more attracted to *P. paradoxus* plants that had been damaged only half an hour before the experiment (short term attack) than they were to undamaged plants (Figure 1D, $P = 0.43$).

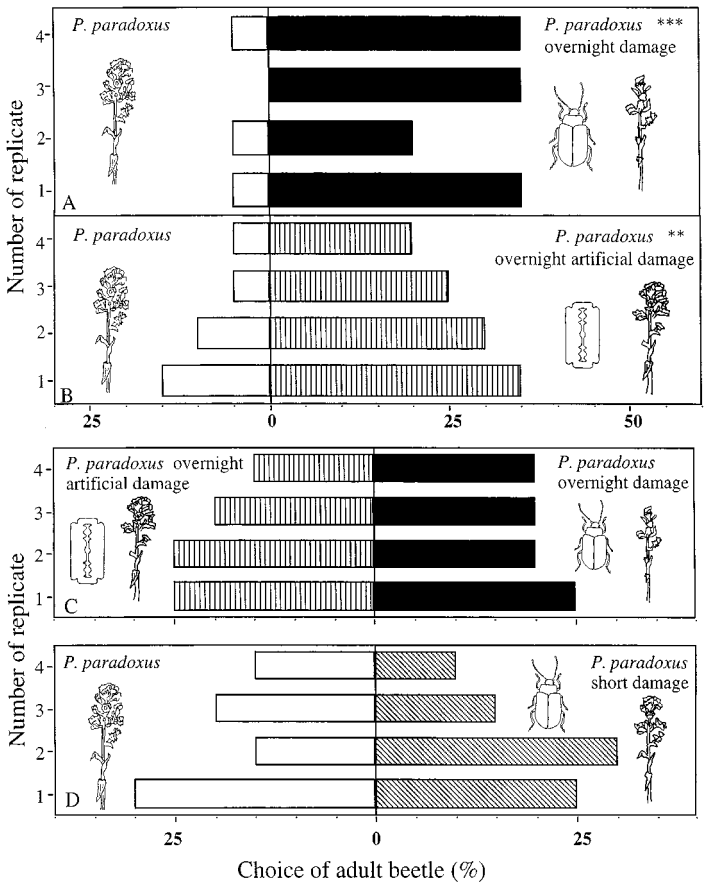

FIG. 1. Choices of *Oreina cacaliae* in wind-tunnel experiments with *Petasites paradoxus.* The bars represent the percentage of tested beetles that made a particular choice. The asterisks indicate a significant preference for a treatment (two-tailed binomial test; $^{**}P < 0.01$, $^{***}P < 0.001$).

Damaged vs. Undamaged. Adenostyles alliariae, *Vegetative State.* Freshly damaged leaves of *A. alliariae* were more attractive to beetles than undamaged leaves, regardless whether leaf damage had been inflicted by adult or larval feeding (Figure 2A, $P < 0.01$ and Figure 2B, $P < 0.05$). Freshly damaged *A. alliariae* leaves were significantly more attractive than overnight damaged leaves (Figure 2C, $P < 0.001$). Artificial fresh attack was as attractive as fresh damage caused by adult beetles feeding on the plant (Figure 2D, $P = 0.42$). Plants damaged over night by adult beetles were not more attractive than undamaged plants (Figure 2E, $P = 0.42$).

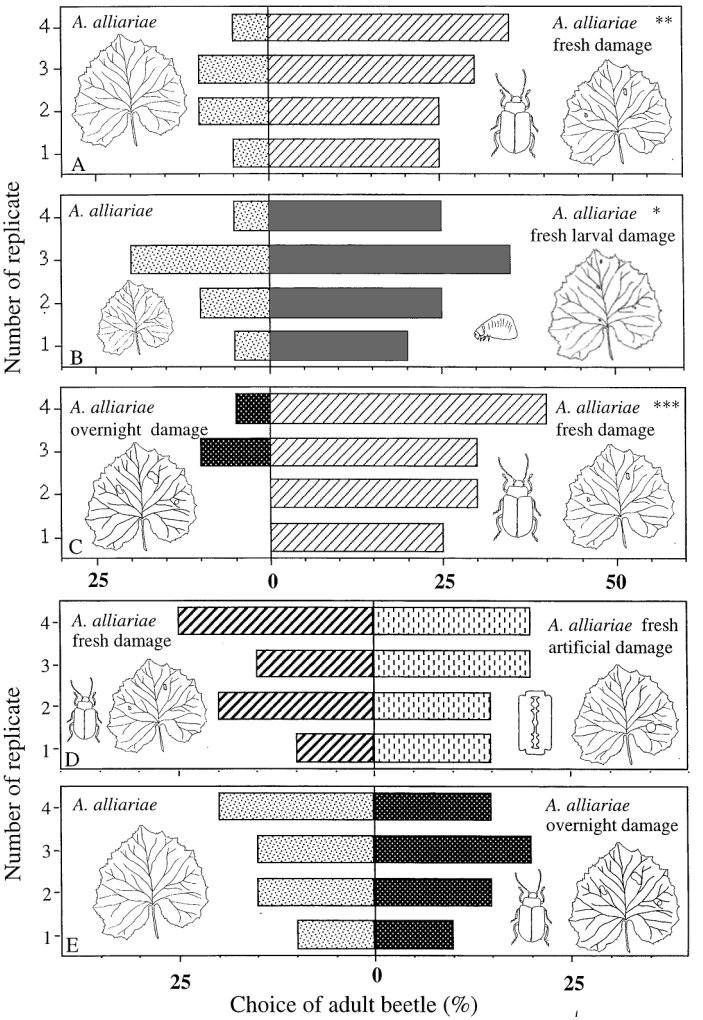

FIG. 2. Choices of *Oreina cacaliae* in wind-tunnel experiments with *Adenostyles alliariae.* The bars represent the percentage of tested beetles that made a particular choice. The asterisks indicate a significant preference for a treatment (two-tailed binomial test; $*P < 0.05$, $**P < 0.01$, $***P < 0.001$).

Host Odor without Visual Cues. The tube releasing odor collected from an undamaged *A. alliariae* plant attracted significantly more beetles than the tube releasing clean air (Figure 3A, $P < 0.05$). Collected headspace volatiles of a freshly damaged *A. alliariae* leaf presented on a filter paper, attracted more

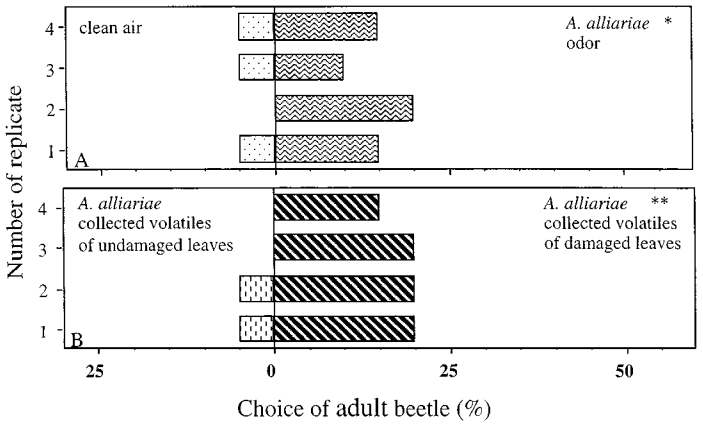

FIG. 3. (A) Choice experiments without visual cues, where the host odor entered the wind-tunnel from plants standing outside the wind-tunnel. Odor from *A. alliariae* plants attracted more beetles than pure air. (B) Collected headspace volatiles from damaged *A. alliariae* leaf put on a filter paper attracted more beetles than the collected odor of a undamaged *A. alliariae* leaf. The asterisks indicate a significant preference for a treatment (two-tailed binomial test; $*P < 0.05$, $**P < 0.01$.

beetle than did collected headspace volatiles of an undamaged leaf (Figure 3B, $P < 0.01$).

Attractiveness of Conspecifics. O. cacaliae beetles of one sex were not attracted by conspecifics of the other sex. Neither overwintered males nor new generation females attracted more adults of the opposite sex than did an empty cage (Figure 4, $P = 0.34$, both sexes). When two potted *A. alliariae* plants were added at the upwind end of the wind-tunnel, beetles still did not discriminate between the cage with conspecifics and the empty cage ($P = 0.4$, data not shown).

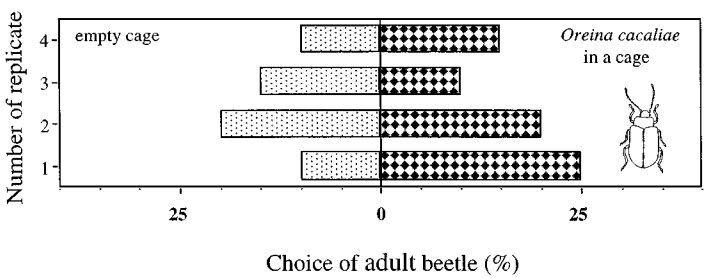

FIG. 4. *O. cacaliae* was not attracted to the smell of the opposite sex and did not approach the conspecifics hidden in a metallic cage more often than an empty cage ($P = 0.34$).

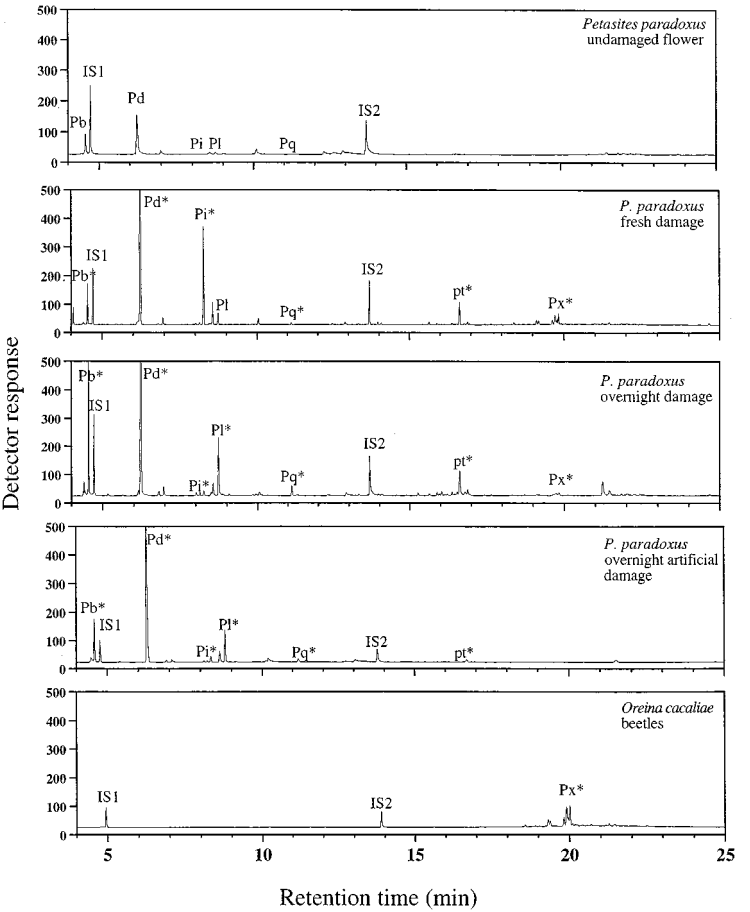

FIG. 5. Representative gas chromatographic profiles of headspace volatiles from undamaged, freshly damaged, overnight damaged and artificially overnight damaged *Petasites paradoxus* plants. The bottom chromatogram shows the odor from *Oreina cacaliae* beetles. Peak identities: (P for *Petasites*) Pb, unknown; Pd, nonene; Pi, α-phelandrene; Pl, limonene; Pq, unknown; Pt, eremophylene; Px, chromolaenin. IS1 and IS2 represent the internal standards *n*-octane and nonyl acetate, respectively. Asterisks indicate significant differences in the amount of an emitted substance as compared to a undamaged *P. paradoxus* flower.

Analysis of Headspace Volatiles

Petasites paradoxus *Flowering State*. Representative gas chromatographic profiles of headspace volatiles collected from *P. paradoxus* plants illustrate the differences in volatile blends between undamaged and damaged plants (Figure 5).

TABLE 1. DATA OF ANOVA TEST FOR COLLECTED PLANT ODOR COMPOUNDS OF DAMAGED PLANTS COMPARED WITH UNDAMAGED CONTROL PLANTS[a]

Compound	MS	*F*	*P*
Petasites paradoxus flowering			
Unknown (Pb)	0.49	7.69	0.0013
Nonene (Pd)	1.16	7.8	0.0012
(*E,E*)-α-phellandrene (Pi)	5.81	11.7	0.0001
Limonene (Pl)	1.15	4.94	0.01
Unknown (Pq)	4.33	12.63	0.0001
Eremophylene (Pt)	4.29	23.59	0.0001
Chromolaenin (Px)	7.64	69.48	0.0001
Adenostyles alliariae vegetative			
(*Z*)-3-Hexenol (a)	2.69	3.34	0.025
Unknown (b)	1.75	3.27	0.028
(*Z*)-3-Hexenyl acetate (c)	1.9	3.84	0.015
Linalool (e)	0.94	7.38	0.0005
Dodecanol (h)	2.78	6.14	0.0014
α-Humulene (k)	0.87	7.51	0.0004
Germacrene D (n)	0.48	3.61	0.019
(E,E)-α-fannesene (p)	0.25	2.42	0.075

[a] Significant differences between treatments are indicated with an asterisk in the Figures 4 and 5.

Control collections from empty PET bags showed no background odor. The sesquiterpene α-phellandrene was emitted in large amounts by freshly damaged *P. paradoxus* plants (Figure 5, peak Pi). Overnight damaged plants (adult and artificial attack) with enhanced attractiveness emitted significantly more limonene (peak Pl) than both undamaged and freshly damaged plants. The other volatile compounds—nonene, eremophylene, and two unknown substances were released in significantly larger amounts by damaged plants (either fresh or overnight damage) than by undamaged plants (Table 1, Figure 5).

Adenostyles alliariae *Vegetative State*. Representative gas chromatograms of headspace volatiles collected from *A. alliariae* leaves following different treatments are shown in Figure 6. Freshly damaged leaves with enhanced attractiveness, damaged either by adult beetles, larvae, or artificially, contained significantly larger amounts of linalool (e), dodecanol (h), α-humulene (k), and germacrene D (n) than did undamaged leaves (Table 1, Figure 6). When *A. alliariae* leaves were damaged overnight by adults, they emitted additional volatiles such as (*Z*)-3 hexenol (a), (*Z*)-3-hexenyl acetate (c), (*E,E*)-α-farnesene (p), and an unknown substance (b). In undamaged and overnight damaged *A. alliariae* more (*E,E*)-α-farnesene (p) is produced compared to α-humulene (k) and germacrene D (n), whereas in freshly damaged leaves (by adults, larvae, or artificially) more α-humulene (k) and germacrene D (n) are emitted compared to (*E,E*)-α-farnesene (p).

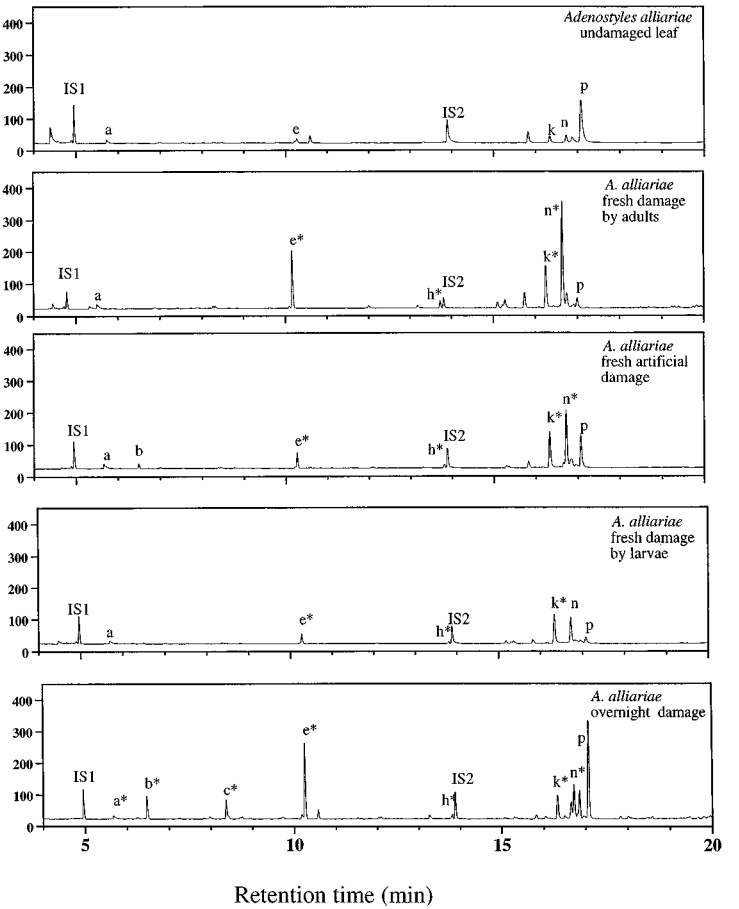

FIG. 6. Representative gas chromatographic profiles of *Adenostyles allliariae* headspace volatiles collected from leaves after various treatments. Treatments from top to bottom were: undamaged *A. alliariae* leaf, a leaf freshly damage by adult *O. cacaliae*, a leaf artificially damaged with a razor blade, a leaf freshly damaged by *O. cacaliae* larvae, and a leaf damaged overnight by *O. cacaliae* adults. Peak identities: a, (*Z*)-3-hexenol; b, unknown; c, (*Z*)-3 hexenylacetate; e, linalool; h, dodecanol; k, α-humulene; n, germacrene D; and p, (*E*,*E*)-α-farnesene. IS1 and IS2 represent the internal standards *n*-octane and nonyl acetate, respectively. Asterisks indicate significant differences in the amount of an emitted substance as compared to a undamaged *A. alliariae* leaf.

Results of Beetle Odor Collections

Oreina cacaliae. Chromolaenin was the only identified substance emitted from *O. cacaliae* beetles and was also present in plant odor collections from damaged plants, where beetles had fed on the plant during collection (Figure 5).

DISCUSSION

Wind-tunnel experiments with *O. cacaliae* and the host plants *P. paradoxus* and *A. alliariae* provide evidence that this alpine leaf beetle is more attracted to volatiles released by damaged host plants than it is to undamaged hosts. Domek and Johnson (1988) found that green June beetles feeding on ripe peach attract significantly more conspecifics than did ripe sliced fruit or beetles alone, demonstrating that beetles feeding on a host attract more conspecifics than the presence of host plants or conspecifics alone. The attraction to a general odor of wounded plants could be excluded in an experiment with *Phyllotreta cruciferae* (Coleoptera: Chrysomelidae), where beetles were attracted to conspecifics feeding on the host plant oilseed rape, but not to conspecifics feeding on the nonhost crambe (Peng and Weiss, 1992). *O. cacaliae* beetles responded similarly to insect (larvae or adult) or artificially damaged host plants, showing that the volatile blend emitted is solely a result of plant injury and not part of the odors emitted by the insect while feeding.

Even in the absence of any visual cues characterizing its host plant in the wind tunnel *O. cacaliae* approached the host plant odor inlet more often than the clean air inlet. Nevertheless, the fact that fewer beetles responded in experiments without visual cues than in trials in which plants were placed in the wind tunnel indicates that some visual cues might help the beetles to approach a plant. In the field, the role of visual cues in host plant finding behavior is clearly less important than the role of odor cues (Kalberer, 2000).

Pasteels et al. (1994) speculated on the existence of a sexual pheromone in *O. gloriosa*, based on differences in the composition of defensive secretion, between the sexes (Eggenberger and Rowell-Rahier, 1991, 1993). We found no evidence for a sex pheromone in *O. cacaliae.* Our beetles were transported together in a pot from the field to the lab, and they may have released their defensive secretion during transport, which could have affected their subsequent responses. Keeping the beetles separate may yield different results.

Short- or long-term attack, respectively, lead to an enhanced attractiveness in one host plant of *O. cacaliae* but not in the other. The spring host *P. paradoxus* was more attractive after overnight damage, whereas *A. alliariae* had an enhanced attractiveness only after a fresh attack, but lost this enhanced attractiveness hours later. An enhanced attractiveness for overnight damaged plants similar for the one on *P. paradoxus* had been described for the Japanese beetle on crabapple leaves where overnight damaged leaves attract more beetles than undamaged leaves or leaves with fresh damage (Loughrin et al., 1995).

Collected headspace volatiles from damaged *A. alliariae* leaves were more attractive to the beetles than collected volatiles from undamaged *A. alliariae* leaves, showing that the compounds triggering a response in *O. cacaliae* had been collected. The compounds collected were analyzed in order to determine how the

composition of the odor blend changed as a result of herbivore attack. Visser et al. (1979) showed that fresh attack by Colorado potato beetles results in the emission of green leaf volatiles from injured plant cells. These volatiles are emitted by most plant species after damage as a result of the oxidative degradation of plant lipids (Visser and Avé, 1978). The compounds (*Z*)-3-hexenol and (*Z*)-3-hexenyl acetate that were released from damaged *A. alliariae* leaves after a short attack belong to this category, nevertheless they were also produced after overnight attack. Several studies have shown that the production of other volatiles is induced in the plant following the attack by a herbivore (Turlings et al., 1990, Takabayashi et al., 1994) and is the result of active chemical processes in the plant (Paré and Tumlinson, 1997). Mono- and sesquiterpenes, built via the isoprenoid pathway, belong to this category and are the most common volatiles induced by herbivore attack (Paré and Tumlinson, 1997). Nonene, α-phelandrene, limonene, and eremophylene, were the compounds emitted in higher amounts by damaged *P. paradoxus* plants compared to undamaged plants. After an overnight infestation by beetles as well as after artificial damage the previous evening, *P. paradoxus* flowers released significantly more limonene than plants that were less attractive for the beetles. It is tempting to speculate that the enhanced attractiveness of overnight damaged *P. paradoxus* is due to an increased amount of limonene in the emitted plant volatiles. Nevertheless it is risky to speculate that a single compound evokes the observed response in the beetle, because several studies have shown that the blend of odor components is crucial to provoke a certain behavioral response (Visser and Avé, 1978; Saxena and Goyal, 1978).

Linalool, dodecanol, α-humulene, and germacrene D were the compounds emitted in higher amounts by damaged *A. alliariae* leaves compared to undamaged leaves. In freshly damaged *A. alliariae* leaves with enhanced attractiveness, more α-humulene and germacrene D were emitted compared to (*E,E*)-α-farnesene whereas in the less attractive *A. alliariae* undamaged and overnight-damaged plants, more (*E,E*)-α-farnesene was emitted compared to α-humulene and germacrene D. This reverse relationship between those sesquiterpenes might be responsible for the enhanced attractiveness of freshly damaged *A. alliariae* leaves.

Most of the compounds that we found after an attack of *O. cacaliae* in its host plants have been described for damaged host plants of other systems. For instance the terpene (*E,E*)-α-farnesene is released by damaged crabapple and by *Psylla*-infested pear trees (Loughrin et al., 1995; Scutareanu et al., 1997), (*Z*)-3-hexenyl acetate was found to be associated with herbivory in maize (Turlings et al., 1990), and the sesquiterpene (-)-germacrene D appears to mask the attractiveness of undamaged pine trees to *Monochamus alternatus* (Coleoptera: Cerambycidae) (Yamasaki et al., 1997).

The fact that damaged host plants are more attractive than undamaged plants may promote aggregation of *O. cacaliae* on plants suitable for feeding and larval

development. The difference in the attractiveness of the two host plants with respect to time since attack corresponds nicely with field observations of beetle densities on plants. Dozens of beetles often feed on a single flowering *P. paradoxus* plant in spring, while only a few beetles (2–4) were ever observed on *A. alliariae* plants. The long-lasting attraction of flowering *P. paradoxus* early in the season may facilitate mating in *O. cacaliae.* It might be especially rewarding for the females to remate in spring with a male who successfully overwintered, to increase the fitness of their offspring (Stevens and Cauley, 1989).

Acknowledgments—We thank Sandrine Gouingueuné for the GC-MS analyses and Jonathan Gershenzon at the Max-Planck-Institut für Chemische Ökologie in Jena, Germany, for access to equipment. Ann Fraser, Bernd Hägele, and Håkan Häggström made helpful comments on the manuscript.

Abstract—In the Republic of Benin, the scelionid egg parasitoid *Telenomus isis* (Polaszek) is one of the most important control factors of the noctuid maize stem borer *Sesamia calamistis.* In the present study, the role of various sources of contact kairomones (male or virgin or mated female moths) and of the moth's oviposition substrate (leaf sheath versus filter paper; host plant species) in host location and oviposition behavior of *T. isis* was investigated in Munger cells, open arenas, and/or Petri dish assays. Furthermore, its ability to distinguish between unparasitized eggs and eggs parasitized by a conspecific female or by the trichogrammatid *Lathromeris ovicida* was studied. In the Munger cell experiment, *T. isis* spent more time in moths' odor fields than in the control. There was no difference between virgin and mated females. In the open arena assay, traces left by both the male and female moths acted as contact cues, which elicited an arrestment response in the parasitoid. The residence and patch retention time in the arena with virgin or mated females of *S. calamistis* was about 4.8 times as long as that with males. The presence of maize leaf sheaths stimulated the oviposition behavior of *T. isis* when compared to eggs offered on filter paper. During the first 6 hr, more eggs were parasitized on maize leaves, although there was no difference in the final number of offspring between the two substrates. In addition, if eggs of *S. calamistis* were offered together with different host plant species or alone, maize and sorghum were both more attractive than millet or the egg alone and equally attractive between themselves, indicating that the plant tissue influences host finding of *T. isis.* Both *T. isis* and *L. ovicida* recognized

0098-0331/01/0400-0663$19.50/0

markings of conspecific females, and intraspecific superparasitism was therefore low. Interspecific superparasitism was more than three times higher for *L. ovicida* than for *T. isis*, indicating that only *T. isis* was able to recognize the marking of the other species and tried to avoid superparasitism. Emergence of parasitoids from multiparasitized eggs generally was in favor of *L. ovicida* regardless of species order.

Key Words—*Telenomus isis*, *Lathromeris ovicida*, *Sesamia calamistis*, host location, host discrimination, superparasitism, West Africa.

INTRODUCTION

In southern Benin, the solitary scelionid egg parasitoids *Telenomus busseolae* (Gahan) (Hymenoptera: Scelionidae) and *T. isis* (Polaszek) (Hymenoptera: Scelionidae) are the most important natural control factors of the maize stem borer *Sesamia calamistis* Hampson (Lepidoptera: Noctuidae) (Sétamou and Schulthess, 1995; Schulthess et al., 1997). A third species commonly found on *S. calamistis* eggs, but of low importance, is the gregarious trichogrammatid *Lathromeris ovicida* Risbec (Hymenoptera: Trichogrammatidae). *T. busseolae* is a relatively well-described species known as an important biological control agent of several noctuid pests throughout Africa as well as Greece and the Middle East (Alexandri and Tsitsipis, 1990; Kornosor et al., 1994; Polaszek, 1998). In contrast, *T. isis* was described only in 1993 (Polaszek et al., 1993) and, so far, has been reported only from West Africa, including Cameroon (Polaszek, 1998; Ndemah, 1999). As a result, there is little information about the biology and ecology of this species, although, as shown for southern Benin, it can contribute significantly to reducing noctuid stem borer populations on maize (Schulthess et al., 1997).

Southern Benin is characterized by derived savanna vegetation, which forms a continuum of wild and cultivated host plants of *S. calamistis*, most of them belonging to the family Poacea. Both the generally low egg batch densities, ranging between 0.01 and 0.1 per tiller (Schulthess et al., 2000) and their regular dispersion pattern (Sétamou and Schulthess, 1995) make host finding difficult. Nevertheless, in region-wide surveys in southern Benin in 1995–1996, up to 62% of the egg batches were parasitized by *T. isis*, indicating good host-finding ability (Schulthess et al., 2000). It is not clear how *T. isis* detects its host. The importance of chemical stimuli orienting females to their host has been documented for several egg parasitoids species (Noldus and van Lenteren, 1985; Aldrich et al., 1984; Mattiaci et al., 1993). These stimuli vary in their information content and in their detectability. Stimuli from the host itself are more reliable but generally difficult to detect by the parasitoid, whereas stimuli from the host microhabitat or food plants can be detected easily, but generally carry less host-specific information (Vet et al., 1991; Vet and Dicke, 1992; Wäckers and Lewis, 1994). The first objective of this

study was to investigate the potential sources of infochemicals used by *T. isis* in its host location process by testing virgin or mated females moths and male moths, as well as several host plants of *S. calamistis.*

Surveys showed that ca. 15% of the *S. calamistis* egg batches were detected and parasitized by up to three species (Schulthess et al., 2000), and it was theorized that this may have been a result of superparasitism. Agboka (1998) demonstrated, however, that both *T. isis* and *T. busseolae* were able to detect eggs already parasitized by a conspecific female or another *Telenomus* species and, thus, tended to avoid superparasitism. If superparasitism occurred, *T. busseolae* won over *T. isis,* irrespective of species order. During the surveys, *L. ovicida* was more often found together with *T. isis* than *T. busseolae.* Thus, a second objective of this study was to assess the ability of the two species to discriminate between parasitized and nonparasitized eggs and the outcome in the case of interspecies superparasitism. This study is part of a larger project to assess the chances of *T. isis* to becoming established in East and southern Africa.

METHODS AND MATERIALS

Insect Colonies. Eggs of *S. calamistis* were obtained from a colony maintained on an artificial diet at the International Institute of Tropical Agriculture (IITA), Calavi, Benin, following the protocol developed by Bosque-Pérez and Dabrowski (1989). Adults of both *T. isis* and *L. ovicida* were reared on *S. calamistis* eggs according to the method of Chabi-Olaye et al. (1997). The parasitoids originated from parasitized eggs of *S. calamistis* collected in the derived savanna in southern Benin. For the behavioral assays, female and male pupae of *S. calamistis* were isolated in plastic containers (5 cm high $\times$ 18 cm diameter), and kept at $27 \pm 1^{\circ}$C, $75 \pm 5\%$ relative humidity, and 10D:14L photoperiod. After emergence, three groups of moths were tested: newly emerged males, virgin females, and mated females.

Munger Cells Behavioral Assays. Three-chamber Munger cells were used to investigate the response of *T. isis* females to moths of *S. calamistis.* The device is a transparent glass plate (10 cm long $\times$ 5 cm wide $\times$ 1 cm thick) composed of three cells (2 cm diameter $\times$ 1 cm deep), i.e., a central cell, and two side cells. Each side cell is situated 0.5 cm from the central cell and 1.5 cm from the edge of the device. The device is provided with a longitudinal ventilation system (0.4 cm diameter), consisting of two interior air ducts connecting each side cell to the central cell, and two side air ducts from the side cells to the outside. The top and the bottom of the device were covered with two transparent glass plates (10 cm long $\times$ 5 cm wide $\times$ 0.3 cm thick).

The experiment consists of four tests (virgin female versus control field, mated female versus control field, male versus control field, and virgin female

versus mated female of *S. calamistis*). For the first three tests, the bait, i.e., a male, a virgin female, or a mated female moth was placed in one of the side cells, while the second cell served as the control (control field). In the last test, the mated and virgin females of *S. calamistis* were placed separately in each side cell. One ca. 0.5-day-old, naïve, mated female parasitoid was introduced into the central cell and was allowed 10 min to choose one of the side cells. Thereafter, the wasp was discarded whether or not it had made a choice. A choice was defined when a wasp had crossed any interior air duct, penetrated into a side cell, and remained there for at least 2 sec. After every five observations, the device was rotated to prevent bias due to positional factors. A minimum of 30 wasps was observed for each tested bait type. After each experiment, the whole system was cleaned with chloroform and neutral soap. All tests were conducted at 26 $\pm$ 1°C and 65 $\pm$ 5% relative humidity under permanent light conditions. Data were gathered on the proportion of wasps that made a choice for each side cell and the time spent by wasps in each side cell.

Open Arena Behavioral Assays. Arena experiments were conducted on filter paper (18.6 cm diameter). The parasitoids could easily move within this area or fly away. In the center of the filter paper, a circular area 9.3 cm diameter was either left untreated or treated in the following way: one adult *S. calamistis* was exposed under a plastic cover (9.3 cm diameter $\times$ 1 cm high) to the circular area for 1 hr. All bioassays were performed with naïve, mated, female parasitoids ca. 0.5 days old collected from the stock culture. One individual was placed in the middle of the treated area with a camel-hair brush. The response of the parasitoid was determined by monitoring the retention of the wasp on the treated surface (patch retention time) and in the experimental arena (arena residence time) by using a stopwatch. The measurement began when the wasp touched the treated surface and was terminated when it left the arena. Each observation lasted 15 min. Each treatment (i.e., filter paper treated with a male, virgin female, or mated female *S. calamistis*) was replicated 42 times. All experiments were conducted at 27 $\pm$ 1°C and 65 $\pm$ 5% relative humidity regime.

The arena residence time was defined as the time from when a female parasitoid entered the arena until it flew away or walked out of the arena. The patch retention time is the total time the female parasitoid spent in the treated surface.

Response of T. isis *to* S. calamistis *Oviposition Substrate.* Prior to this experiment, maize stems collected in a nearby field were exposed overnight to *S. calamistis* adults for oviposition. Leaf sheaths containing one egg mass with approximately 100 eggs were selected for subsequent testing. One naïve, mated female parasitoid ca. 0.5 days old was placed with a camel-hair brush in a vial (11 cm long $\times$ 4.5 cm diameter) containing 100 eggs of *S. calamistis* either on maize leaf sheaths or on filter paper. After 6 hr, eggs were renewed, and then provided ad libitum until the death of the female. Removed eggs were transferred to another vial of similar dimensions and incubated at 28 $\pm$ 1°C and 70 $\pm$ 5%. Each

treatment was replicated 20 times for each substrate. Six traits were observed, i.e., percent parasitism after 6 hr, time to first oviposition (in seconds), total number of offspring, percent emergence, oviposition time, and sex ratio of F_1 progeny.

Relative Attractiveness of Different Host Plants of Stem Borers to Female T. isis. A four-arm olfactometer, similar to that described by Scholz et al. (1997), was used to investigate the attractiveness of odors from different host plants of cereal stem borers for *T. isis* females. The experiment was designed to test the following assumptions: (1) that *S. calamistis* eggs with leaf sheaths of different host plants of stem borers are more attractive than eggs without leaf sheaths, and (2) that attraction varies among the three different host plants tested. The device has been used successfully in several studies on the host-finding behavior of Coleoptera (e.g., Scholz et al., 1998; Borgemeister et al., 1999). Females were released into the central arena through a hole, which was drilled into the bottom of the olfactometer. Five minutes before the females were released into the olfactometer, the odor sources were introduced into the device to ensure a gradient of volatiles. Each bait was introduced into a 500-ml jar. Four different baits were tested simultaneously. Initially, the different baits were distributed at random among the four jars. After 25, 50, and 75% of the replications, the positions of the odor sources were permutated to reduce bias due to environmental factors such as light. The following odor sources were tested: (1) eggs of *S. calamistis*, (2) maize leaf sheaths with eggs of *S. calamistis*, (3) sorghum leaf sheaths with eggs of *S. calamistis*, and (4) millet leaf sheaths with eggs of *S. calamistis*. Eggs of *S. calamistis* were artificially released in the leaf sheath of each host plant, and the control jar contained only one egg of *S. calamistis*. Before and after use, the olfactometer and the jars containing the different odor sources were cleaned with methanol, rinsed in hot water, and dried in an oven at 45°C. Experiments were conducted in a climatic chamber (25°C, $70 \pm 5\%$ relative humidity) with a light source above the olfactometer. In total, 20 female *T. isis* were tested (i.e., 20 replicates). Each observation lasted 15 min, and the total time spent in each odor field was recorded.

Host Discrimination by T. isis *and* L. ovicida. Both intraspecific and interspecific host discrimination was tested. The objective of the study on intraspecific competition was to examine the response of a *T. isis* and a *L. ovicida* female to eggs previously parasitized by a conspecific female. Only experienced females were used. Parasitoids were considered experienced after they had oviposited in and had marked at least one host egg. According to Bosque and Rabinovich (1979), oviposition experience improves the ability of egg parasitoids to discriminate between parasitized and nonparasitized hosts. A 12 to 24-hr-old egg mass of *S. calamistis*, containing ca 20 eggs was exposed to a female parasitoid in a glass vial (28 mm long $\times$ 23 mm diameter). All eggs within an egg mass were numbered in order to observe the oviposition sequence of a particular parasitoid. The first female was allowed to probe and mark half of the egg mass and was then removed. After 1 hr, a second female was introduced to the egg mass, and the ovipositional

behavior was observed. The interspecific host discrimination study was carried out to examine the response of a *T. isis* female to egg masses previously parasitized by *L. ovicida* and vice versa.

Parasitized eggs were removed and incubated in a glass vial at $27 \pm 1°C$ and $75 \pm 5\%$ relative humidity. Emergence of parasitoids from eggs parasitized by the two females was recorded for both conspecific and interspecific pairs. Upon emergence, all individuals were identified and sexed. *Telenomus isis* adults were isolated from *L. ovicida* according to Polaszek et al. (1993). The time between removal of the first parasitoid and introduction of the second parasitoid was fixed at 1 hr. Both experiments were replicated 10 times.

Statistical Analysis. In the Munger cells bioassay, differences in wasp choices were analyzed by means of a χ^2 test, and the mean percent time spent in tested fields with Wilcoxon signed ranks test. Differences in patch retention time, residence time, percent parasitism, time to first oviposition, total number of offspring, percent eggs with parasitoid emergence, the oviposition time, and the sex ratio of the F_1 progeny for different ovipositional substrates were analyzed by analysis of variance (ANOVA), by using the general linear model (GLM) procedure of SAS (SAS Institute, 1992). In case of significant *F* values, means were compared by using the Student-Newman-Keul test. Friedman two-way analysis of variance by ranks, based on time spent by female *T. isis* per odor field, was used to test for field preferences in the four-chamber olfactometer experiment. Mean time spent per odor field was compared by using Wilcoxon signed ranks test. The significant level was set at $P = 0.05$.

For host discrimination behavior, the numbers of ovipositions per female, expressed as probing and marking (see Agboka, 1998), in parasitized and nonparasitized eggs (eggs acceptance) were calculated for each treatment and compared by means of a χ^2 test. Emerged parasitoids from multiparasitized host eggs were compared by using a *t* test with a Bonferroni probability adjustment procedure at $P = 0.05$ (SAS Institute, 1992).

RESULTS

Responses of T. isis *to Adult* S. calamistis *Exposed in Munger Cells.* In a control position (empty cells), *T. isis* females did not show any preference for either side cell and spent about equal percentage of their time in each (12.4 ± 3.7 right vs. 12.1 ± 3.3 left, $N = 20$, $Z = 0.112$, $P = 0.911$). Similarly, no differences in the percentage of first choices of the parasitoids were recorded between the control field and test fields containing a male, virgin female, or mated female *S. calamistis* (Figure 1). However, *T. isis* females spent more time in the side cell containing any of the tested type of *S. calamistis* adults than in the control field (Figure 2). Yet,

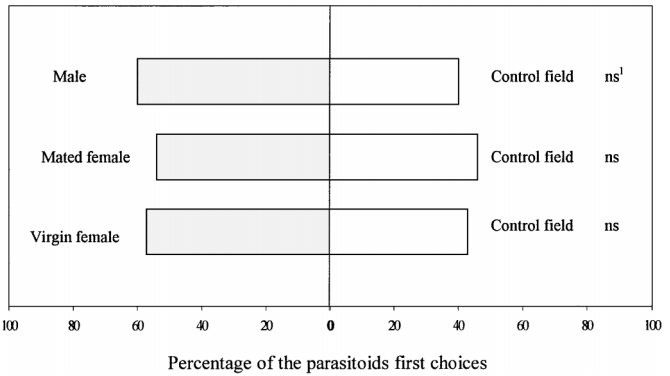

FIG. 1. Percentage of *T. isis* females' first choices in each side cells of the Mugen cell to males, virgin females and mated females of *S. calamistis.*[1] not significant; parasitoid choices were analyzed with χ^2 test.

no differences in the time spent were observed between cells containing a virgin and a mated female (Figure 2).

Responses of T. isis *to Contact Kairomones of* S. calamistis *in an Open Arena.* In a control situation, i.e., without the presence of contact kairomones of *S. calamistis* adults, the patch area did not elicit any response from *T. isis.* The parasitoids spent little time in the patch area (mean 18.1 sec.), walking fast, and left the arena after an average of 44.4 sec (Table 1). In presence of contact kairomones of *S. calamistis* adults, however, female parasitoids were arrested in the patch area

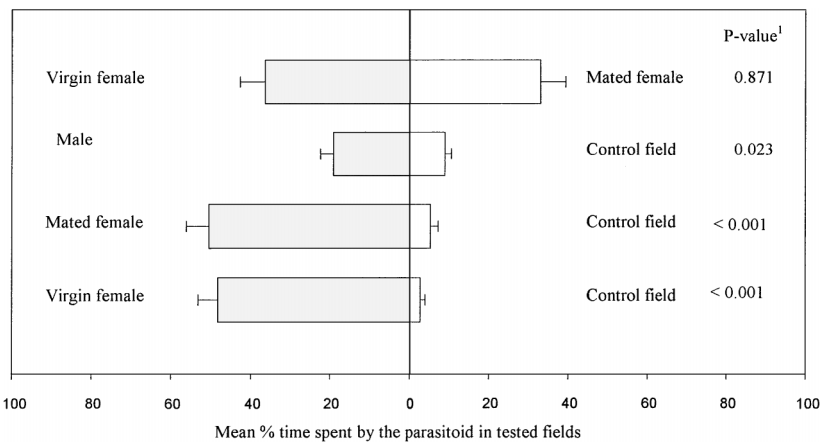

FIG. 2. Response of *T. isis* to males, virgin females and mated females of *S. calamistis.* [1]Wilcoxon signed ranks test for pairwise comparison.

TABLE 1. ARENA RESIDENCE TIME, PATCH RETENTION TIME, AND DURATION OF STOP OF *T. isis* IN PATCH TREATED WITH MALE, VIRGIN FEMALE, OR MATED FEMALE OF *S. calamistis*

	Type of baits			
	Control	Virgin female	Mated female	Male
Residence time (sec)	44.4 ± 3.25 a[a]	599.1 ± 0.72 b	598.2 ± 0.89 b	124.0 ± 8.50 c
Patch retention time (sec)	18.1 ± 1.45 a	577.3 ± 3.42 b	577.1 ± 3.61 b	57.6 ± 5.33 c
Duration of stops (sec)		124.1 ± 7.40 a	121.6 ± 7.30 a	7.1 ± 0.86 b

[a]Within row, means followed by different letters are significantly different at $P = 0.05$ (Student-Newman-Keul test).

and stayed longer (Table 1). The response of the wasp began with a stop. After a few seconds, it began to walk very slowly within the treated patch area, intensively searched the treated and eventually the surrounding area, and then returned to the patch area. Wasps interrupted their searching behavior with stops while searching intensively the treated patch areas. Each parasitoid female displayed 0–11 stops. All parasitoid females made stops when the patch area had been previously exposed to a virgin female or a mated female *S. calamistis.* In contrast, only 16.7% of the wasps tested made a stop in the patch area previously exposed to a male *S. calamistis.* Each stop lasted on average of 124.1, 121.6, and 7.1 sec. after prior exposure of the patch area to a virgin female, mated female, or male, respectively, and was significantly higher for the two female treatments compared to the male (Table 1). The residence time in the arenas treated with virgin or mated females was about 4.8 times longer than that of arenas treated with a males (Table 1). The patch retention time followed the same pattern.

Response of T. isis *to* S. calamistis *Oviposition Substrate.* The presence of maize leaf sheaths stimulated the oviposition behavior of *T. isis* on *S. calamistis* eggs. Within the first 6 hr of exposure, oviposition on eggs on leaf sheaths commenced earlier than on filter paper, and consequently more eggs were attacked on maize leaf sheaths than on filter paper (Table 2). However, no differences in the total number of offspring, the percentage of emergence, or the sex ratio of the F_1 progeny were recorded between the two treatments, but mean oviposition time was longer for females on filter paper than on maize leaf sheaths (Table 2).

Relative Attractiveness of Different Host Plants of Stem Borers for Female T. isis. Female parasitoids preferred odors from *S. calamistis* eggs accompanied by certain host plants of stem borers (Figure 3). The wasps spent more time in the maize and *S. calamistis* eggs and in the sorghum/eggs compared to the millet/eggs and the *S. calamistis* eggs only fields.

Host Discrimination by T. isis *and* L. ovicida. Both females of *L. ovicida* and *T. isis* were able to discriminate between host eggs that had been previously

TABLE 2. RESPONSE OF *T. isis* TO *S. calamistis* EGGS EXPOSED ON TWO DIFFERENT OVIPOSITIONAL SUBSTRATES

	Ovipositional substrates	
	Maize leaf sheaths	Filter paper
Eggs attacked after 6 hr (*N*)	63.1 ± 1.19 a[b]	47.2 ± 2.06 b
Time to first oviposition (sec)	23.7 ± 1.53 a	123.2 ± 12.9 b
Total offspring (*N*)	85.9 ± 1.85	82.7 ± 2.32
Emergence (%)	99.8 ± 0.10	99.7 ± 0.20
Sex ratio[a]	89.1 ± 0.67	88.9 ± 0.32
Oviposition time (days)	2.5 ± 0.14 a	4.6 ± 0.27 b

[b]Within row, means followed by different letters are significantly different at $P = 0.05$ (Student-Newman-Keul test).

parasitized by a conspecific female. *T. isis* accepted 79.9% and 8.8% of the unparasitized and parasitized eggs, respectively, vs. 68.3% and 27.4% for *L. ovicida* (Table 3). Hence, superparasitism in *T. isis* was lower than in *L. ovicida* ($F = 25.47$, $df = 18$, $P < 0.001$).

