Several benefits associated with predator inspection in fishes have been demonstrated, including visual alarm signaling (Smith and Smith, 1989; Murphy and Pitcher, 1997; Brown et al., 1999), predator deterrence (Magurran, 1990; Godin and Davis, 1995 a,b; Brown et al., 1999), and the preferential mate selection of inspecting males by females (Godin and Dugatkin, 1996). One of the potentially most important benefits associated with predator inspection is the ability to acquire information regarding local predation risk (Dugatkin and Godin, 1992a; Pitcher, 1992; Brown and Godin, 1999a). By inspecting potential predators, prey can assess local predation risk (Licht, 1989; Murphy and Pitcher, 1997) or acquire the recognition of a novel predator (Brown and Godin, 1999a).

Predator inspection behavior appears to involve assessment of both visual and chemical information (Licht, 1989; Murphy and Pitcher, 1997; Brown et al., 2000). Visual cues, such as the posture and behavior of potential predators, can provide reliable information to inspecting prey regarding the likelihood of an attack by predators (Licht 1989; Murphy and Pitcher, 1997). Chemical cues, such as a predator's dietary odor, can also provide reliable cues regarding a predator's past foraging preferences and/or hunger status (Mathis and Smith, 1993; Smith, 1997; Brown and Godin, 1999a). A likely source of chemical information in Ostariophysan prey fishes is conspecific alarm pheromones in the diet of potential predators (Mathis and Smith, 1993; Brown and Godin, 1999a).

Many fishes of the superorder Ostariophysi (approximately 65% of all freshwater species; Nelson, 1994) possess chemical alarm signals or alarm pheromones (Smith, 1992; Chivers and Smith, 1998). This chemical is released into the water column following mechanical damage to the skin. Conspecifics and some sympatric heterospecifics respond with dramatic, short-term increases in antipredator behavior (Smith, 1992; Chivers and Smith, 1998). Alarm pheromones can chemically label a predator as dangerous, and inspecting individuals may modify their predator inspection behavior in the presence of conspecific alarm pheromones in the diet of potential predators. Glowlight tetras (*Hemigrammus erythrozonus*), inspected in smaller numbers, remained further from the predator and took longer to initiate inspection visits when the predator had been fed tetras (with an alarm pheromone) than when either swordtails (lacking Ostariophysan

alarm pheromones) or food deprived (Brown and Godin, 1999a; Brown et al., 2000). Similar results have been shown for finescale dace (*Phoxinus neogaeus*; Brown and Cowan, 2000).

Dugatkin and Godin (1992b) have demonstrated that wild Trinidadian guppies typically inspect the trunk and tail region of a model predator more often than the head region. This 'attack cone avoidance' (George, 1960) is argued to reduce the individual's risk associated with approaching a potential predator. However, there may be costs associated with this avoidance, such as loss of information about the posture and/or behavior of the predator (Licht, 1989; Murphy and Pitcher, 1997). Also, if predator inspection functions in attack deterrence (Godin and Davis, 1995 a,b; Brown et al., 1999), inspection visits that are directed away from the head would dilute the effectiveness of this benefit.

We conducted this study to determine the effects of predator dietary cues on the predator inspection behavior, particularly attack cone avoidance, of free ranging finescale dace towards a model predator. Previous studies looking at attack cone avoidance (i.e., Dugatkin and Godin, 1992b) have not considered chemical cues associated with the predator's diet. Thus, it is unknown if attack cone avoidance during predator inspection visits is likewise affected by conspecific alarm pheromones in the diet of potential predators. We predict that attack cone avoidance should only be present under high risk situations, such as in the presence of dietary cues containing conspecific alarm pheromones.

METHODS AND MATERIALS

Field trials were conducted at Lock 7 Kill, a small tributary stream to the Mohawk River, near Schenectady NY. This small, spring-fed stream is devoid of predator fishes and is dominated by finescale dace. Pearl dace (*Margariscus margarita*), red-bellied dace (*Phoxinus eos*), and emerald shiners (*Notropis atherinoides*) were also present in the stream at lower frequencies (personal observations). Observations were conducted in a series of pools, separated by runs and riffle sections.

Stimulus Preparation. We collected predator odor from two adult yellow perch (14.7 and 15.2 cm S.L.). We fed the perch two finescale dace (with alarm pheromone) or two green swordtails per day for five consecutive days, or food deprived them for a period of 96 hr prior to stimulus collection. Swordtails were used as a control diet, as they lack Ostariophysan alarm pheromones and are native to Central America (Axelrod and Vorderwinkler, 1983) and hence do not co-occur with finescale dace. Following the final feeding (or the final day of food deprivation), we transferred the perch to 5-l tanks which contained an airstone but were unfiltered. We left the perch in the stimulus collection tanks for a period of

36 hr, at which time we returned them to their holding tanks. The stimulus water from the two perch fed the same diets was mixed, and we collected and filtered 1 l and froze it in 50 ml aliquots at -20°C until needed. As a control, we also froze 50 ml aliquots of distilled water. The order of stimulus collection was random, and perch were fed *ad libitum*, twice daily with brine shrimp (*Artemia francisca*) for 7 days between feedings for specific diets.

Experimental Protocol. Observations were conducted in a series of 10 pools along a 600-m stretch of the stream. Pools were separated by at least 40 m, had similar mixed cobble and fine-cobble substrates, and an average ($\pm$S.E.) surface area of 6.8 ± 1.2 m^2. Each pool was tested once for each chemical stimulus, and the order of treatments was randomized with the proviso that no pool could be tested twice for the same treatment. We allowed at least 24 hr between trials for each pool. During each trial, we conducted a five min prestimulus and a five min poststimulus injection observation period.

From a vantage point on the bank of the stream, we submerged a model predator, suspended from a 2-m fiberglass rod by monofilament nylon lines, into a pool and held it stationary, about 5 cm above the substrate. The model predator consisted of an 18 cm long fishing lure, painted to resemble an esocid predator. We positioned the model near the center of the pool, perpendicular to the current and away from any obstructions, to remove any bias associated with individual dace approaching from downstream versus upstream. A 3-m length of airline tubing, which was attached to a rubber stopper located under the model, was used to introduce the chemicals remotely. We tested a total of four chemical stimuli: distilled water (DW), the odor of perch fed dace (DACE), perch fed swordtails (SWT), or the odor of a perch that had been food deprived (FD). We injected 50 ml of stimuli into the tubing and flushed it through with stream water at a rate of approximately 10 ml/min.

During both pre- and poststimulus observation periods, we recorded: 1) the number of finescale dace within a 50 cm radius of the model, 2) the number of predator inspection visits, 3) the size of each inspecting group, and 4) the location of the inspection visit (head = anterior half of model; tail = posterior half of model). In addition, we recorded the occurrence of dashing behavior, defined as the rapid, apparently disoriented swimming of at least one dace. Prior to each trial, we established visual landmarks in each pool to facilitate recording the number of dace present within a 50 cm radius of the model.

Statistical Analysis. For all behavioral measures, except the frequency of occurrence of dashing, we calculated the difference between the pre- and poststimulus injection observation periods and compared these difference scores among diet treatments by using one-way ANOVA's. Planned contrasts were made with Fisher's PLSD tests. Frequency of occurrence of dashing behavior was compared among the treatment groups by using a χ^2 analysis.

RESULTS

We observed a significant effect of predator diet on the number of dace within a 50 cm radius of the predator model ($F_{(3,36)} = 32.54$, $P < 0.0001$; Figure 1A). Planned contrasts revealed that there was a reduction in the number of dace present following the injection of DACE versus the remaining diet treatments (Figure 1A). In addition, there was an increase in the frequency of dashing behavior during the poststimulus observation periods when the model was paired with the odor of a perch fed dace versus distilled water, food deprived perch, or perch fed swordtails (DACE = 80%, DW = 0%, FD = 30%, SWT = 0%, $\chi^2_3 = 21.44$, $P < 0.0001$).

We found an effect of predator diet on the overall frequency of predator inspection vists as well ($F_{(3,36)} = 8.38$, $P < 0.001$; Figure 1B). Again, planned contrasts revealed that this overall effect was due to a reduction in the number of inspections following the injection of DACE versus DW, FD, or SWT (Figure 1B). When we calculated a per capita rate of inspection, we found an overall effect ($F_{(3,36)} = 3.39$, $P < 0.03$; Figure 1C), with dace increasing their rates of inspection following the injection of DACE and FD (Figure 1C).

We also observed an effect of predator diet on the change in the proportion of inspections directed towards the tail ($F_{(3,36)} = 20.76$, $P < 0.0001$; Figure 2A) and proportion of inspections towards the tail by singletons ($F_{(3,36)} = 4.45$, $P < 0.01$; Figure 2B). Following the injection of DACE, we observed an increase in the proportion of inspections towards the tail versus the remaining diet treatments (Figure 2A, Table 1). In addition, we observed an increase in the proportion of inspections towards the tail by singletons following the injection of DACE and FD (versus DW and SWT; Figure 2B, Table 1).

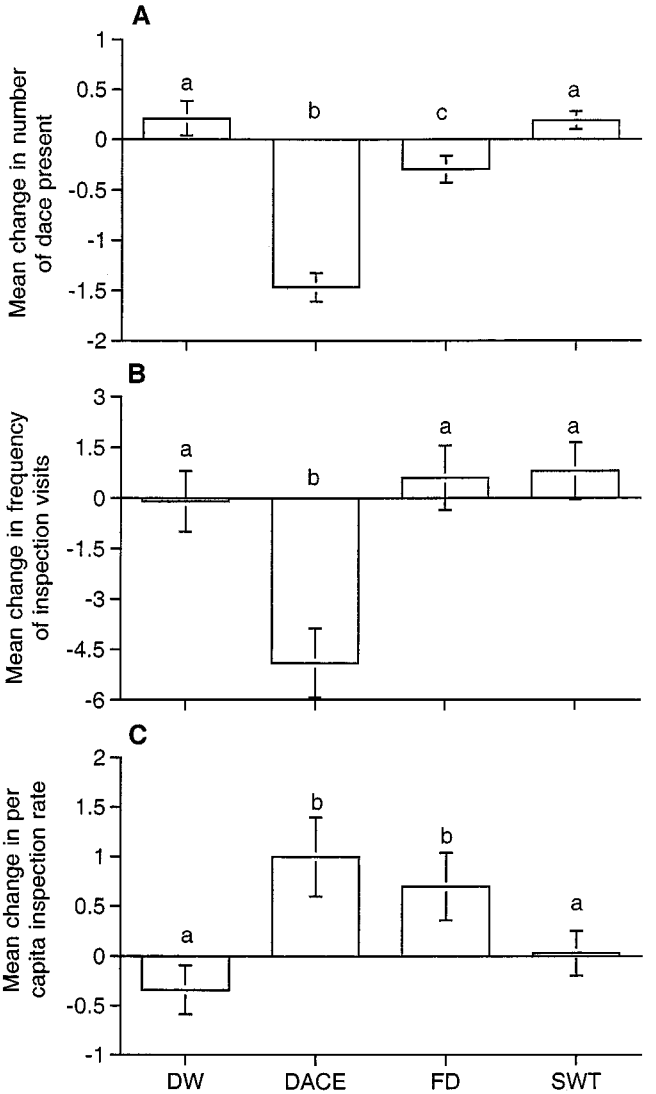

FIG. 1. Mean (±S.E.) change in the number of individuals present within a 50 cm radius (A), frequency of predator inspection visits (B), and per capita inspection rate by finescale dace exposed to a model predator (C) paired with distilled water (DW), the odor of perch fed dace (DACE), food deprived for 96 hours (FD) or fed a diet of swordtails (SWT). Different letters denote significant differences ($P < 0.05$) based on Fisher's PLSD.

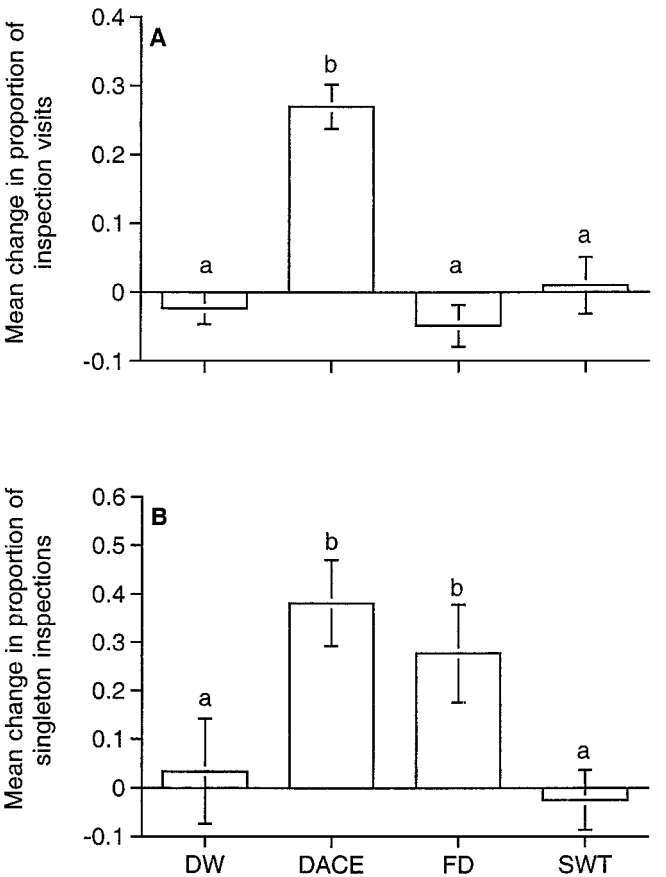

FIG. 2. Mean (±S.E.) change in the proportion of inspection visits (A) and change in proportion of inspections by singletons (B) directed towards the tail of the model predator paired with dietary cues. Treatment abbreviations as in Figure 1. Different letters denote significant differences ($P < 0.05$) based on Fisher's PLSD.

DISCUSSION

Our data demonstrate that wild finescale dace alter the form of predator inspection behavior based on the availability of predator dietary cues. Dace exhibited a significant increase in predator avoidance (fewer individuals present within 50 cm of the model and increased occurrence of dashing) when the model predator was paired with the odor of a perch fed dace. Similarly, dace reduced their frequency of predator inspection visits when exposed to the model paired with dace-fed perch

odor. However, we observed an increase in the per capita rate of inspection by dace exposed to the odor of dace-fed perch or food-deprived perch, suggesting that those individuals remaining inspected at a higher rate.

In the presence of dietary alarm pheromone cues, dace inspected the tail region more often and directed more initial inspections towards the tail. In contrast, Dugatkin and Godin (1992b) demonstrated that Trinidadian guppies (which possess an alarm pheromone; Nordell, 1998; Brown and Godin, 1999b) inspect the head of a model predator less often than the trunk or tail region, and those that do inspect the head, do so more often as singletons. This 'attack cone avoidance' (sensu George, 1960) has been suggested as a mechanism by which inspectors can gain information regarding local risk of predation while reducing their individual risk of mortality. Our results, however, demonstrate that in the absence of dietary cues containing conspecific alarm pheromones, inspectors directed a greater proportion of their inspections towards the head of the predator. Brown and Schwarzbauer (in press) have shown that under laboratory conditions, glowlight tetras (Superorder Ostariophysi) similarly modified their inspection behavior. Tetras directed a greater proportion of inspection visits to the tail region of a live cichlid predator (*Cichlasoma octofasciatum*), when the predator had been fed tetras (with alarm pheromone) versus swordtails (lacking Ostariophysan alarm pheromone) or food deprived.

This apparent conflict may be due to one of two (or both) differences between previous studies and ours. Initially, prior studies (i.e., Dugatkin and Godin, 1992b) were conducted on populations exposed to high levels of predation risk, and hence they were likely experienced with a variety of predators. Prey populations, which are under moderate to heavy predation pressure, may inspect more cautiously than those under lower predation risk (Magurran and Seghers, 1994). Secondly, previous studies examining attack cone avoidance have not included chemical cues. Our results demonstrate that dietary cues are an important source of information regarding local predation risk. Attack cone avoidance may occur only after an inspecting prey has determined that local predation risk is high based on the presence or absence of specific chemical cues. Diet-related chemical signals are honest indicators that the predator has previously selected conspecifics as food items or is hungry and, therefore, motivated to forage.

Dace also exhibited a graded response in singleton inspections, with the greatest proportion of solitary inspections towards a dace-fed predator and the lowest proportion towards a swordtail-fed predator. Dugatkin and Godin (1992b) argued that an increase in the proportion of singleton inspections indicates an increased perceived risk of predation. The observation that the proportion of solitary inspectors towards the food-deprived perch was intermediate to the dace-fed and swordtail-fed perch odor treatments suggests that dace are perceiving a food-deprived predator as a greater risk than a predator fed a neutral diet, but not as risky as predators fed a diet containing an alarm pheromone.

Inspecting prey, upon encountering a potential predator, may benefit from initially sampling chemical information and basing decisions regarding subsequent inspection behavior on the presence or absence of conspecific alarm pheromone. If the predator is 'chemically labeled' as dangerous (i.e., has been eating prey with an alarm pheromone; sensu Mathis and Smith, 1993), then high-level antipredator measures such as attack cone avoidance should be utilized. If no chemical labels are detected, the inspecting prey may more closely assess visual cues. By doing so, prey individuals may be able to obtain significant benefits associated with inspection visits while reducing their immediate risk of predation.

Abstract—Bullfrogs (*Rana catesbeiana*), native to eastern North America, were introduced into Oregon in the 1930's. Bullfrogs are highly efficient predators that are known to eat a variety of prey including other amphibians. In laboratory experiments, we investigated whether juvenile Pacific treefrogs (*Hyla regilla*) recognize adult bullfrogs as a predatory threat. The ability of prey animals to acquire recognition of an introduced predator has important implications for survival of the prey. We found that treefrogs from a population that co-occurred with bullfrogs showed a strong avoidance of chemical cues of bullfrogs. In contrast, treefrogs from a population that did not co-occur with bullfrogs, did not respond to the bullfrog cues. Additional experiments showed that both populations of treefrogs use chemical cues to mediate predation risk. Treefrogs from both populations avoided chemical alarm cues from injured conspecifics.

Key Words—Predator recognition, introduced predators, chemical cues, alarm signals, Pacific treefrogs, bullfrogs, *Hyla regilla*, *Rana catesbeiana*.

INTRODUCTION

The failure of a prey animal to recognize and respond to a predator increases the probability that it will be captured during an encounter with a predator. As a result, there should be strong selective pressure for prey to identify potential predators (Sih, 1987; Lima and Dill, 1990). Studying the responses of prey

to recently introduced predators provides an ideal system for testing the acquisition of predator recognition by prey populations (Kiesecker and Blaustein, 1997a).

Previous studies have demonstrated that in populations where larval amphibians have a long evolutionary history with a particular predator, they often recognize and respond to the predator without any prior experience. For example, Kats et al. (1988) demonstrated that larval amphibians, collected as eggs from a pond with predatory fish, responded to chemical cues of the fish predators. Similar results have been reported by Sih and Kats (1994). Kiesecker and Blaustein (1997a) documented that larval red-legged frogs (*Rana aurora*), collected as eggs from populations that co-occur with predatory bullfrogs (*Rana catesbeiana*), exhibit an antipredator response to the bullfrogs. In this case the response occurs even through red-legged frogs and bullfrogs do not share a long evolutionary history; they have co-occurred for less than 70 years (Nussbaum et al., 1983).

The first objective of this study was to examine the responses of Pacific treefrogs (*Hyla regilla*) from west central Oregon to chemical cues of introduced adult bullfrogs. We tested two different populations of treefrogs, one of which is syntopic with bullfrogs and one that is allotopic from bullfrogs. Bullfrogs were introduced into Oregon in the 1930's (Nussbaum et al., 1983). The adults are predators that are known to feed on a variety of invertebrate and vertebrate prey including other amphibians (Bury and Whelan, 1986; Werner et al., 1995; Kiesecker and Blaustein, 1997a, 1998). In our study, we tested the response of post-metamorphic (hereafter juvenile) treefrogs. Although studies of larval amphibians to chemical cues of predators are widespread (e.g., Kiesecker et al., 1996; Kats and Dill, 1998), few studies have examined responses of post-metamorphic amphibians to predators (but see Flowers and Graves, 1997; Chivers et al., 1999). It is unknown whether chemosensory responses of post-metamorphic anurans are widespread.

A second objective of our study was to examine the responses of juvenile Pacific treefrogs from both populations to chemical alarm signals released from injured conspecifics. A wide variety of larval amphibians, including those of the Pacific treefrogs (Adams and Claeson, 1998), exhibit an avoidance response to chemical alarm cues (see review by Chivers and Smith, 1998). However, to our knowledge only one study (Chivers et al., 1999) has documented responses of post-metamorphic anurans to chemical alarm cues. In that study, western toads (*Bufo boreas*, Family Bufonidae) and red-legged frogs (Family Ranidae) responded to cues of injured conspecifics while those of Cascades frogs (*Rana cascadae*) did not. The absence of a response in juvenile Cascades frogs is particularly noteworthy because tadpoles are thought to respond to cues of injured conspecifics (Hews and Blaustein, 1985). Our study is the first to test whether metamorphic frogs from the Family Hylidae respond to cues of injured conspecifics.

MATERIALS AND METHODS

We tested juvenile treefrogs from each of two populations for a response to both cues of injured conspecifics and cues of introduced bullfrogs. Recently metamorphosed treefrogs from the first population were collected in the Willamette Valley at the E. E. Wilson Wildlife Refuge (16 km north of Corvallis, Benton County, Oregon). Bullfrogs are common in the Willamette Valley. The specific pond where the treefrogs were collected contains a breeding population of bullfrogs (pers. obs.). Treefrogs from the second population were collected from a pond in the Oregon Cascade Mountains (89 km east of Albany, Linn County, Oregon). Bullfrogs are absent from this location. The closest bullfrog population is approximately 25 km away from this site.

Treefrogs were collected in the summer and fall of 1996 and transported to Oregon State University for testing. We maintained the treefrogs individually in Petri dishes (150 mm diameter $\times$ 25 mm high) lined with damp paper towels. The frogs were kept on a 14 hr light:10 hr dark photoperiod at approximately 16°C for a minimum of two weeks prior to testing. Treefrogs were fed *ad libitum* with crickets.

Responses of Treefrogs to Cues of Bullfrogs. In these experiments we tested the avoidance response of individual treefrogs exposed to chemical cues from: 1) predatory adult bullfrogs and 2) non-predatory adult conspecifics. Testing the response of treefrogs for a response to non-predatory treefrogs was done as a control to determine whether an avoidance of the predator stimulus could be simply a general response to any amphibian cue. Experiments on the two populations were completed separately.

Bullfrogs spend considerable periods of time sitting on the banks of ponds, lakes, slow moving streams, and rivers. As a result they are in a good position to encounter treefrogs that are undergoing metamorphosis and leaving the water. Many amphibians, including treefrogs, may spend several days at the water/land interface before moving to land. Bullfrogs that spend time at the water's edge may also be in a good position to prey on adult treefrogs that return to breed. To prepare the bullfrog cue we placed a single bullfrog into a container that was filled with 3 l of dechlorinated tap water. The bullfrog was removed after 24 hr at which time the experiments began. We used two different bullfrogs (mass = 27.6 and 33.3 g) as alternative donors in our experiments. We prepared the treefrog stimulus in the same manner as the bullfrog stimulus. However, to prepare the treefrog stimulus we added either 7 or 8 treefrogs to the stimulus collection chamber to match the mass of the particular bullfrog that we used. Prior to collecting stimuli, the bullfrogs and treefrogs were maintained on a diet of crickets for at least 2 wk.

For each trial we lined half of a rectangular plastic container (32 $\times$ 18 $\times$ 8 cm) with paper towel that was moistened with dechlorinated tap water (control side). The treatment side was lined with paper towel that contained 5 ml of the bullfrog

or treefrog cue. The two paper towel substrates in each container were separated by approximately 2 cm to reduce contamination of chemicals between the sides. After the appropriate stimuli were added to each side of the test containers, we used a spray bottle containing dechlorinated tap water to saturate the paper towels. This ensured that any observed avoidance of the control or treatment sides was not attributable to differences in moisture level.

At the start of each trial, we introduced a single test animal into the center of the test container. Every 30 min for 2.5 hr we recorded whether the test animal was located on the control or treatment side of the container. In the event the treefrog was positioned across the middle of the container, we used the position of the snout to assign location. We rotated the containers 180° every half hour during the experiment to control for the possibility of a bias in the treefrogs' orientation in the room. Our observation schedule followed the design of Chivers et al. (1999). We made observations only every half hour because juvenile anurans will not move if they are disturbed by an observer.

For the Cascade Mountain population we tested 30 frogs in the control treatment and 30 in the experimental treatment. Our sample size for the Willamette Valley population was reduced to 27 and 25 in the bullfrog (experimental) and treefrog (control) treatments respectively. Individual treefrogs were used in only one test. For each trial, we summed the number of times each animal was located on the treatment side of the container out of a possible 5 observations (one observation every 30 min for 150 min = 5 observations). For both of the treatments, we compared whether treefrogs spent significantly less time than expected on the treatment side of the containers using a Wilcoxon Signed Rank test (Siegel and Castellan, 1988). Several researchers (e.g., Lutterschmidt et al., 1994; Chivers et al., 1996a, 1997, 1999) have used a similar bioassay for testing responses of terrestrial amphibians to chemical cues.

Responses of Treefrogs to Cues of Injured Conspecifics. In these experiments we tested the avoidance response of individual treefrogs exposed to chemical stimuli from: (1) injured juvenile conspecifics, and (2) non-injured juvenile conspecifics. Experiments on the two populations were completed separately. Testing the response of treefrogs to non-injured conspecifics was done as a control to determine whether any avoidance of the injured stimulus was a general response to any conspecific stimulus (Chivers et al., 1996a, 1997).

Treefrogs are subject to predation by many different predators, including frogs, snakes, birds and mammals (Nussbaum et al., 1983). The amount of alarm cues released onto the ground and surrounding vegetation during a predation event must be highly variable. In designing this experiment, we followed the methodology of Chivers et al. (1999) to prepare the injured treefrog stimulus. We dispatched ten animals by decapitation and removed their viscera, spinal column and legs. The tissue (approximately 4.5 g, which contained mostly skin, but also some muscle tissue) was homogenized with 150 ml of dechlorinated tap water in a blender. The

homogenate was filtered through a 0.5 mm mesh net. We used 5 ml of injured treefrog stimulus per trial. The stimulus was used within 30 min of preparation. For a source of chemical stimuli from non-injured treefrogs, we used moistened paper towels that had housed a single conspecific for 48 hr.

For each trial, we lined half of a rectangular plastic container (32 × 18 × 8 cm) with a paper towel that was moistened with dechlorinated tap water (control side). The treatment side was lined with a paper towel that contained cues from injured treefrogs or cues from non-injured treefrogs. We used the same experimental protocol and statistical analyses as in the previous experiments. For both populations of treefrogs, we tested the response of 30 individuals to cues of injured conspecifics and 30 individuals to cues of non-injured conspecifics. Individual treefrogs were used in only one test.

RESULTS

Treefrogs from both the Willamette Valley and Cascade Mountain populations showed an avoidance response to cues from injured conspecifics (Willamette Valley: $Z = 3.94$, $P < 0.001$; Cascade Mountain: $Z = 3.87$, $P < 0.001$; Figure 1), but not cues of non-injured conspecifics (Willamette Valley: $Z = 0.39$, $P = 0.70$; Cascade Mountain: $Z = 1.13$, $P = 0.26$; Figure 1).

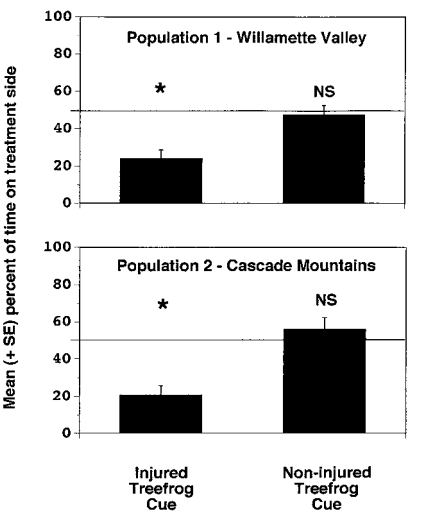

FIG. 1. Mean (+SE) percent time juvenile treefrogs from the Willamette Valley and Cascade Mountain populations spent on the treatment side of test chambers containing cues of injured conspecifics or non-injured conspecifics (NS indicates $P > 0.25$, * indicates $P < 0.001$).

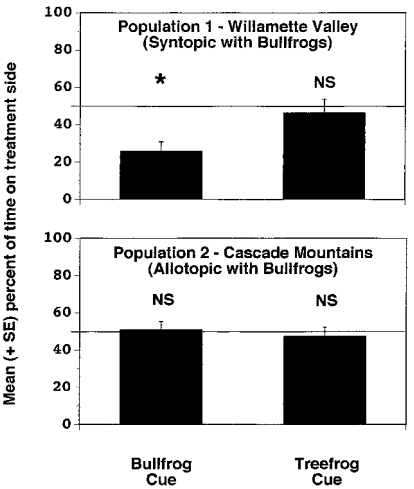

FIG. 2. Mean (+SE) percent time juvenile treefrogs from the Willamette Valley and Cascade Mountain populations spent on the treatment side of test chambers containing cues of predatory bullfrogs or non-predatory treefrogs (NS indicates $P > 0.50$, * indicates $P < 0.001$).

Treefrogs that co-occurred with bullfrogs in the Willamette Valley showed an avoidance response to cues of bullfrogs ($Z = 3.52$, $P < 0.001$, Figure 2), but did not show an avoidance response to cues of treefrogs ($Z = 0.58$, $P = 0.56$, Figure 2). In contrast, treefrogs from the Cascade Mountains did not show an avoidance response to cues of either bullfrogs ($Z = 0.02$, $P > 0.95$, Figure 2), or treefrogs ($Z = 0.57$, $P = 0.57$, Figure 2).

DISCUSSION

Our results show that juvenile treefrogs from two different populations use chemical cues to mediate predation risk. We observed avoidance responses of chemical alarm cues by treefrogs from both populations and avoidance of the bullfrog cues by treefrogs from the population syntopic with bullfrogs.

Numerous species of larval amphibians are known to exhibit antipredator behavior to chemical alarm cues (review Chivers and Smith, 1998). However, the responses of post-metamorphic anurans are less well known. Our results with Pacific treefrogs (Family Hylidae) show that the response to alarm cues is retained after metamorphosis. In our study, juvenile treefrogs from two distantly separated populations both exhibited avoidance of cues from injured conspecifics. Future studies should determine the amount of alarm cues released during predation events

and determine the threshold levels of responses exhibited by prey animals. This information would allow us to determine the scope of potential responses under natural conditions.

We did not have access to heterospecific frogs at the time of our study and hence could not test whether the avoidance of treefrogs to injured conspecific cues was a specific response to injured conspecifics or was a general response to injured amphibian cues. The avoidance of injured cues did not represent avoidance of a general amphibian cue. Treefrogs did not avoid cues of intact treefrogs. From a predation perspective it is of little importance if the avoidance of injured cues represents avoidance of injured conspecifics specifically or avoidance of injured amphibians in general. The important point is that by avoiding cues of injured conspecifics, treefrogs will decrease their probability of being captured. Chivers et al. (1999) used a similar approach to examine responses of juvenile red-legged frogs to alarm cues.

In our study, we observed that juvenile Pacific treefrogs from a population that co-occurred with bullfrogs exhibited an avoidance response to chemical cues of bullfrogs. The other population of treefrogs that had no contact with bullfrogs did not avoid the bullfrog cues. Inter-population differences in antipredator responses, whereby individuals from populations in which predators are common exhibit stronger antipredator responses than individuals from populations that experience lower levels of predation, have been reported in a variety of taxa (e.g., spiders: Riechert and Hedrick, 1990; salamanders: Ducey and Broodie, 1991; fishes: Seghers, 1974). However, few studies have documented population differences based on responses to chemical cues (but see Mathis et al., 1993). Our results most likely reflect that individuals from one population did not recognize the bullfrog cues, while individuals from the other population did recognize the bullfrog cues. However, our results could also reflect a population difference in the concentration threshold needed to elicit a response.

Population differences in antipredator responses may result from learning by prey in the high predation population (Mathis et al., 1993; Chivers and Smith, 1994). Several recent studies have documented that naïve prey animals can learn the identity of unknown predators by detecting conspecific alarm cues in the diet of the predator (Mathis and Smith, 1993; Chivers et al., 1996b). Population differences in anti-predator responses may also be genetically determined (Kiesecker and Blaustein, 1997a). The importance of genetics should increase if the predator and prey have a long evolutionary history together. Genetic changes can occur rapidly under natural conditions. For example, Reznick et al. (1990) documented changes in genetically determined life history traits in 30–60 generations. Pacific treefrogs and bullfrogs have co-occurred together in Oregon for only about 70 years (Nussbaum et al., 1983). For our experiments, we collected juvenile treefrogs.

Consequently, we do not know whether treefrogs from the population syntopic with bullfrogs have to learn that bullfrogs are a threat or whether this recognition is genetically determined. Future studies should differentiate these alternatives. We should also examine many populations of treefrogs with different densities of bullfrogs in order to determine whether responses vary with the intensity of predation or other site specific characteristics.

Many amphibian populations have been declining and undergoing range reductions over the last few decades (Blaustein and Wake, 1990; Stebbins and Cohen, 1995). The reasons for these declines are complex (Blaustein and Wake, 1995). Some studies have documented the decline of native frogs following the introduction of bullfrogs (Moyle, 1973; Kiesecker and Blaustein, 1998; Kupferburg, 1997). Pacific treefrogs appear to be one species that is not declining (Kiesecker and Blaustein, 1997a,b). This may be in part due to its success in recognizing and avoiding introduced predators such as bullfrogs. Responses of other amphibians to introduced bullfrogs remains mostly unknown (but see Kiesecker and Blaustein, 1997a). The success of treefrogs in regions now occupied by bullfrogs may stem from other factors besides their ability to recognize bullfrogs as predators. For example, treefrogs breed in a variety of habitats, including temporary ponds, where bullfrogs do not occur (Nussbaum et al., 1983).

The effects of introduced predators on native species are complex (Kiesecker and Blaustein 1997a, 1998). The ability of prey to recognize an introduced predator should minimize the prey's risk of capture. However, recognition of the predator does not by itself imply that there will not be significant predator effects. For example, Kiesecker and Blaustein (1997a) showed that red-legged frogs shift their microhabitat use in the presence of adult bullfrogs, and that this has a substantial cost in terms of decreasing growth rates and altering metamorphic characteristics, including time to and size at metamorphosis.

Casilla 653, Santiago, Chile

(Received October 24, 2000; accepted April 16, 2001)

Abstract—Interspecific chemical variation of precloacal pore secretions of *Liolaemus* lizards was characterized in 20 species, and intraspecific chemical variation was characterized using nine individuals of *L. bellii*. The latitude (Chile, 18° to 33° South latitude) and altitude (100 to 4350 m.a.s.l.) of the capture sites were recorded, as well as the number of precloacal pores of each lizard. Secretions were analyzed by GC-MS. A total of 49 compounds were found distributed among the 20 species of *Liolaemus*. Different chemical patterns occurred at intra- and interspecific levels. Compounds belonged to three main families: *n*-alkanes, long chain carboxylic acids, and steroids. Cholesterol and five carboxylic acids (tetradecanoic, hexadecanoic, hexadecenoic, octadecanoic, and *Z*-9-octadecenoic) appeared in all species. The number of precloacal pores correlated positively with altitude and negatively with latitude, suggesting that lizards produce more secretions under harsh environments.

Key Words—Chilean lizards, Tropiduridae, *Liolaemus*, precloacal pores, holocrine glands.

INTRODUCTION

Chemical communication is a well-documented phenomenon in different lizard genera (for reviews, see Mason, 1992; Font, 1996; Cooper, 1998). Pheromones are important for territory marking (e.g., Alberts, 1992), discrimination of familiar from unfamiliar individuals (e.g., Cooper, 1996), self-recognition (Graves and Halpern, 1991), and sexual recognition (Cooper et al., 1996). Although *Liolaemus* is a lizard genus with more than 150 species (Etheridge, 1995), little is known

*To whom correspondence should be addressed.

0098-0331/01/0800-1677$19.50/0

about the pheromones and chemical communication of its species. Chemical self-recognition and conspecific discrimination have been shown in *L. tenuis* (Labra and Niemeyer, 1999) and *L. bellii* (Labra et al., 2001). Potential sites of semiochemical production are the cloaca and the precloacal pores, the latter located in the external border of the cloacal shield and present mainly in males in the genus *Liolaemus* (Donoso-Barros, 1966). Given that precloacal pores have been described as producing secretions in lizards (Chauhan, 1986a, 1986b), and amphisbaenians (Antoniazzi et al., 1993, 1994), and that these secretions have pheromonal properties (Cooper et al., 1994; López et al., 1997), it is likely that precloacal secretions in *Liolaemus* also are involved in chemical communication. In fact, *Liolaemus* males are often seen dragging their cloaca over the substrate (Labra, personal observations), as has been observed in amphisbaenians (Chauhan, 1986b), a behavior allowing the release of secretions.

Proteins and lipids are the main compounds involved in chemical communication of squamates, although it is not clear which particular chemical compounds (or combination of them) are most relevant in this process. Although inter- and intraspecific variation in the protein content of femoral glands are claimed to be responsible for specific, self, and sex chemical recognition in different lizard species (Alberts, 1991; Alberts et al., 1993), most evidence points to lipids in pheromonal secretions as the main compounds involved in communication. The lipid content in the secretion of femoral glands (Alberts et al., 1992) and skin secretions (Mason and Gutzke, 1990) has been extensively studied, and *n*-alkanes, long chain carboxylic acids, and cholesterol and its derivatives have been found (Alberts, 1990; Weldon et al., 1990; Alberts et al., 1992). Bull et al. (1999) proposed that discrimination of individuals is determined by a complex relationship among different lipidic compounds found in feces, and Cooper and Garstka (1987) found that neutral lipid fractions of urodaeal glands secretions had pheronomal properties.

We report herein a characterization of the lipidic fraction of precloacal secretions of 20 *Liolaemus* species from different localities of Chile and from nine individuals of *L. bellii*, in order to evaluate the chemical patterns at the species and individual levels. The potential effect of environmental factors on the chemical composition of secretions was evaluated.

METHODS AND MATERIALS

Sample Collection. Liolaemus males were captured between October 1999 and February 2000, in northern and central Chile (Table 1). To collect secretions, males were placed backwards and pores were pressed gently with forceps. The yellow-reddish greasy secretion of each individual was dissolved in 400 μl purified *n*-hexane (see below), and placed individually in glass ampoules, which were

sealed and kept at −18°C until use. After extraction of the secretion, lizards were released at their sites of capture. The chemical characterization of the secretion of each species was performed after mixing secretions from three randomly selected individuals.

Solvent Purification. The *n*-hexane (Merck, chromatography grade) used for dissolving the precloacal secretions was previously purified by stirring over H_2SO_4 overnight, decanting, and stirring over K_2CO_3 for two hours. The solution was filtered, dried ($MgSO_4$), and redistilled before use. The glass ampoules used to keep secretions were heated to 150°C for four days before use.

GC-MS Analysis of Secretion Samples. The chemical characterization of the secretion of each species started with a pool of 150 μg of secretion, 50 μg from each individual (except in the case of *L. dorbigni*, where 50 μg were used from the single individual available). An aliquot (ca. 20 μl) of the mixture dissolved in *n*-hexane, containing 50 μg of the mixed secretion was submitted to the derivatization procedure (see below). The chemical characterization of the secretion of each individual

of *L. bellii* was performed by submitting directly 50 μg of each individual's secretion dissolved in *n*-hexane (ca. 20 μl), to the derivatization procedure.

Derivatization was performed by treating 50 μg of the secretion in v-vials with excess (5 μl) of N-methyl-N-trimethylsilyltrifluoroacetamide (MSTFA), and heating the closed vial to 90°C for 60 min. Thereafter, vials were cooled on ice, and excess MSTFA eliminated under a stream of dry nitrogen. The solution was concentrated to 2 μl and injected in the GC-MS.

Analyses were performed in a capillary column (Ultra 2, 25m $\times$ 0.2 mm ID) directly coupled to a mass detector with an integrated data system (GC model HP-5890, MD model HP-5972). Ionization by electron impact (70 eV) was carried out at 280°C. The GC oven was programmed to remain at 50°C for 10 min, then to increase up to 280°C at a rate of 5°C/min, and to remain at 280° for 45 min. The presence or absence of a given compound in the chromatographic profile of each *Liolaemus* species or individual of *L. bellii*, was determined by coinjection of commercial standards and comparison of retention times and mass spectra. GC peaks of coinjected compounds were considered coincident if retention times did not differ by more than $\pm$ 0.03 min. When standards were not available, spectra were compared with a library database by a reverse search technique, which verifies that main peaks in the reference spectrum are present in the unknown spectrum (Pesyna et al., 1976). Spectra were considered coincident if the similarity index was higher than 95% (Pesyna et al., 1976). Alternatively, mass fragmentation patterns were used to determine tentative chemical structures.

Data Analysis. Pearson product-moment correlations (Zar, 1984) were used to test relationships between normalized chromatographic areas of the different compounds in different species and environmental variables (altitude and latitude of capture site), and lizard characteristics (mean number of precloacal pores, snout-vent length, and weight of individuals, and mean weight of precloacal pore secretions). Analysis of similitude of the chemical composition of the secretions using normalized chromatographic areas, were performed among species and among individuals of *L. bellii*. Clusters of species and individuals of *L. bellii* were estimated by using unweighted pair-group of arithmetic average (UPGMA) as a linkage rule (Manly, 1994). The use of the comparative method has been recommended for interspecific comparisons (Martins and Hansen, 1996). However, since the phylogeny hypothesis proposed by Shultte et al. (2000) included only 11 of the 20 *Liolaemus* species in the present study, and those 11 species did not encompass a wide range of environments, a phylogenetic analysis was not performed.

RESULTS

GC-MS Analysis. The mean total mass of the secretions was 1.02 mg (SE = 0.25; N = 58, corresponding to the secretions that were analyzed by

GC-MS). The part soluble in *n*-hexane constituted approximately 67.5% (SE = 2.6; $N = 20$) of the total mass of the secretion. Eighteen compounds were found in the nine individuals of *L. bellii* studied (Table 2). Three different groups of compounds were found: *n*-alkanes, representing 5.8% (SE = 1.0; $N = 9$); long chain carboxylic acids, representing 48.7% (SE = 5.5; $N = 9$), and steroids, representing 45.5% (SE = 5.9; $N = 9$). Tricosane, tetradecanoic acid, hexadecanoic acid, hexadecenoic acid, octadecanoic acid, *Z*-9-octadecenoic acid, eicosanoic acid, and cholesterol, were present in all individuals analyzed. Among the major compounds found in the secretions of *L. bellii* are hexadecanoic and *Z*-9-octadecenoic acids, and cholesterol. Compounds found in *L. bellii* were also present in the other species. From the 20 *Liolaemus* species studied, a total of 49 compounds were identified (Table 3), which belong to the same three categories described for *L. bellii*: *n*-alkanes, representing 18.6% (SE = 4.0; $N = 20$);

long chain carboxylic acids, representing 61.5% (SE = 4.8; $N = 20$), and steroids, representing 19.9% (SE = 4.6; $N = 20$). All the species shared six compounds: cholesterol and five carboxylic acids (tetradecanoic, hexadecanoic, hexadecenoic, octadecanoic, and Z-9-octadecenoic). Hexadecanoic acid was the main compound of the carboxylic acid fraction, and cholesterol was the major steroidal compound.

Environmental Relationships. The number of precloacal pores (np) negatively correlated with the latitude ($r = -0.61$; $P = 0.004$) and positively correlated with the altitude ($r = 0.67$; $P = 0.001$) of the collection site. Different correlations were attempted among the normalized chromatographic areas of the different compounds and environmental or specific lizard characteristics. Nevertheless, the only significant correlations found were between the normalized chromatographic area of hexadecenoic acid and altitude ($r = 0.49$; $P = 0.028$), and latitude ($r = -0.44$; $P = 0.050$) of the collection site. Furthermore, for each species, the volatility of the secretion was estimated by using a melting point index (MPI) defined as the sum of the products between the normalized chromatographic areas and the melting point of each compound present in the secretion. No significant correlations were found between MPI and the environmental variables tested.

Similitude Analysis. The similitude analysis (UPGMA) performed with nine individuals of *L. bellii* (Figure 1A) shows the existence of variation in chemical composition at the individual level. A similitude analysis was performed with all 20 species together (Figure 1B). The relationship between the species could not be related to their phylogeny (Schulte et al., 2000).

DISCUSSION

Pheromone research in squamates is a relatively recent endeavor. The most precise knowledge of pheromonal compounds come from studies in snakes, where the nature of the active compounds has been elucidated in some cases (Mason, 1992, 1999; Mason et al., 1989). For lizards, most studies have dealt with the description of components that are part of secretions that are claimed to have pheromonal properties, rather than with the nature of the active compounds (Chauhan, 1986b; Alberts, 1990; Mason and Gutzke, 1990; Weldon et al., 1990; Alberts et al., 1992).

In all the *Liolaemus* species studied herein, the families of chemical components in the lipidic fractions of the precloacal secretions are similar to those reported for other lizards species, i.e., *n*-alkanes, carboxylic acid, and steroids (Chauhan, 1986b; Mason and Gutzke, 1990; Alberts et al., 1992). In *L. bellii*, the similitude analysis (Figure 1A) indicates that there are no two individuals with secretions having the same chemical composition. These differences among individuals may be important for self-recognition.

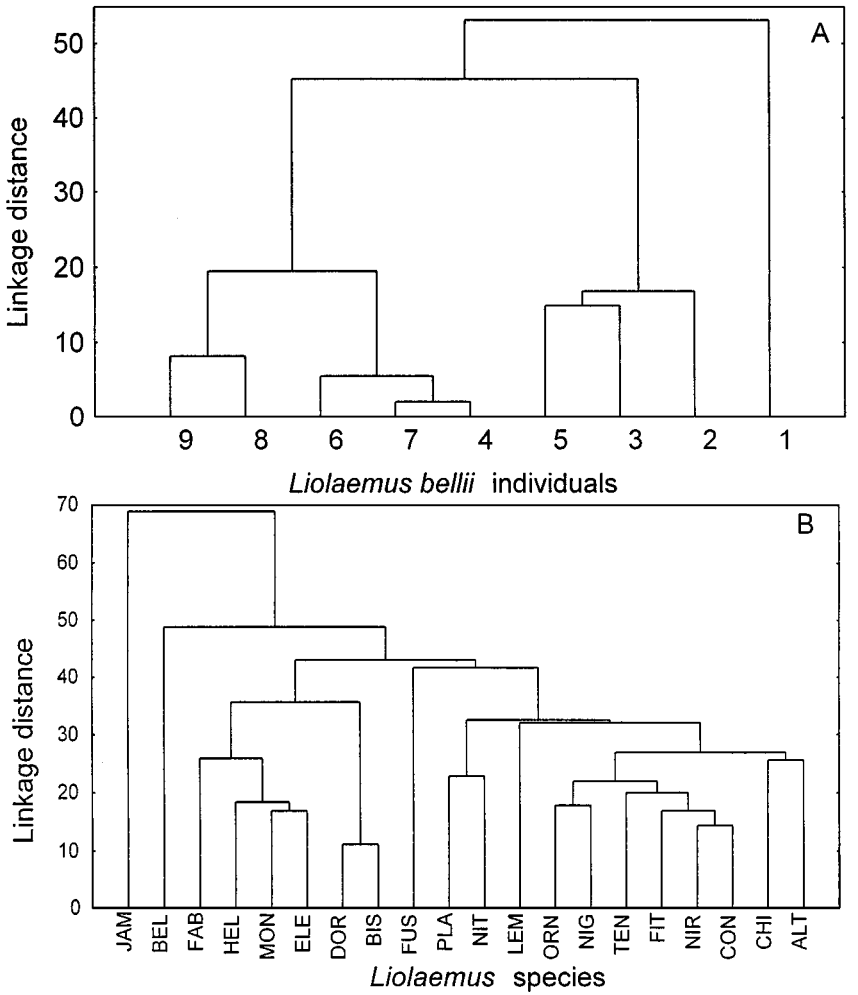

FIG. 1. Similitude analysis (UPGMA) of the normalized chromatographic areas of the different compounds found in the secretions of nine individuals of *Liolaemus bellii* (A) and in the secretions of 20 *Liolaemus species* (B). See Table 3 for meaning of abbreviations in Figure 1B.

The secretions of precloacal pores in *Liolaemus* contained a series of *n*-alkanes. In earlier studies with snake skin, these compounds were associated with sample contamination (Ahern and Downing, 1974), although it is now accepted that *n*-alkanes are components of saurian skin secretions (Weldon and Bagnall, 1987; Mason, 1992). Most of the *n*-alkanes of *Liolaemus* had an odd

number of carbon atoms. Since hydrocarbons of biogenetic origin generally consist of a greater proportion of odd over even number of carbon atoms (Weldon et al., 1990), *n*-alkanes in our samples are likely to be of biogenetic origin rather than a product of contamination. Nevertheless, the exact function of *n*-alkanes in *Liolaemus*, as well as in other lizard species (Mason and Gutzke, 1990), remains unknown.

Long chain carboxylic acids are common constituents of lizards skin and femoral glands (Mason and Gutzke, 1990; Alberts et al., 1992), and now they are reported in precloacal secretions of *Liolaemus* lizards. Carboxylic acids in *Liolaemus* belong to two categories: those common to all species analyzed (i.e., tetradecanoic, hexadecanoic, hexadecenoic, octadecanoic, and Z-9-octadecenoic), and those that are randomly distributed and present in minor amounts across the species (heptadecanoic, eicosanoic, and docosanoic). As previously suggested for snakes (Burken et al., 1985), compounds shared by different species may have a common function in all of them. Therefore, the five ubiquitous carboxylic acids may provide information related to genus status of the lizards (i.e., *Liolaemus*), while the randomly distributed carboxylic acids may be involved in specific discrimination, or species-specific functions.

The ubiquitous and most abundant carboxylic acid in *Liolaemus* secretions was hexadecanoic acid, also found in femoral secretions of *Iguana iguana* in breeding and nonbreeding seasons (Alberts et al., 1992). However, *Liolaemus* secretions showed differences with respect to previous records in squamates. In fact, hexanoic and nonanoic acids are reported for first time in squamate secretions. In addition, an important difference of *Liolaemus* secretions is the presence of compounds of lower molecular mass than compounds in other squamate species. Thus, in the leopard gecko, *n*-alkanes ranged from C_{18} to C_{32} and carboxylic acids from *n*-C_{16} to *n*-C_{18} (Mason, 1990); in *Iguana iguana*, carboxylic acids ranged from *n*-C_{14} to *n*-C_{26} (Alberts, 1992) and in the Florida indigo snake, carboxylic acids ranged from *n*-C_{12} to *n*-C_{18} (Ahern and Downing, 1974). In contrast, *Liolaemus* *n*-alkanes ranged from C_{10} to C_{25} and carboxylic acids from *n*-C_3 to *n*-C_{26}. Additional comparative research will be necessary to explain the biological implications of the presence of more volatile compounds in *Liolaemus* than in other squamates.

In squamates, precloacal (Chauhan, 1986a; Antoniazzi et al., 1993; Jared et al., 1999) and femoral glands (Weldon et al., 1990) have been described as exocrine organs producing a holocrine secretion (Alberts, 1990), which is constituted, among others, by long chain carboxylic acids (myristic, palmitic, stearic, and oleic acids), compounds normally present in internal tissues (Nicolaides, 1974). The presence of these carboxylic acids in the precloacal secretions of *Liolaemus* suggests the holocrine nature of the gland.

Cholesterol is of frequent occurrence in secretions involved in chemical communication, having been found in lizard skin (Weldon and Bagnall, 1987; Mason and Gutzke, 1990), femoral glands (Alberts et al., 1992) and now in precloacal pores in *Liolaemus* species. It has been suggested that steroids identified in lizards,

although not being sex steroids, may still give information about the sex of the individual (Mason and Gutzke, 1990). Since *Liolaemus* precloacal secretions analyzed were only from males, it may be speculated that the function of cholesterol derivatives is to provide information about the condition of the male, for example its dominance status or genetic quality (e.g., Martin and López, 2000).

It may be hypothesized that lizards deposit on the substrate a given "effective" amount of pheromones, which allows for efficient communication. However, these "effective" amounts may depend on the interplay of environmental or climatic conditions, and the volatility and chemical characteristics of the semiochemical. Thus, it would be expected that under conditions of high temperature, wind, and low atmospheric pressure, such as occur at higher altitudes and lower latitudes among the collecting sites studied, lizards would be equipped to produce higher quantities of secretion, or compounds in the secretions would be less volatile and chemically more stable. For *Liolaemus*, the main strategy seems to be the first one, given the significant relationships between number of precloacal pores with the altitude and latitude. Interestingly, the most volatile and one of the most chemically reactive members of the carboxylic acid family showed a negative correlation with latitude, and a positive one with altitude. However, the lack of correlation, between melting point index and both altitude and latitude, indicates that environmental conditions did not impose major changes in the pattern of chemical characteristics of the secretions.

(Received August 10, 2000; accepted April 9, 2001)

Abstract—An analytical technique employing gas chromatography and tandem mass spectrometry (GC/MS/MS) was employed to systematically screen fifty-eight wheat accessions for their differential production of 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) from three consecutive sources, i.e., the shoots, roots, and in the associated agar growth medium (collected as root exudates) of 17-day-old wheat seedlings. DIMBOA content differed significantly in the shoots, roots, or in the agar growth medium between accessions. DIMBOA accumulated differentially within the plant, with roots containing more DIMBOA than the shoots. Only 19% of accessions were able to exude DIMBOA from living roots into their growth medium, indicating the exudation of DIMBOA is accession-specific. DIMBOA level in root tissues is expected to be high when a high level of DIMBOA content is detected in the shoots. Wheat seedlings did not release detectable amounts of DIMBOA when the DIMBOA level was low in the root tissues. The valuable genetic material with high levels of DIMBOA in the shoots or roots identified in the present research could be used to breed for wheat cultivars with elevated allelopathic activity.

Key Words—Wheat (*Triticum aestivum* L.), allelochemicals, 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one, root exudates; weed suppression.

INTRODUCTION

Cyclic hydroxamic acids (Hx), a novel class of alkaloids, have been claimed as natural defense agents against bacteria, fungi and insects (Bohidar et al., 1986; Niemeyer, 1988a; Leszczynski et al., 1995; Figueroa et al., 1999; Wilkes et al., 1999). Hx are also associated with allelopathic activity for weed suppression (Pérez, 1990; Blum et al., 1992). DIMBOA and its decomposition product 6-methoxy-benzoxazolin-2-one (MBOA) inhibited root growth of wild oats (*Avena fatua*) by 50% at a concentration of 0.7 and 0.5 mM, respectively. MBOA also inhibited seed germination of *A. fatua* (Pérez, 1990). Blum et al. (1992) found that MBOA was more potent than its precursor (DIMBOA) and inhibited germination, radicle and hypocotyl length of *Trifolium incarnatum* and *Ipomoea hederacea*.

The hydroxamic acids have been found in a wide range of Gramineae, including wheat (*Triticum aestivum*) (Niemeyer, 1988a,b). The most abundant of these acids in wheat is 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) (Bohidar et al., 1986). In the search for wheat accessions with a high level of DIMBOA for integrated pest management, intensive research has been undertaken to determine the differential production of DIMBOA in shoots/leaves of *Triticum* spp. In a direct screening of 55 accessions of 17 wheat progenitors, Niemeyer (1988b) found that DIMBOA was highest in *T. speltoides* (16.0 mmol/kg fw) and lowest in *T. tauschii* (0.21 mmol/kg fw). In a collection of 52 Chilean cultivars of *T. aestivum* and *T. durum*, Copaja et al. (1991) demonstrated that cultivars differed significantly in the production of DIMBOA, ranging from 1.4 to 10.9 mmol/kg fw Nicol et al. (1992) extended the screening work to a worldwide collection of 47 cultivars of *Triticum* (mainly *T. aestivum*), and found that the contents of DIMBOA in the shoots ranged from 0.99 to 8.07 mmol/kg fw. These results have provided valuable information on potential genetic material with high levels of DIMBOA that could be used to enhance allelopathy in wheat breeding programmes.

Further research has shown that the DIMBOA content in wheat shoot tissues is genetically inheritable. Chromosomes 4A, 4B and 5B may contain genes for DIMBOA synthesis, and chromosome 4D may contain genes inhibiting the accumulation of DIMBOA (Niemeyer and Jerez, 1997). Genetic studies of DIMBOA in maize (*Zea mays*) have also demonstrated that the accumulation of DIMBOA could be monogenic or polygenic depending on particular populations (Klun et al., 1970; Dunn et al., 1981; Simcox and Weber, 1985). Studies on the genetic control of DIMBOA could further facilitate the genetic manipulation of DIMBOA levels in wheat.

Research so far has only concentrated on the evaluation of DIMBOA content in shoots or leaves of young wheat seedlings. Little data have been accumulated for DIMBOA production in roots, and for exudation of DIMBOA by living roots

of wheat seedlings into the growth medium. Wheat accessions with relatively high levels of Hx in the roots could prove effective in the control of root pests and valuable in allelopathic suppression of weeds (Copaja et al., 1999). Furthermore, the identification of wheat roots with high contents of Hx is not adequate for the selection of varieties with allelopathic potential. Root exudate analysis is also required (Pérez and Ormeño-Núñez, 1991).

An analytical tool employing gas chromatography and tandem mass spectrometry (GC/MS/MS) has recently been developed to simultaneously identify and quantify eight known allelopathic compounds in wheat, including DIMBOA, *p*-hydroxybenzoic, vanillic, syringic, *trans*-*p*-coumaric, *cis*-*p*-coumaric, *trans*-ferulic, and *cis*-ferulic acids (Wu et al., 1999). The purposes of the present research were: (1) to use the developed analytical technique to evaluate 58 wheat accessions originating from 19 countries for the differential production of DIMBOA from shoots, roots, and in the associated agar growth medium of 17-day-old wheat seedlings; (2) to determine the relationship of DIMBOA level between the shoots and the roots of wheat seedlings; and (3) to investigate the exudation of DIMBOA from living wheat roots into the growth medium.

METHODS AND MATERIALS

Wheat Growth. Based on previous experiments, a worldwide collection of 58 wheat accessions (*T. aestivum* L.) from the Australian Winter Cereals Collection was selected and grown according to the procedure described previously (Wu et al., 2000). Briefly, twelve pre-germinated wheat seeds (surface-sterilised) from each accession were uniformly selected. They were aseptically sown on an agar surface with the embryo up, in three rows on one half of a glass beaker (500 ml) pre-filled with 30 ml of 0.3% water agar. The beaker was wrapped with a piece of parafilm and placed in a controlled growth cabinet with a daily light/dark cycle of 13 hr/11 hr and a temperature cycle at 25°C/13°C. After 7 days, a piece of pre-autoclaved white paperboard was inserted across the centre and down the middle of the beaker with the lower edge of the paperboard kept one cm above the agar surface. The beaker was again wrapped with parafilm and placed back in the growth cabinet for 10 more days.

Preparation of Shoot or Root Extracts. The procedure previously described for the preparation of shoot or root extracts was used (Wu et al., 1999). Shoots or roots of 17-day-old wheat seedlings were harvested for each accession and immediately freeze-dried. An amount of 0.100 g of shoot or root material was cut into 2-mm lengths, ground into powder, macerated with 3 ml of 0.001 M HCl, sonicated at 5°C for 15 min, and then centrifuged at 20,000 rpm at 10°C for 15 min. The supernatant was collected and extracted three times with 10 ml portions of diethyl ether. The ether was evaporated under reduced pressure at 35°C.

Collection of Root Exudates from the Agar Medium. Wheat seedlings were uprooted from their soft nutrient-free agar medium and the roots rinsed twice with 5 ml portions of distilled water to remove residual agar. The washings were pooled into the agar medium. The growth medium was collected, adjusted to pH 3.0 by dropwise addition of 0.06 M HCl, stirred thoroughly, and then sonicated at 5°C for 15 min. The agar medium was extracted three times with 60 ml portions of diethyl ether. The ether was then evaporated under reduced pressure at 35°C.

Derivatization and Quantitation. The derivatization and quantitation of wheat samples were identical to those described previously (Wu et al., 1999). Silylation of wheat shoots, roots and agar samples was accomplished by the addition of 1.0 ml of MSTFA (Alltech Australia) at 60°C for 30 mins. Silylated samples were directly analysed by GC/MS/MS. DIMBOA was identified and quantified by comparing retention times and product ion spectra with that in the user library created from the standard compound. Quantitative analysis was performed by the internal standard method (Wu et al., 1999) and reported in units of mg/kg of dry matter for wheat shoots and roots, and μg/l for water agar.

GC/MS/MS Analysis. Analyses were carried out on a Varian 3400 CX gas chromatograph coupled with a Varian Saturn 2000 ion trap mass spectrometer. Samples were introduced via a DB-5MS fused-silica capillary column of 30 m $\times$ 0.25 mm $\times$ 0.25 μm (J & W Scientific, Alltech Australia). Gas chromatographic and tandem mass spectrometric conditions for the analysis of wheat samples were identical to those reported previously (Wu et al., 1999). Mass spectral scan time from *m/z* 50 to 450 was 1.0 second (using 3 microscans). Nonresonant collision-induced dissociation (CID) was used for MS/MS. All samples were run in triplicate.

Data Analysis. All experimental data were subjected to analysis of variance by using Genstat 5 (Anonymous, 1995) and the treatment means were tested separately for least significant difference (l.s.d.) at a 5% level of probability.

RESULTS

DIMBOA Variation in Wheat Shoots. Wheat accessions produced differential amounts of DIMBOA in their shoot tissues (Table 1). There were 20 accessions with a level of DIMBOA less than 300.0 mg/kg dry matter and 8 accessions with more than 700.0 mg/kg. Thirty accessions contained DIMBOA ranging from 300.0 to 700.0 mg/kg. Accessions Canada 51 and Hartog produced no detectable DIMBOA, while the accession Khapli contained the highest amount of DIMBOA (730.4 ± 1.4 mg/kg).

DIMBOA Variation in Wheat Roots. Wheat accessions also differed significantly in DIMBOA levels in the roots of 17-day-old wheat seedlings (Table 1). There were five accessions with a level of DIMBOA below 300.0 mg/kg dry matter and 36 accessions with greater than 700.0 mg/kg. Seventeen accessions contained

[a] Data presented are the means ± standard deviation (S.D.).
[b] Shoot and root results are reported as mg/kg dry matter.
*nd: not detected.

DIMBOA between 300.0 to 700.0 mg/kg. Canada 4215 produced no detectable DIMBOA in root tissues, while the Batten contained the highest amount (734.1 ± 3.2 mg/kg).

Wheat plants differentially accumulated more DIMBOA in root tissues than in shoots (Table 1). The average level of DIMBOA was 643.0 mg/kg in roots and 439.4 mg/kg in shoots. Of the 58 accessions, 50 contained higher levels of DIMBOA in roots than in shoots. Meering, AUS# 12627, L 1512-2721, Canada 56 and Canada 4125 were the exceptions. Three accessions, Altar 84, Khapli and Tasman, did not differ significantly in DIMBOA between roots and shoots.

There was no correlation in DIMBOA content between the shoots and roots when a low level of DIMBOA content was found in the shoots of wheat seedlings. However, a high level of DIMBOA is expected in root tissues when a high level of DIMBOA content is found in shoots. Among the 38 accessions with more than 300.0 mg/kg of DIMBOA in their shoots, 36 produced DIMBOA above 650.0 mg/kg (95%) in their roots. Only two accessions (L 1512-2721 and AUS# 12627) had less than 260.0 mg/kg of DIMBOA in their roots. Among the 20 accessions with less than 300.0 mg/kg of DIMBOA in shoot tissues, 14 produced more than 600 mg/kg of DIMBOA in their roots (70%), while 10 accessions (50%) produced more than 700 mg/kg of DIMBOA (Table 1).

DIMBOA Variation in Root Exudates. Wheat accessions differed significantly in the amount of DIMBOA exuded into the growth medium (Table 1). Forty-seven out of 58 accessions (81%) did not exude detectable amounts of DIMBOA through their living roots into the agar growth medium, although substantial levels of DIMBOA were found in shoot or root tissues. Only 11 accessions (19%) were capable of exuding DIMBOA into the growth medium, with amounts ranging from 8.56 μg/l of water agar for SST 6 to 79.08 μg/l of water agar for L1512-2721.

There were seven accessions with DIMBOA levels lower than 550.0 mg/kg dry mater in their root tissues (Table 1). Among them, six accessions did not exude DIMBOA into the associated growth medium, the exception being L 1512-2721. Canada 4125 contained no detectable DIMBOA in roots, nor was DIMBOA detected in the agar growth medium that had supported the seedling growth for 17 days. Among the 11 accessions capable of exuding DIMBOA from their roots, ten accessions contained DIMBOA at concentrations higher than 550.0 mg/kg dry matter in their root tissues, the exception being L 1512-2721. It is concluded that wheat seedlings do not release DIMBOA when DIMBOA levels are low in root tissues.

DISCUSSION

Significant genetic variation in the production of DIMBOA was not only found in wheat shoot tissues, but also in root tissues. Some accessions produced high levels of DIMBOA, while others had no detectable DIMBOA in shoots or roots of 17-day-old wheat seedlings (eg., shoots of Canada 51 and Hartog, and roots of Canada 4215). The extremely low level of DIMBOA in leaves of Hartog has also been reported (Nicol et al., 1992; Copaja et al., 1999). The substantial genetic variation of DIMBOA production in wheat germplasm implies that it may be possible to manipulate DIMBOA levels by means of modern biotechnology, thereby reducing the dependence on synthetic pesticides.

Exudation of allelochemicals by living plants is one of the important processes necessary for crop allelopathy to occur (Rice, 1984). In the investigation of the allelopathic potential of quackgrass (*Agropyron repens*) seedlings, Friebe et al. (1995) reported that the cyclic hydroxamic acids were important constituents in root exudates of *A. repens*. The concentration of DIMBOA was 0.4 μ mol/l in root exudates. The present study shows that DIMBOA exudation differs between wheat accessions. Only 11 out of 58 wheat accessions (19%) exuded DIMBOA into the growth medium. These results demonstrate that release of DIMBOA is accession-specific, suggesting the presence of genetic factors governing the exudation process of DIMBOA. Such an accession-dependent exudation of DIMBOA has also been reported by others. Pérez and Ormeño-Núñez (1991) claimed that DIMBOA was not detectable in the root exudates of three wheat cultivars despite its presence in

their roots. However, using hydroponic cultures and placing the plants in distilled water for two to six hours after removal from the nutrient solution, Pethós (1992) reported that wheat and maize seedlings exuded DIMBOA through their living roots.

Hydroxamic acids, including DIMBOA, isolated from crop residues are allelopathic to the germination and growth of certain weed species (Barnes and Putnam, 1987; Pérez, 1990; Blum et al., 1992). DIMBOA exuded from living roots is also one of the bioactive compounds responsible for the allelopathic activity of *A. repens* seedlings (Friebe et al., 1995). In the present study, the substantial amounts of DIMBOA in wheat shoots and roots might be involved in wheat residue allelopathy for weed suppression under conservation farming systems where wheat stubbles remain in the field. On the other hand, the exudation of DIMBOA from living roots of wheat seedlings might be genetically regulated, and affected by a number of other biotic and abiotic factors. Exudation of DIMBOA and its involvement in wheat seedling allelopathy for weed suppression needs further investigation.

The magnitude of crop allelopathic activity is not determined by one single compound, but by a mixture of many biologically-active allelochemicals (Einhellig, 1995). DIMBOA, exuded by wheat seedlings, is only one of many allelochemicals that could collectively interact with other allelochemicals to produce significant wheat allelopathy against pests, diseases and weeds. Many other allelopathic agents have been identified from wheat (Neves and Gaspar, 1990; Gaspar and Neves, 1993, 1995). These bioactive compounds could form a complex allelochemical mixture that exhibits combined effects with much greater allelopathic activity than any one individual compound (Einhellig, 1995). Further investigation of the additive or synergistic effects between DIMBOA and related compounds, in combination with other chemically-distinct compounds, is therefore needed to understand the chemical basis of crop allelopathy prior to its use in integrated pest and weed management.

Acknowledgments—This research is funded by both Charles Sturt University (CSU) and the Australian Cooperative Research Centre for Weed Management Systems. The authors are thankful for the kind provision of wheat accessions from the Australian Winter Cereals Collection, the provision of GC/MS/MS instrumentation from the Environmental and Analytical Laboratories at CSU, and the kind provision of DIMBOA standard from Dr W. S. Chilton of the Department of Botany, North Carolina State University, Raleigh, USA.

(Received October 18, 2000; accepted March 29, 2001)

Abstract—[Ring-U^{14}C] *p*-hydroxybenzoic acid (POH) translocation during radish germination and early seedling growth was studied to compare two culture conditions (sterile/non-sterile) and two modes of POH extraction (ethanol/oxidizing). Quantification of POH in organs was performed by grinding them in a mortar with ethanol or by combusting them in a biological oxidizer. Comparison of these extraction methods revealed that the oxidizer provides higher POH concentrations than grinding. Uptake and translocation of POH into radish seedlings occured in the first 24 hr with the highest accumulation in cotyledons. POH in cotyledons ranged from 8 to 12.4 μmol g^{-1} FW. Two forms of POH were found in seedlings, an ethanol-soluble one and a "bound" one. After 96 hr incubation, half of the recovered POH was "bound" in roots and hypocotyls. POH recovery in seedlings was also higher under axenic rather than non-axenic conditions. POH was degraded into $^{14}CO_2$ by microorganisms under non-sterile cultures, its concentration in culture medium decreased from 10^{-3} to 10^{-4} M between the first and the fourth day of incubation. Choice between sterile and non-sterile culture conditions as a method depends on particular research objectives. Non-sterile methods can be used to reflect natural processes whereas sterile methods can be used if the objective is to determine allelochemical penetration and biological effects on target plants.

Key Words—Allelopathy, ^{14}C, allelochemical degradation, allelochemical translocation, methodology, microorganisms, *p*-hydroxybenzoic acid, radish germination.

INTRODUCTION

Allelopathy is the direct or indirect effect of one plant upon another through the production of chemical compounds released into the environment (Rice, 1984). Many investigations in this area are focused on the identification of released bioactive compounds by plants (Mizutani, 1999). When these compounds are clearly identified and quantified, studies pinpoint their possible phytotoxic effects upon target plants (Blum et al., 1999). Nevertheless, absorption and translocation mechanisms of such allelochemicals by target species have been poorly investigated. This work compares plant culture and chemical extraction methods in order to determine a more appropriate means for further investigating allelochemical uptake and translocation into target seedlings.

An experimental model was selected using *p*-hydroxybenzoic acid (POH) as the phytochemical of choice and radish (*Raphanus sativus* var. 18 days) as the target plant. POH is a widespread phenolic acid released into soil by root exudates, leaf leachates, and decomposed plant tissues (Dalton, 1999). It delays germination and growth of several plant species, but its effects are less severe than many more active phenolic compounds (Maffei et al., 1999). In target plants, POH mainly interferes with nucleic acid and protein metabolism (Baziramakenga et al., 1997). Radish is one of the most widely used target species in allelopathy studies, due to its rapid germination and growth, its easy dissection and sensitivity to phenolic or phytotoxic compounds (Haugland and Brandsaeter, 1996).

Bioassay is an indispensable tool in allelopathy investigations because it allows one to readily establish the specific biological activities associated with a particular allelochemical or mixture of allelochemicals. Allelochemical phytotoxicity is generally tested under non-sterile conditions. However, little information is available on possible allelochemical transformations in the culture medium by microorganisms and consequently, the real quantities absorbed by target seedlings. This is a crucial step in the assessment of phytotoxicity in plants.

A more pertinent technique is to have recourse to ^{14}C radiolabeled chemicals. However, the procedure selected to extract ^{14}C-labelled compounds is still a limited step (Van Sumere, 1989). Grinding samples in a mortar with adequate solvent or combusting samples in a biological oxidizer are two widely used methods of extraction (Chao et al., 1994; Simmen and Gisi, 1996).

Thus, objectives of the present work were to: 1) compare allelochemical absorption under sterile and non-sterile conditions; 2) quantify phytochemical penetration into target plants; 3) and compare grinding and oxidization as methods of extraction.

METHODS AND MATERIALS

General Procedure (Figure 1). We concentrated on characterizing POH kinetic translocation into radish seedlings in order to determine the influence of microorganisms on POH uptake and translocation under sterile and non-sterile cultures and, to compare two methods of POH extraction, by grinding and oxidizing.

Chemicals and Solutions. P-Hydroxybenzoic acid (POH) and [ring-U^{14}C] *p*-hydroxybenzoic acid (radiochemical purity >97%, specific activity 12 mCi mmol^{-1}) were purchased from Sigma Chemicals Ltd.

An aqueous solution of POH was prepared at 10^{-3} M with demineralized water and buffered to pH 5.5 with NaOH. [^{14}C] *p*-Hydroxybenzoic acid was dissolved in 1 ml of 99.9% ethanol (reaching a concentration of 8.7 10^{-3} mmol ml^{-1}). Ten to 15 μl of this radiolabeled POH solution were added to the non-labeled POH solution to obtain approximately 0.008 μ Ci ml^{-1} in the final solution. This mixed solution of POH and ^{14}POH was immediately used in radish culture.

Radish Culture Under Non-Sterile Condition. Twenty radish seeds (*Raphanus sativus* L., var. 18 days) were placed into a glass (7 cm diameter and 9 cm high, closed with a cap) with 5 ml of the chemical solution. In order to trap potential $^{14}CO_2$, a Petri-dish containing 5 ml of 10 N NaOH was added into the top of each

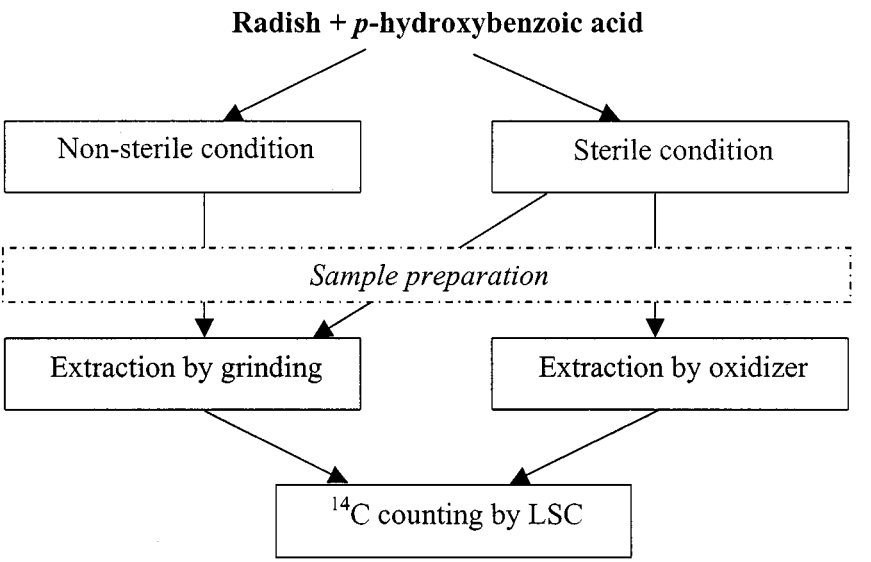

FIG. 1. General investigation procedure of POH kinetic translocation into radish seedlings using two culture conditions (sterile and non-sterile) and two types of extraction (by grinding and by oxidizer).

glass. Glasses were placed for a maximum of 4 days in a thermostatic growth chamber (20°C, photoperiod 8 h light/16 h dark).

Radish Culture Under Sterile Condition. Radish seeds were disinfected by immersion for 10 min in sterile, demineralized water and 110 volumes hydrogen peroxide (70:30 v/v), followed by rinsing (3 x's) in sterile, demineralized water. Twenty seeds were then placed into a sterile glass containing the CO_2 trap and closed with a sterile cap. Five ml of POH solution sterilized by filtration through a 0.22 μm membrane were added to each glass and 5 ml of 10 N NaOH solution were added to the CO_2 trap. Glasses were placed for a maximum of 4 days in a thermostatic growth chamber (20°C, photoperiod 8 hr light/16 hr dark). Two investigations under sterile conditions were conducted (one followed by grinding and the other by oxidizing). The average recovered ^{14}POH concentration in the culture medium was then calculated for both experiments and combined.

Sample Preparation. At the end of each incubation period (24, 48, 72 and 96 hr), radish seedlings from each glass were washed (3 x's) in ethanol to remove adsorbed compounds. Then, seedling parts were separated. Day 1 (24 hr) corresponded to germinated seeds (separation of seed and seed coat), day 2 (48 hr) to seedling radicle growth (separation of roots + hypocotyls and cotyledons), day 3 (72 hr) to seedling hypocotyl elongation and beginning of photosynthesis (separation of roots, hypocotyls and cotyledons) and day 4 (96 hr) to physiologically active seedlings (separation of roots, hypocotyls and cotyledons). Each organ type was removed from the same glass (20 seedlings), weighed and frozen together (−25°C). These constituted one sample of one organ type. There were either three or four replicates per organ type.

Extraction by Grinding. Samples were ground with a mortar and pestle. Soluble POH was extracted with 3 ml ethanol (purity 97%), a common solvent for extraction of phenolic acids (Van Sumere, 1989). Homogenates were centrifuged (3000 rpm) for 3 min at 20°C. The supernatant was set aside for further analysis after each extraction. The ground residue was extracted twice more with ethanol in the mortar and pestle. Supernatants were combined. Supernatants (5 ml) and pellets (5 ml) were mixed with 10 ml liquid scintillation cocktail (Ultima Gold, Packard). Radioactivity within samples was counted for 10 min by using a liquid scintillation counter (1500 TriCab, Packard).

Extraction by Oxidizing. This investigation was conducted with 3- and 4- day old seedlings. Frozen samples were wrapped in paper (Germaflor) for ovendrying at 80°C for 48 hr. Each sample was then combusted in a biological oxidizer (Ox-500 EG&G instruments) at 900°C for 3 min. The released $^{14}CO_2$ was directly trapped in a vial containing liquid scintillation cocktail (Oxysolve C400, Zinsser Analytic Co.) before counting as above.

Expression of Results. POH levels from radish seedlings were either expressed as concentration (μmol g^{-1} FW) or as quantity (% of applied ^{14}POH) for 20 seedlings (equivalent to one glass). Quantity is the ratio between the disintegrations per minute (DPM) of the initial^{14} POH solution which was added to each glass, and the recovery obtained from the separated organs of 20 seedlings. The total DPM counted in one glass (seedlings + culture medium + rinsing + $^{14}CO_2$) was between 85 and 100% of the initial radioactive solution added to the original culture medium. POH concentration in seedlings was calculated, based upon the equivalence of 10^{-3} POH moles represented by x DPM, detected in the final solution (see above). Concentration pattern reflects the distribution of POH in plant organs. This parameter is widely used to obtain a ratio between compound content and plant biomass, which allows comparisons between different studies. However, using only concentrations could lead to erroneous conclusions because seedling biomass *per se* is necessary to understand plant distribution of POH in target organs (Koricheva, 1999). Table 1 shows the biomass of each radish organ. It reveals the importance of cotyledon biomass which was about three times more than roots or hypocotyls ($P < 0.05$). Thus, POH content was used in order to detect preferential organ accumulation.

Statistical Analyses. As data were not normally distributed and variances were heterogeneous, the Mann-Whitney U non-parametric test ($P < 0.05$) was used for analysis. Three categories of tests were performed to compare: 1) POH content (concentration and quantity) in different organs within the same incubation day; 2) differences in POH concentration from one incubation day to the next, for the same organ; and 3) differences in POH concentration between methods (sterile *vs*. non-sterile and grinding *vs*. oxidizing).

TABLE 1. BIOMASS (MG FRESH WEIGHT ± SD) OF DISSECTED RADISH SEEDLINGS GROWN WITH 10^{-3}M MIXED SOLUTION (POH + ^{14}POH) UNDER STERILE AND NON-STERILE CONDITIONS

Incubation period (in days)	Medium	Roots + hypocotyls	Roots	Hypocotyls	Cotyledons
D2	Sterile	109 ± 9			284 ± 13*
	Non-Sterile	101 ± 32			277 ± 40*
D3	Sterile		104 ± 20	61 ± 7	264 ± 33*
	Non-Sterile		76 ± 21	77 ± 9	329 ± 32*
D4	Sterile		156 ± 18	107 ± 24	326 ± 11*
	Non-Sterile		168 ± 26	147 ± 9	458 ± 19*

Data represent means of at least 3 replicates per incubation time and per culture condition.
*Indicates significantly higher biomass compared to other organs ($P < 0.05$).

RESULTS

Recovery of Unincorporated POH and Released $^{14}CO_2$. Under non-sterile conditions, POH concentrations in the culture medium drastically decreased from 1.7 (D1) to 0.2 (D4) μmol ml^{-1} (Figure 2). The initial POH concentration, 10^{-3}M, fell to 10^{-4}M. Meanwhile, $^{14}CO_2$ release increased from 0.01 ± 0.005 μmol ml^{-1} at D1 to 0.03 ± 0.02 μmol ml^{-1} at D3 followed by a significant increase up to 0.05 ± 0.02 μmol ml^{-1} at D4 (data not shown). Under sterile conditions, no $^{14}CO_2$ was released for any incubation period and POH concentration decreased from 1.6 to 0.7 μmol ml^{-1} over 4 days, a 50% decrease.

POH Translocation under Non-Sterile Conditions and Extraction by Grinding. POH uptake began with seed germination (D1 : 1.8 μmol g^{-1} FW in germinated seeds, data not shown) and was translocated into all radish organs. POH concentration in each organ was compared between incubation days. Cotyledons contained the highest POH levels (10.3 μmol g^{-1} FW), but only on the third day of incubation (Table 2). POH on D4 was only half of the D3 POH concentration in roots, hypocotyls and cotyledons. The total concentration in seedlings also declined by 50% between D3 and D4.

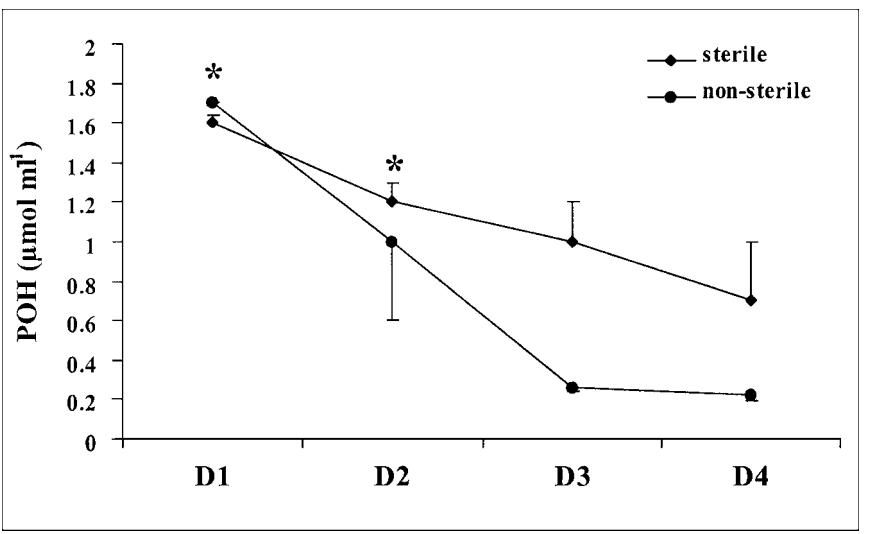

FIG. 2. POH concentration (expressed as μmol ml$^{-1} \pm$ SD) recovered in the radish culture medium under sterile and non-sterile conditions during the four incubation periods (D1 to D4, refers to day 1 to 4). Data represent means of at least 3 replicates per incubation time and per culture condition. * Refers to difference between sterile and non-sterile conditions being significant ($P < 0.05$).

TABLE 2. POH TRANSLOCATION IN RADISH SEEDLINGS UNDER NON-STERILE CONDITION OF INCUBATION. POH CONCENTRATION (EXPRESSED AS μMOL G^{-1} FRESH WEIGHT $\pm$ SD) AND QUANTITY (EXPRESSED AS % OF APPLIED ^{14}POH FOR 20 SEEDLINGS $\pm$ SD) WERE MEASURED AFTER GRINDING EXTRACTION METHOD

	POH concentration (μmol g^{-1}FW)			POH applied (%)		
	Day 2	Day 3	Day 4	Day 2	Day 3	Day 4
Plant Organs						
Roots + Hypocotyls	3.3 ± 0.7			5 ± 1		
Roots		5.9 ± 1.4	2.8 ± 1.4		8 ± 1	5 ± 2
Hypocotyls		5.8 ± 0.9	2.7 ± 1.3		5 ± 0.4	4 ± 1
Cotyledons	4.7 ± 1.8	10.3 ± 1.8*	5.5 ± 1.9	18 ± 8*	35 ± 3*	23 ± 8*
Total	8.1 ± 2.5	22 ± 4	10.9 ± 4.5	22 ± 9	47 ± 4	32 ± 11

Data represent means of at least 3 replicates per incubation time. *Indicates inside a same incubation time, POH content of the organ is different from the others ($P < 0.05$).

POH Translocation under Sterile Conditions and Extraction by Grinding. POH was absorbed by germinating seeds at D1 and accumulated to a concentration of 1.9 ± 0.04 μmol g^{-1} FW (data not shown). Comparisons between POH recovery in organs for each day revealed that POH was concentrated in cotyledons at D2 and D3 (8.2 and 11.2 μmol g^{-1} FW, respectively (Table 3)). POH occurred both in roots (7.7 μmol g^{-1} FW) and cotyledons (8.1 μmol g^{-1} FW) by D4. Total POH concentration in seedlings increased by 7 from D1 to D2 and by 2 from D2 to D3, before declining at D4. Consequently, the highest POH concentration in radish seedlings was found on D3, with about 24 μmol g^{-1} FW.

POH Translocation under Sterile Conditions and Extraction by Oxidizing. Contrary to the results obtained by grinding, no significant differences were found between the POH concentration at D3 and D4 in all organs (Table 4). This was confirmed in whole seedlings where statistical differences of POH recovery were not found between D3 and D4.

Comparison of POH Translocation between Sterile and Non-Sterile Conditions. POH recovery was different between radish organs, but only on the fourth day of incubation (Tables 2 and 3). Hypocotyls contained twice as much POH under sterile conditions than they did under non-sterile conditions, and roots had three times more. Higher accumulation of POH under sterile conditions was also obtained when POH accumulation was compared in whole seedlings.

Comparison of POH Translocation between Grinding and Oxidizing Extractions. POH recovery in radish seedlings was higher following oxidizing extraction than the grinding extraction (Tables 3 and 4). For example, POH content on D3 was 1.5 times higher in hypocotyls and 2 times higher in roots. On D4, only amounts

TABLE 3. POH TRANSLOCATION IN RADISH SEEDLINGS UNDER STERILE CONDITION OF INCUBATION. POH CONCENTRATION (EXPRESSED AS μMOL G^{-1} FRESH WEIGHT $\pm$ SD) AND QUANTITY (EXPRESSED AS % OF APPLIED ^{14}POH FOR 20 SEEDLINGS $\pm$ SD) WERE MEASURED AFTER GRINDING EXTRACTION METHOD

in roots and cotyledons were statistically greater after oxidizing extraction. This better recovery was also observed on D3 (1.5 times more) and on D4 (2.5 times more) in whole seedlings.

POH Storage in Radish Organs. In terms of POH content in radish organs, these results suggest cotyledons are POH sinks on D2 to D4 (Tables 2–4). Depending on method and incubation time, the percentage of ^{14}POH recovered in cotyledons from 20 seedlings varied from 18 to 52%. Generally, POH recoveries in roots and hypocotyls were similar (between 5 to 18%).

TABLE 4. POH TRANSLOCATION IN RADISH SEEDLINGS UNDER STERILE CONDITION OF INCUBATION. POH CONCENTRATION (EXPRESSED AS μMOL G^{-1} FRESH WEIGHT $\pm$SD) AND QUANTITY (EXPRESSED AS % OF APPLIED ^{14}POH FOR 20 SEEDLINGS $\pm$ SD) WERE MEASURED AFTER OXIDIZER EXTRACTION METHOD

Data represent means of at least 3 replicates per incubation time. * Indicates inside a same incubation time, POH content of the organ is different from the others ($P < 0.05$).

DISCUSSION

This work characterized POH translocation in radish seedlings. Results of all experiments revealed that POH uptake begins with germination and is translocated into all organs of radish seedlings. The highest POH concentrations were found in cotyledons (8 to 12.4 μmol g^{-1} FW) and/or roots (7.7 to 15.7 μmol g^{-1} FW).

Initially, POH uptake depended upon the presence (non-sterile culture) or absence (sterile culture) of microorganisms. Indeed, $^{14}CO_2$ release occurred from D1 to D4 under non-sterile culture conditions, but not in sterile cultures. This suggests that $^{14}CO_2$ was released as microorganisms degraded POH. POH is known to be transformed by bacteria and/or fungi into protocatechuic acid and then to aliphatic compounds such as acetyl-CoA and succinate (Bartz and Weltring, 1985). It seems that POH mineralization begins during the first hours of incubation because $^{14}CO_2$ was detectable at D1. This process is also well described in soil where bioavailable phenolic compounds are rapidly degraded by microbes. Martin and Haider (1980), showed that 95% of ^{14}C carboxyl carbon of POH added into non-sterile soil was lost as $^{14}CO_2$ within one week, and the main degradation product was protocatechuic acid. Testing ^{14}C Ring-U protocatechuic acid degradation in soil, they also found that it was readily degraded into $^{14}CO_2$ (35% in one week). POH mineralization depended on experimental conditions (soil specificity) and microbial species. For example, POH mineralization by *Arthrobacter sp.* ranged from 32% to 80% in one day depending on the type of soil (Johnson et al., 1998).

Because this experiment showed that POH was degraded under non-sterile conditions, the lowest POH concentrations were recovered in the culture medium and in radish organs compared to sterile culture. Non-Sterile bioassays are mostly used in allelopathy studies. Therefore, the presence of microorganisms should be determined to interpret the tested allelochemical effect.

The highest POH concentration in seedlings was obtained under sterile conditions using the oxidizing extraction method. Of course, when samples are oxidized, every ^{14}C is recovered. This is quite impossible with the grinding extraction method. From D3 to D4, stability of POH concentration in organs was noticed. Concentrations were equal in roots and cotyledons but, the biomass of cotyledons was about 3 times more. Cotyledons appeared to be the main POH sink.

Being water soluble and lipophilic, POH is able to pass through cell membranes (partition coefficient in octan-1-ol/water : $\log P = 1.1$). In radish seedlings, POH uptake can occur by roots and then is able to penetrate through the root symplast of endodermic cells, apoplast and finally reach the xylem (Delrot and Bonnemain, 1991). POH storage in cotyledons could occur both in vacuoles

(as aglycosidic form) and probably in walls or membranes in "bound" form. This leads to various potential cellular targets of POH in allelopatically stressed plants. Thus, various physiological disorders can occur simultaneously in such plants.

This study further revealed that POH was recovered in radish seedlings in two different chemical forms: an ethanol "soluble" form and a "bound" form that is unextractable by ethanol. Differences between grinding and oxidizing results could be explained in terms of its ethanol solubility. POH concentration differences between these two extraction methods revealed the amount of "bound" POH. For example, half of POH recovered in roots on D3 was bound (i.e., 8.5 μmol g^{-1}). On D4 it was also half of the POH recovered in roots and cotyledons, 9.8 μmol g^{-1} FW and 6.9 μmol g^{-1} FW, respectively. No statistical differences were found for hypocotyls suggesting that hypocotyls only act as a translocating organ between roots and cotyledons. Photosynthesis is supposedly fully active in seedlings by D4, implying that physiological processes such as enzymatic reactions also are active. The conversion of POH into the "bound" form could be more efficient than in younger seedlings. Moreover, secondary compounds are known to be covalently linked to plant cell walls (Hutzler et al., 1998), in waxes (Schmutz et al., 1994), or on external surfaces of plant organs (Cuadra and Harborne, 1996).

This investigation confirmed that POH was taken up by roots and translocated into different organs of radish seedlings. POH quantification was more efficient by oxidizing plant organs than grinding them in ethanol. The oxidizing extraction technique gave more precise results to quantify allelochemicals in plants. Differences between concentrations obtained by these two methods of extraction gave preliminary indication of two forms, soluble and bound, of POH in cells. Both techniques are then complementary to characterize and quantify forms of POH within the plant. It is also important to consider both concentration and quantity to better understand POH translocation in cells, organs and whole plant. Cotyledons seem to act as POH sink.

The role of microorganisms and seedlings in POH degradation is still not clear at this stage. Further, this study was performed counting radiolabeled carbons and stating that all of those belong to POH. Nevertheless, it is likely that metabolic products of POH were counted as ^{14}POH because any detected ^{14}C was considered in these analyses. Thus, further investigation with a radiolabel TLC-scanner is necessary for the differentiation of all ^{14}C molecules (Dayan et al., 1997).

Acknowledgments—The authors would like to thank Dr. Christiane Gallet (University of Savoie) for her constructive remarks and Dr. Christian Gauvrit (INRA, Dijon) and his team in welcoming us in their laboratory to perform oxidizing extraction. They also wish to thank the two anonymous referees for their valuable review of this work.

(Received June 22, 2000; accepted May 10, 2001)

Abstract—Evaluation of biotic interactions along geographic gradients reveals that pressure on plant populations by herbivores and pathogens increases as latitude decreases, and is accompanied by a parallel increase in the number and toxicity of alkaloid-bearing plants. We compared rhizome alkaloid content with plant reproductive and vegetative characters in *Sanguinaria canadensis* (Papaveraceae) along an elevational gradient over two growing seasons to ascertain 1) if alkaloid production in bloodroot varies among populations and systematically with elevation, and 2) if there exists a correlation between isoquinoline alkaloid, vegetative and reproductive production. In general, alkaloid content in bloodroot rhizomes declines with elevation, increases with rhizome water content, varies by site, and fluctuates seasonally with plant growth and reproduction. Alkaloid content was positively correlated with vegetative and reproductive effort with few exceptions. Analysis of total protopine and benzophenanthridine alkaloid concentrations revealed generally similar patterns as those of individual alkaloid concentrations, although significant differences did appear between individual alkaloid concentrations.

Key Words—*Sanguinaria canadensis*, bloodroot, isoquinoline alkaloids, elevation, plant defense, elaiosome.

INTRODUCTION

Abiotic and biotic environmental factors, as well as plant genotype, phenology and ontogeny can all influence the allocation of resources within plants (Coleman and Jones, 1991). Geographic gradients are useful in studying biotic interactions as

* To whom correspondence should be addressed. Current address: Great Lakes WATER Institute, 600 E. Greenfield Ave., Milwaukee, WI 53204.

they constitute natural experiments by providing variations in abiotic factors under which the biotic interactions can be evaluated. This has proven particularly effective for investigating facets of plant-herbivore interactions. There exists compelling evidence that pressures on plant populations by herbivores and pathogens increase with decreasing latitude (reviews by Levin, 1976; Vermeij and Veil, 1978; Jeanne, 1979; Gaines and Lubchenco, 1982); in a parallel fashion, there is an increase in the percent of alkaloid-bearing plants within and among plant families and an increase in toxicity of those alkaloids with decreasing latitude (Levin, 1976; Levin and York, 1978). These relationships are reflected in elevational gradients as well. Herbivory often declines with increasing elevation (Breulheide and Scheidel, 1999; Fuentes-Contreras et al., 1999 but see Reynolds and Crossley, 1997; Suzuki, 1998; Hengxiao et al., 1999), with evidence for decreasing alkaloid chemical defenses with increasing elevation (Chandra and Purohit, 1980; Carey and Wink, 1994).

Such patterns support hypotheses regarding selection on and costliness of plant defense. Considerable effort has been dedicated to determining the direct costs of chemical defense in terms of metabolism, growth, and reproduction, with the goal of illustrating a decrease in fitness with increasing defense in the absence of herbivores, but studies have shown a range of conflicting results (reviews by Gershenzon, 1994; Bergelson and Purrington, 1996). Mauricio and Rausher (1997) recently demonstrated that *Arabidopsis thaliana* plants released from insect and pathogen pressure experience a decrease in selection pressure on glucosinolate concentration and trichome density. It follows, then, that with decreasing herbivore and pathogen pressure toward higher latitudes or elevations, chemical defenses may similarly decline or show higher variation due to the release from selection pressure. Moreover, a relative increase in vegetative or reproductive effort in higher latitudes or elevations should be apparent if defenses are costly.

We present here a study of variation in isoquinoline alkaloid chemistry, vegetative growth, and reproduction among populations of *Sanguinaria canadensis* along an elevational gradient. The goals of our research are 1) to describe variation in isoquinoline alkaloid concentrations among populations and systematically with elevation in *S. canadensis* (bloodroot), and 2) to determine if there is a negative correlation between alkaloid production and efforts toward vegetative growth and reproduction.

Natural History. S. canadensis (bloodroot) is a perennial herb that occurs in a widespread but patchy distribution in eastern North America from Florida to Nova Scotia, and produces several highly bioactive isoquinoline alkaloids in the rhizomes, stems, and leaves, noticeable as a bright orange-red latex. These broad-spectrum defense chemicals deter or kill bacteria, fungi, insects, nematodes, and protozoa (Miller and Feeny, 1983; review in Downum, 1992; Schmeller et al., 1997). Plants reproduce both by seeds and by vegetative propagation of the rhizome. Pods are produced from May through early July and may contain up to 50 seeds, each displaying an oil-rich seed appendage (elaiosome). The elaiosomes

contain fatty acids, amino acids, and diglycerides that attract and stimulate ants to act as dispersal agents (Marshall et al., 1979; Skidmore and Heithaus,1988; Gunther and Lanza, 1989). Germination rates in *S. canadensis* are greater after elaiosome removal by ants (Lobstein and Rockwood, 1993) and ant dispersal may influence genetic relatedness of local bloodroot populations (Pudlo et al., 1980).

METHODS AND MATERIALS

Field Sites. We monitored populations of bloodroot along an elevational transect between Athens, Georgia, and Franklin, North Carolina, during the 1998 and 1999 growing seasons. All populations were located within mesic coves in deciduous hardwood forest. Cover for these sites ranged from 68 to 92% after canopy leaf emergence, estimated using a densiometer estimation. Low-elevation populations ranged from 195 to 215 m in Clarke, Oglethorpe, and Oconee Counties,Georgia; mid-elevation populations between 340 and 550 m were located in Habersham and Rabun Counties, Georgia; high-elevation sites were found between 760-1280 m in Macon County, North Carolina within the Coweeta Hydrologic Laboratory LTER boundaries. Samples included 4 to 12 individuals per population (i.e., per site). Up to 14 sites were included per elevation. Spring 1999 samples ($n = 206$) included a second sampling of plants from November 1998 ($n = 120$), as well as newly sampled plants.

Buds and leaves emerged from the soil between February and April each year. After emergence, plants were tagged around the base of the leaf stem. In both years of study, field data were collected on rhizome width and length, flower and leaf phenology, leaf number and size at time of seed-set, and number of flowers and seeds produced. Sites were visited starting in February when plants emerged in the spring. Each site was visited weekly during flowering, twice monthly during early seed-set, and bi-weekly as seeds ripened. As the pods opened on the plant, seeds were collected, and diaspore and elaiosome weights were recorded. Elaiosome tissue was dissected from the seed and weighed. In November 1998, tissue samples were taken during plant dormancy for chemical analysis ("Fall 1998" samples). In 1999, March-May tissue samples were taken at the time of seed collection ("Spring 1999" samples). To take tissue samples, we first uncovered the rhizome and measured length and width; the roots were left undisturbed. We excised 0.5-1g of tissue from the middle of the rhizome equidistant from the base of the growing bud and the end of the living rhizome tissue. We then weighed the tissue sample using a portable digital balance, and placed it in a foil- covered glass vial with 10 ml of 100% HPLC-grade methanol. Vials were stored at -20° C until processed for chemical analysis.

Chemical Analysis. Tissue samples for HPLC analysis were homogenized up to one minute in the original vial using an Omni homogenizer fitted with a

saw-tooth rotor. The resulting slurry was filtered using a 13 mm nylon syringe-tip filter, transferred to a clean vial, and stored at -20°C until HPLC analysis. The homogonizer was rinsed with 1 ml of methanol, adding to the total volume of the samples. No further pre-purification of the samples was performed. Due to the photosensitivity of sanguinarine, extraction procedures were conducted under low-light conditions, and vials were either amber glass or wrapped in aluminum foil. Filtered samples (40 μl each) were analyzed at 284 nm using an HPLC Separations Module 2690 and Waters 996 Photodiode Array Detector (Waters Assoc, Milford, MA). Alkaloids were separated using a Phenomenex Silica C18 column (5 μm, 1.5×46) with a mobile phase of 0.1 N tartaric acid (0.125% SDS) in 1:1 v:v in acetonitrile; the flow rate was 0.5 ml/min (Hashimioto et al.,1986; Mahady et al., 1993). External standards were obtained for sanguinarine ($R_T = 11.87$), berberine ($R_T = 14.94$), and chelerythrine ($R_T = 16.13$) from Sigma Chemical Co. (St. Louis, MO). Remaining peaks were tentatively identified as protopine ($R_T = 8.59$), allocryptopine ($R_T = 9.42$), chelirubine ($R_T = 11.13$), sanguirubine ($R_T =$ approx. 14.79), chelilutine ($R_T = 19.53$), and sanguilutine ($R_T = 21.49$) by comparing elution times and relative peak areas from previous papers (Hashimoto et al., 1986; Thorne et al., 1986; Mahady et al., 1993). Because of extensive work on the pharmacological properties of bloodroot alkaloids, these identifications should be robust but we stress that we did not identify them ourselves. Consequently, we consider these identifications as tentative and their concentrations are given as sanguinarine equivalents. In some HPLC profiles, the peaks for sanguirubine coeluted with berberine and resolved with inconsistent clarity; we therefore excluded them from subsequent analyses.

Statistical AnalysIs. Data were analyzed using generalized linear model in SAS (PROC GENMOD; Anonymous, 1996) by eliminating variables and interaction terms sequentially from the model to provide the most simple and parsimonious models available (Agresti, 1996). Alkaloid concentrations were analyzed individually and as alkaloid group totals. The protopine group totals include protopine and allocryptopine; the benzophenanthridine group totals include chelirubine, sanguinarine, chelerythrine, chelilutine, and sanguilutine.

RESULTS

Variation in Alkaloid Characters. Alkaloid concentrations either declined or were unrelated to elevation. Total benzophenanthridine group concentrations decreased with increasing elevation for both Fall 1998 and Spring 1999, whereas total protopine group concentrations were unrelated to elevation for either date (Table 1; Figure 1). Individual concentrations of sanguinarine and chelerythrine were unrelated to elevation in Fall 1998, but the remaining individual alkaloid concentrations declined with increasing elevation. In Spring 1999, sanguinarine

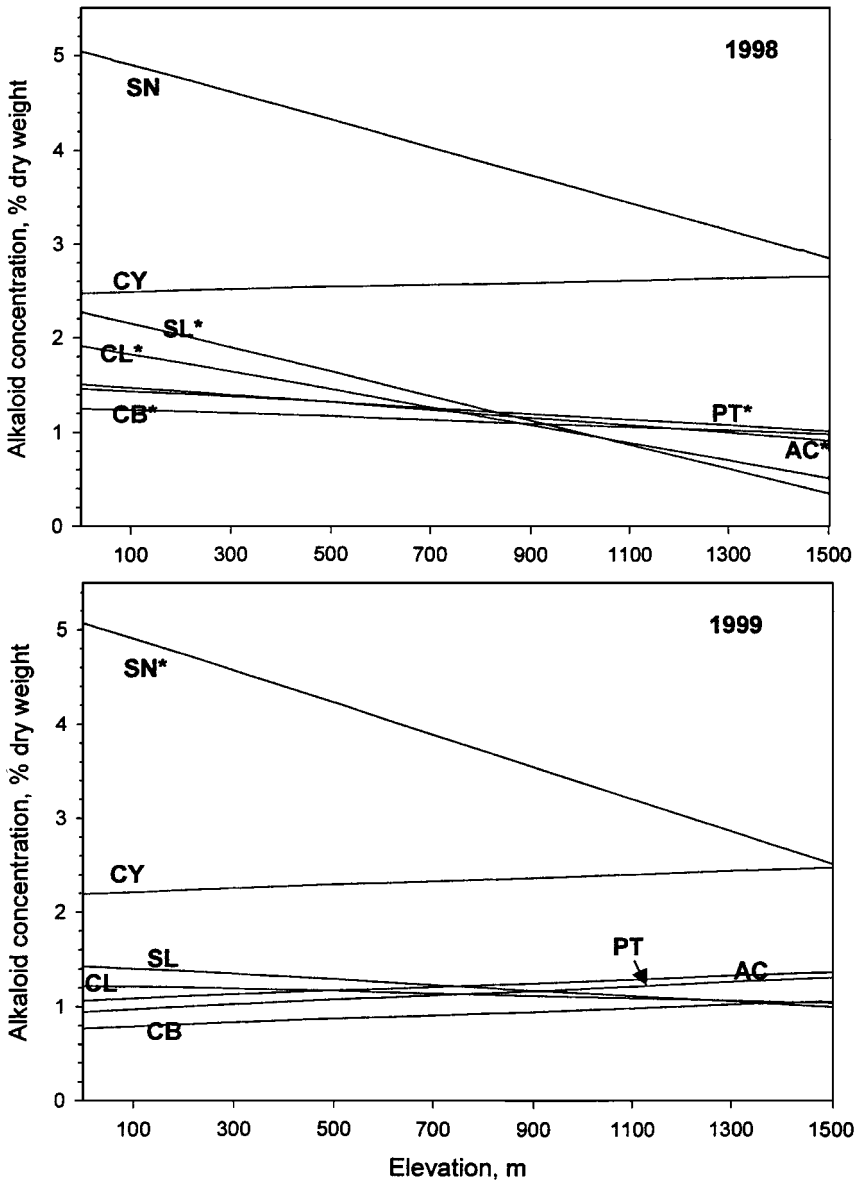

FIG. 1. Comparison of trends in alkaloid concentrations of *Sanguinaria canadensis* over an elevational gradient between November 1998 and Spring 1999. PT: protopine, AC: allocryptopine, CB: chelirubine, SN: sanguinarine, CY: chelerythrine, CL: chelilutine, SL: sanguilutine. ∗ indicates significant relationships.

was the only individual alkaloid that significantly declined with elevation; the concentrations of all other alkaloids were unrelated to elevation (Table 1; Figure 1). Total benzophenanthridine group and total protopine group concentrations differed among sites in both 1998 and 1999. Individual alkaloid concentrations, with the exception of Spring 1999 chelirubine concentrations, showed variation by site for both dates (Table 1). Alkaloid content of rhizomes declined from dormancy (Fall 1998) to active growth (Spring 1999), with the exception of total protopine and sanguinarine concentrations (Table 1).

Variation in Vegetative and Reproductive Characters. Elevational trends observed in vegetative and reproductive characters varied with character and sample date. Leaf size increased with elevation in 1998, but decreased with elevation in 1999. Rhizome length and width were unrelated to elevation for either date (Table 2). Mean rhizome width was greater in 1999. Notably, water content of rhizomes declined with elevation for both dates. In general, the majority of vegetative characters did not vary according to site, although in some instances, weak correlations were evident for rhizome width, rhizome length, and leaf size (Table 2).

In 1998, the number of flowers per plant and elaiosome weight were unrelated to elevation, whereas they both declined with increasing elevation in 1999 (Table 2). The number of seeds per plant increased with elevation in both years. Reproductive characters varied more strongly by site in 1999 than in 1998, although seed weight variation was unrelated to among-site differences (Table 2). Elaiosome weight was higher and average flowers per plant lower in 1999. Reproductive characters were unrelated to percent water in the rhizome in both 1998 and 1999.

Alkaloids vs Vegetative and Reproductive Characters. Alkaloid content generally increased with, or was unrelated to, vegetative and reproductive effort, with a few exceptions. Total Fall 1998 benzophenanthridine and protopine group concentrations increased with rhizome size, and total protopine group concentrations decreased with leaf size in 1998 (Table 3). Total protopine concentrations sampled in Spring 1999 were unrelated to vegetative characters, whereas total benzophenanthridine concentrations increased with rhizome size and decreased with leaf size. Total benzophenanthridine and protopine group concentrations increased with rhizome water content in both fall 1998 and Spring 1999. With the exception of chelirubine, individual alkaloid concentrations reflected the same correlation for both sample dates (Table 3).

Total alkaloid concentrations in Fall 1998 were higher in plants that had produced more flowers and heavier seeds during the 1998 growing season. Individually, all alkaloids increased with seed weight, allocryptopine increased with number of flowers per plant, and chelerythrine increased with number of flowers and number of seeds per plant in 1998 (Table 4). In contrast, protopine, allocryptopine, and sanguilutine concentrations decreased with an increase in the number of seeds per plant in 1998. No relationships were found between either total benzophenanthridine or total protopine group concentrations and Spring 1999

Overall Predictive Model. In a model assessing the relative contributions of elevation, site, reproductive, and vegetative characters to rhizome alkaloid content of bloodroot, rhizome water content and site explained most of the variance in both total benzophenanthridine and total protopine group concentrations for both 1998 and 1999 (Table 5). The strongest predictor of individual alkaloid concentrations in Fall 1998 was seed weight in most cases. Elevation and percent water in the rhizome were related to individual concentrations in Spring 1999 (Table 5).

DISCUSSION

Elevational Variation. Our results provide further evidence for an elevational cline in alkaloid production. Because we did not quantify herbivory or pathogen load, it cannot be determined if lower rhizome alkaloid content observed at higher elevations is a result of release from selective pressure, but our results are consistent with this hypothesis. Significant site effects suggest there are local influences on alkaloid production apart from larger climatic forces that accompany elevational gradients, or genetic variation in the alkaloid production of local populations.

The strong increase in alkaloid concentration with rhizome water content may result from nitrogen- or micronutrient-limitations. Water availability can constrain nutrient absorption because diffusion rate is the limiting step in the uptake of scarce nutrients (Landers et al., 1997) and soil nutrients influence alkaloid production (Waterman and Mole, 1989; Ohnmeiss and Baldwin, 1994; Baldwin et al., 1998; Salmore and Hunter, 2001). The observed increase in seed number and leaf size with elevation suggests that any nutrient limitation to alkaloid biosynthetic pathways may be a consequence of a within-plant allocation shift, rather than an overall nutrient limitation to the whole plant. Furthermore, the ability to generate secondary compounds under nutrient enrichment may be constrained genetically (reviews in Waller and Nowacki, 1978 and Roberts and Wink, 1998).

The decrease in rhizome alkaloid content between fall and spring sample dates supports the findings of Bennett et al. (1990), that showed the lowest concentration alkaloids in the rhizome at late seed-set. During active growth, alkaloid production may appear to decline due to an increase in biomass, even though total production may be equivalent or greater in the spring. Little change in rhizome size was observed between years to account for this. Translocation of alkaloids from the rhizome to fine roots or above-ground parts could cause this pattern, but currently no evidence exists for long-distance transport of alkaloids in *S. canadensis* (Kutchan et al., 1985). Alternatively, alkaloid production in fine roots or above-ground parts could increase at the expense of alkaloids produced in the rhizome.

Competition for substrate during the production of alkaloids derived from similar metabolic pathways may explain some of the variation in individual alkaloid concentrations. The isoquinoline alkaloids found in bloodroot are biosynthetically

closely related; protopine is a key substrate for the more highly oxidized benzophenanthridine alkaloids, and these derived molecules may compete for substrate as well (Zenk, 1994; Roberts, 1998).

Correlations Between Defense, Growth, and Reproduction. Contrary to our prediction, sanguinarine was positively correlated with seed and elaiosome size, all alkaloids increased with seed weight, and higher alkaloid concentrations occured in larger rhizomes. If herbivory drives the level of defense investment (Feeney, 1976; Rhoades and Cates, 1976), then better defended plants escape herbivory and are able to produce higher quality seeds, or if resource availability determines the amount of nutrients available (Bryant et al., 1983; Coley et al.,1985), then bloodroot plants that are able to invest in higher quality seeds also are able to invest more in sanguinarine production. Quantification of herbivory and pathogen loads would provide insight into the mechanism driving patterns of alkaloid production. An increase in 1998 concentrations of protopine, allocryptopine, and sanguilutine with a decline in the number of seeds produced in the previous growing season may provide evidence for a trade-off, but this pattern is evident only in the 1998 sample date and for three of the seven alkaloids. A more likely cause for this correlation is the production of sanguinarine, which requires available protopine pools, and competes for a biosynthetic dihydro-intermediate with more oxidized alkaloids (Roberts, 1998) like sanguilutine.

Conclusion. Alkaloid concentrations in *Sanguinaria canadensis* provide further evidence for an elevational cline in the production of defensive compounds, although the results of this study demonstrate that rhizome alkaloid content varies with seasonal plant activity. The manifestation of trade-offs involving alkaloid production, in turn, is affected by these fluctuations and may lead to different conclusions based on the date that samples were taken. Total alkaloid group concentrations provide insight into main biosynthetic activities, while patterns seen in individual alkaloids illustrate complex within-organism metabolic allocation. Alkaloid content data resulting from growing clones or transplants of *S. canadensis* over several years under an experimental manipulation of herbivores and pathogens would better delineate trade-offs between defense, growth, and reproduction.

Acknowledgments—The authors thank M. Thomas, R. Klaper, and A. Reynolds for assistance in the field, and T. Maddox, T. Ackerman, and M. Madritch for technical assistance. We are grateful to A. Shenk, S. Sanders, and J. Schmidt for permission to visit their property. Invaluable access to analytical equipment was graciously offered by Prof. W. Randle. The paper was much improved by helpful comments from R. Klaper, M. Thomas, and two anonymous reviewers. Finally, we thank the UGA Museum of Natural History Josh Laerm Award for financial assistance.

ENVIRONMENTAL AND GENOTYPIC INFLUENCES ON ISOQUINOLINE ALKALOID CONTENT IN *Sanguinaria canadensis*

ALISSA K. SALMORE and MARK D. HUNTER*

Institute of Ecology
University of Georgia
Athens, Georgia 30602

(Received June 22, 2000; accepted May 12, 2001)

Abstract—In a common garden, we investigated genetic and environmental influences on alkaloid production using *Sanguinaria canadensis* as a model. Nutrient and shade regimes were applied to replicated clones over one growing season, and induction of alkaloid production in bloodroot was tested on a whole-plant basis using jasmonic acid as an elicitor. Alkaloid concentrations increased with decreasing light intensity and fertilizer levels. Induction was not achieved by foliar application of jasmonic acid. Genetic influences represented by clone effects may be indicated by variation in alkaloid concentration by clone, but this experimental design did not allow us to distinguish genetic from pre-experiment environmental influences on the rhizomes.

Key Words—*Sanguinaria canadensis*, bloodroot, alkaloids, sanguinarine, phototoxicity, shade, jasmonic acid.

INTRODUCTION

Since the response of plants to herbivory is limited by the availability of resources, the allocation of limiting nutrients defines the quality and quantity of plant defenses (Bryant et al., 1983; Coley et al., 1985). Evidence exists that some alkaloid synthesis is relatively constant (Ralphs et al., 1998) or can be functionally variable (review by Eilert, 1998), where chemical or physical changes following damage can occur within a matter of hours, or after a long period as a response in the next growing season (Coleman and Jones, 1991; Baldwin, 1998). Such inducible defenses may be adaptive because individuals that express a costly defense only when needed can otherwise increase allocation to growth and reproduction

(Feeney, 1976; Fagerstrom et al., 1987; Agrawal,1998; Baldwin, 1998), or because herbivores experience reduced performance in dealing with variability in defense systems and therefore avoid such plants (Karban et al., 1997).

Induction has been demonstrated experimentally for specific alkaloids in cell culture (Gundlach et al., 1992; Cline et al., 1993; Facchini, et al., 1996) and in whole plant systems (VanDam, 1993; Aerts et al., 1994; Baldwin, 1996; Baldwin et al., 1998). *Sanguinaria canadensis* cell cultures respond to fungal cell wall, hormone, and micronutrient elicitors with increased production of the isoquinoline alkaloid sanguinarine (Cline et al., 1993; Facchini et al., 1996). In cell cultures of *S. canadensis*, jasmonic acid increased alkaloid-synthesis enzyme activity to double that of control levels, whereas methyl jasmonate increased activity three- to four-fold higher (Ignatov et al., 1996).

Although environment may modify the production of defenses, the regulation of quantity and quality of production falls under genetic control (Waller and Nowacki, 1978; Saito and Murakoshi, 1998) with evidence for polygenic inheritance and chemical heterosis in hybrid studies (review by Levin, 1976). Furthermore, since phenotype reflects the interaction of a developmental program and genotype with a particular environment (Sultan, 1995), genetically controlled defense characters may vary with environment (Maddox and Cappuccino, 1986).

The purpose of this study was to assess the relative influence of genes and environment on the chemical defenses of *Sanguinaria canadensis* (bloodroot). We ask: what is the contribution of gene and environment to the production of these alkaloids? Is alkaloid production inducible on a whole-plant basis in *S. canadensis* and does induction vary by genotype? For these experiments, we propagated clones of individual plants under varying environmental conditions and subsequently collected information on alkaloid content and plant phenology.

Natural History. S. canadensis (Bloodroot) is a perennial herb that occurs in mesic deciduous hardwood forest and has a widespread but patchy distribution in eastern North America from Florida to Nova Scotia. Plants reproduce by seeds and via vegetative propagation of a fleshy rhizome. Bloodroot plants produce and store several highly bioactive benzophenanthridine alkaloids in their rhizomes, which act as broad-spectrum defense chemicals that deter or kill bacteria, fungi, insects, nematodes, and protozoa (Miller and Feeny, 1983; review by Downum, 1992; Schmeller et al., 1997). Pods are produced from May through early July and contain up to 50 seeds that have oil-rich seed appendages (elaiosomes) that are attractive to several ant species (Beattie and Culver, 1981).

METHODS AND MATERIALS

Experimental Design. In February 1998, we obtained rhizomes from Sunlight Gardens in Andersonville, Tennessee, and planted them in fertilizer-free potting

mix. Initial relatedness for the rhizomes is unknown, and given a common source, this could mean that the initial sample expressed low genetic variation. We assembled the potting mix with 25% composted pine bark mulch, 45% peat, 15% vermiculite, and 15% perlite (Conrad Fafard, Inc., Agawan, MA). Each rhizome was assigned to be fertilized at either no, medium (200 ppm), or high (400 ppm) levels using standard Hoaglan's NPK 20-10-20 fertilizer (Peters, St. Louis, MO). Fertilizer was applied bi-weekly for two months (through the growing season). When plants became dormant, they were maintained with water only. All plants were propagated in a greenhouse for the first year (Figure 1, A and B).

Ten rhizomes from each fertilizer group were assigned to the induction experiment. The remaining rhizomes from each fertilizer group were designated for the shade experiment (Figure 1C). In February 1999, when plants were still dormant, we divided each rhizome into a set of three clones (Figure 1, D and E). These pieces were measured for length and width, and tissue samples were collected from the middle of the rhizome as each rhizome was divided for HPLC analysis; up to 1 g wet weight of rhizome tissue was removed with a razor blade and placed directly into a glass scintillation vial with 10 ml of 100% HPLC-grade methanol. Samples were stored at -20°C until HPLC analysis. Clones were replanted in fertilizer-free potting mix in separate 6″ plastic pots and maintained with water for the duration of the experiments. Weekly observations on leaf, flower, and fruit number, and leaf appearance were recorded. Bloodroot facultatively self-pollinates in the absence of pollinators (Lyon, 1992); therefore, no hand-pollinations were performed. Most plants initiated seed pods, but they all eventually aborted in both the induction and shade experiments. In October 1999, the experimental plants were harvested. Rhizome length and width were measured, and a final rhizome tissue sample was taken as before and stored in 100% methanol at -20°C until analysis by HPLC.

Shade Experiment. Outdoor shade houses for the treatments were constructed by using black nylon 50% and 80% shade cloth (Synthetic Industries; Gainesville, GA) and 1″ id. PVC pipe anchored to 2.4 m by 4.6 m wooden ground frames. The no-shade treatment was placed in a ground frame without a shade cloth-PVC pipe structure. Weed cloth was placed on the ground to prevent additional shading by volunteer plants and to discourage infestation by fire ants.

One rhizome from each of the clone sets was randomly assigned to 80%, 50%, and 0% shade treatments. All clones were randomly placed within a single block in each treatment. Plants were watered 2 to 3 times during the week to maintain soil moisture. Aphids colonized some of the plants for 3 weeks mid-season, and presence/absence data were recorded.

Induction Experiment. One clone from each of the 10 sets was randomly assigned to a jasmonic acid, water, and control treatment. All clones were randomly placed within a single block on a greenhouse bench. Jasmonic acid was obtained from Sigma Chemical, Inc. (St. Louis, MO), dissolved in 1 ml 100% ethanol, and diluted to a 100 mM stock solution with distilled, deionized water and stored at

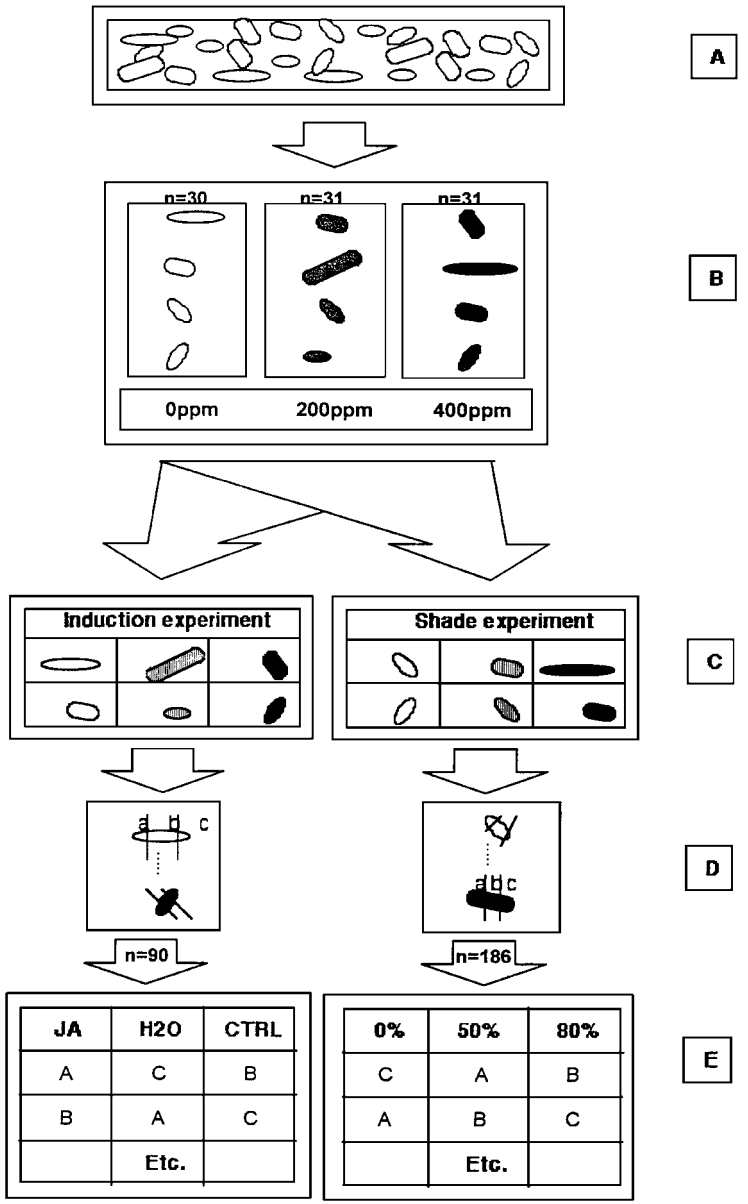

FIG. 1. Experimental design. Initial pool of rhizomes (A) assigned to fertilizer treatments (B) and propagated in the greenhouse for 1 year. Rhizomes assigned to either induction or shade experiment (C), cut into clone sets (D), and randomly assigned to treatment blocks (E).

−20°C. Jasmonic acid-treated (JA) clones received via spray bottle 5 ml of 1 mM JA in distilled, deionized water over the entire above-ground plant (Thaler et al., 1996); water-treatment clones received an application of 5 ml distilled, deionized water; control plants had no foliar application. Foliar treatments were applied by spray bottle once a week and began after the primary leaf of the individual clone was fully expanded after emerging from the soil. Treatments continued until dormancy (approximately 15 weeks). Plants were removed from the block during treatment to prevent cross-contamination by aerial spray. All plants were watered in the morning before the treatment and one additional day during the week to maintain soil moisture.

Chemical Analysis. Rhizome tissue samples were reduced to small pieces in the original vial using a scalpel. Any liquid or tissue remaining on the scalpel was rinsed back into the vial with 1 ml 100% methanol. The resulting slurry was filtered with a 13 mm nylon syringe-tip filter, transferred to a clean vial, and stored at −20°C. No further pre-purification of the samples was performed. Due to the photosensitivity of sanguinarine, extraction procedures were conducted under low-light conditions and all vials used were either amber glass or wrapped in aluminum foil. Samples (40 ul each) were analyzed with an HPLC Waters Assoc. (Milford, MA) Separations Module 2690 and Waters 996 Photodiode Array Detector, reading at 284 nm. Alkaloids were separated by using a Phenomenex Silica C18 column (5 um, 1.5 × 46 mm) with a mobile phase of 0.1N tartaric acid (0.125% SDS) in 1:1 v:v in acetonitrile; the flow rate was 0.5 ml/min (Hashimoto et al.,1986; Mahady et al., 1993). Standards were obtained for sanguinarine, berberine, and chelerythrine from Sigma Chemical Co. (St. Louis, MO). Remaining peaks were tentatively identified as protopine, allocryptopine, chelirubine, sanguirubine, chelilutine, sanguilutine and by comparing the elution time and relative peak areas from previous papers (Hashimoto et al., 1986; Thorne et al., 1986; Mahady et al., 1993). Because of extensive work on the pharmacological properties of bloodroot alkaloids, these identifications should be robust, but we stress that we did not identify them ourselves. Consequently, we consider these identifications as tentative and their concentrations are given as sanguinarine equivalents.

Statistical Analysis. Data were analyzed by using generalized linear model procedures in SAS (PROC GENMOD; Anonymous, 1996). Variables and interaction terms were sequentially eliminated from the model to provide the most simple and parsimonious model available (Agresti, 1996). Alkaloid concentrations were analyzed individually and as alkaloid group totals. The protopine group included protopine and allocryptopine; the benzophenanthridine group included chelirubine, sanguinarine, chelerythrine, sanguilutine, and chelilutine. Clone and fertilizer effects were analyzed in separate models. Although all clones in 1999 experiments were represented in each treatment, the individuals from which these clones were derived received differing fertilizer levels during 1998.

RESULTS

Alkaloids present in *S. canadensis* rhizome tissue from our experimental plants include (in order of elution) protopine ($R_T = 8.48$), allocryptopine ($R_T = 9.29$), chelirubine ($R_T = 10.94$), sanguinarine ($R_T = 11.71$), sanguirubine ($R_T =$ approx. 14.67), berberine ($R_T = 14.71$), chelerythrine ($R_T = 15.84$), chelilutine ($R_T = 19.20$), and sanguilutine ($R_T = 21.09$). Sanguinarine and chelerythrine constitute the most abundant alkaloids. Alkaloid concentrations overall were consistently lower after the shade and induction experiments compared to the pre-experiment levels (Table 1). In some HPLC profiles, the peaks for sanguirubine and berberine were small, eluted very close together, and resolved with inconsistent clarity; we therefore excluded them from subsequent analyses.

Shade Experiment. Because not all clones were in all fertilizer treatments, clone and fertilizer effects could not be directly compared and were analyzed in separate statistical models. Most individual alkaloid concentrations and total benzophenanthridine group alkaloid concentrations were influenced by clone (Table 2), with up to 10-fold variation in the production of alkaloids among clones (Figure 2). Chelirubine and total protopine group concentrations were unrelated to clone.

In either clone or fertilizer models, total benzophenanthridine alkaloid concentrations increased with increasing shade, which followed the individual concentrations of sanguinarine and chelerythrine (Figure 3, Table 2). Total protopine group concentration was higher in the 50% and 80% shade treatment, although alkaloid concentrations among these two treatments were not statistically different.

TABLE 1. COMPARATIVE MEANS (±SE) OF POSTFERTILIZER ALKALOID CONCENTRATIONS GIVEN AS PERCENT DRY WEIGHT FOR FEBRUARY 1999 AND OCTOBER 1999

	Shade experiment		Induction experiment	
Alkaloid	February 1999	October 1999	February 1999	October 1999
Protopine	0.71 ± 0.26	0.37 ± 0.16	0.74 ± 0.38	0.32 ± 0.03

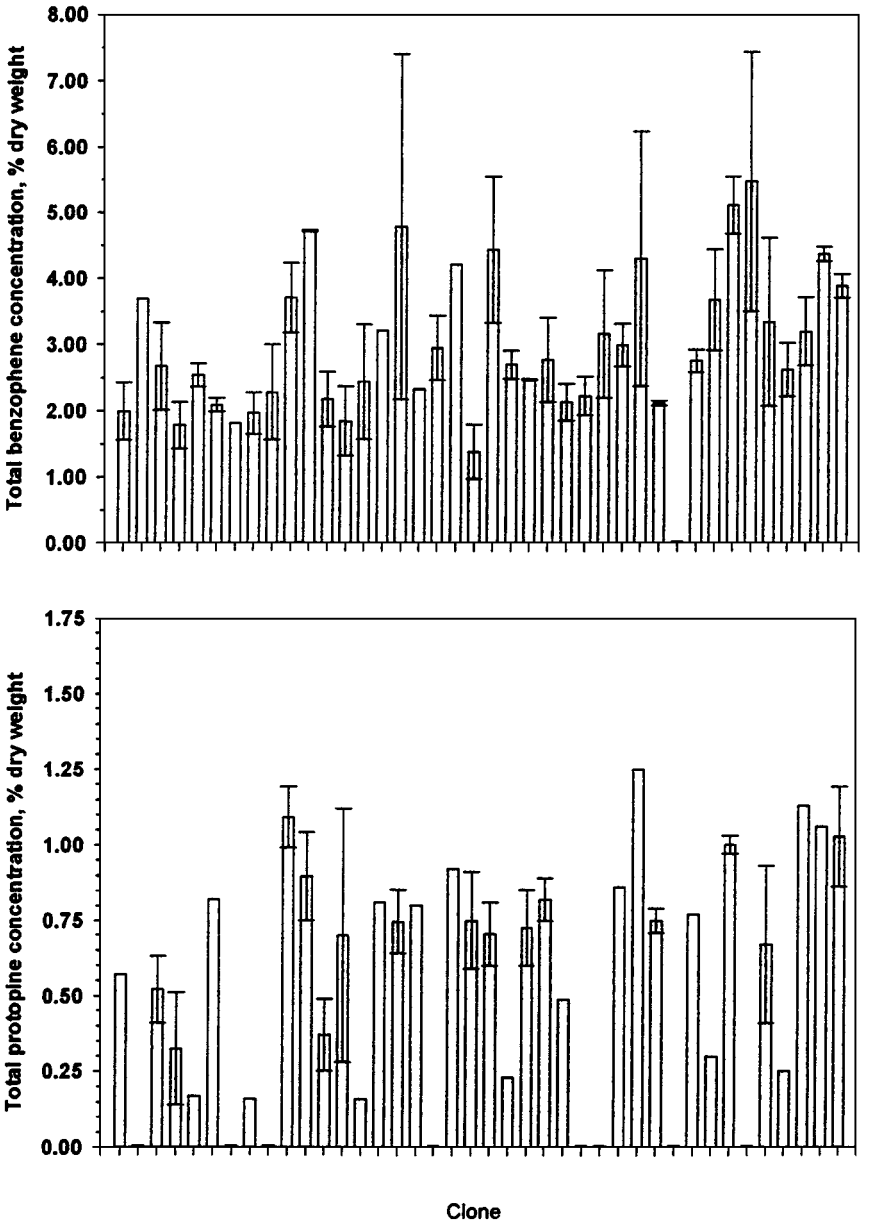

FIG. 2. Variation in total benzophene and protopine concentration among clones in *Sanguinaria canadensis*, across all fertilizer and shade treatments. Error bars are standard errors. For single clone samples ($N = 1$), data are without error bars.

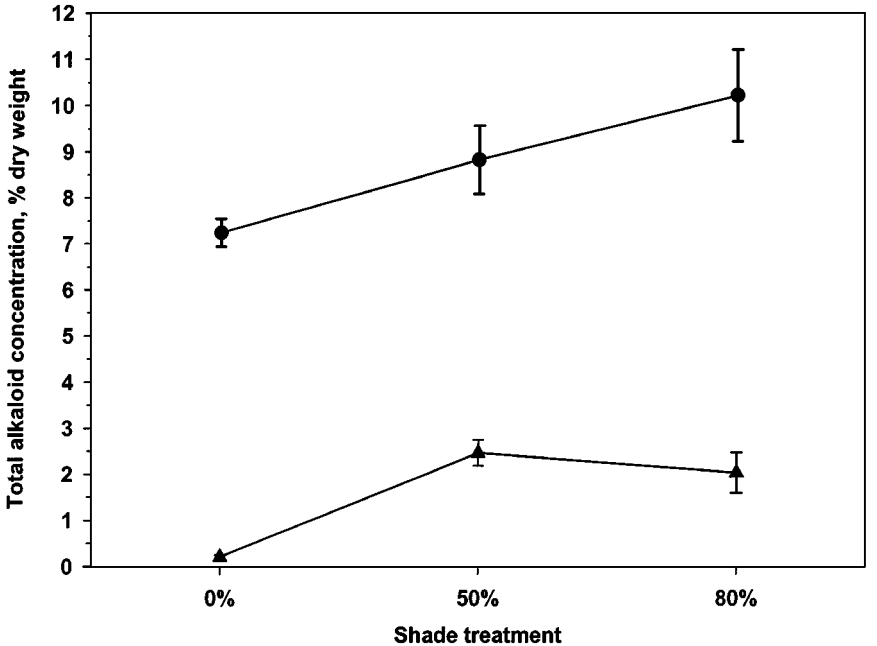

FIG. 3. The effect of shade on alkaloid concentrations in *Sanguinaria canadensis*. Total benzophenanthridine group concentration = •; total protopine group concentration = ▲. Points are the means (±SE) of 5, 61, and 58 replicates per treatment for 0%, 50%, and 80% shade, respectively. High mortality occurred in the 0% shade treatment.

This had the net effect of a weak increase in total protopine alkaloids with increasing shade (Table 2). Protopine, allocryptopine, and chelilutine concentrations increased with shade when modeled with fertilizer as a main effect, but this relationship was not significant in the clone model (Table 2).

Total benzophenanthridine group concentration was influenced by previous year fertilizer and increased with rhizome water content; neither influenced total protopine group concentrations. Zero and medium fertilizer levels produced higher mean alkaloid concentrations than plants that were provided with a high level of fertilizer (Figure 4). Fertilizer levels explained most of the variance in chelirubine, chelilutine, and sanguilutine concentrations along with rhizome water content. Sanguinarine, chelirubine, chelilutine, and sanguilutine concentrations increased with increasing rhizome water content in the model including fertilizer; however when clone was included as a variable in the model, only chelirubine concentration significantly increased with rhizome water content (Table 2).

Total protopine group alkaloid concentration, as well as individual protopine and chelilutine concentrations decreased with increasing rhizome width, and

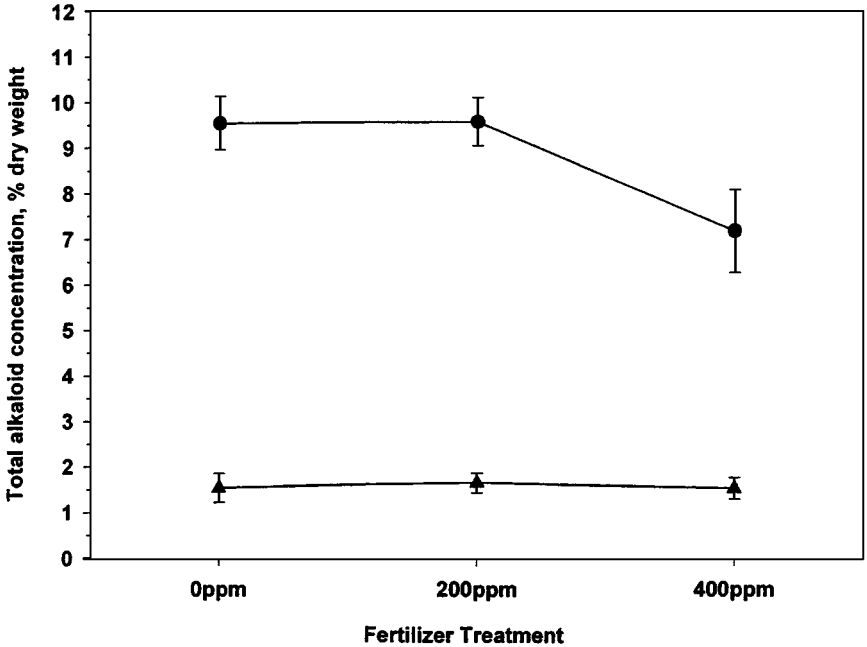

FIG. 4. Alkaloid concentration response to different fertilizer levels in *Sanguinaria canadensis*: Shade experiment. Total benzophenanthridine group concentration = •; total protopine group concentration = ▲. Points are the means (±SE) of 45, 43, 34 replicates for no, low, and high fertilizer treatments, respectively.

allocryptopine and chelirubine concentrations decreased with increasing rhizome length. Total benzophenanthridine concentration was unrelated to rhizome size. The relationship between chelirubine and chelilutine and rhizome size was not significant in the clone model (Table 2).

Induction Experiment. As in the shade experiment, not all clones were included in all fertilizer pre-treatments, so clone and fertilizer effects were analyzed in separate statistical models. All individual and total alkaloid group concentrations varied significantly by clone in this experiment (Table 3) with alkaloid concentrations varying up to 10-fold among clones (Figure 5).

Jasmonic acid applications did not increase the concentration of any of the alkaloids, individually or as group totals, over the concentrations of the control treatments (Figure 6, Table 3).

Individual and total benzophenanthridine alkaloid concentrations decreased with increasing fertilizer levels (Figure 7, Table 3), although fertilizer did not influence total protopine group concentration over all. The interaction between fertilizer and rhizome width significantly influenced protopine, allocryptopine, chelirubine,

and sanguilutine (Table 3); these alkaloids increased weakly with increasing rhizome width under medium fertilizer levels, but decreased weakly with increasing rhizome width under high fertilizer levels. No relationship between alkaloid concentration and rhizome width was apparent in the non-fertilized treatment.

The interaction between clone and rhizome length significantly influenced protopine, allocryptopine, and chelirubine levels, although total protopine and benzophenanthridine group concentrations were not influenced by rhizome size in this experiment (Table 3). The change in individual protopine, allocryptopine, and chelirubine concentrations with rhizome length varied among clones in no predictable manner.

Total benzophenanthridine concentrations increased weakly with rhizome water content, but no significant relationship between total protopine levels and rhizome water content was found. Chelilutine concentration increased and sanguilutine concentration decreased with increasing rhizome water content in the clone model (Table 3). An interaction between clone and rhizome water content explained a minor part of the variance in chelilutine and sanguilutine concentrations (Table 3). The change in chelilutine and sanguilutine concentration with increasing rhizome water content varied unpredictably among clones.

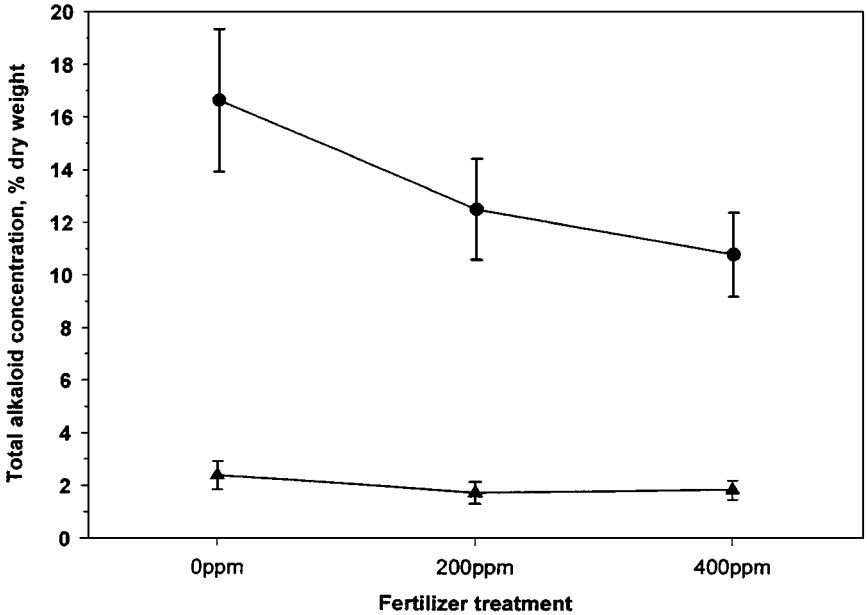

FIG. 7. Alkaloid concentration in response to fertilizer levels in *Sanguinaria canadensis*: Jasmonic acid experiment. Total benzophenanthridine group concentration = •; total protopine group concentration = ▲. Points are the means (±SE) of 30 replicates per treatment. For single clone samples (n = 1), data are without error bars.

DISCUSSION

Shade Experiment. Total benzophenanthridine alkaloid concentrations, mainly sanguinarine and chelerytherine, decreased with increasing sunlight while the protopine alkaloids only weakly reflected this trend. Benzophenanthridine alkaloids are highly photoreactive toxins and may cause increasing autotoxicity with increasing light levels (Arnason et al., 1992). One target of photosensitized alkaloids is cell membranes (Downum, 1992). When benzophenanthridine alkaloids are sensitized by light, an oxygen singlet is released by each alkaloid molecule, which can oxidize unsaturated fatty acids, cholesterol, and membrane-associated proteins (review by Downum, 1992). Degradation of vacuole membranes that sequester alkaloids could lead to an autotoxic event. If photosensitive alkaloids cause intercellular damage at high light levels, then plants under higher light conditions may maintain lower concentrations of alkaloids in their tissues to avoid autotoxicity. However, since high mortality occurred in the 0% shade treatment, the plants in that treatment may have produced lower alkaloid concentrations due to poor vigor from abiotic stress rather than due to a down-regulation response to high light. The

contribution of autotoxicity to the decline in vigor could not be determined from the data collected.

The shade experiment also showed that different alkaloids varied in their response to ambient light levels in *S. canadensis*. In contrast to sanguinarine and chelerythrine, concentrations of chelirubine, chelilutine, sanguilutine, and total protopine alkaloid concentrations varied weakly or were unaffected by light level. The parallel patterns seen between more similar alkaloids (e.g., sanguinarine and chelerythrine; chelirubine, chelilutine, and sanguilutine; protopine and allocryptopine) reflect the common metabolic pathways that produce these compounds. Protopine serves as a precursor for several more highly oxidized alkaloids, such as sanguinarine and chelirubine (Roberts, 1998), and all the isoquinoline alkaloids found in bloodroot are biosynthetically closely related (Roberts, 1998). The alkaloids in bloodroot may be produced in parallel, compete for substrate or common enzymes, or provide substrate for the formation of other alkaloids.

Induction Experiment. In our experiments, bloodroot alkaloids were not induced by jasmonic acid. Although jasmonate-induced alkaloid production has been demonstrated in bloodroot cell culture (Ignatov, 1996), no whole-plant benzophenanthridine alkaloid induction has been recorded for this or any other plant species. It may, therefore, be misleading to extrapolate results from cell culture experiments to whole-plant induction, or from one biosynthetic pathway to others. It may be possible that the lack of induction by jasmonic acid in our experiments may have been due to inappropriate application techniques and not lack of inducibility. The amount of jasmonic acid sprayed per application in this experiment was equivalent to the amount used as a high but non-toxic level known to result in significant induction responses in tomato plants (Thaler et al., 1996, 1999). However, foliar application of jasmonic acid to the waxy leaves of bloodroot may not have effectively introduced the jasmonic acid to plant tissues. A more appropriate application method could be to add the solution directly into the roots, as was successful with nicotine induction in *Nicotiana attenuata* (Baldwin, 1998).

Additionally, the time lag between jasmonic acid application and rhizome tissue collection may have been sufficiently long that any temporary response to the jasmonic acid applications was missed. *Nicotiana* spp. respond in a few hours to a few days to methyl jasmonate exposure (Baldwin et al., 1998), and tomatoes show elevated levels of the defensive enzyme polyphenol oxidase between eight days to five weeks following application of jasmonic acid (Thaler, 1999).

Patterns Across Experiments. Alkaloid concentrations varied among bloodroot clones across all treatments in both experiments (e.g., Figures 2 and 5). While this variation likely results from genetic effects, we cannot discount the unknown effects of the abiotic conditions under which seedlings developed. An experimental design that includes all clones in all treatments and establishes relatedness among different clones would offer greater insight into the genetic component of alkaloid

production in bloodroot. We were able to demonstrate, however, that alkaloid concentrations exhibit some plasticity in response to abiotic factors in *S. canadensis*.

Over the course of the experimental period, concentrations of alkaloids declined across all treatments for both shade and induction experiments (Table 1). Since plants were maintained without fertilizer for an entire growing season, nutrient scarcity most probably limited their metabolism and, subsequently, alkaloid production.

In both experiments, plants that received high fertilizer levels in the previous year had lower alkaloid concentrations than those that received low or moderate fertilizer levels. Supplemental nutrients in the fertilizer treatments may have caused a shift in allocation from storage and defense to growth (Tuomi et al., 1984; Herms and Mattson, 1992; Marino et al., 1997), resulting in a dilution of alkaloid content (Figure 7) due to increased biomass. Some evidence to support this theory may be found in the decrease in a subset of individual alkaloid concentraitons with an increase in rhizome size in both the induction and shade experiments (Tables 2 and 3). Much of the alkaloid-bearing latex stored in the rhizome of bloodroot is found in a thick layer of vacuolar cells just below the epidermis (Wink and Roberts, 1998). There are vacuolar cells present throughout the interior of the rhizome, but the density is much lower. If bloodroot alkaloids are synthesized and/or stored mostly in the vacuolar cell layer, then an increase in rhizome diameter would appear to cause a decline in alkaloids stored there due to a shift in the diameter to volume ratio. As rhizome length and width were not correlated, the decrease in some of the alkaloid concentrations with increasing rhizome length may be related to the number of leaves present on longer rhizomes. Alternatively, high (400 ppm) fertilizer levels may have injured fine roots due to nutrient burn, leaving those plants less vigorous.

CONCLUSION

Light intensity and mineral nutrition influence alkaloid concentration in *Sanguinaria canadensis*. Whole-plant response of bloodroot to a jasmonic acid elicitor was not observed. Phototoxicity may explain increased alkaloid production and plant vigor under higher shade. Since concentrations of individual alkaloids varied differentially in experimental treatments, there may exist direct or sequential competition for substrate or enzymes during alkaloid biosynthesis. Or, if no association exists, alkaloids may be functionally uncoupled to some extent. Genetic influences represented by clone effects may be indicated by variation in alkaloid concentration by clone, but this experimental design did not allow us to distinguish genetic from pre-experiment environmental influences on the rhizomes.

Acknowledgments—The authors thank M. Thomas, R. Klaper, J. Johnston, A. Tull, M. Zimmerman, T. Maddox, T. Ackerman, A. Reynolds, and M. Madritch for technical assistance. Invaluable access to analytical equipment was graciously offered by Prof. W. Randle. The paper was much improved by helpful comments from R. Klaper, M. Thomas, and two anonymous reviewers. Finally, we thank the UGA Museum of Natural History Josh Laerm Award for financial assistance.

Abstract—In plant growth room (PGR) and open-air pot (OAP) experiments, potato cvs King Edward and Maris Piper were grown under two nitrogen levels or two different nitrogen release patterns. Plants were subjected to infestation by peach potato aphids *Myzus persicae* (Homoptera: Aphididae). Total glycoalkaloid (GA) levels were measured in the foliage of both infested and non-infested plants, before, during and after aphid infestation. In the PGR experiment, aphid infestation reduced the amounts of total GAs in both cultivars. This reduction is attributed to the sugar deficiency induced in the plants owing to the dense aphid colonization. Results from the OAP experiment showed a temporal increase of GAs produced by potato cv. King Edward plants subjected to aphid infestation. Elevated amounts of nitrogen in the nutrient solutions (PGR experiment) reduced total GAs, while no differences were observed between manure and fertilizer treated plants (OAP experiment). It is concluded that the source of available nitrogen does not affect foliar GA synthesis in potatoes, and as a consequence, does not affect its endogenous chemical defense against insect herbivory. The case for insect-induced chemical defense mechanisms as triggered by low rates of aphid infestation is discussed.

Key Words—Aphid, Aphididae, *Myzus persicae*, potato, *Solanum tuberosum*, glycoalkaloids, solanine, chaconine, insect herbivory, nitrogen, chemical defense.

INTRODUCTION

Part of the defensive mechanisms of plants against pathogens or herbivorous insects is related to the synthesis of secondary plant metabolites or allelochemicals. In many cases, the increased allelochemical content of damaged plant tissue is considered to be the reaction of plants to stress induced by fungi or phytophagous insects. Phytochemical responses to insect herbivory have been reported for alkaloids in wild tobacco (Baldwin, 1989; Baldwin et al., 1990), furanocoumarins in wild parsnip (Zangerl, 1990; Zangerl and Berenbaum, 1995) glucosinolates in swede, kale and oilseed rape (Birch et al., 1992) and most recently hydroxamic acids in wheat (Gianoli and Niemeyer, 1997a,b).

The main products of secondary metabolism in potato *Solanum tuberosum* (L.) are glycoalkaloids (GAs). GAs are steroid glycosides formed when the alkaloid solanidine is attached to carbohydrate moieties. Depending on cultivar, 95% or more of the total glycoalkaloid (GA) fraction in tubers and vegetative parts, consists of the α-forms of solanine and chaconine (Jadhav et al., 1981).

The inhibitory effects of GAs on both fungal and insect pests of potato suggest their significance as natural pesticides (Jadhav et al., 1981). There are a limited number of studies investigating the effects of insect herbivory on the GA content of *Solanaceae*. In particular, Hlywka et al. (1994) suggested that insect herbivory, either increases (Colorado potato beetle, *Leptinotarsa decemlineata*) or has no effect (potato leafhopper, *Empoasca fabae*) on the total GA content of potato tubers, depending on the type of damage. By contrast Zullo et al. (1984) reported that infestation of *S. americanum* plants by the aphid *Aphis fabae* ssp. *solanella* reduced total GAs in stems, leaves, and fruits.

The objective of this work was to examine the effects of aphid infestation on the GA content in the foliage of potato plants during their early stages of growth. As nitrogen availability has been shown to affect GA concentration in potato foliage (Fragoyiannis, 1999), the foliar GA content of potato plants subjected to extensive damage by the aphid *Myzus persicae* was examined. Plants were fertilized with two different levels and sources of nitrogen.

METHODS AND MATERIALS

In plant growth room (PGR) and open-air pot (OAP) experiments, the potato *Solanum tuberosum* L. cultivars King Edward (KE) and Maris Piper (MP) were infested by the aphid *Myzus persicae*. In the PGR experiment, a semi-hydroponic set-up was established involving two different nitrogen regimes - low and high. In the OAP experiment, the same amount of nitrogen was available to potato plants in the form of fertilizer and manure. In both experiments, GAs produced by aphid-infested plants were compared to those produced by aphid-free plants.

Plant Growth Room Experiment. Small tuber pieces of approximately similar size developing one sprout per piece (surplus sprouts were excised) were cut from mother tubers of clonal origin. Each growing sprout was planted in one plastic pot (diameter: 15 cm; depth: 14 cm) using perlite (1:1 mix of horticultural to seed grade) as growing substrate. The pots stood on plastic rectangular trays ($22 \times 16.5 \times 4.5$ cm), were placed in a plant growth room (20°C, 50% R.H., and long day 16:8 conditions) and watered with nutrient solutions. Two nutrient solutions, N_{Low}, N_{High}, representing nitrogen concentrations of 100 and 300 mg total N/l, respectively applied. The total amounts of N added per pot were 200 and 600 mg for N_{Low} and N_{High}, respectively. Phosphorus and potassium applications remained constant at 40 mg/l and 300 mg/l, respectively, for both N treatments. Equal amounts of distilled water were added to all replicates to compensate water evaporation. In all solutions, the NO_3^- to NH_4^+ ratio was the same at 4:1. This proportion ensured the tendency for slight acidification of the growing media. The insignificant buffering capacity of perlite (Hall and Smith, 1994) was counterbalanced by adding ground magnesian limestone (1.5 g/l perlite). Trace element availability was supported by adding fritted trace elements (WM 253A, 0.5 g/l perlite). Pots were randomly relocated every second day. Growing one or, at most, two sprouts per pot allowed ease of watering and random plant relocation without damaging plants in the restricted space of the plant growth room. Two different fertilization treatments (N_{Low} and N_{High}) were combined with aphid-infested and non-infested plants harvested 15, 45, or 60 days after planting.

Open-Air Pot Experiment. Potato tubers (*S. tuberosum* L. cvs. King Edward and Maris Piper) were planted in pots (diameter: 23 cm; depth: 23 cm) under open field conditions. The pots contained topsoil, classified as poorly drained clay soil of Stirling Series (SG), randomly sampled from two neighboring farms one of which practiced organic agriculture, the other conventional agriculture. Semi-composted sheep manure was obtained from the Scottish Agricultural College farm at Bush Estate, Lothian Region. Soil samples and sheep manure were analyzed for pH, extractable ammonium N, nitrate N and total N after sieving and mixing. Soil analyses revealed that the soil derived from the conventional farm had higher N content owing to previously applied ammonium nitrate. The N content of the soil derived from the organic farm was amended by adding a small amount (approx. 13 g/pot) of sheep manure, thus ensuring that the total available N in both soil samples was the same at 415 mg total N/pot. The two different fertilization treatments (fertilizer and manure) were combined with aphid-infested and non-infested plants harvested 20, 40 or 60 days after planting.

Aphid Infestation. Thirty standardized adults (approximately five/leaf) derived from a clone lineage culture of the aphid *M. persicae* were transferred to the treatments subjected to infestation in the PGR and OAP experiments, once the second true leaf had fully expanded. Due to differences in N fertilization, N_{High} plants reached this stage faster compared to N_{Low}, hence they were infested first

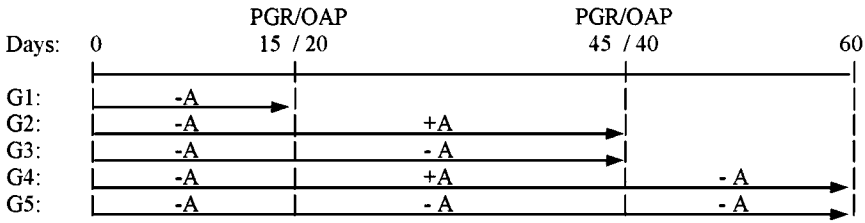

FIG. 1. Schematic representation of the *Myzus persicae* infestation groups (G1, G2, G3, G4, and G5) applied to the potato plants in plant growth room (PGR) and open-air pot (OAP) experiments, plotted against times of harvesting; +A: aphid-infested period, −A: aphid-free period.

with the aphids. In the OAP experiment, part of the aphid infestation (five aphids on the first true leaf) were protected from aphid predators using a nylon mesh pocket. The rest were set free to colonize the plant. Removal of aphids from the aphid-infested G2 and G4 plants was achieved by spraying the plants with a 0.5% soft soap solution. A schematic representation of the aphid infestation treatments applied to the potato plants and times of harvesting is given in Figure 1.

Sample Preparation and Analysis. Potato leaves, petioles and growing tops were excised, weighed, packed in muslin sachets and immersed in liquid nitrogen. The tissues remained in the freezer (−40°C) prior to lyophilisation for approximately 72 hr/sample. Each sample was ground using a water cooled mill and stored in the freezer. The extraction and analytical techniques used for the quantification of α-solanine and α-chaconine were based on those of Hellenäs (1986). Total GAs were the sum of α-solanine and α-chaconine in each sample. High performance liquid chromatography (HPLC) analysis equipment consisted of a high pressure isocratic pump (Spectra Physics Analytical P1000), programmable wavelength detector (Spectra 200), sample injector (Gilson 232 BIO) combined with a dilutor (Gilson 401) fitted with a 20 μl loop, and a datajet integrator (Spectra Physics SP4270). A stainless steel column (Phase Separations model Spherisorb), packed with ODS2-hypersil (Shandon, 3 μm) was used for analysis. The mobile phase was acetonitrile/water: 34:66 (v/v) and 0.5 ml/l ethanolamine adjusted to pH 4.55–4.56 with orthophosphoric acid (12% solution). The chromatograph was set to deliver solvent at 1 ml/min at 0.002 absorbance units full scale (AUFS) output. Peaks were detected by UV absorbance at 202 nm. All chemicals used were 'pure UV grade' (Fisons Ltd. UK). Both experiments were replicated three factor with N applied at 2 levels (N_{Low}/N_{High} in the PGR and manure/fertilizer in the OAP) to 5 levels of aphid/harvest plants (G1, G2, G3, G4 and G5) to potato cultivars King Edward and Maris Piper. Treatment combinations were repeated four times. In total, 80 pots were placed in the plant growth room in two cages (4.5 m × 1 m × 1 m) made of nylon mesh isolating the infested from the

non-infested plants and another 80 pots in open-air conditions. Pots were randomly relocated every second day. PGR experimental data were analysed using the Analysis of Variance procedure for factorial design of MINITAB® (vs. 11.1). OAP experimental data were analyzed using the General Linear Model procedures of MINITAB® (vs. 11.1), in order to deal with a few missing values derived from hail-damaged plots. Significant differences between treatment means were identified using t-tests.

RESULTS

In the PGR experiment, elevated amounts of N in the nutrient solution reduced GA levels in both cultivars (Table 1). By contrast, the main effect of N source in the OAP experiment was not significant. As a result, the type of N (e.g., manure or fertilizer), did not affect foliar GA synthesis (Table 2). In both

experiments, cv. King Edward produced elevated amounts of foliar GAs compared to those produced by cv. Maris Piper. In the PGR experiment, aphid-infested plants had reduced amounts of total foliar GAs compared to non-infested (G2 vs. G3) (Table 1). This lasted even after the extermination and removal of aphids from the plants (G4 vs. G5). Although aphid infestation induced an increase in GAs in the OAP experiment (G2 vs G3), this increase was temporary because differences were not observed between G4 and G5 plants (Table 2). An analysis of the interactions between the main effects is presented separately for each experiment.

Plant Growth Room Experiment

Analysis of variance indicated that all three 2-way interactions (N fertilization × cultivar, N fertilization × aphid infestation and cultivar × aphid infestation) and one 3-way interaction (N fertilization × cultivar × aphid infestation) were significant (Table 1).

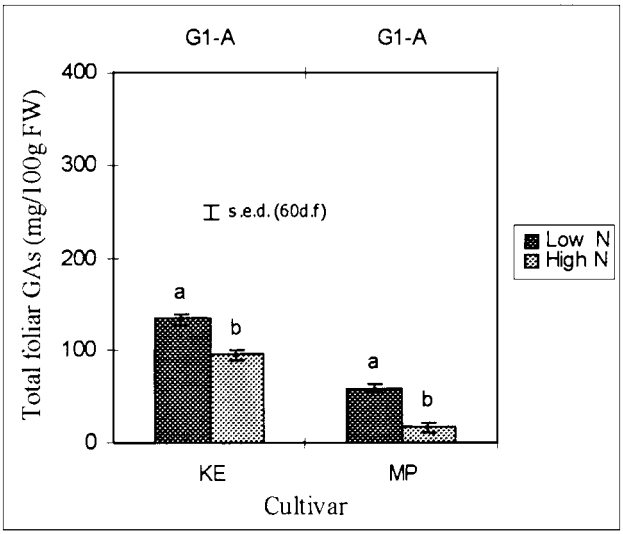

FIG. 2. Total foliar fresh weight glycoalkaloid (GA) content (mean ± SE, four replicates of potato cvs. King Edward (KE) and Maris Piper (MP) grown in low (100 mg N/liter) and high (300 mg N/liter) nitrogen fertilization levels harvested 15 days after planting (G1, plant growth room experiment). Means in columns of the same potato cv. followed by different letters are significantly different (t-test following balanced ANOVA).

Plants from both cultivars grown in low N nutrient solution harvested 15 days after planting (G1) had higher levels of GAs than those grown in high N solution (Figure 2).

Similar differences were observed between high and low N treatments in non-infested plants (G3 and G5) harvested at the next two time points (30 and 45 days after infestation, Figures 3a, 3b). Aphid infestation reduced GA levels in either low or high N treated plants of both cultivars that were harvested 30 days after infestation (G2 vs G3, Figure 3a). An exception was observed on potato cv. Maris Piper; a significant difference was not observed between aphid-infested and non-infested plants grown in high N solution. The effects of aphid infestation lasted even after aphid extermination. The differences between aphid-infested and non-infested plants were significant for both N levels and both cultivars (G4 vs G5, Figure 3b).

Open-Air Pot Experiment

Significant effects were observed in the interactions N source × aphid infestation, and potato cultivar × aphid infestation. The N source × cultivar and the N source × cultivar × aphid infestation interactins were not significant (Table 2).

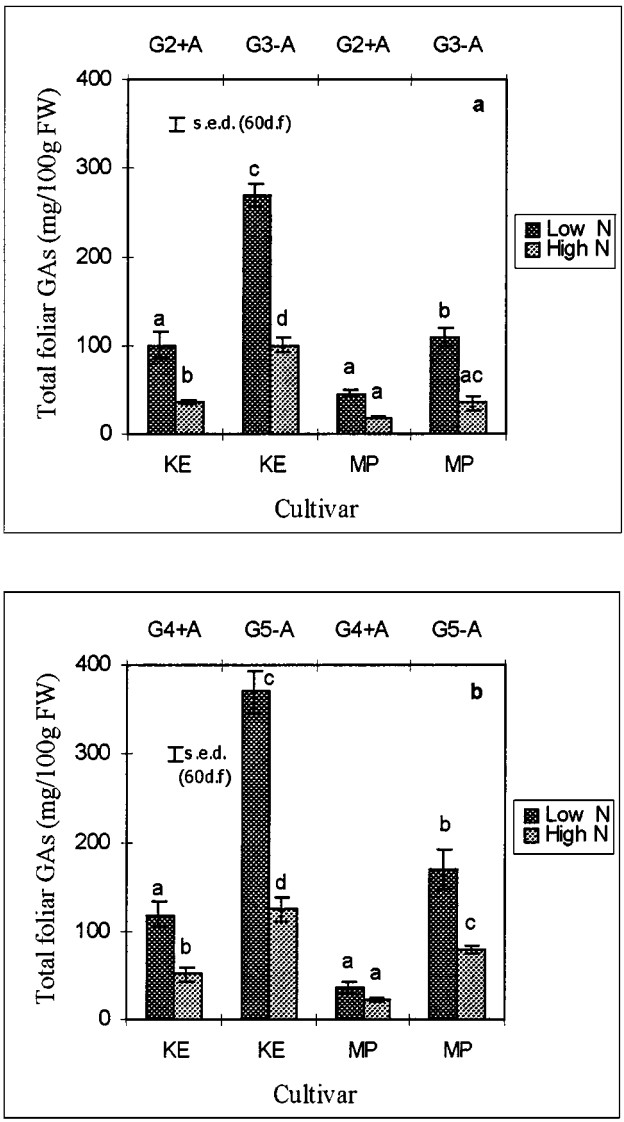

FIG. 3. Total foliar fresh weight glycoalkaloid (GA) content (mean ± SE, four replicates) of aphid-infested (G2 + A and G4 + A) and non-infested (G3 − A and G5 − A) potato cvs. King Edward (KE) and Maris Piper (MP) grown in low (100 mg N/liter) and high (300 mg N/liter) nitrogen fertilization levels and harvested 30 (Figure 3a) and 45 (Figure 3b) days after aphid infestation (plant growth room experiment). Means in columns of the same potato cv. followed by different letters are significantly different (t-test following balanced ANOVA).

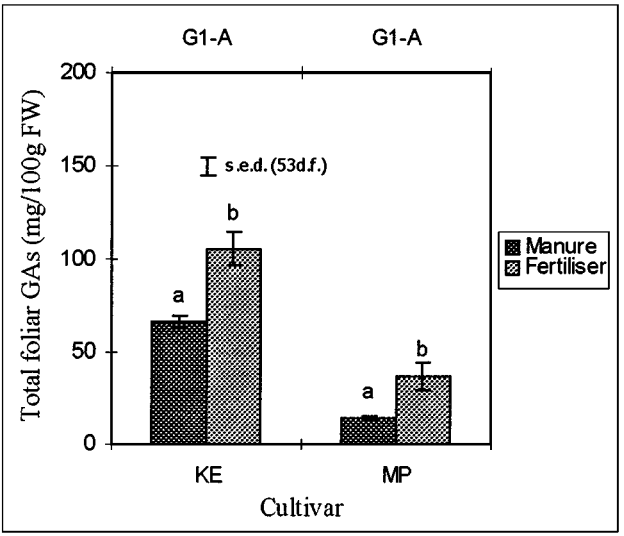

FIG. 4. Total foliar fresh weight glycoalkaloid (GA) content (mean ± SE, four replicates) of potato cvs. King Edward (KE) and Maris Piper (MP) grown with manure and fertilizer harvested 20 days after planting (G1, open-air pot experiment). Means is columns of the same potato cv. followed by different letters are significantly different (t-test following linear model).

Manure-treated potato cv. King Edward plants, harvested 20 days after planting (G1) produced less GAs compared to those treated with fertilizer (Figure 4). A difference also was observed between manure- and fertilizer-treated potato cv. Maris Piper plants.

Manure-treated plants of both cultivars harvested 20 days after infestation (G2 and G3), produced similar GA levels to fertilizer-treated plants (Figure 5a). In addition, effects of N source on the foliar GA production were not observed between manure- and fertilizer-treated plants of any cultivar harvested at the next time point (G4 and G5 Figure 5b).

The effect of cultivar × aphid infestation interaction indicates that apart from cutivar, aphid infestation affected foliar GA production. In particular, an increase of foliar GAs was observed in both manure- and fertilizer-treated aphid-infested cv. King Edward plants, compared to non-infested, harvested 20 days after infestation (G2 and G3 Figure 5a). These differences ceased in cv. King Edward plants harvested at the next time point (G4 and G5 Figure 5b). Aphid infestation did not have any effect on cv. Maris Piper. Differences between aphid-infested and non-infested cv. Maris Piper plants harvested at 20 (G2 and G3) and 40 (G4 and G5) days after infestation were not significant.

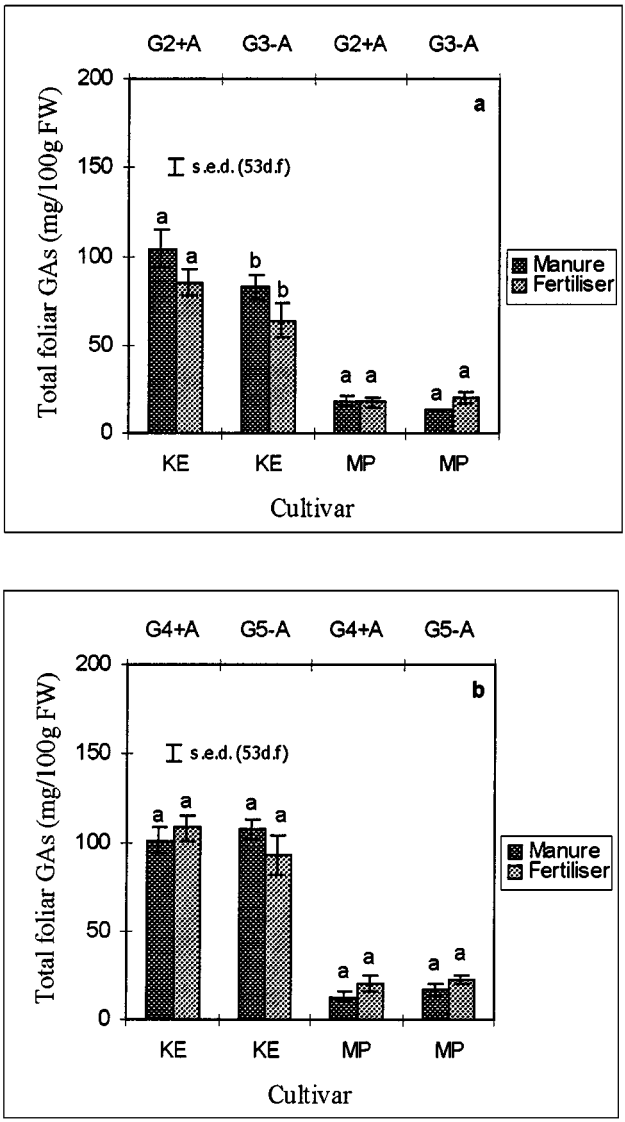

FIG. 5. Total foliar fresh weight glycoalkaloid (GA) content (mean ± SE, four replicates) of aphid-infested (G2 + A and G4 + A) and non-infested (G3 − A and G5 − A) potato cvs. King Edward (KE) and Maris Piper (MP) grown with manure and fertilizer and harvested 20 (Figure 5a) and 40 (Figure 5b) days after aphid infestation (open-air pot experiment). Means in columns of the same potato cv. followed by different letters are significantly different (t-test following linear model).

DISCUSSION

Mechanical damage has the potential to cause wound defensive reactions by plants including the accumulation of secondary defensive substances. It has been reported (Olsson, 1986) that GA synthesis in potato tubers is increased as a result of enhanced physiological activity of cells neighboring sites of mechanical damage. During aphid stylet penetration, usually considered to be intercellular, some cell walls are grazed, and/or ruptured (Spiller et al., 1985; Kimmins and Tjallingii, 1985), and cells are destroyed (Pollard, 1973). Such reactions have been documented in field and growth room studies, where defoliation damage by Colorado potato beetles *Leptinotarsa decemlineata* resulted in increased tuber GA concentrations (Hlywka et al., 1994). Damage by potato leafhoppers *Empoasca fabae* did not have any apparent effect on the tuber GA content (Hlywka et al., 1994). The difference was attributed to the type of herbivory stress induced by each of these species: Colorado potato beetles are very destructive chewing insect pests, whereas potato leafhoppers are phloem feeders. Since aphids are phloem feeders, it is possible that the mechanical damage associated with stylet penetration of potato plants by *M. persicae* could have altered GA concentration in the foliage.

The results obtained from the PGR experiment showed that GA levels of aphid-infested plants were reduced in both potato cultivars and both N levels applied. This was not only an immediate and direct effect of the dense colonization of the plants, but also an after-effect that followed elimination of aphids. It has been suggested that synthesis of solanidine - the aglycon moiety of the GA molecule - occurs in plastids (Ramaswamy et al., 1976). One response of plants to phloem-feeding insects is the degeneration and disappearance of chloroplasts in the area neighboring stylet punctures (Miles, 1989; Pollard, 1973). Aphid herbivory can induce photosynthetic stress at the level of the chloroplast and limit the photosynthetic rate, while other cellular components like mitochondria and plasma or vacuolar membranes are damaged. This damage leads to cell death and, therefore, chloroplast death (Miles, 1989). The reduction observed in the foliar GA levels could be a result of a reduction in solanidine biosynthesis, following a decrease in the number of undamaged plastids occurring in potato leaf cells.

Structural differences between solanine and chaconine and between their α-, β-, and γ- forms are related to carbohydrate moiety composition (Nair et al., 1981). Synthesis of the γ-, β-, and α- forms of solanine and chaconine occurs when the aglycon steroid solanidine molecule is glucosylated in a stepwise synthesis with one, two or three sugars (Osman and Zacharius, 1979). The presence of soluble sugars that exist in the GA molecule in sufficient quantities during the final steps of GA formation may play a crucial role in the amount of GAs that will finally be synthesized and expressed. Aphids interfere with photosynthetic efficiency in the infested plant and provide a rich medium for fungal growth through their excretion products (Schepers, 1989). Due to the normally low nitrogen/carbon ratio

of phloem sap, aphids also have to adapt to a nutrient source with a suboptimal supply of nitrogen during much of the growing season. To extract enough nitrogen and acquire sufficient protein, aphids eliminate large quantities of phloem sap and excrete carbohydrate-rich honeydew (Llewellyn et al., 1974). Hence, it is possible that lack of glucose, rhamnose and galactose - which make up the sugar part of the GA molecule - resulting from both photosynthesis rate reduction and carbohydrate absorption by the aphids, led to a reduction in the amount of GAs foliage.

The results from the PGR experiment suggest that heavy aphid infestation negatively affects the defensive system of potato plants, and that this is related to secondary metabolism. This effect was obvious for both low and high levels of available nitrogen. However, it appears that reduction of GA synthesis was greater when nitrogen was applied at high or excessive quantities. Nitrogen availability appears to play a crucial role related to the general health status of the potato crop. In the OAP experiment, manure-treated potato cv. King Edward plants, harvested early in G1 treatment, had decreased amounts of GAs compared to fertilizer-treated plants (Figure 4). This was observed as well for the cultivar Maris Piper. The amount of green matter harvested in G1 treatment was almost the same for both manure and fertilizer treatments for each cultivar (data not shown). This suggests that the increase of GA production in G1 treatment observed in fertilizer grown plants could not be related to differences in the amount of green matter produced by manure and fertilizer treatments. A possible explanation may be attributed to the different rates of N release and plant uptake between plants treated with manure and with fertilizer, at the early stages of plant growth. No differences were observed in foliar GA production between manure-treated and fertilizer-treated, aphid-infested and non-infested plants during and after the period of aphid infestation. Hence, the source of available N does not play any role in GA synthesis in the subsequent stages of plant growth.

The PGR experimental results are in agreement with those obtained by Zullo et al. (1984) who reported decreased GA levels in stem, leaf and fruits of *Solanum americanum* plants infested by the aphid *Aphis fabae* ssp. *solanella*. The OAP experiment showed that the two cultivars reacted in a different way during aphid infestation. An increase in the amounts of GAs was observed in the aphid-infested, manure- or fertilizer-treated King Edward plants; such an increase was not observed in Maris Piper. In addition, no after-effects of aphid infestation were observed in either of the cultivars examined in the OAP experiment. The discrepancy between the PGR and OAP experiments may be attributed to the restricted aphid infestation that took place in the field; the presence of aphid predators and parasitoids combined with the average low summer temperatures did not allow the expected dense aphid colonization to occur. No decrease, in foliar GA production was observed as a result of low aphid infestation in either potato cultivar.

When damage is caused by arthropod herbivore feeding, leaves distant from the site of injury often accumulate compounds toxic or distasteful to the arthropod

(Tallamy and Raupp, 1991). It is possible that such systemic 'induced resistance' to aphids may have occurred for potato cv. King Edward in the OAP experiment. A signal internal to the plant may have induced the increase of the foliar GAs in both manure- and fertilizer-treated plants of potato cv. King Edward. In addition, removal of the aphids from the plants brought GAs back to the levels prior to aphid infestation. However, it seems that for some reason such a signal was not detected in the cultivar Maris Piper. A similar signal possibly was generated during the early stages of aphid infestation in the PGR experiment. The subsequent dense aphid colonization of plants presumably concealed expression and resulted in a decrease of the foliar GAs owing to a reduced solanidine and/or carbohydrate synthesis.

The results suggest that low densities of aphid infestation stimulate a temporary increase of potato foliar GAs, and the existence of an induced defensive allelochemical response in potato. Further studies are required to examine the mechanisms and characteristics of this response. An implication of these results is that in organic farming where nitrogen availability is restricted, plants may be effectively protected from pests owing to the presence of the natural defense system. In conventional farming systems where nitrogen availability is high, plants may be more susceptible to pest infestation because of a reduction of natural defensive toxins.

Acknowledgments—This research was funded by a grant from the Commission of the European Communities, Directorate General for Agriculture (Contract No. AIR-3-BM93-2418). We wish to thank Dr G. Percival of the Scottish Agricultural College Auchincruive, for his technical advice on GA analyses and Mr E.A. Abstract—Phytic acid is abundant in the fruits and seeds of many plants and is found in foliage to a lesser extent. Among its several properties, phytic acid is a potent chelator of essential minerals and proteins; thus, the possibility exists that heme-based enzymes such as cytochrome P450 monooxygenases in herbivores are detrimentally affected by phytic acid via chelation of dietary iron. Mortality, growth performance, and P450-mediated metabolism of xanthotoxin, a plant allelochemical, were examined in the presence of phytic acid in three lepidopteran species: a polyphagous seed-feeding species (*Heliothis virescens*), a polyphagous foliage-feeding species (*Trichoplusia ni*), and a species oligophagous on immature reproductive structures of two genera of Apiaceae (*Depressaria pastinacella*). While first instar *H. virescens* experienced no increase in mortality after 120 hours on a diet containing 1% phytic acid compared to a control diet, both *T. ni* and *D. pastinacella* experienced virtually complete mortality over the same time period. Ultimate instars of all three species experienced reductions in relative growth rates (RGR) and relative consumption rates (RCR) in the presence of phytic acid, although the only species to experience reduced digestive efficiency (ECI) was *H. virescens.* Cytochrome P450-mediated metabolism of xanthotoxin was reduced 60% in the presence of phytic acid in *D. pastinacella*, although metabolism remained unaffected in the two noctuids. These studies suggest a defensive function of phytic acid in addition to its primary functions of phosphorus storage, energy storage, and cell wall precursor source.

Key Words—phytic acid, herbivory, cytochrome P450, mineral bioavailability, plant resistance, primary metabolite, secondary metabolite.