When female *L. ovicida* were exposed to egg masses partially parasitized by *T. isis*, they displayed no discrimination behavior, as indicated by a high acceptance of already parasitized and unparasitized eggs (74.7 and 68.7%, respectively; Table 4). In contrast, *T. isis* displayed high discrimination behavior towards eggs already parasitized by *L. ovicida*. *T. isis* females rejected up to 77.6% of the eggs already parasitized by *L. ovicida*, whereas 57.2% of the unparasitized eggs were accepted (Table 4).

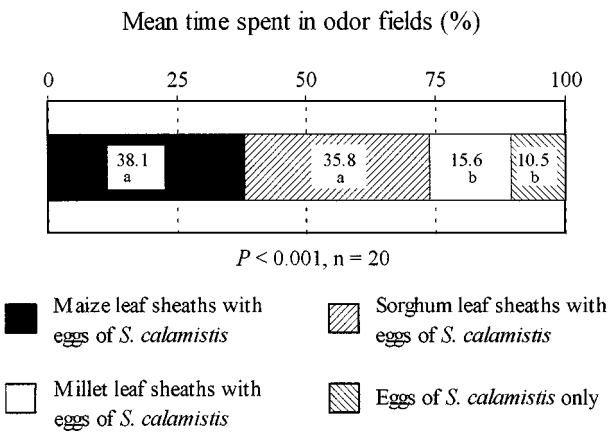

FIG. 3. Response of *T. isis* to different host plants with eggs and eggs alone. Percentages followed by different letters are significantly different.

TABLE 3. RESPONSE OF *L. ovicida* AND *T. isis* TO UNPARASITIZED EGGS AND EGGS PARASITIZED BY CONSPECIFIC FEMALE

Species	Host eggs[a]	Egg acceptance (mean %)
L. ovicida	Unparasitized	68.3 ± 3.23
	Parasitized	27.4 ± 2.50
		($\chi^2 = 31.81$; $P < 0.001$)
T. isis	Unparasitized	79.9 ± 3.77
	Parasitized	8.8 ± 2.69
		($\chi^2 = 100.1$; $P < 0.001$)

[a]For each species a total of 10 egg batches were observed.

The percentage of emergence did not vary with the sequence of introduction of the two parasitoid species (Table 5). Irrespective of which parasitoid species was first introduced, a higher proportion of *L. ovicida* offspring emerged from the multiparasitized eggs (Table 5). Moreover, in 80% of the cases, two *L. ovicida* emerged from a single *S. calamistis* egg. In *T. isis*, in all cases, only one adult parasitoid emerged per host egg.

DISCUSSION

In the Munger cell experiments, no significant differences were found in first choice between control and the different moth types. Host-finding behavior of egg parasitoids is often governed by long-range chemical cues such as sex pheromones (Lewis et al., 1982; Colazza et al., 1997). However, as shown by Babilis and Mazomenos (1992) for the noctuid *Sesamia nonagrioides* (Lefebvre), the production of sex pheromones is often influenced by the photoperiod. Female moths started calling about 4–6 hr after onset of scotophase, while our bioassays were carried out during the photophase. The wasps spent significantly more time in

the cells containing adult *S. calamistis* than in the empty cells, however, suggesting that the response pattern of the parasitoids was induced through physical contact with or through kairomones produced by the moth (Noldus et al., 1990; Gazit et al., 1996). Often *T. isis* females mounted on the wings of *S. calamistis* females, searched actively, or stopped in front of their abdomen for a long time. Such a behavioral pattern suggests that the moth scales and the abdomen of adult female may be sources of chemical cues that elicit arrestment behavior by *T. isis.* Scales of various moth species contain contact kairomones that arrest egg parasitoids (Jones et al., 1973; Shu and Jones, 1989). This is also corroborated by the results from the open arena experiments, which showed that traces of *S. calamistis* moths acted as contact kairomones, eliciting an arresting response and induced the wasps to remain longer in the arena. An arrestment response elicited by cues from host stages other than eggs is common in *Telenomus* spp. (Gazit et al., 1996; Arakaki et al., 1996). The role of contact kairomones for guiding parasitoids to their hosts eggs has been investigated by various authors (e.g., Lewis et al., 1972; Jones et al., 1973; Beevers et al., 1981; Noldus and van Lenteren, 1985; Zaborski et al., 1987).

Host eggs are not easily detected because they do not emit long-range volatiles (Noldus, 1989; Kaiser et al., 1989) and in the case of *S. calamistis* are hidden within the leaf sheath. The present finding suggests that the parasitoid is attracted by unspecific chemical clues, volatiles emanating from the plants rather than the host. Volatiles play an important role in the long-distance orientation and host location of parasitoids (e.g., Vinson 1976; Tumlinson et al., 1992; Vet and Dicke, 1992; Turlings et al., 1995). The presence of the host plant also stimulated the oviposition behavior of *T. isis* and oviposition happened significantly faster. In addition, the parasitoid distinguished between host plant species. The nonpreference for millet makes sense. This crop is prevalent in the Sudan savanna and Sahel, which is outside the geographic range of *S. calamistis,* and the major stem-boring pest in these zones, the crambid *Coniesta ignefusalis* Hampson, is not attacked by *T. isis*

(Chabi-Olaye et al., 2000). Both millet and sorghum are indigenous to Africa, but maize originated in Meso-America, and in most of West Africa became important only in the 20th century. Thus, the equal preference for maize and sorghum appears not to be logical. However, *S. calamistis* is highly polyphagous and is found on many gramineous species (Schulthess et al., 1997) that may have similar volatile profiles. The host plant preference indicates that *T. isis* females increase their foraging activity in areas or on plants where host egg masses are more likely to be present.

Avoidance of superparasitism is only possible when a parasitized host egg can be recognized by a parasitoid female. Such recognition is often based on the marking of host eggs after oviposition (Strand and Vinson, 1983; Okuda and Yeargan, 1988; Higuchi and Suzuki, 1996; Agboka, 1998). Our results show that both *T. isis* and *L. ovicida* were highly efficient in recognizing marks of conspecific females. The ability of parasitoids to recognize host eggs already parasitized by conspecifics prevents females from wasting their eggs (van Lenteren, 1981). Consequently, parasitoids will disperse in areas where suitable eggs are available. However, in situations with a low probability of finding unparasitized host stages and a certain likelihood of survival of offspring of the second female in superparasitized hosts, intraspecific superparasitism may be an adaptive strategy (Bakker et al., 1985; van Alphen and Visser, 1990; Visser et al., 1990; Visser, 1993).

Interspecific mark recognition is rare in nature and often occurs among closely related species (Rosen and DeBach, 1979). Our results show that, in contrast to *L. ovicida*, *T. isis* females tend to avoid eggs already parasitized by an interspecific female. Similarly, in a study by Agboka (1998), *T. isis* rejected up to 82.8% of eggs parasitized by *T. busseolae.* Bakker et al. (1985) argued that interspecific host discrimination is not an evolutionarily stable strategy. Hence, species that start to discriminate interspecifically would face a disadvantage. This implies that the behavior of *T. isis* may be an adaptation strategy for its oviposition. A significantly greater proportion of *L. ovicida* emerged from the offspring of multiparasitized eggs of *S. calamistis*, regardless of the sequence of introduction of the two parasitoid species. Similar results were obtained by Agboka (1998) when the same eggs were parasitized by *T. isis* and *T. busseolae.* Thus, efforts by *T. isis* to superparasitize eggs already parasitized by another sympatric species are not likely to be productive and, thus, interspecific mark recognition is an advantage.

In contrast to *T. isis*, which only parasitizes noctuid eggs laid within leaf sheaths of grasses, *L. ovicida* has been reported from the pyralids *Chilo zacconius* Bleszynski, *Scircophaga subumbrosa* Meyrick, and *Maliarpha separatella* Ragonot that oviposit on the lower or upper surfaces of leaves (Polaszek, 1998). In Benin, parasitism by *L. ovicida* was low, ranging between 1.6 and 5.3%, and parasitism within parasitized egg batches was, on average, only 27% vs. >70 for *T. isis* and *T. busseolae* (Schulthess et al., 2000). In 93% of the cases on maize and 88% on grasses, *L. ovicida* was obtained from egg batches also parasitized by

another *Telenomus* species and mainly by *T. isis.* It appears that the trichogrammatid is not only attracted by the female moth, but also by the other parasitoid species, and the question arises whether *L. ovicida* is a facultative hyperparasitoid.

We conclude that the intra- and interspecific mark recognition ability of *T. isis*, coupled with its ability to respond to volatiles of the host plant and the contact kairomones of its host *S. calamistis* for host location, could make it a promising candidate for future biological control programs outside its area of distribution.

Acknowledgments—We thank G. Goergen (IITA) for help in identifying *T. isis* and *L. ovicida.* The research was supported by IITA's Maize Health Management Project, funded by the International Fund of Agricultural Development (IFAD). A. Chabi-Olaye was partly supported by a grant of the German Academic Exchange Service (DAAD).

Abstract—We investigated the effect of exogenous methyl jasmonate (MeJA) on the emission of herbivore-induced volatiles; these volatile chemicals can signal natural enemies of the herbivore to the damaged plant. Exogenous treatment of cotton cv. Deltapine 5415 plants with MeJA induced the emission of the same volatile compounds as observed for herbivore-damaged plants. Cotton plants treated with MeJA emitted elevated levels of the terpenes (*E*)-β-ocimene, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, (*E*,*E*)-α-farnesene, (*E*)-β-farnesene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene compared to untreated controls. Other induced components included (*Z*)-3-hexenyl acetate, methyl salicylate, and indole. Methyl jasmonate treatment did not cause the release of any of the stored terpenes such as α-pinene, β-pinene, α-humulene, and (*E*)-β-caryophyllene. In contrast, these compounds were emitted in relatively large amounts from cotton due to physical disruption of glands by the herbivores. The timing of volatile release from plants treated with MeJA or herbivores followed a diurnal pattern, with maximal volatile release during the middle of the photoperiod. Similar to herbivore-treated plants, MeJA treatment led to the systemic induction of (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, (*E*,*E*)-α-farnesene, (*E*)-β-farnesene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. Our results indicate that treatment of cotton with MeJA can directly and systemically induce the emission of volatiles that may serve as odor cues in the host-search behavior of natural enemies.

Key Words—Cotton, *Spodoptera exigua*, methyl jasmonate, induction, plant defense, volatile semiochemicals.

INTRODUCTION

Plants protect themselves against herbivory by deploying a wide array of chemical defenses (Karban and Myers, 1989; Agrawal et al., 1999). Wounding-induced plant responses can directly target herbivores by stimulating the synthesis of toxic or antifeedant metabolites, as well as by activating antinutrient enzymes such as proteinase inhibitors or polyphenol oxidases (e.g., Felton et al., 1994; Stout et al., 1996). Plant volatiles can also serve as a chemical defense by recruiting beneficial insects that are natural enemies of the herbivore, thereby providing an indirect protection to the plant (Dicke and Vet, 1999; Paré and Tumlinson, 1999). These volatile organic compounds increase the foraging success of natural enemies by providing reliable odor cues for prey/host location (Dicke and Sabelis, 1988; Dicke et al., 1990; Turlings et al., 1995).

Currently, there is increasing evidence of a common biosynthetic pathway linking direct and indirect induced plant defenses. Wounding of leaf tissue activates the octadecanoid/lipoxygenase (LOX) pathway, a lipid-based signaling sequence, resulting in the accumulation of 12-oxyphytodienoic acid and 7-isojasmonic acid (JA) (Farmer and Ryan, 1990; Constabel and Ryan, 1998). The involvement of JA in regulating gene activation subsequent to wounding has been established in several plant species (Wasternack et al., 1998; Staswick and Lehman, 1999). The LOX pathway also plays an important role in regulation of indirect plant defenses. Volatile emissions can be stimulated by exogenous JA (see Boland et al., 1998, for review) and by a select group of amino acid conjugates of JA (Krumm et al., 1995) taken up through the stems of a plant. Another connection of the LOX signaling pathway with volatile synthesis and emissions was the identification of *N*-(17-hydroxylinolenoyl)-L-glutamine (volicitin), an herbivore-specific elicitor that is derived from linolenic acid and induces volatile production (Alborn et al., 1997). Incubation of amino acid conjugates of linolenic acid (e.g., linolenoyl-L-glutamine) mimics the action of 12-oxophytodienoic acid (PDA), an early intermediate on the LOX pathway, in inducing emission of a blend of volatiles in a Lima bean cut seedling bioassay (Koch et al., 1999). This elicitor response appears to be highly specific since *N*-(17-hydroxylinoleoyl)-L-glutamine, a compound closely related to volicitin, is ineffective in inducing volatile emissions (Alborn et al., 2000).

In several agricultural species that have been studied, volatile chemicals emitted from both damaged and undamaged portions of herbivore-injured leaves serve as essential host-location cues for parasitic insects (see review by Dicke and Vet, 1999). Chemical labeling studies have established that a subset of volatiles emitted from cotton (*Gossypium hirsutum* L.) damaged by insects is synthesized and rapidly emitted from damaged and undamaged leaves, while other chemical constituents, stored in specialized glands, are volatilized only from the leaves that are damaged by insects (Paré and Tumlinson, 1997a,b, 1998). In mint leaves, such

glands contain enzymes required for terpene synthesis (Gershenzon et al., 1989). By directly comparing volatile emission patterns of glanded cotton plants treated with jasmonates or damaged by herbivores, compounds induced by jasmonates can be distinguished from those that are emitted due to mechanical damage.

Our objectives were to compare the emission of volatiles from cotton plants treated with methyl jasmonate (MeJA), a volatile derivative of JA, or subjected to herbivore damage. Specifically, we determined the diurnal pattern of volatile emission induced by these treatments. Finally, we report that MeJA induces the systemic release of the same volatile compounds that are systemically induced by herbivore feeding.

METHODS AND MATERIALS

Plants and Insects

Four- to 6-week-old glanded cotton, *G. hirsutum* cv. Deltapine 5415, plants with four to six fully expanded true leaves were used in all experiments. Cotton was grown in air-conditioned greenhouses under natural light (2000 μmol/m^2/sec^{-1} max daily photosynthetically active radiation) and Arizona fall–spring conditions (11L:13D photoperiod, and 28°C day, 24°C night). Plants were grown in 15×15-cm pots containing a commercial potting mixture (Grow More, Gardena, California) and fertilized three times a week with 750 ml of a solution containing 2 g/liter Grow More 20-20-20 fertilizer. The nutrient solution was supplemented with 0.5 ml/l micronutrient solution containing 2 mM $MnCl_2$, 10 mM H_3BO_3, 0.4 mM $ZnSO_4$, 0.2 mM $CuSO_4$, 0.4 mM Na_2MoO_4, and 0.1 mM $NiCl_2$. All plants employed were free of insects and mites.

The generalist beet armyworm, *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae), was used in all experiments because cotton plants damaged by this herbivore emit a blend of volatiles important for parasitic insects in host location (Loughrin et al., 1994; Röse et al., 1996). Larvae were reared on an alfalfa-based diet (Henneberry and Kishaba, 1966) at 28°C and 50% relative humidity. The colony has been maintained in culture at the Western Cotton Research Lab., USDA-ARS, Phoenix, Arizona for more than 10 years, and had new genetic material added within 12 months prior to the study from the Southern Insect Management Research Unit, USDA-ARS, Stoneville, Mississippi.

Volatile Collection System

Volatile chemicals emitted by individual cotton plants were collected in a push/pull apparatus constructed after Heath and Manukian (1994). The system consisted of four independent glass chambers that allowed for simultaneous collections. Air entering each of the glass chambers initially was split into two

directions: in one, air was pushed through a flowmeter (to measure and regulate the amount of air) followed by a charcoal filter (to purify the air) and a humidifier bubbler (wet air). Air in the second direction was pushed through a flowmeter and a charcoal filter (dry air). Both moist and dry air entered a glass cylinder (42.5 cm high and 18 cm diameter; Analytical Research Systems, Inc., Gainesville, Florida) at 5 L/min (Loughrin et al., 1994; Röse et al., 1996). The air passed over a cotton plant placed inside the cylinder through the opened bottom (see Röse et al., 1996; Turlings et al., 1998, for details). The bottom of the chamber was then sealed by using a guillotine-like support base (Analytical Research Systems, Inc.) leaving a hole in the center around the stem of the plant. The system allows sampling volatiles from the aerial parts (all of its leaves) of a plant, while the pot remains outside. At 5 cm from the base of the cylinder, eight openings allowed for attachment of collection filter traps (Analytical Research Systems, Inc.). Collection traps consisted of 10 cm long and 6 mm diameter glass filters containing 30 mg of Super-Q adsorbent (Alltech Assoc. Inc., Deerfield, Illinois). Manual switching valves allowed the sample to be diverted to individual filter traps, thus facilitating volatile collection at various times of the day.

The tip of each collection trap was placed a few millimeters from the plant. During collection, air was pulled through one of the collection traps at a rate of 1 l/min (Loughrin et al., 1994; Röse et al., 1996). Thus, only 20% of the air passed through the collector trap, the remaining escaped through the opening at the bottom of the guillotine base, which was loosely closed with cotton to prevent abrasion (see Röse et al., 1996; Turlings et al., 1998).

Analysis of Headspace Volatiles

Volatiles were extracted from the collector traps by rinsing them with 180 μl of methylene chloride. An internal standard (600 ng of *n*-octane in 5 μl of methylene chloride) was added to the extract. From each sample, 1 μl was analyzed on a Hewlett-Packard model 6890 gas chromatograph (GC) equipped with a capillary injector system and flame ionization detector. Samples were injected by a Hewlett-Packard auto injector model 7683, programmed in a split mode (25:1). All samples were analyzed on a HP1 methyl siloxane column (30 m $\times$ 0.32 mm ID, 0.25 μm film). Helium at a linear flow velocity of 40 cm/sec was used as a carrier gas. Following injection, column temperature was maintained at 50°C for 3 min and then increased at 5°C/min to 190°C and maintained at 190°C for 5 min. Data were analyzed with Hewlett-Packard ChemStation software. For each sample, amounts of the detected volatiles were based on comparison of their peak areas with that of the internal standard.

Selected samples were analyzed by GC–mass spectroscopy (GC-MS) with a Hewlett-Packard model 5973 mass selective detector operated at an initial temperature of 40°C for 1 min, then programmed at 14°C/min to 180°C. The column

oven was maintained at 180°C for 2 min and then raised at 40°C/min to 200°C and held for 2 min. For GC-MS samples, a DB5-MS column (J&W Scientific, Folsom, California) 30 m × 0.25 mm ID, with a 0.1-μm-thick film of bonded methyl silicone with 5% phenyl, was used. Spectral data were compared with commercially available standards and spectra from the National Institute of Standards and Technology (NIST, 1995) database.

Comparison of Cotton Volatiles Induced by Herbivory versus MeJA Treatment

Volatiles were collected from cotton damaged by *S. exigua* larvae, treated with MeJA, and controls. Volatiles were collected as previously described beginning at 10:00 hr for a total of 22 hr. At least one control was run simultaneously with other treatments at a particular collection time. Treatments were replicated five times.

Herbivore-Damaged Plants. A cohort of recently molted third instar *S. exigua* from the colony was transferred from artificial diet cups to cotton plants (approx. 10 larvae/plant) 12 hr prior to the experiment to allow the larvae to habituate to the new diet. Larvae were allowed to feed on cotton overnight. The following morning larvae were removed from the plants, starved for 2 hr to encourage immediate feeding, and placed inside a collection chamber with a new cotton plant. At 10:00 hr, 10 larvae were placed inside a volatile collection chamber containing a plant and allowed to feed *ad libitum* over 22 hr.

Methyl Jasmonate-Treated Plants. Cotton was treated with MeJA (Aldrich, Milwaukee, Wisconsin) overnight, starting at 16:00 hr, in the greenhouse. Plants were treated by applying 20 μl of an ethanol–MeJA (9:1) solution (after Thaler et al., 1996; Constabel and Ryan, 1998) onto a 15-cm cotton tipped applicator (Fisher, Pittsburgh, Pennsylvania). Two treated cotton wicks (total of 18 μmol MeJA/plant) were placed underneath cotton leaves, without physically contacting the treated plants. Plants were treated inside a Plexiglas cylindrical chamber (26 cm diameter × 60 cm high with the top of the chamber and a 14-cm-diameter opening in the middle covered by a fine nylon mesh to allow air circulation). Control cotton plants were exposed to 40 μl ethanol but no MeJA and placed in separate chambers under the same conditions. Plants were kept in the chambers for 18 hr, after which cotton wicks from the treated plants were removed and plants were placed inside the chambers for volatile collection.

Timing of Induction

Volatiles released over time were collected from cotton damaged by *S. exigua* larvae, treated with exogenous MeJA, and controls. At least one control was run simultaneously with other treatments at a particular collection time. Volatiles were collected for 4-hr periods over two consecutive days: on day 1 at 10:00, 14:00, 18:00, and 22:00 hr; and on day 2 at 06:00, 10:00, 14:00, and 18:00 hr. Treatments

were replicated four times. In addition, daily fluctuation in leaf temperature was monitored for plants inside the collection chamber by using a thermocouple pressed to the bottom of a fully expanded leaf.

Herbivore-Damaged Plants. In the first series of experiments 10 *S. exigua* larvae were allowed to feed on cotton plants overnight, starting at 16:00 hr. Larvae were kept on the leaves by enclosing them inside a fine-mesh nylon bag sealed around the leaf petiole with Velcro. The following day (06:00 hr) larvae and plants were placed inside collection chambers (see above) for volatile collections. In these experiments, caterpillars were allowed to feed continuously. In a second set of experiments, larvae were also allowed to feed on cotton plants overnight, starting at 16:00 hr; however, herbivore feeding was stopped by removing larvae from the plants at the time when the plants were placed inside the collection chambers at 06:00 hr.

Methyl Jasmonate-Treated Plants. Starting at 16:00 hr, plants were placed inside Plexiglas cylinders and treated with MeJA as previously described. The following morning at 06:00 hr, cotton wicks were removed and plants were placed inside collection chambers and volatiles were collected. In addition, control plants were placed under the same conditions but with no exposure to MeJA.

Systemic Induction

In order to maximize treatment differences, systemically induced volatiles were collected in the same filter trap during the photoperiod for four consecutive days. Volatile collection was started at 10:00 hr each day and ended at 20:00 hr on days 1 to 3, and at 18:00 hr on day 4. At least one control was run simultaneously with other treatments at a particular collection time. Treatments were replicated 4 times.

Herbivore-Damaged Plants. Four beet armyworm larvae were enclosed in a fine-mesh nylon bag and allowed to feed on the lower two leaves of a cotton plant, while volatiles were collected from the undamaged upper leaves. Larvae started feeding on the lower leaves 18 hr before the beginning of the volatile collections.

Methyl Jasmonate-Treated Plants. Systemic response of cotton treated with MeJA was tested by treating the two lower leaves on a plant with 20 μl of an ethanol– MeJA (9:1) solution (total of 18 μmol MeJA/plant). Leaves and the cotton wicks treated with MeJA were enclosed in a perforated Ziploc plastic bag. Lower leaves were treated with MeJA at 16:00 hr the day prior to volatile collections and were treated with MeJA daily at 16:00 hr by reapplying 18 μmol of MeJA to the cotton wick. For controls, the lower two leaves were enclosed in plastic bags containing cotton wicks treated with 20 μl of ethanol each, but received no MeJA treatment.

Statistical Analyses

A completely randomized one-way ANOVA (SigmaStat, San Rafael, California) was used to determine differences in total volatile emissions among treatments (herbivore, MeJA, and controls). If significant differences were detected, an all pairwise multiple comparison procedure (Tukey test) was conducted. Differences in individual volatile components among treatments were determined by using the MULTTEST PROC (SAS Institute Inc., Cary, North Carolina).

RESULTS

Comparison of Cotton Volatiles Induced by Herbivory versus MeJA Treatment. Differences in volatile emissions were observed for cotton plants damaged by *S. exigua* larvae, treated with MeJA, or undamaged controls (Table 1). Control plants emitted much lower amounts of volatiles compared to herbivore damaged plants and plants treated with MeJA (Table 1).

Plants treated with herbivores or MeJA emitted a blend that consisted of (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, indole, (*E*,*E*)-α-farnesene, (*E*)-β-farnesene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Figure 1). These compounds are commonly referred to as inducible because they are synthesized *de novo* by herbivore-damaged cotton (Paré and Tumlinson, 1997a,b). Other detected components were methyl salicylate and an unidentified sesquiterpene (Figure 1). Control plants also emitted the inducible linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Figure 1; see also Röse et al., 1996).

The terpenes α-pinene, β-pinene, myrcene, limonene, (*E*)-β-caryophyllene, and α-humulene were detected only from herbivore-damaged cotton (MULTTEST;

Methyl jasmonate	573.4 ± 147.8 a	5173.6 ± 1388.3 a
Control	139.5 ± 50.2 b	376.3 ± 121.8 b

[a] Volatiles collected continuously for 22 hr; $N = 5$.
[b] Cumulative volatiles emitted during the Photoperiod of 4 consecutive days were collected; $N = 4$.
[c] Different letters within columns indicate statistical differences among treatments (Local: $F = 6.4; df = 2,14; P = 0.013$; systemic: $F = 6.8; df = 2,11; P = 0.016$; Tukey test; $P < 0.05$).

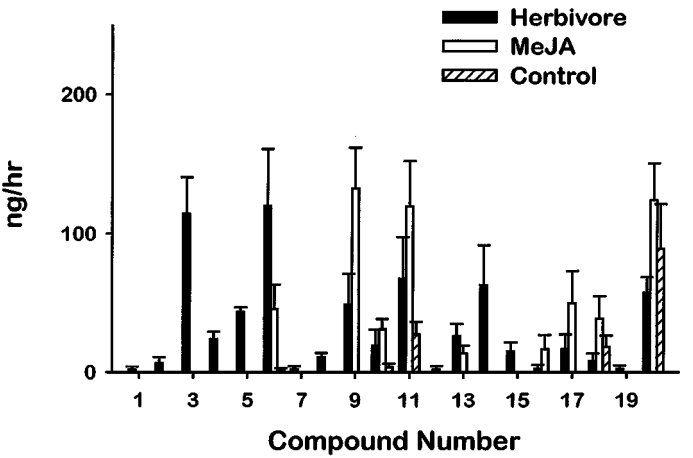

FIG. 1. Volatiles collected from the aerial portions of undamaged cotton plants (Control), plants damaged by *S. exigua*, and plants treated exogenously with methyl jasmonate (MeJA). Volatiles were collected continuously for 22 hr. Each bar represents the mean ± SE for five replicates. 1 = Hexanal; 2 = (*Z*)-3-hexenol; 3 = α-pinene; 4 = β-pinene; 5 = mycene; 6 = (*Z*)-3-hexenyl acetate; 7 = hexyl acetate; 8 = limonene; 9 = (*E*)-β-ocimene; 10 = linalool; 11 = (3*E*)-4,8-dimethyl-1,3,7-nonatriene; 12 = methyl salicylate; 13 = indole; 14 = (*E*)-β-caryophyllene; 15 = α-humulene; 16 = (*E*)-β-farnesene; 17 = (*E*,*E*)-α-farnesene; 18 = tentatively identified as δ-cadinene [based on comparison of mass spectra with spectra published by Stenhagen et al. (1974) and the Eight Peak Index of Mass Spectra by the Mass Spectrometry Data Centre, Reading, UK]; 19 = nerolidol; 20 = (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

$P < 0.05$). This result was expected, since these compounds, commonly referred to as constitutive, are predominantly stored in the glands of cotton leaves (Elzen et al., 1985; McAuslane and Alborn, 1998).

Hexanal, (*Z*)-3-hexenol, and hexyl acetate, all LOX-pathway compounds, were detected in response to herbivore damage, but not in response to MeJA treatment (Figure 1). These compounds result from the breakdown of stored lipids (Hatanaka et al., 1987) and are released during insect damage (McCall et al., 1994), but not systemically (Röse et al., 1996). (*Z*)-3-Hexenyl acetate was the only LOX pathway volatile detected from MeJA treatment (Figure 1).

Timing of Induction. The emission of inducible terpenes followed a diurnal cycle for herbivore-damaged, MeJA-treated, and control plants (Figures 2–5). In general, volatile emission was much higher for plants treated with herbivores and MeJA compared to controls.Volatile emissions were highest during the period of highest radiation (from 10:00 to 14:00 hr and from 14:00 to 18:00 hr), and emissions decreased markedly during the night. Periods of maximum volatile emission corresponded to times of the day when leaf temperatures were the highest

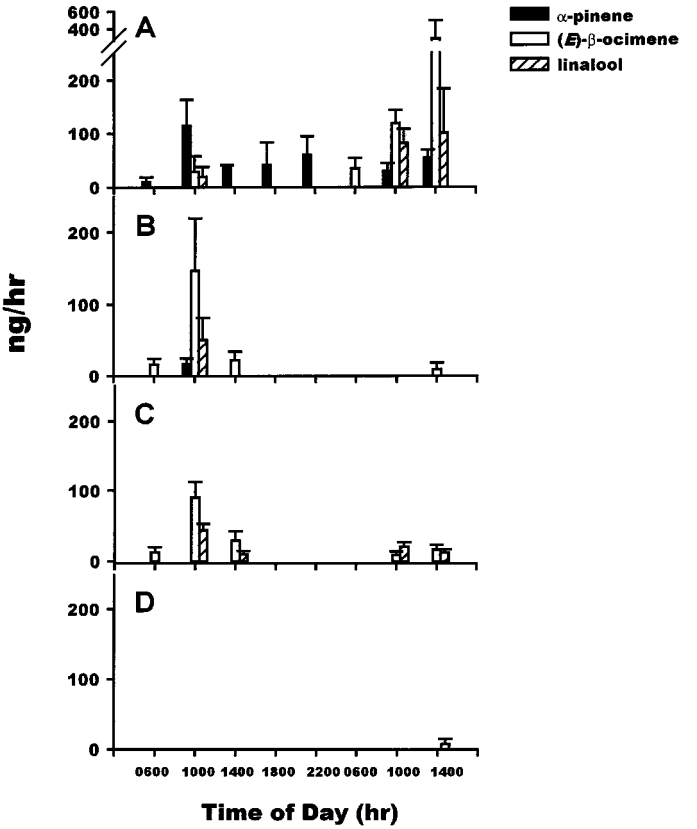

FIG. 2. Emissions of the monoterpenes α-pinene, (E)-β-ocimene, and linalool by aerial portions of cotton plants under continuous herbivore damage (A); with caterpillars removed from plants before being placed in collection chambers (B); treated overnight with exogenous methyl jasmonate prior to volatile collection (C); and undamaged controls (D). Each bar represents the mean $\pm$ SE for four replicates. Time of day indicates the time of initiation of each collection period and each collection represents a 4-hr interval.

[29.5 ± 0.3 (SE) and $35.5 \pm 0.5^{\circ}$C at 10:00 and 14:00 hr, respectively]. Lowest leaf temperatures were recorded at 06:00 hr ($22.9 \pm 0.4^{\circ}$C) and 22:00 hr ($22.6 \pm 0.5^{\circ}$C), which corresponded to the times of minimal volatile emission (Figures 2–5).

For plants subjected to continuous herbivore feeding, the emission of volatiles was highest during the second day of treatment (Figures 2A–5A). In contrast, when insect feeding was interrupted prior to collecting samples, volatile emission was much reduced on the second compared to the first day of the treatment (Figures 2B–5B). Additionally, plants treated with MeJA one time at the beginning of

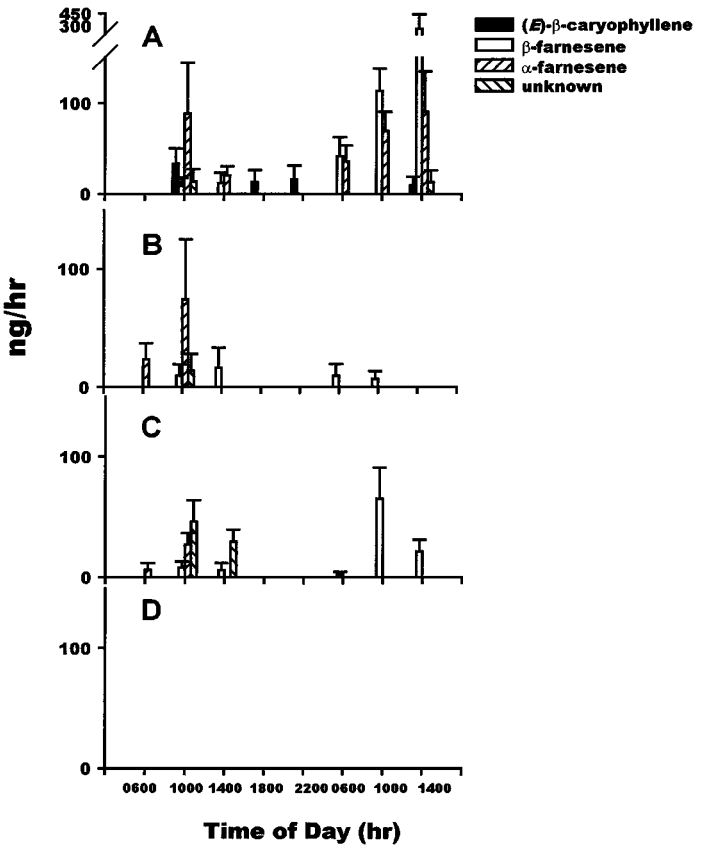

FIG. 3. Emissions of the sesquiterpenes (*E*)-β-caryophyllene, β-farnesene, α-farnesene, and an unknown by aerial portions of cotton plants under continuous herbivore damage (A); with caterpillars removed from plants before being placed in collection chambers (B); treated overnight with exogenous methyl jasmonate prior to volatile collection (C); and undamaged controls (D). Each bar represents the mean $\pm$ SE for four replicates. Time of day indicates the time of initiation of each collection period and each collection represents 4-hr interval.

the experiment had lower total volatile emission during the second, compared to the first, day of the experiment (Figures 2C–5C). In contrast to the inducible terpenes, the emission of the constitutive α-pinene and (*E*)-β-caryophyllene, released only from herbivore-damaged plants, did not follow a diurnal pattern (Figures 2A and 3A).

Systemic Induction. Both herbivore feeding and treatment with MeJA led to the systemic induction of volatile emission (Table 1; Figure 6). The blend of

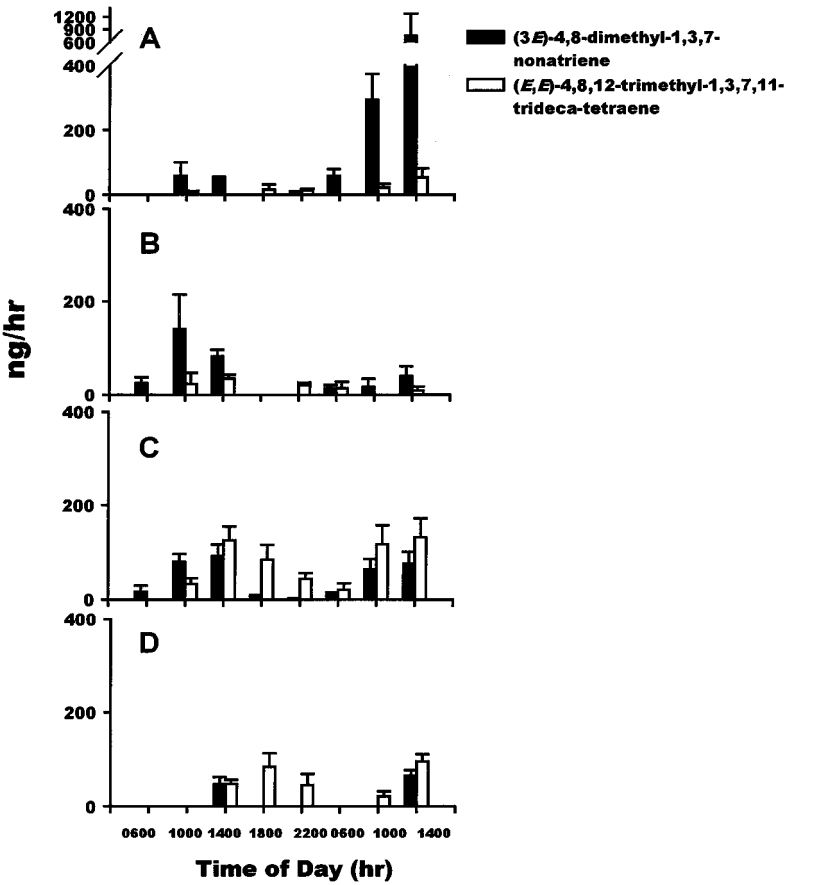

FIG. 4. Emissions of the homoterpenes (3*E*)-4,8-dimethyl-1,3,7-nonatriene and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene by aerial portions of cotton plants under continuous herbivore damage (A); with caterpillars removed from plants before being placed in collection chambers (B); treated overnight with exogenous methyl jasmonate prior to volatile collection (C); and undamaged controls (D). Each bar represents the mean ± SE for four replicates. Time of day indicates the time of initiation of each collection period and each collection represents a 4-hr interval.

volatiles emitted included (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, (*E*)-β-farnesene, (*E*,*E*)-α-farnesene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Figure 6). This systemically induced volatile blend was similar to the blend reported by Röse et al. (1996) for herbivore-damaged cotton.

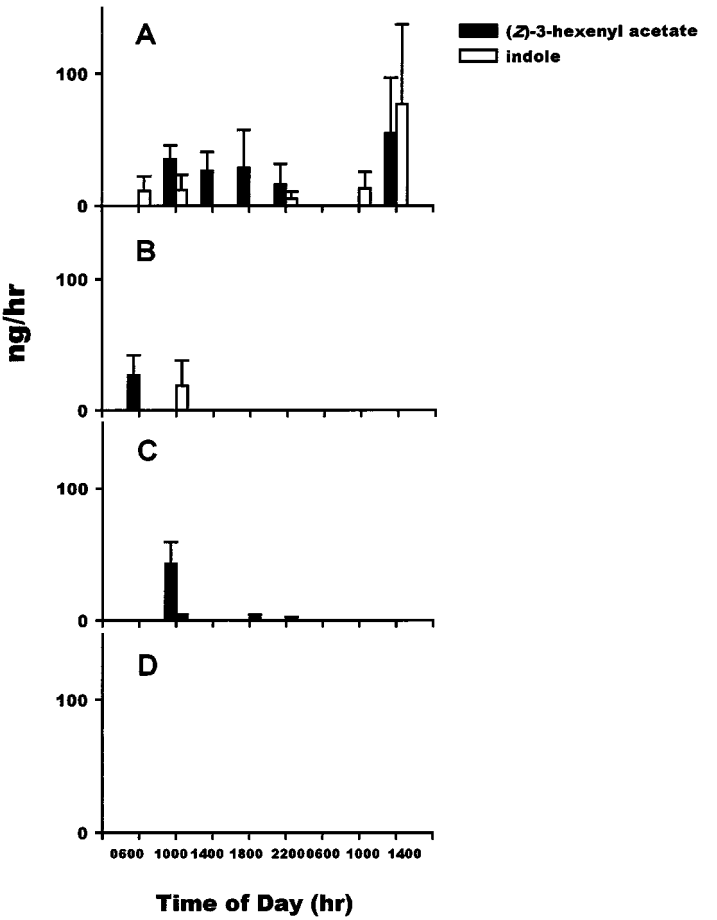

FIG. 5. Emissions of the LOX product (*Z*)-3-hexenyl acetate and indole by aerial portions of cotton plants under continuous herbivore damage (A); with caterpillars removed from plants before being placed in collection chambers (B); treated overnight with exogenous methyl jasmonate prior to volatile collection (C); and undamaged controls (D). Each bar represents the mean ± SE for four replicates. Time of day indicates the time of initiation of each collection period and each collection represents a 4-hr interval.

DISCUSSION

The induction of volatiles in cotton plants by herbivore damage has been documented (McCall et al., 1994), although the association of jasmonates in the induction of indirect defenses in cotton has not been previously reported. In cotton, MeJA mimicked the response of volatile emission induced by insects (Figure 1).

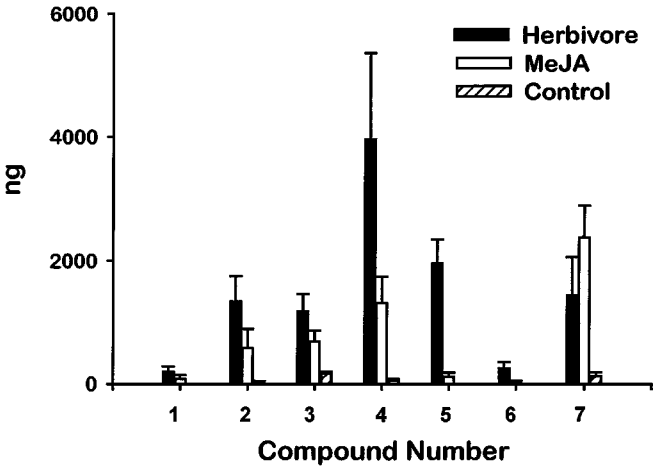

FIG. 6. Volatiles collected from the aerial portions of undamaged cotton plants (Control), undamaged leaves of cotton plants induced systemically by herbivore damage, and untreated leaves induced systemically by exogenous methyl jasmonate (MeJA). Cumulative volatiles emitted during the photoperiod of 4 consecutive days were collected. Each bar represents the mean ± SE for four replicates. 1 = (*Z*)-3-hexenyl acetate; 2 = (*E*)-β-ocimene; 3 = linalool; 4 = (3*E*)-4,8-dimethyl-1,3,7-nonatriene; 5 = (*E*)-β-farnesene; 6 = (*E*,*E*)-α-farnesene; 7 = (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

In fact, a blend of volatiles released by cotton plants treated exogenously with MeJA contained all compounds synthesized *de novo* following herbivore damage (Paré and Tumlinson, 1997b). Methyl jasmonate did not induce emissions of stored terpenes, a result that was expected since the release of stored terpenes is dependent on physical damage caused by herbivores.

These results also indicate that MeJA activates multiple biosynthetic pathways involved in the synthesis of cotton volatiles: the classic mevalonic acid pathway leading to sesquiterpenes, the alternate isopentenyl pyrophosphate pathway producing the monoterpenes, the homoterpene pathway producing the C_{11} and C_{16} unit terpenes, the shikimic acid/tryptophan pathway leading to the synthesis of methyl salicylate and indole, and the LOX pathway that leads to (*Z*)-3-hexenyl acetate (Paré and Tumlinson, 1996, 1999).

Similar to reports by Loughrin et al. (1994) and Turlings et al. (1998), herbivore-induced volatile emission was highest during the photoperiod (Figures 2–5). Our results indicated that MeJA-induced volatile emission followed a diurnal trend similar to herbivore treatment (Figures 2–5). Thus, volatile emission is highest during the time when natural enemies tend to forage (Turlings et al., 1995), when leaf temperature is highest, and when leaves are conducting photosynthesis (Paré and Tumlinson, 1997a,b).

The induction of volatiles was greatly diminished over time when herbivore feeding was interrupted or when MeJA was applied only one time (Figures 2B,C–5B,C). This indicates that the induction is dependent on a continuous supply of a chemical signal. Obviously, the reduced emission of constitutive volatiles after insect feeding was stopped due to the cessation of physical damage by the insects (Figures 2B–5B).

Systemically induced volatile emission for herbivore-damaged plants has been reported for cotton and other plant species (Turlings and Tumlinson, 1992; Röse et al., 1996). Additionally, it has been shown that jasmonates induce volatile emission by plants (Boland et al., 1998; Dicke et al., 1999; Gols et al., 1999). Here we show for the first time that jasmonates can systemically induce the emission of volatile compounds. The systemic emission of volatiles points to a mobile signal or signals that move from damaged leaf to the undamaged portions of the plant. Paré and Tumlinson (1998) in studies with $^{13}CO_2$, have established that the systemically released volatiles are synthesized at the site of release. However, to date no systemic signals specific for volatile induction have been identified. Our results indicate that MeJA, or an induced product, was transported to distal leaves leading to the systemic emission of the same cotton volatiles systemically induced by *S. exigua* (Figure 6).

In conclusion, our results indicate that indirect defenses in cotton can be activated by MeJA. Volatiles released from cotton after herbivore feeding and induced by MeJA treatment provide cues for natural enemies to locate hosts (McCall et al., 1993; De Moraes et al., 1998). Our results suggest that jasmonates may be used as an elicitor of volatiles to attract natural enemies in cotton cultivars. For instance, in other plant systems, indirect evidence has been presented that volatiles induced by jasmonates serve as important cues for natural enemies to locate potential host/prey sites. Although volatiles were not measured, the aggregation of beneficial parasitic wasps was greater in field plots of tomato treated exogenously with JA than for untreated control plots (Thaler, 1999).

Recently, Dicke et al. (1999) showed that Lima beans treated with JA or MeJA produce a volatile blend that is similar to plants infested with the two-spotted spider mite *Tetranychus urticae* Koch. Jasmonate-treated plants attracted more predatory mites, *Phytoseiulus persimilis* Athias-Henriot, than untreated plants. Comparable results were obtained when gerbera leaves were treated with exogenous JA (Gols et al., 1999). Thus, it appears that jasmonates are potential agents that may be used to improve biological control in agricultural crops.

Acknowledgments—The authors are grateful to Drs. Heather McAuslane (University of Florida), James Tumlinson (USDA-ARS, Gainesville, Florida), and Kenneth Korth (University of Arkansas) for comments on an earlier version of this manuscript. We thank Donald Brummett and Frances Arvallo who helped in keeping cotton plants available for the experiments. We also thank Anna Cervantes for providing us with the insects to conduct the experiments and Terry Steele for helping in the

construction of the volatile-collection apparatus. Statistical advice was provided by Bruce Mackey (Consulting Statistician at USDA-ARS, Albany, California).

(Received July 10, 2000; accepted December 12, 2000)

Abstract—Lindgren multiple funnel traps were set up in pine forests of central Oregon to determine the response of scolytid bark beetles to ethanol and 4-allylanisole (4AA). Traps were baited with two release rates of ethanol (4.5 or 41.4 mg/hr) and three release rates of 4AA (0, 0.6, or 4.3 mg/hr) in a 2×3 factorial design. All traps also released a 1:1 mixture of α- and β-pinene at 11.4 mg/hr. Of 13,396 scolytids caught, *Dendroctonus valens* made up 60%, *Hylurgops* spp. 18.5%, *Ips* spp. 16%, *Hylastes* spp. 1.8%, *Ganthotrichus retusus* 0.9%, and bark beetle predators another 2.8%. Increasing the release rate of ethanol in the absence of 4AA increased the number of most scolytid species caught by 1.5–3.7 times, confirming its role as an attractant. *Ips latidens*, *Temnochila chlorodia*, and clerid predators were exceptions and did not show a response to higher ethanol release rates. Release of 4AA at the lowest rate inhibited attraction of most scolytids, with a significant reduction in *G. retusus*, *Hylastes macer*, and *Hylurgops porosus* when compared to traps without 4AA. A high release rate of 4AA further inhibited responses for most beetles compared to low 4AA. Seven species were significantly deterred by high 4AA, including the latter three, and *Hylastes longicollis*, *Hylastes nigrinus*, *Hylurgops reticulatus*, and *Ips latidens*. Exceptions include *Hylurgops subcostulatus*, which was significantly attracted to both low and high 4AA, and *I. pini*, which was attracted to low and high 4AA in combination with low ethanol, but unaffected by either release of 4AA with high ethanol. *Dendroctonus valens* was significantly attracted to low 4AA and

unaffected by high 4AA. Predators appeared to be less inhibited by 4AA than most bark beetles. Although 4AA can deter the attraction of some secondary bark beetles to ethanol in combination with α- and β-pinene, this inhibition could be weakened for certain species by increasing ethanol release rates. 4-Allylanisole may have some utility for managing the behavior of secondary bark beetles sensitive to this compound.

Key Words—Methyl chavicol, bark beetles, primary attraction, host selection, host volatiles.

INTRODUCTION

The compound 4-allylanisole [4AA; 1-methoxy-4-(2-propenyl)benzene] is present in oleoresin of various pine species (Drew and Pylant, 1966; Werner, 1972; Pierce et al., 1987; Hayes et al., 1994) and is a known deterrent to primary bark beetles (Hayes et al., 1994; Hayes and Strom, 1994; Werner, 1995). It has been tested extensively in the lab and field as a potential antiaggregation semiochemical. *Dendroctonus frontalis* Zimmerman (Hayes et al., 1994), *D. rufipennis* (Kirby) (Werner, 1995), *D. ponderosae* Hopkins, *D. brevicomis* LeConte (Hayes and Strom, 1994; Hobson, 1996), and *Ips pini* (Say) (Hayes and Strom, 1994) were all significantly inhibited by 4AA in the presence of their specific aggregation pheromones.

Oleoresin in healthy trees usually contains higher concentrations of 4AA than stressed trees. For instance, quantities of 4AA in lodgepole pine (*Pinus contorta* Dougl. ex. Loud. var. *latifolia* Engelm.) infected with Comandra blister rust (*Cronartium comandrae* Pk.) or armillaria [*Armillaria mellea* (Vahl.: Fr.) Kummer] were 43.6–63% less than in healthy trees (Nebeker et al., 1995). Similarly, concentrations of 4AA in ponderosa pine (*Pinus ponderosa* Dougl. ex. Laws.) damaged by smog were 71% less than in undamaged trees (Cobb et al., 1972). Lower quantities of 4AA in smog stressed pine could be partially responsible for their greater vulnerability to bark beetle attacks than healthy trees (Stark et al., 1968).

Ethanol also occurs naturally in trees and is an important host-derived semiochemical. It is a product of fermentative respiration in plant tissues and is usually associated with hypoxic or anoxic conditions (Davies, 1980; Bennett and Freeling, 1987; Harry and Kimmerer, 1991). In contrast to 4AA, ethanol accumulates in severely stressed, dying, or recently dead trees. High ethanol concentrations have been reported in tissues of flooded (Crawford and Baines, 1977; Crawford and Finegan, 1989; Joseph and Kelsey, 1997), mechanically injured (Sjödin et al., 1989), or diseased trees (Gara et al., 1993; Kelsey and Joseph, 1998; Kelsey et al., 1998), severely water stressed branches (Kelsey and Joseph, 2001), stumps (von Sydow and Birgersson, 1997; Kelsey and Joseph, 1999a), and logs (Kelsey, 1994a,b; Kelsey and Joseph, 1997, 1999b). Ethanol, released alone or in

combination with host terpenes, is a well-known primary attractant for various species of weevils and scolytid secondary bark beetles (Moeck, 1970; Klimetzek et al., 1986; Nordlander et al., 1986; Liu and McLean, 1989; Phillips et al., 1988; Chénier and Philogène, 1989; Schroeder and Lindelöw, 1989; Sjödin et al., 1989; Byers, 1992; Kelsey, 1994a,b). If ethanol accumulates and 4AA declines in severely stressed pine trees, they are likely to be more susceptible to attack by secondary bark beetles than healthy trees.

While secondary bark beetles and weevils are normally less aggressive than primary bark beetles, they still cause a variety of problems in forest management that warrants mitigation. For example, the value of commercial logs and lumber can be reduced by pinhole-sized galleries and stain fungi introduced to the sapwood by ambrosia beetles (McLean, 1985). Numerous other species colonize woody debris or stumps and can damage or kill regeneration seedlings or saplings (Nordlander, 1987; Ciesla, 1988; Wilson et al., 1996; Salom, 1997). In some instances larger trees under stress can be killed (Furniss and Carolin, 1977). When secondary bark beetles or weevils are attracted to trees infected with certain root disease organisms, they can vector the pathogen to adjacent healthy trees or nearby healthy stands (Harrington et al., 1985; Witcosky et al., 1986a,b; Bedard et al., 1990; Nevill and Alexander, 1992a,b; Klepzig et al., 1991, 1995).

Although 4AA inhibits the response of various primary bark beetles to their pheromones, its effect on responses of secondary bark beetles to primary host attractants, such as ethanol, has not been thoroughly tested. In one study, *Dendroctonus valens* was unaffected by 4AA when *S*-(−)-β-pinene was used as the attractant (Hobson, 1996). The objective of our experiment was to determine whether 4AA deters attraction of scolytids to ethanol released simultaneously with a mixture of α- and β-pinene and whether the deterrency of 4AA is affected by ethanol release rates. A mixture of α- and β-pinene was used at a constant release rate because they occur in ponderosa pine tissues (Drew and Pylant, 1966) when ethanol is synthesized. Furthermore, the combined release of ethanol with α - and β-pinene will attract a broader range of scolytids and in larger numbers than ethanol alone (Chénier and Philogène, 1989; Schroeder and Lindelöw, 1989; Phillips et al., 1988; Lindelöw et al., 1993).

METHODS AND MATERIALS

Chemicals and Release Rates. Release rates of 4AA (98%, Aldrich), ethanol (100% USP grade, Georgia Pacific), and a 1:1 (v/v) mixture of (±)-α-pinene (98%, Aldrich) and (1*S*)-(−)-β-pinene (99%, Aldrich) in the laboratory and field were determined gravimetrically. All compounds were released from glass scintillation vials (20 ml) inside a perforated plastic container with lid (50 ml). There were 12 holes (0.8 cm diam.) on its side and two on the bottom, allowing free exchange

of chemicals with surrounding air. This setup prevented rain from diluting the compounds and altering their release rates.

Laboratory release rates were determined in an incubator at 30°C, and on a bench at 21°C. To simulate field conditions on the bench an electric fan was used to generate a wind speed of 1.1 m/sec. Two release rates were tested for 4AA and ethanol and one release rate for the pinene mixture, each averaged from five replicates. A high release rate for 4AA was achieved by placing three string wicks into the liquid and draping them over the open vial rim. A low release rate for 4AA was achieved with an open vial without strings. Ethanol was released from vials with lids having a 0.7- or 0.2-cm-diam. hole for high and low rates. The α- and β-pinene mixture was released from a separate open vial. Field release rates were determined by weighing vials before and after use in traps. These vials were capped for transport to and from the field.

Our field design consisted of a 2×3 factorial combination with two release rates of ethanol (low or high) and three release rates of 4AA (0, low or high) for a total of six treatments. Each treatment had the same α- and β-pinene release rate.

Field Tests. Lindgren 16-unit multiple funnel traps (Phero Tech, Delta, British Columbia, Canada) were replicated at 10 sites in Central Oregon, east of La Pine at 1494 to 1525 m elevation. Five sites separated by distances of 1.0–7.2 km were located in an area near 43°43′N; 120°52′W. These sites were thinned in 1996 to obtain a species composition of about 80% ponderosa and 20% lodgepole pine with diameters of approximately 20–30 cm at breast height (dbh). About 40 km southwest, in the vicinity of 43°35′N; 121°21′W, were another five sites separated by distances of 0.4–2.2 km. These sites were thinned in 1995 to obtain a species compositon of 70–100% ponderosa and 0–30% lodgepole pine, with 10–18 cm dbh. Disturbance from thinning helped ensure adequate beetle populations were available to successfully conduct the experiment. Sites had various levels of burned or unburned slash remaining.

Temperature data were collected from one site in each of the two areas with sensors attached to a datapod (Omnidata, Logan, Utah). One sensor was placed inside a weather shelter to measure ambient temperatures, while another sensor was placed inside the plastic bait container to determine temperature changes near the chemicals. These containers were not sheltered and could have received direct sun periodically during the day depending on crown positions of adjacent trees, etc.

At each site, six funnel traps were placed a minimum of 50 m apart along a transect. Traps were hung 0.5–1.0 m above ground from rope tied between two closely spaced trees and tethered with twine to keep them from swaying with wind. Traps were baited randomly by securing a plastic container to the middle funnel. Baits were replaced with fresh chemicals every two weeks and rerandomized among traps (by moving baits only) within a site to minimize the influence of

trap location on beetle catch numbers. Collection cups contained a piece of plastic releasing 2,2-dichlorovinyl-dimethylphosphate (Peststrip, Loveland Industries, Greeley, Colorado) to kill trapped insects. Traps were initially baited on May 8, 1997, and rebaited with fresh chemicals on May 19 and 30, and June 12. Insects were collected on the latter three dates and finally on June 26. Beetles were sorted into major scolytid species or their predators and counted.

Statistical Analysis. Data were analyzed using SAS software (SAS Institute, 1989, 1996). Release rates were summarized with their mean, minimum, and maximum values. Beetle numbers for each treatment and site were summed over the four collection dates and the analyses conducted on these values. Data were analyzed as a randomized complete block design with 4AA and ethanol as two factors. Beetle numbers were square-root transformed to meet homogeneity of variance and normality assumptions. Means were back-transformed for presentation. Significant differences between means were separated using Fisher's protected LSD at $\alpha = 0.10$.

To help compare behavior among species, ratios of beetles attracted to ethanol (high–low ethanol when 4AA was absent), or 4AA with ethanol (low–zero 4AA, and high–zero 4AA) were calculated. 4AA ratios were calculated with beetle averages across low and high ethanol treatments within each level of 4AA. Values above 1 indicate beetle attraction, while values below 1 show the degree of deterrence to each chemical.

RESULTS

Release Rates. There was substantial variation between laboratory and field release rates (Table 1). All chemicals, except the high ethanol treatment, had lower field release rates than in the laboratory at 21°C with air movement. Ambient field

TABLE 1. RELEASE RATES OF HOST VOLATILES IN INCUBATOR, LABORATORY, AND FIELD

Volatile	Release rates (mean, mg/hr)[a]		
	Incubator (30°C)	Laboratory (21°C)	Field (min 3.3, max 19.7°C)
α- + β-Pinene mixture	6.1 (5.7–6.3)	25.2 (14.6–34.1)	11.4 (6.4–16.3)
High ethanol	34.2 (33.7–35.0)	30.8 (28.1–37.2)	41.4 (30.1–57.2)
Low ethanol	11.7 (11.1–12.8)	6.7 (5.7–8.0)	4.5 (3.7–5.0)
High 4-allylanisole	5.2 (3.3–6.6)	10.4 (7.3–14.9)	4.3 (3.1–5.9)
Low 4-allylanisole	0.5 (0.3–0.7)	0.8 (0.1–0.8)	0.6 (0.5–0.9)

[a]The incubator (30°C) had no air movement, but in the laboratory (21°C) a fan generated a wind speed of 1.1 m/sec. Wind speed in the field was not measured. Numbers in parentheses are the range of release rates.

TABLE 2. SCOLYTIDS AND PREDATORS COLLECTED FROM 60 FUNNEL TRAPS (4 COLLECTION DATES) BAITED WITH α- AND β-PINENE PLUS DIFFERENT RELEASE RATES OF ETHANOL AND 4-ALLYLANISOLE, MAY 8–JUNE 26, 1997, IN PINE FORESTS OF CENTRAL OREGON

Beetle species	Number trapped	% of total
Bark beetles (Scolytidae)		
Dendroctonus valens	7,962	59.4
Ips latidens	1,989	14.8
Hylurgops porosus	1,349	10.1
Hylurgops subcostulatus	972	7.3
Ips pini	214	1.6
Hylurgops reticulatus	150	1.1
Hylastes macer	130	0.9

Hylastes nigrinus	74	0.5
Hylastes longicollis	53	0.4
Predator beetles		
Cleridae	240	1.8
Temnochila chlorodia (Trogositidae)	141	1.0
Total number of beetles	13,396	100.0

temperatures in weather shelters ranged from 3.3 to 19.7°C (average min–max). Inside plastic bait containers, average minimum and maximum temperatures were 2.1°C cooler at night, or 2.6°C warmer during the day than ambient temperatures, probably because these containers were not sheltered.

Field Test. In ponderosa pine forests of central Oregon, 10 species of secondary scolytid beetles and some of their predators were attracted to ethanol released in combination with a mixture of α- and β-pinene. *Dendroctonus valens* LeConte was the most abundant scolytid species trapped, comprising 59.4% of the total beetles caught (Table 2). Other abundant speices included *Ips latidens* LeConte at 14.8%, *Hylurgops porosus* (LeConte) 10.1%, and *Hylurgops subcostulatus* (Mannerheim) 7.3%. No primary bark beetles such as *Dendroctonus brevicomis* or *D. ponderosae* were caught in any traps. Aerial survey maps for 1996 and 1997 indicated endemic levels of activity for *D. brevicomis* and *D. ponderosae* in the forest surrounding our sites. Bark beetle predators such as clerids and *Temnochila chlorodia* (Mannerheim) were a small fraction of total beetles caught.

Dendroctonus valens responded about four times more frequently to traps with high ethanol compared to low ethanol regardless of 4AA levels (Figure 1). Low 4AA treatment caught significantly more *D. valens* than either the high ($P < 0.002$) or zero 4AA ($P = 0.029$). There was no difference in beetle numbers between high and zero 4AA ($P = 0.270$).

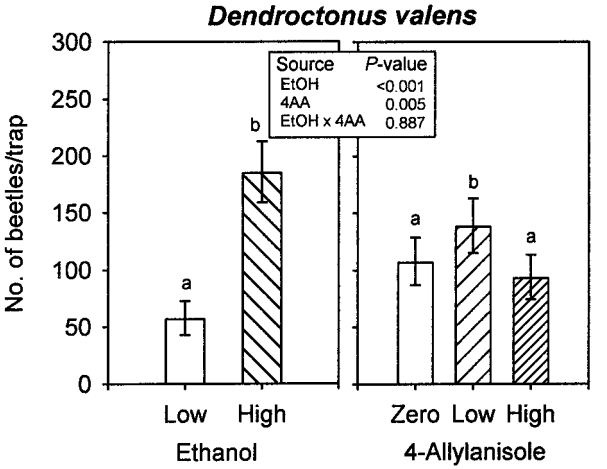

FIG. 1. Response of *D. valens* to traps baited with α- and β-pinene, ethanol, and 4-allylanisole. Vertical bars are means $\pm$ SE, $N = 10$.

Ips latidens was unaffected by ethanol treatments ($P = 0.288$), but was deterred at high 4AA compared to zero ($P = 0.004$) and low 4AA ($P = 0.037$, Figure 2). Beetle catches were not different between low and zero 4AA ($P = 0.385$). In contrast, *I. pini* showed a significant interaction between ethanol and 4AA (Figure 2). When 4AA was absent, *I. pini* numbers were greater at high ethanol than low ethanol ($P = 0.035$). The opposite was observed with low 4AA present ($P = 0.061$), and there was no difference in trap catches between ethanol release rates at high 4AA ($P = 0.974$). Low ethanol with either low or high 4AA attracted more *I. pini* than low ethanol alone ($P = 0.017$ and 0.054, respectively). Attraction of *I. pini* to high ethanol was unaffected by the presence of 4AA. There was a decrease in numbers in combination with low 4AA, but this was not significantly lower than trap catches for high ethanol with zero or high 4AA ($P = 0.113$, and 0.154, respectively).

All three *Hylurgops* species responded more strongly to high ethanol than low ethanol, regardless of amounts of 4AA (P values in Figure 3), but they each responded differently to 4AA. High and low 4AA inhibited *Hylurgops porosus* compared to zero 4AA ($P < 0.001$ and $P = 0.092$, respectively), whereas both release rates attracted *H. subcostulatus* ($P = 0.008$ and 0.052, respectively). *Hylurgops reticulatus* Wood was inhibited by high 4AA ($P < 0.014$), but not low 4AA ($P = 0.858$). Trap catches with high 4AA were smaller than those with low 4AA for *H. porosus* ($P < 0.030$) and *H. reticulatus* ($P = 0.009$), but not *H. subcostulatus* ($P = 0.432$).

Hylastes longicollis Swaine showed a significant 4AA and ethanol interaction (Figure 4). High ethanol caught more beetles than low ethanol at both zero

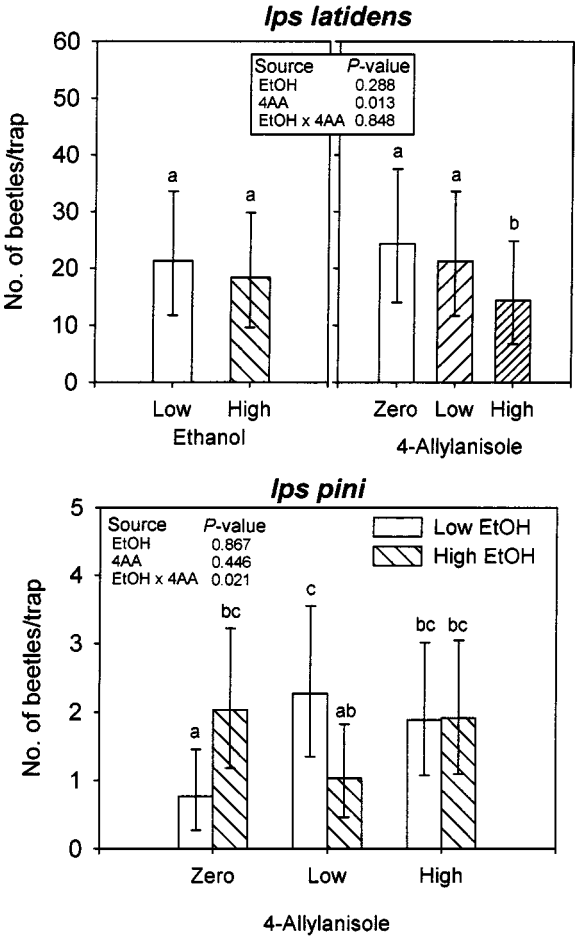

FIG. 2. Response of *Ips* spp. to traps baited with α- and β-pinene, ethanol, and 4-allylanisole. Vertical bars are means $\pm$ SE, $N = 10$.

($P < 0.001$) and low 4AA ($P = 0.025$), but not at high 4AA ($P = 1.000$). Low ethanol attracted the same number of *H. longicollis* regardless of 4AA treatments ($P \geq 0.727$). However, when the ethanol release rate was high, the high 4AA treatment reduced beetle numbers compared to zero ($P = 0.001$) and low 4AA ($P = 0.011$). *Hylastes macer* LeConte and *H. nigrinus* (Mannerheim) responded more strongly to high ethanol than low ethanol release rates (*P* values in Figure 4). Increasing the 4AA release rate from zero to low, and low to high, reduced *H. macer* almost linearly (all $P \leq 0.062$), whereas high, but not low 4AA reduced trap catches for *H. nigrinus* ($P = 0.074$ and 0.187, respectively).

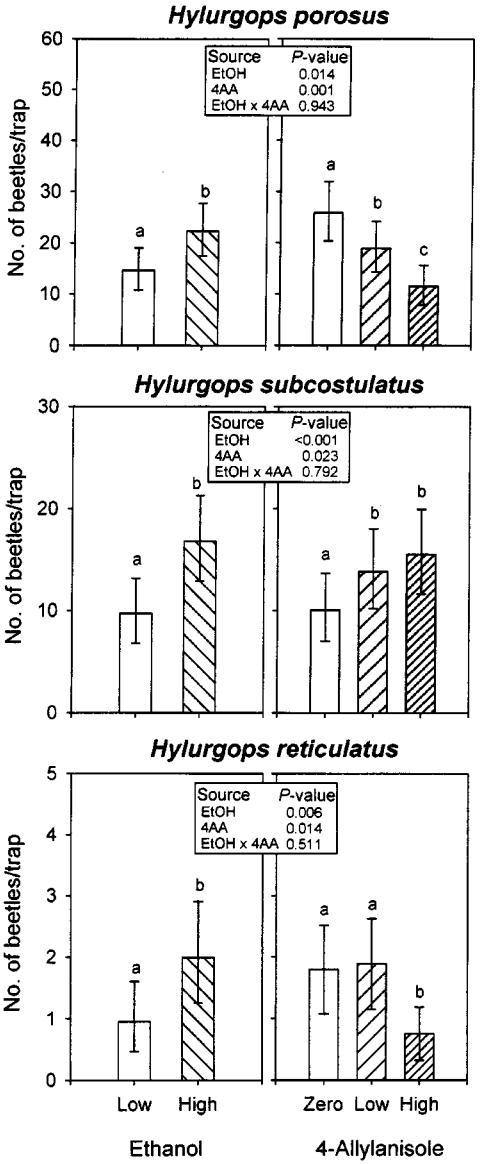

FIG. 3. Response of *Hylurgops* spp. to traps baited with α- and β-pinene, ethanol, and 4-allylanisole. Vertical bars are means $\pm$ SE, $N = 10$.

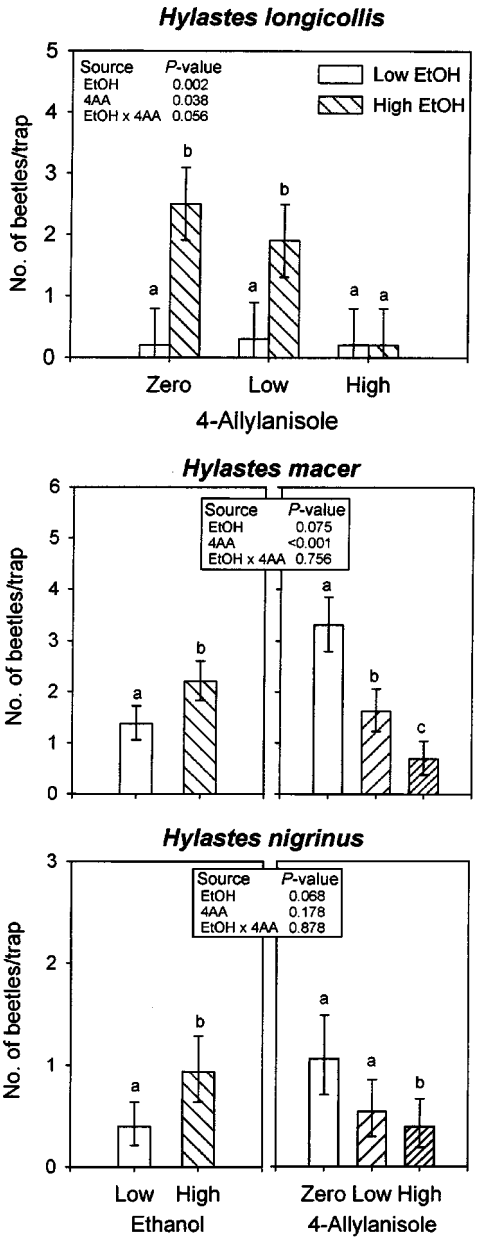

FIG. 4. Response of *Hylastes* spp. to traps baited with α- and β-pinene, ethanol, and 4-allylanisole. Vertical bars are means $\pm$ SE, $N = 10$.

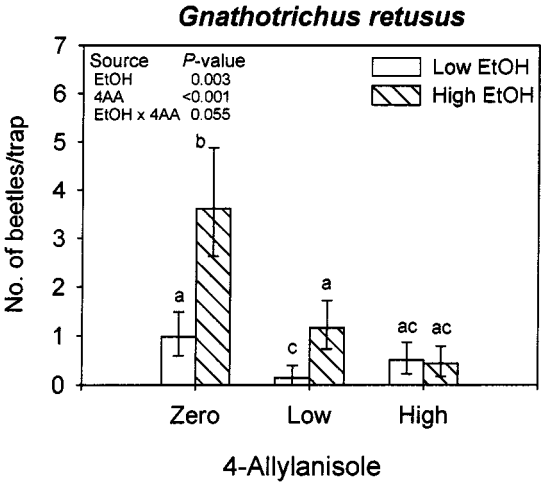

FIG. 5. Response of *G. retusus* to traps baited with α- and β-pinene, ethanol, and 4-allylanisole. Vertical bars are means $\pm$ SE, $N = 10$.

Gnathotrichus retusus (LeConte) numbers showed a significant interaction between 4AA and ethanol (Figure 5) similar to *Hylastes longicollis*. When 4AA was absent or low, the high ethanol release rate caught more beetles than low ethanol ($P = 0.003$ and $P = 0.014$), but when 4AA was high there was no difference in beetle numbers between ethanol treatments ($P = 0.858$). When ethanol was low, trap catches were inhibited by low 4AA, but not high 4AA, compared with zero 4AA ($P = 0.031$ and 0.287, respectively). When ethanol was high, trap catches of *G. retusus* were reduced by both low and high 4AA compared with zero 4AA ($P = 0.008$ and <0.001, respectively).

Clerids and *Temnochila chlorodia* were the only predators caught. Most clerids were either *Enoclerus* spp. or *Thanasimus* spp. However, neither clerids nor *Temnochila chlorodia* responded significantly to ethanol or 4AA treatments (*P* values are in Figure 6).

Relative responses of all species to ethanol and 4AA are shown in Figure 7. Most beetles responded 1.5–3.7 times more frequently to traps with high ethanol release rates (41.4 mg/hr) than those with low release rates (4.5 mg/hr) when 4AA was absent, except *Hylastes longicollis*, which was 12.5 times higher. Responses of *Ips latidens*, *T. chlorodia*, and clerids were not affected by ethanol release rates. Low release of 4AA reduced trap catches of four species by 25% or more, with significant inhibition for three of them compared to zero 4AA (*Gnathotrichus retusus*, *Hylastes macer*, and *Hylurgops porosus*). In contrast, *Hylurgops subcostulatus*, *I. pini*, and *D. valens* were attracted to low 4AA. Increasing the release rate of 4AA enhanced repellency, with significant inhibition for seven species. At high

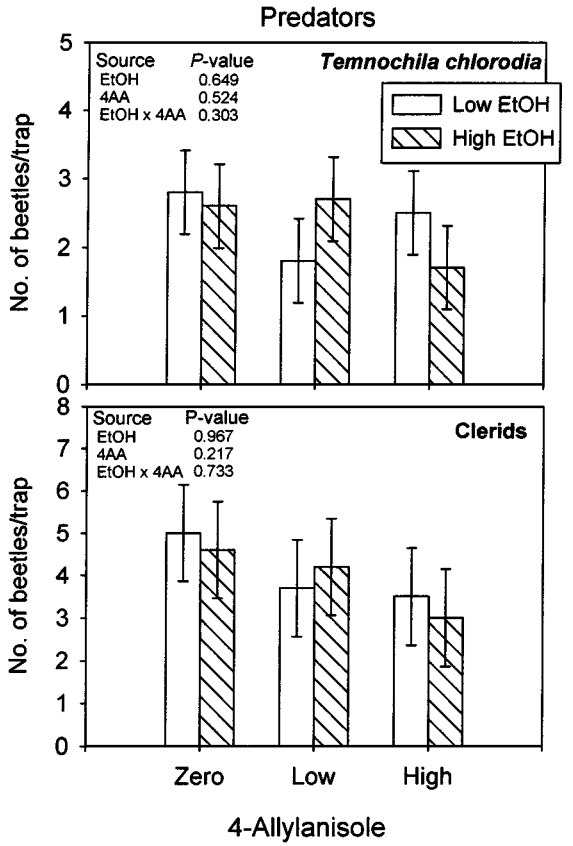

FIG. 6. Response of *T. chlorodia* and clerid predators to traps baited with α- and β-pinene, ethanol, and 4-allylanisole. Vertical bars are means $\pm$ SE, $N = 10$.

4AA, *Hylastes longicollis*, *Hylastes macer*, and *G. retusus* were most inhibited, while *Hylurgops subcostulatus* and *I. pini* (with low ethanol only) were attracted. Increasing the release rate of 4AA from 0.6 to 4.3 mg/hr had its greatest impact on *Hylastes longicollis* and *Hylurgops reticulatus* and least affect on *G. retusus*, *Hylastes nigrinus*, *Hylurgops subcostulatus*, and *I. pini*.

DISCUSSION

Ethanol, released in combination with α- and β-pinene, is an important primary attractant for many secondary bark beetles in ponderosa pine forests of central Oregon. Attraction of *Dendroctonus valens* to a similar combination was previously demonstrated in Wisconsin forests where traps baited with a 1:1

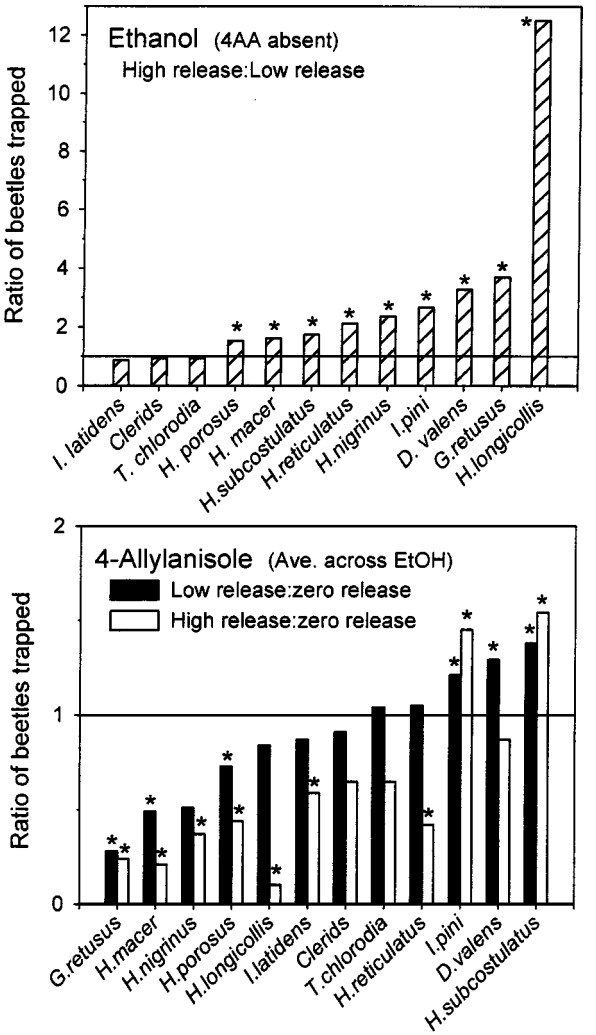

FIG. 7. Ratios of beetles trapped by different release rates of ethanol or 4AA. For species with a significant interaction between 4AA and ethanol, we used the main effect means for 0, low, and high 4AA. Values greater than 1 (horizontal line) indicate attraction and values less than 1 indicate deterrence. Asterisks indicate species where the number of beetles captured by treatments used in the numerator and denominator of a ratio were significantly different by ANOVA. *Ips pini* was attracted to 4AA only in combination with low ethanol release rates (see Figure 2 for details).

ethanol–terpentine (α- and β-pinene plus other terpenes) mixture captured 60 times more beetles than traps with terpentine alone (Klepzig et al., 1991). All *Hylastes* and *Hylurgops* at our sites preferred traps with the highest ethanol release rate, much like related species in Europe. For example, ethanol alone attracts *Hylurgops palliatus* (Gyll.) and the beetle numbers rise as the release rate increases (Klimetzek et al., 1986; Schroeder, 1988; Schroeder and Lindelöw, 1989; Byers, 1992). α-Pinene alone does not attract this species, but the combination of α-pinene and ethanol results in a synergistic response, with greater trap catches than the total from both compounds individually (Schroeder, 1988; Schroeder and Lindelöw, 1989; Byers, 1992). Although *Hylastes longicollis* in this experiment showed the largest proportional increase in trap catches between the two release rates of ethanol, this could have resulted, in part, from the low number of individuals trapped. Their typical response to ethanol is probably more similar to the other species. Numbers of *G. retusus* captured were low also, but their affinity for a high ethanol release rate reflects their preference for logs with high ethanol concentrations over logs with low concentrations (Kelsey, 1994a,b; Kelsey and Joseph, 1999b). α-Pinene most likely does not enhance, and may inhibit, the attraction of *Gnathotrichus* spp. to ethanol (Kelsey and Joseph, 1997).

Ips latidens was not attracted to ethanol, which is similar to *I. grandicollis* (Eichhoff) (Chénier and Philogène, 1989) and *I. typographus* (L.) (Klimetzek et al., 1986). For the latter species, combining ethanol with its pheromone reduced the beetle numbers compared to traps baited with pheromone alone, although the differences were not significant. In contrast, *I. pini* in the current experiment was attracted to ethanol. Why it responded differently than the *Ips* species listed above is unclear. Increasing the ethanol release rate also failed to enhance trap catches of clerids and *Temnochila chlorodia* in central Oregon. Other clerid predators, such as *Thanasimus formicarius* (L.) in Sweden (Schroeder, 1988) or *T. dubius* (Fabricius) in Canada (Chénier and Philogène, 1989), are attracted to α-pinene but not ethanol or their combination.

Effectiveness of 4AA in central Oregon as a repellent for secondary bark beetles attracted to host kairomones is dependent on the beetle species, and release rates of 4AA and ethanol. In general, 4AA was effective at inhibiting some beetles, such as *G. retusus* and the three species of *Hylastes.* In contrast, one or both release rates of 4AA attracted other species, including *Hylurgops subcostulatus*, *I. pini*, and *D. valens.* Hobson (1996) reports 4AA failed to inhibit attraction of *D. valens* to β-pinene. His release rate of 4AA was nearly 19 times (80 mg/hr) greater than our highest level. The response of *D. valens* to traps baited with ethanol and 4AA is consistent with their preference for colonizing the base of diseased ponderosa pine boles (Moeck et al., 1981), which can have lower amounts of 4AA (Nebeker et al., 1995) and higher ethanol concentrations than healthy trees (Kelsey et al., 1998).

Attraction of bark beetles to 4AA has been reported previously for *I. grandicollis* (Eichh.), particularly the males (Werner, 1972). In the current study, *I. pini*

was also attracted to 4AA, but only when ethanol release rates were low, whereas *I. latidens* showed no signs of attraction to 4AA. In studies where traps were baited with pheromone attractants, 4AA has inhibited the response of *I. pini.* Hobson (1996) reduced trap catches of *I. pini* by 29% with a release rate of 80 mg/hr 4AA, but it was not significant. In contrast, Hayes and Strom (1994) reported a 43% reduction in numbers of *I. pini* caught by traps in Wisconsin releasing 4AA at 6.6 mg/hr, or 1.5 times greater than our highest treatment. Attraction to 4AA also was previously reported for the bark beetle predator *T. chlorodia* when tested in Oregon, but not when tested in California (Hayes and Strom, 1994). Our trap catches of *T. chlorodia* and clerid predators were reduced by a high release rate of 4AA, but not significantly. Thus, it appears some bark beetle predators are not adversely impacted by 4AA.

It is becoming apparent that ethanol accumulates in woody tissues more often than anyone previously suspected. It can be synthesized by many tree species (Kimmerer and MacDonald, 1987; Kimmerer and Stringer, 1988; Kelsey, 1996) and by all of their tissues (Kimmerer and Stringer, 1988; Kelsey et al., 1998) under appropriate conditions. Synthesis of ethanol in small quantities is probably an important physiological process for normal tree growth (Harry and Kimmerer, 1991; Joseph and Kelsey, unpublished data). However, ethanol can accumulate to abnormally high concentrations when trees are subjected to various types of severe stress or when tissues are dying, as in logs and stumps (Kimmerer and Kozlowski, 1982; Sjödin et al., 1989; Kelsey, 1994a,b; von Sydow and Birgersson, 1997; Kelsey and Joseph, 1999a,b, 2001). Quantities of ethanol synthesized in wood residues are highly variable and strongly influenced by environmental parameters such as precipitation, and temperature (Kelsey and Joseph, 1999a,b). This variability can provide opportunities to manipulate ethanol production and mitigate the behavior of some secondary bark beetles. One alternative is to minimize slash and woody debris, but stumps are usually left intact, and current forest practices are moving toward leaving more coarse woody debris in the forest to allow important ecological processes to function normally and sustainably (Schowalter and Filip, 1993). Thus, other alternatives may be needed to help manage secondary bark beetles.

4AA is an allomone with potential utility for management because it inhibits responses for a wide range of scolytid beetles to primary and secondary attractants (Hayes and Strom, 1994; Werner, 1995). It might have the added advantage of not adversely interfering with the attraction of bark beetle predators, as observed here and by others (Hayes and Strom, 1994). 4AA also has shown some promise in suppressing or reducing growth of small infestations of *D. frontalis* (Hayes and Clarke, 1998). Consequently, it seems worthwhile to further examine the use of 4AA for protecting high-value logs, individual trees, and possibly small stands or plantations from unwanted attack and colonization by secondary bark beetles that are sensitive to this compound.

Acknowledgments—We thank the staff of Bend/Ft Rock Ranger District, especially Matt Deppmeier, for assistance in locating suitable sites for this experiment. We thank Dr. J. L. Hayes and Dr. R. A. Werner for reviewing the manuscript, and Dr. Lisa Ganio and Manuela Huso for statistical advice. The use of trade, firm, or corporation names is for information and convenience of the reader. Such use does not constitute an official endorsement or approval by the US Department of Agriculture of any product or service to the exclusion of others that may be suitable.

(Received August 28, 2000; accepted December 12, 2000)

Abstract—Antitermitic activity of Taiwania (*Taiwania cryptomerioides* Hayata) against *Coptotermes formosanus* Shiraki was demonstrated in laboratory tests. Blocks of sapwood and heartwood from *T. cryptomerioides* exhibited antitermitic activity. Bioassays revealed that heartwood essential oil exhibited the highest antitermitic activity, followed by sapwood essential oil and then the *n*-C_6H_{14} soluble fraction when tested at 10 mg/g. The order of termite mortality of three compounds purified from *n*-C_6H_{14} soluble extracts of heartwood was cedrol > α-cadinol > ferruginol. The termite resistance of *T. cryptomerioides* wood can be attributed to the termiticidal activity of cedrol and α-cadinol.

Key Words—*Taiwania cryptomerioides* Hayata, *Coptotermes formosanus* Shiraki, antitermitic activity, essential oils, cedrol, α-cadinol, ferruginol.

INTRODUCTION

Biodegradation is recognized as one of the most significant problems for wood utilization. Among several factors leading to biodegradation, termites are one of the most damaging to wooden structures worldwide. There are several properties that determine wood's natural resistance to termite attack. For example, hardness of wood affects the termite's ability to fragment the wood with its mandibles (Bultman et al., 1979). It is also well known that extractives have a significant effect on the durability of wood (Chang et al., 1999b). Certain extractives from wood

0098-0331/01/0400-0717$19.50/0

tissues can provide protection against harmful insects. For nondurable woods, it may be necessary to use inorganic compounds or synthetic pesticides to preserve woods and prolong their application life. To avoid environmental pollution and health problems caused by the use of traditional wood preservatives or synthetic pesticides, there is a trend to search for naturally occurring toxicants in plants. Accordingly, many researchers are focusing on the separation and identification of extractives from some durable woods and examining bioactivities.

Taiwania (*Taiwania cryptomerioides* Hayata) (*Taxodiaceae*) is an endemic tree that grows at elevations of 1800–2600 m in Taiwan's central mountains. The heartwood of *T. cryptomerioides* is yellowish red with distinguished purplish pink streaks. *T. cryptomerioides* timbers are well known in Taiwan for their decay resistance and excellent durability. Recently, we have illustrated the relationships between extractives and wood properties, including the photodiscoloration, antifungal, and antibacterial activity in *T. cryptomerioides* heartwood (Chang et al., 1998, 1999a,b, 2000a,b). To our knowledge, there are no prior studies of the antitermitic activity of chemical constituents from *T. cryptomerioides. Coptotermes formosanus* Shiraki is the termite mainly responsible for wood destruction in many countries, including Taiwan, Japan, and parts of the United States. Thus, many researchers have investigated antitermitic compounds of wood species using *C. formosanus* as a test termite (Yaga and Kinjo, 1986; Kinjo et al., 1988; Yaga et al., 1991; Ohtani et al., 1997; Sogabe et al., 2000a,b). In this study, we examined the antitermitic activity of the essential oils and dominant constituents isolated from *T. cryptomerioides* against *C. formosanus*.

METHODS AND MATERIALS

Wood Samples. Test blocks, 2.0 × 2.0 × 2.0 cm, were cut from the sapwood and heartwood of a 27-year-old *T. cryptomerioides* tree collected from the Experimental Forest of National Taiwan University. The blocks were oven-dried (60 ± 2°C, 24 hr) and weighed before treatment. Heartwood and sapwood blocks were extracted in a Soxhlet apparatus with alcohol–toluene (1 : 2) for 24 hr.

Termites. The test termites were from a *C. formosanus* colony from S.-J. Lin's laboratory at the Taiwan Forest Research Institute. The colony has been reared on wood pieces in the dark at 26.5°C and 85% relative humidity for more than two years.

General Procedures. Merck (Germany) Kieselgel $60F_{254}$ sheets were used for analytical thin layer chromatography (TLC). High performance liquid chromatography (HPLC) was performed with a Jasco model PU980 pump equipped with a Jasco RI-930 RI detector and Hibar Lichrosorb Si-60 column (25 × 1 cm ID). FTIR spectra were recorded on a Bio-Rad model FTS-40 spectrophotometer, and the MS was obtained using a Finnigan MAT-95s Mass spectrometer. The ^{13}C and ^{1}H NMR spectra were recorded on a Bruker Avance-500 MHz FT-NMR.

Extraction and Isolation. T. cryptomerioides heartwood chips were prepared from the freshly cut tree. The essential oils from sapwood and heartwood of this tree were obtained by water distillation. The air-dried heartwood chips (5.7 kg) were exhaustively extracted with methanol (MeOH). The extracts were condensed to 286.4 g by rotary evaporation, followed by extraction with *n*-hexane (*n*-C_6H_{14}), chloroform ($CHCl_3$), ethyl acetate (EtOAc), and methanol (MeOH) successively. After removing solvents from the combined extracts, the *n*-C_6H_{14}, $CHCl_3$, EtOAc, and MeOH soluble fractions and MeOH insoluble fraction were obtained. The *n*-hexane soluble fraction (5 g) of methanol extracts was fractionated initially by gradient elution with EtOAc/*n*-C_6H_{14} on a silica gel column (800 g). Fractions were tracked by TLC, and compounds with similar R_f values were pooled to give 41 subfractions (H1–H41). α-Cadinol (**1**) (27.6 min retention time) was isolated and purified from H16 to H22 by semipreparative HPLC [Si-60 column, EtOAc–*n*-C_6H_{14} (30 : 70) mobile phase, 1.0 ml/min flow rate]. Ferruginol (**2**) (16.2 min retention time) was collected from H2–H8 with the same HPLC system. The mobile phase was changed to EtOAc–*n*-C_6H_{14} (10 : 90). Cedrol (**3**) (20.0 min retention time) was isolated from H10 with the same HPLC system. The mobile phase was changed to EtOAc–*n*-C_6H_{14} (20 : 80), 1.0 ml/min flow rate. Structures of compounds isolated from *T. cryptomerioides* were identified using FTIR, MS, and NMR spectrometry. Their spectral data are consistent with those reported in the literature (Chang et al., 1998, 2000a,b).