INTRODUCTION

Phytic acid (myo-inositol-1,2,3,4,5,6-hexakis-dihydrogenphosphate) is a common constituent of oilseeds, legumes, and cereals. In germinating seedlings, phytate, the salt form of phytic acid, serves as the major storage form of phosphorus, often accounting for more than 85% of the total phosphorus in legumes and grains upon seed ripening (Reddy et al., 1989). Phytic acid is a potent chelator of essential minerals, including iron, calcium, magnesium, and zinc, as well as a chelator of positively charged proteins. Once bound to phytic acid, minerals and proteins form insoluble complexes that are unavailable for absorption under normal physiological conditions. Thus, the bioavailability of minerals and protein in an animal's diet may be reduced by the concomitant consumption of phytic acid.

Although the antinutritive effects of phytic acid on vertebrates are well-documented (Zhou and Erdman, 1995; Pillauf and Rimbach, 1997), the effects of this ubiquitous plant constituent on insects are less well-known. Studies of seeds in storage indicate that phytic acid may be an insect antifeedant; increased phytic acid content, for example, is associated with reduced risk of infestation by *Bruchus pisorum* in peas (Marzo et al., 1997). Apparent increases in phytic acid content of infested legume and cereal seeds in storage may be due to selective removal of seed parts free of phytic acid by insects (mung bean, chickpea, pigeon pea, Modgil and Mehta, 1997; wheat and sorghum, Jood et al., 1995).

Effects of phytic acid on insect infestation of plants in field situations are less well-documented. In addition to acting as an antifeedant, phytic acid may act to reduce digestibility of foliage and fruits by forming complexes with dietary proteins. As a mineral chelator, phytic acid is known to reduce bioavailability of such minerals as calcium, magnesium, zinc, and iron (Reddy et al., 1989). Of particular importance to insect herbivores, and potentially vulnerable to the action of phytic acid, are the cytochrome P450 iron-based heme proteins. Cytochrome P450 monooxygenases (P450) constitute an iron-based enzyme system that both detoxifies hostplant allelochemicals and other xenobiotics and synthesizes endogenous hormones (Berenbaum, 1991). Because phytic acid is an iron chelator, the possibility exists that phytic acid may interfere with cytochrome P450 function. It is conceivable that iron deficiency could result in a reduction of cytochrome P450 activity and an overall decrease in allelochemical metabolism.

To determine whether phytic acid may serve as a defense against consumers of foliage and fruits, survivorship and growth parameters were measured for three lepidopteran larvae that vary in the frequency with which they encounter phytic acid. The tobacco budworm, *Heliothis virescens* (Noctuidae), is a fruit feeder that attacks tobacco, tomatoes, and other solanaceous plants as well as cotton and some legumes (Metcalf and Metcalf, 1993). As a consumer of legume fruits, then, *H. virescens* likely frequently encounters high levels of phytic acid in its diet. Phytic acid is present in several of its hosts, including legumes, at levels ranging

from 0.28–1.26% in chickpeas to 1.00–2.22% in soybeans (Reddy et al., 1989). The cabbage looper, *Trichoplusia ni* (Noctuidae), is a generalist folivore on herbaceous plants of over 80 known species (Tietz, 1972; Eichlin and Cunningham, 1978). Although phytic acid can be found in foliage of a range of plants, it generally occurs at levels considerably lower than those found in seeds (e.g., 0.002% in fluted pumpkin, Ladeji et al., 1995; 0.009% in *Launaea taxaracifolia* to 0.655% in *Euphorbia hirta*, Wallace et al., 1998). The parsnip webworm, *Depressaria pastinacella* (Oecophoridae), feeds on buds, flowers, and immature fruits of two genera of Apiaceae, *Pastinaca* and *Heracleum*. Although mature fruits of *P. sativa* vary in phytic acid content, often exceeding 0.5% fresh weight, levels of phytic acid are low to undetectable in buds, flowers, and immature fruits, the principal food of this specialist (A. Zangerl and M. Berenbaum, unpublished).

Despite differences in diet breadth, all three of these species rely on cytochrome P450 monooxygenases for detoxification of furanocoumarins, secondary metabolites found in several (*H. virescens*, *T. ni*) or all (*D. pastinacella*) of their hostplants (Berenbaum, 1995). Thus, we measured rates of metabolism of xanthotoxin, a furanocoumarin, in the presence and absence of phytic acid in these species in order to determine whether it can act as an inhibitor of detoxification enzymes.

MATERIALS AND METHODS

All three lepidopterans can be reared on the same artificial diet (Nitao and Berenbaum, 1988), which can easily be modified to reflect various degrees of nutritional quality. Three different experiments were conducted with artificial diets in order to assess impacts of phytic acid on mortality rates, growth performance, and xenobiotic metabolism.

First Instar Survivorship. To determine if phytic acid affects mortality rates during early development, a first instar survivorship experiment was performed. For all three species, neonates were allowed to feed on an artificial diet containing 1% fresh weight phytic acid (Sigma, St. Louis, MO) or on an artificial diet with no additives as a control. Sample size for each diet type was 20 for *D. pastinacella* and *H. virescens*, and 25 for *T. ni*. Mortality was assessed every 24 hours up to 120 hr. All larvae developed at approximately the same rate. A two-dimensioned contingency table with Yates continuity correction was analyzed by chi square to determine if mortality differed between control and phytic acid treatments for all three species.

Gravimetric Estimates of Performance. To assess the effects of phytic acid on growth and feeding efficiency, gravimetric estimates of performance were determined for all three caterpillar species. Ultimate instars (fifth instar for *T. ni* and *H. virescens*, sixth instar for *D. pastinacella*) were fed an artificial diet containing

either 1% phytic acid or no additives as a control and were allowed to feed for 72 hr. After three days of feeding, the uneaten portions of diet were oven-dried and weighed. For sixth instar *D. pastinacella*, sample size for each diet type was 20; for fifth instar *T. ni*, sample size for each diet type was 10, and for fifth (ultimate) instar *H. virescens*, sample size for each diet type was 28. Sample size differed among species due to differences in availability at the time of experimental set-up and differences in synchrony of the colonies.

For all three species, gravimetric estimates of caterpillar performance were calculated by using parameters from Waldbauer (1968). One-way analyses of variance for relative growth rates (RGR), relative consumption rates (RCR), and efficiency of conversion of ingested material (ECI) were performed with phytic acid as the main effect. Use of this approach allows for comparisons with a vast literature of performance data on lepidopterans (Scriber and Slansky, 1981). However, Raubenheimer and Simpson (1992) have suggested that analysis of covariance is a more appropriate way to analyze growth and feeding measures as a result of difficulties in interpreting ratios used in conventional gravimetric indices of performance. The numerator and denominator of these ratios are not independent variables because elements of the numerator are included in the denominator. Accordingly, analysis of covariance was also performed for final larval mass and consumption with initial larval mass as the covariate; biomass gained (growth) was evaluated with amount of food consumed as the covariate. The analyses were first performed with a model statement including an interaction effect between the covariate and treatment to test for homogeneity of slopes. Homogeneity of slopes was confirmed ($P > 0.10$) in all analyses.

Xanthotoxin Metabolism. To determine if phytic acid interferes with cytochrome P450 function, xanthotoxin metabolism assays were performed for each species. For this assay, ultimate instars were raised on one of four artificial diets for 72 hours: control diet (lacking any additives), diet containing added phytic acid, diet containing added xanthotoxin, and diet containing both phytic acid and xanthotoxin. For all three species, the amount of phytic acid added, 1% fresh weight, was identical. The amount of xanthotoxin added to the experimental diets varied according to the known level of tolerance; whereas *T. ni* and *H. virescens*, polyphagous species that rarely encounter furanocoumarins, received diets amended with 0.05% xanthotoxin, commensurate with their sensitivity to this allelochemical, *D. pastinacella* received diet amended with 0.2% xanthotoxin, consistent with its level of resistance (Berenbaum, 1995). After 72 hours, the entire midgut of each caterpillar was removed and homogenized in cold phosphate buffer. These homogenates were incubated with a known concentration of xanthotoxin in a buffer containing a NADPH-generating system in order to measure cytochrome P450 activity. The disappearance of xanthotoxin over a 30-min period was measured by quantification of remaining xanthotoxin by HPLC. Details of the metabolism assay protocol are described in Zangerl and Berenbaum (1993). For *T. ni* and *H. virescens*, four

midguts were pooled for each replicate because cytochrome P450 activity in these insects is sufficiently low as to be undetectable with a single midgut. In the parsnip webworm, which specializes on furanocoumarin-containing plants, cytochrome P450 activity is measurable in a single midgut (Berenbaum and Zangerl, 1992). To prevent the total loss of xanthotoxin due to high metabolism rates in this insect, the reaction was allowed to run for 15 min instead of the standard 30 min. The rate of xanthotoxin metabolism was calculated as nanomoles per min per gram of fresh caterpillar mass. Differences between treatments were analyzed by two-way analysis of variance.

RESULTS

First Instar Survivorship. For the seed-feeding generalist, *H. virescens*, mortality after 120 hr was 0% and 10% on control and phytic acid diets, respectively (Table 1); no effect on survival could be discerned over this time interval. For the folivorous generalist *T. ni*, however, mortality was significantly higher on diet containing phytic acid for all time periods tested (Table 1). By 120 hours, all caterpillars in the phytic acid treatment had died, whereas mortality on control diet for this same time interval was 16% ($P < 0.0005$). For the oligophagous *D. pastinacella*, mortality was significantly greater after 120 hr on the diet containing phytic acid ($P < 0.0005$). By the end of one week, all webworms had died

approximately 50%; relative growth rate reduction in *D. pastinacella* exceeded 90%. Relative consumption rates for the two noctuid species were reduced by approximately 50% as well, and in *D. pastinacella*, relative consumption rate was reduced by approximately 80%. In *H. virescens*, phytic acid also reduced the efficiency of conversion of ingested food (ECI) (Table 2) (Figure 2). ANCOVA results are in agreement with conventional gravimetric estimates of performance (Table 3).

Xanthotoxin metabolism. In *T. ni* and *H. virescens*, phytic acid did not affect xanthotoxin metabolism (Table 4). In *D. pastinacella*, xanthotoxin metabolism was reduced by 60% in the presence of phytic acid (Table 4) (Figure 1).

DISCUSSION

While there is a substantial amount of information regarding the effects of phytic acid on vertebrate nutrition (Reddy et al., 1989), literature regarding the influence of phytic acid on insect growth and detoxification enzymes is more limited. There is some correlative evidence of antifeedant effects in stored product insects (Jood et al., 1995; Marzo et al., 1997; Modgil and Mehta, 1997). We present here evidence for antifeedant effects of phytic acid on both folivorous and frugivorous insects that consume fresh tissues. Levels of 1% phytic acid, which are within the range encountered by fruit-feeding lepidopterans, can reduce consumption rates by 50% or greater. In the case of *H. virescens*, phytic acid slightly reduced the ability of this insect to convert ingested food into body mass. Moreover, we present evidence of outright toxicity of phytic acid to early stage caterpillars.

In vertebrates, phytic acid reacts with enzymes such as pepsin, α-amylase, β-galactosidase, and lipase, resulting in a decrease in their activities and concomitant reduction in digestive efficiency (Vaintraub and Bulmaga, 1991; Knuckles, 1998); it can also interfere with the activation of trypsinogen to trypsin and, thus, reduce the efficiency of protein utilization (Caldwell, 1992). Mechanisms thought to underlie these antinutritive activities include chelating essential minerals necessary for proper enzyme function and/or direct binding to enzymes, possibly at an allosteric site. Reduction in digestive efficiency in *H. virescens* may be the result of this form of interaction with digestive enzymes. In addition to possible effects on digestive enzymes, phytic acid had a demonstrable effect on the ability of *D. pastinacella* to metabolize xanthotoxin via cytochrome P450 monooxygenases (Table 4). This reduction in P450-mediated metabolism by phytic acid is most likely not due to reduced iron availability. In other studies (Green, 2000), P450-mediated metabolism of xanthotoxin in this species was not signficantly reduced when iron was omitted from the diet. In the case of *D. pastinacella*, which depends on cytochrome P450 monooxygenases to metabolize hostplant allelochemicals, phytic acid clearly inhibits P450-mediated metabolism of xanthotoxin (Table 4). Such P450 inhibition could contribute to reduced survival by exposing insects to the toxic effects of their hostplant allelochemicals. Indeed, survival of *D. pastinacella* on hostplants with above-average furanocoumarin concentrations is correlated with P450-mediated furanocoumarin metabolism rates (Berenbaum and Zangerl, 1998).

It is evident from these studies that phytic acid can interfere with growth and survival of caterpillars. In all three species examined, phytic acid reduced growth rates as compared to controls, and in two species caused significant mortality during the first five days of life. The general pattern of susceptibility is consistent with the ecological probability of exposure to phytic acid; the seed-feeding generalist, *H. virescens*, was largely unaffected, consistent with the widespread distribution

of phytic acid in seeds, whereas the foliage-feeding generalist, *T. ni*, and the bud-, flower-, and immature seed-feeding Apiaceae specialist, *D. pastinacella*, displayed substantial sensitivity to phytic acid, consistent with the fact that this compound is encountered rarely and at low concentrations. In its principal hostplant wild parsnip, *Pastinaca sativa* (A. Zangerl and M. Berenbaum, unpublished), as well as in other species in the family Apiaceae (Gupta et al., 1991) and other unrelated plants (Raboy and Dickinson, 1987), phytic acid does not appear in reproductive structures until 3–4 weeks after anthesis. Thus, the relative unsuitability of mature parsnip fruits for webworm growth (Zangerl et al., 1993) may be due in part to the accumulation of phytic acid with ripening. Date of first flowering in the field is negatively correlated with resistance to webworms (i.e., plants that flower early experience lower levels of herbivory) (Berenbaum et al., 1986); phytic acid accumulation in ripe seeds may contribute to this correlation.

Collectively, these experiments suggest that phytic acid in plant tissues may play a defensive function over and above its primary functions of phosphorus storage, energy storage, and cell wall precursor source (Reddy et al., 1989). In several crop species, phytic acid content varies among genotypes (Mebrahtu et al., 1997) and can be altered by artificial selection (Raboy et al., 1989). If this phytochemical trait is under genetic control under natural conditions, it may be available for selection by herbivorous insects such that the natural variation observed in nature may reflect past interactions with these herbivores.

Abstract—Brook charr (*Salvelinus fontinalis*) lay their eggs in gravel nests called redds. The nests are not defended for extended periods and the eggs and young may be subject to predation from predators that travel through the substrate into the redd. In this study we tested whether long-term exposure of brook charr eggs to chemical cues from predatory sculpins (*Cottus cognatus*) resulted in an adaptive shift in the timing of emergence of charr alevins from artificial redds. We reared brook charr eggs in the presence of chemical cues from sculpins fed brook charr eggs, sculpins fed brine shrimp, and a well water control. Significantly more alevins emerged during the first week of the emergence period when exposed to chemical cues from sculpins fed eggs than from cues from sculpins fed brine shrimp or from well water. Alevins that emerged sooner were smaller and possessed larger yolk sacs than alevins that emerged later in the emergence period. Our results suggest that alevins that emerge sooner may escape predation in the redd, but may pay a cost in being under-developed upon emergence into the open water of the stream or lake.

Key Words—Alevin, redd, brook charr, slimy sculpin, emergence, predation, egg yolk.

INTRODUCTION

Salmonid fishes (salmon, charr, and trout) lay their eggs within the substrate of streams and lakes by hollowing out spaces in the gravel and burying their eggs or by depositing their eggs into interstitial spaces between rocky cobble (Greely, 1932; Scott and Crossman, 1973). These 'nests' are termed redds. Eggs and newly-hatched young (alevins) remain in the redds for varying periods, where they develop by utilizing nutrients and energy from their yolk sacs. After a certain period alevins will begin to emerge from the gravel into the open-water habitats.

The mechanism that induces the migration of alevins out from the gravel is unclear but we do know that alevins possess the ability to alter their emergence behavior (Godin, 1982). Migration out of the gravel may be the result of environmental cues such as dropping dissolved oxygen levels in the gravel, changes in temperature, and/or the presence of predators. Moreover, emergence can be influenced by gravel size and sedimentation (Witzel and MacCrimmon, 1981).

Although burying eggs in the gravel affords some measure of protection from predation for the developing embryos, certain predators may still be able to enter the redd and prey upon developing embryos and newly-hatched alevins. For example, sculpins are small benthic fishes found in freshwater streams and lakes throughout North America (Van Vliet, 1964; Scott and Crossman, 1973). Sculpins typically reach lengths of 70–90 mm as adults and possess large flattened, shovel-shaped heads and large pectoral fins that may assist them in burrowing into the substrate. Several researchers have documented the presence of salmonid eggs in the stomachs of sculpins (e.g., Greely, 1932; Moyle, 1977; Hudson et al., 1995). Until recently, it was generally accepted that these were eggs that had been dislodged from redds and were consumed after they floated away from the redd. However, Dittman et al. (1998) have reported that sculpin enter redds and prey upon salmonid eggs.

Defenses of salmonid eggs and alevins towards in-gravel predators are presently unknown. However, we can predict that eggs may be able to hatch sooner and that alevins may leave the redd sooner in response to nest predators, thereby potentially avoiding predators within the redd. A few studies have documented that amphibians can alter hatching in response to predators. Sih and Moore (1993) report that amphibians can delay hatching in response to predators that forage on tadpoles. By delaying hatching the tadpoles reach a developmental stage where they are less vunerable to predators preying on larvae. Alternatively, Warkentin (1995, 1999) and Chivers et al. (2001) demonstrate that amphibians can hatch earlier in response to egg predators. It is not known whether charr possess the ability to alter their timing of hatching in response to predation risk, but even without this ability they may be able to alter their emergence behavior in response to perceived ambient risk of predation.

Aquatic animals can assess local predation risk by detecting chemical alarm cues released by nearby conspecifics (reviewed in Chivers and Smith, 1998), or by detecting chemical cues emanating from predators (reviewed in Kats and Dill, 1998). In many cases, prey animals need to be feeding on conspecifics of the prey in order for the latter to respond to the predator (reviewed in Chivers and Mirza, 2001). For example, Mathis and Smith (1993) found that fathead minnows (*Pimephales promelas*) responded to chemical cues from pike (*Esox lucius*) fed a diet of minnows, but not to cues from pike fed a diet of a different fish allopatric to minnows.

A common predator on brook charr, *Salvelinus fontinalis*, eggs is the slimy sculpin, *Cottus cognatus* (Greely, 1932). We (Mirza and Chivers unpubl. data) have recently observed that slimy sculpins are attracted to chemical cues of charr eggs emanating from the gravel. In the present study, we tested whether exposure to predator cues would cause brook charr alevins to alter their emergence patterns from artificial nests so as to reduce the risk of mortality within the redd. We predict that exposure to chemical cues from sculpins feeding on eggs would cause alevins to emerge earlier from the gravel. Furthermore, the individuals that emerge earlier should also be less well-developed (i.e., have larger yolk sacs at emergence). Individuals that emerge earlier may pay a fitness cost by emerging into an open water habitat in a less developed state (Gustafson-Greenwood and Moring, 1990).

MATERIALS AND METHODS

Our study was approved by the Institutional Animal Care and Use Committee of the University of Maine (Animal Research Protocol No. A98-10-03). Fertilized brook charr eggs (Maine wild strain) were supplied by the Enfield state hatchery in Enfield, ME in December of 1998. They were produced by mixing gametes from 1 large adult female and 5 large adult males. We obtained eggs immediately after fertilization. They were held in trays in flowing well water (9.5°C, 5 l/min) in the dark, in our lab at the University of Maine. Slimy sculpin were captured from Spruce Mountain Brook in central Maine using a backpack electroshocker and transported to our lab. Prior to the experimental trials sculpin were held in our lab in a 350-l artificial stream tank at 12°C under a 14:L 10:D photoperiod and fed frozen brine shrimp (*Artemia* spp.) ad libitum.

The experiment was conducted in a modified gravitational flow-through apparatus under a 12 L:12 D illumination regime. Well water was pumped into a large 890 l tank, chilled to 7.5°C, and then pumped into three separate header tanks at a rate of ~5 l/min. The header tanks contained either i) 10 sculpins (mean $\pm$ SD $=$ 68.2 $\pm$ 3.4 mm standard length) fed *ad libitum* brook charr eggs, ii) 10 sculpins (67.4 $\pm$ 2.1 mm standard length) fed *ad libitum* with brine shrimp

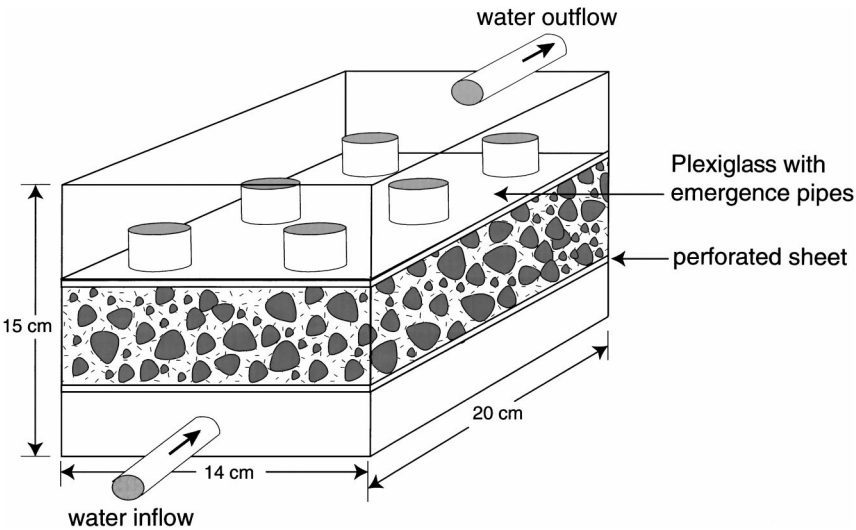

FIG. 1. Diagrammatic representation of an artificial redd.

or iii) well water only. Each header tank (76 × 38 × 36 cm) had nine outflows to artificial redd boxes, plus an overflow. Each outflow had a control valve for setting the flow rate to an artificial redd. Water flowed through each redd box and then was recaptured in catch basins which overflowed down the drain.

The type of artificial redd boxes we used (Figure 1) were modified from those used by Godin (1980). Each redd box consisted of a rectangular plastic box (20 × 15 × 14 cm) into which we placed a perforated Plexiglas sheet 3 cm above the bottom of the box. On top of this sheet we placed 5 cm of gravel (2.48 ± 0.63 cm diam.). The perforated plate allowed for water to flow up through the redd box without the inflow from the header tank being plugged by the gravel. A second Plexiglas sheet was placed on top of the gravel to stop alevins from re-entering the gravel once they emerged. Six holes (4.4 cm diam.) were cut into the sheet and each fitted with a 4-cm long piece of PVC pipe to allow alevins to swim up after emergence. Water flowed out the top of the redd box (Figure 1). This set-up allowed us to mimic the upwelling effect which occurs in natural brook charr redds (Greely, 1932). The sides of the redd boxes were wrapped in black plastic which would allow entry of light from the tops of the redd boxes only.

Charr eggs were placed within the gravel layer and covered the same day they were fertilized. We placed 150 eggs in each redd box. Redd boxes were randomly assigned one of the three treatments (9 redd boxes/treatment). Water flow and temperature were monitored daily in each individual redd box and the header tanks. The mean temperature (±SD) was 9.4 ± 0.19°C, and the mean flow-rate

($\pm$SD) was 344 ± 37 ml/min. There were no differences in temperature (ANOVA, $F_{2,14} = 2.37$, $P = 0.13$) or flow rate (ANOVA, $F_{2,14} = 0.06$ $P = 0.94$) among treatments.

Fresh eggs to be used for food were placed on a flat screen mesh tray (50×30 cm) in the catch basins. Because egg mortality was high due to fungal growth, eggs were frozen 14 days into the experiment. For the duration of the experiment, sculpins were fed previously frozen charr eggs *ad libitum*. Uneaten eggs were removed daily.

Redd boxes were monitored twice a day (05:00 hr and 17:00 hr) for emerging alevins. Early morning emergence checks corresponded with our simulated sunrise and the late afternoon check corresponded with sunset. By checking the redd boxes for emergence at sunrise and sunset we were able to determine whether the alevins emerged at night or during the day. Emergence from gravel nests in salmonids is largely nocturnal (Dill and Northcote, 1970; Godin, 1980;1982; Carey and Noakes, 1981). In the present study, the first alevin emergence was recorded 75 days after fertilization of eggs. This was designated as the first day of emergence. Emergence was recorded for five weeks after this date. Alevins were collected from the redd boxes using pasteur pipettes and euthanized with an overdose of methyl tricane sulphonate (MS-222). Alevins were then preserved in 5% buffered formalin, for at least 90 days, for morphometric analysis.

All emergent alevins were enumerated. For each redd box, in each of the three treatments, we calculated the percentage of alevins that emerged during each week. We compared the percentage of alevin emergence among the three treatments, using Kruskal-Wallis one-way ANOVAs for each week. This was followed by post-hoc non-parametric pair-wise comparisons where appropriate; comparing the sculpin-fed egg treatment to the other two treatments (Siegel and Castellan, 1988).

For the morphometric analysis we measured standard length and then weighed each specimen (after towel drying), removed the yolk plug, and re-weighed the specimen to determine the mass of the yolk plug. Preservation of the yolk plug in formalin caused it to harden and be easily removed from the yolk sac (Godin et al., 1977). We then conducted two-way ANOVAs on the standard length, yolk plug mass, and ratio of yolk plug mass to standard length, testing for treatment effects, time effects, and treatment $\times$ time interactions (Zar, 1996).

RESULTS

Exposure to chemical cues originating from sculpins had a marked effect on the pattern of emergence of brook charr alevins (Figure 2). For both the sculpin-fed brine shrimp treatment and the blank control treatment there was a steady increase in emergence that peaked in week 3, and then a steady decrease. In contrast, an initial pulse of emergence occurred in week 1 in the sculpin-fed egg treatment.

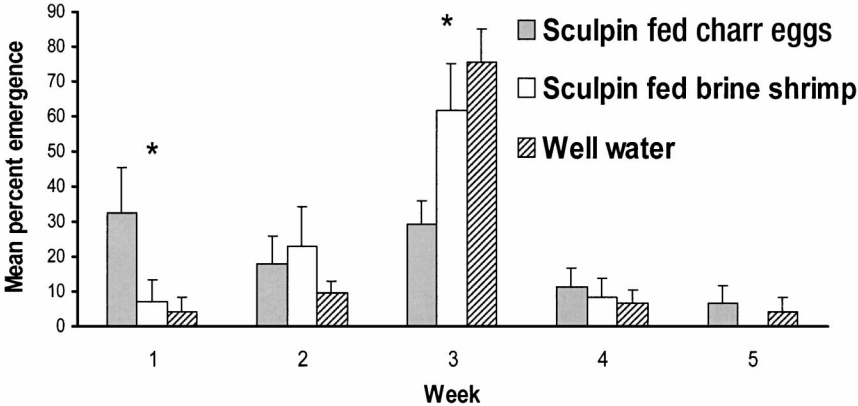

FIG. 2. Mean (+SE) percent emergence of alevins exposed to chemical cues from either sculpins fed charr eggs, sculpins fed brine shrimp or well water. Percent emergence was calculated as the number of alevins that emerged each week over the total number emerged after 5 weeks. All tests were conducted using non-parametric statistics (see text for details). *Denotes a significant difference at $P < 0.05$.

There was a general decline in emergence from week 1 through week 5. There was a difference in alevin emergence among the treatments during the first week ($X^2 = 7.85$, $df = 2$, $P = 0.01$, 1-tailed). Significantly more alevins emerged during week 1 in the sculpin-fed egg treatment than either of the other two treatments (non-parametric pair-wise comparison, $P < 0.05$). There was also a difference in alevin emergence among the treatments during week 3($X^2 = 7.39$, $df = 2$, $P = 0.013$, 1-tailed) as more alevins emerged from the blank control treatment than the sculpin-fed egg treatment (non-parametric pair-wise comparison, $P < 0.05$). There were no differences in the percentage of emergence among the treatments in weeks 2, 4, and 5 ($X^2 = 0.72$, $df = 2$, $P = 0.70$; $X^2 = 0.62$, $df = 2$, $P = 0.74$; $X^2 = 3.8$, $df = 2$, $P = 0.15$, respectively; Fig 2). Overall, we found that 61% of alevins emerged at night. However, there was no significant treatment difference in the overall numbers of alevins that emerged at night ($X^2 = 1.78$, $df = 2$, $P = 0.41$, 2-tailed).

There were effects of time since deposition into the redd on alevin length, yolk plug mass, and ratio of yolk plug mass to length (Table 1; Figure 3A). However, there were no treatment effects on length, yolk plug mass, or ratio of yolk plug mass to length; nor were there any interaction effects between treatment and time (Table 1). For both mass of yolk plug and mass to length ratio, individuals that emerged early had a larger yolk plug and larger mass to length ratio than those individuals that emerged later (Figure 3B,C). A comparison of the results of the morphometric analysis with the emergence data reveals that those individuals that

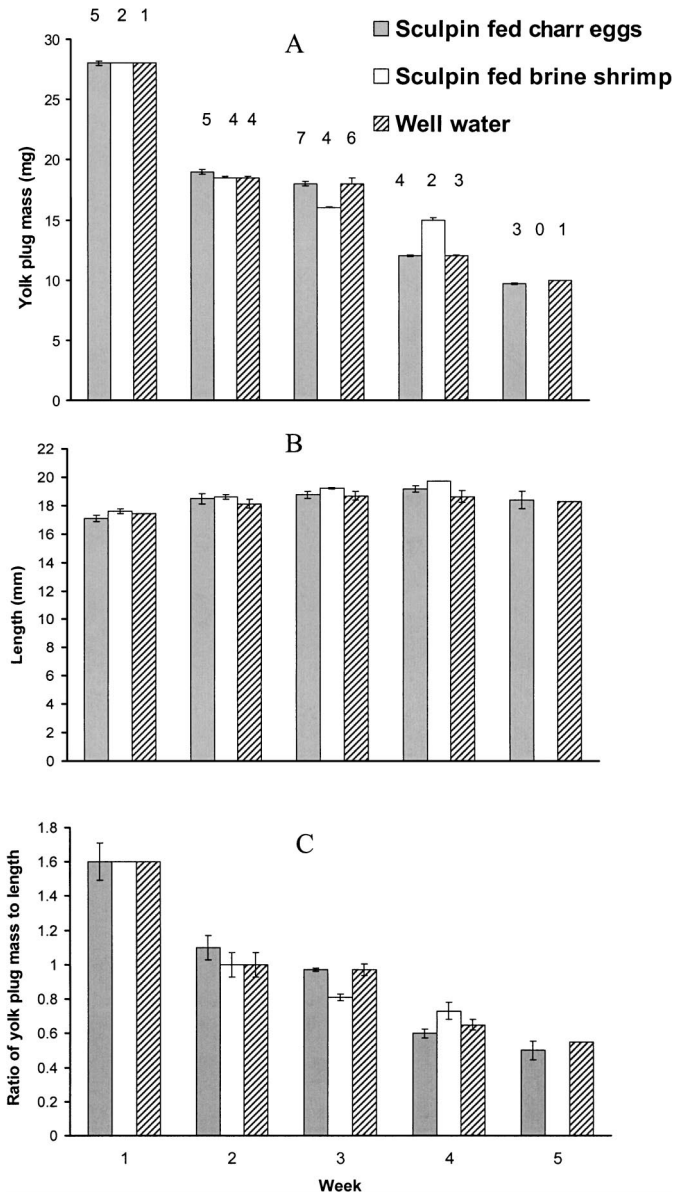

FIG. 3. Mean (±SE) of A) yolk plug mass (mg), B) standard length (mm) and C) ratio of yolk plug mass/length of alevins exposed to chemical cues from either sculpins fed charr eggs, sculpins fed brine shrimp or well water. Numbers above bars represent the number of redds in which emergences were recorded for that particular week (see text for details).

TABLE 1. RESULTS OF TWO-WAY ANOVAS TESTING FOR EFFECTS OF TREATMENT AND TIME (WEEK), AND THEIR INTERACTIONS ON ALEVIN LENGTH, YOLK PLUG MASS, AND RATIO OF YOLK PLUG MASS TO LENGTH

	F	*df*	*P*

emerged earlier had larger yolk sacs and that a larger proportion of those individuals emerged from the sculpin-fed egg treatment during the first week.

DISCUSSION

Our results demonstrate that brook charr alevins alter their pattern of emergence from the redd when exposed to chemical cues from sculpins fed brook charr eggs. By leaving the nest sooner, alevins may evade predation within the redd. However, escaping predation in the redd may have a cost associated with it, since individuals that emerged sooner were smaller and possessed larger yolk sacs than individuals that emerged later. Typically, alevins emerge from the redd after absorbing most of their yolk sac and then rest on the substrate outside the redd reabsorbing the remainder of the yolk sac before dispersing in the stream or lake (Godin, 1982). However, alevins may be vulnerable to predators outside the redd during this period. If alevins are emerging with large yolk sacs, it may hamper swimming ability making it harder to evade predators (Gustafson-Greenwood and Moring, 1990). Thus, individuals which emerge earlier may be more at risk to predation in the open-water habitat (Godin, 1982; Huntingford et al., 1988).

We also found that the pattern of alevin emergence differed between the sculpin-fed egg treatment and the other two treatments. In the sculpin-fed egg treatment, most of the emergence occurred in the first week and then slowly trailed off. By comparison, in the other two treatments there was a steady increase in emergence that peaked at week 3 and then steadily declined. Altering the natural

pattern of emergence may also increase susceptibility of emerging alevins to predators outside the redd (Godin 1980, 1982). Alevins that synchronize emergence may gain antipredator benefits from being in larger numbers through the predation risk dilution and confusion effects (Godin, 1982,1986).

Alevins exhibit a trade-off in predation risk. If they were to stay within the redd predation risk would be high. However, since alevins do not disperse right away after emergence the risk of predation outside the redd may also be high because other predators may be in the vicinity. Typically, most streams offer little shelter since the substrate consists mainly of cobble and gravel. Benthic predators, such as sculpins, would most likely be proficient in searching for prey in these habitats. Thus, it may be difficult for alevins which emerged with larger yolk sacs to hide and compensate for lost developmental time in the nest.

In addition to increased predation risk, there may be other costs associated with early emergence. Impaired swimming ability due to possessing a larger yolk sac may render alevins more prone to being displaced by water currents (Gustafson-Greenwood and Moring, 1990). Similarily, presence of predators outside the redd may induce downstream displacement which may be energetically costly (Bardonnet and Heland, 1994).

Our study is the first to demonstrate experimentally a shift in the timing of nest emergence behavior by alevins in response to chemical cues from predators. The response we observed was not a general response to sculpin chemicals, but rather was a response to cues of sculpins feeding on brook charr eggs. Cues from sculpins feeding on brine shrimp were not sufficient to elicit this change in emergence pattern. We do not know whether the observed shift in emergence would also occur in response to injured eggs alone. Is the response we observed a response to injured eggs or a response to injured eggs combined with predator odor? In either case, predation is the causal factor changing the emergence pattern.

We observed that brook charr alevins altered their nest emergence patterns in response to chemical cues associated with predation risk. The most likely explanation for the observed pattern is that alevins made behavioral decisions regarding when to emerge. However, it is possible that eggs detect chemical cues from predators and hence alter their development, which in turn influences timing of emergence. Blaustein (1997) hypothesizes that cladocerans and copepods were less abundant in the presence of fire salamander larvae (*Salamandra infraimmaculata*) because they exhibited hatching inhibition. Chivers et al. (2001) showed that both Pacific tree frog (*Hyla regilla*) and Cascades frog (*Rana cascadae*) eggs hatch faster in the presence of chemical cues from predatory leeches (families Glossiphonidae and Erpobdellidae), but not chemicals from non-predatory earthworms (*Lumbricus terrestris*). It is not known whether fish eggs detect chemical cues from predators and facultatively adjust timing of hatching in a similar manner. Further research should address this question.

Acknowledgements—We would like to thank Matt Puttlitz and Pam Bryer for technical assistance. We would also like to thank the Maine Department of Inland Fisheries and Wildlife and the Enfield State Hatchery for assistance and providing the trout eggs for this study. This study was funded by a grant to D.P. Chivers from the Maine Agriculture and Forest Experiment Station. The research presented here was described in Animal Research Protocol No. A98-10-03 by the Institutional Animal Care and Use Committee of the University of Maine, Orono.

(Received September 5, 2000; accepted May 6, 2001)

Abstract—Queens of the slave-maker ant, *Polyergus breviceps,* take over nests of their *Formica* host species by fatally attacking the resident queen. As workers only begin grooming the *P. breviceps* queen once she has ceased her attack, we investigated whether a change in parasite queen chemistry may account for the change in worker behavior. Cuticular hydrocarbon profiles of newly mated *P. breviceps* queens and of queens of their two *Formica* host species were found to be species-specific. Profiles of newly mated *P. breviceps* queens that had attacked a *Formica* queen, however, were virtually identical to the queen profile of the species killed. Mass spectral analysis revealed that the hydrocarbons on the cuticles of newly mated *P. breviceps* changed from primarily normal alkanes to methyl and di-methyl branched alkanes after attacks. The results suggest that cuticular compounds from the host queen were transferred to the parasite queen during their aggressive interaction.

Key Words—Cuticular hydrocarbons, Formicidae, slave-maker, *Polyergus breviceps, Formica gnava, Formica occulta,* colony takeover, queen killing, chemical camouflage.

INTRODUCTION

Species of the ant genus, *Polyergus*, are all obligate social parasites, unable to survive without the foraging, feeding, and brood care behaviors of their *Formica* hosts. *Polyergus* workers acquire host workers ("slaves") by robbing host species nests of their pupae during summer months. The *Formica* pupae mature in the slave-maker's nest and become full-functioning colony members. Queens of *Polyergus* also depend on the behaviors of their slaves, and new queens require a slave supply to establish their colonies. However, rather than raiding a host nest for brood, a new queen secures her initial slave supply by taking over a host species nest. Frequently, an alate *Polyergus* gyne will mate while running alongside nestmates that are advancing towards a *Formica* nest to raid. By the time the newly mated queen reaches the targeted *Formica* nest, the inhabitants have already abandoned it (temporarily) and the raiders have all but completed their pillaging and are making their way back to their natal nest. The newly mated *Polyergus* gyne enters the nest, as do the *Formica* soon thereafter, and locates and fatally attacks the resident queen (Wheeler, 1906; Topoff et al., 1988; Mori et al., 1995). In laboratory nests, *Formica* workers at first will attack the invading queen, but attacks diminish once the *Polyergus* queen has begun her attack on the *Formica* queen. *Formica* workers during this time seem to be either appeased (Topoff et al., 1988; Mori et al., 2000a,b) or repelled (D'Ettorre et al., 2000) by a secretion from the Dufour's gland of the *Polyergus* queen. Immediately after the *Polyergus* queen ceases her attack on the host queen, approximately 25 min after attack onset, workers begin grooming the slave-maker queen. Results of laboratory experiments indicate that the aggressive interaction between the *Polyergus* and *Formica* queens is a key component in the ultimate acceptance of the *Polyergus* queen (Zaayer, 1967; Topoff et al., 1988, 1990; Topoff and Zimmerli, 1993; Mori et al., 1995). First, *Polyergus* queens are more successful in their attempts to take over a nest when a *Formica* queen is present (and the *Polyergus* queen kills her) than when the *Formica* nest is queenless. Worker attacks on an invading *Polyergus* queen in queenless colonies tend to be relentless and almost always result in her death (Zaayer, 1967; Topoff et al., 1988, 1990; Topoff and Zimmerli, 1993). Second, the associated change in worker behavior takes place immediately after attacks on the host queen cease, even if the *Formica* queen is still alive (although maimed, person. obs.). This is unlike the delayed and gradual decrease in worker aggression that is sometimes observed in other species when the resident queen is removed experimentally.

The prevailing hypothesis is that *Formica* workers adopt a *Polyergus* queen because she is "camouflaged" with the host queen cuticular chemicals, chemicals familiar to the workers (Topoff et al., 1988, 1990; Topoff and Zimmerli, 1993; Zimmerli and Topoff, 1994). The lipid layer of the insect cuticle is capable of absorbing other lipid soluble compounds (Soroker et al., 1994, 1995; Vienne et al., 1995), and it has been demonstrated that chemicals can be transferred among

individuals, even across higher level taxa, through social contact (see Vander Meer and Wojcik, 1982). Thus, while attacking a *Formica* queen, *Polyergus* queens may be absorbing chemicals involved in nestmate/queen recognition from the *Formica* queen. The recent results of Errard and D'Ettorre (1998) support this contention; after a *Polyergus rufescens* Latreille queen kills a *Formica cunicularia* Latreille queen, her cuticular hydrocarbon profile resembles the hydrocarbon profiles of *F. cunicularia* queens.

In this study, we examined whether a newly mated *Polyergus breviceps* Emery queen also undergoes changes in hydrocarbon profile after killing a queen of her host species, and whether the resulting profile is then similar to the queen profile of the host species. By comparing profiles of *P. breviceps* queens that had killed either a *Formica gnava* Buckley or *Formica occulta* Francoeur host queen, we were further able to ascertain whether the changes in hydrocarbon profiles were specific to the species of *Formica* queen killed. Of the lipids found on the cuticle, a significant percentage tends to be hydrocarbons (Jackson and Blomquist, 1976). Numerous studies have demonstrated a correlation between hydrocarbon patterns and nestmate recognition (e.g., Bonavita-Cougourdan et al., 1987; Vander Meer and Morel, 1998). Recently, the importance of hydrocarbons in nestmate recognition has been confirmed for some ant species (e.g., Lahav et al., 1999), although other classes of compounds are undoubtedly also involved (Obin, 1986). The particular pattern of hydrocarbons, frequently characteristic of a species (nest [Nowbahari et al., 1990] or caste [Wagner et al., 1998]), is likely to reflect similarities or differences in other non-polar and polar cuticular lipids among species. Hydrocarbon profiles can, therefore, be used to investigate the transfer of cuticular lipids, which are likely to contain nestmate recognition cues. Certainly, the strong correlation between hydrocarbon profiles shared by other parasites and predator myrmecophiles and their hosts and adoption by the host colony is suggestive of this (e.g., Vander Meer and Wojcik, 1982; Franks et al., 1990; Vander Meer et al., 1989).

METHODS AND MATERIALS

Ant Collections and Housing. Ant colonies were collected during June and July of 1997 and 1998 from the Chiricahua Mountains of southeastern Arizona, U.S.A.. Fifteen queenright colonies of *F. gnava* were collected from the Arizona oak-alligator juniper woodlands of the Southwestern Research Station (SWRS) of the American Museum of Natural History (el. 1646 m). Thirteen queenright colonies of *F. occulta* were collected from an area just east of the Barfoot Peak trailhead (el. 2750 m) in Coronado National Forest populated with ponderosa pine. Colonies were brought into the laboratory at SWRS and kept in large Tupperware® boxes lined with Fluon® (Northern Products, Woonsocket, RI) to prevent escape.

Newly mated *P. breviceps* queens from three nests with *F. gnava* slaves ($N = 49$) and from two nests with *F. occulta* slaves ($N = 13$) were collected as they approached the *Formica* nest being raided by their non-reproductive nestmates and placed in individual 4 dram vials that contained a cotton ball moistened with water.

Solvent Extraction of Queens. Twelve established (with colony) *F. gnava* queens and ten established *F. occulta* queens were removed from their nests and placed in individual Tupperware boxes ($20.5 \times 45 \times 3.5$ cm) lined with a thin layer of soil. A single newly mated *P. breviceps* queen was introduced into the box and allowed to attack the *Formica* queen. Immediately after attacks ceased, *P. breviceps* and *Formica* queens were placed in individual 7 ml scintillation vials and a quantity of high purity hexane (GC^2 Grade [B & J, Muskegon, MI]) sufficient to cover the entire body (approximately $0.3 - 0.5$ ml) was added to extract cuticular components (see Table 1). After 10 min, the solvent extract was transferred from the sample with a Pasteur pipette to a 2 ml scintillation vial and allowed to evaporate. In addition, cuticular chemicals from newly mated *P. breviceps* queens (that had not attacked a host queen) from nests containing *F. gnava* slaves and from nests containing *F. occulta* slaves, and from established *F. gnava* and *F. occulta* queens that had not been presented to *P. breviceps* queens for attack were extracted using the same protocol presented above (see Table 1). All specimens were preserved for voucher in 70% ethyl alcohol (maintained in personal collection—CAJ).

Chemical Analysis. The evaporated extracts were transported to the United States Department of Agriculture, Agricultural Research Service, Center for Medical, Agricultural, and Veterinary Entomology in Gainesville, Florida where they were reconstituted in 0.2 ml hexane, vortexed for 2–3 sec, and applied to a small silicic acid (70–230 mesh 60 Å, [Aldrich Chemical Co., Inc.]) Pasteur pipette

TABLE 1. SPECIES AND CONDITIONS OF QUEENS FROM WHICH CUTICULAR HYDROCARBONS WERE ANALYZED

Species	Condition	Host species in nest	Number of individuals

Formica gnava	Killed by *Polyergus*	—	12
	No interactions with *Polyergus*	—	3
Formica occulta	Killed by *Polyergus*	—	10
	No interactions with *Polyergus*	—	3

column. Hydrocarbons were isolated from other lipids by eluting the column with hexane. The eluent, containing purified hydrocarbons (ca. 6–7 ml, which from previous experience eluted all hydrocarbons), was concentrated to ca. 10 μl under a stream of N_2. Samples were analyzed by gas chromatography (Varian 3700 [Varian Associates, Walnut Creek, CA] equipped with a split-splitless injector [Agilent Technologies, Palo Alto, CA], a capillary column [DB – 1, 30 m, 0.32 mm i.d., 0.25 μm film thickness; J & W Scientific, Inc., Folsom, CA] and flame ionization detector). The injector and detector were set at 300°C; the oven temperature was programmed from 190°C to 290°C at 5°C/min, and then held at 290°C for 5 min. Hydrogen was used as the carrier gas and nitrogen was used as the makeup gas. Data were analyzed using PE Nelson Turbochrom Navigator 6.1.0.1FO4 (Perkin Elmer Corp., Norwalk, CT). Hydrocarbon standards (C24, C26, C28, C30, C32, #NP-MIX-H [Alltech Associates, Inc., Deerfield, IL]) were injected at regular intervals during sample analysis. The standards were used to calculate Kovat Indices (KI).

Mass Spectrometry. Representative samples of (a) newly mated *P. breviceps* queens from nests containing *F. gnava* slaves, (b) newly mated *P. breviceps* queens that had killed a *F. gnava* queen, (c) *F. gnava* queens, (d) newly mated *P. breviceps* queens from nests containing *F. occulta* slaves, (e) newly mated *P. breviceps* queens that had killed an *F. occulta* queen, and (f) *F. occulta* queens were analyzed by gas chromatography/mass spectroscopy. Electron impact-mass spectra (EI-MS) were obtained with an HP 5890 Series II GC (Agilent Technologies, Palo Alto, CA) connected to an HP 5988A MS instrument (Agilent Technologies, Palo Alto, CA) operated at 70 eV and tuned to accentuate the high mass fragments. The GC, equipped with an on-column injector and a SPB1 capillary column (0.25 μm film; 30 m $\times$ 0.32 mm i.d. [Supelco, Inc., Bellefonte, PA]), was held at 60°C for 2 min and then increased to 200°C at 30°C/min, and then to 280°C at 2°C/min. The MS was controlled and the data analyzed using Vector/Two software (ProLab Resources, Inc., Madison, WI).

Data Analysis. Data were analyzed as two separate groups on the basis of the host species present in the nests of newly mated *P. breviceps* queens. Group 1 compared: (a) newly mated *P. breviceps* queens from nests containing *F. gnava* slaves, (b) newly mated *P. breviceps* queens that had killed a *F. gnava* queen, (c) *F. gnava* queens, (d) and *F. occulta* queens. Group 2 compared: (a) newly mated *P. breviceps* queens from nests containing *F. occulta slaves*, (b) newly mated *P. breviceps* queens that had killed an *F. occulta* queen, (c) *F. occulta* queens, and (d) *F. gnava* queens. For multivariate analysis, it was necessary to preprocess the data. The relative proportions of cuticular hydrocarbons were computed by dividing the area given for each cuticular hydrocarbon by the total integrated peak area of the profile, and then autoscaling each peak to ensure that it had equal weight in the analysis. Principal component analysis (Jolliffe, 1986) was then conducted on 45 normalized variables from Group 1, or on 48 normalized variables

from Group 2. Invariant features were excluded from the principal component analysis, therefore some GC peaks were excluded from the analysis of data sets 1 and 2. In data set 1, one newly mated *P. breviceps* sample and one *F. occulta* sample were deleted because the generalized distance test (Schwager and Margolin, 1982) determined them to be outliers at the 0.01 probability level. In data set 2, one newly mated *P. breviceps* sample, one *F. occulta* sample, and one *F. gnava* sample were also determined to be outliers and were subsequently deleted from the analysis. The multivariate analyses described here were performed by using Pirouette (Infometrix, Woodinville, WA).

RESULTS

Five of the six significant hydrocarbon peaks isolated from the cuticle of newly mated *P. breviceps* queens from nests containing *F. gnava* slaves were determined to be normal alkanes from C25 to C29 (trace of n-C24). The sixth peak was identified as 2-methyl hexacosane. KI data indicate that other 2-methyl even carbon backboned homologues may be present, however, their concentration was inadequate for mass spectral verification. In contrast to the predominance of normal alkanes on the cuticle of newly mated *P. breviceps* queens, the hydrocarbon components of *F. gnava* queens were all methyl or di-methyl branched hydrocarbons (see Table 2). No normal alkanes were detected. Soon after attacking a *F. gnava* queen, the hydrocarbon profile of the newly mated *P. breviceps* queen changed dramatically to one that approximated the profile of a *F. gnava* queen (Figure 1). Mass spectral analysis indicates that the hydrocarbon peaks found on the cuticle of a *P. breviceps* queen that had attacked a *F. gnava* queen contained hydrocarbon components that were identical to those found on host *F. gnava* queens (Table 2, Figure 1).

A plot of the two largest principal components, which account for 58% of the total cumulative variance, for Group 1 (*P. breviceps* associated with *F. gnava*, see Figure 3a) shows that newly mated *P. breviceps* queens were clearly separated from *P. breviceps* queens that had attacked a *F. gnava* queen, *F. gnava* queens, and *F. occulta* queens. *Polyergus breviceps* queens that had attacked a *F. gnava* queen, however, clustered with *F. gnava* queens, indicating hydrocarbon profiles of newly mated *P. breviceps* queens changed after attacks. *Formica gnava* queens killed by *P. breviceps* had variable amounts of the saturated hydrocarbons associated specifically with *P. breviceps* newly mated queens, an indication that there was some reciprocal transfer of cuticular compounds during the interactions between parasite and host queens. *Formica occulta* queens were distinctly separated from the three groups defined above on the second principal component.

The chromatograms of newly mated *P. breviceps* queens reared in nests with *F. occulta* host workers are qualitatively similar to those of queens reared in nests

TABLE 2. COMPOUND STRUCTURES OF PEAKS IN HYDROCARBON PROFILES OF *P. breviceps* QUEENS FROM NESTS WITH *F. gnava* HOST WORKERS THAT EITHER WERE NEWLY MATED OR KILLED A *F. gnava* QUEEN, AND OF *F. gnava* QUEENS

[a] Indicates peak presence.

with *F. gnava* host workers, but the peaks differ in relative amounts (compare Figure 1a with Figure 2a). The cuticular hydrocarbons are composed primarily of normal hydrocarbons (C24 through C29). Minor components, 2-methyl branched hydrocarbons associated with even carbon backbones (C24, C26, C28), are also sometimes present in detectable amounts. The cuticular hydrocarbon profiles of *F. occulta* queens (Figure 2c) are more complex than those of *F. gnava* queens (Figure 1c). Like *F. gnava* queens, however, the cuticular hydrocarbons of *F. occulta* queens are composed exclusively of methyl and di-methyl branched compounds (Table 3). No normal alkanes were detected. Similar to *P. breviceps* queens that attacked a *F. gnava* queen, soon after attacking a *F. occulta* queen, the hydrocarbon profiles of the *P. breviceps* queens changed, mimicking the profile of *F. occulta* queens (Figure 2). Mass spectra of cuticular hydrocarbon peaks of the parasite *P. breviceps* queen after attacking a *F. occulta* queen were identical to

[a] Indicates peak presence.

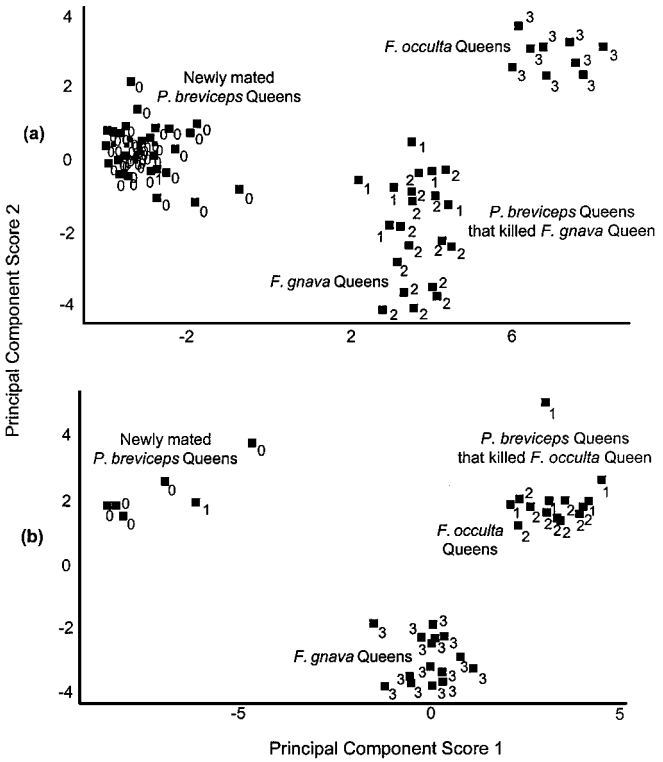

FIG. 3. Principal component maps of cuticular hydrocarbons from *P. breviceps*, *F. gnava*, and *F. occulta* queens. **(a)** 0 = newly mated *P. breviceps* queens from nests containing *F. gnava* slaves, 1 = killer newly mated *P. breviceps* queens from nests containing *F. gnava* slaves, 2 = *F. gnava* queens, 3 = *F. occulta* queens. **(b)** 0 = newly mated *P. breviceps* queens from nests containing *F. occulta* slaves, 1 = killer newly mated *P. breviceps* queens from nests containing *F. occulta* slaves, 2 = *F. occulta* queens, 3 = *F. gnava* queens.

those found on host *F. occulta* queens (Table 3, Figure 2). *Formica occulta* queens killed by *P. breviceps* queens seemed to acquire certain specific hydrocarbons associated with *P. breviceps* queens during the conflict, thus confirming again that there was some mutual transference of cuticular compounds.

A plot of the two largest principal components, which account for 61% of the total cumulative variance, for Group 2 (*P. breviceps* associated with *F. occulta*, see Figure 3b), shows that newly mated *P. breviceps* queens are well separated from newly mated *P. breviceps* queens that had just killed an *F. occulta* queen, *F. occulta* queens, and *F. gnava* queens. *Polyergus breviceps* queens that killed a *F. occulta* queen clustered among *F. occulta* queens. *Formica gnava* queens were distinctly separated from these groups.

DISCUSSION

Chemical Camouflage and Adoption of the Polyergus Queen. *Polyergus breviceps* queens, in taking over a *Formica* colony, must be accepted by adults that have not been exposed previously to her odor. It is clear from initial *Formica* worker aggression directed at *P. breviceps* queens invading a nest, that *P. breviceps* queens are not naturally candidates for adoption. The qualitative differences that we found in hydrocarbons between newly mated *P. breviceps* queens and host *Formica* queens was, therefore, none too surprising and indicate that *P. breviceps* and its host species have not co-evolved such that queen cuticular hydrocarbon profiles, and probably other relevant chemical profiles, are inherently similar. Instead, integration of parasite queen among host workers seems to require several diverse tactics, one of which is chemical camouflage. *Polyergus* queens first ward off attackers with secretions from the Dufour's gland while attacking the resident queen (Topoff et al., 1988; D'Ettorre et al., 2000; Mori et al., 2000 a,b). However, soon after the attack on the host queen ceases, host workers aggregate around the parasite queen and begin grooming her. Sampling of the cuticular hydrocarbons from newly mated queens and from attackers, just as attacks were completed, indicated that the newly mated queen profiles transformed dramatically, containing at first simple hydrocarbons and then harboring complex methyl and di-methyl branched hydrocarbons. These new profiles were virtually identical both in peak quality and relative proportion to the queen profiles of the species of queen attacked, a result similar to that discovered by Errard and D'Ettorre (1998) for *P. rufescens.* This, concomitant with the rapidity of the chemical change and modification in host worker behavior, suggests that the emergence of new chemical components (adoptive properties?) is not due to a biosynthetic change triggered by the aggressive interaction, at least initially, as has been proposed for other social parasites (Bagnères et al. 1996). Of course, only tracing the movement of labeled hydrocarbons could demonstrate chemicals were indeed transferred. It should be furthermore noted that, if this is a system of chemical transfer, it is not perfect. In two instances, profiles of *P. breviceps* queens that had killed a *Formica* queen (one *F. gnava* and one *F. occulta*) did not cluster with the respective *Formica* species, but clustered with newly mated *P. breviceps* (Figures 3a and b).

In the socially parasitic wasp, *Polistes atrimandibularis* Zimmermann, the profile change does undoubtedly seem to be the result of a change in metabolic pathway in addition to adsorption of host chemicals (Bagnères et al., 1996). Over a period of several months, unsaturated hydrocarbons of *P. atrimandibularis* queens that have invaded a nest of *Polistes biglumis bimaculatus* Geoffroy disappear from the parasite cuticle and are replaced with the saturated products of the host species. Generally, the invasion by *P. atrimandibularis* is a passive one and seems to be restricted to usurping incipient nests of its host. This is unlike the strategic invasion by queens of the socially parasitic wasp *Polistes sulcifer*

Zimmermann, which take over nests by expelling or killing the dominant queen of its host species, *Polistes dominulus* (Christ) (Turillazzi et al., 1990). Recently, it was demonstrated that *P. sulcifer* queens also change their chemical profile, resembling the host queen almost completely within 3 days (Turillazzi et al., 2000). The stroking and prolonged licking of host individuals suggest, furthermore, that *P. sulcifer* achieves host chemical similarity by obtaining chemicals directly from the host.

While the acquisition of new cuticular components by newly mated *P. breviceps* queens that have attacked a *Formica* queen is readily explainable, the apparent rapid loss of the n-alkanes in such a short time period is not. Most likely, the abundance of newly acquired material has overwhelmed the original components. Our data, however, were insufficient to determine if this indeed is the case. In the above mentioned species that undergo similar profile changes, pre-invasion or pre-attack profile components are also lost. Although the loss of particular components in these instances takes admittedly longer, one peak in the profile of *P. sulcifer* does show substantial decrease after only 90 min (Turillazzi et al., 2000).

Integration by Other Slave-Maker Species. Queens of other socially parasitic ant species also appear to infiltrate their host species colony by camouflaging themselves with host chemicals. For example, the slave-maker queen, *Leptothorax kutteri* Buschinger, aggressively grooms the host *Leptothorax acervorum* (Fabricius) queen and workers upon invading their nest, resulting in a chemical profile very similar to that of *L. acervorum*. Experimentally preventing a *L. kutteri* queen from grooming host individuals results in aggressive attacks, suggesting that a chemical transfer takes place and that this allows invading queens to become adopted by host workers (Franks et al., 1990). Some dependent colony founding queens, however, do not need to be adopted by adult host workers in order to establish a new colony. The facultative slave-maker, *Formica wheeleri* Creighton, usurps a *F. occulta* nest by invading a nest, inducing the adult inhabitants to flee, and appropriating the brood left behind (Topoff et al., 1990). The workers that emerge from the orphaned brood adopt the slave-maker queen and eventually rear her offspring. Presumably, these newly emerged workers, having been exposed to the *F. wheeleri* queen during early periods of development (Morel, 1983; Errard, 1984, Morel et al., 1988) or soon after eclosion (see Vander Meer and Morel, 1998), incorporate her odor into their nestmate recognition odor template and, thereby, accept her. A preliminary examination of cuticular hydrocarbon data revealed that the queen profiles of *F. wheeleri* and *F. occulta* were not similar, even after a new queen had been residing with *F. occulta* workers for one year (Johnson, 2000). These results promote the contention that the chemical change in *P. breviceps* is not fortuitous.

Newly Mated Queen Profiles. Acquisition of chemicals from a host species queen could facilitate integration of the *P. breviceps* queens among host workers, as well as allow the parasite queen to solicit the particular attention workers often display towards reproductive individuals. Nonetheless, the newly mated

P. breviceps profile should not be dismissed as inconsequential. The cuticular hydrocarbon profiles of *P. breviceps* queens here were clearly simple relative to the profiles of the host species queens. However, the parasite queen profiles were also qualitatively identical to the pupae hydrocarbon profiles of both *F. gnava* and *F. occulta* (Johnson, 2000; Johnson & Vander Meer unpublished data), but differed from pupae profiles of *P. breviceps*! The peaks in profiles of newly mated *P. breviceps* associated with *F. gnava* were, furthermore, of similar relative proportions. Others have noted previously that newly mated *Polyergus rufescens* queens (D'Ettorre et al., 2000) and callows belonging to other species (Lenoir et al., 1999) lack a chemical profile. This "chemical insignificance" is suggested to facilitate integration by minimizing aggression and allowing individuals to acquire the appropriate chemical suit (Lenoir et al., 2001). In the case of newly mated *P. breviceps* gynes, however, it seems that rather than being chemically insignificant, their pupa-like profile may be significant, having similar consequences as those gained by chemically insignificant profiles, such as diminishing aggressive reactions upon invading a nest and facilitating movement towards the host queen.

Visual inspection of hydrocarbon patterns of newly mated *P. breviceps* queens has revealed an additional interesting result. Hydrocarbon components of newly mated *P. breviceps* queens from nests with *F. gnava* slaves differed consistently in relative proportions from newly mated *P. breviceps* queens collected from nests with *F. occulta* slaves (compare Figure 1a with Figure 2a). Because *P. breviceps* are obligatorily dependent on their host species for survival, rearing *P. breviceps* without some chemical influence from their *Formica* host species seems unlikely. However, the clear differences in hydrocarbon profiles of *P. breviceps* female alates and their adult hosts are indicative of minimal chemical interaction. Thus, the consistent differences in cuticular hydrocarbon profiles of newly mated *P. breviceps* queens associated with the two host species could reflect (a) different environmental conditions in each host nest or (b) the emergence of two host races or species. It would be unduly worthwhile to clarify the relationship between these two populations of *P. breviceps.*

Previous Studies on Polyergus Worker Profiles. Not surprisingly, there are some similarities and differences in what we and Errard and D'Ettorre (1998) found with *Polyergus* queen profiles (and the respective changes) and what others have found examining worker profiles of *Polyergus* and other slave-makers and their hosts. The profile from workers of the Japanese slave-maker ant, *Polyergus samurai* Yano, was found to be qualitatively and quantitatively identical to the profile of their host species, *Formica japonica* Motschulsky (Yamaoko, 1990). Differences among colonies and sites for both parasite and host suggested that *P. samurai* synthesize very little of their own cuticular hydrocarbons, receiving the majority from the host species. Habersetzer and Bonavita-Cougourdan (1993) and Habersetzer (1993), on the other hand, found the European slave-maker, *Polyergus rufescens,* to maintain some species specificity in their cuticular

hydrocarbon profiles by retaining five major peaks not found in the profiles of their *Formica cunicularia* host. They also found that the *Formica* lost some of their colony characteristics, although this may be a confounding result of sampling workers from a mixed species nest. Bonavita-Cougourdan et al. (1996, 1997) also found *P. rufescens* to maintain some semblance of specificity by retaining compounds that were not on either of their two potential host species, *F. cunicularia* and *Formica rufibarbis* Fabricius. Their results, however, indicate a complex system of profile convergence that does not involve the transfer of chemicals across species. Instead, the proportions of cuticular hydrocarbons that are shared and normally synthesized by each species are adapted such that the other species profiles are rivaled. *Polyergus,* in the forefront, adjusted its profile the most, but the profile modification by both *Formica* species made them distinct from other monospecific, conspecific colonies.

One might expect similar results from another prominent slave-maker, *Harpagoxenus sublaevis* Nylander. However, *H. sublaevis,* which sometimes maintains two species of *Leptothorax* simultaneously, does not produce their own specific hydrocarbons (Kaib et al.,1993) but acquires constituents through allogrooming. Hence, they contribute nothing to the profiles of their host species. The two *Leptothorax* species, however, modify each other's signatures when both are in a single *H. sublaevis* nest (Kaib et al., 1993).

Differences in integration mechanisms of workers and slave-maker queens that usurp nests of worker adults are not surprising. Typically, both parasite and host workers in slave-maker nests are exposed to the nestmate recognition cues of the other species as immatures or callows, when much of the nestmate recognition template is being formed (see Jaisson 1975a,b; Le Moli and Passetti, 1977, 1978; Le Moli, 1980; Le Moli and Mori, 1982, 1987; Morel et al., 1988). They, therefore, need not rely on camouflage to be accepted by the other species. *Polyergus* queens as dependent colony founders, on the other hand, need an immediate chemical armor.

Acknowledgments—We are grateful to Michele Hosack (United States Department of Agriculture, Center for Medical and Veterinary Entomology) for her help with the gas chromatography and to the staff and volunteers of the Southwestern Research Station of the American Museum of Natural History where the fieldwork was conducted. Early versions of this manuscript were greatly improved by comments from Howard Topoff (Hunter College) and James Carpenter (American Museum of Natural History). We also thank two anonymous reviewers for their constructive comments. The research was aided by grants from the Animal Behaviour Society, Sigma Xi, and the Theodore Roosevelt Memorial Fund and by a fellowship from the Biopsychology subprogram at Hunter College to C.A. Johnson.

Abstract—Within a colony of harvester ants (*Pogonomyrmex barbatus*), workers in different task groups differ in the hydrocarbon composition of the cuticle. Foragers and patrollers, which spend extended periods of time outside the nest, have a higher proportion of saturated, unbranched hydrocarbons (*n*-alkanes) on the cuticle than nest maintenance workers, which spend only short periods of time outside the nest. We tested whether these task-related differences in ant cuticular chemistry arise from exposure to conditions outside the nest. Nest maintenance workers experiencing daily, short-term outside exposure developed a higher proportion of *n*-alkanes on the cuticle than workers kept inside the lab. Independent manipulations of ultraviolet radiation, relative humidity, and temperature revealed that only the combination of high temperature (ca. 38°C) and low relative humidity (ca. 8%) increased the proportion of cuticular *n*-alkanes. The results indicate that warm dry conditions, such as those encountered when an ant leaves the nest, trigger changes in cuticular chemistry.

Key Words—Cuticular hydrocarbons, Formicidae, *Pogonomyrmex barbatus*, *n*-alkanes, task.

INTRODUCTION

A social insect colony performs many tasks, including foraging, nest construction, and feeding the young. In many social insect species, workers are not specialized

to perform a particular task but change tasks throughout their lifetimes (Gordon, 1996; Franks et al., 1997). Typically, the tasks performed early in life take place entirely inside the nest, such as care of the queen and brood, while tasks that require leaving the nest are performed later in life (Wilson, 1971).

Workers of the harvester ant, *Pogonomyrmex barbatus* (F. Smith), perform four tasks outside the nest: nest maintenance, midden work, patrolling, and foraging (Gordon, 1986). Nest maintenance workers work mostly inside the nest, leaving the nest on brief trips lasting less than a minute (personal observation) to remove bits of soil and rock from the nest. Midden workers arrange organic debris on the nest mound. Patrollers choose the day's foraging location and respond to disturbances. Foragers find and retrieve food items. In contrast to nest maintenance, foraging and patrolling require a considerable amount of time outside the nest. A single trip by a forager averages 23 min, with a range of 2–165 min (Gordon and Kulig, 1996). It appears that a worker progresses from nest maintenance to foraging. Nest maintenance workers will switch to foraging when new food sources become available (Gordon, 1989). This transition occurs in one direction only: once a worker switches to foraging, it does not switch back to nest maintenance. New nest maintenance workers, if needed, are recruited from among the pool of interior workers (Gordon, 1989).

The transition to exterior work introduces harvester ants to new and extreme physiological challenges. *Pogonomyrmex barbatus* occupies arid regions of North America. Colonies are active during the warm months of the year, from March to November. Work outside the nest occurs in the daylight hours (Gordon, 1986), and soil temperatures during periods of activity are often very high (Whitford, 1976). In comparison to interior workers, exterior workers experience higher temperature, lower humidity, and direct solar radiation.

Caste differences in cuticular hydrocarbon composition have been reported for several social insect species (Howard et al., 1982; Smith and Taylor, 1990; Bonavita-Cougourdan et al., 1993; Haverty et al., 1996; Kaib et al., 2000). Previous work on *P. barbatus* demonstrated that foragers and patrollers have higher proportions of *n*-alkanes, relative to branched alkanes and alkenes, than nest maintenance workers (Wagner et al., 1998). Because harvester ant foragers and patrollers spend more time outside the nest than nest maintenance workers, the higher proportion of saturated, unbranched hydrocarbons on the cuticle might be a response to the warmer, drier conditions they face. Another possibility is that both task and cuticular composition change independently with age. The purpose of this study was to test the hypothesis that exposure to external conditions (ultraviolet light, warm temperature, low humidity, or some combination of these factors) causes an increase in the percentage of *n*-alkanes on the cuticle.

METHODS

Experiments were conducted at the Southwestern Research Station of the American Museum of Natural History in Portal, AZ, USA. In each experiment we exposed *P. barbatus* nest maintenance workers from 3 colonies to various combinations of the environmental conditions they would be likely to encounter outside the nest. Nest maintenance workers were collected as they left the nest carrying soil in their mandibles. The colonies from which we collected workers were large and appeared mature (5 years or older, Gordon, 1995); the nest mound of each was >1 m in diameter. In the laboratory, the workers from each colony were placed into a plastic box and provided with an aluminum foil shelter, a source of moisture, and an unlimited supply of 20% sucrose solution. On the day an experiment was to begin, a random sample of workers from each colony was killed by placing them in a freezer at -80°C. These ants were used to determine the initial cuticular hydrocarbon composition of the nest maintenance workers.

Exposure to Outside Conditions. Ants in this experiment were subjected to one of two treatments: (1) 50 min periods of exposure to outdoor conditions or (2) no exposure to outdoor conditions. Nest maintenance workers were collected from colonies S1, S6, and S7. Workers were randomly assigned to treatment and holding container. Holding containers were polystyrene dishes with plaster floors and gently sloping sides to prevent shadows on the floor of the dish when placed in the sunlight. The sides of the holding containers were coated with Fluon (Northern Products Inc., Woonsocket, RI) to prevent ants from escaping. There were 3 holding containers per treatment-colony combination, and 1–4 ants per holding container. The plaster was moistened daily with approximately 3–5 ml of water. Except during periods of active exposure, ants were provided with sucrose solution and each holding container was kept covered with a individual plastic plate.

Each morning thereafter between 1000 and 1130, food and shelters were removed from all containers. The lids were then replaced on the containers holding the indoor control ants. Ants to be exposed were carried outside in their open containers and placed on a level surface in direct sunlight for 50 min. The duration of exposure was chosen to be similar to that of two average foraging trips (about 23 min each, Gordon and Kulig, 1996). The positions of containers were rotated from day to day to prevent positional effects. After exposure, ants were returned to the lab and food and shelters were restored to all containers. Ants of the indoor control group were never put outside. Twenty days from the beginning of the experiment, all treatment and control ants were killed, by placing them into a -80°C freezer, and stored for later chemical analysis.

To measure the environmental conditions experienced by ants in the two treatments, we monitored temperature and relative humidity (RH) in holding containers that lacked ants, but that were treated in the same way as containers that

did hold ants (plaster was watered, food changed, and dishes covered as usual). We had to monitor empty containers because ants could escape by climbing onto the temperature probe. We placed two empty containers outdoors during each exposure trial and monitored temperature and humidity in them every few minutes. Temperature was measured on the surface of the plaster using a thermocouple thermometer equipped with a surface probe (Hanna Instruments, Woonsocket, RI). Temperature and RH 1 cm above the plaster surface were measured using a thermohygrometer (Oakton, Forestry Suppliers, Jackson MS #76001). Two additional empty containers were maintained inside the laboratory with the control ants. Once each day, we measured surface temperature, air temperature, and humidity inside the closed containers by inserting probes through doors in the plastic lids.

Ultraviolet Light Manipulation. We manipulated the level of exposure to ultraviolet (UV) light by placing ants outside under canopies constructed of filters that transmitted either low or high levels of UV, while monitoring temperature and humidity to assure that they did not vary among UV treatments. Low-UV canopies were constructed from plastic sheets with transmission of 0% at wavelengths less 380 nm (Lee Filters, Hampshire, UK #226). High-UV canopies were constructed of sheets with 90% transmission at 380 nm, 85% transmission at 350 nm, and 0% transmission at wavelengths less than 310 nm (Lee Filters #226). Canopies were constructed on $50 \times 50 \times 50$ cm frames made of dowels. The filter material was secured across the top and extended out 25 cm to each side. During exposure periods (1030 to 1200), the sun was high overhead and no direct sunlight reached the floor of the canopy without first passing through the filter. Reflected UV light from indirect sources could enter from the sides.

Nest maintenance workers from colonies I, K, and M were randomly assigned to high or low UV exposure, and to one of two holding containers per colony-treatment combination (1–4 ants per holding container). Each morning thereafter, ants were placed under the appropriate canopy for 50 min. All ants experienced a brief period of exposure to UV light, lasting approximately 5–10 sec, as they were carried from the laboratory to the canopies. When not underneath the canopies, ants were kept covered in the laboratory. After 11 days of daily treatments, ants were killed and stored at -80°C.

Temperature and humidity measurements were taken from two containers per treatment that lacked ants, as described above. These containers were moved outside and inside along with the ant containers. We took multiple measurements of temperature and RH from each dish while the ants were outside, and one measurement per day of conditions inside closed containers in the laboratory.

Temperature and Humidity Manipulations. We manipulated temperature and humidity in a 2×2 factorial experiment conducted in the laboratory. Each experimental treatment combination was administered in a plastic chamber, $50 \times 35 \times 20$ cm (length $\times$ width $\times$ depth) in size. Two chambers, one maintained at high

humidity and one at low, sat on a silicone rubber-laminated heating mat attached to a temperature controller (Thermolyne, Dubuque, IO), and two chambers sat on the desktop at room temperature. We defined high temperature as 35–40°C, moderate temperature as room temperature (25–30°C), high humidity as 95–100% RH, and low humidity as 10–30% RH. We created high RH in two chambers by sprinkling approximately 100 ml of water onto the chamber floors, and created low RH by sprinkling approximately 100 ml of desiccant crystals (Drierite, Fisher #07–577) on the floors in a similar manner. Desiccant crystals were regenerated and replaced daily. Chambers were cleaned and dried daily. We rotated chambers through treatments to prevent confounding chamber with treatment effects.

Ants from colonies I, J, and K were assigned randomly to treatment and holding containers. There were 1–5 ants per holding container and 2 holding containers for each treatment-colony combination. Chambers were prepared each morning and were considered ready to use when the temperature in the "warm" chambers was approximately 40°C, the relative humidity in the "dry" chambers was 10–20%, and the RH in the "moist" chambers was 90–100%. Containers holding ants were placed into the chambers between 1000 and 1130 hours. There was an equilibration period, lasting 5–10 min, during which chambers were returned to the target temperature and humidity. Ants were then kept in the chambers for another 50 min. Air temperature and RH inside the chambers were measured by inserting probes into small holes in the chamber walls. Whenever the probe was withdrawn, rubber stoppers were quickly inserted into the holes. The experiment continued for 11 days, after which all ants were killed and stored at −80°C.

Chemical Analysis. Chemical analyses were conducted at Stanford University. Frozen ants were transported to Stanford University on dry ice and stored at −80°C. Methods of extraction and analysis are described in detail in Wagner et al. (1998). We extracted the cuticular lipids from each ant separately by immersion in 1 ml of pentane. The mixture was gently shaken during the first minute of soaking. After 10 min soaking, the fluid was transferred to a clean vial and dried under a stream of N_2. The residue was dissolved in 50 μl of chloroform. Aliquots of 1 μl were introduced by splitless injection onto a SPB-1 fused silica capillary column (30 m, 0.25 mm ID, 0.5 μm film thickness; Supelco, Bellefonte, Pennsylvania); samples were purged after 1 min. The carrier gas was He, flowing at 1 ml/min. The injector was maintained at 300°C. The oven was set at 170°C during injection, raised quickly to 220°C at 25°C/min, then more slowly to 300°C at 3°C/min. Samples of a standardized mixture of hydrocarbons were interspersed among ant samples to confirm the consistency of elution times.

We identified unknown compounds, and confirmed the identity of peaks with retention times and relative positions known from previous work, by analyzing the mass spectra of peaks from a small sample of ants frozen at the time of collection. Lipids were extracted from 3–5 ants from each experiment and the extracts treated as described above. Approximately 2–4 μl were injected onto a capillary column

(DB-1, J&W Scientific, Folsom, CA, USA) and analyzed on an HP 5890/5970 GC/MS. Instrument temperatures and run times were the same as above, except the oven was raised to a final temperature of 310°C. We used Nelson et al. (1980 and *in press*) as references when identifying compounds. For each experiment, we used only those compounds that composed at least 0.5% of the total ion abundance in the data analysis.

Data Analysis. The dependent variable for all statistical analyses was the proportion of *n*-alkanes in the total ion abundance for each ant. Data were arcsine square root-transformed when necessary to meet the assumption of normality. For each experiment, we tested the effect of treatment and colony on proportional abundance of *n*-alkanes using a two-way factorial analysis of variance. For the outside exposure and UV manipulation experiments, we compared the average daily temperature and RH experienced by ants in the two treatments of each experiment using paired *t*-tests.

RESULTS

Chemical Analysis. We found between 21 and 30 cuticular lipid compounds on individual ants in the three experiments. All but two of these compounds had been identified in previous studies (Wagner et al., 1998; Wagner et al., 2000). Compounds included normal alkanes, mono- and di-methylbranched alkanes, alkenes, and esters. We were unable to identify two novel compounds found in trace amounts (each constituted $<1\%$ on average) on ants in the UV exposure experiment. The mass spectra of these unknown compounds indicated that they were not *n*-alkanes. No novel compounds were produced in response to experimental manipulation; rather, changes in *n*-alkane abundance reflected changes in the relative abundance of common compounds.

Exposure to Outside Conditions. During periods of exposure, ants placed outside experienced significantly higher temperatures and lower RH than those kept inside. The mean (range) conditions in containers during exposure and inside containers within the laboratory were as follows: air temperature 34.3°C (25.0–41.0) outside and 25.1°C (21.1–28.5) inside (t_{19}, paired by day, $= -11.6$, $P < 0.0001$); surface temperature 27.0°C (21.0–30.2) outside and 24.6°C (21.0–26.9) inside (paired $t_{19} = -6.2$, $P < 0.0001$); RH 42.4% (16.2–78.1) outside and 87.4% (75.4–97.0) inside (paired $t_{19} = 12.3$, $P < 0.0001$). The sun was obscured by clouds during 7 of the 20 days of exposure.

Mean percentages of cuticular hydrocarbon compounds in this experiment are listed in Table 1 (see Figure 1 for a representative chromatogram). Outside exposure led to an increase in the proportion of *n*-alkanes on the harvester ant cuticle (Figure 2, Table 1). The cuticular lipids of ants that were exposed to outside conditions for 50 min/day contained a significantly higher percentage of *n*-alkanes

than those of ants kept indoors in covered containers ($F_{1,38} = 7.7$, $P < 0.01$). Colonies differed in the percentage of *n*-alkanes on the cuticle ($F_{2,38} = 9.9$, $P < 0.001$). There was no significant interaction between treatment and colony ($F_{2,38} = 0.7$, $P = 0.5$). There was a tendency for ants in both treatments to increase in the proportion of *n*-alkanes from the beginning of the experiment to the end. Ants

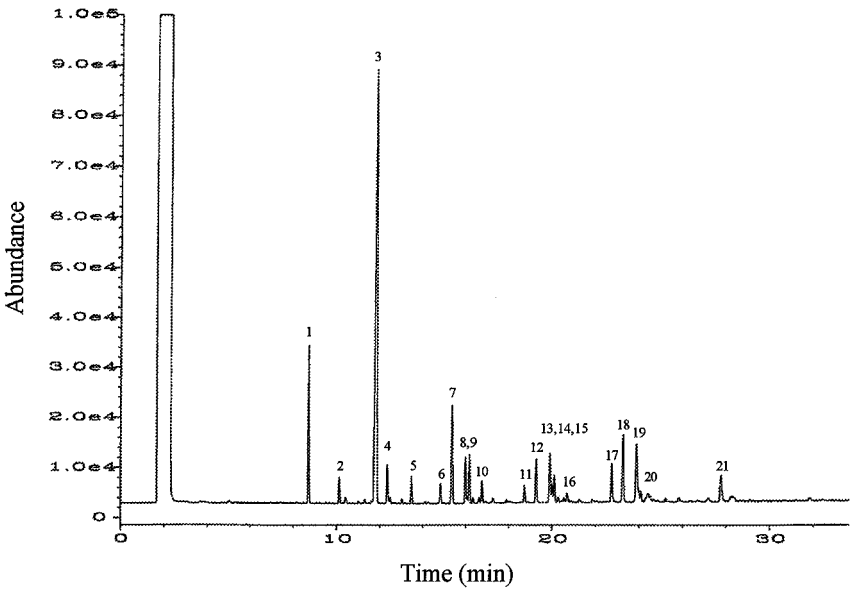

FIG. 1. Representative chromatogram of an ant in the exposure experiment. The large peak at 2 minutes is the solvent, chloroform. Numbers over peaks refer to the compounds listed in Table 1.

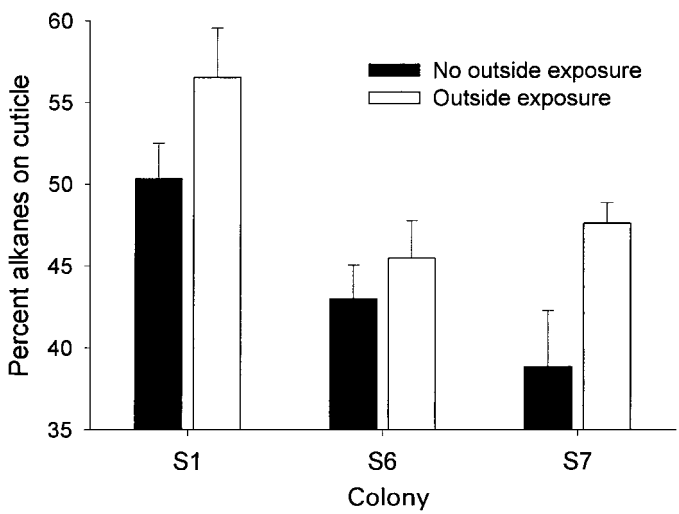

FIG. 2. Percentage of *P. barbatus* cuticular lipids composed of *n*-alkanes on ants exposed to outside conditions for 50 min/d and ants not exposed to outside conditions. Error bars show one mean standard error.

exposed to external conditions increased about 32% in *n*-alkanes over the initial state (overall mean initial % *n*-alkanes = 37.8, SE = 2.1, $N = 18$), while those kept indoors increased by about 16%.

Ultraviolet Light Manipulation. Temperature and humidity did not differ under canopies composed of UV-transmitting and UV-blocking material. Air temperature averaged 36.5°C (range 29.2–41.7) in high UV treatment containers and 37.6°C (30.5–41.7) in low UV treatment containers ($t_{10} = -0.7$, $P = 0.5$); surface temperature averaged 28.9°C (26.2–32.4) in high UV treatment containers and 28.7°C (26.3–32.8) in low - UV treatment containers ($t_{10} = 1.1$, $P = 0.3$); and RH averaged 37.7% (28.4–51.2) in high UV treatment containers and 36.6% (23.3–53.5) in low-UV treatment containers ($t_{10} = 1.1$, $P = 0.3$). Canopies trapped heat, so ants in this experiment experienced warmer conditions during periods outside than ants in the general exposure experiment. While inside the laboratory, within-container air temperature averaged 24.7°C (22.3– 26.5), surface temperature averaged 24.6°C (21.9–26.8), and RH averaged 88.6% (83.0–91.1).

Exposure to UV light had no effect on *n*-alkane abundance ($F_{1,28} = 1.8$, $P = 0.2$; Figure 3). As in the previous experiment, colonies differed in percent cuticular *n*-alkanes ($F_{2,28} = 19.3$, $P < 0.001$; Figure 3) and there was no significant interaction between treatment and colony ($F_{2,28} = 0.7$, $P = 0.5$). Cuticular *n*-alkanes increased about 40% over the course of the experiment, from a mean initial value of 29.8% alkanes (SE = 1.9, $N = 17$) to a final overall mean value of 41.6% (SE = 1.7, $N = 32$).

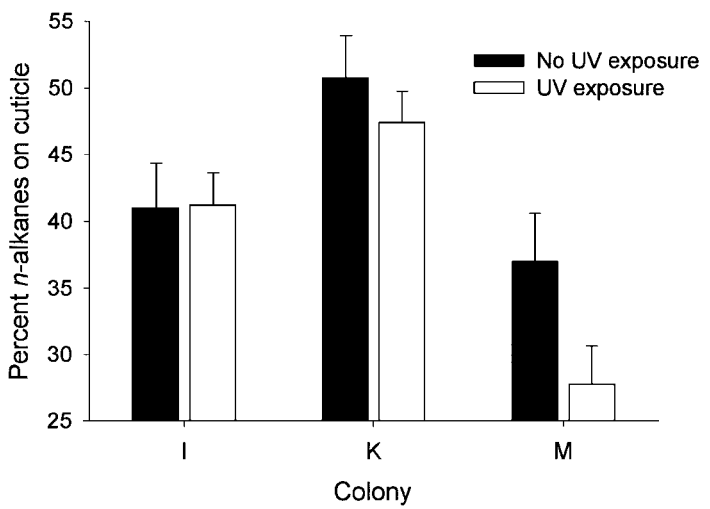

FIG. 3. Percentage of cuticular *n*-alkanes on harvester ants from different colonies exposed to sunlight that had passed through ultraviolet-transmitting and ultraviolet-blocking filters.

Temperature and Humidity Manipulation. The air temperatures and RH to which ants were exposed in this experiment averaged 38.7°C (range = 35.3–41.5) and 8.3% (4.5–12.1) in the high temperature–low RH chamber, 38.8°C (36.8–42.7) and 94.9% (78.9–99.9) in the high temperature–high RH chamber, 26.6°C (20.9–30.3) and 7.8% (4.0–18.2) in the moderate temperature–low RH chamber, and 26.2°C (21.8–28.9) and 86.0% (79.8–90.6) in the moderate temperature–high RH treatments.

The effects of temperature and humidity on cuticular composition were interdependent; in general, warm dry conditions lead to high *n*-alkane abundance (Figure 4). Humidity had a significant effect on *n*-alkane abundance, whereas temperature did not; however, the main effects must be interpreted cautiously because there was a significant interaction between temperature and humidity (Table 2). Inspection of Figure 4 indicates that low humidity affected cuticular composition only in combination with warm temperatures. Variation in humidity had little effect on *n*-alkane abundance at moderate temperatures. Colonies did not differ in *n*-alkane abundance, and there were no interactions involving colony (Table 2).

There was no consistent increase in *n*-alkanes over time in this experiment; rather, the magnitude and direction of change in percent *n*-alkanes depended on treatment. The average cuticular *n*-alkane abundance of ants exposed to warm, humid conditions was about 2% lower than that of the initial sample, whereas the

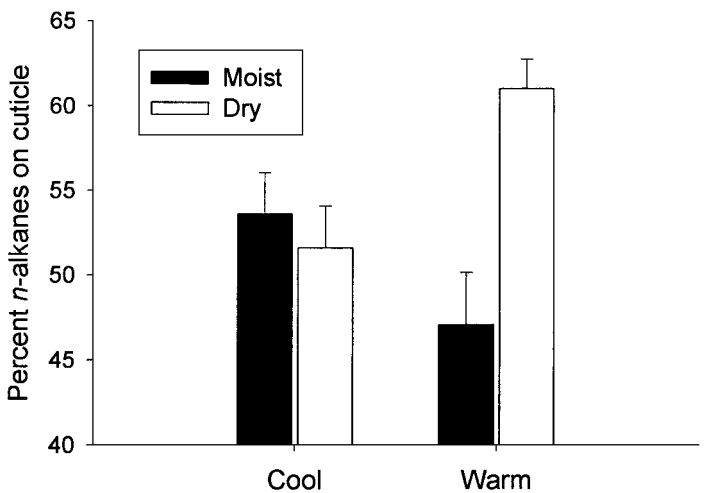

FIG. 4. Percentage of *n*-alkanes in the cuticular lipids of harvester ants subjected to combinations of temperature (warm and cool) and relative humidity (high and low). Colonies did not differ significantly in percent *n*-alkanes in this experiment and data from all colonies are combined for purposes of illustration.

TABLE 2. RESULTS OF ANALYSIS OF VARIANCE INVESTIGATING THE EFFECT OF TEMPERATURE, HUMIDITY, AND COLONY IDENTITY ON THE PERCENT *n*-ALKANES IN HARVESTER ANT CUTICULAR LIPID EXTRACTS

Source	*df*	*F*	*P*
Temperature (*T*)	1	0.1	0.8
Humidity (*H*)	1	6.6	0.01
$T * H$	1	12.6	<0.001
Colony (*C*)	2	1.6	0.2
$C * T$	2	0.1	0.9
$C * H$	2	0.6	0.6
$C * T * H$	2	1.9	0.2
Error	52		

n-alkane abundance of ants exposed to other treatments was 3–22% higher than the initial sample (initial average *n*-alkanes = 49.9%, SE = 2.4, $N = 25$).

DISCUSSION

The results indicate that environmental conditions affect the hydrocarbon composition of the harvester ant cuticle. Exposure to warm, dry conditions triggered an increase in the proportional abundance of cuticular *n*-alkanes. Exposure to UV radiation, in contrast, had little effect on cuticular *n*-alkane abundance. These results support the hypothesis that differences in exposure among task groups explains task-related differences in cuticular hydrocarbon composition. The total increase in *n*-alkane proportional abundance in exposed ants over 20 days (2–12%) was similar to differences between field-sampled nest maintenance workers and foragers reported previously (5–8%, Wagner et al., 1998). Our results corroborate those of previous studies investigating environmental effects on insect cuticular chemistry. Low RH lead to a similar increase in the relative abundance of *n*-alkanes in weevil larvae (*Oryzaephilus surinamensi*), although not in adults (Howard et al., 1995). Acclimation to warm temperatures increased the ratio of straight-chain relative to branched alkanes in the grasshopper *Melanoplus sanguinipes* (Gibbs and Mousseau, 1994).

The primary mechanism of water conservation in insects is a thin layer of lipids on the cuticle that forms a passive barrier to water loss through the integument (Hadley, 1994). In ants and many other arthropod taxa, cuticular lipid composition is dominated by various forms of hydrocarbons. The effectiveness of the cuticular lipid barrier at slowing water loss depends on its composition as well as its thickness. Hydrocarbon compounds differ in physical

properties that influence their effectiveness as waterproofing agents. Permeability to water increases sharply at compound-specific transition temperatures, probably the melting temperatures (Gibbs, 1998; Rourke and Gibbs, 1999). Double bonds and methylbranching dramatically reduce the melting point (Gibbs and Pomonis, 1995), so *n*-alkanes are thought to provide qualitatively better waterproofing than alkenes and branched alkanes of similar size. Studies of water loss in insects appear to support this hypothesis. Methylbranching and unsaturation are positively associated with water loss rate within several insect species (Hadley, 1978; Toolson, 1984). The proportional increase in cuticular *n*-alkanes detected in this study might serve to reduce water loss by ants exposed to warm dry conditions.

The transition from interior work to nest maintenance not only involves short bursts of exterior work, but brings ants closer to the surface while inside the nest, where they encounter warmer, drier internal conditions. Once a harvester ant begins to work outside the nest, it tends to stay in the upper chambers of the nest near the entrance (MacKay, 1983; Tschinkel, 1999). The entrance to a *P. barbatus* nest, which can be 1–4 cm wide, is connected by wide tunnels into one or more chambers just inside the nest entrance. Strong temperature and moisture gradients have been found in *Pogonomyrmex* nests during the summer months: areas near the surface are drier and warmer than deeper areas (MacKay, 1981). After performing nest maintenance work, ants move on to tasks that entail longer periods of external exposure, such as patrolling and foraging.

In addition to treatment effects, there was a general increase in the proportion of *n*-alkanes between the initial and final sampling times in both the outside exposure experiment and the UV exposure experiment, and an increase in three out of four treatments groups of the temperature and humidity experiment. There are two plausible explanations for this trend toward increasing *n*-alkane abundance over time. First, the conditions experienced by the ants in this study, including the indoor controls, may have been drier and warmer than those they experienced in the nest prior to collection, leading to the same sort of environmentally-triggered increase in *n*-alkanes that we detected in our experiments. Second, *n*-alkane abundance may increase as an ant ages, with environment acting to enhance or temper a general increase over time. We cannot reject either of these possibilities at the present time. Working with laboratory colonies of the ant *Myrmicaria eumenoides*, Kaib et al. (2000) found that the cuticular hydrocarbon composition of ants that switched from nest work to foraging changed with age over a period of 30–40 days, whereas the composition of workers that remained in the nest was unchanged over the same period. This result suggests either that task-related changes in cuticular chemistry are triggered by an ant's environment and not its age, or that only particular task groups undergo endogenous age-related changes in cuticular chemistry. Further work is underway to test the hypothesis that the relative abundance of *n*-alkanes is related to age, as well as environment, in *P. barbatus.*

We found that most colonies differed from one another in the proportion of *n*-alkanes in the cuticular lipids of nest maintenance workers. Colony-level differences in ant cuticular lipid composition have been detected in many ant species (Obin, 1986; Bonavita-Cougardan, 1987; Vander Meer et al., 1989; Nowbahari et al., 1990; Wagner et al., 1998; Nielsen, 1999). These differences may be due in part to genetic differences among colonies. There is some evidence of a heritable component to the cuticular hydrocarbon composition of fire ants and honeybees (Ross et al., 1987; Vander Meer et al., 1985; Page et al., 1991). Differences among the colonies we measured may also reflect how recently new nest maintenance workers were recruited from the younger workers inside the nest. For example, a colony whose nest was recently trampled by a cow will have recruited nest maintenance workers to repair the damage. Such a colony may have more new nest maintenance workers than one whose nest was undisturbed. Differences among colonies in cuticular *n*-alkane composition of their nest maintenance workers may reflect, in part, variation in the duration of the nest maintenance workers' tenure in that task, and thus, in how long the workers have been exposed to warm, dry conditions.

Rates of brief antennal contact, which involve the perception of odor, influence task decisions in *P. barbatus* (Gordon and Mehdiabadi, 1999). An ant's response depends on the task of the ant it meets (Gordon and Mehdiabadi, 1999). Cuticular hydrocarbons act as the cue for nestmate recognition in *P. barbatus* (Wagner et al., 2000), as in other ant species (Lahav et al., 1999; Thomas et al., 1999). We infer that task-specific differences in hydrocarbon profiles may also permit an ant to assess the task of a nestmate it meets. Our results show that the environmental conditions associated with a task, in particular exposure to warm temperature and low humidity, can shape task-specific differences in the cuticular hydrocarbon profile. When one ant contacts another, these task-related differences in hydrocarbon composition might provide information about the other's task. Similarly, we might recognize a carpenter by the calluses on her hands, whether or not she holds a hammer.

Acknowledgments—We are indebted to Chris Somerville at the Carnegie Institute of Washington and Martin Reinhard and Jean-Francois Debroux at the Civil and Environmental Engineering Department at Stanford University for the use of their laboratories. Gert-Jan de Boer and Pierre Broun gave us valuable technical assistance. David Millard kindly provided the UV filters. William Cuevas confirmed the identity of the cuticular compounds. The manuscript was improved by thoughtful comments from Nathan Sanders, Stephen Roberts, and Veronica Volny. Many thanks to Craig Heller for his assistance when samples from a earlier set of these experiments were destroyed. The research was supported by National Science Foundation grant IBN-9603639 to DMG.

(Received December 19, 2000; accepted May 12, 2001)

Abstract—Sexually mature virgin adult males of the green stink bug, *Acrosternum hilare* attracted sexually mature virgin adult females in laboratory bioassays using a vertical Y-tube. There was no indication that males attracted other males, or that females attracted either sex. These results suggested that *A. hilare* males produce a sex pheromone. Extracts of odors collected from sexually mature males contained compounds that were not present in extracts from females or sexually immature males. (4*S*)-*Cis*-(*Z*)-bisabolene epoxide ((4*S*)-*cis*-*Z*-BAE) was the major sex-specific component of the extract. The crude extract was attractive to female *A. hilare*, but when separated into four fractions, only the portion containing (4*S*)-*cis*-*Z*-BAE and the minor component (4*S*)-*trans*-*Z*-BAE was attractive to females. This fraction was as attractive as the crude extract, suggesting that the former contained all the pheromone components. Neither synthetic (4*S*)-*cis*-*Z*-BAE nor (4*S*)-*trans*-*Z*-BAE alone was attractive to females, but a 95:5 *cis:trans* blend, mimicing the ratio naturally produced by males, was attractive to females in Y-tube bioassays. Bioassays in a field cage showed that significantly more *A. hilare* females were attracted to cotton string lures treated with 1 mg of a 95:5 blend of (4*S*)-*cis*-*Z*-BAE and (4*S*)-*trans*-*Z*-BAE placed inside a bouquet of alfalfa than to an alfalfa bouquet containing a pentane-treated control. In field cage studies, attraction of females was greatest during the late afternoon and evening hours, and female *A. hilare* approached the synthetic pheromone source almost exclusively by walking.

Key Words—*Acrosternum hilare,* sex pheromone, bisabolene epoxide, (*Z*)-(1*R*,2*S*,4*S*)-4-(1′,5′-dimethyl-1′,4′-hexadienyl)-1,2-epoxy-1-methylcyclohexane, (*Z*)-(1*S*,2*R*,4*S*)-4-(1′,5′-dimethyl-1′,4′-hexadienyl)-1,2-epoxy-1-methylcyclohexane, *Nezara viridula.*

INTRODUCTION

The green stink bug, *Acrosternum hilare* (Say) (Hemiptera: Pentatomidae) is a pest of a variety of crops in North America, including cotton, soybeans, pistachios, and pecans (Miner, 1966; Simmons and Yeargan, 1988; Rice et al., 1988; da Silva et al., 1996; Greene et al., 1999; reviews by McPherson, 1982 and Panizzi, 1997). In addition to direct damage caused by feeding, *A. hilare* vectors plant pathogens such as yeast-spot disease of soybeans (Daugherty, 1967; Clarke and Wilde, 1970) and the fungus *Botryosphaeria dothidea* in pistachios (Daane et al., 2000). Crop damage by these and related species of stink bugs may be exacerbated by recent fundamental changes in crop protection, especially the widespread deployment of genetically modified crop plants that express gene products from *Bacillus thurengiensis* (*B.t.*). Because the *B.t.* proteins expressed by a plant are active against only a limited number of insect families or even genera (e.g., some Lepidoptera and Coleoptera, depending on the *B.t.* strain), these plants are not protected from attack by other insects. For example, the deployment of transgenic cotton in the southeastern United States, and the consequent reduction in pesticide applications has been correlated with increased feeding damage by *A. hilare* and other species of pentatomid and mirid bugs (Turnipseed and Greene, 1996; Greene et al., 1999).

Typical methods for monitoring heteropteran species such as stink bugs include sampling with sweep nets or beating trays, and visual inspection of the crop for damage. These techniques are labor intensive and require multiple replication to generate realistic population assessments. Furthermore, adult bugs fly, and can rapidly migrate into a crop from surrounding fields as crops in those fields are harvested, or move into a crop from surrounding native vegetation as it dries during the summer. Consequently, frequent sampling is required to detect immigration of bug populations into crops, in order to apply control measures before significant damage occurs. Pheromone-baited traps might mitigate some of these problems (McBrien and Millar, 1999).

Previous studies have shown that sexually mature *A. hilare* males produce sex-specific compounds, and it was suggested that these compounds were sex or aggregation pheromones based on comparisons with the known pheromone compounds produced by males of a related species, the southern green stink bug *Nezara viridula* (L.) (Aldrich et al., 1987, 1989, 1993). In particular, the major component emitted by *N. viridula* males, *trans-Z*-bisabolene epoxide (*trans-Z*-BAE, Figure 1), is a minor component of the volatile chemicals produced

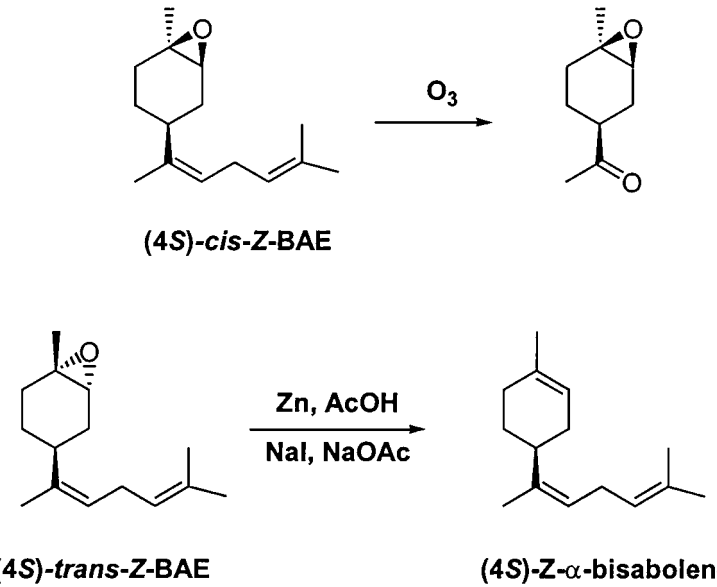

FIG. 1. Structures of (4*S*)-*cis*-*Z*-bisabolene epoxide, (4*S*)-*trans*-*Z*-bisabolene epoxide, and the products from their degradation by ozonolysis and deoxygenation, respectively.

by *A. hilare* males, whereas the major sex-specific component of extracts from *A. hilare* males, *cis*-*Z*-bisabolene epoxide (*cis*-*Z*-BAE, Figure 1), is a minor component in volatiles from *N. viridula* males. The absolute configurations of the BAEs produced by either species have not been determined, although only the (4*S*)-enantiomer of *trans*-*Z*-BAE was attractive to *N. viridula* females in bioassays (Baker et al., 1987). Further laboratory bioassays showed that a blend of (4*S*)-*trans*-*Z*-BAE and (4*S*)-*cis*-*Z*-BAE was more attractive to *N. viridula* females than (4*S*)-*trans*-*Z*-BAE alone (Brézot et al., 1994), suggesting that the *N. viridula* pheromone consists of at least two components. However, the possible function of the male-specific compounds as pheromone components for *A. hilare* has not been tested.

The objectives of the work described here were to:

1. Identify the sex-specific compounds produced by male *A. hilare*.
2. Determine whether the male-produced compounds constituted a sex pheromone only attractive to females, or an aggregation pheromone attractive to both sexes.
3. Fully characterize the pheromone, including determination of the number of components, and the complete identification of each component.
4. Synthesize and bioassay the pheromone components.

METHODS AND MATERIALS

Insect Colonies. Adults and nymphs of *A. hilare* were collected from an almond orchard near Fresno, CA in 1997 and 1998. Adults and nymphs of *N. viridula* were collected from an alfalfa plot at University of California, Riverside, Agricultural Operations. Rearing methods for both species are described in Čokl et al. (2001). Two days after the final moult, adults were separated by sex, and placed in paper ice cream cartons (20×18 cm) covered with cloth screening, with green beans and sunflower seeds supplied for food. These insects were used for collection of insect-produced volatiles or for bioassays, after which they were returned to the breeding colony.

Dissection of Adult Metathoracic Glands for Analysis of Defensive Compounds. Metathoracic glands (MTG) of 5 sexually mature virgin adults of both sexes were dissected following the method of Gilby and Waterhouse (1965), and the contents of each gland were analyzed. A drawn-out glass capillary tube was inserted into the MTG of each bug to collect the fluid contents, the fluid was dissolved in 200 μl pentane, and the pentane solution was analyzed by gas chromatography-mass spectrometry as described below.

Collection of Insect Volatiles. Volatile chemicals were collected from 5 separate groups of virgin adult male and female *A. hilare*. Sexes were aerated separately, and each cohort of bugs was aerated continuously for a period of 2–3 weeks to follow changes in the profile of compounds produced by the bugs as they became sexually mature. Analogous extracts were also prepared from sexually mature adult male *N. viridula* to provide authentic samples of the two BAE's.

Cohorts of 12–20 virgin adults were carefully coaxed (to minimize discharge of defensive secretions) into horizontal cylindrical glass aeration chambers (28×8.0 cm ID) as described in Millar and Sims (1998), with charcoal-filtered, humidified air pulled through the system at a flow rate of 1 liter/min. Each chamber was fitted with a cylinder of aluminum window screen for the bugs to walk and perch on, and 3 green beans and 5 sunflower seeds were provided as food. The aeration apparatus was set up next to a window, with additional light provided with a fluorescent light fixture (2 Sylvania Octron 32W light tubes) mounted above the aeration apparatus to provide a 16L:8D, long-day light cycle to ensure that bugs did not go into reproductive diapause. Ambient temperature during aerations was $\sim$24°C. Insect-produced volatiles were trapped with collectors made from 0.4 cm ID glass tubes containing a 2 mm long bed of activated charcoal (50–200 mesh, stripped of volatiles by heating at 200°C overnight while purging with activated charcoal-purified nitrogen) confined between two glass wool plugs. Collectors were changed every second day, at which time fresh food was also provided. Trapped volatiles were desorbed by rinsing the collectors with three 200 μl aliquots of pentane, followed by three 200 μl aliquots of ether. Extracts of volatiles were stored at -20°C in glass vials with Teflon cap-liners until used

for bioassays or analyses. Cohorts were 8–9 d old when aerations were started, except for one cohort in which aeration commenced with 0–2 d old bugs so that the onset of production of male-specific compounds could be determined. To provide sufficient materials for fractionation and bioassays, three larger cohorts of males (28–49 bugs) were aerated in a larger glass chamber (35 × 15 cm ID), with an air flow of 5 liter/min, and a larger collector (0.6 mm ID, 3 mm long).

Collection of Defensive Compounds. Groups of virgin adult male (10) and female bugs (25) were aerated separately in the glass aeration chamber for 1 hr as described above, except that the glass chamber was shaken vigourously for 3 min immediately before the aeration began, to induce discharge of the defensive compounds.

Analysis and Fractionation of Insect Extracts. Extracts were analyzed by gas chromatography (GC) with a Hewlett-Packard 5890 instrument equipped with DB-5 (30 m × 0.25 mm ID, J&W Scientific, Folsom CA) or DB-17 columns (30 m × 0.25 mm). Helium carrier gas was used, with analyses run in splitless mode with a temperature program of 50°C/1 min, 10°/min to 250°C for both columns. Injector and detector temperatures were 250 and 275°C respectively. Extracts were also analyzed by splitless coupled GC-mass spectrometry by using an HP 6890 GC equipped with an HP-5MS column (30 m × 0.25 mm id) and interfaced to an HP 5973 mass selective detector. All mass spectra were taken in electron impact mode, ionizing voltage 70 eV. The temperature program was the same as above.

Crude aeration extract (15,869 bug-hour equivalents) from sexually mature males was concentrated to 1.0 ml under a gentle stream of N_2. A 200 μl aliquot was set aside, and the remainder was fractionated on a solid phase extraction cartridge (Extract-Clean silica cartridge, 500 mg silica gel; Alltech #209250, Deerfield IL). The cartridge was preconditioned with 5 ml of 25% ether in pentane, then 5 ml of pentane, and the excess solvent was expressed from the cartridge with a pipette bulb. The combined crude *A. hilare* extract was loaded onto the cartridge, rinsing the walls with a few drops of clean pentane. The cartridge was then eluted with gravity flow with 3 × 1 ml pentane, 3 × 1 ml 10% ether in pentane, 3 × 1 ml 25% ether in pentane, and 2 ml ether, collecting each aliquot as a separate fraction. The fractions were analyzed by GC. The first two pentane fractions containing hydrocarbons were combined, the second two 10% ether fractions containing the BAE's were combined, and all the 25% ether in pentane and 100% ether fractions containing traces of more polar compounds were combined. These fractions were used for analyses and bioassays. The third pentane fraction and the first 10% ether in pentane fraction contained no detectable compounds by GC and so they were not combined with the other fractions to avoid unnecessary dilution.

Absolute Configuration of A. hilare *cis-BAE*. The absolute configuration of insect-produced *cis*-BAE was determined by oxidative degradation to *cis*-4-acetyl-1,2-epoxy-1-methylcyclohexane, followed by analysis on a chiral GC column, and comparison of retention times with those of standards of known absolute

configuration. (4*S*)- and (4*R*)-*cis*-4-acetyl-1,2-epoxy-1-methylcyclohexane standards were obtained by phase transfer catalyzed oxidation of commercial (−)- or (+)-limonene oxide with potassium permanganate (Chen et al., 2000). Separation of the resulting *cis*- and *trans*-4-acetyl-1,2-epoxy-1-methylcyclohexanes by flash chromatography on silica gel, eluting with 16% EtOAc in hexanes, yielded the chemically and stereoisomerically pure *cis*-(1*R*,2*S*,4*S*)- and *cis*-(1*S*,2*R*,4*R*)-enantiomers, respectively. ^{1}HNMR (300 MHz): *cis*: $\delta = 1.34$ (s, 3H), 1.40–1.78 (m, 3H), 2.03–2.12 (m, 3H), 2.13 (s, 3H), 2.24 (m, 1H), 3.05 (d, J = 4.9 Hz, 1H). *trans*: $\delta = 1.30$ (s, 3H), 1.32–1.46 (m, 2H), 1.64–2.12 (m, 4H), 2.14 (s, 3H), 2.57 (br. t, J ∼ 10Hz, 1H), 3.08 (t, J ∼ 2Hz, 1H). Spectroscopic data agreed with that previously reported (Delay and Ohloff, 1979; Chen et al., 2000). The enantiomers were resolved on a Cyclodex B GC column (20 m × 0.25 mm ID; J&W Scientific), run isothermally at 90°C in split injection mode with helium carrier gas and an injector temp of 250°C. The (1*R*,2*S*,4*S*)- and (1*S*,2*R*,4*R*)-enantiomers eluted at 20.79 and 21.03 min, respectively.

A total of 1,870 bug-hours of the BAE fraction of volatiles from mature males was concentrated to a few microliters in a conical-bottomed vial under a gentle stream of nitrogen, then taken up in ∼25 μl of CH_2Cl_2. The vial was chilled in a dry ice-acetone bath, and the chilled solution was subjected to microozonolysis for ∼20 sec (Beroza and Bierl, 1969). The solution was then warmed to room temperature and analyzed immediately on the Cyclodex B column, giving a single peak at 20.75 min. Aliquots of the ozonized extract also were coinjected with racemic and (1*S*,2*R*,4*R*)-*cis*-4-acetyl-1,2-epoxy-1-methylcyclohexane, respectively. The first injection resulted in two peaks of unequal size (larger, 20.61 min, smaller 20.88 min), and the second injection gave two peaks (20.64 and 20.82 min), proving that the insect-produced *cis*-*Z*-BAE starting material has the (4*S*)-configuration.

Absolute Configuration of A. hilare trans-*BAE*. The enantiomers of *trans*-4-acetyl-1,2-epoxy-1-methylcyclohexane were not separable on the Cyclodex B column, so a different method was used to determine the absolute configuration of the insect-produced *trans*-BAE. Both cis- and trans-BAE could be deoxygenated to (*Z*)-α-bisabolene, and racemic (*Z*)-α-bisabolene was resolved on the Cyclodex column at 90°C (85.70 and 86.36 min). To determine which enantiomer corresponded to which peak, a standard of (4*S*)-(+)-(*Z*)-α-bisabolene was isolated from *Opoponax* spp. oil (Umbelliferae) (Delay and Ohloff, 1979). Thus, *Opoponax* oil (820 mg; Berje Chemical Products, Bloomfield NJ) was Kugelrohr-distilled at room temperature under vacuum (0.02–0.04 mm Hg) to produce a fraction enriched in sesquiterpenes (680 mg, <10% monoterpenes by GC). This fraction was flash chromatographed on a column (∼25 × 2.5 cm id) of 230–400 mesh silica gel (Merck) that had been activated by heating overnight at 120°C and cooled under N_2 to prevent rehydration. The column was eluted sequentially with 400 ml of hexane, and 200 ml aliquots of 0.2, 0.4, 0.6, and 0.8% CH_2Cl_2 in hexane. A fraction

containing 87% (4*S*)-(*Z*)-α-bisabolene was obtained (88 mg). Spectroscopic and GC retention time data matched those of the racemic standard. On the chiral column, coinjection of this enantiomer with the racemic material determined that the (4*S*)-enantiomer corresponded to the earlier-eluting peak.

To deoxygenate the insect-produced BAE's to (*Z*)-α-bisabolene, an aliquot of the BAE-containing fraction of an aeration extract ($\sim$1500 bug-hours) was concentrated to a few μl under N_2, then taken up in 2 ml of CH_2Cl_2 and added to a mixture of Zn dust (200 mg), NaOAc (15 mg), and NaI (44 mg) in 0.5 ml of AcOH. The mixture was stirred under Ar for 4.5 hr, then filtered. The filtrate was diluted with water (1 ml) and extracted with CH_2Cl_2 (3 $\times$ 2 ml). The CH_2Cl_2 extract was washed sequentially with 1M NaOH (2 $\times$ 2 ml) and brine (2 $\times$ 2 ml), dried over Na_2SO_4, and concentrated by rotary evaporation at room temperature. The residue was taken up in hexane and analyzed on the Cyclodex B column, giving a single peak at 85.67 min. Coinjection of this material with the racemic standard resulted in enlargement of the earlier eluting peak, confirming that the insect-derived material was (4*S*)-(*Z*)-α-bisabolene.

Other Chemicals. (*Z*)-(1*R*,2*S*,4*S*)-4-(1′,5′-dimethyl 1′,4′-hexadienyl)-1,2-epoxy-1-methylcyclohexane ((4*S*)-*cis*-*Z*-BAE), (*Z*)-(1*S*,2*R*,4*S*)-4-(1′,5′-dimethyl 1′,4′-hexadienyl)-1,2-epoxy-1-methylcyclohexane ((4*S*)-*trans*-*Z*-BAE), (*E*)-(1*R*, 2*S*,4*S*)-4-(1′,5′-dimethyl 1′,4′-hexadienyl)-1,2-epoxy-1-methylcyclohexane ((4*S*)-*cis*-*E*-BAE), and (*E*)-(1*S*,2*R*,4*S*)-4-(1′,5′-dimethyl 1′,4′-hexadienyl)-1,2-epoxy-1-methylcyclohexane ((4*S*)-*trans*-*E*-BAE) were synthesized by previously described routes (Chen et al., 2000). (*E*)-2-Hexenal, (*E*)-2-hexenyl acetate, (*E*)-2-decenal, and dodecane were obtained from Aldrich Chemical (Milwaukee WI). Tridecane and pentadecane were obtained from ICN-K&K (Plainview, NY). Racemic (*Z*)-α-bisabolene was synthesized as previously described (Buss et al., 1987).

A mixture of 4 bisabolene epoxide isomers was generated to provide standards, by modification of a previously reported method (Tomioka and Mori, 1992). Thus, a solution of 5-bromo-2-methyl-2-pentene (1 g, 6.12 mmol; Aldrich), triphenylphosphine (1.61 g, 6.12 mmol) and diisopropylethylamine (53.3 μL, 0.306 mmol) in acetonitrile (12.5 ml) was refluxed under Ar for 24 hr. After cooling to room temperature and concentration, the residual viscous oil was heated (80°C) and stirred vigourously with benzene (10 ml) under argon. The mixture was cooled to room temperature and the upper benzene layer was pipetted off. After removal of residual benzene under vacuum, THF (22 ml) and DMPU (3 ml, 12.4 mmol) were added to the resulting gummy phosphonium bromide salt, and the mixture was warmed gently until the salt dissolved. $KN(TMS)_2$ (0.5M in toluene, 11 ml, 5.5 mmol) was then added dropwise, and the mixture was heated to 70°C for 15 min, then stirred at room temperature for 1 hr. The resulting deep red solution was cooled to -78°C and a solution of (4*S*)-*trans*-4-acetyl-1,2-epoxy-1-methylcyclohexane (702 mg, 4.56 mmol; Chen et al., 2000) in THF (10 ml) was added dropwise. The mixture was stirred at -78°C for 1 hr, then

warmed to room temperature over 3 hr and quenched with brine (40 ml). The THF was evaporated *in vacuo*, and the residue was extracted with petroleum ether (4×50 ml). The combined organic extracts were washed with water (4×50 ml) and brine (4×50 ml), dried over Na_2SO_4 and concentrated. Methanol (50 ml) was then added, and the extract was again concentrated to remove the residual toluene azeotropically. This procedure was repeated twice. The residue was distilled (Kugelrohr: room temperature to 100°C/0.03 mm Hg) to give a mixture of 4 diasteromeric bisabolene epoxide isomers, unreacted (−)-(4*S*)-*trans*-epoxyketone, and (4*R*)-*cis*-epoxyketone from epimerization of the (4*S*)-*trans*-isomer. The distillate was chromatographed (5% ether in hexane) to give 325 mg (35%) of a mixture of diasteromeric bisabolene epoxides containing 5% (4*S*)-*trans*-*Z*-BAE, 70% (4*R*)-*cis*-*Z*-BAE, 5% (4*S*)-*trans*-*E*-BAE, and 10% (4*R*)-*cis*-*E*-BAE. The *trans*-Z-α-BAE isomer was isolated in pure form from the mixture by HPLC (200×10 mm Econosil column, 10 μ irregular silica particles), eluting with 1% ether in hexane at 2 ml/min.

General Procedures for Y-tube Bioassays. Bioassays were conducted with a vertical glass Y-tube (5 cm ID; bottom arm = 18 cm long, top arms = 15 cm long, Y angle = 90°) with female ground glass joints, each fitted with male joints terminating in a hose nipple. The Y-tube was lit from above with a 1.2 m long light bank containing a Sylvania Octron 3500K F032/735 32 W fluorescent light and a GE F40PL/AQ Plant and Aquarium wide spectrum fluorescent light connected to a high frequency electronic ballast, providing light intensities of 350 lux at the bottom to 600 lux at the top of the Y-tube. Charcoal-purified air was pulled through the apparatus (2.5 liter/min) with house vacuum.

Virgin, sexually mature adults (16 to 18 d old) were tested individually and used only once. Each bug was gently placed inside the bottom male joint of the Y-tube, which was then inserted into the female joint. *A. hilare* are positively phototactic and walked up towards the light. A positive response was classified as a bug crossing a line 12 cm up either arm from the junction within 10 min of the start of the bioassay. Each Y-tube and joint was used once, then washed, acetone rinsed, and oven-dried at 140°C. Bioassays were conducted in a temperature (22–25°C) and humidity controlled room (50–60% RH) from ≈1100 to 1800 hr, 5 to 12 hr after the onset of photophase. Positions of treatments were alternated with each replicate.

Experiment 1. Live Insects as a Pheromone Source. The top joints of the Y-tube were connected to 125 ml sidearm flasks containing one sexually mature virgin bug and a green bean, or a green bean alone. Flasks were positioned so that their contents were not visible to a bug walking up the tube. Ten to 15 min after the flasks were set up, a test bug was introduced into the bottom of the Y-tube and its response was recorded. The flask and bug serving as a pheromone source was replaced every 2–3 replicates to minimize disturbance and production of defensive compounds, which may mask the effect of attractant pheromones. Four separate

experiments were conducted to test attraction of females to males, females to females, males to females, and males to males. Because males were attractive to females, and all other combinations of attractors and responders failed to demonstrate attraction, females were used as responders in all further experiments.

Experiment 2. Extract of Male-Produced Odors as a Pheromone Source. The numbers of virgin female *A. hilare* attracted to 10 bug-hour equivalents of crude extract in pentane (1 bug-hour equivalent = the volatiles produced by 1 bug in 1 hr) *versus* a pentane blank were compared. Extract or solvent controls were loaded on circular filter papers (1.5 cm diam) mounted on wires in the top of each arm. Ten bug-hours of extract contained ~4 μg of (4*S*)-*cis*-*Z*-BAE, the major component in the male extract, as determined by GC.

A portion of the male extract was separated into 4 fractions (see above), and the attractiveness of 10 bug-hour equivalents of each fraction was compared to a control consisting of the pentane: ether mixture in the fraction. Having determined that only the fraction containing (4*S*)-*cis*-*Z*-BAE and (4*S*)-*trans*-*Z*- BAE was attractive to females, this fraction was tested *versus* an equivalent amount of crude extract.

Experiment 3. Synthetic Chemicals as a Pheromone Source. (4*S*)-*Cis*-*Z*-BAE (chemical purity >92.6%; isomeric purity >97.8%, (4*S*)-*trans*-*Z*-BAE not detectable) and (4*S*)-*trans*-*Z*-BAE (chemical purity >88.6%; isomeric purity >97.8%; *cis*-(*Z*)-BAE not detectable) were synthesized as previously described (Chen et al., 2000). Three Y-tube bioassays were conducted, comparing the attraction of females to: 1) 4 μg of (4*S*)-*cis*-*Z*-BAE *vs* a hexane control; 2) 0.2 μg of (4*S*)-*trans*-*Z*-BAE *vs* a hexane control; and 3) a 95:5 blend (4 μg : 0.2 μg) of (4*S*)-*cis*-*Z*-BAE + (4*S*)-*trans*-*Z*-BAE *vs* a hexane control. This ratio approximates that in the natural extract (see below). Chemicals and solvent controls were loaded onto filter paper discs as described above.

Experiment 4. Field Cage Study Using Synthetic Pheromone Components. A 1 × 1 × 1 m field cage, covered on the top and three sides by aluminum screening and on the front by non-reflective cloth screening was set up at Agricultural Operations, University of California, Riverside. The cage was placed over a stiff cardboard platform covered with brown butcher paper. Cardboard strips (35 cm × 1.75 cm), covered on one side by Scotch® tape coated with Fluon®, were taped along the base of each cage wall to hinder bugs crawling up the walls of the cage. Fifteen min before the start of each bioassay, two freshly-cut bouquets of alfalfa (7 stalks each, 40–50 cm in height, stuck into a modeling clay base, also covered with alfalfa leaves and stalks), were placed 0.5 m apart, 0.25 m from two opposite side walls, and 0.5 m from the front and back walls. A 1-m cotton string was saturated with 3.5 ml of pentane containing 1.05 mg of a 95:5 blend of (4*S*)-*cis*-*Z*-BAE (chem. purity >97%, isomeric purity >98%, 1.9% (4*R*)-*trans*-*Z*-BAE present) and (4*S*)-*trans*-*Z*-BAE (chemical purity >98%, no isomeric impurities), and strung from the base of one bouquet to the cage roof immediately above the

bouquet. A string soaked in pentane was applied to the other bouquet. The positions of the pheromone-treated and control strings were interchanged for each replicate.

Thirty min before being introduced into the cage, 32–54 (mean 41, $N = 6$ trials) sexually mature virgin female *A. hilare* were placed with 2 green beans in a 25 × 15 × 5 cm cardboard box with a paper-lined bottom and Fluon®-coated walls. After 20 min, the beans were removed. Two to three min after positioning the pheromone lure, the paper lining with the bugs was lifted out of the box and placed just inside the front wall of the cage, equidistant from each bouquet. After 40 min, the number of females on each bouquet was counted. Trials were repeated on six separate evenings during August 1999, approximately 40 min before sunset.

Statistical Analyses. Y-tube bioassay data were analyzed using chi-square tests with one degree of freedom, using Yates' correction factor (Steel et al., 1997). Because different numbers of bugs were used for each replicate in the field cage study, the proportion of bugs on each bouquet, as a percentage of the total number of bugs on both bouquets, was calculated at the end of each trial. After arcsine transformation (Steel et al., 1997), treatment means were compared using a two-sample *t*-test. For all statistical tests, $\alpha = 0.05$.

RESULTS

In Y-tube bioassays, sexually mature females were attracted to odors from live males (Figure 2). Males were not attracted to odors from live males, nor were odors from live females more attractive than controls to bugs of either sex (Figure 2). Consequently, all subsequent bioassays used only female responders and extracts of male odors, or fractions thereof.

A crude extract of male-produced odors collected on activated charcoal was more attractive to female *A. hilare* than a solvent control (Figure 3). Bioassays using fractions of the extract indicated that only one of the four fractions, the fraction eluted from silica gel with 10% ether in pentane, was significantly attractive to females (Figure 3). In a two-choice assay, this fraction was as attractive as the crude extract (20 insects tested, 10 walked to each treatment, $\chi^2 = 0.025$, $P > 0.05$), suggesting that it contained all of the biologically active pheromone components.

Comparison of gas chromatograms of extracts of volatiles collected from sexually mature virgin males and females (>12 d old) revealed the presence of several male-specific compounds (Figure 4). These compounds were not found in aerations of sexually immature males, nor were they components of the defensive emissions or the metathoracic gland (MTG) contents (see below). Analysis of the biologically active fraction of the extract by GC and GC-MS determined that the

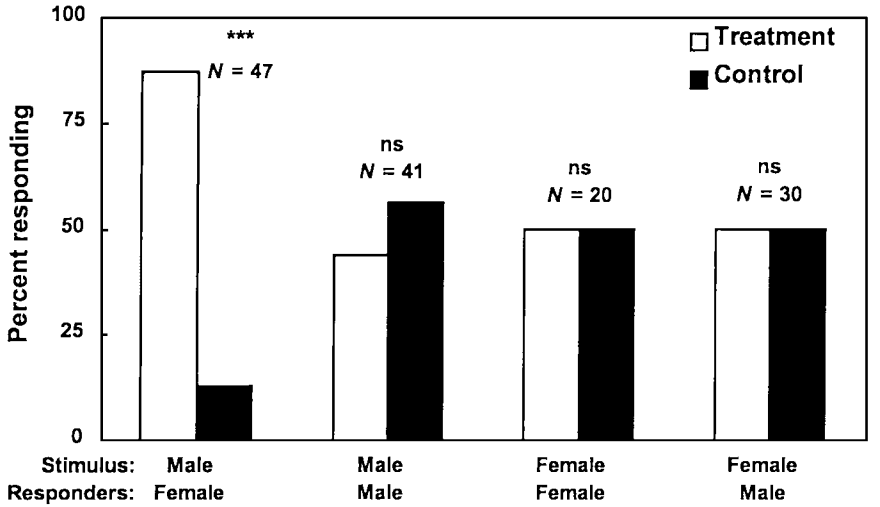

FIG. 2. Results of vertical Y-tube bioassays testing attraction of sexually mature virgin *A. hilare* to odors from sexually mature virgin conspecifics with a green bean *versus* a green bean control. The number of responders in each experiment (N) is indicated above each set of bars. For each experiment, results were analyzed with a χ^2-test. *** = $P < 0.001$, ns = not significant ($P > 0.05$).

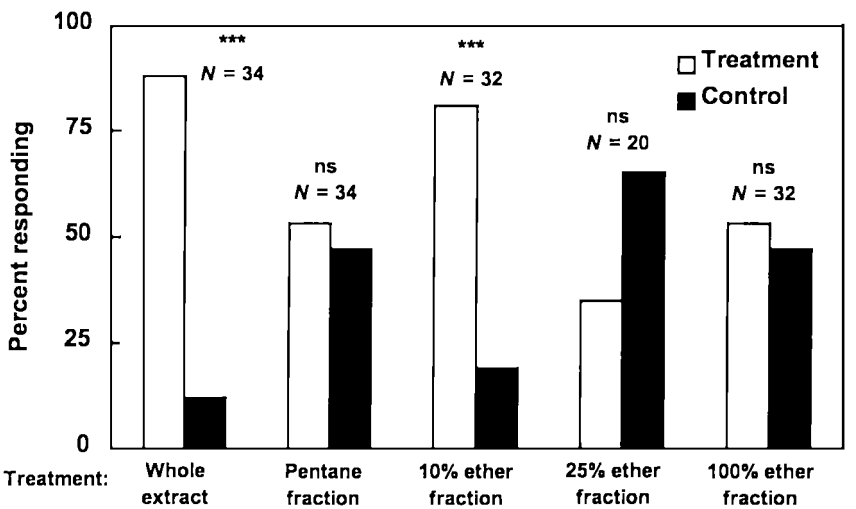

FIG. 3. Results of vertical Y-tube bioassays testing attraction of sexually mature virgin *A. hilare* to an extract or fractions of an extract of odors of *A. hilare* males, *versus* a solvent control. Data were analyzed as described in Fig. 2.

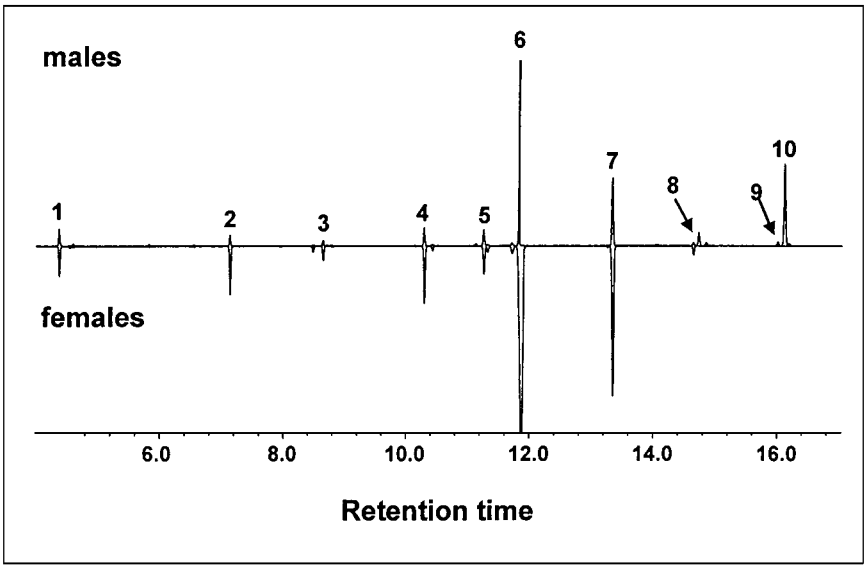

FIG. 4. Gas chromatograms of extracts of odors produced by sexually mature virgin male (top trace) or female (bottom, inverted trace) *A. hilare*, analyzed on a DB-5 column. GC conditions are described in Methods and Materials. Numbered peaks were identified as 1) (*E*)-2-hexenal, 2) (*E*)-2-hexenyl acetate, 3) undecane, 4) dodecane, 5) (*E*)-2-decenal, 6) tridecane, 7) (*E*)-2-decenyl acetate, 8) *Z*-α-bisabolene, 9) *trans*-*Z*-BAE, and 10) *cis*-*Z*-BAE.

major constituents were the two male-specific components, *cis*-*Z*-BAE (major) and *trans*-*Z*-BAE (minor), that had been identified previously by Aldrich et al. (1989). The identifications were confirmed by comparison with the authentic compounds in an extract from male *N. viridula* and finally, by comparisons with synthesized standards (GC retention time matches on DB-5, DB-17, Cyclodex B, and HP5-MS columns; mass spectral matches; GC retention time and mass spectral matches of the products of controlled degradation of the bug-produced BAEs with those of authentic standards, see below). The mean ratio of *cis*-(*Z*)-BAE to *trans*-(*Z*)-BAE in extracts from five cohorts of sexually mature male bugs (mean number of bugs per cohort $\pm$ SD $= 31 \pm 14$) was 95:5 (range = 93:7 to 96:4).

A third male-specific compound, which eluted in the pentane fraction of the crude extract, was identified as (*Z*)-α-bisabolene, as reported previously by Aldrich et al. (1989), by matchup of retention times and the mass spectrum with those of the known compound in the *N. viridula* extract, and confirmed by comparison with an authentic standard. The absolute configuration was determined to be (4*S*) by comparison of its retention time on a chiral Cyclodex B GC column with that of an authentic standard isolated from *Opoponax* oil (Delay and Ohloff, 1979).

Racemic (*Z*)-α-bisabolene gave two distinct but incompletely resolved peaks on this column, the earlier eluting of which was enlarged when the insect-derived and racemic material were coinjected.

The absolute configurations of the *cis*- and *trans*-*Z*-BAE's produced by *A. hilare* were determined indirectly because the enantiomers of *cis*- and *trans*-*Z*-BAE's were not resolved on the Cyclodex B column. *cis*-*Z*-BAE was cleaved by ozonolysis, and the absolute configuration of the resulting *cis*-4-acetyl-1,2-epoxy-1-methylcyclohexane product was determined to be (4*S*) by retention time comparisons on the Cyclodex B column with those of standards of known configuration.

Because the enantiomers of *trans*-4-acetyl-1,2-epoxy-1-methylcyclohexane were not resolved on the chiral column, a different strategy was used to determine the absolute configuration of the insect-produced *trans*-*Z*-BAE. Thus, the insect-produced BAEs were deoxygenated to *Z*-α-bisabolene by treatment with a mixture of Zn/AcOH/AcONa/NaI (Knoll and Tamm, 1975). Analysis of the products on the Cyclodex B column gave one symmetrical peak with no visible shoulder and a retention time matching that of the (4*S*)-enantiomer obtained from *Opoponax* oil (see above). This reconfirmed that the *cis*-*Z*-BAE (the major component in the fraction) had the (4*S*) configuration, and suggested a (4*S*) configuration for the minor *trans*-*Z*-isomer. However, assignment of the absolute configuration of the latter compound remains tentative because of the uncertainty of detecting a small amount ($\sim$5%) of the (4*R*)-enantiomer when the GC peaks from the two enantiomers were not completely resolved. The available evidence suggests that the insect-produced (*Z*)-α-bisabolene, *cis*-*Z*-BAE, and *trans*-*Z*-BAE all have the (4*S*) configuration, but the latter assignment should be confirmed by other methods.

A number of other compounds were identified in aeration extracts from undisturbed or shaken male and female *A. hilare*, and in MTG extracts (Table 1). Neither of the BAEs was detected in the defensive compounds released by disturbed bugs, nor were the BAEs found in the MTG extracts, suggesting that the BAEs are produced from glands other than those used for production and release of the defensive compounds.

Once the identities of the female-attracting male products were confirmed, Y-tube bioassays were continued with synthesized compounds. Neither (4*S*)-*cis*-*Z*-BAE nor (4*S*)-*trans*-*Z*-BAE alone were significantly more attractive than solvent controls. However, a 95:5 blend of the two BAEs, similar to that found in the extracts from males, was more attractive to females than controls (Figure 5), demonstrating that a blend of the two BAEs was essential for attraction.

These observations were verified in replicated field cage trials, in which the 95:5 pheromone blend dispensed from cotton string was more attractive to females than the control (treatment, mean $\pm$ SE, 80.5 $\pm$ 2.5% of the responding bugs, control 19.5 $\pm$ 2.5%, $t = 14.8$, $df = 10$, $P < 0.0001$). From all the bugs released,

an average of 39.3 ± 5.4% were scattered randomly on the floor, walls, or ceiling of the cage at the end of the trial, and were classified as nonresponders. Bugs generally did not fly except immediately after being introduced into the cage, when a few females flew to the cage walls and ceiling. Most of the remaining females walked to the alfalfa bouquets and climbed up the stalks, where many remained for the duration of the trial.

DISCUSSION

In laboratory bioassays, only female bugs were attracted to odors from live males, indicating that mature males produce a sex pheromone, as was observed for the phytophagous stink bug species *Thyanta pallidovirens* (Millar, 1997; McBrien et al., 1998). In contrast, a number of other pentatomid species (*Nezara viridula*, Harris and Todd, 1980; several *Euschistus* spp., Aldrich et al., 1991; *Biprorulus bibax*, James et al., 1994; *Plautia stali*, Moriya and Shiga, 1984 and Sugie et al., 1996; *Piezodorus hybneri*, Leal et al., 1998) are reported to produce aggregation pheromones attractive to both sexes.

We were able to confirm previous suggestions (Aldrich et al., 1989) that the bisabolene epoxides produced by sexually mature male *A. hilare* were indeed

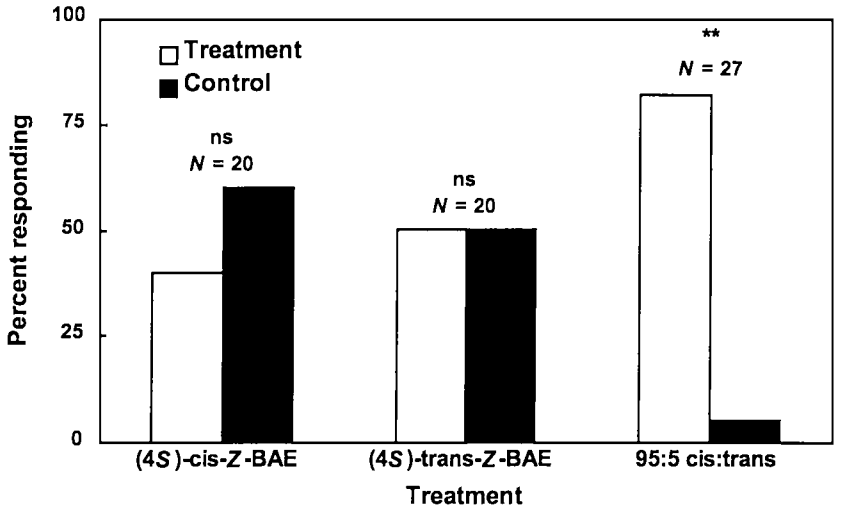

FIG. 5. Results of vertical Y-tube bioassays testing attraction of sexually mature virgin female *A. hilare* to the synthetic pheromone components, (4*S*)-*cis*-*Z*-BAE and (4*S*)-*trans*-*Z*-BAE, or a 95:5 blend of the two components, *versus* solvent controls. Data were analyzed as described in Fig. 2. ** = $P < 0.01$.

the sex pheromone components. Neither (4*S*)-*cis*-*Z*-BAE nor (4*S*)-*trans*-*Z*-BAE alone were attractive to female *A. hilare*, but when combined in the 95:5 ratio naturally produced by males in our Californian population, the blend was attractive to females in both laboratory and field bioassays, demonstrating that the active pheromone consists of at least two components. However, the importance of the specific blend ratio is not clear. The 95:5 ratio of (4*S*)-*cis*-*Z*-BAE to (4*S*)-*trans*-*Z*-BAE produced by Californian males is similar to that reported for male *A. hilare* from Georgia, USA, and also to the ratio produced by males of *A. aseadum* and *A. marginatum* (Aldrich et al., 1989, 1993). In contrast, *A. pennsylvanicum* males produce the two components in an approximately 1:1 ratio (Aldrich et al., 1989). Furthermore, these two components also constitute the sex pheromone of *Nezara viridula*, but the effects of the ratio of the two components produced by males from different populations remains controversial (Baker et al., 1987; Aldrich et al., 1987, 1993; Brézot et al., 1994). To date, large variations in the ratio of the two BAEs between individuals within single populations have confounded attempts to determine the importance of the ratio to *N. viridula* adults (Brézot et al., 1994; Ryan et al., 1995).

The major component produced by *A. hilare* males, *cis*-*Z*-BAE, has the (4*S*) configuration, with indications that the minor *trans*-*Z*-BAE also has the (4*S*) absolute configuration. These compounds have been reported in extracts from several

Nezara and *Acrosternum* species (Baker et al., 1987; Aldrich et al., 1989, 1993), but no attempts to determine the absolute configurations of the insect-produced compounds have been reported previously. There was no evidence to indicate that the third male-produced compound, (4*S*)-(*Z*)-α-bisabolene, is a pheromone component, and the fraction containing this compound was not attractive to female bugs. In addition, the fraction containing the two BAE's was as attractive as the whole extract, indicating that the (4*S*)-(*Z*)-α-bisabolene (and any components in other fractions) had no discernable role as attractant pheromone components. Because many species that produce (*Z*)-α-bisabolene also produce BAEs (Aldrich et al., 1989, 1993), it is unlikely that (*Z*)-α-bisabolene has a role in inhibiting cross-attraction of related species. The obvious structural resemblance between (4*S*)-(*Z*)-α-bisabolene and the BAE's, and the fact that they all have the same configuration at the (4*S*) center suggests that the bisabolene may be a precursor to the pheromone components.

Although the site of production of the BAEs has not been determined for *A. hilare*, they are not produced in the metathoracic glands (MTG), the site of production of the bugs' defensive secretions. The BAEs also are clearly distinct in structure and function from the defensive compounds. The MTG gland contents were not sexually dimorphic, and the compounds were all well-known, common components of hemipteran defensive secretions (Gilby and Waterhouse, 1965; Staddon, 1979; Aldrich, 1988). Significant quantities of these compounds were present in aeration extracts, indicating that they may be released sporadically or continuously at low levels. Alternatively, the relatively crowded conditions of the aeration chambers may have induced low levels of release.

Field cage bioassays using the synthetic pheromone demonstrated that female *A. hilare* approached the pheromone source almost exclusively by walking (McBrien and Millar, 1999). At the time of this study, in late summer, female responses to pheromone were strongest in late afternoon or evening, as has been noted for other pentatomid spp. (Harris and Todd, 1980; Moriya and Shiga, 1984). A significant proportion of the females tested did not appear to respond to the pheromone, but because of the small size of the cage, these females may have already reached their distance of closest approach to the pheromone source. For example, it has been demonstrated that *N. viridula* uses attractant pheromones to bring males and females together on the same plant or substrate. However, once on the same plant, the insects initiate a dialog consisting of substrate-borne vibrational signals, with the male tracking the female's signal along the plant surfaces until he locates her. Periodic vibrational responses by the male while he is searching for the female apparently induce her to continue signalling until she is located by the male (Ota and Čokl, 1991; Miklas et al., 1999). A second *Nezara* species, *N. antennata*, produces analogous signals (Kon et al., 1988), suggesting that this form of short-range communication may be common in the Pentatomidae. Thus, pentatomid sex pheromones may act to attract insects to the vicinity of a

pheromone source, but in the absence of the secondary vibrational cues for short range guidance, insects responding to the pheromone may not actually walk up to and contact the pheromone source.

The presence of host plants or host plant mimics (e.g., vertical silhouettes) also may be important both in attraction of females, and in inducing females that have been attracted to remain near the pheromone source by providing food or shelter. Further studies are needed to clarify possible interactions between host plant cues and the pheromones, and to clarify the relative roles of pheromones and shorter-range substrate-borne vibrational signals in the reproductive behavior of *A. hilare*.

(Received November 30, 2000; accepted May 12, 2001)

Abstract—We identified (*Z*)-9-octadecen-4-olide as a female-specific, antennally active compound from the currant stem girdler *Janus integer* Norton. Female specificity was demonstrated by gas chromatographic comparison of liquid chromatography fractions of male and female volatile emissions and whole body extracts. The γ-lactone was identified by coupled gas chromatographic-electroantennographic detection (GC-EAD), coupled gas chromatographic-mass spectrometric (GC-MS) analysis, microchemical reactions, and GC and MS comparison with authentic standards. GC-EAD analysis of female volatile emissions and cuticular extracts showed a single peak of activity on male antennae, which was not present in male-derived materials. Female antennae did not respond to any of the tested materials. The hydrogenation product of the natural EAD-active material was a known saturated γ-lactone. The mass spectrum of the dimethyl disulfide derivative of the natural γ-lactone was consistent with a double bond present in the 9 position. Comparison of the natural γ-lactone and a synthesized racemic mixture of (*Z*)-9-octadecen-4-olide on a chiral GC column showed the presence of a single enantiomer in the natural material.

Key Words—*Janus integer*, sawfly, Hymenoptera, Cephidae, sex pheromone, (*Z*)-9-octadecen-4-olide, coupled gas chromatographic-electroantennographic detection (GC-EAD).

INTRODUCTION

The currant stem girdler, *Janus integer* Norton (Hymenoptera: Cephidae), is an occasional pest of red currant (*Ribes* spp.) in North America (Crassweller et al., 1997). In spring, egg laying female *J. integer* can make numerous punctures in canes, resulting in drooping and wilting of new shoots. Further damage occurs as emerging larvae tunnel within the canes. This insect also attacks poplar and willow trees, and damage to currants usually is more severe near stands of these trees (Crassweller et al., 1997).

Preliminary field observations indicated that caged virgin females attracted male *J. integer* (D. G. James, unpublished data), thus *J. integer* could utilize a female-produced sex pheromone for mate location. Currently, the only studied cephid pheromone is that of the wheat stem sawfly, *Cephus cinctus* Norton (Cossé et al., unpublished data). The pheromone may be beneficial to current pest control practices, especially since insecticides are ineffective against larvae inside the currant stems.

This paper describes the isolation, structure determination, and electroantennographic activity of a female-specific volatile compound and compares this with other sawfly pheromones.

MATERIALS AND METHODS

Insects. Overwintering currant stem girdler larvae present in dormant red currant stems were collected near Prosser, Washington, during January 2000. Larva-containing stems were placed individually into glass vials, capped with a moist piece of cloth-covered cotton, and sent to NCAUR. Upon arrival in Peoria, Illinois, the vials were kept at 25°C under a 16:8 (L:D) hour photoperiod regime. Adults emerged about three weeks later. Adults used in this study were 1- to 4-days old.

Volatile Collections and Cuticular Extracts. One- to three-day volatile collections were made from individuals or groups of 4 male or female insects. Volatiles were trapped on Super Q porous polymer (80–100 mesh, Alltech, Deerfield, IL) or on solid-phase microextraction (SPME) fibers (100 μm poly(dimethyl)siloxane, Supelco, Bellefonte, PA). Volatile collections were made by methods and equipment generally described by Cossé and Bartelt (2000). Cuticular extracts were obtained by a single rub of the abdomen of individual male or female insects with a SPME fiber. In addition, individuals or groups of 8 male or female insects were killed by freezing when 1–4 days old, and soaked overnight in 1 ml hexane.

Hexane extracts were stored at −20°C. Extracts were concentrated under a gentle stream of nitrogen and fractionated on open columns of silica gel (0.5 × 3 cm). Two-milliliter fractions were collected for each of the following elution solvents: hexane; 5%, 10%, and 25% ether in hexane (by volume); and ether. Fractions were concentrated to a volume similar to the non-fractionated samples prior to any further analysis.

Electrophysiology. Coupled gas chromatographic-electroantennographic (GC-EAD) analyses were made by methods and equipment generally described by Cossé and Bartelt (2000). GC-EAD connections were made by inserting a glass-pipette Ag-AgCl-grounding electrode into the back of an excised sawfly head. A second glass-pipette Ag-AgCl-recording probe was placed in contact with the distal end of one antenna. Both pipettes were filled with Beadle-Ephrussi (Ephrussi and Beadle, 1936) saline.

Instrumentation. Volatile collections, extracts, and liquid chromatography (LC) fractions were analyzed by gas chromatography with flame-ionization detection (GC-FID) and coupled GC-mass spectrometry (GC-MS, electron impact and chemical ionization). Samples were injected in splitless mode using Hewlett Packard 6890 instruments fitted with 30 meter EC-1 capillary columns (0.25 mm I.D., 0.25 μm film thickness, Alltech, Deerfield, IL). Temperature programs were from 50°C to 275°C at 10°C per min (GC-MS) or at 15°C per min (GC-EAD). Injector temperatures were maintained at 250°C, and GC-EAD effluent interface from post-column splitter was kept at 275°C. Injectors were fitted with SPME injector liners (Supelco, Bellefonte, PA) for SPME analysis. Mass spectrometry was performed with a Hewlett Packard 5973 instrument (electron impact, 70 eV). Chemical ionization spectra (isobutane) were obtained on a Thermo Quest Trace GC 2000 quadrupole mass spectrometer. The Wiley mass spectral library, with 275,821 spectra, was available on the MS data system (Wiley, 1995). Chiral resolution was achieved on a capillary column having a diacetyl-derivatized β-cyclodextrin phase, β-DEX 225 (30 m length, 0.25 mm ID, 0.25 μm film thickness; Supelco, Bellefonte, PA) operated at 200°C.

Microchemical Reactions. Hydrogenation of GC-EAD-active LC fractions was used to confirm the number of carbon-carbon double bonds. Samples (100 μl) were stripped to dryness under a stream of nitrogen and resuspended in 100 μl ethanol to which was added ∼0.5 mg of 10% Pd on charcoal. Reduction was accomplished by bubbling a gentle steam of hydrogen through the sample for 5 min at room temperature. The reduced sample was filtered and analyzed by GC-MS and GC-EAD.

Dimethyl disulfide (DMDS) derivatives were prepared for determination of double bond locations of EAD-active material (Carlson et al., 1989). Samples (100 μl) were stripped to dryness under a stream of nitrogen, and DMDS and 5% iodine in ether were added (equal volumes, about 25 μl each). The samples were heated at 45°C for 1–2 hr, then diluted with hexane and worked up with

aqueous sodium thiosulfate to destroy the iodine. The organic layer was dried over sodium sulfate, evaporated under nitrogen, resuspended in about 10 μl hexane, and analyzed by GC-MS. Oven temperature was programmed up to 300°C, and MS scanning range was 40–600 amu.

The antenally active 10% ether/hexane LC fractions contained two major free fatty acids, linoleic- and oleic acid, which were methylated to the corresponding methyl esters with diazomethane. Approximately 5 mg of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Diazald, Aldrich, Milwaukee, WI) were added to a 1:1 mixture of ether and a mixture of 5% aqueous KOH and methanol (1:1). Ten micro liters of the yellow ether layer were added to 100 μl of the EAD-active LC fraction. After 5 min, the mixture was evaporated and the residue dissolved in hexane for GC-MS and GC-EAD analysis.

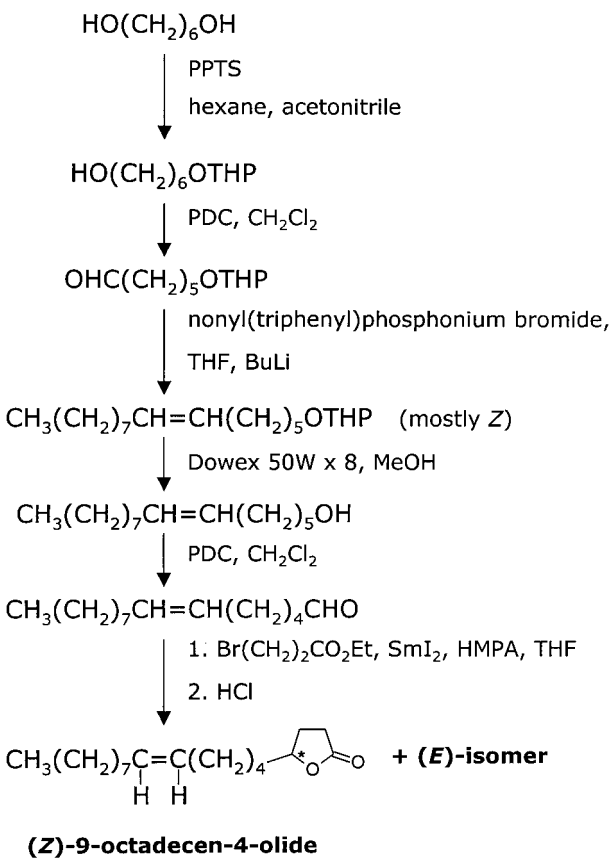

FIG. 1. Synthesis of (*Z*)-9-octadecen-4-olide (see text for abbreviations).

Synthesis of (Z)-9-octadecen-4-olide. A preliminary synthesis to confirm structure was conducted by one of us (RJP), based on well-known reactions (Figure 1). One hydroxy group of 1,6-hexanediol (Aldrich, Milwaukee, WI) was protected as a tetrahydropyranyl (THP) ether by using pyridinium *p*-toluenesulfonate (PPTS) as catalyst (Miyashita et al., 1977). Monoprotection of the diol was accomplished by modification of the published procedure (Miyashita et al., 1977). In a biphasic mixture of acetonitrile and hexane, the reactants were primarily in the more polar (acetonitrile) phase, but the mono ether migrated to the hexane phase, reducing the chance of further derivatization to the diether. The free hydroxyl was oxidized with pyridinium dichromate (PDC) in CH_2Cl_2 to give the aldehyde (Corey and Schmidt, 1979). The aldehyde was reacted with nonyl(triphenyl)phosphonium bromide to give, predominantly, the *Z*-olefin (Sonnet, 1974). The THP protective group was easily removed by acid catalysis (Dowex 50 W $\times$ 8) in MeOH (Beier and Mundy, 1979). The alcohol was oxidized to the aldehyde as described above. Samarium iodide mediated the coupling of $Br(CH_2)_2CO_2Et$ with the aldehyde, to form the 4-hydroxy ester. This cyclized to the desired γ-lactone during the acidic workup (Otsubo et al., 1987). The SmI_2-induced coupling of an unactivated organic halide with an aldehyde is promoted by hexamethylphosphoric triamide (HMPA). Both enantiomers are formed.

RESULTS AND DISCUSSION

Cuticular Extracts and Volatile Collections. Comparisons of the GC profiles of extracted materials obtained by SPME rub and hexane soak showed a high degree of similarity (Figure 2). GC-EAD analyses ($N = 15$) of cuticular extracts (SPME rub and hexane soak) from individuals or groups of male or female insects were obtained by using male and female antennae. EAD activity occurred consistently at one GC retention time (21.8 min) when cuticular extracts from female insects ($N = 6$) (Figure 2) were tested on male antennae, but not on female antennae. Male and female antennae showed no EAD activity with cuticular extracts derived from males ($N = 9$). Similarly, GC-EAD analyses ($N = 10$) of volatiles collected (Super Q and SPME) from individuals or groups of female insects ($N = 5$) consistently indicated the same GC retention time, with EAD activity only on male antennae. Male and female antennae showed no EAD activity with volatiles derived from males ($N = 5$).

Liquid Chromatography. The EAD-activity of female cuticular extracts eluted from silica gel with 10% ether in hexane, suggested an oxygenated compound for the EAD-active material. No other antennal activity was noted for any of the other silica gel fractions (Figure 3).

Comparison of GC-MS analyses of 10% ether/hexane fractions of male versus female cuticular extracts demonstrated a female specific compound, as shown in

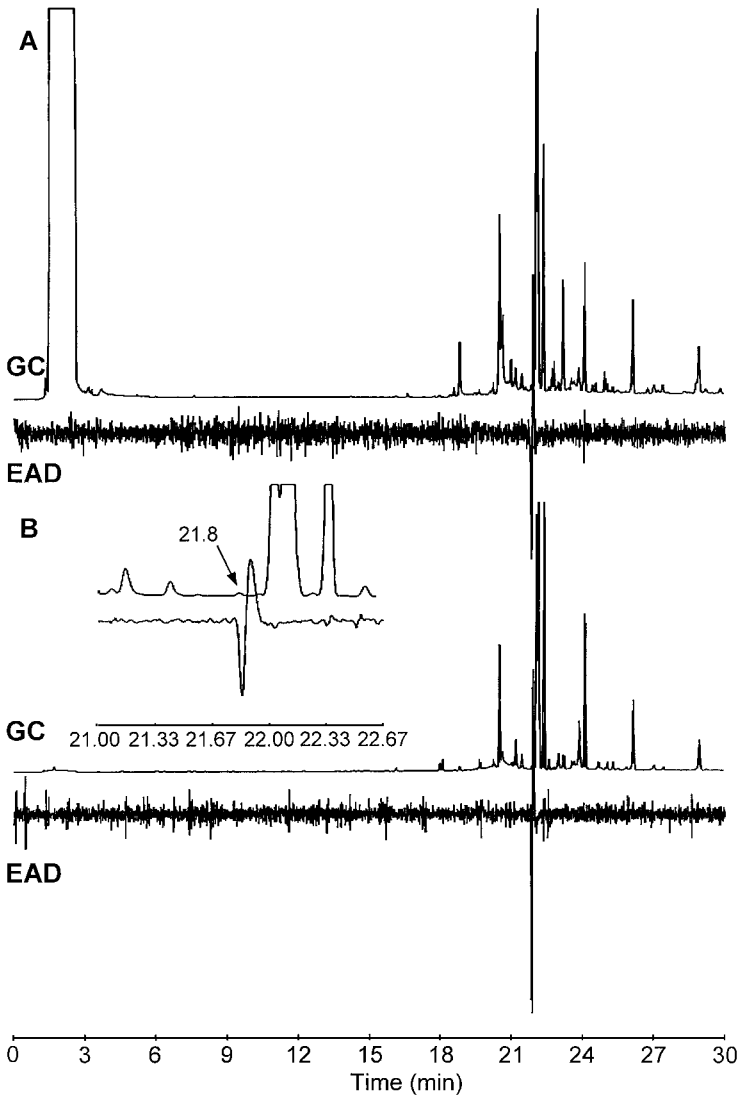

FIG. 2. Simultaneously recorded gas chromatographic (GC) and electroantennographic detection (EAD) of typical male antennae to a hexane extract of female *J. integer* (A) and a SPME cuticular rub of female *J. integer* (B). Insert shows the GC retention time of EAD-activity.

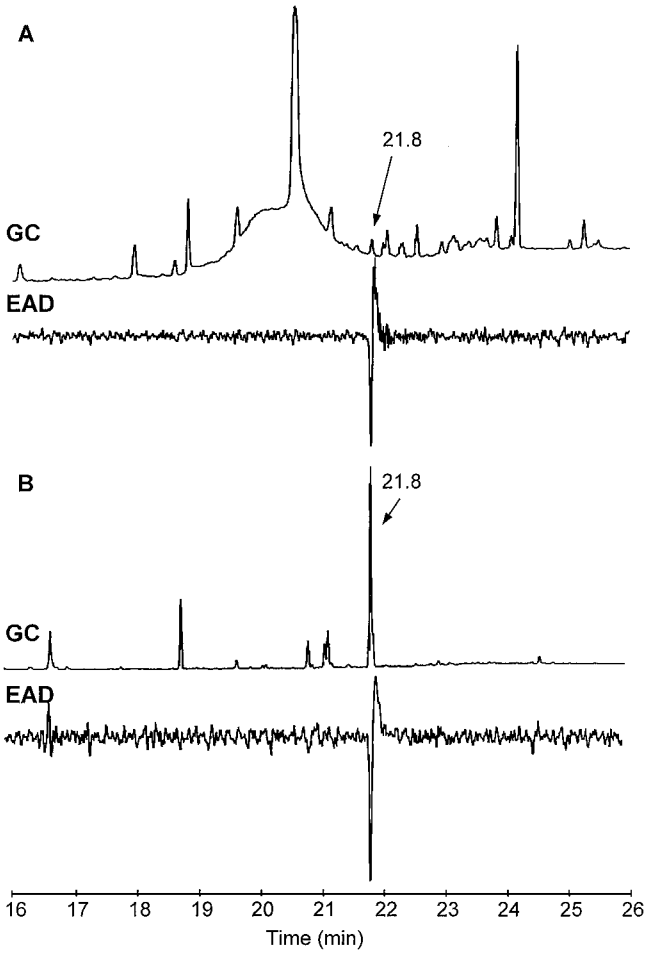

FIG. 3. Simultaneously recorded gas chromatographic (GC) and electroantennographic detection (EAD) of typical male antennae to liquid chromatography fraction (10% ether in hexane) of female *J. integer* hexane extract (A), and synthetic (*Z*)-9-octadecen-4-olide (B). Arrows denotes the GC retention times of EAD-activity.

Figure 4. This compound corresponded to the EAD-active material, based on comparisons of GC-MS and GC-EAD elution profiles (same column, but different temperature ramps).

The mass spectrum of the EAD-active compound indicated a molecular weight of 280 (Figure 5), which was confirmed by the chemical ionization mass spectrum (base peak at m/z 281), but its EI spectrum did not match any of the spectra in the MS library.

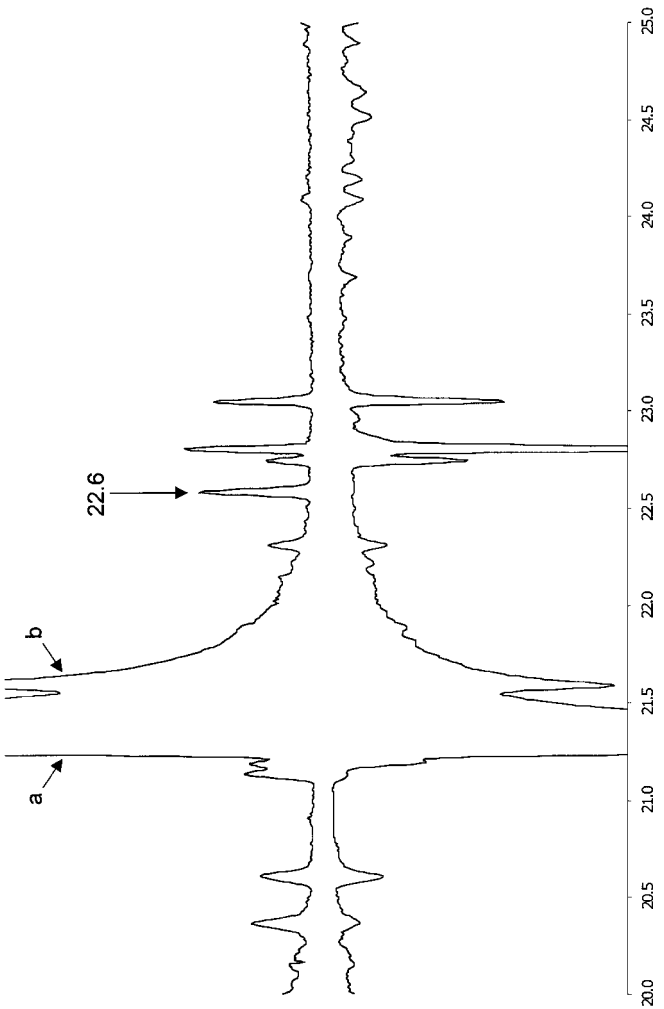

FIG. 4. The gas chromatographic comparison of liquid chromatography fractions (10% ether in hexane) of female (upper) and male (lower) *J. integer* hexane extracts. Arrows denotes the presence of linoleic (a) and oleic acids (b).

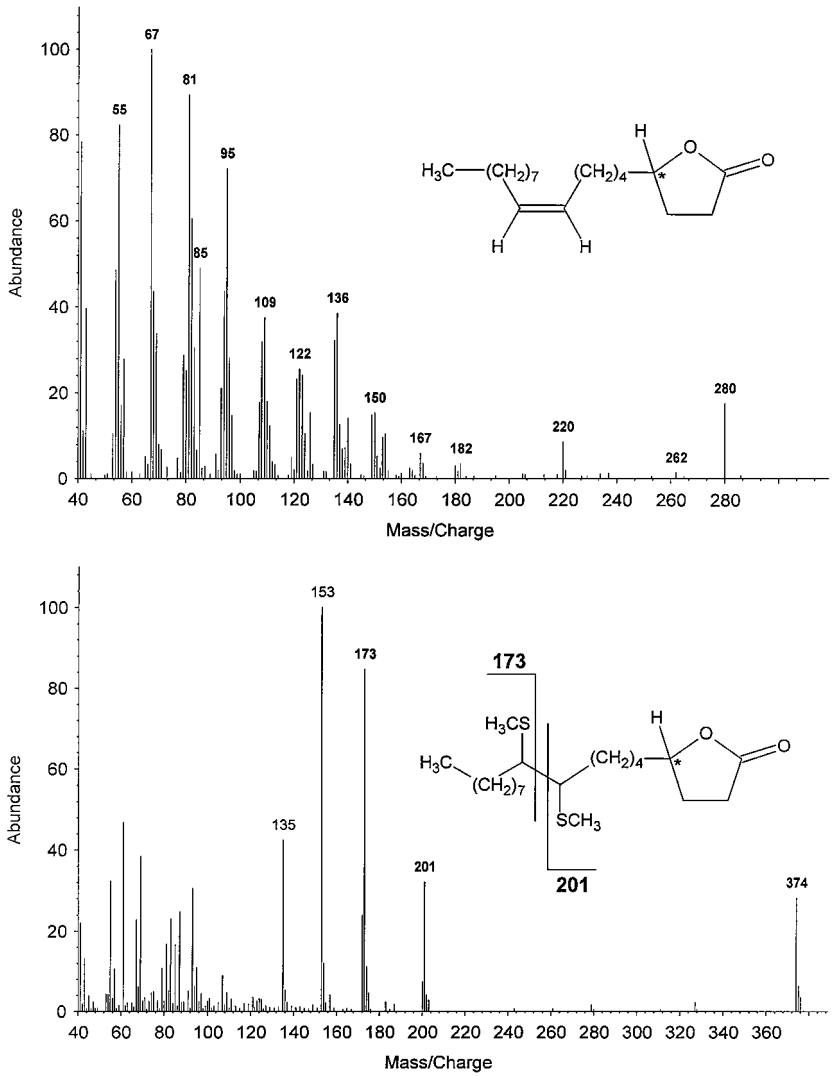

FIG. 5. EI-Mass spectrum of (Z)-9-octadecen-4-olide from female *J. integer* (upper) and EI-mass spectrum of the DMDS derivative of this compound, showing origins of major fragments (lower).

A molecular weight of 280 suggested $C_{19}H_{36}O$ (2 double bonds or ring equivalents) or $C_{18}H_{32}O_2$ (3 double bonds or ring equivalents) as likely molecular formulas. In fact, the silica gel fraction with the female-specific compound contained two relatively abundant fatty acids, which were identified by MS as

linoleic- and oleic acid (Figure 5). The female 10% ether/hexane fraction was treated with several chemical reagents to further elucidate the chemical composition of this EAD-active material.

Methylation. The addition of diazomethane to the female 10% ether/hexane fraction converted the carboxylic acids to the corresponding methyl esters, but did not affect the EAD-active compound, indicating it did not have a free carboxyl group.

Hydrogenation. The mass spectrum of the EAD-active compound after hydrogenation showed a molecular ion at m/z 282, indicating the presence of one carbon-carbon double bond. Furthermore, the MS library picked γ-stearolactone as a likely match for the hydrogenation product. This MS library match was confirmed by comparison of the mass spectra and GC retention times of the hydrogenation product and an authentic sample of γ-stearolactone (Cermak and Isbell, 2000). Similar to the natural product, this synthetic standard also had a fragment ion at m/z 85, which would be expected for a γ-lactone (cleavage where side chain joins ring), suggesting that the natural compound was probably a γ-lactone with one carbon-carbon double bond in the side chain; the fragment ion at m/z 85 would not be present if the carbon-carbon double bond was residing in a ring. The presence of a double bond might also be important for antennal activity, because GC-EAD analysis of the hydrogenation product showed a complete loss of antennal activity. In addition, GC-EAD analysis prior to the diazomethane treatment showed no antennal activity for the oleic acid; surprisingly however, the methyl ester of oleic acid was antennally active.

DMDS Derivatization. The mass spectrum of the DMDS (MW = 94) derivative of the EAD-active compound is presented in Figure 5. The readily formed derivative showed a molecular ion at m/z 374 (= 280 + 94), and the fragment ions (m/z 173 and 201) were consistent with a double bond being present in the 9 position.

Synthetic (Z)-9-octadecen-4-olide. The synthetic γ-lactone matched the natural female-derived *J. integer* compound exactly by mass spectrum, mass spectrum of DMDS derivative, and by GC-EAD analyses (Figure 3). The Wittig synthesis (Figure 1) created both the (*Z*) and (*E*) configurations at the double bond. The *Z*-isomer was recognized because it eluted slightly earlier by GC on the non-polar column (*Z*-isomer at 21.82 min, *E*-isomer at 21.87 min) and because it was more abundant (ca. 70:30), as expected for the Wittig reaction conditions (Sonnet, 1974). GC analysis established that the natural material contained only the earlier-eluting *Z*-isomer, and by GC-EAD the synthetic *Z*-isomer was antennally active (Figure 6). The synthetic γ-lactone was synthesized as a racemic mixture and its two enantiomers showed base-line separation on the chiral GC column (Figure 7). The earlier eluting enantiomer had the same GC retention time as the natural compound. Future chiral synthesis of the γ-lactone will determine the absolute configuration of the natural γ-lactone.

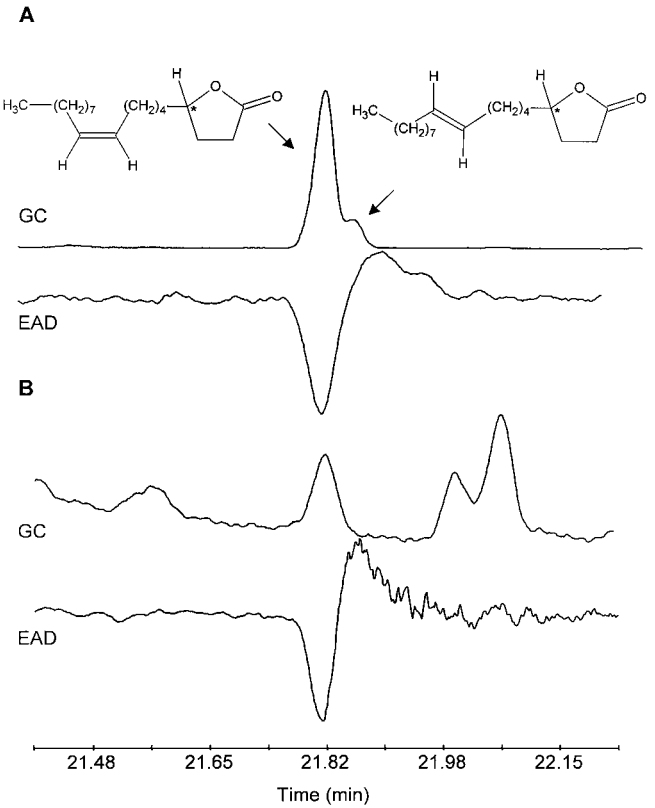

FIG. 6. Simultaneously recorded gas chromatographic (GC) and electroantennographic detection (EAD) of typical male antennae to an isomer mixture of synthetic (*Z*)-, and (*E*)-9-octadecen-4-olide (A) and liquid chromatography fraction (10% ether in hexane) of female *J. integer* hexane extract (B).

Based on GC-FID peak areas and fraction volumes, the estimated maximum release rate of natural γ-lactone was 10 ng/female/day.

Sawfly Sex Pheromones. Forthcoming behavioral tests will determine whether this female-specific γ-lactone of *J. integer* is capable of attracting male sawflies and, thus, be confirmed as a sex pheromone.

Little is published on pheromone systems of sawflies belonging to the family Cephidae. The only studied cephid pheromone is that of the wheat stem sawfly *Cephus cinctus* Norton (Cossé et al., unpublished data).

Insect Specific γ-Lactones. Sex pheromones of sawflies belonging to the family Diprionidae and to one species belonging to the family of Tenthredinidae are well-studied (Bartelt and Jones, 1983; Bartelt et al., 1983; Anderbrant, 1999). However, no γ-lactone containing compounds have been reported as sawfly

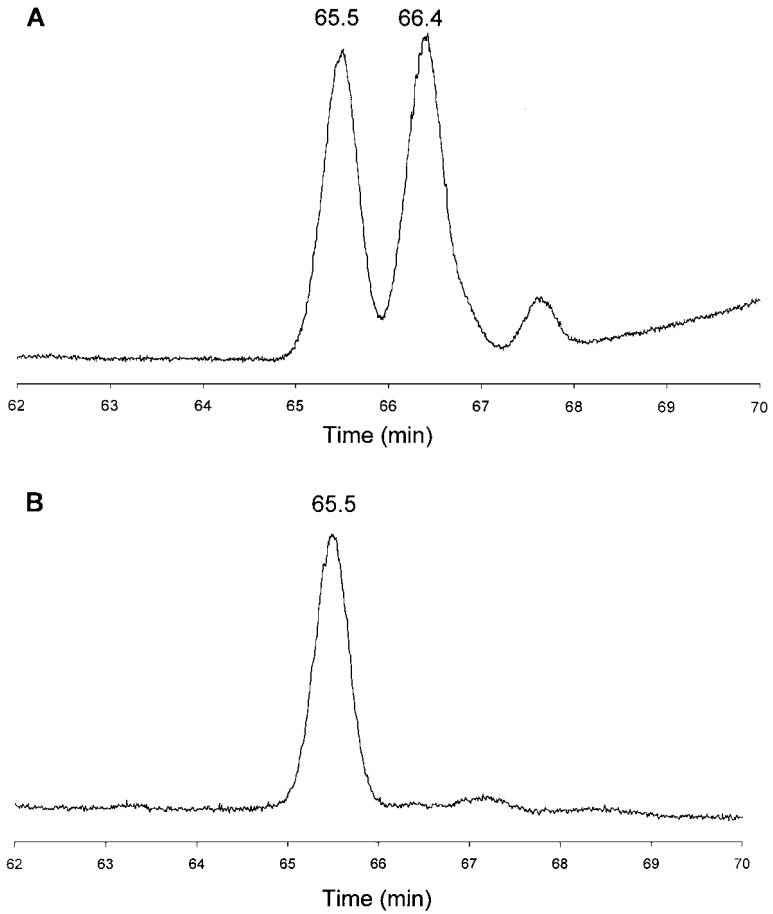

FIG. 7. Chiral separation by gas chromatography of racemic (*Z*)-9-octadecen-4-olide (A) and (*Z*)-9-octadecen-4-olide (B) from female *J. integer*.

pheromones, although related γ-lactones are known as scarab beetle pheromones (Tumlinson et al., 1977; Leal, 1999). For example, the sex pheromone of the yellowish elongate chafer, *Heptophylla picea* Motschulsky was identified as (*R*,*Z*)-7,15-hexadecadien-4-olide and is probably biosynthesized from stearic acid (Leal et al., 1996). Similarly, fatty acid derivatives might be involved in the proposed sex pheromone of currant stem girdler.

Acknowledgments—We thank the following colleagues at NCAUR, Peoria, Illinois: Ronald D. Plattner for assistance in obtaining CI mass spectra and Terry Isbell for the sample of γ-stearolactone.

(Received June 11, 1999; accepted April 25, 2001)

Abstract—Two components, (*Z*)-8-dodecenyl acetate (*Z*8-12:Ac) and (*Z*)-8-dodecenol (*Z*8-12:OH), were isolated from sex pheromone glands of the carambola fruit borer, *Eucosma notanthes*, and were identified by GC, and GC-MS, chemical derivatization, and comparison of retention times. The ratio of the alcohol to acetate in the sex pheromone extracts was 2.7. However, synthetic mixtures (1 mg) in ratios ranging from 0.5 to 1.5 were more effective than other blends in trapping male moths in field tests.

Key Words—Carambola fruit borer, *Eucosma notanthes*, sex pheromone, (*Z*)-8-dodecenyl acetate, (*Z*)-8-dodecenol.

INTRODUCTION

The carambola fruit borer, *Eucosma notanthes* Meyrick (Lepidoptera: Tortricidae), is a key pest of carambola (also known as star fruit), *Averrhoa carambola* L., in Taiwan (Ho, 1985). This insect has 8 generations per year and may attack carambola fruits all year. Its population density remains high from July to

*To whom correspondence should be addressed. e-mail: rhou@dragon.nchu.edu.tw

0098-0331/01/0900-1855$19.50/0

November. At fruiting time, the moths lay eggs on the surface, and the larvae penetrate into the fruits, causing severe damage. Damaged fruits drop or become unedible and unmarketable. Although farmers usually apply insecticides or bag the fruits to protect them from attack by fruit flies and borers, the fruit damage rate varies from 29 to 77% (Ho, 1988a,b).

Recently, (*Z*)-8-dodecenyl acetate (*Z*8-12:Ac) was found to be an effective sex attractant for this borer in field tests and laboratory bioassays (Hwang et al., 1987, 1996; Hwang and Hung, 1994). High concentrations of this component used as a mating disruptant resulted in significant control of the borer (Hwang and Hung, 1997). Therefore, *Z*8-12:Ac was suspected to be one of the sex pheromone components of the carambola fruit borer. However, the natural sex pheromone components and their blend for this borer were still not yet known. In this study, two components of the sex pheromone were extracted from calling virgin females and analyzed by gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS). Attraction of the moth to different blend ratios of the sex pheromone components was determined in field tests.

METHODS AND MATERIALS

Insects. Experimental colonies of *E. notanthes* were initially collected from carambola orchards at Changhua, Taiwan. Larvae were mass-reared on a diet at $25 \pm 1^{\circ}$C, $70 \pm 5\%$ relative humidity, and 12 hr photoperiod (Hung and Hwang, 1991). Sexes were identified at the pupal stage and maintained separately in 200-ml plastic jars until eclosion. Adult moths were supplied with 5% honey in water and maintained in plastic bags (30×40 cm).

Preparation of Sex Pheromone Gland Extracts. At the maximum calling and mating time between 1–3 hr after lights on, ovipositors of 1–4-day-old virgin females were excised (Hung et al., 1997). Pheromone glands were immersed in *n*-hexane for 5 sec and the extract was stored at -19°C.

Sources and Purity of Authentic Samples. Authentic samples used for comparison and bioassay were as follows: decanol (Lancaster, 98%), dodecyl acetate (Aldrich, 97%), (*Z*)-7-dodecenyl acetate (*Z*7-12:Ac) (Instituut voor Planteziektenkundig Onderzoek, the Netherlands, >99%), (*Z*)-8-dodecenyl acetate (*Z*8-12:Ac) (Sigma, 96.8%), (*Z*)-8-dodecenyl acetate (Instituut voor Planteziektenkundig Onderzoek, >99%), (*Z*)-9-dodecenyl acetate (*Z*9-12:Ac) (Instituut voor Planteziektenkundig Onderzoek, >99%), (*E*)-8-dodecenyl acetate (*E*8-12:Ac) (Sigma), dodecanol (12:OH) (Lancaster, 97%), (*E*)-8-dodecenol (*E*8-12:OH) (Chemtech B. V., the Netherlands), (*Z*)-8-dodecenol (*Z*8-12:OH) (Instituut voor Planteziektenkundig Onderzoek, >99%), 1-tetradecanol (Fluka, 97%), 1-hexadecanol (Aldrich, 99%), 1-octadecyl acetate (TCI, 99%) and 1-octadecanol (Lancaster,

97%). Three additional authentic samples, decyl acetate, 1-tetradecyl acetate and 1-hexadecyl acetate, were synthesized from decanol, 1-tetradecanol, and 1-hexadecanol, respectively.