*α-Cadinol (**1**)*. Colorless needle crystal; mp 74–75°C; EI-MS for $C_{15}H_{26}O$ found 222; IR ν_{max}: 3372, 3046, 1660 cm^{-1}; ^1H NMR (in $CDCl_3$): δ (ppm) 0.74 (d, $J = 7.0$, H-12), 0.89 (d, $J = 7.0$, H-13), 1.08 (s, H-14), 1.64 (s, H-15), 2.13 (m, H-11), 5.47 (s, H-4); ^{13}C NMR: δ (ppm) 15.13 (C-12), 20.77 (C-14), 21.51 (C-13), 22.00 (C-1), 22.68 (C-7), 23.81 (C-15), 26.00 (C-11), 30.95 (C-2), 39.89 (C-5), 42.22 (C-8), 46.73 (C-6), 50.04 (C-10), 72.47 (C-9), 122.35 (C-4), 134.94 (C-3).

*Ferruginol (**2**)*. Yellow oil; EI-MS for $C_{20}H_{30}O$ found 286; IR ν_{max}: 3370, 1612, 1501, 1440 cm^{-1}; ^1H NMR (in $CDCl_3$): δ (ppm) 0.89 (3H, s, H-18), 0.93 (3H, s, H-19), 1.15 (3H, s, H-20),1.22 (3H, d, $J = 7.0$ Hz, H-16), 1.29 (3H, d, $J = 7.0$ Hz, H-17), 2.77 (1H, ddd, $J = 17.0$, 10.5, 7.0 Hz, H-7a), 2.81(1H, ddd, $J = 2.0$, 6.5, 17.0 Hz, H-7b), 3.11 (sept, $J = 7.0$ Hz, H-15), 6.62 (1H, s, H-11), 6.81 (1H, s, H-14); ^{13}C NMR: δ (ppm) 19.12 (C-6), 19.18 (C-2), 21.46 (C-19), 22.50 (C-16), 22.67 (C-17), 24.60 (C-20), 26.47 (C-15), 29.60 (C-7), 33.17 (C-18), 33.23 (C-4), 37.27 (C-10), 38.65 (C-1), 41.57 (C-3), 50.23 (C-5), 110.86 (C-11), 126.47 (C-14), 126.27 (C-8), 131.69 (C-13), 148.16 (C-9), 150.95 (C-12).

*Cedrol (**3**)*. Colorless needle crystal; mp 87°C; EI-MS for $C_{15}H_{26}O$ found 222; IR ν_{max}: 3342, 1373 cm^{-1}; ^1H NMR (in $CDCl_3$): δ (ppm) 0.81 (d, $J = 7.2$, H-15), 0.97 (s, H-13), 1.23 (s, H-14), 1.29 (s, H-12); ^{13}C NMR (in $CDCl_3$): δ (ppm) 15.54 (C-15), 25.34 (C-13), 27.61 (C-14), 28.89 (C-12), 30.16 (C-11), 31.58 (C-9), 35.33 (C-10), 36.99 (C-3), 41.45 (C-7), 41.96 (C-4), 43.38 (C-2), 54.08 (C-1), 56.51 (C-5), 61.03 (C-6), 75.10 (C-8).

Termiticidal Tests with Wood Blocks. Sapwood and heartwood (extracted and unextracted) blocks were tested using the no-choice test methods described by the American Wood-Preservers' Association (AWPA, 1997) against *C. formosanus. Pinus taiwanensis* sapwood is well recognized in Taiwan for its poor durability (Chang and Wang, 1995). It was selected as the control in this assay. Oven-dried wood blocks as well as 45 workers and 5 soldiers of *C. formosanus* were placed into the test container (75 mm diameter $\times$ 65 mm high). Three replicates of each treatment were tested in a growth chamber maintained at 26.5°C and 80% relative humidity for four weeks. Termite mortality (percent) and weight loss (percent) of the blocks were recorded periodically up to four weeks, using the following equations:

$$\text{Termite mortality (\%)} = \frac{\text{Number of dead termites}}{\text{Total number of test termites}} \times 100$$

$$\text{Weight loss (\%)} = \frac{W_1 - W_2}{W_1} \times 100$$

where W_1 is the oven-dried weight before termiticidal test (grams) and W_2 is the oven-dried weight after termiticidal test (grams).

We used Duncan's multiple-range test to examine the difference of the results of termiticidal test. Results with $P < 0.05$ were considered statistically significant.

Termiticidal Test with Essential Oils and Compounds. The termiticidal test followed the method of Kang et al. (1990). Each compound (**1, 2** and **3** as shown in Figure 1) and the essential oils (sapwood and heartwood) were dissolved in acetone, to make various concentrations of solutions, which were then applied to filter paper (8.6 cm diameter, Whatman No. 3) and air-dried at room temperature. Control filter paper was treated with solvent only. Fifty active termites (45 workers and 5 soldiers) were put onto the filter paper impregnated with the test materials in the Petri dish (9 cm diam. $\times$ 1.5 cm high). The test dishes were placed in a growth chamber maintained at 26.5°C and 80% realtive humidity for 14 days. A few drops of water were periodically put onto the bottom edge of the dishes. Three replicates were made for each sample, and termite mortality was determined daily. Paired Student's *t* tests were used to evaluate the difference of the results of termiticidal test. Results with $P < 0.05$ were considered statistically significant.

RESULTS AND DISCUSSION

Antitermitic Activity of Woods. Unextracted sapwood of *Pinus taiwanensis* (PSN), used as a control, showed no antitermitic activity (Table 1). In contrast, both the sapwood and heartwood of *T. cryptomerioides* displayed antitermitic activity. Termite mortalities for THN (unextracted *T. cryptomerioides* heartwood), THE (alcohol–toluene-extracted *T. cryptomerioides* heartwood), TSN (unextracted

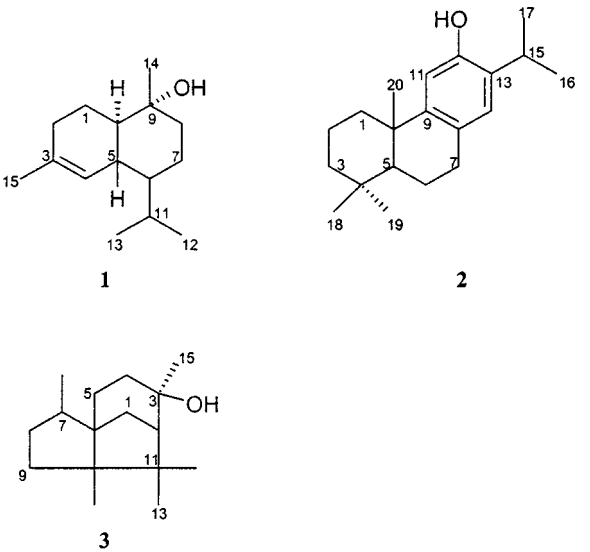

FIG. 1. Structures of α-cadinol (**1**), ferruginol (**2**), and cerdol (**3**) isolated from *T. cryptomerioides* heartwood.

T. cryptomerioides sapwood) and TSE (alcohol–toluene-extracted *T. cryptomerioides* sapwood) after four weeks were 57%, 50%, 48% and 43%, respectively. Duncan's multiple range test showed significant differences in termite mortality between extracted and unextracted wood ($P < 0.05$). Weight losses of heartwood and sapwood blocks extracted by alcohol–toluene (8.2% and 7.8%) were larger than those of unextracted blocks (1.1% and 1.3%) after four weeks. These differences were significant at $P < 0.05$. We conclude that the presence of

T. cryptomerioides wood extractives decreases the weight loss of wood in the presence of termites.

Antitermitic Activity of Essential Oils and Fractions. In our previous studies, the essential oils and *n*-C_6H_{14}-soluble fraction of MeOH extracts of *T. cryptomerioides* were demonstrated to have antifungal and antibacterial activity (Chang et al., 1998, 1999b, 2000a,b). Therefore, the antitermitic activities of essential oils (heartwood and sapwood) and the *n*-C_6H_{14}-soluble fraction of MeOH extracts from *T. cryptomerioides* were determined in this study.

After 14 days, the order of termite mortality from essentials oils and the *n*-C_6H_{14}-soluble fraction at 10 mg/g was: heartwood essential oil (56%) > sapwood essential oil (32%) > *n*-C_6H_{14}-soluble fraction (22%) (Figure 2). All samples demonstrated significant termiticidal activity compared to controls (termite mortality = 4%). According to our previous data, the cadinanes (T-cadinol, T-muurolol, α-cadinol) were the main constituents in heartwood essential oils (66.7%), followed by sapwood essential oils (37.1%), and then *n*-C_6H_{14} extracts (27.4%) (Chang et al., 2000a). These results suggest that antitermitic activity of *T. cryptomerioides* may be related to the cadinane constituents of essential oils or the *n*-C_6H_{14} soluble fraction.

Although the antitermitic activity of the *n*-C_6H_{14}-soluble fraction at 10 mg/g was lower than heartwood and sapwood essential oils, termite mortality increased to 72% when the dosage increased to 50 mg/g.

Antitermitic Activity of Isolated Compounds. The *n*-C_6H_{14} soluble fraction from *T. cryptomerioides* had excellent antitermitic activity at 50 mg/g. HPLC was used to isolate and purify α-cadinol, ferruginol and cedrol for further bioassay. Figure 3 shows the antitermitic activity of the three dominant compounds. The order of antitermitic activity against *C. formosanus* was cedrol, followed by α-cadinol, and then ferruginol. Termite mortalities (at 5 mg/g after 14 days) were

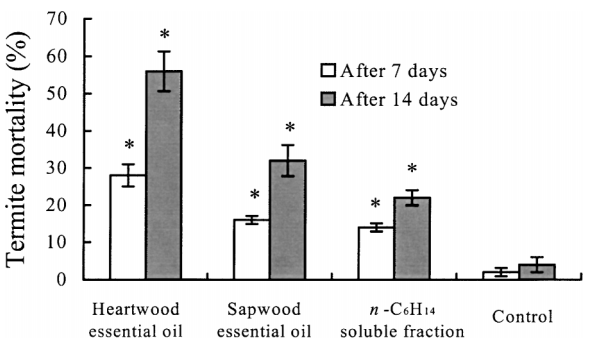

FIG. 2. Antitermitic activity of essential oils and the *n*-C_6H_{14} soluble fraction from *T. cryptomerioides* (bars = SD). $^*P < 0.05$; statistically different from the data of control.

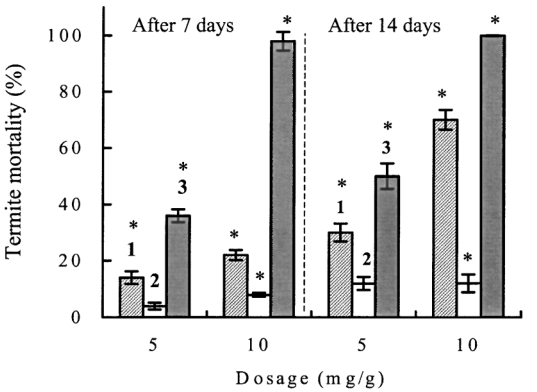

FIG. 3. Antitermitic activity of α-cadinol (**1**), ferruginol (**2**), and cedrol (**3**), (bars = SD). $^{*}P < 0.05$; statistically different from the data of control.

50%, 30%, and 12%, respectively. The antitermitic activities of 10 mg/g α-cadinol and cedrol increased after 14 days, whereas no dosage-dependent-effects occurred with ferruginol. The decreasing order of termite mortality at 10 mg/g dosage for 14 days was cedrol (100%) > α-cadinol (70%) > ferruginol (12%). Overall, cedrol possessed the strongest antitermitic activity.

During the test periods all the termites were killed within eight days at a dosage of 10 mg/g. This suggests that the resistance of *T. cryptomerioides* wood to termite attack may be attributed to the action of both cedrol and α-cadinol. Yaga and Kinjo (1986) previously showed that cedrol from *Sciadopitys verticillata* S. et Z was termiticidal. They also found that α-cadinol was the main termiticidal constituent of *Chamaecyparis obtusa* Endl (Kinjo et al., 1988).

Acknowledgments—This study was supported in part by grant NSC-89-2313-B-002-121 from the National Science Council of the Republic of China. The authors thank Mr. H.-Y. Lin (The Experimental Forest of National Taiwan University) for supplying *T. cryptomerioides* wood and Mr. S.-J. Lin (Taiwan Forestry Research Institute) for providing us with termites.

TANNINS IN *Puccinellia arctica*: POSSIBLE DETERRENTS TO HERBIVORY BY CANADA GEESE

TRENT J. VOLZ and THOMAS P. CLAUSEN*

Department of Chemistry and Biochemistry
University of Alaska Fairbanks
Box 6160, Fairbanks, Alaska 99775-6160

(Received June 12, 2000; accepted December 12, 2000)

Abstract—Urban populations of Canada geese, *Branta canadensis*, pose a nuisance problem throughout most of the eastern United States and in other parts of the United States and Canada. *Puccinellia arctica* is a species of arctic grass that is unpalatable to Canada geese on the North Slope of Alaska and may prove to be an effective long-term and nonlethal means of controlling the growing populations of urban Canada geese. A comparative study of the secondary metabolites of both *P. arctica* and *Puccinellia langeana* and *Poa pratensis*, two palatable grass species that Canada geese generally consume, revealed no significant differences. However, ellagitannin levels were higher in *P. arctica* than in the palatable grass species and may be contributing to its unpalatability to Canada geese. These results support the potential to use *P. arctica* in public areas to control geese intrusions.

Key Words—*Branta canadensis*, carbon nutrient balance, chemical defense, herbivory, *Poa pratensis*, *Puccinellia arctica*, *Puccinellia langeana*, tannins.

INTRODUCTION

Urban populations of Canada geese, *Branta canadensis*, pose a nuisance problem throughout most of the eastern United States and in other parts of the United States and Canada (Conover, 1985). Grazing on lawns has become one of the principal food sources for geese in urban areas (Conover and Kania, 1991). This has created a problem when the geese damage turf by foraging on grass in backyards, golf courses, parks, landscaped areas, and playing fields (Cummings et al., 1991).

The feces the geese leave behind, up to three pounds per goose per day (Sinnott, personal communication), diminishes the aesthetic and recreational value

*To whom correspondence should be addressed.

0098-0331/01/0400-0725$19.50/0

of the grazed areas (Cummings et al., 1991). The accumulated feces can decrease water quality and may have deleterious effects upon public health (Conover and Chasko, 1985). In fact, several public parks and beaches have been closed due to health concerns stemming from goose feces (Conover, 1985).

Puccinellia arctica is a species of arctic grass that is unpalatable to Canada geese on the North Slope of Alaska (McKendrick, 1997; Scorup, personal communication). It is being tested as a goose deterrent in Anchorage, Alaska, in an urban environment. By planting the grass in urban areas where Canada geese forage, *P. arctica* may prove to be an effective long-term and nonlethal means of controlling the growing populations of urban Canada geese.

As part of the testing of *P. arctica*, its secondary metabolite profile was compared to the metabolite profiles of two palatable grass species that Canada geese do eat to determine if *P. arctica* may be chemically defended. Gas chromatography–mass spectroscopy (GC-MS) and thin-layer chromatography (TLC) showed no significant differences between *P. arctica* and the palatable grass species (Volz, 2000). Alkaloids, which may defend tall fescue (*Festuca arundinacea*) from herbivory by Canada geese (Conover and Messmer, 1996), were screened for and not detected (Volz, 2000).

This report details condensed tannin, gallotannin, and ellagitannin assays that were performed on *P. arctica* as well as on *Poa pratensis* and *Puccinellia langeana*, two palatable grass species that Canada geese favor (Scorup, personal communication). These assays were done to investigate whether tannins, which can in some cases deter bird herbivory in plants such as grain sorghum (Watterson and Butler, 1983), are contributing to the unpalatability of *P. arctica* to Canada geese.

Plant samples were also analyzed to investigate factors that may influence tannin levels in *P. arctica.* Since *P. arctica* may eventually be used in an urban setting, some plants were subjected to routine mowing to study the changes in tannin levels. Seedling *P. arctica* samples were analyzed to examine whether plant maturity affects tannin levels. Samples of *P. arctica* growing in the nutrient limited wet sedge tundra of Alaska's North Slope (Shaver and Chapin, 1995) were tested to study the affects of low soil nutrient levels on tannin levels.

METHODS AND MATERIALS

Chemicals. Ellagic acid and gallic acid were purchased from Aldrich. Quebracho tannin was obtained from Pilar River Plate Corporation. All chemicals and solvents were reagent grade, and water was deionized.

Plant Samples. All *P. arctica* samples were collected between May and August 1999. The nutrient-limited wet sedge tundra samples were collected on August 5

near Prudhoe Bay, Alaska. The remaining *P. arctica* samples were collected near Anchorage, Alaska (May 27, July 12, and August 19). The mown *P. arctica* samples were cut to a height of 9 cm an average of once a week in the 1999-growing season and collected on July 12.

The palatable *P. langeana* samples were collected from Prudhoe Bay, Alaska on August 5, 1999. The palatable *P. pratensis* samples were collected near Anchorage, Alaska between May and July 1999. After collection, plant samples were placed in coolers and chilled with freezer packs for transport to the laboratory. Once in the laboratory, plant material was stored in a freezer at -20°C prior to analysis.

Tannin Assays. To quantify condensed tannin levels, 0.20 g of lyophilized plant material was first extracted with 3 ml of 50% (v/v) MeOH in water (Harborne, 1984) for 1 hr at room temperature. The extraction was repeated twice, and the aqueous MeOH extracts were combined. A 1-ml portion of the aqueous MeOH extract was then analyzed using the method of Porter et al. (1986). Condensed tannin levels were reported in terms of the percentage of condensed tannin equivalents (quebracho tannin) by dry weight. Interspecific differences in condensed tannin levels should be interpreted with caution, since tannins from different plant species yield varying responses with this assay (Wisdom et al., 1987).

To extract, hydrolyze, and analyze gallotannins, a 0.20-g portion of lyophilized plant material was extracted with 3 ml of 70% (v/v) acetone in water for 30 min at room temperature. The filtered extract was placed in an ampule with 5 ml of 1 M H_2SO_4, and the sealed ampule was then heated in an oven for 26 hr at 100°C. After cooling, the ampule was opened and the hydrolysate was diluted to 50 ml with water. A 1-ml volume of the diluted hydrolysate was then analyzed by the method of Inoue and Hagerman (1988). This provided a measure of total gallic acid, both free and esterified, in the plant sample.

A second 0.20-g portion of the lyophilized plant material was extracted, diluted to 50 ml with water, and then assayed without hydrolysis to measure the amount of free gallic acid in the plant sample. The amount of free gallic acid was then subtracted from the amount of total gallic acid to determine the amount of esterified gallic acid in the plant sample. Gallotannin levels were reported in terms of the percentage of esterified gallic acid equivalents by dry weight.

To extract, hydrolyze, and analyze ellagitannins, a 0.10-g portion of lyophilized plant material was placed in an ampule with 8 ml of 1 M H_2SO_4. The sealed ampule was then heated in an oven for 24 hr at 100°C, and the concentration of ellagic acid was measured using the method of Wilson and Hagerman (1990). Ellagitannin levels were reported in terms of the percentage of ellagic acid equivalents by dry weight.

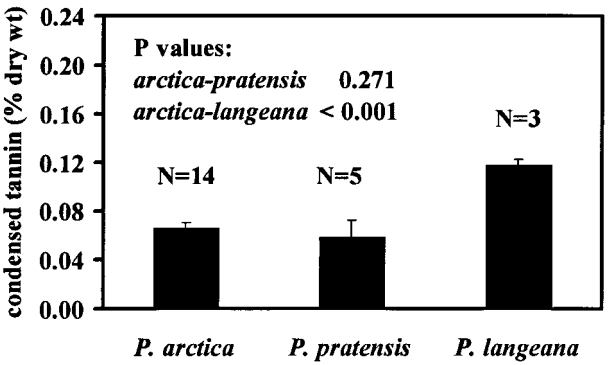

FIG. 1. Mean condensed tannin concentration in *P. arctica* and palatable plants. Vertical lines represent +1 SD, and *N* is the number of samples. One-tailed *P* values from unpaired *t* tests are reported.

RESULTS AND DISCUSSION

There were no seasonal effects or trends on the tannin measures of *P. arctica* and *P. pratensis* (data not shown). Thus, samples from different collection times were pooled in making the following comparisons between species and treatments.

Figure 1 displays the results of the condensed tannin assay done on *P. arctica* and the palatable plants. Condensed tannin levels were low in all of the plant samples. There was no statistically significant difference in condensed tannin levels between *P. arctica* and the palatable *P. pratensis* ($P_{1\text{-tail}} = 0.271$). The condensed tannin levels were 79% higher ($P_{1\text{-tail}} < 0.001$) in the palatable *P. langeana* than in *P. arctica.* Therefore, unless the condensed tannins in *P. arctica* have either a high level of biologically activity (Clausen et al., 1990; Ayres et al., 1997) or are insensitive to the proanthocyanidin assay (Wisdom et al., 1987), they are not primarily responsible for its unpalatability to Canada geese.

Figure 2 shows the results of the condensed tannin assay done on *P. arctica* control and test plants. The condensed tannin levels in the seedlings were 75% higher than in the control grass ($P_{1\text{-tail}} = 0.004$). This may be expected, since a plant's developmental stage may influence the amount of tannins it contains (Hagerman and Butler, 1991).

The *P. arctica* plants grown in nutrient limited soils had condensed tannin levels that were 70% higher than the control plants ($P_{1\text{-tail}} = 0.002$), as would be predicted by the carbon-nutrient balance (CNB) hypothesis (Coley et al., 1985, Bryant et al., 1983). The condensed tannin levels in the mown plants were 95% higher than in the control plants ($P_{1\text{-tail}} = 0.007$).

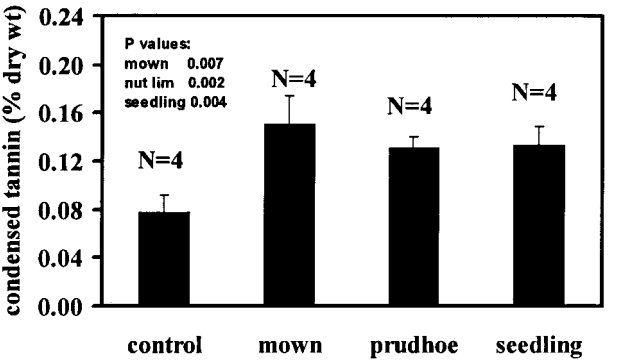

FIG. 2. Mean condensed tannin concentration in *P. arctica* control and test plants. The mown and control samples were collected from a common plot at the same time. Vertical lines represent +1 SD, nut lim = nutrient-limited samples, and *N* is the number of samples. One-tailed *P* values from paired *t* tests are reported.

The response of condensed tannins to mowing also may be explained using the CNB hypothesis. In the unmown control grass, the lower leaves of the grass are blocked from the sun by grass that is growing above them. Thus, a sizable percentage of the unmown control grass leaves have lowered levels of photosynthesis and therefore fix less carbon. In the mown grass, the leaves are exposed to more sunlight and can fix more carbon. The amount of carbon fixed per mass of leaf is thus higher in the mown grass, thus resulting in more tannin being produced per mass of leaf and in higher assayed condensed tannin levels. (Interestingly, this same argument may be used to explain the previously noted elevated condensed tannin levels in the *P. arctica* seedlings).

Figure 3 displays the results of the gallotannin assay done on *P. arctica* and the palatable plants. Gallotannin levels were low in all of the plant samples. There was no statistically significant difference in gallotannin levels between *P. arctica* and the palatable *P. langeana* ($P_{1\text{-tail}} = 0.072$). The gallotannin levels were 118% higher ($P_{1\text{-tail}} < 0.001$) in the palatable *P. pratensis* than in *P. arctica.* As was seen with condensed tannins, unless the gallotannins in *P. arctica* have a high level of biologically activity or are insensitive to the assay, they are not primarily responsible for its unpalatability to Canada geese (Clausen et al., 1990; Ayres et al., 1997).

Figure 4 displays the results of the ellagitannin assay done on *P. arctica* and the palatable plants. *P. arctica* plants contained 105% more ellagitannin than the palatable *P. pratensis* plants ($P_{1\text{-tail}} < 0.001$) and in the *P. arctica* plants contained 90% more ellagitannin than the palatable *P. langeana* plants ($P_{1\text{-tail}} < 0.001$). These elevated ellagitannin levels in *P. arctica* may be contributing to its unpalatability to Canada geese.

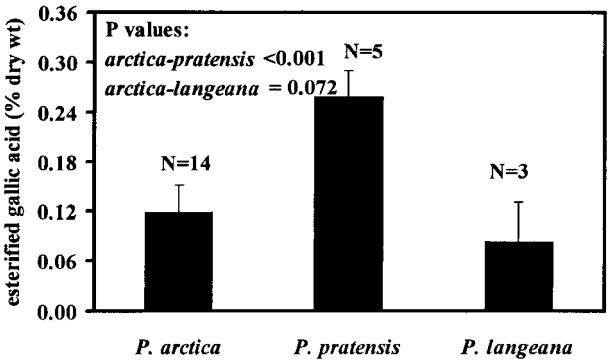

FIG. 3. Mean gallotannin concentration in *P. arctica* and palatable plants. Vertical lines represent +1 SD, and *N* is the number of samples. One-tailed *P* values from unpaired *t* tests are reported.

Figure 5 shows the results of the gallotannin and ellagitannin assays done on *P. arctica* control and test plants. There was no statistically significant difference between the gallotannin and ellagitannin levels of the mown and nutrient-limited test plants and the control plants ($P_{1\text{-tail}} = 0.242$ and 0.198 for gallotannins, $P_{1\text{-tail}} = 0.173$ and 0.305 for ellagitannins). The seedling *P. arctica* plants contained 33% more ellagitannin than the control plants ($P_{1\text{-tail}} = 0.030$) and 174% less gallotannin than the control plants ($P_{1\text{-tail}} = 0.045$). While small, the effects of the test plots on gallotannins are qualitatively different from those of condensed and ellagitannins. This suggests that *P. arctica* has significant control over how it allocates resources to its secondary metabolism while under stress.

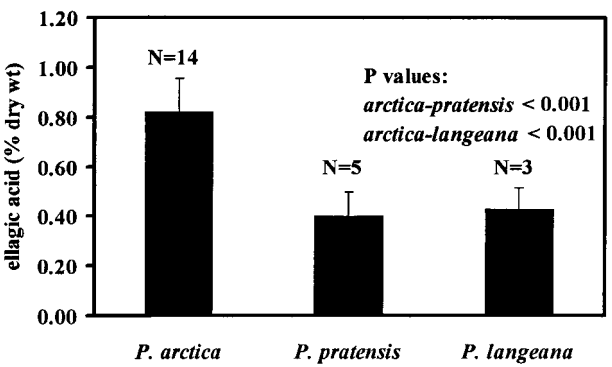

FIG. 4. Mean ellagitannin concentration in *P. arctica* and palatable plants. Vertical lines represent +1 SD, and *N* is the number of samples. One-tailed *P* values from unpaired *t* tests are reported.

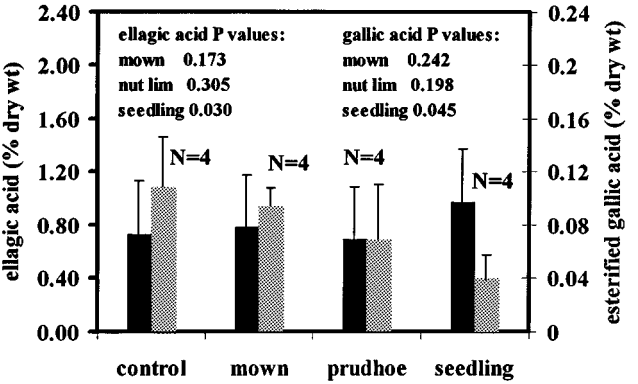

FIG. 5. Mean ellagitannin (dark bars) and gallotannin (light bars) concentration in *P. arctica* control and test plants. Vertical lines represent +1 SD, nut lim = nutrient limited samples, and *N* is the number of samples. One-tailed *P* values from paired *t* tests are reported.

CONCLUSIONS

GC-MS and TLC showed no significant differences between the secondary metabolites of *P. arctica* and grass species that Canada geese usually find palatable (Volz, 2000). Alkaloids were screened for and not detected (Volz, 2000). However, ellagitannin levels were higher in *P. arctica* than in the palatable plant samples. The elevated ellagitannin levels in *P. arctica* may be contributing to its unpalatability to Canada geese. It should be noted that the presence of moderate levels of tannin does not necessarily protect plants from herbivory (Clausen et al., 1992). For confirmation, the tannins would have to be isolated and used in feeding trials. These results suggest that *P. arctica* is, barring the existence of some trace and highly toxic substance, appropriate to plant in areas such as playing fields, lawns, and playgrounds for use as a deterrent to Canada geese.

(Received March 10, 2000; accepted December 12, 2000)

Abstract—Comparisons of release rates, duration in the field, and catch efficiency of polyethylene and cotton roll dispensers for the sex pheromones of sawflies (Hymenoptera: Diprionidae) were conducted. The release rates of the *Neodiprion sertifer* (Geoffr.) and *Diprion pini* (L.) sex pheromones, the acetates of pentadecanol and (2*S*,3*S*,7*S*)-3,7-dimethyl (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tridecanol from polyethylene dispensers were measured at different temperatures in the laboratory. The release rates for the substances depended on both the temperature and initial load in the vials. The catch from cotton rolls baited with 100 μg of the acetate or propionate of 3,7-dimethyl-2-pentadecanol was

compared to the catch from regularly renewed cotton rolls baited with 10 μg of the same acetate. The catch was higher for the 100-μg cotton rolls for, at most, 45 days, and there was no significant difference in catch between the acetate and the propionate. The catch in traps baited with polyethylene or cotton roll dispensers loaded with the acetate of 3,7-dimethyl-2-pentadecanol was compared and showed that cotton roll traps mirrored the decreasing release of the substance rather than the actual flight activity. The length of the flight period of *N. sertifer* in Sweden, the Czech Republic, Italy, and Greece did not exceed 100 days in any of the countries. By adjusting the initial pheromone load of the polyethylene vials to the expected temperatures, it should be possible to get a constant and sufficiently high release rate during the entire flight period.

Key Words—Hymenoptera, Diprionidae, *Diprion pini*, *Neodiprion sertifer*, 3,7-dimethyl-2-pentadecanol, diprionol, 3,7-dimethyl-2-tridecanol.

INTRODUCTION

In addition to the chemical composition, the amount of substance released is of great importance in pheromone based systems for control or monitoring of insect species. Different kinds of dispensers have been tried with respect to constancy and predictability in release rate. An ideal dispenser should have a constant release rate during the whole flight period of the target insect (Byers, 1988).

Although the knowledge of pheromones in sawflies is generally sparse (Anderbrant, 1999), the pheromone systems of *Neodiprion sertifer* (Geoffr.) (Kikukawa et al., 1983; Anderbrant et al., 1992a) and *Diprion pini* L. (Bergström et al., 1995; Anderbrant et al., 1995a) (Diprionidae) are comparatively well understood. The sex pheromone of *N. sertifer*, the most thoroughly investigated species of sawflies, is the acetate or propionate of 3,7-dimethyl-2-pentadecanol (diprionol), a substance it shares with most other diprionids investigated so far (Anderbrant, 1999). The sex pheromone of *D. pini* differs with respect to chain length, viz. 13 instead of 15 carbons, and in stereochemistry.

In an earlier study (Anderbrant et al., 1992b), the release rates of the acetate of 3,7-dimethyl-2-pentadecanol from glass capillaries and dental cotton rolls were measured, and the cotton rolls were found to be the more practical dispenser for this substance. Dental cotton rolls have been used in most field studies on diprionids (Anderbrant et al., 1992b), although rubber septa have been tried and rejected, due to too low release rate, for *D. pini* (Bergström et al., 1995).

Since *N. sertifer* is one of the major defoliators of pine trees, *Pinus spp.*, in parts of its wide distribution area, it would be valuable to have monitoring systems for more efficient control of the species (Anderbrant, 1998). Such monitoring systems, based on sex pheromone trapping with cotton rolls as dispensers, have recently been attempted by Lyytikäinen-Saarenmaa et al. (1999), who pointed out a need to develop and document the release rate of more long-lasting dispensers,

e.g. polyethylene vials. In the present study, such measurements for the *N. sertifer* and *D. pini* pheromones were performed. The attractivity and duration of diprionol acetate and propionate as baits for *N. sertifer* were compared. Parallel with these trials, the phenology of the flight period of *N. sertifer* was studied in different parts of Europe. From these studies we conclude that the release rate of 3,7-dimethyl-2-pentadecanol esters from polyethylene dispensers is reasonably constant for the length of the *N. sertifer* flight period.

METHODS AND MATERIALS

Chemicals

The acetate of (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecanol, synthesized at the Mid Sweden University according to Högberg et al. (1990), was used in all field tests, with the addition of the propionate in 1994. Both compounds contained 1% of the 2*S*,3*S*,7*R* isomer and less than 0.08% of the other isomers (Högberg et al., 1990; Anderbrant et al., 1992a). Release measurements were made with the acetates of (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecanol and (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tridecanol (Bergström et al., 1995), also synthesized at the Mid Sweden University.

Pheromone Release Rates

Polyethylene Vials. Closed polyethylene vials (No. 730, Kartell; 32 mm long $\times$ 8 mm OD $\times$ 6 mm ID) were loaded with neat pheromones and placed in environmental cabinets with temperatures of 12°C, 18–21°C, or 27–30°C. The amount of pheromone in each vial varied from 1.18 to 4.18 mg (mean = 2.35, SD = 0.86). An empty vial was used as a control for each of the filled vials. The vials were weighed at regular intervals with an accuracy of measurement of 10 μg (Mettler AE 240 scale). The weight change of the control vial was subtracted from the weight of its paired pheromone containing vial. The release rate was determined by fitting a linear regression model to the linear part of the curves formed by the corrected weights of pheromone containing vials. To get data on release rates in the field, one pheromone vial with control was weighed immediately before and after its use in the field in Italy 1996.

Cotton Rolls. In order to get an estimate of the pheromone release from the cotton rolls used in the field tests below, a regression model presented by Anderbrant et al. (1992b), $y = a \exp[b \ln(x + 1)]$, where y is the remaining amount and x is the time in days, was used. In all computations the b value (-0.685) calculated by Anderbrant et al. (1992b) for cotton rolls loaded with 60 μg 3,7-dimethyl-2-pentadecyl acetate and released for 33.5 days in the field was used.

Field Tests

In all field tests we used the Lund-I trap (Anderbrant et al., 1989), in which insects are trapped on a horizontally oriented cardboard bottom (21 × 21 cm) covered with insect glue (Stikem Special, Seabright Enterprises) on the upper side. Dental cotton rolls (Celluron No. 2, Paul Hartman SA) and polyethylene vials (No. 730, Kartell) were used as dispensers.

Duration of Cotton Rolls. The experiment was made in a pure, mature Scots pine (*Pinus sylvestris* L.) stand near Ceské Budéjovice, southern Bohemia, Czech Republic, from July 15 to October 30, 1994. Two replicates were made, each consisting of four sets of traps, placed at different sites with an interval of one month. Each set consisted of four traps, placed at the corners of a square with 30-m sides, and baited with cotton rolls containing 100 μg of the acetate of 3,7-dimethyl-2-pentadecanol, 100 μg of the propionate of 3,7-dimethyl-2-pentadecanol, 10 μg of the acetate of 3,7-dimethyl-2-pentadecanol, respectively. One trap in each set was an unbaited control. The 10-μg acetate baits were changed every 10 days, thus giving a more constant release of the pheromone than the other traps that were only examined at the same time interval.

Comparison Between Cotton Rolls and Polyethylene Vials. In 1996, experiments were made in Italy (September 10–November 27) and Greece (September 11–December 4). The Greek trial was made in a 20-year-old *Pinus brutia* Ten. forest at the Forest Research Institute of Thessaloniki in northern Greece. Four traps were set in the corners of a 40-m square at each site, two baited with polyethylene vials containing about 2 mg of the acetate of 3,7-dimethyl-2-pentadecanol each, and two baited with cotton rolls containing about 100 μg of the same substance. The Italian trial was carried out in an ~15-year-old Scots pine forest on Monte Baldo, Trentino, in the Italian Central Alps. The four traps, baited as in the Greek trial, were placed with an intertrap distance of 100–150 m. The cotton rolls were changed after 41 (Italy) or 28 days (Greece), and the sticky bottoms were changed and examined with an interval of about one week.

Phenology of Neodiprion sertifer. In the Czech Republic, catch data from the two 10-μg traps that were used during the whole test period were used to obtain phenological data, whereas the traps baited with polyethylene vials served the same purpose in Italy and Greece. In 1989, a number of traps for studies on the pheromone biology of *N. sertifer* were set up near Valdemarsvik in the province of Östergötland, southeastern Sweden (e.g., Anderbrant et al., 1992a). Catch data from three of these traps, placed in an 8 to 10-year-old Scots pine forest with an intertrap distance of about 30 m, were used in this study. The traps were baited August 2 with dental cotton rolls containing 100 μg of the acetate of 3,7-dimethyl-2-pentadecanol each. Baits and sticky bottoms were changed at intervals varying from one to two weeks until October 4. The catches from each collection were

TABLE 1. RELEASE RATES OF PINE SAWFLY PHEROMONES FROM POLYETHYLENE VIALS (MEAN ± SD)

Temperature	Release rate (μg/day)	Days (N)	r^2 (range)	Vials (N)
Acetate of 3,7-dimethyl-2-pentadecanol				
12°C	5.4 ± 1.1	100	0.737–0.774	2
18–21°C	10.0 ± 1.6	105 ± 10	0.971–0.989	4
27–30°C	15.6 ± 1.6	45 ± 4	0.977–0.989	2
Acetate of 3,7-dimethyl-2-tridecanol

18–21°C	25.8 ± 6.4	65	0.968–0.988	2
27–30°C	38.4 ± 1.3	42	0.971–0.975	2

divided by the number of days since the last examination to get a value of the mean catch per day for each site.

RESULTS

Pheromone Release Rates

Polyethylene Vials. The model gave a fairly good approximation of release rates, as can be seen by the coefficients of determination in Table 1. The release rate was constant for the acetate of 3,7-dimethyl-2-pentadecanol during the first 100 days at the two lower temperatures and decreased after this time period. However, at 27–30°C, the linear part of the curve encompassed only 45 days (Figure 1A). The data from one of the vials used during the field studies in Italy gave, when fitted to the linear model, a daily release rate of 9.4 μg, which seems to be in accordance with the laboratory data (Figure 1A). The release rate of the acetate of 3,7-dimethyl-2-tridecanol was higher and the length of the linear part of the curves consequently shorter (Figure 1B).

Cotton Rolls. The computed curve of release from cotton rolls loaded with 100 μg of the acetate of 3,7-dimethyl-2-pentadecanol, described as amount released substance per day, is inserted in Figure 3A and 3C below. The model was also used for comparison of the release from the 100 μg and 10 μg baits in the Czech field test.

Field Tests

Duration of Cotton Rolls. The unbaited traps did not catch any sawflies during the trial, which was finished October 30 due to night frost. There was no significant

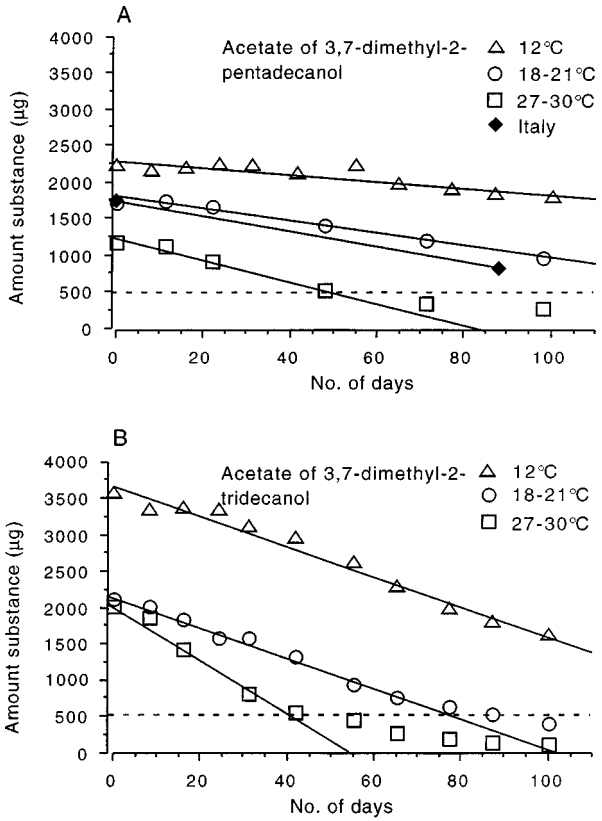

FIG. 1. Residual quantity of the acetates of 3,7-dimethyl-2-pentadecanol (A) and 3,7-dimethyl-2-tridecanol (B) in seven polyethylene vials at different temperatures in the laboratory and in the field (Italy). Dotted line represents proposed minimum amount of substance for linear release.

difference in trap catch between the traps baited with the acetate and propionate of 3,7-dimethyl-2-pentadecanol in any of the sets, according to a Wilcoxon signed-rank test (Wilcoxon, 1945). On average the capture of sawflies in a 100-μg trap was 0.96 per day (SD = 0.92, $N = 16$), while the capture in a 10-μg trap was 0.94 (SD = 0.38, $N = 8$). The relative catch from the traps baited with 100 μg of the acetate or propionate of 3,7-dimethyl-2-pentadecanol, respectively, was computed by dividing it with the catch from the 10-μg traps for the same time period (Figure 2). Thus, a relative catch >1 indicates that the 100-μg bait, without bait renewal, was more efficient than the regularly changed 10-μg bait. The catch in the 100-μg traps was at least as high as the catch from the 10-μg traps and stayed higher for at most 45 days from the onset of the flight period in mid-August. In the

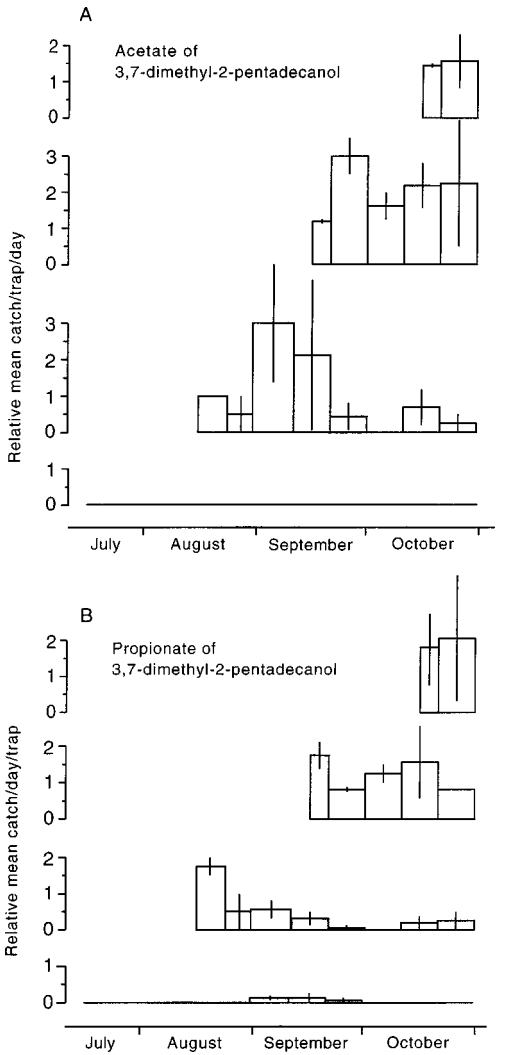

FIG. 2. Catches of male *Neodiprion sertifer* (mean ± SE) per trap per day in traps baited with 100-μg of the acetate (A) or propionate (B) of 3,7-dimethyl-2-pentadecanol divided by the catch in traps baited with 10-μg of the acetate. Each line of histograms represents a set of two 100-μg traps and two 10-μg traps, in which the 10-μg traps were renewed every tenth day. The four sets of each ester were set up with an interval of one month.

first sets of 100-μg traps, the lure did not remain efficient long enough to attract males during the peak flight.

Comparison Between Cotton Rolls and Polyethylene Vials. Two peaks of trap catch were observed for the traps with cotton roll dispensers in both Italy and Greece. These coincided with the change of dispensers but had no correspondence in the catch from polyethylene vials (Figure 3).

Phenology of Neodiprion sertifer. Both the onset and end of the flight period shifted towards later in the season with decreasing latitude (Figure 4). The length of the flight period, if counted as the number of days with a mean catch per trap and day of one or more, seems to be about the same (57.0 $\pm$ 11.4 days, mean $\pm$ SD) at all sites.

DISCUSSION

Dental cotton roll dispensers have been used with satisfactory results in many studies on *N. sertifer* (e.g., Anderbrant et al., 1992a; Jönsson and Anderbrant, 1993; Wedding et al., 1995; Simandl and Anderbrant, 1995). Since the objectives of these studies mainly were to evaluate different factors influencing trap catch (such as weather, trap position, and different amounts and compositions of lures), the long-term constancy of release rates was not a major issue. The limitations of cotton roll dispensers have been brought to light in studies of mating disruption and monitoring. Anderbrant et al. (1995b) found a decreased disruption effect of cotton roll dispensers after five weeks, and Lyytikäinen-Saarenmaa et al. (1999) propose a more reliable monitoring system if dispensers with a longer and more constant attracting power are used.