Chemical Analysis. Gas chromatography analyses were performed on a Hewlett-Packard 5890A GC (Avondale, Pennsylvania) with a capillary DB-Wax column (30 m $\times$ 0.25 mm; 0.25-μm; J&W Scientific, Folsum, CA). The oven temperature was set at 150°C for 20 min, then increased at 8°C/min to final temperature, 240°C. GC-MS spectra were recorded on a Finnigan MAT GCQ system equipped with an ion trap mass analyzer and a DB-Wax capillary column. The temperature program was the same as above. Electron impact (EI) and chemical ionization (CI) mass spectral data of natural and authentic compounds were recorded at 70 eV with the transfer line at 230°C and the ion source at 200°C. Methane was used as a reagent gas for CI analysis. The extract solution of 52,820 ovipositors prepared as described above was subsequently concentrated to 1 ml, and analyzed with the external standard method.

Derivatization. Retention times and retention indices were determined with (*Z*)- and (*E*)-8-12:Ac, and (*Z*)- and (*E*)-8-12:OH as described above in GC analysis. Double bond position and configuration were determined by the mass spectral fragmentation patterns of their dimethyl disulfide (DMDS) derivatives, which were synthesized following the procedure of Buser et al. (1983) and Leonhardt and DeVilbiss (1985). GC-MS was equipped with a CP-Sil 8 CB fused silica capillary column (Chrompack, the Netherlands) (30 m $\times$ 0.25 mm; 0.25 μm). Chromatography was carried out with a temperature program initially at 80°C for 2 min, then increasing at 20°C/min to 140°C, followed by increasing at 4°C/min to 240°C.

Field Tests. To verify the attractiveness of the pheromone components to males of *E. notanthes* and to develop an optimized trap lure, seven field experiments were conducted. The numbers of males captured in traps baited with different components or blend ratios of two authentic compounds were calculated and evaluated. In an attempt to realize the relationship between the attractiveness and the double bond position in the components, three analogs, *Z*7-12:Ac, *Z*8-12:Ac and *Z*9-12:Ac, were used for attraction tests. In addition, both *Z*8-12:Ac and *Z*8-12:OH were suspected to be the main pheromone components; therefore, various blends of these two components were also tested. Since the synthetic *Z*8-12:Ac always contains an impurity of *E*8-12:Ac, which could affect the attractiveness of *Z*8-12:Ac, 7 blends of *Z*8-12:Ac and *E*8-12:Ac were examined.

Field tests were conducted in carambola orchards at Changhua, Taiwan, between August 1996 and October 1997. Each lure comprising 1 mg of content was absorbed on a rubber septa (Aldrich, *Z*-12435-4) and glued to a wing sticky trap (Taiwan Jia-Fu Co.) (Hung et al. 1999). Each trap was hung at 180–200 cm above the ground, and spaced 1–2 trees (10 $\sim$ 15 m) between traps. A randomized

complete block design was used for the field tests. Four orchards spaced 100 ~ 200 m apart were used as blocks. The area of each orchard was between 0.2 and 0.5 ha. Each orchard had all treatments including pheromone formulations and blank. Treatments within a block were randomized. Traps were checked weekly for 4 ~ 8 weeks and treatments within a block were rotated one position each time (Hwang et al., 1987; Hwang and Hung, 1994).

Statistical analysis was conducted with the SAS system. Trap catch data were subjected to an analysis of variance, and treatment means were separated by Duncan's multiple range test.

In the first experiment, each of the three isomers, i.e., *Z*7-12:Ac, *Z*8-12:Ac and *Z*9-12:Ac, was tested. Each isomer was mixed individually with *Z*8-12:OH in a ratio of 1 : 1 and tested for the second experiment. In the third experiment, *Z*8-12:Ac and *Z*8-12:OH were assayed individually in three orchards. In the fourth experiment, five different ratios of *Z*8-12:Ac to *Z*8-12:OH were tested, namely, 100 : 0, 100 : 1, 100 : 100, 100 : 200, and 0 : 100. In the fifth and sixth experiments, ratios of *Z*8-12:Ac and *Z*8-12:OH were reevaluated in order to obtain the optimum ratio of these two components for maximum capture of males in pheromone-baited traps. Additionally, five and three ratios of *Z*8-12:Ac and *Z*8-12:OH in 100 : 5, 100 : 10, 100 : 50, 100 : 100, 100 : 150, and 100 : 100, 100 : 150, 100 : 270, respectively, were assayed. In the last experiment, seven ratios of *Z*8-12:Ac and *E*8-12:Ac in 100 : 0, 99.5 : 0.5, 98 : 2, 96 : 4, 94 : 6, 92 : 8, or 0 : 100 were tested.

RESULTS

Chemical Analysis. A small amount of sex pheromone was isolated from a total of 4,043 females. Only four peaks were found in the gas chromatogram; two major peaks, 1 and 4, and two minor peaks, 2 and 3 (Figure 1B). The retention times of these four peaks matched those of 4 authentic samples; peaks 1 and 4 gave the same retention times as *Z*8-12:Ac and *Z*8-12:OH, respectively, while peaks 2 and 3 were also coincided with 12:OH and *E*8-12:OH, respectively (Figure 1A, B). The gland extracts and 14 authentic samples were analyzed by GC-MS (Figure 1C, D). The retention times of 14 authentic samples are shown as peak 1 to 14 in Figure 1C. Each peak was identified as follows: 1 (10:Ac, 5.02), 2 (10:OH, 6.38), 3 (12:Ac, 10.47), 4 (*E*8-12:Ac , 11.82), 5 (*Z*8-12:Ac, 12.35), 6 (12:OH, 13.98), 7 (*E*8-12:OH, 16.02), 8 (*Z*8-12:OH, 16.72), 9(14:Ac, 22.37), 10 (14:OH, 24.87), 11 (16:Ac, 27.72), 12 (16:OH, 28.95), 13 (18:Ac, 30.85) and 14 (18:OH, 31.75 min). The sex pheromone extracts show 12 peaks in the gas chromatogram (Figure 1D). Their retention times were as follows: 1(9.52), 2(10.13), 3(11.30), 4(12.33), 5(16.83), 6(25.88), 7(29.77), 8(30.15), 9(31.50), 10(31.73), 11(31.83), and 12(33.08 min). Comparison of the retention times and EI and CI mass spectra of the fourth and fifth peaks of the extracts with those of synthetic *Z*8-12:Ac and

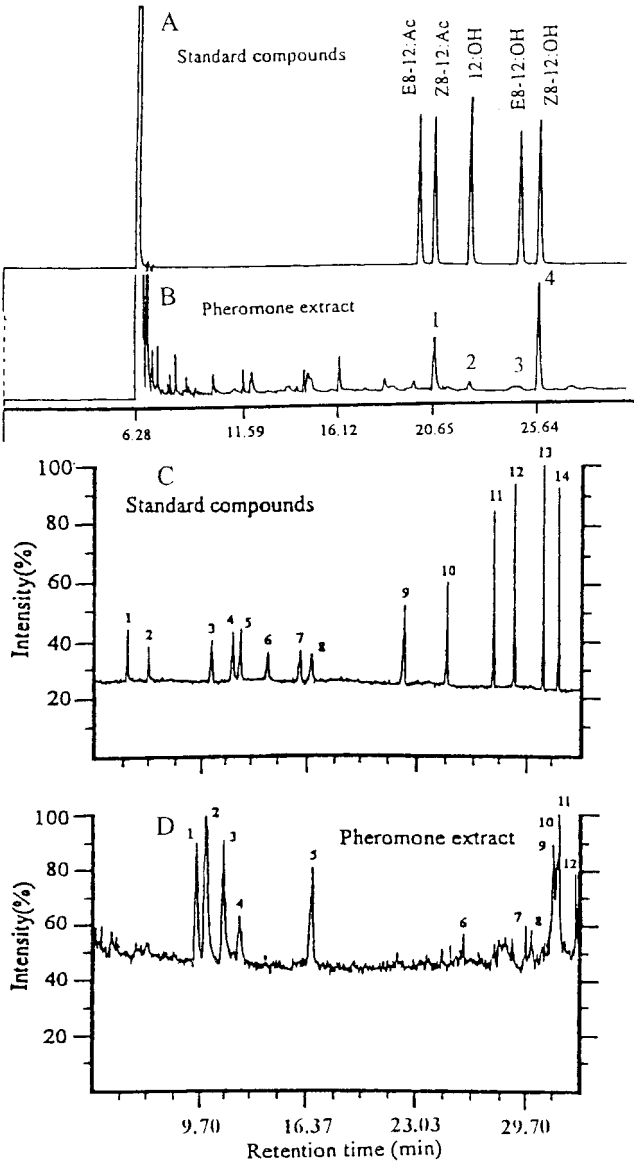

FIG. 1. Comparative GC (A, B) and GC-MS (C, D) chromatograms of pheromone extracts produced by females of *Eucosma notanthes* and standard compounds. Fourteen standard compounds are shown as peaks 1 to 14 in C :1 (10:Ac), 2 (10:OH), 3 (12:Ac), 4 (*E*8-12:Ac), 5 (*Z*8-12:Ac), 6 (12:OH), 7 (*E*8-12:OH), 8 (*Z*8-12:OH), 9 (14:Ac), 10 (14:OH), 11 (16:Ac), 12 (16:OH),13 (18:Ac) and 14(18:OH).

TABLE 1. CI MASS SPECTRAL DATA FOR THE FOURTH AND FIFTH PEAKS OF *Eucosma notanthes* PHEROMONE EXTRACTS AND STANDARD COMPOUNDS OF *Z*8-12:AC AND *Z*8-12:OH

Compound	Source	Mass spectral data, *m/z* (Intensity, %)
*Z*8-12:Ac	Synthetic	227($M+1^+$, 12.31), 165(9.23), 137(9.23), 123(21.54), 111(70.77), 97(78.46), 81(81.54), 69(100), 55(73.85), 43(23.08)
	Natural (peak 4)	227($M+1^+$, 5.88), 165(2.94), 151(2.94), 137(5.88), 123(14.71), 109(38.24), 95(61.76), 81(94.12), 67(100), 55(44.12), 43(8.82)
*Z*8-12:OH	Synthetic	185($M+1^+$, 2.60), 173(1.30), 165(1.30), 137(5.19), 123(18.18), 109(48.05), 95(67.53), 81(76.62), 69(100), 55(89.61), 41(74.03)
	Natural (peak 5)	185($M+1^+$, 1.11)), 173(1.11), 165(1.11), 149(1.11), 141(1.11), 137(5.56), 123(14.44), 109(38.89), 95(64.44), 91(4.44), 85(2.22), 81(92.22), 71(4.44), 67(100), 55(68.89), 43(8.89)

*Z*8-12:OH suggested that peak 4 and 5 were *Z*8-12:Ac and *Z*8-12:OH, respectively (Table 1). The EI mass spectra of *Z*8-12:Ac have two characteristic peaks, one with $m/z = 61$, which is a typical fragmentation peak of acetates, ($AcOH_2^+$), and the other with $m/z = 166$, which corresponds to $(M\text{-}AcOH)^+$. In contrast, the EI mass spectra of *Z*8-12:OH do not show any peak with $m/z = 61$ ($AcOH_2^+$). Therefore, it can be differentiated from acetate to alcohol. The results of our EI mass spectra of peak 4 and 5 are consistent with *Z*8-12:Ac and *Z*8-12:OH. The CI mass spectra of *Z*8-12:Ac and peak 4 both have a mother molecular ion peak with $m/z = 227$ ($M+1^+$) and all identical fragmentation patterns (Table 1). Similarly, the CI mass spectra of *Z*8-12:OH and peak 5 also have a mother molecular peak with $m/z = 185$ ($M+1^+$) and are consistent with the spectral data (Table 1). These data indicate that peak 4 corresponds to *Z*8-12:Ac and peak 5 to *Z*8-12:OH. The total amounts of *Z*8-12:Ac and *Z*8-12:OH obtained from the extraction of 52,820 females were 63.37 and 169.32 μg, respectively. This is equivalent to a ratio of *Z*8-12:OH:*Z*8-12:Ac of 2.7.

Mass spectral analysis of DMDS derivatives resolved the isomer identification of the dodecenyl acetate and dodecenol. Comparison with the data from Buser et al. (1983) and Leonhardt and DeVilbiss (1985), our derivatized standards showed the diagnostic peaks to be [M^+320 (29.2%), A^+103 (2.1%), B^+217 (64.4%)] for *Z*8-12:Ac at a retention time of 27.77 min; [M^+320 (25.2%), A^+103 (2.0%), B^+217 (61.9%)] for *E*8-12:Ac at 28.03 min; [M^+278 (44.7%), A^+103 (2.5%), B^+175 (29.6%)] for *Z*8-12:OH at 25.23 min; and [M^+278 (39.3%), A^+103 (2.6%), B^+175 (28.1%)] for *E*8-12:OH at 25.53 min. The derivatives of two components from the pheromone gland extracts also gave diagnostic peaks of [M^+320 (31.7%), A^+103

(2.2%), B^+217 (69.0%)], at a retention time of 27.78 min; and [M^+278 (39.7%), A^+103 (2.3%), B^+175 (27.5%)], at 25.30 min, confirming their identities as *Z*8-12:Ac and *Z*8-12:OH, respectively.

Field Tests. In the initial comparison of three isomers, *Z*7-12:Ac, *Z*8-12:Ac and *Z*9-12:Ac, as trap lures, the greatest numbers of *E. notanthes* males were captured in traps baited with *Z*8-12:Ac. Other isomers either failed to capture any male or the number of males captured was less than that in unbaited traps (ANOVA $F = 3.96$, $df = 79$, $0.01 < P < 0.001$) (Figure 2A). The total number of *E. notanthes* males captured was 134.

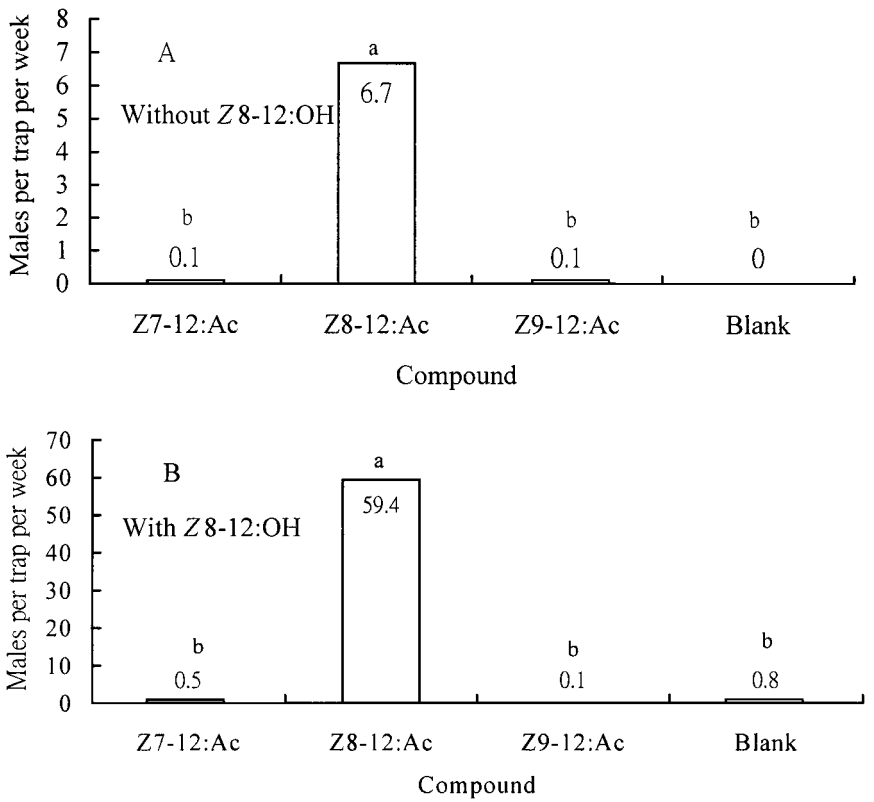

FIG. 2. Mean numbers of male *Eucosma notanthes* moths captured in carambola orchards in traps baited with three isomers, *Z*7-12:Ac, *Z*8-12:Ac, and *Z*9-12:Ac, alone (A) or with equal amount *Z*8-12:OH (B). Experiments were conducted at Changhua, Taiwan, on the following dates: experiment A, July 2–August 6, 1997; experiment B, August 6–September 10, 1997. Bars with the same letter are not significantly different by Duncan's multiple range test ($P = 0.05$).

In the second experiment, where three isomers, *Z*7-12:Ac, *Z*8-12:Ac and *Z*9-12:Ac, were mixed individually with *Z*8-12:OH in ratio of 1 : 1. The greatest numbers of *E. notanthes* males were captured in traps baited with *Z*8-12:Ac and *Z*8-12:OH. In the other two mixtures, the numbers of males captured were nearly 0 and not different from those in unbaited traps (ANOVA $F = 31.41$, $df = 79$, $P < 0.001$) (Figure 2B). The total number of males captured in this experiment was 1,214.

In the third experiment, in which *Z*8-12:Ac and *Z*8-12:OH were compared, the greatest numbers of males were captured in traps baited with *Z*8-12:Ac, ranging from 13 to 208 males/trap/week (mean 60.1), while those captured with *Z*8-12:OH and in the blank were only 1.1 and 0 males/trap/week, respectively (ANOVA $F = 15.4$, $df = 35$, $P < 0.001$) (data not shown). The total number of males captured was 734.

In the fourth experiment, in which comparison of various ratios of *Z*8-12:Ac and *Z*8-12:OH were made, the greatest numbers of males were captured in traps baited with *Z*8-12:Ac and *Z*8-12:OH at a load ratio of 100 : 100. Significant numbers of males were also captured in traps baited with ratios of 100 : 1 and 100 : 200. Capture of males with the remaining ratios were rather small and did not differ from those in unbaited traps (ANOVA $F = 47.87$, $df = 119$, $P < 0.001$) (Figure 3A). The total number of males captured was 2,420.

In the fifth experiment, where the ratios of *Z*8-12:Ac and *Z*8-12:OH were 100 : 5, 100 : 10, 100 : 50, 100 : 100 and 100 : 150, the numbers of *E. notanthes* males captured in traps baited with a load ratio of 100 : 100 did not differ from those with 100 : 50 and 100 : 150, while they were greater than those captured in traps baited with two other load ratios of 100 : 5 and 100 : 10. (ANOVA $F = 12.69$, $df = 143$, $P < 0.001$) (Figure 3B). The total number of males captured was 2,115.

In the sixth experiment, where three ratios of *Z*8-12:Ac and *Z*18-12:OH were 100 : 100, 100 : 150, and 100:270, the numbers of *E. notanthes* males captured in traps baited with a load ratio of 100 : 100 did not differ from those with 100 : 150, while they were greater than those baited with 100 : 270. (ANOVA $F = 16.96$, $df = 99$, $P < 0.001$) (Figure 3C). The total number of males captured was 4,539.

In the last experiment, where *Z*8-12:Ac and *E*8-12:Ac were used, in ratios ranging from 100 : 0 to 0 : 100, the greatest numbers of males were captured in traps baited with a load ratio of 100 : 0. This was not greater than numbers of males captured in traps baited with these compounds at a load ratio of 99.5 : 0.5. Almost no moths was captured in traps baited with these compounds in other load ratios (ANOVA $F = 3.93$, $df = 253$, $P < 0.001$) (Figure 4). A total of 1,285 males were captured.

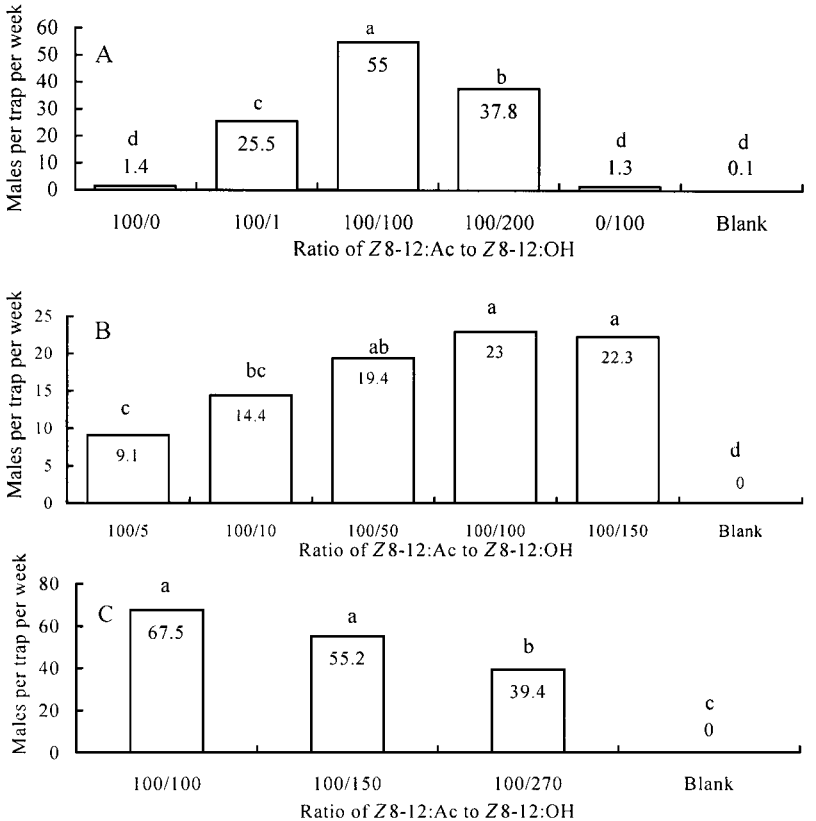

FIG. 3. Mean numbers of male *Eucosma notanthes* moths captured in traps baited with different blend ratios of *Z*8-12:Ac mixed with *Z*8-12:OH in carambola orchards. The first comparison (A) consisted of a broader range of ratios, while comparison of (B) and (C) consisted of a range of ratios closer to that found in the best efficiency lure for trapping carambola fruit borer. Experiments were conducted at Changhua, Taiwan, on the following dates: experiment A, March 19–April 23, 1997; experiment B, April 30–June 11, 1997; experiment C, December 22, 1999–February 10, 2000. Bars with the same letter are not significantly different by Duncan's multiple range test ($P = 0.05$).

DISCUSSION

Our results indicate that the sex pheromone of *E. notanthes* comprises two compounds, i.e., *Z*8-12:Ac and *Z*8-12:OH. Both compounds in combinations or *Z*8-12:Ac alone can capture males, indicating that these compounds are sex pheromone components of this species.

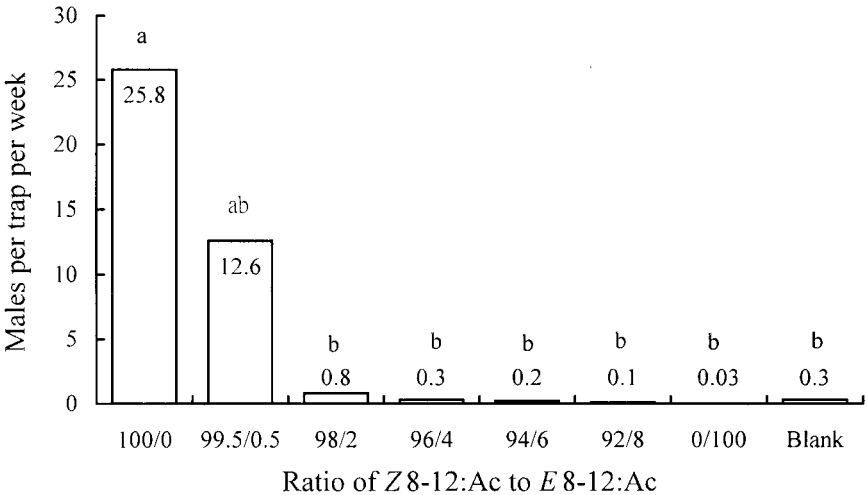

FIG. 4. Mean numbers of male *Eucosma notanthes* moths captured in traps baited with different blend ratios of *Z*8-12:Ac mixed with *E*8-12:Ac in carambola orchards at Changhua, Taiwan, from August 1 to November 11, 1996. Bars with the same letter are not significantly different by Duncan's multiple range test ($P = 0.05$).

The compound, *Z*8-12:Ac, is an attractant for more than 40 insect species, and has been found in females of three species, *Cryptophlebia leucotreta, Grapholita molesta and Hedya nubiferana*, in which it was found with other components including E8-12:Ac, 12:OH, 12:Ac, E5-12:Ac, and *Z*8-12:OH. However, only *Z*8-12:OH is reported to be an attractant of four insect species, and was identified as a sex pheromone component for the Oriental fruit moth, *G. molesta* (Kydonieus et al., 1982). The sex pheromone components of *G. molesta* have been reported to be *Z*8-12:Ac and *E*8-12:Ac, and *Z*8-12:OH and 12:OH (Roelofs et al., 1969; Cardé et al., 1979; Lacey and Sanders, 1992). In this study, two of these four components, i.e., *Z*8-12:Ac and *Z*8-12:OH, were identified as sex pheromone components of *E. notanthes.* Ratios of *Z*8-12:Ac and *Z*8-12:OH ranging from 1 : 0.5 to 1 : 1.5 were more attractive to *E. notanthes* males in orchards, whereas the ratio of these two compounds was 1 : 2.7 in hexane extracts of sex pheromone glands. A concentration of 0.5% or more of *E*8-12:Ac inhibited attraction to *E. notanthes* by the lures containing *Z*8-12:Ac, while 6–7% and 2.2% of *E*8-12:Ac was active as a pheromone component with *Z*8-12:Ac in attracting *G. molesta* and the lesser apple worm, *Grapholita prunivora*, respectively. However, when the amount of E8-12:Ac reached 23% in lures, the trap catch to males of both species decreased (Roelofs and Cardé, 1974). Therefore, isomeric purity of *Z*8-12:Ac is important for attractiveness of lures to *E. notanthes.*

In conclusion, we identified two compounds, *Z*8-12:Ac and *Z*8-12:OH, to be sex pheromone components of *E. notanthes*. Furthermore, based on field tests, *Z*8-12:Ac is regarded as the main component, while *Z*8-12:OH per se does not attract males.

Abstract—The brinjal fruit and shoot borer, *Leucinodes orbonalis* is the major pest of eggplant in South Asia. Analysis of female pheromone gland extracts prepared from insects of Indian and Taiwanese origin confirmed (*E*)-11-hexadecenyl acetate (E11-16:Ac) as the major pheromone component with 0.8 to 2.8% of the related (*E*)-11-hexadecen-1-ol (E11-16:OH), as previously reported from Sri Lanka. The average quantity of E11-16:Ac extracted per female was estimated to be 33 ng, with a range of 18.9 to 46.4 ng when collected 2 to 3 hr into the scotophase. In field trials conducted in India, blends containing between 1 and 10% E11-16:OH caught more male *L. orbonalis* than E11-16:Ac alone. At the 1000 μg dose, on white rubber septa, addition of 1% E11-16:OH to E11-16:Ac was found to be more attractive to male *L. orbonalis* than either 0.1 or 10% E11-16:OH. Trap catch was found to be positively correlated with pheromone release rate, with the highest dose tested, 3000 μg, on white rubber septa catching more male moths than lower doses. Field and wind tunnel release rate studies confirmed that E11-16:OH released from white rubber septa and polyethylene vials at approximately twice the rate of E11-16:Ac and that the

*To whom correspondence should be addressed.

0098-0331/01/0900-1867$19.50/0

release rate of both compounds was doubled in polyethylene vials compared to white rubber septa. This difference in release rate was reflected in field trials conducted in Bangladesh where polyethylene vial dispensers caught more male moths than either black or white rubber septa, each loaded with the same 100 : 1 blend of E11-16:Ac and E11-16:OH in a 3000 μg loading.

Key Words—*Leucinodes orbonalis*, brinjal, sex pheromone, (*E*)-11-hexadecenyl acetate, (*E*)-11-hexadecen-1-ol.

INTRODUCTION

The brinjal fruit and shoot borer, *Leucinodes orbonalis* Guenée (Lepidoptera: Pyralidae: Pyraustinae) is the major insect pest of eggplant, *Solanum melongena*, throughout Asia (Purohit and Khatri, 1973; Kuppuswamy and Balasubramanian, 1980; Allam et al., 1982). Larvae of *L. orbonalis* bore into shoots during the vegetative growth stage and later into flowers and fruits rendering fruit unfit for human consumption. Larvae block their bore holes with frass which protects them from natural enemies and most topically applied insecticides. Indigenous parasitoids of *L. orbonalis* have been recorded, notably *Trathala flavoorbitalis* Cameron (Hymenoptera: Ichneumonidae), *Eriborus argenteopilosus* Cameron (Hymenoptera: Ichneumomidae), *Phanerotoma* sp. (Hymenoptera: Braconidae) and *Campyloneura* sp. (Diptera: Cecidomyiidae) (Tewari and Krishna Moorthy, 1984; Tewari and Sardana, 1987). However, under field conditions, the level of parasitism recorded is often low (<2%) (Srinivasan, 1994), in part because of exposure to excessive amounts of insecticide used for control of *L. orbonalis*.

Eggplant is regarded as a cheap vegetable, available throughout most of the year, but production is seriously affected in many parts of the Indian sub continent because of the high cost and low efficacy of insecticide needed to ensure production of a viable crop. In West Bengal, for example, insecticide applications frequently exceed three per week. Alternative control strategies are needed but, to be effective, they require a sound understanding of the biology and ecology of the insect. As part of this process the need for an adult population monitoring system was recognized by the authors.

Adult *L. orbonalis* are not attracted to light traps but Zhu et al. (1987), working with insects from China, identified (*E*)-11-hexadecenyl acetate (E11-16:Ac) as the major component of the female sex pheromone and suggested that it was attractive to male moths in the field, although no data were presented. Subsequently, Attygalle et al. (1988) confirmed the presence of E11-16:Ac in calling virgin females using insects from Sri Lanka and, in addition, found trace amounts of (*E*)-11-hexadecen-1-ol (E11-16:OH). However, they did not report the results of any field studies to ascertain the behavioral significance of either of these two compounds. This paper reports the results of laboratory and field work

to confirm the composition of the pheromone, and to develop an effective synthetic equivalent for use in monitoring male *L. orbonalis*.

METHODS AND MATERIALS

Insect Material. Larvae were field-collected from eggplant fruit in West Bengal and Andhra Pradesh, India. Infested fruits were placed in pupation dishes filled with damp sand. Mature larvae exited the fruit and dropped into the sand where they pupated. Pupae were recovered by sieving and dispatched by air to NRI. On arrival, pupae were placed individually in Pyrex test tubes sealed with cotton wool and placed in a room maintained under a reversed light-dark cycle of 12L : 12D at 26°C and 22°C, respectively and 60% relative humidity. Laboratory-reared insects dispatched to NRI from the Asian Vegetable Research and Development Centre, Taiwan, were treated in a similar manner.

Pheromone Collection. Pheromone gland extracts were prepared 2 and 3 hr into the scotophase using 1 and 2 day old virgin female moths, by applying light pressure with forceps on the abdominal tip of female moths it was possible to evert the ovipositor and pheromone gland. The gland and exposed abdominal tip were excized with microscissors into a microvial containing hexane (50 μl). Batches of up to 10 ovipositors were prepared and stood at room temperature for 10 min before transferring the supernatant to a new microvial using a microsyringe (10 μl, Scientific Glass Engineering Ltd., Australia) and stored at -20°C.

Gas Chromatography (GC). GC analyses of pheromone gland extracts and pheromone dispensers were conducted on a Carlo Erba Mega Series 5300 instrument fitted with two Grob split/splitless injectors (240°C) and flame ionization detector (FID) (250°C). Fused silica capillary columns were used throughout the study, coated with non-polar CP-Sil 5CB (30 m $\times$ 0.32 mm; 0.25 μm; Chrompack, UK), polar CP-Wax 52CB (30 m $\times$ 0.32 mm; 0.25 μm; Carbowax 20M equivalent; Chrompack, UK) and polar DB23 (30 m $\times$ 0.25 mm; 0.25 μm; 1:1 mixture of chemically bonded methyl- and cyanopropyl-polysiloxane, J&W Scientific, Folsom CA, USA). The carrier gas was helium with an inlet pressure of 40 kPa.

All injections were made with the split value closed for 40 sec onto CP-Sil 5CB and CP-Wax 52CB columns held at 50°C for 2 min and then programmed at 20°C/min to 80°C and then at 5°C/min to 240°C. Confirmation of the isomeric composition of pheromone components was obtained by GC analysis of pheromone gland extracts on a DB23 column that was held at 70°C for two min after injection, and temperature programmed at 20°C/min to 120°C, and then at 4°C/min to 240°C. GC retention times of compounds identified in pheromone gland extracts are quoted as retention indices (RI) relative to the retention times of straight-chain hydrocarbons; thus, for example, hexadecane = 1600 RI.

Electroantennographic Detection (EAD). Linked GC-EAD analyses were carried out as described by Cork et al. (1990) by splitting half the GC effluent

to the FID and the other half to a silanized glass reservoir. Column effluent was expelled from the reservoir at 17 sec intervals for 3 sec in a stream of nitrogen (500 ml/min) over the EAD preparation. The series of EAD responses generated were then compared to identify which were significantly larger than background responses in order to determine the retention times of EAD-active compounds. GC conditions were as described above.

Mass Spectrometry (MS). Electron impact (EI) mass spectra of compounds in pheromone gland extracts were obtained from a Finnigan MAT Ion Trap Detector, model 700, interfaced with a Carlo Erba Mega Series 5160 GC under continuous ion monitoring between m/z 29–300 at 220°C. Chemical ionization (CI) mass spectra were obtained with the same equipment, but monitoring ions between m/z 60–300 with the Ion Trap set at 200°C and using *iso*-butane as the reagent gas. GC conditions were as described above except that the GC was temperature programmed at 6°C/min from 50 to 240°C with the CP-Sil 5CB column, and at 20°C/min from 50 to 100°C and then at 5°C/min to 250°C with the CP-Wax 52CB column.

Synthetic Compounds. Monounsaturated alcohols and acetates were obtained by standard Wittig and acetylenic coupling reactions (Henrick, 1977) or purchased from Shin Etsu Chemical Co. (Tokyo, Japan). Compounds used for analytical studies contained less than 1% of the opposite stereoisomer, while (*E*)-11-hexadecenyl acetate and (*E*)-11-hexadecen-1-ol used for field studies each contained 0.46% of the *Z*-isomer.

Pheromone Dispensers. Pheromone dispensers used in field and laboratory studies were prepared from white rubber septa (Sigma-Aldrich Chemical Company, Gillingham, UK, catalogue No. Z10,072-2), polyethylene vials (25 mm length, 8 mm diameter and 1.5 mm wall thickness, Just Plastics Ltd., UK) or black rubber septa (Biological Control Research Laboratories Ltd., Bangalore, India) impregnated with 0.1 ml of hexane solution containing the synthetic pheromone blend and an equivalent weight of 2,6-di-*tert*-butyl-4-methylphenol as antioxidant.

Field Trials. Field trials were conducted in India in plots of eggplant at the fruiting stage of development at the NARDI research farm, Wargal, 45 km north of Hyderabad, Andhra Pradesh and farmers' fields in the North and South 24-Paganas Districts, West Bengal. In Bangladesh, field trials were conducted in farmers' fields adjacent to the Bangladesh Agricultural Research Institute (BARI) Regional Agricultural Research Station, Jessore. No pesticides were applied for control of *L. orbonalis* at the NARDI research farm, although a foliar application of monocrotophos (0.07%) was made to seedlings before planting to protect them against sucking pests. In West Bengal and Jessore, pesticides were applied at the farmers' discretion, typically between 2 and 6 times per week.

At the NARDI research farm, insects were trapped using yellow plastic funnel traps (Ecomax, India), while white sticky delta traps (Agrisense BCS Ltd., Pontypridd, UK) were used in West Bengal and Jessore. Traps were attached at the

top and, where possible, the side of inverted L-shaped metal or wooden supports to restrict movement. Trap height was periodically adjusted to keep them at crop height, which reached between 1–1.5 m at maturity. Insects trapped in the funnel traps were killed with carbaryl impregnated wettable powder. Treatments in a replicate were randomized with at least 10 m between treatments and 50–100 m between replicates at the NARDI research farm. In West Bengal treatments were separated by 20 m and replicates placed in different villages (>2 km distant). In Jessore, replicates were placed in lines with 10 m between treatments and 15–20 m between replicates. The position of treatments within a replicate was rotated in a clockwise direction every working day at the NARDI research farm and Jessore when trap catches were recorded and insects discarded. For each rotation, trap catch data from the NARDI research farm and Jessore were combined, averaged, and statistically analyzed by analysis of variance (ANOVA) after transforming to log $(x + 1)$. Trap catch data from West Bengal were collected twice weekly but traps were not rotated. Data were converted to catch per trap per night, transformed to log $(x + 1)$ and analyzed by ANOVA. Lures were not changed throughout the duration of each trial at either location. Significant differences in treatment means at the 5% level or lower were compared by Newman-Keuls multiple range test (Statgraphics, Version 2.00).

Release Rate Measurements. White rubber septa loaded with 100, 300 and 1000 μg each of a 100 : 1 blend of E11-16:Ac and E11-16:OH were placed in a shaded position at the RKM research farm, West Bengal with averaged minimum and maximum temperatures of 22.9°C (range, 14.5 to 28.9°C) and 32.9°C (range 24 to 38.4°C), respectively. Septa were randomly collected from the field in batches of two at different time intervals and stored at 0°C before being hand-carried to NRI for analysis of residual pheromone.

Similarly, septa and polyethylene vials loaded with a 1:1 mixture of E11-16:Ac and E11-16:OH were aged in a wind tunnel (WT) at NRI at 27°C with a linear flow-rate of 5 km/hr. Dispensers aged in the WT were collected as described above for field samples and stored at -20°C. In order to extract pheromone from field and WT exposed dispensers they were immersed overnight at room temperature in a hexane solution of pentadecyl acetate (5 ml, 1 mg/ml) as an internal standard. Compounds were quantified by GC, under conditions described above, for analysis of sex pheromone gland extracts on a CP-Wax 52CB column.

RESULTS

Pheromone Identification. GC-EAD analyses of female ovipositor extracts prepared from insects of Indian and Taiwanese origin on both CP-Wax 52CB and CP-Sil 5CB GC columns indicated the presence of two EAD-active compounds. EI-MS analysis using a CP-Sil 5CB GC column confirmed the major GC peak

eluting at 1977 RI was consistent with a hexadecenyl acetate isomer showing characteristic ions at m/z 61 for an acetate functionality and m/z 222 consistent with M − 60. The anticipated hexadecen-1-ol isomer (Attygalle et al., 1988) was not observed. Since the possibility existed that trace quantities of hexadecen-1-ol were being adsorbed irreversibly onto the GC column the analyses were repeated using the CP-Wax 52CB column in CI mode. Under these conditions the hexadecenyl acetate showed characteristic ions at m/z 222 (M − 60) and m/z 283 (M + 1) and identical fragmentation pattern to synthetic (*E*)-11-hexadecenyl acetate (E11-16:Ac). Similarly, the hexadecen-1-ol isomer was observed with significant ions at m/z 241 (M + 1) and identical fragmentation pattern and GC retention time to synthetic (*E*)-11-hexadecen-1-ol (E11-16:OH). The average quantity of hexadecenyl acetate per female moth was estimated to be 33 ng, with a range of 18.9 to 46.4 ng per female moth. Trace quantities of hexadecyl acetate (16:Ac) were also observed by linked GC-MS analysis in EI mode. The mean ratio of hexadecyl acetate : hexadecenyl acetate : hexadecen-1-ol was 2.65 : 100 : 1.78 although the proportion of E11-16:OH to E11-16:Ac was higher in insects from Taiwan compared to those from India (Table 1). GC retention times of the natural compounds were compared with *E* - and *Z*-isomers of the related synthetic compounds on two polar and one non-polar column that confirmed, in each case, the natural compounds were (*E*)-11-isomers (Table 1).

Release Rate Studies. Under field conditions in West Bengal release rate studies with white rubber septa loaded with 100, 300 and 1000 μg of E11-16:Ac and 1% E11-16:OH indicated that approximately 86, 89 and 100% of E11-16:Ac, respectively remained after 40 days. After 90 days 73, 80 and 97% respectively remained, but the quantity of E11-16:OH was too low to measure accurately. In related wind tunnel studies with a 1 : 1 blend of E11-16:Ac and E11-16:OH at a dose of 100 μg each on white rubber septa and polyethylene vials, 92 and 62% E11-16:Ac and 76

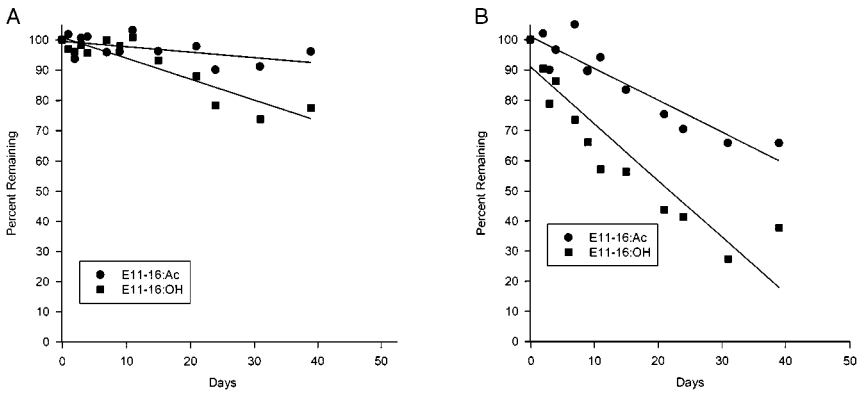

FIG. 1. Release of E11-16:Ac and E11-16:OH from white rubber septa (A) and polyethylene vials (B) in a wind tunnel (27°C, wind speed 5 km/h) with an initial loading of 100 μg per compound.

and 18% E11-16:OH, respectively, remained after 40 days exposure (Figures 1A and 1B).

Field Trials in India and Bangladesh. Trial 1 was undertaken at the NARDI research farm to determine the effect of adding E11-16:OH to E11-16:Ac had on attraction of male *L. orbonalis*. A range of blends was tested which contained between 0 and 10% E11-16:OH to E11-16:Ac at a 100 μg dose loaded on white rubber septa. The results (Table 2) showed that only blends with between 1 and 10% E11-16:OH caught more male moths than the unbaited trap (ANOVA, $F = 73.0, P < 0.001$). In order to optimize further the ratio of E11-16:Ac to E11-16:OH,

Bengal and at the NARDI research farm compared the relative attractiveness of different doses of the 100:1 blend of E11-16:Ac and E11-16:OH on white rubber septa to male *L. orbonalis*. Results from West Bengal (Table 4) suggested that the catch of male *L. orbonalis* was proportional to dose over the range tested (100 to 3000μg) despite low catches (ANOVA, $F = 3.47$, $P = 0.019$). This finding was confirmed by results from Andhra Pradesh where a clear relationship between trap catch and dose of pheromone was apparent (ANOVA, $F = 18.56$, $P < 0.001$).

The effect of dispenser type on attraction of male *L. orbonalis* was tested in farmers' fields near Jessore, Bangladesh (Trial 4). Three dispenser types were tested, polyethylene vials, white and black rubber septa. Each dispenser was loaded with the 100:1 blend of E11-16:Ac : E11-16:OH at a 3000 μg dose. The results (Table 5) confirmed that the polyethylene vials caught more male *L. orbonalis* than either white or black rubber septa at the loading tested, although both white and black septa caught more male *L. orbonalis* than the unbaited trap (ANOVA, $F = 9.03$, $P < 0.001$).

DISCUSSION

This study confirmed and extended the results of Zhu et al. (1987) and Attygalle et al. (1988). EAD-active compounds present in female sex pheromone gland extracts of *L. orbonalis* were confirmed as E11-16:Ac and E11-16:OH in the approximate ratio of 50:1 by GC-MS analysis under EI and CI ionization modes. In addition, trace quantities of 16:Ac were observed that constituted between 2 and 3.3% of E11-16:Ac. Because 16:Ac did not elicit an EAD response in linked GC-EAD analyses it was not considered to be behaviorally-active and so was not field tested.

Zhu et al. (1987) suggested that E11-16:Ac alone was attractive to male moths although they did not publish details of the field work. In this study, catches in traps baited with E11-16:Ac alone did not differ from captures in unbaited trap,

but addition of E11-16:OH increased the catches. However, the data suggested that the optimal ratio of E11-16:Ac to E11-16:OH may be dose-dependent, although further work is required to confirm this observation. The highest trap catch was obtained with the addition of 1% E11-16:OH to E11-16:Ac when presented at a 1000 μg dose in rubber septa which was consistent with the ratio of compounds found in ovipositor extracts.

Release rate data from wind tunnel studies suggested that E11-16:OH was released at approximately twice the rate of E11-16:Ac from both white rubber septa and polyethylene vials, and that the release rates of both compounds were doubled in polyethylene vials compared to rubber septa. The wind tunnel studies suggested that lures prepared from either rubber septa or polyethylene vials with a 100 μg loading of pheromone would have a field longevity in excess of one month. Related studies conducted in the field confirmed this result and suggested that loading in excess of 1000 μg of pheromone should have a field-life that substantially exceeds the four-month cropping season. However, over the winter period when night-time temperatures can drop below 10°C, polyethylene vials may prove to be more efficacious because of higher intrinsic release rates. Of concern was the observed change in ratio of pheromone components over time although its effect on attractiveness of the lures was not tested in this study.

While *L. orbonalis* is by no means the only pest of eggplant, other insect pests, such as gall midge, *Asphondylia* sp. (Diptera: Cecidomyiidae), ash weevils, *Myllcerus discolour* Boheman and *M. subfasciatus* Guerin (Coleoptera: Curculionidae), leaf feeding beetles, *Epilachna vigintioctopunctata* (Fabricius) (Coleoptera: Coccinellidae), and red spider mite, *Tetranychus curcurbitae* (Acari: Tetranychidae) rarely attain economic importance. However, even as early as 1980, Kuppuswamy and Balasubramanian (1980) noted that applying synthetic pyrethroids for control of *L. orbonalis* on eggplant significantly increased the incidence of mites. Given the heavy dependence farmers have on insecticides for control of *L. orbonalis*, alternative control strategies are urgently needed. However, poor levels of parasitism by indigenous natural enemies recorded from *L. orbonalis* and low levels of host-plant resistance so far identified (Dhankhar, 1988) have greatly hampered development of an effective IPM strategy. Nevertheless, field trials are now underway in South Asia to evaluate pheromone-baited traps together with other control options, such as removal and destruction of infested plant material, as the basis for an efficacious means of controlling *L. orbonalis* that is both sustainable and economic to the producer.

(Received January 26, 2001; accepted April 28, 2001)

Abstract—The behavioral activity of some trifluoromethyl ketones (TFMKs) as inhibitors of the pheromone activity of the corn stalk borer *Sesamia nonagrioides* (Lef.) (Lepidoptera: Noctuidae) is reported. The most closely-related analogue to the pheromone tested, (*Z*)-11-hexadecenyl trifluoromethyl ketone (Z11-16:TFMK), elicited a significant decrease in the number of male catches in traps baited with mixtures with the pheromone in 1:1 and 10:1 ratios in comparison to the pheromone alone. The *E* isomer of the analogue as well as two highly hydrated ketones, 3-octylthio-1,1,1-trifluoropropan-2-one (OTFP) and 1,1-difluoropentadecyl trifluoromethyl ketone, were inactive. Conversely, the saturated TFMKs *n*-dodecyl trifluoromethyl ketone and, particularly, *n*-hexadecyl trifluoromethyl ketone induced a synergistic effect when mixed with the synthetic pheromone in 10:1 ratio. However, in a wind tunnel these chemicals did not elicit any differential effect on flying moths attracted to a source containing a 10:1 blend of the analogue and the pheromone. In a dual choice bioassay with two dispensers, containing the pheromone alone, and mixtures of Z11-16:TFMK and the pheromone and separated 5 cm apart, males showed no particular preference for either dispenser. The ketone mixture, however, induced moths to execute erratic flights with frequent crosswind counter-turns and intersections with plume boundaries. The total number of contacts with the source were reduced when a control dispenser was paired with a dispenser containing Z11-16:TFMK and pheromone. Z11-16:TFMK and OTFP showed little toxicity

on mice with a LD_{50} of 1 g/kg after the 6th day of treatment. For comparitive purposes, the major component of the pheromone, Z11-16:Ac, displayed a LD_{50} of 5 g/kg 6 days after application. Our results provide additional information about the activity of the TFMKs, which might be useful for the utilization of these chemicals in future pest control studies.

Key Words—Inhibition, sex pheromone, pheromone inhibitor, *Sesamia nonagrioides*, corn stalk borer, Lepidoptera, Noctuidae, field tests, trifluoromethyl ketones, pheromone inactivation.

INTRODUCTION

Chemical communication in insects can be significantly affected by synthetic biologically-active compounds, related or not to their sex pheromones (Renou and Guerrero, 2000), consequently, many behavior-modifying chemicals have been considered as potentially useful pest control agents (Ridgway et al., 1990; Renou and Guerrero, 2000). Catabolism and inactivation of sex pheromones in insects is carried out by the action of enzymes (esterases, dehydrogenases, aldehyde oxidases) present in the male antennae (Vogt et al., 1985; Prestwich, 1987; Kasang et al., 1989) . Inhibition of these enzymes may lead to a decreased capability by the insect to detect new incoming pheromone molecules, and therefore a new approach to insect control can be envisaged (Prestwich, 1986).

The corn stalk borer *Sesamia nonagrioides* (Lef.) (Lepidoptera: Noctuidae) is a key pest of maize in the Mediterranean area (below 45°N parallel) and North Africa countries (Anonymous, 1979). Broad spectrum insecticides have been applied to control the pest but the results have been poor due to the endophitic habits of the pest, high costs and negative effects on secondary pests, such as aphids, mites and leafhoppers. The sex pheromone of the moth was identified in 1985 by Sreng et al. (Sreng et al., 1985) as a mixture of (*Z*)-11-hexadecenyl acetate (Z11-16:Ac) and (*Z*)-11-hexadecenol (Z11-16:OH). Later, Mazomenos (1989) reported two additional minor components, (*Z*)-11-hexadecenal (Z11-16:Ald) and dodecyl acetate (12:Ac), which improved the efficiency of the pheromone blend. An amended formulation based on a mixture of Z11-16:Ac, Z11-16:OH, Z11-16:Ald and 12:Ac in 77:8:10:5 was later developed by us (Sans et al., 1997). Utilization of the pheromone blend to control the pest in monitoring and mass trapping (Mazomenos et al., 1989) and mating disruption experiments (Perdiguer et al., 1992; Frérot et al., 1997) have been conducted but with relative success.

Trifluoromethyl ketones (TFMKs) are known as potent inhibitors of a number of esterases and proteases, such as acetylcholinesterase, chymotrypsin or human liver carboxylesterases (Gelb et al., 1985; Ashour and Hammock, 1987). They may also inhibit the antennal esterases present in insect olfactory tissues (Vogt et al., 1985; Prestwich and Streinz, 1988; Durán et al., 1993; Parrilla and Guerrero,

1994). In wind tunnel experiments, TFMKs were found to disrupt the orientation flight of *Spodoptera littoralis* and *S. nonagrioides* males to pheromone sources (virgin females or synthetic pheromone) (Bau et al., 1999). However, (*Z*)-1,1,1-trifluoro-14-heptadecen-2-one, a pheromone analogue of *Ostrinia nubilalis*, did not inhibit male attraction when it was coevaporated with pheromone in a wind tunnel assay (Klun et al., 1991). In the field, some TFMKs displayed inhibitory activity of the pheromone action on processionary males when mixed with the pheromone (Parrilla and Guerrero, 1994), but this type of effect was not confirmed on *S. nonagrioides* when (*Z*)-1,1,1-trifluoro-14-nonadecen-2-one, a structurally related analogue of the pheromone, was added to the natural attractant. In this case and unexpectedly, a synergistic effect on the number of catches was observed (Riba et al., 1994). These contradictory data indicate that the relationship between the antiesterase activity of TFMKs and their physiological and behavioral effects on pheromone communication is far from being completely understood, and therefore more work in this regard is needed. We report herein the behavioral activity in the laboratory and in the field of some TFMKs on the corn stalk borer as well as preliminary toxicity studies of these chemicals in mice.

METHODS AND MATERIALS

Insects. The corn stalk borer was reared in the laboratory on a slightly-modified artificial diet (Poitout and Bues, 1974). Pupae were sexed, placed in groups of 20–25 into 20 × 20 cm plastic boxes and maintained in a climatic chamber on a 16 : 8 L:D regime at 25 ± 1°C and 65 ± 10% relative humidity until emergence. Adults were provided with 10% sucrose solution, separated daily by age and kept on filter paper in plastic containers.

Chemicals. The fluoromethyl ketones tested include 3-octylthio-1,1,1-trifluoropropan-2-one (OTFP), *n*-dodecyl trifluoromethyl ketone (12:TFMK), *n*-hexadecyl trifluoromethyl ketone (16:TFMK), (*Z*)-11-hexadecenyl trifluoromethyl ketone (Z11-16:TFMK), (*E*)-11-hexadecenyl trifluoromethyl ketone (E11-16:TFMK) and 1,1-difluoropentadecyl trifluoromethyl ketone (15:PFMK) (Figure 1). They were prepared in our laboratory according to previously published procedures (Parrilla and Guerrero, 1994; Villuendas et al., 1994) except 15:PFMK (unpublished). The major component of the pheromone (*Z*)-11-hexadecenyl acetate, (Z11-16:Ac), was kindly provided by SEDQ, S.A.

Wind Tunnel Experiments. Assays were conducted in a glass tunnel of 180 × 55 × 50 cm, as previously described (Quero et al., 1995). The active space was visualized with the aid of a SO_3 smoke dispenser (Drägerwerk, Germany) and the illumination (2–5 lux) was obtained through a dimmed fluorescent red light. A video camera (Pulnix B/W TM50), linked to a JVC-SR306E video recorder and a Panasonic TC-14S1RC monitor, was placed at 135 cm above the tunnel

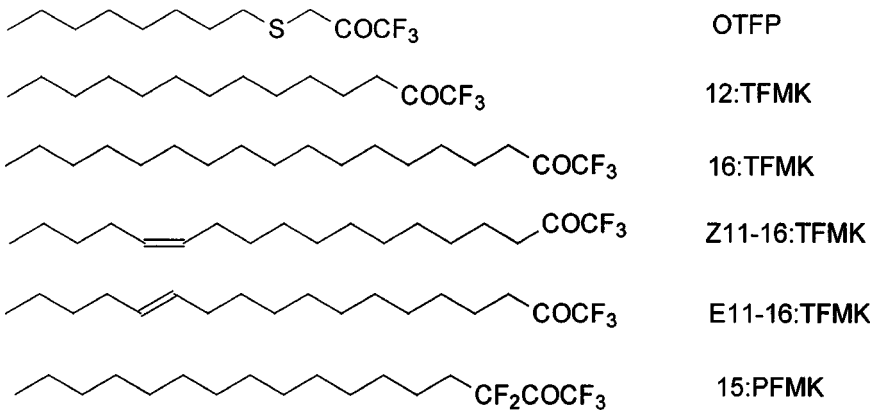

FIG. 1. TFMKs tested in wind tunnel assays and field tests against *S. nonagrioides*.

and in perpendicular position to minimize optical distortion of the flight. The camera allowed the recording of a flight path 130 cm long and 45 cm wide section of the tunnel and the video recordings were analyzed as already reported (Bau et al., 1999). The estimated cross wind dimension of the pheromone plume was 12 and 31 cm wide at 50 and 100 cm, respectively, from the source. Experiments were performed on individuals between the 3rd and the 7th h of the 2nd and 3rd scotophase. Moths were acclimatized to the wind tunnel conditions (temperature of the room 22 $\pm$ 1°C, 60 $\pm$ 10% relative humidity) for 30 min. Males were placed on a Petri dish, cut on the edge to facilitate take off of the moths, over a stainless steel jack 130 cm from the source and 18 cm from the top of the tunnel. Insects were allowed to respond for 5 min. Four types of behavior (wing fanning and taking flight TF; arrival to the middle of the tunnel HW; close approach to the lure CA; and contact with the source SC) were scored and compared with control insects. For out of plume parameters, only males which spent at least 20% of their total flight time outside the plume boundaries were considered. Flight parameters were determined on uninterrupted flights and only those males arresting at the source for a minimum period of 5 s were recorded as SC. Experiments were conducted in blocks including exposed and control insects, and statistical analysis (χ^2 homogeneity test, $P < 0.05$) was performed within every block. On each day of experimentation, three groups of 8–10 males flying towards a mixture of pheromone and trifluoromethyl ketone were compared with 10–14 control males. The attraction source was 0.1 μg of the pheromone blend (mixture of Z11-16:Ac, Z11-16:OH, Z11-16:Ald and 12:Ac in 77:8:10:5 ratio) (Sans et al., 1997). Just prior to the experiments, the required amount of attractant, dissolved in 10 μl of nanograde hexane, was applied to a brown female-shaped piece of cardboard used as dispenser. The solvent was allowed to evaporate and the dispensers were suspended 18 cm from the top and 40 cm from the upwind end of the tunnel. In the

dual choice tests, two dispensers, separated 5 cm apart from each other, were placed in parallel at the same distance from the release platform of the insects. For each flight track the following parameters were recorded: flight distance, flight duration, ground speed, turning frequency, track width, track angle, course angle and drift angle (Marsh et al., 1978), and analyzed for significance (*LSD* test, $P < 0.05$). The activity of the saturated 12:TFMK and 16:TFMK was tested by recording all types of behavior flying to a source consisting of mixtures of the analogue with the pheromone in 10:1 ratio compared to those elicited by the pheromone alone.

Field Tests. The experiments were conducted in infested maize fields of the Lleida province (northeastern Spain) during the 2nd and the 3rd generations of the insect. In the trials from September 2 to October 22 1998, the following compounds were tested: 12:TFMK, OTFP, Z11-16:TFMK and E11-16:TFMK. The field was divided into 4 independent blocks (replications), separated at least 50 m from each other. Funnel traps were hung at a height of 1.5 m and separated 25 m from each other within the block. Every block comprised 5 randomized treatments, those of the TFMKs and the synthetic pheromone, which had the same composition as that used in the wind tunnel experiments (see above). As dispensers, rubber septa were impregnated with mixtures of 0.1 mg of the synthetic pheromone and 1 mg of the inhibitor. Traps were rotated every week and the number of catches recorded. In 1999, the experiments were conducted from July 20 to October 15 and three TFMKs were tested: 12:TFMK, Z11-16:TFMK and 16:TFMK. The dispensers contained blends of the pheromone and the inhibitor in 1:1, 1:10 and 1:0.1 ratios, although 16:TFMK was not tested in mixtures with the synthetic attractant in the last ratio. The amount of pheromone was 0.1 mg in all cases. Three different blocks, separated 100 m apart from each other, were considered and each block comprised 9 randomized treatments, 8 mixtures of TFMK + pheromone and the pheromone alone. In the 2000 experiments, three different blocks with 8 treatments each were set up and the tests were conducted from July 26 to October 11. Baits contained mixtures of the fluoromethyl ketones Z11-16:TFMK, 16:TFMK and 15:PFMK with the pheromone in 1:1 and 10:1 ratios and the pheromone alone. The amount of pheromone was again 0.1 mg. All data were transformed ($\sqrt{x} + 0.5$) and analyzed for significance (Student's t-test, $P < 0.05$). In all experiments dispensers were replaced in the middle of the season flight.

Toxicology. Acute toxicity to vertebrates was determined orally on male and female Swiss mice (22–30 g). Test compounds (OTFP and Z11-16:TFMK) were diluted in corn oil and the appropriate volume of the solution to achieve a 500–1000 mg/kg dose (maximum 0.5 ml of solution per mouse) was introduced into the mouth of the animal, via a syringe equipped with a cannula for small animals. Mice were fed regular rodent diet and water, and weighed the day before treatment and for 7 consecutive days after injection or up to the day of death. Mortality was monitored daily during one week. Toxicity of the major pheromone

component Z11-16:Ac at doses of 500, 1000 and 5000 mg/kg was also determined for comparison purposes.

RESULTS

Wind Tunnel. S. nonagrioides males are delicate and sensitive to several environmental stimuli, such as type and shape of the dispenser, temperature and humidity. We have found that even under careful control and handling conditions the responses can be highly variable from day–to–day of experimentation. This variability induced us to establish a 50% threshold of control moths completing the behavioral sequence to validate the flight results of the day. When 10:1 mixtures of the saturated TFMKs (12:TFMK and 16:TFMK) with the synthetic pheromone blend were used in the source, the number of males displaying the different types of behavior were not significantly different regardless of the presence or absence of the analogue at the source (Figure 2). In this case, the track of the moths resembled that of the insects attracted to pheromone alone. A representative flight track of males flying towards a source containing a mixture of 100 ng of the pheromone blend and 1 μg of 12:TFMK relative to control (100 ng of the pheromone blend) is shown in Figure 3. The flight was quite straight with few counter-turns and intersections with the plume until the insect reached the proximity of the lure. The flight parameters of exposed and control insects were similar, the differences being

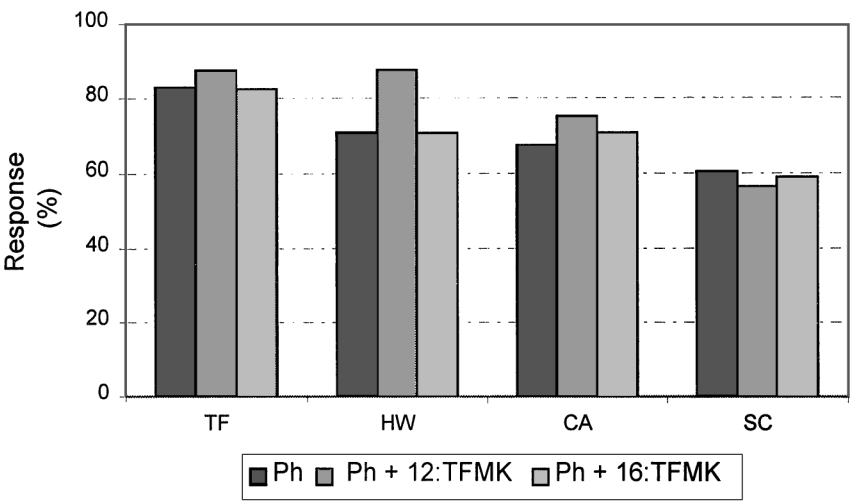

FIG. 2. Response of *S. nonagrioides* males in a wind tunnel to pheromone (Ph, $N = 58$) or to sources containing mixtures of 10 ng of the synthetic pheromone blend and 100 ng of 12:TFMK (Ph + 12:TFMK, $N = 32$) or 16:TFMK (Ph + 16:TFMK, $N = 34$).

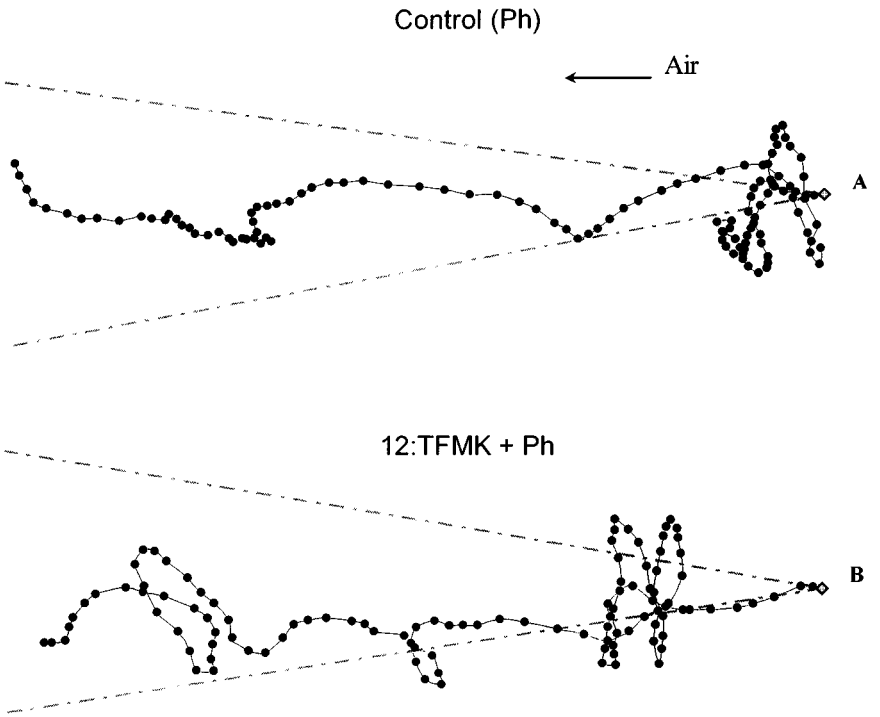

FIG. 3. Representative flight tracks of *S. nonagrioides* males flying upwind towards a dispenser containing a mixture of 100 ng of pheromone blend and 1 μg of 12:TFMK (bait B) relative to control (100 ng of pheromone, bait A). Black dots represent the insect positions at 0.1 s intervals.

statistically insignificant both when the insect was flying inside or outside the plume (Table 1). As expected, moths flying out of the plume displayed higher track width, track angle and course angle than insects flying inside the plume. The drift angle appeared higher but the difference was not significant (Table 1).

In the dual choice assay and in order to test whether the insects were able to discriminate between two overlapping plumes separated 5 cm at their origin, preliminary results showed that males were differently attracted to two lures baited with 100 ng and 1 μg of synthetic pheromone, respectively. Thus, while 17% ($N = 6$ out of 36) of insects were attracted to the lower-dose dispenser, 69% ($N = 25$ out of 36) contacted the source containing the higher dose. Baits with identical pheromone doses (100 ng) elicited no preference on the number of males contacting the source (36% and 43% of contacts in each bait, $N = 20$ and 24 out of 56, respectively) (control test, Figure 4). When serial doses of 1, 5 and 10 μg of Z11-16:TFMK were added to 100 ng of synthetic pheromone (treatment lure)

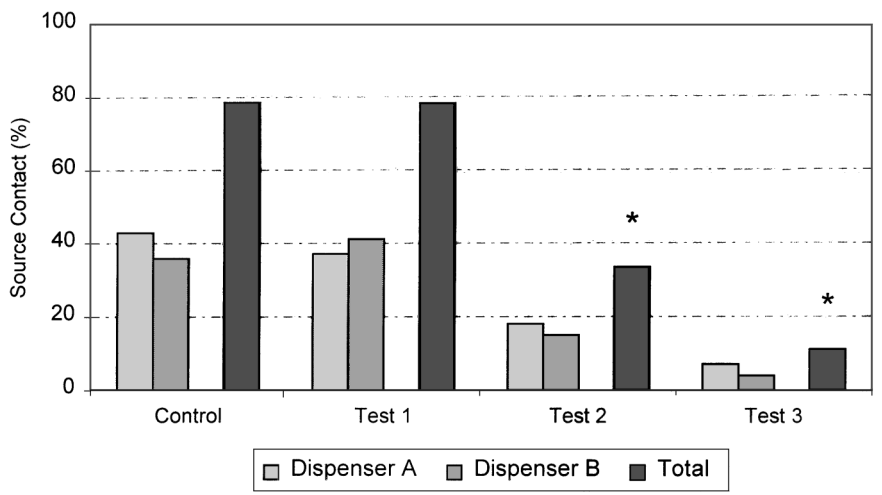

FIG. 4. Source contact behavior of *S. nonagrioides* males in dual choice tests of Z11-16: TFMK with the pheromone. In control test both dispensers contain 100 ng of the pheromone blend. Dispenser A contained 100 ng of pheromone in all cases. In tests 1–3, dispenser B contained a mixture of 100 ng of pheromone and 1, 5 and 10 μg of Z11-16:TFMK, respectively. Bar in black represents the sum of contacts of both dispensers in each test. The asterisk denotes significantly different values from control (χ^2 homogeneity test, $P < 0.05$).

relative to 100 ng of pheromone (reference lure), insects showed no particular preference for either source, irrespective of the amount of inhibitor present in the treatment lure. However, while no inhibition was noted when 1 μg of the inhibitor was present in the bait (78% of moths contact one source or the other vs 79% in the control experiment) (test 1, Figure 4), addition of 5 or 10 μg of the inhibitor elicited lower attraction of males to the source (33% of total number of contacts for 5 μg and 11% for 10 μg, $P < 0.05$) (tests 2–3, Figure 4). At the highest dose, only 1 and 2 insects out of 28 successfully contacted the treatment and the reference lure, respectively, while the percentage of insects arriving at the vicinity of the bait was 57% out of 93% that had taken flight. A representative flight track of a moth flying in this type of test vs a control insect is shown in Figure 5. The moths exhibited erratic progress toward the source, flying across the wind with a

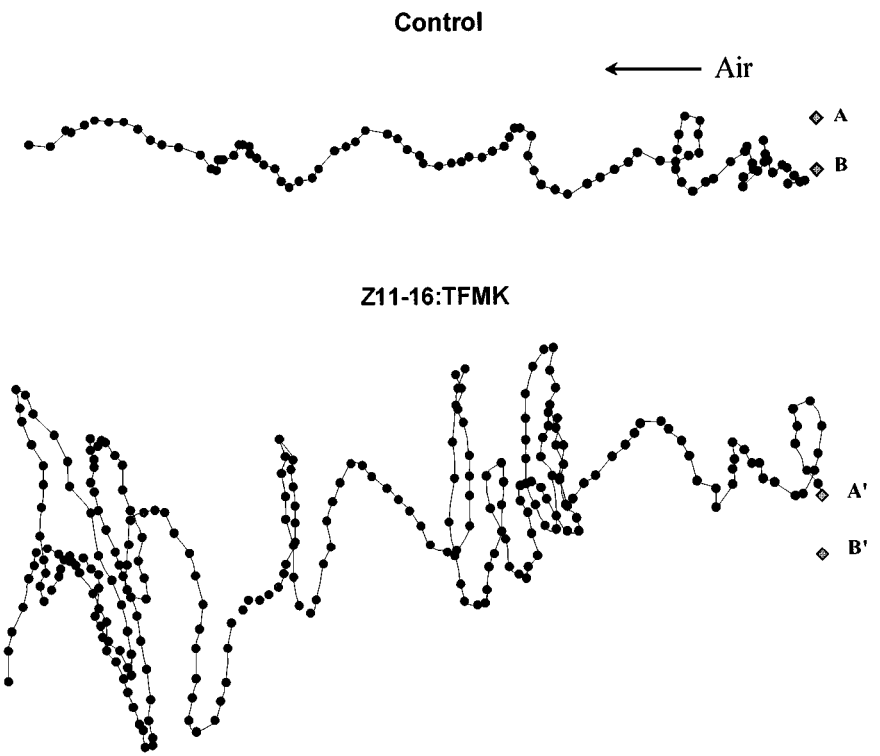

FIG. 5. Representative flight tracks of *S. nonagrioides* males flying upwind towards two dispensers. In the control test both dispensers (A and B) contained 100 ng of pheromone, whereas in the test with Z11-16:TFMK dispenser A′ contained a mixture of 100 ng of pheromone and 1 μg of the inhibitor and dispenser B′ only 100 ng of pheromone. Black dots represent the insect position at 0.1 s intervals.

Note. Means ($\pm$ SEM within a row followed by the same letter are not singificantly different ($P < 0.05$, LSD test).

frequent zigzag movement. The track width was higher in insects flying in plumes containing the TFMK (7.9 vs 4.6 cm), as were the track (67.3° vs 52.2°) and the course angles (48.0° vs 32.6°), while the drift angle (the difference between the course angle and the track angle) remained constant (Table 2). Total flight distance was also higher in TFMK-exposed moths (303 vs 161.6 cm). Flight duration to reach the source (16.7 vs 11.9 s) and the ground speed (18.6 vs 14.6 cm/s) did not differ (Table 2).

Field Tests. The effect of the fluorinated ketones was determined by comparing the number of males caught by mixtures of the chemicals with the pheromone relative to the pheromone alone. In preliminary tests carried out in 1998, a 10:1 mixture of Z11-16:TFMK with the pheromone decreased ($P < 0.05$) in the number of catches with regard to the pheromone (total catches/trap 8.3 ± 3.5 vs 87.8 ± 15.1) (Figure 6). Conversely, OTFP and E11-16:TFMK had no effect when mixed with the pheromone in the same ratio. Surprisingly, the saturated ketone, 12:TFMK, induced a clear synergistic effect (over 2 $\times$ fold) relative to the pheromone alone (Figure 6). In 1999, the activity of the chemicals was evaluated in several mixtures (0.1:1, 1:1, and 10:1) with the pheromone. The effect of 12:TFMK was not significant this time, although baits containing the ketone with the pheromone in 1:1 and 10:1 ratio caught more males than those with the natural attractant. However, 16:TFMK, increased (4 $\times$ fold) the level of captures when mixed with the pheromone at the highest ratio ($P < 0.05$). The inhibitory activity of the unsaturated analogue Z11-16:TFMK was again recorded, particularly in 10:1 mixtures with the pheromone ($P < 0.05$) in which the total number of catches per trap was 11.3 ± 5.7 compared to 56.3 ± 19.1 with the pheromone (Figure 7). In the 2000

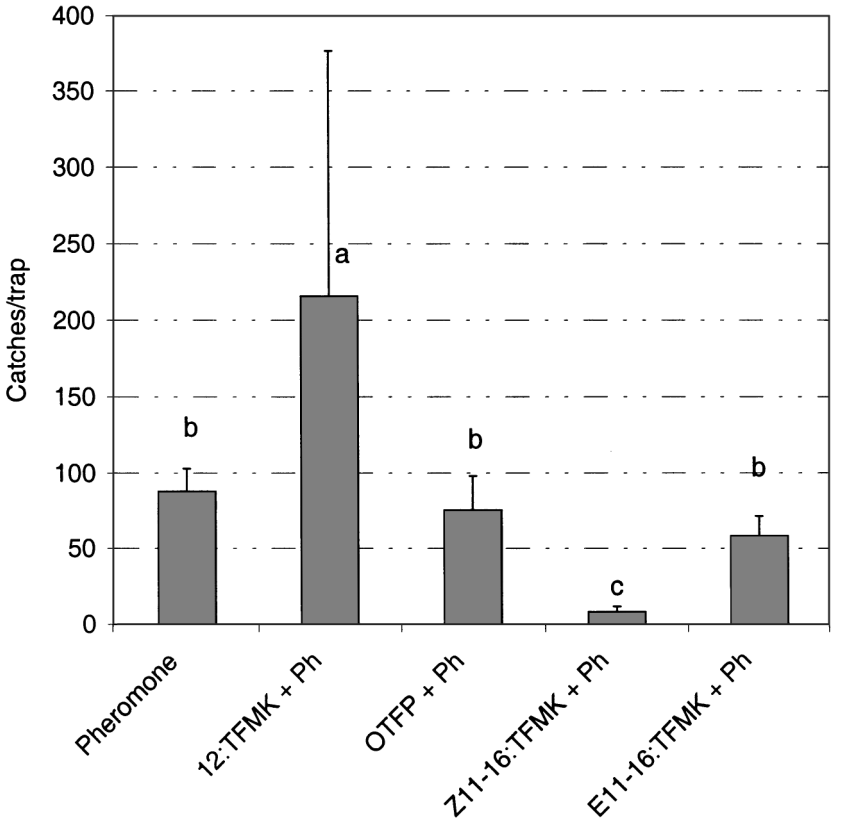

FIG. 6. Number of *S. nonagrioides* males caught in traps baited with mixtures of different trifluoromethyl ketones (12:TFMK, OTFP, Z11-16:TFMK and E11-16:TFMK) and pheromone in 10:1 ratio, compared with the number of males caught by the pheromone blend. Rubber septa were used as dispensers. The amount of pheromone present in all baits was 0.1 mg. Bars (±SEM) containing the same letter are not significantly different according to the Student t-test ($P < 0.05$). Tests were performed in an infested maize field in the province of Lleida (Spain) from September 2 to October 22, 1998.

tests, 16:TFMK again increased the number of catches (over 4 × fold) relative to the pheromone when mixed with the natural attractant in 10:1 ratio. No effect was observed in 1:1 blends (Figure 8). Conversely, Z11-16:TFMK decreased the number of catches even in 1:1 mixtures with the pheromone (total catches/trap 18.6 ± 9.0 vs 53.3 ± 11.3). The inhibitory effect of Z11-16:TFMK increased with dose, and, in the total number of males caught per trap was only 5.0 ± 2.6, 10:1 analogue:pheromone blends. Intrinsically, the analogue was unattractive. In a preliminary experiment, the pentafluoromethyl ketone 15:PFMK was

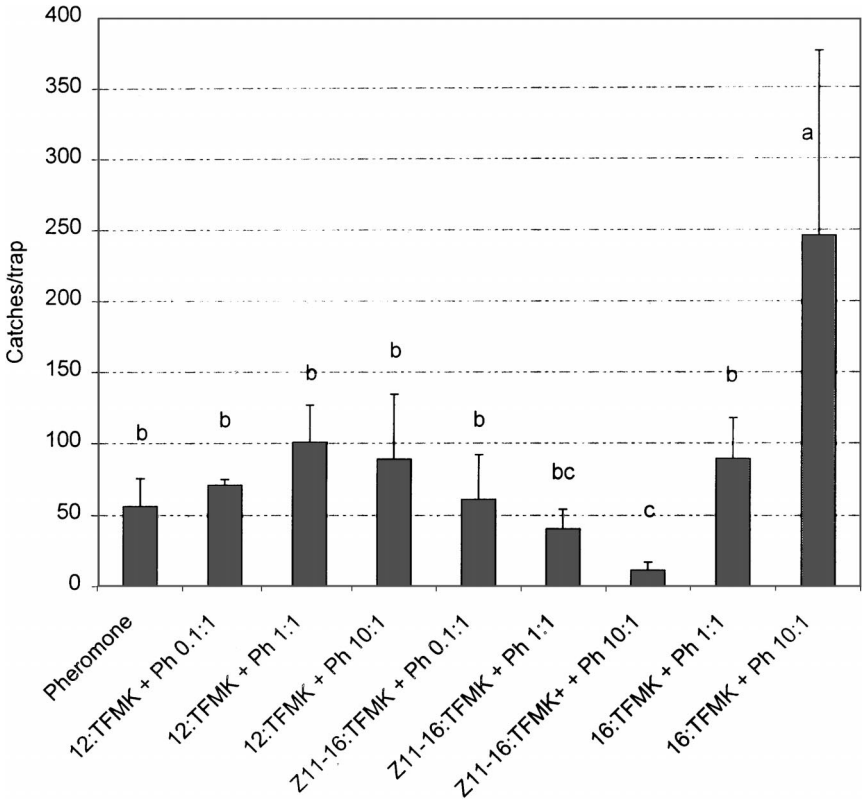

FIG. 7. Number of *S. nonagrioides* males caught in traps baited with mixtures of trifluoromethyl ketones (12:TFMK, Z11-16:TFMK and 16:TFMK) and the pheromone blend at 0.1 : 1, 1 : 1 and 10 : 1 ratios compared with the pheromone alone. Tests were conducted in an infested maize field in the province of Lleida (Spain) from July 20th to October 15th 1999. The amount of the pheromone present in all baits was 0.1 mg. Bars (±SEM) containing the same letter are not significantly different according to the Student t-test ($P < 0.05$).

practically inactive when blended with the pheromone at the highest proportion (Figure 8).

Toxicology. Mortality was not observed when Z11-16: TFMK and OTFP were administered at 500 mg/kg after 7 days. At 1000 mg/kg, all mice survived for 5 days when treated with OTFP and 4 days with Z11-16:TFMK. Administration of up to 2000 mg/kg of the major component of the pheromone induced no death after the 7-day treatment, while a higher dose of the chemical (5000 mg/kg) resulted in 25% mortality by the 5th day of treatment (Table 3). The mean weight gain of the animals was 31% (±4) when 500 mg/kg of Z11-16:Ac was administered.

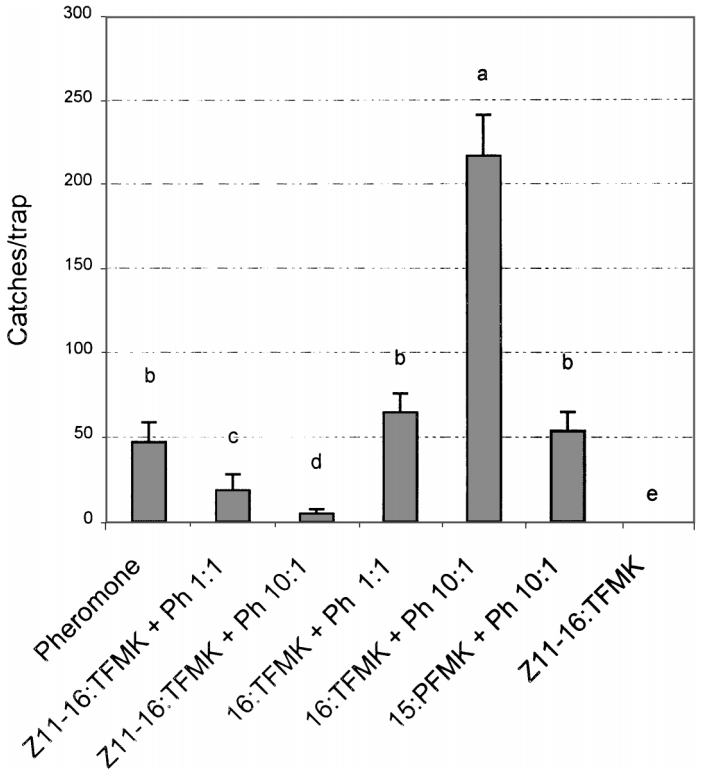

FIG. 8. Number of *S. nonagrioides* males caught in traps baited with mixtures of trifluoromethyl ketones (Z11-16:TFMK, 16:TFMK and 15:PFMK) and the pheromone in 1:1 and 10:1 ratios compared with pheromone alone. The assay was conducted in an infested maize field in the province of Lleida (Spain) from July 26 to October 11, 2000 and the dispensers replaced on September 6. The amount of the pheromone present in all baits was 0.1 mg. Bars (±SEM) containing the same letter are not significantly different according to the Student t-test ($P < 0.05$).

When mice were fed with the same amount of Z11-16:TFMK and OTFP the mean weight gains were 33% (±10) and 14% (±7), respectively. By contrast, doses of 1000 mg/kg of the TFMKs and 2000 mg/kg of the natural attractant caused mice to gain no weight.

DISCUSSION

Inhibition of the catabolic enzymes of the sex pheromone in insects has been considered a potential approach for pest control (Prestwich, 1986; Renou and

TABLE 3. MORTALITY OF SWISS MICE FED WITH DIFFERENT DOSES OF THE TRIFLUOROMETHYL KETONES Z11-16:TFMK AND OTFP AND THE MAJOR COMPONENT OF THE PHEROMONE OF *S. nonagrioides*, Z11-16:Ac[a]

Guerrero, 2000). In this regard, TFMKs reversibly inhibit the antennal esterases responsible for catabolism of pheromone molecules (Vogt et al., 1985; Prestwich and Streinz, 1988; Durán et al., 1993; Rosell et al., 1996), possibly through formation of a stable hemiacetal of tetrahedral geometry with a serine residue at the active site of the enzyme (Linderman et al., 1988; Rosell et al., 1996). These fluorinated chemicals elicited low intrinsic electroantennographic activity (Prestwich and Streinz, 1988; Riba et al., 1994), but reduced EAG pheromone responses in several insect species, such as *S. littoralis*, *Mamestra brassicae* and *Heliothis zea* (Renou et al., 1997), and inhibited the single sensillum responses (SSR) of the pheromone receptor cells of *S. littoralis* (Renou et al., 1997) and *Antheraea polyphemus* (Pophof, 1998; Pophof et al., 2000).

In field tests, the pheromone analogue Z11-16:TFMK consistently inhibited the attractant activity of the synthetic pheromone of the corn borer. In contrast, OTFP was ineffective as an inhibitor, possibly due to interaction/adsorption with the rubber septa since solvent extraction of freshly prepared dispensers containing 1 mg of the chemical failed to appreciably recover the compound. Likewise, E11-16:TFMK was inactive as inhibitor when mixed with the pheromone in 10:1 ratio. In the wind tunnel OTFP induced erratic flights by males flying to the source containing the chemical (Bau et al., 1999). Similarly, topical application of OTFP decreased the number of treated males contacting the pheromone source (Bau et al., 1999). The saturated analogue 12:TFMK, which showed an interesting antiesterase activity in *S. littoralis* (Durán et al., 1993), induced a synergistic effect in 10 : 1 mixtures with the pheromone. The effect was not significant, however, in 1999. 16:TFMK, a more closely related analogue of the pheromone, consistently

elicited a remarkable synergistic effect (4× fold) on the number of catches in a similar formulation both in 1999 and 2000 tests. It should be noted that (*Z*)-1,1,1-trifluoro-14-nonadecen-2-one (Z12-17:TFMK), the one-carbon homologue of Z11-16:TFMK, when added to the natural attractant in 10:1 ratio provoked a 68% increase in the number of catches relative to the pheromone (Riba et al., 1994) and increased the selectivity of the pheromone formulation with regard to other habitat-sharing species. Z12-17:TFMK was a poor inhibitor of the antennal esterase of *Plutella xylostella*, which shares Z11-16:Ac as one main pheromone component with *S. nonagrioides* (Prestwich and Streinz, 1988). These results suggest that small modifications of the analogue structure may imply, in an analogous way to the pheromone itself, a strong behavioral significance, as already described (Renou and Guerrero, 2000 and references cited therein).

We tried to confirm in wind tunnel bioassays the apparent synergistic effect of the two saturated TFMKs found in the field. However, no differential effect was found in any type of behavior when males were attracted to mixtures of the TFMK and the pheromone. Several factors may account for the discrepancy between the field and laboratory results. First, the global release rate of the inhibitor-pheromone blend in the field is clearly different from that in the wind tunnel, mainly due to the different types of dispensers used (the release rate from the cardboard being higher than the rubber septa by some orders of magnitude). For this reason, a 500× higher dosage of the pheromone blend on a rubber septum was required to elicit equal responses *Grapholita molesta* than the natural attractant on filter paper (Valeur and Löfstedt, 1996) and several olefinic compounds were released from rubber caps at approx. $10^3\times$ fold lower rate than from filter paper or cotton pads (Preiss and Priesner, 1988). In addition, and in preliminary tests, showed that a female-shape stimulus was an important factor for attractancy (Sans, unpublished data), although visual cues may be secondary in comparison to an accurate sex pheromone blend (Shorey and Gaston, 1970; Carpenter and Sparks, 1982). Second, the different diffusion rate of the antagonist and the natural pheromone, provided that they do not interact with the support, should imply a different proportion of the compounds in the air. This effect would be independent of the intrinsically different vapor pressure of the chemicals, as noticed by the retention times of 12:TFMK, 16:TFMK, Z11-16:TFMK, Z11-16:Ac, Z11-16:OH, Z11-16:Ald and 12:Ac which have been determined as 13.925, 23.463, 23.351, 28.17, 25.015, 23.539 and 18.835 min, respectively, on a DB-1 capillary column. Third, the effects in the wind tunnel are usually established within a relatively short distance (130 cm from the release platform of the insects to the bait), whereas in the field the flying attraction over much greater distances should be more determinant in assessing the activity of any specific inhibitor/synergist considered. This has been duly addressed in the literature, i.e., Hathaway et al. (1974) found that addition of undecanol to codlemone in 20:1 ratio reduced male catches of *Laspeyresia pomonella* by ca. 50%, while in a wind tunnel, higher than 1000×

fold overdose of the analogue was required to reduce orientation flight responses significantly.

In dual choice tests, males showed no preference for either dispenser when these were baited with identical pheromone doses. However, the moths clearly discriminated between the two overlapping plumes when the lures contained different amounts of the pheromone blend. In the presence of Z11-16:TFMK, the insects displayed no particular choice for either lure, but the ketone significantly decreased arrestment of the upwind flight, particularly at high doses. This indicates that the inhibitor not only exerts its antagonistic effect when evaporated with the pheromone from the same dispenser, but also on insects flying in an overlapping plume originated by a close pheromone source. This fact may have remarkable implications in future field studies since the inhibitor could eventually display its antagonistic action on natural pheromone released by females. Moths executed frequent crosswind counter-turns with a high number of intersections with plume boundaries, very much resembling the track of males topically treated with the chemical onto the antenna (Bau et al., 1999). The successful orientation of the males indicates that the odor filaments emanating from the two sources were sufficiently separated to be distinguished by the flying insects, which agrees with the fine-scale structure of odor plumes reported (Murlis and Jones, 1981; Mafra-Neto and Cardé, 1994; Baker et al., 1998).

Several TFMKs tested have shown a remarkable antiesterase activity *in vitro*. Thus, 12:TFMK displayed an IC_{50} of 4.4 μM in *S. littoralis* (Durán et al., 1993); 16:TFMK IC_{50} of 63 μM (Durán et al., 1993), OTFP of 0.08 μM (Rosell et al., 1996) and Z11-16:TFMK IC_{50} of 1.59 μM (Rosell et al., 1996); while in *S. nonagrioides* Z11-16:TFMK showed an IC_{50} of 123.7 μM (Quero et al., unpublished). However, their distinct activity *in vivo* point to a different mechanism(s) of action and not only to an antiesterase effect (Renou et al., 1997). Among the possible operating mechanisms, it has been suggested the one involving transport of the TFMK through binding with the pheromone binding proteins (PBP) of *A. polyphemus*, and subsequent competition with the PBP-pheromone complex at the pheromone receptor sites (Pophof et al., 2000). In the same trend, we found that some aliphatic TFMKs bind to the PBP of the processionary moth *Thaumetopoea pityocampa* in competition with pheromone molecules (Feixas et al., 1995). However, the structural deficiency of the analogue, which occurs with the saturated TFMKs, makes it unable to interact properly with the receptor site and to trigger adequate receptor cell responses, as shown by the lack of activity in SSR (Bau, 2000), to provoke a successful behavioral output. In the case of the unsaturated Z11-16:TFMK, the presence of the double bond with the right location and stereochemistry as in the pheromone skeleton may be a determinant positive feature for the recognition and the transduction processes (Camps et al., 1988; Renou and Guerrero, 2000). The variety of effects observed by the TFMKs tested in the field, cannot be fully explained since many different parameters may enter into play and affect the overall

behavior of the moths, as discussed above. In toxicity tests, Z11-16:TFMK and OTFP showed little toxicity to mice with an LD_{50} of 1 g/kg after the 6th day of experimentation. The major component of the pheromone, Z11-16:Ac, presented an LD_{50} of 5 g/kg after the same time of treatment, a value that is in the average of mammalian toxicity data available for Lepidoptera pheromones (Weatherston and Minks, 1995). Our data agree with the low acute toxicity to mice of several substituted TFMKs reported earlier (Hammock et al., 1982; Abdel-Aal et al., 1984) and support the lack of mammalian toxicity shown by other pheromones (Weatherston and Minks, 1995).

In summary, new data about the inhibition of pheromone action by a structurally related TFMK have been gathered. Our promising results, such as inhibition of the pheromone action in the field, inhibition of number of contacts to the pheromone source when it is close to another containing the analogue, and low toxicity, should stimulate the study of using TFMKs in future pest control strategies, as it has been proposed for juvenile hormone esterase (Hammock and Philpott, 1992; Bonning et al., 1995).

(Received January 23, 2001; accepted May 6, 2001)

Abstract—Tannins, a large and diverse group of phenolic secondary metabolites, are common in terrestrial plants and marine brown algae. It is sometimes desirable to remove the tannins from plant or algal extracts, e.g., when isolating enzymes and nucleic acids, when using certain colorimetric methods to quantify the tannin content, or to create reliable controls when using tannins in experimental studies. Insoluble polyvinylpolypyrrolidone (PVPP) can be used to specifically remove tannins from solution. In the present study, we evaluated the effect of different factors (amount of PVPP, number of PVPP treatments, type of solvent, pH, and incubation time) on the PVPP removal of dissolved brown algal phlorotannins. Our results imply that there is a limited amount of phlorotannins that can bind to a given amount of PVPP, and that it is preferable to use low quantities of PVPP repeatedly, compared to using fewer treatments with a high amount of PVPP. Furthermore, we found no consistent effect on the removal of phlorotannins due to solvent type (acetone, methanol, distilled water or filtered seawater). There was a slight decrease in the amount of phlorotannins removed from extracts with increasing pH when repeatedly treated with PVPP. All phlorotannins were removed from extracts with pH $\leq$ 6.2, and 89% of the initial phlorotannin content was removed at pH 9.7. These results are compared with previous methodological studies on tannin removal with PVPP. Furthermore, the implications of phlorotannin removal in analytical and ecological investigations are discussed.

Key Words—Bioassay, enzyme, Folin-Ciocalteus, pH, phlorotannins, polyphenolic compounds, polyvinylpolypyrrolidone, PVPP, solvent, tannins.

INTRODUCTION

Polyphenolic secondary metabolites are a large and diverse group of chemical compounds, which are common both in terrestrial plants and in aquatic macrophytes (Waterman and Mole, 1994). One class of polyphenolic compounds that has received much attention from ecologists during the last decades is the tannins (see Harborne, 1983; Karban and Baldwin, 1997), which are water-soluble compounds with the ability to precipitate proteins from solution. They are thought to act as chemical defenses in plants either by having direct toxic effects (e.g., Berenbaum, 1984; Martin and Martin, 1984; Steinly and Berenbaum, 1985), or by decreasing the digestibility of food (Tugwell and Branch, 1992) or the assimilation efficiency of herbivores (Boettcher and Targett, 1993). Tannins can be divided into three chemically distinct groups: condensed tannins, hydrolyzable tannins, and phlorotannins. Condensed tannins are associated with the production of lignin and are common in lignified higher plants, but also occur in some herbs. Hydrolyzable tannins occur in some green alga and in angiosperms, while phlorotannins are restricted to brown algae (Waterman and Mole, 1994). Phlorotannins are the least complex group of tannins and consist of phloroglucinol (1,3,5, trihydroxybenzene) units that are linked by carbon—carbon or carbon—oxygen bonds. They have a wide range of molecular sizes (400 to 400,000 Da) and can occur in variable concentrations (0.5–20% of the dry weight) in the epidermal cortex in brown algae (Ragan and Glombitza, 1986). Phlorotannins are commonly believed to have defensive or protective functions, e.g., against herbivores, bacteria, fungi, fouling organisms and UV-B radiation (see Ragan and Glombitza, 1986; Targett and Arnold, 1998, for references), to function in wound healing processes (Fagerberg and Dawes, 1976), or in cell-wall construction (Schoenwaelder and Clayton, 1998).

Tannins form strong complexes with proteins either reversibly by hydrogen bonding through peptide or amide linkages, or irreversibly by covalent condensations (Loomis and Battaile, 1966; Appel, 1993; Waterman and Mole, 1994; Stern et al., 1996a). This may interfere with, or even prevent, the isolation of enzymes or nucleic acids from plant extracts (e.g., Loomis and Battaile, 1966; Porebski and Bailey, 1997; Koonjul et al., 1999). Furthermore, removal of tannins may be desirable during analytical quantification of total plant phenolic compounds (e.g., Yates and Peckol, 1993; Van Alstyne, 1995; Peckol et al., 1996; Stern et al., 1996b), or when using tannin extracts in experimental studies (e.g., Pavia et al., 1997; Pavia and Toth, 2000; Toth and Pavia, 2000). The strong hydrogen bonding capacity can be used to remove tannins by adding substances that contain groups similar to peptide bonds e.g., nylon or polyvinylpolypyrrolidone (PVPP). Optimal conditions for binding of tannins to PVPP has been evaluated previously (Andersen and Sowers, 1968), but the experimental treatments were not replicated and the data were not statistically analyzed. However, the results suggested that successive

treatments of plant extracts with insoluble PVPP in 1–10 vol% methanol under acidic conditions (pH 3.5) were favorable for specifically removing tannins from solution (Andersen and Sowers, 1968). The aim of the present study was to evaluate the optimal conditions for PVPP removal of brown algal phlorotannins in an experimentally and statistically rigorous way. We performed a series of laboratory experiments where we evaluated the influence of different solvents, extract pH, quantities of PVPP, number of PVPP treatments, and incubation times on the removal of dissolved phlorotannins.

METHODS AND MATERIALS

Collection and Preparation of Algal Phlorotannin Samples. Phlorotannins were extracted from individuals of the brown seaweed species *Ascophyllum nodosum* (L.) Le Jolis, collected randomly from different sites outside Tjärnö Marine Biological Laboratory at the Swedish West Coast (58°54′N, 11°07′E). *A. nodosum* is common at sheltered rocky shores in the north Atlantic, where it can form large stands in the intertidal zone. In the area of investigation, it has a phlorotannin content of 4–15% of the plant's dry weight (Pavia and Åberg, 1996; Pavia et al., 1999). Seaweed individuals were brought back to the laboratory, cleaned of all visible epiphytes and debris, and immediately frozen (−70°C) and freeze-dried. The freeze-dried algal material was homogenized to a fine powder and phlorotannins were extracted in aqueous acetone (60 vol%) on a shaking rack in darkness at 4°C for 24 hr. The extract was centrifuged and filtered (0.2 μm) to remove algal particles. Acetone was evaporated *in vacuo* and the extract was filtered again to remove precipitated lipophilic substances. Fresh extracts were prepared daily and the Folin-Ciocalteus (F-C) analysis for quantification of total phenolic compounds (Van Alstyne, 1995) was used to determine the concentration of F-C reactive compounds. This analysis measures all substances with aromatic hydroxyl groups and does not discriminate between phlorotannins and non-phlorotannin compounds. The effects of different extract solvents, extract pH, quantities of PVPP, number of PVPP treatments, and incubation times on the PVPP removal of the dissolved F-C reactive compounds were determined under different conditions in three separate experiments.

Effects of Solvent and Incubation Time on PVPP-Phlorotannin Binding. In the first experiment, we studied the influence of different solvents (10 vol% acetone and methanol) and incubation times (10 and 30 min) on the ability of PVPP (CAS no. 25249-54-1) to remove F-C reactive compounds from solution. The initial concentration of F-C reactive compounds was 470 mg/l and the pH of the extracts was 5.8. Extract aliquots (5 ml) and PVPP (25 mg/ml) were placed in small brown glass flasks (20 ml) and placed on a shaking rack for the desired incubation time. Two replicates of each treatment were prepared. After incubation, the samples were

centrifuged and the supernatant was filtered (0.2 μm) to remove the PVPP. The concentration of F-C reactive compounds was measured and the amount removed (% of initial concentration) was calculated. Data were analyzed using a two-way analysis of variance (ANOVA) with solvent (2 levels) and incubation time (2 levels) as fixed orthogonal factors.

Effect of Solvent, pH and PVPP Treatment on PVPP-Phlorotannin Binding. In the second experiment, the effects of different solvents, pH and PVPP treatments on the removal of dissolved F-C reactive compounds were studied. Since this experiment was conducted over four days, four different extracts with initial concentrations of F-C reactive compounds between 450–600 mg/l were used. The initial pH of the extracts was 5.8, and was lowered to 3.5 using concentrated hydrochloric acid (0.3 μl HCl/ml extract) in the low pH treatments. Extract aliquots (5 ml), based on distilled water, acetone, or methanol and with different pH, were placed together with low and high (10 or 25 mg/ml) amounts of PVPP in brown glass flasks as in the first experiment. Six replicates of each treatment were prepared and incubated for 10 min. After incubation, PVPP was removed by centrifugation and the supernatant was filtered (0.2 μm) as in the first experiment. The concentration of F-C reactive compounds was measured in two replicates. This procedure was repeated twice with 10 mg fresh PVPP/ml extract, and after each PVPP treatment the concentration of F-C reactive compounds was measured in two replicates. The amount of F-C reactive compounds removed (% of initial concentration) was calculated, and data were analyzed using a three-way ANOVA with solvent (3 levels), pH (2 levels) and PVPP treatment (6 levels) as fixed orthogonal factors.

Effect of pH on PVPP-Phlorotannin Binding. The phlorotannin extract used in the third experiment was purified according to the method described in Steinberg and van Altena (1992), and the phlorotannins were dissolved in filtered seawater (15%). The initial phlorotannin concentration of the extract was 500 mg/l and the initial pH was 6.2. In this experiment, we tested the effect of different pH's on the removal of the dissolved phlorotannins. The extract was divided into three equal volumes and a few μl of concentrated HCl or NaOH was added to adjust the pH to 2.9 and 9.7. Extract aliquots (5 ml) were placed together with PVPP (10 mg/ml) in brown glass flasks as in the previous experiments. Two replicates were prepared and treated three times with PVPP, after which the phlorotannin content was measured as in the second experiment. The amount of phlorotannins removed (% of initial phlorotannin concentration) was calculated, and data were analyzed using a one-way ANOVA with pH as a fixed 3-level factor.

Prior to all analysis, data were tested for homogeneity of variances with Cochran's test (Underwood, 1997). Multiple mean comparisons were made with the Student Newman Keuls (SNK) test (Underwood, 1997).

RESULTS

There was no difference in the amount of F-C reactive compounds removed from extracts containing 10 vol.% acetone or methanol (ANOVA, $F_{1,4} = 0.10$, $P = 0.77$) in the first experiment (Figure 1). Furthermore, incubating the extracts with PVPP for 10 or 30 min removed similar amounts of F-C reactive compounds, since there was no difference between different incubation times (ANOVA, $F_{1,4} = 0.01$, $P = 0.93$, Figure 1).

There was a difference in the amount of F-C reactive compounds removed from extracts with different solvents and pH when subjected to different PVPP treatments, as indicated by the three-way interaction between the factors solvent, pH and PVPP treatment (Table 1) in the second experiment. The SNK test revealed that there was an overall increase in the amount of F-C reactive compounds removed when the extracts were treated three times with PVPP, irrespective of the amount PVPP used in the first treatment (10 or 25 mg PVPP/ml, Figure 2). Furthermore, in accordance with the first experiment, there was no consistent difference in the amount of F-C reactive compounds removed due to the extract solvent

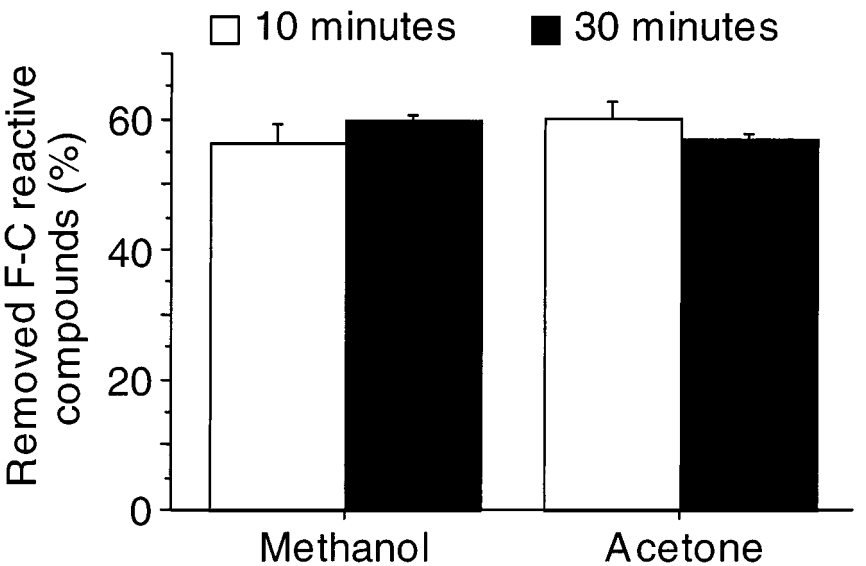

FIG. 1. Removal of Folin-Ciocalteus (F-C) reactive compounds (% of initial concentration) from *Ascophyllum nodosum* extracts based on different solvents (10 vol% methanol or acetone) treated once with 25 mg PVPP/ml extract for 10 or 30 min incubation. The pH of the extracts was 5.8. There were no significant differences among treatments. Error bars show + SE ($N = 2$).

[a] Data on mean values and standard errors are presented in Figure 2.

(Figure 2). The only difference ($P < 0.05$) in the amount of F-C reactive compounds removed due to extract solvent was found when extracts with pH 5.8 were treated twice, first with high and then with low amount of PVPP. Significantly, fewer F-C reactive compounds were removed from the distilled water extracts compared to the methanol and acetone extracts (Figure 2), although the difference was relatively small. The pH of extracts affected the removal of F-C reactive compounds either positively or negatively depending on the PVPP treatment. The largest differences between pH treatments were found when extracts were treated once with a high amount of PVPP. There was a higher removal of F-C reactive compounds from extracts at pH 3.5 compared to extracts at pH 5.8, while the opposite was found in extracts that were treated once with a lower amount of PVPP (Figure 2).

There was a difference in the amount of phlorotannins removed from extracts with different pH (ANOVA, $F_{2,3} = 809.47$, $P < 0.0001$) by three successive PVPP treatments. The SNK test revealed that the phlorotannin removal was most effective from extracts with pH 2.9 and 6.2 and less effective from extract with pH 9.7 (Figure 3).

DISCUSSION

The results in the present study show that the effectiveness of phlorotannin removal with PVPP is dependent on the number of PVPP treatments and the amount of PVPP used in each treatment, i.e., it appears that a limited amount of phlorotannin can bind to a given amount of PVPP. Increasing the incubation time from 10 to 30 min did not increase the amount of F-C reactive material removed from a

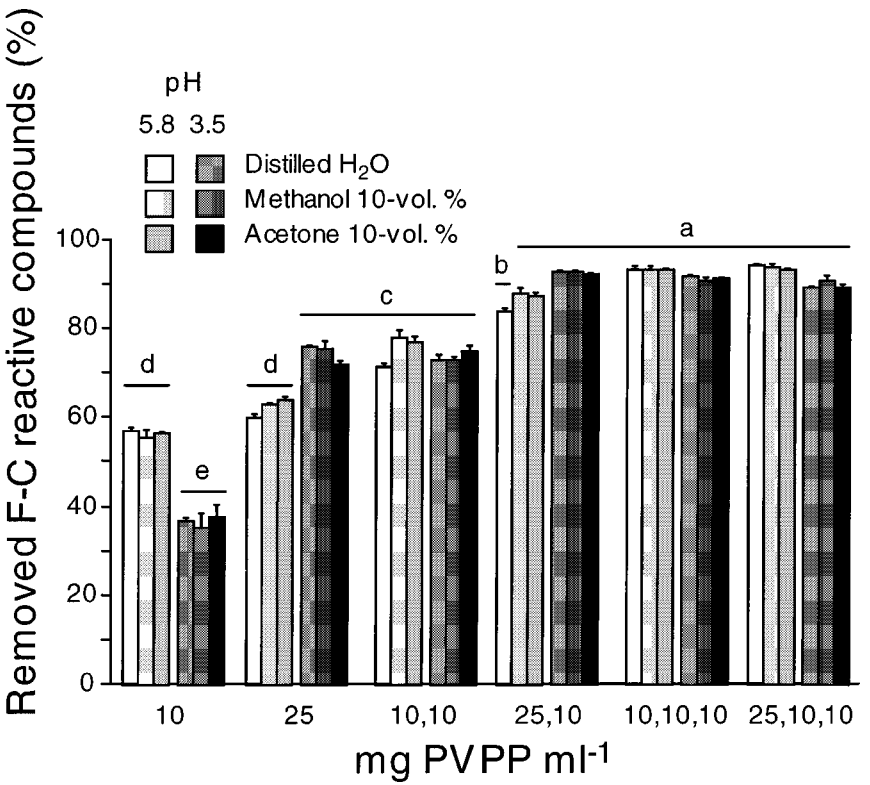

FIG. 2. Removal of Folin-Ciocalteus (F-C reactive) compounds (% of initial concentration) from *Ascophyllum nodosum* extracts based on different solvents (distilled water, 10 vol% methanol or acetone) with different pH (5.8 or 3.5) subjected to different PVPP treatments (10 or 25 mg PVPP/ml in the first treatment and subsequent treatments with 10 mg PVPP/ml). Letters above horizontal bars indicate significant differences among treatments based on Student-Newman-Keuls multiple-comparisons tests ($P < 0.05$). Error bars show + SE ($N = 2$).

single PVPP treatment in the first experiment. In accordance with the findings in previous studies (Andersen and Sowers, 1968; Targett et al., 1995), we found that three successive 10 min PVPP incubations were effective in removing the F-C reactive material from solution. These treatments removed approximately 90% of the F-C reactive compounds from extracts in the second experiment. The remaining F-C reactive substances were probably non-phlorotannin compounds with aromatic hydroxyl-groups, which did not bind to PVPP (Yates and Peckol, 1993; Van Alstyne, 1995; Peckol et al., 1996; Stern et al., 1996b). In the third experiment, when more purified phlorotannin extracts with different pH were treated repeatedly

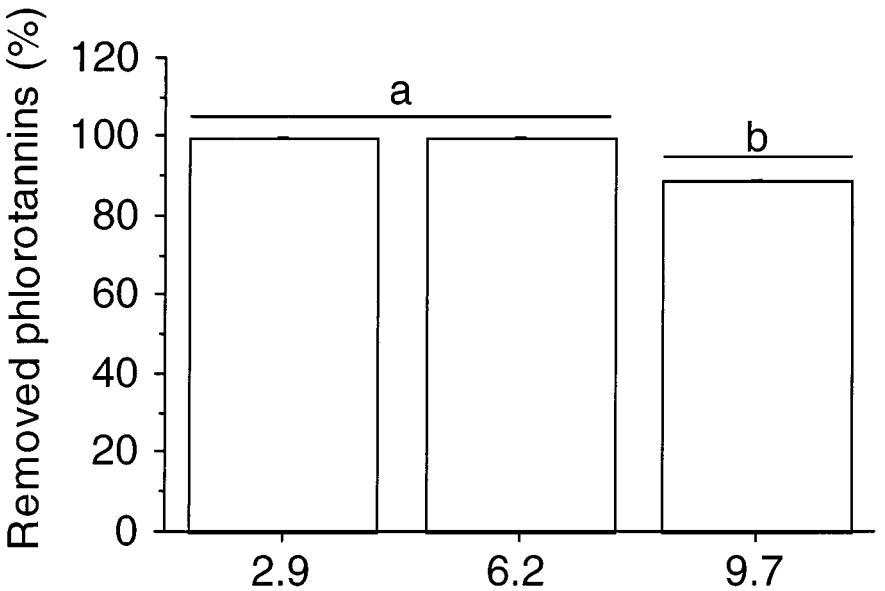

FIG. 3. Removal of phlorotannins (% of initial concentration) from purified *Ascophyllum nodosum* extracts with different pH (2.9, 6.2, and 9.7) after three successive PVPP treatments (10 mg PVPP/ml extract). The extracts were based on artificial seawater (15%). Letters above horizontal bars indicate significant differences among treatments based on Student-Newman-Keuls multiple-comparisons tests ($P < 0.05$). SE was 0.101 at pH 2.9, 0.013 at pH 6.2, and 0.364 at pH 9.7 ($N = 2$).

with PVPP, all (>99%) of the phlorotannins were removed after three successive PVPP treatments both in extracts with pH 2.9 and 6.2. The PVPP removal of dissolved phlorotannins was independent of the solvent used, i.e., there was no consistent difference in the phlorotannin removal between extracts based on distilled water compared to methanol or acetone. Furthermore, 10 mg PVPP/ml extract was preferable to 25 mg/ml, since a larger proportion of the extract was lost due to absorption to the dry PVPP powder when using the high amount of PVPP. Given these results, the initial concentration of the phlorotannin extract probably affects the number of PVPP treatments that are required to remove all phlorotannins. An extract with a higher initial phlorotannin concentration than used in the present study (i.e., >600 mg/l) may require more than three successive PVPP treatments. However, the results in the present study imply that it is preferable to increase the number of PVPP treatments, rather than the amount of PVPP in a given treatment, when the phlorotannin content of the extract increases.

It has been reported that PVPP is most effective in removing tannins from solutions with a low pH (Andersen and Sowers, 1968), and this statement has been

referred to by several authors (Yates and Peckol, 1993; Targett et al., 1995; Van Alstyne, 1995; Stern et al., 1996b). A low pH has been regarded as favorable since tannins are thought to bind to the PVPP molecules with hydrogen bonds (Loomis and Battaile, 1966; Waterman and Mole, 1994; Stern et al., 1996a). The experiment performed by Andersen and Sowers (1968) was not replicated, and, therefore, it is not possible to state that there actually was a significant difference in the tannin removal between extracts with different pH (3.5–8.5). In the present study, we demonstrated that, when treating the extracts repeatedly with PVPP, there is no difference in the amount of phlorotannins removed if pH is increased from 3.5, which was regarded as the optimal pH by Andersen and Sowers (1968), to 6.2. The effectiveness of phlorotannin removal decreases if the pH is increased even further, although three successive PVPP treatments still removed 89% of the phlorotannins in the extract with pH 9.2. The fact that there is no need to adjust the pH of the extract is advantageous if PVPP treated phlorotannin extracts are prepared for the purpose of being used as controls in experimental studies (see discussion of ecological implications below).

Use of PVPP to remove phlorotannins from brown algal extracts has been criticized due to the fact that a single PVPP treatment failed to remove all (i.e., 100%) of the phloroglucinol or phlorotannin content from solution (Van Alstyne, 1995; Stern et al., 1996b). However, calculating the loss of F-C absorbance from solutions treated with PVPP (100 mg/ml) in the study by Van Alstyne (1995) shows that phloroglucinol removal from the 80 vol% methanol solution without BSA was approximately 94% of the initial concentration. Furthermore, PVPP removed 95–97% of the F-C reactive compounds from *Fucus gardneri* extracts. Van Alstyne (1995) pointed out that PVPP might have a greater affinity for complex phlorotannins than for phloroglucinol. This may be correct, but the difference between the removal of dissolved phloroglucinol and phlorotannins in the study by Van Alstyne (1995) is not large, and would perhaps not be statistically significant if tested. Stern et al. (1996b) found that a single PVPP treatment (20 mg/ml) only removed 20% of the Folin-Denis absorbance in purified phlorotannin extracts from *Fucus vesiculosus*, a species that is closely related to *A. nodosum*. We found that when purified, *A. nodosum* phlorotannin extracts (according to the method described in Steinberg and van Altena, 1992) were treated with PVPP (3×10 mg/ml) in the third experiment, no color formation was detected with the F-C method, i.e. all phlorotannins were removed. These results are also in accordance with the results of Targett et al. (1995) who found that 90% of the phenolic compounds were removed from crude methanol extracts of *A. nodosum* after three successive PVPP treatments (15 mg/ml). Furthermore, PVPP removed 98% of dissolved phloroglucinol, between 87–95% of the phlorotannins from crude methanol extracts of *Lobophora variegata*, and between 90–99% of the phlorotannins from purified extracts of *F. vesiculosus* (Targett et al., 1995). Therefore, we suggest that PVPP can be effective in removing both phloroglucinol and phlorotannins

from solution, especially when the PVPP treatments are repeated several times.

The principal implications of the results found in the present study concern several fields of application including both basic and applied research areas. For example, the protein binding properties of tannins make it difficult to isolate enzymes (Loomis and Battaile, 1966; Kranner and Grill, 1996) and nucleic acids (Porebski and Bailey, 1997; Koonjul et al., 1999; Chen et al., 2000) from plant or algal material, and therefore, removal of tannins is often essential. Furthermore, some common methods that are used to quantify total phenolic compounds are based on reactions with free hydroxyl groups and do not discriminate between phenolic and non-phenolic compounds (Waterman and Mole, 1994). Therefore, measurements before and after removal of tannins may be required for proper quantification of tannins in plants (Makkar et al., 1993) and algae (Yates and Peckol, 1993; Peckol et al., 1996). Removal or isolation of tannins may also be important when using bioassays involving tannins in medical (Wall et al., 1969; Béress et al., 1993) or ecological (Pavia and Toth, 2000; Toth and Pavia, 2000) studies. Hypotheses concerning the activity of tannins against different types of threats are usually tested in bioassays using more or less purified plant extracts (Geiselman and McConnell, 1981; Steinberg, 1988; Pavia and Toth, 2000). Problems commonly arise when interpreting the results from such bioassays, since other plant extract properties may correlate and/or interact with the tannins and affect the outcome of the bioassay. To be able to rigorously address questions concerning the protective and defensive functions of tannins, they must either be purified or removed from the extract. By removing tannins with PVPP, a control containing all other chemical compounds in the extract can be created (c.f. Pavia and Toth, 2000).

In conclusion, we suggest that when repeatedly using a small amount of PVPP at pH ≤ 6.2, PVPP can be effective in removing all dissolved brown algal phlorotannins. Furthermore, there is no need to use organic solvents or to adjust the pH of the extracts, which is advantageous when using this method to create controls without phlorotannins in ecological experiments.

(Received November 30, 2000; accepted June 9, 2001)

Abstract—Many plant species defend themselves against herbivorous insects indirectly by producing volatiles in response to herbivory. These volatiles attract carnivorous enemies of the herbivores. Research on the model plant *Arabidopsis thaliana* (L.) Heynh. has contributed considerably to the unraveling of signal transduction pathways involved in direct plant defense mechanisms against pathogens. Here, we demonstrate that *Arabidopsis* is also a good candidate for studying signal transduction pathways involved in indirect defense mechanisms by showing that: (1) Adult females of *Cotesia rubecula*, a specialist parasitic wasp of *Pieris rapae* caterpillars, are attracted to *P. rapae*-infested *Arabidopsis* plants. (2) *Arabidopsis* infested by *P. rapae* emits volatiles from several major biosynthetic pathways, including terpenoids and green leaf volatiles. The blends from herbivore-infested and artificially damaged plants are similar. However, differences can be found with respect to a few components of the blend, such as two nitriles and the monoterpene myrcene, that were produced exclusively by caterpillar-infested plants, and methyl salicylate, that was produced in larger amounts by caterpillar-infested plants. (3) Genes from major biosynthetic pathways involved in volatile production are induced by caterpillar feeding. These include *AtTPS10*, encoding a terpene synthase involved in myrcene production, *AtPAL1*, encoding phenylalanine ammonia-lyase involved in methyl salicylate production, and *AtLOX2* and *AtHPL*, encoding lipoxygenase and hydroperoxide lyase, respectively, both involved in the production of green leaf volatiles.

AtAOS, encoding allene oxide synthase, involved in the production of jasmonic acid, also was induced by herbivory.

Key Words—*Pieris rapae*, Lepidoptera, Hymenoptera, tritrophic interactions, foraging behavior, headspace analysis, terpenoids, green leaf volatiles, methyl salicylate, nitriles.

INTRODUCTION

To defend themselves against herbivorous insects, plants use both direct and indirect mechanisms (Karban and Baldwin, 1997; Dicke, 1999). Direct defense mechanisms have a direct effect on the herbivore, e.g., by negatively affecting the physiology of the herbivore with toxic or antinutritional compounds, or by interfering with the behavior of the herbivore with repelling or deterring compounds (Karban and Baldwin, 1997). Indirect defense mechanisms promote the effectiveness of natural enemies of the herbivore, i.e., predators or parasitoids. One way of promoting the effectiveness of natural enemies is by producing volatiles in response to herbivory that can attract predators or parasitoids. This kind of tritrophic interaction has been shown for many, mainly agriculturally important, plant species. Plants capable of this type of interaction belong to at least 12 plant families, in combination with a diverse range of herbivore and natural enemy species (Dicke, 1999).

Among the volatiles induced by herbivory, terpenoids, lipoxygenase-derived volatiles, and methyl salicylate are commonly found. These compounds are produced via different biosynthetic pathways.

Terpenoids are a large and diverse group of compounds, present in most plant species (Gershenzon and Croteau, 1991). Although the early steps in terpenoid production can be divided into a cytosolic and a plastidic pathway (Lichtenthaler, 1999), products from both pathways are used by terpene synthases (TPS) (Bohlmann et al., 1998, 2000), to produce mono-, sesqui-, and diterpenes.

Lipoxygenase-derived or "green leaf" volatiles are also common in plants. Important enzymes involved in their biosynthesis are lipoxygenase (LOX) (Bell and Mullet, 1993) and hydroperoxide lyase (HPL) (Bate et al., 1998). Another branch of the lipoxygenase pathway produces the plant hormone jasmonic acid, which is involved in the induction of direct (Karban and Baldwin, 1997; McConn et al., 1997) and indirect (Hopke et al., 1994; Dicke et al.; 1999; Gols et al., 1999; Thaler, 1999) defense mechanisms. For the production of jasmonic acid, the products from LOX are used by the enzyme allene oxide synthase (AOS) instead of HPL (Laudert et al., 1996).

Methyl salicylate is a volatile derivative of the plant hormone salicylic acid (Lee et al., 1995). The role of salicylic acid in direct defense mechanisms of plants against pathogens has been extensively reviewed (e.g., Dempsey et al., 1999). Methyl salicylate is produced via the phenyl propanoid pathway. A key enzyme in

the phenyl propanoid pathway is phenylalanine ammonia-lyase (PAL) (Lee et al., 1995; Mauch-Mani and Slusarenko, 1996). Besides (methyl) salicylate, many other products are produced from this pathway, such as lignin and flavonoids (Dixon and Paiva, 1995).

Signal-transduction pathways involved in herbivore-induced plant volatiles have only recently been studied (e.g., Hopke et al., 1994; Paré and Tumlinson, 1997; Boland et al., 1999; Dicke et al., 1999). However, there is a wealth of knowledge on signal transduction pathways in direct defenses against both insects and pathogens (e.g., Karban and Baldwin, 1997; Pieterse et al., 1998). Much of the knowledge has been obtained by taking a molecular genetic approach (e.g., Delaney et al., 1994). The incorporation of the model plant of molecular genetics, *Arabidopsis thaliana*, has contributed enormously to progress in this field (e.g., Dietrich et al., 1994; Pieterse et al., 1998; Thomma et al., 1998).

To date, only a few studies on insect–plant interactions have used *Arabidopsis* as a host plant (Grant-Petterson and Renwick, 1996; Mauricio and Rausher, 1997; McConn et al., 1997; Mauricio, 1998; Reymond et al., 2000; van Loon et al., 2000; Stotz et al., 2000), and only one of those focussed on indirect defenses (van Loon et al., 2000). Yet, *Arabidopsis* is known to be consumed by insects, such as caterpillars of *Pieris rapae* (Yano and Ohsaki, 1993; van Loon et al., 2000), and these caterpillars are hosts to parasitoids such as *Cotesia rubecula* (Agelopoulos and Keller, 1994; Geervliet et al., 1994). Several crucifers are known to produce herbivore-induced volatiles in response to *P. rapae* damage, and *C. rubecula* is attracted to these (Blaakmeer et al., 1994; Geervliet et al., 1994, 1997).

This indicated to us that *Arabidopsis* might be a good candidate for studying signal transduction in indirect defenses in plants. In the present study, we investigate (1) whether *Arabidopsis* produces volatiles induced by *P. rapae* feeding that attract *C. rubecula* parasitoids, (2) the composition of the herbivore-induced volatile blend, and (3) whether genes from major biosynthetic pathways involved in the production of the identified volatiles are induced by caterpillar feeding.

METHODS AND MATERIALS

Plants. Arabidopsis thaliana (L.) Heynh., ecotype Columbia, was grown from seed in a greenhouse (20–30°C, 50–70% relative humidity, 8L : 16D). A few days prior to plant treatment, 9- to 10-week-old plants were transferred to a climate room (23 ± 1°C, 50–70% relative humidity, 10 klux, 8L : 16D). All plants used were in the vegetative state.

Insects. Pieris rapae was reared on Brussels sprout plants (*Brassica oleracea gemmifera* cv. Icarus) in a climate room (21 ± 1°C, 50–70% relative humidity, 16L : 8D). The parasitoid *Cotesia rubecula* was reared on *P. rapae* larvae feeding on Brussels sprout plants, under greenhouse conditions (25 ± 5°C, 50–70% relative

humidity, 16L : 8D). Every year a fresh colony was initiated with individuals collected from fields near Wageningen, The Netherlands. For bioassay experiments, *C. rubecula* pupae were collected and transferred to a gauze cage in a climate room (23 ± 1°C, 50–70% relative humidity, 16L : 8D). The emerging wasps were provided with water and honey. Adult wasps that did not have contact with plant material or caterpillars (no ovipostion experience) are referred to as naive wasps.

Plant Treatments. For headspace collection and analysis, caterpillar-infested plants were obtained by placing 12 first-instar *P. rapae* on each plant. For the two-choice bioassay and gene expression analysis, caterpillar-infested plants were obtained by placing two first-instar *P. rapae* on each leaf with a main vein longer than 3 cm, resulting on average in 24 larvae per plant. In both cases, larvae had fed on the plants for 24 hr before they were used in experiments. Caterpillar-infested plants are referred to as a plant–herbivore complex (PHC).

To obtain artificially damaged (AD) plants, all leaves with a main vein longer than 3 cm were rubbed with carborundum powder no. 180 (Cats Import, Hoogvliet, The Netherlands) on a moist cotton pad, just before an experiment (Mattiacci et al., 1995).

Control (C) plants did not receive any treatment, but were of the same age and size as treated plants, and had been transferred to the climate room at the same time.

Bioassay. Parasitoid flight experiments were conducted in a wind-tunnel set-up (25 ± 5°C, 50–70% relative humidity, 0.7 klux) described by Geervliet et al. (1994), with a wind speed of 0.2 m/sec.

For two-choice flight experiments, two odor sources were placed at the upwind end of the wind tunnel. Each odor source consisted of eight *Arabidopsis* plants that received the same treatment. These eight plants were placed in a 2 × 4 arrangement, with the three plants closest to the center and upwind end of the wind-tunnel on a 4.5 cm elevation (Figure 1). An 11 × 19 cm clear Plexiglas rectangle was placed, at the upwind end of each odor source, on the elevation, to create some air turbulence. The distance between the odor sources was 14 cm.

One day before a bioassay, 4- to 6-day-old, naive *C. rubecula* wasps were sexed and the males removed. Just prior to the bioassay, an individual female wasp was placed onto a microscope slide with one leaf from a caterpillar-damaged *Arabidopsis* from which the caterpillars had been removed. The wasp plus leaf plus slide were transported to the middle of the release cylinder in the wind tunnel, which was 60 cm downwind from the odor sources (Figure 1).

The flight behavior of the wasps was observed. Only flights that resulted in the first landing on one of the odor sources were recorded as a choice. Landings on other parts of the wind tunnel besides the release cylinder or odor sources were recorded as no choice. If the wasp remained in/on the release cylinder for longer than 15 min, this was also recorded as no choice. After a choice or no choice, the wasp was removed.

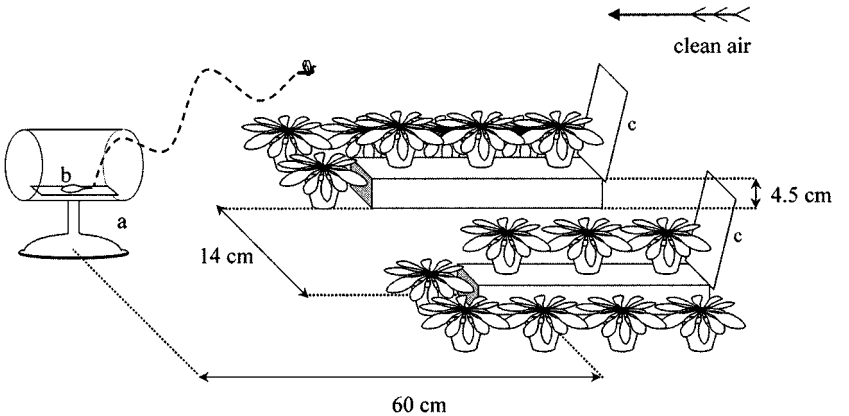

FIG. 1. Wind-tunnel set-up. Two odor sources, each consisting of eight *Arabidopsis* plants were placed 60 cm upwind of the release cylinder (a). Three plants were placed on a 4.5-cm elevation for each odor source. The distance between the two odor sources was 14 cm. Wasps were transported to the release cylinder on a microscope slide with one leaf from a caterpillar-damaged *Arabidopsis* from which caterpillars had been removed (b). Clean laminar air was blown over the odor sources towards the release cylinder at a speed of 0.2 m/sec. Plexiglas rectangles (c) were placed at the upwind end of the odor sources to create some turbulence.

All combinations of the three odor sources (PHC-C, AD-C, PHC-AD) were tested on the same day. For each combination of odor sources, plant positions were changed from left to right and vice versa, to compensate for unforeseen asymmetric effects. In total, 50 wasps in six days were tested per odor combination.

Choices between two odor sources in the bioassay were statistically analyzed by using a chi-square test. Differences in the percentage of wasps making a choice (responsiveness) among the three combinations of odor sources were tested using a contingency table on the absolute numbers.

For the no-choice flight experiment, one odor source was placed at the upwind end of the wind tunnel. The odor source consisted of one *Arabidopsis* plant placed on a 4.5-cm elevation. To create some air turbulence, an 11- $\times$ 19-cm clear Plexiglas rectangle was placed at the upwind end of the odor source on the elevation. Selection and handling of the wasps was the same as for the two-choice experiments. On one day, the behavior of 10 female wasps was subsequently recorded. Only flights that resulted in the first landing on the odor source were recorded as a successful landing. Landings on parts of the wind tunnel other than the release cylinder or odor sources were recorded as nonsuccessful landings. If wasps remained in/on the release cylinder for longer than 20 min, this was also recorded as a nonsuccessful landing. After a successful or nonsuccessful landing, the wasp was removed. On day 0, a single, undamaged *Arabidopsis* plant was used as an odor source, and the

behavior of the 10 female wasps was recorded. After this test, a single first-instar *P. rapae* caterpillar that had just hatched was placed on the *Arabidopsis* plant. After 1, 2, 3, 4, and 6 days, this plant was used as odor source for the bioassay. Every day, the behavior of a new set of 10 females was recorded. This experiment was repeated three times. After pooling the data for every infestation period, differences between the number of wasps making a successful landing among the subsequent days was tested using a contingency table. A Spearman rank correlation test was used to analyze whether more days of feeding resulted in greater attraction.

Headspace Collection and Analysis. For dynamic headspace collection, 40 plants per treatment were used and experiments were performed in a climate room ($23 \pm 1^{\circ}$C, 50–70% relative humidity, 10 klux). Soil was removed from the roots by rinsing with tap water, and the plants were placed into a 5-liter glass jar on wet filter paper. The jar was closed with a glass lid having an air inlet and air outlet. A viton O-ring was placed between the lid, and jar and the lid was closed tightly with a metal clamp. Pressurized air was filtered over silica gel, a molecular sieve, and activated charcoal. The resulting cleaned air was led through the jar with plants for 6 hr, at a flow rate of 240 ml/min. To collect the headspace, the airstream was filtered at the outlet with 90 mg Tenax-TA in a glass tube. Subsequently, the Tenax tube was closed with a 1/4-in Swagelok cap and transferred to the GC-MS for analysis.

Collected volatiles were released from the Tenax by using a Thermodesorption Cold Trap set-up (Chrompack, Middelburg, The Netherlands) as described by Mattiacci et al. (1995) and transferred to the analytical gas chromatography column (Supelcowax 10 or Rtx-200, 60 m $\times$ 0.25 mm ID, 0.25-μm film thickness). The initial linear velocity of the helium carrier gas was 22 cm/sec. The temperature of the column was raised from 40°C to 270°C at 4°C/min. Volatiles were analyzed by a mass spectrometer (Finnigan MAT 95) and identified by comparison of the mass spectra with those in the NIST98 library, and the Wageningen Mass Spectral Database of Natural Products, and by checking the retention index, unless stated otherwise.

Headspace collections of control (C) plants were carried out simultaneously, in parallel, with each of the two treatments (AD and PHC) to minimize variation among plant batches and day-to-day variation. Collections were made in triplicate.

When comparing damaged (either AD or PHC) with undamaged control (C) plants, a compound was considered to be emitted in larger amounts, if that compound showed a larger peak area in all three replicates of damaged plants, compared with the three replicates of undamaged control plants, or if that compound showed a larger peak area in two of the three replicates of damaged plants, and the third (and smallest) peak area was equal to the largest peak area of the three replicates of undamaged control plants. The latter occurred mostly when the compound was not detected in any of the three replicates of undamaged control plants and detected in two of the three replicates of damaged plants.

Gene Expression Analysis. The protocol for RNA isolation, described by Chang et al. (1993) was followed. Leaf material from 5 or 6 plants was pooled to obtain a total of 5 g, and the protocol was adjusted to these 5 g. Isolated RNA was DNase treated (DNase I, GibcoBRL) using an RNase inhibitor (RNaseOUT, GibcoBRL) to preserve RNA quality. The concentration of total RNA was spectrophotometrically determined.

From the total RNA, 10 μg was separated on a formaldehyde–agarose gel, blotted on a nylon membrane (Hybond-N+, Amersham) (Sambrook et al., 1989), and UV cross-linked. These northern blots were prehybridized and hybridized at 65°C in hybridization buffer (Church and Gilbert, 1984). The blots were washed for 15 min under medium stringency conditions (one wash with 2 × SSC, 0.1% SDS at room temperature, one wash with 2 × SSC, 0.1% SDS at 55°C).

All probes were made by using the RadPrime DNA Labeling System (GibcoBRL). Templates for the probes were obtained by PCR from cDNA clones (*AtTPS03*, *AtTPS10*, *AtLOX2*, *AtAOS*, *AtHPL*) or by RT-PCR from *Arabidopsis* total RNA (*AtPAL1*, *AtPAL2*, *AtPAL3*). Plasmids containing full-length cDNAs of *AtTPS03* and *AtTPS10* were provided by Jörg Bohlmann (see Bohlmann et al., 2000). The plasmids containing cDNAs of *AtLOX2*, *AtAOS*, and *AtHPL* were described by Bell and Mullet (1993), Laudert et al. (1996), and Bate et al. (1998), respectively. Primers used for PCR were 5′-TAT-ACG-CGA-CCG-CCC-TTG-AG-3′ and 5′-GGC-GGA-GCT-TCG-AAC-TAC-AGA-G corresponding to bases 172827–172846 and 174843–174864 of *AtTPS03* (GenBank Accession No. Z97341); 5′-TTC-CGA-CTT-TTC-AGG-CAA-CAT-3′ and 5′-GAG-AGC-TGG-TCG-GAG-AAT-ACG-3′ corresponding to bases 327–347 and 1247–1267 of *AtTPS10* (GenBank Accession No. AF178535); 5′-GGA-TCG-ATA-AGA-CCG-CAG-AAC-ATG-GAG-3′ and 5′-GCT-GTC-GAC-TCA-TAG-AAC-TCT-TTT-AAG-G-3′ corresponding to bases 1969–1994 and 2364–2391 of *AtLOX2* (Bell and Mullet, 1993) (underlined parts do not correspond to the plasmid template); 5′-CTT-TTC-ACC-GGT-ACT-TAC-ATG-CCG-3′ and 5′-GAT-AAC-CGT-AAA-GCA-TCT-CAC-CG-3′ corresponding to bases 447–470 and 1274–1291 of *AtAOS* (Laudert et al., 1996); 5′-TCA-CAG-CTT-CCC-CTC-CGT-ACA-ATG-3′ and 5′-CCG-GAG- TCA-CCA-GTA-ATC-GTA-TCA-3′ corresponding to bases 147–170 and 1487–1510 of *AtHPL* (Bate et al., 1998); 5′-AAG-AGC-AAC-GGA-GGA-GGA-GTG-G-3′ and 5′-GTG-GCG-GAG-TGT-GGC-AAT-GT-3′ corresponding to bases 150–171 and 603–622 of *AtPAL1* (Ohl et al., 1990); 5′-AAC-GGC-ACC-GCA-TTA-CAA-ACA-GAA-3′ and 5′-AGA-TCC-AAC-CGC-CGT-GCC-ATT-A- 3′ corresponding to bases 1838–1861 and 2455–2476 of *AtPAL2* (GenBank Accession no. L33678); and 5′-AGC-GAG-TGG-AGG-AGG-ACC-GAC-AGT-3′ and 5′-GGG-CGC-CCG-ATG-AGG- AAT-3′ corresponding to bases 2117–2140 and 3242–3259 of *AtPAL3* (GenBank Accession no. L33679). Ubiquitin expression served as a constitutive control.

For first-strand cDNA synthesis, 10 μg of total RNA was used together with M-MLV Reverse Transcriptase, Random Primers and RNaseOUT (GibcoBRL). One twentieth of the cDNA mixture was used for subsequent PCR reactions with Taq DNA polymerase (GibcoBRL).

All mRNA analyses were done in triplicate, using new sets of plants.

RESULTS

Bioassay. Cotesia rubecula females clearly preferred volatiles from *Pieris rapae*-infested (plant–herbivore complex, PHC) or artificially damaged (AD) *Arabidopsis* plants over those from undamaged plants (C). Wasps preferred odors from PHC over AD (Figure 2). The percentage of wasps making a choice did not differ among the PHC-C (66%), AD-C (70%), or PHC-AD (82%) combinations (contingency table, $P = 0.17$).

The two-choice test was performed using eight *Arabidopsis* plants per odor source with, in the case of PHC, on average 24 first-instar *P. rapae*. To test whether a single *Arabidopsis* plant damaged by a single *P. rapae* also attracted *C. rubecula* females, we performed a no-choice test (Figure 3). The results show that a single plant infested by a single caterpillar attracts the parasitoid. The number of attracted wasps differed among the different days (contingency table, $P < 0.001$). More days of feeding resulted in more attractive plants (Spearman's rank correlation test, $P < 0.0025$).

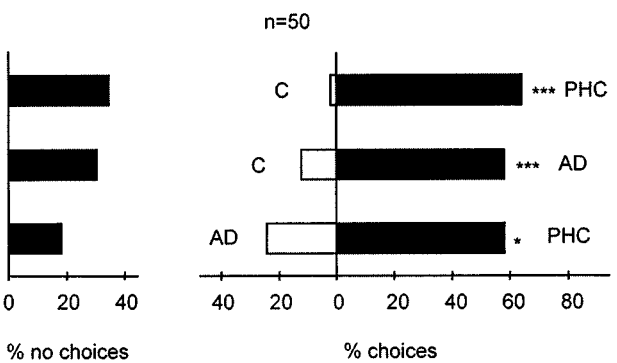

FIG. 2. Responses of *C. rubecula* to herbivore-infested (PHC), artificially damaged (AD), and undamaged (C) *Arabidopsis* in a two-choice set-up. Asterisks indicate a significant difference within a choice test: $^{***}P < 0.001$, $^{*}P < 0.05$ (χ^2). The left part of the figure shows the percentage of wasps that did not land on one of the two odor sources, for each odor combination. The right part of the figure shows the percentages of wasps landing on either odor source, also for each odor combination. In total, 50 wasps were tested per combination.

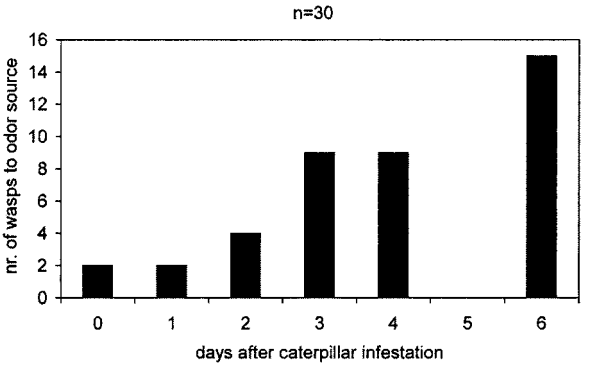

FIG. 3. Response of *C. rubecula* to a single herbivore-infested *Arabidopsis* plant in a no-choice set-up. At day 0, an undamaged *Arabidopsis* plant was tested for attractiveness to *C. rubecula* females. Subsequently, a single *P. rapae* larvae that had just hatched was placed on the plant. After 1, 2, 3, 4, and 6 days of infestation, the plant was tested again for attractiveness. In total, 30 wasps were tested in three replicate experiments per infestation period.

Headspace Analysis. A total of 38 compounds derived from different biosynthetic pathways were identified in the headspace of *Arabidopsis* plants (Figure 4), including methyl salicylate, terpenoids, green leaf volatiles, sulfides, nitriles, alcohols, aldehydes, ketones, and two cycloheptadienes.

Artificially damaged plants emitted larger amounts of volatiles than undamaged plants (Figure 4A), including more green leaf volatiles [(*Z*)-3-hexen-1-ol (peak 14), (*Z*)-3-hexen-1-yl acetate (15), and 1-hexanol (16)]. Emission of terpenoids [β-ionone (4) and β-cyclocitral (5)], sulfides [dimethyl disulfide (8) and dimethyl trisulfide (9)], alcohols [3-pentanol (20), 1-penten-3-ol (21), and 2-ethyl-1-hexanol (23)], and ketones [3-pentanone (29) and 1-penten-3-one (30)] was also induced by artificial damage (Figure 4A).

Caterpillar-infested plants emitted slightly larger amounts of volatiles than undamaged plants (Figure 4B). Caterpillar-infested plants emitted more methyl salicylate (1), terpenoids [myrcene (2) and β-ionone (4)], sulfides [dimethyl disulfide (8) and dimethyl trisulfide (9)], nitriles [5-(methylthio)-pentanenitrile (10) and 6,7-dithiaoctanenitrile (11)], green leaf volatiles [(*Z*)-3-hexen-1-ol (14) and 1-hexanol (16)], some alcohols [1-pentanol (19), 1-penten-3-ol (21), and 2-penten-1-ol (22)], and ketones (1-penten-3-one and 2-pentanone) than undamaged plants (Figure 4B). In fact, the monoterpene myrcene (2), the two nitriles (10 and 11), and the alcohol 2-penten-1-ol (22) were exclusively found in the volatile blend of caterpillar-infested plants. Methyl salicylate (1), the two nitriles (10, and 11), the alcohol 1-pentanol (19), and the ketone 2-pentanone (28) were induced by caterpillar feeding (Figure 4B), but not by artificial damage (Figure 4A). The green leaf

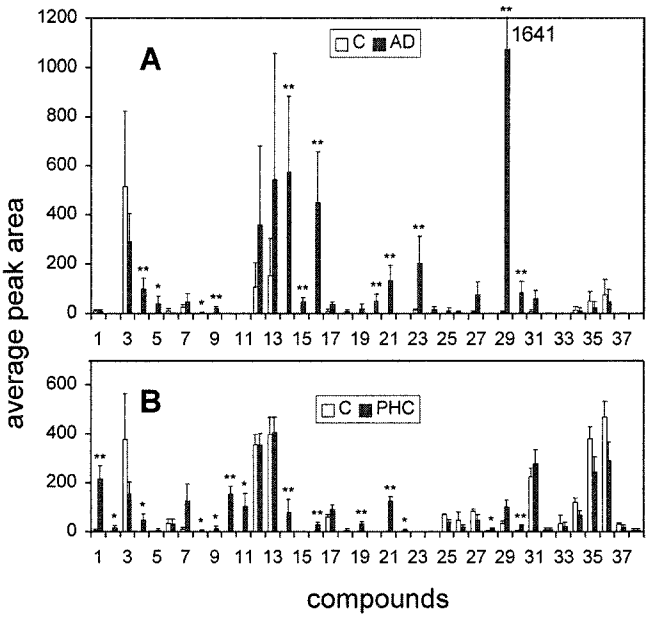

FIG. 4. Headspace analysis of herbivore-infested (PHC), artificially damaged (AD), and undamaged (C) *Arabidopsis*. Average peak areas of three replicates are shown. Error bars indicate the standard error. Compounds marked with ** showed larger peak areas in all three replicates of treated plants (either AD or PHC), compared with the three replicates of undamaged control plants (C). Compounds marked with * showed larger peak areas in two of the three replicates of treated plants, the peak area of the third (and smallest) peak area being equal to the largest peak area of the three replicates of undamaged control plants. Compound numders are: (1) methyl salicylate, (2) myrcene, (3) limonene, (4) β-ionone, (5) β-cyclocitral, (6) longifolene, (7) (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, (8) dimethyldisulfide, (9) dimethyltrisulfide, (10) 5-(methylthio) pentanenitrile, (11) 6, 7-dithiooctanenitrile, (12) 6-[(*Z*)-1-butenyl]-1,4-cycloheptadiene, (13) 6-butyl-1,4-cycloheptadiene, (14) (*Z*)-3-hexen-1-ol, (15) (*Z*)-3-hexen-1-yl acetate, (16) 1-hexanol, (17) hexanal, (18) 1-butanol, (19) 1-pentanol, (20) 3-pentanol, (21) 1-penten-3-ol, (22) 2-penten-1-ol, (23) 2-ethyl-1-hexanol, (24) 1-octen-3-ol, (25) 1-nonanol, (26) 1-dodecanol, (27) 1-tetradecanol, (28) 2-pentanone, (29) 3-pentanone, (30) 1-penten-3-one, (31) 4-methyl-3-heptanone, (32) 4-methyl-4-hepten-3-one, (33) heptanal, (34) octanal, (35) nonanal, (36) decanal, (37) undecanal, and (38) 1-nonene.

volatile (*Z*)-3-hexen-1-yl acetate (15) and the alcohol 3-pentanol (20) were found only in the blend of artificially damaged plants. In contrast to herbivore-infested plants, artificially damaged plants showed induced emission of the terpenoid β-cyclocitral (5), the alcohol 2-ethyl-1-hexanol (23), and the ketone 3-pentanone (29). Two remarkable compounds that made up a large part of the blend emitted by

undamaged, artificially damaged, and caterpillar-infested plants were tentatively identified as 6-[(*Z*)-1-butenyl]-1,4-cycloheptadiene (12; ectocarpene) and 6-butyl-1, 4-cycloheptadiene (13; dictyotene), based on mass spectra.

Gene Expression Analysis. The expression of some genes (*AtLOX2*, *AtAOS*, and *AtPAL2*) could be detected using northern blot analysis. For other genes (*AtPAL1*, *AtPAL3*, *AtTPS03*, *AtTPS10*, and *AtHPL*), northern blot analysis resulted in weak or undetectable radioactivity signals (data not shown). In those cases, RT-PCR was used. Gene expression was considered to be induced by *P. rapae* feeding if all three replicates from caterpillar-damaged plants showed higher expression than the three replicates from undamaged plants.

Expression of three genes from the lipoxygenase pathway, *AtLOX2* (Bell and Mullet, 1993), *AtHPL* (Bate et al., 1998), and *AtAOS* (Laudert et al., 1996), was induced by caterpillar feeding (Figure 5A, B). The expression of two genes involved in terpenoid biosynthesis was examined: *AtTPS03* and *AtTPS10*. Expression of *AtTPS03*, a novel monoterpene synthase gene (Bohlmann, unpublished results), and *AtTPS10*, myrcene/ocimene synthase gene (Bohlmann et al., 2000), was also induced by 24 hr of caterpillar feeding (Figure 5B).

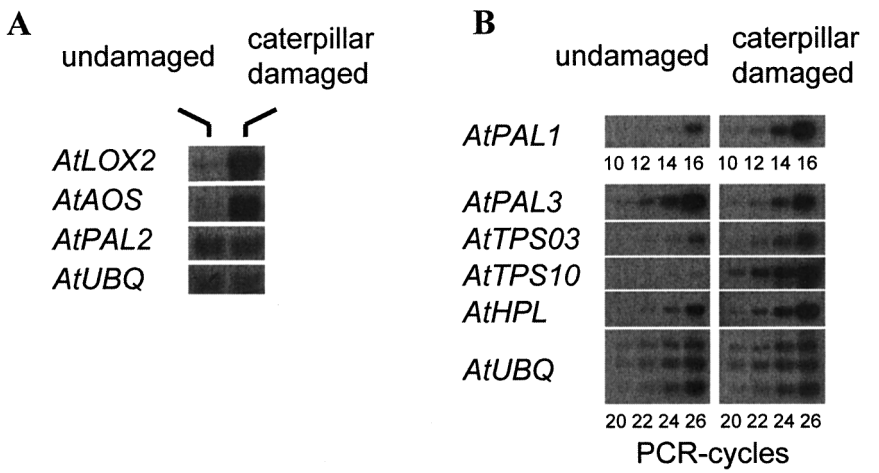

FIG. 5. Induction of gene expression by herbivore damage. RNA was extracted from undamaged *Arabidopsis* plants or *Arabidopsis* plants that had been subjected to 24 hr of *Pieris rapae* caterpillar feeding. For northern analysis (A), 5 μg of RNA was loaded in each lane. Northern blot analysis was performed for *AtLOX2*, *AtAOS*, and *AtPAL2*. RT-PCR analysis and subsequent blotting and radioactive labeling were performed for *AtPAL1* (10, 12, 14, and 16 PCR cycles), *AtPAL3*, *AtTPS03*, *AtTPS10*, and *AtHPL* (20, 22, 24, and 26 PCR cycles) (B). Ubiquitin expression served as a constitutive control, both for northern and RT-PCR (20, 22, 24, and 26 PCR cycles) analyses. Note that autoradiography films were exposed differently for different genes; therefore, comparison of expression levels among genes is not possible.

Three genes encoding for phenylalanine ammonia-lyase, an enzyme involved in the production of methyl salicylate, have been isolated in *Arabidopsis*,: *AtPAL1* (Ohl et al., 1990), *AtPAL2*, and *AtPAL3* (Wanner et al., 1995). *AtPAL1* was clearly induced by caterpillar feeding, whereas *AtPAL2* and *AtPAL3* were not (Figure 5A, B)

DISCUSSION

The attraction of carnivorous arthropods by plants in response to herbivory has been intensively studied over the past 15 years (Turlings et al., 1995; Dicke, 1999). This phenomenon has been shown for a large number of plants in various families, including the Brassicaceae (Dicke, 1999). Our data show that *Arabidopsis thaliana* plants are able to do so as well. Damage results in the production of volatiles that attract *C. rubecula*, a specialist parasitoid of *Pieris rapae*. The parasitoids prefer volatiles from caterpillar-infested or mechanically damaged plants over those from undamaged plants. They also distinguish between artificially damaged and caterpillar-infested plants, preferring the latter (Figure 2). This resembles the findings for agricultural plants in the Brassicaceae family with the same herbivore and parasitoid species (Agelopoulos and Keller, 1994; Geervliet et al., 1994). The difference in attractiveness between artificially damaged and caterpillar-infested plants cannot be explained by a response to odors emitted by the caterpillars themselves or their by-products. *Pieris rapae* larvae or their by-products are only slightly attractive to *C. rubecula* females (Geervliet et al., 1994). Moreover, the wasps do not distinguish between caterpillar-infested plants and previously infested plants from which the caterpillars and their by-products were removed 24 hr after infestation (Geervliet et al., 1994). Additionally, feeding damage of only a single *P. rapae* caterpillar on a single *Arabidopsis* plant results in increased attractiveness of the plant to *C. rubecula* females (see Figure 3). This is before the larva reaches the third instar, so the biomass of the caterpillar is small, and feces production is at a relatively low level, compared to later instars.

Recently, it was demonstrated that seed production of *Arabidopsis* plants, on which caterpillars of *P. rapae* are feeding that had been parasitized by *C. rubecula*, is similar to the seed production of undamaged plants and greater than the seed production of plants fed upon by unparasitized caterpillars (van Loon et al., 2000). This finding shows that *Arabidopsis'* fitness may benefit greatly from the attraction of parasitoid wasps by means of herbivore-induced volatiles.

Both artificially damaged and caterpillar-infested plants emit larger amounts of volatiles than undamaged plants (Figure 4). The volatile blend of damaged plants, either artificially or by caterpillar feeding, contains compounds that could not be detected in the blend of undamaged plants. These blends are quite similar, although some differences can be found. Artificially damaged plants showed

induced emission of especially green leaf volatiles and ketones, but also of alcohols, terpenoids, and sulfides. Caterpillar-pinfested plants showed induced emissions of methyl salicylate and nitriles, but also of alcohols, ketones, sulfides, and terpenoids. The nitriles and the terpenoid myrcene were not detected in blends of artificially damaged plants and undamaged plants. Methyl salicylate (Dicke et al., 1990, 1998; C.E.M. Van den Boom et al., unpublished data) and terpenoids (Dicke et al., 1990, 1998; Turlings et al., 1990; Loughrin et al., 1994) are known to be induced by herbivory in many plant species. Both methyl salicylate and several terpenoids are attractants for predatory mites (Dicke et al., 1990). Moreover, terpenoids are likely to be involved in the attraction of parasitoids (Turlings et al., 1991). Nitriles are induced by spider mite feeding on cucumber (Takabayashi et al., 1994) and on apple (Takabayashi et al., 1991). However, in cruciferous plants such as Brussels sprouts (Blaakmeer et al., 1994) and red and white cabbage (Geervliet et al., 1997), methyl salicylate, terpenoids, and nitriles are either not induced by herbivory or only very slightly. Therefore, induction of methyl salicylate, the terpenoids myrcene and (3*E*,7*E*)-4, 8,12-trimethyl-1,3,7,11-tridecatetraene, and the nitriles 5-(methylthio) pentanenitrile and 6,7-dithiooctanenitrile by *P. rapae* infestation is noteworthy.

In all plant species studied so far, artificial damage leads to the emission of green leaf volatiles (e.g., Dicke et al., 1990; Turlings et al., 1990; Whitman and Eller, 1990; Takabayashi et al., 1991). It is not surprising that green leaf volatiles are also present in the volatile blends of all caterpillar-infested plant species tested so far (e.g., Whitman and Eller, 1990; Turlings et al., 1990) and now including *Arabidopsis*. In Brussels sprouts and red and white cabbage, they are highly induced by caterpillar feeding, forming the largest part of the volatile blends (Blaakmeer et al., 1994; Mattiacci et al., 1995; Geervliet et al., 1997). Females of the parasitoid wasps *Microplitis croceipes* and *Netelia heroica* are attracted to individual green leaf volatiles (Whitman and Eller, 1990).

The presence of two compounds in the volatile blend of *Arabidopsis*, tentatively identified as the cycloheptadienes ectocarpene and dictyotene is remarkable, as these compounds are not common among higher plants. They are mostly known as sex pheromones in algae (Boland, 1995). Yet, they have been found in some higher plants, e.g., in *Senecio isatideus* (Bohlmann et al., 1979). These compounds are not induced by caterpillar feeding in *Arabidopsis*.

Emission of volatiles after herbivory can be a passive release of stored compounds but also can result from an increased production of volatiles. Using isotope labeling techniques, Paré and Tumlinson (1997) showed that in response to herbivory, cotton produces some volatiles *de novo* and others not. In Lima bean and cucumber, the activity of a terpenoid-producing enzyme is induced by herbivore damage (Bouwmeester et al., 1999). Here, we studied the expression of genes involved in early (*AtLOX*, *AtPAL1*, *AtPAL2*, and *AtPAL3*) or late (*AtTPS03*, *AtTPS10*, and *AtHPL*) steps of several biosynthetic pathways of volatiles emitted

by *Arabidopsis* (Figure 5). Gene expression levels correlated well with the emission of induced volatiles.

Bohlmann and coworkers recently reported the isolation of a terpene synthase from *Arabidopsis*, *AtTPS10*. Functional characterization showed that the AtTPS10 protein is a myrcene/ocimene synthase. Myrcene is the major product of the enzyme, and ocimene is produced in lower amounts (Bohlmann et al., 2000). Both myrcene emission and *AtTPS10* gene expression are induced by 24 hr of caterpillar feeding, indicating that herbivory leads to induced myrcene production. Expression of a novel monoterpene synthase gene, *AtTPS03* (Bohlmann, unpublished results), also was induced by caterpillar feeding (Figure 5B).

Three PAL genes have been identified in *Arabidopsis* (Wanner et al., 1995). Mauch-Mani and Slusarenko (1996) have shown that a major function of PAL in *Arabidopsis* is the production of salicylic acid. As methyl salicylate is a derivative of salicylic acid (Lee et al., 1995), it is likely that induced PAL gene expression can lead to increased production of methyl salicylate. This is supported by our data, which show an induced *AtPAL1* expression after caterpillar feeding (Figure 5B) and an increased emission of methyl salicylate. Expression of the other two known genes encoding for PAL in *Arabidopsis*, *AtPAL2* and *AtPAL3*, was not induced. Possibly, these two genes are involved in other processes within the phenyl propanoid pathway than production of methyl salicylate. Similar expression patterns were reported by Reymond et al. (2000) after 3 hr of *P. rapae* feeding on *Arabidopsis*, although they found a weak induction of *AtPAL3*.

Genes important in the production of green leaf volatiles, such as *AtLOX2* (Bell and Mullet, 1993) and *AtHPL* (Bate et al., 1998), are induced in caterpillar-infested *Arabidopsis* (Figure 5A, B). However, the products formed by lipoxygenase are also used by allene oxide synthase (AOS), involved in jasmonic acid production. Expression of the *AtAOS* gene in *Arabidopsis* is also induced by caterpillar feeding (Figure 5A). Therefore, we cannot predict whether increased *AtLOX* and *AtHPL* expression will lead to increased green leaf volatile production, increased jasmonic acid production, or both. Jasmonic acid is an important elicitor involved in induced indirect defenses of plants. In *Vicia faba* (Blechert et al., 1995) and tobacco (McCloud and Baldwin, 1997), caterpillar feeding results in increased endogenous jasmonic acid levels. Jasmonic acid treatment induces volatile emissions in several plant species (Boland et al., 1995) including Lima bean (Hopke et al., 1994; Dicke et al., 1999), maize (Hopke et al., 1994), and gerbera (Gols et al., 1999), resulting in the attraction of carnivores (Dicke et al., 1999; Gols et al., 1999), and leads to higher parasitism rates of caterpillars feeding on tomato (Thaler, 1999). Expression of *AtLOX2*, *AtAOS*, and *AtHPL* is already induced at 3 hr of *P. rapae* feeding on *Arabidopsis* (Reymond et al., 2000).

To our knowledge, no genes involved in the production of nitriles have been identified in *Arabidopsis* so far.

Herbivory-induced expression of genes involved in volatile production indicates that *Arabidopsis* is actively producing volatiles following herbivory. Moreover, differences in attraction of *C. rubecula* and composition of volatile blends of artificially damaged and caterpillar-infested plants suggest that herbivory leads to production of *C. rubecula*–attracting volatiles that are distinct from the volatiles emitted after artificial damage. However, mimicking mechanical aspects of caterpillar damage correctly is difficult if not impossible. Expression of *AtLOX2* (Bell and Mullet, 1993), *AtHPL* (Bate et al., 1998), *AtAOS* (Laudert et al., 1996), and *AtPAL1* (Mizutani et al., 1997) is also induced by artificial damage. Further experiments are needed and currently in progress to investigate whether *Arabidopsis* indeed produces volatiles specific for herbivory compared to mechanical damage.

CONCLUSIONS

This study on indirect plant defense combines behavioral and chemical analyses with gene expression analysis. Our data show that *Pieris rapae*-infested *Arabidopsis thaliana* attract *Cotesia rubecula* parasitoids. Caterpillar-infested plants release volatiles from several major biosynthetic pathways, and genes involved in the production of these volatiles are induced by herbivory. Many mutants and transgenic lines of *Arabidopsis* are available that are altered in signal transduction pathways of direct defense mechanisms or in the biosynthesis of secondary plant metabolites. In addition, the entire genome sequence of *Arabidopsis* has been completed, and knowledge of direct defense mechanisms is steadily increasing (e.g., Pieterse and van Loon, 1999). Therefore, *Arabidopsis* constitutes an interesting tool to study signal transduction of induced indirect defense in plants.

Acknowledgments—We thank Maarten Koornneef, Kees van Loon, Corné Pieterse, and Joop van Loon for their advice on this research and valuable comments on the manuscript; Herman Dijkman, Leo Koopman, Frans van Aggelen, and Andre Gidding for the insect rearing; Casper Pillen for rearing of *Arabidopsis* plants; Jörg Bohlmann and Jonathan Gershenzon for the *AtTPS03* and *AtTPS10* plasmids; Steven Rothstein, Jocelyne Le Tarte, and Richard Stahl for providing the *AtLOX2*, *AtAOS*, and *AtHPL* plasmids; and the PhD discussion group of the Laboratory of Entomology for comments on this manuscript. M.D. was partly funded by the Uyttenboogaart-Eliasen Foundation, Amsterdam.

(Received November 30, 2000; accepted June 13, 2001)

Abstract— Volatile compositions of receptive (ready to be pollinated), postpollinated, and postparasitized figs, and leaves of *Ficus hispida* were analyzed. Differences among them were examined, and the specificity of fig wasp attractiveness was investigated. Linalool was the major constituent of steam-distilled oil of either male or female receptive figs, while dibutyl phthalate was the major compound of the oils of postparasitized and postpollinated figs. In petroleum ether extracts, palmitic oil, and 9,12-octadecadienoic acid were the main constituents of male and female receptive figs, while hexadecanoic acid ethyl ester was the major compound of postparasitized and postpollinated figs. In dichloromethane extracts, linalool was the major constituent of male and female receptive figs, 1-hydroxylinalool was the major component of male postparasitized figs, and 1-hydroxylinalool and benzyl alcohol were the major constituents of female postpollinated figs. Bioassays with sticky traps showed that *Ceratosolen solmsi-marchal* was attracted to dichloromethane extracts of male and female receptive figs and to petroleum ether extracts of female receptive figs, but was not attracted to dichloromethane and petroleum ether extracts of male postparasitized and female postpollinated figs. Figs were attractive to pollinating wasps only at the receptive stage. The volatile constituents of receptive figs were different from those of postpollinated or postparasitized figs. From a receptive to a postpollinated state, figs changed in their volatile composition. Some compounds disappeared or decreased in amount. These include linalool, linalool oxide, α-terpeneol, and 2,6-dimethyl-1,7-octadiene-3,6-diol, which may act as the attractants of the wasps. Others increased in amount, or several additional chemicals appeared. These include dibutyl phthalate, 1-hydroxylinalool, and

*To whom correspondence should be addressed.

0098-0331/01/1000-1929$19.50/0

benzyl alcohol, which may be repellents of the wasps. That dichloromethane extracts of male and female receptive figs showed similar activities in attracting fig wasps indicates that receptive figs of both sexes are similarly attractive to fig wasps, which is further supported by their similar volatile composition. Leaf extract was not attractive to the wasps.

Key Words—*Ficus hispida*, *Ceratosolen solmsimarchali*, fig volatile, chemical attraction.

INTRODUCTION

Specialist insects often choose their host plants carefully. They may feed on one or only a few closely related plant species. Although visual factors may be important (Rausher, 1978; Owens and Prokopy, 1986), the search for and identification of preferred host plants are usually olfactory (Miller and Strickler, 1984). The nondirected dispersal flight of the specialist insect is converted into active search behavior once specific host volatile information is perceived (Cardé, 1984).

Mutualism between fig (*Ficus*) and fig wasp (*Agaonidae*) is species-specific. Each species of *Ficus* is generally pollinated by one specific species of fig wasp (Ramirez, 1974; Wiebes, 1979). Fig trees are totally dependent on wasps for pollination, and as a reward, figs provide food for wasp larval development inside the fruit (Janzen, 1979). The high degree of specificity that pollinating wasps show to their particular fig species led to the assumption that the trees attract their specific pollinators through the release of volatile chemicals when the figs are ready to be pollinated (Ramirez, 1970; Hills et al., 1972; Galil, 1977; Janzen, 1979). Olfactory attraction is considered a reasonable way by which fig trees attract huge number of these tiny specific pollinators from far away. Although chemical attraction was suggested more than 50 years ago (Condit, 1947), studies on it are still preliminary (Barker, 1985; Baijnath et al., 1986; Bronstein, 1987, 1992; van Noort et al., 1989; Ware et al., 1993; Ware and Compton, 1994; Gibernau et al., 1997; Grison et al., 1999). An investigation using fig-bearing trees and arrays of sticky traps baited with figs suggested that the wasps are attracted to the trees by volatiles emanating from the figs and that wasps are specifically attracted to figs of their host species only at the time when figs are ready to be pollinated (Ware and Compton, 1994).

In order to elucidate the chemical mechanisms underlying the specific attractiveness of fig trees to their pollinating wasps, we analyzed the chemical constituents of volatiles from receptive (ready to be pollinated), postpollinated, and postparasitized figs of *Ficus hispida* L. and the difference in composition of volatiles among these states of figs. Using arrays of sticky traps baited with fig volatiles, we investigated the specificity of fig wasp attraction to these volatiles.

METHODS AND MATERIALS

Materials. *Ficus hispida* L. is a pioneer tree growing in abundance in the wastelands of the tropics. It is gynodioecious and bears fruit year round. Our previous investigation showed that two or three pollinating wasps were found inside each receptive fig and that all of them were *Ceratosolen solmsimarchali* Mayr (Yang et al., 1997).

Fresh male and female receptive figs, female postpollinated, and male post-parasitized figs and leaves were collected from fruit-bearing healthy *F. hispida* trees inside Xishuangbanna Tropical Botanical Garden, Yunnan, China. Receptive figs are flowering inflorescences that receive pollinating wasps. Figs at different developing stages were determined by fig dissection. Fresh leaves were taken from female and male trees and mixed at a 1 : 1 ratio.

Collection of Volatiles. For steam distillations, immediately following collection, all materials were ground and subjected to vacuum steam distillation for 6 hr at 100°C. Distillates were extracted 3 times with diether ether and dried over sodium sulfate. The oils obtained were then frozen. For solvent extraction, fresh ground plant materials were soaked twice in petroleum ether (30–60°C) or dichloromethane for 24 hr at room temperature. Extracts from each soaking were combined and reduced in volume at 30°C by rotary evaporator. Extracts were dried over sodium sulfate and frozen.

Analysis of Volatiles. Frozen samples were subjected to gas chromatography–mass spectrometry by using a Finnigan 4510 GC/MS/DC. An HP-5 column (30 m long, 0.25 mm ID) was used under the following conditions: 10 psi head pressure, split flow ratio 30 : 1, and oven temperature program of 80–250°C at 5°C/ min . The carrier gas was helium, the injector was maintained at 230°C, and injection volume was 0.2 μl. Mass spectra conditions: ion source, EI; temperature, 175°C; electron energy, 70 eV; signal-enhancing voltage, 1300 V; bulb current, 0.25 mA; IS scan. Data analyses were carried out by using the EPA/NIH/MASS database (NBS Library database). Retention times and mass spectra of compounds detected in the samples were compared with those of authentic compounds.

Bioassay of Volatiles. A 20 cm^{-2} colorless plastic plate sprayed with odorless peach gum was used as a sticky trap. A cotton ball soaked with 0.2 ml dichloromethane solution of the sample (concentration 10% v/v) was placed at the center of the sticky plate to attract fig wasps. Sticky traps were placed on poles. Two arrays of three sticky traps for each treatment were placed 3 m from the fig tree canopy. The plates were positioned 1 m away from each other and 1.5 m above ground. Cotton balls with 0.2 ml dichloromethane were used as solvent controls. The sticky traps were place at 6:30 AM in May 2000. Insects trapped were recorded and collected at 1200 hr and 1800 hr for two days. The number of the wasps used

is the total of wasps trapped in two days. ANOVA of data were done with Winks software.

RESULTS

Volatiles of figs from steam distillation were present in small quantities, about 20 μl/kg fresh wt of fig material. Compounds may have been altered by heat. Headspace extraction is nondestructive, but yield of volatiles is even less. Therefore, lower polarity solvents (petroleum ether and dichloromethane) were used to extract enough volatiles from the figs for bioassay. Solvent extraction may also yield some nonvolatile compounds. The following are the comparative analyses of volatiles from figs and leaves of *F. hispida*.

Constituents of Steam Distilled Oils. Large numbers of volatile compounds were obtained through steam distillation (Table 1). Fifty-five compounds from steam distilled oil of male receptive figs were isolated, and 44 of them were identified by GC-MS. Among them, palmitic oil (30.74%), linalool (18.77%), and 9,12-octadecadienoic acid (5.43%) were the major constituents. *cis*-Linalool oxide, *trans*-linalool oxide, 2,6-dimethyl-3,7-octadiene-2,6-diol, and some other compounds were found as well. In the oil of postparasitized male figs, 21 compounds were isolated and 19 were identified. Dibutyl phthalate (41.07%), palmitic oil (27.80%), 9,12 -octadecadienoic acid (9.31%), and heptadecane (3.24%) were the major compounds found. From the oil of female receptive figs, 31 compounds were isolated and 21 were identified. Linalool (19.83%), β-pinene (11.65%), α-terpeneol (9.90%), 3-phenyl-2-propenal (7.83%), sabinene (7.76%), α-pinene (6.85%), terpene-4-ol (6.77%), geraniol (6.00%), 2,6-dimethyl-3,7-octadiene- 2,6-diol (4.90%), and γ-terpene (4.80%) were the major compounds. 1-Hydroxy-linalool, 6-methyl-(*E*)-3,5-heptadien-2-one, and 2,6-dimethyl-3,7-octadiene-2,6-diol were not found in oils of other fig materials. From the oil of postpollinated female figs, 13 compounds were isolated, and two were identified. The major compound was dibutyl phthalate (72.71%).

According to the data, a large change occurred in the volatile composition of figs from the receptive stage to the postpollinated or postparasitized stage. Forty of the 44 identified compounds from male receptive figs were not detected from the oil of postparasitized figs, while 15 compounds from postparasitized figs were not found in the oil of receptive figs. Similarly, 20 compounds from female receptive figs were not found in the oil of female postpollinated figs, which, in turn, have their own special compounds. However, female and male receptive figs share some volatile compounds together. After pollination or parasitization, some volatile compounds in the figs disappeared or were present in reduced amounts (such as linalool and α-terpeneol), while other compounds occurred newly or in increased amount (such as dibutyl phthalate, which is a known insect repellent).

[c] Combined percentage of unidentified compounds.

Constituents of Solvent Extracts. Sixteen compounds were isolated from petroleum ether extracts of male receptive figs (Table 2). Eight were identified. Palmitic oil (51.90%) and 9,12-octadecadienoic acid (39.39%) were the major constituents. Fifteen compounds were isolated from petroleum ether extracts of male postparasitised figs, and 10 were identified. Hexadecanoic acid ethyl ester (29.69%) and hexadecanoic methyl ester (22.26%) were the major constituents. Thirteen compounds were isolated from petroleum ether extracts of female receptive figs, and four were identified. Palmitic oil (68.73%) and 9,12-octadecadienoic acid (25.99%) were the major constituents. Eleven compounds were isolated from female postpollinated figs, and five were identified. Major compounds were hexadecanoic acid ethyl ester (34.32%), hexadecanoic methyl ester (24.01%), and palmitic acid (22.35%). Sixteen compounds were isolated from petroleum ether extracts of leaves, and seven were identified. Major constituents were 9,12-octadecadienoic acid (43.39%) and palmitic acid (28.82%). In comparison with steam distillation, petroleum ether extraction yielded fewer volatile compounds. That female and male receptive figs were different in volatile composition from female postpollinated or male postparasitized figs was confirmed by petroleum extraction. Female and male receptive figs have their own special volatiles, characterized by a greater proportion of 9,12-octadecadienoic acid and palmitic acid. The main constituents of leaf extracts were similar to those of female and male receptive figs.

In dichloromethane extracts of male receptive figs (Table 3), 17 compounds were detected, and eight were identified. The major constituents were linalool (51.20%), 1-hydroxylinalool (11.45%), bicyclo[2,2,1]hepta-2,5-dien-7-ol (11.46%), and 2,6-dimethyl-1,7-octadiene-3,6-diol (5.22%). Fifteen compounds were isolated from dichloromethane extract of male postparasitized figs, and 11 were identified, with 1-hydroxylinalool (33.00%), linalool (22.32%), and benzyl alcohol (20.56%) being the main constituents. In dichloromethane extracts of female receptive figs, 20 compounds were detected, and 13 were identified. The

[c] Combined percentage of unidentified compounds.

but more than that from petroleum ether extraction. The chemical constitution of dichloromethane extracts was similar to that of distilled oil; however, it was rather different from that of petroleum ether extracts. For dichloromethane extracts, female and male receptive figs were similar, while both were different from female postpollinated figs and male postparasitized figs. Female and male receptive figs have their own special volatile compounds. The content of linalool was higher than that for female postpollinated figs and male postparasitized figs. On the other hand, the content of 1-hydroxylinalool and benzyl alcohol of female postpollinated figs and male postparasitized figs was higher than that for receptive figs.

Attractiveness of Volatiles of F. hispida to C. solmsimarchali. Bioassays using sticky traps showed that there were significantly more *C. solmsimarchali* trapped by dichloromethane extracts of female and male receptive figs and by petroleum ether extract of female receptive figs ($P < 0.05$) and that there were no significantly more fig wasps trapped by petroleum ether extract of leaves than by solvent controls (Table 4). Moreover, there were more wasps trapped by petroleum ether extracts of female receptive figs than by those of postpollinated figs ($P < 0.05$). As for dichloromethane extracts, those of receptive figs attracted significantly more wasps than those of postpollinated or postparasitized figs, either female or male ($P < 0.05$). However, there were no differences in fig wasp numbers trapped by either dichloromethane or petroleum ether extracts of female postpollinated and male postparasitized figs and solvent control ($P > 0.05$). Wasps trapped by dichloromethane extracts of female and male receptive figs were not different either ($P > 0.05$). The sticky plate trapped many other insects but no other fig wasp species.

DISCUSSION

Results of bioassays indicate that receptive figs are attractive but postpollinated and postparasitized figs are not attractive to the pollinating wasp in the case of *F. hispida*. Different responses of wasps to receptive figs, postpollinated figs, postparasitized figs, and leaves of the *Ficus* tree were caused by the varying volatile constitutions of these plant materials. The unique volatile constituents and special volatile blend-up are the chemical basis of the receptive figs of *F. hispida* to attract *C. solmsimarchali*.

Field bioassay results of fig volatile extracts of *F. hispida* confirmed conclusions drawn from previous studies on other fig species (Ware and Compton, 1994). Figs are attractive to their wasp pollinator only at the receptive stage.

To identify chemical cues for fig wasps, we adopted a comparative approach. Figs changed in their volatile constituents from receptive to postpollinated or postparasitized states. Some compounds decreased in concentration or disappeared,

*$P < 0.05$, significant difference; NS: no significant difference at $P > 0.05$.

while others increased in concentration or several additional chemicals appeared. The compounds that disappeared or decreased in amount after pollination or parasitization were linalool, linalool oxide, α-terpeneol, and 2,6-dimethyl-1,7-octadiene-3,6-diol, which may act as attractants for the wasps. Compounds that increased in amount or newly occurred were dibutyl phthalate, 1-hydroxylinalool, and benzyl alcohol, which could be deterrents to the wasps.

The composition of volatiles of receptive figs produced by steam distillation and dichloromethane extraction was similar to that from the headspace collection (Grison et al., 1999) and pentane extraction (Gibernau et al., 1997) used in investigations of other fig species. The essential chemicals suggested to attract fig

wasps, such as linalool, linalool oxide, and benzyl alcohol, were detected in this investigation also. Linalool and linalool oxide were found in the distilled oil, and linalool, benzyl alcohol, and 1-hydroxylinalool (rather than linalool oxide) were found in dichloromethane extracts. However, benzyl alcohol did not appear to act as a fig wasp attractant but rather as a repellent, because its content in figs increased after pollination or parasitization. Characteristic or major volatile compounds and special blends of volatiles may be important in attractiveness of receptive figs to wasps. Some volatile compounds found in trace amounts may also play a role in this attraction. A much greater amount and number of volatile compounds were produced from steam distillation and dichloromethane extraction compared with previous methods (Gibernau et al., 1997; Grison et al., 1999). It is interesting that dibutyl phthalate, a known insect repellent, was found in large quantity in postpollinated and postparasitized figs. This indicates that figs may, in fact, be repellent to fig wasps after losing attractiveness following pollination or parasitization. Compounds yielded by petroleum ether extraction were largely fatty acid derivatives. Only the extract from female receptive figs showed activity in fig wasp attraction. Extraction with petroleum ether is not ideal for obtaining fig volatiles in large quantity.

Although volatile compositions of receptive figs, male or female, proved much different from those of postpollinated or postparasitized figs, compositions of male and female receptive figs proved similar. They differed only in the quantity of some major compounds; this corresponds to findings on other fig species (Grison et al., 1999). That dichloromethane extracts of male and female receptive figs showed similar activities in attracting fig wasps indicates that receptive figs of both sexes are similarly attractive to fig wasps. This is further supported by their similar volatile composition. Pollinating fig wasps should favor male receptive figs and avoid female figs because they can lay eggs only in male figs, not in female ones, where they pollinate and die. On the other hand, in order to attract wasps for pollination, female receptive figs could imitate the odor of male receptive figs. There could be an intersexual mimicry of odor in the case of *F. hispida*.

Leaf extracts did not show significant activity in the wasp attraction. This suggests that the canopy of fig trees may not play a role in long distance odor attraction of fig wasp. Compounds in leaf extracts were mainly fatty acid derivatives; this is similar to previous findings on other fig species (Buttery et al., 1986).

The species-specific mutualism between a fig tree and its pollinating wasps is based on some unique volatile compounds and special volatile blends of receptive figs. Our bioassays showed that volatile extracts of receptive figs of *F. hispida* were attractive only to one species of fig wasp, its pollinator *C. solmsimarchali*. They were not attractive to other fig wasps, although the sticky plates baited with the extracts trapped some other insects. Furthermore, only *C. solmsimarchali* were found in more than 10,000 dissected receptive figs.