The dispensers in the studies cited above, mainly loaded with 100 μg of the acetate of 3,7-dimethyl-2-pentadecanol, were changed at intervals varying from a week to a month. Our results from the Czech field test suggest that the latter time period is about as long as the cotton roll dispensers can be expected to be efficient. The release from the 10 μg baits, which were changed at a 10-day interval, will follow the same regression model as the unchanged 100-μg baits since the proportional release rate from cotton rolls at these loads is independent of the initial load (Anderbrant et al., 1992b). Thus, as the release from the 100-μg baits decreases, the release from the 10-μg baits will be proportionally higher. Using the model of Anderbrant et al. (1992b), it will take about 30 days before the release from the 10-μg baits becomes higher than the release from the 100-μg baits for a whole 10-day period, although it will be temporarily higher already at the first change of baits. After a month, the daily release from the 100-μg baits should be about 0.2 μg and the remaining substance reduced to about 10% of the initial load. These shifting patterns of relative release could probably account for the variations in relative catch shown in Figure 2.

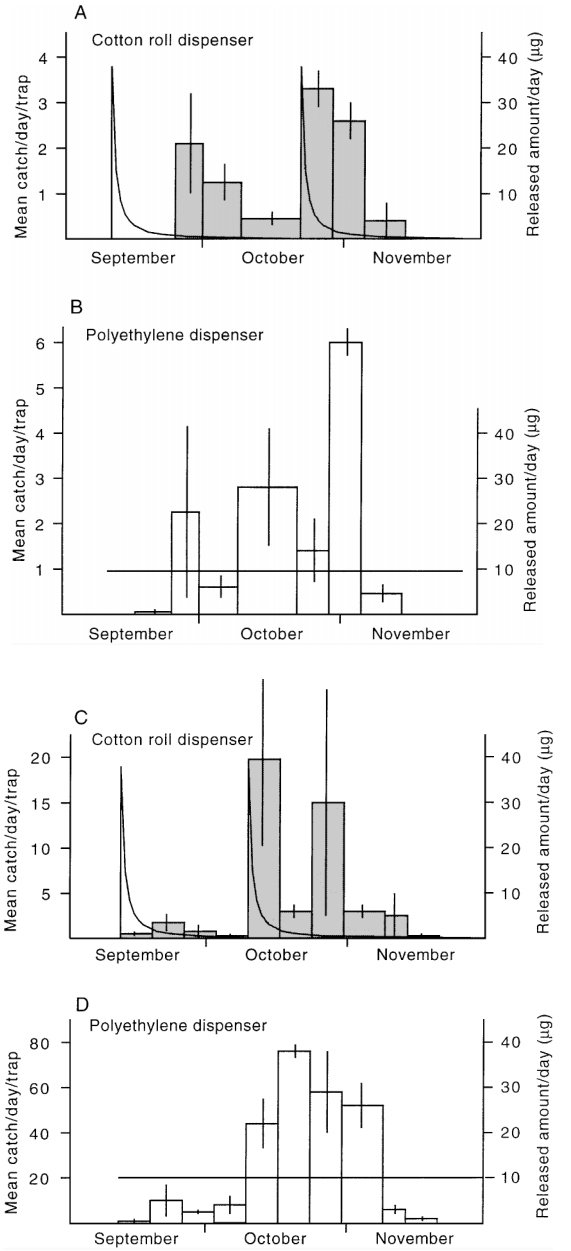

FIG. 3. Catches of male *Neodiprion sertifer* (mean ± SE) per trap per day (filled bars) in traps with cotton roll dispensers ($N = 2$) baited with 100 μg of the acetate of 3,7-dimethyl-2-pentadecanol in Italy (A) and Greece (C) and calculated release of the substance (curves). Corresponding catches (empty bars) in traps with polyethylene vial dispensers ($N = 2$) in Italy (B) and Greece (D) and calculated release of the substance (horizontal line). Note different scales at *y* axes.

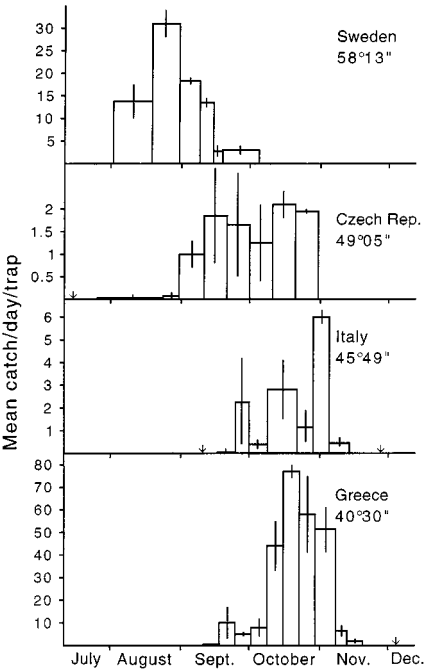

FIG. 4. Catches of male *Neodiprion sertifer* (mean ± SE) in pheromone traps in Sweden ($N = 3$), the Czech Republic ($N = 2$), Italy ($N = 2$) and Greece ($N = 2$). Arrows indicates start and end of trapping when not evident from bars. Note different scales at *y* axes.

This approximate duration of the cotton roll dispensers is further confirmed by the trap catch in Italy and Greece, although the period of efficient trapping seems to be longer later in the season in Greece. Lower temperatures probably have a leveling effect on the release curve. When compared to the trap catch from polyethylene vials, the pattern shown by the cotton rolls seems more to reflect the decreasing release of the pheromone than the actual flight activity (Figure 3).

The indifference of *N. sertifer* males to whether the acetate or propionate of 3,7-dimethyl-2-pentadecanol is used as an attractive component (Figure 2) has been shown previously in Sweden (Anderbrant et al., 1992b) and North America (e.g., Kikukawa et al., 1983) and is discussed by Anderbrant (1999).

From the laboratory studies, it seems reasonable to assume that the length of the period with a constant release rate depends on both temperature and the initial load of the polyethylene vials. The latter conclusion is based on the observation that the release rates for both substances investigated decrease when the residual amount of substance in the vials is about 500 μg (Figure 1). This could be due to the decrease in surface area wetted by the substance (Brown et al., 1992). If there is at least 500 μg of substance left in the vial at the end of a chosen time period,

the release rate should be constant for a given temperature in the interval 12–30°C. The initial load could be computed with the linear regression model $y = a - bx$, where y is the remaining amount of substance, a the initial load, b the release rate, and x the number of days. Thus, if we chose 100 days as the time period that encompasses the length of flight for *N. sertifer* and take the release rates from Table 1, the initial load of the acetate of 3,7-dimethyl-2-pentadecanol at a temperature of 18–21°C should be $y + bx$ or about 1.5 mg and at 27–30°C about 2 mg.

The relative constancy in the length of the flight period is in contrast to the preceding summer diapause which varies from 1–2 months in Scandinavia to 5–6 months in the Mediterranean (Pschorn-Walcher, 1982). According to Kolomiets et al. (1979), the length of the flight period varies from about one and a half months to three, but from the results of the present study this variation seems not to be correlated with latitude. However, the onset and end of the flight is clearly influenced by latitude and, as Kolomiets et al. (1979) suggested, two approximate zones can be recognized: the first encompassing eastern and northwestern Europe with a flight period from the beginning of August to October and the second western and southwestern Europe where the species fly from September to the middle of November.

D. pini has a longer flight period that can start at the end of April and continue, through several flight waves, to the end of August (Pschorn-Walcher, 1982). In a recent monitoring study of *D. pini*, Herz et al. (2000) tried both polyethylene vials and cotton rolls. The polyethylene vials caught very few animals in comparison with the cotton rolls in this study, in which the cotton rolls were loaded with new pheromone solution weekly and the polyethylene vials just once. This might be due to the fast release of the acetate of 3,7-dimethyl-2-tridecanol and the long exposure period of the polyethylene vials. If we apply the formula for computing initial loads presented above and choose 180 days as the length of the flight period for *D. pini*, the polyethylene vials should be loaded with about 5 mg of 3,7-dimethyl-2-tridecyl acetate 18–21°C, and about 7.4 mg at 27–30°C. The longer flight period of *D. pini*, and the higher volatility of the pheromone may call for an even slower release than from the present polyethylene dispensers.

For applications such as mating disruption and monitoring, the polyethylene vial is a sufficiently reliable and constant dispenser, with respect to release rate and the length of the *N. sertifer* flight period. However, cotton roll dispensers are useful for short-term studies and, furthermore, have the advantage that the proportional release rate is independent of the load (Anderbrant et al., 1992b). Thus, within a given temperature interval, the release rate from cotton rolls will follow the same regression curve no matter which initial amount of pheromones that are loaded, in contrast to the case in polyethylene vials.

(Received August 21, 2001; accepted December 15, 2000)

Abstract—A screening was conducted to study the allelopathic potential of Australian-held accessions of *Triticum speltoides*. Of 26 accessions, four were found to inhibit root growth in the indicator species, lettuce (*Lactuca sativa*). The methanol leaf extracts of these accessions significantly reduced the root length of wild oat (*Avena* spp.). In all but one case, alellopathic accessions contained higher amounts of DIMBOA than did nonallelopathic accessions. Since some variation in allelopathic response was detected within lines, random amplified polymorphic DNA (RAPD) markers were used to estimate genetic diversity between and within the allelopathic accessions of *Triticum speltoides* L. The average genetic similarity between all possible pairs of selected accessions was found to be 55% and ranged from 44% to 88%. Comparison of DNA extracted from different single seedlings within the same accession revealed significant intraaccession genetic diversity (4–24%), although this was much less than that observed between accessions tested. This intraaccession diversity has significant implications for the selection of *T. speltoides* accessions in breeding or screening programs.

Key Words—Allelopathy, wheat, RAPD, genetic diversity, weed, wild oats, lettuce.

INTRODUCTION

Weed management is a significant problem in agriculture and accounts for some 30% of the variable cost of wheat production in Australia (Medd, 1997). Despite the overwhelming economic benefits, the heavy reliance on chemical herbicides is considered a potential threat to public health and to the environment (Jiwan and Gates, 1994). Furthermore, the appearance of herbicide-resistant weeds is an increasing problem (Boutsalis and Powles, 1995). These factors have prompted research into alternative means of weed control. Allelopathy, the release of biomolecules into the environment by one plant, which subsequently influences the growth and development of neighboring plants, has been proposed as a possible alternative weed management strategy (Einhellig, 1995).

Allelopathic potential has been identified in most major cereal crops (Lovett and Hoult, 1995). One of the mechanisms through which allelopathic potential is recognized is by the plant exuding active metabolites from roots into the environment. Such activity can be observed in soils during or following the presence of the crop (Lovett and Hoult, 1995). In barley, the exudates of living plants and living roots were found to be more inhibitory than aqueous leachate of dead roots (Rice, 1979). Liu and Lovett (1993) found lower germination and reduction in radicle length of white mustard (*Sinapis alba* L.), when it was grown alongside germinating barley seeds. Hoffman et al. (1996) found that germinating sorghum reduced the radicle length of several weed species.

While the biomolecules responsible for allelopathy in many species are unknown, in maize the major allelochemical is 2,4-dihydroxy-7-methoxy-1, 4-benzoxazin-3-one (DIMBOA) (Niemeyer and Perez, 1995), a product that has also been identified in *Triticum speltoides*, where it is present in significantly higher quantities than in commercial wheats, *Triticum aestivum* (Niemeyer, 1988).

Although insect and disease resistance genes have been incorporated into wheat cultivars through introgression from *Triticum speltoides*, there has been no attempt to screen wheat lines crossed to *T. speltoides* for allelopathy. Significantly, one recent study has indicated that *T. speltoides* does segregate for allelopathic effects. In an *in vitro* screening experiment with 29 accessions, Hashem and Adkins (1998) found that one accession of *T. speltoides* reduced radicle length of wild oat by 50%, while another two accessions reduces radical length of Indian hedge mustard (*Sisymbrium orientale* L.).

Based on these possibilities, the intentions of this study were to screen Australian collections of *T. speltoides* for allelopathic potential and to determine DIMBOA levels and genetic diversity, assessed by random amplified polymorphic DNA (RAPD) analysis, in a selection of these accessions. The assessment of genetic diversity became necessary when a significant level of intraaccession variability in allelopathic expression became evident.

METHODS AND MATERIALS

Plant Materials. Twenty-six accessions of *T. speltoides* (Ts) were screened. The heads containing seeds of *T. speltoides* and seeds of barley (cv. Tallon), wheat (cv. Hartog), and wild oat (*Avena ludoviciana*) were obtained from collections at the Leslie Research Centre, Toowoomba, Queensland, and from the Australian Winter Cereals Collection, Tamworth, New South Wales. Lettuce seeds (*Lactuca sativa* L., cv. *Salad Mix*) were obtained from Arthur Yates & Co Ltd, Milperra, New South Wales. Sorghum seeds (PAC. 8306) were obtained from Pacific Seeds, Toowoomba.

Each individual seed of *T. speltoides* was manually dehusked. The wild oat seed husks were removed by agitating for a few seconds in a blender. All seeds were surface sterilized with 70% ethanol for three min then 4% (v/v) sodium hypochlorite solution for five min (lettuce) or 15 min (all other seeds). Seeds were then rinsed and dried under sterile conditions.

Screening for Allelopathic Potential. The procedure was adapted from the plant box (Fujii et al., 1995) and double filter paper (Latto and Wright, 1995) methods. Under sterile conditions, 0.5% water agar (15 ml) was poured into plastic Petri dishes, then covered by a 9-cm filter paper. A single seed of *T. speltoides* was placed in the middle of each Petri dish, which was then sealed with Parafilm. For control dishes, seeds were omitted. All treatments were placed in the dark for three days at $20 \pm 2^{\circ}$C to stimulate germination and root elongation. After three days, Petri dishes were transferred to a 16-hr light (200 μmol/m^2/sec^1)–8-hr dark cycle for 14 days at $20^{\circ}\text{C} \pm 5^{\circ}$C. After this time, the filter paper and seedlings were removed, nine lettuce seeds were placed within 2 cm of where the seedlings had been positioned, and the dish was resealed and incubated in the dark at $20 \pm 2^{\circ}$C for three days before being transferred to a 16 hr light–8-hr dark cycle for two days. The root lengths of individual lettuce seedlings were recorded.

Effects of Methanol Leaf Extracts of T. speltoides on Test Species. These experiments were based on the method of Jimenez-Osorino et al. (1996) to observe the effect of leaf extracts from selected accessions of *T. speltoides* on lettuce and weed species. The 0.2 g (per treatment) of immature green leaves of 90-day-old accessions were extracted by grinding in 98.8 % ice-cold methanol with a mortar and pestle. Extracts were collected into a 10 centrifuge tube. Final volume of the extracts was adjusted to 7 ml, and centrifuged at 3000 rpm for 10 min. Two milliliters of supernatant was added to a 5.5-cm filter paper (Whatman No. 1) placed on a sterile 9-cm Petri dish, and the methanol was allowed to evaporate. Each treatment was replicated three times. Washed sand (10 g) was placed in a clean Petri dish, and lettuce or weed seeds were sown into the sand. A filter paper containing dried leaf extract was placed on top of the sand, and analytical grade water (3 ml) was added onto the filter paper. Petri dishes were placed in the dark at $20 \pm 2^{\circ}$C. Filter papers were removed from the dishes after 24 hr for lettuce and

72 hr for other seeds. After three days (for lettuce) or five days (wild oat), the root lengths were recorded.

Estimation of DIMBOA Content in T. speltoides Accessions. Five allelopathic and five randomly selected nonallelopathic accessions (based on experiments described above) together with the wheat cultivar Hartog were studied in this experiment. DIMBOA extraction was performed by the method of Bohidar et al. (1986). The *T. speltoides* accessions and wheat plants were grown in MS (Murashige and Skoog) media under a 16L:8D hrs cycle at 26°C for 14 days. Seedlings were collected and frozen at −20°C. Plant tissue (0.2 to 1.5 g) was macerated with a mortar and pestle in deionized water (3 × 2 ml), filtered through cheesecloth, and left for 15 min at room temperature. The extract was adjusted to pH 3 with 1 M HCl and centrifuged at 10,000g for 10 min. The supernatant was extracted three times into equal volumes (6 ml) of diethyl ether, and the organic phases were evaporated to dryness. Ferric chloride reagent (3 ml) (50 g $FeCl_3 \cdot 6H_2O$, 500 ml 95% ethanol, and 5 ml 10 M HCl) was added, and the absorbency of extracts was measured at 590 nm. Each extraction was replicated three times. The concentration of DIMBOA in the tissue was determined by comparing the absorbance of extracts with a DIMBOA standard, which had previously been purified from 7-day-old seedlings of maize by the method of Tripton et al. (1967).

DNA Extraction and RAPD Analysis. All seeds were grown in Petri dishes containing 0.5% water agar under sterile conditions. Seeds were allowed to grow for 14 days (accessions) or 7 days (wheat) under dark conditions. Genomic DNA was extracted from duplicate samples from a single seedling by the method of Weining et al. (1994). Six 10mer primers (up to 70% GC) were selected from a previous study on the basis of polymorphisms revealed in hybrid wheat lines (Ma, 2000). The polymerase chain reaction (PCR) was performed in a 12.5-μl reaction mixture, as in Williams et al. (1990). The operon (OP) random primers used were OPC7, OPI18, OPI4, OPA4, OPW3, OPW8. A polyacrylamide gel electrophoresis (PAGE) method (Weising et al., 1995) was used to separate different sizes of RAPD-PCR products. The gels were silver stained for visualization of DNA bands by using a method developed by Bassam and Caetano-Anolles (1993). Only RAPD bands duplicated from independent DNA extractions were scored for the estimation of genetic diversity.

Statistical Analysis. Analyses of variance (ANOVA) were carried out by using the computer package SPSS 8.0 for Windows. For LSD, group comparison and pair comparisons were performed for means with equal replications and unequal replications, respectively (Sokal and Rohlf, 1981).

Genetic data analyses were performed by using the computer package NTSYS (Numerical Taxonomy System) PC version 1.8 (Rohlf, 1993). The data matrix was used to compute Jaccard's similarity coefficients for interval measurement within and between accessions by using the SIMQUAL program of NTSYS-PC (Link et al., 1995). These coefficients were used as operational taxonomic units

(OTUs) to construct dendrograms by the unweighted pair group method (UPGMA) (Sneath and Sokal, 1973) and the SAHN (sequential, agglomerative, hierarchical, and nested clustering) routine to produce a dendrogram for each individual primer. Finally, for comparisons between accessions, a consensus tree was constructed by combining all individual band sizes, generated by each primer, into one input file for SIMQUAL and subsequently for SAHN-clustering programs. Similarly, a tree was constructed from the band sizes of seedlings of accessions and the wheat cultivar Hartog, generated by primer Operon C07. The wheat cultivar Hartog was used as a homozygous control.

RESULTS

Screening for Allelopathic Potential. Of 26 accessions, four (Ts9, Ts10, Ts22 and Ts25) significantly reduced the mean root lengths of the test species lettuce (Table 1). Inhibition ranged from 34% (Ts9) to 63% (Ts25).

Effect of Methanol Leaf Extracts of T. speltoides on Test Species. Leaf extracts of the four inhibitory accessions in Table 1 and from Ts1 and Ts8 were tested for their ability to inhibit root growth in lettuce and wild oats. Accessions Ts8, Ts9, Ts10, Ts22, Ts25, and barley significantly reduced (20–67%) the root length of lettuce, while all accessions of barley and wheat reduced the root length of wild oats by between 36 and 87% compared to controls (Table 2). Notably, extracts from all *T. speltoides* accessions inhibited root lengths in both test species, when compared to the effects of wheat extracts.

Estimation of DIMBOA Content in T. speltoides Accessions. The amounts of DIMBOA in 14-day-old seedlings of 10 accessions, five of which had yielded methanol extracts that suppressed lettuce root growth (Table 2: Ts8, Ts9, Ts10, Ts22, Ts25) and five accessions which had not suppressed root growth (Table 1: Ts1, Ts7, Ts14, Ts15, and Ts20), were estimated (Table 2). Four of the five that gave suppressive extracts ranked higher than the nonallelopathic accessions with regard to their DIMBOA levels. Only Ts9 did not fit this pattern.

Genetic Diversity Between Accessions. A subset of five accessions (Ts1, Ts8, Ts9, Ts22, and Ts25), comprising four allelopathic and one nonallelopathic accession, were used to study variability among and within accessions. One randomly selected seedling per accession was used. Each of the six RAPD primers amplified an average of eight bands per accession of *T. speltoides*, ranging from 4 to 12 bands per accession. A total of 231 bands were scorable, of which 196 were polymorphic (Table 3). All 231 bands were used to calculate the genetic similarity (GS) among the five accessions. The average GS was found to be 55% for all possible pairs of accessions and ranged from 44% to 88% (Table 4). This revealed the presence of a significant variation among the accessions of *T. speltoides*. The highest similarity (88%) was observed between accessions Ts22 and Ts25, while lowest similarity (44%) was recorded between accessions Ts1 and Ts22.

Genetic Homogeneity Within Accessions. Five randomly selected seedlings of promising allelopathic accessions, one nonallelopathic accession of *T. speltoides* (Ts1), and the wheat cultivar Hartog (*T. aestivum*) were assessed to observe the genetic homogeneity within the accessions. The DNA fingerprints generated from each of the five randomly selected individual seedlings of each accession and the wheat variety Hartog, by the operon C7 primer, were evaluated. High levels of polymorphism were detected among individuals of each accession (Figure 1). Twenty-four RAPD bands were used to estimate a GS within the seedlings of accessions. Accession Ts8 showed the highest level of polymorphism (75%) among individual plants, while Ts22 and Ts25 showed the lowest (10%). The highest numbers of genotypes were found in accessions Ts1, Ts8, and Ts10 while,

as expected, no variability was recorded among the five seedlings of wheat cultivar Hartog (Table 5).

Clustering. Accessions Ts22 and Ts25 were grouped into one main group, while Ts8, Ts9, and Ts10 were grouped into another (Figure 2). Accession Ts1 and cultivar Hartog were grouped into two individual main groups. The GS levels among accessions ranged from 61% to 95%. The GS level among seedlings of the accessions varied from 76% to 100%. Seedlings of accessions Ts1, Ts8, Ts9, Ts10, and wheat cv. Hartog separated into five distinct groups according to their accession, while seedlings of the accessions Ts22 and Ts25 were grouped closely together and did not segregate according to accession.

DISCUSSION

Screening for Allelopathy. Many of the problems encountered in separating allelopathy from resource competition can be attributed to a lack of convincing methodology (Fuerst and Putnam, 1983). One early survey of published bioassays revealed that the results may depend as much on the choice of methods as on the choice of species (Stowe, 1979). Clearly, the actual bioassay technique is a major determining factor in a screening program seeking to draw conclusions about the allelopathic potential of the species being assessed. The key criteria for developing convincing methods must be that the investigations are on intact plants and that experiments should reasonably simulate the real situation of plant interference.

Germinating seeds of cereal crops are able to take up 88% of their dry weight in water (Albabushev, 1977). For example, the average water uptake by germinating barley can be 83% of the initial dry weight on filter paper (Liu and Lovett, 1993). The amount of water absorbed by barley at barley densities of 0.5 seeds/cm^2 or more (Liu and Lovett, 1993) could certainly alter water availability for other species. Therefore, addition of water to compensate for water depletion by germinating seeds is essential in a bioassay when an attempt is made to reduce physical competition, especially in a limited test medium such as Petri dishes. On the other hand, addition of water can disturb the osmotic potential gradients between test species and allelochemical(s) released by suspected allelopathic plants. This study has addressed those problems by using 0.5% water agar media, which ensured equal water uptake and enabled conclusive separation of competition for water from allelopathic interference. In addition, accessions were grown for much longer periods of time in Petri dishes containing 0.5% water agar to create nutritional stress, which could influence the defence mechanism leading to expression of allelopathy by the accessions (if any). There is evidence that any kind of stress may induce expression of allelopathy in plant communities and enhance the production of allelochemicals (Putnam, 1985).

All promising accessions showed allelopathic potential in both bioassay systems, with the exception of Ts8. This was an encouraging finding because lack of reproducibility is a common phenomenon in allelopathy research (Latto and Wright, 1995). Veronneau et al. (1997) have suggested that reproducible results from two or more bioassay systems are required to indicate allelopathic potential in tested plant species. The allelopathic accessions identified in this study are consistent with the findings of previous work that used a similar method (Hashem and Adkins, 1998), where allelopathic effect was detected in accessions Ts8, Ts9, and Ts10 of *T. speltoides*. Similarly, in rice, allelopathic accessions have been identified that inhibited lettuce root length by 75% or more (Fujii, 1993).

Since numerous organic compounds are present within plants, the results obtained from solvent extractions or from maceration and grinding of plant materials have their limitations. These approaches may result in the liberation of chemicals that would not be released in the field by living tissue (Lovett, 1982). Nevertheless, such assays do indicate allelopathic potential where it occurs, both during the life of the plants and during subsequent decomposition of plant residues.

The significant growth-suppressing activity of the methanol leaf extract of the accessions tested suggests high levels of the allelochemical in these extracts. Leaf extracts of other allelopathic crops, such as rye and barley, can also reduce the growth of certain test and weed species. A methanol leaf extract of rye (0.33 g rye shoot/Petri dish) reduced lettuce seed germination up to 100% in filter paper placed on a 10-cm Petri dish (Creamer et al., 1996). Wardle et al. (1996) found that the aqueous extract of 10 grassland forage species severely inhibited the root elongation of a common test species *Carduus nutans* L.

The higher levels of DIMBOA in the putative allelopathic accessions suggest the possibility of a relationship between the allelopathic potential of the accession and the amount of DIMBOA in the accession. Considerable variation was noted in DIMBOA levels in *T. speltoides* accessions. Nevertheless, DIMBOA levels were, in all cases but one (Ts14), higher than Hartog. DIMBOA levels detected in Hartog were two to four times greater than levels measured in the range of wheat cultivars studied by Niemeyer (1988). The significance of these results is clouded by the variability we observed within and among different assays (e.g., for Ts8 and Ts9), especially those based on allelopathic effects due to single seedlings of the source species. To address this issue, it was essential to investigate the underlying genetic diversity of the accessions being examined.

Genetic Homogeneity Study. Bustos et al. (1998) have successfully used RAPD markers to investigate the genetic diversity within and among wild populations of species of the genus *Hordeum* (Poaceae). The high level of intraaccession genetic variability observed in our study might be due to the outbreeding reproductive system of *T. speltoides*. Morrison (1993) has observed different morphological forms, especially in inflorescence structure and disarticulation mode, within accessions of *T. speltoides*. Reproducibility is a critical factor in evaluating the usefulness of a DNA fingerprinting technique. It is a major issue in the use of RAPD-based techniques in wheat (Devos and Gale, 1992). However, by careful screening and replication, this study has demonstrated that RAPD fingerprints of *T. speltoides* and wheat are reproducible. Similarly, Ma (2000) has generated reproducible RAPD fingerprints in a doubled haploid population derived from the F_1 progeny of a cross between the wheat line WW21MMT70 and the cultivar Mendos.

The wheat cultivar Hartog, as expected, showed no polymorphism among the individuals tested. This result reflects the genetic homogeneity of commercial cultivars of inbred wheat (Chen et al., 1994). The genetic diversity within and among *T. speltoides* accessions observed in this study confirms *T. speltoides* as a potentially useful source of genetic variation for introgression into commercial wheats in which low levels of diversity are widely acknowledged by cereal breeders (Chen et al., 1994).

The significant genetic heterogeneity observed within the accessions tested opens the possibility of segregation within accessions for allelopathic characteristics, consistent with the variability in phenotype observed during experimentation. Clearly, there is a need for careful screening of individuals within these accessions before material can be selected for experiments attempting to cross allelopathic character into commercial wheat backgrounds.

Apart from the observed genetic diversity within the accessions of *T. speltoides* in the current study, the outbreeding character (Morrison, 1993) of *T. speltoides* has implications for germplasm maintenance. Germplasm curators must take extreme care to maintain individual accessions and recognize the possibility

of genetic drift over time within accessions. Additionally, in the case of screening or genetic studies, researchers may have to select at the single-plant level within accessions.

In the future, identification and purification of allelochemical(s) from a variety of growth media, and a study of the effect of the identified allelochemical(s) on weed species will be required to establish unequivocally the presence of allelopathy in *T. speltoides* (Fuerst and Putnam, 1983). Research is required to attempt the transfer of allelopathy gene(s) from selected *T. speltoides* material into cultivated wheat. This should be possible by conventional breeding, as *T. speltoides* is known to suppress the activity of the *Ph1* gene in hybrids with wheat, resulting in homologous pairing (Riley, 1996). If it is confirmed that DIMBOA is responsible for *T. speltoides* allelopathy, then a robust and cost-effective technique must be developed to identify DIMBOA gene(s). One of the possible techniques would be use of expressed sequenced tag (EST) technology, which involves partial cDNA sequencing to identify the gene of interest. This technique is becoming widely used in the identification of gene(s) of interest in plants.

Abstract—We examined the response of the widely used Folin-Denis assay to purified tannins from 16 woody plant species and to three commercial polyphenol preparations often used as standards. The reagent's response to these chemical mixtures differed significantly among sources (tree species, commercial preparations) and sampling dates, even though the mixtures contained the same total dry weight of tannins. Response to commercial standards usually did not resemble response to actual plant tannin and produced estimates that differed from actual concentrations by as much as twofold. Species-based and seasonal differences in polyphenol composition are evidently responsible for these variable results. Reagents that depend on redox reactions, such as the Folin-Denis, do not produce reliable absolute or relative quantification of phenolics when different species or samples from different dates are compared, and use of commercial standards does not resolve this problem.

Key Words—Phenolics, tannins, polyphenols, Folin-Denis assay, plant allocation theory.

INTRODUCTION

Folin-type assays (FA; Folin-Denis, Folin-Ciocalteau, Prussian blue) are widely used to estimate amounts of total phenolics in vascular plant tissues. Plants produce a diverse array of phenolics, ranging in size from simple, substituted

monomers to the complex polyphenols called tannins. Within each structural class there are hundreds to thousands of structurally distinct compounds. A single plant can produce a diverse mixture of phenolics, some with primary roles in metabolism, and some with sole or secondary functions in secondary metabolism. All vascular plant species produce a common set of monomeric phenolics, but there is substantial variation in which molecules predominate and in the conformation and substitution patterns of phenolics produced. For example, although virtually all vascular plants contain caffeic and chlorogenic acids, each plant taxon is usually characterized by one or a few particular types or groups of polyphenols (e.g., anthocyanins in *Arabidopsis*, phenolic glycosides in *Populus*). Similarly, among tannin-producing species, some produce only condensed tannins (e.g., grasses), some only hydrolyzable tannins (e.g., *Pelargonium*), and some produce both (e.g., oaks, maples, elms, birches, raspberries). These combinations often change as tissues age (e.g., Feeny, 1968; Scalbert and Haslam, 1987), and in response to a wide variety of biotic and abiotic stresses (Rossiter et al., 1988; Karban and Baldwin, 1997).

Probably because of their ubiquity among plant species and functions in defense, phenolics are among the most frequently studied plant secondary metabolites (Schultz, 1988). Ecologists have used the FA to estimate the quality of food for herbivores, the induction of polyphenols by herbivore feeding, and the investment by plants in defensive chemistry. Indeed, many influential ecological theories and generalizations have been based at least in part on the FA, including the plant apparency theory, optimal defense theory, resource availability hypothesis, carbon–nutrient balance hypothesis, and growth–differentiation balance hypothesis (e.g., Feeny, 1976; Rhoades and Cates, 1976; Rhoades, 1983; Coley et al., 1985; Herms and Mattson, 1992).

The chemistry underlying the FA and other redox-based assays limits their value in comparing different samples quantitatively. FAs employ one of several redox-based colorimetric reagents, e.g., Folin-Denis, Folin-Ciocalteau, Prussian blue (Folin and Denis, 1915; see Waterman and Mole, 1994). These reagents measure the ability of any mixture to reduce phosphomolybdic and phosphotungstic acids, which are blue when reduced (Swain and Hillis, 1959). At least as early as 1959, Swain and Hillis (1959) pointed out that Folin reagents may be inappropriate for comparisons of phenolic samples from different sources because the absorbance of the reagents is influenced by structural variation in phenolics within and among species, as well as by the presence of interfering metabolites and varying extraction and reaction conditions. Although phosphomolybdic and phosphotungstic acids are reduced by the aromatic hydroxyls characteristic of all phenolics, the degree to which they are depends on phenolic structure (Swain and Goldstein, 1964), and they may be reduced by many other plant constituents (e.g., alkaloids, proteins). If phenolics from different sources differ sufficiently in structure (especially the number or position of hydroxyls), or if plant extracts differ

in the presence of other reducing agents, Folin-reagent assays cannot accurately quantify differences in the amounts of phenolics present.

The FA is easy to perform and provides consistent estimates of the reducing power of phenolics within a sample, as evidenced by the high R^2 of standard curves relating absorbance to known concentrations of a standard and by the relatively low variance among aliquots from a sample. However, when samples from different sources (e.g., species, tissue, time, treatment) are compared, it is difficult to interpret FA values because different sources may comprise different mixes of phenolic structures as well as different amounts of the same structures. If those differences result in the same overall capacity to reduce the FA reagent, then the FA values will be the same. If the differences result in a different capacity to reduce the FA reagent, then the FA values will differ. Both the composition and amount of phenolics can differ among samples without a change in FA value.

Thus, although the FA is often used to measure the "amount" of phenolics in a mixture, it does not do so, but rather provides an estimate of the overall reducing capacity. The importance of this distinction between the amount of phenolics and their reducing capacity depends on the specific goals of the study and on what is known about the mode of action of the phenolics in the bioassay. If the goal is to measure the *amount* of phenolics, e.g., as a measure of plant investment in their production, then the FA is inappropriate. If the goal is to measure the redox-based *activity* of a mixture, then the FA can be very useful. FA results have been useful predictors of biological activity in several systems, either because they are correlated with some other key component of activity or because biological activity depends directly on the reducing capacity of the phenolic mixture.

The structural specificity of Folin reagents is also a major problem when selecting appropriate standards for these colorimetric assays. If the standard chosen fails to duplicate the phenolic extract's ability to reduce the Folin reagent—likely unless the standard is precisely the same as the extracted phenolics—then concentrations calculated from a standard curve do not reflect sample concentrations. Even relative concentrations derived this way may not be useful. We believe that dependence on Folin assays and the widespread use of convenient commercial standards by the ecological community has often produced misleading results in intraspecific or interspecific comparisons. Martin and Martin (1982), Hagerman and Butler (1989), and Wisdom et al. (1987) have suggested that purified phenolics from the plant and tissue being studied should be used as standards ("self" standards), but we have seen little adoption of this approach in recent publications.

Despite these chemical arguments, little experimental work has addressed the actual impact of qualitative structural variation on estimates of phenolic concentrations using Folin reagents (but see van Alstyne, 1995). To assess the limitations of Folin-type assays in intra- and interspecific comparisons and the value of using self standards, we compared results of FAs of known concentrations of purified tannins from 16 woody plant species and three commercial standards. We found

that the relationship between FA absorbance and the amount of self or commercial standard differed significantly with sample source, confirming our expectation of qualitative variation and demonstrating that a single standard cannot be used in comparisons of this sort. With few exceptions, using commercial standards significantly over- or underestimated actual polyphenols to a degree that would produce misleading ecological or evolutionary conclusions.

METHODS AND MATERIALS

Foliage Collection. We examined phenolic extracts from five oak species sampled on three dates in May, June, and July 1994. Three species were sampled from the subgenus Erythrobalanus (red oaks: red oak, *Quercus rubra* L.; black oak, *Quercus velutina* Lam.; and scarlet oak, *Quercus coccinea* Muench.), and two from the subgenus Lepidobalanus (white oaks: chestnut oak, *Quercus prinus* L.; and white oak, *Quercus alba* L.)

To examine interspecific differences in foliar tannins, foliage from 16 woody plant species was collected in July 1997: sugar maple, *Acer saccharum* Marsh.; red maple, *Acer rubrum* L.; striped maple, *Acer pensylvanicum* L.; yellow birch, *Betula lutea Michx. f.*; ironwood, *Ostrya virginiana* (Mill.) K. Koch; American ash, *Fraxinus americana* L.; black cherry, *Prunus serotina* Ehrh.; flowering dogwood, *Cornus florida* L.; witch hazel, *Hamamelis virginiana* L.; maple-leaf viburnum, *Viburnum acerfolium* L.; and blueberry, *Vaccinium angustifolium* Ait.

Leaves were collected haphazardly from 10 young trees (3–7 m in height) of each species in a mixed stand at Wind Ridge Farm, Union Township, Centre County, Pennsylvania. The leaf tissue was immediately frozen in liquid nitrogen in the field, transported to the lab on Dry Ice, freeze-dried, ground in an air-driven UDY Cyclone Mill (to reduce heating and oxidation) and the lyophilized powder stored at -20°C until use. For each species, leaves from the 10 trees were combined for tannin measures.

Tannin Extraction and Purification. Five grams of lyophilized leaf powder were washed in 100 ml of ether for 30 min to remove pigments and waxes, and then extracted three times in 125 ml 70% acetone at 45°C for 1 hr under sonication. Ascorbate (10 mM) was added to the acetone to prevent oxidation. Acetone was removed by evaporation under reduced pressure, and distilled water was added to the aqueous extracts to a constant volume of 125 ml. This procedure favors extraction of polymeric tannins (Hagerman and Klucher, 1986) and is not exhaustive; substantial amounts of polyphenols may remain covalently bound to cells walls or other cellular components (Appel and Schultz, unpublished data).

Tannins in the polyphenol extracts were separated from nontannin polyphenols by the method of Hagerman and Klucher (1986). A slurry of 50 g of Sephadex LH20 (Pharmacia, Piscataway, New Jersey) and approximately 1 liter of 95%

reagent-grade ethanol was equilibrated overnight and then mixed thoroughly with 125 ml of crude extract. Using a large Buchner funnel and vacuum filtration, nontannin, monomeric polyphenols were eluted from the slurry by washing it with 95% ethanol until the eluant contained no polyphenols. Polyphenols were detected by the ferric chloride assay (Waterman and Mole, 1994), in which a drop of the yellow ferric chloride reagent was mixed with a drop of eluant, immediately resulting in a blue color in the presence of polyphenols. Larger polymeric polyphenols (tannins) were subsequently eluted with 70% acetone until the eluant tested negative with ferric chloride, indicating an absence of polyphenols, irrespective of their composition. Acetone was removed from the filtrate by evaporation under reduced pressure, and the extract was freeze-dried and stored under nitrogen at -10°C. This is a crude purification. While nonphenolic materials are unlikely to be present (Hagerman and Klucher, 1986; Appel and Schultz, unpublished data), the product is merely a more representative sample of extractable polyphenols found in the actual plant than is a commercial standard from some other source. Yields of the off-white tannin powder averaged 5% of the dry weight of the leaf.

Three commercial sources of tannins commonly used by ecologists as standards in the Folin-Denis assay were also purified with LH20 to remove low-molecular-weight contaminants: two different sources of the hydrolyzable tannin mixture called "tannic acid" (Sigma T0125 prepared from Rhus sp., Anacardiaceae, and T8406 from *Caesalpinia spinosa*, Leguminosae tara tannin), and the condensed tannin quebracho (Leon Monnier, Inc., from *Schinopsis* spp., Anacardiaceae).

Polyphenol Assays. Purified tannins of each species were assayed for (1) *total phenolics* by the FA (Swain and Hillis, 1959; Swain and Goldstein, 1964), which measures the ability of phenolics to reduce a mixture of phosphomolybdic and phosphotungstic acids; (2) *condensed tannins* by the butanol HCl assay (Bate-Smith, 1977), which quantifies hydrolyzed proanthocyanidin residues; and (3) *hydrolyzable tannins* by the potassium iodate method modified for quantitative use (Schultz and Baldwin, 1982), which quantifies galloyl esters. Serial dilutions were made of each extract to provide final concentrations of dry weight leaf powder per milliliter of DD water of 2, 8, 14, and 20 mg/ml, and these were assayed in triplicate for each assay. The data are reported as averages, and standard deviations of triplicate measurements of absorbance of single extracts of each sample comprising foliage combined from 10 trees. To determine the impact of the use of commercial standards, we calculated the values obtained for a hypothetical absorbance of 0.200 using the regression equations for commercial standards and for individual species, and then expressed each pair of values as a proportion.

Statistics. Linear regression was used to construct standard curves relating absorbance of the FA reaction mixture to the known concentration (mg/ml) of tannin. The relationships among absorbance of the FA reaction, polyphenol concentration, species, sampling date, and their interactions were examined using

GLM (SAS 1996). Significant differences among species in their absorbance at each concentration were determined by Tukey's studentized range test, which corrects alpha for the number of pairwise comparisons. To determine how compositional variation (i.e., condensed versus hydrolyzable tannin contents) among the tree species might influence FA results, the relationships among absorbance of the FA reaction mixture, condensed tannin levels, hydrolyzable tannin levels, and their interactions were examined in a separate GLM analysis. To evaluate the relative impact of these polyphenol types on variation for each species, we conducted stepwise multiple regression (best model) of FA values with the variables condensed tannins, hydrolyzable tannins, and their sum (SAS Institute, 1996).

RESULTS

All Species. As expected, all relationships between FA absorbance and tannin concentration (all species) were strongly and significantly linear. The R^2 values ranged from 0.970 to 0.999 (all $P = 0.0001$), confirming that the FA can generate standard curves relating absorbance and polyphenol concentrations for a wide range of individual species. However, slopes ranged from 0.009 to 0.0328 (Figure 1) and intercepts from 0.005 to 0.030 among species, making the use of a single standard inappropriate for comparisons among them. GLM analysis revealed strong significant statistical interactions between polyphenol concentration

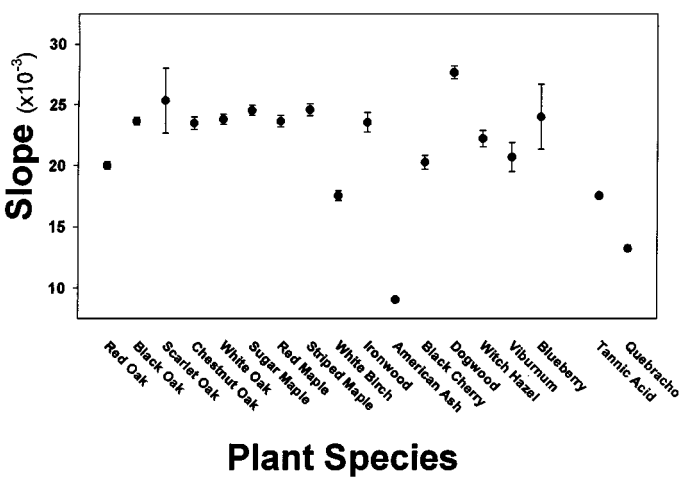

FIG. 1. Slopes and 95% confidence intervals for linear regressions of absorbance as a function of concentration (milligrams purified polyphenol per milliliter) in the Folin-Denis assay of total phenolics in foliage of 14 tree and two shrub species collected on July 14, 1998, and two commercial standards. Tannic acid used was Sigma T0125.

TABLE 1. GLM ANALYSIS OF EFFECTS OF SPECIES ON ESTIMATES OF FOLIN-DENIS REACTIVE PHENOLICS IN 14 FOREST TREES AND 2 SHRUBS AT 4 CONCENTRATIONS OF PURIFIED POLYPHENOLS FROM EACH SPECIES

Source	*df*	Type III SS	*F*	*P*
Concentration = 2 mg/ml				
Species	15	0.00930	249.01	0.0001
Concentration = 8 mg/ml				
Species	15	0.06145	278.01	0.0001
Concentration = 14 mg/ml				
Species	15	0.18192	73.70	0.0001
Concentration = 20 mg/ml				
Species	15	0.32462	1190.52	0.0001

and source (species) at every concentration (Table 1), and specific pairwise comparisons revealed significant sample absorbance differences among most species as a result (Tukey's studentized range test $P < 0.05$). The slopes of American ash and white birch were substantially lower and that of flowering dogwood much higher, than all the other species (Figure 1). No single standard could represent the phenolics in comparisons of all species. Single standards also are not representative in comparisons within genera. Among oaks, no single standard would be appropriate because the slope of red oak is much lower and that of scarlet oak much higher, than the black, chestnut, or white oaks (Figure 1). Note that the slopes do not segregate among subgenera. Slopes were more similar among the three species of maple than among the oaks, but they too produced statistically different absorbances at the $P < 0.05$ level in pairwise comparisons.

Interspecific differences in slope are likely due to different ratios of polyphenol types (Swain and Goldstein, 1964; Feeny, 1968). Both condensed and hydrolyzable tannins contributed significantly to FA results in these assays, with significant interactions between them (Table 2), indicating that the presence of each class of tannin influences the other's impact on FA absorbance. For some species, hydrolyzable tannins were the best predictor of FA values, for others condensed tannins or the sum of hydrolyzable and condensed tannins was the best predictor of FA values (Table 3).

Blueberry (*Vaccinium angustifolium*)	CT	0.9873	311.2	0.0001

[a]No other classes contributed more than 2% of the variation in Folin absorbance. CT = condensed tannins, HT = hydrolyzable tannins in foliage of 14 forest tree and 2 shrub species collected in July 1998.