About 900 species of *Ficus* (Janzen, 1979) are widespread in tropical ecosystems. They not only provide food to many diverse animals and microorganisms, but also act as habitats for epiphytes, saprophytes, parasites, and shade-requiring plants. They are keystone species in tropical ecosystems (Wiebes, 1979; Xu, 1994; Yang et al., 1997, 1999). In Xishuangbanna, the tropical area of China, *Ficus* species (such as *F. hispida*, *F. semicordata*, and *F. tinctoria* subsp. *gibbosa*) grow quickly as pioneer woody plants after deforestation. Inside or under the canopy of these plants, a community with rich animal, plant, and microorganism diversity is likely to build and expand gradually. Thus, *Ficus* trees are important in the restoration of tropical ecosystems. The species-specific mutualism between *Ficus* trees and their pollinating wasps makes their reproduction extremely efficient. However, this special relationship is vulnerable. The decrease or extinction of any partner in the mutualism could lead to a decrease or extinction of the corresponding other partner. The study of chemically based mechanisms of species-specific pollination of *Ficus* trees might be significant in the conservation of these keystone species and the whole tropical forest ecosystem. The collection, isolation, identification, and bioassay of the fig wasp attractants from *Ficus* trees deserve further attention.

(Received January 23, 2001; accepted June 20, 2001)

Abstract—The volatile compounds emitted by leaves of 10 willow varieties that differ in their susceptibility to damage by blue (*Phratora vulgatissima*), brassy (*P. vitellinae*), and brown (*Galerucella lineola*) willow beetles were examined both before and after mechanical damage and correlated with feeding preferences of these beetles determined under laboratory conditions. Three compounds were identified from intact undamaged leaves of six willow varieties, namely *cis*-3-hexenyl acetate, *cis*-3-hexenol, and benzaldehyde. After mechanical damage, the yield and number of volatile compounds increased for all varieties. There were significant differences among willow varieties for both the concentration of *cis*-3-hexenyl acetate and the relative proportion of this compound to *cis*-3-hexenol (green leaf volatile ratio). The 10 varieties collectively showed a significant negative correlation between the relative resistance of each variety to blue and brown willow beetles and the yield of *cis*-3-hexenyl-acetate from damaged plants. The green leaf volatile ratio of damaged plants was also negatively correlated with the relative resistance of willow variety to these two beetle species.

Key Words—Attractant, *Galerucella*, green leaf volatiles, *Phratora*, semiochemicals, short-rotation coppice.

INTRODUCTION

The blue [*Phratora vulgatissima* (L.)], brassy [*P. vitellinae* (L.)] and brown [*Galerucella lineola* (L.)] (Coleoptera: Chrysomelidae) willow beetles are the

*To whom correspondence should be addressed; e-mail: lori.peacock@bbsrc.ac.uk

0098-0331/01/1000-1943$19.50/0

major insect pests of short-rotation coppice willows grown as a potential source of renewable energy. Willow beetles have an aggregated distribution on preferred hosts in willow plantations (Peacock et al., 1999). The combined effects of the presence of conspecifics and beetle-feeding induced plant kairomones are suggested as factors affecting this aggregative behavior (Peacock et al., 2001). This agrees with data from many Coleoptera that have been shown to use feeding-induced odors as aggregation kairomones (Harari et al., 1994; Loughrin et al., 1995; Bolter et al., 1997; Landolt et al., 2000; Kalberer et al., 2001). Under laboratory conditions, three volatile compounds were recorded from undamaged *Salix dasyclados* Wimm. plants [benzaldehyde and the green leaf volatiles (GLVs) *cis*-3-hexenyl acetate and *cis*-3-hexenol] (Peacock et al., 2001). After beetle-feeding damage, the yield and number of volatiles increases. GLVs are thought to be used by plants for allelopathy or to attract or repel insects (Hatanaka, 1996). Thus, plant resistance could be influenced by the overall characteristics of individual or blends of volatiles by either increasing or decreasing damage (see references in Loughrin et al., 1996, 1997a).

Willow varieties differ in their susceptibility to willow beetles (Kendall and Wiltshire, 1996) due to differences in feeding preferences of the beetles. The willow beetle species considered here tend to have different feeding preferences, with *P. vulgatissima* and *G. lineola* preferring willows low in phenylglucosides (Kelly and Curry, 1991; Kendall et al., 1996), while *P. vitellinae* prefers poplars and willow varieties high in phenylglucosides (Pasteels and Rowell-Rahier, 1992). It is unclear, however, how willow beetles locate their host plants. Due to differences in host preference, a major insecticide-free pest management strategy is a mixture of willows that differ in their susceptibility to the willow beetle (Peacock and Herrick, 2000). A better knowledge of the mechanisms of host resistance, especially as regards potential attractants, such as volatile chemicals, is necessary for effective deployment of varieties in mixtures.

Salix dasyclados Wimm., the variety shown by Peacock et al. (2001) to emit volatile compounds, is the willow variety most preferred by *P. vulgatissima* in a feeding preference assay of 106 different willow varieties (Kendall and Wiltshire, 1996). It is unknown if the types and levels of volatile emissions collected from *S. dasyclados* Wimm. are specific to this willow or if they differ among varieties. Therefore, we examined the volatile compounds emitted by intact undamaged and damaged leaves of willow varieties. The aims of this study are: (1) to compare and contrast the volatile emission profile of different willow varieties; (2) to assess whether varieties differ in their volatile emission response to mechanical damage; and (3) to determine whether volatile compounds correlate with feeding preferences of willow beetles under laboratory conditions for different willow varieties.

METHODS AND MATERIALS

Plants. Five cuttings (25 cm length each) of 10 willow varieties were taken from cold storage in February 2000, planted individually in 10-cm-diameter pots, and maintained in a greenhouse until required for volatile analysis (between March 6 and April 12, 2000). The following year, cuttings for the beetle feeding preference tests were grown under similar conditions, but planted in March 2001 and used May 22, 2001. The 10 varieties were *Salix dasyclados* Wimm., *S. viminalis* Bowles Hybrid, *S.* x *sericans* Coles, *S. burjatica* Germany, *S. viminalis* 79046, *S.* x 445 de Biardii, *S. purpurea* 012, *S. triandra* Black Maul, *S. burjatica* Korso, and *S. eriocephala*.

Volatile Compound Collection and Analysis. The emissions of volatile compounds from individual plants were collected and measured following the procedure described in Peacock et al. (2001). Briefly, the terminal 20 cm of a plant was placed in an inverted glass beaker (155 $\times$ 90 mm) held by a retort stand, and the opening loosely sealed with aluminium foil. After 90 min, the trap was desorbed in a SGE Unijector fitted to a Carlo Erba Mega GC into a Superox II column that was connected to a Kratos MS80RFA mass spectrometer. After collection, the plant was removed and, to simulate beetle damage, five of the leaves contained within the beaker space had five holes punched into each one with a standard hole-punch. The volatile emissions were collected for 90 min and treated as previously described. All 10 varieties were assessed in this way, with the procedure being replicated on three plants for each variety.

Mechanical damage, as opposed to beetle damage, was chosen to standardize the amount and timing of damage, as it has been shown that different leaf volatiles may be released at different times or even follow a diurnal pattern of emission (Loughrin et al., 1997b; Turlings et al., 1998). Standardization was essential, as the main emphasis of the study was to detect whether there were any differences in the quantity of volatiles among varieties, which could be affected by any variations in the timing and amount of damage produced.

Compound identities were confirmed by a library search against the Wiley/NBS Registry of Mass Spectral Data, and the area under each peak was estimated. To estimate the concentration of compounds detected (in nanograms), stock standard solutions of the two major volatiles previously detected (*cis*-3-hexenol and *cis*-3-hexenyl acetate) (both Sigma) were made up in ethyl acetate. Serial dilutions of these solutions were then used to prepare the calibration graphs to convert area to approximate concentration.

Beetle Feeding Preferences. Standard sized leaf disks (110 mm diameter) of each willow variety were cut from 2-month-old (500 cm tall) potted willows. One disk of each variety was placed in a Petri dish (14 cm diameter) lined with

a damp filter paper to form a circle, and secured into position with a stainless steel entomological pin. This was replicated six times (for each beetle species), each dish with a different random arrangement of willow varieties. Ten beetles of one species were put in the center of each dish and maintained at 15°C. Blue and brown willow beetles had been collected the previous day from a planting of *S. viminalis* Bowles Hybrid, and brassy willow beetles from a planting of poplars at Long Ashton Research Station; they were not fed for seven hours before the start of the experiment. After 18 hr, beetles were removed, and the leaf disks were transferred to acetates and mounted flat under clear adhesive tape. The remaining leaf area of each disk was measured with an Optomax Image Analyser (cf. Kendall et al., 1996). This was done for each of the three beetle species separately.

Statistical Methods. Taking the feeding preference experiments for the three species of beetle separately, analysis of variance (ANOVA) was performed on the measurements of leaf area remaining, taking account of variation due to dishes and position as dictated by the experimental design. For each of the three volatiles detected in undamaged plants (*cis*-3-hexenyl acetate, *cis*-3-hexenol, and benzaldehyde), ANOVA was applied separately to assess any difference in quantity emitted by undamaged compared with damaged plants across the different varieties. ANOVA was also used to consider any differences in quantity of each compound emitted by the 10 varieties after mechanical damage. The ratio of *cis*-3-hexenyl acetate to *cis*-3-hexenol (referred to as the GLV ratio) emitted after damage was also analyzed in this way. The correlation between mean emission of volatile and mean amount of leaf area remaining across pairs of these measurements for all the varieties was made for each volatile separately and for the GLV ratio. A significant negative correlation implied that willow varieties with less leaf area remaining (i.e., relatively susceptible) tended to have a high concentration of volatile compound and GLV ratio, and vice versa.

RESULTS

Volatile Compounds. Three volatile compounds were emitted from undamaged plants (*cis*-3-hexenyl acetate, *cis*-3-hexenol, and benzaldehyde), which increased in yield after they were damaged, as did the number of different volatile compounds detected (Table 1). There were differences among undamaged willow varieties for the yield of compounds: four gave no detectable volatile compounds, while relatively low levels were collected from six. Of the three compounds tested, the yield difference between undamaged and damaged plants was significant for only *cis*-3-hexenyl acetate and *cis*-3-hexenol ($F = 10.97$ and $F = 4.57$, $df = 10, 38$; $P < 0.001$) and for certain varieties (Table 1, undamaged). There were also significant differences among varieties after damage for certain compounds

[a] The mean quantity (ng ± SE) of volatile compounds emitted in 90 min from the top 20 cm of stem from three plants of 10 willow varieties before and after mechanical damage (numbers related to compounds for undamaged plants). Different letters indicate significant difference ($P < 0.05$) between varieties for the yield of each compound separately.

[b] — indicates compound was not detectable.

[c] Yields are significantly different ($P < 0.05$) between undamaged and damaged plants for individual variety.

[d] For compound name see a) undamaged above.

TABLE 2. RATIO OF TWO MAJOR VOLATILES EMITTED FROM DAMAGED WILLOW VARIETIES ($N = 3$)

Willow variety	Ratio (±SE) of *cis*-3-hexenyl acetate to *cis*-3-hexen-1-ol
Salix dasyclados Wimm.	3.03 ± 0.98 c[a]
Salix viminalis Bowles Hybrid	0.03 ± 0.03 a
Salix x *sericans* Coles	1.20 ± 0.66 ab
Salix burjatica Germany	1.72 ± 0.78 b
Salix viminalis 79046	0.73 ± 0.17 ab
Salix x 445 de Biardii	1.32 ± 0.23 ab
Salix purpurea 012	0.26 ± 0.19 a
Salix triandra Black Maul	0.31 ± 0.04 a
Salix burjatica Korso	0.73 ± 0.26 ab
Salix eriocephala	0.13 ± 0.08 a

[a] Ratios with different letters are significantly different at $P < 0.05$.

(Table 1, damaged), with *S. viminalis* Bowles Hybrid having the lowest number of compounds and yield of all the varieties.

There were differences among willow varieties for the GLV ratio (*cis*-3-hexenyl acetate to *cis*-3-hexenol) from damaged plants ($F = 3.5$, $df = 8, 18$; $P < 0.01$). *Salix dasyclados* had the ($P < 0.05$) highest ratio of all varieties, with *S. viminalis* Bowles Hybrid having the lowest (Table 2).

Beetle Feeding Preferences. There were differences for all beetle species in their feeding preferences of the 10 willow varieties (*P. vulgatissima* $F = 5.9$, $df = 9,54$; $P < 0.001$; *P. vitellinae* $F = 15.2$, $df = 9,54$; $P < 0.001$; *G. lineola* $F = 2.5$, $df = 9,54$; $P < 0.02$). *Salix dasyclados* was the most preferred variety of both *P. vulgatissima* and *G. lineola* (Table 3), whereas *P. vitellinae* preferred *S. burjatica* Germany and *S. purpurea*.

Correlations. For both *P. vulgatissima* and *G. lineola*, there were negative correlations between the amount of leaf area remaining and the absolute concentration of *cis*-3-hexenyl acetate (*P. vulgatissima* $r = -0.88$, $P < 0.001$; *G. lineola* $r = -0.84$, $P < 0.01$). Two other compounds showed no correlation: *trans*-2-hexenyl acetate (*P. vulgatissima* $r = -0.57$, $P = 0.08$; *G. lineola* $r = -0.52$, $P = 0.12$) and benzaldehyde (*P. vulgatissima* $r = -0.59$, $P = 0.07$; *G. lineola* $r = -0.54$, $P = 0.10$). In comparison, for *P. vitellinae*, there were no significant correlations between leaf area remaining and any of the emitted compounds.

Likewise, there was a negative correlation between the GLV ratio and the remaining leaf area after feeding by *P. vulgatissima* ($r = -0.95$, $P < 0.001$) and *G. lineola* ($r = -0.84$, $P < 0.01$), with none for *P. vitellinae*.

TABLE 3. FEEDING PREFERENCES OF *Phratora vulgatissima*, *P. vitellinae*, AND *Galerucella lineola* FOR 10 POTTED WILLOW VARIETIES

Willow variety	Leaf area remaining[a] (mm)		
	P. vulgatissima	*P. vitellinae*	*G. lineola*

[a] Values represent the mean amount of leaf area remaining (from a 110-mm diameter leaf disk) 18 hr after beetles were placed in dishes containing a disk of each variety ($N = 7$).

DISCUSSION

The present findings for the willow *S. dasyclados* corroborate previous results for this variety (Peacock et al., 2001), with only *cis*-3-hexenyl acetate, *cis*-3-hexenol, and benzaldehyde emitted from undamaged plants, increasing in yield after damage, as did the number of different volatile compounds detected. While this pattern of volatile emission was similar for the other willow varieties tested, there were differences among varieties in the concentration of compounds and GLV ratio. Correlation analysis indicated a significant relationship between susceptibility to feeding damage by *P. vulgatissima* and *G. lineola* and a relatively high concentration of both *cis*-3-hexenyl acetate and GLV ratio (*cis*-3-hexenyl acetate to *cis*-3-hexenol).

These two green leaf volatiles have previously been shown to be insect attractants (Schütz et al., 1997; Rojas, 1999; Coghlan, 2000). The relationship found for the GLV ratio is of note, as it has been suggested that specialized herbivores (like the Colorado potato beetle and, in the present case, the willow beetle) would likely be attracted to a blend of compounds in a definite ratio, in contrast to generalist insects (like the Japanese beetle) (see references in Loughrin et al., 1996).

The two varieties of *S. burjatica* tested differed significantly in their susceptibility to *P. vulgatissima* and *P. vitellinae. Salix burjatica* Germany, the more susceptible variety, appeared to have a higher GLV ratio than the relatively resistant *S. burjatica* Korso (although not significant at $P > 0.05$). This is of interest as

S. burjatica Germany is one of only a small number of willow varieties that is host to both these *Phratora* species. Usually the adult feeding preferences are different between these two beetle species; this is thought to be due to differences in the phenylglucoside content of the leaves. *Salix burjatica* has relatively high levels of these chemicals (Kelly and Curry, 1991) and, thus, should be a suitable host for *P. vitellinae* but relatively unsuitable for *P. vulgatissima*. However, if there were a higher proportion of *cis*-3-hexenyl-acetate to *cis*-3-hexenol after damage, and if it had an attractant effect on *P. vulgatissima*, any difference in GLV ratio between *S. burjatica* varieties might help explain the anomaly of the similar feeding preference. Under field conditions, more *P. vulgatissima* were found on *S. dasyclados* Wimm. plants that had conspecifics and beetle-feeding damage than on undamaged plants, suggesting the occurrence of a feeding induced plant kairomone (Peacock et al., 2001). These authors found that the GLV ratio had increased from 0.54 in undamaged plants to 2.18 after 24 hr of beetle feeding.

While significant differences among damaged varieties for some volatile compounds and correlations between these quantities and susceptibility to willow beetles were found, green leaf volatiles may not necessarily be the key components in host selection because they are emitted by almost all damaged plants. Volatile collections were made immediately after damage, yet it may be that other, induced compounds associated with the presence of these green leaf volatiles are involved in host plant choice. Many green leaf volatiles are assumed to "bleed" from damaged sites, whereas *cis*-3-hexenyl acetate is known to be partially induced in response to herbivory (Loughrin et al., 1994; Turlings et al., 1998). Therefore, further studies are needed to determine the behavioral responses of beetles to induced leaves and to compare the volatile chemicals after mechanical and beetle damage.

Abstract—The common spiny mice *Acomys dimidiatus* and golden spiny mice *Acomys russatus* coexist in the extreme warm and dry parts of the Rift Valley in Israel. However, they are temporally segregated in that the former is nocturnal, whereas the latter is diurnal. Daily rhythms of physiological and behavioral variables in *A. russatus* responded to semiochemical signals released by *A. dimidiatus* (in the urine and feces). Both species feed upon the same food items but at different times of the 24-hr cycle. The main aim of the present study was to test under field conditions the foraging response of *A. russatus* to odors of different ages released by *A. dimidiatus*. Various feeding and behavioral variables were compared in three groups of *A. russatus*. The results show that fresh semiochemical signals released by *A. dimidiatus* decrease the feeding efficiency and increase the rate of smelling from a distance in *A. russatus*. These results support the idea that temporal segregation between the two coexisting species is at least partly through semiochemicals present in the urine and feces.

Key Words—Heterospecific chemical signals, feeding behavior, urine and feces, *Acomys*, spiny mouse, arid environment.

INTRODUCTION

The coexistence of spiny mice of the genus *Acomys*, the common spiny mouse *A. dimidiatus* (Harrison and Bates, 1991) and the golden spiny mouse *A. russatus*, has been shown to be through exclusion of the latter from nocturnal activity by the former (Shkolnik, 1971). Attempts have been made in the last decade to understand the mechanisms for such temporal segregation. Under laboratory conditions when *A. russatus* is kept separately from *A. dimidiatus*, it manifests body temperatures and oxygen consumption daily rhythms typical of nocturnal species (Rubal et al., 1992). Body temperature and oxygen consumption daily rhythms of *A. russatus*, exposed to indirect chemical signals released by *A. dimidiatus*, showed a phase shift of approximately 2 hr compared with controls (Fluxman and Haim, 1993; Haim and Fluxman, 1996). However, when studying the response of the daily activity rhythms of *A. russatus* to direct contact with urine and feces released by *A. dimidiatus*, a shift of approximately 7 hr into diurnal activity was observed (Haim and Rozenfeld, 1993). From these studies and others, it was concluded that semiochemicals released from the urine and feces of *A. dimidiatus* are important in maintaining the temporal segregation between the two species.

Furthermore, the hypothesis that the nest site (resting place) could be a source of competition between the congeners was tested under laboratory conditions (Haim and Rozenfeld, 1995). The results supported the hypothesis, and it was also noted that *A. russatus* keeps its resting place only by being active during the daytime when *A. dimidiatus* is inactive. Recently, Van Aarde and Haim (1999) have shown that semiochemical signals released by *A. dimidiatus* may affect aspects of reproduction in *A. russatus*.

Both species utilize the same diet (Shkolnik, 1966), but it is eaten at different times of the 24-hr cycle. However, food is probably the source of competition between the two species. From this, we asked the following question: do semiochemicals of different age released by *A. dimidiatus* have an effect on feeding behavior of *A. russatus*? We recorded feeding behavior of *A. russatus* in the field in relation to the size and quality of food items. We studied the change in frequency of feeding sessions and of behavioral acts in response to semiochemicals released by *A. dimidiatus*.

METHODS AND MATERIALS

Study Area. Field observations were carried out at the foot of Masada cliff, 3 km from the Dead Sea shores in the Jehudean desert, which is a part of the Rift Valley, in Israel. The study area was located close to the ruins of a Roman camp, at about 340 m below sea level. The climate is extremely dry and hot. The average annual precipitation is 47 mm with large year-to-year fluctuations. The mean minimum temperature, recorded in January, was 11°C, whereas the mean

maximum temperature, recorded in July, reached 39°C (Jaffe, 1988). Petri dishes containing different food items were used (see below). The dishes were set close to walls made of rough stones, 2 m wide at their base and 1.2 m high. The walls were built some 2000 years ago and are inhabited by different rodent species; however, the dominant species in the area are the spiny mice *A. russatus* and *A. dimidiatus* (Dobly et al., 1999). Along these walls, garbage has accumulated, some of which is presumably consumed by the mice inhabiting the walls. In order to observe marked individuals, *A. russatus* were trapped before the current study (Dobly et al., 1999) and individually marked with an animal-marking crayon (Raidi-Raider, Ottenbach, Germany).

Feeding Observations. Clean Petri dishes (liquid dish-washing soap, water, and then ethanol 70%) were set on a white piece of filter paper (28 × 23 cm). Each dish contained five different items: (1) an intact grilled peanut ($N = 1$); (2) half a peanut seed ($N = 5$); (3) corn seeds ($N = 10$); (4) wheat seeds ($N = 15$); and (5) oat flakes ($N = 15$). The position of the different food items in the Petri dishes as well as mass and energy contents are presented in Figure 1. Two Petri dishes were positioned at a distance of 1.5 m from each other in each session, which lasted 1 hr. A total of 28 sessions were performed.

Preliminary observations indicated that mice were not disturbed by the observer (Dobly et al., 1999). Direct visual observations were carried out from an exposed spot at a distance of 3 m from 8:45 to 16:00 hr. We chose daytime in order to observe *A. russatus*. Different behavioral variables were recorded (see Dobly et al., 1999): emerging from shelter, watching, approaching a Petri dish, smelling from

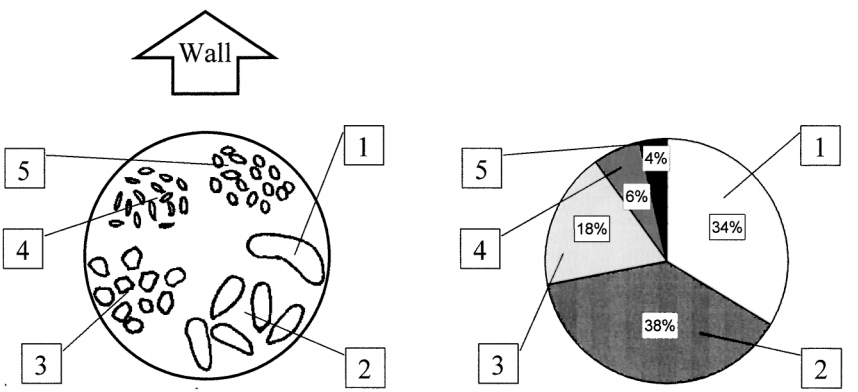

FIG. 1. Presentation and composition of dietary items offered in each Petri dish used as an artificial feeding site. The types, numbers, energy contents, and total weights were as follows: (1) intact grilled peanut (ca. 2 seeds, 1 × 14,000 cal, 2 g), (2) half a peanut seed (5 × 3200 cal, 2.5 g), (3) corn seeds (10 × 750 cal, 1.6 g), (4) wheat seeds (15 × 175 cal, 0.65 g), and (5) oats (15 × 100 cal, 0.35 g). The total energy percentages are given in the pie chart.

a distance, and close sniffing. When more than one mouse was active, behavioral patterns were recorded by using a video camera (Sony Hi8 CCD-TRV70E). Data were analyzed frame by frame. At the end of each session, the food items left over were counted and the Petri dishes cleaned. We also used the number of food items touched, i.e., the number of food categories with at least one item eaten. The energy values of the different food items were determined by using a bomb calorimeter (Semimicro Calorimeter 1425, Parr).

Exposure to Heterospecific Odors. In 15 of 28 sessions, the observed mice were exposed to a type of odor obtained from *A. dimidiatus*. Toilet paper and feces, obtained from traps in which *A. dimidiatus* were successfully trapped, were used as a source of the heterospecific odors. All the collected odorous items were kept in a sealed plastic bag. In eight cases, *A. russatus* were offered, in each session and in each dish, a combination of fresh urine (on one piece of toilet paper) with three fecal pellets collected on the same day (we used three pellets according to the average number available per day). In seven cases, only three fecal pellets were used for testing the response of *A. russatus* to feces alone, 24 hr after collection. Paper was put below the Petri dishes, and the feces were put close to the dishes on the side of the wall. Therefore, three different groups were studied: (1) control (no odor), (2) heterospecific feces only, collected one day before exposure (old odor) and (3) fresh heterospecific urine and feces (fresh odor). We did not compare heterospecific odor to homospecific odor as other laboratory and field studies have shown that only heterospecific odor has a repellent effect on *A. russatus* (Haim and Rozenfeld, 1993; A. Haim and E. Baert, unpublished data). Beyond this identified effect of homospecific versus heterospecific odors, our main purpose was to test the unknown difference between fresh and old heterospecific odor.

Data Analyses. Results are presented as frequency, percentage, mean $\pm$ standard deviation, or median with range. In order to establish differences among studied groups, the following statistical tests were used: chi-square test, Mann-Whitney *U* test, and Kruskal-Wallis one-way ANOVA. All were one-tailed due to the hypothesis of a negative influence of heterospecific odor on feeding. To test the food preference inside one treatment, we used two-tailed Friedman two-way ANOVA. To determine which pairs were the sources of the detected difference in ANOVA tests, we calculated the critical difference necessary for significance in each compared pair.

RESULTS

A total of eight golden spiny mice (five females and three males) were marked and observed. At least one mouse appeared in 22 of the 28 sessions. The six sessions with no mouse were from groups with old [two of seven (29%)] or fresh [four of eight (50%)] odors. This distribution of appearance among the three groups is different (chi-square test, $P < 0.01$, Table 1). Similarly, in all sessions with at

Mean food touched (out of 10)	3.5 (SD = 2.7) ($N = 13$)	2.6 (SD = 2.6) ($N = 7$)	1.1 (SD = 1.8) ($N = 8$)	$P = 0.031$, Kruskal-Wallis one-way ANOVA, $df = 2$

[a] None: no odor (control), old: one-day-old heterospecific feces; fresh: fresh heterospecific urine and feces. Range of median is given in square brackets. SD = standard deviation.

least one animal observed, there were, on average, more individuals per session in the control group than in the fresh odor group; the old odor group was intermediate (Mann-Whitney U test, $N = 21$, $P = 0.045$, Table 1).

No significant difference was noted among the three groups in regards to the median time to appear or to eat (Table 1). Moreover, in three cases (two controls and one old odor, 15% and 14%, respectively), an *A. dimidiatus* was detected; all of them appeared only once and took either an entire or half a peanut in a single trip lasting less than 10 sec.

Not all observed *A. russatus* ate from the Petri dish. Table 1 shows, for the three groups studied, the number of mice that ate food, as well as the number of food types that were touched by mice. Mice from the control group ate more frequently than mice confronted with fresh odor (95% vs 57%, Mann-Whitney U test, $N = 27$, $P = 0.017$). Similarly, with regard to number of food types touched, a significant difference was noted only between control mice and those exposed to fresh odor (Kruskal-Wallis one-way ANOVA, $df = 2$, $N = 28$, $P = 0.031$, Table 1).

Mice of all groups preferred the larger items with a high-energy content per gram. The item most often taken on a first visit was the whole peanut, and then the half peanuts. In total, a larger amount of grilled intact peanuts was eaten than oats, corn, or wheat seeds (Friedman two-way ANOVA, $df = 4$, $N = 28$, $P = 0.017$). The energy context of the five food types is presented in Figure 2. The relationship then became clearer. The energy value of whole peanuts eaten is higher than that of corn, wheat, or oats (Friedman two-way ANOVA, $df = 4$, $N = 28$, $P = 0.008$).

The analysis of behavioral patterns revealed that mice exposed to fresh odor showed more smelling from a distance than control mice (Kruskal-Wallis one-way ANOVA, $df = 2$, $N = 28$, $P = 0.041$, Table 1). However, no difference was detected either in close sniffing or in any other recorded behavior (e.g., while the maximum number of mice approaching a Petri dish decreased among the three treatments, the medians were not different: no odor: 2.5 (range 1–30), old: 2.5 (1–19) fresh: 3.0 (1–10), Kruskal-Wallis one-way ANOVA, $df = 2$, $N = 28$, NS).

DISCUSSION

Food and energy consumption in *A. russatus* have been studied under short and long photoperiod regimes (Haim et al., 1994). Under acclimation to a short day, *A. russatus* consumed significantly more food compared with acclimation to a long day. The energetic demands of *A. russatus* are low in relation to its body mass, compared with mesic species. Field metabolic rates (FMR) were compared between the two *Acomys* species by using the doubly labeled water technique (Degen, 1994). Daily metabolic rates of *A. russatus* were 27% lower than those for a similar sized *A. dimidiatus*. The energy content of the items offered in

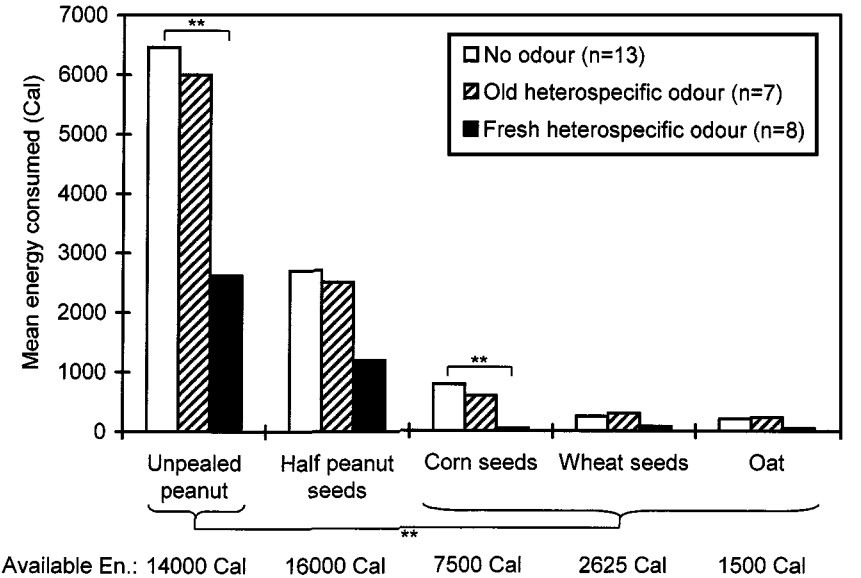

FIG. 2. Mean energy taken from the five food types by the mice under three different treatments. The total energy available is given below each food type (Available En.). Two-tailed Friedman two-way ANOVA, one-tailed Kruskal-Wallis one-way ANOVA, and one-tailed Mann-Whitney U tests were used ($^{*}P < 0.05$, $^{**}P < 0.025$).

the Petri dish exceeded the energy demands, even during the winter season when experiments were carried out.

Our results show that *A. russatus* selected the largest food item (intact peanut), which contained the highest energetic value. Such selection would be advantageous to a diurnal animal by minimizing the time spent foraging and reducing vulnerability to predation or overheating. These requirements are consistent with the high number of distant smelling bouts and the small number of close sniffing bouts recorded in the presence of fresh odor. The results of food selection support the conclusion of Kerley and Erasmus (1991) that rodent preference for seeds is related to the net rate of energy intake provided by the seed.

However, our results revealed a significant decrease in food and energy intake as a result of exposure to fresh urine and feces released by *A. dimidiatus*. In a laboratory study, *A. russatus* marked its food with an oral secretion (Rozenfeld et al., 1994). Oral marking by *A. russatus* may serve to mask the original odor of *A. dimidiatus*. The number of sessions in which mice appeared upon exposure to fresh heterospecific odor and the number of mice per session were significantly lower compared with control sessions. This suggests that odor can act from a distance. However, it seems that under dry desert conditions, odor sources are

not so effective. Therefore, we conclude that, at least partly, scent marking of the habitat by *A. dimidiatus* contributes to the temporal segregation of the two species. As *A. russatus* does not accumulate food in its resting place, the marking of food items supports the hypothesis that such marking has a heterospecific role (Rozenfeld et al., 1994).

From the results of this and previous studies, we conclude that heterospecific odors released in the urine and/or feces of *A. dimidiatus* have an effect on the behavior of *A. russatus*. Activity in *A. dimidiatus* is confined to the early hours of the dark phase (Shkolnik, 1966). Hence, we assume that odors released at night during the activity period of *A. dimidiatus* decline with time, so that when *A. russatus* is active, the odor effect is of little significance.

As the temporal segregation between the two species is maintained, at least partly, by chemicals released by *A. dimidiatus* (Haim and Rozenfeld, 1993), we assume that this depends on fresh urine and feces. The chemicals involved appear to be volatile. Semiochemicals produced in the urine and feces of *A. dimidiatus* can bring about competitive exclusion of *A. russatus* from nocturnal activity and can be used to exclude them from access to food and habitat resources. The isolation of the chemical component of this signal will be important for future studies, involving the segregation of coexisting species.

(Received March 27, 2001; accepted May 29, 2001)

Abstract— We investigated the behavioral feeding preference and the chemoreception of leaf polar extracts from trembling aspen, *Populus tremuloides*, and from sun and shade sugar maple, *Acer saccharum*, by larvae of the polyphagous forest tent caterpillar, *Malacosoma disstria*, a defoliator of deciduous forests in the Northern Hemisphere. Three polar extracts were obtained from each tree species: a total extract, a water fraction, and a methanol fraction. *M. disstria* larvae were allowed *ad libitum* access to an artificial diet from eclosion to the fifth instar. Two-choice cafeteria tests were performed comparing the mean (±SE) surface area eaten of the total extracts, and the following order of preference was obtained: aspen > sun maple > shade maple. Tests with the other fractions showed that *M. disstria* larvae preferred the total aspen extract to its water fraction, and the latter to its methanol fraction. The response to sun maple was similar to aspen. However, for the shade maple experiment, there was no difference between the total extract and its water fraction. Electrophysiological recordings for aspen showed that the sugar-sensitive cell elicited more spikes to the water fraction, followed by the total extract, and finally the methanol fraction. Spike activity to stimulations of sun and shade maple extracts revealed a similar trend, where methanol fraction > water fraction > total extract. Our findings are discussed in light of previously known information about this insect's performance on these host plants.

INTRODUCTION

The primary feeding host of the forest tent caterpillar (*Malacosoma disstria* HBn.) is trembling aspen (*Populus tremuloides* Michx.), but in Québec during epidemics, larvae are known to feed on sugar maple (*Acer saccharum* Marsh.). Aspen is widespread throughout North America (Hodson, 1941), whereas sugar maple forests occur predominantly in the northeastern portion of the continent (Rowe, 1972). Larvae of *M. disstria* develop better on aspen compared to maple foliage (Lorenzetti, 1993; Nicol et al., 1997). Aspen contains twice the amount of soluble sugars of sugar maple, and these were the only constituents of the foliage that could be correlated with the insect's performance (Lorenzetti, 1993). This is consistent with the work of Lindroth et al. (1993), who showed that in aspen leaves, contents of sucrose and hexose (glucose and fructose) and total nonstructural carbohydrates (all expressed in percent dry mass) were more than three times higher than in the leaves of sugar maple. Other common chemical constituents of aspen include tremulacin and salicortin, which constitute 85% of the total phenolic glycosides (Lindroth et al., 1987). Long-chain fatty alcohols and α-tocopherylquinone (α-TQ) have also been identified (Lin et al., 1998a,b). Lindroth and Hemming (1990) reported that poor performance (prolonged duration of instars and reduced growth) of the polyphagous gypsy moth (*Lymantria dispar* L.) can be attributed to levels of tremulacin that are $>3\%$ in poplar leaves. Some maples (*Acer palmatum*, *A. platanoides*, and *A. rubrum*) are known to contain galloylcyanidin glycosides (Shi-Bao, et al., 1992; Abou-Zaid and Nozzolillo, 1999). Sugar maple is characterized by high levels of hydrolyzable (ellagitannins, gallic acid, gallotannins) and condensed tannins (Baldwin et al., 1987; Lindroth et al., 1993). In contrast, aspen leaves possess significantly lower levels of condensed tannins and no traces of hydrolyzable tannins (Lindroth et al., 1987, 1993).

Differences in foliar concentrations of sugars can be found within a tree, depending on vertical distribution (Futuyama and Saks, 1981; Coley, 1983; Lincoln and Mooney, 1984; Ellsworth and Reich, 1992; Dudt and Shure, 1994). Fortin (1994) observed that when larvae of *M. disstria* were fed foliage that had been exposed to the sun versus exposed to shade, there were differences in pupal weights and in larval development time. Recently, Fortin and Mauffette (in preparation) demonstrated that in four consecutive years, the biological performance of *M. disstria* was superior on foliage located on the crown of mature sugar maple compared to that found at the base of the tree. They argue that this might be due to higher amounts of total nitrogen and soluble sugars present at the summit of the crown, which would result in a more nutritious diet for the insect.

Many phytophagous caterpillars perceive sugars, in particular sucrose, as a cue for the selection of a favorable food plant, and sugar-sensitive chemoreceptors are ubiquitous in all lepidopteran larvae that have been studied to date (Schoonhoven, 1967, 1987). In current behavioral experiments with *M. disstria* larvae, we found that sucrose was preferred over water at all concentrations tested (0.1–500 mM). We also found that sucrose elicited a high firing frequency from cell 1 (sugar cell) on the medial styloconic sensillum of the galea at ecologically relevant concentrations. It is known that neural input from these sensilla on the mouthparts of lepidopteran caterpillars is necessary for unimpaired food selection (Ma, 1972; Hanson and Dethier, 1973; Schoonhoven and Blom, 1988; De Boer, 1993). However, there is limited information available on the sensory perception of plant extracts by maxillary styloconic sensilla, probably because the neurophysiological results are difficult to interpret, due to their considerable variability (Schoonhoven et al., 1991), and to changes in spike shape of the same cell, especially at high frequencies (Frazier and Hanson, 1986). Despite these obstacles, unambiguous results have been obtained in several studies where foliage extracts were used as stimuli in electrophysiological (Ohsugi et al., 1978; Toufexis et al., 1996) and behavioral studies (Cobbinah et al., 1982; Albert and Parisella, 1988; Guertin and Albert, 1992; del Campo and Renwick, 1999).

Since there is more information available on the responses of caterpillars to single compounds, and we know that an insect is exposed to a mixture of compounds when feeding on leaves, we examined the responses of *Malacosoma disstria* larvae to extracts from two host plants. The specific objectives were to assess behavioral preferences of *M. disstria* to polar extracts from aspen and from sun and shade sugar maple foliage and to perform feeding and electrophysiological tests with the constituents obtained from each polar extract and from further fractions of these extracts. We hypothesized that larvae would prefer the total extracts in the following order: aspen > sun maple > shade maple since aspen contains higher sugar levels, followed by sun maple, and then by shade maple. We also hypothesized that the methanol fraction whould be the least preferred since it contains mostly phenolic compounds, such as condensed tannins, which are generally believed to act more as deterrents than as phagostimulants (Feeny, 1976; Rhoades and Cates; 1976; Swain; 1979). Finally, we expected that the electrophysiological data would concur with the behavior.

METHODS AND MATERIALS

Insects. Malacosoma disstria larvae were obtained from the Great Lakes Forest Research Center in Sault-St-Marie, Ontario, Canada, and reared on an artificial diet (Addy, 1969) that was slightly modified as follows: raw linseed oil was replaced by wheat germ oil, and whole wheat germ was replaced by whole

wheat flour. We used 5 instead of 8.4 g of cholesterol, 50 instead of 84 g of alphacel, and 42 instead of 70 g of agar. We also added 1.7 g of methyl paraben, a preservative. Larvae were kept in Petri dishes (100 × 15 mm) in an incubator at 24°C and on a 16L:8D cycle. The Petri dishes were cleaned every two days and fresh diet was provided.

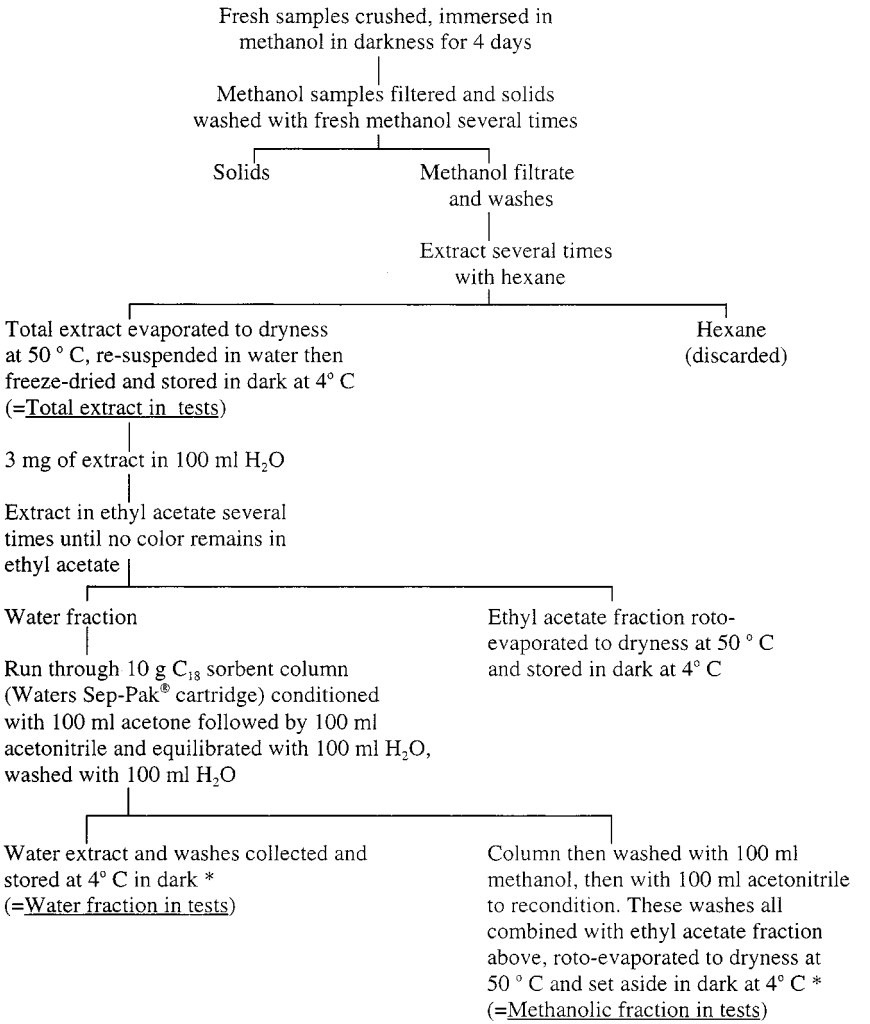
Foliage. Trembling aspen (*Populus tremuloides* Michx.) and sugar maple (*Acer saccharum* Marsh.) foliage was collected on May 18, 1999, at three different locations in southwestern Québec (the region of collection is delimited by the municipalities of Ste-Barbe, Dundee, and Huntington, approximately 60 km south of Montréal). Although collected at an early date, the foliage of both species was well developed and close to full expansion in the case of maple. The spring of 1999 was especially early. It was estimated that leaf age was at least two weeks, but leaves could have been as old as three weeks for some trees. Under natural conditions, leaves of that age are generally fed upon by fourth instar *M. disstria* larvae.

Aspen trees were either growing in small stands adjacent to the sampled maple stands, or they were growing directly at the edge of these. At each location, foliage was collected from two or three trees of each species. Sugar maple foliage was collected from both the top (sun leaves) and the bottom (shade leaves) of the crown. Samples of sun and shade leaves were kept separate. Foliage collected from aspen trees consisted of only sun leaves. In addition to the aspen trees sampled as above, other samples were also collected from an aspen stand in the Montréal area (Rivière-des-Prairies). In all cases, sampling was conducted between morning and early afternoon, and leaves were immediately placed on ice in a cooler. Upon arrival in the laboratory, small subsamples were weighed and placed in an airflow dryer, left to dry completely, and reweighed to calculate the water content (Table 1). The remainder of each sample was weighed and placed overnight in an −80°C freezer. The next day samples were retrieved and crushed into small bits while still frozen, and immediately placed to thaw in pure HPLC grade methanol (1:10 w/w). The extraction flasks were sealed and kept in the dark for four days, with frequent gentle stirring over this period.

Polar constituents from the foliage were obtained as shown in Figure 1. The samples in methanol were filtered, the solids were washed with fresh methanol several times, and the whole volume of methanol (filtrate and wash) was extracted several times with hexane until no appreciable change in color was visible in

TABLE 1. WET AND DRY WEIGHTS OF THREE TYPES OF FOLIAGE

	Aspen	Shade maple	Sun maple
Fresh weight (g)	821.8	768.4	853.6
Dry weight (g)	267.4	223.9	280.9
% Water content	67.5	70.9	67.1



* Note: these last steps were repeated 6 times.

FIG. 1. Procedure for the preparation of polar extracts from the three host plants.

the methanol. The hexane was discarded, and the methanol containing the polar constituents was roto-evaporated to complete dryness under reduced pressure at a temperature of 50°C. The dry extracts were dissolved in a minimal amount of bidistilled demineralized water (H_2O_{bddm}), and freeze-dried. The powdered extracts were collected, weighed, placed in brown-glass bottles, and stored at 4°C.

Extracts were further separated to obtain two fractions, one mainly containing soluble sugars, amino acids, and other highly polar constituents, and the other containing less polar constituents, such as tannins and flavonoids. First, a known amount of extract (ca. 3 mg) was dissolved in 100 ml H_2O_{bddm} and extracted with ethyl acetate as many times as was necessary to see no significant coloration in the ethyl acetate. All volumes of ethyl acetate were pooled, roto-evaporated to dryness at 50°C, and kept in the dark at 4°C. This procedure was performed to reduce the amount of constituents dissolved in water. The extracted volume of water was then run by gravity through a conditioned (100 ml acetone followed by 100 ml acetonitrile) and equilibrated (100 ml H_2O_{bddm}) column packed with 10 g of C_{18} sorbent (Waters Sep-Pak cartridge). The column was washed with 100 ml H_2O_{bddm}, which was collected and pooled with the previously collected volume of water containing the polar extract, and set aside in the dark at 4°C. The column was washed with 100 ml of methanol, followed by 100 ml of acetonitrile to recondition the column. These volumes were collected in the flask from the ethyl acetate extraction performed earlier, pooled, and set aside in the dark at 4°C. The column was once more equilibrated by running 100 ml H_2O_{bddm}, and the water fraction was run through the column again, followed by all the steps previously described. This procedure was repeated six times. At the end, the fraction containing the less polar constituents (the methanol fraction) was roto-evaporated to dryness at 50°C, resuspended in the appropriate volume of H_2O_{bddm}, and freeze-dried. The powdered methanol fraction was collected, weighed, placed in brown glass bottles, and stored at 4°C. The fraction containing the more polar constituents, (the water fraction) was roto-evaporated at 50°C to the final volume necessary to arrive at the concentration (w/w on a dry matter basis) present in the foliage at the time of collection. The water fraction was placed into a small opaque vial and stored at −20°C.

For the behavioral experiments, total extracts and their fractions were reconstituted in distilled water to attain a final concentration equivalent to that found in the foliage at the time of collection (dry weight). A drop of methanol was then added to the extracts and their fractions to increase solubilization. For the electrophysiology, concentrations were adjusted to foliar concentrations on a fresh weight basis, and all extracts and their fractions were prepared in a solution of potassium chloride (10 mM) to ensure adequate electrical conductance.

Behavior. All experiments were conducted in the morning, over a four-day period. For each day, 10–15 larvae were selected from the Petri dishes as mid-fifth instars and starved for one day prior to bioassays to ensure maximum response. They were transferred into an arena consisting of a two-choice situation arranged in the following manner: four Millipore HA 0.045-μm cellulose disks, 9 mm in diameter, were suspended individually on pins 0.5 cm above the floor of the arena. A 20-cm × 5-cm Petri dish served as a cover to the whole setup to keep the larvae from roaming about. Disks were wetted with 20-μl aliquots of extracts or

their fractions and arranged in an alternating manner with the water controls or the other extract solutions. This amount was just sufficient to saturate the whole disk. For every treatment, a minimum of 20 disks were used to determine the average dry weight of each disk containing a specific extract in water, or water alone, after all the water had evaporated. These average weights were used as the initial disk weight prior to feeding by larvae. The setup was transferred to an incubator maintained at the same growth conditions that the larvae had been exposed to, and larvae were allowed to feed for 4 hr, then removed from the arenas, after which time the disks were allowed to dry completely and weighed on a Sartorius single-pin balance to a precision of ± 0.001 mg. The amount of each disk (eaten) was calculated as the difference between the initial and final dry weights of the disk, and this value was used to express the mean surface area eaten of the test and control disks for each experiment. Only insects that ate $>50\%$ of the total disk area, control disks included, were considered for analysis. This cafeteria test was a modification of that of Jermy et al. (1968), and a similar setup is also seen in Albert and Jerrett (1981) and Albert and Parisella (1985). Statistical analysis was done with Number Cruncher Statistical Software (J. L. Hintze, 865 East North, Kaysville, Utah 84037, USA). Parametric tests were used since the data were normally distributed. Comparisons of the treatments versus. water or treatments among themselves were done by using a randomized two-sample *t* test ($P < 0.05$) to examine whether there was a preference between the two choices of the extracts tested. Data also were subjected to a one-way ANOVA ($P < 0.05$) to verify whether there were any differences among the three extracts, i.e., aspen and sun and shade maple.

Electrophysiology. All experiments were performed in the morning. About 10–15 mid-fifth instar larvae were selected from the Petri dishes prior to an experiment. Standard tip-recording was used (see Panzuto and Albert, 1997). The head and the first three thoracic segments were severed from the rest of the body of the larvae, and a glass microcapillary pipet containing insect saline (Schnuch and Hansen, 1989) was fitted into the opening and subsequently into the walls of the hypopharynx to expose the mouthparts. Special care was taken to avoid damaging the gustatory nerve. This preparation was placed onto a reference electrode under a compound microscope, with the larva ventral side up, to facilitate viewing and contact. A second glass micropipet was filled with a test solution. In preliminary experiments, we determined that the lateral styloconic sensilla of the galea did not respond to our extracts, while the medial styloconic sensilla consistently responded to all extracts. Action potentials were recorded for 1 sec on digital audio tape, digitized by using the SAPID Tools program (Smith et al., 1990), and then visually analyzed by counting the number of neural impulses from cell 1 (sugar-sensitive neuron), cell 2 (amino acid-sensitive neuron), and cell 3 (salt-sensitive neuron) in the traces. There were no cell 4 (water-sensitive neuron) responses to the stimuli used in our study. The physiological responses of cell 1 were analyzed

TABLE 2. RESPONSE (SURFACE AREA EATEN) IN TWO-CHOICE TESTS BY FIFTH-INSTAR *M. disstria* REARED ON ARTIFICIAL DIET TO THREE TOTAL EXTRACTS VS WATER

Extract	Surface area eaten (mm^2, mean ± SE)		P^a	N
	Treatment	Water		
Shade maple	268.5 ± 14.8	11.8 ± 7.7	0.0022	6
Sun maple	254.2 ± 15.7	1.4 ± 0.82	<0.0001	9
Aspen	287.2 ± 14.7	16.4 ± 12.16	<0.0001	14

[a] Two-sample *t* test.

statistically with a one-way ANOVA within the various extracts and their fractions as main effect. Another one-way ANOVA was performed to compare sugar cell response to the three extracts (i.e., aspen and sun and shade maple) and to their fractions (e.g., aspen and sun and shade water fractions). In addition, *a posteriori* tests (Newman-Keuls multiple comparison) were run to separate further the means. Statistical significance was accepted at $P < 0.05$ throughout.

RESULTS AND DISCUSSION

In two-choice feeding tests of total extracts of aspen, sun maple, or shade maple, larvae of *M. disstria* strongly and consistently preferred the disks containing extracts over those containing only water (Table 2). However, there was no difference in the responses to the three extracts (one-way ANOVA, $df = 2,26$; $F = 1.25$; $P = 0.3018$). When total extracts of the different hosts were tested against each other, sun maple was preferred over shade maple, and aspen was preferred over both sun and shade maple (Table 3), thus confirming our first prediction: aspen > sun maple > shade maple. These findings are consistent with our current knowledge of *M. disstria*'s performance on aspen compared to sugar maple foliage (Lorenzetti, 1993; Lindroth et al., 1993; Nicol et al., 1997). Aspen leaves have high soluble sugar levels during the larval growth period of *M. disstria*; these constitute about 8.5% of the dry matter of aspen leaves compared to <3.5% for sugar maple (Lorenzetti, 1993). Aspen also has fewer (3% of dry weight) condensed tannins (Bryant et al., 1987), compared to mature sugar maple (30% of dry weight) (Schulz, 1983), which the larvae would normally encounter while in their fifth instar in mid-June. Phenolic compounds, particularly phenolic glycosides, salicin, salicortin, tremuloidin, and tremulacin are common in aspen and constitute 2–6% of fresh leaf weight (Lindroth, 1991). Although sugar maple is not known to contain such compounds, 1-*O*-galloyl-α-L-rhammose has been identified in red maple, (Abou-Zaid and Nozzolillo, 1999). Nicol et al. (1997)

[a] Two-sample *t* test.

measured the performance of *M. disstria* on aspen and on sugar and red maple foliage. They found that larvae reared on aspen ate smaller amounts of foliage than those reared on sugar maple, yet they grew 22.5 times the size of the latter. They also found that larvae refused to eat foliage of red maple, and all starved in less than two weeks. They concluded that red maple foliage contains one or more strong antifeedants and that sugar maple does not contain such antifeedants but has a "physiological growth inhibiting component." They argue that the effect of this component on reduced growth leads to compensatory feeding by larvae, thus accounting for the greater amounts of feeding on sugar maple foliage. A similar study in our lab also showed better growth, survival, and fecundity for larvae of *M. disstria* reared on aspen compared to sugar maple (Lorenzetti, 1993). We suggest that the higher amounts of condensed tannins in sugar maple and of soluble sugars in aspen could explain these observations through a combination of chemosensory as well as physiological effects. The sugar-sensitive cell in the medial styloconic sensillum of the galea gave the highest firing frequency to the water fraction from aspen, an intermediate response to the total extract, and the lowest response to the methanol fraction (Figure 2). During our extraction process, the first sugars to come out of the separation column in sugar maple are sucrose, then glucose, galactose, and finally fructose (Gougeon, personal communication). The methanol fraction should contain the aglycones, monoglycosides, condensed tannins, etc., and the latter, in particular, are known to reduce the digestibility of proteins in many insects (Swain, 1979). This is consistent with the argument of Nicol et al. (1997) that larvae show compensatory feeding on sugar maple and develop poorly compared to those fed on aspen foliage. Our electrophysiological results show that the water fraction from aspen provides the best stimulus for the sugar-sensitive cell in the medial styloconic sensillum, and the methanol fraction is the least stimulative.

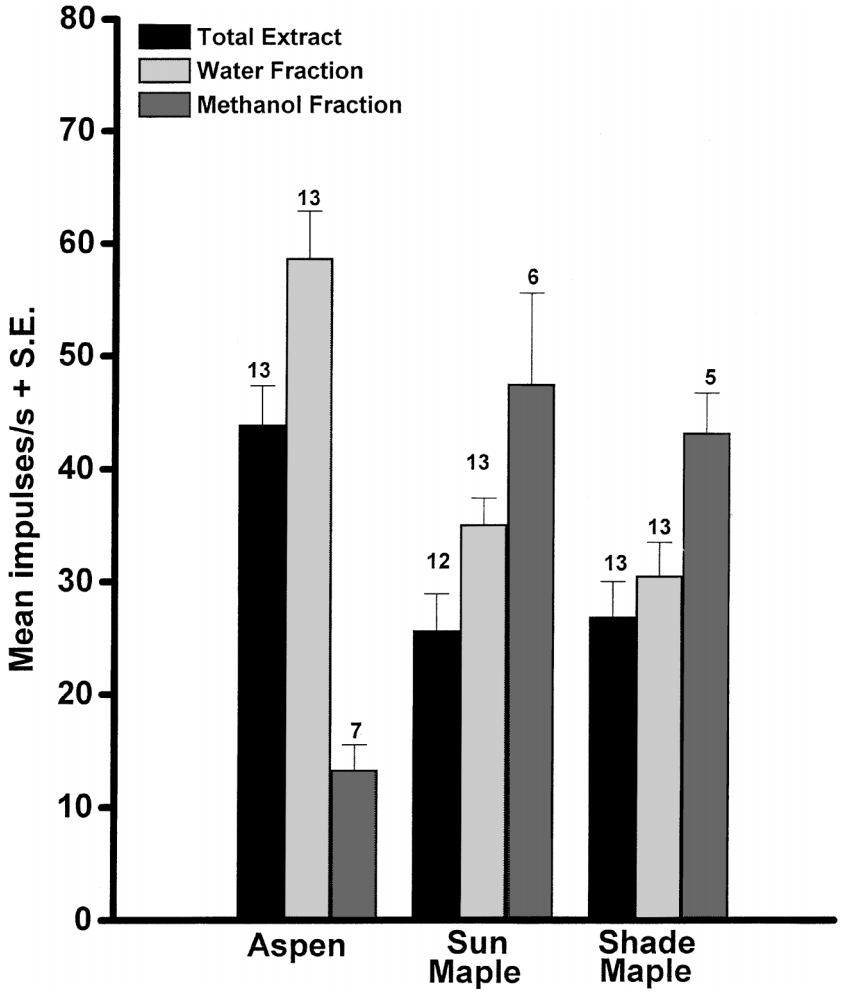

FIG. 2. Mean impulses/sec + SE for cell 1 in medial styloconic sensilla of fifth-instar *M. disstria* larvae in response to stimulation with aspen total extract and its water and methanol fractions (numbers above histograms represent sample size for each stimulus).

When we compared the responses of larvae to the total extract, water, and methanol fractions of the three types of foliage, the following trends were observed. Total extract of a given foliage was always preferred over the methanol fraction (Table 4). The water fraction was usually preferred over the methanol fraction, although not significantly so in the case of aspen. The total extract was preferred over the water fraction for aspen and for sun maple, but not for shade maple. The

[a] Two-sample *t* test.

preference for total extracts over methanol suggests that the more polar compounds are most important in stimulating ingestion, supporting our second hypothesis. There are some subtle differences in the insects' responses to sun versus shade maple extracts, notably that shade maple total extract is not preferred over the water fraction. This foliage is presumably lacking, or has reduced levels, some of the phagostimulants such as sugars, amino acids, etc. compared to sun maple. When *M. disstria* larvae are reared on shade maple versus sun maple foliage, the result is lower pupal weights and longer developmental times (Fortin, 1994). These differences are attributed to the presence of higher levels of soluble sugars, that are responsible for the insect's better performance on sun maple foliage (Fortin et al., 1997; Fortin and Mauffette, in preparation). It is known that sun and shade maple leaves differ in biochemical properties (Lincoln and Mooney, 1984; Ellswoth and Reich, 1992; Dudt and Shure, 1994). Sun/shade differences in herbivory have also been observed in other insects (Janzen, 1975; Coley, 1983; Louda and Rodman, 1983; Louda et al., 1987; Fitzgerald, 1995). For example, the congener eastern tent caterpillar, *M. americanum*, will rarely attack black cherry leaves that are grown in shade (Fitzgerald, 1995). In fact, larvae reared on these leaves produce

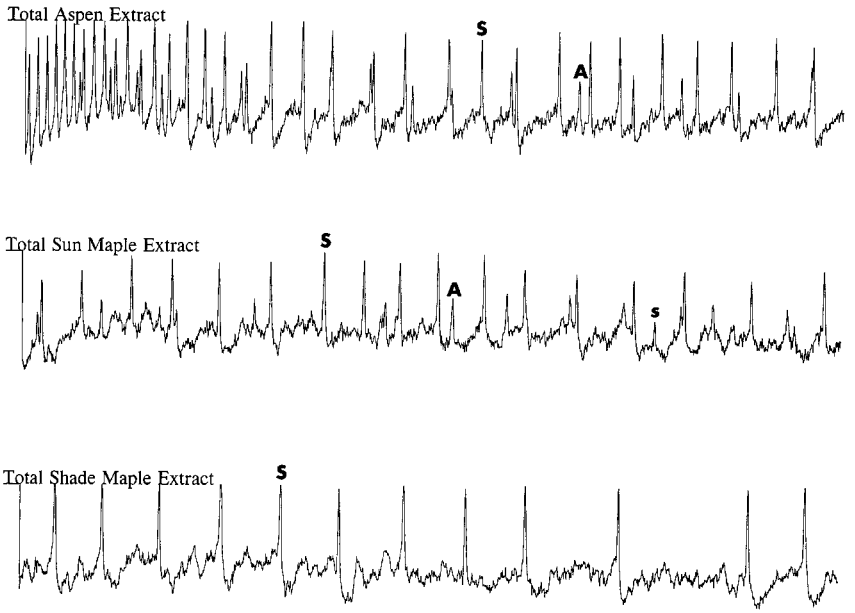

FIG. 3. Representative traces from stimulation of a medial styloconic sensillum of *M. disstria* with total aspen, sun maple and shade maple extracts. A = amino acid cell (cell 2); S = sugar cell (cell 1); s = salt cell (cell 3). All traces durations are 500 msec.

pupae that weigh only 67% of those reared on sun leaves (Futuyama and Saks, 1981).

Samples of the electrophysiological responses of the medial styloconic sensillum to the total extracts are shown in Figure 3. These reveal a response from three of the four neurons innervating this sensillum. These are cell 1 (sugar), cell 2 (amino acid), and cell 3 (salt), which can be differentiated from each other on the basis of their characteristic spike shapes. Cell 1 is monophasic (no prominent negative flank) and has a large amplitude, whereas cell 2 has a lower amplitude. Cell 3 spikes are biphasic, i.e., possess a steep negative flank, and have small amplitudes (Figure 3). In all of our tests, we found no effect of the extracts on the responses of cell 3 (salt), which fluctuated between 1 and 10 impulses/sec and were likely the result of stimulation by the 10 mM KCl solvent present in all solutions. A similar effect was seen for the responses of cell 2 (amino acid), whose means were only 4–8 impulses/sec for all aspen extracts, 8–13 impulses/sec for maple total extract and water fractions, and 19 to 23 impulses/sec for the maple methanol fractions. In only one case, the shade methanol fraction, did cell 2 respond with a higher firing frequency that was different from total extract and water fractions of that foliage; but when we compared the responses of cell 2 for each of the sun and shade maple

extracts, they were not different. However, the responses from cell 1 (sugar) were consistently much higher, ranging from 13 to 59 impulses/sec, and accounted for most of the sensillum's response.

The highest firing frequency (59 impulses/sec) from cell 1 (sugar) was obtained with the aspen water fraction (Figure 2), and the total extract and methanol fraction from aspen produced intermediate and mimimum firing rates, respectively. These responses were all different from each other (one-way ANOVA; $df = 2, 30$; $F = 29.15$; $P = <0.001$ and Newman-Keuls multiple comparison). For sun maple, maximal responses from cell 1 (49 impulses/sec) were obtained with the methanol fraction; intermediate and minimum responses were obtained with the water fraction and the total extract, respectively. The response to the methanol fraction differed from the others (one-way ANOVA; $df = 2, 28$; $F = 6.37$; $P = 0.0052$). An a posteriori Newman-Keuls test showed no difference between the responses to the total sun maple extract and the water fraction. A similar response was found for shade maple with the methanol fraction eliciting maximal firing from cell 1. Again this differed from the responses to total extract and water fraction (one-way ANOVA; $df = 2, 28$; $F = 4.29$; $P = 0.0237$), while the latter two did not differ from each other.

As stated earlier, cell 1 response is lowest to the methanol fraction for aspen, and this concurs with the feeding behavior. However, cell 1 response is highest for the aspen water fraction, and this differs from the behavior where the insect preferred the aspen total extract over the water fraction. This suggests that cell 1 is contributing important information, but that a sensory input other than cell 1 in the medial styloconic sensillum is also responsible for modulating this response. The latter is even more probable in the case of the electrophysiological responses to sun versus shade maple. The lower responses of cell 1 to the total extracts and the water fractions of both sun and shade maple compared to aspen is consistent with the behavioral data, i.e., that larvae prefer total extracts from aspen over the others. This is consistent with the literature, which shows that larvae perform best on aspen. However, we cannot explain the high firing frequencies of cell 1 to both maple methanol fractions, and we are not aware of any compounds in these fractions that might have the required binding properties necessary to stimulate this sugar-sensitive cell.

Both behavioral and physiological experiments indicate that aspen is the preferred choice for *M. disstria* larvae. We find it intriguing that cell 1 in the medial styloconic sensillum of *M. disstria* larvae was the only chemosensory neuron to consistently show differences in response to the various aspen extracts, since these extracts must contain a wide variety of chemicals. Larvae also distinguished between sun and shade maple extracts in the feeding tests, yet the electrophysiological responses from cell 1 to the extracts from these two types of foliage were almost identical. It is generally assumed that the sensory input from both lateral and medial styloconic sensilla of caterpillars is the most important in informing the

animal as to its correct food plant, as was clearly shown in the tobacco hornworm, *Manduca sexta* (De Boer, 1993). This is not the case in the forest tent caterpillar; the preference for sun over shade maple, for example, is likely to be mediated by another chemosensory field such as the epipharyngeal sensilla or the maxillary palps. More work is needed before we can fully understand the effects of these host plant chemicals on chemosensory inputs and the feeding behavior of *M. disstria* larvae.

(Received January 24, 2001; accepted June 13, 2001)

Abstract—The plant genus *Macaranga* is known for its manifold mutualistic associations with ants. The plants provide food for the ants and in turn get protection from herbivores. Depending on the strength of the plant–ant interaction, the plant's investment in ants and the biotic defense derived from them is more or less effective. We conducted a comparative study on tannin content in 12 *Macaranga* species that were selected based on their associations with ants (three nonmyrmecophytes and nine myrmecophytes, three of which start their ontogeny as nonmyrmecophytes). Different developmental stages were investigated in three *Macaranga* species. Extracts of every individual plant analyzed for tannins were also tested for their effects on larval growth employing larvae of the common cutworm (*Spodoptera littoralis*). The studied *Macaranga* species differed significantly in their tannin contents as well as in the effects of their leaf extracts on the growth of *S. littoralis* larvae. A correlation analysis shows a connection between tannin contents and larval growth. High tannin contents and, thus more effective chemical defense, were observed in nonmyrmecophytic *Macaranga* species associated only facultatively with ants as compared to obligate myrmecophytes. Our study supports the hypothesis of a trade-off between chemical and biotic defense in the genus *Macaranga*.

Key Words—Ant–plant associations, biotic defense, chemical defense, herbivory, *Macaranga*, tannins.

INTRODUCTION

Plants face pronounced biotic pressure from phytophagous animals (e.g., Marquis and Braker, 1994) and have, therefore, evolved effective biotic and/or abiotic (physical and chemical) means to counter these pressures in order to enhance their fitness (e.g., Adler, 2000). The chemical defenses of plants are highly diverse (e.g., Rosenthal and Berenbaum, 1991). A widespread form of indirect (biotic) defense is mutualistic interactions with ants (Hölldobler and Wilson, 1990; Davidson and McKey, 1993) that defend plants from herbivores (e.g., Schupp, 1986; Fiala et al., 1989, 1991; Gaume et al., 1997; Gaume and McKey, 1999), from plant pathogens such as fungi (Letourneau, 1998; Heil et al., 1999, 2000, 2001) and, in some cases, even from other competing neighboring plants (Fiala et al., 1989, 1991). The ants, in turn, benefit from food [extrafloral nectar (for an overview see: Beattie, 1985; Huxley and Cutler, 1991)] or food bodies produced by the plants (e.g., Rickson, 1980; Fiala and Maschwitz, 1992a; Heil et al., 1997).

The genus *Macaranga* (Euphorbiaceae) consists of approximately 250 mainly pioneer species that occur in the tropics of the Old World (Whitmore, 1969, 1975) with the center of distribution in (sub-)tropical Asia and the Pacific (Whitmore, 1969, 1975; Fiala, 1996). This genus is known for a wide range of mutualistic associations with ants, ranging from facultative to strictly obligate ones (Fiala et al., 1989; Fiala and Maschwitz, 1990). In the nonmyrmecophytic (but myrmecophilic) species, different opportunistic ant species visit the plants and forage on food bodies and extrafloral nectar. The plants in turn may gain protection due to the ants' foraging behavior. Myrmecophytic species not only produce food but also permanently house specialized ants in their internodes (so-called domatia) (Fiala and Maschwitz, 1992b). Here the interaction is obligate for both partners. The ants protect the plants from phytophagous insects and probably from plant pathogens (Fiala et al., 1989, 1994; Heil et al., 1999, 2001). A few *Macaranga* species change their life-style from myrmecophilic to myrmecophytic at later ontogenetic stages. This change is accompanied by morphological and physiological alterations. Small plants with thin, solid stems mainly secrete extrafloral nectar that attracts different ant species. These species can be colonized by their specific ants only when the stem diameters increase (e.g., in the case of *M. hosei*, at a height of approximately 70 cm). Colonizable plants subsequently start to produce food bodies and usually reduce the production of extrafloral nectar (Fiala, 1996; Fiala et al., 1999). The efficacy of the biotic defense of these different life styles seems to be most pronounced in myrmecophytic species (Fiala et al., 1994; Heil et al., 2001).

Both means of antiherbivore defense (abiotic defense with physical or chemical means and the biotic defense via mutualistic partners) are metabolically costly for the plants. For maintenance of the biotic defense, especially the production of food bodies with their high content of lipids (Rickson, 1980), amino acids and energy-rich carbohydrates (Heil et al., 1998) have to be provided by the plants.

Consequently, the number, biomass, and quality of food bodies differs among *Macaranga* species and is highest in the myrmecophytic species (Heil et al., 1998). For example, Heil et al. (1997) found an investment in food bodies that accounts for up to 5% of the total assimilation of myrmecophytic *Macaranga triloba* plants. The production of Müllerian bodies in the neotropical ant-plant *Cecropia* also causes significant costs to the plants (Janzen, 1973).

Costs involved in the production of defensive compounds can not be accurately quantified. It is reasonable to assume, however, that the production of secondary metabolites reduces the amounts of nutrients and photosynthetic products that otherwise could promote growth and reproduction (Simms and Rausher, 1989). Rhoades (1979) postulates a balance between the costs for defense and the ecological benefit of reduced herbivory. Plants with effective biotic defense are expected to reduce their investment in abiotic (chemical) defense mechanisms since an investment in both would be an unnecessary metabolic burden on the plant (Janzen, 1966; Gershenzon, 1994). Some studies provide support for this assumption. In neotropical acacias, Rehr et al. (1973) found lower contents of cyanogenic glycosides in myrmecophytic species in comparison to nonmyrmecophytic ones (but see also Seigler and Ebinger, 1987). Another potential trade-off between chemical and biotic defenses in neotropical myrmecophytic acacias has been demonstrated by Heil et al. (2000), who reported reduced chitinase activity in the myrmecophytes *M. triloba* and *M. hosei* compared to other plant taxa. In addition, leaves of the myrmecophytic *Leonardoxa africana* had lower tannin contents than those of the nonmyrmecophytic *L. gracicaulis* (Bidal, 1997). According to Janzen (1973), in the neotropical *Cecropia*, the lack of latex-bearing ducts is probably one of the reasons for the herbivore susceptibility following ant removal experiments.

In the genus *Macaranga*, there is almost no information regarding a possible reduction of chemical defense as a result of the symbiotic relationship with ants. However, regarding resource allocation by the plant into effective means of biotic defense, such as food bodies or extrafloral nectar, a high investment of the nonmyrmecophytes into chemical defense should be expected. Turner (1995), for example, found lower contents of condensed tannins in two myrmecophytes (*M. hypoleuca* and *M. triloba*) as compared to three nonmyrmecophytic species employed in this investigation (*M. conifera, M. gigantea*, and *M. heynei*). Nomura et al. (2000) reported a less pronounced abiotic defense in three myrmecophytic species compared to two nonmyrmecophytes, as indicated by the growth performance of cutworm larvae on an artificial diet spiked with the respective leaf powders. In the same publication, the authors also determined the intensity of physical defense of *Macaranga* species by measuring leaf toughness of selected species. Again, the nonmyrmecophytes had tougher leaves than the myrmecophytes. In a feeding experiment with fresh leaves, only two of the myrmecophytes allowed the development of pupae (Nomura et al., 2000). The diet

containing plant material of the other *Macaranga* species analyzed proved lethal to the larvae. These data support the hypothesis of a more pronounced abiotic defense in the nonmyrmecophytes compared to myrmecophytic species of the genus *Macaranga*. However, no broad comparative phytochemical analyses exist within the genus *Macaranga*. For the first time, in this study we tested for secondary compounds with relevance to antiherbivore defense using 12 *Macaranga* species, which included three nonmyrmecophytes and nine myrmecophytes (three of which started their ontogeny as nonmyrmecophytes). In this study, we focused on tannins, which have previously been shown to be among the secondary compounds accumulated by *Macaranga* species (Lin, 1993, 1994; Lin et al., 1990a,b).

METHODS AND MATERIALS

Sampling Sites and Selected Species. Leaves for phytochemical investigation were collected in Malaysia between September and December 1998. Six species were collected in the area around the Ulu Gombak Field Studies Centre of the University of Malaya northeast of Kuala Lumpur (3°17′ N, 101°44′ E): the nonmyrmecophytes *M. gigantea*, *M. heynei*, *M. tanarius*, and the myrmecophytic *M. hullettii*, *M. triloba*, and *M. hosei* (the latter being colonized only later in its ontogeny). (*M. triloba* probably has to be renamed *M. bancana*, T. C. Whitmore and S. J. Davies, personal communication.) Plants were mainly found along former logging roads in secondary forest and along the road to Genting Highlands. *M. pruinosa*, which also becomes inhabited by ants at a later stage, was obtained from a peat swamp forest in the north of Kuala Selangor (3°24′ N, 3°44′E). In the eastern part of Malaysia in the Mount Kinabalu park in Sabah, Borneo (6°5′N, 160°33′E), four obligate myrmecophytic species [*M. angulata* (Davies, 1999), *M. hypoleuca*, *M. indistincta*, *M. winkleri*] as well as one species with changing life-style (*M. pearsonii*) were collected. Plants were identified following Whitmore (1975). We used the youngest two to six leaves of 1.5- to 2.5-m-high plants. In three species, additional ontogenetical comparisons were carried out. From the species with the changing life-style (*M. hosei* and *M. pruinosa*), we also analyzed young saplings that were not yet inhabited by ants and young trees (*M. pruinosa* only). In addition, we studied trees (6–12 m high) of *M. tanarius*, which at that developmental stage produce no more extrafloral nectaries. For the collected species, leaves from at least 10 individuals (with the exception of the grown-up trees and not colonizable plants of *M. pruinosa* where five individuals were collected) were combined for subsequent phytochemical studies.

Myrmecophytes that start their ontogeny as nonmyrmecophytes and are, therefore, colonized later by ants are referred to as late myrmecophytes, compared to the early myrmecophytes, which are already colonized as small saplings.

Processing of Plant Material. Fresh plant material was dried in a drying oven (40–45°C) on the peninsula and under a fan in Borneo. It was subsequently stored in air-tight Ziploc bags over silica gel. Dried leaf material was ground with a mill and sieved. Nerves of bigger leaves were removed prior to grinding.

Tests for Alkaloids, Cyanogenic Glycosides, and Saponins. To test for other classes of secondary compounds that might interfere with development of insects, quick tests for alkaloids, cyanogenic glycosides, and saponins were conducted. For alkaloids, dried and powdered plant material of one individual of each collected species was extracted with 20 ml sulfuric acid over night. After filtration, the extract was alkalized with 25% NH_3 (pH 10–11). Extrelut 3 columns (Merck) were used for eluation of alkaloids with dichloromethane. Thin-layer chromatography (silica gel 60 F254, 0.2 mm; Merck) with Dragendorff spray reagent (German Pharmacopoea, DAB 9) was used to detect alkaloids. To test for cyanogenic glycosides, the sodium picrate test (Brinker and Seigler, 1989) was used on fresh plant material of one individual of each species. To test for hemolytic saponins, a blood agar test was used on three individuals of each species.

Tannin Quantification. For tannin quantification, the skin-powder method of the German Pharmacopoea (DAB 7) in combination with photometric quantification using Folin's reagent was used in a modified way as follows: 0.75 g plant powder of each individual was extracted with 150 ml hot water (in a waterbath at 90°C) for 30 min. After cooling to room temperature, the extract was diluted to 250 ml and filtered. The first 50 ml of each filtrate was rejected in order to allow for saturation of the filters with tannins. For the determination of total phenolics, 5 ml of the remaining filtrate was diluted with water to 25 ml. To 0.5 ml of this solution, 100 μl wolframium phosphoric acid was added, and the mixture was diluted to 5 ml with sodium carbonate solution (15%). After 1.5 min, the absorption of the solution was measured at λ 715 nm. In the same way, the absorption of the remaining phenolics was measured after binding the tannins to skin powder. 10 ml extract was shaken with 0.1 g skin powder CRS (European Directorate for the Quality of Medicines, Strasbourg, France) for 1 hr. For each extract, the content of total phenolics and phenolics, after removal of tannins, was determined three times. Pyrogallol was used as reference. Pyrogallol (50 mg) was dissolved in 100 ml water. 5 ml of this solution were diluted to 100 ml with water, all under light exclusion due to the light sensitivity of the compound. To 5 ml of the resulting solution, 1 ml wolframium phosphoric acid and sodium carbonate solution was added to give a total of 50 ml. After 1.5 min, the absorption at λ 715 nm was measured. Absorption of pyrogallol was measured three times for each determination of tannin content.

The content of the leaf tannin ($T = 13.12 * (A_1 - A_2)/A_R * m$) was calculated from the absorption of the total phenolics (A_1), the remaining phenolics (A_2), the reference substance (A_R), and the mass of plant material (0.75 g leaf powder) (m).

In addition, the content of tannins present in two methanolic plant extracts was measured. Two plants (one *M. heynei* and one *M. triloba* with tannin contents of 30.17% and 2.83%, respectively, as determined in the water extract) were used. From each plant, 0.75 g powdered leaf material was extracted with an adequate amount of methanol over 12 hr. The dried methanolic extract was processed by using the regular skin-powder method for tannin quantification (see above). With this method the *M. heynei* plant specimen showed a content of 23.69%, whereas virtually no tannins were detected in the extract of *M. triloba*.

To prove the linearity of the applied method for tannin quantification, the water extract of one plant individual was dissolved with water to 25, 50, and 75% of the original concentration. Each concentration was tested in triplicate with the skin-powder method as described above. This dilution experiment showed a linear correlation between tannin content and the result of the quantification in the whole range of results between less than 3% and more than 30% tannins (linear Spearman Rank correlation; $r = 0.99877$; $N = 4$; coefficient: 1.0; $P < 0.01$) and thereby proved the suitability of the method.

Extraction for Bioassay. Depending on the amount of plant powder available, 0.5, 1.0, 2.0, or 5.0 g of plant material was extracted three times with 20, 40, 50, or 100 ml methanol, respectively. The leaf material of several *M. hosei* saplings had to be combined to get enough crude extract for the bioassay.

Bioassay. For the bioassay, newly hatched caterpillars of the common cutworm *Spodoptera littoralis* (so-called neonates) were used. These polyphagous pest insects were reared in the laboratory on an artificial diet under controlled conditions (see Srivastava and Proksch, 1991). A known amount of artificial diet was treated with the equivalent of 10 mg of crude extract. Each plant individual was tested with 20 neonates, which fed on the prepared food for eight days. Afterwards, the surviving caterpillars were counted and weighed. The survival and growth rates of the test caterpillars were compared with control larvae that had been exposed to diet treated with the solvent (methanol) only. Of the seedlings of *M. hosei*, only a pool of the collected leaves could be tested with *Spodoptera* due to the small amount of plant material. The same pool of dried leaf powder was extracted three times, and each of the extracts was also tested three times.

In one experiment, the tannin content of the extracts of two plants with a relatively strong effect on the growth rates of the caterpillars (one *M. triloba* and *M. winkleri*) was removed with skin powder prior to incorporation into the diet. The crude extract equivalent to 0.3 g plant powder was extracted with 60 ml hot water (following the protocol of the skin-powder method with a smaller amount). After centrifugation, the water fraction was filled with water to give 100 ml, and 1 g skin powder was added and shaken for 60 min. After filtration the residue was combined with the remaining methanol residue and freeze dried. For the bioassay with *Spodoptera* larvae, 10 mg of each of the two extracts were used and tested three times.

As positive control, amounts of 0.25, 0.5, 1.0, 2.0, 3.0, and 4.0 mg pure tannic acid were tested (three times each) with the bioassay. As expected, the pure tannic acid in the artificial diets (used instead of plant extracts) also had an negative effect on the growth of *Spodoptera*. The effect was dependent on the concentration ($r = 0.98626$) with a nonlinear course.

Statistical Analysis. The tannin contents of the *Macaranga* plants and the growth rates of the *Spodoptera* larvae in the bioassay were compared by using a univariate ANOVA with the LSD post-hoc test. Correlations between the measured tannin content and the effects of the plant extracts on the growth of the larvae were analyzed with Spearman Rank correlation.

RESULTS

Tannin Quantification. Analysis revealed significant differences among the various species analyzed with regard to tannin contents (Figure 1, univariate ANOVA: $N = 149$, $P < 0.001$). The nonmyrmecophytic *M. heynei*, in particular, had strikingly high tannin contents (up to 33% of the dry weight). However, the

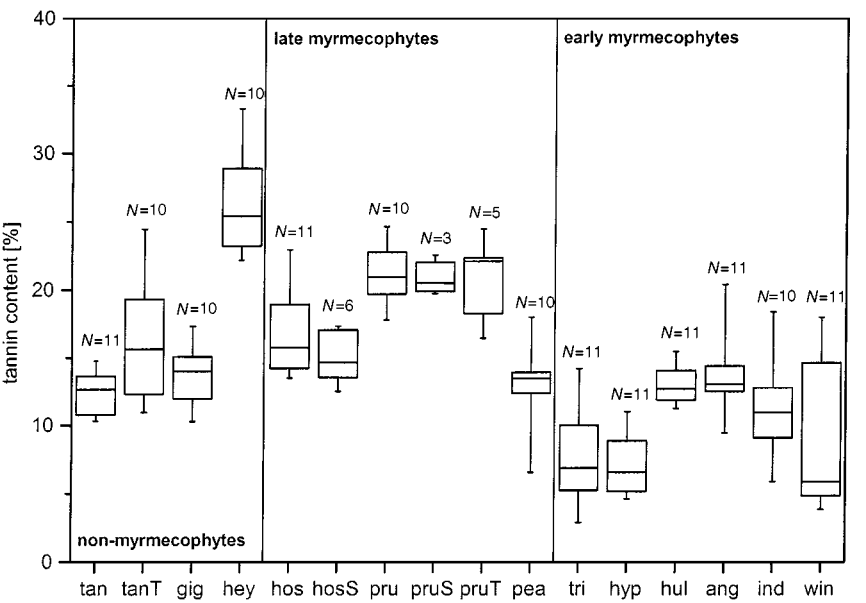

FIG. 1. Tannin contents of the investigated *Macaranga* species: tan = *M. tanarius*; gig = *M. gigantea*; hey = *M. heynei*; hos = *M. hosei*; pru = *M. pruinosa*; pea = *M. pearsonii*; tri = *M. triloba*; hyp = *M. hypoleuca*; hul = *M. hullettii*; ang = *M. angulata*; ind = *M. indistincta*; win = *M. winkleri*; T = adult trees; S = saplings, not colonizable plants.

myrmecophytic species that start their ontogeny as nonmyrmecophytes (*M. hosei* less than *M. pruinosa*) had high tannin contents (up to 25% of dry weight) as well. These proved to be even higher than those from most of the nonmyrmecophytes (except *M. heynei*). The tannin content of *M. pearsonii* from the same section was comparable to that of the majority of the nonmyrmecophytes analyzed (except *M. heynei*) and higher than the tannin contents observed for some of the "early" myrmecophytes (Figure 1). In general, a tendency for lower tannin contents was observed for the early myrmecophytes when compared to nonmyrmecophytes. Significant differences in tannin contents ($P < 0.05$), however, were only found for the early myrmecophytes *M. triloba, M. hypoleuca*, and *M. winkleri*, compared to the remaining species analyzed (non-myrmecophytes as well as myrmecophytes). Within the group of early myrmecophytes, which are already colonized at juvenile stages of their life cycle, striking differences in tannin contents were found: *M. triloba, M. hypoleuca*, and *M. winkleri* had lower tannin contents when compared to other early myrmecophytes analyzed (univariate ANOVA; $P < 0.05$ for each combination, except *M. winkleri* and *M. indistincta*; $P = 0.270$), whereas they did not differ from each other ($P > 0.05$).

When comparing different ontogenetic stages of *Macaranga* species (*M. tanarius, M. hosei*, and *M. pruinosa*), differences of tannin contents were only found among juvenile plants of *M. tanarius* (2 m height) and adult trees (univariate ANOVA; $P = 0.011$). No such differences were observed among small saplings of *M. hosei* and already colonizable plants of this species (univariate ANOVA; $P = 0.278$) or among the different ontogenetical stages analyzed for *M. pruinosa* (univariate ANOVA; $P > 0.05$ for each combination).

Bioassay. Most *Macaranga* extracts had a negative effect on the growth of *Spodoptera littoralis* larvae as judged from the weights of the treated larvae compared to controls. However, the bioassays also showed differences among the species analyzed with regard to the extent of reduction of larval growth when compared to controls (Table 1; Figure 2; univariate ANOVA: $N = 153$, $P < 0.001$). These differences are in most cases, paralleled by similar differences in tannin contents.

Some of the *Macaranga* species analyzed (*M. tanarius, M. pruinosa*, *M. hullettii*, and *M. angulata*) were particularly active in reducing larval growth. However, the feeding experiments did not reveal a clear correlation between the influence on larval growth and life form (myrmecophytes versus nonmyrmecophytes). For example, within the group of nonmyrmecophytes, the extract of *M. gigantea* caused a lower reduction of larval growth than that observed for the extracts of *M. tanarius* and *M. heynei*. The myrmecophytes with late colonization showed similar effects on larval growth compared to *M. tanarius* and *M. heynei*. Among the myrmecophytes with late colonization, *M. pruinosa* caused the strongest reduction of larval growth. The highest growth rates of larvae were found when treated with extracts of the myrmecophytic species, especially with those of *M. triloba* and

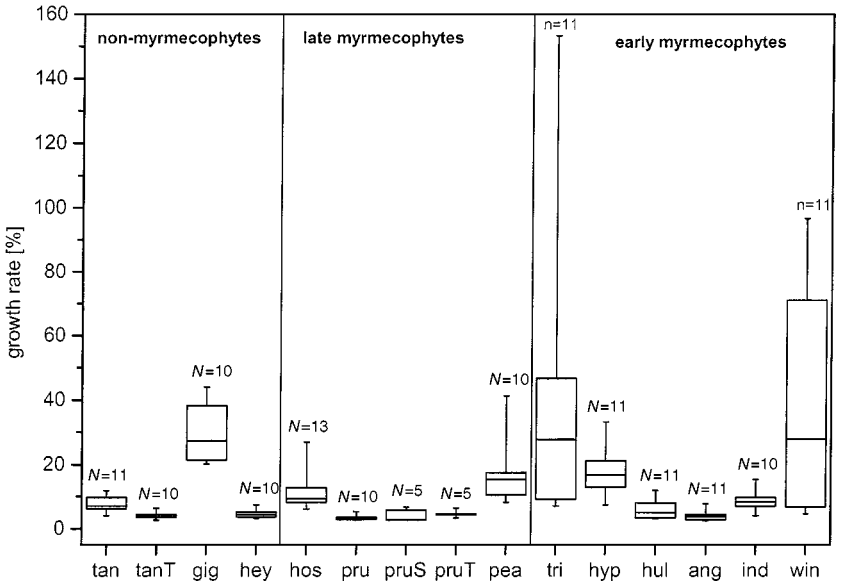

FIG. 2. Growth rates of *Spodoptera littoralis* larvae grown on artificial diet treated with extracts of different *Macaranga* species (mean growth rate of controls is set to 100%). Abbreviations as in Figure 1 legend.

M. winkleri. Surprisingly, high growth reduction was caused by extracts of the myrmecophytes *M. angulata, M. hullettii*, and *M. indistincta*.

For some of the *Macaranga* species (e.g., *M. triloba* and *M. winkleri*), considerable intraspecific variability of tannin contents as well as of their effects on larval growth were found. No significant differences with regard to larval growth were found when testing extracts derived from different ontogenetic stages of *M. tanarius, M. hosei*, and *M. pruinosa* (univariate ANOVA; $P > 0.05$).

Correlation Between Tannin Contents and Influence on larval Growth. There was a general correlation between the amounts of tannin *contents* in the different *Macaranga* species and the extent to which larval growth was reduced (Figure 3; $N = 136$; $P < 0.001$). This correlation (Figure 4), however, was statistically significant only for *M. pruinosa* saplings that were not colonizable and for larger plants of *M. pruinosa* ($N = 5$; $P < 0.05$), *M. triloba* ($N = 11$; $P < 0.001$), *M. indistincta* ($N = 10$; $P < 0.05$), and *M. winkleri* (up to 2 m height) ($N = 11$; $P < 0.001$). A relatively strong correlation of tannin contents and larval growth was also observed for young trees of *M. pruinosa* ($N = 11$; $P = 0.066$) and *M. tanarius* ($N = 11$; $P = 0.066$). When a tannin-free extract of *M. triloba* (following removal of tannins with skin powder) was incorporated into the artificial diet and offered to neonate larvae, the larval growth rate was similar to that of the controls

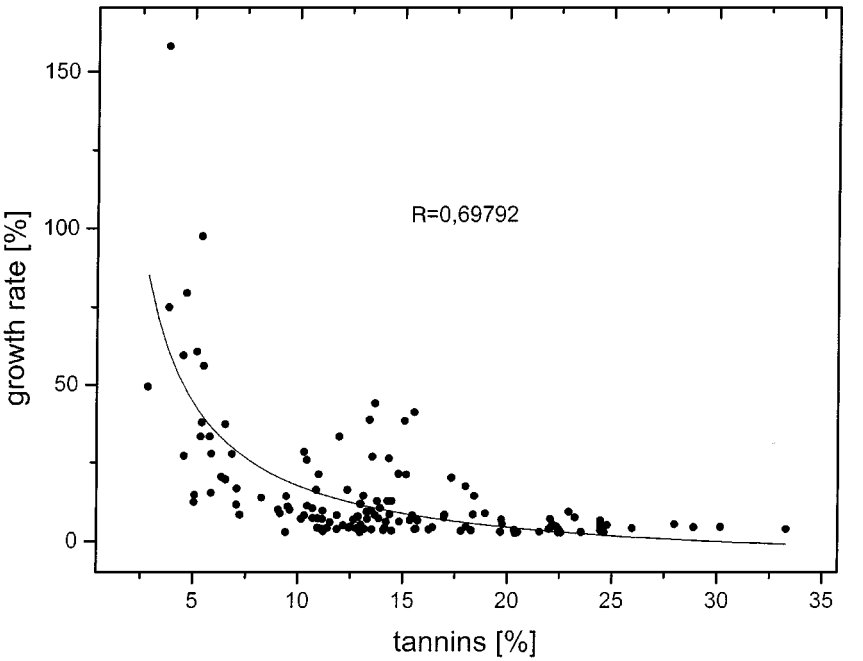

FIG. 3. Connection between tannin contents of individual *Macaranga* plants and growth rates of *Spodoptera littoralis* larvae.

(100%) compared to a growth rate of only 8.4% for the respective extract prior to tannin removal. A similar result was obtained for *M. winkleri* (larval growth rate of 4.5% compared to 100% following removal of tannins). Both chosen plants originally had the strongest effect on larval growth of the respective species.

Tests for Presence of Alkaloids, Cyanogenic Glycosides and Saponins. Besides tannins, *Macaranga* species were also tested for alkaloids, cyanogenic glycosides, and saponins. A weak indication for the presence of alkaloids (following spraying of TLC plates with Dragendorff reagent) was only found for *M. tanarius* and *M. winkleri*, whereas no hints for the presence of cyanogenic glycosides or saponins could be obtained for any of the species analyzed.

DISCUSSION

Consumption of tannins by herbivores is generally associated with depressed growth rates and reduced efficiency of food utilization (Hagerman and Butler, 1991). In Coley's (1986) studies of *Cecropia peltata*, leaf tannin concentrations were negatively correlated with herbivory rates on seedlings and also with the

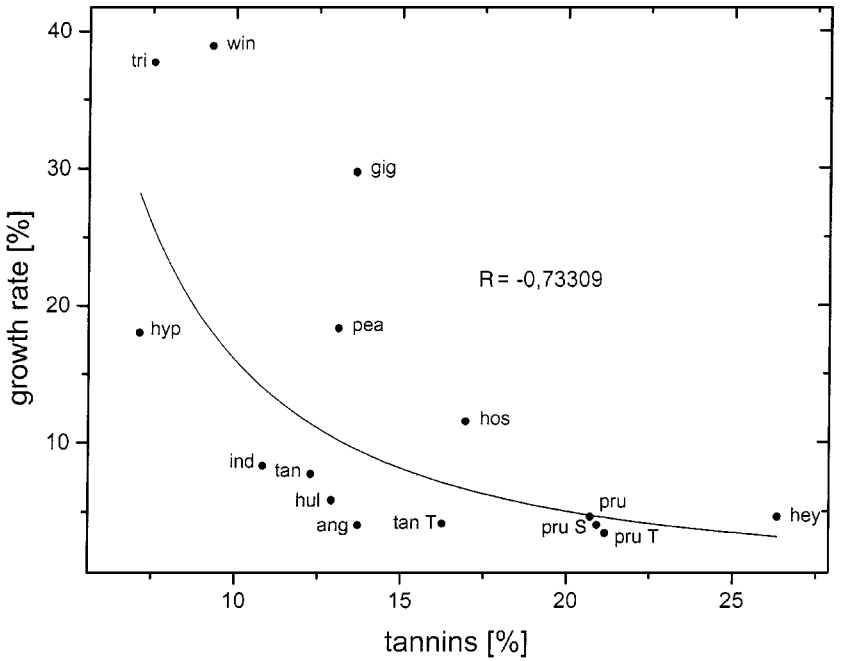

FIG. 4. Connection between mean tannin contents of analyzed *Macaranga* species and mean growth rates of *Spodoptera littoralis* larvae: Abbreviations as in Figure 1 legend.

number of newly produced leaves. High tannin levels also reduced herbivory in *Psychotria horizontalis* and were negatively correlated with growth, suggesting metabolic costs for tannin production (Sagers and Coley, 1995). It was also suggested that tannins play an important role in the defense of plants against bacterial or fungal infections (Bernays et al., 1989).

Some of the *Macaranga* species investigated in our study are extremely rich in tannins, exhibiting tannin contents $\geq$30% dry weight of leaves (Figure 1). Tannin-rich extracts of *Macaranga* species severely depressed the growth of larvae of *Spodoptera littoralis* that were used as experimental insects in this study despite their well-known tolerance of many plant secondary compounds (Figure 2). This effect could be reversed by the removal of tannins from the extracts, leading to larval growth rates comparable to those of control larvae.

In general, there was a negative correlation between larval growth rates and the tannin contents of *Macaranga* species (Figure 3), even though this negative correlation was not significant for every species studied (Figure 4). For some species (e.g., *M. angulata*), the reduction of larval growth was stronger than originally expected based on the analyzed tannin contents. Even though tannins play a major role in the chemical defense of *Macaranga* species (as shown in the tannin removal

experiment), it can not be excluded that other secondary compounds contribute to their defense. Tests for the presence of alkaloids, cyanogenic glycosides, and saponins with hemolytic activity in *Macaranga* consistently gave negative or inconclusive results. For a second group of *Macaranga* species (e.g., *M. gigantea*), larval growth rates were higher than expected from their respective tannin contents. It is possible that qualitative differences in the different species are responsible for this unexpected result. In this context, it is interesting to note that Ayres et al. (1997) reported differences in tannin structure among congeneric plant species that were responsible for differences of antiherbivore activity of the respective tannins.

When the tannin contents of the various *Macaranga* species were analyzed with regard to their respective life forms, it became obvious that most of the early myrmecophytes had lower tannin contents than those observed for the nonmyrmecophytes (Figure 1) although these differences were not significant for every pair of species studied. Superior growth performance of *Spodoptera* larvae on an artificial diet spiked with *Macaranga* leaf powder from myrmecophytic species compared to leaf powder from nonmyrmecophytes was also reported by Nomura et al. (2000), who studied three myrmecophytic and two nonmyrmecophytic species. Two of them, *M. winkleri* and *M. gigantea*, were also treated in our study. Unfortunately, our results are not directly comparable to those of Nomura et al. (2000), since they used different amounts of dried leaf powder (based on leaf area rather than on dry weight) in the artificial diets. The highest amounts of leaf powder incorporated into artificial diet originated from the nonmyrmecophytic species (Nomura et al., 2000), which might have biased the results obtained (higher growth rates on extracts from myrmecophytic species compared to extracts from nonmyrmecophytic species). Nomura et al. (2000) correlated their cutworm survival results on artificial diet treated with one of the three myrmecophytic species analyzed with the intensity of the biotic defenses of the respective species. In another study (Itioka et al., 2000), the myrmecophytic species recorded to be most intensively defended by ants (*M. winkleri*) had the weakest effect on larval survival. In our investigation, which covers several species with the same ant inhabitants, a more complex pattern than that reported by Nomura et al. (2000) emerges. We found high tannin content and indications for more intense chemical defense in *M. hypoleuca*, a sister species to *M. beccariana* used in the studies mentioned above. Both plants are inhabited by the same morphospecies [Fiala et al., 1999 (probably *Crematogaster decamera*)]. However, other *Macaranga* species analyzed in our study and inhabited by the same ant species (Fiala et al., 1999) show different tannin contents and vary with regard to their influences on larval growth. Thus, our study, with its large sample sizes of 10 or 11 plants from 13 species, revealed a more differentiated picture, even within the group of myrmecophytes.

The myrmecophytes from our study that are colonized by ants only at later stages of their ontogeny (with the exception of *M. pearsonii*) had strikingly high

contents of tannins compared to the early myrmecophytes and to the nonmyrmecophytic species (Figure 1). The former species apparently do not rely as heavily on biotic defense by ants as compared to the early myrmecophytes. *M. pruinosa*, which belongs to the group of late myrmecophytes and has an exceptionally high tannin content, features a rather low percentage of ant inhabitation even at later ontogenetic stages, when its stem structure would, in principle, allow colonization (Fiala et al., 1999). *M. hosei* and *M. pearsonii*, however, which had a lower tannin content than *M. pruinosa*, are usually inhabited by ants as soon as colonization is possible. Interestingly, investment into ant food (nutrient value of food bodies) was lowest in *M. pruinosa* when compared to other late myrmecophytes (Heil et al., 1998).

The theory of optimal defense postulates a protection of plant parts or tissues in relation to their value to the plant (Rhoades, 1979). The resource availability hypothesis (Coley et al., 1985) predicts a pattern of defense corresponding to the supply of nutrients and light at the plants' location. At locations rich in resources (e.g., light and/or nutrients), plants are able to compensate for tissue losses caused by herbivores more easily. Furthermore, following Herms and Mattson (1992), there is competition between biosynthetic pathways involved in growth (primary metabolism) and the production of secondary metabolites. According to these theories, plants pursue different strategies: depending on resource availability and growth rates, plants may be able to compensate for tissue losses caused by herbivory by increased biomass production or by protection through physical means and/or secondary metabolites or, as in the case of ant plants, by mutualistic ants. In a comparative study of three pairs of pioneer and forest gap species in *Cecropia* myrmecophytes, Folgarait and Davidson (1994) report faster plant growth and higher investment in biotic defense in pioneer species than in gap species, which possess longer-lived and tougher leaves. These considerations complicate the interpretation of results obtained in our study on *Macaranga*. Interspecific differences with regard to plant growth rates and with regard to the amounts of macronutrients present in leaves (N, S, P, C) were found among three *Macaranga* species from one study site: for example, *M. tanarius* has a growth rate that is two times higher than that of *M. triloba* and three times higher than that of *M. hosei* (Heil, 1998). *M. gigantea* also grows fast (Davies, 1996; Fiala, unpublished results). These findings could serve as an adequate explanation for the rather low tannin contents in the high disturbance pioneers *M. tanarius* and *M. gigantea* compared to myrmecophytic species such as *M. angulata, M. hullettii*, and *M. indistincta*, which grow in less disturbed forests.

In conclusion, our results indicate a tendency for a trade-off between chemical and biotic defense in *Macaranga* species featuring different life forms. As Heil et al. (1997, 1998) demonstrated, myrmecophytic plants invest more of their photosynthetic assimilates, i.e. sugars, into nutrition for ants and thus into biotic defense. Metabolic costs of nutrition of defending ants can be quite high (Heil et al., 1997),

but, on the other hand, defense by specific, obligate ant inhabitants seems to be efficient and fulfills a number of different defense functions for the plants. Thus, metabolic costs for additional chemical defense can be reduced. The differences in tannin contents of juvenile and mature trees of *M. tanarius* (Figure 1) also point to a change of resource allocation. Leaves become smaller and tougher as the plants mature. Nitrogen and phosphate contents decrease but carbohydrates increase with age (Heil, 1998). In larger trees of *M. tanarius*, the development of extrafloral nectaries ceases and the opportunistic ants no longer visit these plants (Fiala and Maschwitz, 1991). The investment of these plants seems to shift from biotic towards abiotic defense.

In some of the analyzed species, especially in *M. triloba* and *M. winkleri*, we found remarkable intraspecific variation of tannin contents (Figure 1), which might be due to different resource qualities but may also reflect genetic differences. Perhaps these species are particularly euryotopic, i.e., they can be found at locations differing widely with regard to their resources. As predicted by the C/N balance hypothesis (Bryant et al., 1983; Folgarait and Davidson, 1994, 1995), intraspecific differences in defenses can be caused by different resource qualities since an excess of carbon (caused by a high light regime at the plants location) compared to other nutrients (mainly nitrogen) can promote the carbon-based defense (like the tannins investigated in this study) of the plant.

Macaranga is a genus with a remarkable diversity of ecophysiological and life-history attributes, with variation even among sympatric species (Davies, 1998). This diversity strongly contrasts with the lack of molecular differentiation, especially in the group of obligate myrmecophytes (section *Pachystemon* s. stricto) (Davies, 1996; Blattner et al., 2001). Apparently, these species share close phylogenetic relationships but have diverged ecologically. Our study shows a great deal of intrageneric variation among the defensive mechanisms in this genus. Mutualistic relationships with ants may have contributed to this diversity.

(Received October 24, 2000; accepted May 29, 2001)

Abstract—The taste responsiveness of six squirrel monkeys, five pigtail macaques, four olive baboons, and four spider monkeys to polycose, a starch-derived polysaccharide, was assessed in two-bottle preference tests of brief duration (2 min). In experiment 1, the monkeys were given the choice between tap water and defined concentrations of polycose dissolved in tap water. In experiment 2, the animals were given the choice between polycose and sucrose, fructose, glucose, lactose, and maltose presented in equimolar concentrations of 100 and 200 mM, respectively. The animals were found to prefer concentrations of polycose as low as 10 mM (pigtail macaques), 30 mM (olive baboons and spider monkeys), and 60 mM (squirrel monkeys) over tap water. Relative taste preferences were stable across the concentrations tested and indicate an order of relative effectiveness (sucrose > polycose ≥ maltose) in squirrel monkeys, spider monkeys, and olive baboons that is similar to the order of relative sweetness in humans. Pigtail macaques, however, displayed an order of relative effectiveness (maltose > polycose ≥ sucrose) that differs markedly from that found in the other primate species tested and is similar to relative taste preferences found in rodents such as rats. Both the high sensitivity of the pigtail macaques to polycose and their vivid predilection for this polysaccharide and its disaccharide constituent maltose suggest that *Macaca nemestrina*, unlike other primates, but like rodents, may have specialized taste receptors for starch.

Key Words—Gustatory preference thresholds, relative taste preferences, polycose.

INTRODUCTION

Carbohydrates, in the form of sugar and starch, represent a major source of metabolic energy for a great number of animal species. With the exception of some fruits, plants usually contain much more starch than sugar (Hizukuri, 1996). However, whereas taste perception of sugars has been the subject of considerable research at both the behavioral and the electrophysiological level in a variety of species (Spector, 2000), studies on the taste of starch have been restricted to the rat. One possible reason for this bias may be the fact that sugars have a highly attractive taste both for humans and many other species, whereas starch has a rather bland taste for humans and has been assumed to be tasteless and, thus, unattractive to other animals as well (Kare, 1971; Pfaffmann, 1977).

Comparative studies of sugar taste sensitivity and preference have revealed marked differences among species. With regard to sensitivity, for example, preference thresholds for sucrose may differ by more than two orders of magnitude, even between closely related species belonging to the same order of mammals, such as the spider monkey and the slow loris (Laska et al., 1996; Glaser, 1986). While many species display a strong preference for the taste of sugars, others, such as cats and chickens, are indifferent to soluble carbohydrates (Kare, 1971; Beauchamp et al., 1977). Species have also been found to differ in their relative preference for individual sugars. Among species that prefer sucrose, some, such as rats, spiny mice, and gerbils, show a preference for maltose, while others, such as dogs, armadillos, or cows, are either indifferent or averse to maltose (Kare, 1971; Feigin et al., 1987).

In contrast to the wealth of knowledge about differences among species regarding their responsiveness to sugars, little is known as to whether species also differ in their sensitivity and preference for starch and other polysaccharides.

In a series of landmark studies, Sclafani and coworkers have shown that rats are strongly attracted to starch and starch-derived polysaccharides such as polycose (Sclafani and Clyne, 1987). Further, they showed that rats have a markedly lower taste preference threshold for polycose than for sugars such as sucrose (Sclafani and Nissenbaum, 1987), and that, at least at concentrations up to 300 mM, they clearly prefer this polysaccharide to sucrose and other mono- or disaccharides (Sclafani and Mann, 1987). These results, along with other findings, led the authors to conclude that rats have two types of carbohydrate taste receptors, one for polysaccharides and one for sucrose, which produce qualitatively distinct gustatory sensations (Nissenbaum and Sclafani, 1987). Recent electrophysiological studies lend support to this idea, as they have demonstrated the neural activity profile of the rat evoked by polycose and other starch-derived polysaccharides to be markedly different from those of other taste stimuli termed sweet by humans (Giza et al., 1991; Sako et al., 1994).

The presumed function of polysaccharide taste receptors is to facilitate the identification of starch-rich foods (Sclafani, 1991). This latter supposition is supported by findings that showed other rodents, such as gerbils, hamsters, and spiny mice, which also feed on grains and other parts of plants containing high amounts of starch, display similar preferences for polysaccharides as rats (Feigin et al., 1987; Rehnberg et al., 1996).

Given the paucity of data on taste sensitivity and preference for polysaccharides in species other than rodents, we decided to test the gustatory responsiveness of four species of nonhuman primates to polycose. This highly water-soluble mixture of glucose chains with α-1,4 linkages (2% glucose, 7% maltose, 55% maltooligosaccharides of 3–10 glucose units, and 36% maltopolysaccharides of >10 glucose units) is produced from an acid enzyme hydrolysis of corn starch and, apart from its frequent use as a taste stimulus in studies of gustatory performance in rodents, it is also used as a dietary supplement in humans.

The four primate species employed here, squirrel monkeys, spider monkeys, olive baboons, and pigtail macaques, are known to differ—at least to some degree—in their dietary habits (Clutton-Brock and Harvey, 1977; Caldecott, 1986; Chapman, 1987; Ross, 1992), allowing us to address the question of whether possible differences in taste responsiveness to polysaccharides in nonrodent mammals may reflect an evolutionary adaptation to dietary specialization.

Thus, the aims of the present study are threefold: (1), to assess whether different species of nonhuman primates are attracted to polycose; (2), to determine taste preference thresholds for this substance as a first and conservative approximation of gustatory sensitivity; and (3), to assess relative preferences for this polysaccharide in direct comparison with five food-associated mono- and disaccharides.

The possibility of including two New World primate species and two Old World primate species in this study allowed us to address additionally the question of whether the degree of phylogenetic relatedness rather than dietary specialization may affect the taste responsiveness of nonhuman primates to polysaccharides.

METHODS AND MATERIALS

Animals. Testing was carried out with six male adult squirrel monkeys (*Saimiri sciureus*), two male and three female adult pigtail macaques (*Macaca nemestrina*), two male and two female adult olive baboons (*Papio hamadryas anubis*), and one male and three female adult spider monkeys (*Ateles geoffroyi*). Animals of all four species were housed as social groups in enclosures with adjacent single cages that could be closed by sliding doors to allow temporary separation of animals for individual testing [for details of maintenance see Laska (1996, 2000) and Laska et al. (1996, 1999a,b)]. Animals were fed commercial monkey chow, fresh fruit,

and vegetables *ad libitum* but were deprived of water overnight before testing on the following morning. The amount of food offered daily to the animals was such that leftovers were still present on the floor the next morning and, thus, it was unlikely that ravenous appetite affected the animals' ingestive behavior in the tests.

Procedure. Gustatory responsiveness to polycose (reagent grade, Ross Products, Columbus, Ohio) was assessed by using a two-bottle preference test of short duration (Richter and Campbell, 1940). Twice each day, approximately 1 and 2 hr before feeding, the animals were separated and allowed 2 min to drink from a pair of simultaneously presented graduated cylinders with metal drinking spouts.

In experiment 1, monkeys were given a choice between tap water and defined concentrations of polycose dissolved in tap water. Testing started at a concentration of 200 mM and proceeded in the following steps (100, 50, 20, 10 mM, etc.) until the animals failed to show a significant preference. Subsequently, intermediate concentrations were tested in order to determine the preference threshold value more exactly. To keep up the animals' motivation and willingness to cooperate, testing did not follow a strict descending staircase procedure but followed a pseudorandomized scheme in which trials with high and, thus, presumably readily perceptible and attractive concentrations of polycose were alternated with low and presumably less attractive concentrations.

In experiment 2, monkeys were given a choice between equimolar concentrations of polycose and sucrose, fructose, glucose, maltose, and lactose (reagent grade, Merck, Darmstadt, Germany). In order to assess whether preferences are stable at different concentration levels, two test series were performed at 100 and 200 mM, respectively.

In both experiments, each pair of stimuli was presented 10 times, and the position of the stimuli was randomized in order to counterbalance possible position preferences. All animals had served in previous studies using the same method (Laska, 1994, 1996, 1997, 1999, 2000; Laska et al., 1996, 1998, 1999a,b, 2000). They were trained to enter the single cages voluntarily and were completely accustomed to the procedure.

The experiments reported here comply with the Guide for the Care and Use of Laboratory Animals (National Institutes of Health Publication no. 86-23, revised 1985) and also with current German and Mexican laws.

Data Analysis. For each animal, the amount of liquid consumed from each bottle was recorded, summed for the 10 test trials with a given stimulus combination, converted to percentages (relative to the total amount of liquid consumed from both bottles), and 66.7% (i.e., 2/3 of the total amount of liquid consumed) was taken as the criterion of preference. This rather conservative criterion was chosen for reasons of comparability of data, as the same criterion had been used in previous studies using the same method with the same primate species (Laska, 1994, 1996, 1997, 1999, 2000; Laska et al., 1996, 1998, 1999a,b, 2000), and in order to avoid misinterpretation of data due to a too-liberal criterion.

Additionally, two-tailed binomial tests (Siegel and Castellan, 1988) were performed, and an animal was only regarded as significantly preferring one of the two stimuli if it reached the criterion of 66.7% and consumed more from the bottle containing the preferred stimulus in at least 8 of 10 trials (binomial test, $P < 0.05$).

Preliminary analysis of the data indicated that there were no reliable differences in choice behavior and liquid consumption between the males and females of a species nor between the first and the second presentation of the day. Intraindividual variability in the amount of liquid consumed across the 10 test trials with a given stimulus combination was low and averaged less than 20%. Thus, a theoretically possible bias in the overall preference score due to excessive drinking in aberrant trials did not occur. Therefore, the data for the males and females of a species obtained in the 10 test trials were combined and are reported as group means and standard deviations.

Comparisons of the rank order of preference for the five saccharides tested across species and concentrations, respectively, were made by calculating Spearman rank-order correlation coefficients (r_s), which were tested for significance by computing z scores (Siegel and Castellan, 1988).

RESULTS

Experiment 1. Figure 1 shows the taste preference thresholds for polycose to be 10 mM in the pigtail macaques, 30 mM in the spider monkeys and the olive baboons, and 60 mM in the squirrel monkeys. All animals of a given species significantly discriminated these concentrations from tap water, and in some cases single individuals even scored slightly lower preference threshold values. All animals, however, failed to show a significant preference for the lowest concentrations presented, suggesting that the preference for higher concentrations was indeed based on the chemical nature of the stimulus. In most cases, interindividual variability of scores was low for both sub- and suprathreshold concentrations tested (cf. SDs in Figure 1).

Across-species comparisons of the degree of preference for polycose displayed by the four primate species showed that at concentrations of 50, 100, and 200 mM, respectively, the pigtail macaques were more attracted to the polysaccharide than the other species.

Experiment 2. Figure 2 shows the mean group preferences of the four primate species given a choice between polycose and maltose, sucrose, fructose, glucose, and lactose, presented at equimolar concentrations of 100 mM.

Squirrel monkeys significantly preferred sucrose and fructose over polycose and showed a trend to prefer polycose over maltose, glucose, and lactose that fell short of statistical significance. Spider monkeys significantly preferred sucrose and fructose over polycose, polycose over glucose and lactose, and showed a

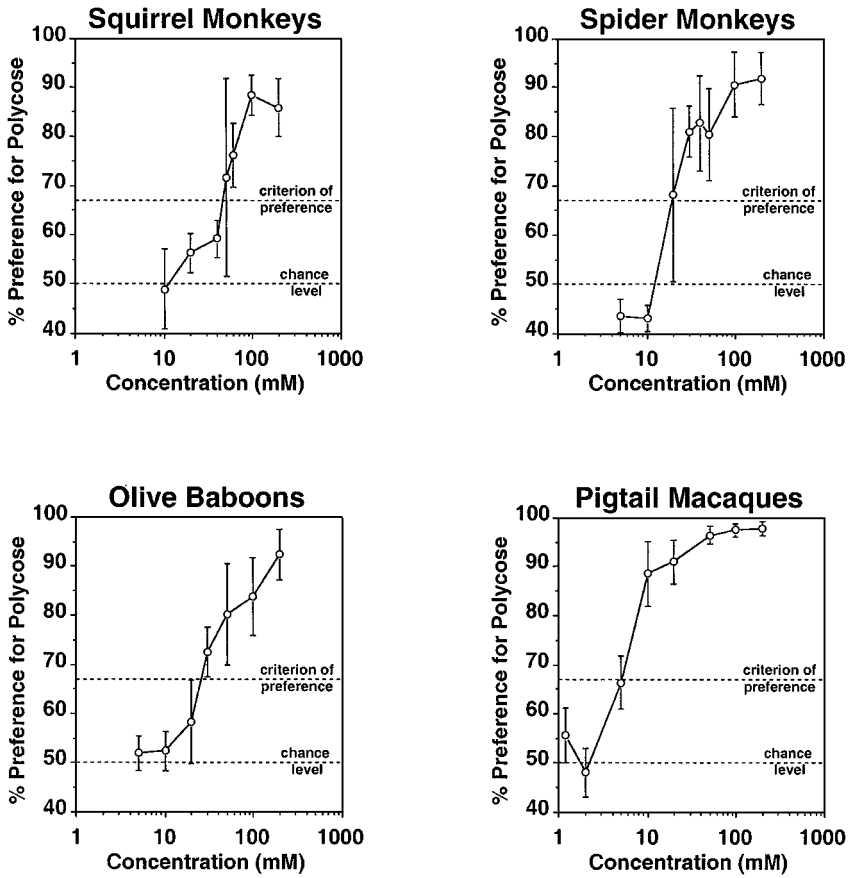

FIG. 1. Taste responsiveness of six squirrel monkeys, five pigtail macaques, four spider monkeys, and four olive baboons to aqueous solutions of polycose tested against tap water. Each data point represents the mean value (±SD) of 10 test trials of 2 min per animal.

nonsignificant trend to prefer polycose over maltose. Olive baboons significantly preferred sucrose over polycose; polycose over maltose, glucose, and lactose; and showed a nonsignificant trend to prefer polycose over fructose. Pigtail macaques significantly preferred maltose over polycose; polycose over fructose, glucose, and maltose; and showed a trend to prefer polycose over sucrose that fell short of statistical significance.

Interindividual variability within a given species was remarkably low, as can be inferred from the small SDs, and with only few exceptions all animals of a species either reached the criterion of preference (>66.7% of total consumption, plus binomial test, $P < 0.05$) in a given task or all failed to do so.

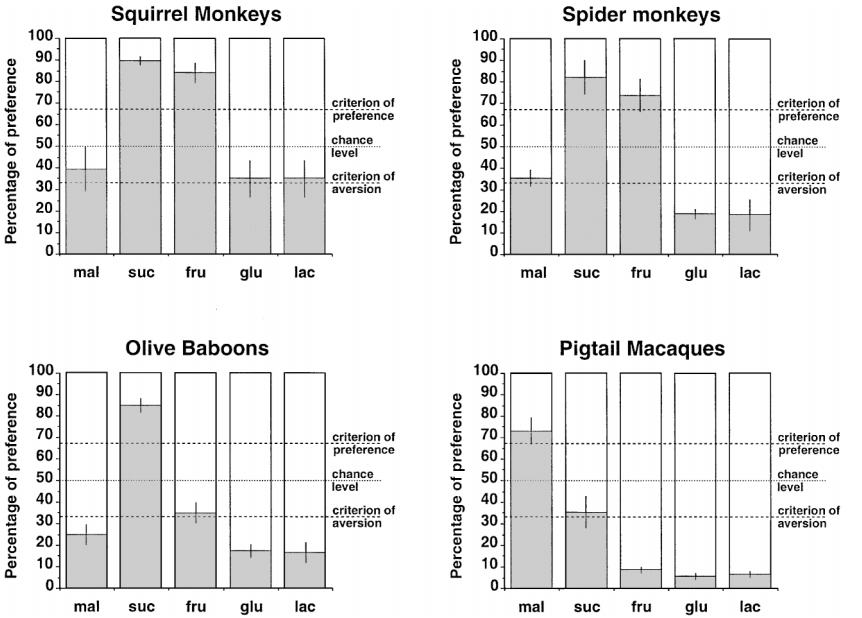

FIG. 2. Relative taste preferences of six squirrel monkeys, five pigtail macaques, four spider monkeys, and four olive baboons given a choice between aqueous solutions of polycose and sucrose, fructose, glucose, maltose, and lactose presented at equimolar concentrations of 100 mM. The shaded portion of a bar indicates the preference for a given saccharide and the white portion of a bar indicates the preference for polycose. Each bar represents the mean value (±SD) of 10 test trials of 2 min per animal.

Across-species comparisons of the patterns of preferences displayed by the four primate species showed that the preference rankings of squirrel monkeys, spider monkeys, and olive baboons for the five mono- and disaccharides tested against polycose were the same (sucrose > fructose > maltose > glucose > lactose) and, thus, significantly correlate with each other (Spearman, $P < 0.05$ for all pairs). The preference ranking of pigtail macaques for the same sugars tested against polycose (maltose > sucrose > fructose > lactose > glucose) was markedly different from that of the other three species (Spearman, $P > 0.05$ for all pairs).

Figure 3 shows the mean group preferences of the four primate species given a choice between equimolar concentrations (200 mM) of polycose and maltose, sucrose, fructose, glucose and lactose.

Squirrel monkeys significantly preferred sucrose and fructose over polycose and failed to show any preference in the combinations of polycose versus maltose, glucose, and lactose. Spider monkeys significantly preferred sucrose over polycose, polycose over glucose and lactose, and showed a nonsignificant trend to prefer fructose and maltose over polycose. Olive baboons significantly preferred sucrose

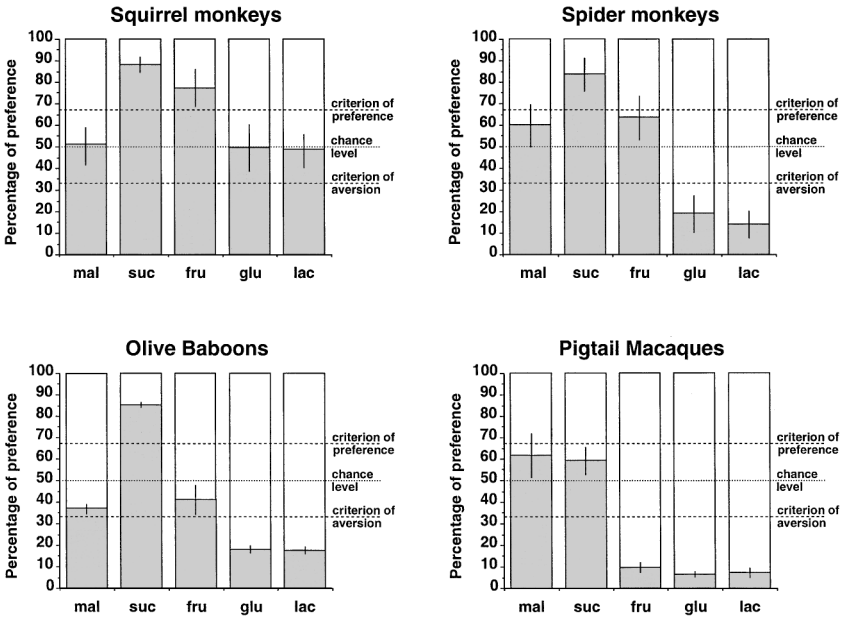

FIG. 3. Relative taste preferences of six squirrel monkeys, five pigtail macaques, four spider monkeys, and four olive baboons given a choice between aqueous solutions of polycose and sucrose, fructose, glucose, maltose, and lactose presented at equimolar concentrations of 200 mM. The shaded portion of a bar indicates the preference for a given saccharide and the white portion of a bar indicates the preference for polycose. Each bar represents the mean value (±SD) of 10 test trials of 2 min per animal.

over polycose, polycose over glucose and lactose, and showed a nonsignificant trend to prefer polycose over maltose and fructose. Pigtail macaques significantly preferred polycose over fructose, glucose, and maltose and showed a trend to prefer maltose and sucrose over polycose that fell short of statistical significance.

Interindividual variability within a given species was remarkably low as can be inferred from the small SDs, and, with only few exceptions, all animals of a species either reached the criterion of preference in a given task or all failed to do so.

Across-species comparisons of the patterns of preferences displayed by the four primate species revealed that the preference rankings of squirrel monkeys, spider monkeys, and olive baboons for the five mono- and disaccharides tested against polycose were the same (sucrose > fructose > maltose > glucose > lactose) and, thus, significantly correlate with each other (Spearman, $P < 0.05$ for all pairs), whereas the preference ranking of the pigtail macaques for the same sugars tested against polycose (maltose > sucrose > fructose > lactose > glucose) was markedly different from that of the other three species (Spearman, $P > 0.05$ for all pairs).

Within-species comparisons of the patterns of preference across the two concentrations tested revealed that the preference rankings of all four primate species for the five mono- and disaccharides tested against polycose remained the same at 100 mM and 200 mM and thus correlate significantly with each other (Spearman, $P < 0.05$ for all four pairs).

There was, however, a general trend (16 of 20 cases) for the preferences to be less pronounced with the higher concentration tested (200 mM) compared to the lower concentration (100 mM).

DISCUSSION

Table 1 compares the taste preference threshold values for polycose obtained in the present study with those for maltose and sucrose obtained with the same method in the four primate species tested here, with those of other mammalian species obtained by using a similar method, and with detection or recognition threshold values obtained for humans, with psychophysical procedures. A comparison of the preference threshold values for polycose shows *Macaca nemestrina* to be the most sensitive nonhuman primate species tested so far. Remarkably, their preference threshold value for this polysaccharide is even lower than the recognition threshold value of humans (Hettinger et al., 1996) in which, to the best of our

[a1]Present study, [2]Laska (1996), [3]Laska et al. (1996), [4]Laska et al. (1999), [5]Laska (2000), [6]Sclafani and Nissenbaum (1987), [7]Feigin et al. (1987), [8]Hettinger et al. (1996), study established a recognition threshold for polycose, [9]ASTM (1973) study established detection thresholds rather than preference thresholds for maltose and sucrose.

knowledge, no proper detection threshold value has been determined. More importantly, pigtail macaques are the only primate species tested so far whose preference threshold value for polycose and maltose is as low as that for sucrose. Thus, they differ from the other primates tested that all, including humans, display lower thresholds for sucrose compared to polycose and its disaccharide constituent maltose. The pattern of preference threshold values displayed by the pigtail macaques for these three saccharides is similar to that reported in rodents such as rats, hamsters, gerbils, and spiny mice, which all have been shown to be at least as sensitive to polycose and maltose as to sucrose (Sclafani and Nissenbaum, 1987; Feigin et al., 1987).

The reliability of the preference thresholds established here is supported by one of the few earlier studies that assessed taste responses of nonhuman primates to polycose. Using 24-hr solution versus water tests, Sunderland and Sclafani (1987) reported that squirrel monkeys prefer polycose over water at concentrations of 100 and 200 mM, but not at 10 and 50 mM. Bonnet macaques prefer this polysaccharide over water at all four concentrations.

Although all rodent species tested so far show lower preference threshold values for polycose than the pigtail macaques and, thus, all primates tested here, the similarity in the across-substance patterns of sensitivity between *Macaca nemestrina* and rats, hamsters, gerbils, and spiny mice (cf. Table 1) suggests that this primate species, and perhaps also other members of the genus *Macaca*, may have specialized taste receptors for starch and starch-derived polysaccharides that other primates are thought to lack (Sclafani, 1991).

This supposition is supported by our findings in the second experiment. Table 2 compares the relative taste preferences for suprathreshold concentrations of polycose, maltose, and sucrose in the four primate species tested here with those of other mammalian species obtained with the same or a similar method and with ratings on relative sweetness obtained in humans with psychophysical procedures.

Squirrel monkeys, spider monkeys, and olive baboons clearly preferred sucrose over equimolar concentrations of polycose and maltose and, thus, show a pattern of relative preferences that is similar to the ranking of relative sweetness of these three saccharides found in humans (Feigin et al., 1987). Pigtail macaques, in contrast, were at least as attracted to the polysaccharide and its disaccharide constituent as to sucrose. Their pattern of relative preferences is similar to that found in rats. Using solution versus solution tests of brief duration, a method almost identical to the one employed here, Sclafani and Mann (1987) showed that, at concentrations of 30, 100, and 300 mM, *Rattus norvegicus* prefers polycose and maltose over sucrose and that this ranking of relative preference is reversed only when presenting the saccharides at equimolar concentrations of 500 mM.

The reliability of the relative preferences reported here is supported by earlier studies that assessed relative taste preferences for food-associated mono- and disaccharides in squirrel monkeys (Laska, 1997), spider monkeys (Laska et al.,

TABLE 2. RELATIVE TASTE PREFERENCES FOR POLYCOSE, MALTOSE, AND SUCROSE IN FOUR PRIMATE SPECIES TESTED AND IN OTHER MAMMALIAN SPECIES

Species and concentration (mM)	Rank order of preference
Saimiri sciureus[1a]	
100	sucrose > polycose ≥ maltose
200	sucrose > polycose = maltose
Ateles geoffroyi[1]	
100	sucrose > polycose ≥ maltose
200	sucrose ≥ maltose ≥ polycose
Papio hamadryas anubis[1]	
100	sucrose > polycose > maltose
200	sucrose > polycose ≥ maltose
Macaca nemestrina[1]	
100	maltose > polycose ≥ sucrose
200	maltose = polycose = sucrose
Rattus norvegicus[2]	
30	polycose > maltose > sucrose
100	polycose ≥ maltose ≥ sucrose
300	polycose ≥ sucrose ≥ maltose
500	sucrose > maltose ≥ polycose
Saimiri sciureus[3]	
100	sucrose > maltose = polycose
Macaca radiata[3]	
100	polycose = maltose = sucrose
Homo sapiens[4]	
100	sucrose > maltose = polycose
200	sucrose > maltose > polycose

[a1]Present study, [2]Sclafani and Mann (1987), [3]Sunderland and Sclafani (1988), [4]Feigin et al. (1987) study established relative sweetness rather than preference.

1998), and pigtail macaques (Laska, 2000). Using the same method as in the present study, i.e., solution versus solution tests of brief duration, *Saimiri sciureus* and *Ateles geoffroyi* preferred sucrose over maltose at equimolar concentrations of 50, 100, 200, and 400 mM, respectively, whereas *Macaca nemestrina* preferred maltose over sucrose at all four concentrations.

In line with these findings, Sunderland and Sclafani (1987) reported that squirrel monkeys showed a significantly higher degree of preference for sucrose than for polycose or maltose in 24-hr solution versus water tests using concentrations of 10, 50, 100, and 200 mM, respectively, whereas bonnet macaques displayed preferences for maltose and polycose that were at least as strong as those for sucrose.

The question arises as to possible reasons why the pigtail macaques differ from the other primates tested in their responsiveness to polycose. Old World

primates and New World primates have been shown to differ in their ability to perceive substances such as aspartame and thaumatin, which both taste sweet to humans, suggesting that phylogenetic relatedness might account for differences or correspondences in taste perception among species (Glaser, 1993). However, in the present study, olive baboons, an Old World primate species like the pigtail macaques, showed the same pattern of relative preferences for polycose as squirrel monkeys and spider monkeys, two New World primate species. Thus, it seems unlikely that membership in one of these taxa is responsible for the observed differences among species.

Differences in dietary habits have been shown repeatedly to provide plausible explanations for differences in taste performance among species (Kare, 1971; Pfaffmann, 1977). Among New World primates, for example, the degree of frugivory has been found to correlate positively with sensitivity to food-associated mono- and disaccharides (Laska, 1996). This seems to make sense in terms of optimal foraging theory, as frugivorous species rely on soluble carbohydrates to meet their energy requirements more than nonfrugivores (Laska et al., 1996).

Sclafani (1991) proposed that the high sensitivity and preference for polycose and other starch-derived polysaccharides observed in the rat may also be explained by dietary habits. Anatomical features such as teeth and gut morphology suggest that members of the genus *Rattus* are primarily granivorous, i.e., they feed on a starch-rich diet, lending support to this hypothesis. Although considerable information on the dietary habits of the four primate species employed in the present study are at hand (Clutton-Brock and Harvey, 1977; Caldecott, 1986; Chapman, 1987; Ross, 1992), no definitive conclusions can be drawn at to whether differences in feeding specializations may account for the observed differences in polycose responsiveness, because unfortunately, none of the studies reported the proportion of starch-rich plants in the diet of any species. Furthermore, pigtail macaques do not seem to differ markedly in the proportion of fruits and seeds in their diet (72% of total intake) from olive baboons (63%) and spider monkeys (80%), but only from squirrel monkeys (26%) (Clutton-Brock and Harvey, 1977). Using the proportion of animal matter in the diet as an indicator of the maximally possible proportion of starch-containing plants also shows the squirrel monkey (72%) to be markedly different from the other three species (1–10%), (Clutton-Brock and Harvey, 1977), but nevertheless the squirrel monkeys showed the same pattern of relative preference for polycose as the spider monkeys and the olive baboons. Thus, the ultimate reason for the observed differences in polycose responsiveness between pigtail macaques and olive baboons, spider monkeys, squirrel monkeys, and humans remains elusive. One can speculate, however, as to the possible proximate reason.

In addition to behavioral studies measuring voluntary intake of sapid solutions, two lines of evidence lend further support to the idea that rats have specialized taste receptors for starch and stach-derived polysaccharides. Firstly,

studies using conditioned taste aversion paradigms showed that rats display little cross-generalization between polycose and sucrose, but some degree of cross-generalization between polycose and its disaccharide constituent maltose (Nissenbaum and Sclafani, 1987; Sako et al., 1994). Similar results were obtained using the same method in the hamster, another rodent species that cross-generalized between glycogen and maltose, but not between glycogen and sucrose (Rehnberg et al., 1996). A more recent study showed cross-generalization between sucrose and polycose in the same rodent species, suggesting that the two substances share common perceptual taste characteristics (Formaker et al., 1998). Secondly, electrophysiological studies have shown that the rat's chorda tympani responses to sugars were strongly suppressed by gurmarin, an antisweet peptide, whereas this substance had essentially no effect on polycose responses (Sako et al., 1994). Application of $KHCO_3$ onto the rat's tongue enhanced chorda tympani responses to sugars, but not to polycose (Sako et al., 1994). In line with these findings, single unit activity in the nucleus tractus solitarius of the rat in response to polycose was markedly different from that in response to substances representing the traditional four basic taste qualities (Giza et al., 1991).

To the best of our knowledge, studies on conditioned taste aversion using polycose in nonhuman primates have not been performed, but findings from electrophysiological studies in cynomolgus and rhesus macaques lend some support to the idea that members of the genus *Macaca* might have specialized taste receptors for starch and other polysaccharides. Plata-Salaman et al. (1993) recorded the activity of single neurons in the gustatory cortex of *Macaca fascicularis* in response to 19 chemicals sweet to humans. They found that all 19 substances formed a coherent cluster in the taste space generated from the correlations among patterns of neural activity evoked by the stimuli, suggesting relative similarity of taste quality across substances. Whereas simple carbohydrates such as glucose, fructose, sucrose, and maltose formed the center of this cluster, polycose was somewhat distant from these sugars, indicating some degree of difference in taste quality.

The results of the present study demonstrate that all four species of nonhuman primates employed here are clearly attracted to aqueous solutions of polycose. Further, we showed that pigtail macaques have lower taste preference thresholds for this starch-derived polysaccharide compared to squirrel monkeys, spider monkeys, and olive baboons and that their pattern of relative preference (maltose $>$ polycose $\geq$ sucrose) differs from that of the other three primate species (sucrose $>$ polcose $\geq$ maltose). These findings suggest that *Macaca nemestrina*, unlike other primates, but similar to rodents, may have specialized taste receptors for starch.

Spodoptera exigua OVIPOSITION AND LARVAL FEEDING PREFERENCES FOR PIGWEED, *Amaranthus hybridus*, OVER SQUARING COTTON, *Gossypium hirsutum*, AND A COMPARISON OF FREE AMINO ACIDS IN EACH HOST PLANT

ALLAN T. SHOWLER

Kika de la Garza Subtropical Agricultural Research Center, USDA-ARS
2413 E. Highway 83, Bldg. 201
Weslaco, Texas 78596

(Received March 28, 2001; accepted June 14, 2001)

Abstract—The beet armyworm, *Spodoptera exigua* (Hübner), can utilize a number of different host plants for oviposition and larval development, but some host plants are preferred over others. This study, using cage choice tests and olfactometer assays, demonstrates the beet armyworm's preference for pigweed, *Amaranthus hybridus* L., over cotton, *Gossypium hirsutum* L. Cage and olfactometer choice assays indicated that olfaction plays an important role in host selection by ovipositing females. First instars exhibited no feeding preference, but the more mobile third instars showed a significant feeding preference for excised pigweed leaves. The higher quantities and more diverse accumulations of free amino acids in pigweed might, in conjunction with other physiochemical and mechanical attractant and deterrent factors in the two-plant species system, play roles in the tendency of the beet armyworm to select pigweed over cotton and in providing a superior array of easily absorbed amino acids as compared to cotton.

Key Words—*Gossypium hirsutum*, cotton, *Amaranthus*, pigweed, beet armyworm, *Spodoptera exigua*, host plant selection, oviposition, free amino acids.

INTRODUCTION

The beet armyworm, *Spodoptera exigua* (Hübner), is known to feed on more than 50 plant species from over 10 families worldwide (Wilson, 1932; Smits et al., 1987). It originated in southern Asia and was introduced to the United States in Oregon in 1876 and again in California in 1882 (Wilson, 1932). It has since become

0098-0331/01/1000-2013$19.50/0

a pest of many crops in the United States and Mexico. In cotton, the beet armyworm is deleterious especially when pesticide applications disrupt beneficial arthropod populations (Eveleens et al., 1973; Raulston et al., 1997). However, Ali and Gaylor (1992) determined that beet armyworm larvae took longer to develop, had lower pupal weight, and required a greater number of stadia when raised on cotton, *Gossypium hirsutum* L., as compared to artificial diet or pigweed, *Amaranthus hybridus* L., a preferred wild host (Taylor, 1931). Similarly, *Amaranthus* spp. and *Portulaca oleracea* L. were found to be the most suitable hosts for *Spodoptera latifascia* (Walker) based on larval and pupal weights, survival, and development times in contrast to host plants such as maize, *Zea mays* (L.), sorghum, *Sorghum bicolor* (L.), *Ixophorus unisetus* (Presl.) Schlect., *Ipomoea* sp., and *Melampodium divaricatum* (Rich. ex. Pers.) Dc. (Portillo et al., 1998). *Spodoptera latifascia* was unable to utilize sorghum and maize sufficiently to sustain growth and development, but no evidence of decreased oviposition preference for these crop hosts was observed (Portillo, 1994). Despite heavy damage to sorghum and maize caused by *S. latifascia*, these crop plants are relatively unsuitable hosts for larval development (Portillo et al., 1998).

It is known that cotton leaves contain chemicals, including volatile terpenoids, that attract and/or deter herbivorous arthropods (Harborne, 1988). Gossypol has been shown to reduce beet armyworm larval weights, increase the length of the egg to adult development interval, and cause mortality (Bottger and Patana, 1966). Hairs, trichomes, nectaries, other deterrents and attractants (Schuster and Maxwell, 1974; Reynolds et al., 1975; Hassan et al., 1990; Ring et al., 1993), and various ecological factors (Berdegué et al., 1998) can also influence preference for one plant or another.

Host plant free amino acid accumulations have been associated with higher numbers of nematodes (Showler et al., 1990) and arthropods (Jayaraj and Seshadri, 1967; Blua et al., 1994). Gravid beet armyworms appear to prefer to oviposit on drought-stressed cotton (Ruberson et al., 1994; Ruberson, 1996), and it is known that water-deficit stress in many plants results in elevated levels of some free amino acids (Labanauskas et al., 1981; Shen et al., 1989; Gzik, 1996). Feeding behavior of tobacco budworm, *Heliothis virescens* (F.), corn earworm, *Heliothis armigera* (Hübner), and *Spodoptera littoralis* (Boisdval) adults was correlated with the electrophysiological response of sensilla on the proboscis. Responses of the sensilla to amino acids and sugar were correlated to feeding behavior of each of these species (Blaney and Simmonds, 1988).

This study compares the oviposition and feeding preference of beet armyworm adults and larvae for pigweed or early squaring cotton. The free amino acid analyses of both plant species might indicate that, in addition to volatiles and other chemical and mechanical defenses, free amino acid accumulations might play a role in host plant selection and contribute to the nutritional value of the preferred host plant species being compared.

METHODS AND MATERIALS

Oviposition Preference. Beet armyworm larvae were obtained from a laboratory colony at the Kika de la Garza Subtropical Agricultural Research Center in Weslaco, Texas, and reared on a soybean-wheat germ diet (Shaver and Raulston, 1971). The insects were maintained in environmental chambers at 30°C, 85% relative humidity, and a 13L : 11D photoperiod. Pupae were sexed and placed in individual cups until adult emergence. On the day of emergence, females were paired individually with single males in 0.5-liter cardboard containers. The next day, females were placed alone in a container lined with wax paper as oviposition substrate. Each container was monitored daily for the appearance of the first egg mass, which signified the presence of a gravid female moth. Different females were used for each replication.

Gravid beet armyworm females were provided a choice of cotton or pigweed for oviposition in 1.8- × 1.8- × 1.1-m cages. Since maximum egg-laying occurs during the first and second nights of ovipositional activity (Fye and McAda, 1972; Tisdale and Sappington, 2000), only females that had initiated ovipositional activity on the previous night were used in the oviposition choice assays. Four 7.5-liter pots of cotton plants (three per pot) at early squaring (diameter 3–5 mm), and four pots of pigweed plants (three per pot) at heading stage were randomly placed within each cage. Four gravid beet armyworm females were placed in each cage and allowed to oviposit for 48 hr, then each plant was inspected for egg masses. The assay was replicated 30 times during May–July 2000.

In order to determine whether female beet armyworms select the host plants by olfaction, a 78- × 32- × 38-cm introduction chamber with screen ventilation on three sides and Plexiglas on the front was connected to two separate 90- × 40- × 40-cm plywood choice chambers (each with a wire mesh back door) using two 25-cm-diameter × 35-cm-long white plastic tubes; one tube connected one choice chamber to the Plexiglas front panel of the introduction chamber, and the other tube connected from a second choice chamber to the front panel of the introduction chamber. An electric fan (20 cm diam.) was placed 1.5 m behind each choice chamber so that airflow through the tubes was about 0.4 m/sec. The introduction chambers were positioned at the open entrance of a 4.9-m-wide workshop door so that volatiles blown through the chambers would dissipate into the atmosphere (pilot tests using colored smoke demonstrated air flow). A 7.5-liter pot containing three pigweed plants at the heading stage was placed at random in one of the choice chambers and a 7.5-liter pot containing three cotton plants at the early squaring stage was placed in the other choice chamber. The plants were not tall enough to be seen through the plastic connecting pipes. Five gravid female beet armyworm moths were placed in the introduction chamber. After 48 hr, the host plants in the choice chambers and the walls of the choice chambers were examined for egg clusters. This experiment was replicated 30 times.

Feeding Preference of Larvae. Ten beet armyworm first instars were placed in covered, ventilated Petri dishes containing one cotton leaf of intermediate age and one pigweed leaf of similar size (17.40 ± 0.13 and 17.14 ± 0.15 cm^2, respectively, $N = 40$, $P = 0.203$) each with the petiole inserted through the cap of a 0.6-ml plastic vial of water to maintain leaf turgor. The two leaves were placed 2 cm apart, and the larvae were introduced 2 cm away from either leaf. This arrangement was replicated 100 times. After being stored for 24 hr at ambient room temperature ($\approx$23.9°C, 13L : 11D photoperiod), larval positions relative to the leaves were recorded.

In a separate Petri dish assay, one third instar was placed equidistant from a pigweed leaf and a cotton leaf. Larval position relative to the leaves was recorded after 1, 4, 6, and 24 hr. Each of the 30 replications was comprised of 10 Petri dishes.

Analysis of Free Amino Acids. Fully extended leaves among the topmost six leaves on the plant were taken from six different cotton plants at the squaring stage, and leaves from six different pigweed plants at head stage were collected. These 12 samples were immediately used to obtain 1 g leaf material per sample and completely homogenized with 10 ml 0.1 N HCl using a Virtishear homogenizer (Virtis, Gardiner, New York). At least 5 g homogenate from each sample was placed in separate 10-ml tubes and centrifuged at 10,000 rpm for 30 min. Samples were stored at −80°C.

One ml of supernatant from each sample was passed through a 0.5-μm filter fitted to a 5-ml plastic syringe. Samples were placed in the autosampler of an Agilent (Agilent Technologies, Atlanta, Georgia) reversed-phase high-performance liquid chromatograph (HPLC) with a binary pump delivering solvent A [1.36 g sodium acetate trihydrate + 500 ml purified HPLC grade water + 150 μl triethylamine (TEA) + sufficient acetic acid to bring pH to 7.2 ± 0.05] and solvent B [1.36 g sodium acetate trihydrate + 100 ml purified HPLC grade water (acetic acid added to this mixture to bring pH to 7.2 ± 0.05) + 200 ml acetonitrile + 200 ml methanol] at 0.3 and 0.45 ml/min on a concave gradient through a C_{18} fluorescence column. Absorbances at 262 and 338 nm were monitored on a variable wavelength detector for 40 min/sample. The autosampler measured and mixed a total of 6 μl sodium borate buffer (0.4 N, pH 10.2 in water), 1 μl 9-fluorenylmethylchloroformate (FMOC), and 1 μl orthophthalaldehyde (OPA) derivatizing agents, and 2 μl of sample; then 2 μl was injected for chromatographic separation of free amino acids. Identification and quantification of derivatized free amino acids was achieved by calibrating with a standard mixture of amino acids. Peak integration accuracy was enhanced by manual establishment of peak baselines.

For normally distributed data, statistical differences were determined using the paired t test, and for nonparametric data, Yates' corrected χ^2 test was used (Analytical Software, 1998). All experiments were conducted between March and July 2000.

RESULTS

Oviposition Preference. In the cage assay, beet armyworm females oviposited 4.69 times more egg clusters on pigweed than on cotton (Table 1). On pigweed, the mean number of eggs was 4.55 times higher than that deposited on cotton, and the number of eggs per cluster was 1.12 times higher on pigweed than on cotton. In the olfactometer assay, 3.27 times more egg clusters were found on pigweed than on cotton (Table 1). Pigweed had 3.44 times more eggs compared to cotton, and the number of eggs per cluster was 1.03 times higher on pigweed than on cotton. There were 2.05 times more egg clusters deposited on the choice chamber walls and the plant pots in the cotton chambers (1.23 ± 0.21) than in the pigweed chambers (0.60 ± 0.14; $\chi^2 = 2.74$; $df = 29$, $P = 0.098$)

Feeding Preference of Larvae. First-instar beet armyworms showed no preference for excised cotton (4.68 ± 0.24 larvae/leaf) or pigweed (4.29 ± 0.23 larvae/leaf) leaves ($\chi^2 = 0.76$, $df = 99$, $P = 0.38$). Once first instars found either of the hosts, they stayed on them. However, third instars displayed a preference for pigweed over cotton ($\chi^2_{24\text{hr}} = 44.8$, $df = 29$, $P < 0.0001$) at each of the four time intervals (Figure 1). After 24 hr, pigweed leaves that had been chosen were usually chewed to the midribs and some larvae consumed the petioles inside of the plastic water capsules rather than moving over to untouched cotton leaves. Those larvae that fed on the cotton leaves consumed a visually estimated 25% or less than the pigweed leaf area eaten.

TABLE 1. EGGS, CLUSTERS, AND EGGS/CLUSTER OVIPOSITED BY BEET ARMYWORMS ON PIGWEED AND COTTON: CAGE AND OLFACTOMETER CHOICE ASSAYS

Experiment and host	Eggs[a]	Clusters[a]	Eggs/cluster[b]

[a]Means for cotton and pigweed ($N = 30$) compared within each assay using χ^2.
[b]Means in cage and olfactometer assays for cotton ($N = 17$ and 27, respectively) and pigweed ($N = 30$ of each plant). Compared within each assay using t test.
[c]Mean ± SE.

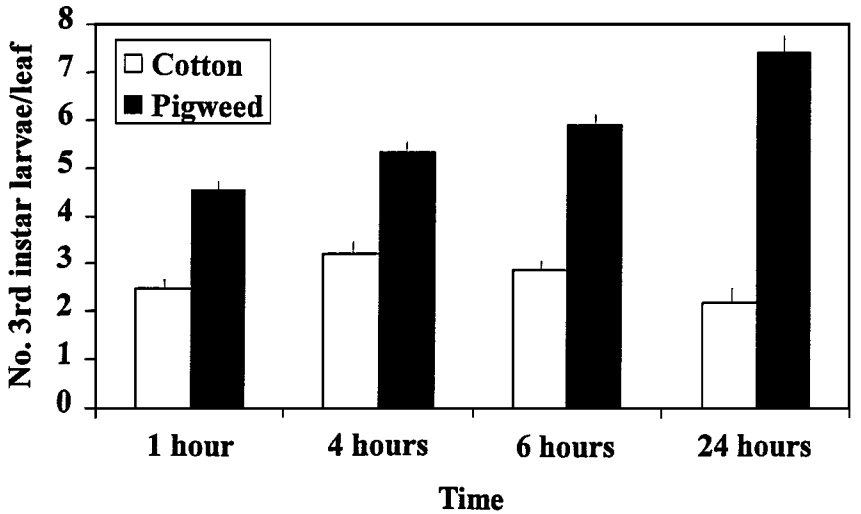

FIG. 1. Numbers of third instar beet armyworms (±SE) (one larva used per dish, 10 dishes per replication) on pigweed and cotton leaves over time in excised leaf choice assay ($N = 30$).

Analysis of Free Amino Acids. Free alanine, arginine, aspartic acid, glutamic acid, glycine, histidine, isoleucine, leucine, phenylalanine, proline, serine, threonine, and valine were detected in either or both cotton and pigweed (Table 2). Free cysteine, lysine, methionine, and tyrosine were not found in any of the samples. Other free amino acids, such as tryptophan, could not be detected. Twelve of the 17 detectable free amino acids were found in pigweed. Ten to 12 of the detectable free amino acids were found in cotton; the variation occurred because, in some cotton plants, free histidine and free phenylalanine were absent.

Pigweed leaves contained 1.86 times ($t = 3.91$, $df = 5$, $P = 0.0002$) the quantity of total free amino acids as compared to cotton. The greater accumulation of total free amino acids in pigweed over cotton largely resulted from higher concentrations of arginine (5.28 times, $t = 7.19$, $df = 5$, $P = 0.0008$), glutamic acid (1.85 times, $t = 3.53$, $df = 5$, $P = 0.0168$), glycine (4.03 times, $t = 2.73$, $df = 5$, $P = 0.0415$), histidine (98.03 times, $t = 8.12$, $df = 5$, $P = 0.0005$), leucine (absent in cotton, $t = 3.94$, $df = 5$, $P = 0.0104$), proline (2.27 times, $t = 2.76$, $df = 5$, $P = 0.0396$), and serine (2.25 times, $t = 2.39$, $df = 5$, $P = 0.0621$). In cotton, four free amino acids occurred in significantly higher quantities than in pigweed: alanine (absent in pigweed, $t = 11.11$, $df = 5$, $P = 0.0001$), isoleucine (2.88 times; $t = 3.79$; $df = 5$; $P = 0.0128$), phenylalanine (2.65 times, $t = 9.45$, $df = 5$, $P = 0.0002$), and threonine (3.07 times, $t = 5.16$, $df = 5$, $P = 0.0086$).

Amino acids that are indispensable to insects are arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and

TABLE 2. FREE AMINO ACID (FAA) CONCENTRATIONS IN PIGWEED AND COTTON LEAVES

FAA	Concentration (pmoles/μl extract, mean $\pm$ SE)		P^a

Total free essential amino acids	9471.8 $\pm$ 980.5	2818.2 $\pm$ 184.5	0.0020
Total FAAs	17551.0 $\pm$ 1675.5	9431.3 $\pm$ 576.0	0.0112

[a] Level of significance shown in right column determine by paired t test; $N = 6$.

valine, although there are variations with regard to different insect species (Chapman, 1971). The HPLC was able to detect all of the free essential amino acids except tryptophan. Of the nine detectable free essential amino acids, cotton had up to six (arginine, histidine, isoleucine, phenylalanine, threonine, and valine), and pigweed had seven (arginine, histidine, isoleucine, leucine, phenylalanine, threonine, and valine). In addition to having one more free essential amino acid than cotton, pigweed had 3.36 times higher concentration of total free essential amino acids ($t = 5.92$; $df = 5$; $P = 0.0020$) than cotton (Figure 2). In cotton, free essential amino acids constituted 29.88% of the total amount of free amino acids; in pigweed free essential amino acids comprised 53.97% of the total quantity of detectable free amino acids. Three of cotton's six free essential amino acids were significantly more abundant in cotton than in pigweed: isoleucine, phenylalanine, and threonine.

DISCUSSION

Whatever the interplay of mechanisms or cues that govern beet armyworm oviposition preference for one host plant or another, the extent to which the beet armyworm propagates itself is in the balance. Many insects prefer to oviposit on

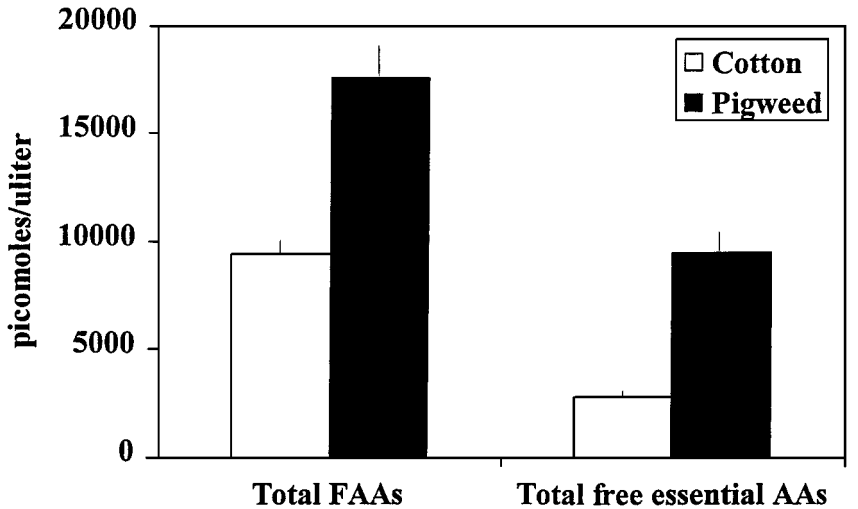

FIG. 2. Picomoles (±SE) of total free amino acids in pigweed and cotton contrasted to quantities of free essential amino acids ($N = 6$). Cotton and Pigweed had significantly different ($p \leq 0.05$) quantities of total free amino acids, and total free essential amino acids.

certain plant species because those hosts enhance larval development and survival by providing a suitable diet (Singer, 1972, 1983), although there are exceptions (Wiklund, 1974; Courtney, 1981). Berdegué et al. (1998) demonstrated that beet armyworm choice of oviposition host was not molded by the nutritional quality of the two common host plants studied, *Chenopodium murale* L. and *Apium graveolens* L. Thompson (1988) described four ecologically based hypotheses that suggest selection pressures acting alone or together help explain host plant preferences, in addition to nutrition and attractive and deterrent plant volatiles.

In the time hypothesis, which seems to best explain the result of the beet armyworm's choice between *C. murale* and *A. graveolens* (Berdegué et al., 1998), females may oviposit on unsuitable novel hosts without the benefit of evolutionary time to select away from detrimental behavior. Examples of this involve introduced insects with novel plants or the introduction of exotic plants where the insects are indigenous (Straatman, 1962; Chew, 1977; Rodman and Chew, 1980; Legg et al., 1986). The patch dynamic hypothesis predicts that eggs will be laid mostly on the plant host that they encounter more frequently, but this fails to explain examples of strong preference for scattered weed species in large monocultures (Koike et al., 1996). In the enemy-free-space hypothesis, herbivores might prefer nutritionally inferior host plants if they offer superior protection from natural enemies (Kester and Barbosa, 1991; Fox and Eisenbach, 1992; Benrey and Denno, 1997). Further,

volatiles emitted by cotton leaves damaged by feeding larvae can alert biological control agents to their presence (Elzen et al., 1984; Tumlinson et al., 1992). The parasite/grazer hypothesis suggests that herbivores that can develop on more than one host are less likely to exhibit strong host plant oviposition preferences than are herbivores that can develop on only one host plant (Thompson, 1988). Although the beet armyworm adult and larval choice of pigweed over cotton could involve one or more of these explanations, they do not identify the cues that the insect responds to in making the choice.

Cotton leaves and squares emit volatile terpenoids and other compounds (Thompson et al., 1971), the composition of which can change in response to various stimuli (Heath and Manukin, 1992; Surburg et al., 1993). Loughrin et al. (1995) found that 23 volatiles are emitted from cotton leaves by damaged beet armyworm larvae (terpenes and lipoxygenase-hydroperoxidase lyase-derived volatiles predominated). Although there were no apparent differences in volatile emission among different varieties of undamaged cotton, average volatile emission from damaged leaves of a naturalized variety was about 7 times higher than from damaged leaves of commercial varieties. In choice tests, however, the larvae preferred feeding on leaves of the commercial cultivars. Huang and Renwick (1992) showed that the oviposition preference for host plants of *Pieris rapae* L. and *P. oleracea* Harris were explained in most cases by the presence of stimulants and deterrents in plant extracts. The two *Pieris* species apparently evolved differential sensitivities to the chemical stimuli that trigger or deter oviposition. The balance of positively and negatively interpreted sensory signals evoked by plant chemicals appears to have played an important role in acceptance or rejection of a plant by both *Pieris* species. Such intermingling of cues, however, makes definitive identification of chemical causal agents challenging. Attraction of tobacco budworm (Tingle and Mitchell, 1992), pink bollworm, *Pectinophora gossypiella* (Saunders) (Wiesenborn and Baker, 1990), and the boll weevil, *Anthonomus grandis* Boheman (Geuldner et al., 1970; Chang et al., 1985; Dickens, 1990) to cotton blossom volatiles has been demonstrated, and green leaf volatiles linalool, myrcene, and benzaldehyde were shown to elicit responses in the beet armyworm (Dickens et al., 1993). Cotton plants with gossypol, however, were less preferred as hosts to many herbivorous arthropods (Bottger et al., 1964; Maxwell et al., 1965; Lukefahr and Martin, 1966). Hedin et al. (1991) showed that female tobacco budworm moths oviposited in the terminals of the cotton plant; the hatched larvae migrated to the terminal area and then to small squares on which they fed, finally burrowing into the anthers where they developed. Calyx crowns of resistant lines are high in terpenoid aldehydes, including gossypol. The cage and olfactometer assays in this study suggest that volatiles emitted from cotton and pigweed play roles in the tendency for beet armyworms to oviposit on pigweed, which lacks gossypol. That the numbers of egg clusters deposited on cotton choice chamber walls and plant pots were double those on the pigweed choice chambers further suggests that, although not

statistically significant ($P = 0.098$), cotton may be less preferred than pigweed once the moths entered the choice chambers.

Yoshida and Parella (1992) concluded that factors other than total nitrogen and leaf moisture may influence the nutritional ecology of *S. exigua* in the case of various chrysanthemum varieties. As little as 0.1% concentration of gossypol in the diet reduced weights of larval beet armyworm, boll weevil, cotton bollworm, *H. zea* (Boddie), cabbage looper *Trichoplusia ni* (Hübner), and salt-marsh caterpillar *Estigmene acrea* (Drury) and increased the number of days required for development from eggs to adults (Bottger and Patana, 1966). Gossypol, generally accepted as being an element of cotton's resistance to some pests (Lukefahr and Martin, 1966), was found to be present in equal quantities in both susceptible and resistant lines, while the hemigossypolone and heliocides H_1 and H_2 were greatly increased in resistant lines (Hedin et al., 1991).

In the case of the common cutworm, *S. litura* F., larvae fed less as the quality of their diet declined. The longer development time, involving extra stadia, permitted the larvae to consume as much as those raised on a better diet (Itoyama et al., 1999). This accounts for the conclusion of Ali and Gaylor (1992) that cotton is a relatively poor host plant for the beet armyworm. In this experiment, first-instar beet armyworms fed on the plant, cotton or pigweed, that they first encountered regardless of nutritional value, or the presence of deleterious chemicals or any mechanical defenses (e.g., trichomes and hairs). The limited mobility of first-instar beet armyworms makes them highly dependent on the female parent's ability to select the most nutritious host. The more mobile third-instar beet armyworm (Smits et al., 1987), however, exhibited a significant tendency to feed on pigweed even after 1 hr had elapsed following their release. The mechanism for making the selection, however, could not be determined in this study. Many of the larvae moved about the Petri dish and over both leaves before settling onto one or the other to feed. However, the third instars did tend to choose the plant species with the higher amounts of more diverse free amino acids. Third-instar beet armyworms can move from one plant to another, but it is likely that the need for mobility arises primarily when the larvae defoliate leaves and must move on to find other leaves on the same plant. In the case of first- and third- instar beet armyworms, survival and vitality of progeny probably depend heavily on host selection by the gravid female.The results of Itoyama et al. (1999) also agree with the observation that beet armyworm third instars consumed less cotton leaf area than pigweed leaf area during 48 hr intervals. Nevertheless, similar to the findings of Portillo (1994) using *S. latifascia*, the beet armyworm will oviposit on cotton and can inflict economic damage.

In this two-plant system, it appears that gravid beet armyworms tend to negatively interpret the blend of volatiles emanating from cotton leaves and, thus, apparently orient mostly toward pigweed, although it might also be that the insect

orients toward pigweed because it is a superior food source. Cavin and Rodriguez (1988) found that β-carbolene alkaloids are found worldwide among many plant families. Chronic dietary exposure tests of harman, harmine, and other simple β-carbolene alkaloids for activity against beet armyworm revealed potent antifeedant and possible toxic effects. It seems that in this study, pigweed did not repel or deter oviposition and larval feeding, and, in agreement with Ali and Gaylor (1992), larval development did not appear to be impeded by nutritional deficiencies or toxins. Blaney and Simmonds (1988) correlated feeding behavior of tobacco budworm, corn earworm, and *S. littoralis* adults with the electrophysiological response on sensilla on the proboscis. Assuming that beet armyworms can detect amino acids and sugars, that such detection has a role in determination of host plants for oviposition, and that foliar free amino acid content is detected by the sensilla, the greater levels of important unbound amino acids in pigweed help to explain the oviposition preference for pigweed. Al-Zubaidi and Capinera (1984) demonstrated that beet armyworm larval development time and mortality were decreased and egg production was increased by nitrogen application to host plants, including pigweed. Foliage became more digestible and efficiency of conversion of ingested and digested food increased as nitrogen levels increased. Nitrogen application to plants has been shown to result in increased levels of free amino acids (Magalhaes et al., 1995).

Insect physiologists have shown that individual amino acids differ greatly in their effect on insect performance; subsets of amino acids are the mechanistic basis of the correlations between total plant nitrogen and insect performance. Synthetic diets mimicking amino acid distribution in anthers were found to be successful for tobacco budworm larval growth and development (Hedin et al., 1991). At least to some extent, nutritional strength has been linked with insect host plant preference (Scribner and Slansky, 1981; Bernays and Chapman, 1994), and higher levels of readily available (unbound) nitrogen presumably improve insect development (Helms et al., 1971). Similarly, host plant increases in concentrations of certain free amino acids have been shown, in some cases, to be preferred by herbivorous insects. Studies show that plants stressed by moisture (Labanauskas et al., 1981; Shen et al., 1989; Gzik, 1996; Showler, in preparation) and diseases (Seitz and Hochster, 1964; Jensen, 1969; Lodh et al., 1971) accumulate significantly higher quantities of some free amino acids, especially proline. McQuate and Connor (1990) demonstrated that mildly water-deficit-stressed soybeans were preferred by larvae of Mexican bean beetle, *Epilachna varivestis* Mulsant. Beet armyworm eggs were reported as being most concentrated on stressed cotton plants in fields (Ruberson et al., 1994; Ruberson, 1996). Jayaraj and Seshadri (1967) found that nymphs of *Empoasca kerri* Pruthi were consistently more abundant on the leaves of pigeon pea, *Cajanus cajan* (L.) Millsp., infected with a mosaic virus than they were on healthy plants. The infected leaves

had a higher content of total nitrogen, peptides, and free amino acids than the healthy plants. Several species of aphids have been shown to benefit more from plants infected with viruses than from uninfected plants (Kennedy, 1951; Ajayi and Dewar, 1982; Blua et al., 1994), and other studies demonstrate altered free amino acid concentrations in virus-infected plants (Singh et al., 1974; Showler et al., 1990).

Insects absorb nitrogen through the gut primarily in the form of free amino acids or very small peptides (Brodbeck and Strong, 1987). Thus, the initial cost of proteolysis is saved if amino acids are ingested in this form. The distinction between free amino acids and those bound in proteins may be important for insects that are physiologically incapable of ingesting large peptides (e.g, aphids), but this issue is separate from the energy costs of proteolysis. In terms of optimizing insect development, it is probable that the balance between different amino acids is particularly important (Chapman, 1971). Vanderzant (1958), for example, found that although pink bollworm larvae could survive on a diet that included only the essential amino acids, growth was slow and adults were small. The inclusion of certain dispensable amino acids was necessary for optimum growth and development, and in some cases, amino acids such as glycine have been shown to be essential (Hinton et al., 1951; Davis, 1956). It is suggested that beet armyworm larvae obtain a less diverse source of readily available (unbound) essential amino acids on cotton (because cotton leaves lack free leucine and sometimes free histidine and free phenylalanine) than on pigweed. Those essential amino acids that are not available in the soluble form in pigweed (alanine, lysine, and methionine) and cotton (leucine, lysine, and methionine) can be acquired in varying extent through proteolysis of foliar proteins. Pink bollworm larvae raised on a diet in which one of the essential amino acids was omitted grew slowly and failed to survive beyond the second instar (Vanderzant, 1958). Increased glutamic acid caused growth stimulation in pink bollworm, and this could also be the case with the higher concentrations of glutamic acid in pigweed than in cotton. Vanderzant (1958) also determined that increased arginine and histidine was associated with larger pink bollworm larvae, so it is possible that the higher accumulation of free essential amino acids and total free amino acids could make pigweed more nutritious and attractive to the beet armyworm. The greater diversity and abundance of free essential amino acids in pigweed, in combination with other governing factors, might have a role in host selection, and corresponds to evidence that pigweed is a superior host for developing beet armyworm (Ali and Gaylor, 1992).

Abstract—The partnership in the *Crematogaster–Macaranga* ant–plant interaction is highly species-specific. Because a mutualistic relationship on a *Macaranga* plant starts with colonization by a foundress queen of a partner *Crematogaster* species, we hypothesized that the foundress queens select their partner plant species by chemical recognition. We tested this hypothesis with four sympatric *Macaranga* species and their *Crematogaster* plant-ant species. We demonstrated that foundress *Crematogaster* queens can recognize their partner *Macaranga* species by contact with the surface of the seedlings, that they can recognize compounds from the stem surface of seedlings of their partner plant species, and that the gas chromatographic profiles are characteristic of the plant species. These findings support the hypothesis that foundress queens of the *Crematogaster* plant-ant species select their partner *Macaranga* species by recognizing nonvolatile chemical characteristics of the stem surfaces of seedlings.

Key Words—partner-plant selection, partner-plant recognition, ant–plant interactions, mutualism, chemical recognition, myrmecophyte, ant dispersal, insect–plant coevolution.

INTRODUCTION

Myrmecophytism, a type of ant–plant interaction, is one of the most conspicuous examples of the coevolution of mutualism between an animal and a plant (Huxley and Cutler, 1991; Davidson and McKey, 1993). In the mutualistic interactions, the ants (plant-ants) protect their host plants from herbivores and clinging vines, while the host plants (myrmecophytes) provide nest sites and, in some cases, food for the ants (Janzen, 1966; Buckley, 1982; Davidson and McKey, 1993). Myrmecophytism is often obligate: plant-ants and myrmecophytes cannot survive or have difficulty in surviving without each other. Many characteristics of both plant-ants and myrmecophytes are highly specialized and adapted for the mutualistic interaction (Davidson and McKey, 1993).

Macaranga (Euphorbiaceae) is a tree genus including more than 25 species of myrmecophytes, found predominantly in the tropical areas of South East Asia (Whitmore, 1969; Fiala and Maschwitz, 1991, 1992a). Most myrmecophytes have obligate mutualistic relationships with the species-specific specialist ant (plant-ant) species of the genera *Crematogaster* and *Camponotus*. The plants harbor partner plant-ants in their hollow stems and produce food bodies that the plant-ants harvest as their main food (Fiala et al., 1989; Fiala and Maschwitz, 1991, 1992b). In many obligate myrmecophytic species, the mutualistic and symbiotic interactions begin with the foundress ant queens colonizing the plant partners at a very early stage of plant growth. The queens produce ant workers who patrol the host trees and exclude herbivores (Fiala et al., 1989). Both host plants and plant-ants are dependent on each other for survival (Fiala and Maschwitz, 1990; Fiala et al., 1999).

In some cases, many myrmecophytic species have evolved within a particular genus, such as *Acacia* (Leguminosae), *Cecropia* (Cecropiaceae), and *Macaranga* (McKey and Davidson, 1993). The *Macaranga–Crematogaster* system, however, is the only case where the partnership between plant and ant species is highly species-specific in a wide variety of myrmecophytic species within a single genus (Fiala et al., 1999). One species of *Macaranga* has mutualistic relationships mainly with only one or two species of *Crematogaster* plant-ants, and one ant species interacts with a narrow range of *Macaranga* species, in some cases just one or two species (Fiala et al., 1999). Although several species of obligate myrmecophytic *Macaranga* species often coexist in similar habitats in a locality (Davies et al., 1998; Itioka et al., 2000), the species-specificity is well maintained (Itino et al., unpublished data). What factors affect the species-specific partnership in *Macaranga–Crematogaster* myrmecophytism? The first objective of this study was to test whether foundress queens of *Crematogaster* plant-ants can distinguish between *Macaranga* species.

It is well known that ants use various semiochemicals, such as pheromones and cuticular hydrocarbons, for communication in their socialized colonies and

for recognition of nestmates, trophobionts, and prey organisms (Traniello, 1980; Jessen and Maschwitz, 1986; Bonavita et al., 1987; Hölldobler and Carlin, 1987). We also know that closely related but different plant species have different nonvolatile chemicals on their surfaces. Thus, it is likely, in the *Macaranga*–*Crematogaster* system, that foundress queens may recognize their host plant species chemically. The second objective of this study was to examine whether chemical cues, characteristic of each *Macaranga* species, are used for host plant recognition by *Crematogaster* foundress queens.

To examine these two objectives, we conducted three experiments on four obligate myrmecophytic species of *Macaranga* and their specific *Crematogaster* plant-ants: (1) preference experiments to observe how foundress queens of each ant species respond to seedlings presented experimentally; (2) chemical analyses of extracted from the stem surfaces of *Macaranga* seedlings; and (3) preference experiments using esters extracted from the stem surfaces of *Macaranga* seedlings to test whether foundress queens use these as chemical cues for host plant recognition.

METHODS AND MATERIALS

Study Site. All experimental plants and ants were collected in lowland mixed dipterocarp forest in Lambir Hills National Park, Sarawak, Malaysia (4°20′N, 113°50′E, altitude 55–70 m). The details of the study site were described by Watson (1985), Inoue and Hamid (1994) and Kato et al. (1995). At least 20 species, including at least 11 myrmecophytic species, of *Macaranga* occur at the study site (Nagamasu and Momose, 1997).

Life History. We investigated four *Macaranga* species: *M. winkleri*, *M. trachyphylla*, *M. beccariana*, and *M. hypoleuca*, which are all abundant at the study site. Although the preferred light and soil conditions differ widely among the four species (Davies et al., 1998), it is not uncommon to find seedlings and mature trees of multiple species sharing a single microhabitat, such as a tree gap or a riverbank (Itioka, personal observation). All the experiments, except for chemical analysis, were conducted during September and October 1998 and March 1999.

The four species are all obligate myrmecophytes that harbor specific plant-ant species of the *Crematogaster* genus. The details of the basic biology of the mutualistic interactions between typical obligate myrmecophytes of *Macaranga* and their *Crematogaster* plant-ants have been described by Fiala et al. (1989) and Fiala and Maschwitz (1990, 1991, 1992a,b). The *Macaranga* plants produce pearly secreta, called food bodies, on the backs of young leaves or stipules. These food bodies, which the symbiont ants utilize as their main food resource, are rich in carbohydrates, sugars, and lipids (Rickson, 1980; Fiala and Maschwitz, 1992b; Heil et al., 1997). In return, the symbiont ants protect their host plants from

phytophagous insects and clinging vines (Fiala et al., 1989). When they reach 10–30 cm in height, the hollow stems of *Macaranga* seedlings swell and then form domatia between the nodes. At this stage, foundress ant queens settle on the seedlings, although the average heights of seedlings that ant queens begin to colonize depends on species. A foundress makes a hole in the wall of a domatium, enters the domatium, closes the hole, and starts to make her new colony. Thereafter, the mutualism begins.

Each of the four *Macaranga* species associates with a unique plant-ant species at the study site. The *Crematogaster* ant species associated with the four *Macaranga* species have not yet been described, although they have been distinguished by analysis of mtDNA (Itino et al., unpublished data). At the study site, the ant species inhabiting *M. beccariana* and *M. hypoleuca* are almost identical to *Crematogaster decamera*. Those inhabiting *M. trachyphylla* and *M. winkleri* are a species closely related to *C. borneensis* and an undescribed non-*decamera Crematogaster* species, respectively (Seiki Yamane, personal communication; see Itioka et al., 2000 for further details). Although the two species resembling *C. decamera* are morphologically indistinguishable, they can be clearly distinguished from the species inhabiting *M. trachyphylla* and *M. winkleri* by the morphology of queens and workers.

Host Plant Recognition by Ant Queen (Preference Experiments). To examine whether foundress ant queens recognize and differentiate among different congeneric plant species, we offered seedlings of each of the four *Macaranga* species to foundress ants of each *Crematogaster* plant-ant species. Seedlings that were less than 30 cm in height and not yet colonized by ants were collected at random from several tree gaps and riverbank areas within the study site. The seedlings were potted in a shade house at a distance from the forest ridge. We used cloth shades to match the light levels in the shade house to those of a typical forest gap. We allowed the seedlings to grow until they bore one to three domatia and used them for the preference experiments described below. Nulliparous ant queens were collected from domatia of intact and 10- to 20-cm-high seedlings of each *Macaranga* species in the field, and kept in a plastic bag for one day before they were used. We considered a queen with no offspring in the domatia to be nulliparous. We omitted queens that were in domatia with lignified entrance holes, which indicated that a long time had elapsed after the queens' settlement. We checked the species of the ant queens morphologically. When we found nonspecific plant-ant queens in the collection, which was rare, we omitted them. Single ant queens were placed on the youngest well-developed leaf of a potted seedling and observed to see whether they entered the stem of the offered seedling within an hour or within a day. Each individual queen was used in the experiments only once or twice; each queen was placed once on a seedling of the same species from which she was collected and once on a seedling of one of the other three species. The order of the two trials was randomized and the interval between the trials was an hour. The experimental seedlings were used only once for the experiments.

Chemical Analyses of Surface Extracts of Macaranga *Seedlings.* To investigate the differences in chemical characteristics that might be used as cues for host recognition by the foundress ant queens, we obtained extracts from the stem surfaces of seedlings of each species. Seedlings were collected and cultivated in the shade house as above, then the hollow stems were cut out. The stem part that covered two or three consecutive nodes (domatia) was sampled from each seedling. Each stem sample was soaked in ethyl acetate for 30 min. The extracts from each stem sample were analyzed separately by gas chromatography (GC) and used as samples in the bioassays (see below). We sampled stem pieces from at least seven seedlings of each species.

Each ethyl acetate extract was evaporated completely and then dissolved in 40 μl hexane. We added 100 ng docosane as an internal standard and then analyzed 2 μl of each sample by GC in a GC-14A gas chromatograph (Shimadzu Inc.) equipped with a flame ionization detector and a DB-1 glass capillary column (30 m $\times$ 0.25 mm ID; 0.25 μm film thickness; J&W Scientific Inc.). Helium was used as the carrier gas. The oven temperature was programmed as follows: 80°C for 1 min, increasing by 20°C/min to 320°C and held there for 10 min.

Bioassays Offering Extracts of Macaranga *Seedling to Ant Queens.* To examine whether the chemicals extracted from *Macaranga* seedlings can be used as chemical cues for host plant recognition by ant queens, we offered the extracts from the stem surfaces to foundress queens. Ethyl acetate extracts of each *Macaranga* species were applied to tube-shaped filter papers (60 mm $\times$ 5 mm ID) and allowed to dry completely. The quantity of extract was equivalent to the extract from the stem part of a node. About 1 hr after the application of the extract, single ant queens were placed on the center of a glass tray (90 mm ID $\times$ 20 mm) with the extract-impregnated paper tube, and their behavior was observed for 30 min. Talc was applied to the wall of the glass tray so that the ant queen inside could not climb up the wall. When the ant queen climbed the paper tube and touched it with her antennae, we regarded the behavior as showing interest and recorded the time during which she showed such behavior and stayed on the paper tube. A paper tube treated with pure ethyl acetate was used as a control treatment. Experimental ants were prepared and collected in the same way as in the preference experiments, and the trial schedule was also the same. Each ant queen was used twice: she was offered a paper tube containing the extract of her host species once and one containing the extract of one other species or a control once, in random order.

RESULTS

Host Recognition by Ant Queen. We defined a partner *Macaranga* species for a particular experimental ant queen as the *Macaranga* species of the seedling from which the queen was derived. The frequencies with which ant queens of the

TABLE 1. COMPARISON OF ANT QUEEN PREFERENCES TO SEEDLINGS OF DIFFERENT *Macaranga* SPECIES[a]

Plant species of offered seedlings	Ant species (plant species that ant queens associate with)			
	M. winkleri	*M. trachyphylla*	*M. beccariana*	*M. hypoleuca*
M. winkleri	77.8 (18)	15.3 (13)	42.9 (7)	40.0 (5)
M. trachyphylla	0 (8)	71.0 (31)	50.0 (4)	60.0 (5)
M. beccariana	0 (7)	13.3 (15)	91.3 (23)	81.3 (25)
M. hypoleuca	0 (7)	0 (4)	77.8 (18)	84.0 (25)

[a] Percentage of ant queens that entered the offered seedlings of each species; the number of experimental ant queens is given in parenthesis.

three species that associate with *M. winkleri*, *M. trachyphylla*, and *M. beccariana* entered the stem domatia of the partner *Macaranga* species were higher than those at which queens entered the stem domatia of the other two nonpartner *Macaranga* species (Table 1; Fischer's exact test, $\chi^2 = 20.263$, $P < 0.0001$ for queens from *M. winkleri* and $\chi^2 = 19.177$, $P < 0.0001$ for queens from *M. trachyphylla*, and $\chi^2 = 8.694$, $P = 0.0069$ for queens from *M. beccariana*). The queens derived from *M. winkleri* rejected all seedlings of the three nonpartner *Macaranga* species, including *M. hypoleuca*. Some individual ant queens derived from *M. trachyphylla* and *M. beccariana*, however, entered the seedling domatia of nonpartner *Macaranga* species, although they showed a significant preference for their original partner species as shown above. Ant queens from *M. trachyphylla* did not enter the seedlings of *M. hypoleuca* at all, whereas queens from *M. beccariana* entered them frequently (77.8%, 14/18 queens). For queens derived from *M. beccariana*, there was no difference between the frequency of entrance into *M. beccariana* seedlings and into *M. hypoleuca* seedlings (Fischer's exact test, $\chi^2 = 1.479$, $P = 0.377$). The frequency with which ant queens derived from *M. hypoleuca* entered the seedling domatia of *M. hypoleuca* was not higher than the frequency with which they entered the domatia of the three nonpartner species (Fischer's exact test, $\chi^2 = 1.545$, $P = 0.324$). The difference was smallest in the case of *M. beccariana*; ant queens derived from *M. hypoleuca* entered the seedling domatia of *M. hypoleuca* and *M. beccariana* with almost equal frequency.