Oaks. Relationships between FA absorbance and tannin concentrations were strongly and significantly linear, as expected, for all oak species on each of three dates (R^2 values ranged from 0.960 to 0.999, all $P = 0.0001$). However, even within the genus *Quercus* and within subgenera, there were differences among the slopes and intercepts of standard curves [slopes ranged from 0.019 to 0.029 (Figure 2), intercepts from 0.004 to 0.021. GLM analysis revealed strong statistical interactions between polyphenol source (species) and date, and between species and date at all but the lowest concentration (Table 4). Specific pairwise comparisons revealed differences among species in their absorbance in the FA (Tukey's studentized range test $P < 0.05$). The relationship (slope) between polyphenol concentration and FA absorbance differed among the oak species, differed within species among dates, and shifted among species from date to date (Figure 2). In four of the five species, May values were highest and July values lowest. In some cases, the *same amount* of purified tannins from May and July leaves produced a twofold difference in FA values. These seasonal and intrageneric differences are as large in magnitude as the interfamilial differences in Figure 1.

Seasonal shifts in FA values within oak species are likely due to changing ratios of polyphenol types (Feeny, 1968; Hatano et al., 1992). Both condensed and hydrolyzable tannins contributed significantly to FA results, with significant

Schinopsis spp., Anacardiaceae) had a much lower slope than that of all the plant species except American ash (AA) and substantially lower slope than the two hydrolyzable tannin standards. Sigma's T-0125 tannic acid, a mixture of gallotannins and monomers extracted from *Rhus* (Anacardiaceae) (Figure 1), produced slopes and intercepts significantly lower than Sigma's T-8406 product (tara tannin, a mixture of gallotannins from *Caesalpinia spinosa*, Leguminosae). Thus, none of the commonly used commercial standards better approximated the FA slopes and intercepts of the plants examined here, and in most cases were substantially out of range.

To compare results using a commercial standard with those using a standard purified from each plant species (self standard), we calculated the ratio of FA values obtained from the standard curves of the commercial standard and from those of purified tannin from each species, for a hypothetical absorbance of 0.2 (Figure 3). This ratio reflects the degree of over- or underestimation of the tannin content of each species by three commercial standards. Since the slopes of the commercial standards differed, none over- or underestimated the tannin content of all species to the same degree, producing widely varying errors of up to twofold in

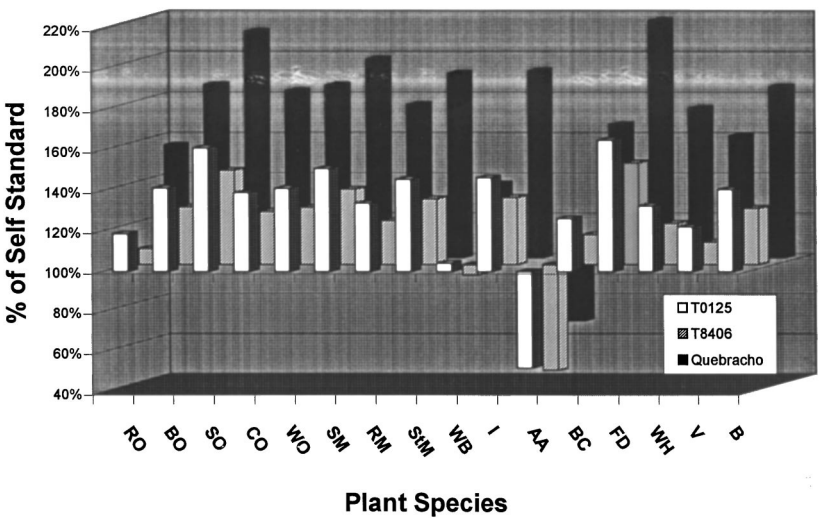

FIG. 3. The effect of choice of standard on Folin-Denis estimates of total phenolics in leaf extracts. the estimates of polyphenol concentrations (Figure 3). All three standards consistently overestimated tannin content in all but ironwood (I), and to a lesser extent white birch (WB), the one species that had a lower slope than the commercial standards. In a few cases, commercial standards came close to approximating tannin levels in some species. Both tannic acid sources estimated WB within 5%, and the tara tannic acid (Sigma T-8406) came within 10% for red oak (RO) and viburnum (V). Even seasonal variation in polyphenol composition is sufficient to invalidate the use of commercial standards to compare FA values within a species across sampling dates (Figure 4). In five oak species, the same amount of polyphenols produced significantly different FA values at different times of the season (Table 4), and none of the commercial standards reflected this variation (Figure 4).

DISCUSSION

Our study examined the utility of the Folin-Denis assay (FA) to compare the levels of polymeric polyphenols (tannins) in leaves of 16 woody plant species at a

single sampling date and of five closely related tree species at three sampling dates within one season. We found that there was dramatic variation among species in the reactivity of the *same amount* of purified tannins in the FA assay, even among related species, and even among sampling dates of the same species. This variation was associated with differences in the relative amounts of hydrolyzable and condensed tannins in the tannin mixtures and probably also reflected variation in a potentially large number of other phenolics.

Our study was a conservative test of the limitations of the FA because it was designed to minimize structural differences among tannin sources. First, we compared primarily tannins, and not total phenolics, which reduced the potentially great variation among species in the amounts and structures of simple, nontannin phenolics. For oaks, this approach restricted analyses to less than one third of the phenolic species likely to be present (Knopps and Jensen, 1980; Appel and Schultz, unpublished data). Second, we included a comparison of five related species of oaks, known to have structurally related and less seasonally variable tannin chemistries than some other tree species [e.g., *Liquidambar* (Hatano et al., 1992; Appel and Schultz, unpublished data)]. As is true for other classes of secondary metabolites, the more distantly related two plant species are, the greater the potential difference between them in phenolic composition; Folin-type assays should be less reliable as these differences grow greater. However, our conservative estimates indicate that even congeneric comparisons with FA using a single standard produce errors likely to be biologically significant, and intraspecific comparisons through time may require separate standards. This would also be true for other redox-based assays like the Prussian blue (Price and Butler, 1977), and to a lesser extent, for more structurally specific assays, such as the butanol HCl proanthocyanidin assay for condensed tannins (Hagerman and Butler, 1989) and the potassium iodate method (Schultz and Baldwin, 1982) for hydrolyzable tannins.

These observations are not new. Over 30 years ago, Swain and Goldstein (1964) described 10-fold variation in FA estimates of phenolic content among 20 different equimolar samples of purified phenolics. Feeny's (1968, 1969) widely cited papers on the tannin chemistry and ecology of English oak indicated clearly that phenolic composition changes seasonally within a single plant. Caveats about Folin methods have appeared sporadically since then (Martin and Martin, 1982; Mole and Waterman, 1987; Wisdom et al., 1987; Hagerman and Butler, 1989; Waterman and Mole, 1994), but with little evident effect: every ecological paper we could find in two major journals during 1994–1999 in which phenolics were "quantified" used Folin methods without appropriate standards. In the same search, we could not find any phenolic quantification (including condensed tannins, hydrolyzable tannins, etc.) in which appropriate standards were used.

The complete phenolic composition of most plants is unknown, and the relationships among phenolic concentration, phenolic composition, reducing power, and FA absorbance are unknown and unpredictable for most species. Hence, one

can say very little *a priori* about the likely relationship between composition or concentration and FA absorbance within or between species. Failing to do so can lead to serious over- or underestimates of total concentrations or amounts of phenolic fractions, as shown in this study.

Although the relationships between actual purified phenolic concentrations and FA absorbance for all but three species we examined had slopes between 0.019 and 0.026, these differences are biologically significant. For example, constitutive and induced levels of tannins in oaks differ to a similar degree and are related to herbivore performance (Schultz and Baldwin, 1982; Rossiter et al., 1988; Hunter and Schultz, 1993). Levels of tannins in flowering dogwood vary in similar magnitudes as a function of microsite and are related to levels of herbivory (Dudt and Shure, 1994). These biologically significant differences in tannin content would go undetected if inappropriate standards were used.

The magnitude of seasonal differences estimated—or mistaken—with the FA are also biologically significant (Schultz et al., 1982; Schultz, 1983) but would go undetected with inappropriate standards. Temporal differences in FA reactivity of phenolic extracts from the same species and tissues clearly make the use of a single standard across the season inappropriate, even though the standard may be from the same trees at an earlier or later date.

The widespread use of commercial standards only exacerbates the problem. Our results indicate that the use of commercial standards often fails to yield results similar to those obtained with self standards comprising phenolics extracted and purified from the material under study. Using these commercial standards can over- or underestimate presumed actual concentrations by as much as twofold in the species examined and may not even retain the rankings among species or between dates. These deviations from reality presumably arise from structural differences between the standards and the material actually being assayed in the plant extract, yielding different impacts on the FA reagent. For example, different plant species produce condensed tannins containing different mixtures of anthocyanidins and catechins, hydrolyzable tannins containing different mixtures of gallotannins and ellagitannins, and hybrid molecules containing gallotannins and flavonoids (gallocatechins). As a result, standards containing only a single structure or structural group (e.g., tannic acid or quebracho) may be irrelevant or misleading.

Commercially available standards with the same name ("tannic acid") can produced significantly different results. This is not surprising, given that some are extracted from plants in different families. We have also found measurable variation among batches of the same product, as have others (Hagerman and Butler, 1989), but purification of standards reduces much of this batch-to-batch variation (Appel and Schultz, unpublished data).

Purifying self standards from the same leaf material to be used in the FA assay resolves this problem because it provides a standard curve that allows one to interpret sample absorbances in the same currency in which they exist in the

leaf. Rather than using a commercial standard that may over- or underestimate the reducing power of one's extract, self standards quantify exactly what is present in the leaf. If one wishes to compare results with previously collected data lacking a self standard, one can simply generate a second standard curve with the previous standard.

Purifying self standards is neither complex nor expensive and would greatly improve the ecological inferences arising from any study of plant phenolics. Ideally, one would develop separate self standards for each sample that might have a different phenolic composition, e.g., different tissues, tissues of different ages, plants of different ages, samples from different dates, and possibly from different treatments if treatments are expected to change composition. This is clearly not feasible for large numbers of different sources of samples or for limited amounts of samples. However, one can create standards that are a mixture of sample material, reflecting the diversity of phenolics present within a population, treatment, etc., to which individual samples are compared. Valid comparative results can be obtained using mixtures of tissues from potentially differing sources as long as attention is given to the proportions of different tissue sources used. Modern microtiter plate readers and the ability to store standard curves facilitate this approach. The FA is still in widespread use by ecologists to quantify the relative and absolute amounts of phenolics produced in response to environmental variables or correlated with biological activity, but failure to use self standards can result in under- or overestimates of up to twofold, depending on the species compared and the commercial standard selected (see Figure 3), even for intraspecific comparisons (see Figure 4). Many influential papers on plant herbivore interactions, as well as some of our own, have based conclusions, in part, on variation within the range we find is generated by using inappropriate standards (Coley, 1983; Rossiter et al., 1988; Denslow et al., 1990; Shure and Wilson, 1993; Dudt and Shure, 1994; Shure et al., 1998). We find that differences in such studies probably need to exceed 100% to be biologically meaningful and account for error introduced by the use of inappropropriate standards for the FA reagent.

Biological activity can be estimated reliably by the Folin-type redox assay when it is known to depend directly or indirectly on phenolic oxidation. This is the case in many ecological settings (Appel, 1993). In our own studies (e.g., Schultz, 1983; Rossiter et al., 1988; Hunter and Schultz, 1993; Appel and Schultz, 1994) and some others (e.g., Dearing, 1997), FA values have been consistent correlates of the biological activity of plant phenolics for this reason.

It is clear that the Folin assays cannot be used to determine absolute amounts of phenolics to test hypotheses about plant investment in phenolics (e.g., Coley et al., 1985; Herms and Mattson, 1992; Shure and Wilson, 1993; Dudt and Shure, 1994; Shure et al., 1998). As we have demonstrated, there is no absolute relationship between FA values and the amount of phenolics in a plant extract. Interspecific comparisons, differences in tissue age or condition, and the use of a single commercial

standard make estimates of amounts impossible to obtain with this reagent. The only truly reliable and accurate way to estimate amounts of "total phenolics" or phenolic classes is to extract, purify, and weigh them, but this is not feasible for large numbers of small samples. Estimates may be obtained with the FA and self standards, but their approximation of reality should be determined by extracting and weighing a subset of samples. Even extensive extraction is unlikely to recover bound polyphenols and provide a true measure of 'total phenolic' mass.

We suggest that Folin reagents can be useful in ecological studies as indicators of redox-based biological activity and as indicators of relative amounts of phenolics if appropriate standards are used, but never as indicators of absolute concentration or mass and never for interspecific or temporal comparisons using a common standard. We recommend that investigators considering the use of Folin-type assays do the following: (1) Decide whether the goal is to quantify the *amount* or *activity* of phenolics. (2) If measuring amount is the goal, then the most accurate approach is to purify and weigh total phenolics, although extraction is unlikely to be complete. Colorimetric assays can be made semiquantitative by using purified self standards. (3) If measuring *activity* is the goal, use purified plant phenolics for standards and measure the samples' redox potential with the FA. (4) Always make separate colorimetric standards for each plant species. (5) Within species, design standards or standard mixtures to reflect the range of variation encountered within the desired unit of comparison, i.e., include subsamples of the sources in appropriate proportions. (6) When reporting results, be specific about assay limitations.

TESTING THE EFFECTS OF DRYING METHODS ON WILLOW FLAVONOIDS, TANNINS, AND SALICYLATES

RIITTA JULKUNEN-TIITTO* and SINIKKA SORSA

University of Joensuu
Department of Biology
Box 111 FIN-80101 Joensuu, Finland

(Received August 31, 2000; accepted December 14, 2000)

Abstract—In this study, we compared the effects of several preservation methods on the secondary phenolics of the mature leaves of purple willow (*Salix purpurea* L., Salicaceae) with results obtained with fresh leaf analyses. Conventional freeze-drying, in which the leaves were first frozen with liquid nitrogen and then placed in a freeze-dryer, produced substantial qualitative and quantitative changes in purple willow flavonoids and salicylates. Modified freeze-drying, in which leaves were put into a freeze-dryer without being prefrozen, gave concentrations that, for most secondary components, were comparable with those found in fresh leaves. Reducing the freeze-dryer chamber temperature hindered the decomposition of phenolics in prefrozen leaves and in leaves dried without prefreezing. Heat drying induced substantial changes in the composition of all phenolics, except for apigenin-7-glucoside. Vacuum drying at room temperature gave the highest concentrations for nearly all phenolics, while room-drying with desiccation gave results that were comparable with those obtained by fresh leaf analyses.

Key Words—Drying tests, phytochemicals, flavonoids, tannins, salicylates, leaves, willow, *Salix*.

INTRODUCTION

One problem in phytochemical research is the difficulty of obtaining valid results due to the high chemical and biochemical lability of many of the phytochemicals found in plants. In order to obtain accurate results for concentrations of secondary products, it is important to use a suitable method of prehandling the fresh plant material. This is especially critical in ecophysiological and ecobiochemical research, where a small group of components or even a single component may determine

the primary biological or chemical response of plant tissues to biotic factors such as herbivores and pathogens and abiotic factors such as nutrition and UV radiation (e.g., Tahvanainen et al., 1985; Hakulinen et al., 1995; Julkunen-Tiitto, 1996; Juntheikki et al., 1996; Lavola et al., 1998). Phytochemical preservation is also essential in herbal drug production and chemotaxonomical research (e.g., Julkunen-Tiitto, 1989; Julkunen-Tiitto and Meier, 1992).

Salicaceous plants produce a wide variety of lower molecular mass phenolics, mainly glycosylated flavonoids and salicylates, together with high concentrations of condensed tannins. During the last 30 years these have been studied intensively by European and American researchers investigating defense functions, ontogeny, phenology, chemotaxonomy, herbal medication, etc. (e.g., Thieme, 1965; Pearl and Darling, 1970; Egloff, 1982; Bryant et al., 1987; Meier et al., 1988; Julkunen-Tiitto, 1989; Shao, 1991). The occurrence of these bioactive components is fairly species-specific and plant-part specific, and their relative proportions in specific tissues may change substantially as the plant matures (Bryant and Julkunen-Tiitto, 1995).

Most of the flavonoids are considered to be fairly stable under different prehandling and extraction conditions (e.g., Markham, 1982; Keinänen and Julkunen-Tiitto, 1996), while several higher molecular mass salicylates, such as salicortin and tremulacin, are known to be labile and prone to decomposition during sample preservation and extraction (e.g., Thieme, 1965; Meier et al., 1988; Julkunen-Tiitto, 1989). Neutral and alkaline conditions, certain organic solvents, and being soaked in water readily result in lower molecular mass salicylates (e.g., Julkunen-Tiitto, 1985; Julkunen-Tiitto and Meier, 1992). It has been reported that conventional freeze-drying induces deleterious changes in the leaves of *Populus* and *Salix species* (Lindroth and Pajutee, 1987; Julkunen-Tiitto and Tahvanainen, 1989; Orians, 1995). Vacuum-drying (Orians, 1995) and conventional freeze-drying (prefreezing with liquid nitrogen) at low temperature (Lindroth and Koss, 1996) are previously recommended methods of preserving *Populus tremuloides*, *Salix sericea*, and *S. eriocephala* leaves. Unfortunately, vacuum-drying has been found to alter the carbohydrate content in the leaves of *Populus tremuloides*, with the result that the decrease in starch content is reflected by an increase in percent leaf dry mass for glucose (Lindroth and Koss, 1996). Oven-drying mature willow leaves at low temperature (48°C) gives practically no qualitative or quantitative differences in salicylates compared those found in fresh leaves (Julkunen-Tiitto and Tahvanainen, 1989). As expected, tissue destruction before oven-drying induces deleterious changes in willow salicylates (see Lindroth and Pajutee, 1987)

In this study, the appropriateness of different plant preservation methods was studied in order to find a faster and safer method of preserving the most labile phytochemicals. The mature leaves of purple willow (*Salix purpurea* L.) were used because purple willow contains the two most labile salicylates, tremulacin and

salicortin, together with a small amount of salicin and tremuloidin. It also contains partners of three different flavonoid groups: flavanones, flavones, and flavan-3-ol, the lability of which has not been thoroughly studied previously.

METHODS AND MATERIALS

Leaf Material. Leaves were collected from an ornamental purple willow (*S. purpurea* L.) clone growing on the campus of the University of Joensuu, Finland. Fully expanded, mature leaves were detached from their shoots, put into a plastic bag, and placed in a Styrox container, where they were kept at $<4^{\circ}$C. The leaves were taken to the laboratory within 5 min and randomly separated into batches of 20 for the prehandling tests. We tested 10 different drying methods (Table 1). Immediate fresh analyses were carried out as a control treatment. In method II the leaves were dried on the laboratory table. In methods III and IV, which used drying media, the fresh leaves (2.9 g) were processed in desiccators each containing 300 g of drying medium (20 leaves, one leaf fresh wt $= 0.143 \pm 0.011$). Well-ventilated ovens were used for air drying in methods X and XI.

Chemical Analyses. Eight mature leaves from each preparation method were analyzed separately for willow flavonoids, condensed tannins, and salicylates. In order to ensure complete recovery of the soluble compounds, care was taken not to overload the extraction solvent. Three to four milligrams of leaf tissues, cut so as to avoid main veins, were extracted three times with 400 μl of the solvent. Methanol was used for flavonoids and salicylates. This extraction procedure gave more than 98% recovery for the components. Soluble condensed tannins were extracted with 70% acetone (as above) and quantified by oxidative depolymerization

to anthocyanidins in acid butanol, as described by Porter et al. (1986). The extraction residue was hydrolyzed with acid butanol for insoluble tannins. The sum of soluble and insoluble condensed tannins was quantified using Sephadex LH20 purified tannin from *S. purpurea* leaves (see Hagerman, 1995). The residual water was measured by drying the leaves for 12 hr at 105°C. The results are expressed as milligrams per gram dry weight at 105°C. Flavonoids and salicylates were quantified by HPLC-DAD as reported by Julkunen-Tiitto et al. (1996). HPLC-MS was used to identify the components. The gradient used is described in Table 2. HPLC/API-ES (positive ions) conditions were as follows: the column was Hypersil Rp C-18, 2 mm ID, 10 cm long; the ES fragmentor voltage was 80–120, depending on the components; the flow rate was 0.4 ml/min.

The quantification of components was determined as follows: salicin, salicyl alcohol, tremulacin, eriodictyol-7-, naringenin-7-, luteolin-7-, apigenin-7-glucoside, and luteolin were based on commercial standards; salicortin and tremuloidin were based on purified standards obtained from Prof. Beat Meier, ETH, Zurich, Switzerland. The derivatives of eriodictyol, naringenin, and luteolin were based on corresponding flavonoid-7-glucoside. HPLC/API-ES produced the following molecular weights: eriodictyol-7 glucoside, 473 (M + 23); eriodictyol-glycoside 2, 922 (M + 23, tentatively identified as dieriodictyol-monoglucoside); naringenin-7-glucoside, 457 (M + 23); luteolin-7-glucoside, 471 (M + 23); luteolin-glycoside 2, 557 (M + 23, tentatively identified as diacetylderivative of luteolin-monoglucoside); luteolin-glycoside 3, 499 (M + 23, tentatively identified as methylderivative of luteolin-glucuronide); apigenin-7-glucoside, 455 (M + 23); (+)-catechin, 291 (M + 1); salicin, 309 (M + 23); salicortin, 447 (M + 23); tremuloidin, 413 (M + 23); and tremulacin, 551 (M + 23). In addition, two unknown salicylates (871, M + 23) were detected in very tiny amounts (results not shown). These were tentatively identified as disalicortins.

RESULTS AND DISCUSSION

In this study mature, fully expanded purple willow (*S. purpurea*) leaves were used to test the effect of 10 preservation methods on flavonoids, condensed tannins, and salicylates. During heat-drying the leaves turned brown or blackish, indicating kinone formation and advanced decomposition of the phenolics. After all the other drying methods the leaves were still green or, after freeze-drying with prefreezing, slightly pale green. The residual water content of the dried material varied between methods. In methods III and IV it was $4.80 \pm 0.11\%$ and $3.02 \pm 0.08\%$, respectively, while in methods II and V–IX the mean residual water was $6.65 \pm 0.31\%$.

We found four flavanones (naringenin-7-glucoside, eriodictyol-7-glucoside, and two unknown eriodictyol-glycosides), six flavones (apigenin-7-glucoside, luteolin-7 glucoside, luteolin-glycosides 1-3 and luteolin), two flavan-3-ols [(+)-catechin and condensed tannins], and four salicylates (salicortin, tremulacin, salicin, and tremuloidin) and compared the concentrations with those found in the fresh leaf extracts. We found that the concentrations of individual phytochemicals were significantly affected by the prehandling method (Figures 1–3). Aglycons identified as decomposition products of the corresponding glycosides included luteolin, naringenin, salicyl alcohol, and 6-OH-oxocyclohexenone, depending on the preservation method.

The most abundant flavonoids in purple willow leaves are flavanones, eriodictyol-7-glucoside (more than 3% dry wt), and naringenin 7-glucoside (about 0.4% dry wt) (Figure 1) (Meier, 1988; Shao, 1991). Both flavanones (except for minor eriodictyol-glycoside 2) were significantly reduced by conventional freeze-drying (method VI). In this method, the prefrozen samples were put into an external drying chamber normally used for drying solid material. The temperature inside the chamber was 18°C. For some flavanones, room-drying without desiccation (method II) and freeze-drying at a low temperature (method VIII) also gave concentrations that were lower, although not significantly so. Air drying at an elevated temperature (method X and XI) was deleterious to leaf flavanones: there was a greater than 50% reduction in the concentration of naringenin-7-glucoside and a greater than 60% reduction in that of eriodictyol glycosides. All the other methods tested gave concentrations of flavanones that were similar to those found in the fresh leaf analyses.

The responses of flavones, luteolin glycosides, and apigenin-7-glucoside to conventional freeze-drying (method VI) were similar to those of flavanones (Figure 2). The amounts of luteolin-7-glucoside and apigenin-7-glucoside were reduced by more than 30% compared with those found in the fresh leaf analyses. The concentrations of apigenin-7-glucoside, luteolin-7-glucoside, and two luteolin-derivatives were also reduced by method VII (freeze-dying without prefreezing). Room drying (method II) also caused a moderate reduction in the amounts of luteolin-7-glucoside and its two derivatives (1 and 2). Desiccation at

Multiple comparisions were done using the Dunnett *t* test, with method I as the control ($^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$).

room temperature (methods III and IV) enhanced the yield of apigenin-7-glucoside as compared to the control level (method I). Heat drying at 60°C and 90°C (methods X and XI) was too high for most luteolins, but apigenin-7-glucoside remained fairly stable. Our results show that the flavanone glucosides and flavone glucosides of purple willow leaves are very sensitive to preservation methods compared with flavonol glycosides, which are the most abundant flavonoids in birch (*Betula pendula* Roth) leaves. The concentrations of quercetin and myricetin glycosides

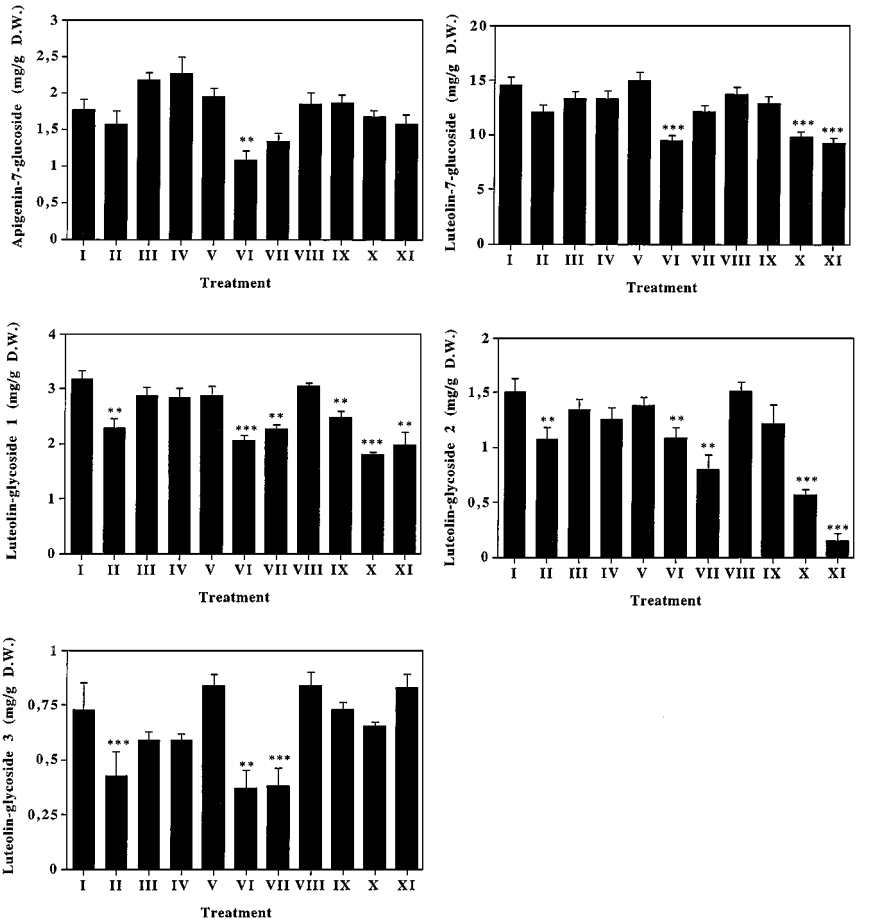

FIG. 2. The effects of prehandling methods on flavones in mature leaves of purple willow (*S. purpurea*). The results are expressed as means ± SE from eight separate leaves. Multiple comparisions were done using the Dunnett *t* test with method I as the control (** $P < 0.01$; *** $P < 0.001$).

were significantly higher in leaves dried at 80°C than in leaves dried at 40°C or 20°C (Keinänen and Julkunen-Tiitto, 1996). Conventional freeze-drying (prefreezing at −18°C) yielded higher concentrations of those flavonols compared with those found when the leaves were dried without prefreezing.

The third flavonoid group in purple willow is flavan-3-ols, comprising (+)-catechin (0.25% dry wt) and condensed tannins (about 5–6% dry wt) (Figure 1). The concentrations of (+)-catechin were similar for all methods except for both

heat-drying methods (X and XI). Heat drying induced strong decomposition, tight binding with other components, or both for (+)-catechin, leaving no traces at all of (+)-catechin after treatment. This result is very different from those obtained from mature birch (*Betula pendula* Roth) leaves in our laboratory, where a <20% decrease in (+)-catechin was found after drying at 80°C (Keinänen and Julkunen-Tiitto, 1996). Except for the heat drying methods (methods X and XI), none of the methods used resulted in a significant reduction of condensed tannins (oligomeric and polymeric flavan-3-ols). Hagerman (1988) recommends freeze-drying for condensed tannins, while Orians (1995) and Lindroth and Koss (1996) prefer vacuum drying. Increasing the drying temperature to 60°C (method X) lowered the condensed tannin amount by >60%, and using 90°C for drying (method XI) gave only 21% of the tannin amount compared with that found in the fresh analyses. The effect of heat drying on purple willow condensed tannins was similar to that found in *Salix* cv. *aquatica* and *S. phylicifolia* leaves (Julkunen-Tiitto, 1985). On the other hand, heat drying had a less severe effect on the condensed tannins found in *Salix eriocephala, S. sericea*, and their hybrid compared with freeze-dried leaves by Orians (1995).

The highest concentrations of the most abundant salicylates, salicortin and tremulacin, were obtained from vacuum-dried leaves (method V) (Figure 3). This difference in secondary products may be due to changes in other metabolites, such as volatiles induced by vacuum drying. Lindroth and Koss (1996) have reported that, compared with freeze-drying, vacuum drying using *Populus tremuloides* leaves increased hexoses and reduced the starch level by 38%. The salicylate results with vacuum drying are consistent with those obtained from *Salix sericea* (Orians, 1995) and *Populus tremuloides* leaves (Lindroth and Koss, 1996).

We found that conventional freeze-drying in an external drying chamber (material kept frozen, method VI) induced completely artifactual concentrations of the main salicylates (Figure 3) (Julkunen Tiitto and Tahvanainen, 1989). The high amounts of decomposition products, such as salicyl alcohol (10,07 $\pm$ 1.16 mg/g dry wt) and 6-OH cyclohexenone (not quantified), as well as significantly increased salicin and tremuloidin confirm the unsuitability of method VI. Freeze-drying is too slow and, although most of them may be frozen, some thin leaves may thaw sufficiently during water sublimation to induce interconversion among the compounds by chemical or even biochemical decomposition. Freeze-drying, without prefreezing, in an external drying chamber (method VII) proved to be a far better method, but it still reduced the concentrations of salicortin and tremulacin compared with those found in the fresh analyses. This indicates that not only thawing, as suggested by Lindroth and Koss (1996), but also prefreezing matters in the freeze-drying process. Method VIII, which is comparable to VI except that chamber temperature in the freeze-dryer during sublimation was -30°C, led to a small, but nonsignificant loss of the most abundant salicylates. In contrast, method IX (comparable to method VII), which used the same freeze-drying temperature but

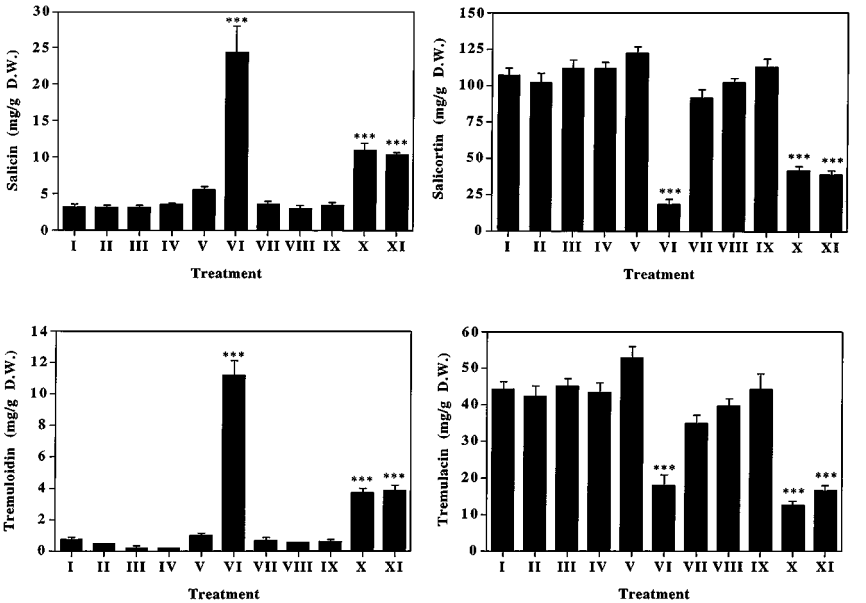

FIG. 3. The effects of prehandling methods on salicylates in mature leaves of purple willow (*S. purpurea*). The results are expressed as means ± SE from eight separate leaves. Multiple comparisions were done using the Dunnett *t* test with method I as the control (*** $P < 0.001$).

did not prefreeze the leaves, gave amounts that were quite similar to those found in the fresh leaf analyses. Thus, if one wants to use a freeze-dryer to preserve salicylate material, prefreezing with liquid nitrogen or at −20°C should be avoided or the temperature in a drying chamber must be low (less than −20°C).

Air drying at room temperature (method II) (Figure 3) and at 45°C (Julkunen-Tiitto and Tahvanainen, 1989) and the use of drying media (silica gel in method III and molecular sieves in method IV) proved to be safe and suitable drying techniques for labile *S. purpurea* leaf salicylates. The results show levels for salicortin and tremulacin similar to those found in the fresh analyses. The effect of using silica gel and molecular sieves is to speed up the drying process compared with the air drying at room temperature. They are also cheap and easy to use in the field, so that samples can be treated on the way to the laboratory. Increasing the drying temperature to 60°C induced very significant losses of salicortin and tremulacin, increased the levels of salicin and tremuloidin, and possibly caused them to decompose further. Interestingly, similar air drying at 60°C reduced the concentrations of salicortin and 2′-*O*-cinnamoylsalicortin in *S. sericea* leaves only slightly (Orians, 1995).

Salicortin, which contains a carboxyl ester bond, decomposed much more easily under the drying conditions than tremulacin, which also contains a benzoyl

ester bond. Freeze-drying method VI reduced the amount of salicortin by more than 83%, while that of tremulacin was reduced by about 60%. Thus, it may be that the benzoyl ester stabilizes the compound under these drying conditions while the carboxyl esters are very labile. Decomposition of salicortin and tremulacin produce salicin and tremuloidin, respectively, as their first decomposition products. Tremuloidin further decomposes to salicin. In this study, salicin and tremuloidin were detected in low amounts in fresh leaves. So far, we do not know if salicin is a precursor of salicortin and tremulacin, but earlier phenological and ontogenetic screening of willow leaves in our laboratory indicates that salicin is a real component and not simply induced by decomposition of higher molecular mass salicylates. This is consistent with the results of Meier (1988) and Shao (1991), who have reported 0.1–1.6% of salicin in Central European *S. purpurea* leaves, and Thieme and Benecke (1970), who detected 1–2% of salicin in *P. tremuloides* leaves. Our results disagree with the findings of Orians (1995) and Lindroth and Koss (1996), who did not detect salicin in *S. sericea* and *P. tremuloides* leaves.

In our study we used fully expanded, mature, undamaged leaves that had a moderately low water content ($59.22 \pm 0.34\%$). We found that fresh analyses should be made whenever possible. However, if analytical procedures necessitate sample preservation, then desiccation at room temperature and freeze-drying at low temperature, preferably without prefreezing, are the best methods for mature willow leaves.

(Received July 10, 2000; accepted December 14, 2000)

Abstract—The lepidopteran genus *Saturnia* has three representatives in North America, *S. walterorum*, *S. mendocino*, and *S. albofasciata*. (*E*4,*Z*9)-Tetradecadienal (*E*4,*Z*9–14 : Ald) was identified as a sex pheromone component for all three species by combinations of coupled gas chromatography–electroantennogram detection (GC-EAD), GC–mass spectrometry (MS), and field trials. In field trials, all three species were strongly attracted to (*E*4,*Z*9–14 : Ald) as a single component. Small amounts of (*Z*)-9-tetradecenal (*Z*9–14 : Ald) also were found in extracts of all three species, but blends of this compound with *E*4,*Z*9–14 : Ald were no more attractive to male moths than *E*4,*Z*9–14 : Ald alone. Extracts of pheromone glands of female *S. walterorum* occasionally contained a third, trace compound eliciting responses from male antennae in GC-EAD experiments, but this compound was not identified. It is suggested that the three species can use the same, single component as a sex attractant because the flight period of *S. albofasciata* (fall) is different than that of the other two species (spring), whereas the geographic distributions of *S. mendocino* and *S. walterorum* overlap over only small portions of their ranges. Furthermore, the latter two species readily hybridize, so there may be minimal fitness cost to cross-attraction.

Key Words—(4*E*,9*Z*)-tetradecadienal, (*Z*)-9-tetradecenal, *Saturnia* spp., pheromone.

INTRODUCTION

The genus *Saturnia* (Lepidoptera: Saturniidae) is represented by three species in the New World, *Saturnia mendocino* Behrens, *S. walterorum* Hogue and Johnson, and *S. albofasciata* (Johnson), all of whose distributions and biologies have been described by Tuskes et al. (1996). All three species are univoltine. *S. mendocino* and *S. walterorum* are sister species that are found in both montane and coastal chaparral plant communities, whereas *S. albofasciata* is restricted to montane chaparral. *S. mendocino* ranges from central California to Oregon and is found in both the coastal and Sierra Nevada mountain ranges, whereas *S. walterorum* is found from southern California to northern Baja California, Mexico. The ranges of the latter two species overlap in San Luis Obispo and Monterey counties of California. The range of *S. albofasciata* spans that of the other two species, and it is found at higher elevations from northern California to northern Baja California, Mexico. Adults of *S. mendocino* and *S. walterorum* emerge from February through May and are diurnally active. In contrast, *S. albofasciata* flies from mid-October to mid-November, with males being active in the late afternoon until dusk, and females ovipositing just after sunset. Eggs of all three species are laid singly or in small clusters on the larval hosts, which include manzanita (*Arctostaphylos* spp. Adanson) and madrone (*Arbutus menziesii* Pursh) for *S. mendocino*, manzanita (*Arctostaphylos* spp.) and laurel sumac (*Malosma laurina* Nuttall) for *S. walterorum*, and several *Ceanothus* spp. L. and *Cercocarpos betuloides* Nuttall for *S. albofasciata* (Tuskes et al., 1996). Eggs of *S. mendocino* and *S. walterorum* hatch in approximately three weeks, whereas those of *S. albofasciata* overwinter and hatch the following spring. Larvae of all three species develop through the spring, spin silk cocoons on or near the host, and subsequently emerge in the fall of that year for *S. albofasciata*, or in the spring of the following year for the other two species.

In conjunction with an ongoing study of sex attractant pheromones of saturniid moth species in the western United States, we undertook a study of the sex pheromone chemistry of these three *Saturnia* spp. We describe here the identification and field testing of (*E*4,*Z*9)-tetradecadienal (*E*4,*Z*9–14 : Ald) as a female-produced sex pheromone component for all three species.

METHODS AND MATERIALS

Insects

Pupae of *S. mendocino* were obtained from a culture maintained by one of the authors (D.R.) at the Division of Insect Biology, University of California, Berkeley, California. This culture had been outcrossed frequently by mating

laboratory-reared females with wild males collected from several northern California counties, so as to maintain the vigor of the laboratory colony. Specimens of *S. walterorum* were obtained from C. Conlan and were from cultures that originated in San Diego County, California. Larvae of both species were reared on cut bouquets of natural hosts in water or in nylon sleeves directly upon living plants. Cocoons were kept outdoors in screen cages (approx. 30 cm square) in the shade until adult emergence. Freshly emerged adults were separated by sex and were either used immediately for preparation of pheromone gland extracts (females) or for electroantennograms (males' antennae), or were held at 4–10°C in glassine envelopes for up to one week. Storing at cool temperatures was necessary because the nonfeeding adult moths typically live less than one week.

A few pupae of *S. albofasciata* were obtained from C. Conlan, and these produced a single female and several males. Further males used in GC-EAD studies were collected from field sites, using *E*4,*Z*9–14 : Ald lures to attract them (see below).

Extraction of Sex Pheromone Glands

Sex pheromone glands were removed from 1- to 4-day-old calling virgin females. The gland was extruded by applying gentle pressure to the abdomen to evert the ovipositor, and the terminal abdominal segments were excised into a 0.25-ml conical glass vial insert containing ~30 μl pentane. Care was taken to avoid contamination of the samples with the dark-colored material that was abundant in the abdomen, which may be used to glue eggs to the host plant. The glands were extracted for 2–20 min, and the extract was transferred to a clean insert, with two rinses with 1 drop of pentane. Extracts were concentrated by passive evaporation as needed prior to analysis. If not used immediately, extracts were stored at −20°C. Approximately 20 extracts of female *S. walterorum* were obtained, whereas fewer than 10 *S. mendocino* female extracts and only a single *S. albofasciata* extract were available.

Gas Chromatography

GC analyses were conducted with Hewlett-Packard 5890A or 5890 Series II gas chromatographs (H-P = Agilent, Palo Alto, California), with helium carrier gas, in splitless mode. Columns and programs used to analyze female extracts of *S. walterorum* included DB-225 (J&W Scientific, Folsom, California; 30 m × 0.26 mm ID, 0.25-μm film, 100°C/0 min, 15°C/min to 130°C/0 min, 3°C/min to 175°C/0 min, then 20°C/min to 220°C for 60 min), DB-WAX (J&W Scientific; 30 m × 0.32 mm ID, 0.25-μm film, 100°C for 1 min, 5°C/min to 240°C for 10 or more min), DB-5 (J&W Scientific; 30 m × 0.25 mm ID, 0.25-μm film, 100°C for

1 min, 5°C/min to 275°C for 60 min). *S. mendocino* extracts were analyzed on the DB-225 column as described above. Extracts also were analyzed by coupled GC-EAD (see below). Tentative identifications were made by comparison of retention times of compounds in extracts to those of synthetic standards.

Coupled Gas Chromatography–Electroantennography (GC-EAD)

Antennae from male *S. mendocino* ($N = 3$) were stimulated with standards of the *E* and *Z* isomers of each of the monounsaturated tetraenals with the double bond in positions 3–12. One-microliter aliquots containing approx. 50 ng of a given standard in hexane were injected in random order onto a DB-5 column (30 m × 0.32 mm, 0.25-μm film) in split mode with a 20 : 1 split ratio, run isothermally at 200°C. Antennal response peak heights were measured to the nearest 0.5 mm, then analyzed using two-way analysis of variance of the log transformed data followed by a Student-Neumann-Keuls means separation test. Because these standards were the products of microscale oxidations and partial purifications, their concentrations varied. Concentrations of individual samples were adjusted to keep the amount of each compound injected within a twofold range, but no further compensation was made for variability in amounts injected because antennal responses were relatively insensitive to variations in the quantity injected. For example, halving the amount of *Z*9–14 : Ald injected resulted in only a 27% reduction in antennal response.

Aliquots of pheromone gland extracts from females and synthetic standards were analyzed by splitless coupled GC-EAD, using an H-P 5890 series II GC equipped with a DB-5 column (30 m × 0.32 mm ID, 0.25-μm film, 100°C/1 min, 5°C/min to 150°C/5 or 10 min, then 25°C/min to 275°C/30 min for *S. walterorum* and *S. mendocino*, and 100°C/1 min, then 10°C/min to 275°C/25 min for *S. albofasciata*), using an injector temperature of 250°C. The column effluent was split equally with a press-fit Y-connector (J&W Scientific) into two branches of 0.25-mm-ID, uncoated fused silica tubing, with one branch going to the GC flame ionization detector (FID), and the other being directed through a heated transfer line (275°C) to a 15-mm-diameter glass stimulus delivery tube. The capillary effluent was diluted with humidified air (400 ml/min) and passed over the male moth antennal preparation (see below). The moth antenna was suspended between glass capillary electrodes filled with modified Locke's saline (7.5 g NaCl, 0.21 $CaCl_2$, 0.35 g KCl, 0.20 g $NaHCO_3$ in 1 liter distilled water) (Humason, 1972) or Kaissling's saline (Kaissling and Thorson, 1980), with electrical contact to the custom-built amplifier made with AgCl-coated silver wires. The amplifier and FID outputs were simultaneously recorded on a matched pair of H-P 3394 recording integrators.

Male antennae were removed using fine forceps to firmly hold the scape and pull the antenna free of the head, without crushing the scape. The terminal rami and tip of the antenna were removed so that the end of the antenna could be placed into

the saline-filled recording electrode. The antenna was positioned on the amplifier mount at the end of the delivery tube such that the plane of the antennal branches was perpendicular to the air flow from the stimulus delivery tube. A single antenna preparation could be used for several hours with periodic additions of saline.

Field Trials

Pherocon 1C sticky traps (Trécé Inc., Salinas, California) were used in all trials, with 11-mm red rubber septum lures (Wheaton Scientific, Millville, New Jersey), loaded with heptane solutions (100 μl) of test compounds, plus 2 drops of 10 mg/ml butylated hydroxytoluene (BHT) in heptane as an antioxidant. Lures were kept in 20-ml glass vials in a freezer or an ice-chest when not in use. Traps were placed in areas where host plants were common. Traps were spaced approximately 8 m apart and blocks were 600 m or more apart. Traps were suspended from shrubs at heights of 0.5–1.5 m above ground. Trapped moths were counted at irregular intervals of 3–11 days for *S. mendocino* and *S. walterorum*, with traps left in the field for nearly one month in total.