Chemical Analyses of Extracts of Surfaces of Macaranga *Seedling.* Figure 1 shows gas chromatograms of the extracts from the seedling stem surfaces of the

FIG. 1. Gas chromatograms of ethyl acetate extracts from the surface of the four *Macaranga* species. The chromatograms presented are those that contain the least "noisy" peaks of all the individual seedlings of each species. Arrows mark the main peaks that are found in the samples from each seedling of that species in notable amounts. Asterisks indicate the peaks of the internal standard, docosane C_{22} (100 ng).

four *Macaranga* species. All seedlings of a species had the same main GC peaks without exception. The four main GC peaks of *M. winkleri* were not found in any gas chromatograms of the other three species, and similarly the four main peaks in the gas chromatograms of *M. trachyphylla* were not found in the other three species. *M. hypoleuca* and *M. beccariana* showed seven and six main GC peaks, respectively; six were the same for these two species and were not found in the other two species. Moreover, the relative proportions of the six peaks (peak heights) were similar in *M. hypoleuca* and *M. beccariana*.

Bioassays Offering Extracts of Macaranga *Seedlings to Ant Queens*. More than 90% of bioassayed ant queens stayed longer on the paper tubes treated with the extracts of their partner species than on those treated with the nonvolatile extracts of their nonpartner species or controls (Figure 2; *t* test: $df = 14$, $t = 5.791$, $P < 0.0001$ for ants from *M. winkleri*; $df = 14$, $t = 2.162$, $P = 0.0484$ for ants from *M. trachyphylla*; $df = 12$, $t = 6.315$, $P < 0.0001$ for ants from *M. beccariana*; $df = 22$, $t = 6.963$, $P < 0.0001$ for ants from *M. hypoleuca*).

DISCUSSION

Recent work on the specificity in the partnership between *Macaranga* myrmecophytes and *Crematogaster* plant-ants (Fiala et al., 1999; Itino et al., unpublished data) has verified that the *Macaranga–Crematogaster* myrmecophytism is highly species-specific. To clarify the mechanisms of this species specificity, it

is necessary to investigate the colonizing process of the partner myrmecophytes by foundress queens, since a mutualistic relationship (symbiosis) on a particular *Macaranga* plant starts with colonizing or settling of a seedling by a foundress queen. The recognition of the partner plants by foundress queens is a crucial phase in the process.

The results of the preference experiments, in which foundress queens were artificially placed on seedlings, suggest that foundress queens of some *Crematogaster* species can recognize their partner *Macaranga* species by contact with the plant surface at the colonizing phase. Foundress queens derived from *M. winkleri* and *M. trachyphylla* seedlings showed clear acceptance of their original partner *Macaranga* species but rejected nonpartner species. Simultaneously, however, the results suggest that the recognition of or preference for the original partner myrmecophyte is not complete in some cases, especially with foundress queens derived from *M. beccariana* and *M. hypoleuca* seedlings. These foundress queens more frequently accepted the nonoriginating *Macaranga* myrmecophytes as nest sites than did the ant queens derived from *M. winkleri* and *M. trachyphylla*. Moreover, foundress queens from *M. beccariana* and *M. hypoleuca* seemed almost equally to accept *M. beccariana* and *M. hypoleuca*. The ability to distinguish between *M. beccariana* and *M. hypoleuca* by contact with seedlings seems to be weaker in the foundress queens derived from either of these two species than in the other two ant species. Thus, the ants vary in the intensity of their preferences for or in their ability to recognize particular partner species of *Macaranga* by contact with the plant surface.

There are two possible reasons for the differences among the ant species and among the plant species in the results of the preference experiments: the phylogenetic relationships between the *Macaranga* species and the strength of the mutualistic relationships. Because *M. beccariana* and *M. hypoleuca* are considered to be phylogenetically closely related species (S. J. Davies, personal communication), the queens derived from these two species tend to have a weaker preference for a particular one. The characteristics that ant queens use to discriminate among partner plants may be similar in the two plant species. In fact, as mentioned below, the characteristics of nonvolatile chemicals on the stem surfaces of these two plant species are almost identical. On the other hand, *M. winkleri* is phylogenetically more remote from the other three species, which may be why ant queens derived from *M. winkleri* are the most persistent in their preference for their original partner species.

The strength of the mutualistic relationship or interdependency may be an important factor in the persistent preference by foundress queens for a particular partner species. It is reasonable to infer that ant species that are most dependent on partner myrmecophytes have been selected for their superior ability to distinguish their own partner plant species because they have a particularly strong preference for the partner species. Among *M. winkleri*, *M. trachyphylla*, and *M. beccariana*,

the myrmecophytism—the intensity of the mutual dependency between plant and ant—is highest on *M. winkleri* and next highest on *M. trachyphylla* (Itioka et al., 2000; Nomura et al., 2000). Although the intensity of the interdependency between *M. hypoleuca* and its plant-ant has not yet been investigated, it seems to be the weakest in these four *Macaranga* species. Because the microhabitat of *M. hypoleuca* is the most shady and, therefore, its growth is slowest, the food supply provided for its plant-ants appears to be lower than that of the others (Murase, personal observation), and the plant-ant is observed to be the least aggressiveness (Itioka, unpublished data).

Together with the clear results of the preference experiments, the results of the bioassay offering extracts of *Macaranga* seedlings to ant queens suggest that foundress queens recognize their own specific partner-plant species from the chemical characteristics of the plant surface and that they use compounds of low volatity on the stem surfaces of *Macaranga* seedlings in the recognition. These findings are supported by the differences among the gas chromatographs of the surface extracts. The fact that the GC profiles of *M. winkleri* and *M. trachyphylla* are distinct from those of the other species is consistent with the finding that foundress queens derived from these two species much less frequently failed to recognize their own original partner species. Further, the similarity of the chemical patterns of *M. beccariana* and *M. hypoleuca* is consistent with the finding that these two species are equally accepted as partner plants by foundress queens derived from either of them. It may be difficult for these two ant species to distinguish their own partner species from a closely related species. Thus, the extent to which the chemical patterns differ correlates with the ability of foundress queens to distinguish the partner plant in the preference experiment.

Our results demonstrate that high-boiling compounds on the stem surface play an important role as semiochemicals in the recognition of the partner-plant species by plant-ant foundress queens; however, this does not exclude other mechanisms from being involved in the process of selection and recognition of the partner plant species. Differences in microhabitat; in the ant's reproductive, dispersal, and colonization seasons (or the plant's receptive season for ant colonization); characteristics of volatile chemicals of seedlings; morphology, coloration, and physical features of seedling surfaces, etc., might all be used by foundress queens. These factors should be investigated in the future. However, differences in microhabitat are unlikely to be involved in the selection of the partner species by foundress queens in our system, because, except for *M. hypoleuca*, the spatial distribution of seedlings of the *Macaranga* species studied overlapped markedly at the microhabitat level (unpublished data). This is different from the habitat segregation in the myrmecophytism between *Cecropia* plants and their plant-ants reported by Yu and Davidson (1997). In the case of *M. hypoleuca*, differences in microhabitat, coloration of foliage, and leaf surface texture might be

cues in selection and recognition by plant-ants, because only *M. hypoleuca* favors a shady habitat, such as the forest floor, and has whitish, lustrous and waxy leaves.

Acknowledgments—We thank Hua Seng Lee and Abang A. Hamid of the Forest Department of Sarawak, Tamiji Inoue of the Center for Ecological Research, Kyoto University, and Kazuhiko Ogino of the University of Shiga Prefecture for providing the opportunity to carry out this study. We also thank Seiki Yamane of Kagoshima University for valuable comments on ant identification, and Takayuki Ohgushi for helpful comments on the early version of the manuscript. Abstract— The sex pheromone of the citrus fruit borer *Ecdytolopha aurantiana* has been identified by gas chromatography coupled to an electroantennographic detector (GC-EAD). The electron impact mass spectral (EI-MS) fragmentation of the major EAD-active peak gave identifying features for a monounsaturated acetate. Further analyses by chemical ionization mass spectrometry (CI-MS), vapor-phase infrared spectroscopy (GC-IR), along with chemical derivatization (DMDS reaction), led to full characterization of the major component as (*E*)-8-dodecenyl acetate (*E*8–12 : Ac). The second constituent was identified as the related alcohol, (*E*)-8-dodecenol (*E*8–12 : OH). The two compounds were indistinguishable from the authentic synthetic standards in chemical and EAD analyses. Samples of the two compounds were obtained by a facile synthesis utilizing lithium chemistry. Field tests showed that captures in traps baited with a mixture of *E*8–12 : Ac and *E*8–12 : OH at 100 : 1 and 10 : 1 ratios were not significantly different from the catches in traps having two virgin females. Dosage tests showed better performance of traps baited with 1 mg than those with 0.1 mg of the pheromone blend, either in 100 : 1 or 10 : 1 ratio.

Key Words—Lepidoptera, Tortricidae, *Ecdytolopha aurantiana*, sex pheromone, (*E*)-8-dodecenol, (*E*)-8-dodecenyl acetate, GC-EAD.

INTRODUCTION

The citrus fruit borer *Ecdytolopha aurantiana* Lima (Lepidoptera: Tortricidae) is an economically important pest in Latin America, in particular, in Brazil, where it causes crop losses to orange growers estimated at US$ 50 million/yr (Anonymous, 2000). Recent studies on the sexual behavior and field ecology of *E. aurantiana* on citrus trees suggest that a female-released sex pheromone may be useful for monitoring populations of the citrus fruit borer (Bento et al., 2001). A synthetic pheromone system would allow growers to minimize the number of insecticide sprays, which, without a reliable monitoring system, becomes an economically and environmentally costly way to prevent crop damage. This prompted us to undertake the identification, synthesis, and field evaluation of the citrus fruit borer pheromone.

METHODS AND MATERIALS

Analytical Procedures. Low-resolution electron impact mass spectrometry (EI-MS) was carried out with a HP 6890 gas chromatograph (GC; Agilent, formerly Hewlett-Packard, Palo Alto, California) linked to a mass selective detector (MSD 5973; Agilent). Chromatographic resolution was done on a HP-5MS column (30 m $\times$ 0.25 mm; 0.25 μm) that was operated at 70°C for 1 min, increased to 270°C at a rate of 10°C/min, and finally held at this temperature for 10 min. Chemical ionization (CI) was performed on a HP 5890 II Plus GC connected to a Mass Engine 5989B (Agilent). The reactant gas was 5% ammonia diluted in helium. Samples were separated on a HP-5MS column (30 m $\times$ 0.25 mm; 0.25 μm). The oven temperature was set at 60°C for 1 min, increased to 200°C at a rate of 5°C/min, increased again to 270°C at 10°C/min, and finally held at this temperature for 10 min. Vapor-phase Fourier transform infrared (FTIR) spectra were recorded with a HP 6890 GC coupled to a FTIR system equipped with a light pipe interface, FTS-40A, GC/C32 (Bio-Rad, Cambridge, Massachusetts). The GC was equipped with a HP-5 column (30 m $\times$ 0.32 mm; 0.25 μm) operated at 70°C for 1 min, increased to 250°C at a rate of 10°C/min, and finally held at this temperature for 10 min. The light pipe and the transfer line were set at 230°C and 250°C, respectively. In all GCs, helium was used as carrier gas at 1 ml/min, except for the GC-FTIR, for which the flow rate was 2 ml/min. GC with electroantennographic detection (EAD) was performed according to the method of Struble and Arn (1984). A HP 5890 II Plus GC was modified to have the effluent from the capillary column split into EAD and flame ionization detector (EAD/FID, 3 : 1).

E. aurantiana antennae were placed in the previously described acrylic stage (Leal et al., 1992). The stage was set inside the glass transfer line (2 cm away from the GC outlet) and connected with gold wires to an amplifier (gain 5) and filtered through a passive filter (cutoff frequency 0.12 Hz). The signal was fed into an A/D 35900E interface (Agilent). FID and EAD signals were acquired with a 3365 Series II Chemstation (Agilent). To obtain EAD responses for synthetic (*Z*)- and (*E*)-8-dodecenyl acetate (10 ng of each), six to eight samples of the two isomers were injected successively within 5–6 min in split mode.

Pheromone Extraction and Isolation. For extraction, hexane (Fisher, Pesticide Residue Grade) was distilled in an all-glass distillation apparatus. The last segments of the abdomen (segments VIII and IX) of 400 three-day-old virgin females were extracted with distilled hexane (4 ml). Extractions were done between 6:00 and 8:00 PM, coinciding with the mating time of *E. aurantiana*, as previously observed in a greenhouse (Bento et al., 2001). The crude extract was subjected to flash column chromatography on a Pasteur pipet filled with silica gel (Wakogel C-200; Wako, Tokyo, Japan) and eluted successively with solutions of ether in hexane (0, 1, 3, 5, 10, 15, 20, 50, and 100%). All fractions were concentrated to ca. 1 virgin female-equivalent per microliter.

Derivatization. An aliquot of the ether–hexane (5 : 95) fraction (50 μl) was concentrated in a 1-ml V-vial (Wheaton, Millville, New Jersey) by a slow stream of argon. The residual material was dissolved in distilled dimethyl disulfide (DMDS, 80 μl), and a small crystal of iodine (ca. 200 μg) was added. A magnetic spin vane was introduced, and the vial was sealed with a Teflon-lined cap. The reaction mixture was stirred at 60°C overnight. After cooling to room temperature, hexane (100 μl) was added and the reaction was quenched and washed with sodium thiosulfate (5%; 50 μl). The organic phase was dried over anhydrous sodium sulfate, concentrated to 50 μl, and analyzed by GC-MS.

Syntheses. For identification purposes, commercially available (*Z*)- and (*E*)-8-dodecenyl acetate (IPO-DLO, Wageningen, The Netherlands) were used. (*Z*)- and (*E*)-Dodecenol were obtained by alkaline hydrolysis (KOH/MeOH) of the corresponding acetates. For field experiments, samples of (*E*)-8-dodecenyl acetate **1** and (*E*)-8-dodecenol **2** were prepared utilizing lithium chemistry (Figure 1). A solution

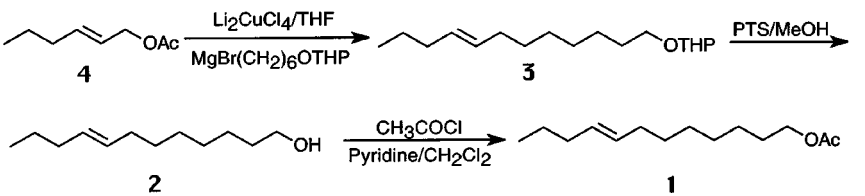

FIG. 1. Scheme for the preparation of (*E*)-8-dodecenol (**2**) and (*E*)-8-dodecenyl acetate (**1**) for the field evaluations.

of (*E*)-2-hexenyl acetate **4** (24 g, 90 mmol) and Li_2CuCl_4 (0.31 g, 1.44 mmol) in THF (14.4 ml) was added to 100 ml of a solution of $MgBr(CH_2)_6OTHP$ (26 g, 90 mmol) in THF at 10° (Figure 1). After stirring for 3 hr, the reaction mixture was poured into dilute HCl and extracted with ether. The organic layer was washed with brine, dried over anhydrous sodium sulfate, and concentrated under vacuum to give **3**. The crude product was stirred with *p*-toluenesulfonic acid monohydrate (PTS; 0.86 g, 4.5 mmol) in methanol (MeOH; 100 ml). After stirring for 2 hr, K_2CO_3 (1.3 g, 9 mmol) was added and stirring was continued for 2 hr. The reaction mixture was filtered, concentrated, and distilled to give **2** (6.6 g, 36 mmol; bp 107°/1.5 mm Hg) in overall 40% yield. EI-MS data: 55(100%), 41(55), 42(10), 43(14), 53(10), 54(39), 56(15), 57(13), 66(8), 67(98), 68(55), 69(35), 70(8), 71(6), 79(9), 81(90), 82(84), 83(20), 95(57), 96(45), 97(9), 109(24), 110(18), 123(9), 124(6), 138(5), 166(8). IR ν_{max} (cm^{-1}): 2960 (s), 2925 (s), 2860 (s), 1740 (s), 1675 (w), 1240 (s), 965 (s).

To a solution of **2** (1.84 g, 10 mmol) and pyridine (1.19 g, 15 mmol) in CH_2Cl_2 (30 ml) at 10°, CH_3COCl (1.02g, 13 mmol) was added. After stirring for 2 hr, the reaction mixture was poured into water and extracted with ether. The ether layer was washed with brine, dried over anhydrous sodium sulfate, concentrated, and distilled to give **1** (2.21 g, 9.8 mmol; 98% yield; bp 104°/1.5 mm Hg). EI-MS data: 82(100%), 41(39), 43(63), 54(33), 55(70), 56(10), 61(8), 67(90), 68(45), 69(25), 81(87), 83(20), 95(58), 96(63), 97(10), 109(29), 110(26), 123(13), 124(9), 137(7), 138(6), 166(29). IR ν_{max} (cm^{-1}): 3640 (s), 2962 (s), 2926 (s), 2862 (s), 1675 (w), 1050 (s), 965 (s). The sample was devoid of the *Z*-isomer as determined by chemical derivatization with *m*-chloroperbenzoic acid (Attygale, 1998). Under the above GC conditions, the epoxide derived from *E*8–12 : Ac appeared at 13.95 min, and no trace peak was detected at 14.18 min, the retention time for the epoxide derived from *Z*8–12 : Ac.

Field Experiments. Tests were done in commercial citrus groves in São Paulo, Brazil. The ratio of the two components (1 mg) was tested at the Fazenda São João, in Altair, which has 13-year-old, 3.5-m-high trees (variety: Valencia) planted in a 5-×8-m fashion. On the other hand, two dosages (0.1 and 1 mg) and two ratios (10 : 1 and 100 : 1) of the pheromone components were tested at the Fazenda Entre Rios, in Gavião Peixoto, which has 5-year-old, 3-m-high trees (variety: Pera Rio) planted in a 7- ×3.5-m arrangement. The test compounds were incorporated in a Fuji Flavor slow-releasing device made of ES fiber (Chisso Co. Ltd, Tokyo, Japan) and covered with polyethylene film. The pheromone dispensers were loaded into Sticky Delta traps (Fuji Flavor Co. Ltd. Tokyo, Japan), which were suspended at 3 or 3.5 m. The treatments were replicated four times over three consecutive days in a completely randomized block design and with an intertrap distance of 40 m. All treatments, including 2-day-old virgin females, were renewed daily. To stabilize the variance, capture data were transformed to log $(x + 1)$, in particular, because of the occurrence of zero catches in the unbaited traps (Snedecor and Cochran,

1989). The figures were drawn with the original data (before transformation). The means of the transformed data were tested for significance by ANOVA with JMP Software, Version 2 (SAS Institute, Cary, North Carolina). Treatments followed by the same letters are not significantly different at the 5% level in the Tukey-Kramer honestly significant difference test.

RESULTS AND DISCUSSION

The response-guided strategy for the isolation of the citrus fruit borer sex pheromone, i.e., fractionating crude extract and monitoring the biological activity of each fraction with a bioassay, was unrewarding. Although observations of the typical behavioral responses of moth to pheromones, namely, wing-fanning, precopulatory behavior, and attraction, led us to the active fractions, activity was observed in multiple fractions for which GC-MS analyses showed many peaks, including homologous compounds. For example, the ether–hexane (5 : 95) fraction contained various monounsaturated acetates. It is unlikely these homologous compounds can be clearly separated by further purification by silica gel column so as to allow unambiguous identification of the pheromone components. On the other hand, gas chromatography–electroantennographic detection (GC-EAD), with the male *E. aurantiana* as the sensing element, allowed rapid identification of the active compounds. Analyses of the crude extract showed two EAD-active peaks, which appeared at 10.9 and 12.4 min (Figure 2). The results were consistent when GC-EAD was repeated either with the same or different antennae ($N = 16$). The

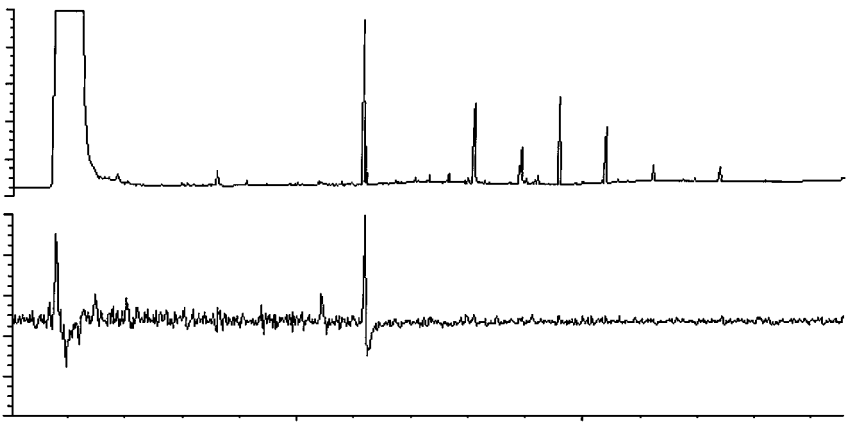

FIG. 2. Responses from flame ionization detector (FID, top) and electroantennographic detection (EAD, bottom; sensing element: male *E. aurantiana* antenna) to a hexane extract from abdominal tips of females (ca. 5 female-equivalents).

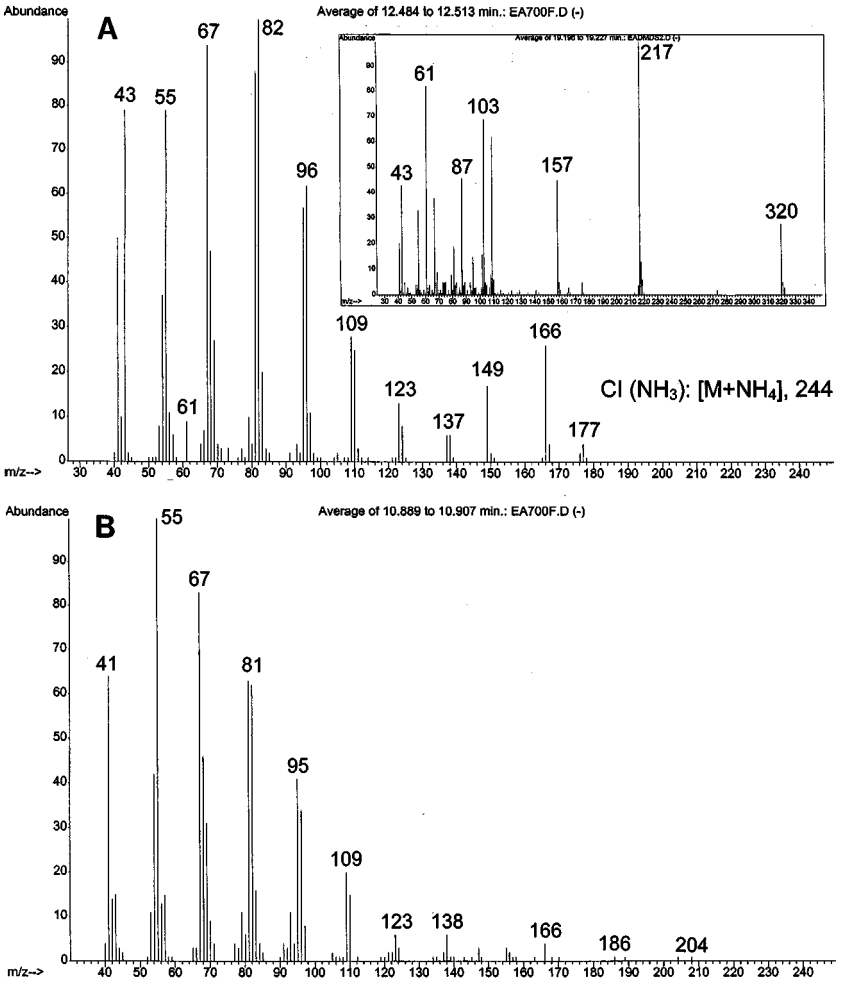

FIG. 3. Mass spectral data from the EAD-active peaks (Figure 2) at 12.4 min (A) and 10.9 min (B). Inset: MS of the major EAD-active peak after derizativation (DMDS adduct).

two EAD-active peaks were also detected in the fraction separated by silica gel column, the major compound being detected in the 3, 5, and 10% fractions and the minor compound in the 15 and 20% fractions. These are the biologically active fractions (above), but attraction was found only when two fractions (one of each group) were tested together.

The fragmentation pattern of the major EAD peak (Figure 3A) suggested that it was an acetate, as evidenced by the diagnostic peaks at *m/z* 61 from elimination

of the alkyl moiety and transfer of two hydrogen atoms to the fragment containing the oxygen atom. The quasimolecular ion (M^+-60) at *m/z* 166 indicated that the compound was a monounsaturated acetate with a molecular weight of 226. Chemical ionization mass spectrometry (CI-MS), with ammonia as the reactant gas, gave a base peak at *m/z* 244, which confirmed the molecular weight of 226. These findings suggested that the major EAD-active compound was dodecenyl acetate, in agreement with a library (Wiley) search, in which the best fit was 8-dodecenyl acetate. GC-MS analysis of the DMDS adducts showed the molecular weight at *m/z* 320 (Figure 3A, inset), an increment of *m/z* 94, suggesting the incorporation of two SCH_3 in one unsaturation in the parent compound. In addition, the base peak at *m/z* 217 and the peak at *m/z* 103 indicated that the unsaturation was located at position 8. Therefore, the compound was confirmed to be 8-dodecenyl acetate. The stereochemistry of the pheromone was determined by vapor-phase IR (Figure 4), which showed a typical *trans* band at 971 cm^{-1} (out of plane CH bending) and the lack of the =CH stretching (*cis* band) at ca. 3010 cm^{-1} (Leal, 1998). In conclusion, the major constituent was unambiguously identified as 8-(*E*)-dodecenyl acetate (**1**). In GC, GC-MS, GC-FTIR, and GC-EAD analyses, synthetic 8-(*E*)-dodecenyl acetate was indistinguishable from the natural product. Moreover, male antennae responded more strongly to the *E* than the *Z* isomer in EAD measurements (Figure 5), and the *Z* isomer was not detected in the gland extracts.

Although the FID peak of the EAD-active compound at 10.9 min (Figure 2) was very small, based on the structure of the major peak and the MS data of the minor component (Figure 3B), the second component was suggested to be the

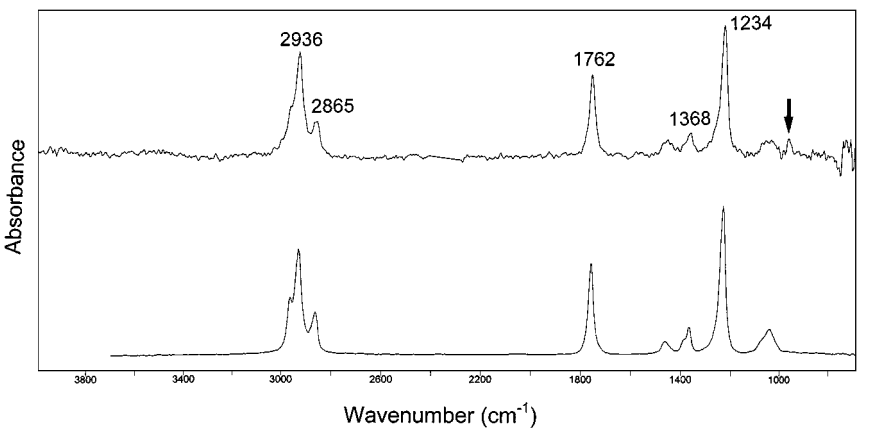

FIG. 4. Vapor-phase IR data generated with 10 female-equivalents of the major EAD-active peak (top). A library spectrum of a saturated homolog is given as reference (bottom). Arrow shows a characteristic *trans* band at 971 cm^{-1}.

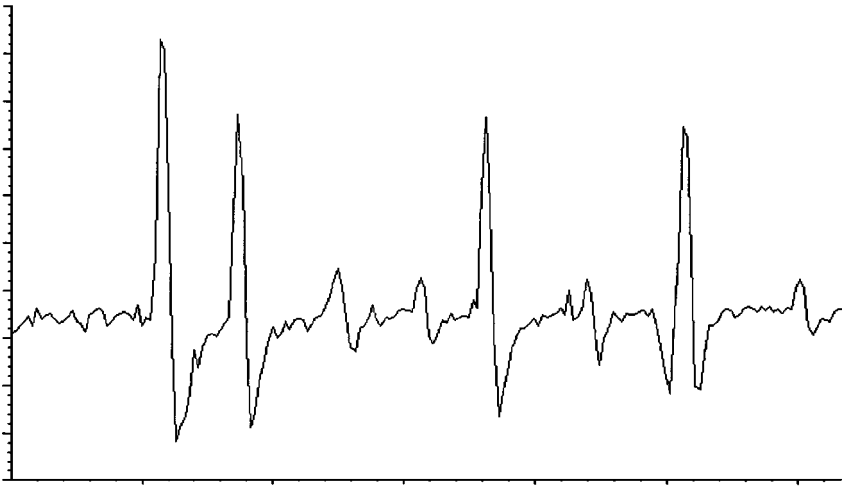

FIG. 5. Responses of a male *E. aurantiana* antenna to multiple injections of (*E*)- and (*Z*)-8-dodecenyl acetate introduced through a GC in split mode (50 : 1; ca. 0.2 ng/injection).

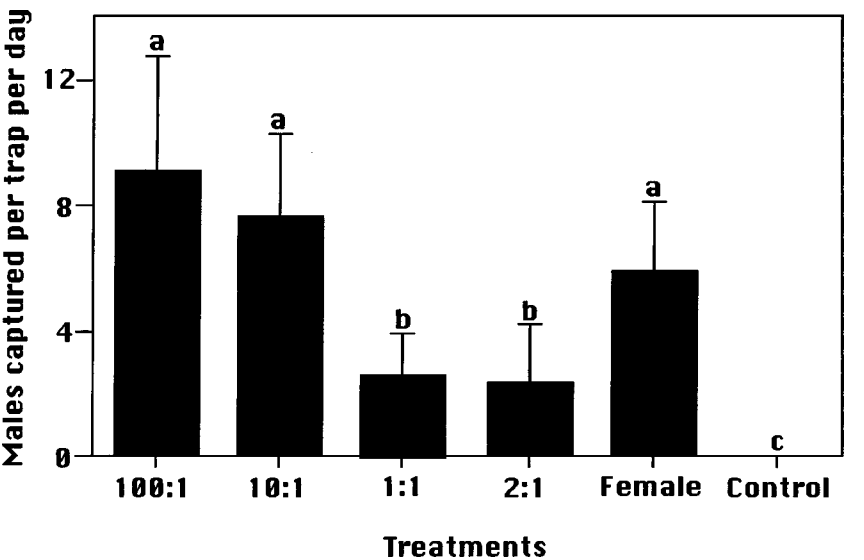

FIG. 6. Captures of *E. aurantiana* in sticky Delta traps baited with synthetic mixtures of the two pheromone components, (*E*)-8-dodecenyl acetate and (*E*)-8-dodecenol (1 mg of pheromone per trap).

related alcohol (**2**). A synthetic sample of the alcohol gave the same retention time as the minor peak, was EAD-active, and showed a similar MS profile. The MS of the synthetic compound devoid of impurities lacks some of the minor fragments, in particular, the ones at *m/z* 186, 189, 204, and 208, which are probably derived from an overlapping peak. Preliminary field experiments showed no significant catches of *E. aurantiana* in traps baited with only one of the two compounds, i.e., either (*E*)-8-dodecenol or (*E*)-8-dodecenyl acetate. However, captures in traps baited with the binary mixture were higher than control traps (Figure 6), regardless of the ratio of the two compounds. Captures in traps baited with high rates of *E*8–12 : Ac/*E*8–12 : OH (100 : 1 and 10 : 1) were not significantly different from the catches in traps baited with two virgin females. Performance of the traps with *E*8–12 : Ac/*E*8–12 : OH at 1 : 1 or 2 : 1 ratios were lower than the female traps, but better than the unbaited traps (control). Interestingly, there was no difference between the captures in traps having a 100 : 1 or 10 : 1 ratio of the two pheromone components. This is suggested to be due to the large number of treatments or because of the amount of pheromone (1 mg per device). In a separate set of experiments, the two ratios (100 : 1 and 10 : 1) were tested at different dosages. That traps baited with 1 mg of the pheromone blends captured more than those with

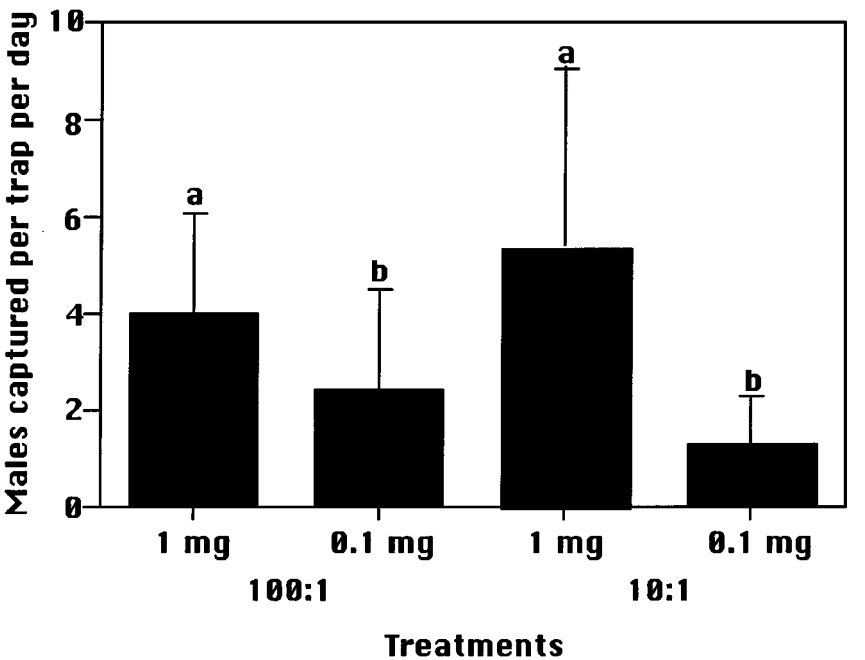

FIG. 7. Catches of *E. aurantiana* in sticky Delta traps with synthetic mixtures of the two pheromone components at two dosages and two different ratios.

0.1 mg (Figure 7) indicated that there was no saturation at the 1-mg level. In fact, the release rate of pheromone dispenser is very low as compared to the rubber septum. Furthermore, the catches in traps baited with 0.1 mg of the pheromone at the 100 : 1 and 10 : 1 ratios were not significantly different. It may be possible that the optimum ratio can be determined only in experiments under controlled conditions, such as wind tunnels. However, the optimal ratio for practical application in monitoring the insect population lies between 100 : 1 and 10 : 1 (*E*8–12 : Ac/*E*8–12 : OH). Although the scanty amount of the minor component prevented accurate analytical measurement of the ratio of the two compounds in the pheromone gland, it was closer to 100 : 1 than to 10 : 1.

Tortricid moths have been favorites of pheromone research. Sex pheromones have been characterized in over 60 species, and attractants of another 300 have been determined in field tests (Arn, 1991). The known female sex pheromones are all composed of primary aliphatic alcohols and their corresponding acetates and aldehydes. In general, they have 12 or 14 carbon atoms in the primary chain and one or two double bonds. (*E*)-8-Dodecenyl acetate and (*E*)-8-dodecenol have been identified as pheromone components of various moth species (Arn et al., 1998) and binary mixtures of **1** and **2** have been identified at least in two species, i.e., a sex pheromone from *Hedya chionosema* (Roelofs and Brown, 1982) and a sex attractant for *Strophedra nitidana* (Ando et al., 1977).

Acknowledgments—We appreciate the helpful discussion with members of our laboratory. We thank Rosa Molina, Peter Kasten, Jr., and Neide M. G. Zério (ESALQ/USP) for assistance in rearing insects.

Abstract—Males and virgin females of the citrus fruit borer *Ecdytolopha aurantiana* Lima, displayed two flight peaks during a 24-hr period, one at dawn and the other at dusk in an orange grove near Gavião Peixoto, São Paulo, Brazil. During the day, when temperatures were highest and relative humidity lowest, most individuals rested on leaves in the lower and middle crown. Moths rapidly moved higher in the crown after sunset, and many were observed flying above the tree canopy. This behavior was mainly associated with mating. Males and virgin females marked with fluorescent powder of different colors were observed in the dark with the aid of a black light. Mating was observed only in the upper crown of citrus trees from 6:00 to 9:00 PM, with a peak (64%) between 7:00 and 8:00 PM. Males of *E. aurantiana* were captured in traps baited either with virgin females or female extracts, suggesting the use of a long-range sex pheromone. At close distance (1–2 cm), males and females displayed a short-range communication behavior, with males exposing hairpencils and vibrating their wings. Females were frequently stimulated to contact the body of a male before copulation. The mean duration of copulation was 1 hr 40 min.

Key Words—Sex pheromone, *Ecdytolopha aurantiana*, attraction, mating behavior, hairpencils, diel periodicity.

INTRODUCTION

The citrus fruit borer *Ecdytolopha aurantiana* Lima (Lepidoptera: Tortricidae) is a multivoltine species of brown and gray coloration (Lima, 1927; Schultz, 1939, White, 1993). *E. aurantiana* occurs in most neotropical areas, including Brazil (Prates and Pinto, 1988, 1991), Argentina (Schultz, 1939), Costa Rica and Trinidad-Tobago (Pickles, 1936). The larvae of *E. aurantiana* feed on and destroy citrus fruit, guava, *Psidium guajava* L. (Lima, 1927); banana, *Musa acuminata* Colla; coconut, *Cocos nucifera* L. (Meyrick, 1931); cherimolia, *Annona cherimolia* Mill. (Schultz, 1939); litchi, *Lichi chinensis* Sonn. (Lima, 1945); macadamia, *Macadamia integrifolia* Maiden and Betche (White, 1993), and sugar apple (fruta-do-conde), *Annona squamosa* L. (Nakano and Soares, 1995).

E. aurantiana was first observed to cause damage to citrus trees in the State of São Paulo, southeast Brazil, in 1915 (Lima, 1927). By the mid-1980s, this pest had been found in 54 municipalities in the State of São Paulo (Prates and Pinto, 1995) and in 10 other Brazilian States, with consequent reduced citrus production in these regions (Prates and Pinto, 1988, 1991). Yield losses of up to 50% in infested areas were estimated to occur in the State of São Paulo (Garcia et al., 1998), and the latest crop losses throughout the country are estimated at US$ 50 million pr/yr (Anonymous, 2000).

E. aurantiana is a difficult pest to control. Females usually deposit only one egg per fruit, and lay 150–200 eggs during their life (Garcia, 1999). After hatching, larvae pierce the peel and penetrate inside the fruit, where they feed on the pulp (Fonseca, 1934). Once larvae are inside the fruit, their control is impossible, and the fruit becomes unfit for consumption.

The major difficulty in the management of *E. aurantiana* is the lack of an accurate method for monitoring populations. Different sampling methods based on counts of eggs and first-instar larvae on the fruits are costly and inaccurate (Garcia, 1999). A system for adult detection by means of pheromone-based trapping of males would be an alternative method to anticipate the occurrence of this pest, and to control it in a more effective and economic manner, but the mating behavior of *E. aurantiana* has not been previously studied. Our objective was to report the sexual behavior and daily activity pattern of males and virgin females of *E. aurantiana* on citrus trees in an attempt to set up a rational program for the control of this pest.

METHODS AND MATERIALS

Insects. Adults of *E. aurantiana* were maintained in the laboratory on an artificial diet developed by Garcia and Parra (1999) at $27 \pm 2^{\circ}$C, $65 \pm 10\%$ relative humidity, and a 14D:10L photoregime. After emergence, the adults were sexed by the method of Garcia (1999) and transferred to wood cages ($25 \times 25 \times 25$ cm)

covered with nylon mesh. Males and virgin females were kept in different cages, with 200–400 individuals per cage. The production of adults in the laboratory varied during the experiment, ranging from 200 to 400 pairs a day. A small portion of insects (ca. 10–20%) was used for continuous rearing in the laboratory.

Greenhouse Experiments. Experiment 1 was conducted to determine the time of day, duration, and insect age at first mating. For each experiment, 10 pairs of *E. aurantiana* were selected soon after emergence and individually placed into transparent plastic cups (200 ml) inverted on Petri dishes (12 cm in diameter). The insects were maintained in a greenhouse at $25 \pm 2^{\circ}$C; $65 \pm 10\%$ relative humidity, and under natural light. Each Petri dish was lined with a filter paper of the same size, which was moistened daily with distilled water to keep the humidity high inside the plastic cup.

Preliminary assays showed that adults of *E. aurantiana* remained at rest during most of the day and the night, especially from 8:00 AM to 4:00 PM and from 10:00 PM to 5:00 AM. Thus, we observed pairs daily between 4:00 and 10:00 PM for seven days, with behavior recorded at 1-min intervals. To study mating behavior at night, we used a torchlight dimmed by three red sheets of cellophane paper and kept 1 m away from the subject. This experiment was replicated four times (i.e., 10 pairs with four replicates each; $N = 40$) in a completely randomized block design. Data (age at first mating and mating time) were transformed to percentage, and the differences between means were tested for significance by analysis of variance and compared by the Tukey test at 5% level. Tests were conducted on alternate days from November 5, 1998, to January 26, 1999.

Field Cage Experiments. Experiment 2 was designed to analyze the distribution and locomotion of males and virgin females of *E. aurantiana* during the day, as well as to determine the site of mating on the citrus trees. A $6 \times 25 \times 3.5$ m ($150\ m^2$) nylon field cage was constructed, covering six orange trees (6 years old) of the Pêra variety, 2.5–3 m high, in a commercial orange grove located on the campus of Escola Superior de Agricultura "Luiz de Queiroz" (ESALQ), Piracicaba-SP, Brazil. The field cage was constructed in such a manner that the trees occupied its central line. Spacing between trees in the line was 4 m. Weeds present in the area covered by the field cage during the experiment were not eliminated.

Diel Distribution and Activity of Adult Moths. After emergence, males and females were sexed by the method of Garcia (1999) and maintained in cages, as previously described. At 2 days of age, males and females were marked with yellow and orange fluorescent powder, respectively. Insects were marked with ink diluted in ethyl alcohol, sprayed with a nasal spray, and dried with an electric fan at low speed (Southwood, 1995). Immediately after marking, the moths were released in the field cage at about 10:00 PM. On the following day, starting at 4:00 AM, observations were made for a period of 30 min at 1-hr intervals for 24 hr. During observations, the location and number of males and virgin females of *E. aurantiana* were recorded for: citrus trees, weeds, and soil and nylon netting.

When on citrus trees, moths were recorded on: leaves, fruit, and branches and trunk. The corresponding height on the tree was also considered: lower crown (0.5–1 m), middle crown (1.1–1.8 m), and upper crown (1.8–3 m). The sites of moth copulation and resting during day were marked with white plastic tape of ca. 20 cm. At night, the marked moths were visualized with the aid of a hand-held black light (model B-160 Spectroline). Movement of the moths was calculated as the difference between the individuals that moved from one place to another in relation to the previous hour. After each hour interval, males and virgin females of *E. aurantiana* were again localized and counted to compensate for individuals that had moved away or had been preyed upon. Therefore, it was possible to calculate the number of males and virgin females that stayed in the same place each hour. Preliminary studies with marked and unmarked adults in the greenhouse did not show any interference of the fluorescent powder with insect longevity or behavior, including mating. Three replicates of 24 hr each were performed, with a total of 250 pairs being released during a 24-hr period on February 9 and 24 and March 9, 1999. Temperature and relative humidity were measured with a thermohygrograph set up inside the field cage in the shade 1.0 m above ground during the assays. Official times of sunrise and sunset were provided by Instituto Astronômico e Geofísico da Universidade de São Paulo, São Paulo-SP, Brazil.

Female Attractiveness. Experiments 3–6 were designed to provide evidence for a long-range sex pheromone in *E. aurantiana*. Traps (stick Delta traps, Fuji Flavor Co., Tokyo, Japan) were baited with small cages ($2.5 \times 2.5 \times 2$ cm) containing two virgin females, two males, a rubber septum with 0.5 ml of female extract (25 female-equivalents), or a rubber septum with 0.5 ml solvent (control). The female extract was obtained on two consecutive days by cutting the last segments of the abdomen (segments VIII and IX) of 250 three-day-old virgin females and dipping (3-5 min) in hexane (5 ml). The time of the extractions was between 6:00 and 8:00 PM, coinciding with the mating time of *E. aurantiana*, previously observed in a greenhouse.

Experiments 3–6 were carried out in field cages, and tested virgin females versus empty trap (control) (experiment 3); virgin females versus males (experiment 4); virgin females versus female extract (experiment 5); and female extract versus solvent (control) (experiment 6). Each assay was carried out separately, and each treatment was replicated three times over two consecutive days in a completely randomized block design, with the treatments being renewed after 24 hr. Traps were placed in the upper crown of the tree (1.9–3 m) with an intertrap distance of 4 m. A total of 328, 290, 350, and 280 two-day-old virgin pairs were released between 4:00 and 5:00 PM on March 15, 22, and 29, and on April 5, 1999. Response to sex pheromone was quantified by counting the males captured in the traps each day. Capture data were transformed to log $(x + 1)$, and the differences between means were tested for significance by analysis of variance, with treatments being compared by the Tukey test at the 5% level of probability.

Attraction of Males to Pheromone Source in the Field. Experiment 7 was conducted in a 1200-ha commercial citrus grove (Ficher Co.) near Gavião Peixoto, SP, Brazil on April 7 and 8, 1999 to confirm the presence of sex pheromone. The experiment was conducted on the Hamlin orange variety, consisting of 12-to 15-year-old, 4-m-high trees spaced 4 m apart, with a 6-m space between rows. Delta sticky traps (Fuji Flavor Co., Tokyo, Japan) containing two virgin females, female extract (40 female-equivalents), and empty traps (control) were used. Each treatment was replicated four times over two consecutive days in a completely randomized block design, with the treatment being renewed after 24 hr. Each trap was placed in the upper third of the crown (2.5–3.5 m), with a 50-m space between traps and between rows and traps. The time when the experiment was started and the method for evaluation were the same as described for the field cage. Similarly, the natural extract of *E. aurantiana* was obtained as described previously, except that it was obtained on only one day from 400 virgin females using 5 ml of hexane. Capture data were transformed to log $(x + 1)$, and the differences between means were tested for significance by analysis of variance, with treatments being compared by Tukey test at the 5% level of probability.

RESULTS

Age, Time, and Duration of Mating. In a greenhouse, about 80% of the mating behavior of *E. aurantiana* was observed on the third and fourth days of life, corresponding to 44.7 and 36.8%, respectively (Figure 1A). Of the 40 pairs studied, 95% mated by the seventh day of life. Most mating behavior (60%) occurred between 7:00 and 8:00 PM, although the mating interval ranged from 5:00 to 9:00 PM (Figure 1B). The mean duration of copulation was 101.5 ± 62.1 min ($X \pm$ SEM; $N = 38$; range: 3–312 min).

Diel Distribution and Activities of Adult Moths. Field cage experiments showed that during the day most *E. aurantiana* moths were found in the lower and middle crown of citrus trees, with the presence of at least 34% and 38% of males, and 37% and 42% of virgin females, respectively (Table 1). This period was characterized by reduced flight activity with the moths usually resting on the surface of leaves, seemingly due to the high temperatures and low relative humidity (Figure 2). In the evening, about 88% and 75% of males and virgin females, respectively, were observed in the upper crown of citrus trees. This locomotion occurred between 6:00 and 7:00 PM, just after dusk (Figure 2). It was in the upper crown of the trees that all copulations took place (Table 1), peaking one hour after dusk, between 7:00 and 8:00 PM (64% of all episodes) (Figure 2).

During the night, after 8:00 PM, the locomotion and number of matings decreased quickly (ca. 8%; Figure 2). Most moths remained at rest, especially

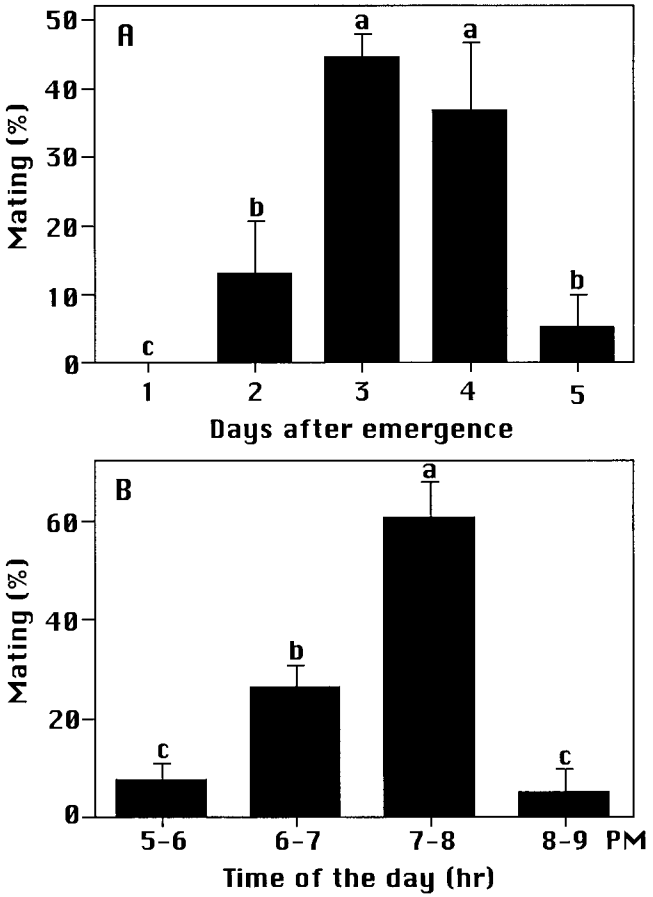

FIG. 1. Mating activities of *E. aurantiana* as function of age (A), and time (B), under greenhouse conditions. Bars with the same letter are not significantly different at the 5% level (Tukey test).

on leaves, occasionally engaging in walks and short flights. Many moths were observed flying for short distances after mating, although these data were not quantified. Adults were never observed feeding, although these data are not conclusive, requiring confirmation in future studies.

Just before dawn, a new peak of flight activity was recorded (Figure 2), and several moths were observed flying into the inner part of trees, especially towards the lower and middle crown of the host tree, reestablishing the same pattern of distribution as observed on the preceding day.

TABLE 1. DAY AND NIGHT DISTRIBUTIONS OF *E. aurantiana* IN CROWN OF CITRUS TREES UNDER FIELD CAGE CONDITIONS

Sex and status	Period	Height (m)		
		0.5–1.0	1.1–1.8	1.9–3.0
Male	Day	10.8 (34.7)[a]	12.1 (38.9)	8.2 (26.4)
	Night	0.5 (1.4)	3.7 (10.1)	32.3 (88.5)[b]
Virgin female	Day	12.2 (37.2)	14.0 (42.7)	6.6 (20.1)
	Night	1.0 (2.5)	8.8 (22.3)	29.7 (75.2)
Mating couples	Night[c]	0 (0)	0 (0)	22.5 (100)

[a] Percentages in parentheses.
[b] Includes individuals of mating couples.
[c] See Figure 2 for time.

Reduced numbers of males and virgin females were recorded on weeds or on the ground/screen during the experiment (Table 2). Although no counts were made, most moths found on the ground were weakened or dead.

Mating Behavior. Males of *E. aurantiana* hovering beside leaves with females in the upper crown of citrus trees were responding to female sex pheromone. Traps containing virgin females or a natural female extract in a solvent (25 female-equivalents) caught on average 8 and 6 male/trap/day in field cages (Figure 3). The same results were obtained in the field in a commercial area, with 13 and 8 males caught per trap per day in traps containing females and natural female extract in a solvent (40 female-equivalents), respectively (Figure 4).

DISCUSSION

The distribution (i.e., observed average number) and behavior of males and virgin females of *E. aurantiana* were synchronized and varied with respect to

TABLE 2. DISTRIBUTION OF *E. aurantiana* IN DIFFERENT PARTS OF CITRUS TREES OVER A 24-HR PERIOD

Place	Males	Virgin females	Total number (% mean)
Citrus			
Leaves	25.9 (88.7)	33.9 (90.8)	59.8 (89.7)
Fruits	0.7 (2.6)	0.4 (1.2)	1.1 (1.9)
Branches/trunk	0.5 (1.8)	0.8 (2.2)	1.3 (2.0)
Weeds	0.2 (0.7)	0.5 (1.4)	0.7 (1.1)
Soil/Netting	1.8 (6.2)	1.1 (4.4)	2.9 (5.3)

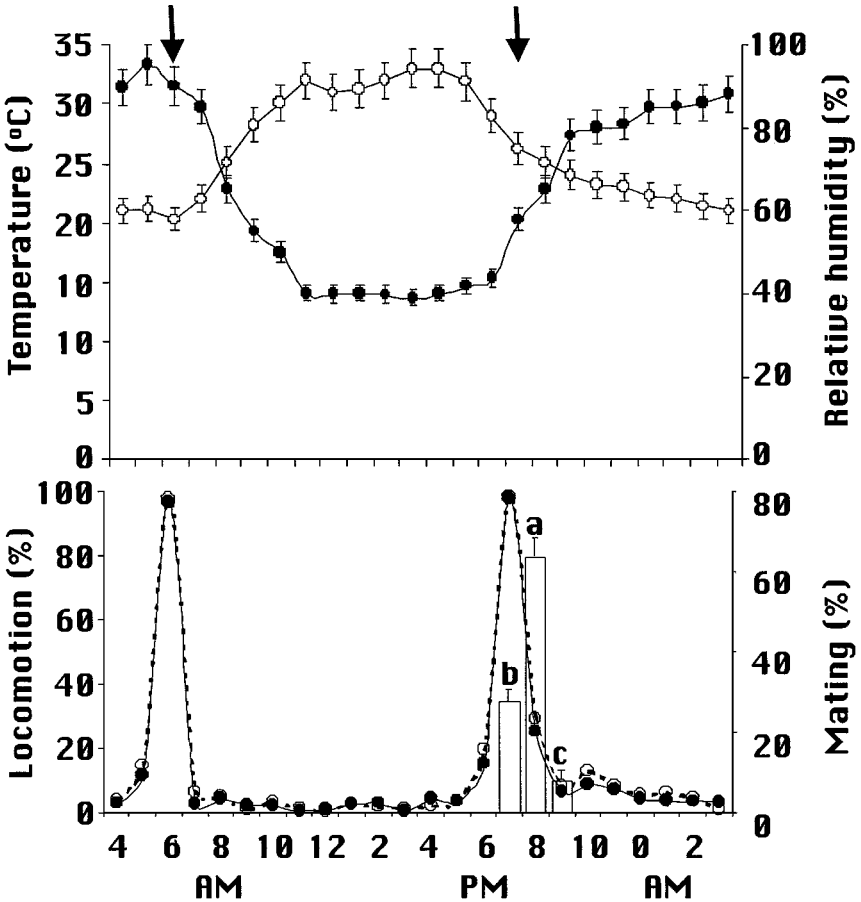

FIG. 2. Diel periodicity of locomotion and mating in adult *E. aurantiana* in relation to air temperature and relative humidity. (Top) Average temperature (—○—) and relative humidity (—●—) with SEM (bars); (Bottom) females (—○—) and males (—●—) locomotion. Arrows indicate time of sunrise and sunset. Bars with the same letter are not significantly different at the 5% level (Tukey test).

location in the crown of citrus trees and time of day. About 1 hr before dawn, many moths started to fly, and flight activity peaked just before dawn, as also reported for many other tortricids (Lewis and Taylor, 1964; Dreisig, 1986; Quiring, 1994). For *E. aurantiana*, the increase in flight activity during this period was not associated with mating or oviposition. Temperature increased quickly during the morning, and probably moth flight activity was due to the search for microhabitats with a reduced risk of hygrothermal stress. When temperature

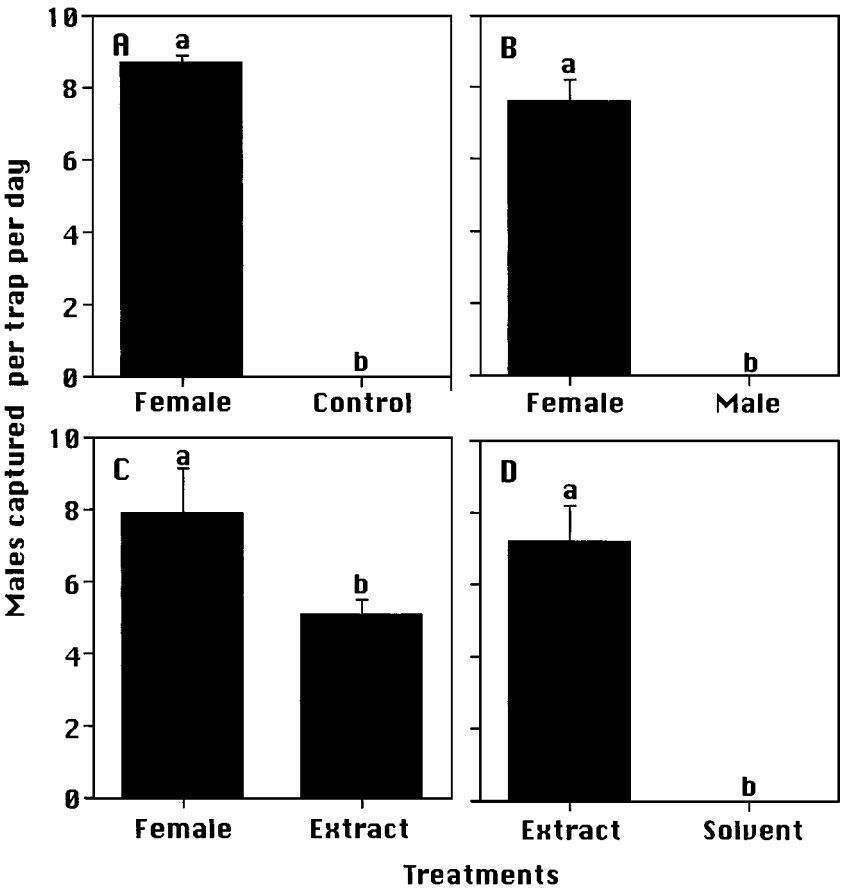

FIG. 3. Trap catches of male *E. aurantiana* in field cage experiments 3–6 baited with females (A), males (B), natural female extract in a solvent (C), or solvent alone (D). Bars with the same letter in each experiment are not significantly different at the 5% level (Tukey test).

was highest and relative humidity lowest, moths spent most of the day resting on leaves in the lower and middle crown of their host tree. Garcia (1999) reported that the viability and longevity of *E. aurantiana* is much reduced when the moth is exposed to temperatures above of 32°C and relative humidity below 50%.

During the day, some moths flew among the leaves of the tree or adjacent ones. However, these flights were sporadic and covered a short distance. Probably, they were motivated by the incidence of sunlight and the presence of different ant species and predators. Escaping predators may also explain the larger

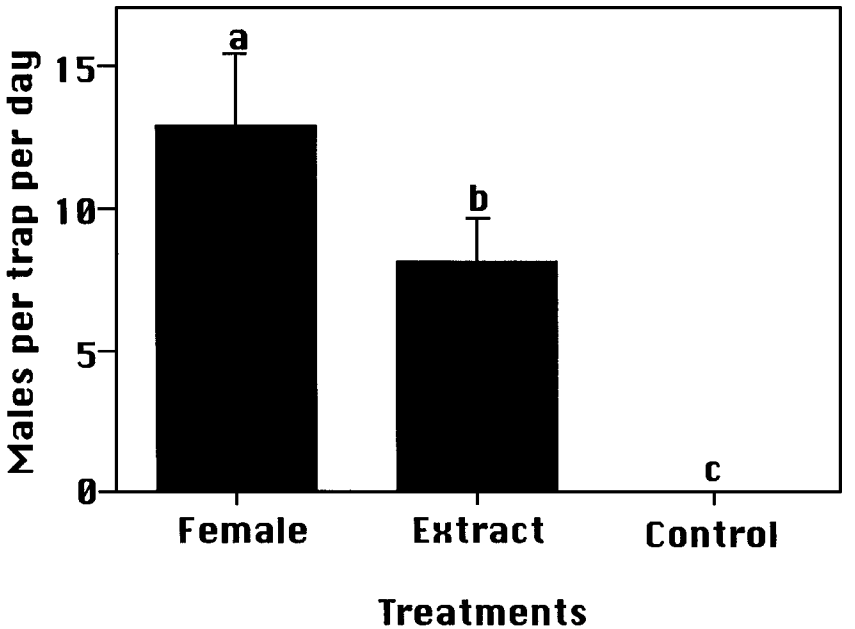

FIG. 4. Captures of male *E. aurantiana* in experiment 7 in traps baited with live virgin females, pheromone gland extract, or solvent controls. Bars with the same letter are not significantly different at the 5% level (Tukey test).

numbers of males and virgin females frequently found resting on leaves rather than on other parts of the trees. The large numbers of ants foraging on branches for nectar, oils, and honeydew throughout the day probably explain the escape behavior of the moths. Although this was not quantified, on several occasions various species of spiders also were observed preying on *E. aurantiana* adults on the leaves.

The second major peak of *E. aurantiana* activity started at dusk and continued for about 2 hr between 6:00 and 8:00 PM. Several moths were observed flying above the host tree canopy at dusk, as also reported for many other tortricids, an activity usually associated with oviposition and mating (see Pointing, 1961; Dustan, 1964; Turgeon, 1985; Turgeon et al., 1987; Quiring, 1994). Redfern and Di Giácomo (1991) and Garcia (1999) reported that oviposition of *E. aurantiana* is concentrated during the twilight period, with the latter author detecting about 60% of the eggs during this period.

In the present study, the flight activity of *E. aurantiana* in the evening was primarily associated with sexual behavior. In our experiment, we did not observe

oviposition because we only used males and virgin females. Most of the mating activity occurred about 1 hr after dusk and only in the upper crown of the host tree. This is an original finding concerning tortricid moths since there are no previous studies describing the exact site of copulation on host trees (Howell, 1995). The fact that the mating site may be related to the calling ability of females, or more probably to a better release of sex pheromone by them, may explain the capture of males in traps placed in the upper crown of trees. It was not possible to determine why copulation pairs were not observed at other sites on the tree even after repeated observations, although a likely hypothesis is that staying on the top of the tree represents an adaptive advantage. In addition, capture of tortricid moths with fermented products (Yothers, 1927), pheromone baited traps (Lewis and Macaulay, 1976; Riedl et al., 1979; McNally and Barnes, 1981; Ahmad and Al-Gharbawi, 1986; Weissling and Knight, 1995), and light traps (Borden, 1931; Hamilton and Steiner, 1939) has been reported to be more effective when the traps are set on tree tops.

The presence of males close to virgin females just before mating was due to long-distance attraction elicited by a female sex pheromone. Observations in greenhouses suggest that visual or short-range communication signals may play a role. Usually, males approached females within a distance of 1–2 cm, then presented a stereotyped sequence of behaviors, including vibration of the wings and hairpencil display toward the female, which frequently attracted the female towards them. The female then contacted the body or the end of the abdomen of the male, and this stimulus caused the male to turn quickly and attempt copulation. When copulation was successful, male and female remained attached through the abdomen in opposite direction for ca. 1 hr and 40 min. A similar courtship was described for the oriental fruit moth *Grapholita molesta* (Busck) (Baker and Cardé, 1979). On the other hand, mean copulation time varies widely among tortricids. Copulation time is 40–60 min in *Cydia pomonella* (L.) (Howell, 1995) and about 29 min in *G. molesta* (Dustan, 1964), while in *Zeiraphera canadensis* Mut. & Free, it is 4 hr and 20 min (Turgeon et al., 1987).

In summary, this study determined the time when mating takes place, and thus, when pheromone glands should be extracted for pheromone identification. In addition, observations that mating occurs on the top of trees from 6:00 to 9:00 PM are of importance not only for the design of trap experiments, but also for future utilization of sex pheromones for monitoring citrus fruit borer populations.

Abstract—The reproductive behaviors of the stink bugs *Chlorochroa ligata* and *C. uhleri* were studied in the laboratory. Adults of both species became sexually mature about 12–14 days after the final molt, and both sexes mated multiple times during their lifetimes. The mean duration of copulation was 54 ± 24 min for virgin bugs and 46 ± 33 min for experienced bugs for *C. ligata* and 78 ± 55 min for field-collected *C. uhleri* of unknown mating status. Male *C. ligata* were found to transfer a significant fraction of their body mass (19%) to females during mating. Sexually mature *C. uhleri* males produced three sex-specific compounds, methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate, methyl (2*E*,6*E*)-farnesoate, and methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate, in a ratio of 100:0.9:0.6. These three compounds were also produced by sexually mature male *C. ligata* in a ratio of 100:0.5:0.4. Identifications of the compounds were confirmed by synthesis. Production of the male-specific compounds peaked in late afternoon to early evening, coincident with the peak period of reproductive activity. Laboratory and field bioassays demonstrated that female bugs were attracted to odors from live males and to reconstructed blends of the male-specific compounds.

Key Words—*Chlorochroa ligata*, *Chlorochroa uhleri*, Pentatomidae, pheromone, methyl (*E*)-6-2,3-dihydrofarnesoate, methyl (2*E*,6*E*)-farnesoate, methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate, reproductive behavior.

INTRODUCTION

Phytophagous pentatomid bugs are pests of a broad spectrum of agriculturally important crops including fruits, nuts, row crops, and vegetables (McPherson and McPherson, 2000). These insects are characterized by piercing and sucking mouth parts, which both immatures and adults use to inject saliva into plants, liquefying plant tissues. This feeding damage causes premature abortion or deformation of seeds and fruiting bodies and also transmits disease. The adult insects are strong fliers and can migrate from field to field as hosts are harvested or senesce (McPherson and McPherson, 2000). Current monitoring methods include beating tray or sweep-net sampling (McPherson and McPherson, 2000), both of which are labor intensive and time consuming. There is an urgent need for better monitoring methods, and traps baited with attractant pheromones may provide such methods. However, sex specific compounds have been identified for only a few stink bugs, including *Nezara viridula* (L.) (Aldrich et al., 1987; Baker et al., 1987; Brézot et al., 1994), *Euschistus spp*. (Aldrich et al., 1991, 1994; Borges et al., 1998a), *Plautia stali* Scott (Sugie et al., 1996), *Thyanta pallidovirens* Stål (Millar, 1997), *Piezodorus hybneri* Gmelin (Leal et al., 1998), *P. guildinii* (Westwood) (Borges et al., 1998b), and *Biprorulus bibax* Breddin (James et al., 1994). The complexities involved in the identification and development of applications of stink bug pheromones have been summarized by McBrien and Millar (1999) and are further complicated by the growing body of evidence that stink bug reproductive behaviors are mediated by both chemical and substrate-borne vibrational signals (e.g., Ota and Çokl, 1991; Çokl et al., 2001).

The conchuela stink bug, *Chlorochroa ligata* (Say), is found in the western regions of the United States and Canada, and it has been reported as far east as Missouri, Kansas, and South Dakota (Buxton et al., 1983; Henry and Froeschner, 1988). *C. ligata* adults are usually large grayish black bugs but the species exhibits a wide variation in color. Overall, the species is generally dark in color, with the lateral margins of the thorax, the basal third to two thirds of the costal margins of the wing corium, and the tip of the scutellum varying in color from pale yellow to bright crimson (Morrill, 1910; Buxton et al., 1983). The strain infesting apple and pear orchards in California is commonly black with reddish marginal borders and a reddish spot in the middle of the back (Ohlendorf, 1999), whereas *C. ligata* found in blackberry fields in Washington State were black with pale yellow borders (Fish and Alcock, 1973).

A congeneric species, *Chlorochroa uhleri* (Stål), commonly known as Uhler's stink bug, is distributed through the western United States, where it damages wheat (Caffrey and Barber, 1919), tomato (Ohlendorf, 1990), cotton (Morrill, 1910), and alfalfa (Russell, 1952). In California, it can have several generations per year, and details of its life history have been reported by Morrill (1910) and Russell (1952). The color of *C. uhleri* is green above and paler and yellower ventrally. The

callosities at the base of the scutellum are moderate to small. *C. uhleri* is morphologically similar to another congener, *Chlorochroa sayi* Stål, and the two species frequently have been confused (McPherson and McPherson, 2000), particularly as both *C. sayi* and *C. uhleri* can be found on the same host plants. The most useful character for separating the two species is the purple flecks on the membrane of the hemelytra of *C. sayi*, which are absent in *C. uhleri* (Buxton et al., 1983).

We recently reported the identification of pheromones from *C. sayi* (Ho and Millar, 2001a). Here, we report the results of investigations of the reproductive behavior and semiochemistry of *C. uhleri* and *C. ligata.* Our specific objectives were: (1) to describe the reproductive behaviors of *C. uhleri* and *C. ligata*; (2) to identify volatile chemicals produced by each species, focusing particularly on sex-specific compounds that might be sex pheromone components; and (3) to test reconstructed blends of sex-specific compounds as stink bug attractants in laboratory and field bioassays.

METHODS AND MATERIALS

Insects. A colony of *C. uhleri* was started from egg masses obtained from Paul da Silva, Kearney Agricultural Station, Parlier, California. Additional bugs were collected from Russian thistle (*Salsola iberica* Sennen) in Riverside County in the summers of 1998 and 1999. A colony of *C. ligata* was started from adult bugs provided by Dr. Les Ehler, University of California, Davis, California. A second colony of *C. ligata* was started in the summer of 1999 from specimens provided by Christian Krupke, Washington State University Tree Fruit Research and Extension Center, Wenatchee, Washington. Both species were reared on green-bean pods grown without pesticides, raw shelled peanuts and sunflower seeds, and bouquets of alfalfa and seasonal weed species, exactly as previously described for *C. sayi* (Ho and Millar, 2001a). Bugs were kept under a 16L:8D cycle, at 23 $\pm$ 2°C, and $>$50% relative humidity.

Observations of Reproductive Behavior. Mating behaviors of sexually mature adult *C. ligata* and *C. uhleri* were video-taped in time lapse mode as described for *C. sayi* (Ho and Millar, 2001a), using individual pairs of bugs in plastic tubes, with green-beans provided for food. Observations of mating behaviors were carried out using virgin, laboratory-reared *C. ligata.* For *C. uhleri*, due to the low number of bugs in the laboratory colony at the time the experiments were conducted, field collected insects of unknown age and mating status were used, after first segregating the bugs by sex for 4 days. A total of 27 matings were observed from 13 pairs of *C. ligata* in 14 days, and 28 matings from 12 pairs of *C. uhleri* over eight days. The time each copulation started, duration of each copulation, and the total numbers of copulations per pair were recorded. The numbers of matings initiated per 2 hr time period were plotted.

Weight Change during Mating. The experimental setup to examine weight change during mating was as previously described for *C. sayi* (Ho and Millar, 2001a). For *C. ligata*, 122 virgin pairs and 52 experienced pairs were observed between March 27 to April 10, 2000. Copulations were observed among a total of 13 virgin pairs and 11 experienced pairs. Because there were not enough *C. uhleri* in the laboratory colony, weight changes during mating experiments were not recorded.

Collection and Analysis of Insect-Produced Compounds. Volatile chemicals were collected and analyzed as previously described for *C. sayi* (Ho and Millar, 2001a). Briefly, volatiles were collected on activated charcoal traps from groups of sexed virgin adult bugs held in glass aeration chambers with green-beans. Volatiles from green-beans were collected as a control. Compounds were eluted from the traps with pentane and ether, and analyzed by splitless gas chromatography on a DB-17 column (30 m $\times$ 0.25 mm, J&W Scientific, Folsom, California), with a temperature program of 50°C for 1 min, 10°C/min to 250°C. Injector and detector temperatures were 250°C and 280°C, respectively, with helium carrier gas. Extracts were also analyzed by splitless coupled gas chromatography-mass spectrometry (GC-MS) with a Hewlett-Packard 5890 GC fitted with a DB5-MS column (20 m $\times$ 0.2 mm id.), and interfaced to an H-P 5970B mass selective detector (electron impact ionization, 70 eV). The GC was programmed from 40°C/1 min, 10°C/min to 250°C, with injector and transfer line temperatures of 250 and 280°C, respectively. Compounds were tentatively identified from interpretation of the mass spectra, and from matches with the NBS-NIH mass spectral data base. Identifications were confirmed by comparison of retention times and spectra with those of authentic standards.

Bioassays Using Odors from Live Male Bugs, Extracts of Bug Volatiles, or Synthetic Chemicals as Test Stimulants. Laboratory bioassays were carried out with a vertical glass Y-tube olfactometer, exactly as described previously (Ho and Millar, 2001a), using sexually mature virgin adults. Bugs were used only once. Not all cohorts of virgin male *C. uhleri* produced male-specific compounds, as determined by GC analysis of collected bug odors. Consequently, only live males from *C. uhleri* cohorts that had been demonstrated to be producing male-specific compounds were used as sources of attractant in bioassays, with female responders.

Field Bioassays. The complete blend of male-specific compounds from each species (see below) was tested in field bioassays as described by Ho and Millar (2001a). Lures consisted of solutions of 20 mg of the racemic major compound, methyl (*E*)-6-2,3-dihydrofarnesoate, together with the minor components, methyl (2*E*,6*E*)-farnesoate (0.12 mg) and racemic methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate (0.18 mg) absorbed onto 10 cm lengths of natural latex rubber tubing. Controls consisted of sections of tubing treated with CH_2Cl_2. Lures and controls were hung in Russian thistle plants, with the number of bugs on each plant counted daily during the late afternoon. Lures and controls were rerandomized

among plants after each count. In the first sets of trials (see below), responding bugs were collected, counted, and released, whereas in later trials, all responding bugs were collected and taken back to the laboratory to augment the laboratory colonies.

For trial 1, August 3–16, 1999, lures with the three-component blend of *C. uhleri* together with solvent-treated controls were deployed at test sites in Ontario, Moreno Valley, Redlands, and Riverside, California, with three replicates of each treatment in each block. Bioassays were evaluated as described above, with the counted bugs being released.

For trial 2, August 19–24, 1999, six experimental blocks were set up in Russian thistle patches in Moreno Valley and Riverside, testing the three-component blend of *C. uhleri*, and a solvent control. Each treatment and control was replicated three times at each site. Bioassays were evaluated each evening from ~17:00 till dusk, collecting all responding bugs.

For both trials, where appropriate, the numbers of responding bugs were transformed, using the square root $(x + 0.5)$ transformation, and the transformed data were subjected to two-way ANOVA, with differences between treatments and controls determined by Dunnett's method. For those data sets that did not satisfy the assumptions of ANOVA, differences between treatments and controls were determined with the nonparametric multiresponse permutation procedure (Biondini et al., 1985; McCune and Mefford, 1999).

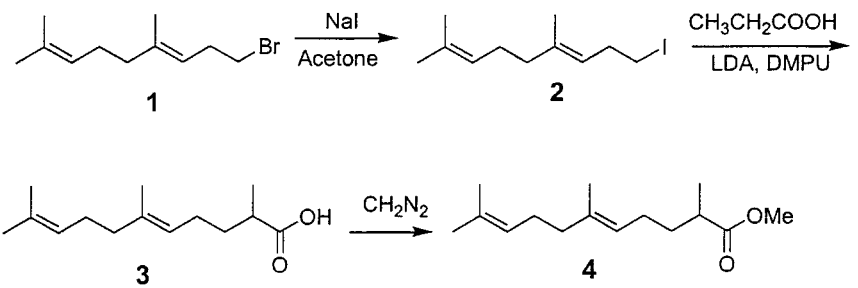
Chemicals. (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-hexenyl acetate, undecane, dodecane, tridecane, tetradecane, and pentadecane were purchased from Aldrich Chemical (Milwaukee Wisconsin), and (*E*)-2-octenyl acetate was obtained from Bedoukian Research (Danbury, Connecticut). (*Z*)-2-Octenyl acetate was synthesized by acetylation of (*Z*)-2-octenol with acetyl chloride and triethylamine in ether. Racemic methyl (*E*)-6-2,3-dihydrofarnesoate was synthesized as previously described (Ho and Millar, 2001a). (*E*)-4-Oxo-2-hexenal was synthesized as described by Ho and Millar (2001b).

Synthesized Compounds. Flash chromatography was carried out with 0.04 to 0.063-mm silica gel (Aldrich Chemical Co., Milwaukee, Wisconsin). ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ at 300 and 75.48 MHz, respectively, using a General Electric QE 300 instrument. GC-MS analyses (electron impact ionization, 70 eV) were performed on a Hewlett-Packard 5890 gas chromatograph interfaced to an HP 5970B mass selective detector (Palo Alto, California). A DB-5MS column was used (20 m $\times$ 0.2 mm, 0.25 μm; J&W Scientific, Folsom, California). Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl immediately before use. Routine work-up of reactions included drying solutions over anhydrous Na_2SO_4 and concentrating by rotary evaporation under partial vacuum (~80 mm Hg). All reactions were carried out under argon atmosphere in oven-dried glassware unless otherwise specified.

Synthesis of Methyl (2E,6E)-Farnesoate. A solution of trimethylphosphonoacetate (2.18 g, 12 mmol; Lancaster Synthesis, Windham, New Hampshire)

in THF (20 ml) was cooled to −30°C under Ar, and *n*-butyllithium (4.8 ml of 2.5 M in hexane, 12 mmol) was added dropwise. The mixture was warmed to 0°C, and geranyl acetone (1.94 g, 10 mmol) was added dropwise. The mixture was warmed to room temperature, stirred 2 hr at room temperature, during which time considerable precipitate formed, then heated to reflux for 1 hr. The mixture was then cooled, poured into 1 M aq. $NaHCO_3$, and extracted three times with hexane. The combined hexane extracts were backwashed with brine, dried over anhydrous Na_2SO_4, and concentrated, giving a crude yield of 3 g of a ∼2:1 mixture of (2*E*,6*E*)- and (2*Z*,6*E*)-methyl farnesoates. The crude mixture was purified by flash chromatography on silica gel (5 × 25 cm, eluting with 1 liter each of 1%, 1.5%, and 2% ether in hexane). The combined fractions containing each component were concentrated and Kugelrohr distilled (oven temperature 120°C, 0.2 mm Hg vacuum), yielding 1.2 g and 0.3 g of pure (2*E*,6*E*)- and (2*Z*,6*E*)-methyl farnesoates, respectively. Methyl (2*E*,6*E*)-farnesoate: ^{1}H NMR: δ 5.68 (br. s, 1H, H2), 5.09 (br. t, 2H, $J = \sim 8$ Hz, H6,10), 3.69 (s, 3H, OCH_3), ∼2.18 (m, 4H, H4, H5), 2.18 (d, 3H, $J = 1.23$ Hz, H3′), 2.12–1.95 (m, 4H, H8, H9), 1.69 (br. s, 3H, H12), 1.61 (br. s, 6H, H7, H12′). ^{13}C NMR (CDCl3, 75.48 MHz): δ 167.27, 160.19, 136.16, 131.41, 124.20, 122.85, 115.20, 50.78, 40.94, 39.67, 26.66, 25.69, 25.94, 18.84, 17.69, 16.02. EI-MS: 250 (M^+, 1), 207 (2), 136 (4), 121 (13), 114 (24), 81 (22), 69 (100), 53 (18), 41 (85). Methyl (2*Z*, 6*E*)-farnesoate: ^{1}H NMR: δ 5.68 (br. s, 1H, H2), 5.18 (br. t, 1H, J = 6.2 Hz, H6), 5.10 (br. tt, 1H, $J = 6.7$, 1.1 Hz, H10), 3.69 (s, 3H, OMe), 2.65 (t, 2H, $J = 7.8$ Hz, H4), 2.18 (overlapped dt, 2H, $J \sim 7.8$, 7.7 Hz, H5), 2.12–1.95 (m, 4H, H8, H9), 1.90 (d, 3H, $J = 0.8$ Hz, H3′), 1.68 (br. s, 3H, H12), 1.62 (br. s, 3H, H12′), 1.59 (s, 3H, H7′). EI-MS: 250 (M^+, 7), 235 (1), 218 (1), 207 (12), 175 (5), 149 (17), 137 (10), 121 (36), 114 (28), 109 (22), 81 (31), 69 (100), 53 (19), 41 (55). The ^{1}H NMR and mass spectral data for both compounds matched literature data [NMR: Savu and Katzenellenbogen (1981); MS: Wainwright et al. (1996)].

Synthesis of Racemic Methyl (E)-5-2,6,10-Trimethyl-5,9-Undecadienoate (Scheme 1). For homogeranyl iodide (**2**), NaI (2.3 g, 15 mmol) was dried in a Kugelrohr distillation apparatus at 100°C under vacuum for 2 hr. After cooling,

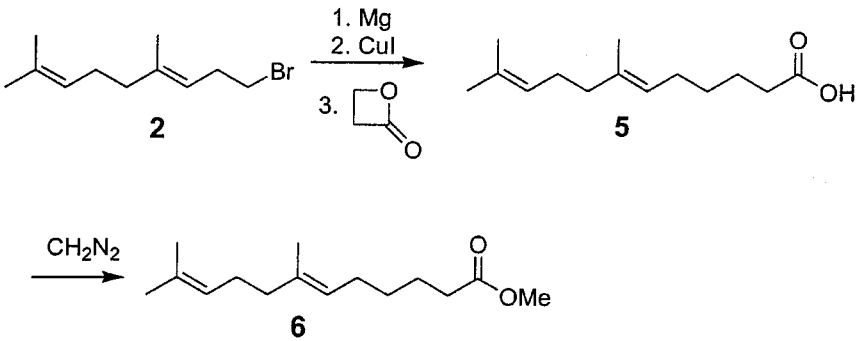


SCHEME 1.

25 ml acetone, homogeranyl bromide **1** (0.7 g, 3 mmol, prepared as described by Ho and Millar, 2001a), and 10 mg of Na_2CO_3 were added, and the mixture was stirred under Ar at room temp, monitoring the reaction by GC. When the reaction was complete (~4 hr), the mixture was poured into 150 ml water and extracted with hexane. The hexane layer was washed with aq. sodium bisulfite and brine, dried, and concentrated. The crude product was stored in the freezer until used, with a piece of copper wire added to retard degradation. EI-MS *m/z*: 278 (M^+, 0.7), 263 (1.3), 235 (9), 151 (2.7), 123 (12), 95 (150) 81 (16), 69 (100), 41 (74).

For (*E*)-5-2,6,10-*trimethyl-5,9-undecadienoic acid* (**3**), the procedure was adapted from that of Prashad et al. (1993). Lithium diisopropylamide (LDA) (1.5 M, 7.5 ml, 11.23 mmol) was added to 20 ml freshly distilled THF in an oven dried flask in an ice bath. Propionic acid (0.36 ml, 5 mmol) then was added dropwise, followed by 1,3-dimethyl-3,4,5,6-tetrahydro-2(1H)-pyrimidinone (DMPU) (0.7 ml, 5.7 mmol) as cosolvent. The mixture was stirred at room temperature for 20 min, then cooled to 0°C, and crude homogeranyl iodide **2** (0.7 g, 2.5 mmol) in 2 ml THF was added over 10 min. The mixture was stirred at room temperature, monitoring by GC. When there was no further change in the product ratio, the mixture was poured into 100 ml 1 M HCl and extracted with hexane (1 × 100 ml, 2 × 50 ml). The combined hexane layers were extracted with 1 M NaOH (1 × 100 ml, 2 × 50 ml). The combined aq. NaOH layers were back-extracted with ether, then acidified with 100 ml 3 M HCl and extracted with ether (1 × 100 ml, 2 × 50 ml). The combined ether layers were backwashed with brine, dried, and concentrated, yielding 0.4 g of acid **3** (purity 95% by GC, 71% yield). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 5.1 (m, 2H, H5 and H9), 2.5 (sextet, 1 H, $J = 7$ Hz, H-2), 2.06 (m, 7H, H2, H4, H7, and H8), 1.8 (m, 1H, H3), 1.69 (s, 3H, H11), 1.61 (2 × s, 2 × 3H, H6′ and H11′), 1.45 (m, 1H, H3′), 1.19 (d, 3H, J = 7 Hz, H2′). ^{13}C NMR ($CDCl_3$, 75.48 MHz): δ 182.99, 136.03, 131.41, 124.27, 123.33, 39.71, 38.75, 33.50, 26.62, 25.71, 25.48, 17.70, 16.86, 15.99. EI-MS *m/z*: 224 (M^+, 1), 209 (1.6), 181 (34), 163 (7.5), 137 (5.4), 109 (43), 81 (19), 69 (100), 41 (96). The spectra matched those reported by Coates and Freidinger (1970).

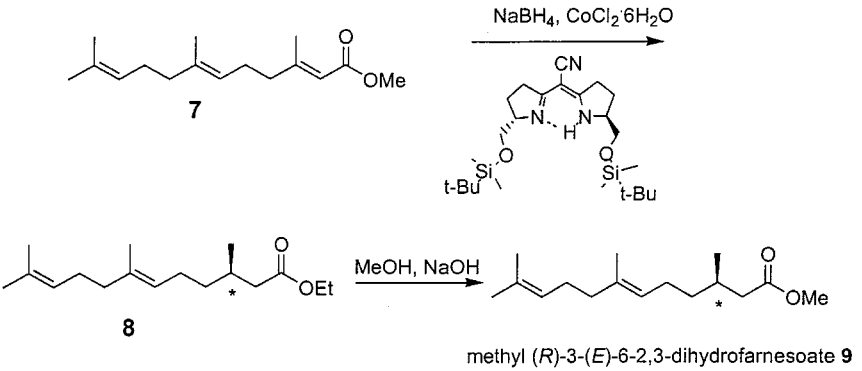
For *methyl* (*E*)-*5-2,6,10-trimethyl-5,9-undecadienoate* (**4**), acid **3** was dissolved in ~5 ml ether, cooled in an ice bath, and a freshly prepared solution of diazomethane in ether (prepared according to Aldrich Tech. Information Bulletin AL-180, Aldrich Chem. Co., Milwaukee, Wisconsin) was added until the free acid was consumed (monitoring by persistence of the yellow color of excess diazomethane). Nitrogen was bubbled vigorously through the solution to discharge traces of excess diazomethane; then the mixture was concentrated and Kugelrohr distilled at 0.1 mm Hg, oven temperature 70°C, yielding 0.34 g of ester **4** (58% yield, 92% purity by GC). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 5.09 (t, 2H, $J = 7$ Hz, H5 and H9), 3.67 (s, 3H, OCH_3), 2.46 (sextet, 1H, $J = 6.9$ Hz, H2), 1.88–2.15 (m, 7H, H2, H4, H7 and H8), 1.6–1.8 (m, 1H, H3), 1.68 (s, 3H, H11), 1.60 and 1.58



SCHEME 2.

(2 × s, 2 × 3H, H11′ and H6′), 1.35–1.5 (m, 1H, H3′), 1.15 (d, 3H, $J = 6.9$ Hz, H2′). ^{13}C NMR ($CDCl_3$, 75.48 MHz): δ 177.33, 135.82, 131.37, 124.28, 123.50, 51.48. 39.73, 38.89, 33.79, 26.65, 25.71, 25.57, 17.69, 17.09, 15.95. EI-MS *m/z*: 238 (M^+, 0.7), 223 (3.3), 195 (19), 163 (10), 123 (7.4), 109 (75), 88 (22), 69 (84), 55 (20), 41 (100).

Synthesis of Racemic Methyl (*E*)*-6-7,11-Dimethyl-6,10-Dodecadienoate (Scheme 2).* For (*E*)-6-7,11-dimethyl-6,10-dodecadienoic acid (**5**), the procedure was adapted from those described by Fujisawa et al. (1980) and Sato et al. (1980). Homogeranyl bromide **2** (0.9 g, 3.9 mmol, purity 82%) was dissolved in ~10 ml of freshly distilled THF in a dropping funnel. One milliliter of the solution was added to a flask containing Mg turnings (0.2 g, 8 mmol), with several small crystals of iodine and 5 drops of dibromoethane. The mixture was stirred until the iodine color disappeared, and then the rest of the solution was added dropwise over ~2 hr, warming gently to 30–40°C with an oil bath. When the addition was complete, the solution was heated at 40°C for 1 hr, then cooled to room temperature The resulting solution of Grignard reagent was transferred by syringe into a solution of β-propiolactone (0.25 g/0.22 ml, 4 mmol; Aldrich Chemical) and powdered CuI (0.04 g, 0.2 mmol) in 5 ml dry THF at ~−10°C (ice-salt bath) in a 100-ml flask under Ar over 30 min. The mixture was warmed to 0°C and stirred until the reaction was complete. The reaction mixture was poured into 100 ml 1 M HCl and extracted with hexane (1 × 100 ml, 2 × 50 ml). The combined organic layers were extracted with 1 M NaOH (1 × 100 ml, 2 × 50 ml), and the combined aq. NaOH extracts were then back-extracted once with ether. The aq. NaOH extract was then acidified with 100 ml 3 M HCl, and extracted with ether (1 × 100 ml, 2 × 50 ml), the combined ether extracts were washed with brine, dried, and concentrated, yielding 0.4 g of acid **5**. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 10.75 (br s, 1 H, COOH), 5.11 (m, 2H, H6 and H10), 2.36 (t, 2H, $J = 7.4$ Hz, H2), 1.9–2.1 (m, 6H, H5, H8, H9), 1.68 (s, 3H, H12), 1.60 (s, 6H, H7′ and H12′), 1.5–1.7 (m, 2H, H3), 1.3–1.5



SCHEME 3.

(m, 2H, H4). ^{13}C NMR ($CDCl_3$, 75.48 MHz): δ 180.52, 135.49, 131.38, 124.36, 123.99, 39.78, 34.11, 29.25, 27.52, 26.73, 25.74, 24.32, 17.73, 16.05. EI-MS *m/z*: 224 (M^+, 0.5), 209 (1.8), 181 (28), 137 (5), 123 (15), 109 (12), 95 (36), 69 (100), 41 (77).

For *methyl* (*E*)*-6-7,11-dimethyl-6,10-dodecadienoate* (**6**), a portion of (*E*)-6-7,11-dimethyl-6,10-dodecadienoic acid **5** was esterified with diazomethane as described for 4. EI-MS *m/z*: 238 (M^+, 0.5), 223 (0.6), 195 (18), 163 (6), 137 (9), 123 (11), 109 (21), 95 (49), 69 (82), 41 (100).

Synthesis of Methyl (R)-3-(E)-6-2,3-Dihydrofarnesoate (Scheme 3). The reaction was carried out exactly as described by Pfaltz (1989) and Leutenegger et al. (1989). A successful reaction required rigorous degassing of solvents and starting materials, and exclusion of oxygen. Thus, methyl (2*E*,6*E*)-farnesoate **7** (0.25 g, 1 mmol) in a 25-ml three-necked round-bottom flask equipped with a magnetic stir bar, with the necks fitted with a stop-cock and two new rubber septa, was degassed by several cycles of pumping under vacuum and refilling the flask with N_2. All solvents and solutions were degassed by sonicating while pumping under house vacuum, then refilling with N_2; this was repeated several times. Then 0.5 ml ethanol were added to the flask by syringe, followed by 0.25 ml of a solution of $CoCl_2 \bullet 6H_2O$ (100 mg, 0.42 mmol) in ethanol (5.5 ml), a solution of (1*S*,9*S*)-1,9-bis[(*t*-butyldimethylsiloxy)-methyl]-5-cyanosemicorrin (10 mg, 0.022 mmol; Fluka #14556) in 0.5 ml ethanol (mixture turns deep blue), and a solution of $NaBH_4$ [85 mg (2.2 mmol) in 0.8 ml dimethylformamide] (mixture turns brown, cloudy). The mixture was degassed again by several freeze–pump–thaw cycles, using a Dry Ice–acetone bath. The flask was then sealed tightly and the mixture was stirred for 45 hr at room temperature. A sample taken indicated that the reaction was complete, with no trace of starting material, but that the product had been 60% transesterified to the ethyl ester. The mixture was worked up by

pouring into 100 ml water and extracting with 3 × 50 ml CH_2Cl_2. The combined CH_2Cl_2 extracts were washed with water and brine, dried, and concentrated. The crude ethyl ester **8** was then transesterified by stirring with methanol (10 ml) and one pellet of NaOH (∼250 mg) overnight at room temperature. The mixture was poured into 50 ml water and extracted with hexane, washing the hexane solution with brine. The solution was dried, concentrated, and Kugelrohr distilled (oven temperature 110°C, 0.3 mm Hg), yielding 229 mg of methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate **9**, >98.5% pure by GC. The enantiomeric excess was determined to be 89.6% by hydrolysis of the acid followed by formation of the diastereomeric amides by reaction with (*S*)-(–)-α-methylbenzylamine and GC analysis (see below).

Determination of Absolute Configuration of Insect-Produced Methyl (E)-6-2,3-Dihydrofarnesoate. This procedure was adapted from a method reported by Huffer and Schreier (1990), scaling down the apparatus and quantities of reagents used. Thus, 10 μg of synthetic racemic or methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate was hydrolyzed in 20 μl of EtOH and 2 μl of aq. 4 M NaOH in a Keele vial (Wheaton Scientific Products, Millville, New Jersey), heating in a 50°C water bath for 2 hr. After cooling, the EtOH was evaporated under a gentle stream of N_2. Then 20 μl of 1 M HCl were added to the dry vial, and the mixture was extracted with pentane (3 × 100 μl) to recover the free (*E*)-6-2,3-dihydrofarnesoic acid. The pentane solution was dried by filtering through a Pasteur pipet containing a 0.5-cm layer of anhydrous $MgSO_4$, then transferred to a 250-μl conical glass vial insert inside a 4-ml glass vial. The solution was evaporated just to dryness under a gentle stream of N_2 and 20 μl of $CHCl_3$ were added, followed by 2 μl of a $CHCl_3$ solution of (*S*)-(–)-α-methylbenzylamine (10 μg/μl; Aldrich Chemical) and 4 μl of a solution of dicyclohexylcarbodiimide (DCC) (6 μg/μl in $CHCl_3$). The vial was sealed tightly with a Teflon-lined screw-cap, and the vial was heated in a 50°C water bath for 30 min. The mixture was then analyzed by GC and GC-MS on DB-5 and DB5-MS columns (20 m × 0.32 or 0.2 mm, respectively, J&W Scientific, Folsom, California) in splitless mode. GC and GC-MS conditions were: 150°C/0 min, 4°C/min to 275°C, hold at 275°C for 10 min, injector temp 300°C, detector or transfer line temp 280°C.

A pooled aeration extract from mature male *C. uhleri* containing approximately 1.2 mg of the major defensive compound, tridecane, and 22 μg of the major male-specific compound, methyl (*E*)-6-2,3-dihydrofarnesoate was fractionated on a silica gel solid-phase extraction cartridge as previously described (Ho and Millar, 2001a). The fraction containing methyl (*E*)-6-2,3-dihydrofarnesoate was hydrolyzed, and the resulting (*E*)-6-2,3-dihydrofarnesoic acid was converted to the diastereomeric methylbenzylamide derivative and analyzed as described above. This procedure was repeated with pooled aeration extracts from *C. ligata* males containing approximately 64 μg of tridecane and 11 μg of the major male-specific compound, methyl (*E*)-6-2,3-dihydrofarnesoate.

RESULTS

Basic Reproductive Behaviors. The reproductive behaviors of *C. uhleri* and *C. ligata* were similar. For both species, the male bug began close-range courtship with antennation of the female bug, followed by head butting the posterior end of the female bug. If the female was receptive, she stopped walking, lowered her head, and raised her abdomen. Then, the male turned around, coupled his genitalia with those of the female, and copulated in an end-to-end position. During mating, both female and male bugs were in a 'head-stand' position, shaped as an inverted 'V', with the abdomen higher than the head. When copulation was complete, one of the bugs swung from side to side to disengage from the other. If the female was not receptive, she walked away. In some cases, even though the female bug stopped and raised her abdomen in the receptive position, the male would still head butt for some time before he turned around and mated with her. In cases where the female assumed the receptive position with her abdomen raised, and the male failed to couple with her genitalia, the male resumed head butting and started over again. In some cases, the male had to pursue the female with periodic bouts of head butting for hours, before the female acquiesced and copulated with the male. In other cases, the female mated with the male after a relatively brief courtship of only a few minutes of head butting.

Weight Change after Mating. Experiments with 122 virgin pairs and 52 experienced pairs of *C. ligata* resulted in a total of only 13 observations of copulation between virgin pairs and 11 copulations of experienced pairs. For virgin insects, females gained $28 \pm 1\,0$ mg in weight (mean $\pm$ SD, $11 \pm 4\%$ of body weight), and males lost 42 ± 11 mg ($19 \pm 5\%$ of body weight) during copulation (Figure 1a). There was negligible weight change in the control group, with females losing 3 ± 3 mg, and males losing 1 ± 2 mg ($N = 16$). There was a trend towards increasing weight change in both sexes with increasing duration of mating [Figure 1a, $R^2 = 0.1527$ (females) and 0.4926 (males)].

For experienced pairs, weight change was not correlated with duration of mating for either sex (Figure 1b, experienced pairs, females, $P = 0.72$ and males, $P = 0.42$). Experienced males lost an average of 42 ± 7 mg ($19 \pm 3\%$ of body weight) during mating, and females gained 24 ± 10 mg ($11 \pm 5\%$ of body weight). Overall, these results indicate that virgin and experienced males transfer material equivalent to a significant fraction of their body mass to females during mating. For both virgin and experienced pairs, there was a small overall net weight loss, probably due to defecation; drops of feces were frequently seen on the walls of the cages at the termination of the experiments.

We were not able to carry out analogous experiments with *C. uhleri* because of insufficient numbers of bugs in the laboratory colonies.

Diurnal Patterns in Mating Behavior. The diurnal rhythm of mating behavior of adult *C. ligata* is shown in Figure 2a. Of 23 sexually mature, lab-reared pairs

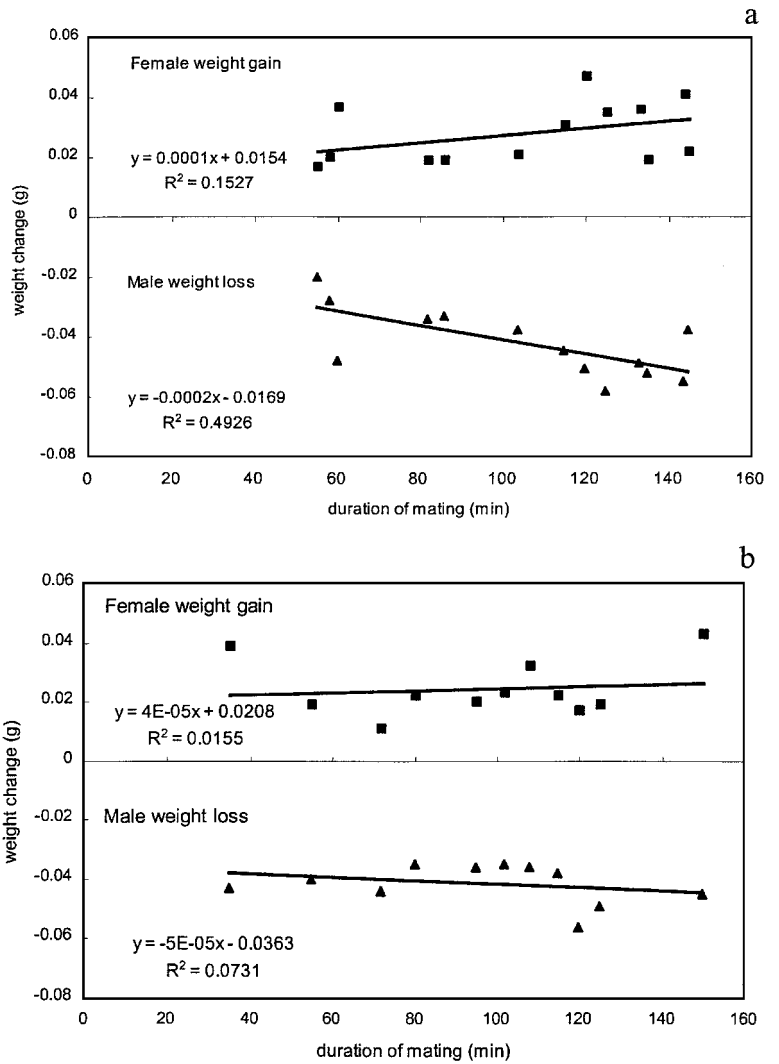


FIG. 1. Weight change of *C. ligata* after mating. (a) Virgin insects: females gained 0.028 ± 0.010 g (mean $\pm$ SD) (*t* test versus controls, $P = 6 \times 10^{-8}$, and males lost 0.042 ± 0.011 g in weight during mating (*t* test versus controls, $P = 1.8 \times 10^{-8}$) ($N = 13$). Linear regression was carried out on the weight change versus duration of mating for each sex. Female weight gain was not correlated with duration of mating ($P = 0.1868$), whereas male weight loss was correlated with mating duration ($P = 0.0075$). (b) Experienced insects: females gained 0.024 ± 0.010 g (mean $\pm$ SD) in weight (*t* test versus controls, $P = 1.3 \times 10^{-6}$), and males lost 0.042 ± 0.007 g with every mating (*t* test versus controls, $P = 1 \times 10^{-9}$) ($N = 11$). Linear regression was carried out on the weight change versus duration of mating for each sex. Neither female weight gain ($P = 0.7154$) nor male weight loss ($P = 0.4212$) was correlated with mating duration.

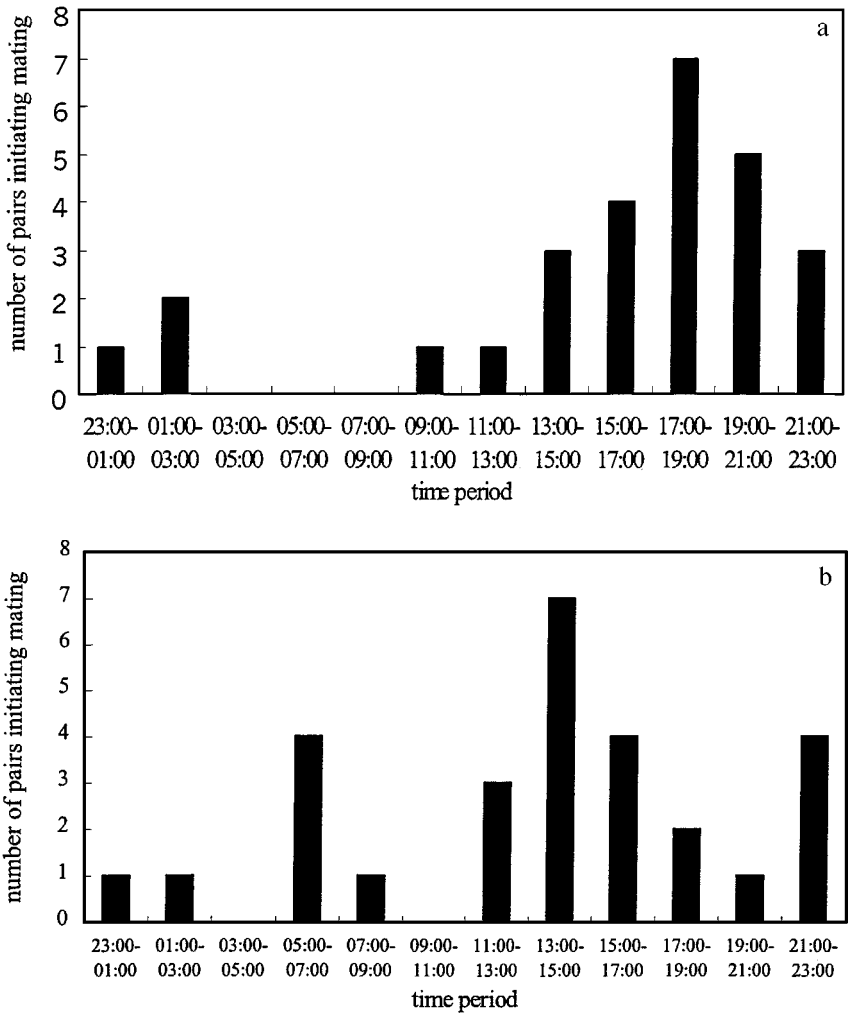

FIG. 2. Diurnal pattern of mating behavior of *C. ligata* (a) and *C. uhleri* (b), showing number of pairs that initiated copulation during successive 2-hr time periods. Lights were on from 06:00 to 20:00 hr each day. The *C. ligata* trial was run with 13 pairs of insects for 14 consecutive days, with 27 matings observed. The *C. uhleri* trial was run with 12 individual pairs of insects for 8 consecutive days, with 28 matings observed.

observed over a 14 day period, 13 pairs mated a total of 27 times. No mating was observed for the other 10 pairs because of the death of one or both bugs of the pair. For pairs that mated more than once, the mean latency between copulations was 50 ± 20 hr (range 22–92 hr). The duration of mating for virgin females

paired with virgin males (54 ± 24 min; $N = 12$), and for experienced females and males (46 ± 33 min; $N = 15$) was not different (two tailed t test, $df = 25$, $P = 0.44$). The largest percentage of copulations (>25%) were initiated between 17:00–19:00 hr (Figure 2a). The remainder of copulations generally were initiated in the afternoon and evening hours, from 13:00 to 23:00 hr, indicating that this species is sexually active primarily during the latter half of the photophase.

Twelve pairs of field-collected *C. uhleri* adults of unknown age and mating status, held in sexed groups for 4 days before beginning observations, mated a total of 28 times during the 8 day observation period. The overall pattern of reproductive activity is shown in Figure 2b. Mating duration ranged from 8 to 193 min, (mean ± SD, 78 ± 55 min). Eight of the 12 pairs mated more than once, one pair did not mate at all, and three pairs mated only once due to the death of one of the pair. Of the eight multiply-mating pairs, two pairs mated twice the same day, and then every one to two days. Another three pairs mated every other day. The interval between mating ranged from 10 to 51 hr (mean 26 ± 14 hr). Females usually laid eggs between copulations. Mating was initiated mostly in the afternoon, with 25% of the 28 matings observed being initiated between 13:00–15:00.

Identification of Compounds from Odors Produced by Adult C. uhleri and C. ligata. Typical gas chromatograms of aeration extracts from groups of 5–10 sexually mature, virgin adult female and male *C. uhleri* are shown in Figure 3. Several compounds appeared in both female and male aeration extracts, including (*E*)-2-hexenal, (*E*)-2-octenal, dodecane, (*E*)-2-octenyl acetate, tridecane, tetradecane, and pentadecane. Female extracts also contained the known bug defensive compound (*E*)-4-oxo-2-hexenal (Aldrich, 1995) and a small amount of undecane. All compounds except (*E*)-4-oxo-2-hexenal were tentatively identified by comparison of their mass spectra with those from the National Bureau of Standards GC-MS database. (*E*)-4-Oxo-2-hexenal was tentatively identified by comparison of the mass spectrum with a reference spectrum obtained from J. R. Aldrich. Identifications then were confirmed by comparison of retention times and mass spectra of the insect-produced compounds with those of authentic standards. The C_{11}-C_{15} hydrocarbons, (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-octenyl acetate, and (*E*)-4-oxo-2-hexenal are probably defensive compounds from the metathoracic glands (Ho and Millar, 2001b). Aeration extracts from green-bean controls were found to contain trace amounts of the common plant volatiles hexanol, (*E*)-2-hexenol, (*E*)-2-hexenal, and linalool.

Three male-specific compounds (Figure 3, peaks A, B, and C) in a ratio of 0.9:100:0.6, were first detected in aeration extracts 12 days after the final molt in each of two cohorts of virgin males. The mass spectrum of the most abundant of the three compounds, peak B, suggested a molecular mass of 252 with major fragment ions of *m/z* 69, 109, 123, 177, and 209. The compound was tentatively identified as methyl (*E*)-6-2,3-dihydrofarnesoate by comparison of its mass spectrum with the

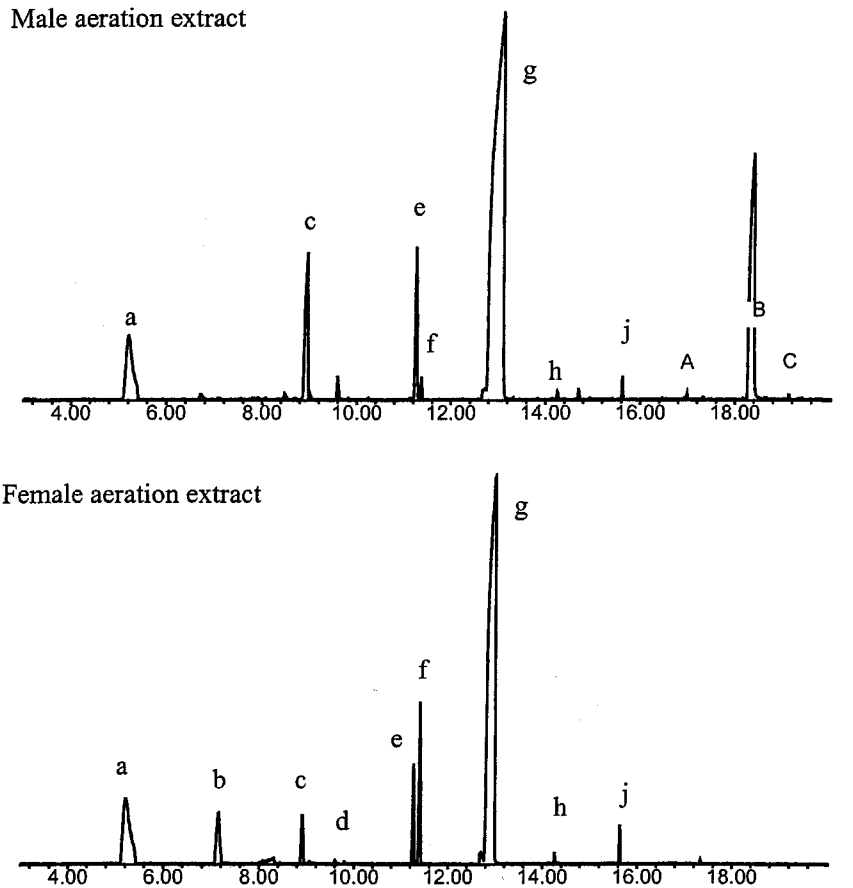

FIG. 3. Gas chromatograms of aeration extracts of sexually mature male (top trace) and female (bottom trace) *C. uhleri*. GC conditions: column DB5-MS (20 m × 0.2 mm ID), initial temperature 50°C (1 min), 10°C/min to 250°C, 250°C (10 min). Three compounds were found only in male aeration extract: A: methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate; B: methyl (*E*)-6-2,3-dihydrofarnesoate; C: methyl (2*E*,6*E*)-farnesoate. Other peaks: a: (*E*)-2-hexenal; b: (*E*)-4-oxo-2-hexenal; c: (*E*)-2-octenal; d: undecane; e: dodecane; f: (*E*)-2-octenyl acetate; g: tridecane; h: tetradecane; j: pentadecane.

mass spectral database. The identification was confirmed by synthesis of methyl (*E*)-6-2,3-dihydrofarnesoate, and match-up of mass spectra and GC retention times on two columns of different polarity (DB-5MS and DB-17).

Peak C was tentatively identified as methyl (2*E*,6*E*)-farnesoate based on its molecular ion at *m/z* 250 (corresponding to a possible molecular formula of

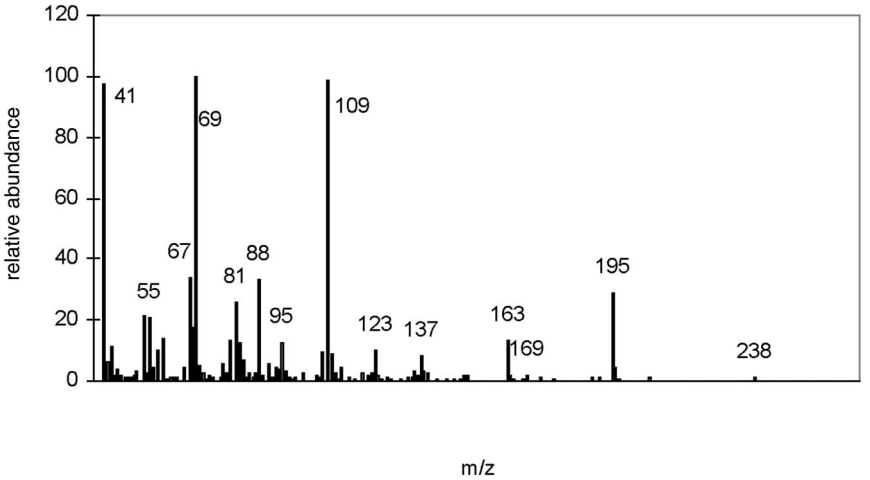

FIG. 4. Mass spectrum of (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate.

$C_{16}H_{26}O_2$); significant fragment ions of *m/z* 41, 69, 114, 136, and 235; and an excellent match with a spectrum of the authentic compound in the mass spectral database. The identification was confirmed by matching the mass spectrum, and retention times on DB-5MS and DB-17 GC columns, with those of a synthesized standard of methyl (2*E*,6*E*)-farnesoate.

The mass spectrum of the small peak A showed a possible molecular weight of 238 amu (Figure 4). The molecular weights of peak A and the major component, methyl (*E*)-6-2,3-dihydrofarnesoate, were 14 mass units different, and both gave similar mass spectral fragmentation patterns in the lower mass ranges. This suggested that the unknown might be a homolog of methyl (*E*)-6-2,3-dihydrofarnesoate, with one methylene group less. There were two obvious possibilities. First, the compound might be derived from chain shortening of methyl (*E*)-6-2,3-dihydrofarnesoate by one carbon, that is, methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate. Alternatively, the structure might be methyl (*E*)-6-7,11-dimethyl-6,10-dodecadienoate, from removal of the methyl group on carbon 3 of methyl (*E*)-6-2,3-dihydrofarnesoate. Other possibilities, such as removal of a methyl group further along the chain, seemed unlikely because of the similarities between the mass spectra of this compound and methyl (*E*)-6-2,3-dihydrofarnesoate, whereas removal of an allylic methyl from carbons 7 or 11 of methyl (*E*)-6-2,3-dihydrofarnesoate would have shifted the masses of most of the major fragments by 14 mass units. To confirm the structure of the unknown, the two most likely compounds were synthesized. By comparison of the retention times and mass spectrum of the unknown with those of the synthetic compounds, compound A was identified

as methyl (*E*)-5-2,6,10-trimethyl- 5,9-undecadienoate. A diagnostic mass spectral fragment with *m/z* 88 (Figure 4), arising from McLafferty rearrangement of the methyl ester (Silverstein and Webster, 1998), aided the conclusive identification. This fragment was not seen in the spectrum of methyl (*E*)-6-7,11-dimethyl-6,10-dodecadienoate, and the retention time of this compound was different from that of the insect-produced compound.

The absolute configuration of the insect-produced methyl (*E*)-6-2,3-dihydrofarnesoate was determined by hydrolysis of the ester to the free acid, followed by derivatization with (*S*)-(–)-α-methylbenzylamine. GC analysis of the resulting amide diastereomer determined that its retention time matched that of the corresponding derivative prepared from synthetic methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate. The pair of derivatives from derivatization of racemic (*E*)-6-2,3-dihydrofarnesoic acid were resolved to baseline on a DB-5MS column [(*R*)-3- enantiomer, 22.76 min; (*S*)-3 enantiomer, 22.94 min], unequivocally indicating that the bugs produce methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate.

There was also a chiral center in the minor component, (*E*)-5-methyl-2,6,10-trimethyl-5,9-undecadienoate. This compound was present in trace amounts in the fraction containing methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate, but after the two-step hydrolysis and derivatization procedure, a peak corresponding to this compound could not be located in the chromatograms.

Typical gas chromatograms of aeration extracts from female and male *C. ligata* are shown in Figure 5. The compounds shared by both females and males included (*E*)-2-octenal, dodecane, tridecane, and pentadecane. Extracts from females also contained (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, undecane, and tetradecane. Sexually mature males also produced the same three male-specific compounds as *C. uhleri*, in a similar ratio [methyl (*E*)-6-2,3-dihydrofarnesoate, methyl (2*E*,6*E*)-farnesoate, methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate, 100:0.4:0.5]. Furthermore, GC analysis of the diastereomeric derivative formed from the *C. ligata*-produced methyl (*E*)-6-2,3-dihydrofarnesoate determined that it too had the (*R*)-3 configuration. As with *C. uhleri*, the amount of the minor component methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate was too small to be able to determine its absolute configuration by the derivatization method. Thus, the male-specific blends of compounds from *C. uhleri* and *C. ligata* appear to be remarkably similar, even to the extent of the major, chiral component having the same absolute configuration.

Dynamics of Production of Male-Specific Compounds. Less than half the cohorts of virgin male *C. uhleri* produced male-specific compounds. For example, between November 1997 and November 1998, of 28 cohorts of virgin males $>$10 days old that were aerated continuously for at least 8 days, only 13 cohorts produced detectable amounts of male-specific compounds. In a second set of aerations conducted between February 6 and March 24, 1999, only three of 17 cohorts

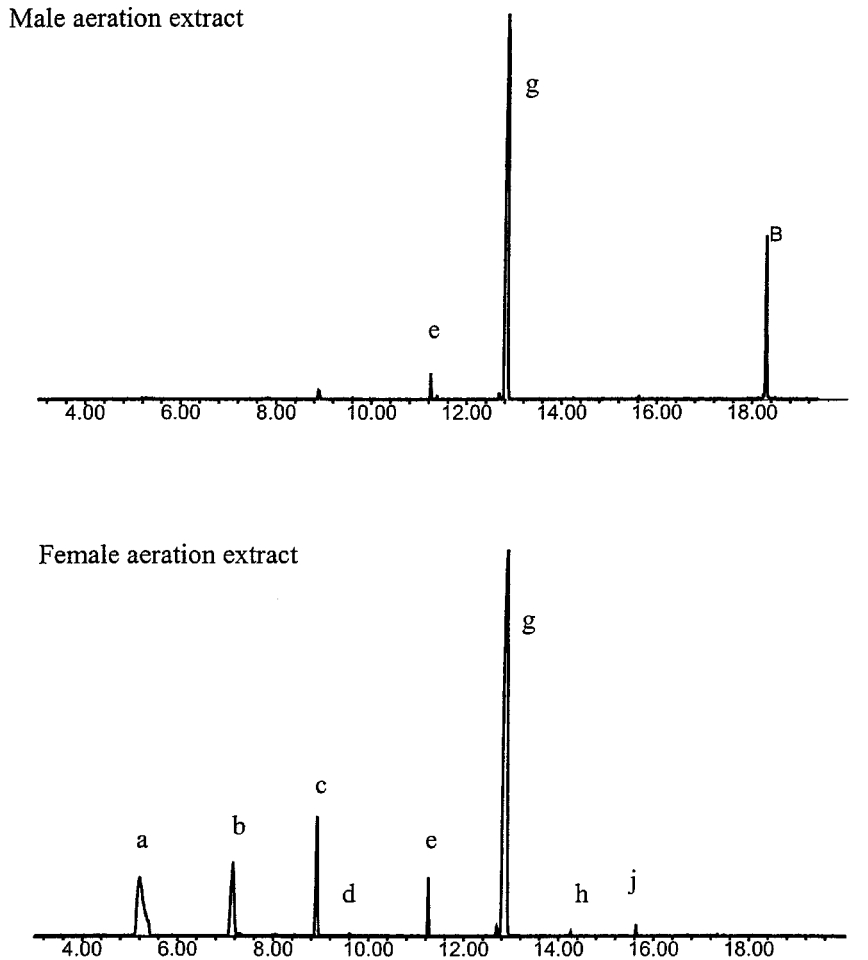

FIG. 5. Gas chromatograms of male (top trace) and female (bottom trace) *C. ligata* aeration extracts. GC conditions: column DB5-MS (20 m × 0.2 mm ID), oven temperature: 40°C (1 min), 10°C/min to 250°C, 250°C (10 min). Peak B: methyl (*E*)-6-2,3-dihydrofarnesoate. Other peaks: a: (*E*)-2-hexenal; b: (*E*)-4-oxo-2-hexenal; c: (*E*)-2-octenal; d: undecane; e: dodecane; f: (*E*)-2-octenyl acetate; g: tridecane; h: tetradecane; j: pentadecane.

of virgin males >12 days old aerated for periods of one week produced male-specific compounds. This second set of aerations was conducted with individuals reared from eggs laid by bugs collected in late fall of 1998.

For *C. ligata*, male-specific compounds were first detected from three cohorts of virgin males 13, 14, and 14 days, respectively, after the final molt. Unlike

C. uhleri, all cohorts (>20 total) of males that were aerated produced male-specific compounds.

Diurnal Rhythm of Production of Male-Specific Compounds. Aeration data from seven cohorts of male *C. ligata* were pooled and analyzed by 2-way ANOVA to determine the diurnal rhythm of production (Figure 6a). Maximum production of male-specific compounds occurred from 19:00 to 21:00 hr, and the quantities produced were significantly greater than for the next most productive periods between 17:00 and 19:00 and 21:00 and 23:00 hr. During peak production, males produced about 35 ng/bug/hr of the major male-specific compound.

For cohorts of male *C. uhleri* that did produce male-specific compounds, production followed a diurnal cycle, increasing from midday and peaking in the late afternoon at 17:00–19:00 (Figure 6b). The mean amount of the most abundant compound, methyl (*E*)-6-2,3-dihydrofarnesoate, produced during the peak production period was 8.8 ± 4.7 ng/bug/hr. Lower levels of this compound were detected during the entire 24 hr cycle.

Laboratory Bioassays. In vertical Y-tube bioassays, female *C. uhleri* were more attracted to odors from live males than to clean air controls (male odor stimulus, 24 responders, control, 10 responders, 3 nonresponders; χ^2 test, $P = 0.016$). In subsequent bioassays testing different doses of aeration extracts of males (doses of 8–32 ng of the major male specific compound), female bugs showed no preference for the odor extract from males versus the solvent control (extract, 14 responders, control, 18 responders). Because the effects of the pheromone might have been confounded by the presence of defensive chemicals in the crude extracts, no further bioassays were conducted with extracts.

When tested as a single component, 2 μg of the synthesized major male-specific compound, methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate, attracted 26 females, versus 12 females attracted to the solvent control (χ^2 test, $P = 0.023$), with 10 nonresponders. In further bioassays testing the effects of the minor male-specific components, and using racemic (*E*)-6-2,3-dihydrofarnesoate instead of the (*R*)-3 enantiomer, results were unclear. With 4-μg doses of the three-component blend, there were no significant differences in responses of females to the treatment or the control, ($N = 16$; treatment = 6, control = 8, 2 nonresponders). However, a second set of bioassays using 40 μg of the three-component blend resulted in attraction of female bugs to the treatment (treatment = 25, control = 10, 5 nonresponders; $P = 0.011$). In a direct test of the attractiveness of the three-component blend versus the single major component methyl (*E*)-6-2,3-dihydrofarnesoate (40 μg doses), female bugs responded equally to each stimulus (three-component blend = 10, single component = 14, 4 nonresponders; χ^2, $P = 0.414$). This result suggested that the two minor components of the male-specific volatiles are not required for attraction and that they are not pheromone components.

In a final set of laboratory bioassays, mature male *C. uhleri* were repelled by 40 μg of the three-component pheromone blend. Of the 20 bugs tested, 3 went to

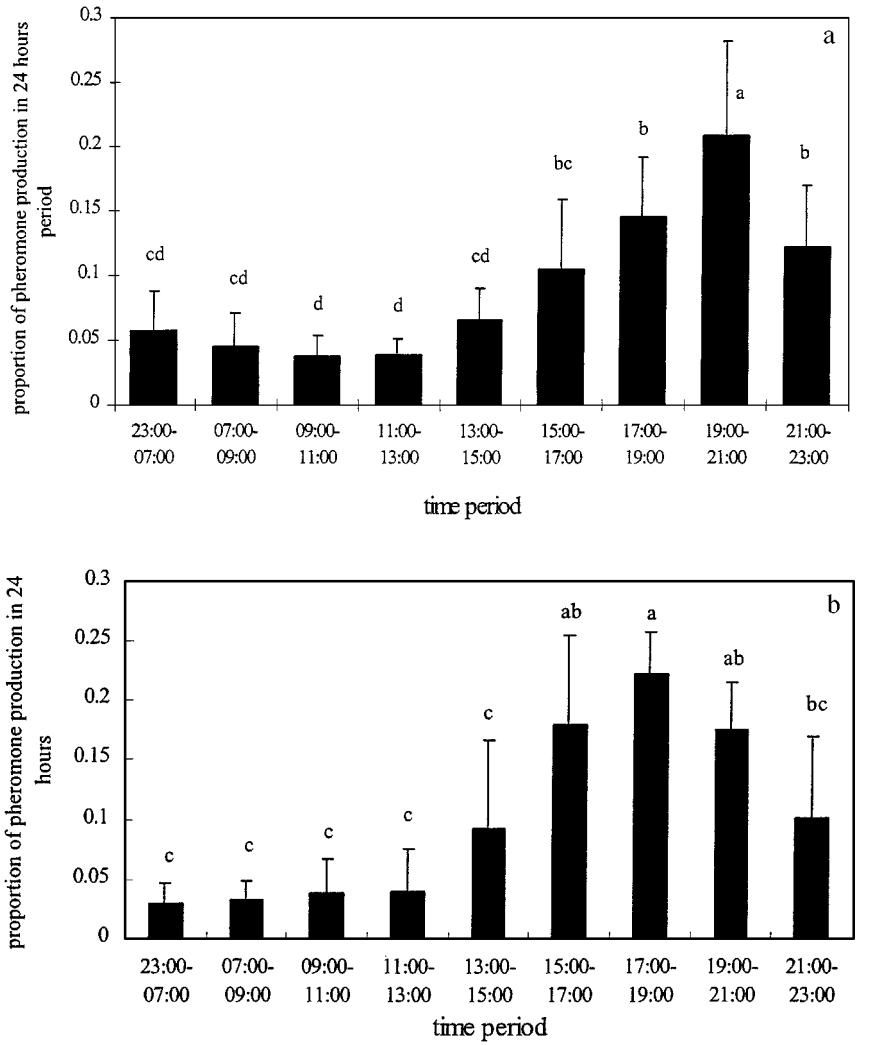

FIG. 6. Diurnal rhythm of production of the major male-specific compound, methyl (*E*)-6-2,3-dihydrofarnesoate, by 7 cohorts of *C. ligata* (a) and 4 cohorts of *C. uhleri* (b) males. *C. ligata*: 2-way ANOVA, for cohort effect, $F = 0.495$, $df = 6, 48$, $P = 0.8086$; for time interval effect $F = 13.326$, $df = 8, 48$, $P < 0.0001$. The maximum amount produced, from 19:00–21:00 hr, was 35.3 ± 32.2 ng/bug/hr. *C. uhleri*: 2-way ANOVA for cohort effect, $F = 0.519$, $df = 3, 24$, $P = 0.6732$; for time interval effect $F = 3.750$, $df = 8, 24$, $P = 0.0056$. The maximum amount, produced from 17:00 to 19:00 hr, was 8.8 ± 4.7 ng/bug/hr. Bars surmounted by the same letter(s) are not significantly different (Student-Newman-Keuls test, $P < 0.05$).

the arm containing the test treatment, 14 went to the control arm, and 3 bugs did not respond (χ^2, $P = 0.008$).

In the vertical Y-tube olfactometer, virgin female *C. ligata* were attracted to odors from live males (male odors versus control, 20 vs. 8 responders, χ^2 test, $P = 0.02$). The results were further categorized into response times of less than or greater than 1 min. This more detailed analysis indicated that when bugs responded more slowly, circling around and taking time to sample the airstreams (i.e., response time >1 min), they chose the arm with the odor of the male bug a large percentage of the time (treatment = 13, control = 2, χ^2, $P = 0.0045$). Furthermore, some of these bugs started up the control arm, then turned back and finally moved all the way to the end of the treatment arm of the olfactometer. In contrast, bugs that made a choice in less than 1 min showed no significant discrimination between the treatment and control arm (seven and six bugs, respectively).

Attempts to demonstrate attraction of sexually mature virgin *C. ligata* females to extracts of male volatiles were not successful, using several different aeration extracts containing varying amounts of the male-specific compounds and the defensive compounds. Possible reasons for this lack of attraction include incorrect dose or interference from the defensive compounds present in the extracts. Consequently, all further laboratory bioassays were conducted with synthetic compounds, in which the blend and dose could be completely controlled.

In the first bioassay of synthetic compounds with female *C. ligata* responders, there were indications that methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate as a single component (2 μg dose) might be attractive to female bugs (treatment = 17, control = 9, nonresponders = 8; χ^2 test, $P = 0.11$). Further bioassays conducted with the two-component blend of methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate with methyl (2*E*,6*E*)-farnesoate (100:1, total dose 2.02 μg) indicated that the two-component blend was more attractive than the control (treatment = 19, control = 6, 6 nonresponders, χ^2 test, $P = 0.009$). In a third series of bioassays, female bugs were more attracted to a three-component blend consisting of racemic methyl (*E*)-6-2,3-dihydrofarnesoate, methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate and methyl (2*E*,6*E*)-farnesoate (100:0.8:0.4, total dose 4 μg) than to the control (treatment = 15, control = 1, 4 nonresponders, χ^2 test, $P = 0.0004$). Bioassays directly comparing the attraction of female bugs to the three-component blend versus methyl (*E*)-6-2,3-dihydrofarnesoate as a single component (2 μg doses) were inconclusive due to the limited number of bugs available for bioassays. Of the 11 bugs available, 6 went to the arm containing the single component and 3 went to the arm containing the three-component blend, and 2 did not respond.

In an abbreviated series of bioassays, there was no indication that male *C. ligata* were attracted to or repelled by the three-component blend (treatment = 5, control = 5, nonresponders = 7), but the numbers tested were too low to reach any firm conclusion.

Field Bioassays with C. uhleri *and* C. ligata. In the first field trials conducted August 3–16, 1999, more female *C. uhleri* were attracted to lures containing a three-component blend of the synthesized male-specific components than to solvent treated controls (67 to treatment, 7 to control; two-way ANOVA for treatment effect $F = 7.42$, $df = 2,10$, $P = 0.011$; for block effect $F = 3.48$, $df = 5,10$, $P = 0.043$). Although three times as many males were found on plants with lures versus control plants, the numbers of males attracted were not different between the treatment and control (36 to treatment and 12 to control, multiresponse permutation procedure (MRPP), $P > 0.05$). Interpretation of field test results was complicated by large variations in bug populations among blocks.

A second trial conducted in six blocks from August 19 to 24, 1999, attracted only low numbers of bugs. Significantly more female bugs were collected on baited plants than on control plants (9 vs. 0, MRPP test, $P = 0.01558$). Of the 9 males collected, 7 were on baited plants, and 2 were on control plants.

Because we did not find significant populations of *C. ligata* in the Riverside area in 1999, no specific field experiments were deployed for this species. However, two female *C. ligata* were collected from plants baited with lures for *C. uhleri*. Because male *C. ligata* and *C. uhleri* produce virtually identical blends of male-specific compounds, this was not unexpected. However, it is noteworthy because no other *C. ligata* were seen or collected at that site using visual observations and sweep-netting sampling.

DISCUSSION

Reproductive Behavior. The close-range courtship of phytophagous stink bugs follows characteristic steps, including males approaching females (over short distances), followed by antennation and head-butting of females by males, and end-to-end copulation (Fish and Alcock, 1973; Borges et al., 1987; Wang and Millar, 1997; Ho and Millar, 2001a). The daily rhythms of reproductive activity also appear similar among species, with courtship and copulation being initiated primarily in the afternoon and evening [e.g., *Chlorochroa ligata* (Fish and Alcock, 1973), *Nezara viridula* (Harris and Todd, 1980), *Euschistus heros* (Borges et al., 1998a), *Thyanta pallidovirens* (Wang and Millar, 1997), *Acrosternum hilare* and *T. pallidovirens* (H. McBrien and J. Millar, unpublished data)]. Thus, late afternoon and evening were chosen as the optimum time to conduct both laboratory and field bioassays.

The patterns of *C. uhleri* and *C. ligata* reproductive activity coincided with the maximum production of male-specific compounds. However, male-specific compounds were detected throughout the 24-hr monitoring periods, suggesting that the compounds were produced continuously with only the production rate varying. This pattern may have developed for several possible reasons. First, parasitoids use stink bug pheromones as kairomones (Aldrich, 1995), and timing peak production to parts of the day with waning light levels may reduce the risk of

parasitization (Harris and Todd, 1980). Second, because of the long copulation times, pheromone production in late afternoon may be timed so that males and females find each other around dusk and then continue copulation under the cover of darkness. Third, mating activities may be timed for optimum temperature and humidity conditions. Reproductive activities in the heat of the day increase the risk of desiccation, whereas cooler nighttime temperatures may hinder movement and activity.

Male *C. ligata* transferred substantial weights of material to females during mating, with body weights of both sexes changing significantly after copulation. Weight changes occurred with both virgin and experienced insects, and mean duration of copulation was similar for virgin and experienced insects. Similar weight changes after mating occur with *T. pallidovirens* (Wang and Millar, 1997), and it has been documented that pentatomid females obtain nutrients from males, often in the form of large, nonfertilizing sperm (Schrader, 1960; Mitchell and Mau, 1969; Mau and Mitchell, 1978; Kasule, 1986). For *T. pallidovirens*, these materials resulted in enhanced egg production by females, increasing the reproductive output of both sexes (Wang and Millar, 1997). This increase in reproductive output should in turn encourage multiple copulations by both sexes, which is indeed a characteristic of pentatomid reproduction.

There are several possible explanations for male stink bugs being the pheromone-producing sex. For example, adult stink bugs are polyphagous and mobile, and they move into and out of habitats quickly (McPherson and McPherson, 2000). However, the details of the dynamics of these migrations are unknown, and it is possible that males are the pioneering sex in colonizing new habitats. Under such a scenario, males, upon finding a good habitat, might produce pheromones to attract females, with oviposition commencing within a day or so after copulation to the mutual benefit of both sexes. Alternatively, because parasitoids use bug semiochemicals as kairomones to locate their hosts (Aldrich, 1995), selective pressures may have favored males as the pheromone-producing gender.

Male Specific Compounds. The male-specific compounds produced by *C. uhleri* and *C. ligata* included two known terpenoid compounds, methyl (*R*)-3-(*E*)-6-2,3-dihydrofarnesoate and methyl (2*E*,6*E*)-farnesoate, and a new terpenoid natural product, methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate. The blends of male-specific compounds produced by the two species were remarkably similar, even to the extent that the absolute configuration (3*R*) of the major compound, methyl (*E*)-6-2,3-dihydrofarnesoate, was the same. In contrast, the two species are quite different morphologically, with *C. ligata* adults being dark brown or black with a band of orange or yellow outlining the body, whereas *C. uhleri* are green in color. Although detailed distribution records and habitat preferences are not available, these two species appear to share or at least overlap in ranges and host plants, and we have caught bugs of both species in the same field plots on the same day. The fact that the two species are sympatric, coupled with the apparently identical

pheromone blends, suggests that communication with pheromones is only part of the mate location system. Research on these (McBrien and Millar, unpublished data) and other species (Harris et al., 1982; Çokl, 1985; Kon et al., 1988; Ota and Çokl, 1991; Ryan and Walter, 1992; Jeraj and Walter, 1998; Miklas et al., 1999, Çokl et al., 2001) suggests that over shorter distances, mate location by phytophagous pentatomids involves species-specific and possibly even strain-specific substrate-borne vibrational signals (Ryan et al., 1996; Jeraj and Walter, 1998).

The blend of male-specific compounds produced by the congener *C. sayi*, which is morphologically very similar to and is frequently confused with *C. uhleri* (McPherson and McPherson, 2000), is entirely different from that produced by *C. uhleri* and *C. ligata.* The *C. sayi* blend is composed primarily of the monoterpenoid methyl geranate, with traces of methyl citronellate and methyl (*E*)-6-2,3-dihydrofarnesoate (Ho and Millar, 2001a), the latter being the only shared compound between *C. sayi* and the other two species. To our knowledge, these are the only reports of methyl (*E*)-6-2,3-dihydrofarnesoate being found in nature. It was first synthesized for treating liver disease (Yamatsu et al. 1981), and because of its structural similarity to insect juvenile hormones, it also has been used in the study of juvenile hormones (Campbell et al., 1998). The homolog, methyl (*E*)-5-2,6,10-trimethyl-5,9-undecadienoate, has never been reported from natural sources. Methyl farnesoate has been found to function as a juvenile hormone in crustaceans (Homola and Chang, 1997), but to our knowledge, it has never before been reported as an insect pheromone component.

In studying the dynamics of production of the male-specific compounds, it is unclear why they were detected in all of the *C. ligata* cohorts aerated but less than half of the *C. uhleri* cohorts. One possible explanation is that reproductive diapause, and the cessation of pheromone production, might be triggered easily in *C. uhleri*, despite the fact that the temperature, humidity, diet, and the length of the photophase (16L:8D) in the rearing room were constant. Even cohorts that failed to produce detectable levels of pheromone were not in complete reproductive diapause because mating did occur in the laboratory colonies. However, the close confines and relatively crowded conditions under which the bugs were reared may have precluded any need for the use of pheromones.

Laboratory Bioassays. Laboratory and field bioassays were complicated by the fact that females did not respond strongly to odors from conspecific males, to extracts from males, or to reconstructed blends of male specific compounds. Analogous problems have been reported during attempts to bioassay possible pheromone components for other phytophagous bug species. For example, blends of two male-specific compounds, *trans*- and *cis*-(*Z*)-bisabolene epoxide, were weakly attractive to female *Nezara viridula* in laboratory bioassays (Brézot et al., 1994). Despite the importance of this bug as a worldwide agricultural pest (Panizzi, 1997), there has been only a single short report of field bioassays of the pheromone, in which low numbers of bugs were attracted (Aldrich et al., 1993). Male-specific compounds

also have been identified from a number of *Euschistus* spp. (Aldrich et al., 1991), but field bioassays resulted in collection of less than one bug per trap-day (Aldrich et al., 1991; Borges et al., 1998b). Laboratory bioassays with *Euschistus heros* (Borges et al., 1998a), *E. obscurus* (Borges and Aldrich, 1994), and *Piezodorus hybneri* (Leal et al., 1998) also demonstrated that attraction of female bugs to male volatiles or synthetic pheromone components was relatively weak, with less than 50% of the individuals tested being attracted to the test treatments.

Field Bioassays. Several reports indicated that commonly used insect trap designs were not effective for phytophagous stink bugs and that bugs were frequently attracted to the vicinity of traps but not right into traps (Aldrich et al., 1991; Sugie et al., 1996). In perhaps the most extreme example, James et al. (1996) caught no spined citrus bugs (*Biprorulus bibax*) in pheromone-baited traps placed in citrus trees, but found that large numbers of bugs were attracted to trees containing traps. Consequently, instead of using traps of unknown efficacy, we decided to use a "trap plant" concept, in which the numbers of bugs on plants baited with pheromone lures or solvent controls were counted. Before deploying bioassays, in a pilot experiment run to determine the optimum time to conduct bug counts, female bugs were not seen close to lures in the early morning when temperatures were still cool, nor were they seen in the upper half of the plants close to the lures during the heat of the day. The optimal period for attraction, in agreement with the laboratory studies and with previously reported data from other species, appeared to be late afternoon through to darkness. Consequently, field tests were evaluated from about 17:00 hr until dark.

Field test results followed the same general pattern as that seen in the laboratory, with weak attraction of adult female bugs to lures. Several other points emerged. First, there were indications that lures also attracted male bugs; the number of males on baited plants was always higher than the number near controls, in all tests run. However, there may be an alternative explanation for this apparent attraction of males to pheromone lures. Males foraging for females may be attracted to or arrested on plants with females in response to cues associated with females, such as the shorter range substrate-borne vibrational cues described above. Further studies will be required to determine whether males are indeed attracted to the synthetic male pheromone or whether the apparent attraction is actually arrestment or attraction in response to female-produced cues. There was no indication that the lures were attractive to immature bugs, as has been reported for at least one other stink bug species (Aldrich et al., 1987).

It must be mentioned that the trap plant concept has limitations. First, bugs that were attracted to lure-baited plants in the late afternoon had disappeared by the next morning, indicating that the attraction is transient. Thus, if used as a bug monitoring strategy, trap plants would need to be checked consistently during late afternoon each day. Second, because bugs are free to move away from the lure-baited plants, counting the bugs on a trap plant provides a snapshot of one point

in time, rather than a cumulative count of all the bugs that have been attracted. Consequently, a trap plant strategy may be less sensitive than a method that retains most or all of the bugs attracted.

In total, the laboratory and field bioassay data provide strong evidence that one or more of the *C. uhleri* and *C. ligata* male-specific compounds are sex pheromone components. Because of the weak attraction to the male-produced compounds, and despite laboratory and field bioassay attempts extending over several years, it remains to be determined whether the male-produced pheromones consist of the single component methyl (*E*)-6-2,3-dihydrofarnesoate, or a blend of this compound with minor male-specific components. Efforts to address this question are continuing, in parallel with trap development and study of stink bug substrate-borne vibrational signals.

(Received December 26, 2000; accepted June 12, 2001)

Abstract—Five candidate pheromone components were identified by analyzing pheromone gland extracts by gas chromatography (GC), coupled GC-electroantennographic detection (EAD), and coupled GC-mass spectrometry (MS): (*E*)-11-hexadecenol(*E*11–16 : OH), (*Z*)-11-hexadecenol (*Z*11–16 : OH), (*E*)-11-hexadecenal, (*E*)-11-hexadecenyl acetate, and (*Z*)-3,(*Z*)-6,(*Z*)-9-tricosatriene (*Z*3,*Z*6,*Z*9–23 : Hy). In electroantennogram (EAG) recordings, synthetic *E*11–16 : OH elicited stronger antennal responses at low doses than other candidate pheromone components. Field tests demonstrated that synthetic *E*11–16 : OH as a trap bait was effective in attracting males, whereas addition of *Z*11–16 : OH inhibited the males' response. *Z*3,*Z*6,*Z*9–23 : Hy strongly enhanced attractiveness of *E*11–16 : OH, but was not attractive by itself. A pheromone blend with synergistic behavioral activity of an alcohol (*E*11–16 : OH) and hydrocarbon (*Z*3,*Z*6,*Z*9–23 : Hy) component is most unusual in the Lepidoptera. The synthetic two-component pheromone is approximately 60 times more attractive than the female-produced blend and might facilitate the control of this pest.

Key Words—*Neoleucinodes elegantalis*, Lepidoptera, Crambidae, sex pheromone, (*E*)-11-hexadecenol, (*Z*)-3,(*Z*)-6,(*Z*)-9-tricosatriene, (*Z*)-11-hexadecenol, GC-EAD, tomato.

INTRODUCTION

The tomato fruit borer, *Neoleucinodes elegantalis* (Lepidoptera: Crambidae), is one of the most important economic pests of tomato (*Lycopersicum esculentum*) crops in tropical South America. Current control tactics include frequent applications of pesticides (Reis and Souza, 1996) that may lead to the development of insecticide resistance. Moreover, once larvae have entered the fruit, pesticides and biological control agents are ineffective. Pheromone-based mating disruption represents an alternative tactic to manage this pest insect but requires identification of the female-produced sex pheromone. We know that virgin females attract males in the field (Mirás et al., 1997), and extracts of abdominal tips with pheromone glands from virgin females attract males in wind tunnel bioassays (Eiras, 2000). Here we report identification, electrophysiological studies, and field experiments of sex pheromone components of *N. elegantalis.*

METHODS AND MATERIALS

Insects. Tomato fruits infested with *N. elegantalis* larvae were collected in commercial tomato crops in the states of Lara and Aragua, Venezuela, and in Rio de Janeiro, Brazil. Fruits were kept in plastic containers until larvae emerged from the fruit to pupate. Adult insects were maintained according to Eiras (2000). During peak calling activity, abdominal tips with pheromone glands of 2-to 3-day-old virgin female moths were removed and extracted for 10–15 min in hexane. The supernatant was withdrawn and stored in microcapillaries at -15°C.

Chemical Analyses. Pheromone extracts were subjected to gas chromatographic (GC) and coupled GC-electroantennographic detection (EAD) analyses, using a Hewlett Packard 5890A gas chromatograph equipped with fused silica columns (30 m $\times$ 0.25 or 0.32 mm ID) coated with DB-5, DB-210, or DB-23 (J&W Scientific, Folsom, California). Forty female equivalents of pheromone gland extract were also analyzed by coupled GC-mass spectrometry (MS), employing a Perkin Elmer QMass-910 attached to a GC-Autosystem 2000, equipped with a DB-5 column (25 m $\times$ 0.18 mm ID, Quadrex, New Haven, Connecticut).

The position and geometry of a double bond in an EAD-active hexadecenol were determined by: (1) GC-EAD analyses of synthetic hexadecenols (*E*2 to *E*14 and *Z*2 to *Z*14); (2) derivatization of extract with *m*-chloroperbenzoic acid (Bierl-Leonhardt et al., 1980), followed by GC-MS analysis of the resulting epoxide; and (3) acetylation of pheromone extract with acetic anhydride and

pyridine, followed by GC analyses [HP-GC equipped with a SP-1000-coated column (30 m × 0.25 mm ID; Supelco, Bellefonte, Pennsylvania)] with improved chromatographic resolution of the acetylated alcohol and synthetic acetate standards.

Effluvia of calling, 1- or 2-day-old female *N. elegantalis* were adsorbed on a solid-phase microextraction (SPME) fiber coated with 100 μm polidimethylsiloxane (Supelco). The fiber was exposed to a female during the entire calling period and then desorbed at the capillary injection port (270°C) of the GC equipped with columns (30 m × 0.25 mm ID or 25 m × 0.18 mm ID; Quadrex, New Haven, Connecticut) coated with methyl–5% phenyl silicone or Carbowax 20 M. Retention characteristics of female-produced, fiber-desorbed compounds were compared with those of authentic standards.

Electrophysiology. Electroantennogram (EAG) recordings were carried out, using a Syntech EAG system (NL-1200 BM Hilversum; The Netherlands). Five compounds (*E*11–16 : OH, *Z*11–16 : OH, *E*11–16 : OAc, *E*11–16 : Ald, and *Z*3,*Z*6,*Z*9–23 : Hy) at increasing logarithmic doses (10 to 10^6 ng) were tested with each of five 48- to 72-hr-old male antennae. An antenna was stimulated by subjecting it to puffs (0.5 sec) of purified and humidified air (1.5 liters/min) delivered through a Pasteur pipet (15 cm long), containing a filter paper strip (1 × 5 cm) impregnated with 50 μl of a test solution. Air puffs from an empty pipet, pipet plus filter paper, or filter paper plus solvent served as control stimuli.

Syntheses. (*Z*)-9,(*Z*)-12,(*Z*)-15-octadecatrien-1-ol (99%) was synthesized from methyl linolenate after reduction with $LiAlH_4$. This alcohol was oxidized with pyridinium chlorochromate (PCC) to afford (*Z*)-9,(*Z*)-12,(*Z*)-15-octadecatrienal (98%). *n*-Pentyl magnesium bromide was added to a solution of this aldehyde in anhydrous ether to obtain 6-hydroxy-(*Z*)-14,(*Z*)-17,(*Z*)-20-tricosatriene. A solution of this compound in anhydrous pyridine was treated with methane sulfonyl chloride (Kocovský and Cerný, 1978). The obtained mesylate was reduced with zinc dust and sodium iodide (Kocovský and Cerný, 1978) to obtain (*Z*)-3,(*Z*)-6,(*Z*)-9-tricosatriene, which was purified (>99%) by flash silica column chromatography using *n*-hexane as eluent. ^{1}H NMR (ppm; δ): 5.35 (m), 2.80 (t), 2.05 (m), 1.25 (m), 0.95 (t) 0.85 (t); EI-MS [*m*/*z* (relative intensity)]: 79 (100); 108 (98); 67 (49); 93 (48); 262 (6); M^+ 318 (2).

Sources of Candidate Pheromone Components. (*E*)-11-Hexadecenol (*E*11–16 : OH) was obtained from the Research Institute for Plant Protection (IPO-DLO), Wageningen, The Netherlands; (*Z*)-11-hexadecenol (*Z*11–16 : OH) was purchased from Aldrich Chem. Co. (Milwaukee, Wisconsin); (*E*)-11-hexadecenyl acetate (*E*11–16 : OAc) was prepared by acetylation of *E*11–16 : OH with acetic anhydride and pyridine; (*E*)-11-hexadecenal (*E*11–16 : Al) was prepared by oxidation of E11-hexadecenol with PCC in dichloromethane; (*Z*)-3,(*Z*)-6,(*Z*)-9-tricosatriene (*Z*3,*Z*6,*Z*9–23 : Hy) was synthesized as described above. All compounds were >98% chemically pure.

Field Experiments. Field experiments were conducted in commercial tomato plantations in Aragua State, Venezuela, employing a complete randomized block design. Water traps (Mirás et al., 1997) were suspended ~1 m above ground at 20-m intervals and baited with red rubber septa (Aldrich Chemical Co., Milwaukee, Wisconsin, catalog No. *Z*12,434-6) that were Soxhlet-extracted with ethanol for 24 hr, and impregnated with candidate pheromone components in HPLC-grade dichloromethane. Location, experimental period, and number of replicates for each experiment are reported in the captions of Figures 3 and 4 below.

Experiment 1 tested traps baited with *E*11–16 : OH (1 mg) and *Z*11–16 : OH (1 mg), singly and in binary combination at ratios of 1 : 0.1 and 1 : 0.01 mg. Solvent-impregnated rubber septa served as baits in control traps. Both experiments 2 and 3 tested traps baited with two virgin females or *E*11–16 : OH (1 mg). Experiment 4 tested traps baited with *Z*3,*Z*6,*Z*9–23 : Hy (1 mg) or *E*11–16 : OH (1 mg) singly, and *E*11–16 : OH (1 mg) in binary combinations with *Z*3,*Z*6,*Z*9–23 : Hy (0.025, 0.05, or 0.1 mg) and in penternary combination with *Z*11–16 : OH (0.07 mg), *E*11–16 : Ald (0.02 mg), *E*11–16 : OAc (0.02 mg), and *Z*3,*Z*6,*Z*9–23 : Hy (0.04 mg) at ratios as determined in pheromone gland extract. Experiment 5 tested traps baited with *E*11–16 : OH (1 mg) in binary combinations with *E*11–16 : OAc (0.05 mg), *E*11–16 : Ald (0.05 mg), or *Z*3,*Z*6,*Z*9–23 : Hy (0.05 mg), in ternary combination with *E*11–16 : OAc (0.05 mg), and *E*11–16 : Ald (0.05 mg), and in quaternary combination with *E*11–16 : OAc (0.05 mg), *E*11–16 : Ald (0.05 mg), and *Z*3,*Z*6,*Z*9–23 : Hy (0.05 mg). Experiment 6 tested traps baited with *E*11–16 : OH (1mg) singly, and in combination with *Z*3,*Z*6,*Z*9–23 : Hy (0.05 mg).

Statistical Analysis. Multivariate analysis with the using Mann-Whitney test (Spiegel, 1991) was performed to analyze data from field tests.

RESULTS

Pheromone Identification. GC-EAD analysis of pheromone gland extracts of female *N. elegantalis* revealed six components that elicited an antennal response (Figure 1). The most abundant and EAD-active component **2** (Figure 1) was hypothesized to be a hexadecenol, based on its retention indices on DB-5 (1865), DB-210 (2078), and DB-23 (2406) columns. Position and geometry of the double bond was approximated by comparative GC and GC-EAD analyses of synthetic hexadecenols. (*E*)-11- and (*E*)-12-hexadecenol (*E*11- and *E*12–16 : OH) had retention times identical to, and EAD-activity comparable with, female-produced **2**. Epoxidation (Bierl-Leonhardt et al., 1980) of female-produced **2**, and GC-MS analysis of the epoxy alcohol revealed fragmentation ions at *m/z* 99 and 199 (due to α-cleavage of the epoxy group), confirming the double bond at C-11. GC-EAD analyses of pheromone extract on a DB-23 column, which separates the *E* and *Z* isomers, provided tentative evidence also for trace amounts of the *Z* isomer.

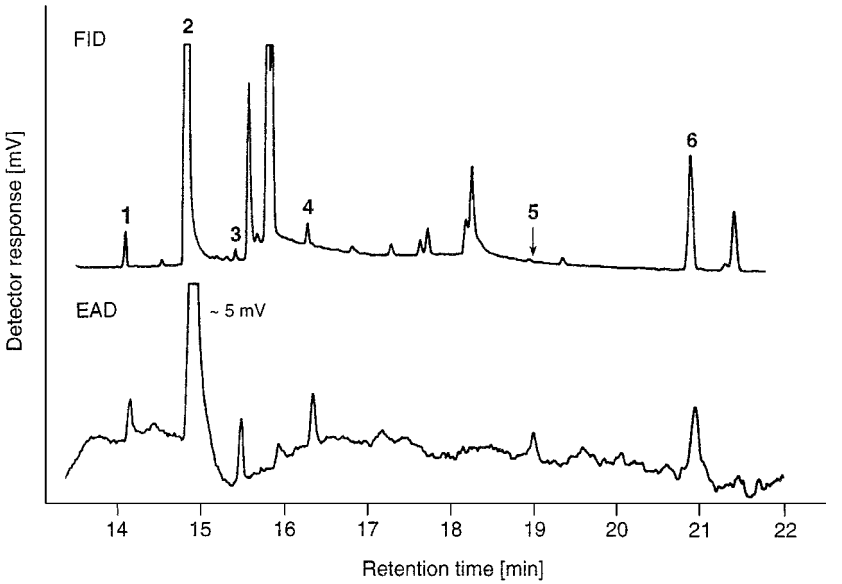

FIG. 1. Flame ionization detector (FID) and electroantennographic detector (EAD: male *N. elegantalis* antenna) responses to one female equivalent of pheromone gland extract, chromatograph on a DB-5 column; temperature program: 100°C (1 min) then 10°C/min to 240°C. Compound identity as follows: 1 = (*E*)-11-hexadecenal (*E*11–16 : Ald); 2 = (*E*)-11-hexadecenol (*E*11–16 : OH); 3 = unknown; 4 = (*E*)-11-hexadecenyl acetate (*E*11–16 : OAc); 5 = unknown; 6 = (*Z*)-3,(*Z*)-6,(*Z*)-9-tricosatriene (*Z*3, *Z*6, *Z*9-23 : Hy). Note: GC-EAD analyses of pheromone extract on a DB-23 column, which separated *E* and *Z* isomers of candidate pheromone components, provided tentative evidence also for trace amounts of (*Z*)-11-hexadecenol (*Z*11–16 : OH).

EAD-active **1** and **4** (Figure 1) were hypothesized and, through comparative GC analyses of authentic standards, confirmed to be *E*11–16 : Ald (**1**) and *E*11–16 : OAc (**4**). Mass spectrum and retention indices of EAD-active **6** were indicative of an triunsaturated C_{23} hydrocarbon, such as *Z*3,*Z*6,*Z*9–23 : Hy (Bell and Meinwald, 1986). Identical retention and mass spectrometric characteristics of an authentic standard and female-produced **6** confirmed this structural assignment. EAD-active compounds **3** and **5** occurred below detection threshold of the flame ionization detector and are yet to be identified.

In GC analyses of SPME-desorbed volatiles, small amounts of *E*11–16 : OH and *Z*3,*Z*6,*Z*9–23 : Hy could be detected.

Electrophysiology. Synthetic equivalents of candidate pheromone components evoked significant EAG responses. *E*11–16OH was most EAG-active and, unlike other test stimuli, elicited >5 mV EAG responses from male antennae already at a 10 ng dose (Figure 2). *Z*11–16 : OH, *E*11–16 : OAc, *E*11–16 : Ald,

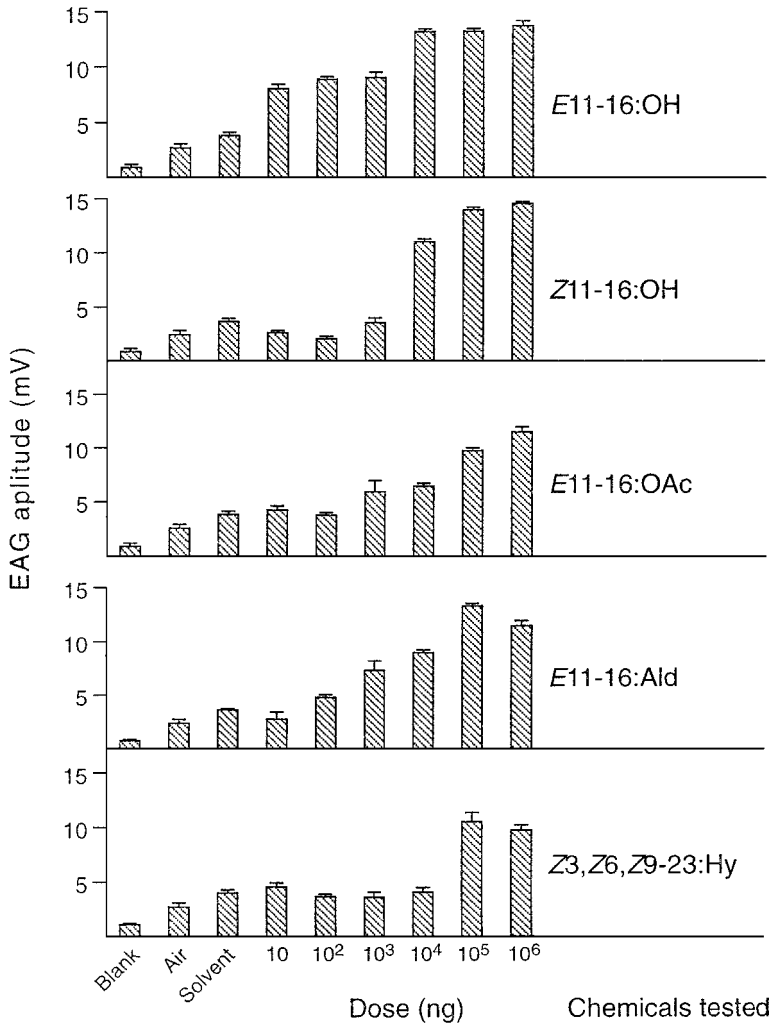

FIG. 2. Responses by male *N. elegantalis* antennae in electroantennogram (EAG) recordings to increasing amounts of five candidate pheromone components; compound nomenclature as in Figure 1.

and *Z*3,*Z*6,*Z*9–23 : Hy required doses of 10^4, 10^3, 10^2, and 10^5 ng, respectively, to induce EAG voltages greater than those of control stimuli (Figure 2).

Field Tests. Traps baited with *E*11–16 : OH captured significant numbers of male moths (Figure 3, experiment 1). *Z*11–16 : OH, in contrast, was not attractive and, when added to *E*11–16 : OH, strongly reduced captures of males. Traps baited

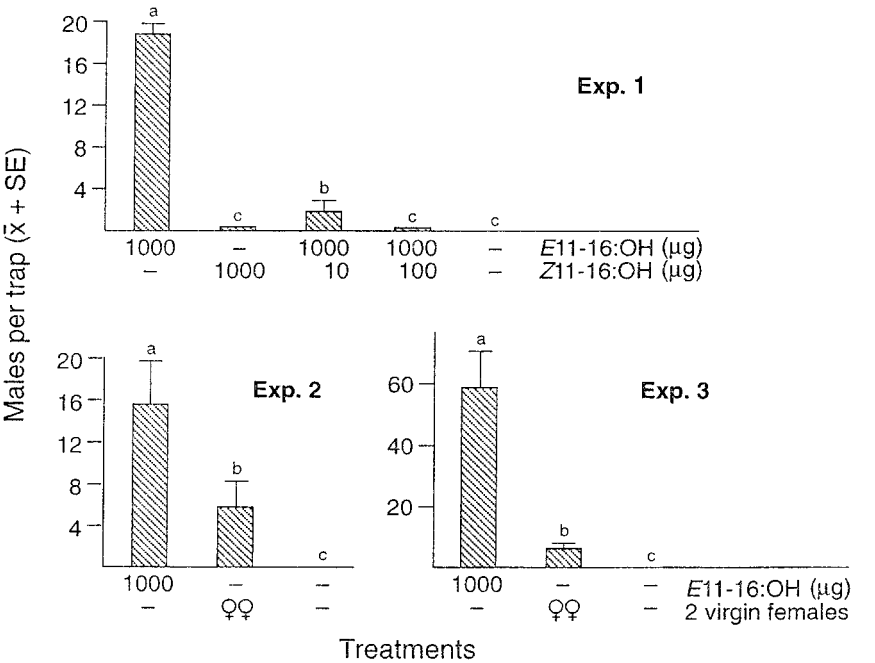

FIG. 3. Captures of male *N. elegantalis* in experiments 1–3 in water traps baited with two virgin female *N. elegantalis* or candidate pheromone components singly and in various combinations. Experiment 1: Casablanca, Aragua State; October 16–December 1, 1996; four replicates. Experiment 2: Casablanca, Aragua State; December 5–19, 1996; 7 replicates. Experiment 3: Múcura, Aragua State; February 15–20, 1997; 4 replicates. In each experiment, bars with the same letter superscript are not significantly different, $P > 0.05$.

with *E*11–16 : OH at 1 mg captured more males than those baited with two virgin female moths (Figure 3, experiments 2, and 3). *Z*3,*Z*6,*Z*9–23 : Hy enhanced attractiveness of *E*11–11 : OH, but was not attractive by itself (Figure 4, experiment 4). *E*11–16 : OH plus *Z*3,*Z*6,*Z*9–23 : Hy was the most attractive blend among several two-, three-, or four-component blends of candidate pheromone components (Figure 4, experiment 5). Synergistic activity of *Z*3,*Z*6,*Z*9–23 : Hy was confirmed in experiment 6 (Figure 4).

DISCUSSION

Our data show that *E*11–16 : OH and *Z*3,*Z*6,*Z*9–23 : Hy are sex pheromone components in *N. elegantalis*. Evidence in support of this conclusion includes the following: (1) both compounds were present and EAD-active in pheromone

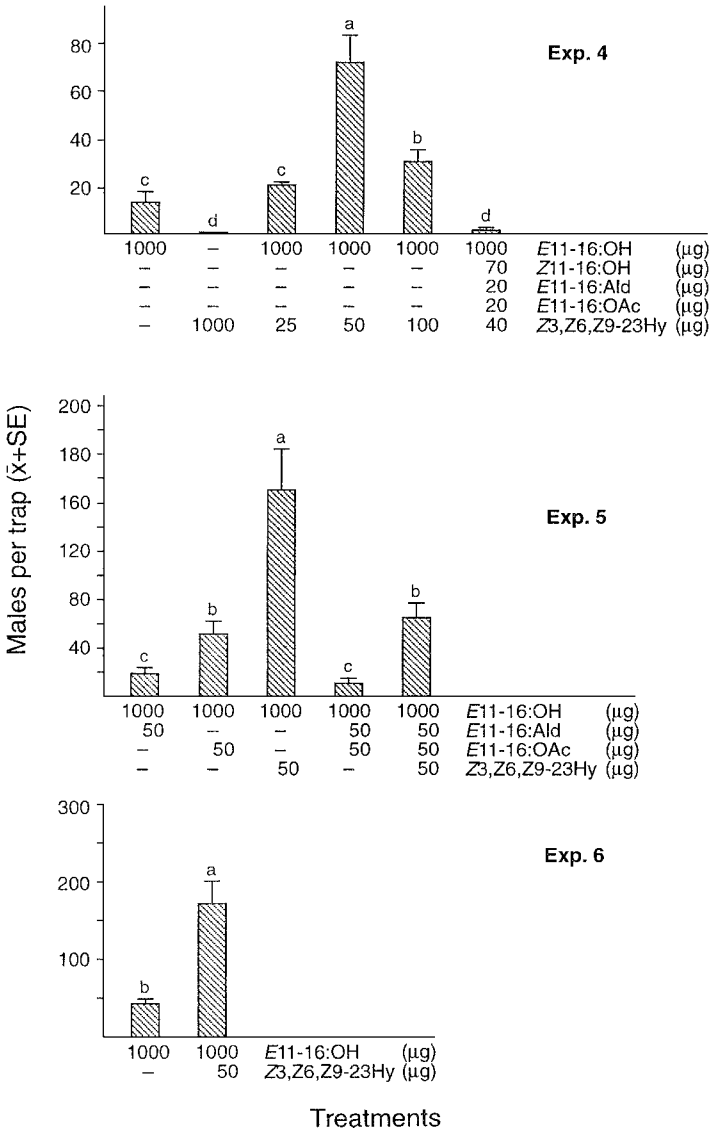

FIG. 4. Captures of male *N. elegantalis* in experiments 4–6 in water traps baited with candidate pheromone components singly and in various combinations. Experiment 4: Pao de Zárate, Aragua State; June 23–August 3, 1998; 5 replicates. Experiment 5: Valle de Tucutunemo, Aragua State; February 5–March 26, 1999; 5 replicates. Experiment 6: Pao de Zárate, Aragua State; July 3–25, 2000, 10 replicates. In each experiment, bars with the same letter superscript are not significantly different, $P > 0.05$.

gland extracts and effluviums of female moths (Figure 1); (2) identifications were based on comparative GC, GC-MS, and GC-EAD analyses of female-produced compounds and authentic standards; (3) both compounds elicited stronger antennal responses from male antennae in EAG recordings than did control stimuli (Figure 2); and (4) blends of *E*11–16 : OH and *Z*3,*Z*6,*Z*9–23 : Hy attracted significant numbers of males (Figure 4). *E*11–16 : OH is the major pheromone component, because it was most abundant in gland extracts (Figure 1), elicited the strongest EAG response at low doses (10 or 100 ng) (Figure 2), and, unlike *Z*3,*Z*6,*Z*9–23 : Hy, was attractive by itself as a bait (Figures 3 and 4).

*E*11–16 : OH has also been identified as a sex pheromone component in other moths. It is the major pheromone component of the pod worm, *Leucinodes orbonalis* (Zhu et al., 1987; Attygalle et al., 1988), and a minor pheromone component of female pickleworms *Diaphania hyalinata* and *D. nitidalis* (Raina et al., 1986; Klun et al., 1986). It was also present in pheromone gland extracts of eggfruit caterpillar, *Sceliodes cordalis* (Clearwater et al., 1986) and of sugarcane borer, *Sesamia grisescens* (Whittle et al., 1995), but behavioral activity of *E*11–16 : OH in these two species is yet to be determined.

*Z*3,*Z*6,*Z*9–23 : Hy is reported here for the first time as a sex pheromone component in the Lepidoptera. While it was identified as a trace component in pheromone glands of the arctiid moth *Creatonotos gangis* (Bell and Meinwald, 1986), behavioral activity was not determined. A sex pheromone blend with synergistic behavioral activity between a triene hydrocarbon (*Z*3,*Z*6,*Z*9–23 : Hy) and an alcohol (*E*11–16 : OH), as demonstrated in our study, is most unusual. Most triene hydrocarbons as pheromone components in the Lepidoptera are either attractive by themselves (Millar et al., 1992) or serve as synergists of corresponding diene epoxides (Tóth et al., 1994).

Further compounds (*Z*11–16 : OH, *E*11–16 : Ald, *E*11–16 : OAc) in pheromone gland extracts of female *N. elegantalis* seem to have no pheromonal activity. This conclusion is based on their low EAG activity at low doses (Figure 2) and/or lack of attractiveness in field experiments. The role of *Z*11–16 : OH is interesting. Its low EAG activity but strong behavioral inhibition at a low dose (Figures 2 and 3) suggests that mate-seeking males may select calling females based on the presence or absence of *Z*11–16 : OH in the pheromone effluvium, providing a basis for a highly efficient system of sexual selection (Jaffe, 1996, 1998, 1999), as only very fit females would produce *E*11–16 : OH with small amounts of *Z*11–16 : OH. Alternatively, *Z*11–16 : OH may serve as a bifunctional pheromone component (Linn and Roelofs, 1995) in a sympatric species to enhance the specificity of the communication signal, although no such sympatric species is known.

The two-component pheromone blend of *E*11–16 : OH and *Z*3,*Z*6,*Z*9–23 : Hy seems to work as a supernormal stimulus (Tinbergen and Perdeck, 1950), as it is approximately 60 times more attractive than the natural pheromone blend emitted by the females (Experiments 3 and 4, in Figures 3 and 4, respectively).

A synthetic mixture of *E*11–16 : OH and *Z*3,*Z*6,*Z*9–23 : Hy as a trap bait is currently used by Brazilian and Venezuelan tomato growers to reduce infestations of *N. elegantalis*, promising efficient control in pheromone-based mass trapping programs.

(Received December 19, 2000; accepted June 1, 2001)

Abstract—An indoor mating disruption experiment was performed on the stored-product pest *Plodia interpunctella*. The female of this species emits a four-component pheromone blend consisting of *Z*9,*E*12–14 : OAc, *Z*9,*E*12–14 : OH, *Z*9,*E*12–14 : Ald, and *Z*9–14 : OAc. Mating of *Plodia interpunctella* was disrupted up to 93% by using synthetic pheromone in small-scale plot experiments. The study was performed in 2.5 m × 2.5 m × 2.5 m polythene cubicles housed in a greenhouse, and pheromones were released by MSTRS spraying every 15 min. The disruption effect was tested at different doses 0.075, 0.75, and 3.75 mg/spray (corresponding to 5, 50, and 250 μg/min), different pheromone formulas (one-component (*Z*9,*E*12–14 : OAc) and four-component), and at different population densities (10, 20, and 30 individuals, equivalent to 0.32, 0.64, and 0.96 individuals/m^2). The moths were released into the cubicles and recaptured 24 hr later. The females were checked for spermatophore presence indicating successful mating. The mating was significantly suppressed in all treatments compared to the control. There was, however, no difference in mating activity between the one-component and four-component disruptants. In addition, EAG measurements were conducted with a portable device to keep track of aerial concentrations of pheromone. The results show that the one-component formula disrupts mating as efficiently as the more complete four-component blend at doses applied in this study. This fact improves the prospects for mating disruption of indoor pyralids, since many pyralid species share the major component in their pheromones, and, thus, can probably be controlled simultaneously by using this compound only.

Key Words—*Plodia interpunctella*, Lepidoptera, Pyralidae, stored-product, EAG, mating disruption, electroantennography.

INTRODUCTION

Male upwind flight in response to the female sex pheromone release in moths can be disrupted by emission of large quantities of synthetic pheromones. Mating disruption has been successfully used for population control in many cases. The Oriental fruit moth (*Grapholita molesta*) is controlled by means of mating disruption in France, Spain, Italy, China, and Brazil (Cardé and Minks, 1995). Pink bollworm (*Pectinophora gossypiella*) populations have been successfully reduced with the mating disruption technique in the United States (Staten et al., 1987). The success, however, varies depending on dispensers (Thorpe et al., 1999), pheromone formula (Evenden et al., 1999), number and type of dispensers (Sauer and Karg, 1998), and population dynamics of the target species (Cardé and Minks, 1995).

Several mechanisms have been suggested to be responsible for mating disruption in moths. Sensory fatigue can be caused either by adaptation of the peripheral receptors on the antennae or habituation at the central nervous level. It could also be that the synthetic pheromones camouflage the females' pheromone plumes and, thus, make it more difficult for the male to locate a calling female. Pheromone point sources may compete with pheromone plumes from calling females, thus creating a "false-trail following" by the males (Cardé and Minks, 1995).

One of the world's most important stored-product pest insects is the Indian meal moth [*Plodia interpunctella* (Hübner); Lepidoptera: Pyralidae]. The larvae feed on fruits, nuts, cereals, legumes, and other food products, causing large economic losses due to infestations (Phillips, 1994). *P. interpunctella* is a species that is highly resistant to insecticides, such as pyrethrine and malathion, which makes it a target for alternative control methods (Arthur et al., 1988). Insecticide resistance (Halliday and Zettler, 1988) and restrictions on the use of insecticides because of human health concerns have stimulated research on the applicability of pheromones and integrated pest management (IPM).

The sex pheromone emitted by female *P. interpunctella* was first identified as (*Z*,*E*)-9,12-tetradecadienyl acetate (*Z*9,*E*12–14 : OAc) by Kuwahara et al. (1971b) and Brady et al. (1971). Additional pheromone components have since been identified. However, a recent reinvestigation of the pheromone and associated behavioral studies revealed that the female emits at least three additional components (Zhu et al., 1999, and references therein). The three components are (*Z*,*E*)-9,12-tetradecadienol (*Z*9,*E*12–14 : OH), (*Z*,*E*)-9,12-tetradecadienal (*Z*9,*E*12–14 : Ald), and (*Z*)-9-tetradecenyl acetate (*Z*9–14 : OAc). The four components were reported in a blend ratio of 100 : 7 : 16 : 6, respectively, and are all important for maximum male attraction and upwind flight (Zhu et al., 1999).

Stored-product pest insects are characterized by inhabiting indoor localities, and if they occur outside storage facilities, they are not considered pests due to the

lower population levels. Few studies have focused on the use of mating disruption for control of stored-product pests in indoor facilities, even though the conditions for mating disruption indoors have some advantages. Outdoors, migrating males attracted to an area with a higher pheromone release can decrease the success of mating disruption. Gravid females, who are mated outside a treated area, may be able to immigrate into the area to oviposit. The storage facilities create natural boundaries that limit these outdoor constraints, even though contaminated food products transported into storage facilities may act as boundaries, producing vectors for adults and larvae. However, if an already established mating disruption method together with other methods for control are available, an increase in population would be made difficult.

Early studies on pheromone-based control of stored-product pests were conducted almost exclusively under laboratory conditions, using boxes or cages (Brady and Daley, 1975). One study by Mafra-Neto and Baker (1996) concerns mating disruption of the almond moth [*Cadra (Ephestia) cautella*], in which they were able to disrupt mating by 100% in free flying moths for 24 hr and by 92% for 72 hr. The study was conducted in rooms of $3 \times 3 \times 3$ m. The disruption was independent of moth population densities and the use of one or two dispensers (Mafra-Neto and Baker, 1996).

The attraction of males is usually improved with the identification of additional pheromone components in moth species (Zhu et al., 1999). The mechanism of disruption and the efficiency in mating disruption with more complete blends are not yet fully understood. However, indications that more complex blends are not necessarily more efficient in mating disruption have been reported. Evenden et al. (1999) found that the use of a more complex blend did not yield a higher mating disruption in the oblique-banded leafroller (*Choristoneura rosaceana*).

By using mating disruption techniques similar to those that Mafra-Neto and Baker (1996) used to disrupt *E. cautella*, we wanted to see whether it was possible to disrupt the mating of free-flying *P. interpunctella* and if a higher mating disruption effect was obtained by using the recently identified Four-component blend compared to the major pheromone component (*Z*9,*E*12–14 : OAc) alone at different emission rates and population densities.

METHODS AND MATERIALS

Insects. P. interpunctella moths were taken from a culture maintained at the Department of Ecology, Lund University, Lund, Sweden. The culture originates from the Danish Pest Infestation Laboratory, Lyngby, Denmark. Additional moths have been incorporated from a laboratory culture provided by The Central Science Laboratory, Slough, England. Larvae were reared on an artificial diet consisting of

100 g wheat germ, 10 g brewer's yeast, and 20 g glycerol. Insects were separated by sex during the pupal stage (Zhu et al., 1999). Emerged males and females were kept in separate environmental chambers at 23°C and 60% relative humidity with a 17L : 7D photoperiod.

Chemicals. The synthetic compounds *Z*9,*E*12–14 : OAc, *Z*9,*E*12–14 : OH, and *Z*9–14 : OAc were purchased from Bedoukian Research Inc., Danbury, US, Connecticut. *Z*9,*E*12–14 : Ald was synthesized from *Z*9,*E*12–14 : OH (described in Zhu et al., 1999) at the Department of Organic Chemistry, Royal Institute of Technology, Stockholm, Sweden.

Two disruptants were used: *Z*9,*E*12–14 : OAc alone or in a Four-component blend consisting of *Z*9,*E*12–14 : OAc, *Z*9,*E*12–14 : OH, *Z*9,*E*12–14 : Ald, and *Z*9–14 : OAc in the proportions 100 : 7 : 16 : 6, as described in Zhu et al. (1999). Disruptants were diluted in 95% ethanol to correspond to emission rates of 5, 50, and 250 μg/min of the main component *Z*9,*E*12–14 : OAc.

Pheromone Releasing System. The synthetic pheromone was emitted from MSTRS dispensers set at spraying approximately 70 μl/spray every 15 min. all day, giving off 0.075, 0.750, or 3.75 mg/spray of the main component (*Z*9,*E*12–14 : OAc) depending on the experiment (Table 1). The pheromone was sprayed onto an acrylic pad stretched out on a needlepoint frame (15 cm InD) positioned 20 cm from the nozzle of the pheromone canister (Mafra-Neto and Baker, 1996). The pad, in turn, emitted the pheromone between sprays. The MSTRS advantages are controlled emissions, even in conditions with high temperature fluctuations, and that the canister is airtight, which will decrease the risk of oxidizing sensitive pheromone components such as aldehydes.