S. mendocino field trials were conducted in the western Sierra Nevada mountains near Hams Station, Amador County, California in April 1997 using 10 blocks of treatments and controls. A second *S. mendocino* trial, comparing a blend of *E*4,*Z*9–14 : Ald and *Z*9–14 : Ald (100 : 10 μg) to 100 μg *E*4,*Z*9–14 : Ald alone, was conducted in Del Puerto Canyon, Stanislaus County, California in March 1998. *S. walterorum* field trials were conducted in late March to April 1997 with five blocks of traps placed in the vicinity of Viejas grade near Descanso, and the Laguna Mountains along Highway S1 between Monument peak and Kwaaymii Point, San Diego County, California. *S. albofasciata* field trials were conducted in November 1998 near Thomas Mountain, Riverside County, California. A single block of traps was used, consisting of three traps baited with 100 μg *E*4,*Z*9–14 : Ald and three traps baited with blank controls. Traps were left in place for one day, after which time the treatment trap bottoms were completely covered with male moths and so further testing was discontinued.

For the purposes of statistical analysis, a replicate consisted of a single block, and counts for a particular treatment in a given block were pooled to eliminate day effects. Trap catches were analyzed using two way analysis of variance of the square root $(x + 0.5)$ transformed counts.

Synthesis of Authentic Standards

Standards of tetradecenals with the double bonds at carbons 3–12 were prepared by oxidation of samples of the corresponding alcohols, obtained from the Research Institute for Plant Protection, Wageningen, The Netherlands, with excess pyridinium dichromate in methylene chloride for 2 hr (Corey and Suggs, 1979).

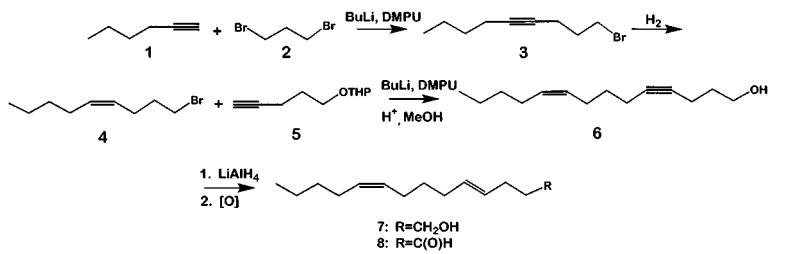
The reaction mixtures were diluted with 10 volumes of pentane, then vortexed for 30 sec. The precipitate was allowed to settle, and the supernatant solutions were filtered through 2.5-cm plugs of Celite. The resulting solutions were used immediately for electroantennogram studies as described above.

4,9-Tetradecadienals

Proton NMR spectra were taken on a General Electric QE-300 instrument (300 MHz), as $CDCl_3$ solutions. Electron impact mass spectra (70 eV) were taken with a Hewlett-Packard 5970B mass selective detector interfaced to a 5890 gas chromatograph fitted with a DB-5MS column (20 m × 0.2 mm ID, J&W Scientific). Mass spectra are reported as *m*/*z* (abundance). All reactions were carried out in oven-dried glassware. THF was purified by distillation from sodium benzophenone ketyl under nitrogen. Unless otherwise specified, worked up reaction mixtures were dried with anhydrous Na_2SO_4 and concentrated by rotary evaporation under reduced pressure. Flash chromatography (Still et al., 1978) and vacuum liquid chromatography (Coll and Bowden, 1986) were carried out with 230 to 400-mesh silica gel (Aldrich Chemical Co.).

Synthesis of (E4,Z9)-Tetradecadienal (Scheme 1)

*1-Bromonon-4-yne **(3)***. Butyllithium (42.5 ml of 2.5 M solution in hexanes, 110 mmol) was added dropwise over ∼20 min to an icebath-cooled solution of 1-hexyne **1** (8.2 g, 100 mmol) in THF (100 ml) under Ar. The mixture was stirred 20 min, then warmed to room temperature, and 1,3-dibromopropane **2** (12.2 ml, 120 mmol) was added dropwise. The mixture was warmed to 55°C for 24 hr, then cooled and quenched with water (250 ml). The mixture was extracted with hexane, and the hexane extracts were washed with brine, dried, and concentrated, yielding a mixture of unreacted starting material, the desired bromide **3**, and the alkadiyne from coupling at both ends of 1,3-dibromopropane (16 : 66 : 12 by GC). The residue was slowly Kugelrohr distilled, yielding 20.11 g of a purified monobromide fraction, oven temperature 55–60°C (0.4 mm Hg). NMR: δ 3.54



SCHEME 1

(t, 2H, $J = 6.9$ Hz), 2.34 (tt, 2H, $J = 6.7$, 2.1 Hz), 2.15 (tt, 2H, $J = 6.7$, 2.3 Hz), 2.02 (quint, 2H, $J = 6.6$ Hz), 1.52–1.35 (m, 4H), 0.91 (t, 3H, $J = 6.9$ Hz). MS: *m*/*z* 202/204 (1/1, M^+), 174/176 (8/7), 132/134 (31/30), 123 (5), 107 (8), 95 (67), 81 (99), 79 (58), 77 (49), 67 (78), 53 (69), 41 (100).

*(*Z*)-1-Bromo-4-nonene **(4)***. Cyclohexene (8.3 ml, 82 mmol) was added dropwise to BH_3-dimethylsulfide complex (4.0 ml, 40 mmol) in 50 ml of THF at 0°C under Ar. The mixture was warmed to room temperature for 2 hr, then cooled to 0°C again, followed by dropwise addition of 4.06 g (20 mmol) of bromoalkyne **3** to the white slurry. The mixture was warmed to room temperature, stirred 2 hr, then cooled in an icebath while glacial acetic acid (16 ml) was added. The mixture was stirred overnight, then cooled in an icebath during sequential slow addition of 5 M NaOH (60 ml) and 30% H_2O_2 (16 ml; Caution: Exothermic). The resulting mixture was diluted with water, extracted twice with hexane, and the hexane extracts were washed with brine, dried, and concentrated. The more volatile fraction of the residue (∼4 g) was removed by careful Kugelrohr distillation, oven temperature 30–35°, ∼0.4 mm Hg. The remaining liquid (∼6 g) was purified by vacuum flash chromatography in a 150-ml sintered glass funnel, eluting with hexane. The purified bromoalkene was Kugelrohr distilled (oven temperature ∼50°C, 0.4 mm Hg), yielding 2.22 g of **4** as a colorless oil. The yield was not optimized, and the volatile fraction removed before chromatography contained approx. 25% of the bromoalkene. NMR: δ 5.49–5.62 (m, 2H), 3.42 (t, 2H, $J = 6.5$ Hz), 2.20 (br. quart, 2H, $J = 7.3$ Hz), 2.1–2.0 (m, 2H), 1.92 (quint, 2H, $J = 6.9$ Hz), 1.4–1.28 (m, 4H). MS: *m*/*z* 204/206 (4/4, M+), 162/164 (4/4), 148/150 (9/9), 135 (4), 109 (4), 95 (9), 83 (20), 81 (21), 69 (46), 55 (78), 41 (100).

*(*Z*)-9-Tetradecen-4-yn-1-ol **(6)***. Butyllithium (6.4 ml of a 2.5 M solution in hexanes; 16 mmol) was added to a solution of THP-protected pentynol **5** (2.54 g, 15 mmol) in THF (25 ml) at −10°C, under Ar. The solution was stirred 20 min, followed by sequential addition of 1,3-dimethyl-3,4,5,6-tetrahydro-2(1H)-pyrimidinone (DMPU, 8 ml) and bromoalkene **4** (2.05 g, 10 mmol). The reaction was warmed to room temperature and stirred overnight, then poured into water and extracted with hexane. The hexane extract was washed with dilute HCl, water, and brine; dried; and concentrated. The residue was taken up in 25 ml MeOH, and *p*-toluenesulfonic acid was added until the solution became acidic to moistened litmus paper. The mixture was stirred at room temperature until the transacetalization reaction was complete (∼2 hr), the reaction was quenched by addition of 1 g $NaHCO_3$, and the solvent was removed on a rotary evaporator. The residue was partitioned between hexane and water, and the hexane extract was washed with brine, dried, and pumped under vacuum (0.1 mm Hg) to remove the THP methyl ether byproduct. The crude enynol **6** (96% pure by GC) was used without further purification. NMR: δ 5.46–5.28 (m, 2H), 3.77 (t, 2H, $J = 6.1$ Hz), 2.29 (tt, 2H, $J = 6.8$, 2.3 Hz), 2.19–1.95 (m, 6H), 1.75 (quint, 2H, $J = 6.4$ Hz), 1.54 (quint, 2H, $J = 7.3$ Hz), 1.39–1.25 (m, 4H), 0.91 (t, 3H, $J = 6.9$ Hz). MS: *m*/*z* 164 (2), 149

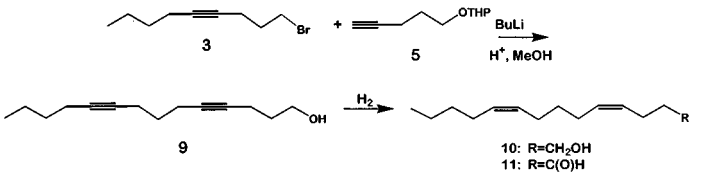
(8), 137 (16), 121 (17), 119 (18), 108 (44), 107 (21), 105 (22), 93 (49), 91 (50), 79 (61), 67 (59), 55 (65), 41 (100).

*(*E*4,*Z*9) -Tetradecadienol **(7)***. $LiAlH_4$ (2 g, 53 mmol) was added in portions to an ice-cooled mixture of dry diglyme (20 ml) and THF (2.5 ml) under Ar. When the vigourous foaming had subsided, 2 g of the crude enynol **6** (∼9.6 mmol) in 5 ml diglyme was added to the thick slurry. When the foaming had subsided, the mixture was heated to 110°C overnight. The next morning, the mixture was cooled to 0°C, then hexane (150 ml) was added, followed sequentially by cautious dropwise addition of 2.1 ml water (Foams!), 1.6 ml 20% NaOH, and 7.5 ml water. The mixture was stirred for 15 min to allow the precipitate to granulate, then the hexane layer was decanted, and the residue was rinsed several times with aliquots of hexane. The combined hexane solutions were washed several times with water and once with brine, then dried and concentrated. The residue was purifed by flash chromatography (2.5 × 25 cm), eluting with a stepwise gradient of 15–25% EtOAc in hexane. The purifed product was Kugelrohr distilled (bp ∼80°C at 0.1 mm Hg), yielding 1.1 g of (*E*4,*Z*9)-tetradecadienol **7**. NMR: δ 5.48–5.41 (m, 2H), 5.41–5.32 (m, 2H), 3.66 (t, 2H, $J = 6.5$ Hz), 2.12–1.94 (m, 8H), 1.64 (quint, 2H, $J = 6.9$ Hz), 1.40 (quint, 2H, $J = 7.5$ Hz), 1.36–1.25 (m, 4H), 0.91 (t, 3H, $J = 6.9$ Hz). MS: *m*/*z* 210 (trace, M^+), 138 (5), 135 (4), 121 (6), 110 (9), 95 (22), 82 (25), 81 (50), 79 (59), 67 (61), 55 (62), 41 (100).

*(*E*4,*Z*9)-Tetradecadienal **(8)***. Dienol **7** (0.42 g, 2 mmol) was added to a slurry of pyridinium dichromate (2.26 g, 6 mmol) and powdered 3Å molecular sieve (2 g) in CH_2Cl_2 (12 ml) (Herscovici et al., 1982). The mixture was stirred vigourously for 30 min, then diluted with 50 ml hexane. After stirring for 5 min, the mixture was filtered, decolorized with ∼2 cc decolorizing charcoal, filtered again, and concentrated. A few milliliters of toluene were added to the residue, which was concentrated again to azeotrope out traces of pyridine. The clear liquid was then Kugelrohr distilled (oven temperature 80–105°C, 0.1 mm Hg), yielding 325 mg of aldehyde **8**, >98% pure by GC. The aldehyde was diluted with hexane to a concentration of 20 mg/ml, butylated hydroxytoluene was added (∼10 mg), and the solution was stored at −20°C under N_2. NMR: δ 9.77 (t, 1H, $J = 1.2$ Hz), 5.54–5.28 (m, 4H), 2.50 (tt, 2H, $J = 6.9$,1.2 Hz), 2.34 (br. quart., 2H, $J = 6.5$ Hz), 2.0 (m, 6H), 1.46–1.28 (m, 6H), 0.91 (t, 3H, $J = 7.0$ Hz). MS: *m*/*z* 208 (trace, M^+), 164 (3), 151 (2), 135 (3), 121 (4), 110 (10), 95 (19), 82 (33), 81 (34), 67 (60), 55 (71), 41 (100).

*Synthesis of (*Z*4,*Z*9)-Tetradecadienal **(11)** (Scheme 2)*

*4,9-Tetradecadiynol **(9)***. Butyllithium (10 ml of 2.5 M solution in hexanes, 25 mmol) was added dropwise to an icebath-cooled solution of 4-pentyn-1-ol THP ether **5** (4.2 g, 25 mmol) in 25 ml THF under Ar. The mixture was stirred 10 min, then bromoalkyne **3** (5.1 g, 25 mmol) was added. The mixture was warmed to



SCHEME 2

55°C and stirred overnight. GC analysis showed considerable quantities of starting material remaining. However, further heating resulted in no change in the product–starting material ratio so the mixture was worked up by quenching with water and extracting with hexane. The hexane extracts were washed with brine, dried, and concentrated. The residue was transacetalated by treatment with MeOH and PTSA as described above. The crude diynol **9** (3 g) was purified by vacuum flash chromatography in a 150-ml sintered glass funnel, eluting with 20% EtOAc in hexanes. The purified alcohol was Kugelrohr distilled (oven temperature ∼100–120°C, 0.1 mm Hg), yielding 2.1 g of clear oil. NMR: δ 3.76 (t, 2H, $J = 6.2$ Hz), 2.33–2.22 (m, 6H), 2.14 (tt, 2H, $J = 7.0$, 2.1 Hz), 1.74 (quint, 2H, $J = 6.3$ Hz), 1.67 (quint, 2H, $J = 7.0$ Hz), 1.52–1.33 (m, 4H), 0.91 (t, 3H, $J = 7.1$ Hz). MS: *m*/*z* 177 (3), 163 (35), 150 (11), 135 (16), 131 (14), 119 (27), 117 (29), 105 (40), 91 (100), 79 (57), 67 (41), 55 (45), 41 (94).

*(Z4,Z9)-Tetradecadienol **(10)***. $Ni(OAc)_2 \cdot 4H_2O$ (150 mg, 0.6 mmol) was dissolved in 20 ml 95% EtOH (Brown and Ahuja, 1973). The solution was purged with Ar, then 0.6 ml of a filtered 1 M solution of $NaBH_4$ (prepared by dissolving 0.2 g $NaBH_4$ in 4.75 ml EtOH and 0.25 ml 2 M aq. NaOH) was added by syringe. After bubbling ceased, the reaction vessel was flushed with H_2 and maintained under H_2 for the duration of the reduction. Ethylene diamine (0.1 ml) was added, followed 5 min later by addition of diynol (1.04 g, 5 mmol). The mixture was stirred 2 hr, monitoring by GC, then poured into 300 ml of 0.2 M HCl and extracted with hexane. The hexane extracts were washed with water and brine, dried, concentrated and Kugelrohr distilled (oven temperature ∼110–120°C, 0.1 mm Hg), yielding 0.85 g of dienol **10**. NMR: δ 5.48-5.33 (m, 4H), 3.67 (t, 2H, $J = 6.5$ Hz), 2.12 (br. quart, 2H, $J = 7.5$ Hz), 2.10–1.98 (m, 6H), 1.64 (quint, 2H, $J = 7.0$ Hz), 1.42 (quint, 2H, $J = 7.6$ Hz), 1.38–1.28 (m, 4H), 0.91 (t, 3H, $J = 6.8$ Hz). MS: *m*/*z* 210 (trace, M^+), 138 (5), 135 (4), 121 (8), 110 (8), 95 (27), 82 (27), 81 (49), 79 (58), 67 (65), 55 (70), 41 (100).

(*Z4,Z9*)-*Tetradecadienal **(11)***. (*Z*4,*Z*9)-tetradecadienol **10** (20 mg) was oxidized to the aldehyde as described above for the *E*4,*Z*9-isomer. The crude aldehyde **11** was purified by passage through a short column of silica gel in a disposable pipet, eluting with ether. NMR: δ 9.78 (t, 1H, $J = 1.4$ Hz), 5.49–5.29 (m, 4H), 2.50 (tt, 2H, $J = 7.3$,1.3 Hz), 2.38 (br quart, 2H, $J = 7.0$ Hz), 2.11–1.99 (m, 6H), 1.48–1.20 (m, 6H), 0.91 (t, 3H, J = 7.0 Hz).

Scrambling of Double Bonds of (Z4,Z9)-Tetradecadienol (Sonnet, 1974). (*Z*4,*Z*9)-tetradecadienol **10** (0.21 g, 1 mmol) was mixed with 52 μl 2M aq. $NaNO_2$ and 36 μl 6M HNO_3 in a heavy-wall conical bottomed vial, and the mixture was flushed with Ar, sealed, and heated 45 min at 75°C with stirring. The cooled mixture was extracted with hexane, and the hexane solution was washed with dilute $NaHCO_3$, water, and brine; simultaneously dried and decolorized with a mixture of charcoal and anhyd. Na_2SO_4; filtered; and concentrated. The crude mixture was used in the next step.

4,9-Tetradecadienal Isomer Mixture. The mixture of 4,9-tetradecadienol isomers was oxidized as described above for (*E*4,*Z*9)-tetradecadienal. In GC analyses of the two pure isomers and the scrambled mixture, all four isomers were distinguishable on the DB-5 and DB-Wax columns using a 5°C/min temperature program. The isomers were identified by comparison with the two authentic standards (*Z*4,*Z*9 and *E*4,*Z*9), and on the assumption that the most abundant isomer in the scrambled mixture would be the most thermodynamically stable *E*4,*E*9-isomer. By elimination, the fourth isomer was *Z*4,*E*9–14 : Ald.

RESULTS

Pheromone gland extracts of females contained only a single compound that elicited large and consistent responses from male antennae in coupled GC-EAD experiments, for all three species (Figure 1). The compound was the same for all

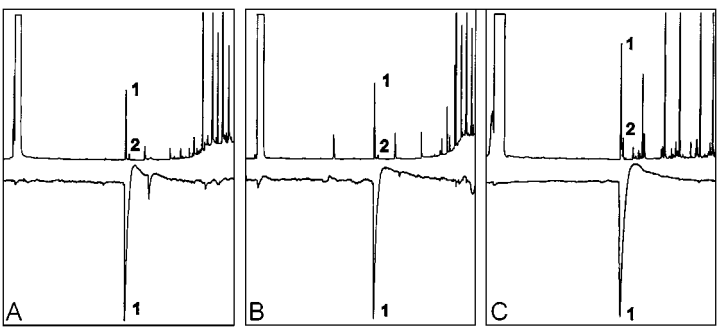


FIG. 1. Coupled gas chromatogram–electroantennograms of pheromone gland extracts from single females and antennae from males of : (A) *Saturnia walterorum*, (B) *S. mendocino*, and (C) *S. albofasciata*. Column: DB-5 (30 m × 0.32 mm, 0.25-μm film; program for *S. walterorum*, 100°C for 0 min, 15°C/min to 275°C for 25 min; for *S. mendocino*, 100°C for 1 min, 15°C/min to 150°C for 5 min, then 25°C/min to 275°C for 40 min; for *S. albofasciata*, 100°C for 1 min, 10°C/min to a final temperature of 275°C for 25 min. The male *S. albofasciata* was field collected using a lure containing *E*4,*Z*9–14 : Ald at Thomas Mountain, Riverside County, California.

three species, based on identical retention times on polar and nonpolar columns. On a nonpolar DB-5 column, the retention time was slightly shorter than that of a *Z*9–14 : Ald standard. Furthermore, during preliminary trials to determine the retention characteristics of the antennal stimulatory compound on various GC columns, it was discovered that the *Z*9–14 : Ald standard elicited strong responses from male moth antennae, providing circumstantial evidence that the insect-produced compound was probably a 14-carbon aldehyde, possibly with a double bond in the 9 position. The fact that the retention time of the insect-produced compound was slightly shorter than that of *Z*9–14 : Ald eliminated the possibility that the compound might be an α, β-unsaturated aldehyde or a conjugated dienal, because both of these structural units result in significant increases in retention times on DB-5 columns versus a monoenal (Marques et al., 2000). The mass spectrum also suggested a C_{14} dienal, with a small molecular ion at *m*/*z* 208, a small ion at *m*/*z* 190 from loss of water from the M^+ ion, and abundant ions at *m*/*z* 67 (100%), 81 (70%), 95 (43%), and 110 (30%), characteristic of unsaturated hydrocarbon fragment ions.

Further GC-EAD studies were carried out with the complete series of (*Z*)- and (*E*)-tetradecenal isomers with double bonds in the C_3 to C_{12} position, using *S. mendocino* as the test species. These experiments provided compelling evidence for a *Z* double bond at C_9, with male moth antennae being strongly stimulated by the *Z*9–14 : Ald standard (Figure 2). However, the slightly shorter retention time of the insect-produced compound (10.32 min) versus the *Z*9–14 : Ald standard (10.62 min) on the nonpolar DB-5 column, and the slightly longer retention time (11.35 min) versus *Z*9–14 : Ald (11.19 min) on a polar DB-225 column suggested the presence of a second, unconjugated double bond. The most likely position and geometry appeared to be *E*4, based on the GC-EAD trials with tetradecenal standards (Figure 2), but the antennal responses to *E*4-14 : Ald were much smaller than those to the *Z*9–14 : Ald standard. On the assumption that alkenes with double bonds in the 7, 8, 10, and 11 positions could be excluded because this would result in conjugated dienes with significantly longer retention times than the monoenes; a second analysis of treatments 3, 4, 5, 6, and 12 (Figure 2) showed that response to *E*4–14 : Ald was significantly larger than the responses elicited by the other possible isomers with double bonds at positions 3, 5, 6, and 12.

Comparison of the retention times of authentic *E*4,*Z*9–14 : Ald on polar and nonpolar GC columns with those of the other three stereoisomers confirmed that *E*4,*Z*9–14 : Ald was the isomer in the female extracts of all three species. On DB-5 all four isomers were resolved using a 5°C/min ramp (*ZZ* = 15.47, *ZE* = 15.51, *EZ* = 15.59, and *EE* = 15.72 min), and an exact retention time match with *E*4,*Z*9–14 : Ald was obtained upon coinjection of standards and an *S. walterorum* female extract. On DB-Wax, all four isomers also were resolved (*ZE* = 10.89, *ZZ* = 10.94, *EZ* = 11.02, and *EE* = 11.11 min), and the retention time of the insect-produced compound exactly matched that of *E*4,*Z*9–14 : Ald. Final proof of

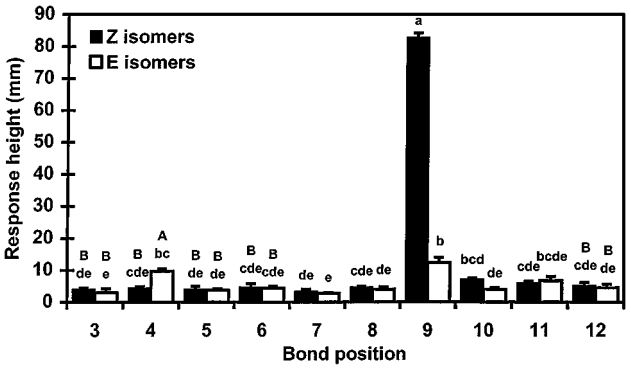

FIG. 2. Mean (±SE) electroantennographic responses from antennae of three male *S. mendocino* to monounsaturated tetradecenals. Data were analyzed first by two-way ANOVA of all data points ($\log_{10} x + 1$ transformed) (bond position effect, $F = 20.55$, $df = 19,38$, $P < 0.0001$; for male effect $F = 9.91$, $df = 2,38$, $P = 0.0003$) followed by a Student-Neuman-Kuels means separation test ($\alpha = 0.05$); bars surmounted by different lowercase letters were significantly different. Second, the data were reanalyzed, assuming that one double bond was at C-9, and that the compound was not conjugated or an allene, so that only the C-3–C-6 and the C-12 positions were included in the two-way ANOVA (for bond position effect $F = 13.4$, $df = 8,26$, $P < 0.0001$; for male effect $F = 26$, $df = 2,26$, $P = 0.0001$) and Student-Neuman-Kuels means separation test ($\alpha = 0.05$, bars surmounted by different uppercase letters are significantly different).

the structure was obtained from match-up of the electron impact mass spectrum of the compound with that of the standard and by the strong responses of male moths to *E*4,*Z*9–14 : Ald in field trials.

In addition to the dienal, pheromone gland extracts of all three species contained small amounts of *Z*9–14 : Ald (compound 2 in Figure 1A–C). The antennal responses to this compound were not resolved from those of the slightly earlier eluting *E*4,*Z*9–14 : Ald. The identification was confirmed by matching of retention times on three GC columns, and matching of the mass spectra with that of an authentic standard. Although the molecular ion at *m*/*z* 210 was not seen, there was a significant ion at *m*/*z* 192 from loss of water from the parent ion. Furthermore, match-up of retention times on both DB-5 and DB-Wax columns excluded all other monoene aldehyde positional and geometrical isomers from consideration (Marques et al., 2000). The relative amount of *Z*9–14 : Ald as a percentage of *E*4,*Z*9–14 : Ald for *S. walterorum* was 9.7 ± 2.6 % (mean of eight single-female extracts) and 10.9% for a four-female composite extract, whereas the amounts found in single extracts of *S. mendocino* and *S. albofasciata* females was 9.3% and 19.5%, respectively.

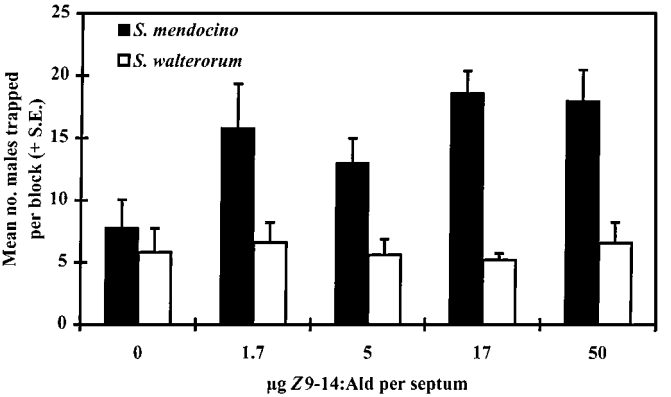

FIG. 3. Results of *S. mendocino* and *S. walterorum* field trials using blends of *E*4,*Z*9–14 : Ald (100 μg) and *Z*9–14 : Ald as trap lures. *S. mendocino* field trials were conducted in Amador County, California from April 27 to May 10, 1997, with a total of 381 moths trapped. Two-way ANOVA for *Z*9–14 : Ald dose effect, $F = 2.733$, $df = 4,16$, $P = 0.0633$, for block effect, $F = 0.909$, $df = 4,16$; $P = 0.4824$. *S. walterorum* field trials conducted in San Diego County, California from March 27 to April 24, 1997, total of 149 moths trapped. Two-way ANOVA for *Z*9–14:Ald dose effect, $F = 0.128$, $df = 4,16$; $P = 0.9702$, for block effect, $F = 4.203$, $df = 4,16$; $P = 0.0163$.

A second EAD response was seen sporadically to a trace component in *S. walterorum* extracts. This compound was not identified, but comparisons of its retention time on a DB-5 column with those of standards determined that it was possibly *E*4,*Z*9–14 : OH or a geometrical isomer, a compound that might be expected to be present as a precursor to *E*4,*Z*9–14 : Ald.

Field Trials. Sticky traps baited with synthetic *E*4,*Z*9–14 : Ald (100 μg) were attractive to male *S. mendocino* and *S. walterorum* moths (Figure 3). For both species, addition of *Z*9–14 : Ald did not significantly increase the attractiveness of blends relative to the diene alone. These results were corroborated for *S. mendocino* in a subsequent field trial in Del Puerto Canyon, in which there was no difference in attractiveness between baits containing *E*4,*Z*9–14 : Ald alone and baits with a 10 : 1 blend of *E*4,*Z*9–14 : Ald + *Z*9–14 : Ald (2-way ANOVA, for blend effect: $F = 0.0101$, $df = 1,9$, $P = 0.9221$, for block effect $F = 1.2018$, $df = 9,9$, $P = 0.3944$, based on totals of 100 moths in the treatment with *Z*9–14 : Ald, and 90 moths in the treatment without *Z*9–14 : Ald). Thus, the available data suggest that *Z*9–14 : Ald is not a pheromone component for these two species.

In a single field trial with *S. albofasciata*, three traps baited with *E*4,*Z*9–14 : Ald (100 μg) caught a total of 151 moths in one night whereas the control traps caught no moths. This number may underestimate the attractiveness of the lures because the sticky trap surfaces were completely covered with moths. In addition,

males showed no hesitation in approaching lures, and, when in close proximity, were observed to initiate copulatory attempts with lures, further suggesting that the pheromone consists of a single component.

DISCUSSION

There have been few reports of 14-carbon 4,9-diene compounds as lepidopteran pheromone components, and even in those few reports, details have been sketchy. For example, Bestmann et al. (1987a) identified *E*4,*Z*9–14 : Ac in pheromone gland extracts from the silk moth *Antheraea pernyi*, and located a large-spiking antennal cell that was stimulated by this compound. However, the effects of this compound on male moth behavior were not reported. A second study by Bestmann et al. (1987b) examining the effects of differing functional groups on the responses of single receptor cells used both *E*4,*Z*9–14 : Ac and *E*4,*Z*9–14 : Ald, but in neither case were the syntheses of the compounds reported. Tomida et al. (1987) prepared all four 4,9–14 : OH isomers and tested the formate derivatives in laboratory bioassays as mimics of E6,Z11-16 : Ald, a sex pheromone component of the eri-silk moth *Philosamia cynthia ricini*; no synthetic details were given. Other syntheses of *E*4,*Z*9–14 : OH (Sharma et al., 1990; Du et al., 1994) and Z4,*Z*9–14 : OH (Ducoux et al., 1992) have been published, but there have been no other reports of biological activity associated with any C_{14} 4,9-dienes as lepidopteran pheromone components.

The numbers of moths of each of the three *Saturnia* species available for study varied. Pheromone gland extracts were obtained from 21 female *S. walterorum* and five female *S. mendocino*, providing sufficient material for GC and GC-EAD analyses on several columns and GC-MS studies. In contrast, only a single extract from a female *S. albofasciata* was obtained, due to the relative scarcity of this species and difficulties in rearing it. This extract provided only sufficient material for GC-EAD analysis on a DB-5 column. Nevertheless, given that the retention time exactly matched that of *E*4,*Z*9–14 : Ald and that all four 4,9–14 : Ald stereoisomers were separable under the conditions used, there can be little doubt that *E*4,*Z*9–14 : Ald is indeed a sex pheromone component for this species.

All three species appear to use the same, single compound as their pheromone, leading in theory to the possibility of interspecific interference in the pheromone channels. However, the flight period of *S. albofasciata* is in the fall, whereas the other two species fly in the spring, precluding any interference between *S. albofasciata* and the other two species. Furthermore, experimental manipulation of *S. walterorum* to encourage unnatural fall emergence of adults by exposing pupae to an artificially lengthened cold period (November of one year until October of the next) resulted in *S. walterorum* males that were attracted to and attempted to mate with *S. albofasciata* females and vice versa (K. Wolfe and C. Conlan, personal

communication, 2000), despite gross differences in size. No copulations occurred due to the physical incompatibility of the two species. Nevertheless, these results suggest that separation in time provides an effective barrier to interspecific mating between these two species, allowing them to share the same sex pheromone with no fitness cost. For the other two species, only small parts of their ranges overlap, and the two species are closely related and known to hybridize (Tuskes and Collins, 1981), so the costs of cross-attraction may be minimal. Overall, it is clear that the pheromone chemistry is highly conserved within the North American members of the genus.

Furthermore, there are obvious parallels with the pheromone chemistry of other members of the Saturniinae subfamily. For example, the pheromone blends of *Antherea pernyi* Guérin-Méneville (Bestmann et al., 1987a) and the congeneric *A. polyphemus* Cramer (Kochansky et al., 1975) are reported to consist of *E*6,*Z*11–16 : Al and the corresponding acetate, both of which contain the same diene motif as *E*4,*Z*9–14 : Ald, but with two more carbons in the chain. *E*4,*Z*9–14 : Ac also was reported from *A. pernyi* gland extracts. In another genus and tribe, the pheromone blend of *Samia cynthia ricini* Donovan consists of *E*4,*Z*6,*Z*11–16 : Ald and *E*4,*Z*6,*Z*11–16 : Ac, again with two of the three double bonds in the same position relative to the nonfunctionalized end of the chain. Finally, Bestmann et al. (1982) mentioned that *E*6,*Z*11–16 : Ac was attractive to *Eudia* (= *Saturnia*) *pavonia*, but provided no further details.

In conclusion, we have presented spectroscopic, retention time, and field trapping data that indicate that the three North American *Saturnia* species share the same sex pheromone component, *E*4,*Z*9–14 : Ald. Possible negative effects of cross-attraction between species are largely avoided by temporal and geographic barriers that keep the species apart in space and time.

Acknowledgments—We thank Christopher Conlan and Kirby Wolfe for their generous donations of insects and for sharing unpublished information used in this study.

CAN SIMULTANEOUS INHIBITION OF SEEDLING GROWTH AND STIMULATION OF RHIZOSPHERE BACTERIAL POPULATIONS PROVIDE EVIDENCE FOR PHYTOTOXIN TRANSFER FROM PLANT RESIDUES IN THE BULK SOIL TO THE RHIZOSPHERE OF SENSITIVE SPECIES?

Abstract—In order to demonstrate that allelopathic interactions are occurring, one must, among other things, demonstrate that putative phytotoxins move from plant residues on or in the soil, the source, through the bulk soil to the root surface, a sink, by way of the rhizosphere. We hypothesized that the incorporation of phytotoxic plant residues into the soil would result in a simultaneous inhibition of seedling growth and a stimulation of the rhizosphere bacterial community that could utilize the putative phytotoxins as a sole carbon source. If true and consistently expressed, such a relationship would provide a means of establishing the transfer of phytotoxins from residue in the soil to the rhizosphere of a sensitive species under field conditions. Presently, direct evidence for such transfer is lacking. To test this hypothesis, cucumber seedlings were grown in soil containing various concentrations of wheat or sunflower tissue. Both tissue types contain phenolic acids, which have been implicated as allelopathic phytotoxins. The level of phytotoxicity of the plant tissues was determined by the inhibition of pigweed seedling emergence and cucumber seedling leaf area expansion. The stimulation of cucumber seedling rhizosphere bacterial communities was determined by the plate dilution frequency technique using a medium containing phenolic acids as the sole carbon source. When sunflower tissue was incorporated into autoclaved (to reduce the initial microbial populations) soil, a simultaneous inhibition of cucumber seedling growth and stimulation of the community of phenolic acid utilizing rhizosphere bacteria occurred. Thus, it was possible to observe simultaneous inhibition of cucumber seedlings and

stimulation of phenolic acid utilizing rhizosphere bacteria, and therefore provide indirect evidence of phenolic acid transfer from plant residues in the soil to the root surface. However, the simultaneous responses were not sufficiently consistent to be used as a field screening tool but were dependent upon the levels of phenolic acids and the bulk soil and rhizosphere microbial populations present in the soil. It is possible that this screening procedure may be useful for phytotoxins that are more unique than phenolic acids.

Key Words—Allelopathy, bulk-soil and rhizosphere bacteria, *Cucumis sativus, Helianthus annuus, Triticum aestivum, Amaranthus retroflexus,* phenolic acid mixtures, chlorogenic acid, phytotoxicity.

INTRODUCTION

In order to establish that inhibitory plant–plant allelopathic interactions are operative in the field, one must demonstrate, among other things, that potential organic phytotoxins released into the soil by living plants (e.g., root exudates, leachates) or plant residues contact the roots of a sensitive plant (Willis, 1985; Blum et al., 1999). Because of the lack of direct access to roots and the dynamic nature of field soil processes (e.g., sorption, oxidation, microbial interconversion, polymerization, and leaching of phytotoxins in soils), direct tracing of the movement of phytotoxins from living plants or plant residues to the roots of another plant in the soil is extremely difficult, if not impossible. Establishing that such transfer actually occurs under field conditions is an essential step in demonstrating the existence and importance of allelopathic interactions. At present, no definitive data on direct transfer of phytotoxins between living roots of one plant (and/or plant residue) to another plant root system have been obtained under field conditions. The objective of this research was to determine if evidence for such a transfer could be obtained.

Research by Blum and Shafer (1988), Shafer and Blum (1991), and Blum et al. (2000) suggested such a means. They observed that phenolic acid enrichments of soils inhibited cucumber seedling growth and stimulated both bulk soil and rhizosphere microorganisms. Of particular interest was the observed increase of bacteria in the rhizosphere that could utilize phenolic acids as a sole carbon source. Assuming that phytotoxic levels of phenolic acids released from plant residues in the field would also increase phenolic acid-utilizing bacteria in the rhizosphere of sensitive species, such increases could provide the first evidence for the transfer of phytotoxic concentrations of phenolic acids from the bulk soil to the rhizosphere. We, therefore, hypothesized that phenolic acids released at phytotoxic levels from living plants or plant residues should simultaneously inhibit the growth of sensitive plant species and stimulate phenolic acid utilizing bacteria within the rhizosphere of sensitive species.

We initially chose to test this hypothesis in the laboratory using field grown wheat shoot and root tissue and sunflower leaf tissue, since a variety of potential

phytotoxins, including phenolic acids, have been identified for wheat (Chou and Patrick, 1976; Liebl and Worsham, 1983; Barnes et al., 1986; Blum et al., 1991) and sunflower (Armstrong et al., 1970, 1971; Hall et al., 1982, 1983; Macias et al., 1993, 1998, 1999). Among the phenolic acids that have been identified for these species are ferulic acid, *p*-coumaric acid, vanillic acid, *p*-hydroxybenzoic acid, and chlorogenic acid. Since wheat and sunflower tissue phytotoxicity has been characterized by inhibition of several weed species, including pigweed, pigweed seedling emergence was used to characterize wheat and sunflower tissue phytotoxicity (Blum et al., 1997; Lehman and Blum, 1997). Simultaneous inhibition of growth and stimulation of rhizosphere bacteria, however, was determined for cucumber seedlings to be consistent with earlier observations of Shafer and Blum (1991) and Blum et al. (2000).

METHODS AND MATERIALS

Plant Tissue and Soil Materials. Living wheat (*Triticum aestivum* L. Southern States 555) roots and shoots were collected on May 15, 1997, and June 8 and 9, 1998, from experimental plots at the Lake Wheeler Field Laboratory, approximately 5 km south of North Carolina State University. Roots and shoots were immediately separated, and the remaining soil was removed from freeze-dried roots with a fine bristle brush. Sunflower leaves (*Helianthus annuus* cv. Black Oil) were collected in July 1999 from plots 20 miles west of North Carolina State University. Freeze-dried plant tissue samples were stored in closed plastic bags at room temperature in the dark. On May 7, 1998, Cecil A_p horizon soil material (pH 5.06, total C = 2.24%, and total N = 0.21%) was collected from plots adjacent to the wheat plots. This soil was sieved (2.5-mm mesh), air dried, and stored at room temperature in the laboratory. Prior to each experiment, wheat shoot, wheat root, and/or sunflower leaf blade tissue was ground in a Wiley mill (20-mesh screen). A range of 0–10 mg/g soil of the plant tissue collected in 1997 and/or 1998 was incorporated into a 150 g mixture of washed river sand and the Cecil A_p soil (2:1 sand to soil ratio, w/w).

Pigweed Seedling Emergence. Plant tissue–soil mixtures (150 g/Petri dish) were placed into 100 × 25-mm Petri dishes. Petri dishes were used to provide sufficient surface area for planting the pigweed seeds. The dishes were seeded just below the soil surface with 50 pigweed seeds (*Amaranthus retroflexus* L.; Azland Seed Service, Leland, Mississippi), and the loosely covered Petri dishes were placed under a light bank (140 μmol/m^2/sec PAR supplied by cool white florescent bulbs, 12-hr photoperiod, room temperature). All Petri dishes were watered to 0.093 g H_2O/g soil each day.

Emerging pigweed seedlings were counted each day and removed from the Petri dishes. Lehman and Blum (1997) had previously determined that total

seedling emergence over six days was adequate for characterizing the phytotoxicity of wheat tissue, thus, the experiments were terminated after six days and cumulative (days 1–6) seedling emergence was calculated.

Phenolic Acid Utilizing-Bacteria in Bulk Soil. Petri dishes or cup systems (see below) containing soil and/or plant tissue–soil mixtures were placed under a light bank (140 μmol/m^2/sec PAR supplied by cool white florescent bulbs, 12-hr photoperiod, room temperature) and supplied with water to bring the water content of the soil to 0.093 g H_2O/g soil each day. Soil in Petri dishes or cup systems was subsampled to determine soil moisture (100°C) and in the presence of soil-borne bacterial populations that could utilize phenolic acids as a sole carbon source. Bacterial populations were determined on day 6 by the plate-dilution frequency technique (Harris and Sommers, 1968). Approximately 20 g of a given soil sample plus 30 ml of a solution containing 8.5 g/liter NaCl and 0.1% agar were shaken on a wrist action shaker for 30 min. The resulting soil suspensions were diluted (10-fold series) to 1×10^{-9} or 1×10^{-10} using the aqueous agar–NaCl solution. Colony forming units (CFU) were determined on an agar (15g/liter) medium composed of mineral salts (1 g/liter KH_2PO_4, 0.4 g/liter $MgSO_4 \cdot 7H_2O$, 0.13 g/liter $CaCl_2 \cdot 2H_2O$, 0.1 g/liter NaCl, 0.01 g/liter $FeCl_3$, 0.5 g/liter KNO_3), Delvocid (0.05g/liter natamycin, an antimycotic; G B Fermentation Industries, Inc. Charlotte, North Carolina), and a 0.5 mM phenolic acid mixture composed of 0.071 mM caffeic, ferulic, *p*-coumaric, *p*-hydroxybenzoic, sinapic, syringic, and vanillic acids, or a 0.5 mM phenolic acid mixture composed of 0.125 mM ferulic, *p*-coumaric, *p*-hydroxybenzoic, and vanillic acids. Inoculated plates were incubated in the dark in closed plastic bags at 30°C. CFU were determined after six or seven days of bacterial growth.

Cucumber Seedling Growth and Phenolic Acid-Utilizing Bacterial Populations in the Rhizosphere. Cucumber seeds (*Cucumis sativus* cv. Early Green Cluster; Wyatt Quarles Seed Company, Raleigh, North Carolina) were germinated in the dark at 30°C in a tray containing vermiculite and distilled water. After 48 hr, seedlings were transferred to a light bank (140 μmol/m^2/sec PAR supplied by cool white florescent bulbs, 12-hr photoperiod, room temperature). After 48 hr in the light bank, seedlings were transplanted into cups containing 150 g of an autoclaved or nonautoclaved soil–sand mixture (Cecil Ap; 1 : 2 w/w) and 0–10 mg/g soil wheat or sunflower tissue collected in 1998 or 1999. For the autoclaved soil mixture, batches (approximately 3 kg) of the soil–sand mixture were autoclaved once for 30 min at 16–18 psi and 121°C in a 29 × 17-cm steel tray before placing 150 g into each cup. The autoclaving procedure was used not to sterilize the soil but to reduce the initial microbial populations. The initial log CFU per gram of soil for the autoclaved and nonautoclaved soil was 3.47 ± 0.02 (2945 actual CFU per gram soil) and 3.59 ± 0.01 (3912 actual CFU per gram soil), respectively.

In addition, soil–sand mixtures without plant tissue added were treated with 0.6 μmol/g soil (days 5, 7, 9, 11) of chlorogenic acid (a phenolic acid, pH 5) or

a phenolic acid mixture (equimolar solution of ferulic, *p*-coumaric, *p*-hydroxybenzoic, and vanillic acids, pH 5). The seedling cup systems (Blum et al., 1989) were also supplied with 7 ml double-strength Hoagland's solution (pH 5.0) on days 4, 6, 8, 10, 12, 14, and 16. Water (controls) or phenolic acids were added on alternate days. Systems were harvested on day 6, 7, 8, 10, 12, or 17. Water content of soil was brought up to 0.167 g H_2O/g soil each day.

Leaf areas for seedlings were nondestructively measured to calculate absolute rates of seedling leaf expansion over days 9–11, 9–12, 11–13, 13–15, and/or 15–17 (Blum et al., 1985). For each harvest at the termination of the experiment, shoot and root dry weights (100°C) were determined. Prior to dry weight determinations, the root systems were dipped three times in sterile deionized water to dislodge larger soil particles. Root systems with remaining rhizosphere soil were transferred to bottles containing 99 ml of a sterile solution composed of 8.5 g/liter NaCl, 0.1% aqueous agar, and 1 g of sand. Bottles were shaken on a platform shaker for 30 min. The resulting suspension of rhizosphere soil was diluted and assayed by the plate-dilution frequency technique (Harris and Sommers, 1968). Colony forming units (CFU) were determined on mineral agar medium (see previous section, "Phenolic Acid-Utilizing Bacteria in Bulk Soil" for details) containing either a 0.5 mM phenolic acid mixture composed of equimolar 0.125 mM ferulic, *p*-coumaric, *p*-hydroxybenzoic, and vanillic acids, or 0.5 mM chlorogenic acid (all at pH 5). The root systems were subsequently recovered from the dilution bottles to determine their dry weights. Shoots and roots were dried in an oven at 100°C. Then CFU per gram of root dry weight, seedling leaf area, and shoot and root dry weights were determined.

Plant Tissue Analysis. The phenolic acid content of the tissue was determined by the polyvinylpyrrolidone (PVP) method (Anderson and Todd, 1968). Tissue extracts were obtained by autoclaving 200 mg of ground tissue (Wiley mill, 60 mesh screen) in 50 ml deionized water. Extracts were filtered prior to phenolic acid analysis (Whatman No. 1) (Lehman and Blum, 1997).

Data Analyses. All data were subjected to analysis of variance and/or regression analysis using the Statistical Analysis Systems of JMP (SAS Institute, Cary, North Carolina). Means comparisons were made by the Tukey-Kramer HSD test. Alpha was set at 0.05 for all analyses. Analyses of CFU of bacterial populations that could utilize phenolic acids as a sole carbon source were all based on log CFU per gram soil or log CFU per gram root dry weight (Harris and Sommers, 1968; Loper et al., 1984). All experiments were organized in the light bank in a randomized complete block design. Calculations were as follows: Absolute rates of seedling leaf expansion (AGRSL) = [leaf area on day 11 (or 13, 15, 17) − leaf area on day 9 (or 11, 12, 15, respectively)]/2 or (leaf area on day 12 − leaf area on day 9)/3; % Inhibition of cumulative pigweed emergence or AGRSL = [(individual treatment unit − control mean)/control mean] ∗ 100; and % stimulation of CFU = [(individual treatment unit − control mean)/control mean] ∗ 100.

Experimental Objectives and Designs. The objectives for each experiment are provided in the Results section. The specific design for each experiment is provided in Table 1.

RESULTS

For comparative purposes, percent changes from the control are presented for cumulative pigweed seedling emergence, absolute rates of seedling leaf expansion (ARGSL), and shoot and root dry weights. For the sake of clarity, inhibitory effects are presented as negative values, while stimulatory effects are presented as positive values. Both soil and rhizosphere bacterial colony forming units (CFU) are presented as log CFU and actual CFU. However, all statistical analyses of CFU for bulk-soil and rhizosphere bacteria were based on log CFU (Harris and Sommers, 1968; Loper et al., 1984). The initial log CFU per gram soil for the autoclaved and non-autoclaved soil was 3.47 ± 0.02 (2945 actual CFU per gram soil) and 3.59 ± 0.01 (3912 actual CFU per gram soil), respectively. Finally, for all regression models the tissue concentrations added to soil are in milligrams per gram of soil and time is in days.

Experiment 1

The purpose of experiment 1 was to determine the effects of soil-incorporated wheat shoot and root tissue on pigweed seedling emergence (experiment 1a) and on bulk-soil bacterial populations that can utilize phenolic acids as a sole carbon source (experiment 1b). Wheat shoot and root tissues collected during May 1997 and June 1998 significantly reduced pigweed seedling emergence when these tissues ranging from 0 to 10 mg/g soil were incorporated into a Cecil A_p substrate (Figure 1). The main treatment effects of tissue type (shoot vs. root tissue), tissue concentration, and the interactions between tissue type $\times$ concentration were significantly different for pigweed emergence. The effects of collection time (1997 vs. 1998) of wheat tissues on seedling emergence, however, were not significantly different. The cumulative emergence of pigweed seedlings (over days 1–6) in soils without tissue incorporated (i.e., control; mean $\pm$ SE) was 27.5 ± 0.91 out of 50, or 55%.

The percent change in cumulative pigweed seedling emergence became more negative (i.e., more inhibitory) in a concave manner with increasing concentrations of wheat shoot tissue (Figure 1; % change in emergence $= 0 - [18.59 * \text{concentration}] + [1.08 * \text{concentration}^2]$; $P < 0.001$; $R^2 = 0.91$) and became more negative (i.e., more inhibitory) in a linear manner with increasing concentrations of wheat root tissue (Figure 1; % change in emergence $= 0.16 - [2.10 * \text{concentration}]$; $P = 0.009$; $R^2 = 0.27$). Soil-incorporated shoot tissues (-78% change for 10 mg/g soil) were more inhibitory to cumulative seedling emergence than root tissues (-21% change for 10 mg/g soil).

TABLE 1. EXPERIMENTAL DESIGNS

Exp.	System	Bioassay species	Autoclaved soil	Tissues and/ or phenolic acids	Concentration in soil	Treatment day[a]	Harvest day	C source of bacterial media	Rep

6	Cup	Cucumber and rhizosphere bacteria	yes	sunflower leaf, chlorogenic acid	0, 5 mg/g 0.6 μmol/g	4 5, 7, 9, 11	6, 7, 8, 10, 12	4 phenolic acid mixture chlorogenic acid	5/day

[a]Hoagland's solution was added every other day beginning with day 4 for all cucumber seedling experiments.
[b]All wheat shoot experiments used tissue collected in 1998 except 1a, which used tissue collected in 1997 and 1998. All sunflower experiments used leaf tissue collected in 1999. The sunflower petioles were removed, and only the leaf blade tissue was incorporated into the soil.
[c]Emerging seedlings were determined each day up to day 6 and summed to obtain a cumulative value for pigweed emergence.
[d]The following were determined for cucumber seedlings: shoot and root dry weight, and absolute leaf area on days 9, 11, 12, 13, 15, and/or 17.
[e]Soils were autoclaved only once to reduce soil-borne bacteria.
[f]Phenolic acid mixture and chlorogenic acid treatments were given on days 5, 7, 9, and 11.

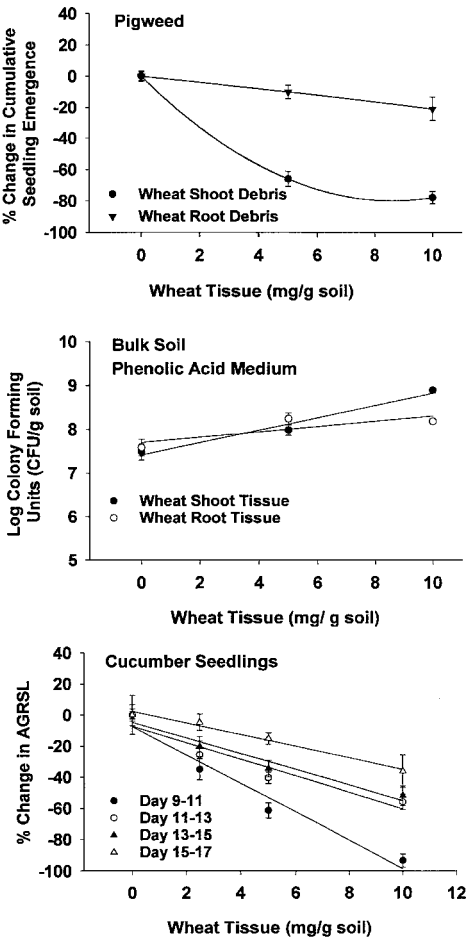

FIG. 1. Percent change in cumulative pigweed seedling emergence (Experiment 1a), log colony forming units of bulk soil bacteria (Experiment 1b) and percent change in cucumber seedling absolute growth rates of seedling leaf expansion (AGRSL) (Experiment 2) in the presence of soil-incorporated wheat shoot or root tissue. For the sake of clarity, inhibitory effects are presented as negative numbers while stimulatory effects are presented as positive numbers. Data in figures are means ± SE.

Wheat shoot and root tissues collected during June 1998 significantly stimulated the bulk-soil bacteria that could utilize phenolic acids as a sole carbon source when these tissues, ranging from 0 to 10 mg/g soil, were incorporated into the Cecil A_p substrate. Only the main treatment effects of concentration and the interactions between tissue type × concentration were significantly different.

Log bacterial colony forming units (Figure 1; log CFU on day 6) per gram of soil (bulk soil) increased linearly with increasing concentrations for both soil-incorporated shoot (log CFU $= 7.41 + [0.14 * \text{concentration}]$; $P < 0.001$; $R^2 = 0.84$) and root tissues (Figure 1; log CFU $= 7.70 + [0.06 * \text{concentration}]$; $P = 0.024$; $R^2 = 0.41$). The stimulatory effects of 10 mg/g soil-incorporated wheat shoot tissues were significantly greater (+2412% change in actual CFU per gram soil for 10 mg/g soil) than wheat root tissue (+298% change in actual CFU per gram soil for 10 mg/g soil). However, there were no significant differences in log CFU per gram of soil for incorporated wheat shoot and root tissue at 5 mg/g soil when compared to each other. The mean ± SE for CFU per gram for soils without tissue incorporated (i.e., control) was 7.58 ± 0.19 log CFU per gram of soil (3.8×10^7 actual CFU per gram soil).

Experiment 2

The purpose of experiment 2 was to determine the effects of soil-incorporated wheat shoot tissue on cucumber seedlings and on rhizosphere bacteria that can utilize phenolic acids as a sole carbon source. Soil-incorporated wheat shoot tissue (0–10 mg/g soil) collected during June 1998 significantly inhibited absolute rates of cucumber seedling leaf expansion (AGRSL) for seedlings measured over days 9–11, 11–13, 13–15, and 15–17 (Table 2, Figure 1). Percent changes for these intervals were −99%, −61%, −55%, and −35% for the 10 mg/g soil, respectively. Control AGRSL (mean ± SE) were 4.61 ± 0.53, 8.38 ± 0.57, 11.97 ± 0.46, and 13.56 ± 0.33 (cm^2/day), respectively.

Shoot dry weight determined on day 17 was significantly reduced (% change in shoot dry weight $= -9.25 - [4.64 * \text{concentration}]$; $P < 0.001$; $R^2 = 0.64$;

TABLE 2. PARTIAL REGRESSION COEFFICIENTS AND R^2 VALUES FOR PERCENT CHANGE IN AGRSL OF CUCUMBER SEEDLINGS GROWN IN PRESENCE OF SOIL-INCORPORATED WHEAT (EXPERIMENT 2) OR SUNFLOWER SHOOT TISSUE (EXPERIMENT 4C)

Growth period (days)	Intercept	Linear	Quadratic	R^2	P
Wheat shoot tissue					
9–11	−7.58	−9.12		0.80	<0.001
11–13	−7.21	−5.34		0.66	<0.001
13–15	−4.69	−5.05		0.71	<0.001
15–17	2.29	−3.75		0.54	<0.001
Sunflower shoot tissue					
9–11	2.07	−7.84		0.77	<0.001
11–13	5.85	−6.57		0.60	<0.001
13–15	12.33	−6.74		0.55	<0.001
15–17	0.58	+7.17	−1.19	0.64	<0.001

−56% change for 10 mg/g soil) by wheat shoot tissue. The soil-incorporated shoot wheat tissue had no effect on root dry weight or the rhizosphere bacteria of cucumber seedlings that could utilize phenolic acids as a sole carbon source. Shoot and root dry weights (mean ± SE) of cucumber seedlings and rhizosphere log CFU per gram root dry weight (day 17) for soils without incorporated tissue (i.e., control) were 248.88 ± 16.93 mg, 35.34 ± 3.79 mg, and 10.71 ± 0.41 log CFU per gram root (5.13×10^{10} actual CFU per gram root), respectively.

Experiment 3

The purpose of experiment 3 was to determine how cucumber seedlings and rhizosphere bacteria that can utilize phenolic acids as a sole carbon source respond over time (transplanted day 4; harvested days 6–12) in autoclaved (to reduce initial microbial populations) soil to soil-incorporated wheat shoot tissue or multiple soil applications of a phenolic acid mixture.

Soil-Incorporated Wheat Tissue. Wheat tissue (5 mg/g soil) had no negative effect on AGRSL (days 9–12 only measurement) and shoot and root dry weights. However, shoot and root dry weights increased over time (days 6–12) in an exponential manner: (a) shoot dry weight (mg) = 92.35 − [22.24 ∗ time] + [1.64 ∗ time^2]; $P < 0.001$; $R^2 = 0.88$, and (b) root dry weight (mg) = 16.59 − [3.60 ∗ time] + [0.27 ∗ time^2]; $P < 0.001$; $R^2 = 0.75$. Control mean ± SE for AGRSL (days 9–12) was 5.26 ± 0.24 cm^2/day. Control means ± SE for shoot and root dry weights for days 6–12 ranged from 16.46 ± 1.27 to 65.24 ± 3.59 mg, and from 4.26 ± 0.72 to 11.88 ± 1.06 mg, respectively.

The main treatment effects of time (days 6–12), soil-incorporated wheat shoot tissue (0 or 5 mg/g soil), and the interaction between incorporated shoot tissue and time significantly impacted log CFU per gram root of rhizosphere bacteria that utilize phenolic acids as a sole carbon source. The log CFU per gram cucumber root dry weight increased linearly over time for both soil with incorporated wheat shoot tissue (Figure 2; log CFU per gram root = 10.80 + [0.15 ∗ time]; $P = 0.004$; $R^2 = 0.30$) and without (Figure 2; log CFU per gram root = 10.23 + [0.16 ∗ time]; $P = 0.001$; $R^2 = 0.48$). Based on means comparisons, the log CFU per gram root were significantly higher than the controls only on days 7 (+496% change in actual CFU) and 12 (+333% change in actual CFU). The log CFU/per gram root for soil without incorporated wheat shoot tissue (i.e., control) on days 6, 7, 8, 10, and 12 was 11.04 ± 0.07, 11.56 ± 0.16, 11.38 ± 0.06, 12.16 ± 0.28, and 11.99 ± 0.07, respectively. Mean actual values ranged from 1.10×10^{11} to 1.44×10^{12} CFU per gram root.

Multiple Application of Phenolic Acid Mixture. The four-phenolic acid mixture (0.6 μmole/g soil) significantly impacted cucumber AGRSL (−24% ± 8 change; days 9–12) only when an outlier from the phenolic acid treatment was removed. No significant effects of the phenolic acid mixture were observed for

shoot and root dry weights over the 4 to 12-day period. However, both shoot (mg $= 51.12 - [12.34 * \text{time}] + [1.10 * \text{time}^2]$; $P < 0.001$; $R^2 = 0.88$) and root dry weight (mg $= -3.13 + [1.16 * \text{time}]$; $P < 0.001$; $R^2 = 0.69$ increased in an exponential and linear manner, respectively, with time. Control mean $\pm$ SE for AGRSL (days 9–12) was 5.26 ± 0.24 cm^2/day. Control means $\pm$ SE for shoot and root dry weights for days 6–12 ranged from 16.46 ± 1.27 to 65.24 ± 3.59 mg, and from 4.26 ± 0.72 to 11.88 ± 1.06 mg, respectively.

The main treatment effects of time (days 6–12), phenolic acid mixture (0 or 0.6 μmol/g soil), and the interaction between time and phenolic acid mixture significantly impacted log CFU per gram root dry weight of rhizosphere bacteria that utilize phenolic acids as a sole carbon source. The log CFU per gram root of the controls (no phenolic acid treatments) increased in a linear manner over time (Figure 2; log CFU per gram root $= 10.23 + [0.0163 * \text{time}]$; $P = 0.001$; $R^2 = 0.48$), while the log CFU per gram root increased in an asymptotic manner when the phenolic acid mixture (0.06 μmol/g soil) was applied to the soil (log CFU per gram root $= 4.21 + [1.50 * \text{time}] - [0.06 * \text{time}^2]$; $P < 0.001$; $R^2 = 0.83$). Based on means comparisons, the log CFU per gram root values were significantly higher than the controls on days 8 (+626% change in actual CFU per gram root) and 12 (+1029% change in actual CFU per gram root). The values of log

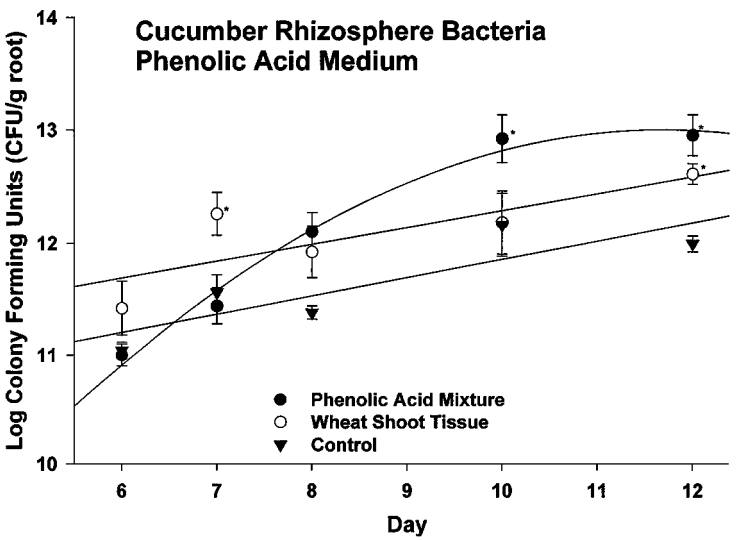

FIG. 2. Log colony-forming units of rhizosphere bacteria based on phenolic acid medium on days 6, 7, 8, 10, and 12 (Experiment 3) for cucumber seedlings treated with 0.6 μmol/g soil of a phenolic acid mixture or 5 mg/g soil wheat shoot tissue. Data in figures are means $\pm$ SE. Asterisks indicate significant differences between control and treatments.

CFU per gram root for soil without phenolic acid treatment (i.e., control) on days 6, 7, 8, 10, and 12 were 11.04 ± 0.07, 11.56 ± 0.16, 11.38 ± 0.06, 12.16 ± 0.28, and 11.99 ± 0.07, respectively. Mean actual CFU per gram root ranged from 1.10×10^{11} to 1.44×10^{12}.

Experiment 4

The purpose of experiment 4 was to determine the effects of soil-incorporated sunflower leaf tissue on pigweed seedling emergence (experiment 4a), bulk-soil bacteria that can utilize phenolic acids as a sole carbon source (experiment 4b), and cucumber seedlings and rhizosphere bacteria (day 17) that can utilize phenolic acids as a sole carbon source (experiment 4c). The incorporation of 0–10 mg/g soil of sunflower leaf tissue collected in 1999 to the Cecil A_p substrate significantly reduced (days 1–6) cumulative pigweed seedling emergence (Figure 3; % change in emergence $= -0.13 - [8.05 * \text{concentration}]$; $P < 0.001$; $R^2 = 0.70$; -81% change for 10 mg/g soil). Control mean $\pm$ SE of cumulative pigweed seedling emergence was 21.43 ± 2.27 out of 50 or 43%.

Sunflower leaf tissue significantly stimulated the bulk-soil bacteria that could utilize phenolic acids as a sole carbon source when these tissues ranging from 0 to 10 mg/g soil were incorporated into the Cecil A_p substrate. Log bacterial CFU (Figure 3; log CFU on day 6) per gram of soil (bulk soil) increased in a convex manner with increasing concentrations of soil-incorporated sunflower leaf tissue (log CFU $= 6.80 + [0.07 * \text{concentration}] - [0.004 * \text{concentration}^2]$; $P < 0.001$; $R^2 = 0.70$. Mean $\pm$ SE for CFU per gram for soils without tissue incorporated (i.e., control) was 6.80 ± 0.02 log CFU per gram soil (6.4×10^6 actual CFU per gram soil).

Cucumber AGRSL were inhibited by sunflower leaf tissue over days 9–11, 11–13, 13–15, and 15–17 (Table 2, Figure 3). Percent changes for these intervals were -76%, -60%, -55%, and -47% for the 10 mg/g soil treatment, respectively. Control means $\pm$ SE for AGRSL over days 9–11, 11–13, 13–15, and 15–17 were 6.79 ± 0.22, 8.94 ± 0.74, 11.63 ± 0.88, and 12.75 ± 0.64 (cm^2/day), respectively.

Shoot (% change $= 6.78 - [6.01 * \text{concentration}]$; $P < 0.001$; $R^2 = 0.61$; -53% change for 10 mg/g soil) and root dry weights (% change $= 0.063 - [6.31 * \text{concentration}]$; $P = 0.001$; $R^2 = 0.59$; -63% change for 10 mg/g soil) determined on day 17 were also significantly reduced by sunflower leaf tissue. Means $\pm$ SE (day 17) for shoot and root dry weights were 219.54 ± 12.83 and 38.58 ± 2.82 mg, respectively. Soil-incorporated sunflower leaf tissue, however, did not modify the cucumber seedling rhizosphere bacteria (day 17) that could utilize phenolic acids as a sole carbon source (log CFU per gram root dry weight $= 11.69 \pm 0.15$, actual CFU per gram root $= 4.87 \times 10^{11}$).

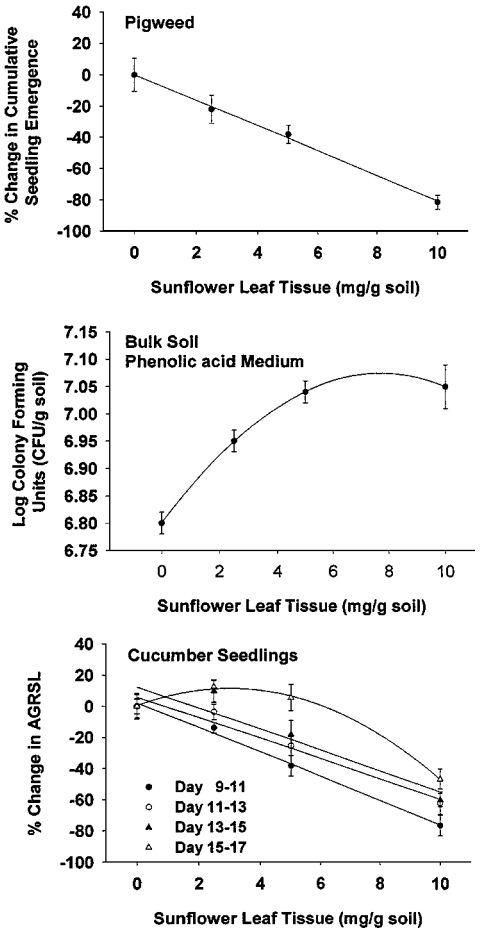

FIG. 3. Percent change in cumulative pigweed seedling emergence (Experiment 4a) log colony forming units of bulk soil bacteria (Experiment 4b) and cucumber seedling absolute growth rates for seedling leaf expansion (AGRSL; Experiment 4c) in the presence of soil-incorporated sunflower leaf tissue. For the sake of clarity, inhibitory effects are presented as negative numbers while stimulatory effects are presented as positive numbers. Data in figures are means ± SE.

Experiment 5

The purpose of experiment 5 was to determine the effects of soil-incorporated sunflower leaf tissue on cucumber seedlings and rhizosphere bacteria (day 12) that can utilize phenolic acids as a sole carbon source. The incorporation of 5 mg/g soil of sunflower leaf tissue to the Cecil A_p substrate significantly inhibited

AGRSL ($-25\% \pm 3$ change; days 9–12), shoot ($-27\% \pm 3$ change; day 12) and root dry weights ($-36\% \pm 6$ change; day 12) when compared to the control (no soil-incorporated sunflower leaf tissue). Mean control values $\pm$ SE for AGRSL and shoot and root dry weight were 6.42 ± 0.23 cm^2/day, 80.01 ± 4.01 mg, and 14.31 ± 1.23 mg, respectively. However, cucumber seedling rhizosphere bacteria (control $= 11.56 \pm 0.13$ log CFU per gram root dry weight, 3.63×10^{11} actual CFU per gram root) that could utilize phenolic acids as a sole carbon source were not changed in the presence of soil-incorporated sunflower leaf tissue.

Experiment 6

The purpose of experiment 6 was to determine how cucumber seedlings and rhizosphere bacteria that can utilize phenolic acids as a sole carbon source respond over time (days 6–12) in autoclaved (to reduce initial microbial populations) soil to soil-incorporated sunflower leaf tissue or multiple applications of chlorogenic acid.

Soil-Incorporated Sunflower Leaf Tissue. Soil-incorporated sunflower leaf tissue (5 mg/g soil) significantly reduced AGRSL ($-52\% \pm 11$ change), which was only determined over days 9–12. Control mean $\pm$ SE for AGRSL was 4.83 ± 0.51 cm^2/day.

The main treatment effects of time (days 6–12), soil-incorporated sunflower leaf tissue (0 or 5 mg/g soil), and the interaction between time and tissue significantly impacted shoot and root dry weights. Cucumber seedling shoot dry weight significantly increased over time in the presence ($\text{mg} = -5.85 + [3.54 * \text{time}]$; $P < 0.001$; $R^2 = 0.67$) and absence ($\text{mg} = -33.66 + [7.87 * \text{time}]$; $P < 0.001$; $R^2 = 0.88$) of soil-incorporated sunflower leaf tissue. Cucumber seedling root dry weight did not increase over time in the presence of soil-incorporated sunflower leaf tissue, while in the absence of soil-incorporated sunflower leaf tissue root dry weight increased in a linear manner with time ($\text{mg} = -1.03 + [0.88 * \text{time}]$; $P < 0.001$; $R^2 = 0.57$).

Based on means comparisons, soil-incorporated sunflower leaf tissue had no effect on shoot and root dry weight from days 6 to 8. On day 10, soil-incorporated sunflower leaf tissue significantly reduced shoot dry weight ($-27\% \pm 7$ change), but not root dry weight. On day 12, soil-incorporated sunflower leaf tissue significantly reduced shoot ($-43\% \pm 6$ change) and root dry weight ($-48\% \pm 10$ change) of cucumber seedlings. Control means $\pm$ SE (days 6–12) for shoot and root dry weight ranged from 18.14 ± 1.96 to 64.54 ± 3.76 and 4.78 ± 0.35 to 10.16 ± 1.48 (mg), respectively.

For rhizosphere bacteria grown on medium with chlorogenic acid as a sole carbon source, the main treatment effects of time (days 6–12) and incorporated sunflower leaf tissue (0 or 5 mg/g soil) and the interaction between time and tissue significantly impacted the log CFU per gram root dry weight. Rhizosphere bacteria

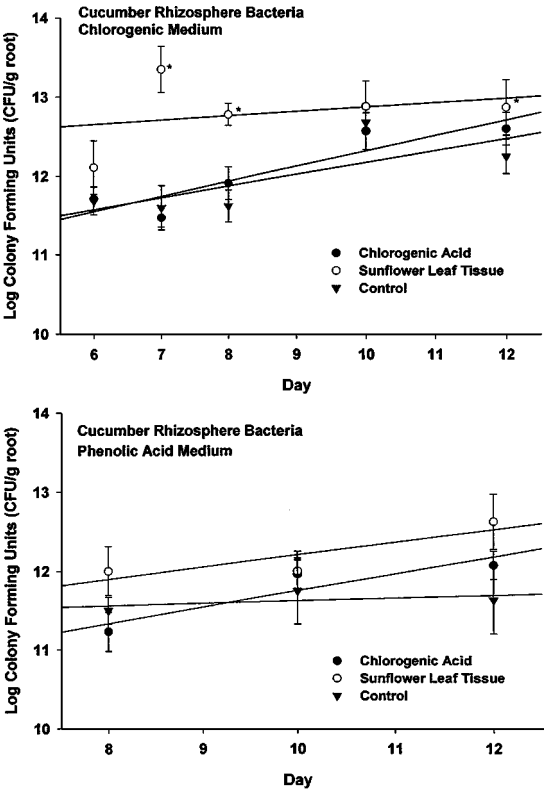

FIG. 4. Log colony forming units of cucumber rhizosphere bacteria based on chlorogenic medium or phenolic acid medium on days 6, 7, 8, 10, and 12 or days 8, 10, and 12, respectively (Experiment 6). Cucumber seedling systems were treated with 0.6 μmol/g soil chlorogenic acid or 5 mg/g soil sunflower leaf tissue. Data in figures are means $\pm$ Standard errors. Asterisks indicate significant differences between control and treatments.

were harvested on days 6, 7, 8, 10, and 12. Log CFU per gram root of chlorogenic acid utilizing rhizosphere bacteria for the soil-incorporated sunflower leaf tissue treatment did not change with time. However, log CFU per gram root of the control (no tissue incorporated) significantly increased in a linear manner (Figure 4; log CFU per gram root $= 10.69 + [0.15 * \text{time}]$; $P = 0.005$; $R^2 = 0.31$).

Based on means comparisons, incorporated sunflower leaf tissue significantly stimulated log CFU per gram root of rhizosphere bacteria grown on media with chlorogenic acid as a sole carbon source on days 7 (+4798% change of actual CFU per gram root), 8 (+1095% change of actual CFU per gram root), and 12 (+586% change of actual CFU per gram root) when compared to their respective controls

(Figure 4). Means ± SE for control log CFU per gram root for days 6, 7, 8, 10, and 12 were 11.68 ± 0.17, 11.60 ± 0.28, 11.62 ± 0.20, 12.68 ± 0.12, 12.25 ± 0.22 log CFU, respectively. Mean actual CFU per gram root ranged from 3.98×10^{11} to 4.79×10^{12}.

For rhizosphere bacteria grown on medium with phenolic acids as a sole carbon source, the main treatment effect of soil-incorporated sunflower tissue (5 mg/g soil) significantly increased the log CFU per gram root of rhizosphere bacteria (+279% change in actual CFU per gram root) when compared to the control (11.63 ± 0.10 log CFU per gram root; 4.27×10^{11} actual CFU per gram root). There was no significant change in log CFU per gram root over time (days 8, 10, and 12) for control and tissue treatments (Figure 4).

Multiple Application of Chlorogenic Acid. Multiple applications of chlorogenic acid (0.6 μmol/g soil) had no effect on cucumber AGRSL (control; days 9–12 = 4.83 ± 0.51 cm^2/day) or shoot or root dry weights. However, time (days 6–12) significantly impacted shoot dry weight in an exponential manner (mg = $64.03 - [14.85 * \text{time}] + [1.24 * \text{time}^2]$; $P < 0.001$; $R^2 = 0.89$) and root dry weight in a linear manner (mg = $-0.17 + [0.78 * \text{time}]$; $P < 0.001$; $R^2 = 0.58$). Mean ± SE (days 6–12) for control shoot and root dry weight ranged from 18.14 ± 1.96 to 64.54 ± 3.76 and 4.78 ± 0.35 to 10.16 ± 1.48 (mg), respectively.

For rhizosphere bacteria grown on medium with chlorogenic acid as a sole carbon source, the multiple applications of 0.6 μmol/g soil of chlorogenic acid had no effect on the log CFU per gram root dry weight when compared to the control (no applications of chlorogenic acid). The log CFU per gram root of rhizosphere bacteria for control and treatment increased over time (Figure 4; log CFU per gram root = $10.39 + [0.19 * \text{time}]$; $P < 0.001$; $R^2 = 0.50$). The log CFU per gram root ranged from 11.53 ± 0.15 (3.39×10^{11} actual CFU per gram root) to 12.62 ± 0.12 (4.17×10^{12} actual CFU per gram root).

For rhizosphere bacteria grown on medium with phenolic acids as a sole carbon source, the multiple applications of chlorogenic acid had no effect on the log CFU per gram root of phenolic acid utilizing bacteria in the rhizosphere of cucumber seedlings. However, the rhizosphere log CFU per gram root dry weight of cucumber seedlings for both control and treatment increased (log CFU = $10.47 + [0.12 * \text{time}]$; $P = 0.025$; $R^2 = 0.17$) with time (days 8, 10, and 12). The log CFU per gram root ranged from 11.35 ± 0.15 (2.2×10^{11} actual CFU per gram root) to 11.85 ± 0.15 (7.1×10^{11} actual CFU per gram root).

DISCUSSION

We hypothesized that soil-incorporated wheat or sunflower tissue would simultaneously inhibit cucumber seedling absolute rates of seedling leaf expansion (AGRSL) and stimulate the log colony forming units (CFU) per gram root

of phenolic acid utilizing rhizosphere bacteria, and therefore provide indirect evidence of phytotoxin transfer from residues in the bulk soil to the rhizosphere of a sensitive species. In nonautoclaved soil, soil-incorporated sunflower or wheat tissue inhibited cucumber seedling AGRSL but had no effect on the log CFU per gram root of phenolic acid utilizing bacteria. In autoclaved soil (−25% reduction in initial microbial populations), soil-incorporated wheat tissue significantly stimulated the log CFU per gram root of phenolic acid utilizing bacteria, but had no effect on cucumber seedling AGRSL. However, soil-incorporated sunflower tissue did simultaneously inhibit cucumber seedling AGRSL and stimulate log CFU per gram root of phenolic acid utilizing rhizosphere bacteria.

Allelopathic cover crop residues that will provide consistent year-to-year weed control and help reduce the use of preemergence herbicides have been eagerly sought by farmers, weed scientists, regulators, and environmentalists. However, the complex nature of the soil environment, the intensity of biological activity and associated chemical transformation within soils (e.g., sorption, oxidation, microbial interconversions, polymerization, and leaching), and the lack of direct access to roots in the field have prevented researchers from actually documenting the transfer and efficacy of phytotoxins produced by cover crop residues, such as wheat residues, under field conditions. At present, no definitive data on direct transfer of phytotoxins (i.e., substances that inhibit germination and/or seedling growth at field concentrations) from putative cover crop residues in or on the soil to roots of sensitive weed or crop species have been obtained under field conditions. The objective of this research was to determine if evidence for such transfer could be obtained by other than direct means, since evidence for direct transfer has eluded researchers so far.

Wheat residues have been observed to be phytotoxic to a variety of weeds, including pigweed, prickly sida, and morning-glory (Lehman and Blum, 1997; Blum et al., 1997). Potential allelopathic compounds identified in living and decomposing tissue of small grain cover crops, such as wheat, include phenolic acids (Liebl and Worsham, 1983; Blum et al., 1991), organic acids (Patrick, 1971; Lynch, 1977; Tang and Waiss, 1978; Shilling et al., 1985), hydroxamic acids and related compounds (Willard and Penner, 1976; Niemeyer et al., 1989), and volatiles (Buttery et al., 1985; Bradow, 1991). However, phenolic acids, in particular cinnamic (e.g., ferulic acid, *p*-coumaric acid) and benzoic acid (e.g., p-hydroxybenzoic acid, vanillic acid) derivatives, have been the most frequently cited allelopathic agents for wheat residues.

It has also been observed that phenolic acids, individually or in mixtures, applied to soil–microbe–plant systems not only inhibit germination and seedling growth, but also stimulate bulk soil and rhizosphere bacteria that can utilize phenolic acids as a sole carbon source (Blum and Shafer, 1988; Shafer and Blum, 1991; Blum et al., 2000). More importantly, Blum et al. (2000) noted that there was an inverse relationship between phytotoxicity and rhizosphere bacterial populations

that could utilize phenolic acids as a sole carbon source when cucumber seedlings growing in Cecil A_p soil were treated with a phenolic acid mixtures.

Phenolic acids released from wheat residues, however, do not enter soils in isolation. In fact, leachates from such debris are not only composed of a variety of phenolic acids, but also of other organic molecules and inorganic ions. Such complex mixtures of promoters, inhibitors, ions, and carbon sources will influence plant growth and associated microbial populations in a variety of ways. For example, the presence of carbohydrates, amino acids, or other organic molecules can increase the inhibitory activity of phenolic acids in soils; as the addition of noninhibitory levels of glucose or inhibitory levels of methionine to soil has been shown to increase the inhibitory activity of *p*-coumaric acid on morning-glory seedling biomass production (Blum et al., 1993; Pue et al., 1995). Additionally, Pue et al. (1995) and Blum et al. (2000) observed that phenolic acid utilization by soil microbes was reduced in the presence of other more readily available carbon sources. This induction and/or selection of phenolic acid–utilizing bacteria in bulk soil and in the rhizosphere of cucumber seedlings was not dramatically impacted by the presence of another carbon source, such as glucose. However, no matter how complex such debris leachates may be, if phenolic acids are to have a phytotoxic effect, they must pass through the rhizosphere where they will, depending on the rate of their movement and the nature of the rhizosphere bacterial populations, lead to various levels of selection and/or induction of phenolic acid–utilizing bacteria.

If the observations made for phenolic acid treatments could be demonstrated for wheat residues or other plant residues high in phenolic acids, such as sunflower (Armstrong et al., 1970, 1971; Hall et al., 1982, 1983; Macias et al., 1993, 1998, 1999), then the simultaneous inhibition of seedling growth and stimulation of rhizosphere bacteria that can utilize phenolic acids as a sole carbon source could provide indirect evidence for the transfer of phenolic acids released from soil debris particles to the rhizosphere and root surface of sensitive species.

Before field trials were initiated, however, the potential of the simultaneous inhibition of plant growth and stimulation of phenolic acid–utilizing rhizosphere bacteria was tested for wheat and sunflower tissue in the laboratory. Since the phytotoxicity of wheat and sunflower tissue varies with growth conditions and age of plants (Koeppe et al., 1970; Armstrong et al., 1970, 1971; del Moral, 1972; Lehman and Blum, 1997), we utilized pigweed seedling emergence to determine if phytotoxicity was similar to past experiments. The levels of phytotoxicity for wheat and sunflower tissue observed for pigweed seedling emergence were consistent with those observed by Lehman and Blum (1997) and Hall et al. (1982, 1983), respectively. However, Hall et al. (1983) observed that total phenolic acid content in sunflower tissue did not account for a significant amount of inhibition of pigweed plant biomass unless the N, P, K content of the sunflower tissue was included in the response model. Total phenolic acid and N added to soil by sunflower tissue

were negatively correlated with pigweed plant biomass, whereas P and K were positively correlated.

Total phenolic acid content ± SE for wheat shoot and root tissue and sunflower leaf tissue determined by Folin and Ciocateau's phenol reagent were 98 ± 5, 75 ± 0.6, and 465 ± 67 μg/g as ferulic acid equivalents, respectively. The inhibition of pigweed seedling emergence for 5 mg/g soil-incorporated wheat shoot and root tissue and sunflower leaf tissue were −66%, −10%, and −40%, respectively. The unexpected pattern of ferulic acid equivalence and percent inhibition was very likely a result of both qualitative and quantitative tissue differences in the phenolic acids present (e.g., for wheat cinnamic and benzoic acid derivatives and sunflower chlorogenic acids, isochlorogenic acids, the coumarins scopolin and ayapin, cinnamic acid derivatives, and benzoic acid derivatives) (Wilson and Rice, 1968; Koeppe et al., 1970; Macias et al., 1999), differences in color development for different phenolic acids (Blum et al., 1991), and the presence of a number of other phytotoxins (see Macias et al., 1999) and nontoxins (Gerig and Blum, 1991; Blum et al., 2000).

We chose to use the cucumber bioassay system used by Shafer and Blum (1991) and Blum et al. (2000) to test the effects of wheat shoot and sunflower leaf tissues on cucumber seedling absolute rates of leaf expansion and rhizosphere bacteria that could utilize phenolic acids as a sole carbon source. For comparative purposes we discuss only the results for 5 mg/g tissue soil treatments and the 0.6 μmol/g soil phenolic acid treatments.

The inhibition of AGRSL by 5 mg/g soil-incorporated wheat shoot and sunflower leaf tissue in both autoclaved and nonautoclaved soil ranged from −0% to −53% and from −25% to −52%, respectively. Such variation in inhibition by similar concentrations of plant tissue samples is not uncommon and results from differences in tissue chemistries and bioassay environments. Recall that new tissue samples were ground for each experiment. The inhibition of AGRSL by the 0.6 μmol/g soil four-phenolic acid mixture (primary phenolic acids in wheat) and the 0.6 μmol/g soil chlorogenic acid (primary phenolic acid in sunflower) treatments in autoclaved (to reduce initial microbial populations) soil were −24% and 0%, respectively. This effect of the phenolic acid mixture is consistent with Blum et al. (2000), who found that the 0.6 μmol/g soil phenolic acid mixture reduced cucumber seedling AGRSL by 20–23%. The absence of a chlorogenic acid effect on seedling growth, in the presence of nutrient solution treatments, has also been observed by Hall et al. (1983) for pigweed seedlings. The stimulation of rhizosphere bacteria that utilize phenolic acids as a sole carbon source in both autoclaved and nonautoclaved soil was just as variable from one tissue experiment to another as that of the inhibition of cucumber seedling AGRSL. Stimulation of rhizosphere bacteria ranged from 0% to +496% when 5 mg/g wheat shoot tissue was incorporated into soil and ranged from +0% to +4798% when 5 mg/g sunflower leaf tissue was incorporated into soil. The stimulation of rhizosphere bacteria over days 5–11

ranged from +0% to +1029% for the 0.6 μmol/g soil four-phenolic acid mixture (primary phenolic acids in wheat), but was not modified by the 0.6 μmol/g soil chlorogenic acid (primary phenolic acid in sunflower).

In nonautoclaved soil, the incorporation of wheat or sunflower tissue consistently inhibited cucumber seedling AGRSL, but had no effect on log CFU per gram root of phenolic acid–utilizing bacteria. Potential reasons for these results could be that phenolic acid–utilizers were not competitive in nonautoclaved soils and that these populations were already at carrying capacity. Another potential reason could be that cucumber inhibition was not due solely to phenolic acids, but to a complex mixture of molecules such as organic acids, volatiles, hydroxamic acids, etc., so selection pressure of phenolic acids was negated. In autoclaved soil (−25% reduction in initial populations), the log CFU per gram root of phenolic acid–utilizing rhizosphere bacteria consistently increased while cucumber seedling AGRSL declined only when sunflower tissue was incorporated into the soil. A possible reason for these results could be that phenolic acids released by wheat tissue stimulated rhizosphere bacteria that could utilize phenolic acids as a sole carbon source; the bacteria utilized the phenolic acids and prevented them from reaching the root surface. Conversely, levels of phenolic acids in sunflower tissue were much higher than in wheat, so the bacteria may not have utilized them all, thus cucumber seedling AGRSL was inhibited.

Blum et al. (2000) used the range of response by individual seedlings and their rhizosphere phenolic acid-utilizing bacteria to the 0.6 μmol/g soil equimolar four-phenolic acid mixture from several experiments to determine how changes in phenolic acid-utilizing rhizosphere bacteria might influence seedling inhibition and found that an increase of 500% in rhizosphere phenolic acid-utilizing bacteria would lead to a 5% decrease (e.g., 20–25%) in inhibition of absolute rates of leaf expansion. Attempts to model these relationships were not successful from our data due to low replicate numbers. The soils used by Blum et al. (2000) and for these experiments were collected at the same location but several years apart. For our soils, the log CFU of bacteria that could utilize phenolic acids as a sole carbon source at harvest were much higher. The log CFU per gram root for Blum et al. (2000) experiments were all below 11, whereas for our experiments they were all above 10 and ranged up to 13 log CFU per gram root. The inconsistent relationships between inhibition of AGRSL and the stimulation of rhizosphere phenolic acid-utilizing bacteria may thus have been a result of these high bacterial populations, since no response would be expected if bulk-soil and rhizosphere bacteria were phenolic acid limited and/or the resulting level of phenolic acids reaching the root surfaces were too low for inhibition. This observation is supported by the fact that consistent relationships were only observed in autoclaved soil (i.e., soils with lower microbial populations).

Since a simultaneous expression of inhibition for cucumber seedling AGRSL and stimulation of the community of rhizosphere bacteria that could utilize phenolic

acids as a sole carbon source occurred only for phenolic acid treatments and incorporated sunflower tissue in autoclaved soil, we are left to conclude for the present set of experiments that the strong selection pressure observed for individual phenolic acids or phenolic acid mixtures by Blum et al. (2000) was not consistently evident for either the phenolic acid mixture treatments or the incorporated wheat shoot and sunflower leaf tissue treatments in these nonautoclaved soils.

Inhibition of AGRSL, however, was observed for nonautoclaved soils in the absence of a stimulation of rhizosphere phenolic acid-utilizing bacteria for both incorporated wheat and sunflower tissue. This suggests that the inhibition observed for both autoclaved (only to reduce initial microbial populations) and nonautoclaved soil was due to phytotoxin mixtures, which may have included phenolic acids (see beginning of Discussion for potential list of phytotoxins). At the same time the effects of phenolic acids were clearly evident (i.e., stimulation of phenolic acid–utilizing bacteria) when phenolic acid-utilizing bacteria were free (e.g., could be due to the absence of more aggressive microbial species in autoclaved soil or that reduced microbial populations prevented phenolic acid carbon from being limiting) to respond to the phenolic acid carbon source.

In summary, our data suggest that given the right conditions (e.g., right levels of phenolic acid concentrations and bulk-soil and rhizosphere bacterial populations), it is possible to observe a simultaneous inhibition of seedling growth and stimulation of phenolic acid–utilizing rhizosphere bacteria as was hypothesized, and, thus, provide indirect evidence for phenolic acid transfer from sources within the soil (e.g., plant debris) to root surfaces. We suspect that such simultaneous behavior will probably be even more difficult to detect under field conditions and thus is unlikely to be a useful tool for characterizing phenolic acid transfer from the bulk soil to the rhizosphere of sensitive species. However, it is possible that this screening procedure may be useful for phytotoxins that are more unique than phenolic acids.