Experimental Sites. The experiments were conducted in transparent polythene cubicles, measuring 2.5 × 2.5 × 2.5 m, with zip-lock entries (The Central Science Laboratory, Slough, England). Cubicles were in a greenhouse at the Swedish Agricultural University in Alnarp, Sweden. Different treatments were conducted in separate rooms (6 × 3 m^2), two cubicles per room. Two net-covered holes (10 × 15 cm^2) were cut out from the walls of the cubicles, one at the bottom and one at the top of the opposite wall of the cubicle, in order to create a passive ventilation system. The control cubicles did not contain any pheromone dispensers, except when testing 0.75 and 3.75 mg/spray of the Four-component blend (trial 3), where we put a dispenser spraying only 95% ethanol every 15 min to see if mating activity was affected by the solvent. Different blends, emission rates, and densities of moths were used as described in Table 1. Due to the limited number of cubicles and rooms, we used the same cubicles for different pheromone treatments. However, we always went from lower to higher doses and from One-component to Four-component blends when reusing the same cubicles. A month passed between changing from the emission rate of 3.75 to 0.75 mg/spray of Four-component blend, during which the cubicles were thoroughly aired out (between trials 3 and 4, Table 1).

TABLE 1. ORDER OF TREATMENTS AND ANIMAL DENSITIES[a]

	Treatment A			Treatment B		
Trial	Disruptant	Emission rate (mg/spray)	Density (males + females)	Disruptant	Emission rate (mg/spray)	Density (males + females)
1	1-component	0.075	10 + 10	4-component	0.075	10 + 10
2	1-component	0.75	10 + 10	1-component	3.75	10 + 10
3	4-component	0.75	10 + 10	4-component	3.75	10 + 10
4	1-component	0.75	5 + 5	1-component	0.75	15 + 15
5	4-component	0.75	5 + 5	4-component	0.75	15 + 15

[a] Treatments and control consisted of two cubicles each. Doses refer to amount of *Z*9,*E*12–14 : OAc in both one-component and four-component blends. The controls contained no synthetic pheromone. The control cubicles in trial 3 contained a MSTRS spraying only the solvent (ethanol).

Experimental Design. One MSTRS device was placed in the middle of each treatment cubicle on a stand approximately 1 m high and was set to spray synthetic pheromone at least 24 hr before introducing insects. Male and female *P. interpunctella* were randomly picked from the laboratory culture at 2–4 days old. The females and males were held separately until introduced into the cubicles. The animals were left in the cubicles for 24 hr, and they were then picked from the walls and put in individual vials. New males and females were then released, and the procedure was repeated for five or six consecutive days. The recaptured animals were immediately brought to the laboratory, where they were frozen, and the females were later dissected under a microscope to determine the presence of spermatophore, indicating mating (Mafra-Neto and Baker, 1996). The disruption effect was calculated as: [(mating frequency$_{\text{control}}$ − mating frequency$_{\text{treatment}}$)/mating frequency$_{\text{control}}$] × 100 Three different population densities were tested—10, 20, and 30 individuals in total—with males and females in equal numbers.

EAG Recordings. A portable EAG device was provided by Syntech/VDP Laboratories, Hilversum, The Netherlands. We used the apparatus to monitor pheromone accumulation and relative doses in different treatment cubicles as well as for checking that the control cubicles were not contaminated. A freshly excised antenna from a 0-to 1-day-old male was mounted in the airtight holder and the two ends of the antenna covered with electrically conductive gel (Spectra 360, Parker Laboratories, Orange, New York), making a bridge over the central hole. A rubber septum acting as a reference stimulus was treated with 10 μg of *Z*9,*E*12–14 : OAc. A continuous flow (0.5 m/sec) of air, cleaned through an activated charcoal filter, maintains the nonstimulated condition of the antenna, forming the baseline. Each recording consisted of reference recording (R_1) (0.3 sec), ambient air recording (A) (0.3 sec), and reference recording (R_2) (0.3 sec) with 5-sec intervals. Relative EAG responses were calculated as: $\{(A/[(R_1 + R_2)/2])\} \times 100$.

For detailed information about the EAG device, see Van der Pers and Minks (1998). The EAG responses were continuously recorded as a frequency modulated signal on a portable audio tape recorder (SONY TDC-D7) and later stored and analyzed on a PC equipped with an IDAC card and the program EAG version 2.2a (both from Syntech, Hilversum, The Netherlands).

All insects were removed from the cubicles prior to recordings. Eight recordings were made for each treatment (four in each cubicle), starting in control cubicles and moving into cubicles with higher concentrations or from one-component to four-component treatments. A time period between two recordings was at least 30 sec to let the antenna recover from adaptation, and the time to move from one cubicle to another was approximately 1–2 min . Since the four measurements in one cubicle are pseudoreplicates, only the mean value of the recordings was calculated and used. Measurements were conducted at the beginning and at the end in 0.75 mg/spray of one-component and 0.75 mg/spray of four-component treatments (trials 2 and 3).

Statistical Analysis. The proportional difference in mating frequency among treatments as well as the difference in disruption effects was analyzed with ANOVA, on arcsin $\sqrt{x}$-transformed data.

RESULTS

Blend and Emission Rate Effects. No statistical differences in mating disruption effect could be observed between the one-component and four-component disruptants, in either 0.075, 0.750, or 3.75 mg/spray (Figure 1). The single component in the 0.075 mg/spray suppressed mating by 80 ± 3%, and the four-component blend disrupted the mating by 78 ± 6% (Figure 1). The mating frequency was lower in both treatments compared to the control (ANOVA; $F_{2,32} = 113.69$; $P < 0.001$). Tukey's post-hoc test showed a significant effect between treatments and control in mating frequency ($P < 0.001$), but a non-significant effect among the treatments. The mating frequencies in the different treatments were: 79 ± 3% (control), 16 ± 3% (one-component), 17 ± 4% (four-components).

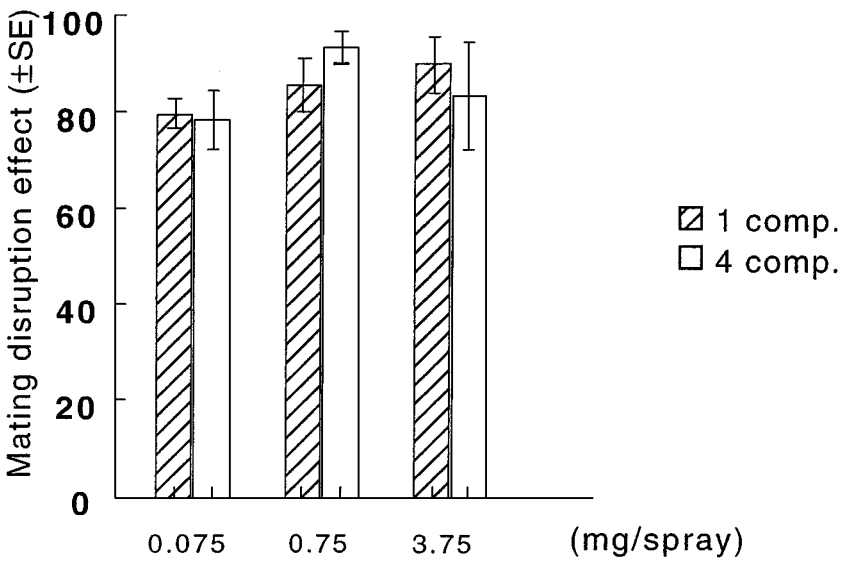

FIG. 1. Mating disruption effect (mean ± SE) in an environment treated with 0.075, 0.75, and 3.75 mg/spray of *Z*9,*E*12–14 : OAc ($N = 10$) and of a four-component blend at the same emission rate of *Z*9,*E*12–14 : OAc ($N = 10$). All females were checked for spermatophore presence, indicating mating. No statistically significant difference between the treatments (ANOVA $F_{5,56} = 1.379$; $P > 0.05$).

There were no differences in mating frequency in the controls among the trials where we had a MSTRS device spraying only ethanol and no MSTRS at all. Hence, the controls were pooled in the statistical tests. The sprayer was removed from the control in later trials. By increasing the emission rate from 0.075 mg/spray to 0.75 mg/spray, the mating was suppressed by $88 \pm 5\%$ (one-component) and $93 \pm 3\%$ (four-component), and the mating frequency was different from the control (ANOVA; $F_{4,54} = 38.72$; $P < 0.001$). Tukey's *post-hoc* test showed a significant effect on mating frequency between control and treatments ($P < 0.01$) and a non-significant effect among treatments. The mating disruption effect did not differ among treatments (ANOVA; $F_{5,56} = 1.379$; $P > 0.05$) (Figure 1). By increasing the dose to 3.75 mg/spray, we did not achieve higher disruption compared to the 0.75 mg/spray, rather disruption stayed at the same level ($93 \pm 5\%$ (one component) and $89 \pm 11\%$ (four components)) as for the 0.75 mg/spray (Figure 1). The mating frequencies in the treatments were $58 \pm 7\%$ (control), $7 \pm 3\%$ (0.75 mg/spray of one component), $4 \pm 2\%$ (3.75 mg/spray of one component), and $47 \pm 6\%$ (control), 3 ± 2 % (0.75 mg/spray of four components) and $5 \pm 2\%$ (3.75 mg/spray of four-components).

Density Effects. Population densities were tested at the emission rate of 0.75 mg/spray of one- and four-component blends, and five females and five males (0.32 individuals/m^2), or 15 females and 15 males (0.96 individuals/m^2) were released into the cubicles. The treatments were significantly different from the control considering mating frequency (10 individuals; ANOVA; $F_{2,27} = 16.869$; $P < 0.001$, 30 individuals; ANOVA; $F_{2,27} = 36.257$; $P < 0.001$). Tukey's post-hoc test showed no difference in mating frequencies between one-component and four-component treatments in both density trials and a significant effect between control and treatments ($P < 0.001$) (Figure 2). At a population density of 10 individuals, the mating was disrupted by $58 \pm 14\%$ in one-component- and by $84 \pm 10\%$ in four-component-treated a cubicle. At a density of 30 individuals, mating was suppressed by $67 \pm 11\%$ in one-component- and $78 \pm 4\%$ in four-component-treated cubicles. The mating frequencies in the different population densities were for 10 individuals: $54 \pm 9\%$ (control), $14 \pm 5\%$ (one component), $4 \pm 3\%$ (four components), and for 30 individuals: 57 ± 5 (control), $16 \pm 4\%$(one component), $12 \pm 2\%$ (four components).

EAG Recording. In spite of the passive ventilation, EAG recordings showed an accumulation of the disruptants in the treatment cubicles during the experiments. No severe contamination of pheromones in the control cubicles could be observed from the EAG recordings (Figure 3). Antennal responses showed a high level of adaptation in the high doses. The adaptation could be observed since the responses to the reference decreased markedly and were unstable in different measurements within a treatment cubicle (example in Figure 3b). The decrease in reference responses, combined with a maximal response to ambient air, increased the relative EAG values from 343 to 669 in 0.75 mg/spray trials. This effect was even larger in

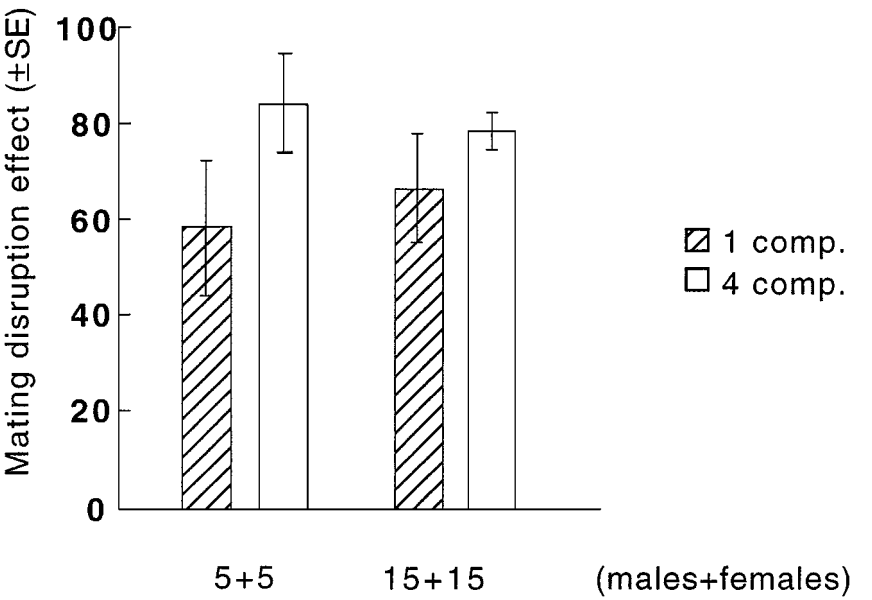

FIG. 2. Disruption effects (mean ± SE) in different population densities in an environment of 0.75 mg/spray of *Z*9,*E*12–14 : OAc and of a four-component blend at the same emission rate of *Z*9,*E*12–14 : OAc. (a) Five males and five females were released each day and retrieved 24 hr later ($N = 10$). (b) Fifteen males and 15 females were released and recaptured 24 hr later ($N = 10$). All females were checked for spermatophores under microscope. No significant difference between the treatments and densities (ANOVA $F_{3,34} = 0.656$; $P > 0.05$).

higher doses, which resulted in unreliable EAG responses and are, therefore, not shown.

DISCUSSION

In this study, mating was disrupted up to 93% by using high emission rates of synthetic pheromones. The disruption effect was measured by the presence of spermatophores in females' bursa copulatrix, which is the most relevant measure of mating activity. Counting spermatophores in the field, however, can be a misleading measurement due to underestimation (Drummond, 1984). The male can fail to pass a spermatophore and still have a successful mating, which was reported in multiply mated males of *Grapholita molesta* (George and Howard, 1968). An underestimation is also possible due to deterioration of the spermatophore if the

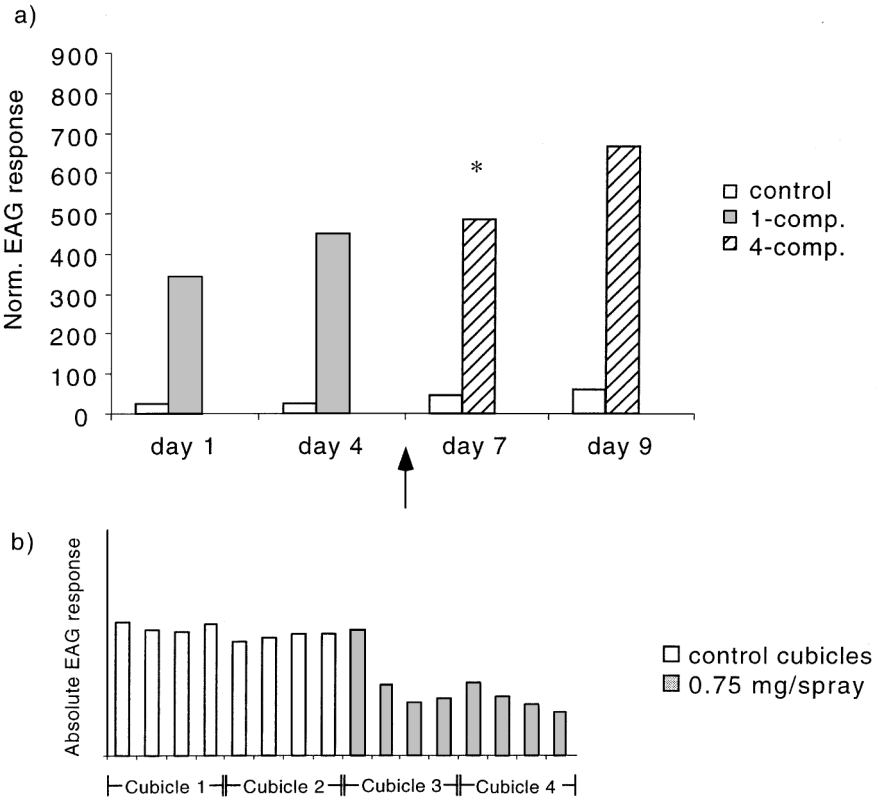

FIG. 3. (a) Pheromone accumulation recorded as electroantennographic responses (mean of four recordings in the same cubicle and the mean of two cubicles for each recording period) of *Plodia interpunctella* conducted on a portable EAG device inside plastic cubicles. The graph shows the sampling sequence, at the beginning and end of each treatment. The asterisk indicates where the MSTRS was spraying only the solvent (ethanol) in the control cubicles. The arrow shows when the treatment was changed from one-component to four-component mixtures. Responses are normalized to a response to a reference containing 10 μg of *Z*9,*E*12–14 : OAc. (b) A typical response to the reference, indicating that the antenna is adapted by the high pheromone concentrations. Responses are stable and of equal size through out the test (four tests in four cubicles; 16 bars). The measurements were taken with a 30-sec recovery time within each cubicle. Moving between the cubicles created a time lapse of 2–3 min in which the antenna can be seen to recover. The grey bars are responses to the reference inside cubicles with 0.75 mg/spray of *Z*9,*E*12–14 : OAc. The white bars are responses to the reference inside control cubicles containing no pheromone dispensers. Bars are decreasing in size for each antennal response, indicating adaptation.

time between the mating and the dissection is too long (Drummond, 1984). However, in this test, an underestimation is not likely since male *P. interpunctella* pass a large spermatophore in all first matings, and during the 24 hr, the males mate only once (Ryne et al., unpublished results). The time between collection and freezing of the females did not exceed 2 hr, and all the spermatophores observed were large in size. Other methods to measure mating activity are by tethered females (e.g., Evenden et al., 1999), by sticky traps with pheromone dispensers (e.g., McBrien et al., 1998), or by crop damage estimations (e.g., Mazomenos et al., 1999). These data are easier to collect, but they do not show the actual mating activity. The risk of the tethered female being disturbed by the handling, and thus ceasing to call is high, and the probability of a tethered female being mated is higher than that of a free-flying female. The efficacy of a pheromone dispenser is decreased by other calling females in the vicinity, which will also attract males.

In the study by Mafra-Neto and Baker (1996), the mating of *E. cautella* was suppressed by 100% in the low population densities (1.27 moths/m^2) with one MSTRS emitting 50 μg/spray of the major component every 15 min. The mating activity in that study was also measured by the presence of spermatophores in females. The higher mating disruption level obtained, even though higher dosages of pheromone was used in our study, was most probably due to the fact that they had constant darkness during the testing period (T. C. Baker, personal communication). Since our cubicles were placed in a greenhouse, a normal day and night rhythm was obtained, thus enabling the moths to use vision for mate finding. The difference in mating suppression between these two closely related species, using similar pheromone disruption conditions, suggests that these moths are using additional cues other than long-range sex pheromones and odor perception for tracking and finding mates. It also suggests that higher doses of pheromone do not necessarily produce a higher mating disruption effect. Other studies have shown that pyralid males [*P. interpunctella* (Mankin et al., 1999) and *E. cautella* (Mankin and Hagstrum, 1995)] perceive and orient toward pheromones at 40–50 cm from the source. At closer distances, males and females can recognize each other by visual and/or acoustic cues. Trematerra and Pavan (1995) showed that female *P. interpunctella*, *E. kuehniella*, and *E. cautella* use ultrasound produced by the male's wing-fanning in order to identify the courting male. The exact utilization of the visual cues by the moths has never been investigated, but it has been shown that male and female *P. interpunctella* orient toward figures of definite shapes, indicating that vision is used in finding sites for settling, calling, and mating (Levinson and Hoppe, 1983).

The moths were often observed aggregating in corners in the cubicles. Females were observed calling in treatment cubicles, with other males and females in close vicinity, without being mated. Aggregation to specific areas in the environment may increase an individual's chance of being mated. This behavior may even occur without the aid of pheromone cues. The cubicles in this study consisted

of straight walls, ceilings, and floors, and the only object in the tents was the MSTRS, standing in the middle of the cubicle. Thus, the environment in which the moths were placed was very simple. As the complexity of the room increases, the number of possible aggregation spots increases. The number of moths in the different possible aggregation spots will be fewer, and the chance of finding a mate in one of those spots will decrease, thus increasing the mating disruption effect. If the behavior of aggregating in corners and crevices enhances the chance of mate finding, then the result of a 93% mating disruption effect, as was the case with 0.75 mg/spray of the four-component blend (Figure 1), is an exceptionally good result, considering the non-complex environment.

Population densities of Phycitinae are sometimes reported as number of insects per square meter of ceiling and walls, since mating behavior occurs on those surfaces (Sower and Whitmer, 1977; Hodges et al., 1984; Mafra-Neto and Baker, 1996). For simplicity, we chose to refer to the number of animals as the true number, but for easier comparison with other studies (e.g., Mafra-Neto and Baker, 1996), the densities are 0.32, 0.64, and 0.96 individuals/m^2. The population densities used in this experiment are referred to as low, intermediate, and high. However, we are not positive that the population densities we chose are relevant in true indoor conditions with infestations. Mafra-Neto and Baker (1996) performed their tests with twice as many males as females, while we used equal numbers of males and females in the cubicles. This was partly due to the fact that a female-biased sex ratio tends to increase male mating, i.e., males increase their mating activity and mate more frequently when the number of available females increases (Brower, 1975). This means that in our study, moths had a higher possibility of mating because of the equal sex ratio compared to a 2 : 1 male–female sex ratio.

The most commonly suggested mechanisms behind mating disruption are either local adaptation of the antennal receptors, habituation on a central level, false trail following, or camouflage of the female's pheromone plume (Cardé and Minks, 1995). High levels of antennal adaptation were clearly observed in the EAG traces (Figure 3), and the adaptation was as high for the one-component as for the four-component treatment. It is difficult to draw any conclusions from the EAG measurements since the high concentrations of disruptant in the cubicles made the antennal responses to the reference septum lower and more unstable than in control cubicles. The portable EAG device would be more useful in conditions where the pheromone concentrations are much lower than in our treatments. While measuring antennal responses in the cubicles, there was a trade-off between minimizing the time between recording due to the short life-time of the antenna and maximizing the time to enable the antenna to fully recover. In order to retrieve statistically sound data, a series of recordings from many antennae is necessary.

The minor increase observed in EAG responses in control cubicles between the beginning of the trial period and the end (Figure 3a) can be explained by pheromones still present in the cubicles from earlier, removed calling females, as

well as contamination from one room to thr other. The larger increase of pheromone concentration between the beginning and the end of the trial period in the one-component trial (Figure 3a) is most probably due to an accumulation of pheromone during the trial period. Pheromone is likely to be absorbed into the plastic of the cubicles, which would then act as secondary dispensers and create a stable background pheromone concentration. It is not known whether the EAG responses by the antenna were derived from pheromones only or whether the antenna also detected the ethanol solvent. The large increase in the EAG responses are probably deriving from the pheromones present in the tents and not the ethanol solvent. Figure 3a shows normalized EAG responses when the control tents had a MSTRS spraying only ethanol, and no elevated responses can be seen. Cossé et al. (1994) reported receptors sensitive to ethanol in females of the pyralid *Ectomyelois ceratoniae*, but whether or not ethanol-sensitive receptors occur in male *P. interpunctella* has not been investigated.

Only a few males were seen orientating towards, or sitting on, the pads of the MSTRS, which indicates a low level of false trail following in both laboratory and field studies (Valeur and Löstedt, 1996; McBrien et al., 1998). The mechanisms by which males are disrupted may depend on the concentration level of the disruptant and the sensitivity of the male receptors. The importance of using a more complete blend in a specific dose is of interest for commercial purposes, and a more complete blend is often more attractive to a male than an off-blend (Zhu et al., 1999). Cardé and Minks (1995) suggested that a complete blend would by definition be the most effective in mating disruption since it evokes the whole behavioral repertoire and, therefore, the complete blend would possess the lowest threshold for most or all behaviors. On the other hand, an off-blend might, evoke a sensory imbalance effect (Cardé and Minks, 1995). Flint and Merkle (1983) showed that by disrupting pink bollworm (*P. gossypiella*) with an off-blend or a partial blend, the male moths experienced an imbalance in sensory input, which impaired the male's ability to respond correctly to the natural blend.

A small-scale experiment of this kind is valuable since it allows for control plots, which are almost impossible to achieve in field experiments. However, the true efficiency of mating disruption can only be seen when conducting the experiments in storage facilities. Since our experiments resulted in a 93% mating disruption in 24 hr, it is likely that the population would decrease. The emission rates in this experiment are comparable to the study by Mafra-Neto and Baker (1996). It can be argued that the emission rates were too high in the small experimental sites. The high concentration may be the reason for not achieving a difference in disruption between the one-component and four-component trials [a female gland contains approximately 4 ng of the main component (Zhu et al., 1999)]. However, we chose to concentrate on the effect of blends in a situation where the mating disruption was efficient, rather than to investigate the impact of blends when disruption effect was low and not acceptable for IPM.

Pheromone-based mating disruption conditions may produce a high selection pressure on the communication channel in the target species in which more sensitive males and/or females producing off-blends are favored. If large variation exists in pheromone production among females, individuals emitting large quantities or blends not similar to the disruption blend may be favored. Moreover, selection could be acting on the males who are able to locate a female in high ambient pheromone concentrations. A project is now in progress to evaluate the evolutionary consequences of the selection pressures imposed on the pheromone-based mating-system of *P. interpunctella* in high atmospheric concentrations of synthetic pheromones. The implementation of mating disruption indoors, and to some extent mating disruption outdoors, may be prevented by the fact that toxicity tests are needed before using pheromones in "high" doses in close contact to personnel and food products.

The potential for indoor mating disruption of *P. interpunctella* is promising. Our study shows that it is possible to achieve a high degree of disruption. The fact that the one-component (*Z*9,*E*12–14 : OAc) formula is used as part of the pheromone blend in many pyralid species (Phelan and Baker, 1990) makes the applicability of mating disruption with the one-component formula even greater. The compound is shared by *E. kuehniella* (Kuwahara et al., 1971a), *Ephestia (Cadra) cautella* (Kuwahara et al., 1971b; Brady, 1971), *P. interpunctella*, and other pyralid species, and since the species can occur in the same habitat, it may on these occasions be possible to control the pests with only one pheromone formula.

Acknowledgments—We would like to thank Dr. Rikard C. Unelius and Ellen Mattos Santangelo, Sweden, for synthesizing the aldehyde used in the experiments. Prof. Jan Löfquist, Sweden, for letting us use the greenhouses for the cubicles, Dr. Jan van der Pers, for lending us the portable EAG device, and Dr. P. A. Nilsson for valuable discussions on earlier versions of the manuscript. This study was funded by Cerealia Research and Development, MISTRA, the Swedish Council for Forestry and Agricultural Research, and the Knut and Alice Wallenberg foundation.

Abstract—Epicuticular hydrocarbon variation was investigated among the three species of the *Drosophila mojavensis* cluster (*D. mojavensis*, *D. arizonae*, and *D. navojoa*) within the large *D. repleta* group. Because these hydrocarbons serve as contact pheromones in adult *D. mojavensis*, the chemical characteristics and differences in hydrocarbon profiles in populations of these three sibling species were further investigated. Twenty-seven hydrocarbon components with chain lengths ranging from C_{28} to C_{40}, including *n*-alkanes, methyl-branched alkanes, *n*-alkenes, methyl-branched alkenes, and alkadienes were observed. Hydrocarbon profiles among the three species reared on different cactus hosts were easily aligned with previously identified components in *D. mojavensis*. Male and female *D. navojoa* possessed a 31-methyldotricont-6-ene absent in both *D. arizonae* and *D. mojavensis*, while lacking the 8,24-tritricontadiene present in these two species. *D. navojoa* adults had far less 2-methyloctacosane than these sibling species, but the significance of this difference was obscured by the degree of variation among populations in amounts of this hydrocarbon. Mainland and Baja California populations of *D. mojavensis* were fixed for differences in the amounts 8,24-tritricontadiene, 9,25-pentatricontadiene, and 9,27-heptatricontadiene, consistent with all previous studies. Amounts of 18 of the 27 hydrocarbon components were greater in flies reared on *Opuntia* cactus. Canonical discriminant function analysis resolved all three species into distinct, nonoverlapping groups, suggesting that epicuticular hydrocarbon profiles are species-specific in the *D. mojavensis* cluster. Based on the amounts of interpopulation variation in hydrocarbon profiles in these three species, we hypothesize

[1]This is paper VI in the series "Premating isolation is determined by larval rearing substrates in cactophilic *Drosophila mojavensis*."

that epicuticular hydrocarbon differences may evolve early during the formation of new species.

Key Words—Species recognition, cuticular hydrocarbons, *Drosophila*, cactus, speciation.

INTRODUCTION

In closely related animal species that no longer share a common fertilization system, species recognition systems may be preserved by strong stabilizing selection (Paterson, 1993) and perhaps enhanced by reinforcement of these barriers if there is continuing gene exchange (Dobzhansky, 1951; Coyne and Orr, 1989; Noor, 1995, 1999). In order to understand more fully the origin of new species, the conditions that cause particular isolating mechanisms to arise must be identified (Masters, 2000), and the progression of changes in courtship cues during the evolution of reproductive isolation across species groups must be understood. Mate recognition in many *Drosophila* species involves a stereotyped series of behavioral cues exchanged between males and females. Courtship is elicited by males and may involve behavioral, acoustic, and chemical cues that females use in the evaluation of prospective mates. In the initial stages of reproductive isolation, how does selection shape divergence in mating systems prior to complete isolation? Do mate recognition systems function within populations in the same ways that they function between populations and species? If sexual selection is unrelated to sexual isolation (Boake et al., 1997; Carson, 2000) and if we are to understand how species originate in general, comparative studies of within- and between-species mating systems may offer insight into the sequential evolution of recognition signals.

A common form of chemical communication in *Drosophila* species involves contact pheromones made of epicuticular hydrocarbons biosynthesized in the pupal stage and early in adult life (Ferveur et al., 1997). Specific components of cuticular hydrocarbons of females elicit male courtship behaviors in *Drosophila melanogaster* (Antony and Jallon, 1982). (*Z*,*Z*)-7,11-Heptacosadiene elicits courtship from *D. melanogaster* males (Antony and Jallon, 1982). (*Z*)-11-Pentacosene (Oguma et al., 1992a) along with (*Z*,*Z*)-5,13-pentacosadiene, (*Z*,*Z*)-5,15-pentacosadiene, and (*Z*,*Z*)-7,15-heptacosadiene elicits courtship from *D. virilis* males (Oguma et al., 1992b). The multimethylene interrupted alkadiene, (*Z*,*Z*)-5,25-hentricontadiene, elicited courtship from male *D. pallidosa* (Nemoto et al., 1994). All of these hydrocarbons have long chains and are thought to act as contact pheromones, probably by stimulating chemoreceptors on the male foreleg or proboscis (Jallon, 1984; Oguma et al., 1992b; Nemoto et al., 1994).

In addition to the exchange of behavioral cues during courtship including courtship songs (Spieth, 1974; Ewing and Miyan, 1986), epicuticular hydrocarbons have been implicated as determinants of mate choice in *D. mojavensis* (Markow

and Toolson, 1990; Toolson et al., 1990; Stennett and Etges, 1997). Hydrocarbon transfer experiments (cf. Coyne et al., 1994) have demonstrated that epicuticular hydrocarbons are involved in mate recognition with mainland and Baja *D. mojavensis* (Etges and Ahrens, 2001). Previous analysis of the epicuticular hydrocarbon profiles of *D. arizonae* and *D. mojavensis* revealed a high degree of similarity between species, some large differences in particular hydrocarbon components among populations of *D. mojavensis*, and significant effects of larval rearing substrates, particularly laboratory food versus cactus, on amounts of epicuticular hydrocarbons (Stennett and Etges, 1997). Detailed analysis of multiple populations of *D. mojavensis* from different parts of the species range revealed consistent geographical differentiation in amounts of C_{33}, C_{35}, and C_{37} alkadiene components, and gender–specific amounts of 16 different hydrocarbons. Further, significant sex $\times$ region interactions for eight of these hydrocarbons showing sexual dimorphism were statistically significant, indicating region-specific male–female hydrocarbon differences (Etges and Ahrens, 2001). In the present study, we characterized the chemical nature of these epicuticular hydrocarbons for all three *D. mojavensis* cluster species so that we can begin to understand the role of these chemical cues in between-species mate recognition.

Phylogeny and Natural History of D. mojavensis *Cluster Species*. The *D. mojavensis* cluster is part of the *D. mulleri* species subgroup inferred from the sharing of chromosomal gene arrangements and phylogenetic analyses of nuclear and mitochondrial gene regions (Wasserman, 1992; Durando et al., 2000). The *mulleri* cluster (*D. aldrichi*, *D. mulleri*, *D. wheeleri*, and *D. nigrodumosa*) is the sister group to the *D. mojavensis* cluster (Durando et al., 2000). Although *D. huaylasi* from Peru is closely related to the *D. mojavensis* cluster and has sometimes been included within it (Durando et al., 2000), we do not include it here because hybridization data, gene arrangements, and differences in male genitalia clearly point to a closer affiliation with the *mulleri* subgroup (Fontdevila et al., 1990). *D. navojoa* is ancestral to both *D. mojavensis* and *D. arizonae*: the latter two species share a common intermediate ancestor (Figure 1). The range of *D. navojoa* extends from the lowlands along the Pacific coast of southern Mexico and north to southern Sonora. *D. arizonae* is widespread from Guatemala and southern Mexico to Arizona and New Mexico, and is sympatric with *D. mojavensis* and *D. navojoa* in southern Sonora. The range of *D. mojavensis* is restricted to the Sonoran desert, Sinaloan thornscrub, and adjacent areas including the Colorado/Mojave deserts in southern California (Heed, 1982). Ecologically, *D. navojoa* is restricted to the more ancestral *Opuntia* breeding habit, similar to most other members of the *mulleri* subgroup, whereas both *D. mojavensis* and *D. arizonae* use a variety of hosts including a number of more derived columnar cacti (Ruiz et al., 1990).

The goals of this study were to characterize the epicuticular hydrocarbons of the three *D. mojavensis* cluster species in order to understand more about

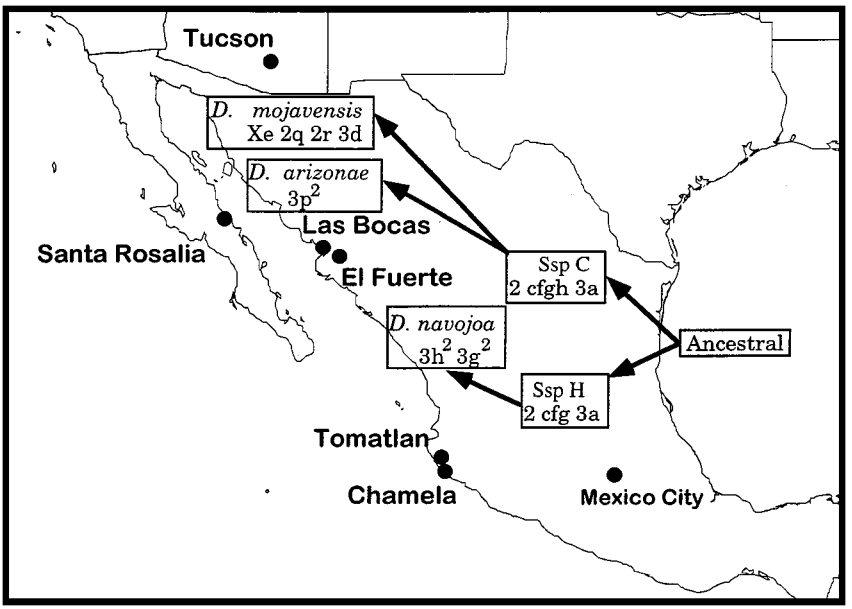

FIG. 1. Map of Mexico and the southwestern United State showing the locations of the populations sampled for this study and a phylogeny of the three *D. mojavensis* cluster species based on chromosomal gene arrangements (Wasserman, 1992).

the magnitude of species-specific mate recognition systems. We assessed variation between two populations of each species reared on fermenting *Opuntia* and *Stenocereus gummosus*, pitaya agria, tissues in order to estimate the degree of intraspecific and substrate-induced variation in hydrocarbon profiles previously documented in *D. mojavensis*. In this study, we used fermenting *Opuntia ficus-indica* and the more chemically specialized agria cactus rearing substrates to characterize further the consequences of this ecological transition of feeding and breeding sites on both expression of adult epicuticular hydrocarbons and components of fitness.

METHODS AND MATERIALS

Origin of Stocks. A stock of *D. arizonae* from Tucson, Arizona, was founded in November 1995 by aspirating approx. 35 adults from the fermenting fruits of *Opuntia ficus-indica*. Another stock originated from seven adults that were baited in a *Stenocereus thurberi–S. alamosensis–Opuntia wilcoxii* forest near Las Bocas, Sonora in April 1996 (Figure 1). Both *D. navojoa* stocks were collected by baiting

and rearing from *Opuntia* pads in March 1997. Eight females and 10 males were collected west of Tomatlan, Jalisco, in a dry forest where *S. standleyi*, *Pachycereus pecten-aboriginum*, *Cephalocereus purpusii*, and an arborescent *Opuntia* species were common. At several locations within the Chamela Biological Station reserve in Jalisco, 34 female and 29 male *D. navojoa* were collected from giant *Opuntia excelsa* plants. The *D. mojavensis* stocks originated from collections made in 1996 in Santa Rosalia, Baja California, and El Fuerte, Sinaloa. The Baja stock was founded from 468 adults that emerged from a *S. gummosus* rot and the Sinaloa stock was initiated with 185 adults from baits and flies that emerged from a *S. thurberi* rot. All flies were reared in the laboratory in large numbers on banana food (Brazner and Etges, 1993) prior to cactus rearing and hydrocarbon analysis.

Chemical Analysis of D. arizonae and D. navojoa Hydrocarbons. The four *D. arizonae* and *D. navojoa* stocks were reared for one generation on banana food in 8-dr shell vials in an incubator programmed on a 14L:10D cycle at 27°C during the day and 17°C at night. All emerged adults were separated by sex and aged for at least 10 days on banana food at room temperature. Epicuticular hydrocarbons were extracted from adults ($N = 549$–902) of each group in Biosil mini-columns. Each column consisted of a Pasteur pipet that contained packed glass wool and Biosil (silica gel, Sigma S-4133) washed several times with HPLC grade hexane. Flies were then added, washed in 8 ml of hexane, and the hydrocarbons were collected in hexane-rinsed vials. After the hexane was evaporated with nitrogen, each sample was sealed and stored at −20°C. Each sample extract was characterized by gas chromatography–mass spectrometry (GC-MS) of the most abundant components composed of methyl-branched hydrocarbons, alkenes, and alkadienes. The samples were analyzed by capillary gas–liquid chromatography by using a Hewlett Packard 5890 GC fitted with a 12-m HP-1 fused silica column. The GC was programmed from 150°C to 300°C at 10°C/min and held at 300°C for 5 min. The temperature of the injector and detector (Hewlett Packard 5971 mass selective detector) was 280°C. The internal standard was 100 ng/fly of octacosane (C_{28}). The unsaturated epicuticular hydrocarbons were derivatized with dimethyl disulfide, and the resulting thiomethyl derivatives were analyzed by GC-MS to identify the positions of the double bonds (Toolson et al., 1990).

Cactus Rearing Experiment. All populations of *D. arizonae*, *D. mojavensis*, and *D. navojoa* were cultured on fermenting cactus tissues in 1997 in order to assess the degree to which rearing substrates affected adult epicuticular hydrocarbon composition. Several hundred adults were collected from each population that had been cultured as described above. Eggs were collected from aged adults and washed in deionized water, 70% ethanol, and again in sterile deionized water. Eggs were counted out in groups of 200, transferred to a 1-cm^2 piece of sterilized filter paper, and placed on fermenting cactus. Cactus cultures were set up in plugged 8-oz bottles with 75 g of aquarium gravel at the bottom covered with a 5.5-cm-diameter piece of filter paper. Bottles were then autoclaved, and after 60 g

of either agria or *O. ficus-indica* tissues were in place, autoclaved again for 10 min. After cooling to room temperature, each culture was inoculated with 0.5 ml of a pectolytic bacterium, *Erwinia cacticida* (Alcorn et al., 1991), and 1.0 ml of a mixture of seven species of yeast common in natural agria rots (Starmer, 1982): *Pichia cactophila*, *P. mexicana*, *P. amethionina* var. *amethionina*, *Cryptococcus cereanus*, *Candida valida*, *C. ingens*, and *C. sonorensis*. Three replicate cultures of each cactus type were started for each of the two populations for each species and cultured in an incubator programmed as above. All unhatched eggs were counted to allow calculation of egg to adult viability. Eclosed adults from each replicate culture were counted daily allowing determination of egg-to-adult development time, separated by sex, and aged on banana food in vials at room temperature.

Aged adults were then transferred to hexane rinsed vials and stored at −20°C until hydrocarbon extracts were prepared by using groups of adults (usually 20–30) as described above. Each hydrocarbon sample was redissolved in hexane (2.5 μl/fly) containing 385 ng of docosane (C_{22}) per microliter as an internal standard. One microliter of each sample was analyzed by capillary gas–liquid chromatography with a Shimadzu G14 fitted with a 30-m DB-1 fused silica column. Injector and detector temperatures were set at 345°C with the injector port in split mode. Running temperatures started at 200°C and increased to 345° at 10°/min, with a hold at 345°C for 7 min (Stennett and Etges, 1997).

Statistical Analyses. Development time was measured in days, and viability was calculated as the number of eclosed adults divided by the number of counted eggs that hatched. Variation in egg to adult development and viability was assessed by ANOVA with PROC GLM in SAS (SAS Institute, 1989). Viability data were arcsin transformed, and development time data were $\log_{10}$ transformed prior to analysis.

Hydrocarbon amounts were estimated by analysis of peak integrations using EZCHROM software (ver. 2.1) provided by Shimadzu. Each sample amount was normalized by the measured amount of the internal standard. Replicate groups of flies were analyzed together. All data were expressed as nanograms per fly of cuticular hydrocarbons and were analyzed with population, rearing substrate, and sex as main effects, and for all interactions between main effects. Population, replicates, and all interactions with population were considered random effects. The TEST command was used in the RANDOM statement to generate the appropriate F ratios and adjusted degrees of freedom by using Satterwaite's approximation (SAS Institute, 1989). Within-species ANOVAs were also evaluated to more closely assess some of the higher order interaction terms. Canonical discriminant function analysis (PROC CANDISC) (SAS Institute, 1989) was performed on the replicate means of each population ignoring sex and cactus differences for all hydrocarbons analyzed. This procedure forms linear combinations of the hydrocarbons with the highest multiple correlation with the populations and maximizes the univariate F ratios. Each canonical variable was obtained by finding the linear combination

least correlated with the previous canonical variable: the first three canonical variables were used to plot the variation in hydrocarbons among populations.

RESULTS

Chemical Descriptions of Hydrocarbons. The major epicuticular hydrocarbons are alkanes, 2-methylalkanes, alkenes, methyl-branched alkenes, and multimethylene interrupted alkadienes (Table 1). The location of the double bonds in the alkenes were at odd-numbered carbons for the hentricontenes (7-hentricontene and 9-hentricontene) but were at even-numbered carbons for the longer-chained alkenes (e.g., 10-tritricontene, 10-tetratricontene, and 14-hexatricontene). Locations of the double bonds in the methyl-branched alkenes were also at even-numbered carbons. The multimethylene interrupted alkadienes had an odd number

[a] Equivalent chain length calculated as in Stennett and Etges (1997).

of carbons to the double bond from one end, and an even number of carbons from the other end to the double bond. In the tetratricontadienes (34 dienes), the double bonds were an even number of carbons from both ends.

Epicuticular Hydrocarbon Differences Among Species. A total of 27 hydrocarbon peaks were scored in each sample with chain lengths ranging from C_{28} to C_{40}. The number of observed peaks and their retention times were similar among the three species with only a few notable qualitative differences. The most ancestral species, *D. navojoa*, possessed 31-methyldotricont-6-ene, which was not observed in the other two species with an equivalent chain length of $C_{32.56}$. 8,24-Tritricontadiene was present in high quantities in *D. arizonae* and mainland *D. mojavensis* but was absent in *D. navojoa*. The Baja California population of *D. mojavensis* population from Santa Rosalia was characterized by the near absence of the $C_{32.63}$, $C_{35.59}$, and $C_{36.5}$ alkadienes that are major peaks in mainland populations, such as El Fuerte, consistent with all previous studies (Stennett and Etges, 1997; Etges and Ahrens, 2001). *D. navojoa* was also characterized by far lower amounts of 2-methyloctacosane ($C_{28.65}$) than *D. arizonae* and *D. mojavensis* (± 1 SD); $35.4 \pm 11.9 < 123.1 \pm 32.4 < 175.3 \pm 71.6$ ng/fly, respectively. This difference was not significant in the mixed model nested ANOVA (Appendix 1) because the mean square error term, populations nested within species, was so large. This was also the case for $C_{32.63}$ (absent in *D. navojoa*), $C_{34.59}$, and $C_{36.5}$, indicating that significant geographic variation in a variety of hydrocarbon components has obscured the levels of statistical significance of the differences between species.

Population Differences. Within-species ANOVAs were performed with populations to consider random effects in order to assess more directly hydrocarbon differences among populations and some of the higher order interaction terms. The degree of geographic variation observed between the Baja California and mainland population of *D. mojavensis* in hydrocarbon amounts (Table 2) was consistent with earlier results (Stennett and Etges, 1997). These same two populations were part of a larger study of epicuticular hydrocarbon variation among six populations from Baja California and five mainland Mexico populations (Etges and Ahrens, 2001). Thus, we can directly compare the magnitude of interpopulation variation in epicuticular hydrocarbons with that of the other two species. Here 15 of the 27 hydrocarbon components varied geographically: these were the same components that contributed to the overall geographic differences between Baja California and mainland populations of *D. mojavensis*. A greater proportion, 22/27, differed between the Tucson, Arizona, and southern Sonoran populations of *D. arizonae*. Just 11 of these components varied among the two populations of *D. navojoa*; only four of these are major peaks: C_{28} alkane, 2-methyloctacosane, 7,25-tricontadiene, and 8,26-pentatricontadiene (Table 2). Such intraspecific variation in *D. navojoa* was surprising given that the two populations studied were only 45 km apart (Figure 1).

Together, these 27 hydrocarbon components significantly discriminated among each of the six populations. The first three canonical variables accounted

[a] For each component, F values and significance levels are listed for differences between populations (P) over that for differences between cactus hosts (C). Significance of all P values was adjusted using the sequential Bonferroni procedure across species.
C_{RT} refers to the hydrocarbon component's retention time or carbon chain length as described in Stennett and Etges (1997) or in this paper. NA: not applicable because hydrocarbon component is absent for this species. $^{*}P < 0.05, ^{**}P < 0.01, ^{***}P < 0.001$; significance tests are based on a stepwise Bonferroni test with initial $P = 0.05$ using the number of P values in each row to correct for the number of simultaneous tests.

for 93.9% of the total hydrocarbon variation (Figure 2). All pairwise squared Mahalanobis distances between populations were significant ($p < 0.0001$), as were the overall multivariate differences among populations (Wilks $\lambda = 0.00012742$, $F = 20.56$, $p < 0.0001$). The first five canonical correlations were all significantly greater than zero ($p < 0.0001$). Thus, significant geographic variation exists in the epicuticular hydrocarbon profiles of the populations of these three species.

Sex Differences. Amounts of 2-methyloctacosane, 2-methyltricontane, the C_{38} alkene, and the C_{40} alkene differed between males and females of all three species (Appendix 1). However, 17 hydrocarbon components differed between males and females in a population-specific manner as indicated by the significant sex × population within-species interaction terms. Such interactions imply that male–female differences in amounts of these hydrocarbon components differ among populations of these three species. These interactions were also observed in the larger analysis of epicuticular hydrocarbon variation between Baja California and mainland populations of *D. mojavensis* (Etges and Ahrens, 2001), so local variation in sexual dimorphism of hydrocarbon profiles is not restricted to this species.

Substrate Differences. Although not statistically significant in all cases ($P < 0.05$; Appendix 1), hydrocarbon amounts generally differed due to cactus-rearing substrates for 18 of the epicuticular hydrocarbons assayed. In every case, flies reared on *Opuntia* cactus had increased amounts of cuticular hydrocarbons as

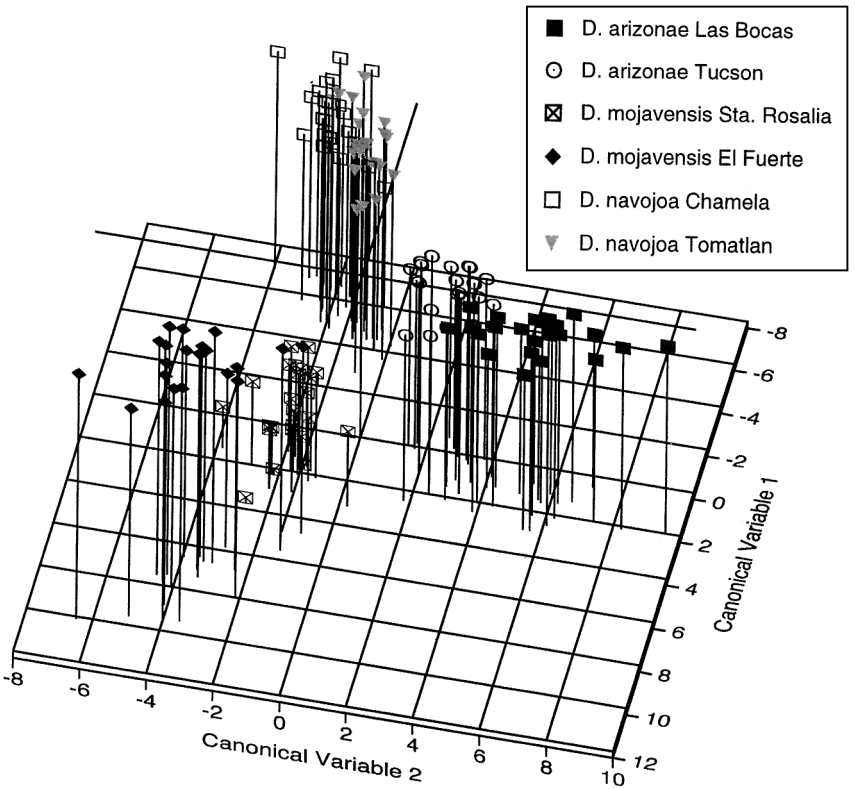

FIG. 2. Three dimensional plot of the populations of *D. mojavensis*, *D. arizonae*, and *D. navojoa* based on the first three canonical discriminant variables (CDVs) formed from the 27 hydrocarbon components observed in this study. CDV 1 accounted for 53.6%, CDV 2 accounted for 26.0%, and CDV 3 accounted for 14.3% of total variance, respectively. Sex and host cactus were ignored to emphasize populations and species differences. All Mahalanobis distances between populations were significant ($P < 0.0001$).

compared to agria-reared flies (Figure 3). Results of the within-species ANOVAs (Table 2) also suggested that the effect of rearing flies on agria versus *Opuntia* was usually statistically significant in one or two of these species for a given hydrocarbon component. Thus, many of the cases of marginal significance in the nested ANOVAs were due to this result. Only the two C_{34} alkenes and one of the C_{36} alkenes differed in amounts between agria and *Opuntia*-reared flies in all three species (Table 2), and the nested ANOVA suggested that 2-methyloctacosane, 2-methyltricontane, and 14-, 16-, and 12-hexatricontene also varied among species (Appendix 1). The 2-methyloctacosane, 7- and 9-hentricontene, 31-methyldotricont-8-ene, and $C_{36.6}$ alkadiene components varied in a species–specific manner as

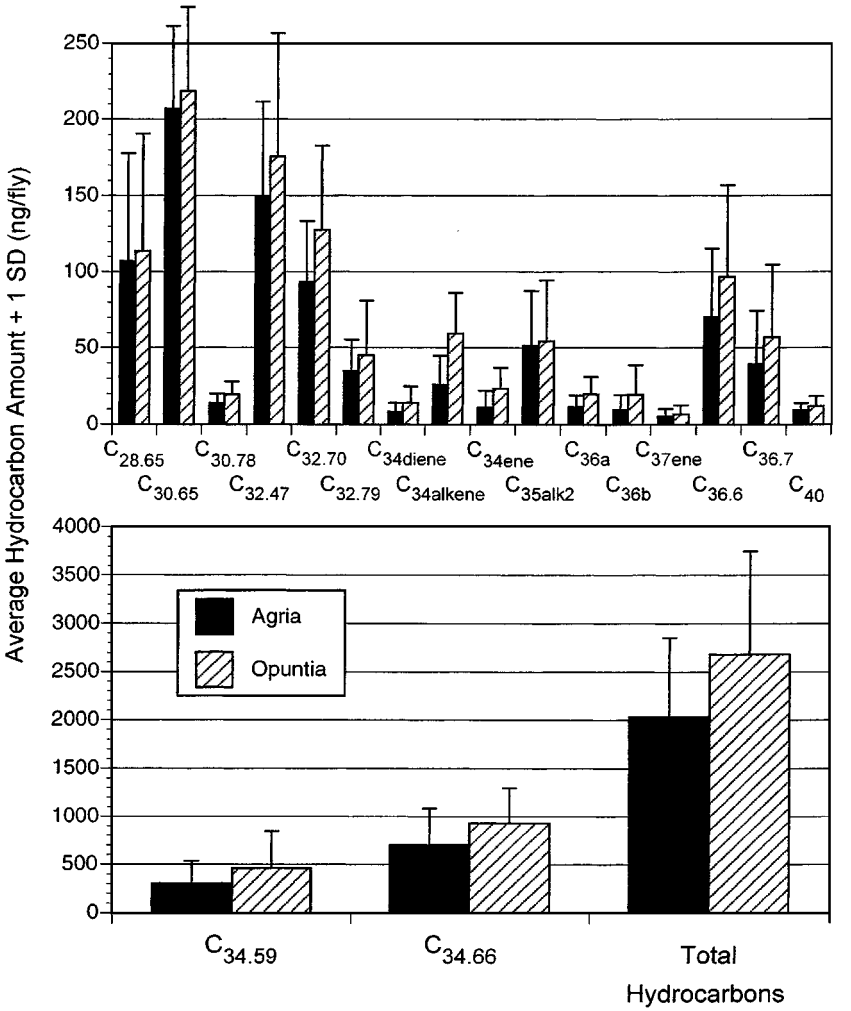

FIG. 3. Averages (+1 SD) of *D. arizonae*, *D. mojavensis*, and *D. navojoa* hydrocarbon amounts for the 18 components that differed between rearing substrates. In all cases, hydrocarbon amounts were greater in flies reared in *Opuntia* than in agria tissues. Individual components are referred to by their equivalent chain lengths or other names (Appendix 1); see Table 2 for chemical names.

shown by the significance of the cactus × species interaction terms. These cactus substrates also influenced the total amounts of hydrocarbons per fly (Figure 3) for *D. arizonae* and *D. mojavensis*, but not for *D. navojoa* (Table 2). Overall, fermenting *Opuntia* cactus tissues must contain more available precursors for synthesizing

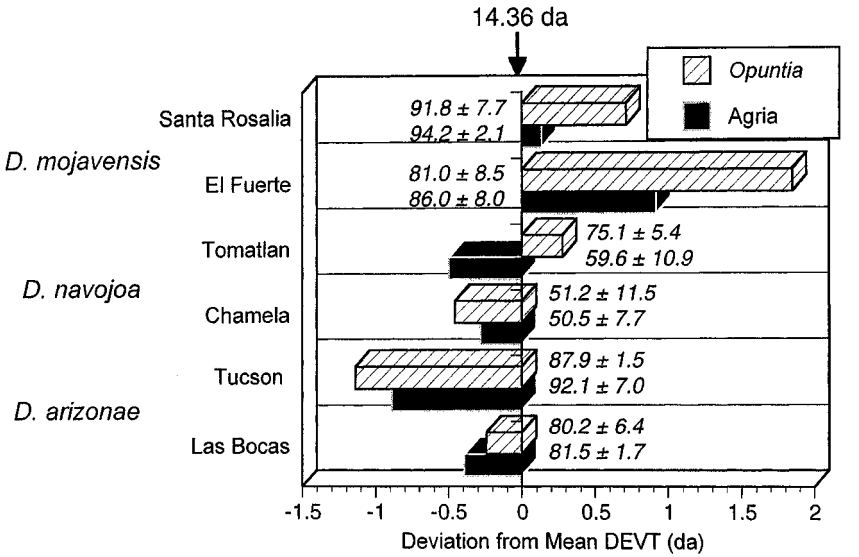

FIG. 4. Deviations in egg to adult development time from the overall mean (indicated above the graph) for the six populations of *D. mojavensis* cluster species in this study illustrating the significant population × cactus interaction term from the ANOVA. Mean egg to adult viability (±1 SD) is indicated in italics adjacent to each type of cactus substrate for each population.

the majority of adult epicuticular hydrocarbons in these three *Drosophila* species than do agria tissues.

Life History Differences. Differences in egg-to-adult development time among populations were expressed in a substrate-specific manner (Figure 4). Although overall differences in development time were only marginally significant among species ($F = 5.42$, $P = 0.10$) in the nested design, females emerged earlier than males in all three species ($F = 94.52$, $P = 0.002$). the interaction between cactus hosts and populations nested within species was also significant ($F = 3.84$, $P = 0.022$). Only *D. mojavensis* populations consistently expressed shorter development times on their primary host plant, agria cactus. The correlation between development time and total hydrocarbons per fly was not significant ($r = 0.52$, $P > 0.05$, $N = 12$), so variation in hydrocarbon amounts was unrelated to the length of preadult development time. Egg to adult viability was lower in the two populations of *D. navojoa* ($F = 39.87$, $P < 0.0001$), in part due to the lower viabilities observed on agria versus *Opuntia*-reared flies (Figure 4). Overall, these life history differences are consistent with the known patterns of host plant use in nature (Ruiz and Heed, 1988) and suggest that any host cactus-induced variation in hydrocarbon amounts should also be expressed in natural populations.

DISCUSSION

The overall chemical similarity of the epicuticular hydrocarbon components among the three *D. mojavensis* cluster species suggests that the biosynthetic pathways for hydrocarbon production and deposition have not yet widely diverged. However, significant quantitative differences in hydrocarbon amounts among populations (Figure 3) indicate that the chemical signatures of these hydrocarbons have evolved within and between species. Whether individual or groups of these epicuticular hydrocarbons serve as within- and/or between-species signaling systems remains to be determined. In *D. mojavensis*, transferring male mainland-specific hydrocarbons to Baja males in "perfuming" experiments significantly enhanced the mating success of these perfumed Baja males with mainland females in comparison with controls. Thus, these cuticular hydrocarbons are part of the mate recognition system in this species (Etges and Ahrens, 2001). Certainly, the role of these chemical cues must be evaluated in the context of other components of the mating systems of these species expressed in an environment-specific manner, including mating behavior (Etges, 1992; Brazner and Etges, 1993; Stennett and Etges, 1997) and courtship songs.

The influences of rearing substrates on adult epicuticular hydrocarbon profiles suggests that an extensive understanding of the ecology and distribution of natural populations is necessary if we are to identify the mechanisms responsible for shaping mate recognition divergence. For a number of *Drosophila* species, preadult rearing environments are significant determinants of both genetic and phenotypic variation in fitness characters (Etges and Heed, 1987; Ruiz and Heed, 1988; Etges and Klassen, 1989; Etges, 1990, 1993; Fanara et al., 1999) as well as mating behavior (Ehrman, 1990; Brazner and Etges, 1993; Kim et al., 1996; Kim and Ehrman, 1998) and epicuticular hydrocarbon variation. Thus, the use of discrete resources in nature, such as fermenting cactus rots, is a key determinant of variation in fitness characters and intraspecific mate recognition systems. The frequency and intensity of courtship interactions should be determined largely by the abundance of adults, the number of different species present, and the male mating propensity at feeding and breeding sites. There can be considerable overlap of species feeding on rots of any of the major host cacti in the Sonoran Desert (Fellows and Heed, 1972), although host plant specificity, resulting from the effects of stem chemistry on larval growth and development (Fogleman and Heed, 1989; Fogleman and Abril, 1990) and interspecific larval competition (Heed and Mangan, 1986), is the general rule.

Since *D. navojoa* is restricted to *Opuntia* cacti and its range only overlaps that of *D. mojavensis* in a small area of southern Sonora and northern Sinaloa (Heed, 1982), these two species probably do not encounter each other frequently in nature. However, Markow and Maveety (1985) documented higher premating

isolation among sympatric populations than allopatric populations of each species and concluded that reproductive character displacement was responsible. Although they included no statistical analysis of their data concerning the significance of the differences in premating isolation between sympatric and allopatric populations, further analysis of their data supports their contention. Their estimates of premating isolation using the Joint I statistic (Stalker, 1942) were greater in sympatric than allopatric populations (two-group comparison; $\chi^2 = 20.56$, 1 *df*, $P < 0.0001$) (Sauer and Williams, 1989). Thus, there is geographic variation in levels of premating isolation between *D. mojavensis* and *D. navojoa*, even though they do not regularly share host plants.

The ecology of *D. mojavensis* is perhaps the best known as it uses different host cacti throughout its range (Heed and Mangan, 1986; Etges et al., 1999). In Baja California, pitaya agria, *S. gummosus*, is the preferred host even though several secondary hosts used elsewhere are sympatric with agria such as organ pipe cactus, *S. thurberi*, and California barrel cactus, *Ferocactus cylindraceous*. In mainland Sonora, Sinaloa, and Arizona, organ pipe cactus is the major host except for where a small patch of agria grows in coastal Sonora and occasional use of sina cactus, *S. alamosensis*, in southern Sonora and coastal Sinaloa (Markow et al., 1983; Ruiz and Heed, 1988). In the Mojave/Colorado deserts of southern California, *D. mojavensis* use California barrel cactus and have been found on Santa Catalina Island near Los Angeles using the fruits and pads of *Opuntia demissa*. The more widespread *D. arizonae* has been reared out of sina, saguaro, *Carnegiea gigantea*, and more rarely from *S. gummosus* in coastal Sonora and the Cape region in Baja California along with *D. mojavensis*. To the north in Arizona and New Mexico outside of agricultural areas, *D. arizonae* breeds in *Opuntia* pads and fruits and feeds on a variety of cacti (Fellows and Heed, 1972; Heed, 1982). In southern Mexico, *D. arizonae* has been collected from fermenting *Myrtillocactus geometrizans* and *S. pruinosus* arms in Chiapas, as well as *Opuntia* pads north of Pachuca, Hidalgo (Etges, unpublished data).

Reproductive character displacement has been described in mainland Mexico and Arizona populations *D. mojavensis* due to sympatry with *D. arizonae* (Wasserman and Koepfer, 1977). Mainland populations of *D. mojavensis* are considered derived from those in Baja California where *D. arizonae* is absent except for a few small demes outside of the desert in the more subtropical thornscrub in the Cape region of Baja California. Johnson (1980) hypothesized that *D. mojavensis* colonized mainland Mexico from Baja California by switching to a secondary host plant, organ pipe cactus, and secondarily became sympatric with *D. arizonae*. Both species occasionally use sina cactus in southern Sonora (Markow et al., 1983; Ruiz and Heed, 1988), and *D. arizonae* has been reared out of agria in low frequencies in coastal Sonora following the summer monsoons, but then disappears through December and January (Etges and Heed, unpublished data). The presence of

D. arizonae on the mainland was hypothesized to have caused a shift in patterns of mate preference in *D. mojavensis*, so that now these populations exhibit behavioral isolation with the more ancestral *D. mojavensis* populations from Baja California (Zouros and d'Entremont, 1980). However, the species range of sina cactus is small relative to the range sizes of both species limiting the overall degree of host plant sharing. Furthermore, rearing *D. mojavensis* on agria cactus reduces premating isolation among populations to nonsignificant levels in comparison to laboratory food and organ pipe cactus (Etges, 1992, 1998; Brazner and Etges, 1993). In similar laboratory trials, rearing *D. mojavensis* and *D. arizonae* on agria cactus also reduced premating isolation from that observed with laboratory-food-reared flies (Yule's $V \pm 1$ SE, $0.811 \pm 0.076 > 0.643 \pm 0.008$, ($\chi^2 = 4.83$, 1 *df*, $P = 0.028$) (Etges, unpublished data), and alters amounts of a number of cuticular hydrocarbon components (Table 2). Thus, the documented sharing of host plants is crucial to the understanding of the evolution of sexual isolation within *D. mojavensis* and between *D. mojavensis* and *D. arizonae*. In the group as a whole, ecological isolation is perhaps the main factor contributing to species isolation.

There have been no studies of sexual isolation between *D. arizonae* and *D. navojoa*, but the degree of genetic differentiation and postmating isolation between them (Ruiz et al., 1990) suggests sexual isolation should be at least as strong as that between *D. mojavensis* and *D. navojoa* (Markow and Maveety, 1985). The role of epicuticular hydrocarbon variation in sexual isolation among *D. mojavensis* cluster species has yet to be studied. Given the degree of geographic variation within *D. mojavensis* cluster species in epicuticular hydrocarbons, it is reasonable to infer that epicuticular hydrocarbons may differentiate prior to species divergence. This is consistent with the broad-scale variation between Baja California and mainland populations of *D. mojavensis* that is responsible for premating isolation between populations (Stennett and Etges, 1997; Etges and Ahrens, 2001). Species-specific mate recognition and sexual isolation may then be more influenced by behavioral and mating song differences (Wasserman and Koepfer, 1977; Byrne, 1999) when species are drawn to the same cacti. Further within-species data concerning mating song variability as well as determination of the role of epicuticular hydrocarbons in species mate recognition is badly needed.

Acknowledgments—Miguel Armella, Chris Babcock, Celeste Durando, Greg Huckins, Conrad Istock, Francisco Molina, and Sandra Perez helped collect wild flies. Mitch Ahrens collected cactus-reared flies in the laboratory and Andre Lechance and Tom Starmer graciously provided yeast stocks. Jim Dunn suggested the nested ANOVA design, and Bill Durham provided us with a GC. Two anonymous reviewers provided helpful advice on the manuscript. We thank the director of the Chamela Biological Station in Jalisco for allowing us to collect there. We are indebted to the Direccion General de Conservacion Ecologico de los Recursos Naturales in Mexico City for issuing cactus collecting permits. This work was funded by NSF BSR-9509032, INT-9724790, and the Universidad Autonoma Metropolitana-Iztapalapa in Mexico City.

APPENDIX 1. NESTED ANOVA RESULTS FOR MAJOR HYDROCARBON COMPONENTS IN TWO POPULATIONS OF *D. mojavensis*, *D. Arizonae*, AND *D. navojoa* REARED ON AGRIA AND *Opuntia* CACTI[a]

CALL FOR PAPERS

SPECIAL ISSUE ON AQUATIC CHEMICAL ECOLOGY

There will be a special issue of the *Journal of Chemical Ecology* devoted entirely to papers dealing with "Aquatic Chemical Ecology". Publication is planned for late summer/early fall 2002. The issue will consist of invited mini-reviews and contributed papers. Those wishing to submit a paper for consideration for this special issue should do so by February 1, 2001.

Please send the original and two copies of the manuscript (including illustrations) and the names and addresses of three potential reviewers to:

(Received March 6, 2001; accepted July 5, 2001)

Abstract—All stereoisomers of three diepoxyalkenes derived from (3*Z*,6*Z*,9*Z*)-trienes with a C_{21}, C_{19}, or C_{18} straight chain, lymantriid sex pheromones and their candidates, were synthesized by MCPBA oxidation of optically active epoxyalkadienes. Their chromatographic behaviors were examined with GC and LC equipped with achiral and chiral columns. Detailed inspection of the mass spectra of these epoxides indicated the following diagnostic ions for determining the chemical structures: *m/z* 128, 167, M-87 and M-85 for (*Z*)-*cis*-3,4-*cis*-6,7-diepoxy-9-enes; *m/z* 111, M-125 and M-69 for (*Z*)-*cis*-6,7-*cis*-9,10-diepoxy-3-enes; and *m/z* M-125 and M-139 for (*Z*)-*cis*-3,4-*cis*-9,10-diepoxy-6-enes. Mass chromatographic analysis that monitored these fragment ions revealed the existence of a new pheromonal compound with a C_{21} chain in an extract from virgin females of a lymantriid species, *Perina nuda* F. The three diepoxyalkenes were converted into the corresponding DMDS adducts, which showed characteristic ions from fragmentation between the two thiomethyl groups, reflecting the position of an original double bond.

Key Words—*cis*-epoxides, sex pheromones, Lepidoptera, Lymantriidae, mass spectrometry, chiral HPLC, stereochemistry, diepoxyhenicosene, leucomalure.

INTRODUCTION

Sex pheromones have been identified from female moths of more than 500 species. About 75% of them are composed of unsaturated C_{10}–C_{18} straight-chain compounds with a functional group at the terminal position (type I), which are biosynthesized in the pheromone glands from saturated fatty acids. Another 15% consist of unbranched C_{17}–C_{23} (3*Z*,6*Z*,9*Z*)-trienes, (6*Z*,9*Z*)-dienes, and their monoepoxy derivatives (type II), which lack a terminal functional group and are biosynthesized from linolenic acid and linoleic acid. The type II pheromones have been identified from geometrid, noctuid, arctiid, and lymantriid species, which belong to highly evolved families (Arn et al., 1992, 1997; Millar, 2000).

Despite the great number of species in the above families, the structural diversity known for pheromonal compounds in type II is limited. Some females may be able to oxidize monoepoxy derivatives further to diepoxides, potentially generating a greatly increased number of pheromone components. From a (3*Z*,6*Z*,9*Z*)-triene, for example, epoxidation of two double bonds makes three positional isomers of diepoxyalkenes (**1**–**3**) in Figure 1, each of which has four stereoisomers. The first example of a diepoxy compound was reported by Gries et al. (1997), who have identified (*Z*)-*cis*-6,7-*cis*-9,10-diepoxy-3-henicosene (**2a**, leucomalure) from the satin moth, *Leucoma salicis* L. Although the syntheses of all stereoisomers of **2a** were published in our previous paper (Yamamoto et al., 1999a), other compounds with a different chain length and epoxy rings at different positions are also candidates for lymantriid pheromones. Therefore, we systematically synthesized all stereoisomers of the diepoxyalkenes (**1**–**3**) with a C_{21}, C_{19}, or C_{18} chain (Figure 1). This paper presents a convenient method to prepare them and describes their chromatographic behaviors on achiral and chiral columns. Furthermore, these diepoxyalkenes were analyzed by GC-MS without and with derivatization. We report here the diagnostic fragment ions for distinction of the positional isomers, which were applied to the identification of (*Z*)-*cis*-3,4-*cis*-6,7-diepoxy-3-henicosene (**1a**), a minor component of the sex pheromone of *Perina nuda* F. This lymantriid female moth secretes a monoepoxy derivative as a main component of its pheromone (Wakamura et al., unpublished date).

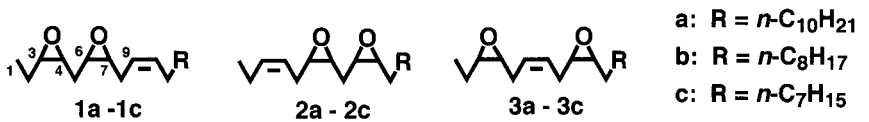

FIG. 1. Chemical structures of diepoxyalkenes with a C_{21}, C_{19}, or C_{18} chain: (*Z*)-*cis*-3,4-*cis*-6,7-diepoxy-9-enes (**1a**–**1c**), (*Z*)-*cis*-6,7-*cis*-9,10-diepoxy-3-enes (**2a**–**2c**), and (*Z*)-*cis*-3,4-*cis*-9,10-diepoxy-6-enes (**3a**–**3c**).

METHODS AND MATERIALS

Chromatography. GC analysis was done on an HP GC System 6890 series with a flame ionization detector and a DB-23 or DB-1 capillary column (0.25 mm ID × 30 m, J & W Scientific). The temperature program was 50°C for 2 min, 10°C/min to 160°C, and finally 4°C/min to 220°C. HPLC involved a JASCO PU-980 liquid chromatograph equipped with an integrator (System Instrument Chromatocorder 21J), an RI detector (Labo System RI-98SCOPE, Tokyo, Japan), and one of the following columns: a Grand pack ODS column (2.0 cm ID × 25 cm, Senshukagaku, Tokyo, Japan) or a Chiralpak AD column (0.46 cm ID × 25 cm, Daicel Chemical Industry Co., Ltd., Tokyo, Japan). Into the former reversed-phase achiral column, a mixture of several milligrams was injected per run by using 5% water in MeOH as a solvent (4.0 ml/min). Into the latter normal phase chiral column, a mixture of less than 0.1 mg was injected per run by using 0.5% 2-propanol in *n*-hexane (0.45 ml/min). A medium pressure liquid chromatographic (MPLC) system was constructed with a solvent pump (JASCO 880- PU), double Lobar columns (Merck Lichroprep Si 60, 1.0 cm ID × 24 cm, 40–63 μm), and an RI detector. About 20 mg of a mixture were injected per run by using 8% THF in *n*-hexane as a solvent (2.0 ml/min).

Instruments. ^{1}H and ^{13}C NMR spectra were recorded on a Jeol Alpha500 Fourier transform spectrometer at 500.2 and 125.7 MHz, respectively, for $CDCl_3$ solutions containing TMS as an internal standard. ^{1}H–^{1}H-COSY and HSQC spectra were also measured with the same spectrometer, using the usual pulse sequences and parameters. Electron impact (EI) GC-MS was performed on a Jeol JMS SX-102A mass spectrometer (magnetic sector type) equipped with an HP-1 (0.25 mm ID × 15 m, Hewlett-Packard Co.) or an HP 5973 mass spectrometer (quadrupole type) equipped with another HP-1 capillary column (0.32 mm ID × 30 m). The column temperature program for the Jeol JMS SX-102A was 50°C for 1 min, 20°C/min to 150°C, then 5°C/min to 220°C, and for HP 5973 it was 120°C for 2 min, then 6°C/min to 270°C. The ionization voltage was 70 eV, and the ion source temperature was 230°C. The specific rotation of each $CHCl_3$ solution was measured on a JASCO DIP-4 polarimeter.

*(*Z*)-*cis*-3,4-*cis*-6,7-Diepoxy-9-enes (**1a**–**1c**) and (*Z*)-*cis*-6,7-*cis*-9,10-Diepoxy-3-enes (**2a**–**2c**).* Synthesis of all stereoisomers of **1a** and **2a** was reported previously (Yamamoto et al., 1999a). In brief, MCPBA oxidation of (6*S*,7*R*)-**4a** produced two pairs of diastereomers of **1a** with a 3*S*,4*R*,6*S*,7*R* and 3*R*,4*S*,6*S*,7*R* configuration (**1a-i** and **1a-iii**) and **2a** with a 6*S*,7*R*,9*S*,10*R* and 6*S*,7*R*,9*R*,10*S* configuration (**2a-i** and **2a-ii**) in a ratio of 2 : 3 : 2 : 3. These four components were separable by MPLC equipped with a Lobar column, and their chemical structures were confirmed by 2D-NMR. From (6*R*,7*S*)-**4a**, other stereoisomers of **1a** with a 3*S*,4*R*,6*R*,7*S* and 3*R*,4*S*,6*R*,7*S* configuration (**1a-ii** and **1a-iv**) and **2a** with a 6*R*,7*S*,9S,10*R* and 6*R*,7*S*,9*R*,10*S* configuration (**2a-iii** and **2a-iv**) were

synthesized. By using the same procedure as for the diepoxy compounds with a C_{21} chain, all stereoisomers of 3,4-6,7-diepoxy-9-enes (**1b** and **1c**) and 6,7-9,10-diepoxy-3-enes (**2b** and **2c**) with a C_{19} or C_{18} chain were prepared by starting from optically active (3*Z*,9*Z*)-*cis*-6,7-epoxy-3,9-nonadecadiene (**4b**) and octadecadiene (**4c**). NMR data of newly synthesized C_{19} and C_{18} diepoxy compounds were analogous to those of the corresponding C_{21} compounds, except for the intensity of the methylene protons at δ1.25 ppm, and the number of methylene carbons around δ29.5 ppm.

*(*Z*)-*cis*-3,4-*cis*-9,10-Diepoxy-6-enes (**3a–3c**).* Optically pure 3*S*,4*R* and 3*R*,4*S* isomers of (6*Z*,9*Z*)-*cis*-3,4-epoxy-6,9-henicosadiene (**5a**) were obtained by chiral HPLC resolution of the racemic mixture (Qin et al., 1997). These enantiomers (5 mg, 16 μmol), separately dissolved in dry CH_2Cl_2 (20 ml), were added to MCPBA (70% pure, 4.0 mg, 23 μmol) and stirred at 0°C for 1 hr. After further stirring at room temperature for 2 hr, the reaction mixtures were washed with 3 N NaOH solutions and dried over Na_2SO_4. Preparative TLC gave a mixed product of two diastereomers of **3a** with 3*S*,4*R*,9*S*,10*R* and 3*S*,4*R*,9*R*,10*S* configurations (**3a-i** and **3a-ii**, 2.6 mg, 50% yield) derived from (3*S*,4*R*)-**5a**, and those with 3*R*,4*S*,9*S*,10*R* and 3*R*,4*S*,9*R*,10*S* configurations (**3a-iii** and **3a-iv**, 2.8 mg, 54% yield) derived from (3*R*,4*S*)-**5a**. Each compound was isolated by chiral HPLC with a Chiralpak AD column. NMR of **3a-i** and **3a-iv:** ^{1}H δ ppm: 0.88 (H-21, t, J = 7 Hz), 1.06 (H-1, t, J = 7.5 Hz), ~1.25 (H-12–20, broad), ~1.55 (H-2 and 11, m), ~2.25 and ~2.4 (H-5 and 8, m), ~2.95 (H-3, 4, 9 and 10, m), 5.60 (H-6 and 7, m); ^{13}C δ ppm: 10.6 (C-1), 14.1 (C-21), 21.1 (C-2), 22.7 (C-20), 26.4, 26.5, and 26.6 (C-5, 8, and 12), 27.8 (C-11), 29.4–29.7 (C-13–18), 31.9 (C-19), 56.22 and 56.35 (C-9 and 10), 57.18 (C-4), 58.30 (C-3), 126.80 and 126.87 (C-6 and 7). NMR of **3a-ii** and **3a-iii**: ^{1}H δ ppm: 0.89 (H-21, t, J = 7 Hz), 1.06 (H-1, t, J = 7.5 Hz), ~1.25 (H-12–20, broad), ~1.55 (H-2 and 11, m), ~2.25 and ~2.35 (H-5 and 8, m), ~2.95 (H-3, 4, 9 and 10, m), 5.61 (H-6 and 7, m); ^{13}C δ ppm: 10.6 (C-1), 14.1 (C-21), 21.1 (C-2), 22.7 (C-20), 26.4, 26.5, and 26.6 (C-5, 8, and 12), 27.8 (C-11), 29.4–29.7 (C-13–18), 31.9 (C-19), 56.30 and 56.43 (C-9 and 10), 57.20 (C-4), 58.32 (C-3), 126.86 and 126.93 (C-6 and 7). $[\alpha]_D$ at 25°C: **3a-i** + 0.4 (c = 0.4), **3a-ii** + 6.0 (c = 1.7), **3a-iii** − 5.7 (c = 2.1), and **3a-iv** − 0.4 (c = 0.6).

Optically pure 9*S*,10*R* and 9*R*,10*S* isomers of (3*Z*,6*Z*)-*cis*-9,10-epoxy-3,6-henicosadiene (**6a**) were also obtained by chiral HPLC resolution of the racemic mixture (Qin et al., 1997). Two other sets of diastereomers were prepared, i.e., **3a-i** and **3a-iii** from (9*S*,10*R*)-**6a** and **3a-ii** and **3a-iv** from (9*R*,10*S*)-**6a**. By the same procedure, all stereoisomers of **3b** and **3c** were synthesized from optically active (6*Z*,9*Z*)-*cis*-3,4-epoxy-6,9-nonadecadiene (**5b**) and octadecadiene (**5c**).

Pheromone Extract. Pheromone glands were removed from 1-day-old virgin females of *P. nuda* around 30 min after lights went on, and soaked in *n*-hexane for 15 min to extract the pheromone. This extract was fractionated on a column with Florisil (200 mg, 100–200 mesh, Floridin Co.). Substances were eluted

successively with 1 ml each of *n*-hexane and 5%, 20%, and 50% ether in *n*-hexane, and an aliquot [3 female equivalents (FE)] of the third fraction, which was recovered with 20% ether in *n*-hexane and included diepoxyalkenes, was analyzed by using a JMS SX-102A GC-MS.

Derivatization with DMDS. Each synthetic diepoxyalkene (10 μg) was dissolved in a mixture of DMDS (10 μl) and diethyl ether (100 μl) including iodine (1.8 mg). The reaction mixture was kept at 40°C for 3 hr and diluted with diethyl ether after cooling. Iodine was removed by shaking with a 10% aqueous $Na_2S_2O_3$ solution, and crude products were analyzed by an HP 5973 GC-MS.

RESULTS

Synthesis of C_{21}, C_{19}, and C_{18} Diepoxyalkenes. MCPBA oxidation of 6,7-epoxy-3,9-dienes (**4**) proceeded without regioselectivity and produced a mixture of 3,4-6,7-diepoxy-9-enes (**1**) and 6,7-9,10-diepoxy-3-enes (**2**). (6*S*,7*R*)-**4a** was converted into four C_{21} diepoxy compounds with a 6*S*,7*R* configuration (**1a-i**, **1a-iii**, **2a-i**, and **2a-ii**), and (6*R*,7*S*)-**4a** was converted into the others with a 6*R*,7*S* configuration (**1a-ii**, **1a-iv**, **2a-iii**, and **2a-iv** as shown in Figure 2A (Yamamoto et al., 1999a). Each compound isolated by a chromatographic technique was identified by the NMR data. The methyl protons at position 1 of **1a** resonated

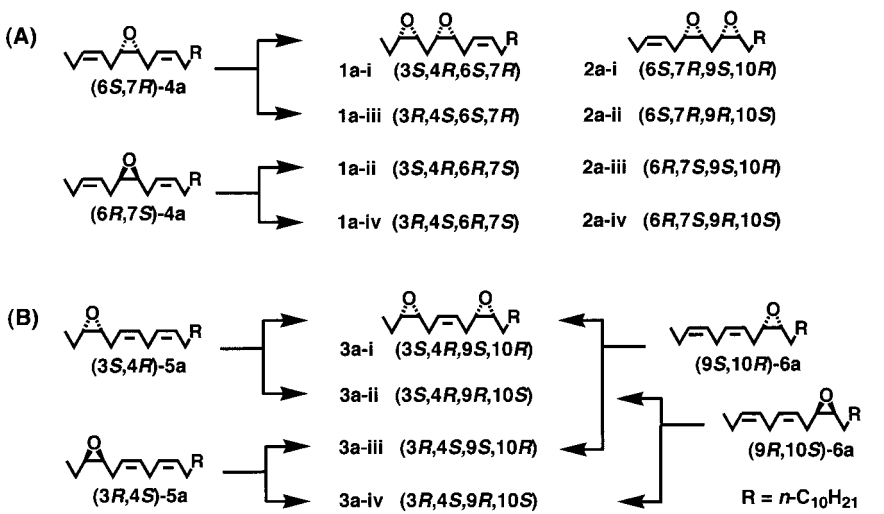

FIG. 2. Conversion of optically active epoxyhenicosadienes (**4a**–**6a**) into diepoxyhenicosenes (**1a**–**3a**): synthesis of all stereoisomers of **1a** and **2a** from *cis*-6,7-epoxy-3,9-henicosadiene (**4a**) (A), and synthesis of all stereoisomers of **3a** form *cis*-3,4-epoxy-6,9-henicosadiene (**5a**) and *cis*-9,10-epoxy-3,6-henicosadiene (**6a**) (B).

at a lower field than those of **2a**, and splitting of the methylene protons between two epoxy rings in stereoisomers with a symmetrical S^*,R^*,R^*,S^* configuration[4] was simpler than those with another S^*,R^*,S^*,R^* configuration (Yamamoto et al., 1999a). All stereoisomers of **1b** and **2b** with a C_{19} chain and **1c** and **2c** with a C_{18} chain were synthesized and characterized in the same manner. Oxidation of 3,4-epoxy-6,9-dienes (**5**) and 9,10-epoxy-3,6-dienes (**6**) happened exclusively at one of two double bonds located far from the epoxy ring of the parent monoepoxides. Stereoisomers of **3** were prepared by selective monooxidation of optically active **5** or **6**. MCPBA oxidation of (3*S*,4*R*)-**5a** produced a mixture of 3*S*,4*R*,9*S*,10*R* and 3*S*,4*R*,9*R*,10*S* isomers of **3a** (**3a-i** and **3a-ii**), and oxidation of (9*S*,10*R*)-**6a** produced another mixture of 3*S*,4*R*,9*S*,10*R* and 3*R*,4*S*,9*S*,10*R* isomers (**3a-i** and **3a-iii**), as shown in Figure 2B. Since these three stereoisomers were separable on a chiral HPLC column (Table 1) and these two sets of the mixtures include **3a-i** as a common component, the absolute configuration of each separated isomer could be assigned. In addition, the 3*R*,4*S*,9*R*,10*S* isomer of **3a** (**3a-iv**) was prepared as a common component of the monooxidation products from (3*R*,4*S*)-**5a** and (9*R*,10*S*)-**6a**. All stereoisomers of 3,4-9,10-diepoxy-6-enes with a C_{19} or C_{18} chain (**3b** and **3c**) were synthesized in the same manner.

Chromatographic Behavior of Diepoxyalkenes. Table 1 shows the retention times of diepoxyhenicosenes (**1a**–**3a**) from GC and LC analyses. On capillary GC columns, the diastereomers of each positional isomer were separable. The isomers with the S^*,R^*,R^*,S^* configuration, orienting two epoxy rings to the opposite face, eluted faster than the isomers with the S^*,R^*,S^*,R^* configuration, orienting two epoxy rings to the same face. A polar DB-23 column was better for the separation of the diastereomers than a nonpolar DB-1 column. However, **1a** and **2a** with the S^*,R^*,R^*,S^* configuration showed the same retention time, and it was not possible to separate all six isomers of the diepoxide on either GC column. GC could not be used to determine unambiguously which isomer was present in all cases. A chiral capillary GC column (Chiraldex A-PH), which resolved racemic 3,4-epoxy-6,9-nonadecadiene **5b** (Ando et al., 1997), did not separate the enantiomers of any diepoxyalkenes synthesized in this study. The diastereomers of **1a** and **2a** were also separated by either normal phase LC by using a Lobar column or reversed-phase LC with an ODS column. Although a diastereomeric mixture of **3a** showed only one peak on the LC, the first half of the elution was enriched with (S^*,R^*,S^*,R^*)-**3a**, and the second half with (S^*,R^*,R^*,S^*)-**3a**. Thus, each diepoxide with the S^*,R^*,S^*,R^* configuration eluted faster than the corresponding diastereomer on the LC, interestingly, in the reverse order of that on the GC. Since **3a** has a markedly short retention time on an ODS column, the achiral HPLC is also useful for separating **3a**

[4] S^*, R^*, R^*, S^* means 3*S*,4*R*,6*R*,7*S* and 3*R*,4*S*,6*S*,7*R* for **1**, 6*S*,7*R*,9*R*,1*S* and 6*R*,7*S*,9*S*,10*R* for **2**, and 3*S*,4*R*,9*R*,10*S* and 3*R*,4*S*,9*S*,10*R* for **3**.

TABLE 1. CHROMATOGRAPHIC BEHAVIOR OF DIEPOXYALKENES (**1a**–**3a**) DERIVED FROM (*Z*3,*Z*6,*Z*9)-3,6,9-HENICOSATRIENE

	Retention time (min)

[a] S^*,R^*,S^*,R^* means 3*S*,4*R*,6*S*,7*R* and 3*R*,4*S*,6*R*,7*S* isomers of **1a** (**1a-i** and **1a-iv**), 6*S*,7*R*,9*S*,10*R* and 6*R*,7S,9*R*,10*S* isomers of **2a** (**2a-i** and **2a-iv**), and 3*S*,4*R*,9*S*,10*R* and 3*R*,4*S*,9*R*,10*S* isomers of **3a** (**3a-i** and **3a-iv**).

[b] S^*,R^*,R^*,S^* means 3*S*,4*R*,6*R*,7*S* and 3*R*,4*S*,6*S*,7*R* isomers of **1a** (**1a-ii** and **1a-iii**), 6*S*,7*R*,9*R*,10*S* and 6*R*,7*S*,9*S*,10*R* isomers of **2a** (**2a-ii** and **2a-iii**), and 3*S*,4*R*,9*R*,10*S* and 3*R*,4*S*,9*S*,10*R* isomers of **3a** (**3a-ii** and **3a-iii**).

[c] Capillary column (0.25 mm ID × 30 m); temperature program: 50°C for 2 min, 10°C/min to 160°C, and finally 4°C/min to 220°C.

[d] Lobar column: Merck Lichroprep Si 60 (1.0 cm ID × 24 cm, 40–63 μm); solvent: 8% THF in *n*-hexane at a flow rate of 2.0 ml/min.

[e] The first half fraction (Fr. 1) is enriched with (S^*,R^*,S^*,R^*)-**3a**, and the second half fraction (Fr. 2) with (S^*,R^*,R^*,S^*)-**3a**.

[f] Reversed-phase column: Grand pack ODS (2.0 cm ID × 25 cm); solvent: 5% water in MeOH at a flow rate of 4.0 ml/min.

[g] Chiral column: Chiralpak AD (0.46 cm ID × 25 cm); solvent: 0.5% 2-propanol in *n*-hexane at a flow rate of 0.45 ml/min. Values in parentheses mean separation factors (α).

from the other two positional isomers (**1a** and **2a**). Satisfactory resolution of each pair of diepoxyalkene enantiomers was accomplished by chiral HPLC, as indicated by retention times and separation factors (α). Besides the enantiomers, the chiral AD column usefully separated some of the diastereomers and positional isomers of the diepoxyalkenes. The separation profiles of diepoxynonadecenes (**1b**–**3b**) and diepoxyoctadecenes (**1c**–**3c**) were similar to those of **1a**–**3a** listed in Table 1. Without distinction of chain lengths, the elution orders of positional isomers, diastereomers, and enantiomers were the same with all chromatographic methods.

MS Analysis of Diepoxyalkenes. Figure 3 shows the EI mass spectra of three positional isomers of diepoxynonadecene (**1b**–**3b**). In addition to small M^+ and $[M\text{-}18]^+$ ions, each positional isomer showed characteristic fragment ions, i.e., *m/z* 128, 167, 207, and 209 for **1b** (Figure 3A), *m/z* 111, 169, and 225 for **2b** (Figure 3B), and *m/z* 155 and 169 for **3b** (Figure 3C). These ions seemed to reflect the chemical structures, and this was confirmed by a systematic MS analysis of the positional isomers of diepoxyalkenes with a C_{21}, C_{19}, and C_{18} chain. As indicated

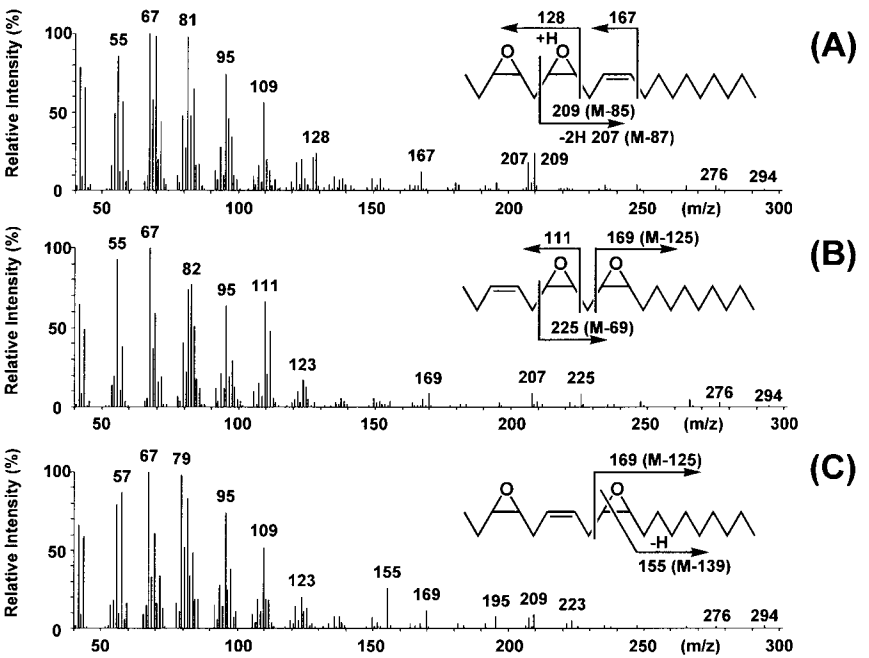

FIG. 3. Mass spectra of three positional isomers of diepoxyalkene: (*Z*)-*cis*-3,4-*cis*-6,7-diepoxy-9-nonadecene (**1b**) (A), (*Z*)-*cis*-6,7-*cis*-9,10-diepoxy-3-nonadecene (**2b**) (B), and (*Z*)-*cis*-3,4-*cis*-9,10-diepoxy-6-nonadecene (**3b**) (C).

in Table 2, the results suggest the following diagnostic ions for determining the position of the two epoxy rings: *m/z* 128, 167, M-87 and M-85 for 3,4-6,7-diepoxy-9-enes (**1**); *m/z* 111, M-125 and M-69 for 6,7-9,10-diepoxy-3-enes (**2**); and *m/z* M-139 and M-125 for 3,4-9,10-diepoxy-6-enes (**3**).

GC-MS Analysis of a Pheromone Extract of P. nuda. Mass chromatograms of a mixture that included three positional isomers of synthetic diepoxyhenicosene, (*S**,*R**,*S**,*R**)-**1a**, (*S**,*R**,*R**,*S**)-**2a**, and (*S**,*R**,*S**,*R**)-**3a**, indicated their coexistence in a ratio of 1 : 1 : 1 and an absence of their diastereomers in the mixture (Figure 4A). The pheromone extract that included diepoxides scarcely showed ion peaks at *m/z* 183 (M-139) and 197 (M-125), which were diagnostic for **2a** and **3a**, at the retention times of these diepoxides. However, diagnostic ions for **1a** at *m/z* 128, 167, 235 (M-87), and 237 (M-85) were observed at two different retention times (Figure 4B). This measurement revealed that *P. nuda* females secrete at least

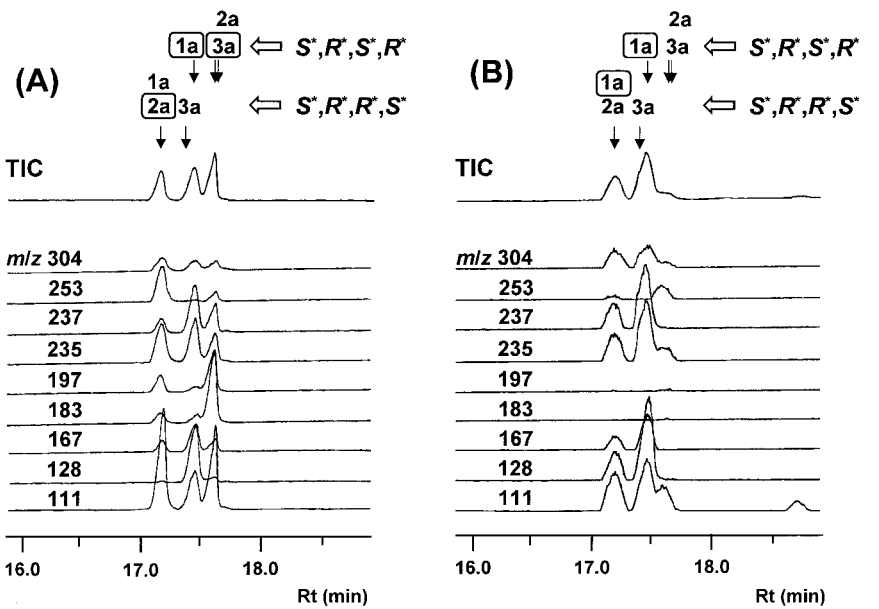

FIG. 4. Mass chromatography of a mixture of three positional isomers of synthetic diepoxyhenicosenes (**1a**–**3a**) (A) and a natural pheromone of *Perina nuda* (B), monitoring their M^+ and diagnostic fragment ions listed in Table 2. GC-MS analysis was achieved with a Jeol JMS SX-102A mass spectrometer equipped with an HP-1 column (0.25 mm ID × 15 m). The column temperature program was 50°C for 1 min, 20°C/min to 150°C, then 5°C/min to 220°C. Synthetic standards [(*S**,*R**,*S**,*R**)-**1a**, (*S**,*R**,*R**,*S**)-**2a**, and (*S**,*R**,*S**,*R**)-**3a**] used in (A) and components estimated for the pheromone [(*S**,*R**,*R**,*S**)-**1a** and (*S**,*R**,*S**,*R**)-**1a**] in (B) are shown with compound numbers in frames.

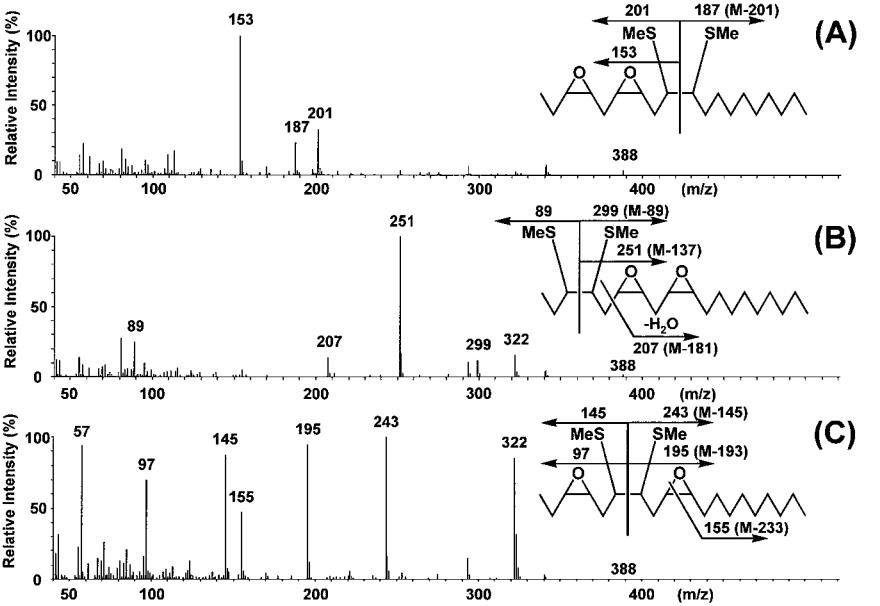

FIG. 5. Mass spectra of DMDS adducts derived from (*Z*)-*cis*-3,4-*cis*-6,7-diepoxy-9- nonadecene (**1b**) (A), (*Z*)-*cis*-6,7-*cis*-9,10-diepoxy-3-nonadecene (**2b**) (B), and (*Z*)-*cis*-3,4-*cis*-9,10-diepoxy-6-nonadecene (**3b**) (C).

two stereoisomers of **1a**. The ratio of (*S**,*R**,*S**,*R**)-**1a** and (*S**,*R**,*R**,*S**)-**1a** was about 3 : 2.

GC-MS Analysis of DMDS Adducts Derived from Diepoxyalkenes. Diepoxyalkenes (**1**–**3**) were converted into DMDS adducts, which showed informative fragment ions reflecting the position of their original double bonds. DMDS adducts derived from **1** produced characteristic ions at *m/z* 201 and M-201 from cleavage of the bond between the 9 and 10 positions. In addition, they showed other significant ions at *m/z* 153, probably derived by further removal of MeSH from the *m/z* 201 ion (Figure 5A). DMDS adducts of **2** produced diagnostic ions at *m/z* 89, M-181, M-137, and M-89 (Figure 5B). The ion at *m/z* M-89 arises from cleavage of the bond between the 3 and 4 positions and might be further degraded to the ion at *m/z* M-137 by removal of MeSH. DMDS adducts of **3** produced abundant ions at *m/z* 97, 145, M-233, M-193, and M-145 (Figure 5C). The ions at *m/z* 145 and M-145 are probably derived from cleavage of the bond between the 6 and 7 positions and might be further degraded to the ions at *m/z* 97 and M-193 by removal of MeSH. The relative intensities of the fragment ions produced from the DMDS adducts with a C_{18}, C_{19}, or C_{21} chain and their retention times are listed in Table 3. The adducts of **1**–**3** with the same chain length eluted separately from a capillary GC column.

DISCUSSION

Several pheromone epoxyalkadienes were previously stereoselectively synthesized by using Sharpless asymmetric epoxidation of an allylic alcohol or pig pancreatic lipase-catalyzed asymmetric hydrolysis of a *meso*-diacetoxyepoxybutane (Mori, 1994; Millar, 2000; and references cited therein). For the synthesis of diepoxyalkenes, stereoselective construction of both epoxy rings seemed quite arduous. Therefore, we chose an alternate route in which the second epoxy ring was introduced into epoxyalkadienes without stereoselectivity, and then chromatographic techniques were effectively utilized to isolate each stereoisomer from the produced mixture. First, each stereoisomer of diepoxyalkenes **1** and **2** was prepared by MCPBA oxidation of optically active 6,7-epoxyalkadiene **4**. This oxidation proceeded without regioselectivity and with low stereoselectivity, yielding a mixture of four components (two sets of diastereomers of **1** and **2**). The four components were separable by one of the following types of chromatography: MPLC with a Lobar column, HPLC with an ODS column, or HPLC with a chiral column. Even though a mixture of all possible stereoisomers of **1** and **2** (a total of eight components) is made by the oxidation of racemic **4**, the separation of each component can be accomplished by a combination of these achiral and chiral types of chromatography, as indicated by the data summarized in Table 1. In contrast, MCPBA oxidation of **5** or **6** was regioselective to yield only **3**. When racemic **5** or **6** is treated with MCPBA, a mixture of four stereoisomers of **3** is produced. Each isomer is separable by chiral HPLC from this mixture. If a (3*Z*,6*Z*,9*Z*)-triene is treated with two equivalents of MCPBA, a mixture composed of all stereoisomers of **1–3** (a total of 12 components with the same chain length) will be obtained. Table 1 shows that each component can be separated by two successive HPLC procedures with achiral ODS and chiral AD columns. For the separation of enantiomers of epoxyalkadienes and epoxyalkenes derived from (3*Z*,6*Z*,9*Z*)-trienes and (6*Z*,9*Z*)-dienes, we utilized chiral HPLC (Qin et al., 1997; Pu et al., 1999; Yamamoto et al., 1999b). The work reported here extends the application of the chiral HPLC technique to diepoxyalkenes.

GC-MS is one of the most useful techniques for analyzing insect pheromones because of its high sensitivity, excellent resolution, and rational data that reflect the structures of samples. Pheromone compounds in type II show characteristic mass spectra, indicating the length of their carbon chain and functionality, i.e., the numbers of double bond(s) and epoxy ring(s). For differentiation of the positional isomers of epoxyalkadienes and epoxyalkenes, both Millar and we have previously offered some diagnostic fragment ions based on the spectra of many compounds systematically synthesized (Ando et al., 1993, 1995; Millar, 2000). In this study, we found additional diagnostic ions for diepoxyalkenes and successfully identified a new diepoxyalkene (**1a**) as a minor pheromonal component from a lymantriid species, *P. nuda*, by examining the profile of those ions in a

GC-MS analysis of the pheromone extract. This species is a defoliator of the Malayan banyan in the Ryukyu Islands of Japan. Although the main pheromonal component has been identified as 6,7-epoxyalkadiene (**4a**) with a 6*S*,7*R* configuration, its attractive activity is weak, suggesting one or more minor components that play an important role for male attraction (Wakamura et al., unpublished date). Diastereomers and positional isomers of diepoxyalkenes show similar chromatographic behavior even on a polar capillary GC column. If a natural pheromone is composed of a diepoxyalkene, these fragment ions are useful for the elucidation of chemical structure. Our GC-MS analysis of the *P. nuda* extract excluded the possibility of the existence of other diepoxyalkenes, **2a** and **3a,** in the fraction containing diepoxyalkenes, but it revealed the presence of two diastereomers of **1a**. Chiral HPLC analysis of the extract showed that they have 3*S*,4*R*,6*S*,7*R* and 3*R*,4*S*,6*S*,7*R* configurations, and field tests with synthetic lures indicated strong synergistic activity for male attraction to **4a** (Wakamura et al., unpublished data).

For many pheromones of type I, the positions of double bonds have been successfully determined by GC-MS after making DMDS adducts (Buser et al., 1983). In the case of the type II pheromones, epoxyalkenes were easily converted to DMDS adducts. The adducts of 6,7-epoxy-9-enes and 9,10-epoxy-6-enes provided diagnostic GC-MS data. For example, by this DMDS method, we have confirmed the structure of the natural pheromone secreted by a geometrid female, *Biston robustum* Butler (Yamamoto et al., 2000). This study found that DMDS adducts of **1**–**3** also showed diagnostic fragment ions for determining the original positions of the double bonds. These ions would be useful in elucidating the chemical structures of natural diepoxyalkenes.

(Received March 24, 2000; accepted July 4, 2001)

Abstract—Whole body extracts of virgin *Eurytoma amygdali* females were attractive to males in laboratory bioassays. Extracts of various body parts of the female wasp elicited different responses to males, with the thorax extract being the most active. Preparative fractionation of the crude hydrocarbon extract on a silver nitrate impregnated silica gel column (alkanes, alkenes, and alkadienes) revealed that the highest male response was elicited by alkadienes and the lowest by alkenes, with the alkane fraction being inactive. The identification of alkenes and alkadienes was based on gas chromatographic, mass spectrometric, and gas-phase infrared data. Laboratory bioassays suggested that the two alkadienes, (*Z*,*Z*)-6,9-tricosadiene [(*Z*,*Z*)-6,9-$C_{23:2}$], and (*Z*,*Z*)-6,9-pentacosadiene [(*Z*,*Z*)-6,9-$C_{25:2}$], and to a lesser extent alkenes, identified in the female extract of *E. amygdali* were male attractants.

Key Words—*Eurytoma amygdali*, Eurytomidae, Hymenoptera, unsaturated hydrocarbons, (*Z*,*Z*)-6,9-tricosadiene, (*Z*,*Z*)-6,9-pentacosadiene, sex pheromones.

INTRODUCTION

The almond seed wasp, *Eurytoma amygdali* Enderlein (Hymenoptera: Eurytomidae), is a serious pest of almonds in a number of southeastern European countries, the Middle East, and some of the countries of the former Soviet Union (Mentzelos and Atjemis, 1970; Plaut, 1971,1972; Talhouk, 1977; Arambourg et al., 1983; Zerova and Fursov, 1991). The damage caused to the crop can reach up to 90% by mummifying the infested almond. Control measures for this pest are based on cultural practices, such as collection of infested almonds and chemical control by the application of a systemic insecticide against the young larvae.

0098-0331/01/1100-2169$19.50/0

The wasp develops one generation per year, and larvae overwinter inside the infested almonds. The adults emerge in the following April, and the females oviposit in the unripe green almonds leaving one egg. The hatching larva feeds on the developing endosperm.

Male attraction to virgin females has been reported by Pittara and Katsoyannos (1985), who suggested that attraction resulted from chemicals released by the virgin females. Katsoyannos et al. (1992) have used traps baited with virgin females to monitor populations of *E. amygdali*; however, use of this trap setup (living female wasps) is limited and can be applied only by trained personnel. There is little knowledge of the chemicals involved in the mating process of the Eurytomidae family, and so far there is no reference in the literature for the determination of sex pheromones. This study reports on the chemical composition and characterization of whole body extracts and headspace volatiles from male and female *E. amygdali* and the identification of chemicals that are involved in the mating process of this wasp.

METHODS AND MATERIALS

Insects. The insects used were obtained from infested almonds collected from the field in late autumn and stored at 4–6°C. Portions of infested almonds were transferred regularly from the cold room to the laboratory. Adults were separated by sex as soon as they emerged and were kept in cages at 25 ± 2°C and 14 L : 10D photoregime. Wasps were provided with a 10% sucrose solution.

Extraction of Cuticular Lipids. Whole bodies of 2- to 3-day-old females or males were extracted with methylene chloride for 20 min. After exchange of the solvent to hexane, extracts were fractionated on a silica solid-phase extraction (SPE) column (Sep-Pak Plus Silica Cartridges, 690 mg, Waters Chromatography Division, Part No. WAT020520) and eluted with approximately 2 ml hexane (fraction I), followed by an equal volume of methylene chloride (fraction II), and finally methanol (fraction III). The three fractions were concentrated by a gentle stream of nitrogen to the appropriate volume and were used for bioassays or further analysis. The hexane fraction was fully characterized by GC-MS and GC-FTIR. For GC-MS, 1 μl containing ca. 2–3 insect equivalents was injected in duplicate, while for GC-FTIR, 1 μl containing ca. 15 insect equivalents was injected in duplicate.

Solid-Phase Microextraction (SPME). Collection of chemicals from the insect cuticle was also performed by rubbing a SPME fiber (100 μm polydimethylsiloxane, Supelco) over the insect body. Two individuals were used for each collection. The same SPME fiber was also used to collect airborne volatiles by headspace extraction. In this case, four individuals were placed in a 4-ml vial, left for 1 hr, and the fiber was subsequently inserted and exposed to the volatiles for 2 hr.

Hydrocarbon Fractionation and Identification. Cuticular hydrocarbons were separated by the degree of unsaturation on a silver nitrate-impregnated silica gel ($AgNO_3$–SiO_2) column (20% w/w $AgNO_3$ impregnated silica gel, 6.5 g, 1 cm ID $\times$ 8 cm height, gravity flow). The column was eluted stepwise by a series of hexane–diethyl ether mixtures (100 : 0, 95 : 5, and 50 : 50 by volume, each 6 ml). Alkanes were collected in the first fraction, alkenes in the second, and alkadienes in the third . The composition of each fraction was determined by GC-MS. The use of equivalent chain length (ECL) values provided a means of identifying the homolog series of branched methylalkanes. ECL values were calculated from a standard containing a series of *n*-alkanes (C_{14}–C_{31}) at concentrations ranging from 100 to 500 ng/μl each in *n*-hexane. All alkane standards were purchased from Aldrich (Sigma-Aldrich Chemie GmbH, Munich, Germany) at a purity of 97–99%.

Determination of Double Bonds. Double-bond positions in mono- and diunsaturated compounds were determined by mass spectral analysis (GC-MS) of the epoxide derivatives (Bierl-Leonhard et al., 1980; Hogge et al., 1985). Epoxy derivatives were prepared at room temperature by overnight reaction of an extract containing ca. 25 insect equivalents with 400 μg of *m*-chloroperbenzoic acid (MCPBA, Sigma-Aldrich Chemie) in a 1 : 1 mixture of *n*-heptane and methylene chloride. After completion of the reaction, an equivalent of ca. 5 female insects were analyzed by GC-MS. Epoxy derivatives of synthetic standards of (*Z*)-9-$C_{23:1}$ (Sigma-Aldrich Chemie), (*Z*,*Z*)-6,9-$C_{23:2}$, and (*Z*,*Z*)-6,9-$C_{25:2}$ (both alkadienes were a kind gift from Vioryl S. A, Athens, Greece) were also prepared by reacting 20 μg of each standard with 100 μg of MCPBA under the above same experimental conditions. The geometry (*E* or *Z*) of the double bonds was determined by GC-FTIR.

Gas Chromatography–Mass Spectrometry. Gas chromatography–mass spectrometry analysis was carried out on a Hewlett Packard 5890 Series II gas chromatograph interfaced to a Fisons VG Trio 1000 (Manchester, UK) quadrupole mass spectrometer. Electron impact ionization was used, with an electron energy of 70 eV and a trap current of 200 μA. Extracts were chromatographed on a 60-m $\times$ 0.25-mm $\times$ 0.1-μm film thickness DB-5 column (J & W Scientific). The oven temperature program was set at 50°C for 2 min, then raised to 250°C at 5°C/min, held for 1 min, then 2°C/min to 280°C, and held for 50 min. Helium was used as the carrier gas at a flow rate of 1 ml/min. Splitless injections were made (1 μl) at an injector temperature of 250°C and a splitless period of 90 sec. For the SPME analysis, the fiber was desorbed into the injection port for 5 min.

Gas Chromatography–Fourier Transform Infrared Spectroscopy. GC-FTIR analysis was carried out on a Perkin Elmer Autosystem gas chromatograph interfaced to a Perkin Elmer System 2000 (Perkin Elmer Ltd.) fourier transform infrared spectrometer equipped with a liquid-nitrogen-cooled narrow-band (4000–750 cm^{-1}) infrared detector (mercury cadmium telluride). Helium was used

as the carrier gas at (2 ml/min), and the effluent from the GC was mixed with the sweep gas helium (0.5 ml/min; transfer line temperature 280°C) and passed through the IR light pipe with KBr windows. Spectra were obtained at 8 cm^{-1} resolution. Extracts were chromatographed on a 30-m × 0.32-mm × 1-μm film thickness DB-5 column (J & W Scientific). The oven temperature program was 50°C for 2 min, then 5°C/min to 280°C, and held for 60 min. Splitless injections were made (1 μl) at an injector temperature of 250°C and a splitless period of 90 sec.

Laboratory Bioassays. Bioassays were performed in a 50- × 40- × 30-cm screen cage; ten 1- to 3- day-old males were present in the cage during the bioassay. The cage was placed in front of an operating hood, and a fan was used to generate the airstream. The appropriate amount of each sample (2–3 female equivalents) was dissolved in 100 μl of *n*-hexane and was poured on a 2- × 2-cm piece of Whatman No. 1 filter paper. The filter paper was hung 5 cm below the top of the cage and served as the source. The SPME fiber that had been used to collect volatiles released by *E. amygdali* females was also evaluated for male response. The SPME holder was standing on the top of the cage in a place that allowed the exposed fiber to penetrate ca. 5 cm inside the cage.

Each test lasted 10 min. The number of males exhibiting wing raising and a lateral swing of the body or landing on the filter paper was recorded. During each testing period, samples were tested individually with 10-min intervals between tests. The experiments were repeated 10 times (filter paper) and five times (SPME) with different batches of males. Samples were tested in random sequence; the same amount of *n*-hexane alone on a similar filter paper was used as control. Bioassays were conducted 3 to 4 hr after the onset of the photoperiod.

Data were transformed by using arcsine transformation and subjected to analysis of variance (ANOVA). Means were separated by Tukey's studentized range honestly significant difference (HSD).

RESULTS AND DISCUSSION

Extraction Techniques. Although methylene chloride extraction was efficient in removing chemicals from the insects' bodies, it proved complicated and time-consuming when further clean-up of the extract was needed to remove inactive lipid material that interfered with the separation and identification of the compounds. The SPME technique offers a fast, solventless alternative, and it can be applied as an easy-to-use first screening to determine the nature of the volatile compounds (Monnin et al., 1998; Turillazzi et al., 1998; Sledge et al., 2000). Comparative GC-MS analysis of male and female extracts with all three techniques (solvent extraction, SPME rubbing, and headspace SPME) exhibited a similar chromatographic profile with mainly quantitative rather than qualitative differences (Table 1). The SPME technique compares well with the conventional solvent

extraction approach and offers the advantage of detecting volatile compounds that could be lost during conventional treatment of a solvent extract.

Cuticular Hydrocarbons. The composition from both sexes is presented in Table 1. The vast majority of compounds identified are long-chain saturated, monounsaturated, and diunsaturated hydrocarbons. The saturated hydrocarbon profile from each sex was qualitatively similar, with some quantitative differences. Each saturated hydrocarbon component was identified based on its equivalent chain length (ECL) and fragmentation pattern when analyzed by GC-MS. Monomethyl alkanes substituted at carbon 3 elute approximately 0.3 carbon units before the corresponding *n*-alkane, and as they fragment on each side of the methyl branch, with the charge retained on the fragment containing the branching methyl group, they give spectra with a strong $(M-29)^+$ ion. A weak ion at $(M-57)^+$ is also observed.

Monomethyl alkanes with a branch on carbons 11–15 have strong *m/z* ion pairs, indicating cleavage internal to the methyl branch. These compounds all elute approximately 0.7 carbon units before the *n*-alkane with the same number of total carbons. The signal intensities for the odd and even fragments in the *m/z* ion couplets for each of the daughter ions are nearly equivalent, indicative of a single methyl branch remaining following a cleavage (Page et al., 1997).

Mass spectra of the epoxide derivatives of alkenes show preferential cleavage *alpha* to the epoxy group (Bierl-Leonhard et al., 1980), producing fragments indicative of the position of the epoxy group and, thus, the position of the double bond in the original compound (Figure 1). Double bonds are located at positions 7 or 9 (major isomer) for the odd-numbered alkenes (C_{23}, C_{25}, C_{27}, C_{29}, and C_{31}) and at positions 5 or 7 for the even-numbered monounsaturated hydrocarbons (C_{28}, C_{30}, and C_{32}). The *E* or *Z* nature of the double bonds for the major compounds present in the alkene fraction was determined by GC-FTIR. The presence (*E* configuration) or absence (*Z* configuration) of an absorption around 970 cm^{-1} was used to determine the configuration of double bonds. Weak but useful bands above 3000 cm^{-1} were used for the assignment of *Z* unsaturated compounds (Doumenq et al., 1989; Leal, 1991; Attygalle et al., 1994). An absorption highly characteristic for the *Z* configuration occurs at 3013–3011 cm^{-1} ($=CH_2$ stretch band), while *E* compounds fail to show any bands in this region. These two absorptions (970 cm^{-1} and 3013–3011 cm^{-1}), in combination, can be used for the unambiguous determination of *Z* or *E* bonds in long-chain unsaturated compounds. All spectra obtained from the alkenes examined showed an absorption at 3013 cm^{-1} and a lack of absorption around 970 cm^{-1}, confirming the *Z* nature of the double bond (Figure 2A). The presence of (*Z*)-9-$C_{23:1}$ in the female extract was also confirmed by comparing chromatographic, mass spectrometric, and IR data with that of a synthetic standard.

The third fraction from the silver nitrate-impregnated silica gel column showed the presence of two alkadienes ($C_{23:2}$ and $C_{25:2}$) when analyzed by GC-MS. Mass spectra for both alkadienes showed an increased ion at *m/z* 222 and *m/z* 250 for $C_{23:2}$ and $C_{25:2}$, respectively (Figure 3). Descoins et al. (1986) reported that 6,9 dienes have a characteristically increased $(M-98)^+$ ion that originates from cleavage between carbons 7 and 8 and subsequent hydrogen transfer. An indication of the position of the double bonds at carbon 6 and carbon 9 was given by epoxidation, under conditions that favor the formation of unsaturated monoepoxides, followed by examination of the mass spectrometric fragmentation pattern. For example, the two peaks that correspond to the unsaturated monoepoxides of $C_{23:2}$ had characteristic ions at *m/z* 153 and 225 (indicative of an epoxide at carbons 9,10) and *m/z* 113 and 265 (indicative of an epoxide at carbons 6,7). The amount of natural alkadienes available did not allow subsequent catalytic hydrogenation of the unsaturated monoepoxides or an unambiguous determination of double-bond positions as has been described by Hogge et al. (1985).

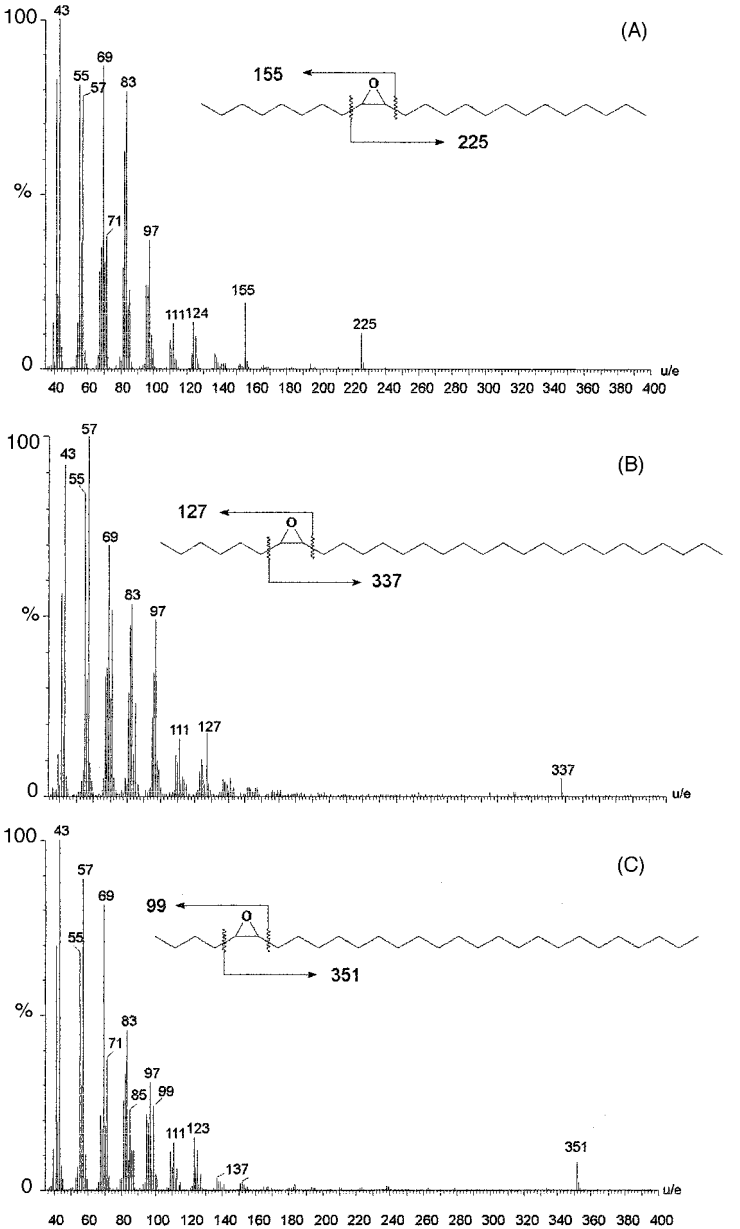

FIG. 1. EI mass spectra of epoxy derivatives of naturally occurring (A) (*Z*)-9-$C_{23:1}$, (B) (*Z*)-7-$C_{29:1}$, and (C) (*Z*)-5-$C_{28:1}$, showing the diagnostic *alpha* cleavage ions at mass 155 and mass 225 for (A), mass 127 and mass 337 for (B), and mass 99 and mass 351 for (C).

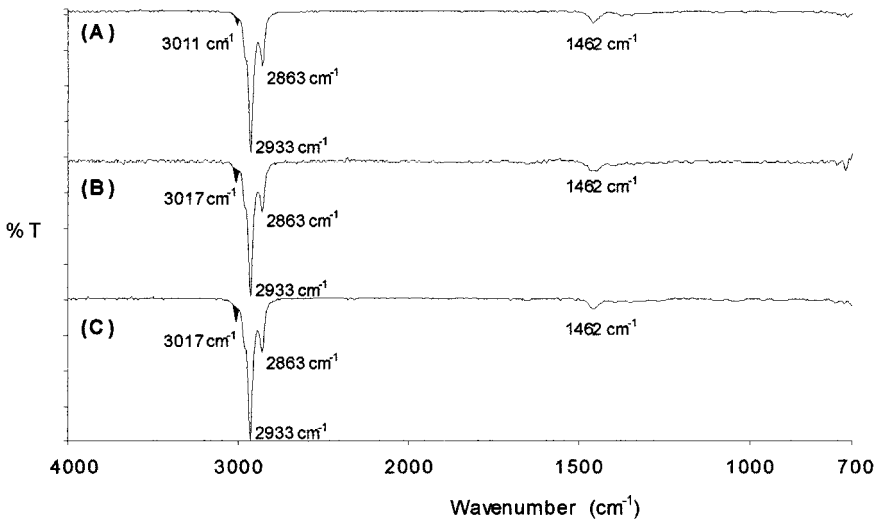

FIG. 2. Gas-phase IR spectra of naturally occurring (A) (*Z*)-9-$C_{23:1}$, (B) (*Z*,*Z*)-6,9-$C_{23:2}$, and (C) synthetic (*Z*,*Z*)-6,9-$C_{23:2}$.

Similar principles for interpreting IR spectra for double-bond configuration of monounsaturated compounds have been applied to diunsaturated compounds as well (Attygalle et al., 1995). The GC-FTIR spectrum of tricosadiene is presented in Figure 2B. The lack of any absorption around 970 cm^{-1} indicates the absence of an *E* bond. Conjugated *E*,*E* polyenes do not show this characteristic *E* absorption.

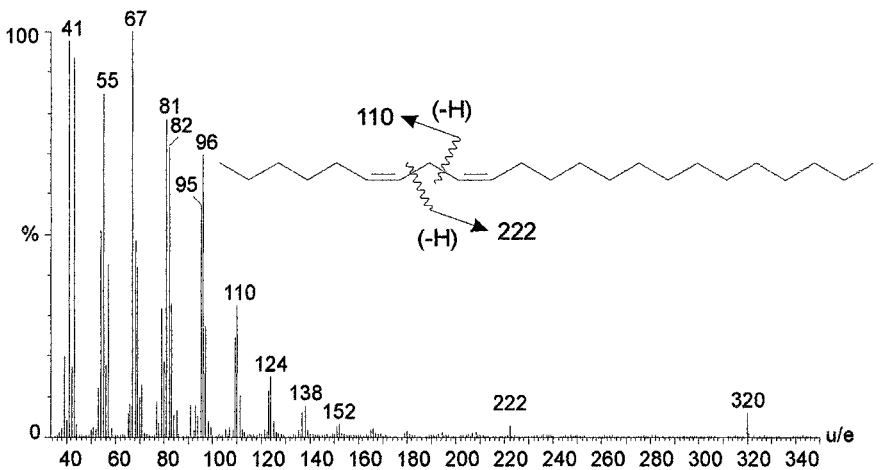

FIG. 3. EI mass spectrum of naturally occurring (*Z*,*Z*)-6,9-$C_{23:2}$.

Instead, a band highly characteristic for (*E,E*)-conjugated diene moieties appears at 983–982 cm-1. In the spectrum of Figure 2B, there is no absorption around 982 cm^{-1}, excluding any possibility for the presence of an *E* bond in tricosadiene. Furthermore, an absorption at 3017 cm^{-1} with significantly enhanced intensity, when compared to the corresponding absorption of the monounsaturated (*Z*)-9 tricosene (Figure 2A,B), supports the presence of two *Z* bonds in the molecule ($A_{3016-3018\,cm^{-1}}/A_{2866-2864\,cm^{-1}} = 0.413$ and 0.198 for $C_{23:2}$ and $C_{23:1}$, respectively). The gas phase IR spectrum of diunsaturated compounds also provides information for the location of the double bonds. Attygale et al. (1995) reported that conjugated *Z,Z* dienes lack a sharp band in the 3036–3011 cm^{-1} area in the GC-IR spectrum and that *Z,Z* dienes whose double bonds are separated by only a single methylene group show the characteristic $=CH_2$ stretch band at 3017 cm^{-1}. The $=CH_2$ stretch band of tricosadiene (Figure 2B) that appears at 3017 cm^{-1} (characteristic of methylene-interrupted double bonds) further supports the mass spectrometric interpretation for the double bonds located at carbons 6 and 9. The structure of (*Z,Z*)-6,9-$C_{23:2}$ and (*Z,Z*)-6,9-$C_{25:2}$ was unambiguously confirmed by comparison of chromatographic, mass spectrometric, and IR data with that of synthetic standards (Figure 2B,C).

Bioassays. Close range laboratory bioassays indicated that whole-body methylene chloride extracts elicited a strong sexual response by males. A high proportion (75%) in the bioassay cage exhibited wing raising and lateral body movement, characteristic mating behavior for Eurytomidae. Close to 40% of the responding males landed on the filter paper baited with the crude extracts. Excited males approached the source mainly by walking on the top of the screen cage. Usually, when the males were close to the source, they tried to copulate, and a number of them jumped on the filter paper (Table 2).

In order to locate the pheromone-producing gland on the female body, extracts from female heads, thoraxes, and abdomens were evaluated for male response. Thorax extracts elicited maximal response, and a high proportion also responded to

abdomen extracts (Table 2). Similar results have been reported for *Bephratelloides pomorum*, another Eurytomidae species (Leal et al., 1997). It is possible that the gland where the pheromone is synthesized is located in the thorax; however, the pheromone components are spread to the abdomen when they are released.

The SPME fiber that was used to collect volatiles was also evaluated for male response just after collection and prior to GC analysis. Males were attracted to the fiber and exhibited a clear sexual behavior. Male attraction to the SPME fiber was lower than to the whole-body extract, indicating that either the quantity of the active chemicals absorbed on the fiber was lower than that obtained in the extract or that the emission rate of substances from the fiber was lower than that of the filter paper (Table 2).

Since the whole-body extract elicited the maximal response from males, subsequent isolation of the active components was based on whole-body extracts. Fractionation dictated the use of a large amount of starting material, and clean-up on a silica SPE cartridge removed coextractable inactive lipid materials. Bioassays revealed that the active components were eluted in fractions I (hexane fraction), while fraction II and III (methylene chloride and methanol) showed low activity. Combination of fraction I with either of the other two fractions did not increase male attractiveness (Table 3).

Bioassays indicated that alkanes were inactive and that alkenes elicited low response (Table 4). A high response, significantly different from the crude female extract, was observed for the third fraction, which contained the two identified alkadienes, (*Z*,*Z*)-6,9-$C_{23:2}$ and (*Z*,*Z*)-6,9-$C_{25:2}$, as well as for the synthetic standard consisting of (*Z*,*Z*)-6,9-$C_{23:2}$ and (*Z*,*Z*)-6,9-$C_{25:2}$ at a ratio of 7 : 3 (the ratio

that had been determined on the female extract after fractionation on the silver nitrate impregnated silica gel column). These findings indicate the importance of these two compounds on the mating behavior of male *E. amygdali*.

The saturated hydrocarbon sex profiles were qualitatively similar with some quantitative differences. The major differences are that alkadienes and, to a lesser extent, alkenes are present only in the female extract (Table 1). The alkadienes have one double bond in the same location as the alkenes (at carbon 9), and whether both originate from the same biosynthetic pathway remains to be established. It has been reported that *Cardiochiles nigriceps* (Hymenoptera: Braconidae) alkadienes, present only in the female extract, are responsible for mediating courtship behavior (Syvertsen et al., 1995). The presence of the two alkadienes only in the female extracts supports our bioassay findings that (*Z*,*Z*)-6,9-$C_{23:2}$ and (*Z*,*Z*)-6,9-$C_{25:2}$ are the chemicals involved in the mating process of *E. amygdali*. Further research is needed for complete identification of the pheromone and to optimize the composition of the blend for its use in practical applications.

Acknowledgments—We are grateful to Dr. N Ragousis (Vioryl S.A, Athens, Greece) who provided us with the synthetic samples of (*Z*,*Z*)-6,9-$C_{23:2}$ and (*Z*,*Z*)-6,9-$C_{25:2}$.

(Received January 29, 2001; accepted July 18, 2001)

Abstract—We have identified and cloned a pheromone-binding protein (EoriPBP) from the Japanese and American populations of the Oriental beetle, *Exomala orientalis* (Coleoptera: Scarabaeidae). The protein showed more than 90% amino acid identity to the previously identified pheromone-binding proteins from *Popillia japonica* (PjapPBP) and *Anomala osakana* (AosaPBP), as well as to one of the odorant-binding proteins from *Phyllopertha diversa* (PdivOBP1). EoriPBP has 116 amino acids, with a calculated molecular mass of 12,981 Da, pI of 4.3, and six highly conserved cysteine residues. 5′-RACE amplifications led to the characterization of a signal peptide with 19 amino acids. The signal peptide showed high amino acid identity to the signal peptide for AosaPBP. Comparison of the amino acid sequences of the PBPs involved in the detection of similar ligands, i.e., monounsaturated lactones and ketone, suggests that the most variable residues among the PBPs from *E. orientalis*, *P. japonica*, and *A. osakana* are probably the most discriminating residues. As with the pheromone-binding protein from *Bombyx mori*, the residues at positions 61, 64, 71, and 82 in EoriPBP, PajpPBP, and AosaPBP, which are either valine, leucine, isoleucine, or methionine, are likely to be specificity determinants.

Key Words—*Exomala orientalis*, *Popillia japonica*, *Anomala osakana*, odorant-binding protein, signal peptide, Scarabaeidae.

INTRODUCTION

Insects depend heavily on their ability to detect chemical cues from the environment. These chemicals are involved in mediating a wide range of behaviors, from communication between conspecific individuals to the recognition of specific features of the environment, such as food sources, oviposition sites, etc. The chemical signals (semiochemicals) are normally buried in a complex mixture of odorants from myriad sources. This has led to the development of a remarkably selective and sensitive olfactory system, which approaches the theoretical limit for a detector. While minimal structural modification of pheromone molecules renders them inactive (Kaissling, 1987), a single molecule of the native ligand is reported to be sufficient to activate pheromone-sensitive olfactory neurons in the antennae of the silkworm moth, *Bombyx mori* (Kaissling and Priesner, 1970).

In order to convey their messages, pheromones and other semiochemicals must reach the dendrites of olfactory receptors neurons, where G protein-coupled olfactory receptors (Clyne et al., 1999; Vosshall et al., 1999, 2000) are supposed to be located. The last part of the journey toward the receptors is protein-assisted, given that dendrites are surrounded by sensillar lymph and pheromones are largely hydropobic in nature. In the perireceptor events (Figure 1), odorant-binding proteins (Vogt and Riddiford, 1981) not only ferry the ligands to their receptors, but also protect the chemical signals from odorant-degrading enzymes (Vogt and Riddiford, 1981; Vogt et al., 1985). Activation of the receptors initiates transduction

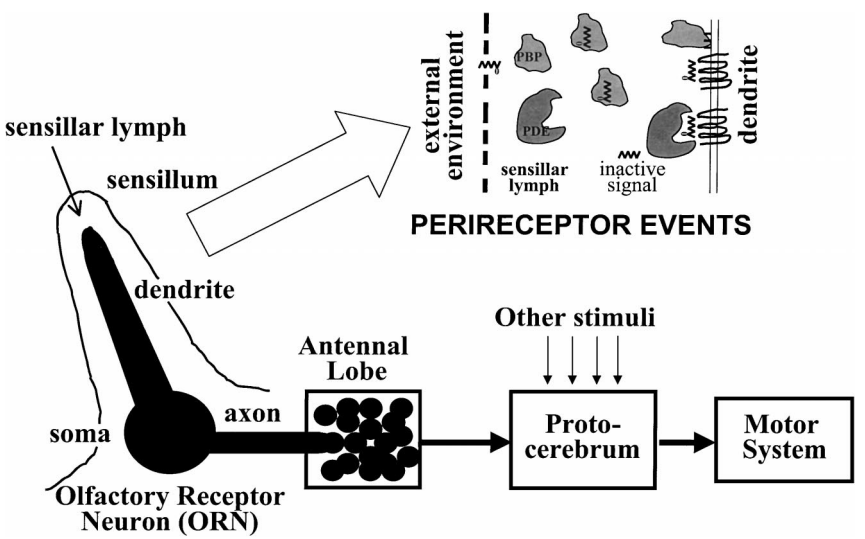

FIG. 1. Schematic view of the overall olfactory processing in insects, highlighting early olfactory processing (perireceptor events).

of the chemical signals into neuronal activities (spikes), which are processed in the antennal lobe, integrated with other stimuli in the central nervous system, and translated into behavior (Figure 1). There is growing evidence in the literature that the inordinated sensitivity and selectivity of the insect olfactory system is achieved by a combination of olfactory-specific proteins, including odorant receptors (Clyne et al., 1999; Vosshall et al., 1999, 2000), odorant-binding proteins (OBPs) (Vogt and Riddiford, 1981; Vogt et al., 1999), and odorant-degrading enzymes (Vogt and Riddiford, 1981; Vogt et al., 1985; Rybczynski et al., 1990; Rogers et al., 1999). Because binding studies have suggested that interactions between odorants and OBPs are specific and selective (Du and Prestwich, 1995), selectivity of the insect olfactory system is achieved at least partly in the early olfactory processing.

We have previously identified odorant-binding proteins from three species of scarab beetles (Coleoptera: Scarabaeidae), i.e., *Popillia japonica*, *Anomala osakana* (Wojtasek et al., 1998), and *Phyllopertha diversa* (Wojtasek et al., 1999), which utilize the enantiomers of japonilure (Tumlinson et al., 1977; Leal, 1996, 1998) and an alkaloid compound (Leal et al., 1997) as their sex pheromones (Figure 2). In order to get a better understanding of the relationship between OBP structures and their ligands, we have identified and cloned a pheromone-binding

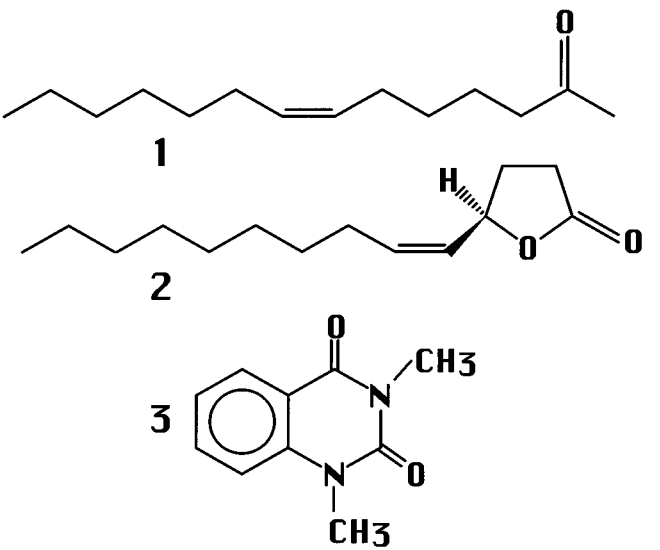

FIG. 2. Structures of some scarab beetle pheromones: **1**, (*Z*)-7-tetradecen-2-one, the sex pheromone of the Oriental beetle (*E. orientalis*); **2**, (*R,Z*)-5-(—)-(1-decenyl)oxacyclopentan-2-one, (*R*)-japonilure, the sex pheromone of the Japanese beetle (*P. japonica*); **3**, 1,3-dimethyl-2,4-(1*H*,3*H*)-quinazolinedione, the sex pheromone of the pale-brown chafer (*P. diversa*).

protein gene from the Oriental beetle, *Exomala orientalis* (Waterhouse), whose pheromone is an unsaturated ketone (Figure 2) both in the Japanese (Leal, 1993; Leal et al., 1994a) and in American populations (Zhang et al., 1994).

METHODS AND MATERIALS

Analytical Procedures. *N*-terminal amino acid sequences were obtained on a Hewlett-Packard Protein Sequencer model 241, with PTH derivatives separated on a Hewlett-Packard (=Agilent) series 1100 HPLC system. Proteins were analyzed on 15% native polyacrylamide gels run in a Mini-Protean II (Bio-Rad) and stained with Coomassie blue R-250. For sequencing, proteins were separated on native PAGE and transferred by electroblotting to polyvinyl difluoride (PVDF) membranes. Bands were cut off, dried, loaded on a column, and the proteins sequenced. DNA sequences were obtained with an automated ABI PRISM Model 377 sequencer (Applied Biosystems). DNA sequences were analyzed using MacVector (Oxford Scientific).

Insects. Adults collected in traps baited with the synthetic pheromone in Tsukuba were kept in culture dishes at 25°C, 75% relative humidity, and 14L:10D photoperiod and provided with saturated sucrose solution on cotton. In the United States, beetles were collected in Rhode Island with pheromone traps, frozen, and shipped to Davis, California.

Protein Extracts. Beetles were anesthetized on ice, antennae and legs were collected, frozen in liquid nitrogen, and lyophilized. Homogenization was performed in ice-cold glass homogenizers in 10 mM Tris HCl, pH 8. Homogenized samples were centrifuged twice at 12,000 rpm, 4°C, for 5 min. The supernatants were concentrated on a SpeedVac.

Molecular Cloning. Total RNA was extracted from 50 antennae of *E. orientalis* males by using TRIzol Reagent (Gibco BRL), and mRNA was purified with the PolyATtract (Promega) kit. The first cDNA strand was synthesized by using the SuperScript preamplification system (Gibco BRL). The following degenerated primer was designed based on the *N*-terminal protein sequences of the mature protein, 5′-ATGWSNGARGARATGGARGAR-3′, and used in polymerase chain reaction (PCR) with oligo-dT 15 plus GAG; the last codon makes subsequent PCR more specific. PCR reactions were carried out in a MiniCycler (model 150, MJ Research) by using Taq DNA Polymerase (Roche), with annealing at 50°C. Optimized PCR products were ligated into the pCR2. 1/TA cloning vector (Invitrogen), and transformed into OneShot Top 10F′ competent cell (Invitrogen). Positive insertions were identified by screening positive colonies by PCR with M13 primers. Sequencing of plasmid DNA from several colonies was performed following extraction with the QIAprep Spin Miniprep Kit (Qiagen). Signal peptide sequences were

obtained by using 5′-RACE System for Rapid Amplification of cDNA Ends (Gibco BRL) with the following primers: 5′-GTGGGTTTGATAAACATT-3′ (GSP1), 5′-CATGGATTCGCTCCAGGTTT-3′ (GSP2), and 5′-CCATCATCGCCAACGATT-3′ (nested GSP); GSP, gene specific primers.

RESULTS AND DISCUSSION

Analysis of protein extracts from antennal and control tissues (legs) of the Japanese population of the Oriental beetle by native polyacrylamide gel electrophoresis (PAGE) showed one antenna-specific protein (Figure 3) migrating at the bottom of the gel, with a mobility similar to those of OBPs identified to date. The profile of bands on native gels obtained from male and female antennal extracts and visualized by Coomassie blue were indistinguishable (data not shown). The lack of sex specificity in the antenna-specific proteins from scarab beetles, which has been also observed in other scarab species (Wojtasek et al., 1998, 1999), is consistent with the fact that both sexes detect the female-produced sex pheromones (Leal et al., 1994a,b, 1996). We have also analyzed extracts from antennal and control tissues of the American population of the Oriental beetle by native PAGE. Beetles were collected in Rhode Island, frozen, and sent to Davis, California. Although the overall profile was similar to that obtained with the Japanese population, there was a faint band migrating just below the major antenna-specific band (Figure 4). Preliminary sequencing data suggested that, as with previous cases (Wojtasek et al., 1999), the band is due to an isoform of the major protein. The fact that the minor band is not detected in females may be related to the quality of the sample. Females from a laboratory colony were frozen and immediately sent

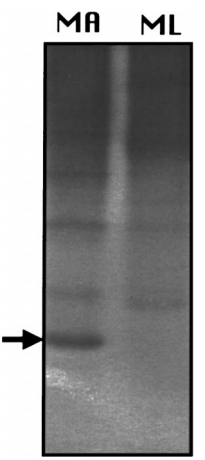

FIG. 3. Soluble protein from the Japanese population of *E. orientalis* separated on 15% native PAGE. MA, male antennae (15 antenna-equivalents); ML, male leg (1 leg equivalent). Arrow indicates an antennae-specific band.

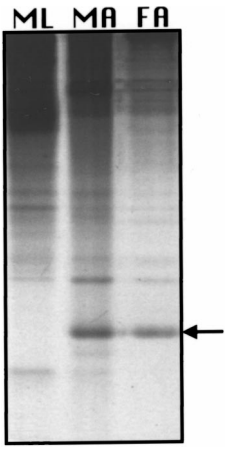

FIG. 4. Soluble protein from the American population of *E. orientalis* separated on 15% native PAGE. MA, male antennae (15 antenna-equivalents); FA, female antennae (18 antenna-equivalents); ML, male leg (2 legs equivalents). Arrow indicates an antenna-specific band.

to Davis, California, whereas males were collected in traps baited with synthetic pheromone and contained beetles that died before the traps were emptied.

We have transferred the antenna-specific band from the native gel to PVDF membrane and obtained its *N*-terminal sequence. Based on the sequence of the first 27 amino acids (MSEEMEELAKQLHDDXVGQTGVDEAHI), the antenna-specific protein from *E. orientalis* showed remarkable similarity to the primary sequence of the PBP from *P. japonica*, PajpPBP (Wojtasek et al., 1998). Given that the undetectable amino acid at position 16 might be due to a cysteine (Leal et al., 1999), only 1 of the 27 amino acids was different from those of PjapPBP sequence.

In order to compare the whole primary sequences of the OBPs from scarab beetles, we cloned the gene encoding the antenna-specific protein in *E. orientalis*. cDNA, derived from the RNA isolated from antennal tissues, was used as template. Polymerase chain reaction (PCR) was carried out by using a degenerate primer based on the *N*-terminal sequence and an oligo-dT to anneal to the poly(A) tail. PCR reactions resulted in amplification of one band of approximately 460 bp. The cDNA encoded a protein with 116 amino acids, with a calculated molecular mass of 12,981Da (considering the formation of three disulfide bonds), and pI of 4.3. Furthermore, the sequence showed six highly conserved cysteine residues at positions 16, 44, 48, 86, 95, and 104 (Figure 5). The occurrence of six cysteines is a hallmark of odorant-binding proteins. They play a pivotal role in 3D structures of PBPs (Leal et al., 1999; Sandler et al., 2000) by forming rigid α-helix links. The amino acid identity between the newly identified protein from *E. orientalis* and PjapPBP, PdivOPB1, and AosaPBP was 93, 91, and 90%, respectively (Figure 5). Because the protein is tissue-specific and shows similarity to previously identified pheromone-binding proteins from scarab beetles,

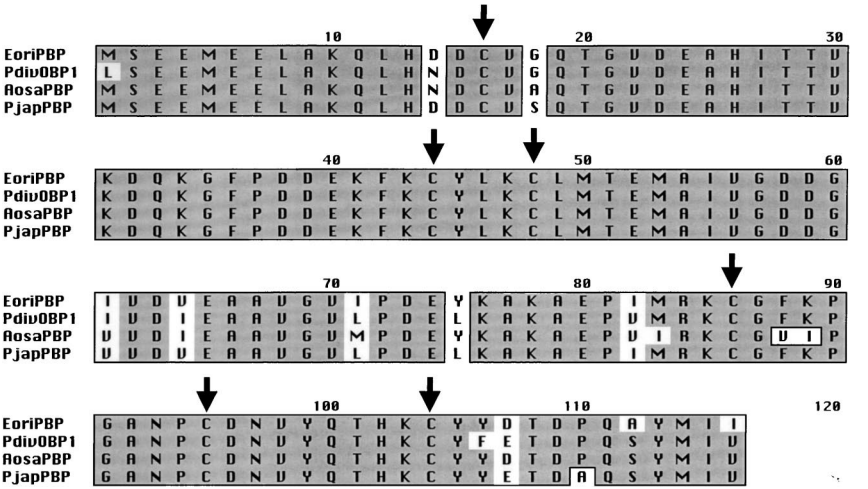

FIG. 5. Sequence alignments of PBPs from *E. orientalis*, *P. diversa*, *A. osakana*, and *P. japonica* using the ClustalW algorithm (MacVector, Oxford Scientific). Arrows indicated the six conserved cysteine residues. The nucleotide sequence data reported in this paper will appear in the DDBJ/EMBL/GenBank nucleotide sequence databases under accession numbers AB040144 (EoriPBP), AB040986 (signal peptide for EoriPBP), and AB040985 (signal peptide for AosaPBP).

we suggest that the antenna-specific protein from *E. orientalis* is a pheromone-binding protein.

Pheromone-binding proteins are synthesized in auxilliary cells (trichogen and tormogen cells) (Vogt et al., 1989; Steinbrecht et al., 1992) and secreted into the sensillar lymph surrounding the ORN dendrites and, as such, they have signal peptides. Because we amplified the cDNA with a primer based on the *N*-terminal sequence, the cloned cDNA encoded only the mature protein. In order to obtain the full length cDNA, including the signal peptide, we carried out 5′-rapid amplification of cDNA end (5′-RACE), which leads to an extension of approximately 100 bp. The sequence analysis showed that the signal peptide for EoriPBP has 19 amino acids (MLKLVVLLTLGIYVPAVMS), follows the (-3,-1) rule (von Heijne, 1986), and shows a hydrophobic profile (Figure 6). 5′-RACE with *Anomala osakana* cDNA led to the identification of the signal peptide for AosaPBP, which differs from the signal peptide for EoriPBP only in two positions. In AosaPBP, the amino acids at positions −1 and −11 are Cys and Ser, respectively, as opposed to Ser and Thr in EoriPBP.

Prediction of the secondary structure of EoriPBP by the Chou-Fasman method indicated that the protein is helical-rich (42%), as has been experimentally demonstrated with the pheromone-binding protein from *B. mori*. In BmPBP, the same

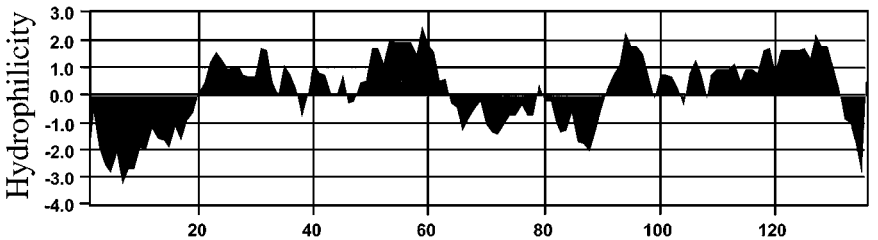

FIG. 6. Hydrophilicity plot of EoriPBP by the von Haijne algorithm (MacVector, Oxford Scientific) indicating the hydophobic nature of the signal peptide (first 19 amino acids).

method predicts 31%, but the crystal structure showed a much higher helical component (60%). Although biased on the low helical component, the method suggests that EoriPBP is possibly part of a family of helix-rich proteins.

In *P. diversa*, two odorant-binding proteins have been previously identified and cloned, but their cognate ligands have never been clearly assigned. On the other hand, binding data support that PjapPBP and AosaPBP are involved in detection of sex pheromones and behavioral antagonists in *P. japonica* and *A. osakana*. Based on the sensitivity of insect olfactory systems to pheromones, one may speculate that the more abundant of the OBPs in *P. diversa*, i.e., PdivOBP2, is involved in the transport and protection of the sex pheromone. However, *P. diversa* has highly sensitive olfactory receptor neurons tuned to green leaf volatile compounds (Hansson et al., 1999; Nikonov et al., 2001). By contrast, the PBPs identified from *P. japonica*, *A. osakana* (Wojtasek et al., 1998), and *E. orientalis* (this paper) have known ligands. Both the lactone pheromones and the unsaturated ketone (Figure 2) have a polar head (functional group) and a hydrophobic tail with unsaturation. The structures of the pheromones for *P. japonica* and *A. osakana* differ in their absolute configurations, whereas the pheromone for *E. orientalis* differs in the functional group and position of the unsaturation. In BmPBP, the double bonds are sandwiched by two of the five phenylalanines, i.e., Phe12 and Phe118, and they were considered to form a general hydrophobic surface for binding and are not specificity determinants for the double bonds in bombykol (Sandler et al., 2000). EoriPBP has only three phenylalanines, i.e., Phe36, Phe42, and Phe88, but Phe88 is unlikely to be participating in the hydrophobic binding site because both AosaPBP and PjapPBP bind the same ligands, the enantiomers of japonilure, and yet AosaPBP has a Val88, as opposed to Phe88. On the other hand, of the residues involved in binding bombykol in BmPBP, the most variable ones are Met61, Leu62, lle91, and Val114, which are likely to be specificity determinants and are near the ends of the pheromone. These residues are either valine, leucine, isoleucine, or methionine, and this variation could be a way to alter the binding pocket (Sandler et al., 2000). Despite the low number of sequences

known from scarab PBPs, the same picture is emerging with four positions, i.e., 61, 64, 71, and 82, which are either valine, leucine, isoleucine, or methionine. In conclusion, despite the high similarity in the amino acid sequences of EoriPBP, PjapPBP, and AosaPBP, the least conserved residues may be involved in binding specificity.

Acknowledgments—The authors would like to thank Dr. Steven R. Alm, University of Rhode Island, for providing frozen beetles of the US population, and Dr. Karl-Ernst Kaissling for his critique of an earlier draft of the manuscript. Abstract—The ability of snakes to follow pheromone trails has significant consequences for survival and reproduction. Of particular importance is the ability of snakes to locate conspecifics during the breeding season via the detection of pheromone trails. In this study, the ability of male brown tree snakes (*Boiga irregularis*), a tropical, rear-fanged colubrid, to follow pheromone trails produced by reproductively active conspecifics was tested in the laboratory by using a Y maze. Males displayed a trailing response to both female and male pheromone trails over blank controls. As males of this species display ritualized combat behavior, these responses likely represent both direct and indirect mechanisms, respectively, for the location of potential mates in the wild. Males did not, however, discriminate between male and female trails when given a choice on the Y maze.

Key Words—Trailing behavior, Y maze, mate location, brown tree snake, *Boiga irregularis*, reptile pheromones, Reptilia, Colubridae, male combat behavior, invasive pest species.

INTRODUCTION

Many species of snakes have demonstrated the ability to locate conspecifics during the breeding season by following pheromone trails passively laid on the substrate as they move through the environment (e.g., Ford, 1982; Ford and Schofield, 1984; Plummer and Mills, 1996; LeMaster et al., 2001). Trailing behavior is also used by snakes in other behavioral contexts, including migration to and from winter hibernacula, in aggregation, and in prey location (reviewed by Ford, 1986;

Mason, 1992; Mason et al., 1998). The majority of studies concerning snake trailing behavior have been conducted with northern temperate species, with particular emphasis on the garter snakes of the genus *Thamnophis* (Ford, 1986).

The purpose of this study was to characterize the pheromone-mediated trailing behavior of the brown tree snake, *Boiga irregularis*. The brown tree snake is a rear-fanged, tropical colubrid native to Australia, Papua-New Guinea, and the Solomon Islands (Rodda et al., 1997). The species can reach snout-to-vent lengths of up to 3 m, weighs up to 2 kg, and possesses a relatively thin body typical of arboreal snakes (Rodda et al., 1997). Brown tree snakes are generalist predators that actively forage for a diet consisting of mammals, reptiles, amphibians, and birds (Savidge, 1988). Although primarily arboreal, it spends a significant proportion of its time on the ground and typically forages within the lower 3 m of vegetation (Cogger, 1992). The snake is an introduced pest species in the Pacific, notably on the island of Guam, where it is responsible for the extinctions of several native forest bird species and has caused considerable economic damage (Rodda et al., 1997).

Brown tree snakes display reproductive behaviors similar to other colubrid snake species (Greene and Mason, 2000). Males of this species display stereotyped courtship behaviors that are triggered by a sex pheromone located in female skin lipids (Greene and Mason, 1998). This pheromone has been isolated and initially characterized as a suite of nonvolatile, nonpolar skin lipid molecules (Greene and Mason, 1998). Male brown tree snakes also display ritualized combat behavior in response to other reproductively active males (Greene and Mason, 2000). In snakes, ritualized combat serves as a competition among males to gain access to females during the breeding season (Andrén, 1986; Schuett and Gillingham, 1989). This behavior appears to be stimulated by a pheromone located in male brown tree snake skin lipids (Greene and Mason, 2000).

The brown tree snake does not form large breeding aggregations, although small nonbreeding winter aggregations have been reported in its native and introduced range (Pendleton, 1947; Covacevich and Limpus, 1973). Therefore, it is likely that brown tree snakes, like other snakes, utilize pheromone trails to locate spatially distributed conspecifics during the breeding season. In this study, the ability of the brown tree snake to trail reproductively active conspecifics was tested by using a Y maze in the laboratory.

METHODS AND MATERIALS

Husbandry. The animals used were collected on Guam and housed under laboratory conditions for six years prior to being used in the experiment (Greene et al., 1997). Seven female and 10 male snakes, individually housed in Plexiglas cages designed specifically for arboreal reptiles, were used (Mason et al., 1991). Males in the colony had a mean (±SD) snout-to-vent length (SVL) of 162.2 ±

22.1 cm and a mean mass of 647.5 ± 265.7 g. Females had a mean SVL of 137.9 ± 9.9 cm and a mean mass of 385.7 ± 81.5 g. Snake cages contained branches for climbing and hide boxes attached to the roofs of the cages, in which the snakes spent the majority of their time. Room temperature cycled daily from 24°C to 30°C, and relative humidity was maintained at approximately 80% by using a room humidifier and by daily spraying of the inside of the cages with water. Light (12L : 12D) was provided by overhead fluorescent lights. Snakes were fed thawed mice or chicks every three weeks, and water was available *ad libitum* for drinking and soaking. All snakes in the captive colony were mature adults in breeding condition during the study.

Y-maze Design. To test the ability of the snakes to trail conspecifics, a Y maze was constructed of clear polyvinyl chloride tubing (PVC) with an internal diameter of 5.2 cm (Figure 1). The maze consisted of an initial stretch of tubing 96 cm long that connected to a Y junction separated by a 45° angle into two arms, each also 96 cm long. The maze was elevated at an angle of 25° from the floor to entice the snakes into the initial stretch, as they are excellent climbers and prefer to move to the highest point possible when given a choice. All hide boxes used in housing the snakes could be attached to the initial stretch by using PVC adapters. Empty, clean hide boxes were attached to the ends of the arms, also by using PVC adapters, for collection of the snakes at the conclusion of a trial. The initial stretch, Y junction, and the arms could be taken apart for cleaning between trials.

This maze design allowed for minimal handling of the snakes, thus reducing the display of defensive behaviors in this relatively aggressive species. In addition, the design allowed for easy cleaning and reassembly as well as for containment of the snakes in the maze. Importantly, by having a relatively small internal tube diameter, conspecific pheromone trails were laid down in a seminatural manner, as trail-producing snakes deposited odors on a horizontal surface (bottom of tube) and

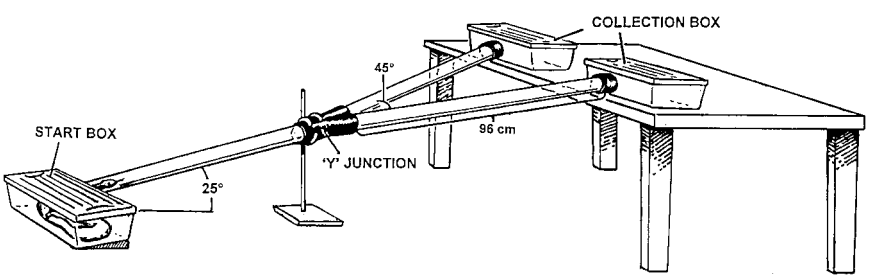

FIG. 1. Diagram of the Y-maze system used to conduct trailing experiments in this study. The Y maze was constructed of 5.2-cm-diameter, clear PVC piping. The initial stretch and arms were each 96 cm long, and the Y junction separated the maze by 45°. The maze was elevated from the floor at a 25° angle. Hide boxes were attached to the maze at the start of initial stretch and at the ends of the arms.

vertical surfaces (sides of the maze) (Ford and Low, 1983). Brown tree snakes, like other snakes species, are highly thigmotactic, preferring to travel along edges as opposed to open areas. The maze design, by having rounded edges and a small internal diameter, reduced concerns of thigmotaxis conflicting with trailing behavior (Costanzo, 1989).

General Experimental Conditions. To characterize the ability of males to trail conspecifics, four experiments were completed: (1) males trailing female pheromone trail versus blank arm ($N = 10$ trials), (2) males trailing male pheromone trail versus blank arm ($N = 9$ trials), (3) males trailing male pheromone trail versus female pheromone trail ($N = 10$ trials), and (4) blank control ($N = 10$ trials, no pheromone trails applied to either arm). Males were tested only once during each experiment. All snakes were in breeding condition when used; courtship and ritualized male combat were exhibited by all snakes during the period of time in which the study was conducted. The trailing ability of females was not tested, as females were generally inactive during this time period and would not exit the start box at the beginning of most trials.

All trials were conducted during the scotophase between 2100 and 0200 hr, when the snakes were normally active and the snake room was dark. Lighting was provided at a minimal level by a red 7 W incandescent bulb placed 2 m behind the maze so that the arms were lit evenly.

Trails were produced by allowing a randomly chosen snake of the desired sex to pass once completely through the initial stretch, Y junction, and one arm of the maze. The side of the Y junction leading to the control arm was blocked with a piece of clean cloth so that no lipids were inadvertently added to the control side. The arm treated with a conspecific pheromone trail was randomly chosen in each case. In experiment 3, in which males were given a choice between male and female pheromone trails, female trails were always applied to the maze immediately before the male trail. Both male and female pheromone trails were present in the initial stretch of the maze and the Y junction, while the arms contained only male or female trails. In experiment 3, a random male and female were chosen to produce the trail for each trial; however, males were never tested against their own trail.

To begin a trial, a hide box containing a snake was removed from its home cage and attached to the initial stretch of the maze. The snake was allowed to enter the maze of its own accord. We defined "trailing" as occurring when a snake's head entered the collection box attached to arms of the maze. During trials, an investigator, blind to the treatment, observed while hidden behind a blind.

A trial was terminated and conducted on another night if a snake exhibited defensive behavior, such as striking and tail-lashing or if a snake did not enter the maze from its hide box within 30 min after the start of the trial. Additionally, trials in which snakes did not display the trail contact response (Brown and MacLean, 1983), a set of behaviors diagnostic of snake pheromone trailing, were not used in the final statistical analyses.

TABLE 1. RESULTS OF EXPERIMENTS TESTING ABILITY OF MALE BROWN TREE SNAKES TO TRAIL CONSPECIFICS

Experiment	Condition	*N*	Trailed	Did not trail	*P* (1-tailed binomial)
1	Males trailing females	10	8	2	0.055
2	Males trailing males	9	8	1	0.020
3	Males trailing females versus males (trailed = male chose female arm)	10	5	5	1.000
4	Males trailing blank maze	10	5	5	1.000

Statistical Analyses. Statistical significance in the trailing response was determined by using a one-tailed binomial test (Sokal and Rohlf, 1995).

RESULTS

In experiment 1, eight of 10 males entered the female-treated arm of the Y maze versus the blank control arm (Table 1; $P = 0.055$). In experiment 2, eight of nine males entered the male treated arm, while only one of nine males entered the blank control arm (Table 1; $P = 0.02$). Males demonstrated no preference for female pheromone trails over male pheromone trails (experiment 3) when given a choice on the Y-maze (Table 1; $P = 1.000$). When tested on a Y maze in which both arms were left blank (experiment 4), males chose the arms of the maze equally (Table 1; $P = 1.000$).

Head-jerking behavior [a behavior only displayed in the context of courtship and male ritualized combat in this species (Greene and Mason, 2000)] was displayed in two trials (by two different males) when males were following female trails in experiment 1 and was observed in two trials (by two different males) when males were following male pheromone trails in experiment 2. Snout-probing behavior, in which the male would press his snout to the pheromone trail, was observed in most trials. While snout-probing, males would often drag their snouts backwards along the pheromone trail. In addition, all individuals that trailed displayed behaviors associated with trailing in other species, including tongue-flicks directed to the trail and periodic pauses with side to side movements of the head (Brown and MacLean, 1983).

DISCUSSION

The ability of male brown tree snakes to follow female pheromone trails most likely represents a mechanism to locate potential mates during the breeding season. Similar responses have been reported in several other species, mostly in colubrids

of the genus *Thamnophis* (Ford, 1986; Mason, 1992; Mason et al., 1998). However, few reports exist of trailing behavior in other snake taxa, including tropical species and those that display combat behavior such as the brown tree snake (Ford, 1986; Mason, 1992).

Male brown tree snakes might follow male pheromone trails in order to locate males that are near or are courting females. By initiating combat, the trailing male may be able to displace the other male and gain access to the local female, as has been suggested for other species (Shine et al., 1981). There would be little cost to this strategy, as combat would be unlikely to ensue without the presence of a female. Field reports of the courtship and combat behavior of the Swedish adder (*Vipera berus*) have described the ability of males of this species to trail both conspecific males and females (Andrén, 1986). Upon contacting and tongue-flicking the integument of a female, courtship will ensue. Conversely, upon contacting another male, males will initiate combat if a female is present. The winner of the combat bout gains access to the local female by establishing a temporary territory that it will defend from other males (Andrén, 1986).

It would be expected that, given a choice between a conspecific male and female trail, males would prefer the female trail. This choice would, at least in a natural situation, lead directly to a female and would allow the male to avoid agonistic interactions with other males. However, in this study, males did not display a significant trailing response to either of the sexes, choosing the male trail as often as the female trail. Behavioral observations and bioassays have shown that male brown tree snakes can discriminate between males and females via pheromones in other contexts, such as courtship, making it unlikely that there are no chemical differences between sexes (Greene and Mason, 1998, 2000). This apparent lack of behavioral discrimination may be an artifact of how the male and female trails were laid down in the maze. In the initial stretch of the maze, both male and female pheromone trails were present together; these trails then diverged at the Y junction. However, the male trail was always laid down on top of the female trail, which may be significant to trailing males, as has been found in vertebrate taxa, such as scent-marking rodents (e.g., Johnston et al., 1997; Ferkin, 1999). Further, under natural conditions, a similar situation might signal to a trailing male that a male and female pair are nearby. If so, following either a male or female pheromone trail may lead to the courting pair where the trailing male would have the opportunity to initiate combat and could, therefore, displace the local male. Also in this situation, the trailing male might attempt to revert to vision in order to locate the movement of the courting pair at short distances, as other species are known to do in the field (Hawley and Aleksiuk, 1975; Andrén, 1986). Unfortunately, because our captive colony of brown tree snakes bred year-round, we were not able to test non-reproductively-active snakes to determine if this particular behavioral response is simply a species recognition response.

It is has been hypothesized that male trailing behavior in response to females is triggered by the female sex pheromone (Mason, 1992). Snake sex pheromones are located in the skin lipids of females and are thought to be composed primarily of long-chain, high-molecular-weight molecules of relatively low volatility (Mason et al. 1989, 1990; Murata et al., 1991; Greene and Mason, 1998). Sex pheromones and other skin lipids are passively deposited on the ground as females pass through the environment, allowing males to trail females upon detection of the skin lipid trail with their vomeronasal organs. In this study, male snakes were observed displaying courtship and combat behaviors (head-nodding in both cases) in response to female and male pheromone trails, respectively. Display of these behaviors by trailing males suggests that the female sex pheromone and the male combat pheromone play a significant role in mediating trailing behavior.

Currently, brown tree snake control methods on Guam are limited to detection by trained dogs and capture by large trapping regimes. However, more attention has been given to using brown tree snake semiochemicals as repellents and attractants to aid in control of this particularly detrimental pest species (Brown Tree Snake Control Committee, 1996; Mason, 1998; Mason and Greene, 2001). Pheromone attractants would be particularly useful in increasing the efficacy of traps in the field by increasing the distances over which trap lures work. Currently, live prey is used to lure snakes into traps, a method that operates over relatively short distances. The results of this study indicate that pheromones located on the skin of male and female brown tree snakes may be effective attractants to males during the breeding season if used in a larger integrated management plan.

(Received January 26, 2001; accepted July 10, 2001)

Abstract—Two encyrtid species, *Acerophagus coccois* and *Aenasius vexans*, parasitoids of the cassava mealybug *Phenacoccus herreni* use a contact kairomone from the body surface of their host as a host-location stimulant. The kairomone was synthesized and identified as *O*-caffeoylserine based on a combination of chromatographic methods. The synthetic compound was determined to be active.

Key Words—*O*-Caffeoylserine, *Acerophagus coccois*, *Aenasius vexans*, Hymenoptera, Encyrtidae, Homoptera, Pseudococcidae.

INTRODUCTION

The cassava mealybug, *Phenacoccus herreni* William & Cock (Homoptera: Pseudococcidae), is an important pest of cassava in South America (Bellotti et al., 1983; Noronha, 1990). Two encyrtid parasitoids, *Acerophagus coccois* Smith and *Aenasius vexans* Kerrich (Hymenoptera: Encyrtidae), are being studied to control *P. herreni* populations at the International Center for Tropical Agriculture (CIAT) in Cali, Colombia. *A. coccois* is considered a generalist because it parasitizes different mealybug species among the Pseudococcidae family. *A. vexans* is a specialist, parasitizing only *P. herreni* (Dorn et al., 2001).

During host selection, parasitoids use a variety of cues to assess the quality of their hosts, such as shape, surface structure, and both external and internal semiochemicals (waxy secretions and honeydew) (Lewis and Martin, 1990; Vinson, 1991; Godfray, 1994). The structure and quantity of these semiochemicals influence host acceptance by parasitoids and vary according to species, age or stage of development, size, condition, and diet of the parasitoid host (Vinson, 1991; Powell, 1992; Takabayashi and Takahashi, 1993; Röse et al., 1997). One important class of these subtances used by parasitic Hymenoptera to identify their hosts is kairomones (Lewis and Martin, 1990). For example, in the California red scale *Aonidiella aurantii* Maskell (Hemiptera: Diaspididae), a kairomone isolated from their cover and identified as *O*-caffeoyltyrosine, the ester of caffeic acid and tyrosine, mediates host recognition and induces oviposition by the parasitic wasp *Aphytis melinus* DeBach (Hymenoptera: Aphelinidae) (Hare et al., 1993; Millar and Hare, 1993).

In cassava mealybug *Phenacoccus manihoti* Matile-Ferrero (Homoptera: Pseudococcidae), a serious pest of cassava in Africa (Neuenschwander et al., 1990; Le Rü et al., 1991), preliminary analyses indicated the presence of a compound composed of a serine and a caffeic acid moiety, probably corresponding to *O*-caffeoylserine (Calatayud, unpublished data). This compound was also detected in *P. herreni*; however, it could not be identified in the mealybug because it was always hydrolyzed during the purification process. It was, therefore, necessary to synthesize the ester and then verify whether the synthetic compound was similar to the compound assumed to be *O*-caffeoylserine. Because this putative compound is similar to the contact kairomone *O*-caffeoyltyrosine, important in another parasitoid–homopteran interaction as reported by Hare et al. (1993) and Millar and Hare (1993), we also hypothesized that this substance would act as a contact kairomone for the cassava mealybug parasitoids. Therefore, the objective of this study was to confirm the identification of *O*-caffeoylserine in *P. herreni* after its synthesis and to study its influence on host-location behavior of *A. coccois* and *A. vexans*.

METHODS AND MATERIALS

Insect Rearing. The cassava mealybug, *P. herreni*, was reared at CIAT on 30 to 40-cm potted cassava plants (cv. CMC 40) in a glasshouse at 27–33°C and 12L : 12D photoperiod. Adult females, the stage most parasitized by *A. coccois* and *A. vexans* (Seligmann, 1998), were collected from the colony for chemical analysis and bioassay.

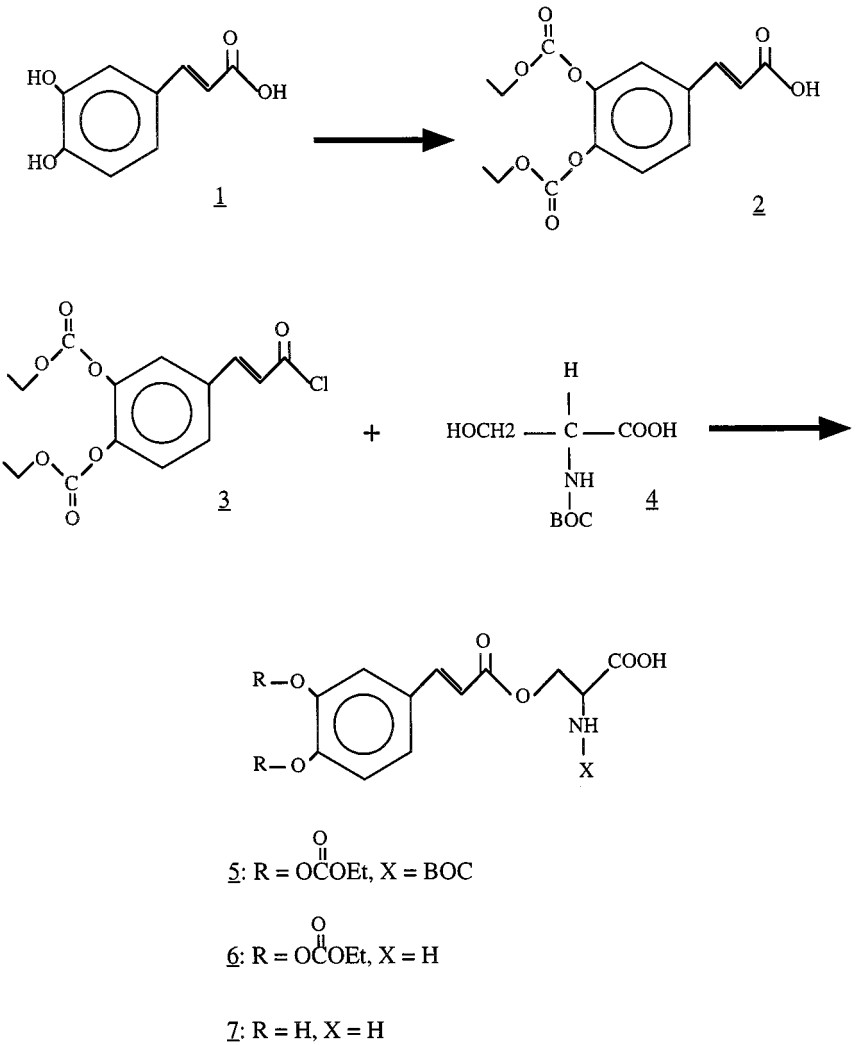
Both parasitoids species, *A. coccois* and *A. vexans*, were reared continuously on mealybug-infested cassava plants (cv. CMC 40) as described above for the cassava mealybug. Emerging adults (both males and females) were placed for 48 hr in transparent polystyrene tubes (15 × 1.5 cm) containing honey droplets as a food source. The wasps were sexed, and females were selected for bioassay.

Synthesis of Kairomone (*Figure 1*). The method used to synthesize *O*-caffeoylserine was that described by Millar and Hare (1993), for synthesizing *O*-caffeoyltyrosine. Caffeic acid (**1**) (10 g, 55 mmol) was added to ethyl chloroformate to produce 13.17 g (73.9% yield) of 3,4-diethoxycarbonyl-caffeic acid (**2**). ^{1}H NMR ($CDCl_3$): ∂ 7.72 (d, 1H, $J = 15.9$ Hz, C<u>H</u>COOH), 7.24–7.46 (3H, m aromatic), 6.42 (d, 1H, $J = 15.9$ Hz, olefinic H), 4.28 (2 overlapped quartets, 4H, $J = 7.1$ Hz, CH_2s), 1.33 (2 overlapped triplets, $J = 7.1$ Hz, methyls).

The acid (**2**) (13.17 g, 40.6 mmol) was stirred with 36.5 ml of thionyl chloride to obtain 10.23 g (73.7% yield) of 3,4-diethoxycarbonyl-caffeoyl chloride (**3**). ^{1}H NMR ($CDCl_3$): ∂ 7.73 (d, 1H, $J = 15.6$ Hz, olefinic H), 7.23–7.48 (3H, m aromatic), 6.56 (d, 1H, $J = 15.6$ Hz, olefinic H), 4.30 (overlapped quartets, 4H, $J = 7.1$ Hz, CH_2s), 1.36 (overlapped triplets, 6 H, $J = 7.1$ Hz, methyls). Then 1.71 g (5 mmol) of the chloride (**3**) was coupled with the *N-t*-BOC-(L)-serine (**4**) (1.03 g, 5 mmol; Sigma Chemical Co., St. Louis, Missouri) to produce 2.39 g (quantitative) of the compound (**5**). ^{1}H NMR ($CDCl_3$): ∂ 7.70 (d, 1H, $J = 16.2$ Hz, olefinic H), 7.22–7.58 (3H, m aromatic), 6.40 (d, 1H, $J = 15.9$ Hz, olefinic H), 5.62 (br. d, 1H, NH), 4.50 (m, 1H, NH-C<u>H</u>), 4.26 (br. quartet, 4H, C<u>H</u>$_2$s), 3.75 (m, 2H, -O-C<u>H</u>$_2$-CH-), 1.27–1.39 (m, 9H, *t*-BOC methyls, 6H, methyls).

After stirring the compound (**5**) (752 mg) with a mixture of methylene chloride and trifluoroacetic acid, the resulting dicarbonate (**6**) was treated with methanolic ammonium hydroxide. *O*-Caffeoylserine (**7**) was purified by TLC using a migration solvent of *n*-butanol–water–AcOH (4 : 1 : 1) for a total yield of 328 mg (87%). Synthesized *O*-caffeoylserine was used to confirm the presence of the compound in *P. herreni* and bioassayed at several concentrations to determine its biological activity on *A. coccois* and *A. vexans*.

To validate the synthetic method, *O*-caffeoyltyrosine was also synthesized, substituting the *N-t*-BOC-(L)-serine with *N-t*-BOC-(L)-tyrosine. The chloride (**3**) (1.71 g, 5 mmol) was coupled with the *N-t*-BOC-(L)-tyrosine (1.41 g, 5 mmol; Sigma) to produce 2.41 g (quantitative) of the compound with the following NMR



5: R = OCOEt, X = BOC

6: R = OCOEt, X = H

7: R = H, X = H

data. ^{1}H NMR ($CDCl_3$): ∂ 7.75 (d, 1H, $J = 15.9$ Hz, olefinic H), 6.95–7.49 (6H, m aromatic), 6.53 (d, 1H, $J = 15.9$ Hz, olefinic H), 5.00 (br. d, 1H, NH), 4.58 (m, 1H, NH-CH), 4.30 (br. quartet, 4H, CH_2s), 3.11 (m, 2H, benzyl CH_2), 1.39 (br. s, 9H, *t*-BOC methyls), 1.34 (t, 6H, $J = 6.5$ Hz, methyls). From 536 mg of this compound, *O*-caffeoyltyrosine was obtained for a total yield of 245 mg (81%). Proton NMR spectra were obtained on an Advance DPX 200 Bruker NMR spectrometer at 200 MHz.

Isolation and Identification of O-Caffeoylserine in Cassava Mealybug. Adult females (2.4 g) were crushed in 5 ml of 70% ethanol. After 8 hr at 10°C, the extract was centrifuged at 21,000 *g* for 3 min, and the aqueous supernatant was washed twice with chloroform to remove lipids. The lyophilisate of the supernatant was suspended in 500 μl of 70% ethanol and banded on to a reverse-phase TLC plate (RP-18, F_{254s}, pre-coated sheet 20 × 20 cm, Merck), developed with acetonitrile–water (50 : 50), and visualized using UV at 254 nm. Two bands with R_f values of 0.75 and 0.69 (shown to contain the putative *O*-caffeoylserine by autoanalysis) were recovered by scraping the plate and extraction in 70% ethanol. After 8 hr at 10°C and centrifugation in 21,000 *g* for 3 min, the supernatants were lyophilized. The lyophilisate was suspended in 70% ethanol and submitted to the same TLC purification as above, but developed in *n*-butanol–2-propanol–water (60 : 20 : 20). Three bands with R_f = 0.81, 0.73, and 0.67 (shown to contain the putative *O*-caffeoylserine by autoanalysis) were recovered as above, let stand at 10°C for 8 hr, centrifuged, and lyophilized. A mixture of compounds including the putative *O*-caffeoylserine remained in the extract. It was not possible to repeat this TLC purification because the putative *O*-caffeoylserine disappeared, probably due to hydrolysis.

The compound was first identified by LC-MS from a portion of the extract. LC-MS experiments were performed on a Finnigan TSQ 700 under atmospheric pressure chemical ionization (APCI) as described elsewhere (Renukappa et al., 1999). In this case, a reversed-phase column (Grom-Sil 120 ODS-5, 250 × 4.4 mm, 5 μm, Grom, Germany) was used. Separation was achieved by using 0.1% aqueous trifluoroacetic acid in a linear gradient of 5–100% with acetonitrile over 35 min and a constant flow of 0.1ml/min.

In the second part, known quantities of the synthetic *O*-caffeoylserine were analyzed, alone or added to the remaining extract, by HPLC and autoanalysis. Samples were analyzed by RP18-HPLC by using the Pico-Tag method from Waters after amino acid derivatization with phenyl isothiocyanate (PITC). The compounds were identified by their retention time and quantified by their UV absorption at 240 nm.

Samples were submitted also to ion-exchange chromatography on an automatic amino acid analyzer (Beckmann 6300). Amino acids were detected by ninhydrin reaction, identified by their retention time and wavelength ratio, and quantified by their absorption at 570 nm.

Determination of O-*Caffeoylserine as Host-Location Kairomone.* To verify that *O*-caffeoylserine is present on the body surface of *P. herreni*, 500 adult females (representing about 500 mg of total fresh weight) without prior maceration were soaked in 500 μl of aqueous 70% ethanol for a final proportion equivalent to 1 μl of extract per individual. Insects without wounds were used, and the suspension was not stirred to limit leaching of internal insect constituents. The suspension was left at 10°C for five days. An aliquot of 100 μl was collected

each day and dried for autoanalysis of amino acids. This experiment was run in triplicate.

To confirm the function of *O*-caffeoylserine as a contact kairomone, 100 mealybugs were soaked in 100 μl of 70% aqueous ethanol at 10°C for three days, pipetted, and used for bioassay. The same experiment was done with pure hexane and bioassayed as a negative control. Because the ethanolic suspension also contained free amino acids, a solution duplicating the composition and concentration of these compounds was also bioassayed. The natural host (i.e., adult female of *P. herreni*) was bioassayed as the positive control. Synthetic *O*-caffeoylserine was bioassayed at several concentrations to confirm its function of as a host-location kairomone for mealybug parasitoids.

Bioassays. Wasps initially investigate mealybugs by palpating with their antennae as they walk from one edge of the mealybug body to the other. They then turn ≈90° and repeat this behavior one or more times. This behavior, previously observed in several Aphelinidae species, has been termed "drumming and turning" by Luck et al. (1982). After drumming and turning, *A. vexans* and *A. coccois* insert their ovipositors inside the host body in most cases, indicating that this behavioral event characterizes their host location. Therefore, the number of drummings and turns was recorded for each wasp observed in the following experiments. The bioassay was conducted on mealybugs or on treated cotton balls, which mimic the mealybug body. For cotton balls, 1 μl of test solution was pipetted onto cotton balls approx. 2.0 mm diameter. One insect or treated cotton ball was placed inside a single glass vial bioassay arena (5 mm diam. × 10 mm high), and for treated cotton balls the solvent was allowed to evaporate. One gravid female was added, and the vial was sealed with a cotton plug. Wasp behavior was observed for 15 min with a 6× dissecting microscope. Bioassays were conducted in the same greenhouse where the parasitoids were reared, between 1000 and 1500 hr at 25–35°C. The natural host (adult females of *P. herreni*) and several solutions were bioassayed as described above.

Five replicate trials of five wasps were bioassayed, with new insects or fresh cotton balls prepared for each trial. Wasps were used only once. The proportion of total drummings and turns on each mealybug or cotton ball was calculated and analyzed by ANOVA after applying $\sqrt{(X+1)}$ transformation. Fisher's (protected least significant difference PLSD) test was used following ANOVA to compare means. Statistical tests were performed with Statview software (Abacus Concept).

RESULTS

Identification of O-*Caffeoylserine in Cassava Mealybug.* LC-MS analysis of *P. herreni* extracts revealed a compound with a molecular weight of 268.3 $(M+H)^+$,

close to that calculated from the formula of *O*-caffeoylserine, corresponding to $C_{12}H_{13}NO_6$, which is 267.2.

To confirm the identity of *O*-caffeoylserine in *P. herreni* extracts, the compound was synthesized according to the method of Millar and Hare (1993), which was used to synthesize another ester, *O*-caffeoyltyrosine. The proton NMRs (CD_3OD) of the two synthetic esters were readily interpreted.

For the *O*-caffeoylserine, we obtained: 7.43 (d, 1H, $J = 15.9$ Hz, olefinic H), 6.78–7.06 (3H, m aromatic), 6.29 (d, 1H, $J = 15.8$ Hz, olefinic H), 5.09 (br s, 1H), 4.10 (m, 1H), 3.79 (q, $J = 11.1$ Hz, 2H). Except for protons lost in exchange in CD_3OD, these NMR data corresponded to those obtained by Lin et al. (1999), confirming the synthesis of this ester.

For the *O*-caffeoyltyrosine, we obtained: 7.77 (d, 1H, $J = 15.9$ Hz, olefinic H β to carbonyl), 7.41 (d, 2H, $J = 8.54$ Hz, aromatic H, tyrosine), 7.04–7.19 (4H, m from aromatic H of tyrosine and caffeic acid), 6.84 (d, 1H, $J = 8.14$ Hz, meta H, caffeic acid), 6.50 (d, 1H, $J = 15.83$ Hz, olefinic H α to carbonyl), 3.82 (dd, 1H, $J = 9.1$, 4.24 Hz, $C\underline{H}NH_2$), 3.35 (dd, 1H, $J = 14.12$, 4.10 Hz, benzylic H), 3.04 (dd, 1H, $J = 14.5$, 9.1 Hz, benzylic H). These NMR data corresponded to those obtained by Millar and Hare (1993), validating the synthesis method.

The retention time of synthetic *O*-caffeoylserine on a reverse-phase HPLC column matched that of the peak at 18.9 min from the *P. herreni* extract. This peak increased in area when the *P. herreni* extract was augmented with 0.4 nmol of synthetic *O*-caffeoylserine (Figure 2).

The retention time of synthetic *O*-caffeoylserine on an ion-exchange column also matched that of the compound isolated from *P. herreni* (chromatograms not shown). This result, together with RP-HPLC data, confirms the identifiy *O*-caffeoylserine in *P. herreni* extracts.

Determination of O-*Caffeoylserine as Host-Location Kairomone.* When mealybugs were soaked in 70% ethanol without prior maceration and submitted to autoanalysis, the *O*-caffeoylserine amounted to 0.026 nmol/mg (approx. 0.03 nmol/mg) or 5.2% (in moles) (Table 1). Compared to the other nitrogenous compounds analyzed, this was not major. Alanine and glutamic acid were much better represented among the compounds analyzed, at 28.4 and 17.1% (in moles), respectively. Furthermore, this concentration of *O*-caffeoylserine was the maximum possible when mealybugs were soaked in 70% aqueous ethanol. In fact, this concentration varied over time (Figure 3) from a minimum of 0.011 ± 0.002 nmol/mg (mean $\pm$ SE, $N = 3$) on day 1 to a maximum of 0.032 ± 0.002 nmol/mg on day 3 and declining to 0.027 ± 0.004 nmol/mg on day 5, probably due to hydrolysis.

The fresh weight of an adult female is about 1 mg on CMC 40. According to the extraction proportion, 1 μl of extract was obtained per individual or per 1 mg of fresh weight. Therefore, 0.03 nmol/mg is equivalent to 0.03 nmol/μl. Synthetic *O*-caffeoylserine was bioassayed based on this concentration (at 0.03 nmol/μl and 10 times higher or 2, 4, or 8 times lower).

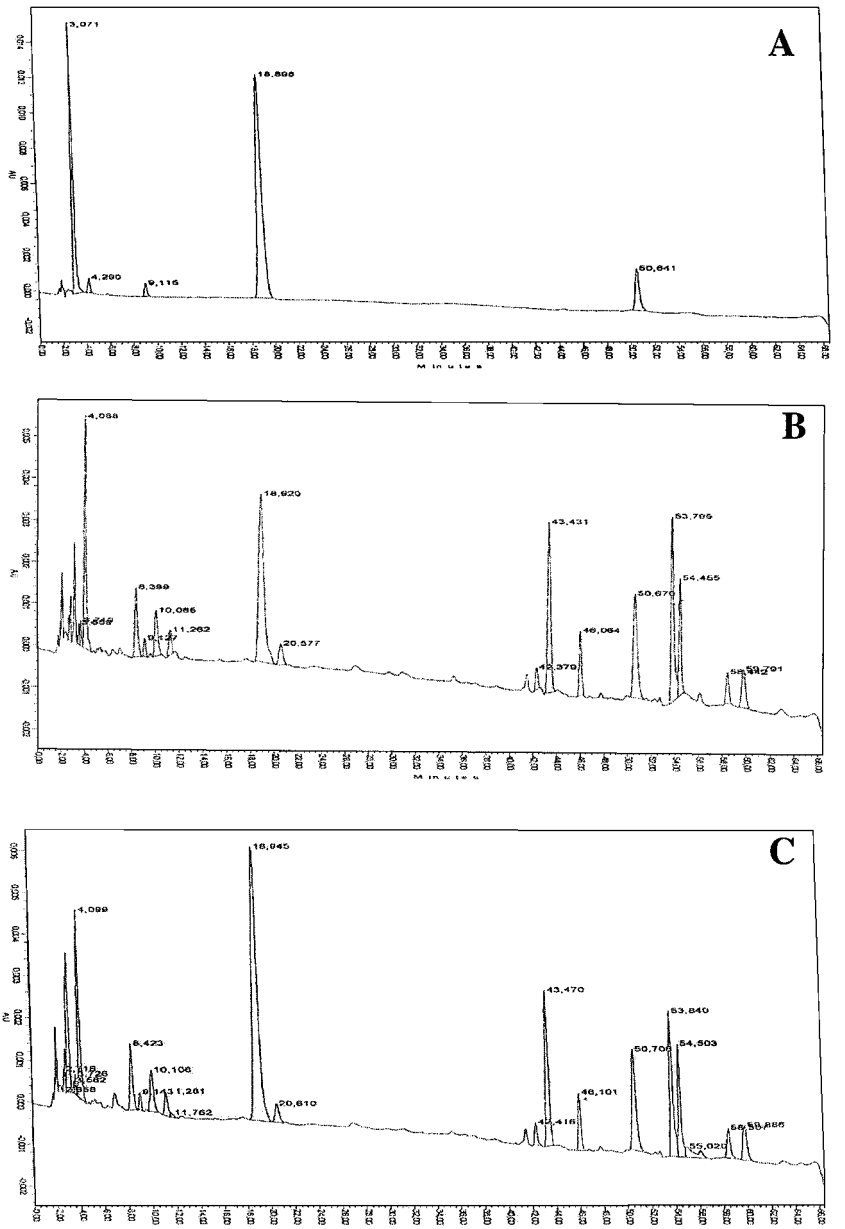

FIG. 2. HPLC chromatograms of (A) the synthetic *O*-caffeoylserine alone (at 2 nmol/10 μl); (B) an extract of *P. herreni* showing the unknown peak at 18.9 min; and (C) the same extract analyzed in (B) augmented with 0.4 nmol of synthetic *O*-caffeoylserine.

TABLE 1. CONTENT AND COMPOSITION OF FREE NITROGENOUS COMPOUNDS IN MEALYBUGS

Free nitrogenous compounds	Concentration (pmol/1 mg)	% (mol)

[a] Values are (mean ± SE, $N = 3$).

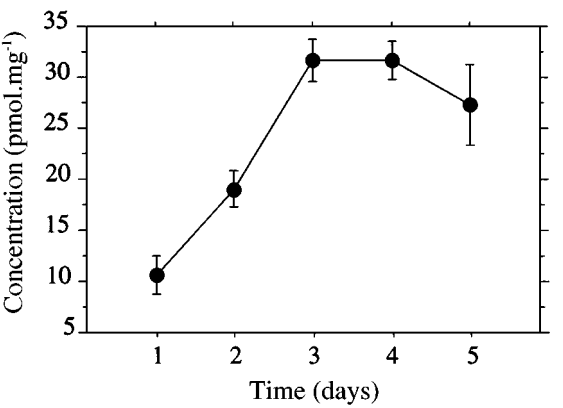

FIG. 3. Concentration of *O*-caffeoylserine in extracts from mealybugs (mean ± SE, $N = 3$) soaked without prior maceration in 70% ethanol as a function of time at 10°C.

For both parasitoid species, the extracts from mealybugs soaked in 70% ethanol were significantly more stimulating for host location than those in hexane (Figure 4), but no oviposition probing was observed. Moreover, these ethanolic extracts showed similar host-location stimulations when *P. herreni* was bioassayed. No stimulation was noted with ethanol alone, suggesting that the mediation of host location was in fact due to compound(s) present in ethanolic extracts of

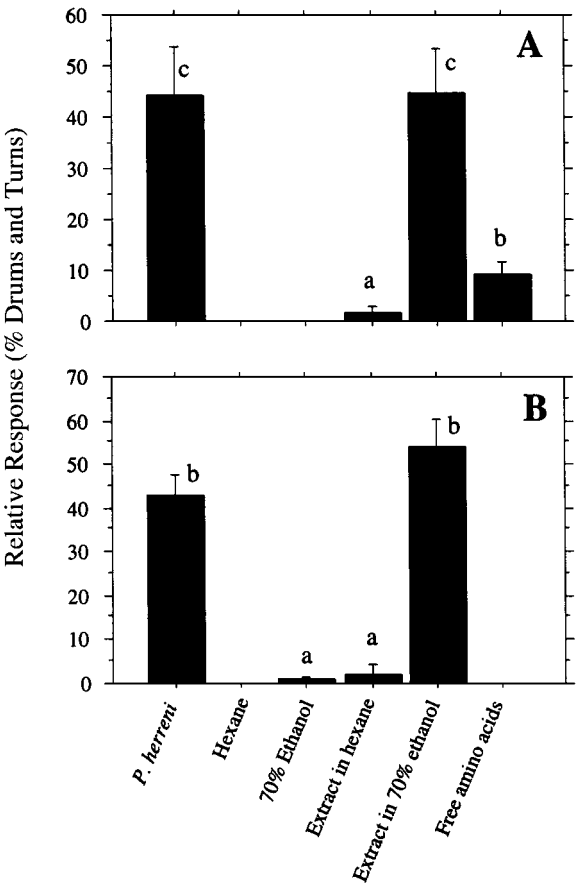

FIG. 4. Percent drums and turns observed for *A. coccois* (A) and *A. vexans* (B) on *P. herreni* and on cotton balls treated with solvent alone (hexane or 70% aqueous ethanol), extracts from mealybugs suspended without prior maceration in hexane or in 70% ethanol, or a mixture of free amino acids using the same concentration and composition as in Table 1. Bars indicate the mean (±SE; five trials with five wasps each). Means with the same letter are not significantly different at 5% level (Fisher's PLSD test following the ANOVA, $P < 0.05$). No statistical comparison was possible for means = 0%.

P. herreni and well solubilized in 70% aqueous ethanol. A mixture of free amino acids, similar in concentration and composition to the one obtained in Table 1, showed no stimulating effects as compared to the extracts of *P. herreni* in ethanol, indicating the presence of other compound(s) in the extracts, different from free amino acids, that have a stimulatory function for host location by *A. coccois* and *A. vexans*.

Among the concentrations in *O*-caffeoylserine tested, 0.03 nmol/μl was highly attractive for *A. coccois* (Figure 5A). Nevertheless, no difference was found between 0.03 and 0.015 nmol/μl. After removing the carbonate-protecting groups

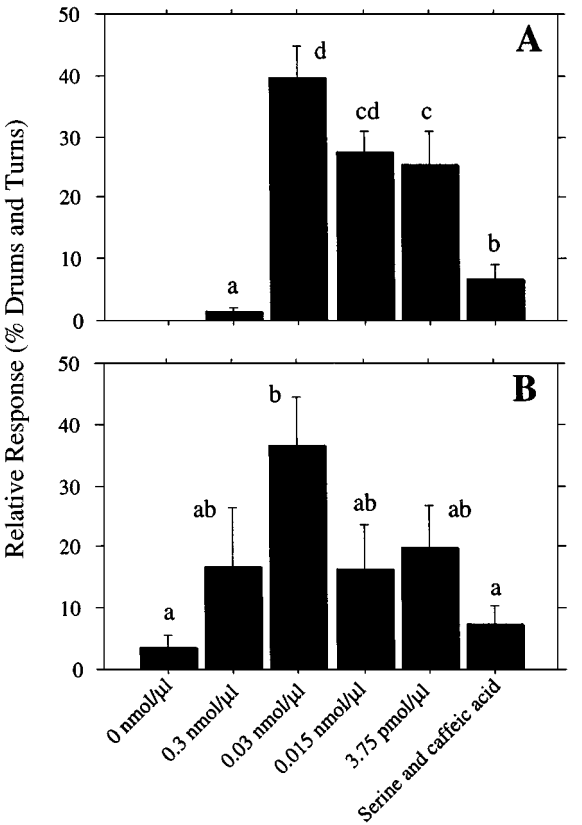

FIG. 5. Percent of drums and turns observed for *A. coccois* (A) and *A. vexans* (B) on cotton balls treated with synthetic *O*-caffeoylserine at several concentrations or with mixture of serine and caffeic acid at 0.03 nmol/μl each compound. Bars indicate the mean ($\pm$SE; five trials with five wasps each). Means with the same letter are not significantly different at 5% level (Fisher's PLSD test following the ANOVA, $P < 0.05$, except for *A. vexans* (B), $P > 0.05$ for ANOVA). No statistical comparison was possible for means = 0%.

(ultimate phase in Figure 1), using Millar and Hare's (1993) synthesis method, there is inevitably a partial ester cleavage, resulting in the presence of free serine and caffeic acid in the synthetic *O*-caffeoylserine solution. Therefore, a mixture of these compounds was also bioassayed at 0.03 nmol/μl, i.e., at the same concentration of *O*-caffeoylserine where the wasps responded better (Figure 5). It appeared that the *A. coccois* female wasps were less stimulated by the hydrolysis products of the *O*-caffeoylserine (caffeic acid and serine) confirming that the ester, *O*-caffeoylserine, is the biologically active compound. Moreover, for this parasitoid species, the ester also induced oviposition probing because 24% (i.e., 6 of the 25) of the wasps bioassayed at 0.03 nmol/μl of *O*-caffeoylserine probed the cotton ball with their ovipositor. Oviposition probing was not observed with the other concentrations of *O*-caffeoylserine tested.

Synthetic *O*-caffeoylserine at 0.03 nmol/μl elicited more drumming and turning of *A. vexans*, but differences were not observed among the concentrations tested (Figure 5B, $P = 0.0547$ for ANOVA), indicating no dosage-dependent response in this parasitoid species. Nevertheless, *O*-caffeoylserine did induce a stimulating effect in this parasitoid species at 0.03 nmol/μl because the wasps exhibited significantly higher drummings and turns than when the solvent alone or the mixture of serine and caffeic acid were bioassayed.

DISCUSSION

The identification of *O*-caffeoylserine in *P. herreni* was confirmed. To our knowledge, this represents the first report of *O*-caffeoylserine isolated from biological material, although this ester was recently synthesized by Lin et al. (1999). Without prior maceration, *O*-caffeoylserine amounted to approx. 0.03 nmol/mg of mealybug fresh weight, representing 5.2% (in moles) of the nitrogenous compounds analyzed (Table 1). Although it can be assumed that the procedure used (i.e., soaking the mealybugs in 70% ethanol for three days at 10°C) is sufficient to leach out a number of internal insect constituents, some arguments support the fact that the method tends to dissolve surface rather than internal constituents and that *O*-caffeoylserine should, in fact, amount to 0.03 nmol/mg on the body surface of *P. herreni* females in the adult developmental stage. First, when mealybugs were crushed, *O*-caffeoylserine amounted to about 9.5 nmol/mg of mealybug fresh weight, i.e., approx. 916 times higher, being much more concentrated than that obtained without maceration. Furthermore, when whole insects were soaked in ethanol, the concentration of *O*-caffeoylserine reached a maximum at three days and was three times higher than on day 1 (Figure 3). If the procedure were efficient in leaching out internal insect constituents, the concentration would increase much more than three times based on the internal concentration of *O*-caffeoylserine mentioned above. Figure 5 shows that both parasitoid species

responded better to 0.03 nmol/μl of *O*-caffeoylserine. This concentration, equivalent to 0.03 nmol/mg of mealybug fresh weight, is similar to that found when mealybugs were soaked in 70% ethanol for three days at 10°C. Given the fact that higher biological activity was obtained at this concentration and that it is the maximum that can be extracted by soaking unmacerated insects in ethanol, we suggest that *O*-caffeoylserine amounts 0.03 nmol/mg on the body surface of adult *P. herreni* females.

The presence of free amino acids in the sample supports the idea that some internal constituents can be leached out as well (Table 1). However, this is more likely due to honeydew secretions containing free amino acids that could stick to the body surface of neighboring mealybugs, given their proximity under mass-rearing conditions. *O*-Caffeoylserine was not found in the honeydew secretion of *P. herreni*.

Using several concentrations of synthetic *O*-caffeoylserine, it was confirmed that this compound influences host-location behavior of two parasitoid species of the cassava mealybug: *A. coccois* and *A. vexans*. Perhaps because of its generalist nature, this was more clearly shown with *A. coccois* due to the fact that the dosage-dependent response was well observed, with higher biological activity at 0.03 nmol/μl (Figure 5A). Although no such response was observed for *A. vexans*, *O*-caffeoylserine also was stimulatory at 0.03 nmol/μl (Figure 5B). In conclusion, for both parasitoid species, 0.03 nmol/μl is the concentration of *O*-caffeoylserine that induces more drummings and turns of wasps (approx. 40% of relative response among the concentrations bioassayed, Figure 5). This concentration, equivalent to 0.03 nmol/mg, is similar, to what can be extracted from the body surface of mealybugs, induces significant drummings and turns (approx. 40% of relative response as compared to the natural host, Figure 4), and indicates that synthetic *O*-caffeoylserine is as active as the chemical isolated from the body surface. All these results are consistent with *O*-caffeoylserine being a contact kairomone that mediates host-location behavior by the two cassava mealybug parasitoids.

Except for *A. coccois* at 0.03 nmol/μl of *O*-caffeoylserine, oviposition probing was not observed with any of the extracts bioassayed, regardless of parasitoid species. It may be that the female wasp behavior for oviposition probing is influenced by other factors such as color and texture of the mealybug body. In fact, in preliminary experiments we observed that for both parasitoid species, texture influenced wasp behavior for host location more than color (Calatayud, unpublished data). Some wasps inserted their ovipositor inside the untreated cotton plug, whereas oviposition probing was not observed with the treated cotton ball inside the glass vial. This was probably due to the fact that the cotton plug was more compact than the cotton ball, suggesting that a good combination between the concentration of *O*-caffeoylserine and texture could enhance oviposition probings. Unfortunately, increasing the pressed texture of the cotton ball was not possible given its size.

O-Caffeoylserine is not provided directly by the host plant; it is either synthesized by the insect itself or with the help of symbiotic bacteria. In fact, it was detected in adult mealybugs reared on holidic diets at 14.9 nmol/mg fresh weight, a higher level than in plant-reared mealybugs (about 9.5 nmol/mg), but not for extracts of host plant (*Manihot esculenta*) leaves. Nevertheless, enzymes commonly involved in the synthesis of phenolic compounds in plants such as phenylalanine or tyrosine ammonia-lyase were not evidenced in *P. herreni* (Calatayud, unpublished data).

The physiological role of *O*-caffeoylserine in the cassava mealybug is not clear. The caffeic acid moiety, as suggested by Hare et al. (1993) for *O*-caffeoyltyrosine, could be a precursor of the quinone compound involved in cuticle sclerotization and tanning. The serine moiety could be a precursor of the bristle (serine polymer) in the ovisacs. The fact that this phenolic compound is present in higher concentration in eggs (at about 26.4 nmol/mg) than in adult females suggests that it may also have a protective function (e.g., antibacterial or antiviral activity) in the insect. All these hypotheses need to be demonstrated explicitly.

VOLATILES FROM POTENTIAL HOSTS OF *Rhopalicus tutela* A BARK BEETLE PARASITOID

EVA M. PETTERSSON[1]

Chemical Ecology Department
Göteborg University
Box 461, SE-405 30 Göteborg, Sweden

(Received January 23, 2001; accepted July 5, 2001)

Abstract—Host location cues for parasitic wasps that attack bark beetle larvae concealed under the bark of spruce trees were analyzed by collecting odor samples from entrance holes into the bark beetle galleries, isolated larvae, and pupal chambers with or without bark beetle larvae. Odor samples were collected by dynamic headspace adsorptions on Porapak Q or static adsorptions by using solid-phase microextraction (SPME) with Carbowax–divinylbenzene as the adsorbing phase. Samples were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) and GC-mass spectrometry (GC-MS). The antennae of *Rhopalicus tutela* females responded primarily to oxygenated monoterpenes that are typical for damaged host trees. These compounds are attractive to bark beetle parasitoids in long-range host location, suggesting that they are used in both long- and short-range host location. No differences could be detected between samples collected from pupal chambers with or without mature larvae. Larvae outside pupal chambers emitted low quantities of the same compounds present in empty pupal chambers. The data support the hypothesis that volatiles used by host foraging parasitoids arise from the interaction between introduced microorganisms and the bark and/or vascular tissue of the host tree rather than from the bark beetle larvae.

Key Words—*Rhopalicus tutela*, Hymenoptera, Pteromalidae, host location, oxygenated monoterpenes, *Ips typographus*, Coleoptera, Scolytidae, bark beetle.

INTRODUCTION

By definition, parasitoids are insects that spend their immature stages feeding on the tissues of other arthropods that are eventually killed. Parasitoids occurs in several insect orders, although the vast majority are hymenopterans (e.g., Quicke,

[1]Present address: Max-Planck Institute for Chemical Ecology, Carl Zeiss Promenade 10, D-07745 Jena, Germany. E-mail: Pettersson@ice.mpg.de

0098-0331/01/1100-2219$19.50/0

1997). The chalcid parasitoid *Rhopalicus tutela* (Walker) (Hymenoptera: Pteromalidae) oviposits on coniferous bark beetles, like the aggressive *Ips typographus* L. (Coleoptera: Scolytidae). In Sweden, *I. typographus* kills large numbers of its principal host Norway spruce (*Picea abies* L. Karst.) during outbreaks (Krol and Bakke, 1986; Leufvén and Nehls, 1986; Krokene and Solheim, 1996). As for most hymenopteran parasitoids attacking bark beetles, a mature larva in a pupal chamber in the bark of the host tree is the preferred host stage (Berisford, 1980). *Rhopalicus tutela* oviposits through the bark, thus detecting the larvae without any obvious visual cues.

Several hypotheses have been proposed for close-range host location mechanisms of parasitoids ovipositing through the bark. Vibrational cues do not seem to be necessary, since oviposition by *R. tutela* on *I. typographus* was not disrupted by killing or removing host larvae (Mills et al., 1991). This is further supported by similar results from the braconid parasitoid *Coeloides brunneri* (Richerson and Borden, 1972). Infrared radiation (heat) also does not seem to be a necessary cue for *Coeloides bostrychorum* and *R. tutela* in locating their bark beetle hosts (Mills et al., 1991; Pettersson et al., 2001b). Because volatiles derived from bark beetle-infested spruce logs containing susceptible hosts elicit both antennal activity and long-range attraction to parasitoids (Pettersson et al., 2000, 2001a, b), the same chemicals may be important in short-range host location.

During host foraging, hymenopteran parasitoids commonly use semiochemicals emitted by the host itself, sources indirectly associated with the presence of the host (e.g., microorganisms), or the host habitat (Madden 1968; Vinson, 1986; Godfray, 1994; Rutledge, 1996). Successful parasitism depends on appropriate habitat identification, i.e., long-range host location (host habitat location), followed by short-range host location that includes host location, host acceptance, host suitability assessment, and host regulation (Vinson et al., 1998). Parasitoids may use different semiochemicals emitted from differnt sources at various stages of the host-selection process. In general, host habitat cues are most important at long distances, while host insect cues are more important at short distances (Weseloh, 1981).

The objectives of this study were to indentify volatile cues of potential use in short-range host location by bark beetle parasitoids, locate the source emitting these compounds, and evaluate the potential of solid-phase microextraction (SPME) as a sampling technique in gas chromatographic-electroantennographic detection (GC-EAD) analysis of volatile compounds from bark beetle infested spruce trees.

METHODS AND MATERIALS

Experimental Insects. Logs cut from five approximately 90-year-old spruce trees infested with bark beetle larvae (*I. typographus*) parasitized by *Rhopalicus*

tutela and *Roptrocerus xylophagorum* were collected in southern Sweden in the province of Småland (58°50′N, 16°20′E). Cut ends were sealed with paraffin. The logs were wrapped in paper sacs and stored at 3°C. When parasitoids or bark beetles were needed, logs were brought to a temperate (20°C) rearing room. Emerged parasitoids and bark beetles were collected daily and kept separated in humidified flasks at 8°C. Parasitoids used in experiments had not had any previous contact with susceptible bark beetle hosts (in experienced parasitoids). In plastic cages, controlled bark beetle attacks were initiated on spruce logs (ca. 20 cm diam., 100 cm long) with the cut ends sealed with paraffin to prevent desiccation. Mature larvae in pupal chambers (the preferred host stage of the parasitoid) were abundant 22–29 days after attack (at ca. 18°C, laboratory conditions).

Sampling of Volatile Compounds. Volatile compounds were collected from entrance holes into the bark beetle galleries, larvae were separated from their pupal chambers (25 individuals/sample in a 40-ml glass container), and pupal chambers, with or without mature larvae, were exposed by removing thin layers of the bark. Sampling was performed by using dynamic headspace aeration on a Porapak Q adsorbent or passive diffusion by SPME (Pawliszyn, 1997). Biologically active compounds were isolated by coupled GC-EAD and identified by GC-mass spectrometry (GC-MS).

Dynamic headspace Porapak-samples were collected from individual sample sites on logs into small Teflon cylinders (ID 4 mm, 5 mm high) directly connected to the Porapak Q adsorbent (75 mg, mesh 80/100, Alltech) packed into Teflon tubes (3 mm ID, 4 cm long). Air was drawn onto the adsorbents for 12 hr (80 ml/min) by a pump. Adsorption for 2–3 hr resulted in samples that had to be concentrated ($>$30 times) to be useful in GC-EAD analysis. Adsorption samples were extracted with diethyl ether (Puriss p.a., Fluka) to a volume of 300 μl. One microliter of each sample was injected on the GC-EAD, approximately corresponding to the amount of volatiles released during 2.4 min of sampling [(12 hr $\times$ 60 min)/300 μl]. Samples used in GC-MS analysis (identification and quantification) were spiked with an internal standard (heptyl acetate, 5 ng/μl eluted sample).

SPME samples were collected during 45 min. Sampling for a longer time did not yield stronger samples, and sampling for shorter durations captured lower quantities of monoterpenes. Carbowax-divinylbenzene, 65 μm (Supelco, Inc.), was chosen as the fiber adsorption phase, as it is similar to the GC-column phase used (Cp-Wax 58 CB), which is suitable for oxygenated (polar) compounds. The fiber was conditioned in the GC injector (230°C) for 1 min before sampling. Sample sites on logs were covered by a small Teflon cylinder (10 mm ID, 15 mm high) equipped with two small openings that enabled simultaneous sampling by two fibers from one site (Figure 1), giving identical samples for both GC-MS and GC-EAD analyses. An external standard (5 ng heptyl acetate) was used for quantification of the GC-MS samples.

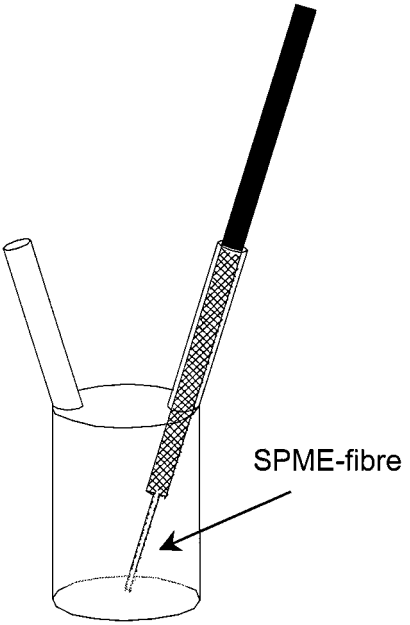

FIG. 1. Teflon cylinder (10 mm ID, 15 mm high) used for SPME sampling with two holes allowing simultaneous sampling by two SPME fibers (one shown in the right hole). Illustration by Claes Johansson.

Chemical Analysis. Eight samples were analyzed for each volatile collection technique. A Hewlett-Packard 5890 series II GC and 5972 MSD was equipped with a fused silica column (25 m $\times$ 0.25 mm) coated with polyethylene glycol nitroterephthalic acid ester (Cp-Wax 58 CB, film thickness 0.2 μm, Chrompack). The carrier gas was helium with a constant flow of 27 cm/sec. One microliter of a Porapak Q sample was injected by using a HP 7673 autosampler. Injector temperature was 210°C, and the splitter was off for 0.5 min; thereafter, it was split with a purge flow of 30 ml/min. SPME samples were injected manually with the injector temperature set at 230°C and with the fiber left in the injector for 20 sec. The GC oven temperature program was: 30°C for 2 min, 10°/min to 230°C, and isothermal for 8 min. The GC-MS transfer line temperature was 240°C. Compounds were identified by mass spectral matches to library spectra (NBS75K, obtained by authentic standards analyzed on the same GC-MS equipment as used in this investigation) and by retention time matches to available known standards. Compounds were quantified by their total ion abundance relative to that of the internal standard (5 ng/μl of Porapak samples). When comparing the sampling techniques, the detection limit for each compound was set to 0.8 ng/sample. Data were square-root transformed to obtain homogeneity in variance and analyzed by

one-way ANOVA, $\alpha = 0.05$ (Underwood, 1997), followed by a *post hoc* Tukey test (Sigma Stat 2.03, SPSS Inc.).

Electrophysiology. GC-EAD analyses employed a Shimadzu 14A gas chromatograph equipped with the same type of column as in GC-MS analysis (Cp-Wax 58 CB). The SPME samples were injected as above, while the Porapak Q samples were injected manually with the injector temperature set at 200°C. Nitrogen was used as carrier gas, with a flow-rate of 12 cm/sec (at 175°C), and the detector temperature at 230°C. The GC oven temperature program was 30°C for 2 min, then 8°/min to 200°C, 30°/min to 230°C, and isothermal for 3.8 min. Further details on this GC-EAD equipment are given in Pettersson et al. (2001b). For details of the EAD setup with parasitoid antennae, see Pettersson et al. (2000). The *R. tutela* parasitoids used for GC-EAD were 1–16 days old, and each individual was used for only one recording. Ten females were used for the Porapak-samples, and 11 females were exposed to the SPME samples. Before and after the GC-EAD recordings, the responsiveness of each antenna was evaluated by a control electroantennogram (EAG), as described in Pettersson et al. (2000, 2001b). A Kolmogorov-Smirnov normality test (Sigma Stat 2.03, SPSS Inc.) showed that the data met the requirements for parametrical statistics. EAD responses to compounds sampled by different sampling techniques were compared by a one-way ANOVA, $\alpha = 0.05$ (Underwood, 1997), followed by a *post hoc* Tukey test (Sigma Stat 2.03, SPSS Inc.).

RESULTS

Oxygenated monoterpenes of damaged conifers constituted the major group of EAD-active compounds, in both Porapak and SPME samples (Figure 2). Most compounds elicited antennal responses of the same magnitude, irrespective of the sampling method (Figure 3). There was no apparent qualitative difference between the sampling methods. However, the methods differed quantitatively since Porapak samples contained more compounds in greater amounts (>0.8 ng/single sample) than the SPME samples (Table 1, Figure 4). Inexplicably, some compounds elicited different EAD activities in response to Porapak and SPME samples, respectively (Figure 3), although no quantitative difference was detected between the sampling methods (Table 1). Samples taken from entrance holes were weaker than samples from pupal chambers (Figure 4) but did not differ qualitatively. Samples from single bark beetle larvae contained no detectable compounds. Samples taken from 25 pooled larvae contained only hexanal and acetic acid in amounts >0.8 ng/sample; these and all other detected compounds were also found in samples from pupal chambers, with or without larvae. In samples from pupal chambers, only α-pinene, β-pinene, and 3-carene were captured in significantly lower amounts by SPME than by Porapak Q (Table 1).

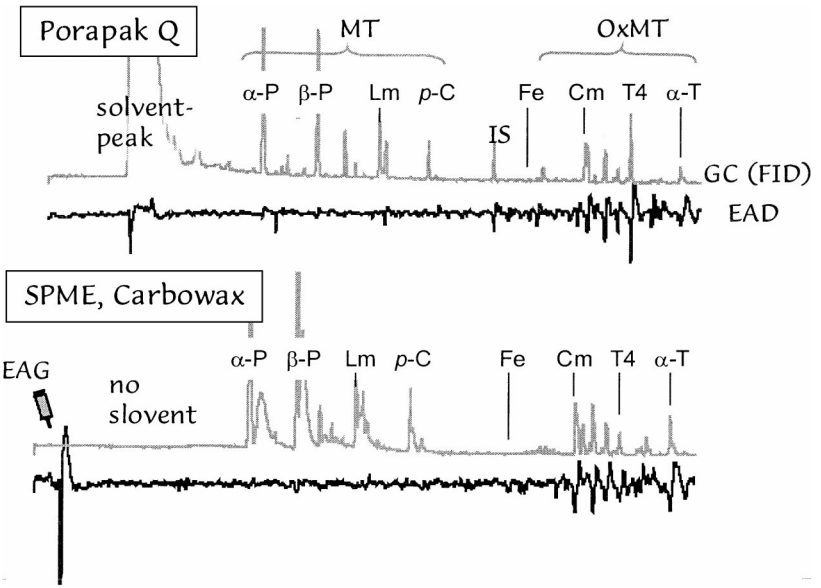

FIG. 2. Representative GC-EAD recordings on female *Rhopalicus tutela* exposed to odor samples from a pupal chamber with bark beetle larva. The Porapak Q-sample was spiked with 5 ng heptyl acetate (IS) for quantification. The double peaks (α-P and β-P) observed in the early MT region of the SPME sample are due to the injector used. Sample compositions are given in Table 1; EAD-active compounds are given in Figure 3. EAG = antennal stimulation by standardized EAG tests indicated by a syringe icon; MT = monoterpenes; OxMT = oxygenated monoterpenes; α-P = α-pinene; β-P = β-pinene; Lm = limonene; *p*-C = *p*-cymene; Fe = fenchone; Cm = camphor; T4 = terpinen-4-ol; α-T = α-terpineol.

DISCUSSION

Most antennal active compounds were oxygenated monoterpenes (Figure 2), indicating damaged spruce trees (Leufvén and Birgersson, 1987), in agreement with previous analyses of volatiles from whole bark beetle infested logs (Pettersson et al., 2000, 2001a). These compounds are also behaviorally active in Y-tube (Sullivan et al., 2000; Pettersson, 2001) and wind-tunnel bioassays (Pettersson et al. 2001a) with bark beetle parasitoids. Although some other parasitoids employ different chemical host location cues at long- and short-range host foraging (Weseloh, 1981), bark beetle parasitoids seems to rely on the same volatile compounds. However, olfaction is probably not the only sensory modality employed in short-range host location. Although metabolic heat or vibrations produced by the host have been ruled out as host location cues (Mills et al., 1991; Pettersson et al., 2001b) for *C. bostrichorum* and *R. tutela* ovipositing through the bark on bark beetle

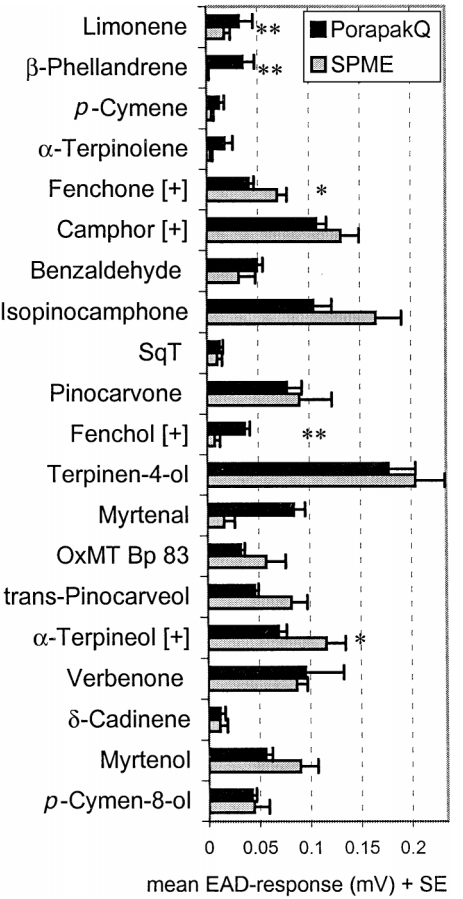

FIG. 3. Mean EAD responses by female *Rhopalicus tutela* to odor samples collected from pupal chambers with bark beetle larvae using either Porapak Q ($N = 10$), or SPME ($N = 11$). Compounds are arranged in order of retention time. [+] = Minor quantities of another compound coeluted on the GC-column: fenchone + nonanal; camphor + pinocamphone; fenchol + bornyl acetate; α-terpineol + borneol. SqT = sesquiterpene; OxMT = oxygenated monoterpene; Bp = base peak, the most abundant ion fragment of the mass spectrum. $^{*}P < 0.05$; $^{**}P < 0.01$; the absence of asterisks indicates that no difference in EAD response was detected ($P > 0.05$).

larvae, vibrations produced by the parasitoid itself may be used in host foraging. The pupal parasitoid *Pimpla turionellae* L. (Hym.: Ichneumonidae), which attacks various lepidopterans, such as *Galleria mellonella*, *Pieris brassicae*, and *Lymantria dispar*, may locate its concealed host by self-produced vibrations (Wäckers et al., 1998), although wind and other factors complicate the interpretation of vibratory

information (Casas et al., 1998). Other possible close-range host location cues may be chemicals of low volatility requiring contact. While host foraging on the bark surface of trees containing bark beetle larvae, a parasitoid would possibly detect low-volatility compounds by chemoreceptors on the antennae, mouth

u.i. [93; 121; 79]	3.3 ± 3.0	2.5 ± 0.6	<

[a] Differences in compound concentration in different samples were analyzed by one-way ANOVA. $^{*}P < 0.05$. The only differences detected were between Porapak and SPME sampling methods. Compounds are arranged in order of retention time on the semipolar column used.

[b] u.i. unidentified compound with predominant ion fragments in brackets; Sqt Sesquiterpene; OxMT oxygenated monoterpene.

[c] Mean abundances calculated from eight samples per category, considering compounds more abundant than 0.8 ng/sample; "<", compounds less abundant than 0.8 ng in the samples were not considered in the comparison of sampling methods.

parts, or tarsi (Slifer, 1970). Parasitoids probably detect differences in the concentration of compounds. The bark layer above a pupal chamber is thinner than that above the rest of the bark beetle galleries. The thin bark layer could allow compounds produced in the phloem to pass through readily, allowing for an increase in release rate. Alternatively, it could result in lower release rates since a thin phloem tissue would contain fewer microorganisms, which are the most probable producers of compounds that attract parasitoids. An unidentified compound has been isolated around the pupal chambers of the southern pine beetle (*Dendroctonus frontalis*) in loblolly pine (*Pinus taeda*) (personal communication: G. Birgersson, Göteborg University; M. Dalusky, University of Georgia). The release rate of this compound, as measured on the undamaged bark surface, is high in the area surrounding an oviposition site (a pupal chamber) but decreases at the oviposition site, suggesting that the phloem surrounding pupal chambers emits greater amounts of compounds than the centers of the chambers.

Pupal chambers are the most likely source of host-finding volatiles for parasitoids since pupal chambers emitted larger quantities of volatiles but did not differ qualitatively from samples from entrance holes (Figure 4). However, Porapak samples (using funnels, 2 cm ID) from undamaged bark of spruce trees containing mature bark beetle larvae did not reveal any detectable difference in volatile composition among oviposition sites and other sites (E. M. Pettersson et al., unpublished data). The similarity in chemical composition and EAD activity of samples from pupal chambers, compared to other analyses of bark beetle associated volatiles (Pettersson et al., 2000, 2001a, b), indicates that the volatile composition of the pupal chambers is not altered by the sampling technique.

Odor samples collected from bark beetle larvae did not reveal any compound that was not also present in empty pupal chambers (Figure 4). Thus, these compounds are most likely contaminants from the pupal chamber. Y-tube walking bioassays with the pteromalid bark beetle parasitoid *Ropalicus xylophagorum* showed that bark beetle larvae were not attractive unless they were in the host tree bark, while infested bark deprived of bark beetle larvae was still attractive (Sullivan et al., 2000). Bark subjected to mechanical damage was not attractive and differed in chemical composition from bark beetle infested bark (Sullivan et al., 2000).

Infestation by *Ips typographus* results in microorganisms being inoculated into host tree phloem (Krokene and Solheim, 1996). As the production of oxygenated monoterpenes increases drastically after an attack by bark beetles and their associated microorganisms (Leufvén and Birgersson, 1987), the compounds attracting bark beetle parasitoids seem to arise from the interaction among bark beetles, microorganisms, and the host tree. Interestingly, physiological changes in the tree phloem polyphenolic parenchyma cells, three weeks after bark beetle attack, (Franceschi et al., 2000) coincide with the presence of mature bark beetle larvae susceptible to parasitation. At this time, a marked increase in the concentration of camphor and certain other oxygenated compounds has been found (Pettersson, unpublished data) that elicits EAD activity in *Rhopalicus tutela* and other bark beetle parasitoids (Pettersson et al., 2000, 2001a). It is possible that the phloem polyphenolic parenchyma cells contribute to the increased production of oxygenated monoterpenes.

Few EAD-active compounds elicited antennal responses of different magnitude as a result of different sampling methods (Figure 3). Thus, both SPME and Porapak sampling are useful in GC-EAD analysis of volatiles from bark beetle infested spruce. The long duration of Porapak sampling did not affect the samples significantly, as there was no apparent qualitative difference between the two sampling methods. The major advantage of the more elaborate Porapak sampling is the large quantity of sample obtained, making it possible to identify compounds present at low levels. Furthermore, the same sample can be used in both GC-MS and GC-EAD, facilitating identification of EAD-active compounds. Several insects can be exposed to exactly the same sample, making it possible to detect compounds that elicit minor antennal activity. One drawback of SPME sampling is that a sample can be used only once.

The results show that the volatiles used in host location by parasitoids attacking bark beetle larvae arise from the host tree phloem, rather than from the host itself. The host trees used were naturally inoculated with microorganisms, which may play a role in the production of host location volatiles. The results do not show how parasitoids could use volatile stimuli to pick out the oviposition sites directly above host larvae in pupal chambers. High-resolution sampling around oviposition sites followed by quantitative analyses of the GC-EAD active compounds may resolve this anomaly by disclosing differences in amounts

of behaviorally active compounds that might be used in the precise location of host larvae.

Acknowledgments—I thank my family for providing spruce logs containing parasitoids and Claes Johansson for technical assistance. Abstract—Feeding by *Pieris brassicae* caterpillars on the lower leaves of Brussels sprouts (*Brassica oleracea* var. *gemmifera*) plants triggers the release of volatiles from upper leaves. The volatiles are attractive for a natural antagonist of the herbivore, the parasitoid *Cotesia glomerata*. Parasitoids are attracted only if additional damage is inflicted on the systemically induced upper leaves and only after at least three days of herbivore feeding on the lower leaves. Upon termination of caterpillar feeding, the systemic signal is emitted for a maximum of one more day. Systemic induction did not occur at low levels of herbivore infestation. Systemically induced leaves emitted green leaf volatiles, cyclic monoterpenoids, and sesquiterpenes. GC-MS profiles of systemically induced and herbivore-infested leaves did not differ for most compounds, although herbivore infested plants did emit higher amounts of green leaf volatiles. Emission of systemically induced volatiles in Brussels sprouts might function as an induced defense that is activated only when needed, i.e., at the time of caterpillar attack. This way, plants may adopt a flexible management of inducible defensive resources to minimize costs of defense and to maximize fitness in response to unpredictable herbivore attack.

Key Words—Tritrophic interactions, plant induced defense, *Cotesia glomerata*, *Pieris brassicae*, *Brassica oleracea*, semiochemicals, pathways, volatiles.

INTRODUCTION

Plants have evolved a range of defensive mechanisms to guard themselves from the wide variety of pathogens and herbivores with which they are confronted. Physiological changes in plants following damage or stress are generally referred to as induced responses. These are named induced defenses when they reduce the negative consequences in terms of plant fitness of the herbivore attack on plants (Karban and Baldwin, 1997). Recent studies indicate that induced plant responses effectively increase plant fitness in the field both by directly reducing herbivory (Agrawal, 1998; Baldwin, 1998) or indirectly through enhanced parasitization, resulting in increased herbivore mortality (Thaler, 1999). Chemical defenses of plants against herbivorous insects are defined as direct defenses when they are related to a systemic production of toxic metabolites and as indirect defenses when they promote the effectiveness of natural enemies of herbivores (Dicke, 1999).

A well-documented inducible response related to direct defense in insects is the so-called "wound response pathway," in which wounding and/or insect feeding trigger the induction of proteinase inhibitors in solanaceous plants (reviewed by, e.g., Karban and Baldwin, 1997; Maleck and Dietrich, 1999). Inducible responses related to indirect defenses have been known for about a decade. Feeding (e.g., Dicke and Sabelis, 1988; Turlings et al., 1990) and even oviposition (Meiners and Hilker, 1997, 2000) by herbivores induce the emission of blends of plant volatiles that are used by predators or parasitoids (parasitic wasps) as a cue to find their prey or hosts. The importance of induced phytochemicals, such as plant volatiles, for plant defense as well as the mechanisms that regulate their synthesis and release are still poorly understood, however (Paré and Tumlinson, 1999).

Induced responses to injury may be systemic, i.e., a signal produced at the damaged site is transported throughout the plant, causing effects at sites distant from the injury (Karban and Baldwin, 1997). In corn seedlings, the emissions of several volatiles that are highly attractive to parasitic wasps occur a few hours after caterpillars start damaging the plants. The response is systemic, as undamaged leaves of injured plants also emit the volatiles (Turlings and Tumlinson, 1992). Various studies indicate that the systemic responses induced by herbivore feeding occur in several plant species and affect the behavior of predators and parasitoids (Dicke et al., 1990; Potting et al., 1995; Röse et al., 1996, 1998; Souissi et al., 1998; Guerrieri et al., 1999).

In this work, we report on the systemic response of Brussels sprouts plants (*Brassica oleracea* var. *gemmifera*; Brassicaceae) to feeding of *Pieris brassicae* (Lepidoptera: Pieridae) caterpillars. In laboratory behavioral assays, the parasitic wasp *Cotesia glomerata* (Hymenoptera: Braconidae) was used as a biological sensor to determine the dynamics of the plant systemic response. In addition we carried out GC-MS identification and quantification of the volatiles emitted by induced plants.

METHODS AND MATERIALS

Rearing Procedures

Brussels sprouts seedlings were individually transplanted into 400-ml pots two weeks after they had been sowed on a commercially available mixture of peat and clay (Optima-Werke, H. Gilgen, Germany). The substrate contained 400 mg/liter total nitrogen, 200 mg/liter phosphorus, 370 mg/liter potassium, 2200 mg/liter lime, and 0.32 mg/liter magnesium. Plants were reared in a walk-in climate room under high pressure sodium lamps (4×400 W, for a total of $10{,}000 \pm 1000$ lux) at 16°C (night), 24°C (day), 50–70% relative humidity, 16L : 8D photoperiod. Leaves from 8- to 10-week-old Brussels sprouts plants with five to eight fully expanded leaves were used for experiments. Plants used were similar with respect to appearance, size, and number of leaves. After treatment, they were kept under the environmental conditions described above and transferred to the bioassay room 30 min prior to the experiment.

Herbivores (*P. brassicae*) and parasitoids (*C. glomerata*) were reared as previously described (Gu and Dorn, 2000). *P. brassicae* larvae were maintained on Brussels sprouts plants, at 21 ± 1°C, 50–70% relative humidity, and 16L : 8D photoperiod. *C. glomerata* were reared in a climate room at 15°C, 90% relative humidity, and a 16L : 8D photoperiod. For parasitization, first- or second-instars of *P. brassicae* were exposed to 4- to 10-day-old parasitoids for 15 min. This method ensures the highest acceptance/rejection ratio (Brodeur and Geervliet, 1992) and decreases risk of multiparasitism. Parasitised hosts were subsequently fed on an ample amount of Brussels sprouts plants and, after they reached the fourth instar, on Savoy cabbage leaves (*Brassica oleracea* var. *sabauda*). Upon egression, parasitoid cocoons were separated from the remains of the host and transferred into a Petri dish. Newly emerged adults were transferred into a nylon gauze cage ($30 \times 30 \times 30$ cm) in groups of uniform age. For all experiments, parasitoids had access to water and honey, and they were able to perform normal flight activities and to mate at random. Females were never exposed to host larvae or plants before bioassay, and, therefore, they were considered "naive."

Behavioral Bioassay

Behavioral experiments were conducted in a Plexiglas wind tunnel that measured $150 \times 35 \times 35$ cm. Air was pulled through the wind tunnel via an activated charcoal filter (0.5 cm thick) at a wind speed of 26–30 cm/sec. The exhaust air was vented outside the bioassay room. A smoke test was carried out to obtain laminar airflow and to ensure that the release point of wasps was within the odor plume. A light intensity of 750–950 lux at the release point and 750–1000 lux at the landing

point was obtained with high-frequency fluorescence tubes. The conditions inside the tunnel were 22 ± 2°C and 50 ± 5% relative humidity.

Brussels sprouts leaves were offered to parasitoids in a dual-choice situation as odor sources. Two sets of two leaves each were excised just before the experiment, their petioles were wrapped in cotton wool, and they were placed in separate 100-ml Erlenmeyer flasks filled with water. Flasks were transferred to the floor of the tunnel, 20 cm apart, so that they formed an isosceles triangle with 30-cm sides with the release point of parasitoids. In order to minimize visual stimuli, white cotton gauze was suspended in front of the leaves. For the bioassay, 4- to 5-day-old female parasitoids were used. Steinberg et al. (1992) showed that wasps of this age offer the strongest and most consistent response to the volatiles. The evening before the experiment, 25 wasps were selected at random in the cage and transferred individually into cotton wool-stoppered glass vials (6 ml) provided with a droplet of honey. The vials were held overnight in a dark box in a climate room and transferred to the bioassay room 30 min prior to the experiment.

For the bioassay, individual females were gently introduced into the wind tunnel and released in the middle of a platform placed 15 cm from the bottom of the tunnel floor. Each wasp was allowed two flight attempts. Based on preliminary observations, most females would not fly toward the odor sources at the first flight attempt. Wasps that did not fly within 5 min from being released in the wind tunnel were discarded. A choice was recorded when wasps completed a flight, landing on the nylon gauze in front of one of the two odor sources. Landing elsewhere in the tunnel was recorded as no choice. The two odor sources were exchanged after testing three wasps to compensate for possible asymmetry in the setup. In order to avoid day-to-day variation in the response of the wasps, we conducted every bioassay on at least two days. A total of 50 wasps were tested for every experiment (one combination of odor sources).

When less than 40% of the females tested responded in a bioassay, the same parasitoids were immediately retested using a leaf infested with approximately 100 first or second instar *P. brassicae* as a test odor source and an undamaged leaf as a control. This standard bioassay was used to assess if the low responsiveness was due to either insufficient concentration of volatiles or to low motivation of the wasps, possibly due to a fluctuation in barometric pressure (Steinberg et al., 1992). We expected a significant increase in responsiveness only in case of problems of odor concentration in the previous bioassay.

Plant Treatments

Timing and Pattern of Systemic Induction. At different time intervals before the bioassay (see below), two basal leaves of a plant were infested each with 100 first- or second-instar *P. brassicae* caterpillars. Herbivores were prevented from feeding on other parts of the plant by sticky strips wrapped around the leaf

petiole. For the bioassays, two uninfested leaves of caterpillar-infested plants were excised and used as odor sources as explained above. These leaves, which we named "induced leaves," were always those immediately above the infested ones. As a control odor source, we used two leaves of an uninfested plant that were approximately the same size and position as those on the infested plant.

In order to investigate the conditions under which Brussels sprouts plants emit systemically induced volatiles, we tested several combinations of herbivore damage on the infested leaves and mechanical damage on the systemically induced leaves. Mechanical damage was inflicted, with the same method and timing, also on leaves excised from control plants. The perimeter of the wound opened by caterpillars on the leaf ranged from 10 (one day feeding) to 40 cm (three days feeding). The perimeter of the mechanically damaged leaves ranged from 15 to 25 cm. This was obtained by punching several 0.5-cm-diam. holes on the leaf surface with a hole-punch. Plants were kept in a common climatic chamber to ensure that possible adsorption of herbivore induced volatiles would be equal for control and test plants (Turlings and Tumlinson, 1992).

Figure 1 depicts an overview of the plant treatments. Each combination of herbivore-induced and mechanical damage was tested in separate bioassays. A first set of bioassays was carried out in order to assess the level of caterpillar infestation and the timing of mechanical damage after initial infestation (one day of feeding, Figure 1A). One hundred caterpillars were allowed to feed for approximately one day (20 hr). Mechanical damage, consisting of 10 holes/leaf, was inflicted (1) 20 hr before the bioassay; or (2) during the bioassay, that is 1 hole/15 min, starting 1 hr before the bioassay; or (3) immediately before the bioassay. In the last case, the experiment was repeated with a higher level of infestation. This was obtained by placing caterpillars (approx. 500) all over the plant except on the two leaves used for the bioassay. The two induced leaves were protected from caterpillars by sticky strips wrapped around the petiole.

A second set of bioassays was carried out to assess the effect of different duration of caterpillar feeding (Figure 1B). One hundred caterpillars were allowed to feed for approximately two (40 hr) or three days (60 hr) before the bioassay. On the induced leaves of plants infested for two days, mechanical damage was inflicted immediately before the bioassay (10 holes/leaf). On the systemically induced leaves of plants infested for three days, mechanical damage was inflicted as follows: (1) no damage, (2) damage one day before the bioassay, (3) damage immediately before the bioassay, or (4) damage of 16 holes immediately before the bioassay. Sixteen holes represent the maximum amount of mechanical damage that can be inflicted on a single leaf without complete alteration of its shape.

A third set of bioassays was carried out to assess the permanence of the induced signal after termination of caterpillar feeding (Figure 1C). One hundred caterpillars were allowed to feed for one or three days before the bioassay and were then removed by means of a brush. Bioassays were then carried out one,

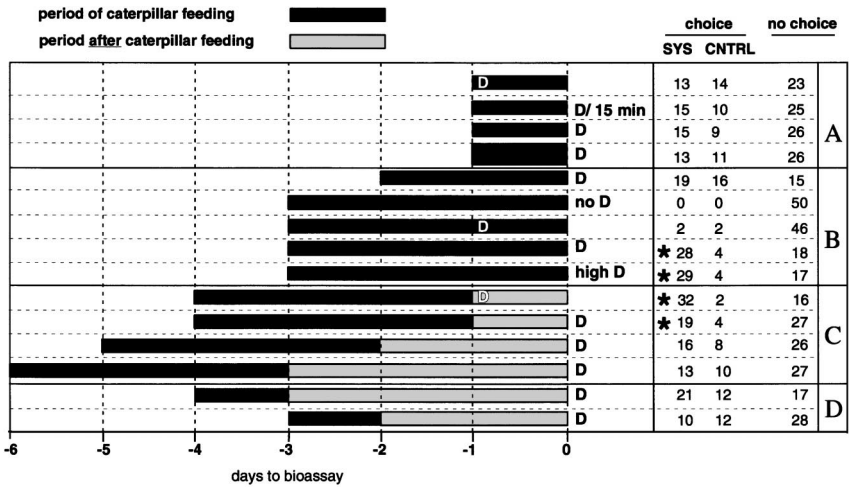

FIG. 1. Response of female *C. glomerata* to systemically induced Brussels sprouts leaves in the wind tunnel. Leaves were excised from plants where caterpillars were released on two different lower leaves one to six days before bioassay, but fed for a maximum of three days. Bioassays were carried out at day 0. Dark gray bars indicate the caterpillar feeding period. The wider bar (4th from top, section A) symbolizes a higher level of caterpillar infestation, i.e., the whole plant was infested except the leaves used in the bioassay. Light grey bars indicate that the bioassay was carried out one to three days after termination of caterpillar feeding. The letter "D" within a bar indicates mechanical damage inflicted one day before the bioassay (10 holes/leaf), "D 15/min" indicates damage inflicted throughout the bioassay (1 hole/15 min), "D" at the right end of a bar indicates damage inflicted just before the bioassay (10 holes/leaf), "no D" indicates no mechanical damage, "high D" indicates maximum possible damage on a leaf (16 holes). The actual number of females choosing either systemically induced leaves (SYS) or control (CNTRL) or making no choice is indicated on the right inside of the figure (sample size $= 50$ per treatment). Asterisks indicate significant differences within the choice test at $P < 0.001$. [Chi-square test for goodness-of-fit; Sokal and Rohlf (1981)].

two, or three days after removal of the caterpillars. Mechanical damage (10 holes) was inflicted just before the bioassay. In one bioassay, mechanical damage was inflicted immediately after caterpillar removal, that is, approximately 20 hr before the bioassay.

A fourth set of bioassays was carried out to assess whether the occurrence of systemic induction depended on the time lag after initial infestation rather than on the duration of feeding (Figure 1D). One hundred caterpillars were allowed to feed for approximately one day (20 hr) and then removed by means of a brush. Bioassays were then carried out two or three days after removal of

the caterpillars. Mechanical damage (10 holes/leaf) was inflicted just before the bioassay.

Plant Age and Systemic Induction. One additional experiment was carried out to study the effect of plant age on systemic emission of volatiles. One hundred caterpillars were allowed to feed for three days on the lower leaves of either a 2- or a 6-month-old plant. Two sets of two leaves were excised from the two plants and offered to parasitoids as explained above. Mechanical damage (10 holes/leaf) was inflicted just before the bioassay.

Level of Infestation for Systemic Induction. To assess the level of infestation necessary to obtain systemic induction of volatiles, 8-week-old Brussels sprouts plants were infested on one single lower leaf for three days with 5, 25, 50, or 100 caterpillars. In preliminary experiments, we observed that five caterpillars feeding for three days will inflict a damage of approximately 2 cm^2 and that a wound of this dimension is sufficient to elicit local emission of attractive volatiles. Two noninfested upper leaves were excised and mechanically damaged (10 holes) immediately before the wind-tunnel bioassay as explained above. As a control odor source, we used two mechanically damaged leaves from an uninfested plant that were approximately the same size and position as those on the infested plant.

Data Analysis. Parasitoid choice response was analyzed with a chi-square test (Sokal and Rohlf, 1981) to determine if the response differed from a 50 : 50 distribution of wasps over the two odor sources. Wasps that did not make a choice within 5 min were excluded from statistical analysis.

Volatile Sampling

In order to collect headspace volatiles from single leaves of living cabbage plants, we used a glass–Teflon chamber similar to others previously described (Heath and Manukian, 1994; Agelopoulos et al., 1999). The chamber consisted of a 10-cm-diam. × 11-cm-high bell-shaped jar in which the two leaves from the treated plant were introduced. Air entered the top of the jar through an activated charcoal filter. At the bottom of the jar, a split Teflon plate with a hole in the center closed loosely around the petioles of the leaves like a guillotine, which prevented air from flowing back into the jar from outside.

The base of the jar allowed the connection of Tenax traps that were used to adsorb the volatiles. Each trap contained 300 mg of Tenax-GR (mesh size 60/80, Alltech Associates) and was thermally conditioned prior to each collection for 4 hr at 300°C with a flow of dried filtered helium (initial purity 99.96%, 50–60 ml/min). Traps analyzed with the Unity thermaldesorber (see below) were conditioned for 15 hr. During collection, air was pulled trough the Tenax-GR trap at 240–340 ml/min. Three plant treatments were sampled for volatiles over 24 hr: (1) A plant-herbivore-complex (PHC) consisted of two infested leaves where first instars (100 leaf) were allowed to feed for 16 hr before volatile collection

and throughout the 24 hr of headspace sampling. The duration of feeding was chosen to ensure that the amount of damage on PHC plants would be comparable to the mechanical damage inflicted on systemically induced ones. (2) Systemically induced leaves (SYS+D) consisted of two noninfested, artificially damaged leaves from an infested plant. The plant was infested with 100 caterpillars/leaf on two basal leaves for 60 hr. Volatiles were sampled from the two leaves located immediately above the infested ones. Artificial damage was inflicted with a hole-punch (10 holes/leaf) just before sampling as described above. (3) Mechanically damaged leaves (MD) consisted of two noninfested, artificially damaged leaves from an uninfested plant. Artificial damage was inflicted with a hole-punch (10 holes/leaf) just before sampling. Headspace sampling was replicated five times for each treatment. This set of samples was analyzed with manual thermaldesorption (see below)

In subsequent expriments, volatiles were collected as described above but with a 340 ml/min airflow through the traps. Three plant treatments were sampled for volatiles over 24 hr: (1) Systemically induced and undamaged leaves (SYS_UND) consisted of two noninfested, leaves from an infested plant. The plant was infested with 100 caterpillars/leaf on two basal leaves for 60 hr. Volatiles were sampled from the two leaves located immediately above the infested ones. (2) Systemically induced and damaged leaves (SYS+D) were as described above. (3) Undamaged leaves (UND) consisted of two leaves from an uninfested, undamaged plant. All sampling procedures were repeated five times. This set of samples was analyzed with automatic thermaldesoprtion (see below).

All collections were carried out in a climate room at 20°C, 60% relative humidity, and a 16L : 8D photoperiod. Light was provided by "Very High Output" Sylvania fluorescent lamps (cold light, 10,000 ± 1000 lux). Headspace collections were started 2–3 hr after beginning of the photophase in the chamber to minimize variations due to changes in plant volatile emissions throughout the day (see e.g., Loughrin et al., 1997).

Volatile Analysis

Manual Thermodesorption. Volatiles were eluted from the Tenax traps with a thermal desorption procedure after headspace sampling. Traps were connected to the inlet of a gas chromatograph (Hewlett Packard 5890 Series II +) by Swagelock connections. The exhaust of the trap was connected to flushed copper tubing and exited the GC oven through the dismantled detector. The oven was programmed with an initial temperature of 100°C, then to 300°C at 45°C/min. The inlet was programmed in the same manner. The GC was operated with a constant pressure (3 kPa) of helium that resulted in a flow rate through the Tenax trap of ca. 20 ml/min at ambient temperature (ca. 25°C). The exhaust from the trap was bubbled into a 2-ml vial containing 500 μl of hexane (Fluka, purity 99.5%) that was kept in an

acetone–ice bath. Samples were stored at −60°C in glass vials with PTFE silicon septa after being concentrated to 15 μl for 5–10 min using a stream of purified nitrogen.

Collected volatiles were analyzed using GC-MS (Hewlett Packard GC model 6890; MSD 5973). Analyses were carried out using a 0.25-mm-diam. × 30-m long HP1, polydimethyl siloxane column with nominal film thickness of 1 μm. Initial oven temperature was 55°C rising 2°C/min up to 102°C, and then to 250°C at 60°C/min. A postrun time of 15 min at 320°C was run to remove impurities from the column. The inlet was operated in the splitless injection mode at a temperature of 250°C with a constant column flow of 1.0 ml/min helium. The effluent from the column was transferred to the MS detector via a transfer line (280°C) and the GC-MS electron impact source was operated in the scan mode with the MS source temperature at 230°C and the MS Quad at 150°C.

Automatic Thermodesorption. In subsequent experiments, volatiles were analyzed with a commercial system (Unity, Markes Int. Ltd.). Using the Unity system with a double split (split ratio 25 : 1, desorption flow 50 ml/min, split flow 30 ml/min), volatiles were desorbed from the Tenax trap for 5 min, starting at 50°C, then up to 300°C at ∼20°C/min, and transferred to the cold trap (50 : 50 Tenax TA + Carbopack B), which was cooled at −10°C. The cold trap was subsequently heated for 3 min to 300°C at ∼60°C/min. The fused silica transfer line to the GC was kept at 200°C. Analyses were carried out with the Hewlett Packard GC-MS and HP column described above. The GC oven was set at 40°C, rising to 300°C at 8°C/min, initial flow of approx. 2.0 ml/min.

Identification of volatiles was achieved by comparing the sample spectra with those in the NIST98 library for all samples. Subsequently, spectra were compared with those of authentic standards and identification was confirmed by coinjection. Quantification of constituents was based on the peak area of an internal standard (hexylbenzene) that was added to the hexane extract (100 ng/μl sample) or injected directly into the Tenax-GR trap (200 ng in 2 μl ethyl acetate). As no response factors were determined, amounts given are only rough estimates.

Data Analysis. Comparisons of the amounts of individual volatiles resulting from the different treatments were analyzed with one-way ANOVA or Kruskal-Wallis, for data not normally distributed, followed by Student-Newman-Keuls test for pairwise comparison between single compounds emitted by plants that underwent different treatments (Sokal and Rohlf, 1981).

RESULTS

Behavioral Bioassays. Emission of systemically induced volatiles from *B. oleracea* varied depending on the duration of caterpillar feeding (one to three days). In the wind tunnel, *C. glomerata* females were not attracted to upper

uninfested leaves (induced) if *P. brassicae* caterpillars had been feeding on the lower leaves (infested) for only one day (Figure 1A). Regardless of the timing of infliction of mechanical damage or the level of infestation, parasitoid choice was equally distributed over the test and control.

After two days of caterpillar feeding, again no preference for induced versus control leaves was observed. In contrast, parasitoid choice shifted significantly to induced leaves when caterpillar feeding time was prolonged to at least three days (Figure 1B). Parasitoids were attracted ($P < 0.001$) to induced leaves if mechanical damage was inflicted immediately before the bioassay regardless of the level of mechanical damage inflicted (see "high D" bar, Figure 1B). Remarkably, parasitoids were not attracted to leaves without mechanical damage or with damage inflicted one day before the bioassay. However, the same parasitoids tested in the standard bioassay preferred an herbivore-infested leaf to an uninfested leaf (56% vs. 24%, with 20% of wasps making no choice), indicating that the induced leaves in the previous bioassays emitted an extremely low concentration of volatiles.

The permanence of the systemic signal after termination of caterpillar feeding is depicted in Figure 1C. One day after removal of caterpillars from the plant, parasitoids preferred the induced leaves over control leaves, even when mechanical damage was inflicted one day before the bioassay. No preference was observed for induced leaves tested two or three days after caterpillar removal, indicating a relevant decrease of the emitted signal.

Parasitoids were not attracted to leaves induced for one day and tested two or three days after termination of caterpillar feeding (Figure 1D). This indicates that, for a detectable systemic response, the duration of feeding is more important than the time lag between infestation and mechanical damage. Furthermore, we did not observe any effect of plant age on systemic emission of volatiles (results not shown). Parasitoids did not prefer induced leaves excised from two-month-old Brussels sprouts over induced leaves excised from 6-month old plants (18 vs. 14, with 18 females making no choice).

The effect of the level of infestation on the emission of systemically induced volatiles is shown in Figure 2. Systemic induction did not occur at low levels of infestation even if caterpillars were feeding on the same leaf for a prolonged time (five caterpillars, three days).

Volatile Analysis. The composition and quantification of the volatile blend emitted by the plant–herbivore complex (PHC), systemically induced and damaged (SYS+D) leaves, or mechanically damaged (MD) leaves of Brussels sprouts plants are depicted in Figure 3. The profiles of systemically induced and caterpillar infested leaves were almost identical, although systemically induced leaves emitted smaller amounts of (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate. Mechanically damaged leaves emitted less (*Z*)-3-hexenyl acetate than infested leaves and did not emit (*Z*)-3-hexen-1-ol or (*E*)-β-caryophyllene.

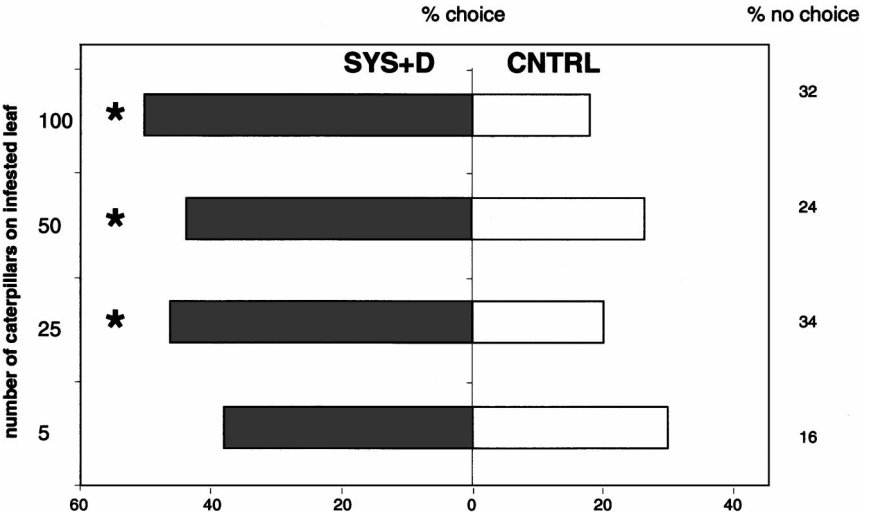

FIG. 2. Level of infestation necessary to obtain systemic induction of volatiles in 8-week-old Brussles sprouts plants. Bars indicate the choice response of female *C. glomerata* to upper leaves of plants that were infested on the lowest leaf by different numbers of *P. brassicae* caterpillars (5–100) for three days. Asterisks indicate significant differences within the choice test at $P < 0.05$ [chi-square test for goodness-of-fit; (Sokal and Rohlf, 1981)]. SYS+D = systemically induced and damaged; CNTRL = noninduced and mechnically damaged. (sample size = 50 per treatment). See Methods and Materials for further explanations.

The composition and quantification of the volatile blend emitted by systemically induced and damaged leaves (SYS+D), systemically induced and undamaged leaves (SYS), or noninduced and undamaged leaves (UND) of Brussels sprouts plants are given in Table 1. Systemically induced but undamaged leaves emit a volatile profile that is similar to that of noninduced undamaged leaves. Compared to undamaged leaves, systemically induced and damaged leaves are characterized by increased amounts of green leaf alcohols (1-hexanol, (*Z*)-3-hexen-1-ol), green leaf esters [(*Z*)-3-hexenyl acetate, (*Z*)-3-hexenyl butyrate, (*Z*)-3-hexenyl isovalerate] and sabinene. Interestingly, in both sets of analyses, α-humulene and (*E*)-β-caryophyllene appear to be the only terpenoids specifically associated with induced responses.

DISCUSSION

Brussels sprouts plants, attacked by *Pieris brassicae* caterpillars, emit volatiles that attract a natural antagonist of the herbivore, the parasitoid *Cotesia*

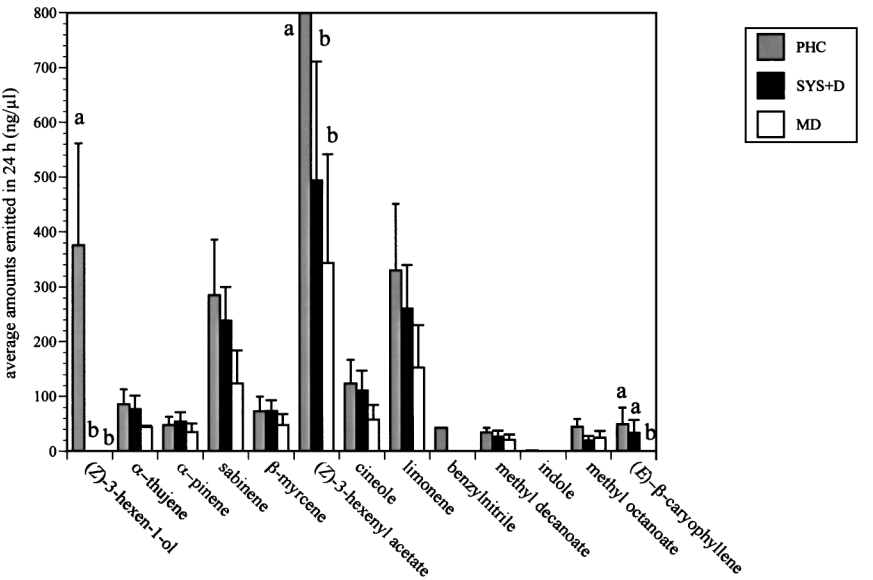

FIG. 3. Quantification of major volatile blends emitted during 24 hr by two leaves of Brussels sprouts plants that were either infested by caterpillars (PHC = plant–herbivore complex), systemically induced and damaged (SYS+D), or mechanically damaged (MD). Samples were analyzed by manual thermaldesorption. Compounds are listed based on their retention time. Different letters close to bars indicate significant differences at $P < 0.05$ (Student-Neuman-Keuls test). The concentration of (*Z*)-3-hexenyl acetate [(avg. 3608 ± 2076 (SE) ng/μl/24 hr)] emitted by PHC has been overscaled to show minor compounds. Statistics and error bars are presented only for compounds that appeared in more than one treatment.

glomerata. Chemical and behavioral experiments show that the induced emission of volatiles is not limited to the site of damage, but occurs throughout the plant. In Brussels sprouts, the systemic emission of volatiles appears only when the surface of uninfested leaves is damaged (Figure 1B). This contrasts with induced responses observed in beans, cassava, and corn, where undamaged leaves of herbivore-infested plants release detectable amounts of volatiles that are attractive to the natural enemies of the herbivores (Table 2). In previous experiments, we observed that detached cabbage leaves that were incubated in a solution of caterpillar gut regurgitate released a volatile blend similar to that of herbivore-damaged plants. The release was detectable only if the leaf surface were wounded prior to bioassay (Mattiacci et al., 1994) . Similarly, leaves that were incubated in a solution of β-glucosidase, an elicitor of volatile emission present in caterpillar salivary secretions, released detectable amounts of volatiles only after mechanical damage

Absolute amount is given for compounds that were detected only in one sample. $N = 5$ for each treatment. *Significant effect of plant treatment (Kruskal-Wallis one-way ANOVA on ranks, $P < 0.05$). Samples were analyzed by automatic thermaldesorption. Statistics are presented only for compounds that appeared in more than one treatment. tr = trace compounds.

(Mattiacci et al., 1995). This indicates that in cabbage a mechanical damage is needed either to release volatiles stored in the induced leaf and/or to activate their precursors.

Induced direct defenses to herbivores have been found in response to both mechanical damage and actual herbivory on plants (Edwards and Wratten, 1987; Alborn et al., 1996; McCloud and Baldwin, 1997). Comparatively indirect defenses, such as the emission of plant volatiles attracting predatory and parasitic arthropods, have been associated with mechanical damage and with herbivory, albeit with different levels of specificity. The majority of plant species studied so far, emit, at the site of herbivory, volatiles that are different from those of

TABLE 2. COMPARISON OF KNOWN MECHANISMS OF EMISSION OF SYSTEMICALLY INDUCED VOLATILES IN DIFFERENT PLANT SPECIES[a]

Plant	Time of emission after herbivore injury	Mechanical damage necessary?	Volatiles emitted at the site of damage	Systemically emitted volatiles	References
Brussels sprouts	3 days	Yes	GLVs Cyclic monoterpenes Sesquiterpenes Nitriles, isothiocyanates	(*Z*)-3-Hexenyl acetate, butyrate, Isovalerate Cyclic monoterpenes Sesquiterpenes	Mattiacci et al. (1994)

[a]GLVs = green leaf volatiles; n.a. = identification of volatiles not available.
[b]Systemic induction elicited through application of jasmonic acid and not by herbivore feeding.

mechanically damaged plant parts. The composition of herbivore-induced volatile blends might vary even with different herbivore species or with different larval instars attacking the same plant (reviewed by Dicke and Vet, 1999; Paré and Tumlinson, 1999; Hern and Dorn, 2001). In contrast, some species emit qualitatively similar chemical blends, irrespective of the damaging agent (Dicke and Vet, 1999). In Brussels sprouts, there is no striking qualitative difference in GC profiles produced in response to herbivory or mechanical damage (Agelopoulos and Keller, 1994; Mattiacci et al., 1994), and it is, therefore, not surprising that volatiles associated with mechanical damage are an important signal for *C. glomerata* (see also Steinberg et al., 1993). In general, the ecological function of volatiles associated with mechanical damage should not be overlooked, as generalist carnivores might use volatiles associated with mechanical damage even when the volatile profiles of herbivore-infested and mechanically damaged plants differ. For example, a generalist parasitoid, *Cotesia marginiventris*, is attracted to volatiles typically emitted by artificially damaged cotton plants, while a specialist, *Microplitis croceipes*, is attracted to volatiles typically induced by herbivores (Röse et al., 1998).

While in cabbage the systemic response is detectable only upon mechanical damage, and in corn the response is detectable without damage, cotton seems to have an intermediate mechanism of response. In cotton, inducible terpenoids and (*Z*)-3-hexenyl acetate are released from undamaged, systemically induced leaves, while several hexenyl butyrates, known to be associated with caterpillar herbivory, are emitted only upon mechanical damage. In addition, the amounts of constitutive compounds emitted by systemically induced and mechanically damaged leaves are larger than those emitted by systemically induced undamaged leaves (Röse et al., 1996).

Time-course experiments on the emission of carnivore-attracting volatiles are available only for corn, cotton, and broad bean (Table 2). Different plant species express a systemic response after a variable time lag from initiation of herbivore feeding, ranging from a few hours (corn) to several days (lima bean). The observed delay in the systemic release could be due to the capability of plants to minimize the costs of defense by activating a systemic response only upon higher levels of herbivore damage or prolonged periods of feeding. Theory predicts that inducible defenses should allow plants to allocate limited resources so as to maximize fitness in response to current unpredictable conditions (see for review Karban and Baldwin, 1997). Broad bean plants emit systemically induced volatiles only when attacked above a certain density of *Acyrthosiphon pisum* aphids and only after 48–72 hr of infestation (Guerrieri et al., 1999). Brussels sprouts seem to minimize the cost of defense even more effectively. Not only are the systemically induced volatiles detectable after at least three days of continuous feeding, but when no further attack occurs (e.g., when caterpillars are removed), the volatile emission stops after one day (see Figure 1). In addition, a systemically induced response does not occur if few caterpillars (5) are feeding on a leaf (Figure 2). Thus, the plant

does not invest in an induced defense when the attack is of short duration or of low intensity. In addition, as no attractive induced volatiles are emitted without damage on the systemically induced parts of the plant, it is likely that the metabolites stored in the induced leaves are reutilized for other biosynthetic needs.

The chemical structures of the volatile compounds emitted by arthropod-damaged leaves have notable similarities in all plants reported so far (Table 2). This structural uniformity has been suggested as evidence for the activation of a common set of biosynthetic pathways shared by a wide range of plant families and used by a broad spectrum of insect parasitoids and predators (Paré and Tumlinson, 1999).

The volatiles emitted upon herbivory have been categorized into three basic groups (Paré and Tumlinson, 1996): lipoxygenase-derived green leaf volatiles, isoprenoid-derived terpenoids, and shikimic acid-derived aromatics such as indole and methyl salicylate. Green leaf volatiles such as (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, and (*Z*)-3-hexenyl acetate are emitted at the site of herbivory by several plants, including Brussels sprouts, corn, cotton, and beans (Table 2). Remarkably, in corn, cotton, and our samples, (*Z*)-3-hexenyl acetate is the only lipoxygenase product that is systemically released by uninfested but undamaged leaves of infested plants. Based on these results, it has been hypothesized that lipoxygenase products need to be converted to the acetate form to be emitted in induced leaves (Paré and Tumlinson, 1999). In our samples, other green leaf esters (Figure 3 and Table 1) are probably associated with fresh mechanical damage, since these compounds are not emitted by systemically induced and undamaged leaves. In addition, systemically induced leaves emit esters in amounts not substantially different from mechanically damaged leaves.

The terpenoids detected in herbivore-damaged plants are products of more than one biosynthetic route or different steps within one pathway (Paré and Tumlinson, 1996). A flexible management of these defensive compounds has been recently elucidated in lima bean. The production of induced terpenoids is regulated by two pathways, of which one is mevalonate-dependent and the other is mevalonate-independent (deoxyxylulose pathway). The mevalonate-independent pathway appears to be important in the release of inducible monoterpenes after elicitation with jasmonic acid (Piel et al., 1998), which has a similar effect as herbivore infestation (Dicke et al., 1998). In contrast, constitutive compounds are synthesized through the mevalonate-dependent pathway and need no elicitation for emission by leaves or flowers (Piel et al., 1998).

In cotton, the acyclic monoterpene β-ocimene, the sesquiterpenes α- and β-farnesene, and the homoterpene (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene are systemically released by herbivore-induced plants. Cyclic and acyclic monoterpenes, such as α- and β-pinene, limonene, and myrcene, and the sesquiterpene (*E*)-β-caryophyllene are released at the site of damage, but not systemically (reviewed by Paré and Tumlinson, 1999). In contrast to cotton, Brussels sprouts emit

α- and β-pinene, limonene, myrcene, sabinene, and (*E*)-β-caryophyllene both systemically and at the site of damage (Figure 3).

The acyclic homoterpenes (*E*)-4,8-dimethyl-1,3,7-nonatriene and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene have been repeatedly identified in the headspace volatiles of herbivore-infested plants, including lima bean, apple, cowpea, cucumber, corn, and cotton (see, e.g., Turlings et al., 1991; Dicke, 1994; Loughrin et al., 1994; Bouwmeester et al., 1999). Therefore, these compounds have been suggested as a general signal of insect infestation (Dicke, 1994). However, virtually no homoterpenes and only trace amounts of indole, a derivative of the shikimic acid pathway, were detected in our study or in previous analyses of cabbage headspace volatiles (Blaakmeer et al., 1994; Mattiacci et al., 1994; Geervliet et al., 1997).

These differences among the systemically induced responses of different species led to the hypothesis that plants might utilize a defensive strategy that is more complex than a common set of biosynthetic pathways shared by a range of plant families. In fact, specific pathways might be activated based on the available "defensive arsenal" of inducible chemicals of a certain plant species (Figure 4). Accordingly, some plant species might utilize different pathways to produce different sets of compounds, of which some are used for local and some for systemic defense.

This could be the case in cotton, where cyclic monoterpenes are emitted locally and acyclic monoterpenes are emitted systemically. Other plants might utilize

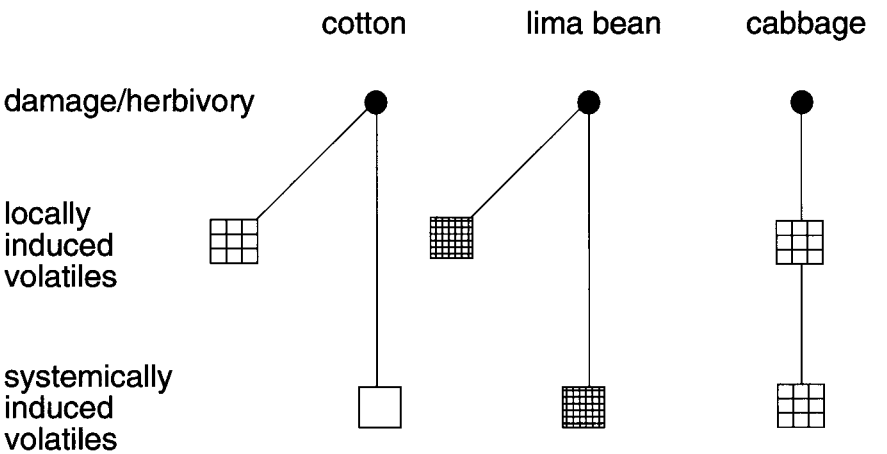

FIG. 4. A hypothesis of flexible use of inducible pathways for the biosynthesis of locally and systemically emitted plant volatiles. Black dots indicate damage or herbivory as the phenomenon triggering volatile emission. Lines indicate biosynthetic pathways. Different squares indicate different chemical compounds emitted by plants.

different pathways to produce the same compounds, for example, the acyclic homoterpenes in lima beans. Other species, with limited biosynthetic capabilities for inducible defensive compounds could be expected to use the same compounds—and possibly the same pathway—at all levels of defense, local and systemic. It would be interesting to investigate whether this is the case for locally and systemically induced cyclic terpenoids in Brussels sprouts.

Understanding the complexity of the changes occurring in plants after herbivore attack is in its infancy. More investigation on the systemically induced volatile emission of different species will prove useful in shedding light on the ecological significance and regulation mechanisms of these defensive responses in plants.

Acknowledgments—We are grateful to R. Camenzind, T. Christoffel, A. Dutton, C. Fornallaz, M. Gandolfi, H. Gu, M. Hollenstein, R. de Jong, and S. Töpfer for help with insect rearing, data analysis, and useful comments on a previous version of the manuscript. We thank J. Tumlinson and H. Alborn for help with identification of homoterpenes.

(Received September 7, 2000; accepted July 1, 2001)

Abstract—Pine weevils (*Hylobius abietis*) fed less on bark of lodgepole pine (*Pinus contorta*) than on bark of Scots pine (*P. sylvestris*). Two pine weevil antifeedants, ethyl *trans*-cinnamate and ethyl 2,3-dibromo-3-phenyl-propanoate, were isolated from bark of lodgepole pine. These two compounds significantly reduced pine weevil feeding in a laboratory bioassay. In field assays, the second compound significantly decreased pine weevil damage on planted seedlings. Ethyl 2,3-dibromo-3-phenylpropanoate has not previously been reported as a natural product.

Key Words—Antifeedant, ethyl 2,3-dibromo-3-phenylpropanoate, ethyl *trans*-cinnamate, *Hylobius abietis*, lodgepole pine, pine weevil, *Pinus contorta*, *Pinus sylvestris*, Scots pine.

INTRODUCTION

Seedling mortality resulting from stem-feeding by adult *Hylobius* weevils (*Col., Curculionidae*) is a major silvicultural problem wherever clear-felling followed by planting of conifer seedlings is practiced in temperate regions of the Northern Hemisphere. All over Europe, the pine weevil *Hylobius abietis* (L.) is the principal noxious species, and seedling mortality due to this insect leads to considerable economic loss. Permethrin has been used to control pine weevil damage in

Sweden, but the use of insecticides for this purpose will soon be prohibited. Alternative measures to manage the pine weevil problem are, therefore, urgently needed.

There is strong evidence that plants have evolved defense systems against predators and that these systems, to a large extent, are based on the production of secondary metabolites (Rosenthal, 1986; Harborne, 1988, and references therein; Sunnerheim-Sjöberg, 1991; Daurade-Le Vagueresse and Bounias, 1992; Suga et al., 1993). Even high priority food plants produce defense compounds against herbivores—presumably to prevent overbrowsing. Although the polyphagous pine weevil prefers pines to a multitude of other plant species (Eidmann, 1974), pines can be expected to contain some antifeedants against pine weevils. However, different species of pines and different parts of a pine tree may contain varying amounts of defense compounds.

Preliminary feeding tests indicated that pine weevils fed less on bark from lodgepole pine, *Pinus contorta*, than on bark from Scots pine, *P. sylvestris*. This result prompted us to look for compounds possessing antifeedant activity derived from *P. contorta*. Scots pine is the most abundant native pine species in Sweden. Lodgepole pine has been introduced from North America and planted on large areas in northern Sweden.

The aims of this study were to determine if compounds (either endogenous or spontaneously modified) possessing antifeedant activity could be isolated from coniferous hosts, and if these compounds could be exploited to reduce weevil damage. We:

- compared the feeding preference of *H. abietis* for bark from Scots and Lodgepole pine;
- isolated, identified, and bioassayed two antifeedants, ethyl *trans*-cinnamate (**1**) and ethyl 2,3-dibromo-3-phenylpropanoate (**2**), from Lodgepole pine;
- performed syntheses and field trials of compound (**2**).

METHODS AND MATERIALS

Plant Material. Stem samples of lodgepole and Scots pine were collected from plantations in northern Uppland (seed sources unknown). All fractions and extracts were subjected to feeding trials, and the results were used for selection of fractions for further fractionation. Fresh inner bark (500 g) was cut into small pieces and extracted in methanol for 24 hr. The extract was filtered, and the plant residue was discharged. The methanol was evaporated, keeping the temperature below 40°C. Water (200 ml) was added, and the suspension extracted with pentane (2×150 ml) followed by ethyl acetate (2×150 ml). The pentane and ethyl acetate fractions were dried over $MgSO_4$, and solvent was evaporated. Extracts of *P. sylvestris* were obtained in the same manner as described for *P. contorta*.

The ethyl acetate extract (8.7 g) was dissolved in ethanol (99.7%, 15 ml) and subsequently fractionated on Sephadex LH-20 using water (250 ml), water–ethanol (7 : 3, 400 ml), water–ethanol (4 : 6, 400 ml), and finally ethanol (99.7%, 400 ml) as eluent. Seven fractions were collected, and the solvent was evaporated (12.1 g, 1.80 g, 1.93 g, 0.33 g, 0.08 g, 0.07 g, and 0.03 g, respectively).

Fraction 2 was dissolved in ethyl acetate (200 ml) and extracted with acid (0.1 M HCl, 2 × 100 ml) followed by base [0.1 M Na_2CO_3 (aq), 2 × 100 ml]. The neutral fraction (0.154 g) was further fractionated on silica using CH_2Cl_2 : $CHCl_3$: MeOH : H_2O (80 : 11 : 8 : 1) as eluent. Four fractions were collected.

Spectroscopy. ^{1}H NMR (400 MHz) and ^{13}C NMR (100.5 MHz) spectra were recorded on a Varian Unity 400 using residual solvent peaks as internal standards.

Chromatography. GC-MS was performed on a Finnigan MAT GCQ Plus system (EI; 70 ev). Thin-Layer chromatography was performed on Merck HF-254 silica gel plates. Merck Kieselgel 60 (230–400 mesh) or Sephadex LH-20 (Pharmacia Fine Chemicals) was used for column chromatography. HPLC was performed on a Waters chromatograph equipped with an autosampler and a diode array detector. Column: LichroCart 125-4 Lichrospher 100 RP-18 (5 μm) (Merck). The mobile phase consisted of solvent A: ammonium formiate buffer pH 3.4, and solvent B: acetonitrile. The gradient program was 0–30 min 100% A to 40% followed by 5 min at 40%, and 35–40 min 40% A to 10%. The flow rate was 1 ml/min.

Isolated Compounds. Ethyl *trans*-cinnamate, [(*E*)-3-phenyl-2-propenoic acid ethyl ester, **1**, 2 mg)] was the main compound in the first fraction, identified by GC-MS and NMR (spectral data were in accordance with Cristau and Taillefer, 1998). Ethyl 2,3-dibromo-3-phenylpropanoate (**2**, 5 mg) was the main compound in the second fraction, identified by GC-MS and NMR (spectral data were in accordance with Kabalka et al., 1998).

Synthesis of Ethyl 2,3-Dibromo-3-Phenylpropanoate (***2***). A racemic mixture of (2*R*,3*S*)- and (2*S*,3*R*)-**2** was prepared by bromine addition to **1** according to standard procedures (Vogel, 1989). Spectral and chromatographic data for the synthesized compound were identical to those obtained from the isolated ones.

Ethyl *trans*-cinnamate was purchased from Aldrich (99%). Bromine (Aldrich). Ethanol (ETAX 99.7 vol-%). Acetonitrile HPLC-grade (Aldrich). Pentane, ethyl acetate, and dichloromethane were dried and distilled according to standard procedures.

Extracts were tested in concentrations slightly higher than the naturally occurring amounts. The amounts to be tested were calculated with the equation: $(E \times B_t \times 4)/B_e$ where E is the dry weight of extract, B_t is the dry weight of extracted bark, B_e is the estimated dry weight of test-bark, and 4 is a factor compensating for losses during the fractionation and the dilution by distribution of compounds over several fractions, and hopefully increases the concentration to slightly above natural.

Test of Host Preference. Pine weevil feeding preference was studied in a two-choice laboratory test. One pine weevil was placed in each of 20 boxes, together with one fresh twig of each of the two pine species. After three days, the feeding area on the twigs was measured with the aid of 1-mm-grid graph paper.

Bioassay. Extracts, fractions thereof, and solutions of single compounds were presented to single pine weevils in two-choice laboratory tests with a treatment and a control area. The bioassay was designed to allow use of small test samples applied on a specified area of bark, i.e., the amount of substance per unit area can be accurately calculated (Nordlander et al., 2000). Fresh pieces of Scots pine twigs (50 mm long, ca. 15 mm diam.) were split, and each half (= test twig) was wrapped in aluminum foil. In each test twig, two metal rings (5 mm diameter) were punched through the foil and into the bark at 25 mm distance. After removal of the aluminum foil inside the ring, 100 μl of the extract/compound to be tested were applied on the bark in one of the two rings. In the other ring, the same amount of the solvent was applied (control). After the solvent had evaporated, the metal rings were removed. Each test twig was placed on moist filter paper in a 142-mm-diam Petri dish with one weevil in each dish. Forty replicates were used, 20 with females and 20 with males. Generally, there was no significant difference in response between the sexes, and, therefore, the data presented are pooled. Each weevil was used only once. The weevils were all in the reproductive phase of their life cycle and were starved for 24 hr before the test period. The bioassays were conducted at room temperature (ca. 22°C).

The amount of feeding on the treatment and control area of each test twig was recorded after 6 and 24 hr. The test areas were commonly either not fed upon or completely consumed before the end of the 24 hr test period. Therefore, we chose to present data based only on the presence or absence of feeding scars, which is a more conservative measure of antifeedant effect than the amount of consumed bark. The effect of the various treatments on the initiation of feeding is described by the index: $[(C - T) \times 100]/(C + T)$ where C is the number of control surfaces with feeding scars and T the number of treated surfaces with feeding scars ($N = 40$). Thus, an antifeedant effect gives positive values up to a maximum of 100. Statistical differences between treatment and control were tested with a chi-square test of a 2×2 table (not continuity corrected): $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ (null hypothesis: no difference).

Field Test. The antifeedant effect of ethyl 2,3-dibromo-3-phenylpropanoate applied on stems of Norway spruce seedlings was assessed in a field test. The active substance was dissolved in methanol and to this solution a liquid wax (AGS 3512 Ultra, Trion Tensid AB, Uppsala, Sweden) was added in the proportion 3 : 1 methanol–AGS), giving 0.056 g active substance per ml of the final mixture. About 2 ml of this mixture (containing 0.11 g active substance) were applied on each seedling in a way that it completely covered the lower half of the stem. Seedlings treated this way were compared with seedlings similarly treated

with the same methanol–AGS mixture without the active substance and with untreated seedlings. A randomized block design was used with each of the 80 blocks containing one seedling of each of the three treatments. The distance between seedlings within a block was about 0.5 m, and the distance between blocks about 2 m. The seedlings were planted on a fresh clear-cutting 13 km NNE Uppsala, Sweden, on June 11, 1999. The amount of pine weevil feeding was recorded for each seedling after 19 and 36 days.

RESULTS

Pine weevils fed about twice as much on *P. sylvestris* twigs as on *P. contorta*. The mean (±SE) bark area consumed per weevil during three days was 43.0 ± 5.1 mm^2 for *P. sylvestris* and 23.0 ± 4.9 mm^2 for *P. contorta* ($P = 0.026$, paired *t* test).

The methanol extracts of the two pine species were divided into ethyl acetate, pentane, and water. The water extracts of both species showed a strong stimulating effect on feeding (Figure 1), whereas the pentane extracts slightly reduced feeding. The ethyl acetate extracts of *P. contorta* had a significant antifeedant effect. In contrast, no significant effect on feeding was found for the EA extract of *P. sylvestris*.

The ethyl acetate extract from *P. contorta* was subjected to Sephadex LH-20 chromatography, and seven fractions were collected. Fraction 2 was the only fraction found to possess significant antifeedant activity and was, therefore, chosen for further fractionation. It was divided into acidic, basic, and neutral phases by

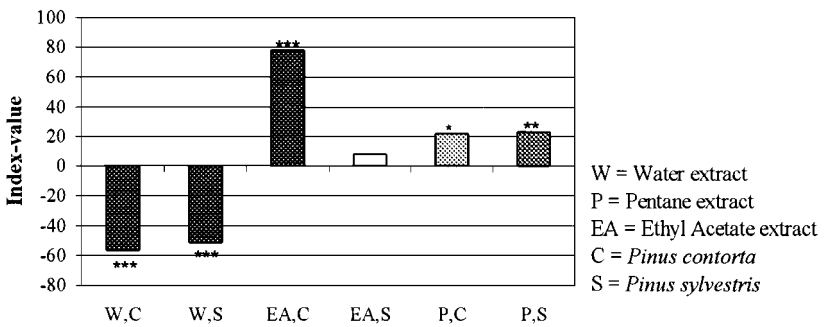

FIG. 1. Results of bioassays of water, ethyl acetate, and pentane extracts of *P. contorta* and *P. sylvestris* after 6 hr of feeding. Note that positive index values indicate antifeedant effect and negative values a stimulating effect on feeding. Shading of the columns highlights significance levels. $*P < 0.05$; $**P < 0.01$; $***P < 0.001$.

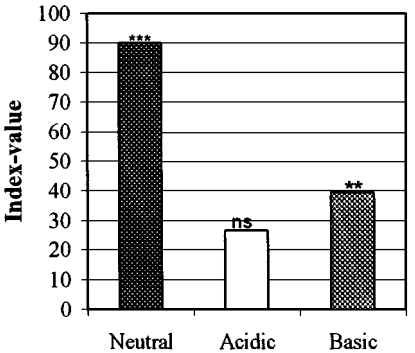

FIG. 2. Results of bioassays of the acidic, basic, and neutral fractions after 6 hr. $*P < 0.01$; $**P < 0.001$.

extraction. All fractions tended to reduce feeding, and a strong antifeedant effect was found for the neutral extract (Figure 2).

The neutral fraction consisted of three major constituents and some minor ones. Two of the major compounds were identified as ethyl *trans*-cinnamate (**1**) and ethyl 2,3-dibromo-3-phenylpropanoate (**2**) (Figure 3). The other compounds in the mixture were not identified.

Both ethyl *trans*-cinnamate and ethyl 2,3-dibromo-3-phenylpropanoate showed high antifeedant activity in the bioassays. After 24 hr the activity was still high for both compounds (Figure 4).

To ensure that 2,3-dibromo-3-phenylpropanoate emanated from the pine bark and was not an artifact, a new methanol extract of *P. contorta* was made. This extract was divided into pentane, ethyl acetate, and water as described above, and the ethyl acetate phase was analyzed using HPLC equipped with a diode array detector; synthetic 2,3-dibromo-3-phenylpropanoate was used as reference compound. A peak with retention time and UV spectrum identical to the reference compound was obtained. A new extract of *P. sylvestris* was treated the same way, and no ethyl 2,3-dibromo-3-phenylpropanoate could be detected.

Field Test. In field tests, ethyl 2,3-dibromo-3-phenylpropanoate significantly reduced the amount of pine weevil feeding on spruce stems (Table 1). After five

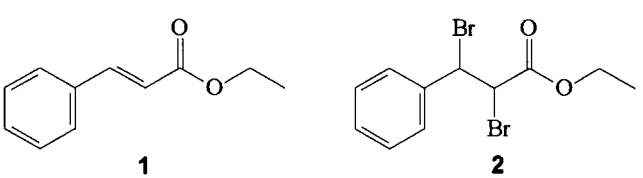

FIG. 3. Structures of ethyl *trans*-cinnate and ethyl 2,3-dibromo-3-phenylpropanoate.

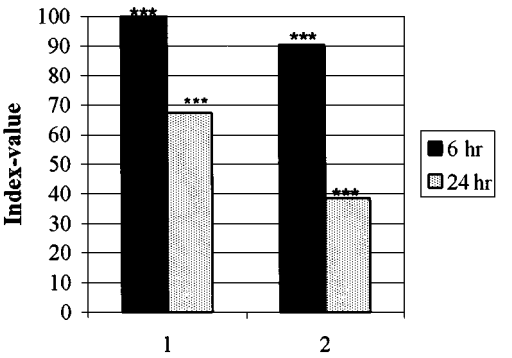

FIG. 4. Results of bioassays of ethyl 2,3-dibromo-3-phenylpropanoate (**1**) ($c = 50$ mM) and ethyl *trans*-cinnamate (**2**) ($c = 50$ mM) after 6 and 24 hr. $^{***}P < 0.001$.

weeks, the damage level was four times higher on control seedlings treated with methanol–AGS without the active substance and three times higher on untreated seedlings. Thus, methanol–AGS alone tended to increase damage, but this effect was counteracted when the active substance was added.

DISCUSSION

Host plants can simultaneously produce both attractant and deterrent compounds. The host monoterpene limonene can, for example, inhibit the attraction of pine weevils to the attractant monoterpene α-pinene and other host volatiles (Nordlander, 1990, 1991). Verbenone is also known to reduce feeding by pine weevils (Lindgren et al., 1996). Other natural plant compounds that have been found to possess antifeedant activity against *Hylobius* are limonin, carvone,

curcubitacin, and coumarin (Salom et al., 1994, 1996; Klepzig and Schlyter, 1999).

We confirm in this study that pine weevils feed less on bark from *P. contorta* than on bark from *P. sylvestris.* (The strong attractivity of the two water extracts was probably due to the content of low-molecular-weight carbohydrates in those fractions (Theander, 1982).) Two compounds possessing antifeedant activities were isolated from *P. contorta*, ethyl *trans*-cinnamate (**1**) and ethyl 2,3-dibromo-3-phenylpropanoate (**2**). Compound **2**, found in *P. contorta* and not in *P. sylvestris*, might also play a role in feeding preference for *P. sylvestris*. Several other factors also may, be responsible for *P. sylvestris* preference over *P. contorta*. *P. sylvestris* may contain more feeding stimulants, and/or additional compounds with antifeedant activity may exist in *P. contorta*.

Ethyl cinnamate has been isolated from several plant species (Pandji et al., 1993; Aubry et al., 1997; Mallavarapu et al., 1999) but not to our knowledge from any pine species. Ethyl cinnamate has not been reported to be an antifeedant but is known to possess other defensive activities (Kiuchi et al., 1988; Pandji et al., 1993). Ethyl 2,3-dibromo-3-phenylpropanoate has been synthesized and shown to possess antibacterial and antifungal activities (patent: US patent 4,397,851). To our knowledge, it has not been detected previously in living tissue.

The existence of a bromine compound in lodgepole pine bark was surprising. However, ponderosa pine (*Pinus ponderosa*) also contains some bromocompounds, since small amounts of bromine were detected in gases from burning biomass (Turn et al., 1997). Bromines emanate from man-made chemicals (Morris et al., 1993) and natural sources (Gribble, 2000; von Sydow et al., 2000; Keppler et al., 2000); however, brominated natural products are not common. Biologically, organobromine compounds are mainly produced by marine organisms and less commonly by plants and other terrestrial organisms. Many of these compounds possess biological activity (e.g., Gribble, 2000).

Host-derived antifeedant compounds of the type identified in this study may be useful for the protection of conifer seedlings against pine weevil damage. However, it is not yet clear whether long-term effects can be achieved with these compounds.

Acknowledgments—This investigation was supported by a grant from SJFR (Swedish council for Forestry and Agricultural Research), which is gratefully acknowledged.

(Received November 7, 2000; accepted July 15, 2001)

Abstract—The chemical components of tarbush (*Flourensia cernua*) leaves were fractionated by extracting successively with hexanes, diethyl ether, and ethanol. Volatile profiles of each fraction were identified by using GC-MS. The hexanes fraction contained mostly monoterpenoids, while the ethanol fraction volatiles were primarily sesquiterpenoids. Crude fractions were tested for activity against fungi, algae, and termites. Application of as little as 1 μg of the essential oil from the hexanes fraction was sufficient to provide visible antifungal activity in bioautography assays. The diethyl ether fraction showed selective activity against the cyanobacterium responsible for the 2-methylisoborneol-induced off-flavor sometimes associated with catfish farming operations. All three fractions exhibited a high degree of antitermite activity.

Key Words—*Flourensia cernua*, fractionation, activity, fungi, cyanobacteria, algae, termite, *Colletotrichum*, *Oscillatoria*, *Selenastrum*, *Reticulitermes*.

INTRODUCTION

At the Natural Products Utilization Research Unit (NPURU), Oxford, Mississippi, we are interested in finding novel uses for products from natural sources, especially as they relate to pest management. *Flourensia cernua* DC (tarbush, hojasen) is an aromatic deciduous shrub endemic to the Chihuahuan Desert of the southwestern United States and northern Mexico. Tarbush flowers are reported to be acutely toxic to livestock (Mathews, 1944; Dollahite and Allen, 1975) when consumed in large amounts (approximately 1% of body weight per day). Additionally, leaves and flower heads are sold in drug markets in Mexico (Dillon, 1984) and local farmers' markets in the United States as a remedy for indigestion. Tarbush is increasing in dominance within the Chihuahuan Desert and is currently the target of several studies involving interactions of herbivory and shrub chemistry at the Jornada Experimental Range (JER), Las Cruces, New Mexico. We previously reported the chemical profile of the essential oil of *F. cernua* (Tellez et al., 1997). In collaboration with the JER, we examined a set of crude extracts obtained from tarbush leaves by sequential extractions with solvents of widely differing properties (hexanes, ether, and ethanol). Bioassays conducted at the JER show all three crude fractions deter consumption by sheep when applied to alfalfa pellets (Estell et al., 2001). Bioassays conducted at the NPURU have shown that the crude hexanes and ether extracts are phytotoxic, whereas the ethanol fraction is inactive (Dayan and Tellez, 1999). Little else is known of the bioactivity of tarbush constituents.

Because volatile chemicals are likely the first line of exposure of a plant to herbivores, one objective of this research was to examine volatile chemical profiles of the three fractions that were deterrent to consumption by sheep (Estell et al., 2001). A second objective was to test these fractions for antifungal, antialgal, and antitermitic activity in an effort to identify potential agricultural and pest management uses of material from this invasive shrub.

METHODS AND MATERIALS

Plant Collection. Plant materials were collected from an area heavily infested with tarbush on the JER. Approximately 300 plants were selected haphazardly over a large area. Leaves were stripped from leaders into plastic bags by hand using gloves, and immediately placed on ice. Leaves were frozen within 2 hr, shipped on Dry Ice to the NPURU, and stored at -20°C until extraction.

Extractions. Tarbush leaves (36.5 kg) were extracted at room temperature in approximately 3-kg batches. Extractions were carried out sequentially with 7 liters each of hexanes, diethyl ether, and 100% ethanol for 22 hr in covered 10-liter round bottom flasks placed in a circular shaker (New Brunswick Co. G10 Gyrotory

Shaker) at 150 rpm. Each fraction was filtered (Whatman No. 1) and the solvents removed under reduced pressure with a rotary evaporator. All fractions from a given solvent were combined. The hexanes fraction produced 415.5 g of a highly aromatic yellow–brown oil, the ether fraction resulted in 984.0 g of a thick green oil, and the ethanol fraction produced 2215.6 g of an extremely thick green oil. All final products were stored at -20°C until used for bioassays. Steam distillations of the extracts were conducted as previously described (Tellez et al., 2000).

Chemical Analyses. Volatile chemical analyses of extracts were performed by GC-MS (EI, 70 eV) with a DB-5 column (30 m $\times$ 0.25 mm fused silica capillary column, film thickness 0.25 μm) with He as carrier gas (1 ml/min), 1 μl injection size, and a programmed (injector temperature: 220°C, transfer line temperature: 240°C, initial column temperature: 60°C, final column temperature: 240°C, 3°C/min) run (Adams, 1995). Octane and eicosane standards were used only for determination of retention times. Identification of extract components was performed by a comparison of mass spectra with literature data (NIST/EPA/NIH, 1990; Adams, 1995), and by comparison of their relative retention times with those of authentic compounds, or by comparison of their retention indices with those in the literature (Adams, 1995). The relative amounts (RA) of individual components of the extracts are expressed as percent peak area relative to total peak area. Analyses were performed on extracts after removal of solvents, since this was representative of their composition as applied to bioassays.

Algicidal Assays. A rapid bioassay (Schrader et al., 1997) was used to determine the lowest-observed-effect concentration and the lowest-complete-inhibition concentration of *F. cernua* extracts towards isolates of the cyanobacteria *Oscillatoria perornata* and *Oscillatoria agardhii,* and the green alga *Selenastrum capricornutum*. Ether, ethanol, and hexanes extracts were dissolved in technical grade acetone, ethanol, and hexane, respectively, and placed into microplate wells by the method of Schrader et al. (1997) to achieve a final test concentration of 50 μg/ml ($N = 4$). Solvents were allowed to evaporate for 10–15 min before adding culture material. Solvents without extracts were used in control microplate wells. The bioassay was modified by using 96-well quartz microplates (Hellma Cells, Inc., Forest Hills, New York) because hexane and acetone were used as loading solvents and are not compatible with polystyrene microplates.

Fungicidal Assays. Pathogen production and inoculum preparation for *Colletotrichum fragariae* Brooks, *C. gloeosporioides* Penz. & Sacc., and *C. accutatum* Simmonds were performed according to published procedures (Wedge and Kuhajek, 1998). Conidia concentrations were determined photometrically (Espinel-Ingroff and Kerkering, 1991; Wedge and Kuhajek, 1998) from a standard curve, and suspensions were adjusted with sterile distilled water to a concentration of 1.0×10^6 conidia/ml. Inhibition of fungal growth on chromatographic plates was evaluated by modifications of thin-layer chromotography (TLC) bioautographic assays (Homans and Fuchs, 1970).

Extracts were spotted on a TLC plate with a disposable glass micropipet, loading 400, 100, 10, 1, and 0.1 μg of each extract and of each essential oil derived from each extract. Loading solvents were used as controls. Each experiment was repeated three times. To detect biological activity directly on the TLC plate, silica gel plates (250 μm, Silica Gel GF Uniplate, Analtech, Inc., Newark, Delaware) were sprayed with a spore suspension as previously described (Wedge and Nagle, 2000). Inhibition of fungal growth for each test fungus was measured four days after treatment. Concentration-dependent sensitivity of the fungal species to each extract or oil was determined by comparing size of inhibitory zones.

Termite Assays. Extracts were tested at different concentrations, proportional to extract recovery. Hexanes, ether, and ethanol extracts (189, 405, and 958 mg, respectively) were each suspended with vigorous shaking in 45 ml of acetone. A 3-ml aliquot of the suspension was placed on each of three absorbent cellulose pads (47 mm diam.) for each of the three extracts ($N = 9$). Pads of cellulose without extract ($N = 3$) were used as a control. All pads remained under a fume hood for 24 hr to allow evaporation of acetone. Plastic containers (5 cm diam. $\times$ 3.5 cm high) served as test containers. A sterile sand–vermiculite (1:1) mixture (50 g) moistened with distilled water was placed in each of 12 test containers. One hundred *Reticulitermes* sp. worker termites were placed on top of the sand in each test unit. After 10 min, a treated cellulose pad that had been moistened with distilled water was placed in each container. Each container was covered and placed in an incubator maintained at 25°C and 53% relative humidity. All test units were observed weekly for five weeks to note any dead termites or unusual termite behavior. After five weeks, test units were disassembled, and termite survival and amount of feeding on treated and untreated cellulose pads was recorded.

RESULTS AND DISCUSSION

Table 1 shows the identity, retention index, retention time, and percent composition of the volatile compounds in the hexanes, ether, and ethanol extracts. The volatile profiles for the three crude fractions were markedly different. Forty-one volatile compounds were identified in the hexanes fraction, accounting for over 91.3% of the composition of the volatiles in the extract. Forty-seven volatile compounds were identified in the ether fraction, accounting for over 84.7% of the composition of the volatiles in the extract; δ-selinene (5.8%) was tentatively identified by MS only. Fourteen volatile compounds were identified in the ethanol fraction, accounting for over 79.3% of the composition of the volatiles in the extract; δ-selinene (8.7%) and 3,7,11,15-tetramethyl-2-hexadecene-1-ol (4.5%) were tentatively identified by MS only. The volatiles in the hexanes extract consisted of a high proportion of monoterpenes, with the 27 identified monoterpenes accounting for 74.7% of the total area. The hexanes fraction contained a low proportion

of sesquiterpenoids, with β-eudesmol accounting for 11.3%, and the remaining 13 accounting for 4.9% of the total relative area. The major monoterpenoids were myrcene (19.9%), 3-δ-carene (12.6%), and limonene (27.7%). The identified volatile compounds in the ether extract consisted of a mixture of monoterpenes (24.9%) and sesquiterpenes (57.0%), with a marked decrease in the proportion of β-eudesmol present (2.8%). The major components included myrcene (6.7%), 3-δ-carene (6.1%), limonene (8.4%), β-caryophyllene (16.0%), α-humulene (5.0%), and germacrene D (24.0%). Finally, the ethanol extract volatile profile was almost completely devoid of monoterpenes (0.2%) and consisted almost exclusively of sesquiterpenes, with the identified sesquiterpenes accounting for 79.1% of the total area. The major constituents included β-caryophyllene (14.3%), α-humulene (6.9%), and germacrene D (43.3%).

The three solvents used to extract tarbush leaves differed in polarity, from the fairly nonpolar hexanes to the fairly polar ethanol. These solvents were selected in order to obtain a crude separation of the components of the leaves. Although selective extraction was achieved, the separation appeared more a function of size (monoterpenoids versus sesquiterpenoids) than polarity, at least for volatile compounds. The observed difference is not an artifact of solvent removal since chromatograms obtained prior to and after solvent removal showed little difference in profile. In the past, we have observed selective extractions of terpenoid

classes with *Artemisia annua* (Tellez et al., 1999; Duke et al., 2000), although what mechanisms might be responsible in this present case remain unexplained.

Steam distillations of each extract afforded 337, 178, and 15 mg of essential oil (volatiles) per gram of hexanes, ether, and ethanol extract, respectively. Thus, a substantial portion of all three crude extracts represented the nonvolatile fraction. This distribution of volatile and nonvolatile components among the three extracts might explain results obtained in sheep feeding studies (Estell et al., 2001), in which all extracts decreased feed intake even though the amounts and profiles of the volatiles were different.

This study demonstrated that all three crude fractions were active in our fungal bioassays. Bioautography data (Table 2) showed that the essential oil derived from the hexanes extract retained activity against *C. gloeosporioides* and *C. fragariae* at lower application amounts than the other treatments. Antifungal activity of the essential oil derived from the hexanes crude extract was detected at the 1 μg dose. Antifungal activity of the essential oils derived from the ether and ethanol fractions was observed only at 10 μg doses and above. Antifungal activity of the ethanol crude extract fraction could be observed only at the highest amount (400 μg)

TABLE 2. FUNGAL GROWTH INHIBITION BY HEXANES, ETHER, AND ETHANOL EXTRACTS OF TARBUSH LEAVES AND THEIR ESSENTIAL OILS BY BIOAUTOGRAPHY USING *Colletotrichum gloeosporioides*, *C. fragaria*, AND *C. accutatum* AS INDICATORS

tested at the end of four days. Comparison among extracts, other than comparing the presence or absence of activity, by comparing size of inhibition zones is not valid because of the different solvents used to spot each extract. Comparing the zones of inhibition within an extract indicates a clear dose response for all three extracts against *C. gloeosporioides*, *C. fragariae*, and *C. accutatum*.

The essential oil of the hexanes extract was consistently more active against fungi than the extract itself, suggesting that a good portion of the activity in the hexanes extract resides in its steam-distilled volatile components. Several major volatile components—α-pinene (2.0%), 3-δ-carene (12.6%), and limonene (27.7%) (Himejima et al., 1992), and β-eudesmol (11.3%) (Miyakado et al., 1976)—are reported to have antifungal activity. Another major component, myrcene (19.9%), is reported to enhance the activity of other antimicrobials (Onawunmi et al., 1984) . The steam-distilled volatiles of the ethanol fraction exhibited inhibitory activity to all three *Colletotrichum* species, but their extremely small presence (1.5%) in the extract makes it unclear whether the inhibitory effect observed for the extract is due mostly to these steam-distilled volatiles or to other non-steam-distilled components.

F. cernua extracts were screened against two species of cyanobacteria (blue-green algae) and one species of green algae to determine their potential as a selective cyanobactericide. An off-flavor in channel catfish (*Ictalurus punctatus*) raised in the southeastern United States creates an unpalatable and, therefore, unmarketable product that results in large economic losses to the industry. Most off-flavor episodes in catfish are attributed to their absorption of earthy/musty compounds produced by certain species of cyanobacteria that grow in catfish production ponds. In west Mississippi, the cyanobacterium *Oscillatoria perornata* (Skuja), a producer of the musty-odor compound 2-methylisoborneol (MIB), is thought to be the major cause of musty off-flavor in farm-raised catfish (van der Ploeg et al., 1995). Green algae are not associated with such undesirable metabolites and are also preferable to cyanobacteria in catfish production ponds because they are better oxygenators of the water and a better base for aquatic food chains (Paerl and Tucker, 1995). Therefore, the discovery of safe compounds that selectively kill cyanobacteria would benefit the channel catfish industry.

Complete inhibition of *O. perornata* was observed for the hexanes and ether extracts of *F. cernua* at 50 (μg/ml (Figure 1B). For *Oscillatoria agardhii* (a non-MIB-producing cyanobacterium), complete inhibition occurred with the hexanes extract, and these results were established visually, i.e., disappearance of filaments in the treatment wells. The formation of black precipitate in wells containing hexanes extracts and *O. agardhii* culture resulted in high absorbance readings that could be misinterpreted as accelerated growth rate by *O. agardhii* based solely on the graphed data (Figure 1A). The other two cultures did not produce any colored precipitate in wells containing hexanes extract. For *S. capricornutum*, complete inhibition was also established only for the hexanes extract (Figure 1C).

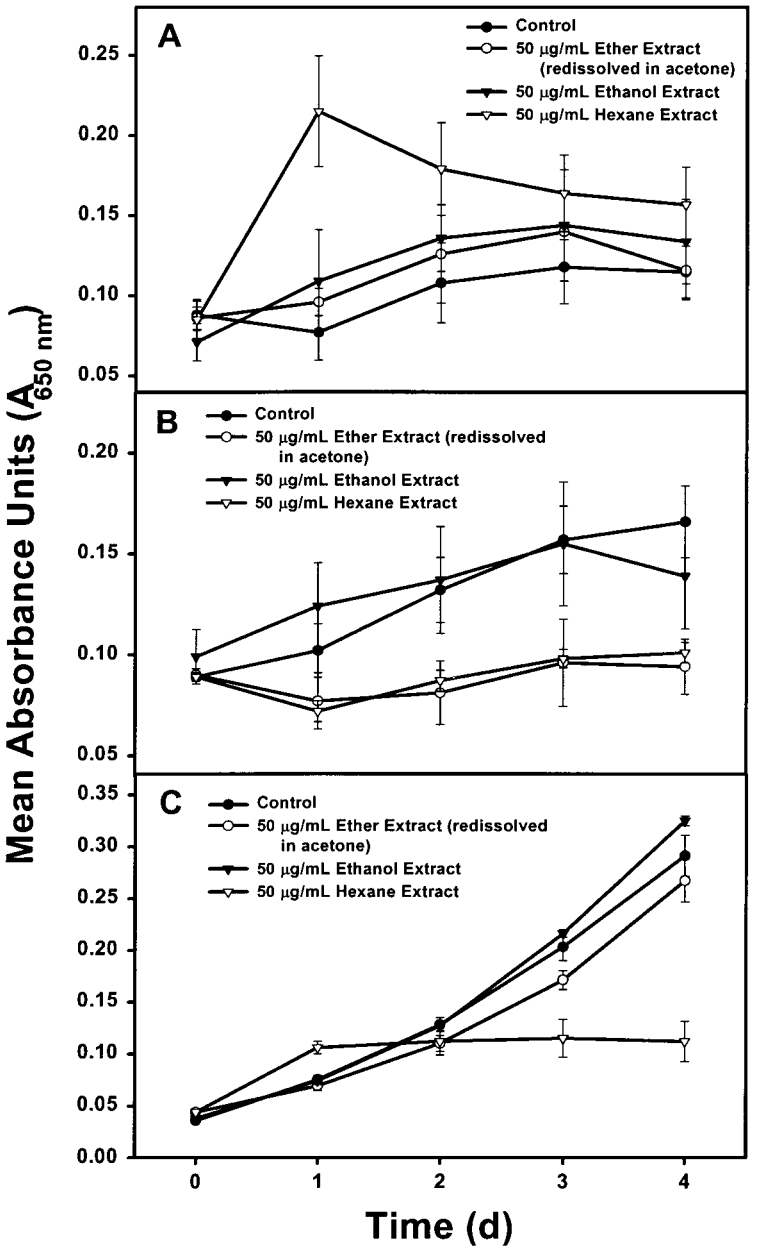

FIG. 1. Effect of tarbush extracts on growth of (**A**) *Oscillatoria agardhii*, (**B**) *O. perornata*, and (**C**) *Selenastrum capricornutum*. Error bars represent standard deviations of the mean ($n = 3$).

These results indicate selective toxicity of the ether extract of *F. cernua* towards *O. perornata* and nonselective toxicity of the hexanes extract towards all three organisms. No toxicity towards the green alga or cyanobacteria tested was observed for the ethanol extract. Additional screening of extracts and their steam-distilled oils revealed that a constituent (s) present in the extract but not the steam-distilled oil is (are) responsible for the selective toxicity of the ether extract towards *O. perornata* (data not shown).

All three crude extracts also showed a high degree of termiticidal activity after five weeks. The ethanol fraction was tested at the highest concentration and had a mean survival of 0%; there were no survivors in any of three replicates ($N = 100$ per replicate). The hexanes extract was tested at the lowest concentration but also had a nearly complete kill (mean of 2.3% survival); there were no survivors in two of the replicates and only seven survivors on the third replicate ($N = 100$ per replicate). The intermediate ether fraction had 15.7% survival (0, 35, and 12 survivors in each replicate, $N = 100$/replicate). Survival of the control group with an acetone blank was 82%. The antitermite properties of different fractions suggest the presence of more than one active compound (or set of compounds).

In conclusion, the three sequential extracts of tarbush exhibited fairly different volatile profiles. The crude organic extracts of tarbush show promise as antitermitic and antifungal agents. The ether extract of *F. cernua* holds promise as a possible selective cyanobactericide against the cyanobacterium thought to be the major cause of musty off-flavor problems in Mississippi farm-raised catfish. We are currently carrying out the bioassay-guided isolation and identification of the active components in *F. cernua.*

(Received November 8, 2000; accepted July 15, 2001)

Abstract—Effects of three extracts (hexanes, ether, and ethanol) from tarbush (*Flourensia cernua*) on intake of alfalfa pellets by lambs were examined. Forty-five ewe lambs were fed one of five treatments for five days (randomized complete block, three lambs per block on each treatment). Treatments were alfalfa pellets (CON) or alfalfa pellets plus ethanol carrier (CAR), hexanes extract (HEX), ether extract (ETH), or ethanol extract (ETOH). Extracts were applied to alfalfa pellets at the same concentration as in an equivalent amount of tarbush (as fed basis) in experiment 1 and at 10-fold dilutions of that concentration in experiment 2. Treatments were isolated from tarbush leaves by using a sequential extraction with hexanes, diethyl ether, and 100% ethanol. Lambs received 640 g of alfalfa pellets (dry matter basis) each morning and intake was monitored during a 20-min interval. Lambs were maintained and fed alfalfa pellets (4.7% of body weight) as one group except during this interval. In experiment 1, mean intake by lambs during the 20-min interval was 361, 393, 204, 212, and 228 g for CON, CAR, HEX, ETH, and ETOH, respectively (SEM = 28.9). All three extracts decreased intake ($P < 0.001$) compared to CON or CAR. Intake did not differ among the three extracts (HEX, ETH, and ETOH) or between the two controls (CON and CAR). Mean intake did not differ among treatments in experiment 2 (468, 455, 389, 381, and 431 g for CON, CAR, HEX, ETH, and ETOH, respectively; SEM = 30.5; $P = 0.187$). Several compounds are probably

responsible for the low palatability and differential use of tarbush typically exhibited by livestock.

Key Words—*Flourensia cernua*, feeding deterrent, intake, plant–animal interactions, plant extracts, sheep.

INTRODUCTION

Tarbush (*Flourensia cernua* DC) is a dominant shrub in the northern Chihuahuan Desert. It is high in crude protein and generally low in antiquality factors (except phenolics) (Estell et al., 1996). Livestock consume tarbush in limited amounts under free-ranging conditions (Nelson et al., 1970; Anderson and Holechek, 1983), depending on season and availability of other forages, but the shrub is not a preferred species. Tarbush may be toxic for some species of herbivores during flowering (Mathews, 1944; Dollahite and Allen, 1975). However, no adverse effects were observed in sheep consuming 30 or 15% tarbush leaves in mixed diets for 30 or 90 days, respectively (Fredrickson et al., 1994; King et al., 1996).

We have been using tarbush as a shrub model to examine chemical interactions between desert shrubs and mammalian herbivory. Ruminants exhibited differential use of individual plants when forced to browse tarbush (Estell et al., 1994b), and removal of surface compounds with organic solvents increased tarbush consumption by sheep (Estell et al., 1994a). Terpenes on the leaf surface of tarbush were related to its use by livestock (Estell et al., 1998a).

The objective of these experiments was to determine effects of extracts of tarbush on intake by lambs when applied to alfalfa pellets. Our hypothesis was that pellet consumption by lambs would decrease when extracts were applied.

METHODS AND MATERIALS

Experimental Protocol and Animal Management. Two experiments to examine intake of lambs consuming alfalfa pellets treated with extracts from tarbush were conducted in accordance with guidelines approved by the New Mexico State University Institutional Animal Care and Use Committee. Both experiments were part of larger studies. Experiment 1 was conducted in conjunction with a series of studies to examine the effect of specific terpenes (α-humulene, 1,8-cineole, *p*-cymene, 3-carene, and sabinene) on intake (Estell et al., 2000), and experiment 2 was part of a similar study that examined another series of terpenes (β-pinene, camphene, caryophyllene oxide, and myrcene; author's unpublished data). Both experiments were conducted as described by Estell et al. (2000). Ninety Polypay ewe lambs [45 lambs per experiment, approximately 5 months of age, mean initial body weight (BW) of 43.0 $\pm$ 0.41 kg and 36.8 $\pm$ 0.42 kg for experiments 1 and 2, respectively] without previous experience browsing tarbush were adapted to

alfalfa pellets [4.7% of BW, dry matter (DM) basis] for two weeks and a drylot pen for one week. A five-day adaptation period was conducted to familiarize lambs with handling procedures and the 20-min pen feeding (week 1), followed by a five-day period to establish baseline intake of untreated alfalfa pellets during the 20-min interval (week 2). Extracts were tested in week 8 (experiment 1) and week 7 (experiment 2). All five-day periods were separated by two-day intervals during which lambs were fed and managed as during the adaptation period.

Lambs were individually fed treated pellets each morning during a 20-min interval in an enclosed metabolism unit (1.22- $\times$ 2.44-m pens). Groups were fed in succession at 08:00, 08:30, and 09:00 hr. During the 20-min feeding, 640 g of pellets (DM basis) were offered daily to lambs, and feed refusals were measured. Except for the morning feeding period, lambs were maintained as one group in an outdoor pen with free access to water and trace-mineralized salt. Alfalfa pellets ($\geq$15% CP, 0.95 cm diam., from sun-cured alfalfa hay) were sampled randomly, composited, ground to pass a 2-mm screen in a Wiley mill, and analyzed for dry matter (93.8% and 94.9% in experiments 1 and 2, respectively) (AOAC, 1990). Lambs were weighed on day 5 each week immediately preceding the 08:00 hr feeding.

Lambs were also group-fed untreated alfalfa pellets twice daily at 13:00 hr (950 g DM/lamb) and 10:00 hr (remainder required to provide a mean intake of 4.7% of BW). An amount of untreated feed equal to the total unconsumed feed during 20-min tests was also fed at 10:00 hr. During the two-day intervals between intake measurements, lambs were fed an additional 640 g DM/lamb at 10:00 hr.

Treatments. Treatments applied to alfalfa pellets consisted of extracts from an equivalent amount of tarbush (as fed basis, 680 g) in experiment 1. These concentrations should most accurately reflect those to which livestock would be exposed when browsing tarbush. For experiment 2, 10-fold dilutions of the extracts served as treatments. Two control groups (one receiving untreated pellets and one receiving pellets sprayed with ethanol carrier) were included in each experiment. Treatment extracts were thawed at room temperature for 24 hr, dissolved in the appropriate amount of ethanol, and stored in amber glass bottles. Extracts were not completely soluble in the amount of ethanol used, and some settling occurred. Consequently, suspensions were swirled immediately before decanting and application.

Solutions were applied at 1 ml/20 g of alfalfa pellets with graduated cylinders (experiment 1) or graduated high-density polyethylene spray bottles (experiment 2). Treatments were sprayed in a stream pattern in experiment 2 to minimize volatilization. Pellets were placed in one end of feed pans, and pans were tilted and gently shaken while treatments were applied in an effort to apply treatments completely and evenly. Approximately 10 min lapsed between application and feeding, and order of application was rotated systematically (within

and across days) to minimize bias due to time between spraying and feeding. Treatments were applied in an adjacent separately ventilated room, and an exhaust fan in the metabolism unit was used to remove aromas and minimize potential drift among pens. One stainless steel pan was used for each lamb in each experiment to minimize cross-contamination, and pans were rinsed with ethanol after each feeding.

Bulk Extraction. Tarbush exhibiting lush green growth (prebloom stage) without visible evidence of insect damage was harvested from one location on the Jornada Experimental Range near Las Cruces, New Mexico. Leaves were removed by hand using gloves and placed in plastic bags on ice. Approximately 36 kg of fresh material representing several hundred plants were collected on September 10, 1997, between 07:30 and 12:00 hr. Leaf material was frozen within 1–2 hr of collection, shipped on Dry Ice to the USDA-ARS Natural Products Utilization Research Unit (Oxford, Mississippi), and stored in a -20°C cold room. Frozen leaves were extracted sequentially with hexanes, diethyl ether, and 100% ethanol. Extractions were conducted in 3-kg batches at room temperature on a circular shaker at 150 rpm for 22 hr in a covered 10-liter round-bottom flask with 7 liters of each solvent. Extracts from each solvent were filtered (Whatmann No. 1 filter paper), solvents were removed with reduced pressure in a 10-liter rotary evaporator, and 12 extracts from each solvent were combined in amber glass bottles and frozen. Oils were stored in a -20°C cold room until shipped on Dry Ice to Las Cruces, New Mexico.

Statistical Analysis. Lambs were randomly assigned to pen, group, and treatment at the beginning of each experiment in a randomized complete block design. Randomization was restricted to three lambs per treatment in each group (block). Repeated-measures analysis of variance was conducted using GLM procedures of SAS Institute (1989) for each experiment to evaluate the consistency of intake among days within experiment. The model contained group (blocking factor), day, treatment, day $\times$ treatment interaction, and experimental error (animal nested within treatment). Orthogonal polynomial contrasts were tested among days in this analysis. Analysis of variance for each experiment was also conducted by using GLM procedures of SAS Institute (1989) with intake (five-day means) during the 20-min interval as the dependent variable and treatment and group as the independent variables in the model. Although pen and animal are confounded and pen was not in the model, previous experiments that used these facilities did not reveal pen effects (Estell et al., 1998b). Means from analysis of variance were separated ($P < 0.05$) by LSD (SAS Institute, 1989) in the case of a significant F value ($P < 0.05$). Intake of control lambs ($N = 9$) was subjected to analysis of variance with time as the treatment factor to evaluate the consistency of intake of controls over time. Means were separated ($P < 0.05$) by LSD (SAS Institute, 1989) in the case of a significant F value ($P < 0.05$).

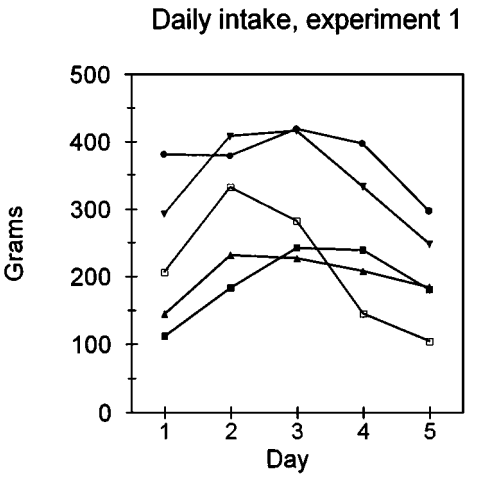

FIG. 1. Daily intake (g/day during 20 min feeding) by lambs of alfalfa pellets treated with *Flourensia cernua* extracts at the same concentration as in intact plants. Treatments were control (▼) and control with carrier (●), hexanes extract (■), ether extract (▲), or ethanol extract (□); $N = 9$ lambs/treatment; SEM = 28.9; linear treatment ($P < 0.001$) and quadratic mean ($P < 0.001$) effects were detected.

RESULTS AND DISCUSSION

When intake was examined by day with a repeated-measures analysis of variance, a linear treatment effect ($P < 0.001$) and a quadratic mean effect ($P < 0.001$) were detected in experiment 1 (Figure 1), and a quadratic ($P = 0.001$) mean effect was detected in experiment 2 (Figure 2). Quadratic mean effects in both experiments reflect the increased intake early in the week and the decrease in the latter part of the week. This shift was evident across treatments and therefore unrelated to treatments. The linear treatment effect in experiment 1 indicates changes in intake over time were not consistent among treatments (day × treatment interaction), and likely reflects the dramatic decrease in the ETOH treatment between days 2 and 5 (Figure 1).

Across days, intakes for CON (361 g) and CAR (393 g) differed ($P < 0.001$) from HEX (204 g), ETH (212 g), and ETOH (228 g) in experiment 1 (Figure 3). Although the pattern was similar in experiment 2 (Figure 4), means were not statistically different (468, 455, 389, 381, and 431 g for CON, CAR, HEX, ETH, and ETOH, respectively). All three treatments clearly reduced intake in experiment 1, supporting our hypothesis; however, the three fractions representing different crude mixtures of volatile and nonvolatile compounds extracted by increasingly polar

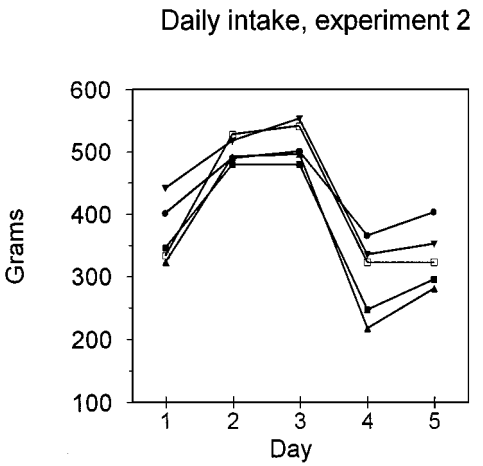

FIG. 2. Daily intake (g/day during 20 min feeding) by lambs of alfalfa pellets treated with *Flourensia cernua* extracts at a 10-fold dilution of the concentration in intact plants. Treatments were control (▼) and control with carrier (●), hexanes extract (■), ether extract (▲), or ethanol extract (□); $N = 9$ lambs/treatment; SEM = 30.5; linear ($P = 0.010$) and quadratic mean ($P < 0.001$) effects were detected.

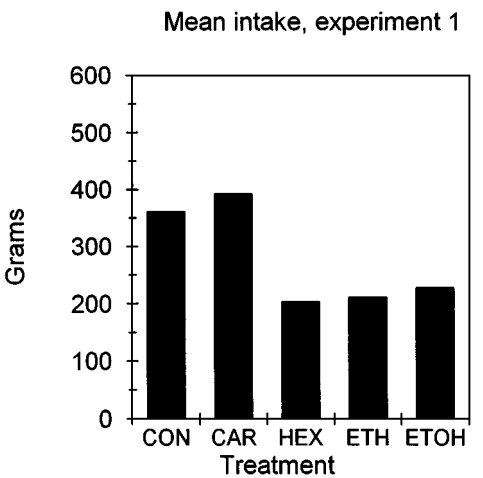

FIG. 3. Mean intake (g/day during 20 min feeding) by lambs of alfalfa pellets treated with *Flourensia cernua* extracts at the same concentration as in intact plants. Treatments were control (CON) and control with carrier (CAR), hexanes extract (HEX), ether extract (ETH), or ethanol extract (ETOH); $N = 9$ lambs/treatment; SEM = 28.9; CON and CAR differed from HEX, ETH, and ETOH ($P < 0.001$).

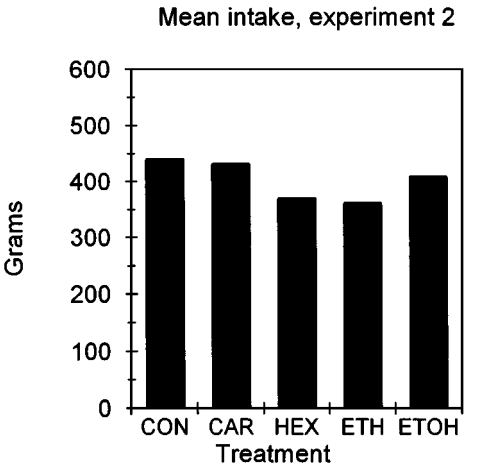

FIG. 4. Mean intake (g/day during 20 min feeding) by lambs of alfalfa pellets treated with *Flourensia cernua* extracts at a 10-fold dilution of the concentration in intact plants. Treatments were control (CON) and control with carrier (CAR), hexanes extract (HEX), ether extract (ETH), or ethanol extract (ETOH); $N = 9$ lambs/treatment; SEM = 30.5; treatment means did not differ ($P > 0.05$).

solvents were equally effective in deterring intake at concentrations equivalent to those encountered in intact plants.

Treatments CON and CAR were not different in experiments 1 or 2, indicating no effect of the ethanol carrier on intake of alfalfa pellets. No effect of group was detected in either experiment. Intake for the CON lambs during the 20-min interval was 361 g (experiment 1) and 468 g (experiment 2). Intake for the same nine lambs during the adaptation period (week 2) was 403 g and 536 g for experiments 1 and 2, respectively. Intake of control lambs during adaptation and week of treatment did not differ in either experiment ($P > 0.05$; SEM = 38.7 and 32.8, respectively). Because intake was adjusted weekly and because prior treatments did not greatly affect intake, we did not expect CON intake to differ over time.

Previously at this location, when a mixture of cattle, sheep, and goats were forced to use tarbush, they preferentially browsed certain plants to the exclusion of others, and this differential use was negatively related to epicuticular wax concentration (Estell et al., 1994b). Lambs consumed more tarbush when surface compounds were removed with organic solvents (Estell et al., 1994a). Concentrations of specific mono- and sesquiterpenes on tarbush leaves were related to this differential use (e.g., α-pinene and flourensadiol) (Estell et al., 1998a). To date, 15 volatile compounds (camphor, limonene, *cis*-jasmone, β-caryophyllene, borneol, α-pinene, sabinene, 3-carene, *p*-cymene, α-humulene, 1,8-cineole, camphene, myrcene, caryophyllene oxide, and β-pinene) have been tested individually

for effects on intake (Estell et al., 1998b, 2000, unpublished data). Results from these studies have generally shown minor or no effects on intake by lambs when individual compounds were applied to alfalfa pellets.

Because all treatments significantly reduced intake in experiment 1, a 10-fold dilution of the extracts was applied in experiment 2 in an attempt to identify the most potent fraction. None of the diluted extracts significantly influenced intake; however, the amount of residue recovered (415, 984, and 2215 g for hexanes, ether, and ethanol fractions, respectively) during extraction suggests the hexanes fraction was most potent, based on the fact that it was recovered in the lowest amount and, therefore, contributed the least mass to its respective treatment solution.

Volatile profiles for each extract were characterized by using gas chromatography–mass spectrometry (Tellez et al., 2001). Volatile profiles in the extracts were related more to molecule size than to any obvious polarity differences. The hexanes fraction contained most of the monoterpenes (and few sesquiterpenes), the ether fraction contained primarily sesquiterpenes (with some monoterpenes), and the ethanol fraction was almost exclusively sesquiterpenes. The volatile compounds contributing greater than 10% of the total peak area in the hexane fraction were limonene, myrcene, 3-carene, and β-eudesmol. For both the ether and ethanol fractions, only germacrene D and β-caryophyllene were present in excess of 10% of the total peak area (Tellez et al., 2001). Limonene, myrcene, 3-carene, and β-caryophyllene did not affect intake when examined individually (Estell et al., 1998b, 2000, unpublished data), although, to our knowledge, effects of germacrene D and β-eudesmol on mammalian herbivory have not been examined . These crude fractions likely also contain numerous nonvolatile compounds, particularly in the more polar ether and ethanol fractions (e.g., alkaloids, flavonoids, etc.). Flavonoids (Rao et al., 1970), 4-hydroxyacetophenone derivatives (Bohlmann and Grenz, 1977), and benzofurans and benzopyrans (Aregullin-Gallardo, 1985) have been characterized in tarbush. Certainly, these or other nonvolatile compounds in the extracts may be responsible for the reduced intake of alfalfa pellets by lambs in this study.

The decreased intake observed in experiment 1 may be due to reduced palatability, given that many compounds in the crude terpenoid fraction are bitter. Bitterness is thought to be a primary aversive stimulus influencing forage preferences (Krueger et al., 1974), although compounds considered to be bitter are not necessarily deterrent to herbivores (Nolte et al., 1994). Hanks et al. (1975) reported that methanolic extracts containing phenolics from a number of subspecies of rubber rabbitbrush, varying in palatability and use by mule deer, resulted in different patterns when subjected to paper chromatography. Dohi et al. (1996) found methanolic extracts of perennial ryegrass sprayed on low-quality hay stimulated intake by goats, whereas pentane extracts either had no effect or reduced intake. Pass et al. (1998) examined the deterrent properties of eucalyptus for

common ringtail possums, using plants that were herbivore deterrent and herbivore susceptible. Several fractions from low-use plants differed from controls, including a methanolic fraction, a chloroform subfraction, and the steam distillate (Pass et al., 1998).

Intake reductions could be attributed to reduced digestibility and or passage rate due to microbial toxicities. Terpenes have been reported to decrease *in vitro* digestibility in ruminants, suggesting microbial toxicities (Oh et al., 1967; Schwartz et al., 1980), particularly if rumen microflora are not adapted to the compounds (Oh et al., 1967). Sinclair et al. (1988) indicated both dry matter and protein digestibility in snowshoe hares were reduced when ether or methanol extracts of white spruce or bog birch were applied to rabbit chow at levels found in those species normally. However, it is doubtful that reduced digestibility was responsible for decreased intake in this study, given the short duration of the study and the fact that lambs maintained an average total intake of 4.7% of BW.

There was little indication that intake reduction was due to negative feedback in this study, even though aversions can be formed within a five-day period (Provenza et al., 1990). The only evidence of aversion to extracts occurred for the ETOH treatment (experiment 1; Figure 1), in which intake decreased substantially during the latter part of the week (linear treatment effect, suggesting a day $\times$ treatment interaction, $P < 0.001$).

In conclusion, compounds in these extracts are probably partly responsible for the low palatability and differential use of tarbush by ruminants. Knowledge of specific chemical interactions with feed intake may ultimately lead to mechanisms to alter feeding behavior and diet selection. Potential benefits of increased shrub consumption would depend on the balance of nutritional benefits and metabolic impacts of phytotoxins.

Abstract— Sacoglossans are a group of opisthobranch mollusks that have been the source of numerous secondary metabolites; however, there are few examples where a defensive ecological role for these compounds has been demonstrated experimentally. We investigated the deterrent properties of the sacoglossan *Elysia rufescens* and its food alga *Bryopsis* sp. against natural fish predators. *Bryopsis* sp. produces kahalalide F, a major depsipeptide that is accumulated by the sacoglossan and that shows in vitro cytotoxicity against several cancer cell lines. Our data show that both *Bryopsis* sp. and *Elysia rufescens* are chemically protected against fish predators, as indicated by the deterrent properties of their extracts at naturally occurring concentrations. Following bioassay-guided fractionation, we observed that the antipredatory compounds of *Bryopsis* sp. were present in the butanol and chloroform fractions, both containing the depsipeptide kahalalide F. Antipredatory compounds of *Elysia rufescens* were exclusively present in the dichloromethane fraction. Further bioassay-guided fractionation led to the isolation of kahalalide F as the only compound responsible for the deterrent properties of the sacoglossan. Our data show that kahalalide F protects both *Bryopsis* sp. and *Elysia rufescens* from fish predation. This is the first report of a diet-derived depsipeptide used as a chemical defense in a sacoglossan.

Key Words—Antipredatory role, herbivore–prey relationship, depsipeptides, kahalalide F, sacoglossan mollusks, green algae, *Elysia rufescens*, *Bryopsis* sp.

INTRODUCTION

Sacoglossans (=ascoglossans) are a group of opisthobranch mollusks that feed primarily on siphonaceous green algae (Williams and Walker, 1999). They are highly specialized herbivores that can sequester functional chloroplasts from their diet and use them as a source of photosynthetic energy (Clark et al., 1990; Williams and Walker, 1999). Sacoglossans can also sequester secondary metabolites from their diets or use the sequestered chloroplasts to convert bicarbonate into a variety of carbohydrates that can be used for the synthesis of secondary metabolites (Ireland and Scheuer, 1979; Ireland and Faulkner, 1981; Paul and Van Alstyne, 1988; Gavagnin et al., 2000). It has been hypothesized that these compounds defend sacoglossans against predators. These putative chemical defenses are throught to provide ecological advantages and may function as a driving force in the evolution of this group (Cimino and Ghiselin, 1998).

Although marine natural products chemists have isolated numerous secondary metabolites from sacoglossans (Faulkner, 1992; Avila, 1995), their ecological roles remain largely uninvestigated. Many species synthesize polypropionates (Ireland and Scheuer, 1979; Ireland and Faulkner, 1981; Ksebati and Schmitz, 1985; Dawe and Wright, 1986; Roussis et al., 1990; Di Marzo et al., 1991; Vardaro et al., 1991; Gavagnin et al., 1996). However, these compounds do not show an antipredatory role when they have been experimentally tested (Hay et al., 1989; Roussis et al., 1990). Both the chemically defended sacoglossan *Cyerce nigricans* and its chemically defended host alga *Chlorodesmis fastigiata* contain chlorodesmin (Hay et al., 1989). Although chlorodesmin significantly deters feeding by herbivorous fishes (Paul, 1987; Wylie and Paul, 1988), it does not account for the antipredatory properties of the mollusk (Hay et al., 1989). Two propionate-derived metabolites isolated from the same mollusk species also lacked the deterrent properties of the extracts (Roussis et al., 1990).

Our study focused on the sacoglossan *Elysia rufescens* and its food alga *Bryopsis* sp. Kahalalide F is the major metabolite of a series of amino and fatty acid-derived depsipeptides produced by the green alga *Bryopsis* sp. that are accumalated by *Elysia* spp. (Hamman and Scheuer, 1993; Hamman et al., 1996). Kahalalide F shows a series of in vitro activities against tumor cell lines, viruses, and fungi (Hamman and Scheuer, 1993), but no ecological roles have been investigated. In our study, we investigated whether or not *Bryopsis* sp. and *Elysia rufescens* are chemically defended against generalist fish predators and, if so, whether or not kahalalide F is the compound responsible for the deterrent properties.

METHODS AND MATERIALS

Extraction and Isolation. We collected 5.4 kg wet mass of *Elysia rufescens* and 4.67 kg wet mass of *Bryopsis* sp. by snorkeling at low tide near Black Point,

Oahu, Hawaii, during February 1995. Marilyn Dunlap and Alison Kay identified the animals. A voucher specimen is deposited at the Bernice P. Bishop Museum, Honolulu, BPBM 247679. *Bryopsis* sp. is an undescribed *Bryopsis* species highly abundant in the reef flat at Black Point. In contrast to *Bryopsis* sp. at other sites (Kan et al., 1999, personal observation), the specimens at Black Point lacked macroepophytes. We used bioassay-guided fractionation to isolate and identify ecologically active compounds. We used various solvents to extract and fractionate the extracts from both species along gradients of polarity (Figures 1 and 2). The general goal and approach was the same for the two species, but the specifics of the process varied between *E. rufecens* and *Bryopsis* sp. The sacoglossans were extracted with ethanol (5×3 liters) and dichloromethane (CH_2Cl_2, 2 liters). Ethanol and CH_2Cl_2 extracts from *E. rufescens* were combined (282.3 g) and partitioned between CH_2Cl_2 and water (Figure 1). The aqueous layer was extracted with *n*-BuOH, leaving 216.4 g of aqueous extract after evaporation. The *n*-BuOH layer was combined with the CH_2Cl_2 layer, concentrated (65.9 g), and partitioned between hexanes (30.5 g) and MeOH–H_2O (9 : 1) (35.4 g). The methanol layer was collected and water was added to adjust the MeOH concentration to 60%. Extraction with CH_2Cl_2 and concentration yielded 23 g of CH_2Cl_2 extract and 12.4 g of the aqueous methanol extract. The CH_2Cl_2 fraction was subjected to ODS flash column chromatography, by using a stepwise aqueous methanol gradient (50% MeOH = ODS1, 70% MeOH = ODS2, 90% MeOH = ODS3, 100% MeOH = ODS4, $CHCl_3$–MeOH–H_2O (7 : 3 : 0.5) = ODS5). Fraction ODS3 (12.2 g), was subjected to ODS flash column chromatography by using a stepwise aqueous acetonitrile gradient [50% MeCN, 60% MeCN, 70% MeCN, 80% MeCN, 100% MeOH, $CHCl_3$–MeOH–H_2O (CMW, 7 : 3 : 0.5)]. The peptide-containing fractions (monitored by TLC) were combined (8.3 g) and purified on an ODS column by using a stepwise aqueous MeCN gradient solvent system (61%, 62%, 70% aqueous MeCN and 100% MeOH). The kahalalide F-containing fraction eluted with 61% MeCN (4.1 g), and it was passed through an ODS BondElut short column. A reverse-phase HPLC separation (Ultracarb 10 ODS PO; MeOH–H_2O–TFA, 65 : 35 : 0.05) led to 2 g of pure kahalalide F. All the non-kahalalide F-containing fractions and the HPLC side fractions were recombined to reconstitute what was called fraction ODS6 (Figure 1).

The methanol (2×3 liters) and $CHCl_3$–MeOH (1 : 1) (2×3 liters) extracts from *Bryopsis* sp. were combined (159.82 g) and partitioned between $CHCl_3$ and water (Figure 2). The aqueous layer was extracted with *n*-BuOH (4.23 g). The $CHCl_3$ layer was concentrated (11.09 g) and partitioned between hexanes (4.71 g) and MeOH–H_2O (9 : 1) (6.87 g). The methanol layer was collected (2.67 g), and water was added to adjust the MeOH concentration to 60%. Extraction with $CHCl_3$ and concentration yielded 4.2 g of chloroform fraction.

We used TLC and proton nuclear magnetic resonance (NMR spectra measured on a General Electric QE-300 or GN Omega 500 instrument) to detect kahalalide

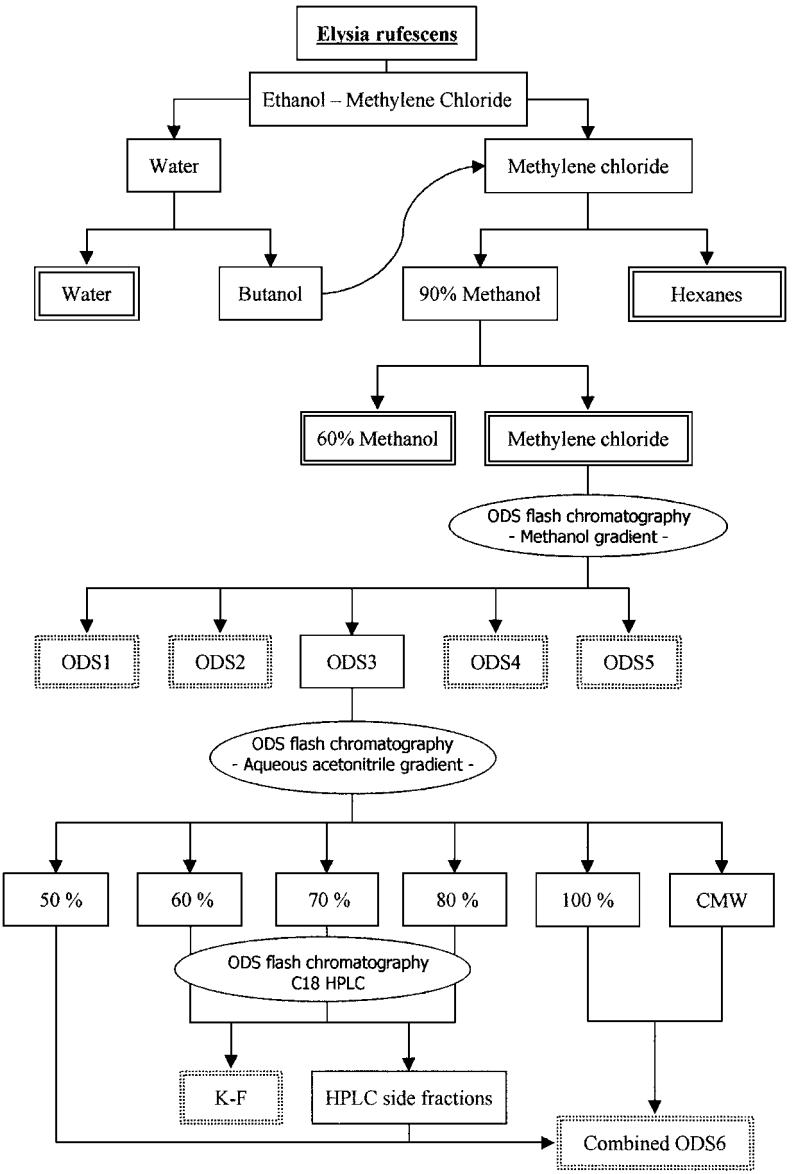

FIG. 1. Scheme of the extraction and partitioning procedure used to obtain secondary metabolites from the sacoglossan *Elysia rufescens*. Fractions enclosed in a double frame were tested at their naturally occurring concentrations against natural fish predators in the field. Fractions sharing the same double frame were tested in the same feeding experiment. See text for more information on the isolation procedure and assay techniques.

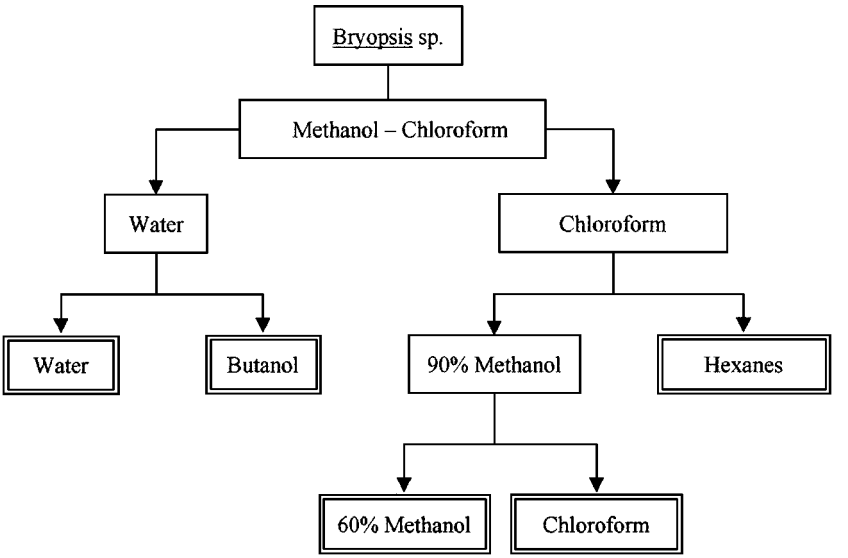

FIG. 2. Scheme of the extraction procedure used to obtain secondary metabolites from the green alga *Bryopsis* sp. Fractions sharing the same double frame were tested at their naturally occurring concentrations against natural fish predators in the same field feeding experiment. See text for more information on the extraction procedure and assay techniques.

F in the fractions and in the mucus produced by *Elysia*. The presence of secondary metabolites in the mucus has been traditionally considered as indirect evidence of the ecological role of the compound (Faulkner, 1992). To collect mucus, we put slugs with seawater in zip-lock bags during collection and then transferred the bags with slugs to containers with ice for transportation to the laboratory. Once in the laboratory we took the slugs out of the seawater, which had taken on a mucilaginous consistency due to the production of mucus by the slugs. We freeze-dried the water–mucus solution, extracted with DCM, and then partitioned using the *Elysia* scheme. Presence of kahalalide F was monitored in the fractions by proton NMR analysis.

Antipredatory Experiments. We used field experiments to determine whether *Bryopsis* sp. and *Elysia rufescens* are chemically defended against a natural coral reef fish assemblage. Methods were similar to those of Becerro et al. (1998). We added extracts from *Bryopsis* sp. and *E. rufescens* to an artificial diet consisting of 5 g of ground food, 2.5 g of carrageenan, and 80 ml of water. We used ground material of the green alga *Enteromorpha* sp. or ground catfish pellets (Kruse's Perfection Brand) in an attempt to better mimic the nutritional characteristics of *Bryopsis* sp. and *E. rufescens* in our artificial diets. We added the necessary amount of extracts, fractions, or compounds relative to wet mass of the food to

match the natural concentration of extracts, fractions, or compounds relative to the wet mass of *Bryopsis* or *E. rufescens*. The actual amount of extract (dissolved in 2 ml of dichloromethane–methanol 1 : 1) added to the mixture varied according to the percent yield (per wet mass) of the particular extract or fraction tested. Control foods were prepared by adding 2 ml of solvent to the carrageenan-food diet. The mixture was poured into 1-cm^3 molds containing a rubber O-ring, so that safety pins could be used to attach cubes to ropes (40 cm long). Each rope contained either four control or four treated food cubes. We placed 20 pairs of control and treated ropes on the reef of Western Shoals, Apra Harbor, Guam. Pairs were removed when approximately half of the cubes were eaten in any of the treatments. We used Wilcoxon signed-ranks test for paired comparisons to test for significant differences in the number of control and treatment cubes eaten.

RESULTS

In field experiments, extracts from *Bryopsis* sp. and *Elysia rufescens* significantly deterred fish predators at naturally occurring concentrations. The antipredatory properties of *Bryopsis* sp. are associated with the butanol and $CHCl_3$ fractions ($P < 0.001$ and $P = 0.01$ respectively, Figure 3). TLC analysis showed that kahalalide F is exclusively present in the active fractions.

The antipredatory properties of *Elysia rufescens* were associated with the methylene chloride fraction ($P = 0.002$, Figure 4), a combination of the butanol and methylene chloride fractions from the first fractionation procedure (Figure 1). Kahalalide F was the only compound responsible for the antipredatory properties of the extract ($P = 0.02$, Figure 5). Kahalalide F was also present in the mucus, as observed by proton NMR, although the concentration at which it occured is unknown.

DISCUSSION

Secondary chemistry seems to play a major role in the biology, ecology, and evolution of mollusks. Sea hares, cephalaspideans, and nudibranchs either sequester secondary metabolites from their diet or synthesize them de novo to use them as chemical defenses (Faulkner, 1992; Avila, 1995). Although the data available for sacoglossan mollusks seem to support a defensive role for these compounds (Gavagnin et al., 1994a), experimental evidence is still scarce and does not always support this hypothesis. Our study provides evidence that the sacoglossan *Elysia rufescens* and its host alga *Bryopsis* sp. are chemically defended against generalist fish predators. Kahalalide F, a major depsipeptide sequestered by *E. rufescens* from the green alga *Bryopsis* sp., is the compound responsible for

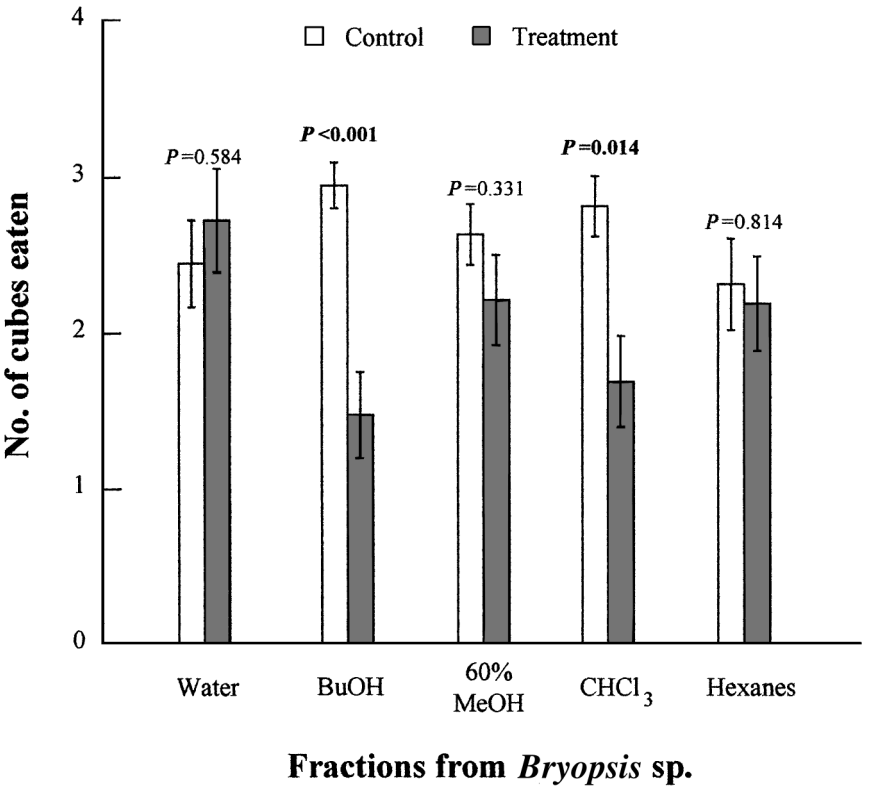

FIG. 3. Feeding deterrence of fractions from the green alga *Bryopsis* sp. towards natural fish consumers in the field. Bars represent average (mean ± 1 SE) number of control (empty bars) and treated (filled bars) cubes eaten in the field by natural fish predators. Mean differences between treatments and their respective controls were tested with Wilcoxon signed-ranks test for paired comparisons. The aqueous (water), butanol (BuOH), 60% methanol (MeOH), chloroform ($CHCl_3$), and hexanes fractions were all tested at their naturally occurring concentrations.

this activity. To our knowledge, this is the first report of a diet-derived depsipeptide used as a chemical defense by sacoglossans.

Sequestration of secondary metabolites is widespread among opisthobranch mollusks. There is ample evidence that sea hares and nudibranchs incorporate biologically active compounds in their tissues and use them for their own defense (Faulkner, 1992; Avila, 1995). Similarly, sacoglossans also accumulate or modify secondary metabolites from their diets. *Elysiella pusilla* (=*Elysia halimedae*) sequesters diterpenoids from its food alga *Halimeda macroloba* and uses them as defense against fish predators (Paul and Van Alstyne, 1988). The sacoglossan

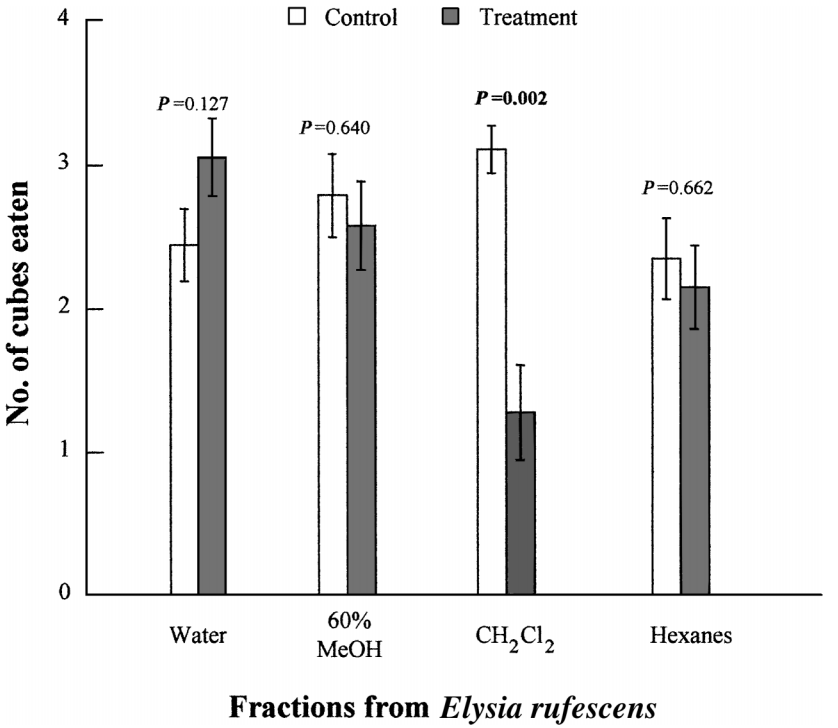

FIG. 4. Feeding deterrence of fractions from the sacoglossan *Elysia rufescens* towards natural fish predators in the field. Bars and statistical values as in Figure 3. The aqueous (water), 60% methanol (MeOH), methylene chloride (CH_2Cl_2), and hexanes fractions were all tested at their naturally occurring concentrations.

Oxynoe panamensis feeds on the chemically defended alga *Caulerpa sertularoides*, from which it incorporates caulerpin and caulerpicin (Doty and Aguilar-Santos, 1970). Chlorodesmin, a diterpenoid from the green alga *Chlorodesmis fastigiata*, significantly deters feeding by some herbivorous fishes (Paul, 1987; Wylie and Paul, 1988). However, the sacoglossan *Cyerce nigricans* specializes on feeding on *Chlorodesmis fastigiata* (Hay et al., 1989), from which it incorporates chlorodesmin. Although the sacoglossan is chemically defended, chlorodesmin does not account for the deterrent properties of the mollusk (Hay et al., 1989). Our data support a deterrent role for the metabolites ingested by *Elysia rufescens* from *Bryopsis* sp. Similarly, the sacoglossan *Costasiella ocellifera* sequesters the brominated compound avrainvilleol from its diet alga *Avrainvillea longicaulis* and uses it as a defense against fish predators (Hay et al., 1990).

The production of polypropionate metabolites by marine mollusks is well documented (Cimino and Sodano, 1993), including that by many sacoglossan

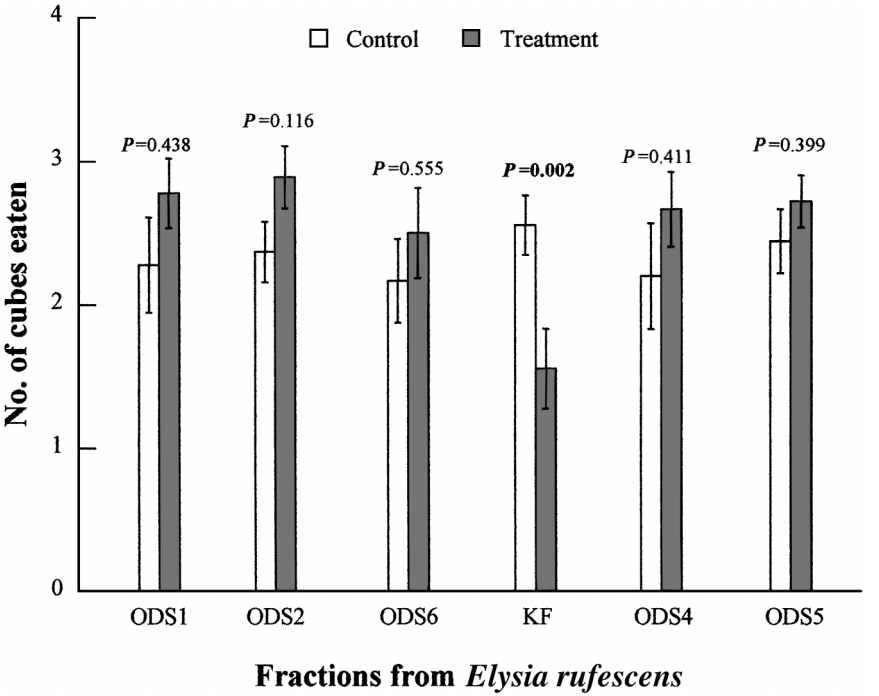

FIG. 5. Feeding deterrence of methylene chloride subfractions from the sacoglossan *Elysia rufescens* towards natural fish predators in the field. Bars and statistical values as in Figure 3. All subfractions were tested at their naturally occurring concentrations. Subfraction labels: ODS1 = 50% methanol, ODS2 = 70% methanol, ODS6 = all compounds (except kahalalide F) obtained from the 90% methanol subfraction, KF = kahalalide F, ODS4 = 100% methanol, ODS5 = chloroform–methanol–water (7 : 3 : 0.5), methylene chloride (CH_2Cl_2), See text and Figure 1 for more information on the partitioning procedure and isolation of kahalalide F).

species (Ireland and Scheuer, 1979; Ireland and Faulkner, 1981; Ksebati and Schmitz, 1985; Dawe and Wright, 1986; Roussis et al., 1990; Di Marzo et al., 1991; Vardaro et al., 1991; Gavagnin et al., 1996). Many polypropionates isolated from mollusks have strong antibacterial (Biskupiak and Ireland, 1983; Dawe and Wright, 1986), cytotoxic (Ksebati and Schmitz, 1985), and ichthyotoxic (Gavagnin et al., 1994b; Vardaro et al., 1991) properties, and crude extracts from species containing polypropionates significantly inhibit feeding by fish predators (Hay et al., 1989). Polypropionates are also present in the mucus of sacoglossans (Di Marzo et al., 1991; Vardaro et al., 1991). Deterrent secretions have been described in many opisthobranchs including sacoglossans (see review by Avila, 1995), and the presence of secondary metabolites in the mucus may be considered as indirect

evidence for the role of these compounds as a defensive mechanism against predators (Faulkner, 1992). The sacoglossan *Elysiella pusilla* (= *Elysia halimedae*) incorporates from its diet *Halimeda macroloba* the aldehyde halimedatetraacetate, which the sacoglossan reduces to its corresponding alcohol and incorporates in high concentrations in its body, mucus, and egg masses (Paul and Van Alstyne, 1988). The alcohol deters feeding by fish predators at natural concentrations (Paul and Van Alstyne, 1988). Polypropionates might function similarly, although experimental data on the sacoglossan *Cyerce nigricans* failed to support a deterrent role for polypropionates (Hay et al., 1989; Roussis et al., 1990), and further research is necessary to establish their role against predation. Whether polypropionates play other biological or ecological roles is uncertain. There is evidence supporting the involvement of cyercenes in the regenerative processes after autotomy of body parts in the sacoglossan *Cyerce cristallina* (Di Marzo et al., 1991), a process widely distributed among sacoglossans that has received little attention (Lewin, 1970; Di Marzo et al., 1991; Trowbridge, 1994).

Our bioassay-guided fractionation procedure shows that kahalalide F is the only compound responsible for the antipredatory properties of *Elysia rufescens*. In the mollusk, kahalalide F is the major metabolite out of a group of several compounds isolated from the mollusk and its dietary alga (kahalalides A–J) (Hamman and Scheuer, 1993; Hamman et al., 1996; Goetz et al., 1997). Kahalalide F is found in *E. rufescens* at concentrations between 0.4% (this study) to 1% (Hamann et al, 1996), which are several orders of magnitude higher than the concentration found in the alga (0.0005%, this study). Kahalalide F shows remarkable clinical bioactivity while the rest of the kahalalides lack significant cytotoxicity (Hamman et al., 1996; Goetz et al., 1997). Although toxicity and deterrent activity are not necessarily related (Pawlik et al., 1995), the diverse biological activity of kahalalide F shows that the same compound may exhibit both clinically oriented and ecologically oriented activities. Since we only performed bioassay-guided fractionation with the extracts from *E. rufescens*, the possibility that the minor, nontoxic kahalalides may help deter predators in *Bryopsis* sp. cannot be completely ruled out. Detailed TLC analyses of every fraction showed that all of the active algal fractions contained kahalalide F, while we found no traces of kahalalide F in the nonactive fractions.

It is worth noting that the concentration at which kahalalide F deters predators in the alga is very low (0.0005% of the algal wet mass). Even if all of the kahalalides contribute to this effect, their total percentage of the algal biomass is 0.0032%. Halimedatetraacetate, the major metabolite in *Halimeda macroloba*, is about 0.2% of the algal wet mass (Paul and Van Alstyne, 1988). Both the sacoglossan *Cyerce nigricans* and its host alga *Chlorodesmis fastigata* contain the cytotoxic diterpenoid chlorodesmin (Hay et al., 1989). Although the sacoglossan is chemically defended against fish predators, chlorodesmin is not responsible for the antipredatory properties of the crude extract when tested at natural

concentrations (less than 1% of the mollusk dry mass) (Hay et al., 1989). Two pyrones from the same sacoglossan species accounted for 0.9% and 0.45% of the dry mass of the mollusk and also failed to account for the repellent properties of the crude extract (Roussis et al., 1990). Because of their low concentrations, minor compounds may be easily overlooked in marine chemical ecology, yet they may play a determinant role in the biology and ecology of benthic organisms. The killer sponge *Dysidea* sp. is chemically defended against fish predators (Thacker et al., 1998). However, the major compound, 7-olepupuane, does not account for the total activity of the extract, suggesting that either addition or synergism of other minor compounds enhances the activity of the major compound (Thacker et al., 1998). Our study may be an example of how minor compounds (kahalalide F, 0.0005% of the algal mass) account for the activities detected in the whole extract.

Elysia rufescens is a highly cryptic but chemically defended species. In fact, *E. rufescens* may have evolved a variety of defensive mechanisms to reduce the chances of predation. We showed that *Bryopsis* sp. is a chemically defended alga, that may provide the sacoglossan an associational refuge (Hay et al., 1990; Hay, 1992; Duffy and Hay, 1994). By feeding on *Bryopsis* sp., *E. rufescens* sequesters algal chloroplasts and makes itself highly cryptic. However, predation may be high on cryptic organisms (Trowbridge, 1994), so the acquisition of other defensive strategies may expand the benefits of crypsis. *E. rufescens* sequesters the antipredatory compound from *Bryopsis*, accumulates the compound up to several times above the concentration in the alga, and becomes chemically defended itself. Moreover, *E. rufescens* releases the antipredatory compound into its mucus, which may be considered as a defensive mechanism to deter predators (Lewin, 1970; Jensen, 1984; Trowbridge, 1994). Predation is an important factor influencing mortality in benthic systems (Lubchenco and Gaines, 1981), and several mechanisms may work together with the same goal. Predator–prey relationships are important processes in marine benthic communities. Many of these relationships are chemically mediated interactions between predators and their prey. By investigating these associations, we will broaden our understanding of the biology and ecology of benthic organisms and the factors that affect the evolution of these predator–prey interactions.

Acknowledgments—We thank D. Galario, D. Ginsburg, C. Lacy, T. Mau, Y. Nakao, C. Nguyen, J. Starmer, and W. Yoshida for their field and laboratory assistance and M. Dunlap and A. Kay for the sacoglossan identification. We also thank staff members of The University of Guam Marine Laboratory and The University of Hawaii Chemistry Department for providing not only their facilities but also a nice environment in which to work. Comments from two anonymous reviewers greatly improved this manuscript and are sincerely appreciated. Abstract—The spatiotemporal information in chemical signals provides critical information for organisms during chemical orientation. Information in chemical signals is influenced by the hydrodynamic conditions of the environment. Hydrodynamically distinct environments will contain different types of information, which will influence how organisms orient. This study was designed to examine how the orientation behavior of the brown bullhead (*Ameiurus nebulosus*) is influenced by flow regime. The experiment was conducted in a flume under two different flow conditions. Treatments consisted of control (no odor) and plain gelatin (odor). Percent success, swimming speed, turning angle, heading angle, heading angle upstream, and net-to-gross ratio were analyzed. Brown bullheads were 100% successful in finding the odor source under no flow and 57% successful in flow. Bullheads swam differently in the no-flow condition when compared to the flow condition. Since, these fish did not orient the same under different flow conditions, it appears that hydrodynamics plays a role in shaping their behavior.

Key Words—Chemical orientation, catfish, swimming behavior, hydrodynamics, chemical signal.

INTRODUCTION

For many organisms, chemical signals are important sources of information that influence behaviors such as orienting toward food, attracting mates, avoiding predators, or determining social status (Lewis and Gower, 1980; Croll and Chase, 1980; Carr, 1988; Tierney and Atema, 1988; Breithaupt and Atema, 1993; Chivers and Smith, 1993; Sorensen and Scott, 1994; Hazlett, 1994; Chivers et al., 1996; Zippel et al., 1997; Bradbury and Vehrencamp, 1998). For instance, starfish are able to

0098-0331/01/1100-2301$19.50/0

respond to a chemical stimulus and orient toward a food source in no-flow conditions (Moore and Lepper, 1997). Ovaries from female frillfin gobies develop a chemical that elicits courtship behavior in males, even in the absence of females (Tavolga, 1956). Western toad tadpoles (*Bufo boreas*) are able to recognize predator odors. They will display antipredator behavior when exposed to chemical cues from familiar predators, but will not display this behavior toward unfamiliar predators (Kiesecker et al., 1996). Yellow bullheads have been found to use chemical signals in recognizing individuals and associating odors with rank in hierarchies. Subordinate fish will avoid an area of an aquarium where water from the tank of a dominant fish has been introduced, even though the dominant fish is not present (Bardach and Todd, 1970).

One of the better-studied aspects of chemical signals is chemical orientation. Chemical orientation is defined as the directional movement of an organism toward an odor source (van der Steen and Maat, 1979). This orientation behavior is also observed in a variety of terrestrial organisms (Kennedy, 1986; Belanger and Arbas, 1998; Willis and Arbas, 1998; Takken et al., 1997). Aquatic organisms, in particular, have the ability to orient toward food, mates, home streams, parents, or offspring (Bardach et al., 1967; Tosi and Sola, 1993; Atema et al., 1980; Stabell, 1992; Weissburg and Zimmer-Faust, 1994). During orientation, fish exposed to chemical stimuli, such as food, display characteristic maneuvers that help them locate the odor source. Dogfish use a figure-eight pattern when searching for food (Parker, 1912), whereas sea robins use an s-shaped or zigzag search pattern when swimming up an odor gradient (Bardach and Case, 1965).

In order for chemical orientation to occur, an organism must be stimulated by a putative cue and must extract directional and distance information from it. Distance and direction information can be gained from a variety of cues, such as wind, flow direction, electroreception, and chemicals (Able, 1991). In the case of a chemical signal, there are two main characteristics that can provide information: quality and quantity of the signal. The quality is the type of chemical compounds that are stimulatory for that organism. It provides the organism with information on source type, i.e., food, predator, and reproductive condition (Sorensen et al., 1989; Schwenk, 1995; Carr et al., 1996; Rasmussen and Schulte, 1998; Swaisgood et al., 1999). For example, gravid garter snake females release nonvolatile methyl ketones from cutaneous glands along the ground as they travel, providing information to males, which follow the females (Mason et al., 1989). Cichlids secrete proteinaceous mucus from their bodies, which maintains contact between the brood and parents, as well as provides food for the young (Barlow, 1974). Several common metabolites of low molecular weight have been found to be feeding stimulants (Carr, 1988). Other types of metabolites such as polyketides or alkaloids are feeding deterrents (Carr, 1988).

The quantity of chemical signals and their distribution in time and space can provide distance and direction information (Atema, 1988; Moore and Atema,

1991; Moore et al., 1994; Murlis, 1986, 1987; Murlis et al., 1992; Vickers, 2000; Zimmer-Faust et al., 1995). At macroscopic size scales, the spatial and temporal information in a chemical signal is structured primarily by fluid flow (Moore et al., 1994; Vickers, 2000). When an odor is released, the concentration fluctuates, creating a signal that is patchy in space and time. This patchiness consists of intermittent plumes in the water column with patches of high, low, or zero odor concentration. As the odor plume moves away from the source it spreads horizontally and vertically. (Murlis and Jones, 1981; Zimmer-Faust et al., 1995; Finelli et al., 1999; Moore et al., 2000). The degree of patchiness is influenced by the hydrodynamic conditions of the particular flow environment (Moore et al., 1994; Weissburg, 1997). Environments with different flow characteristics will consequently have different signal characteristics (Moore et al., 2000). In order to orient efficiently, animals need olfactory behaviors and physiological properties of sensory systems that can extract information from odor fluctuations (Moore et al., 1994; Atema, 1995).

Catfish provide an excellent opportunity to address questions concerning the influence of flow on orientation behavior. Ictalurid catfish are a model system for examining the role of chemical signals in orientation. Many of the species are nocturnal in habit and found in habitats of slow-moving or still waters with poor visibility, whereas others are found in turbulent flow conditions. For example, brown bullheads (*Ameiurus nebulosus*) are typically found in no-flow or low-flow conditions (backwater areas of rivers, ponds, and lakes). These fish are morphologically suited for environments dominated by chemical information (Bardach and Todd, 1970). Their bodies are covered with thousands of external taste buds, as well as dense concentrations on the barbels (Bardach and Todd, 1970; Atema, 1971). The physiological aspects of olfaction and gustation in channel catfish and bullheads have been extensively studied (Caprio and Raderman-Little, 1978; Caprio and Byrd Jr., 1984; Caprio et al., 1989; Miyamoto et al., 1990; Kang and Caprio, 1991; Restrepo et al., 1990; Kanwal and Finger, 1997). However, the behavioral aspects of orientation have not been thoroughly studied. The purpose of this study was to test the hypothesis that catfish, which are adapted to a particular hydrodynamic condition, orient more successfully to an odor source in their normal hydrodynamic environment than in one to which they are not adapted.

METHODS AND MATERIALS

Animals. Brown bullheads (*Ameiurus nebulosus*) were bought from Northeast Aquatics and placed in community tanks for observation over several months. This observation time allowed the fish to become accustomed to their new environment. The mean size for bullheads was 21 ± 0.72 cm. Fish were kept on a reversed 12L : 12D schedule. Fish from the community tank were randomly caught and

isolated in 10-gal tanks (25 × 31 × 51 cm) for at least two weeks before experimentation. Temperature ranged from 55 to 60°F in the winter and to 65°F in the summer. Both community and isolation tanks were routinely cleaned. Diet consisted of goldfish food (Wardley Pond Ten), fish (whitefish or pollack), and catfish food (Net Profit fish food). Fish were fed with the main light on either late morning or early afternoon. Past research has shown that brown bullheads have the ability to exhibit diurnal phasing, showing no or less-pronounced negative phototactic behavior (Eriksson 1978; Eriksson and van Veen, 1980). It has also been shown that, in nature, when there is a rise in water level, catfish will forage during the day (Pflieger, 1975). Valentinčič et al. (1994) reported that channel catfish fed uninhibitedly in a lighted room within a week of being moved to a test tank.

Test Arena. All orientation experiments were conducted in a plywood flow tank (244 × 57.3 × 62 cm; Figure 1). The test section of the flume was 212 cm long. The start gate was placed at the downstream section of the tank. This holding area was 26.5 × 58 cm. The odor source was placed at the upstream section of

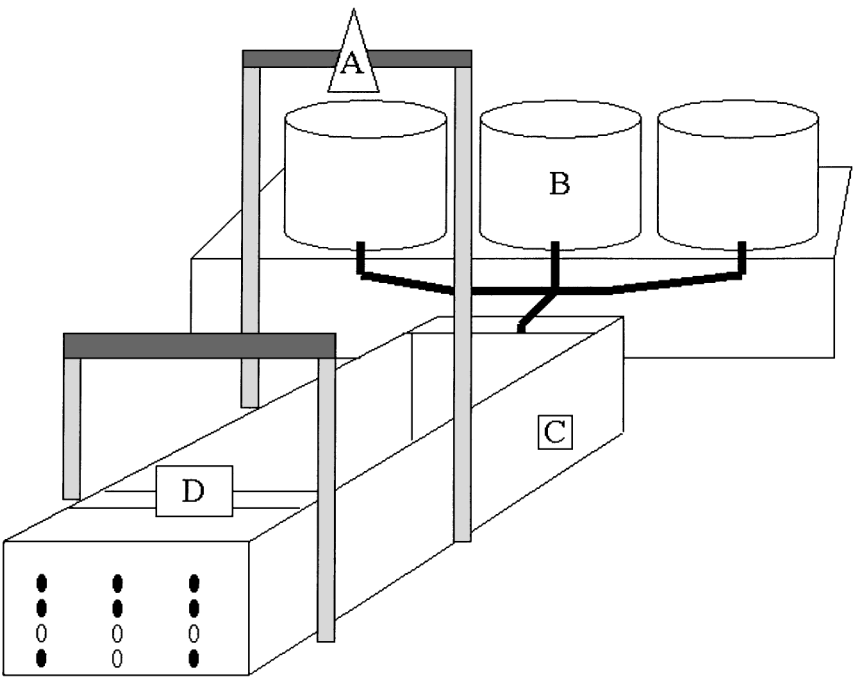

FIG. 1. Diagram of the experimental tank. The triangle with A shows camera location; B represents the head tanks. The flow tank is labeled C and the start gate is labeled D.

the tank, which was placed at least 15 cm away from the upstream collimator. The source was 29 cm from each side of the tank and 22 cm from the head collimator. The odor source was 197 cm away from start gate. This allowed test subjects to move beyond the odor source. Water was kept at a constant depth of 16 cm. Flow velocities were calculated by visually timing a neutrally buoyant object's movement over a given distance five times and taking the average time in seconds. Flow velocity during the flow trials was 4.2 ± 0.88 cm/sec and 0.0 ± 0.0 cm/sec during the no-flow trials. Flume water was stored in head tanks above the flow tank and was allowed to age for two days before use. Head tanks held a total of 115 gal for refilling the flow tank during no-flow trials and providing the water for the gravity feed in the flow trials. After each trial, the tank was drained completely and fresh and distilled water was used to rinse down the tank before the next trial.

Odor Source. Treatments consisted of a control (empty mesh bag), plain gelatin, or fish gelatin. Gelatin has been used as a source of food and a method of delivery for specific amino acid supplementation to test subjects (Keen, 1982; Sarwar and Ratnayake 2000; Buentello and Gatlin III, 2000). Preliminary data showed that plain gelatin produced a stronger response from the research subjects than fish gelatin. Those that did respond to the fish gelatin did not show any overall difference in swimming parameters, and so the data with the fish odor were dropped from further analysis. The odor sources were placed into a mesh bag, which was tied to the head collimator by a 16-cm piece of clear fish line. Weights (6 g) were used to hold down the bag. Four Knox gelatin packages were added to four cups of hot water and placed into a plastic container (30×16 cm). This was stirred together until everything was mixed. It was then placed into the refrigerator. Gel blocks ($2.5 \times 4 \times 2$ cm) were cut from the larger dish of prepared gelatin. The odor treatment was placed into the tank at least 30 sec before the start gate was opened.

Dye Trials. Dye trials were carried out for the no-flow treatment to quantify how fast the odor moved in the flume. 1-$\times$ 2-cm squares were measured, drawn, and numbered on the floor of the tank with a permanent marker. Grid sheets were used for visual marking of the odor trail during a 5-min trial. The dye gel block was made following the same recipe as the odor gel blocks (Moore and Lepper, 1997). The dye gelatin was cut into 1- $\times$ 2-cm squares instead of the size used for the experiment because the dye blocks kept breaking in half. Once placed into the flume, dye filaments would come off the gel block before timing and dissipate quickly, moving about the tank. Once the block was sitting on the bottom of the tank, timing started and the number of 1- $\times$ 2-cm squares covered in dye were marked out on the grid sheet until the 5-min experimental period was up. The number of squares was counted and the average dye movement in no flow was calculated to be 0.056 cm^2/sec.

Experimental Design. Fish were starved for two days before they were used in a trial, and each was given a week between tests to avoid any learning biases. Separate groups were tested for flow ($N = 7$) and no flow ($N = 7$); however, a single fish was randomly tested under all odor conditions within a single flow condition.

Presentation of odor was randomized and each fish was given a week between trials. A randomly chosen fish was placed into the start gate section of tank and given 20 min to acclimate. After 20 min fish were resting on the bottom of tank in the start section. The start gate was slowly opened and left open so fish had the option to stay in this section. The acclimation time was chosen based on other fish research (Bardach et al., 1967; Ellingsen and Døving, 1986; Nevitt, 1991; Giaquinto and Volpato, 1997; Smith, 2000), which examined a variety of different acclimation times and fish behaviors. A camera (Quazar model VM-52 SVHSC CCD) was set 3 ft above the flow tank and connected to a Hi-Fi Stereo Hi 8 recorder (NTSC EV-C100). Recording was carried out under red lights. The no-flow trials were taped for 20 min, and the flow trials were taped for 4.5 min or until the catfish first hit the odor source. Behavioral trials were conducted until an animal successfully located the odor source. A trial was defined successful when the test subject touched the odor source with its mouth.

Data Analysis. The Peak Motus Motion Analysis System was used to digitize orientation paths under both flow conditions. A fish's position was digitized every second. Animals took an average of 30 sec in no flow and 32 sec in flow to locate the odor source. Therefore, control groups were digitized for 30 sec for the no flow and 32 sec for the flow. The coordinate (x, y) data were then put into an in-house standard orientation template to calculate speed, turning angle, heading angle, heading angle upstream, and net-to-gross ratio (Moore et al., 1991) (Figure 2). When calculating the angles, the right and left angles were not differentiated; hence all angles fall between 0 and 180°. This type of analysis allows us to perform statistical analysis with standard linear statistics (e.g., MANOVAs). Circular statistics are slightly more conservative than MANOVAs. Performing an analysis using linear statistics allows us to analyze the fine details of fish movement patterns. The consequences for a linear analysis is that it is possible for a zig-zag pattern typically found in moths to have a mean heading angle of 60°. For statistical analysis, a single mean for each parameter was calculated from the total orientation path. The total path means were subsequently used for all statistical analysis as the data points that were put into the two-way MANOVA. A two-way MANOVA was used to analyze speed, speed towards source, turning angle, heading angle, heading angle upstream, and net-to-gross ratio for bullheads. All significant P values were set at 0.05. A Fisher's exact test was used to analyze percent success.

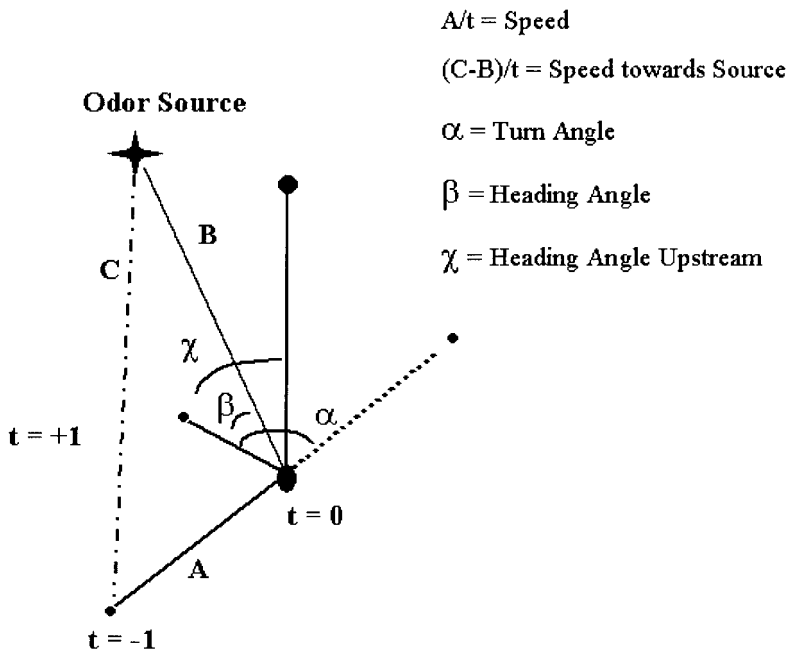

FIG. 2. Diagram shows three successive positions ($t = -1$, 0, and $+1$:•) on a hypothetical orientation path used to define behavioral parameters. The dashed line represents the catfish's projected path (if it continued in a straight line), from which a turn angle value (α) at point $t = 0$ is calculated. The solid line (B) represents the straight line to the odor source (four point star) from which heading angle relative to the odor source (β) is calculated. The unlabeled line represents the path that is straight upstream, from which the heading angle relative to upstream (χ) is calculated. Swimming speed (A) is the distance moved from time point $t = -1$ to $t = 0$. The difference between distance to the odor source at time $t = -1$ (dash–dot line, C) and distance to the odor source at time $t = 0$ (solid line, B) is the swimming speed toward the source.

RESULTS

Success at Finding Odor Source. Brown bullheads were successful in locating the odor source under both flow and no flow conditions. Seven of seven brown bullheads (100%) found the odor source under no flow. Four of seven bullheads (57%) were successful in finding the odor source under flow. The Fisher exact test showed no significant difference between the two odor treatments (Fisher exact, one-tailed; $P > 0.09$).

Qualitative Description of Orientation Behavior. In no flow, catfish swam in a more linear fashion when odor was present. In general, fish made fewer turns

while swimming toward the odor source. Fish were seen mouthing the mesh bag once they found the odor source. During the control trials, fish swam around the tank and did not investigate the mesh bag. They could be seen swimming along the edges more than individuals in the odor trials. The catfish pathway was more circuitous under flow for both treatments. An example of swimming paths for each treatment is illustrated in Figure 3.

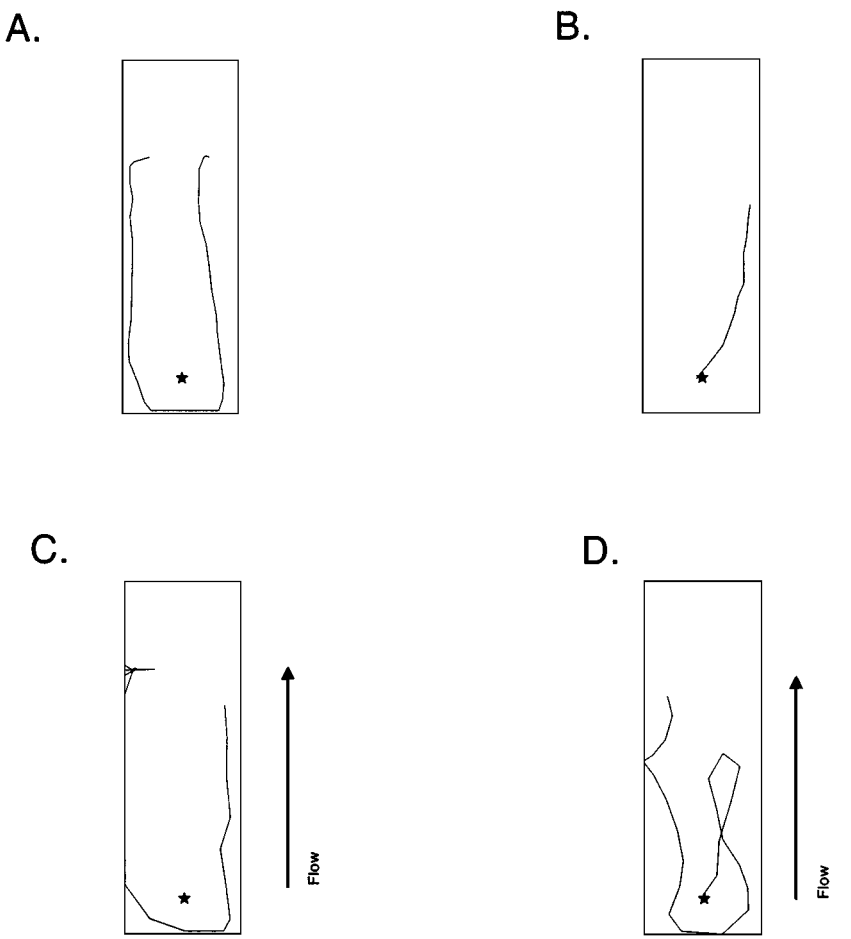

FIG. 3. (**A**) A representation of the path made by a bullhead under no flow and no odor source. (**B**) A typical path made by bullheads with an odor source in no flow. (**C**) A representation of the path made by a bullhead under flow without an odor source. (**D**) A typical path made by bullheads with an odor source under flow. The star represents the odor source (or contial), and the arrows illustrate the direction of the flow.

General Effect. Brown bullheads oriented differently when an odor was present (MANOVA, Rao's $R = 7.04$, $P < 0.01$). They also oriented differently under flow and no flow (MANOVA, Rao's $R = 5.59$, $P < 0.02$). This effect was seen in the net-to-gross ratio, swimming speed, heading angle upstream, heading angle toward source, and turning angle toward source. The post-hoc analysis provided a more detailed view of this behavior.

Effect of Flow and Odor on Swimming Speed. Brown bullheads swam significantly faster under flow (6 ± 2 sec) conditions than during no flow (14 ± 2 sec) in the control trials (Figure 4; Newman-Keuls post-hoc, $P < 0.02$). In addition, brown bullheads also swam faster when stimulated with an odor source in flow (13 ± 1 sec) than no flow (19 ± 1 sec) (Newman-Keuls post-hoc, $P < 0.005$).

Orientation Paths. Brown bullheads swam a straighter path when an odor was present (indicated by a higher net-to-gross ratio) in the no flow conditions (0.85 ± 0.1) (Figure 4; Newman-Keuls post-hoc, $P < 0.001$) as compared to the flow condition (0.19 ± 0.04). Brown bullheads swam more randomly in no flow (0.22 ± 0.09) and flow (0.10 ± 0.01) controls (blanks) (indicated by the lower net-to-gross ratio) (Newman-Keuls post-hoc, $P > 0.05$). Turning angle toward source was lower for brown bullheads during odor trials in no flow ($16 \pm 3^\circ$) condition than flow ($35 \pm 2^\circ$) (Figure 5; Newman-Keuls post-hoc, $P < 0.002$). However, there was no difference in turning angle for the control trials in no flow ($24 \pm 8^\circ$) or flow ($38 \pm 7^\circ$) (Newman-Keuls post-hoc, $P > 0.05$). The heading angle relative to an odor source measures the accuracy of an organism's movement toward an odor source. Brown bullheads had a lower heading angle while orienting in no flow ($23 \pm 9^\circ$) than flow ($68 \pm 4^\circ$) condition (Figure 5, Newman-Keuls post-hoc, $P < 0.001$). The control group in no flow ($55 \pm 15^\circ$) did not differ from the control group in flow ($76 \pm 4^\circ$) for heading angle toward source (Newman-Keuls post-hoc, $P > 0.05$). Brown bullheads had a lower heading angle upstream when orienting to an odor source in no flow ($23 \pm 10^\circ$) condition (Figure 5, Newman-Keuls post-hoc, $P < 0.02$) as compared to flow ($61 \pm 10^\circ$). There was no difference in heading angle upstream between the control group in no flow ($57 \pm 16^\circ$) and flow ($75 \pm 5^\circ$) (Newman-Keuls post-hoc, $P > 0.05$).

DISCUSSION

The results of this experiment indicated two important conclusions for catfish orientation. First, it confirmed our expectations that brown bullheads would orient more successfully under no-flow conditions compared to flow conditions. Although not significantly different, brown bullheads appeared to have a higher success rate in finding the odor source under no flow (100%) than flow (57%). These trends are in the direction of our hypothesis, but the conservative nature of the Fisher exact test does not show significant differences between these two

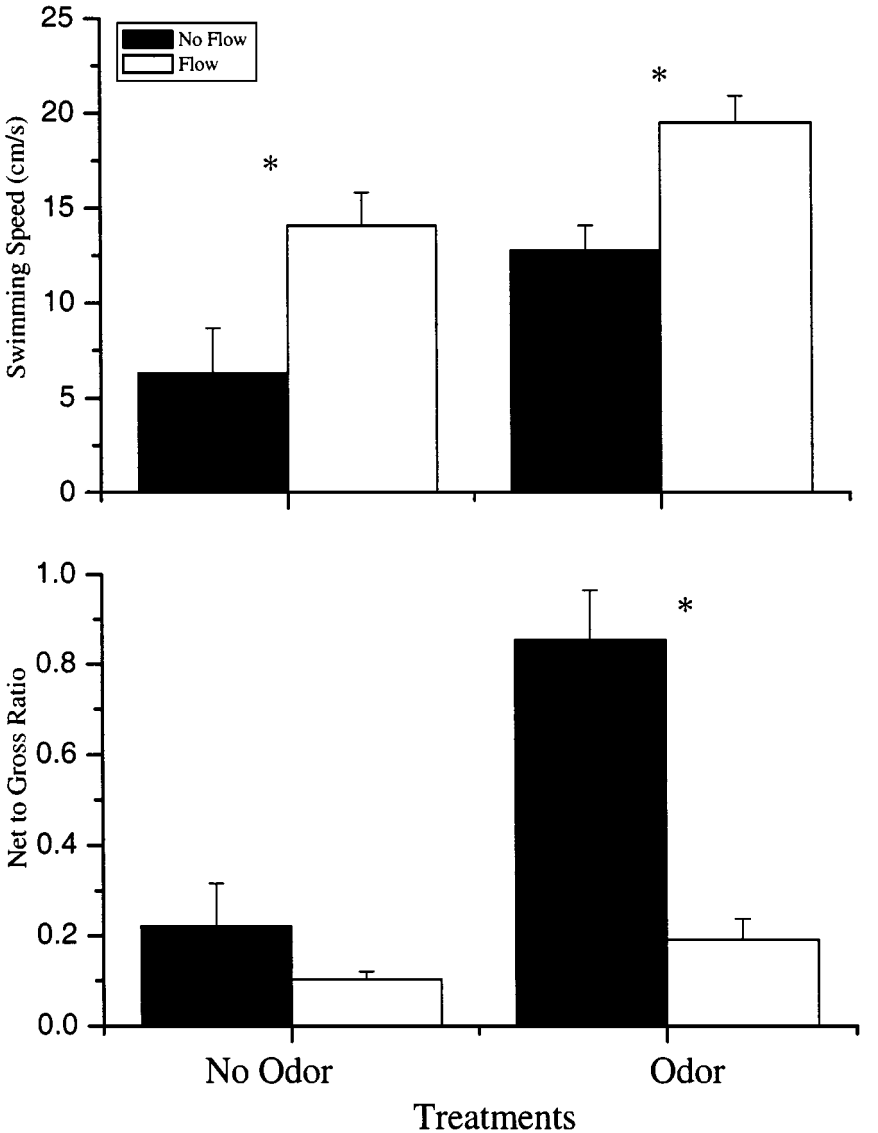

FIG. 4. The upper graph illustrates the swimming speed of bullheads in no-flow (black) and flow (white) conditions. The bottom graph is the net-to-gross ratio of bullheads in no flow (black) and flow (white). An asterisk indicates a significant difference using MANOVA followed by post-hoc test. $N = 7$ for each flow treatment.

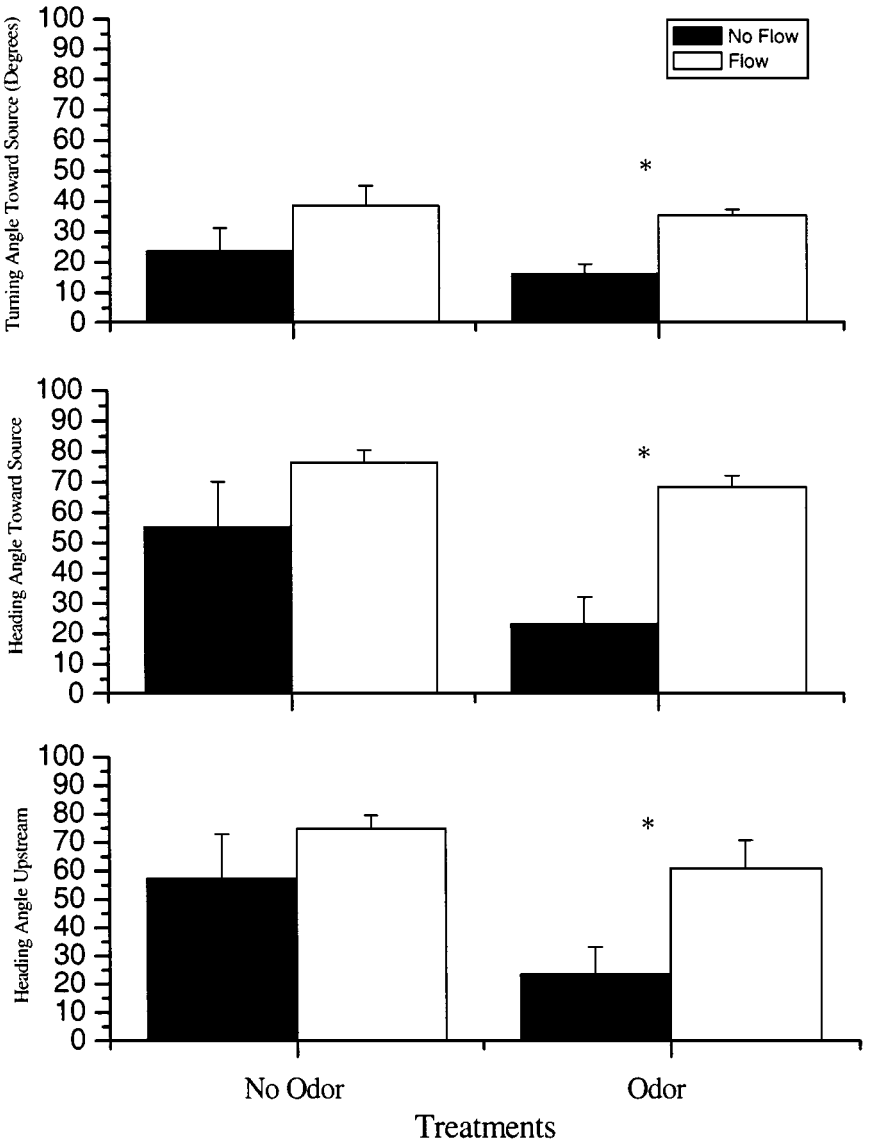

FIG. 5. The upper graph illustrates the turning angle of bullheads in no-flow (black) and flow (white) conditions. The middle graph is the heading angle toward the source of bullheads in no flow (black) and flow (white). The bottom graph shows the heading angle relative to upstream of bullheads in no-flow (black) and flow (white) conditions. The asterisk indicates a significant difference using a MANOVA followed by a post-hoc test. $N = 7$ for each flow treatment.

treatments. We expect either a less conservative test (chi squared) or a larger number of replicates would show significance. Second, it showed that bullhead orientation was influenced by changes in the flow conditions. A statistical interaction was found between the flow/no-flow treatment and the odor treatment with regard to swimming speed. During odor stimulation, bullheads swam faster in the flow condition when compared to the no-flow condition. Since both flow and odor modulated the bullhead's orientation response, this statistical effect suggests that bullheads may use some type of an odor mediated rheotactic response.

The orientation paths exhibited by bullheads during chemical stimulation were different for the flow and no-flow conditions. Bullheads had more linear orientation paths under no-flow conditions than in flow conditions. Post-hoc analysis showed that bullheads did not swim differently in no-flow or flow in the absence of odor. Other spatial aspects of orientation, such as turning angle, heading angle, and heading angle upstream were smaller under no flow when compared to flow conditions. This indicates that bullheads made smaller course corrections when orienting to the odor source under no flow than under the flow condition. Larger angles in the control trials indicate greater course correction, therefore illustrating a less directed swimming. There was no difference between flows in any of these parameters when odor was absent from the trials. Overall, the orientation angles and the net-to-gross ratio indicated that bullheads swam directly to the odor source under no flow. These results suggest that bullheads may be performing a gradient type of search in no-flow conditions, which supports past research on catfish (Bardach et al., 1967). The no-odor results also indicate that the shape of the tank did not influence the swimming behavior of the fish. If the tank were to constrain orientation behavior, we would expect that both no-odor controls would show similar spatial effects.

In the odor/flow treatment, catfish could be gathering information by the distribution of the odor patches and possibly some information on flow direction. Bullheads have been found to be sensitive to odor concentration differences (Johnsen and Teeter, 1980) and have also been found to orient successfully under no-flow to a liquid odor source (Bardach et al., 1967). The odor source used in this study diffused slowly based on dye trials, but patches of odor source came off while placing the source in the tank. These patches could have diffused out in the water column, setting up patches of odor for the bullheads to encounter as they come out of the start gate. Gelatin has several amino acids (Bohidar, 1997; Lüpke and Brückner, 1998) [such as arginine and alanine (Caprio et al., 1993; Ivanova and Caprio 1993; Valentinčič and Caprio, 1994)] that have been found to be stimulatory to catfish.

In flow conditions, turbulence directly impacts odor distribution and indirectly influences an animal to modify its locomotor behavior during orientation (Weissburg and Zimmer-Faust, 1993). Eddies that are formed by turbulence interact

with the odor plume, influencing the spatial and temporal fluctuations of the odor concentration (Moore and Atema, 1991). In addition to flow speed, substrate can also influence the hydrodynamics of a habitat. In a study detailing the influence of habitat on chemical signal structure, Moore et al. (2000) found that chemical signals have different spatial and temporal information on different substrates such as sand, cobbles, or gravel. Presumably, the level of turbulence in a system directly impacts the frequency of odor pulses that are measured in an odor plume (Moore et al., 2000). The modifications in locomotor behavior seen in the brown bullheads between the flow, and no-flow, could be due to either differences in the odor plumes or the flow affecting their swimming ability. Still, the results seem to indicate that the swimming behavior pattern seen is related to the distribution of the odor and not the flow regime. There were no significant differences between the controls in any of the orientation parameters, except speed.

An important hypothesis that has been put forth and is being supported by several studies states that organisms should have sensory systems and behaviors that are adapted to the specific sensory conditions of their environment (Wehner, 1987; Atema, 1988; Moore et al., 1991; Endler, 1995; Huber et al., 1997; Weissburg, 1997; Endler and Basolo, 1998; Kotrschal et al., 1998; Schneider et al., 1998; Land et al., 1999; Persons et al., 1999; Poling and Fuiman, 1999; Schneider and Moore, 2000). From this hypothesis we could predict that organisms should perform behavioral tasks more efficiently or more successfully when presented with conditions that are similar to their natural habitats. If we alter environmental conditions that structure sensory information, we would expect to find either changes in behavior or decreased success in performing a specific behavioral task. We found both of these results with brown bullheads.

This phenomenon has also been found with regard to orientation behavior in other species. For example, blue crabs (*Callinectes sapidus*) traveled upstream and at higher speeds toward a food source (clams) in smooth-turbulent flows (Weissburg and Zimmer-Faust, 1994). These behaviors changed when turbulence shifted from smooth to rough. In this case, crabs were slower and made more frequent stops. It was also found that rheotactic and chemical information are necessary for crab orientation (Weissburg and Zimmer-Faust, 1994). Crayfish (*Orconectes rusticus*) are able to use information from the temporal and spatial distribution of chemicals to make directional decisions. Differences were found in how fast they located a food source, time spent moving, and how fast they moved on different substrates. These differences in orientation behavior were based on the hydrodynamics associated with chemical signal structure (Moore and Grills, 1999). In moths, pheromone pulse frequency determines flight form of males in two phylogenetically distant moths, a noctuid (*Heliothis virescens*) and a pyralid (*Cadra cautella*) (Vickers and Baker, 1994; Mafra-Neto and Cardé, 1994, 1998). These moths fly faster and straighter to sources of high-pulse frequencies and slower and more zigzag to sources of low-pulse frequencies. Finally, tsetse flies (*Glossina pallidipes*) show a

stepwise orientation approach, which allows them to assess wind direction between flight bursts (Bursell, 1984).

In summary, this study demonstrates that bullheads can orient successfully to an odor source and are successful under flow conditions that are similar to their natural environment. It also suggests that bullheads may be generalists in their orientation behavior. Since the spatial pattern of orientation was different in the two flow conditions tested, they may be able to switch search strategies depending on the flow condition and signal structure. This suggests that the hydrodynamic environment may be an important factor in the shaping of an organism's chemosensory behavior. However, further studies need to be done to distinguish if bullheads are really using different search strategies under different flow conditions. More studies are also required in order to understand how bullheads are finding the odor source under no flow.

EVIDENCE FOR USE OF CHEMICAL CUES BY MALE HORSESHOE CRABS WHEN LOCATING NESTING FEMALES (*Limulus polyphemus*)

CYNTHIA HASSLER and H. JANE BROCKMANN*

Department of Zoology
University of Florida
Gainesville, Florida 32611-8525

(Received March 21, 2001; accepted July 15, 2001)

Abstract—Horseshoe crabs come ashore in attached pairs during spring high tides to mate and nest on beaches of the Atlantic and Gulf coasts. Unattached males also come ashore and crowd around the nesting pairs as satellites and engage in sperm competition with the attached male. Females with no satellites and females with large numbers of satellites nest next to one another on the same tide. When females are removed and replaced by a cement model, satellite males continue to be attracted to the same location. Models over sites where females with many satellites had nested are more attractive to males than sites from which a female with no satellites had been removed or a site where no crab had been nesting recently. A second experiment demonstrated that males are responding to chemical cues. A sponge filled with seawater taken from below a female with many satellites and placed under a model female was more attractive to males than a sponge filled with seawater. This is the first demonstration that horseshoe crabs use chemical cues, in addition to visual cues, to locate mates.

Key Words—*Limulus polyphemus*, horseshoe crab, Merostomata, Xiphosura, pheromone, chemical cues.

INTRODUCTION

Chemical cues are used by a wide range of aquatic invertebrates to find food (Ache, 1972; Dunham et al., 1997; Zhou and Rebach, 1999), locate hosts (Mackie and Grant, 1974), identify predators and habitat (Krapf, 1986; Wudkevich et al., 1997; Hazlett, 2000), and recognize conspecifics (Caldwell, 1985; Karavanich and Atema, 1998). Identifying and locating mates with chemical cues is well known

among arthropods (Ache, 1987; Krieger and Breer, 1999), including crustaceans (Atema and Engstrom, 1971; Dunham, 1978; Borowsky, 1985, 1991; Gleeson, 1991; Oh and Dunham, 1991; Stanhope et al., 1992; Hazlett, 1996; Frey et al., 1998; Bushmann and Atema, 2000), spiders (Kaston, 1936; Tietjen and Rovner, 1982; Pollard et al., 1987; Evans and Main, 1993) and scorpions (Gaffin and Brownell, 1992). Although horseshoe crabs (*Limulus polyphemus*) are known to use chemical cues to identify food (Barber, 1956, 1961), no study has demonstrated a role for chemical signals in mate recognition.

Pairs of horseshoe crabs come ashore on spring high tides to lay and fertilize eggs (Shuster, 1982), while lone males roam the beach forming groups around the nesting pairs. A pair is formed when a male grasps a female's terminal spines with his claws (Botton et al., 1996) and rides to the nesting beach with her. A group forms when an unattached male contacts a nesting pair (Rudloe, 1980; Barlow et al., 1986) and becomes a "satellite" of that pair (Figure 1). Satellites push on attached males but rarely displace them (Brockmann, 1990). Paternity analyses demonstrate that the satellite males are engaging in sperm competition with the attached male and with other satellite males that may be present (fertilization is

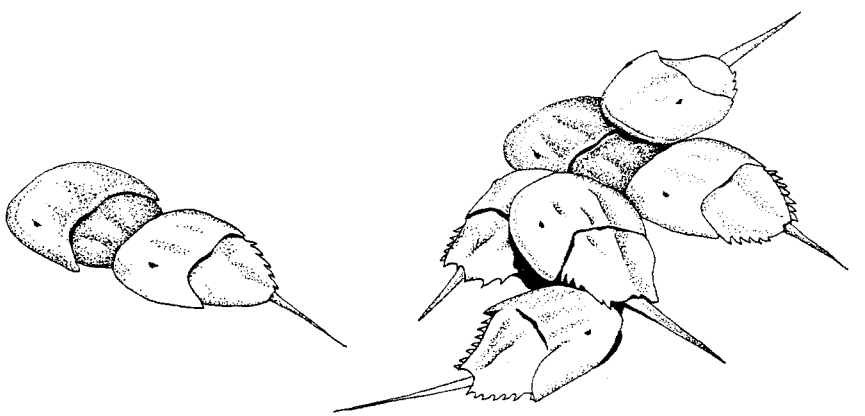

FIG. 1. Pairs of horseshoe crabs with many satellites (right) nest next to pairs with no satellites (left) (drawing by Jennifer Piascik from slide taken at Seahorse Key, Florida). In the experiment to test the role of chemical cues in attracting satellite males, we removed a pair with many satellites and a pair with no satellites and replaced them with cement castings of females (models). Satellite males approached and remained with a concrete model that was pushed into the sand over the spot where a nesting female with many satellites had been removed (along with her associated satellites). The newly arriving males were individuals that had been searching the beach for nesting pairs and had not nested with this female previously.

external and occurs underneath the female as she is laying eggs) (Brockmann et al., 1994). Satellites are remarkably successful at fertilizing eggs if they are in the right position and even those in large groups may have some success (Brockmann et al., 2000). Satellite male groups are distributed unevenly: some nesting pairs have many satellites, whereas others have none (Brockmann, 1996). Larger females and those in better condition have more satellites than smaller, older individuals (Brockmann, 1996; Agresti, 1996). In order to understand the formation of male mating groups, we examined the proximate cues used by males to locate nesting females on the beach.

What are the likely cues used by unattached males to find nesting pairs? By using cement castings of females, Barlow et al. (1982, 1984, 1987, 1988) demonstrated that males use visual cues when locating unattached females offshore. Using a camera-tracking system, he showed that males veer toward other crabs when within visual range (Powers et al., 1991). The crabs can see other crabs or objects resembling crabs under a wide range of conditions including at night (Herzog et al., 1996) and when contrast is low (Passaglia et al., 1997a,b). Although unattached males are, on average, older than attached males and their surfaces, including their eyes, are in poorer condition (Brockmann and Penn, 1992), all show visual activity (Wasserman and Cheng, 1996). Clearly, visual cues are used by unattached males to locate females, and they are probably also used to locate pairs nesting on the beach, just as females use visual cues to avoid the nesting sites of other females (Barlow et al., 1982; Powers et al., 1991).

Several pieces of evidence suggest that chemical cues may also be involved in locating mates. Satellite males walk in circles around the depression left on the beach by recently departed nesting females (Cohen and Brockmann, 1983; Hassler, 1999). Some of these are males that were involved in the satellite group, but some are not (authors' personal observation). Furthermore, when all satellites are removed from a nesting pair, newly arriving unattached males (not those that were removed) are more attracted to those pairs that had many satellites than to those that had few (Brockmann, 1996). Horseshoe crabs have chemoreceptors on all limbs, on the spines of the gnathobases and chilicerae, and on the flabellum (Patten, 1894; Barber, 1961; Hayes, 1966, 1971, 1985; Hayes and Waterman, 1969; Wyse, 1971). Strong and highly specific chemoreceptive responses toward amino acids from prey items have been recorded from these structures (Barber, 1951, 1953, 1956; Wyse, 1971; Hayes and Barber, 1982). Taken together, then, it seems reasonable to suggest that male horseshoe crabs may be using chemical cues, in addition to visual cues, to locate nesting pairs. Patten (1894), Hanström (1926), Pomerat (1933), and Kaplan (1988) speculated that olfactory cues may be used by male horseshoe crabs to find females, but no data were collected. By using cement castings of females in the field, we provide the first experimental evidence that unattached male horseshoe crabs use chemical cues to locate mates.

METHODS AND MATERIALS

Study Sites. Two beaches were used in this study: Seahorse Key (SHK), an island on the west coast of Florida in the northern Gulf of Mexico, approximately 4 km from Cedar Key, Levy County, Florida (29°06′N, 83°04′W) and Breakwater Harbor (BWH) at the mouth of the Delaware Bay in Cape Henlopen State Park (38°45′N, 75°05′W), Lewes, Delaware (Penn and Brockmann, 1994). Horseshoe crabs at SHK nest each spring along a 2-km stretch of low-energy, fine sand beach on the south shore of the island. At BWH they nest along a 4-km section of low-energy, sand and gravel beach on the south side of the harbor. We collected data on the distribution of pairs and group sizes during alternate weeks (new and full moon): at SHK from March 16 to May 8, 1996, and at BWH from June 17 to 30, 1996. We conducted experiments on the responses of unattached males to models of nesting females during alternate weeks from June 6 to July 26, 1997, at BWH.

Location of Nesting Pairs. During four tides in Florida and six tides in Delaware, we surveyed a 100-m stretch of beach (divided into ten, 10-m sections) continually from the peak of the high tide (as predicted by NOAA tide tables) until no crabs remained on the beach. When we encountered a nesting pair, we marked the female's location with a prelabeled vinyl flag and recorded the time, direction the female was facing, and number of satellites in physical contact with the female or her attached male, i.e., group size. During the following daytime low tide, we measured distances from each flag to reference stakes that were placed on the beach at the start of the season. These distances were transformed into X–Y coordinates and plotted on a map of the beach.

Number of Satellites per Female. Many pairs of horseshoe crabs return repeatedly across consecutive tides and nest in different locations on the beach. If unattached males are using cues from individuals, then particular nesting pairs might show some consistency in the number of satellites they attract from one tide to the next. We walked along a 1-km section of beach at Seahorse Key that had been marked off in 100-m sections and counted the number of individually marked nesting pairs and the sizes of the groups of satellites surrounding them. The crabs had been marked as part of another study using methods previously described (Brockmann and Penn, 1992; Brockmann, 1996). Our census was conducted once per tide between the time of the maximum high tide and 1 hr after on alternate weeks (new and full moons) from March 17, to May 20, 1996. For females that returned to nest across two or three different tides (not necessarily consecutive nights), we looked for consistent patterns in the number of satellites they attracted. A complication of this analysis is that there may be different operational sex ratios (OSR) from one night to the next and, thus, different expected numbers of satellites. For this reason, we also examined whether the operational sex ratio affected the numbers of satellites around females.

Chemical Cues Experiments. We examined cues used by unattached males to locate nesting pairs with two experimental manipulations conducted in the field at BWH. A pilot study revealed that unattached males would approach a cement casting of a female (model) and even come out of the water and crawl up the beach to a casting if it were placed over a spot where a female had been nesting recently. In the first experiment, we compared responses of newly arriving, unattached males toward three cement castings (models) of females presented simultaneously: (1) a casting placed over a location from which a pair with many satellites had been removed (many-satellites model); (2) a casting placed over a nearby location where a pair that had no satellites had been removed (no-satellites model); and (3) a casting placed over a nearby location where no horseshoe crabs had been nesting during this tide (no-pair model). If satellites were using chemical cues to locate nesting pairs, then they should approach the many-satellites model more than the no-satellites or no-pair models. In this experiment visual cues were eliminated as a way for crabs to differentiate between models since all three models were alike (and were rinsed off and switched from one trial to the next). Furthermore, no auditory or tactile cues differentiated the models (as may occur with live, nesting females). In the second experiment, we compared the response of satellites to two casts of a female, both placed at sites where no crabs had been nesting (although nesting pairs were nearby). Under one we placed a sponge filled with water collected from underneath a female with many satellites (many-satellites sponge), and under the other model we placed a sponge filled with seawater (seawater sponge). If satellites were responding to chemical cues, then they should approach the first model more than the second.

We prepared 10 cement castings (models) using the undamaged carapaces from similar-sized dead females found on the beach. We rinsed, dried, and filled the cavities of the shells with a mixture of equal parts concrete, sand, and mortar. A finished cast consisted of a female carapace with a hardened concrete filling so the model female would remain in place when placed at the shoreline. A different combination of the 10 models was used for each trial of the two experiments.

We began the first experiment by walking along the beach until we encountered a nesting pair with more than four satellites (where the many-satellites model would be placed) that was located within a meter of a pair with no satellites (where the no-satellites model would be placed) and that were at approximately the same height on the beach relative to the water line (Figure 1). We also chose a nearby patch of sand (1 m away) on which no pair was nesting (where the no-pair model would be placed). After the three locations had been chosen, we began the experiment by quickly removing the nesting crabs and exchanging them for the concrete models. We lifted females out of sand and carefully brought live pairs several meters up the beach, well above the waves, and placed them upside down where they remained for the duration of the trial. We pushed each cement casting into the

depression left in the sand by the female that had just been removed and scraped sand over the front edge of the casting so that it closely resembled a live nesting female. We used the same procedure for the no-pair model by pushing it into the sand so that it resembled the others. We treated satellites in one of two ways: either (1) all satellites were allowed to stay with the model after the live pair was removed (experiment 1 stay) or (2) all satellites were removed from the live nesting pair and placed upside down high on the beach for the duration of the trial, and all new satellites investigating the models were removed (experiment 1 remove). Observation posts were located between models and removed pairs about half a meter above the central model. We alternated the order in which we exchanged pairs for models, and we alternated the use of the cement models among trials (so that all casts were used equally for the three treatments). We recorded the number of new satellite males that approached each model at 30-sec intervals over 10 min by using scan sampling. We defined approach as an unattached male moving within at least 5 cm of the model for at least 10 sec with the anterior portion of the prosoma directed toward the model. For the analyses presented here, we used data from the 30-sec interval preceding 1, 4, 6, and 10 min. For each tide on which this experiment was conducted ($N = 7$), we ran as many trials as possible (two to nine trials per tide, total trials = 36 for experiment 1 stay and 18 trials for experiment 1 remove). If unattached males were using chemical cues to locate nesting pairs, they should approach the many-satellites models more often than the no-satellites or no-pair models.

In the second experiment, we placed the cement models over sand where no pairs had been nesting, placed sponges under the models, and recorded the behavior of approaching males as in the preceding experiment (experiment 1 stay), except that we continued each trial for only 5 min. To collect water from under the female with many satellites, we squeezed out the sponge, lifted the female's carapace slightly, and pushed the sponge underneath, where it remained for 30 sec. To collect water from a nearby site with no female, we squeezed out a sponge and inserted it into the sand to the same depth as the sponge placed under the live female where it remained for 30 sec. Each sponge was then placed under the posterior one third of its assigned model so that only a small portion of the end was visible. We used cellulose sponges (7.5 cm thick $\times$ 11.25 cm wide $\times$ 17.5 cm long) that we squeezed out several times and then soaked in a bucket of fresh seawater before and between trials. Although we alternated the sponges between nights, a sponge was used for only one treatment per night. If satellites are more attracted to the model with the many-satellites sponge than to the model with the seawater sponge, then it would support the hypothesis that unattached males are using chemical cues when choosing to join nesting pairs. We conducted the maximum number of trials possible during each tide ($N = 6$ tides; four to nine trials per tide; total trials = 50).

RESULTS

In both Florida (SHK; $N = 143$ nests) and Delaware (BWH; $N = 192$ nests), pairs with groups of satellites around them were interspersed on the beach with pairs that had no satellites (Figure 2). We found no differences in the distribution of groups and lone pairs, but nesting crabs were aggregated. At SHK, most females nested in a narrow band of beach at the top of the tide line, from 3.5 to 5.5 m above low tide (Figure 2) whereas in BWH females nested across a broader section of beach (1 to 5.5 m above the low tide line; Figure 2). Although we searched for nests over a 100-m section of beach, crabs nested in only 30 m of beach on the 10 tides that we measured locations at SHK and BWH.

When individual females returned repeatedly to nest on the beach, those that had larger numbers of satellites on their first visit were likely to have larger numbers of satellites on subsequent visits ($\chi^2 = 12.6$, $df = 4$, $N = 99$, $P = 0.01$ between the first and second visits). We also found an increase in the number of satellites across three returns by a female (Friedman test: $\chi^2 = 24.8$, $df = 2$, $N = 104$, $P < 0.001$). The numbers of satellites that a pair attracted was correlated with the overall OSR on that tide ($r_s = 0.34$, $P < 0.0001$ for visit 2) and the OSR increased across the three visits. However, OSR cannot be the full explanation because there was an increase in the number of satellites per pair over the first two visits (visit 1: mean 0.6 ± 0.8 satellites; visit 2: mean 1.1 ± 0.1; Wilcoxon test, $Z = -3.7$, $P = 0.0001$), but there was no increase in OSR between those two visits (OSR for visit 1: mean $= 1.2 \pm 0.1$; visit 2: mean = 1.1 ± 0.08; Wilcoxon test, $Z = -1.5$, $P = 0.15$).

The experimental manipulations showed strong effects. When a live nesting pair was removed from a site and replaced with a cement casting of a female, one to three satellite males approached the model each minute. The males left the water and crawled up the beach 1–5 cm and then either returned to the water immediately (26/36) or remained with the model (10/36) grasping the carapace with their claws for 0.5–10 min. When satellites were allowed to remain in the vicinity of the model (experiment 1 stay), there was a difference in the numbers of satellites attracted to the three models (0 min indicates the number of satellites that initially remained with the model; Friedman ANOVA: $N = 36$, $df = 2$; $P = 0.0088$ at 0 min; $P = 0.0022$ at 1 min, $P = 0.0418$ at 4 min, $P = 0.0381$ at 6 min, and $P = 0.0035$ at 10 min; Figure 3a). A difference existed between the responses to the no-satellites and the no-pair models at 1 min ($N = 17$, $P = 0.0184$) and 10 min ($N = 22$, $P = 0.0093$). Experiment 1 stay also revealed a correlation between the number of satellites present around the original nesting pair and the numbers around the models (e.g., $r_s = 0.472$, $P = 0.0066$ for the many-satellites model at 10 min) and a correlation between the number of satellites remaining around the model at the start of a trial and the numbers subsequently attracted to the models

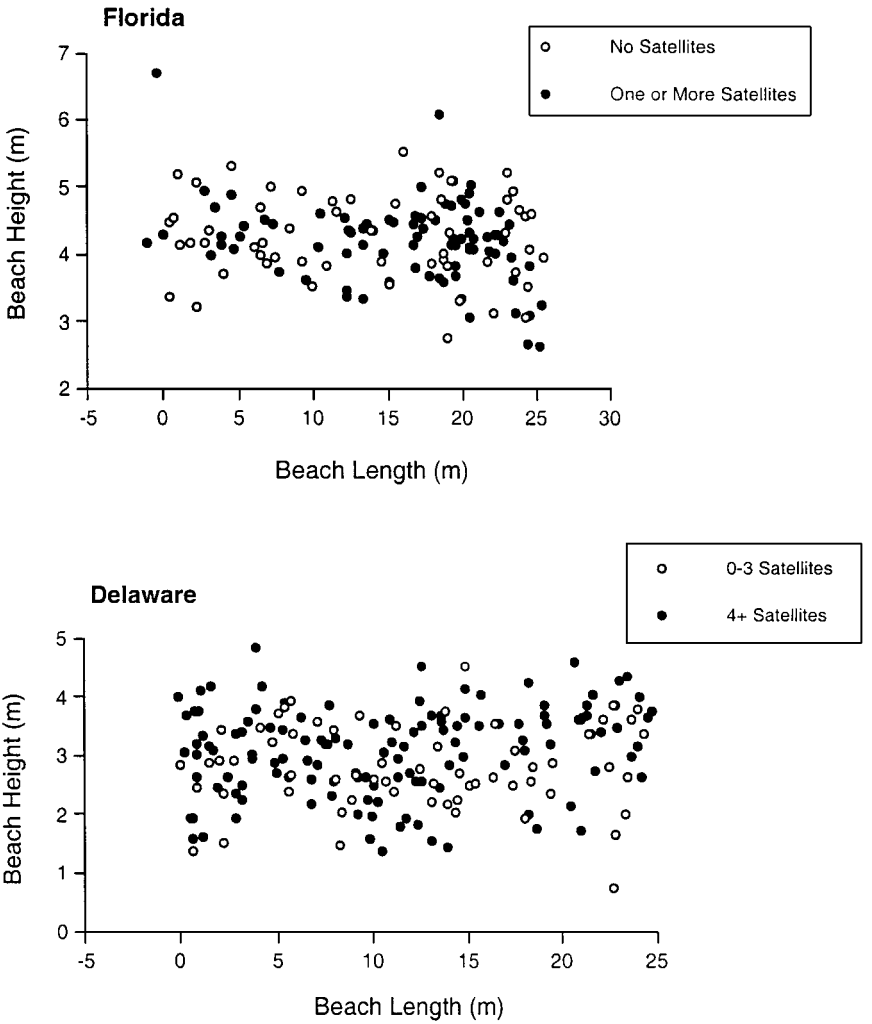

FIG. 2. A comparison of nesting locations of females over four consecutive tides (each point represents one pair) at SHK, when many satellites were present (closed circles, many satellites means ≥ 1; $N = 85$) and with no satellites (open circles, $N = 57$) and at BWH, with many satellites present (closed circles, many satellites means ≥ 4; $N = 130$) and with no satellites (open circles, $N = 62$).

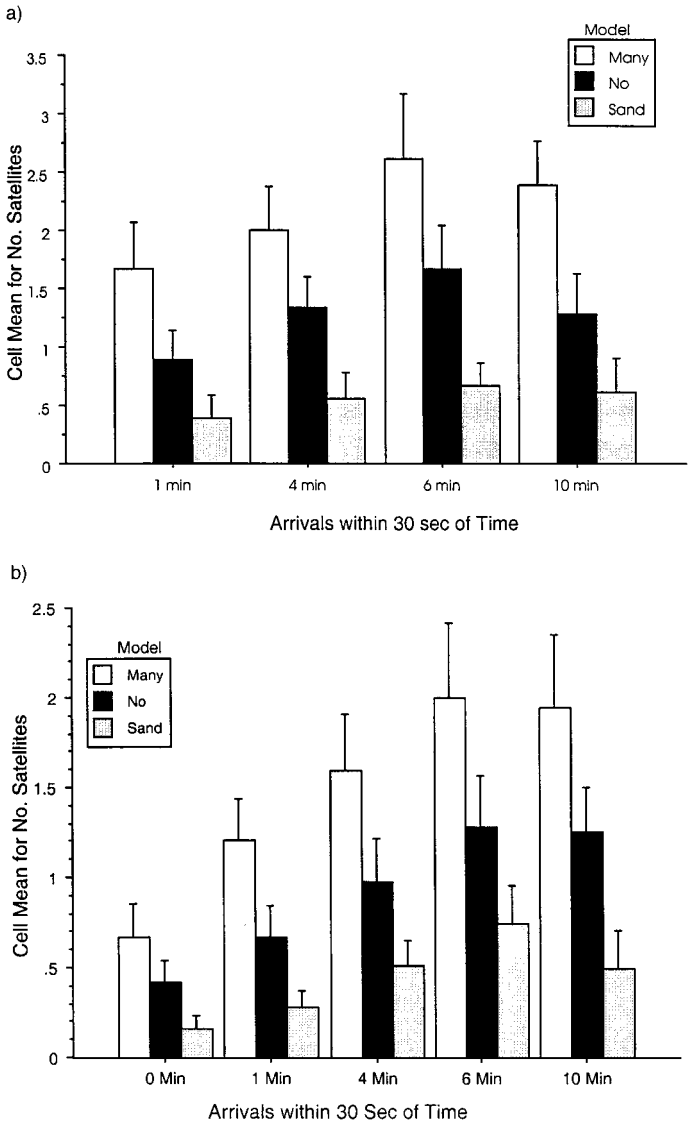

FIG. 3. Total number of satellite males approaching models that were placed over locations where nesting pairs with many satellites had been removed (open bars), where nesting pairs with no satellites had been removed (black bars), and a patch of sand where no pair had been nesting (stippled bars). a) In experiment 1 stay, satellites were not removed, b) but in experiment 1 remove, all satellites were removed when the many satellites pair was picked up and all newly arriving satellites were also removed. The bars show standard errors across all individuals that were tested.

(e.g., $r_s = 0.40$, $P = 0.07$ for number of satellites at start and at 6 min for many-satellites model; $r_s = 0.54$, $P = 0.0155$ for no-satellites model; $r_s = 0.73$, $P = 0.0014$ for no-pair model). When all satellites were removed from around the nesting pairs and all newly arriving satellites were removed (experiment 1 remove), a difference continued to exist in the number of unattached males attracted to the three models (Friedman ANOVA: $N = 18$, $df = 2$; $P = 0.0183$ at 1 min, $P = 0.0105$ at 4 min, $P = 0.0047$ at 6 min, and $P = 0.0037$ at 10 min; Figure 3b). Satellite males were more likely to approach the many-satellites than the no-satellites model at 6 min (Wilcoxon test $N = 14$, $P = 0.0259$) and 10 min ($N = 16$, $P = 0.019$) and were more likely to approach no-satellites than no-pair models at 4 min ($N = 10$, $P = 0.0122$) and 6 min ($N = 12$, $P = 0.0174$).

More unattached males approached models with sponges containing seawater from a live nesting female with satellites (many-satellites sponge: mean 2.6, $N = 50$) than to models with sponges filled with seawater (seawater sponge: mean 1.8, $N = 50$) (Wilcoxon signed-ranks test: $W = 256.5$, $N = 41$, $P = 0.0226$; Figure 4). Satellites also remained longer with the model with the many-satellites sponge than with the model that had the seawater sponge (Wilcoxon signed-ranks

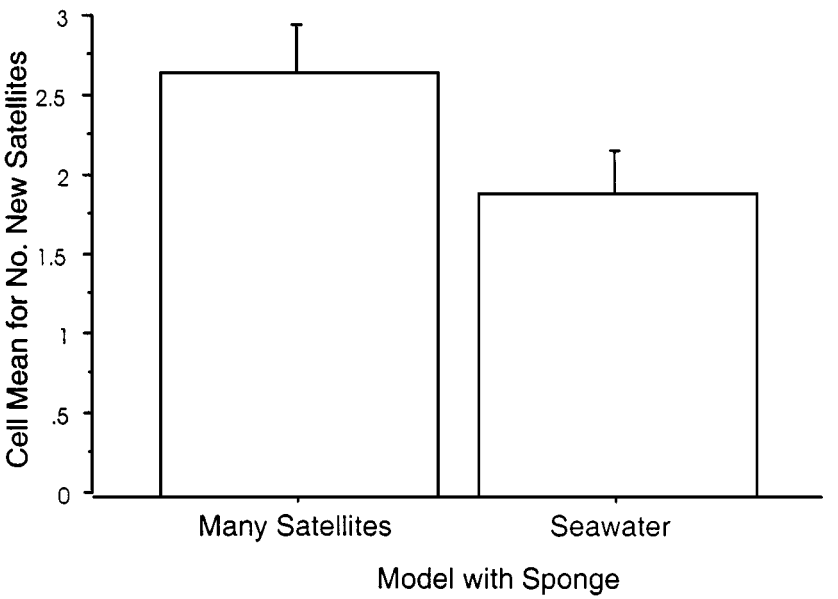

FIG. 4. Satellite male responsiveness (average number of males approaching the two models in 5 min; bars show standard error of the mean) to models with sponges placed underneath; one model had a sponge containing water from underneath a female with many satellites and the other model had a sponge containing seawater.

test: $W = 282.5$, $N = 43$, $P = 0.0216$). Furthermore, there was a correlation between the number of satellites with the original pair (the pair from which the many-satellites sponge water was collected) and the number of satellites that were attracted to the model with the many-satellites sponge ($r_s = 0.379$, $P = 0.0412$).

DISCUSSION

This study provides evidence that unattached males are using chemical cues when choosing to join a nesting pair. Once attracted to a pair, the satellite engages in sperm competition with the attached male and other satellites that have formed a group around the nesting pair (Brockmann et al., 2000). Females with many satellites and females with no satellites often nest side by side (Figures 1 and 2). We took advantage of this behavior when we conducted experimental manipulations in which we removed females from the beach and replaced them with a cement cast (experiment conducted with a paired design). Models that were placed over locations where females with many satellites had been removed were significantly more likely to attract new unattached males than models placed over locations where pairs with no satellites had been removed or where no pair had recently nested (Figure 3). The effect remained whether or not all newly arriving satellites were removed (Figure 3a,b). In a second experiment, we showed that the attractive effect could be transferred to a model by filling a sponge with water taken from underneath a female with many satellites (Figure 4). By replacing the live nesting pair with standardized female models, we removed possible tactile and auditory signals. Although we have clear evidence for chemical cues, visual cues were also important: the cement-filled concrete casts of a female were necessary to produce a consistent and well-oriented response by males. In the experiments that we conducted, however, visual cues could not be responsible for the differences in response among the three models. This study provides a nice example of an increasingly apparent feature of many chemosensory systems (Dunham and Oh, 1996)—hierarchical or multimodal communication (Passaro and Marler, 1999) in which different signals (e.g., visual and olfactory) may be used at different scales (Atema, 1995).

The fact that lone males preferred the many-satellites model supports the hypothesis that chemical cues are being used. However, in the initial model experiment, we did not fully remove cues that may be emitted by the local environment around the nesting pair. To do this we must remove the cues given off by a particular microlocation while trying to maintain cues that are given off by the nesting female. The female model with sponge experiment does this: the sponge filled with water taken from a female with satellites attracted significantly more males than a sponge filled with seawater (Figure 4). In addition, satellites remained longer with the many-satellites sponge model than with the seawater sponge model (Figure 4).

This suggests that satellite males use chemical cues to choose among nesting pairs and that those chemicals are coming primarily from the pair rather than the nesting site. This chemical cue may be a pheromone from the nesting female, the nesting pair and their satellites, or perhaps from the eggs or oviducal fluids.

The models we used were simply concrete-filled shells of females and did not include the attached male that is nearly always present with a nesting female on the beach. Despite this, the lone males treated the model female as though she were an attached female: a newly arriving male moved to a position over the female's incurrent canal, just as he would do with a live, nesting female (Barlow et al., 1988; Brockmann, 1990). This behavior is consistent with previous observations of lone females that sometimes arrive on the beach, probably having lost their attached male on the way to shore (Brockmann and Penn, 1992).

Individual females show a consistent pattern in the number of satellites they attract when they return to the beach to nest over several tides. A female that had more satellites than average on her first visit to the beach was likely to have more satellites than average on subsequent visits. When a female returned to the beach several times, she was likely to gain additional satellites on each subsequent visit so that a female on her third visit had, on average, more satellites than on her first visit. There are several possible explanations for the individual differences among females in their attractiveness to males and for the increased attractiveness of females to satellites over the breeding period (generally one week associated with the new or full moon). In most cases, the first visit was the visit on which the female was marked, measured, and separated from her original attached male. Subsequently, males usually remain attached to the same female. This means that as she returns repeatedly to breed (Brockmann and Penn, 1992), her attached male may be less able to defend against satellite males. If the attached male becomes depleted of sperm, this may mean that satellites are more attracted to the pair because of the reduced sperm competition. Alternatively, females may be increasing their attractiveness by releasing more chemical cues over the week of breeding to ensure that satellites are present to fertilize all their eggs. It is also possible that females may be depositing the majority of their eggs on their third visit and are, thus, more attractive to satellites by releasing more attractant or because more eggs are present.

If chemical cues attract satellites, we must ask who is producing those cues. It seems unlikely that the attached male produces cues that attract satellites since the attached male competes for fertilizations with satellite males (Brockmann et al., 1994). The data collected in this study are consistent with the hypothesis that the satellite males produce a chemical cue that attracts other males or that in combination with female odors attracts males. We think this is unlikely because satellites lose fertilizations when other males are present (Brockmann et al., 2000) and because this hypothesis does not explain consistent differences among females in the numbers of males they attract. The most likely candidate for producing the

chemical signal is the female. It is possible that the female attracts more males to ensure that her eggs are fertilized (Pennington, 1985; Levitan and Petersen, 1995), particularly if the attached male becomes depleted over the week of nesting. Females may also gain from the intensely competitive interactions among males (Brockmann, 1990) if the male that fertilizes her eggs is in some way superior to the individuals he outcompetes. If females are gaining reproductive success, however, why is it that some females apparently fail to produce the chemical attractant (those with no satellites)? Perhaps the most striking result of this study is the consistency of the response by unattached males: in both experiments, the number of males attracted to a model (when only chemical cues were available) is correlated with the numbers that were originally present around the nesting female (from which water was taken or over which the model was placed). It could be that some females are unable to produce the chemical, perhaps due to age or condition, or perhaps some females produce more of the chemical. Brockmann (1996) found that female condition is correlated with the number of satellites, but it is not a strong effect. A far stronger correlation was found between female size and the number of satellites. Perhaps larger females produce more of this chemical cue or perhaps larger females lay more eggs (we have no evidence of this) or have more oviducal fluid associated with their eggs that contains the chemical. Future studies should assay the effects of chemicals produced by females, eggs, attached and satellite males, and their sperm.

The chemical compound to which the satellites are attracted is not known, but this study provides some evidence as to its properties. The chemical continues to attract males for at least 10 min after the nesting pair has left the beach, despite repeated washing by the waves. Horseshoe crab receptors are particularly sensitive to amino acids and steroids from their prey items (Barber, 1956), and many aquatic organisms have been shown to use amino acids and steroids for mate attraction (Liley, 1972). For example, fluid taken from the ovaries of gravid females in some species of fish elicited mating responses in conspecific males (Tavolga, 1956; Partridge et al., 1976; Little, 1983). It seems reasonable that female horseshoe crabs should produce a chemical cue along with the eggs to stimulate spawning by males, as occurs in other externally fertilizing species (Mackie and Grant, 1974), but no such chemical is known from horseshoe crabs. Other chemicals, however, are known. The flatworm *Bdelloura candida*, a parasite that lives in the gills of *Limulus*, is attracted by a substance that is stable in seawater for at least five days and is destroyed by boiling (Chevalier and Steinbach, 1969). Horseshoe crab eggs are known to produce a substance that attracts sperm, but this is known to work only at close range (Shoger and Bishop, 1967). Female horseshoe crabs and their eggs are used as a highly effective bait in the eel and conch fishery, and Ferrari and Targett (2000) have identified a high-molecular-weight protein chemoattractant in the eggs and hemolymph. Clearly, a chemical analysis of the seawater from beneath females with and without satellites is needed to identify the nature of the chemicals involved.

Satellite male horseshoe crabs form groups of highly variable size around some nesting females while ignoring others (Figure 1). The formation of these groups is puzzling since satellite males compete for fertilizations, and increasing group size increases competition (Brockmann et al., 2000). This study demonstrates that satellite males are using chemical signals to choose among nesting pairs when they come ashore to mate. How the chemical is produced and the selective advantages for producing and responding to the chemical are not yet known.

Acknowledgments—Field assistants provided exceptional help in collecting the data reported here: Sandra Nichemias, Mary Hart, Chris Hess, and Patrick McKann at SHK and Kim Abplanalp at BWH. Henry Coulter and Al Dinsmore provided logistic support. We thank the University of Florida Marine Laboratory at Seahorse Key and its director, Frank Maturo, and the Suwannee River National Wildlife Refuge and its manager, Ken Litzenberger, for their support of this project (permit No. 35899). The University of Delaware, College of Marine Studies, Lewes, Delaware, provided research facilities and accommodation, and the Cape Henlopen State Park gave permission to work on the Breakwater Harbor Beach. Dan Brazeau and Nancy Targett provided advice and logistic support. The research presented here was supported in part by a National Science Foundation grant (OCE90-06392) and by the Florida Foundation.

(Received December 27, 2000; accepted July 10, 2001)

Abstract—We compared the ability of urine and ovarian fluid from female Atlantic salmon (*Salmo salar*) to stimulate increase in plasma concentrations of sex steroid hormones in mature conspecific male parr (priming effect of the stimuli). We also tested the hypothesis that prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) may act as a priming pheromone in the tested stimulants. Individual males of salmon parr were exposed to female urine, ovarian fluid, urine–ovarian fluid mix, or $PGF_{2\alpha}$. Plasma concentrations of the sex steroids of 17,20β-dihydroxy-4-pregnen-3-one (17,20β-P) were higher in males exposed to urine, ovarian fluids, and $PGF_{2\alpha}$ compared to control males. $PGF_{2\alpha}$ and a mixture of urine and ovarian fluid also gave increased concentrations of 11-ketotestosterone (11-KT). Concentrations of $PGF_{2\alpha}$ were higher in ovarian fluids than in urine. A behavior test with mature male parr in a fluviarium showed neither attraction to nor avoidance of 0.1 nM $PGF_{2\alpha}$, but plasma levels of 17,20β-P were significantly higher in exposed males compared to controls.

Key Words—Atlantic salmon, salmonids, priming odors, urine, ovarian fluid, steroid hormones, prostaglandin $F_{2\alpha}$.

INTRODUCTION

Previous studies in mature salmonid males have demonstrated both behavioral and endocrine responses to water conditioned by urine and/or ovarian fluid from mature females (e.g., Honda, 1982; Olsen and Liley, 1993; Scott et al., 1994; Waring et al., 1996; Vermeirssen et al., 1997; see also review by Liley, 1995). Scott et al. (1994) showed that plasma sex steroid concentrations in male rainbow trout (*Oncorhynchus mykiss*) were elevated following exposure to the urine of both ovulated and nonovulated conspecific females, but not to ovarian fluid. Waring et al. (1996) showed that sex steroid concentrations in male Atlantic salmon (*Salmo salar* Linné) parr were elevated by exposure to the urine of ovulated females, but they did not test ovarian fluid. Moore and Waring (1996) suggested that F-series prostaglandins such as prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) were acting as priming pheromones. This substance has been reported to be inactive in rainbow trout (Kitamura et al., 1994; Scott and Vermeissen, 1995). Electrophysiological studies have shown that, in contrast to rainbow trout, the olfactory epithelium in salmon detects $PGF_{2\alpha}$ (Moore and Waring, 1995, 1996; Hara and Zhang, 1998).

It is known that prostaglandins are important for the process of ovulation in fish (Goetz et al., 1989), and ovulated eggs and ovarian fluid are present in the body cavity. If ovarian fluids contain high enough concentrations of $PGF_{2\alpha}$ and the prostaglandin has a priming effect, the ovarian fluids should be effective in increasing plasma levels of sex hormone steroids. In a recent study, we have observed that plasma sex steroid levels in male parr of both Atlantic salmon and brown trout (*Salmo trutta* L.) were elevated by exposing them to a mixture of urine and ovarian fluid derived from ovulated females of either species (Olsén et al., 2000). The volumes of strippable milt were also enhanced in Atlantic salmon parr. These results led us to the present study, which compares the responses of Atlantic male parr to urine and ovarian fluid. We wanted to test the hypothesis that the priming response to ovarian fluid should be at least as strong as to urine. We also analyzed the content of $PGF_{2\alpha}$ in the urine and ovarian fluid and detected much higher levels in the ovarian fluid. Furthermore, we tested whether $PGF_{2\alpha}$ had a behavioral effect on male Atlantic salmon parr, as some studies have shown behavioral effects in fish during exposure to F prostaglandins (Stacey et al., 1994; Sveinsson and Hara, 1995, 2000).

METHODS AND MATERIALS

Fish. Experiments were performed during 1996 and 1997 with Atlantic salmon obtained from the Swedish National Board of Fisheries hatchery at Älvkarleby (60°N). Male parr were raised from a wild brood stock, and the adult females were from the same wild stock caught in the River Dalälven. The parr were raised under standard hatchery conditions.

Collection of Female Stimulants. Urine and ovarian fluids were collected by catheters from anesthetized (2-phenoxy ethanol, 0.05%) ovulated Atlantic salmon females (2.780–5.960 g, $N = 8$) at the hatchery on the River Dalälven. Both urine and ovarian fluids were taken from each female. The urine and ovarian fluids were collected in 20-ml polythene tubes on ice and subsequently stored at -80°C. Care was taken to prevent contamination between the two fluid types. It was easy to fill the tubes with ovarian fluid, but the amounts of urine were often less than 10 ml. Prior to freezing, 0.5–1.5 ml of both fluids were decanted into microfuge tubes for analyses of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and 15-keto-dihydro-$PGF_{2\alpha}$ concentrations in individual fish. The remainder of the ovarian fluid and urine samples were pooled into an ovarian fluid mix and a urine mix, respectively, and then frozen in aliquots suitable for the experiments. We also sampled a mixture of urine and ovarian fluid in the same way as in Olsén et al. (2000). The mixture of urine and ovarian fluid was collected at the time (10.00–12.00 hr) when females were stripped of their eggs for artificial fertilization. The fluids used were collected during the process of stripping, up until the appearance of the first eggs in the ovipore. The concentrations of $PGF_{2\alpha}$ and 15-keto-dihydro-$PGF_{2\alpha}$ were also analyzed in urine and ovarian fluid that were collected in 1998 from another group of six ovulated Atlantic salmon females.

Experimental Procedure. Three separate experiments were conducted during 1996–1997 to investigate the priming effects of various substances on mature male parr. The first two were conducted at the Fisheries Research Station, Älvkarleby, while the last was conducted at Uppsala University.

Experiment 1. The priming effect of urine from ovulated females, ovarian fluid, or saline solution (control) was tested on mature male parr (22.9–52.7 g, $N = 23$) during the period November 3–5, 1996. Males were not stripped of milt before the experiment. In a previous study (Olsén et al., 2000), nonstripped salmon parr showed enhanced plasma levels of sex steroids and milt volumes after exposure to from ovulated females. We wanted to keep the effects of handling stress to a minimum.

Tests were done in direct connection to, and in the same way as, the experiments described by Olsen et al. (2000) and are briefly described here: Test areas (test volume: 60 cm long $\times$ 60 cm wide $\times$ 11 cm deep) were continuously supplied with aerated groundwater at a rate of 300–400 ml/min. Temperature of the water varied between 8 and 10°C. Mature male parr were individually placed in the test area ca. 18 hr before the first supply of 2 ml of stimulant at 10:00 hr. They were exposed a second time at 12:00 hr by adding another 2 ml. Two hours later, the first fish was sampled. Tanks were supplied with a continuous flow of ground water and had their own inlet and outlet. A submersible pump circulated the water in each tank and ensured that the stimulants were evenly mixed.

For each sampling, the male parr was first anesthetized (2-phenoxy ethanol, 0.05%), weighed, and the volume of milt determined by collecting in preweighed

glass tubes following gentle abdominal pressure (Olsén and Liley, 1993). Blood was subsequently collected by severing the caudal peduncle and collecting the blood in heparinized tubes. Fish were put to death after blood sampling. Following centrifugation, plasma was collected and stored at -80°C for sex steroid determination. Testes were weighed for the determination of gonadosomatic index [GSI, (gonad weight/body weight) $\times$ 100].

Experiment 2. During the period October 20–24, 1996, the priming effect of the following fluids was studied on mature male parr (45.9–120.2 g, $N = 26$): ovarian fluid/urine mixture (87.5 μl ethanol to 50 ml of mixture); $PGF_{2\alpha}$ (87.5 μl of $PGF_{2\alpha}$ stock solution, 1mg/ml of ethanol, added to 50 ml 0.9% NaCl); control solution (87.5 μl ethanol added to 50 ml 0.9% NaCl). The solution of prostaglandin was added to the test area to give an acute nominal concentration of 0.1 nM. Experiments were performed as in experiment 1, except that males were anesthetized (2-phenoxy ethanol, 2%) and stripped of milt before they were placed in the test area. As there was a lack of increase in milt volumes despite increased plasma concentrations of 17,20β-P in experiment 1, we stripped the fish to make it easier to observe an increase in milt volume. We showed in a previous study that a mixture of urine and ovarian fluid increased the volumes of strippable milt (Olsén et al., 2000).

Fluviarium Test. In this experiment, the behavior and endocrine responses to $PGF_{2\alpha}$ were studied. On November 5, 1996, male parr with running milt were transported to Uppsala University and placed in 400–liter rearing tanks continuously supplied with aerated tap water.

Individual fishes (33.4–81.0 g, $N = 20$) were tested in a fluviarium (Höglund, 1961; Bjerselius et al., 1995) during the period November 14 to December 9, 1996. Males were stripped of milt before they were placed in the test area of the fluviarium. One fish was tested at a time. Water, with or without $PGF_{2\alpha}$, was supplied to opposite halves of the fluviarium and mixed into the main stream of aerated tap water flowing to the test area (temperature 8.3–9.5°C). The test stimuli (ethanol or $PGF_{2\alpha}$ in ethanol added to tap water) were released from 12-liter stainless steel containers by two peristaltic pumps, at the rate of 30 ml/min through two separate magnetic valves. Two magnetic valves automatically switched the supply between the two halves of the test area at regular 90-min intervals. The nominal concentration of $PGF_{2\alpha}$ in the test area was 0.1 nM (stock solution: 7.4 mg in 10 ml 95% ethanol).

A video camera was placed over the test area, and the position of the fish was recorded by a videocomputer image analysis system in IR light ($>$750 nm) between 18:00 and 06:00 hr the next morning. No stimulus was added during the first four 90-min periods (18:00–24:00 hr), but were started at 24.00 hr and lasted until 06.00 hr. The water going through the magnetic valves shifted sides of the fluviarium every 90 min from the start to the end of the experiment. It was only during the last four 90-min periods (24:00–06:00 hr) that the pumps added water with ethanol or water containing $PGF_{2\alpha}$ and ethanol.

For each fluviarium test, we used data from the last 60 min in each of the last four 90-min periods of a test to calculate a reaction value (R_v) according to the equation: $R_v = [(N_L - N_0)/(N_L + N_0)] \times 100$, in which N_L and N_0 represent the number of observations in each side of the test area with water supplied with $PGF_{2\alpha}$ and ethanol or ethanol alone, respectively. The arithmetic means of reaction values from identical tests are designated MR_v. After each fluviarium test, blood samples were taken from fish as described above.

Hormone Measurements. Plasma levels of 11-KT, T (experiment 3 only) and 17,20β-P were measured by specific radioimmunoassay (RIA) according to the method of Mayer et al. (1990). The metabolite of prostaglandin $F_{2\alpha}$, 15-keto-dihydro-$PGF_{2\alpha}$, was analyzed in unextracted media by RIA (Kindahl et al., 1976; Granström and Kindahl, 1982). The antiserum cross-reacted 16% against 15-keto-$PGF_{2\alpha}$, 4% against 13,14-dihydro-$PGF_{2\alpha}$, 0.4% against $PGF_{2\alpha}$, and 1.7% with 15-keto-dihydro-PGE_2, a major metabolite of PGE_2. For other prostaglandins, the cross-reaction was <0.1%. Samples were diluted in a 0.25% bovine γ-globulin buffer. In most cases, 50 μl of media was diluted with 450 μl of the buffer. The practical detection limit of the assay was 300 pmol/liter. If necessary, samples were diluted to allow accurate readings on the standard curve. The interassay coefficient of variation was 14%. Samples were reanalyzed if the coefficient of variation exceeded 10% for duplicate determinations. The intraassay coefficient of variation was evaluated by analyses of 10 different pooled plasma samples in five separate radioimmunoassay tubes and was between 3.4 and 7.6% at different ranges of the standard curve.

The primary prostaglandins $F_{2\alpha}$ and E_2 were analyzed in the media by a modification of the method of Lindgren et al. (1974). Samples were diluted as for the analysis of 15-keto-dihydro-$PGF_{2\alpha}$, described above. The antiserum against $PGF_{2\alpha}$ cross-reacted 75% against $PGF_{1\alpha}$, 2% against $PGF_{2\beta}$, 1.5% against $PGF_{1\beta}$, and <0.1% for PGE_2, PGE_1, PGD_2, TXB_2, and 15-keto-dihydro-$PGF_{2\alpha}$. Samples were analyzed directly for concentrations of $PGF_{2\alpha}$. Then after reduction with sodium borohydride (Lindgren et al., 1974), the samples were reanalyzed for concentrations of $PGF_{2\alpha}$. Reduction with sodium borohydride reduces PGE_2 to a mixture of $PGF_{2\beta}$ and $PGF_{2\alpha}$. With samples containing known amounts of PGE_2, the ratio between the two isomers was found to be 1:1. Therefore, the following estimates, the increase in $PGF_{2\alpha}$ concentrations after reduction was multiplied by two to obtain the PGE_2 content. The practical limits of detection for PGE_2 and $PGF_{2\alpha}$ were 0.5 and 0.3 nmol/liter, respectively. The interassay coefficient of variation was 15%, and the intraassay coefficients of variation varied between 7.3 and 12.5% at different ranges of the standard curve.

Statistical Analyses. Plasma hormone levels and milt volumes were compared between treatments with Kruskal-Wallis nonparametric ANOVA, and in the case of significance, followed by Dunn's multiple-comparison test (Siegel and

Castellan, 1988; Motulsky, 1999). Calculations were performed with GraphPad Prism (Motulsky, 1999).

In the fluviarium tests, the Student's *t* test was used when *MRv*s were compared to the theoretically indifferent reaction, i.e., when $MRv = 0$. MRv is zero when the number of observations in each water quality is the same. The Mann-Whitney U test was used to compare hormone levels, milt volumes, and GSI of control and exposed fish.

RESULTS

Exposure to Female Odors in Tank. In experiment 1, Kruskal-Wallis (KW) analysis of variance showed a significant effect of treatment on plasma levels of 17,20β-P when control solution (0.9% NaCl), ovarian fluid, or urine was added to the tank (Figure 1). Dunn's multiple-comparison test revealed higher plasma 17,20β-P levels after exposure to both female stimuli compared to the control. No effects were observed in the plasma levels of 11-KT (KW = 0.71, $P = 0.70$) or T (KW = 2.18, $P = 0.34$). No differences in volumes of strippable milt (mean ±

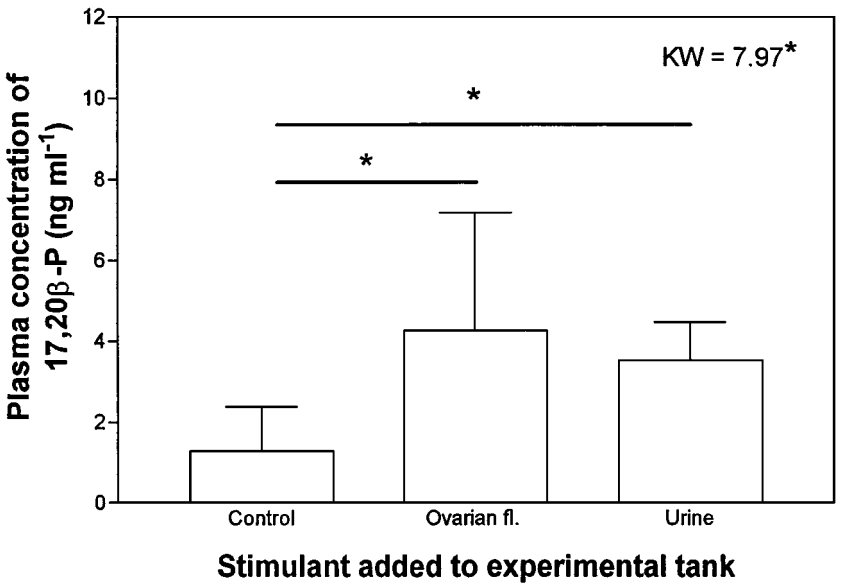

FIG. 1. Blood plasma concentrations of 17,20β-dihydroxy-4-pregnen-3-one in mature Atlantic salmon male parr after exposure to pure ovarian fluid, or urine from an ovulated conspecific female. The control solution contained 0.9% NaCl.* $P < 0.05$.

SD; control: 66.3 ± 18.7 mg/g fish, $N = 7$; urine: 57.9 ± 14.0, $N = 8$; ovarian fluid: 55.1 ± 13.3, $N = 8$; KW = 2.125, $P > 0.05$), and GSI [mean ± SD, (g/g fish) × 100; control: 11.9 ± 2.5, $N = 7$; urine: 10.8 ± 1.4, $N = 8$; ovarian fluid: 9.7 ± 1.7, $N = 8$; KW = 3.59, $P > 0.05$] were observed.

In experiment 2, Kruskal-Wallis analysis of variance showed an effect of treatment on plasma levels of 17,20β-P and 11-KT when control solution (ethanol added to 0.9% NaCl), ovarian fluid–urine mix (ethanol added to the mix), or $PGF_{2\alpha}$ (nominal conc. 0.1 nM in the tank) was added to the experimental tank (Figure 2A and 2B). Dunn's test showed a difference in 17,20β-P levels between the control and the $PGF_{2\alpha}$ -exposed fish. Plasma levels of 11-KT were increased both in the female-odor-exposed fish and fish exposed to $PGF_{2\alpha}$ (Figure 2B). There were no differences in volumes of strippable milt (mean ± SD, mg/g fish; control: 10.0 ± 6.7, $N = 9$; mix: 10.5 ± 4.6, $N = 9$; $PGF_{2\alpha}$: 11.0 ± 4.1, $N = 8$; KW = 0.13; $P > 0.05$) and GSI [mean ± SD, (g/g fish) × 100; control: 6.8 ± 1.5, $N = 9$; mix: 6.6 ± 1.7, $N = 9$; $PGF_{2\alpha}$: 6.5 ± 1.5, $N = 8$; KW = 0.26, $P > 0.05$].

Fluviarium Test. No behavioral responses were observed in parr exposed to 0.1 nM $PGF_{2\alpha}$ in the fluviarium (*MRv*s did not differ significantly from an indifferent response when $MRv = 0$) . The $PGF_{2\alpha}$ was added to one half of the test area (*MRv* ± SD; control: period 1–4: −8.5 ± 21.6, period 5–8: −4.9 ± 9.5; $PGF_{2\alpha}$: period 1–4: −3.7 ± 15.2, period 5–8 ($PGF_{2\alpha}$): 5.8 ± 13.3; *t* test gave $P > 0.05$ for all periods in both treatments). Plasma levels of 17,20β-P were, however, higher in the exposed fish compared to control (Mann-Whitney U test, $U = 11.0$, $P = 0.05$). No differences were observed in 11-KT (Mann-Whitney $U = 15.50$, $P = 0.15$) and T levels ($U = 15.50$, $P = 0.15$), respectively. No difference in volumes of strippable milt (mean ± SD, mg/g fish; control: 21.7 ± 18.2, $N = 7$; $PGF_{2\alpha}$: 25.8 ± 6.33, $N = 8$; $U = 24.0$, $P = 0.69$), and GSI (mean ± SD, (g/g fish) × 100; control: 7.4 ± 2.8, $N = 7$; $PGF_{2\alpha}$: 7.1 ± 0.9, $N = 8$; $U = 25$, $P = 0.78$) were observed.

Prostaglandin Concentrations. Concentrations of $PGF_{2\alpha}$ and its metabolite 15-keto-dihydro-$PGF_{2\alpha}$ were measured in urine and in ovarian fluid. There were high concentrations of $PGF_{2\alpha}$ in ovarian fluid (range: 200–796 nmol/liter, $N = 6$), and somewhat lower concentrations in the ovarian fluid–urine mixture (69–166 nmol/liters^{-1}, $N = 6$). Concentration of $PGF_{2\alpha}$ was low in urine (<0.3–1.1 nmol/liter, four samples <0.3, $N = 11$). The concentrations of 15-keto-dihydro-$PGF_{2\alpha}$ were lower than $PGF_{2\alpha}$ in ovarian fluid (5.4–29.4, $N = 7$, vs 200–796 nmol/liter), but in urine the reverse was found, with concentrations of the metabolite being somewhat higher than the hormone (0.5–4.6 vs <0.3–1.1 nmol/liter; $N = 11$ and $N = 7$, respectively). Levels of 15-keto-dihydro-$PGF_{2\alpha}$ were lower in urine (0.5–4.6 nmol/liter) compared to ovarian fluid (5.4–29.4 nmol/liter). Concentrations of 15-keto-dihydro-$PGF_{2\alpha}$ in the ovarian fluid–urine mix varied between 3.5 and 15.0 nmol/liter ($N = 7$). The concentration of PGE_2 varied in urine

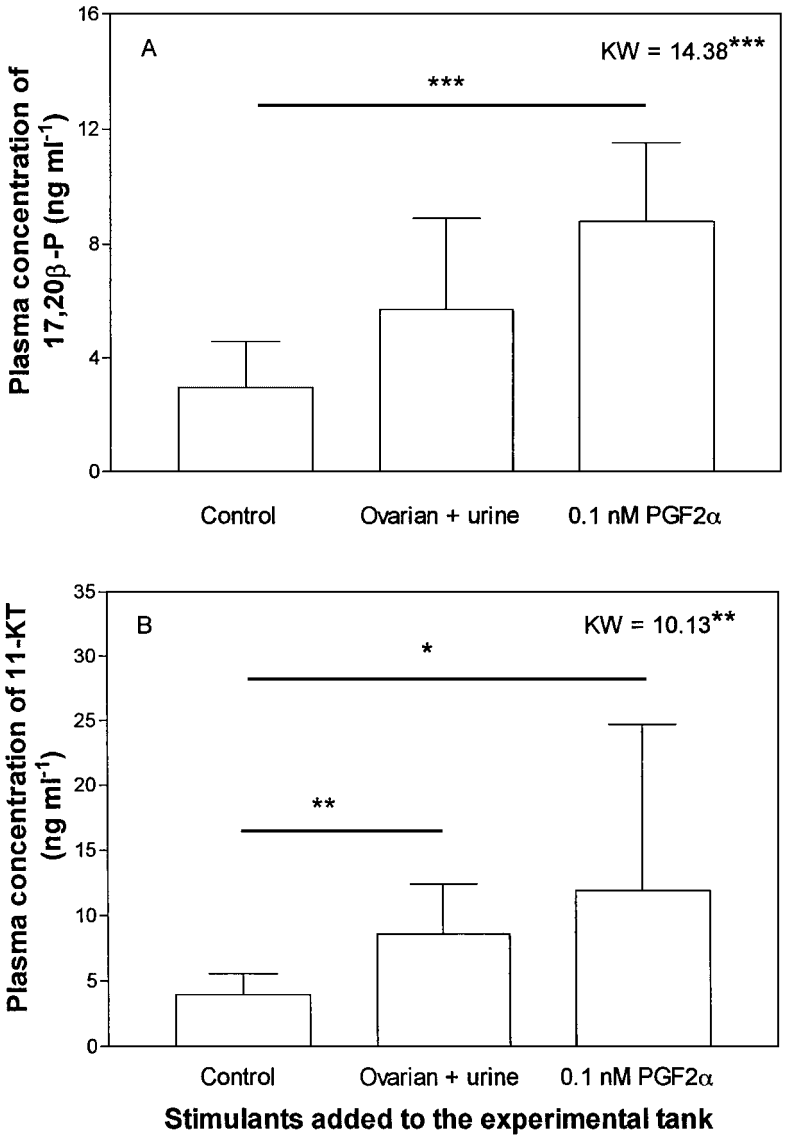

FIG. 2. Blood plasma concentrations of (A) 17,20β-dihydroxy-4-pregnen-3-one and (B) 11-ketotestosterone in mature Atlantic salmon male parr after exposure to conspecific female odor (mix solution of urine and ovarian fluid), 0.1 nM prostaglandin $F_{2\alpha}$ or control (ethanol added to 0.9% NaCl). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

between 1 and 6.8 nmol/liter ($N = 6$), but no PGE_2 was detected in ovarian fluid (detection threshold 0.5 nmol/liter).

DISCUSSION

The results of the present study show that both urine and ovarian fluid from ovulated Atlantic salmon females increase plasma levels of 17,20β-P in male parr. The mixture of urine and ovarian fluid and pure 0.1 nM $PGF_{2\alpha}$ also gave enhanced levels of 11-KT. In contrast to the previous study (Olsén et al., 2000) that was done with the same equipment and during the corresponding time of the spawning period (c.f., Moore and Waring, 1996), no difference in volumes of strippable milt was observed between control and exposed males. Previous studies with ovulated female odors have mostly reported enhanced plasma concentrations of the progestin 17,20β-P, which is involved in control of spermiation and sperm performance (e.g., Scott and Baynes, 1982; Ueda et al., 1983; Sakai et al., 1989; Miura et al., 1992), but the occurrence of increased milt volumes in these studies has varied (Scott et al., 1994; Moore and Waring, 1996; Waring et al., 1996; Vermeirssen et al., 1997; Olsén et al., 2000). This could reflect that stimulation of milt volumes is influenced by the season (Moore and Waring, 1996; Waring et al., 1996) and that there are individual differences among males (Vermeissen et al., 1997). The reason behind this lack of response in some males is not known. 17,20β-P is probably a good indicator of priming as it is directly connected to spermiation.

Analyses of the ovarian fluid and urine revealed that $PGF_{2\alpha}$ and its metabolite 15-keto-dihydro-$PGF_{2\alpha}$ are present in both fluids. The concentrations of $PGF_{2\alpha}$ were, however, much higher in ovarian fluid than in urine, while the metabolite was at about the same level. Previous studies have suggested $PGF_{2\alpha}$ as a priming pheromone in Atlantic salmon female urine (Moore and Waring, 1996). In some teleost species, prostaglandins can act as releaser pheromones (e.g., Sorensen et al., 1989; Sveinsson and Hara, 1995), and acute olfactory sensitivity has been demonstrated in different species (e.g., Cardwell et al., 1992; Bjerselius and Olsén, 1993; Kitamura et al., 1994; Essington and Sorensen, 1996; Sveinsson and Hara, 2000). In different species of Pacific salmon within the genus *Oncorhynchus*, priming and releasing sex pheromones are believed to be present, although the chemical identities of these substances are still unknown (Emanuel and Dodson, 1979; Honda, 1980, 1982; Olsén and Liley, 1993; Liley et al., 1993; Scott et al., 1994; Vermeirssen et al., 1997; Yambe et al., 1999). Enhanced plasma levels of sex steroids (but not milt volumes) were detected with mature rainbow trout female urine, but exposure to ovarian fluid failed to elicit an endocrine response (Scott et al., 1994), although the concentration of ovarian fluid in the experimental tanks was probably much higher than in the present study. To date, few sex pheromones

have been identified in fish, but the substances that have been identified are either steroids or prostaglandins (review by Stacey et al., 1994).

Prostaglandin concentrations in ovarian fluid were higher than in female urine. As prostaglandins are important for ovulation in fish, it is no surprise that they are present in ovarian fluids (e.g., Goetz et al., 1989; Peter and Yu, 1997). Both $PGF_{2\alpha}$ and PGE_2 have been detected in high concentrations in both blood plasma and ovarian fluids of brook trout, *Salvelinus fontinalis* (Mitchill), females during or immediately after ovulation (Cetta and Goetz, 1982). The question is whether the prostaglandins are released from the ovary and coelomic fluids into the water and detected by the males before spawning. Directly after spawning, the concentration of $PGF_{2\alpha}$ should be high in water close to the female and detected by males that will subsequently receive a priming effect. Males will, thus, have the advantage of increasing milt volumes until a spawning situation occurs a couple of hours later and probably with another female. There is also a possibility that small amounts of coelomic fluids are released into the water during nest digging when the abdominal pressure increases. Salmonid fish urinate in pulses (Curtis and Wood 1991), which makes it possible for the female to control the priming stimulation of the males. This should be an advantage for the courting males that will have high milt volumes ready for the spawning. A morphological study has, however, opened the possibility that ovarian fluids can also be released voluntarily. The study demonstrated the presence of a sphincterlike musculature that surrounds both the ureter and the oviduct of chum salmon (*Oncorhynchus keta*) (Uematsu and Hibiya, 1983). The authors suggested that the musculature is used to contract both the ureter and the reproductive duct, and, due to this arrangement, it may enclose the latter more tightly. This opens the possibility that both ovarian fluid and urine can be the source of priming chemicals.

Parr did not show any behavioral response to 0.1 nM $PGF_{2\alpha}$ in the fluviarium tests, but blood plasma levels of 17,20β-P were elevated. The same concentration of $PGF_{2\alpha}$ was used in the tank exposure tests that gave enhanced plasma levels of 17,20β-P and 11-KT. A recent study with male salmon parr supports the view that $PGF_{2\alpha}$ is not acting as an attractant (Olsén et al., unpublished results).

If F prostaglandins are the active substances, ovarian fluid should be at least as potent as urine as a priming agents. On the basis of the much greater content of $PGF_{2\alpha}$, it should be even more active than urine. The concentration of the hormone in the test area with urine added should have been 1000 times lower (0.1 pM) compared to the ovarian fluid exposure (experiment 1). One possibility is that in addition to $PGF_{2\alpha}$, other substances may be effective as priming pheromones in the urine. One candidate would be 15-keto-$PGF_{2\alpha}$, which is also detected by the olfactory senses of mature salmon male parr, but at much higher concentrations (Moore and Waring, 1996). In our studies, we do not know the concentrations of 15-keto-$PGF_{2\alpha}$. In addition to $PGF_{2\alpha}$, we measured its major metabolite 15-keto-dihydro-$PGF_{2\alpha}$ (the difference between the two metabolites is

saturation of the 13,14 double bound in 15-keto-dihydro-$PGF_{2\alpha}$). No data are available concerning the olfactory sensitivity of Atlantic salmon and other salmonids to 15-keto-dihydro-$PGF_{2\alpha}$, which means that its importance as a chemical signal and priming pheromone is not known. If it had an effect as a priming substance, ovarian fluid should have been more potent. We found PGE_2 in the urine of adult salmon females at about the same level as $PGF_{2\alpha}$, but in contrast to $PGF_{2\alpha}$, nothing could be detected in ovarian fluid. This suggests that the effect of PGE_2 is of little or no significance.

In summary, the results indicate that both female urine and ovarian fluid contain substances that enhance plasma sex steroid levels in Atlantic salmon male parr. They confirm that $PGF_{2\alpha}$ is one active priming substance. In addition, another unknown substance may be of importance for the potency of female urine.

Acknowledgments—This study was supported by grants from Carl Tryggers Foundation (to K.H.O.) and the Swedish Research Council for Agriculture and Forestry (SJFR; to K.H.O., I.M., and H.K.). Dr. R. W. Schulz (University of Utrecht) is thanked for supplying the steroid antisera. We thank Dr. T. Järvi and Dr. E. Petersson for placing the facilities at the Stream Water Ecology Lab., National Board of Fisheries, at our disposal.

Abstract—A microwave protocol to extract lipophilic substances from tissue was modified to extract essential oils (EOs) from plant tissue and insect feculae. The material, in a solvent transparent to microwave radiation, is exposed for a short time to steam in a microwave oven. EO extracts are analyzed directly by GC or GC-MS when plant material is fresh and terpenes contained in glandular structures on leaf surfaces are readily released into the solvent. For dried material or insect feculae, mechanical means are utilized first to break up tissue; however, the complete procedure is carried out inside the same vial to reduce losses. Statistical analysis shows that the reproducibility of the modified method is high. Several samples can be run within an hour with this method.

Key Words—Microwave, essential oil, *Cordia curassavica*, Chrysomelidae, Boraginaceae, lower terpenes, extraction method, chamomile.

INTRODUCTION

Terpenoids have been studied for different reasons. Leaf terpenoids have been evaluated for chemosystematic and geographic variability (Salgueiro et al., 1997; Fahlen et al., 1997; Souto et al., 1997), biosynthetic studies (Gershenzon, 1994; Clark et al., 1997), herbivore–host-plant relationships (Steinbauer et al., 1998; Gómez et al., 1999), bioassays (Lis et al., 1998), proof of authenticity (Casabianca et al., 1998), and aroma chemistry (Pallado et al., 1997).

A number of methods for obtaining essential oils (EOs) from plant foliage have been published (Ruberto et al., 1999; Simandi et al., 1999; Lis et al., 1998;

*To whom correspondence should be addressed. E-mail: gomezn@tivoli.si.edu

0098-0331/01/1100-2351$19.50/0

Anitescu et al., 1997; Laenger et al., 1997; Muzika et al., 1990). However, many of these techniques require gram amounts of samples and long extraction times. In contrast, methods to extract EOs from insect wastes appear to have received little attention.

A common problem encountered by chemical ecologists during their assessments is the small amount of sample material available for chemical analysis, especially when that material is insect physiological wastes and discharges, e.g., feculae and regurgitates. Similar situations are encountered with plant material, for instance, when herbivory causes defoliation, especially of young leaves (Gómez, 1997; Coley and Kursar, 1996), or conversely, when considerable quantities of plant tissue are needed for studies of geographical distributions of EOs.

We developed a method based on the work of Pare (1994, 1995) and modified by Clark et al. (1997) to quantitatively extract EOs from plant tissue and insect feculae. Here we present data on the reproducibility of that method by quantifying EOs in plant material and insect feculae with known and unknown terpenoid levels and EOs. We also compare our results with those obtained from steam distillation.

METHODS AND MATERIALS

Plant Material. We tested five samples (40 mg) from *Matricaria chamomilla* L. from the company Caolo (30.06.95, Ch. B. 53618395), with 0.63% EO to assess the efficacy of the modified method (see below). Five (40-mg) samples from *Mentha piperita* L. and *Salvia triloba* L., with unknown terpenoid levels, were also examined. Foliage of *Cordia curassavica* (Jacq.) Roem. & Schult. (field plants from Central Panama) also were examined. Branches of *C. curassavica* were collected in the field and transported to the laboratory in plastic bags. Young leaves (newly expanded at nodes 1 and 2) were excised, pooled, dried at room temperature, and then coarsely ground before weighing and extracting. Vouchers of *C. curassavica* were deposited in the Herbarium of the Smithsonian Tropical Research Institute.

Insect Feculae. Larval feculae came from *Eurypedus nigrosignata* Boh. (Coleoptera: Chrysomelidae), a beetle that feeds on *Cordia curassavica* in Central Panama. Feculae were collected from third instars that fed on plants with differing compositional profiles of EOs (Gómez et al., 1999). Larvae of *E. nigrosignata* produce elaborate dorsal structures, by using feculae and cast skins, that can be detached easily from their bodies with forceps. The size and weight of dorsal structures vary with larval age, and their chemical composition varies depending on plant terpenoid content (Gómez et al., 1999). Three groups of feculae (40 mg) were examined. Feculae for batch 1 ($N = 5$) and batch 2 ($N = 4$) came from larvae feeding on *C. curassavica* shrubs carrying the α-pinene profile, and

batch 3 ($N = 5$) came from larvae raised on *C. curassavica* cultivated in a green house (Gómez, 1997) and carrying the β-terpinene profile. Replicates in each batch contained several dorsal structures. Only quantifiable monoterpenoids and caryophyllene were considered for total concentration.

Steam Distillation. Distillation was performed in a steam-distillation apparatus as described in the German Pharmacopoeia (DAB10, 1991). Samples (1 g, $N = 2$) of dried material from *C. curassavica* (see above) were placed in a flask, 200 ml distilled water was added, and the distillation carried out for 5 hr. The distillate was collected in 0.75-ml *n*-hexane. *n*-Octadecane was added to the samples to arrive at a final concentration of 20 μg/mg. Only major terpenoids were used for comparison among methods.

Microwave Method. A method to extract lipophilic substances from fresh material as developed by Pare (1994, 1995) and modified by Clark et al. (1997) was adjusted further to extract EOs from small amounts of fresh and dried samples. The material was extracted with 0.75 ml *n*-hexane (p.a.) containing 50 μg/ml of *n*-octadecane in a vial (2.0-ml, conical, polypropylene Twist Cap vials, with screw caps with an O-ring seal). Two glass beads (4 mm diam.) were added to the sample vial, and shaken in a Vortex at medium speed for approximately 120 sec (or until tissue was crushed). A polypropylene lid with five to six radially symmetrical holes served as a vial holder (Clark et al., 1997). The lid was placed on a 250-ml glass beaker containing 50 ml water at room temperature. Sample vials were then heated in a microwave oven at full power (800 W) for 60 sec. After the microwave exposure, the vials with lids were cooled in a polypropylene jar of cold water and centrifuged at 14,000 rpm for 3 min. The clear supernatant was transferred and kept in 2.0-ml glass vials (screw cap with Teflon lining) at -18°C until GC and GC-MS were carried out (see below). When fresh plant material was used, a clear extract was obtained without the need for maceration or centrifugation. The total EO concentration, and the concentration of the major terpenoids was determined for each sample (see below). Only major terpenoids were considered for comparison of methods.

GC and GC-MS. Separation, quantification, and identification of terpenoids were carried out as described in Gómez et al. (1999).

Scanning Electron Microscopy (SEM). The surface of young *C. curassavica* leaves was viewed directly before and after microwave extraction, by using backscattered electrons at low vacuum, and they were photographed in a Jeol model 5300LV scanning electron microscope.

Statistical Analysis. The reproducibility of the microwave method was tested by comparing coefficients of variation (CV) (Muzika et al., 1990; SYSTAT, 1992), and the intraclass correlation coefficient (ICC) within groups (Sokal and Rohlf, 1995; SYSTAT, 1992). Yields obtained by the microwave method and the distillation method were compared by linear regression (LR) analysis, and the adjusted

squared multiple R was utilized to compensate for unequal sample sizes. In one case, a LR was made by considering the mean values of the distillation method as the independent variable. If the microwave method extracts a higher quantity of terpenoids than the distillation method, then the slope of the LR equation should be larger than unity. A second LR was made by considering the mean values of the microwave method as the independent variable. Correlation coefficients were used to compare the fit and the variance explained by the method.

RESULTS

Plant Material. The EO concentration of commercial *M. chamomilla* samples determined by the microwave method was $0.65 \pm 0.05\%$ (Table 1), the same as the reported one of 0.63%. Terpenoids detected in the yellowish extract of chamomile were β-farnesene, α-bisabolol oxide B, α-bisabolone oxide, α-bisabolol, bisabolol oxide A, and spiroether. Plant material (40 mg) of *M. piperita*, *S. triloba*, and *C. curassavica* (wild plants) with unknown levels of EO also were examined (Table 1). The CV varied from 5% to 15% for the total concentration, and from 3% to 16% for the amount of the major terpenoid.

The ICC was used to evaluate the reproducibility of the microwave method and showed 9% variation for the total concentration within the groups, and 11% for the main component.

Comparison of Extraction Methods. The first LR demonstrates that the microwave method was more efficient in obtaining higher concentrations of components (slope $= 1.729$; $p < 0.001$). The microwave method produced less variable yields ($R^2 = 0.900$) than the distillation method ($R^2 = 0.787$).

SEM. After exposure to hot hexane, glandular trichomes on the surface of fresh leaves collapsed (Figure 1A, B).

Insect Material. Three different batches of insect feculae were utilized to evaluate this method. CVs varied from 14% to 21% for the total concentration of EOs and from 17% to 20% for the main component, depending on fecula origin

TABLE 1. EO CONCENTRATION OF DIFFERENT PLANT SPECIES SAMPLES WITH MICROWAVE METHOD[a]

Plant species	Total concentration	%CV	Major terpenoid concentration	%CV
Matricaria chamomilla	6.59 ± 0.43	7	3.66 ± 0.11^a	3
Mentha piperita	5.30 ± 0.29	5	2.14 ± 0.19^b	8
Salvia triloba	13.50 ± 2.20	15	6.89 ± 1.25^c	16
Cordia curassavica	12.66 ± 0.90	7	3.74 ± 0.54^d	16

[a] $N = 5$; concentration (mean $\pm$ SD) in mg/g, dry weight; %CV, coefficient of variation in percentage; a, bisabololoxide A; b, menthol; c, 1,8-cineol; d, β-terpinene.

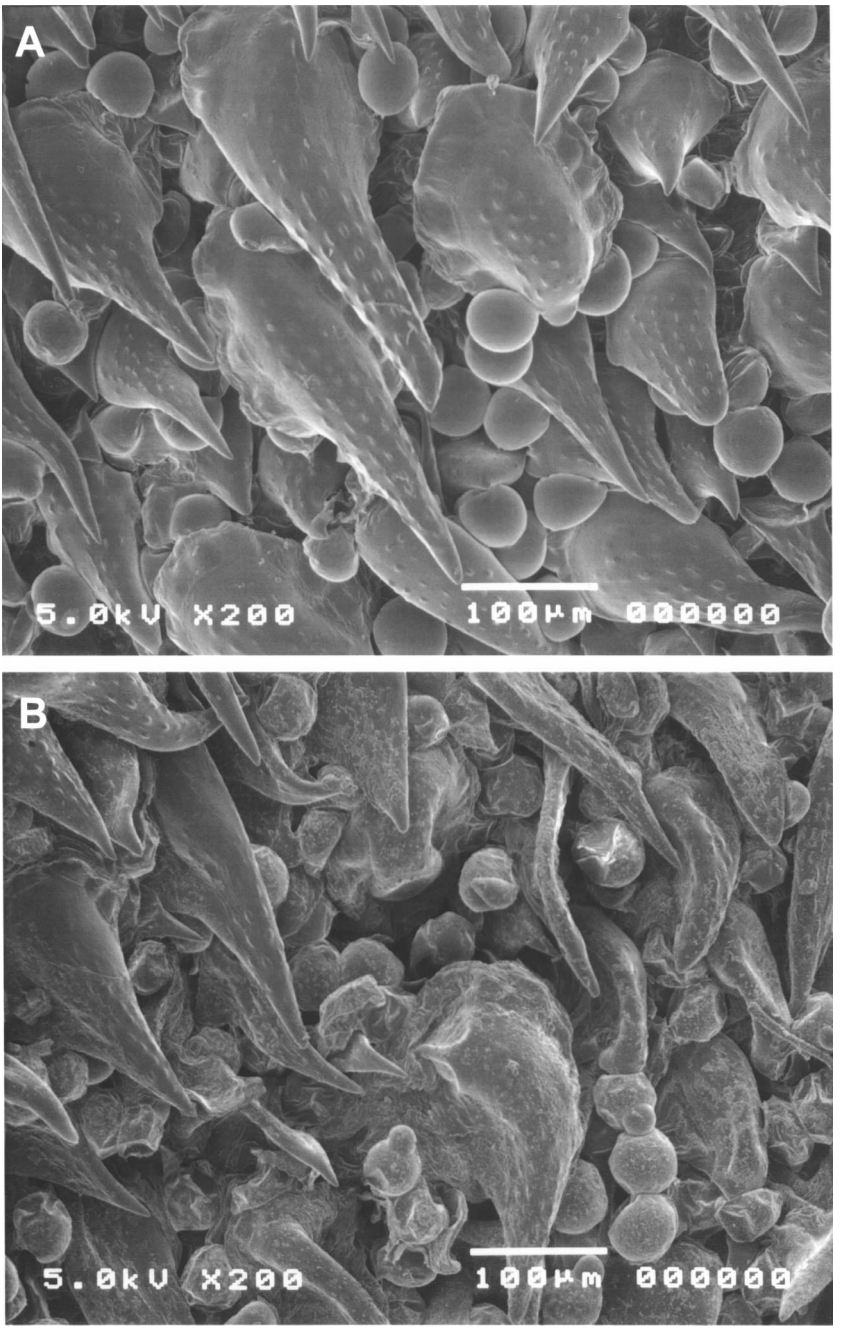

FIG. 1. Adaxial surface of *C. curassavica* showing glandular round trichomes (A) before and (B) after exposure to hot hexane.

TABLE 2. EO CONCENTRATION FOR THREE FECULA BATCHES COLLECTED FROM THIRD INSTARS OF *Eurypedus nigrosignata*[a]

Batch	Avg. weight (mg) (±SD)	Avg. number of dorsal structure per replicate (±SD)	Total concentration (mean ±SD)	%CV	Major terpenoid concentration (mean ± SD)	%CV
Wild larvae ($N = 5$)[b]	40.9 ± 1.2	6.6 ± 0.5	2.88 ± 0.61	21	1.12 ± 0.22	20
Wild larvae ($N = 4$)	39.9 ± 2.6	7.3 ± 0.8	4.99 ± 0.92	18	2.57 ± 0.46	18
Greenhouse larvae ($N = 5$)[c]	37.8 ± 3.2	7.0 ± 1.4	2.67 ± 0.39	14	1.58 ± 0.26	17

[a] Concentration in μg/mg, dry weight; %CV, coefficient of variation in percentage.
[b] α-Pinene profile.
[c] β-Terpinene profile.

(Table 2). Feculae from animals feeding on field plants registered higher CVs than those from animals raised on greenhouse plants.

The ICC was calculated also to evaluate the microwave method for insect samples. The ICC percentage variation within groups was 23% for the total concentration, and 17% for the major component.

DISCUSSION

For fresh plant material containing EOs in glands, the hot solvent was efficient at collapsing glandular structures and extracting terpenes (Clark et al., 1997) without need of maceration. Indeed, treatment of fresh plant material with glass beads in these trials did not cause tissue destruction. Destruction of plant tissue other than that containing EOs may lead to undesirable plant contaminants in the extract. By extracting fresh plant material as described above, the clear extract obtained can be analyzed directly by GC.

In the case of insect material, we found that the use of glass beads to macerate both fresh and dried insect feculae before microwave exposure, in order to destroy the matrix holding EOs, facilitates their release into the solvent. Maceration with glass beads was a good alternative to pulverization with a mill or maceration with a mortar and pestle, because these procedures lead to significant sample loss, particularly when dealing with small samples containing volatile substances. This step usually produced fine particles that were separated by centrifugation. Losses of volatiles can be reduced further by carrying the procedure to completion in the same extraction vial and by avoiding rotary evaporation to eliminate the solvent, because it may lead to the losses of volatile compounds.

The coefficient of variation (CV) has been used as an index of reproducibility of five techniques for extracting volatile compounds from needles of two conifer

species (Muzika et al., 1990). The CV was developed to compare the relative amounts of variation in populations having different means (Sokal and Rohlf, 1995, p. 58). CV analysis indicates that the modified microwave method is reproducible both for total terpenoid concentration and for individual terpenoids. The intraclass correlation coefficient (ICC) measures the similarity of individuals within a group, relative to the degree of difference found among the groups (Sokal and Rohlf, 1995, p. 213). A low value for ICC indicates that there is little or no variance within groups. The ICC showed low variation within groups for both plant and insect materials, supporting the reproducibility of the modified method.

Higher EO yields were attained with the microwave method compared to yields obtained by steam distillation. In addition, this method yields less variable results. Several authors have reported that steam distillation produces lower extraction yields (Simandi et al., 1999; Tuan and Ilangantileke, 1997; Stashenko et al., 1997), contributes to thermolysis of sensitive terpenes (Ruberto et al., 1999; Ammann et al., 1999; Eikani et al., 1999), and takes longer than other techniques (Muzika et al., 1990). With the modified method, we can not rule out the possibility that some thermal degradation may occur. However, we were not able to detect this in our samples. On the other hand, comparison of various methods that have been used to extract EOs from conifer needles has shown that circular steam distillation of 10-g samples for 8 hr yielded higher quantities (Muzika et al., 1990) than did solvent extraction, liquid carbon dioxide extraction, or rapid steam distillation.

The tremendous natural variation in leaf terpenoids (Langenheim, 1994; Gershenzon, 1994) may also influence the composition of physiological discharges from phytophagous insects, e.g., many insects prefer to eat young leaves (Coley and Kursar, 1996). We suggest collecting and extracting newly expanded leaves (assuming that they are small enough to fit inside a vial) and/or removing a predetermined leaf area from more mature leaves. Analysis of fresh material results in higher yields of secondary metabolites (Gómez et al., 1999; Coley and Kursar, 1996) and prevents the loss of volatiles due to drying (Ross and ElSohly, 1996; Yen and McGaw, 1996).

When analyzing insect material with the microwave method, one should consider that variation due to the nature of the sample rather than the method itself may occur. Our particular plant–insect system is under the strong chemical influence of a particular host plant as well as the larval age (Gómez et al., 1999).

Specific Considerations. Because hexane is transparent to microwave radiation, water steam is the heating source. A solvent not transparent to microwave radiation would itself boil, making water steam unnecessary. However, solvent polarity may be important, depending on the chromatographic analysis chosen. Additionally, an explosion-proof oven should be used, in case extraction vials have leaks or if open containers are used. It is advisable to use high-quality, seal-proven extraction vials to assure that solvent fumes (and volatile substances) are not released into the oven chamber. The watt output of the microwave oven

may vary depending on brand, country of manufacture, and local electrical characteristics, so that the exposure time may need adjustment. We found that dried leaflets longer than half of the vial height were difficult to grind with two glass beads. In such a case, smaller beads especially designed for tissue analysis may be needed. Alternatively, the leaf can be broken manually.

Chemical ecologists usually are confronted with a limited sample of insect waste material for analysis. Factors such as insect age and insect preferences for specific plant organs at specific developmental stages are important considerations during the analysis of EOs.

In summary, the microwave method is reproducible, easy to run, allows simultaneous analysis of many samples, and offers an excellent alternative to methods that utilize gram amounts of material, i.e., steam distillation and solvent extraction. Researchers engaged in evaluating the role of EOs in plant–insect interactions, terpenoid differences in individual plants, and biogeographical studies of EOs, may profit greatly from using this modified method.

Acknowledgments—We thank Dr. H.-J. Hammerschmidt of the perfume company Dragoco, Germany, for kindly identifying many sesquiterpenes, T. Hartmann (TU-BS) and P. Solís (University of Panama) for comments on the manuscript, A. Aiello (STRI) for improving the language, and R. Cordero for helping with the statistics. This work was financially supported by a fellowship (to N.E.G.) from the German Academic Exchange Service (DAAD), and by Research Opportunity Funds from the Smithsonian Tropical Research Institute (STRI).

CALL FOR PAPERS

SPECIAL ISSUE ON AQUATIC CHEMICAL ECOLOGY

There will be a special issue of the *Journal of Chemical Ecology* devoted entirely to papers dealing with "Aquatic Chemical Ecology". Publication is planned for late summer/early fall 2002. The issue will consist of invited mini-reviews and contributed papers. Those wishing to submit a paper for consideration for this special issue should do so by February 1, 2001.

Please send the original and two copies of the manuscript (including illustrations) and the names and addresses of three potential reviewers to:

Abstract—Plant allelopathy offers hope as an additional means of weed control in modern agriculture. Its mechanisms and molecular basis are not yet well understood. Research on the chemical basis for allelopathy has often been hindered by the complexity of plant and soil matrices, making it difficult to track active compounds. Recent improvements in the cost and capabilities of bench-top chromatography–mass spectrometry instruments make these tools more powerful and more widely available to assist with molecular studies conducted in today's expanding field. Such instrumental techniques are herein recommended as economically efficient means of advancing the rigor of allelopathy research and assisting the development of a better understanding of the chemical basis for the allelopathy phenomenon.

Key Words—Allelopathy, phytotoxicity, sustainable agriculture, weed management, allelochemicals, chromatography, mass spectrometry, hyphenation, GC-MS, LC-MS, MS-MS.

INTRODUCTION

Within the broader field of chemical ecology, the expanding science of plant allelopathy (biochemical interactions between plants) possesses potential to contribute to the development of sustainable agriculture, especially in the area of weed management, as currently, weed science possesses few alternatives to tillage and to artificial herbicides as means for economically and environmentally sound weed control.

0098-0331/01/1200-2363/0

However, for an adequate understanding of allelopathic effects and mechanisms, a knowledge of specific allelochemicals is required (among other things); yet it is only in comparatively recent times that this sort of information has become readily available. This lag in chemical information is due first to the fact that the compounds from a given plant, microorganism, or soil source usually occur within complex metabolic mixtures and in tiny quantities, thus creating a formidable problem in analysis. Second, the most powerful tool for dealing with such complex organic mixtures, gas chromatography coupled with mass spectrometry, (GC-MS), has only been readily available in commercial economic form since about 1975, while the useful (but presently less powerful) companion tool liquid chromatography-mass spectrometry (LC-MS), has been available for even less time. It is the physical on-line coupling, software-controlled, separate systems unitization, and computerized output data handling (collectively known as "hyphenation") between the physical mixture separation process of chromatography and the structure identifying (and quantifying) ability of mass spectrometry that allows such analytical power to bypass the need for the elaborate and expensive isolation of individual compounds. The key idea behind hyphenation is the significant gain in analyte-signal to background-noise ratio. While with hyphenation the signal decreases with each additional hyphenated analysis stage, the background chemical noise decreases even faster, owing to the higher selectivity of the coupled system. Although the individual compounds within complex mixtures in GC- or LC-MS work may not be actually isolated, the identifying data so obtained can enable the researcher to carry out bioassays and chemical assays with authentic compounds from other sources available in larger quantity.

The major purposes of this review are to assist with the advancement and rigor of plant allelopathy research, in accordance with journal editors' calls (Romeo, 2000) by promoting the use of hyphenated chromatography–mass spectrometry techniques to provide confirming and defining chemical data and also to provide sufficient examples of these techniques to allow the evaluation of their efficacy for the solution of new allelopathic problems that may involve the identification and/or quantification of numerous organic components from complex mixtures. In this respect, the review is meant to be indicative and not exhaustive.

For those newly moving into allelopathy studies, its more recent historical development can be conveniently traced through such works as Rice (1984, 1995), Thompson (1985), Putnam (1985), Putnam and Tang (1986), Waller (1987), Rizvi and Rizvi (1992), Narwal and Tauro (1994), Inderjit et al. (1995, 1999), Olofsdotter (1998), Macias et al. (1999), Narwal (1999a,b), Cutler and Cutler (1999), and Blum et al. (1999), although the phenomenon of allelopathy has a much longer history than this. Chromatography–mass spectrometry has been given little prominence in these works until the late 1990s, and although its analytical power has been widely recognized for some time, the cost of instruments until now has been a hindrance to widespread use, particularly in developing countries. Thus, as late as 1986,

Putnam and Tang (1986) commented that "chemistry has been the Achilles heel of allelopathy." Today, however, most researchers would agree with Weidenhamer's (1996) comment that the Putnam-Tang assertion is no longer true. More specifically, with respect to LC-MS and GC-MS, the 1990s have seen the development of small, relatively inexpensive, bench-top versions of these instruments, with sophisticated software on dedicated personal computers, which require much less operator expertise, and display great reliability and robustness—most notably in the more difficult interface between LC and MS.

For those readers not necessarily intimate with general high-resolution (HR) chromatographic separations, there are numerous descriptive works available to give a sound introduction to each type. For HRLC, examples include: Meyer (1988) and Gooding and Regnier (1990); while for LC-MS, such works as Brown (1990), Lin and Voyksner (1995), Kleintop et al. (1995), and Niessen (1999) serve well. For HRGC, examples include Jennings et al. (1997), Grob (1998), and Heath and Dueben (1998); while for GC-MS the works of Karasek and Clement (1988) and McMaster and McMaster (1998) are helpful. Closer to the theme of this review are the edited publications of Millar and Haynes (1998) (providing a current summary of a range of useful analytical methods in chemical ecology, including mass spectrometry), Linskens and Jackson (1986) (use of GC-MS in plant analysis), Newton and Walton (1996) (plant GC-MS), Alborn and Stenhagen (1987) (LC-MS in allelopathy), and Waller et al. (1999) (allelopathic compounds).

While both hyphenated techniques of LC-MS and GC-MS combine the resolving power of chromatography with the detection specificity of mass spectrometry and possess about the same sensitivity in analysis, together with similar fingerprint-identifying power for unknown compounds (where pure reference compound spectra can be run to build small user-created libraries, or where EI particle beam LC-MS is available), the LC-MS technique has a great advantage over GC-MS in being able to handle effectively the separation of labile, heat-sensitive, involatile, and high-molecular-weight samples, and can, therefore, cover an estimated 80% of all known compounds. The remaining 20% of lighter, more stable, and volatile compounds are best handled by capillary GC-MS (HRGC-MS), which has a much higher chromatographic resolving power than LC-MS because of the long and narrow GC separation columns that help to overcome a large part of the tendency for analyte coelution that occurs with complex mixture analysis. Another significant advantage of GC-MS [whose volatile analyte range may be further extended by chemical derivatization, Halket (1993)] is the availability, for the sake of identification, of quite large (approx. 320,000 Wiley/NIST) commercial libraries of computer-searchable standard electron-impact mass spectra accumulated over many years of research by using magnetic sector and transmission quadrupole spectrometers (classical mass spectra). Such library spectra have been run and collected under physical conditions similar to that occur in the mass spectral detector used in most hyphenated GC-MS instruments, and can, therefore, be directly

compared with analytical spectra by a software computer algorithm for compound matching. For a library-to-analyte computer match number in excess of 800 (1000 is a perfect match), a tentative identification is accepted and will become definitive if the pure reference compound can be found (perhaps by synthesis or from commercial sources) and determined to have the same chromatographic retention time under the same instrumental conditions. For most LC-MS, there is at present no large spectral library equivalent to the GC-MS fingerprint technique (unless an EI particle beam instrument is available) because optimal LC-MS instrument operating conditions and methods of ionization are so variable.

ALLELOPATHY STUDIES ASSISTED BY CHROMATOGRAPHY AND MASS SPECTROMETRY

Studies Using Nonhyphenated Techniques

The allelopathy literature has, of course, many fine examples of chemical identifications (and a few quantifications) carried out by various means that use combinations of separate chromatographic and spectroscopic analyses performed upon the isolated individual compounds. Such papers as Chou and Waller (1980), Phillips and Hedin (1990), Yamane et al. (1992b), Inoue et al. (1992), Li et al. (1993), Waller et al. (1993a,b), Ohwaki et al. (1993), Korhammer and Haslinger (1994), Nakahisa et al. (1994), Macias et al. (1996, 1997), Bah and Pereda-Miranda (1996), Pereda-Miranda (1997), Gumnicka and Oleszek (1998), and Huang et al. (1999) are typical of these types of studies. Provided the investigator is prepared to meet the higher costs involved in time, manpower, instrumentation, and consumables for the isolation and purification of individual compounds from a complex matrix, then the advantages of other powerful analytical tools such as FTIR, PMR, CMR, and MS-MS, can also be brought to bear upon structural elucidation and chemical identifications. In this review, however, the concern is with cheaper, faster, hyphenated chromatography–mass spectrometry methods that rely more upon fast computer spectral library matching for identifications. Hyphenation of GC with FTIR plus MS, and recently between LC and NMR, offers additional analytic power within the range of hyphenated techniques, but again, present instrument cost is a considerable barrier to their widespread use.

Allelochemical Identifications Using Hyphenated Chromatography–Mass Spectrometry

Table 1 lists a comparison of research papers in summary form published between 1979 and 2000 that establish the identity of plant allelochemicals by using chromatography–mass spectrometry. As might be expected for the more mature GC-MS techniques, the number of examples of their use is considerably

TABLE 1. ALLELOCHEMICAL IDENTIFICATIONS USING CHROMATOGRAPHY–MASS SPECTROMETRY

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To develop a procedure for the separation, detection, and identification of hydroxamates and lactams in maize extracts (*Zea mays* L.)	Bioassay not required	GC-MS GC: Varian Aerograph 2700; packed column: glass, 1.8 m × 2 mm ID; stat. phase 3% OV-1; MS: Du Pont 21-491B; EI at 70 eV: source 200°C; inlet 250°C	Six different 1,4-benzoxazin-3-ones (three × hydroxamic acids, three × lactams) and 6-methoxybenzo-xazolinone	TMS derivatives using BSTFA at 70°C for 20 min	Woodward et al. (1979); packed GC column—sensitivity to 100 ng
To examine the weed thorn-apple (*Datura stramonium*) for its allelopathic potential against linseed (*Linum usitatissimum* L.) and to search the seed and leaves aqueous leachate for allelopathic alkaloids	% germination and radicle elongation of linseed (*Linum usitatissimum* L.)	GC-MS Finnigan Quadrupole 3200 system with Incos 2300 Data System; column glass, 1.5 m × 2 mm ID; stat. phase 3% OV-17 and temp. prog.; carrier gas methane at 20 ml/min; ionization: methane CI with ion source pressure 0.8 torr	Alkaloids; hyoscyamine and scopolamine	pentafluoro-propionate derivatives using PFPA	Lovett et al. (1981) methane carrier gas used as CI gas also; seed leachate contained more alkaloid than leaf

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To isolate, identify and measure the biological activities of allelochemicals from water nutgrass (*Cyperus serotinus* Rottb.)	Radicle length and 2nd leaf sheath length of rice seedlings (*Oryza sativa* L. cv. Honenwase) and lettuce (*Lactuca sativa* L. cv. New York) hypocotyl and root length	GC-MS LKB 9000 system; column: glass, 3 m; stat. phase 10% PEG-20 M and a 2% OV-17 column; molec. separator 240°C; source 270°C; EI at 20 eV; ionising current 60 μA	Sesquiterpenoids; β-selinene; 2,6-farnesol; methyl farnesate; *trans*-2, *trans*-6-farnesyl acetate	Steam-distilled volatiles	Komai et al. (1981); packed column GC
To determine if aqueous extracts of wheat straw were inhibitory towards the weed morning glory (*Ipomoea lacunosa* L.) and to identify any inhibitory component	% germination and root length measured on morning glory and on ragweed (*Ambrosia artemisiifolia*)	GC-MS LKB 2091 system; column: 6 ft $\times$ 1/8 in. ID ultrabond at 230°C; helium carrier 8 ml/min; source 210°C; EI at 70 eV; mass scan cycle 2.0 sec	Ferulic acid	No derivatization (some adsorption and thermal decomposition of analyte)	Liebl and Worsham (1983); ferulic acid readily decarboxylated by bacteria to 2-methoxy-4-ethenylphenol, itself phytotoxic

To identify components of the volatiles emitted from harvested Palmer amaranth (*Amaranthus palmeri* S. WATS.) root, stem, and seedhead, and to test their capacity to inhibit germination of onion, carrot, tomato, and Palmer amaranth seeds	Vapor phase seed germination inhibition on onion, carrot, and tomato	GC-MS Finnigan MAT 4000 system; column: 10 ft × 1/8 in. ID nickel tube; stat. phase 8% poly-*m*-phenoxylene; temp. prog. from initial 30°C; MS: scan time 2.0 sec.; mass range 33–450 m/z	20 compounds, mainly simple methyl ketones, alcohols, aldehydes, and two furans	Volatiles stripped off a Tenax trap by thermal desorption at 200°C in a He flow at 20 ml/min into GC inlet	Connick et al. (1987); packed column GC
To identify the major active components in manila-grass [*Zoysia matrella* (L.) Merr.] shoot extracts	% germination and seedling growth of livid amaranth [*Amaranthus lividus* (L.) Merr.]	GC-MS H-P 5980/ MS5970 system; GC column: FSOT, stat. phase DB-1; 15 m × 0.25 mm ID; He carrier gas; temp. prog. from 260°C to 310°C	Two phenolic acids (4-hydroxybenzoic and *p*-coumaric acids), plus nine fatty acids	Diazomethane for methyl esters, and MSTFA for TMS derivatives	Laosinwattana et al. (1999); 4-hydroxybenzoic and *p*-coumaric acids were highly inhibitory to livid amaranth at 62.5 ppm

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To use a circulating root exudate trapping system (CRETS) to collect exuded compounds from Bigalta limpograss (*Hemarthria altissima*) on XAD-4 resin and identify the compounds	Radicle length of lettuce seedlings	GC-MS GC: Varian Aerograph 1400; column 30 m SCOT glass capil.; stat. phase OV-17; injection 220°C, temp. prog. from 150°C; MS: Finnigan 3000 with EI at 69.5 eV	12 compounds, mostly phenolic acids (substituted benzoic and cinnamic acids)	Methyl esters and ethers formed from diazomethane and deuterated diazomethane	Tang and Young (1982); the first successful report of the isolation and identification of phytotoxic compounds from the environment of undisturbed living plant roots
To isolate, identify and determine the biological activities of the non-phenolic phytotoxins found in prostate knotweed (*Polygonum aviculare*) residues and surrounding soil	% germination and seedling growth (radicle, epicotyl, and whole seedling) of Bermuda-grass (*Cynodon dactylon*)	GC-MS H-P 5985 system; column: 25 m × 0.2 mm ID FSOT; stat. phase methyl silicone/ Carbowax-20M; He carrier at 20 psi and 0.6 ml/min; split ratio 50:1; temp. prog. from initial 150°C	Nine compounds identified as various saturated and unsaturated fatty acids	Methyl ester derivatives formed with diazomethane	Alsaadawi et al. (1983); gives the first report implicating long-chain fatty acids in the allelopathic effects of higher plants

To determine if the ability of rye (*Secale cereale* L.) to suppress the growth of weeds Lambsquarters (*Chenopodium album* L.) and Common ragweed (*Ambrosia artemisiifolia*) is caused by phytotoxic compounds, and to identify such possible compounds	% germination and root and hypocotyl lengths of *Chenopodium album* L. seedlings after treatment with extracts of rye	GC-MS H-P 5985B system; column: 30 m × 0.25 mm ID; stat. phase DB-5; FSOT; He carrier at 1.0 ml/min; injection at 250°C of 1-4 μl; temp. prog. from 50°C to 280°C; MS: EI 70 eV, also methane positive CI	3-phenyllactic and 3-hydroxybutanoic acids	TMS derivatives formed using BSTFA	Shilling et al. (1986); TLC then HPLC then GC-MS separation sequence; positive methane CI spectra included std. adduct ions at (M + 1), (M + 29), (M + 41) to assist MW determinations
To investigate the rhizosphere surrounding marigold (*Tagetes patula* L.) roots for the presence of phytotoxins known to be present within the roots	Bioassay not required	GC-MS Finnigan 1020 system; column: 30 m FSOT; stat. phase SE-54; MS scan 40–400 m/z	Four thiophenes and two benzofurans	Volatiles stripped off XAD-4 resin trap	Tang et al. (1987); CRETS methodology

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To describe new developments in micro LC-MS techniques for the analysis of labile allelochemicals from plant materials	Bioassay not required	LC-MS LC: micro-columns of 20–50 cm × 0.22 mm ID packed with 3-5 μm particles; flow rates 1-5 μl/min; injection 0.5 μl; MS: EI positive ions magnetic sector; detection limits ng-μg.	Separations and identifications achieved with cardenolides, chlorogenic acid, and phenolic acids	LC-MS—no derivatization necessary	Alborn and Stenhagen (1987); caffeic, *p*-coumaric, and sinapic acids separated in 10 min on a 18 cm × 0.22 mm column using 3 μm Spherisorb ODS particles in MeOH/water/ HOAc isocratic mobile phase
To investigate the chemical properties of *Calmintha ashei*, a scrub plant with inhibitory effects on Florida sandhill grasses	Seed germination inhibition of *Schizachyrium scoparium*	GC-MS column: 30 m bonded FSOT capillary; injection 250°C; temp. prog. 45°–250°C; MS: 70 eV EI	Evodone, menthofuran, 2,3-dihydroevodone	Steam-distilled volatiles	Tanrisever et al. (1988); results suggest that ursolic acid in aqueous leaf leachate of *C. ashei* may act as micellar host for aqueous transportation of other bioactive compounds

To identify the volatile allelochemicals emitted from *Amaranthus* spp. by adsorption on Tenax and Carbotrap	Seed germination of carrot, tomato, and onion	GC-MS Finnigan MAT 4000 quadrupole system; and a Perkin-Elmer Sigma 300 GC with ion trap detector; GC/ITD column: 50 m × 0.31 mm ID × 0.52 μm with H-P ultra-2 stat. phase; He carrier at 12 psi; MS scan 1.0 sec for 33–250 m/z	34 compounds identified, mostly simple alcohols, aldehydes, esters, ketones, three alkanes, three terpenes, two furans, and dimethylsulfide	Headspace emitted volatiles desorbed off Tenax and Carbotrap tubes over 3 min at 200°C in 10 ml/min He gas flow. Cryoscopic focussing at −30°C	Connick et al. (1989); 31 compounds used in vapor phase bioassay at conc. 34.4 μmol/liter; all compounds showed some level of inhibition
To investigate the leaching of allelochemicals from the leaves of the allelopathic mint *Conradina canescens*	Seed germination and radicle lengths of *Schizachyrium scoparium, Andropogon gyrans,* and *Leptochloa dubia*	GC-MS H-P 5985 system; column: 30 m bonded phase FSOT; injection 250°C; temp. prog. 60°C–210°C; MS: EI at 70 eV	26 terpenoids	Steam-distilled leaf volatiles and bioactive LC column fraction	Williamson et al. (1989)
To develop an improved LC-MS system of micro eluant flow into an EI-MS source to enable identifying mass spectra of thermo-labile allelochemicals	Bioassay not required	LC-MS LC column: 20–50 cm × 0.2 mm ID with 3–5 μm packing; flow rate <2 μl/min with solvent gradient; MS: 70 eV EI; source 140°C	Dhurrin (a cyanogenic glucoside) from sorgum leaf extract	No derivatization necessary	Stenhagen and Alborn (1989)

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To identify compounds which may be responsible for autotoxicity in alfalfa	% germination of alfalfa or velvetleaf seeds	GC-MS (no details given)	Medicarpin; sativan; 4-methoxymedicarpin; 5-methoxysativan	(No details given)	Dornbos et al. (1990); medicarpin is an isoflavanoid phytoalexin
To determine the profiles of the volatiles emitted by residues of winter cover crop legumes berseem clover (*Trifolium alexandrinum* L.), hairy vetch [*Vicia hirsuta* (L.) S. F. Gray], and Crimson clover (*Trifolium incarnatum* L.)	% germination of wetted seeds of onion, carrot, and tomato from volatile test compounds in their vapor state at 34.4 μmol/2.5 liters and other concentrations	GC-MS GC: Sigma 300; column: 50 m $\times$ 0.31 mm ID $\times$ 0.52 μm; stat. phase H-P ultra-2; MS: Finnigan MAT 700 ITD	31 compounds; hydrocarbons, alcohols, aldehydes, ketones, esters, furans, and monoterpenes. (*E*)-2-hexenal was the most inhibitory compound tested	Tenax-trapped volatiles thermally desorbed in an external closed inlet system interfaced with GC	Bradow and Connick (1990); the even-numbered methyl ketones from anaerobic plant residues were among the most inhibitory group of volatiles
To investigate and compare the allelochemicals extracted from soils in which no-tillage and conventional tillage wheat have been grown	Lengths of wheat seedling root and shoot	GC-MS LKB-2091 system; column: 30 m $\times$ 0.32 mm ID; stat. phase DW-5; injection 275°C; He carrier 2-3 ml/min; temp. prog. 65°C–300°C; MS: 70 eV EI; source 265°C; separator 275°C	Soil extracts identified as fatty acids	Diazomethane derivatization to methyl esters	Cast et al. (1990); greater autotoxicity shown in no-tillage soil over that of conventional tillage

To investigate the components of Devil's claw (*Proboscidea louisianica*) oil as potential allelochemical agents on cotton and wheat plants	Radicle length of cotton and wheat seedlings	GC-MS GC: Varian 3700; column: 50 m × 0.32 mm ID FSOT; stat. phase OV-1; temp. prog. 50°C–225°C; He carrier 0.5 ml/min; run time 140 min; MS: Kratos MS-50 with DS-55 data system	150–200 compounds found, mostly hydrocarbons and terpenoids; *p*-vinylphenol; piperitenone; vanillin; ionol; traxolide; 2-methyl-1, 4-naphthoquinone; 1,3,5-tri-t-butyl benzene; alpha-bisabolol; hexa-decanoic acid; delta-cadinene; anthracenedione	Steam-distilled volatiles from roots	Riffle et al. (1990); the monoterpenoid piperitenone was the most inhibitory compound tested
To identify a biologically active constituent from corn pollen (*Zea mays* L., Gramineae)	% germination and radicle length of *Amaranthus leucocarpus* Wats, and of *Echinochloa crusgalli* L. Beauv	GC-MS H-P 5985B system; column 30 m × 0.32 mm ID FSOT bonded RSL-400; stat. phase OV-210, QF-1, or DB-210; He carrier; temp. prog. 100°C–240°C; MS: 70 eV EI	Phenylacetic acid	Diazomethane derivatization to methyl ester	Anaya et al. (1992)

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To identify the active allelopathins present in *Rorippa indica* Hiern roots (Cruciferae)	Lettuce seed germination assay, and for some, a lettuce hypocotyl and radicle growth assay	GC-MS JEOL DX-300 system; column: 25 m; stat. phase OV-1; MS: 70 eV EI; some FDMS done on a JEOL JMS-01SG-2	Hirsutin, arabin, camelinin, and three new methylsulfonylalkyl isothiocyanates	Extracted volatiles directly injected	Yamane et al. (1992a); CRETS used with XAD-4 resin trap; 9-methylsulfonylnonyl isothiocyanate showed remarkable inhibition at just 26 ppm
To identify the leaf volatiles of *Ceratiola ericoides* in conjunction with allelopathic studies on this shrub	Bioassay not required	GC-MS H-P 5792 GC with a H-P 5970 MSD; column: 60 m $\times$ 0.25 mm ID $\times$ 0.25 μm; stat. phase Supelcowax 10; carrier gas 15 psi and 0.74 ml/min; temp. prog. 30°C–175°C; MS:70 eV EI	94 compounds identified, including hydrocarbons, aromatics, esters, alcohols, aldehydes, ketones, monoterpenes, sesquiterpenes	Volatiles collected on Tenax TA trap by a He gas purge (dynamic headspace)	Jordan et al. (1992); thermal desorption off Tenax followed by cryogenic focussing in liquid nitrogen before chromatography
To investigate the chemical basis for cucumber plant allelopathy on weeds	Lettuce seedling radicle length	GC-MS Hitachi M80-B system; GC column: 2 m; stat. phase OV-17; MS: 70 eV EI	*p*-Thiocyanatophenol (at about 0.7 mg/g root exudate)	Volatiles stripped off XAD-4 resin trap	Yu and Matsui (1993); CRETS trapping on XAD-4 resin; the first time such a compound has been isolated from a plant root

To identify volatile compounds from soil and litter associated with the shrub *Ceratiola ericoides* which shows field evidence for allelopathy	Bioassay not required	GC-MS H-P 5792 GC with a H-P 5970 MSD; column: 60 m × 0.25 mm ID × 0.25 μm; stat. phase Supelcowax 10; carrier gas 15 psi and 0.74 ml/min; temp. prog. 30°C–175°C; MS: 70 eV EI	66 compounds identified, including hydrocarbons, aromatics, monoterpenes, sesquiterpenes, alcohols, aldehydes, ketones; the most abundant in litter were 1-octene, 3-octanol, 1-pentanol, and in soil were 3-methyl-1-butanol, 3-octanol, and 3-octanone	Dynamic headspace sampling with He gas purge and trap on Tenax	Jordan et al. (1993)
To identify the components present in an ethereal extract of wheat (*Triticum aestivum*) which shows a positive bioassay for allelopathic activity	Bioassay not required	LC-MS and GC-MS LC: Gilson; column 250 mm × 4 mm ID with 5 μm Chrosorb RP Select B; acetonitrile eluent; MS: VG Trio-1000 with particle beam interface and 70 eV EI GC: Carlo Erba Vega 5300; MS: Shimadzu QP-1000; source 250°C	37 compounds; 21 esters of linear and branched saturated and unsaturated fatty acids; eight ketosterols; seven 3-hydroxysterols, and syringic aldehyde	For GC-MS, TMS derivatives formed using HMDS/TMCS; for double bond localization by MS, dimethyl disulfide derivatives made of the unsaturated esters	Chaves das Neves and Gaspar (1995); *Z* and *E* unsaturated isomers differentiated by diastereomeric adduct formation with dimethyl disulfide

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To compare the essential oil composition of *Hesperozygis ringens* (Benth) Epling and *H. rhododon* Epling and verify their allelopathic potential	Lettuce seed germination	GC-MS a H-P 5970 system; column: 25 m × 0.23 mm ID × 0.25 μm; stat. phase DB-1; He carrier 0.9 ml/min; MS: 70 eV EI	24 compounds, mostly terpenoids; main component of *H. ringens* was pulegone, and of *H. rhododon* was menthone	Steam-distilled volatiles	von Poser et al. (1996); both *cis* and *trans*-pulegone oxides were synthesised for authentic reference compounds
To identify Aponin-3 from the green alga *Nannochloris oculata* as an allelopathic inhibitor of the red-tide dinoflagellate phytoplankton *Gymnodinium breve*	Cell counts of *Gymnodinium breve* cultures	GC-MS a H-P 5890(II) with H-P MSD 5972 system (no other data)	Methyl palmitate and methyl stearate	Extracted volatiles directly injected	Perez et al. (1997); optimum concentration of allelochemicals was about 3 ppm for bioactivity
To investigate the allelochemicals in Beijing wheat #437 rhizosphere fungi and bacteria	Length of radicle in wheat and maize seedlings	GC-MS GC: H-P 5890; column: 30 m × 0.25 mm ID FSOT; stat. phase DB-5; injection 240°C; He carrier 1.0 ml/min; temp. prog. 50°C–275°C; MS: TR 102000 with 70 eV EI; source 150°C; mass scan 30–600 m/z	Approx. 40 compounds; hydrocarbons, acids, alcohols, esters, aldehydes, ketones, nitriles, amines, and some heterocycles but only by library matching	Extracted volatiles directly injected	Ma et al. (1997)

To evaluate the allelopathic potential of several members of the *Brassicaceae* family (crucifers) to suppress weed emergence and growth when green tissues are incorporated into soil; and to determine the major volatiles released by chopped tissues	Inhibition of seed germination and growth of *Sesbania exaltata* and *Triticum aestivum* on exposure to soil green manures. Seed germination of soybean, corn, wheat, rapeseed, dandelion, alfalfa, and cucumber on exposure to *Brassica* volatiles	GC-MS GC: a H-P 6890; column: 30 m × 0.25 mm ID × 0.25 μm; stat. phase HP-5MS; MS: H-P 5973 MSD	Five volatiles found in greatest concentration were allyl isothiocyanate, 3-butenyl isothiocyanate, benzyl isothiocyanate, *cis*-hexen-1-ol, *trans*-2-hexenal	SPME collection of headspace volatiles with direct thermal desorption into GC inlet	Vaughn and Boydston (1997); allyl isothiocyanate completely inhibited the germination of all seven bioassay test species at a level less than 1 ppm
To identify the compounds responsible for the allelopathic effect of rice seedlings upon the aquatic weed ducksalad [*Heteranthera limosa* (SW.) Willd]	Not required in laboratory—preestablished by field studies against ducksalad	GC-MS a Varian Saturn 2 system with septum programable inlet and 8100 auto-sampler; column: 30 m × 0.25 mm ID × 0.25 μm; stat. phase DB-5MS; He carrier 40 cm/sec; temp. prog. 80°C–290°C; MS: 70 eV EI; mass scan 50–600 m/z	41 compounds identified including hydroxy and methoxy substituted benzoic and cinnamic acids, phenylpropanoic and long chain aliphatic acids, some benzaldehydes, phenylalkanols, resorcinol, and 5-hydroxy-2-indolecarboxylic acid	TMS derivatives formed using MSTFA & TMCS	Mattice et al. (1998); simple diethyl ether extraction was found to be superior for recovery of the moderately polar rice allelochemicals, than was SPE, charcoal, styrene-DVB, or XAD-4 resin trapping

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To evaluate the essential oils of 32 aromatic plants for allelopathic properties and to identify constituents in the most active ones	Wheat seed radicle and coleoptile lengths, and seed germination of wheat, black mustard [*Brassica nigra* (L.) Koch], Palmer amarant (*Amaranthus palmeri* S. Watson)	GC-MS (no details given)	From the three most significant aromatic plants *Origanum syriacum, Micromeria fruticosa*, and *syriacum, Cymbopogon citratus*, were isolated 15 terpenoids, of which geranial and neral proved the most active	Steam-distilled volatiles	Dudai et al. (1999); seed germination was inhibited at 20–80 ppm of essential oils
To identify the major active allelopathins in Manila-grass [*Zoysia matrella* (L.) Merr.] shoot extracts	% germination and root and shoot length of livid amaranth [*Amaranthus lividus* (L.) Merr.] seeds	GC-MS a H-P system; GC: 5980; column: 15 m × 0.25 mm ID FSOT; stat. phase DB-1; He carrier; injector 260°C; temp. prog. 100°C–310°C; MS: 5980 MSD; 70 eV EI	Nine fatty acids and *p*-hydroxybenzoic and *p*-coumaric acids	Diazomethane derivatization to methyl esters/ethers, and TMS derivatives from MSTFA	Laosinwattana et al. (1999); preliminary fractionations achieved by solvent partitioning, by LC, and by HPLC
To investigate the culture media of the macrophyte *Pistia stratiotes* and its capacity to allelopathically inhibit algal growth	Growth-water aliquots from *Pistia stratiotes* were tested on agar plates against alga *Selenastrum capricornutum*	GC-MS (no data were given)	Active compounds include 9-hydroxylinolenic acid; 9-hydroxy and 13-hydroxy linoleic acids; α-ascarone; stigmasta-4, 22-diene-3, 6-dione; sinapyl and coniferyl alcohols	An ethyl acetate extract treated with TMCS, and with diazomethane	Greca et al. (1999); α-ascarone was most active compound showing 40% inhibition of algal growth at 10 ppm

To identify the constituents of the volatile oil from *Ageratum conyzoides* and to determine their allelopathic potential upon cultivated crops	Fresh weight, root length and shoot length of seedlings of cucumber, wheat, radish, ryegrass, tomato, and mungbean	GC-MS a Finnigan TSQ 70B-4000 system; GC column: 50 m × 0.32 mm ID FSOT; stat. phase HP-1; He carrier 12 psi; temp. prog. 60°C–280°C; MS: 50 eV EI; source 280°C; scan 35–450 m/z	11 compounds, largely terpenoids	Steam-distilled volatiles	Kong et al. (1999); the most active components were precocene I and beta-caryophyllene
To isolate and identify the water-soluble allelochemicals from extracts of *Scirpus acutus* Muhlenb. rhizomes and *Eleocharis smallii* L. shoots, both aquatic plants associated with wild rice	Lettuce seedling germination and the lengths of radicle and primary shoots	GC-MS a VG Auto Spec high resolution system; GC injection port 280°C; column temp. prog. 50°C–350°C; (no other details)	In excess of 40 compounds from *S. acutus* rhizome including lactic, fumaric, 2-phenyllactic, 3- and 4-hydroxybenzoic, protocatechuic, ferulic, and dehydroabietic acids; *E. smallii* gave 4-methoxyphenol, benzofuran, benzeneacetic acid and some acetophenones	TMS derivatives formed using BSTFA	Quayyum et al. (1999)

TABLE 1. CONTINUED

Purpose of study	Bioassay used	LC-MS or GC-MS conditions	Allelochemicals identified	If GC-MS, then volatiles or derivatization	Reference and comments
To develop a method based upon LC/MS/MS capable of identifying benzoxazinoids as both glycones and aglycones within 5- to 15-day-old maize seedlings	Bioassay not required	LC-MS LC: Spectra System AS3000; column: 25 cm × 2.1 mm ID; 5 μm particles of C-18 Adsorbosphere; injection 5 μl; flow rate 200 μl/min using linear binary gradient. MS: Finnigan MAT TSQ 7000 triple quad with APCI interface	Seven benzoxazinoid glucosides and two aglycones; 2-β-D-glucopyranosyloxy-4,7,8-trimethoxy-1, 4-benzoxazin-3-one (HDM2BOA-glucoside) observed for first time	No derivatization required; negative ion mass spectral mode used	Cambier et al. (1999); MS/MS fragmentation analysis used to identify particular glucoside products

higher than that of the presently developing LC-MS techniques, of which only some five qualitative analysis examples in allelopathy could be found. Data extracted from these papers include: purpose of the study; bioassay used; chromatography–MS conditions; types of compounds identified and if GC-MS, whether volatiles or derivatization; as well as literature reference and comment.

Allelochemical Quantifications Using Hyphenated Chromatography–Mass Spectrometry

Although quantitative studies on plant allelopathic substances yield more useful information per compound than qualitative studies, the literature, as yet, contains few quantitative investigations. This is despite the fact that because of the great selectivity of the MS detector to perform extracted ion, selected ion (SIM), and product ion (MS-MS) analyses, analysis problems of chromatographic coelution in complex mixtures can mostly be avoided. It appears that the greater time, effort, and expense associated with the more demanding quantitative requirements, together with the nonavailability of pure reference compounds for calibration purposes, has often prevented allelochemical analyses from proceeding beyond the qualitative level. Nevertheless, a number of quantitative studies have been published, thereby stimulating deeper levels of scientific enquiry into the molecular mechanisms associated with plant allelopathy.

One such study performed in the early period of GC-MS is that by Lovett and Potts (1987) who investigated the levels of the alkaloids scopolamine and hyoscyamine in thorn apple (*Datura stramonium*) seeds. They wished to test the hypothesis that the early seedling growth of crop plants such as barley and wheat was affected by alkaloid interference with the gibberellin-stimulated food reserve metabolism of germinating seeds. Their GC-MS equipment consisted of a Pye 204 GC using a 25-m $\times$ 0.33-mm-ID FSOT HP-1 column operated isothermally at 220°C interfaced at 220°C to a VG MM70-70F mass spectrometer and VG 2235 Data System, which performed their qualitative work. Quantitative analysis was then carried out by GC-FID with the same column on a HP 5880A instrument. Allelochemical samples were obtained by aqueous leaching of thorn apple seeds over seven days, with both alkaloids being quantitatively determined each day. The aqueous seed leachates were made alkaline and extracted with ether–chloroform. After evaporation of the solvent, the residue was taken up in ethyl acetate and derivatized with pentafluoropropionic anhydride (PFP). The alkaloid scopolamine varied in leached amounts from 0.577 mg/g seed on day1 to 0.14 mg/g seed on day 7, with a total of 2.507 mg/g seed over seven days. Hyoscyamine varied from 0.377 mg/g seed on day 2 to 0.098 mg/g seed on day 7, with a total of 1.825 mg/g over seven days. The authors believed that these seed alkaloids could be leached for up to two weeks into the soil, thereby maintaining a continual supply for allelopathic effects upon the surrounds.

More recent studies by researchers at the University of Bonn (Schulz et al., 1994; Friebe et al., 1995), have been carried out on the allelopathins of quackgrass, a widespread Northern Hemisphere weed. This group's 1994 objective was to identify and quantify constituents in the exudate from quackgrass (*Agropyron repens* L.) rhizome-borne roots. Water flowing at 1 liter/hr through a root exudate recirculation system (RERS) over a period of 10 days was acidified and extracted with ethyl acetate. The organic solvent was removed by evaporation and the residue taken up in a little methanol, followed by transfer to microreaction vials, further solvent evaporation, and then silylation of the residue with BSTFA to volatile TMS derivatives. GC-MS analysis was performed on an Automass 100 (Delsi Nermag, Unicam) instrument using a HP Ultra-2 5% phenylmethylpolysilane, 25-m $\times$ 0.2-mm ID column, 2-μl injections, and a temperature program from 100°C to 280°C in stages. The injector port and detector temperature were both 280°C, while the He carrier gas head pressure was 1 bar. Mass spectra were collected at 70 eV using EI. A cress seedling bioassay based upon biomass and shoot length was used to monitor the phytotoxic effects of quackgrass from variously aged plants, up to 92 days. Exuded compounds were identified by comparison of their mass spectra with those in standard reference data, thereby establishing the presence of 3-hydroxybutyric, vanillic, ferulic, 4-hydroxycinnamic, protocatechuic, and syringic acids, plus vanillin and 2,4-dihydroxy-1,4-benzoxazin-3-one (DIBOA). For vanillic, ferulic, and syringic acids, the concentrations in the aqueous recirculated exudate ranged from 0.1 to 0.2 μM, with other phenolics only in traces. The most active aqueous exudate constituent, DIBOA, was present in 0.01–0.03 μM concentrations from older plants (54 days), while for younger plants it was present at 0.24 μM (0.52 μmol/kg fresh weight quackgrass). The authors carried out a systematic bioassay study using up to six different defined concentrations of the two allelochemicals DIBOA and ferulic acid against eight different test plant species and made the important finding that plant response was species related and dose dependent.

In a second study by the same Bonn group, Friebe et al. (1995) set out to identify and quantify the allelopathic constituents of the roots and shoots of quackgrass seedlings. Aqueous shoot extracts of 10-day-old quackgrass plants were acidified and extracted with ethyl acetate. Rather more importantly, root exudates were obtained from 10-day-old quackgrass seedlings that had been transferred to freshwater alone for a further three days of growth. The water from these plants was extracted with ethyl acetate, and after removal of the organic solvent, the residue was silylated with BSTFA to form TMS derivatives. The GC-MS work was carried out on the same instrument and conditions as for the 1994 study above. Compounds were identified by their retention times and mass spectra as compared with published and authentic reference samples. The significant compounds identified were vanillic, ferulic, and 3-hydroxybutyric acids, together with the benzoxazinoids DIMBOA, DIBOA, HBOA, and DIM_2BOA. Reference

compound calibrations and chromatographic peak areas led to quantitative values in quackgrass root exudates of 0.4 μM for DIMBOA and 0.2 μM for DIBOA. In terms of the allelopathic phenomenon, knowledge of the constituents and the composition of plant root exudate are vital to understanding the plant's allelopathic potential. The authors suggest that the allelopathic effectiveness of quackgrass is due to the result of synergistic interactions among the different allelochemicals exuded.

Another study of the same period is by Yamamoto (1995), who investigated the chemical basis for allelopathy in the pasture plant *Anthoxanum odoratum* towards the native grass *Zoysia japonica*. Yamamoto employed a Petri dish bioassay based upon the hypocotyl length of germinated lettuce seedlings. These seedlings had been treated with chemical and/or solvent fractionated and thin-layer-chromatographed *A. odoratum* extracts, in order to direct his search for allelochemicals. One neutral fraction at R_f 0.6–0.7 on TLC was identified by GC-MS as coumarin, which had the greatest inhibitory activity. The instrument used for identification was a Shimadzu GCMS-QP1000S using an FSOT CBP1-M25-0.25 25-m $\times$ 0.25-mm-ID column with He as carrier gas at 40 ml/min, injector 250°C, and oven temperature programed from 50°C to 250°C at 5°C/min. Quantitative work was done with a Shimadzu GC-15A chromatograph. Coumarin content within the roots, stubble, leaf, stem, and dead litter of *A. odoratum* was measured for various times of the year and was found to vary significantly. Thus, June contents yielded 461 $\pm$ 62 μg/g dry sample for roots and 26,577 $\pm$ 4,531 μg/g for leaf, while November contents were 47 $\pm$ 13 μg/g for roots and 2,773 $\pm$ 956 μg/g dry sample for leaf.

Biofumigation (Angus et al., 1994) was the possible effect being explored in the thorough study conducted by Brown and Morra (1995) on both the volatiles and water-soluble allelochemicals of *Brassica napus* L. These researchers used a GC-MS identification and quantification system from Hewlett-Packard (HP 5890II GC with HP 5972 MSD) operating with a 30-m $\times$ 0.25-mm ID $\times$ 0.25-μm HP-5MS column, injector at 260°C, interface at 320°C, He carrier at 1.14 ml/min, splitless injection, and oven temperature program from 130°C to 320°C at 15°C/min. The mass detector scanned from *m/z* 25 to 470 using 70 eV EI. Glucosinolates (sulfur-containing organic anions with a β-D-thioglucose moiety and variously structured side groups) were identified as the hydrolyzable precursors to a range of allelopathic volatiles from *Brassica napus* seed meal. The volatiles consisted of a range of nitriles and isothiocyanates. Bioassay was conducted by allowing only the volatile compounds released from hydrolyzed glucosinolates to impact lettuce seed germination through vapor-phase contact alone, inside a closed 1.45-liter germination chamber. Glucosinolates were quantified from 0.2 g plant samples, which were first desulfated on Sephadex columns, and the dried products then silylated with BSTFA–TMCS–methylimidazole before GC-FID analysis on a HP 5890II 15-m $\times$ 0.32-mm-ID $\times$ 1.0-μm DB-1 column. The *Brassica*

volatiles were trapped by dynamic headspace sweep onto 100 mg of Super Q porous polymer contained in 16-cm × 0.4-mm-ID glass tubes, which were then stripped with dichloromethane before GC-MS injection. Six nitriles and nine isothiocyanates were identified. Of the volatiles analyzed from a 16-h collection period of headspace sweeping, quantitative results ranged from 0.2 nmol/g meal for phenylethylcyanide and 5-methylhexylisothiocyanate, up to 260.2 nmol/g meal for 3-butenylisothiocyanate. The authors believed their experimental evidence suggested that the volatile glucosinolate degradation products are the causative agents responsible for the observed lettuce seedling inhibition.

Heavy losses in cereal and pasture production southern Australia through the allelochemical effects of residues from the weed silvergrass (*Vulpia myuros*) prompted An et al. (1996) to investigate the chemical constituents of aqueous extracts of *V. myuros* residues. A bioassay based upon radicle and coleoptile elongation of germinated wheat seeds directed solvent fractionation of aqueous *Vulpia* extracts to an active ether fraction that was evaporated to dryness and silylated with PowerSil-prep mixture to give TMS derivatives. These derivatives were injected onto a GC-MS system consisting of a HP 5890II GC fitted with an FSOT DB-5 30-m × 0.32-mm-ID × 1.0-μm column with He carrier at 38 cm/s, injector port 290°C, 3 μl split injection (1:100), oven temperature programed in stages from 80°C to 280°C, and a VG Trio-2 quadrupole MS using 70 eV EI. The GC-MS interface was kept at 295°C, the MS ion source at 250°C, and the mass scan covered m/z 60–460 in 0.8 sec. Twenty-one phytotoxins consisting mainly of shikimic acid metabolites, such as vanillic, ferulic, and 4-hydroxybenzoic acids, were identified and quantified using an internal standard technique and multipoint calibration curves. The quantities of the 21 individual compounds ranged from 1.36 to 81.0 μg/g dry plant residue, and in total accounted for 0.0502% per dry weight of *Vulpia* residue. The authors noted that those allelochemicals present in large amounts possessed low biological activities, while those present in small amounts possessed strong inhibition. Their bioassay studies on artificial solutions of the pure individual allelochemicals and also of mixtures composed of 20 of these compounds demonstrated that a modest level of synergism was exerted by the multicompound mixtures. The synergism of allelochemical mixtures is a dimension of the allelopathic phenomenon that is deserving of further research, as little is presently known of the mechanisms by which allelopathic substances bring about their inhibitory affects.

Developing an analytical method to quantify the allelopathin batatasin-III (3,3′-dihydroxy-5-methoxydihydrostilbene) in the leaves of the dwarf shrub *Empetrum hermaphroditum* was the task undertaken by Wallstedt et al. (1997). They extracted leaf material with either ethyl acetate or water, cleaned up the samples by SPE (Isolute or C-18), and eluted the batatasin-III off the SPE columns with EtOAc–HOAc or EtOAc–MeOH–HOAc. The respective fractions containing the

target compound were each lyophilized and redissolved in 1000 μl of organic solvent, ready for subsample volumes of 20 μl (EtOAc) or 50 μl (water extracts) to be lyophilized before treatment with BSTFA–pyridine for silylation. A standard calibration curve (using 1,6-dihydroxynaphthalene as internal standard) was prepared by plotting area ratios of analyte to internal standard across 14 different concentrations of batatasin-III from 5 to 300 ng/μl. The derivatized analyte was identified by GC-MS using a VG Trio-3 tandem quadrupole MS scanning m/z 50–450, using EI at 70 eV, and ion source at 250°C. Silylated batatasin-III gave characteristic ions at m/z 388 (M^+), 209, and 179. The GC was a HP 5890 containing a DB-5 30-m $\times$ 0.25-mm-ID $\times$ 0.25-μm column with He carrier at 1.0 ml/min, injection volume 1 μl, and initial oven temperature rising from 150°C to 290°C at 7°C/min. Quantifications were performed under the same chromatographic conditions using GC-FID, with detection levels of analyte down to 1 ng. The contents of batatasin-III in *E. hermaphroditum* varied with plant age, and ranged from 0.027 to 0.062-mg/g leaf dry weight across three years of growth.

The power to deal with the analytical complexity of allelochemicals immersed in a matrix of aqueous wheat shoots extract by using GC-MS-MS on a Varian 3400 CX/Saturn 2000 ion-trap spectrometer system was demonstrated by Wu et al. (1999), who focused their attention upon the quantification of DIMBOA and five phenolic acids of recognized phytotoxicity obtained from 17-day-old wheat seedlings. Their tandem (in time) mass spectrometric detector used the chromatographic helium carrier gas (flow rate 34 cm/sec) inside the ion trap as the collision gas for collision-induced dissociation (CID) of selected, single, characteristic, analyte, precursor ions arising from the normal electron impact spectra obtained at the first MS stage of molecular ion fragmentations. The selection again of single, characteristic, quantitation ions from these second-stage product-ion spectra produced at characteristic retention times allowed for great analytical selectivity and significant improvement in the analyte signal-to-noise ratios. Chromatographic conditions consisted of a DB-5 MSITD 30-m $\times$ 0.25-mm-ID $\times$ 0.25-μm column with temperature program from 80°C to 280°C in stages, and run time 29.9 min, divided into nine separate MS-MS acquisition time segments. Injector temperature was 280°C with a splitless 1-μl injection of silylated derivatives. The transfer line was held at 250°C and the ion trap detector at 200°C, while the mass scan covered m/z 50–450 in 1 sec (3 microscans). Nonresonant CID was used for MS-MS with an excitation time of 20 msec. Compound identifications were achieved by comparison of both normal fragment ion and product-ion spectra for the TMS derivatives used against user libraries of the TMS derivatives of authentic reference compounds, as well as by comparison of retention times. Using this approach, both the *cis* and *trans* geometrical isomers of coumaric and ferulic acids could easily be recognized and quantified. Characteristic product-ion chromatographic peak area ratios, with 4-chlorobenzoic acid as internal standard,

were used as the analytical parameter. Results for allelochemicals present in wheat shoots ranged from 2.9 ± 0.1 mg/kg for *cis*-4-coumaric acid to 110 ± 4.8 mg/kg dry shoot mass for DIMBOA.

Gardiner et al. (1999) used GC-MS to confront the problem of measuring glucosinolate breakdown products in field soil following incorporation of winter rapeseed (*Brassica napus*) green manure. Soil samples at 0.0- to 7.5-cm and at 7.5- to 15.0-cm depths were taken from field soils over three weeks in plots that had had *Brassica napus* plants plowed under. Their analytical equipment consisted of a HP 5890II+ GC using a DB-5 30-m × 0.25-mm-ID × 0.25-μm column, He carrier gas, oven temperature program from 40°C to 285°C at 15°C/min, and a HP 5972 quadrupole mass selective detector. Nine phytotoxic glucosinolate degradation products were identified in dichloromethane soil extracts, including five isothiocyanates, three nitriles, and one oxazolidinethione (goitrin). Maximum concentrations were observed 30 h after plowdown, but for all compounds, soil concentrations were quite low, seldom exceeding 1 nmol/g dry weight soil. The plant parts of two *Brassica napus* cultivars (Dwarf Essex and Humus) were also analyzed for precursor glucosinolate contents. This analysis, based upon a 0.2-g sample of plant tissue, took place after desulfation on a Sephadex column treated with imidazole and formic acid, followed by silylation. The GC-MS conditions for this part of the analytical work were similar to those of the breakdown products but used a HP-5MS 30-m × 0.25-mm-ID × 0.25-μm column running He carrier at 1.14 ml/min, with splitless injection at 260°C and interface 320°C. The oven temperature program covered 130°C–320°C at 15°C/min, while mass scanning ranged over m/z 25–470 on the MSD 5972. Glucosinolates were identified by comparison with previously reported mass spectra, and their quantification was assisted by the use of previously published response coefficients and benzyl glucosinolate as an internal standard. The glucosinolate content of tops and roots from cultivar Dwarf Essex at the time of incorporation into the soil ranged from 0.01 μmol/g tops for 4-methoxyindole-3-methylglucosinolate to 12.86 μmol/g roots for 2-phenylethylglucosinolate, causing the authors to comment that the roots of *B. napus* were a more important source of toxic fumigants arising from glucosinolate degradation in the soil than were the shoots.

LC-MS-MS was the analysis technique chosen by Lee et al. (1999) in their development of a quantitative method for the estimation of momilactones A and B in rice straw across a range of different growth stages. Dried rice straw samples were extracted with aqueous methanol, the solutions evaporated to dryness, and the residue taken up in ethyl acetate, washed with $NaHCO_3$ solution, and then concentrated by evaporation. The resulting residue was dissolved in methanol, and the solution was passed through a Sep-Pak Light C-18 cartridge. Five-microliter injections of the eluate were made on the LC-MS-MS system , which was composed of a HP 1100 LC using an Inertsil ODS-2 150-mm × 4.6-mm- ID × 5-μm particle column, 80% aqueous CH_3CN containing 0.1% formic acid at a flow rate of

0.6 ml/min. The detector was a Sciex API-300 (Perkin-Elmer) with atmospheric pressure chemical ionization (APCI) inlet that used the positive ion mode and nitrogen as collision gas for CID. Momilactone A gave a precursor ion $(M+1)^+$ at m/z 315 with corresponding product ion at m/z 271. For momilactone B, a $(M+Na)^+$ ion was observed at m/z 353, and a useful precursor ion at m/z 331 that afforded two product ions at m/z 313 (-18, H_2O) and m/z 269 ($313 - 44$). For MS-MS quantifications, the m/z 315/271 pair was used for momilactone A and the m/z 331/269 pair for momilactone B under metastable reaction monitoring (MRM) conditions. Calibration curves for both compounds were obtained by using two reference standard concentrations for each at 0.5 and 2.5 ng on the same instrument. Detection limits of the method were established at 0.5–1.0 ng. On the basis of 180 days of growth and a water-only extraction of rice straw, the concentrations of momilactone A were determined as 1.01 μg/g dry weight straw and those of momilactone B as 0.81 μg/g dry weight straw. Using an 80% methanol extraction of straw of 180-day-old rice, momilactone A rose to 3.80 μg/g and momilactone B to 2.01 μg/g dry weight straw.

DISCUSSION

The foregoing material constitutes a cross-section of the types of LC/GC-MS-aided plant allelopathy studies described in the literature and illustrates the capacity of the mass spectrometric detector to cope selectively with complex plant mixtures. The older (photodiode array) (PDA) and UV-V detectors for HPLC, and the older FID-type detectors for HRGC, all with their limited selectivity and capacity to deal with chromatographic coelution in complex matrices, are gradually being replaced by highly selective, chemical noise-reducing mass spectrometric detectors. The high level of integration found in the modern, inexpensive, bench-top, hyphenated, chromatography–mass spectrometric systems with their fast, sophisticated, software-driven control from dedicated system computers, makes it possible for technicians of only modest training to achieve remarkable results.

One important point not to overlook, when involved in pioneering work on new allelopathy investigations, concerns the need for a means of recognizing those individual compounds within a complex plant-related sample that actually carry the biological activity. If the sample were a simple mix of several components, then the task of tracking compound-related bioactivity and identifying each separate substance would be comparatively easy (although not trivial), but in the more typical complex sample cases, with so many different compounds present, the investigator is faced with the difficult problem of knowing which substances to focus upon. The usual means of addressing this problem is to perform bioassay-directed fractionations (Rimando et al., 2001), whereby the original mixture is gradually

separated in stages (using such means as differential chemical solubility, sequential solvent partitioning, preparative column chromatography, TLC, HPLC, etc.) into fractions that demonstrate no activity or are determined to be active under the bioassay. The process of fractionation and bioassay is repeated until pure active compounds are isolated. It is at the last fractionation stage that chromatography–mass spectrometry has its most valuable input because of the usually small amount of active fraction remaining and the probable need for still further resolution and identification of compounds. Even with the availability of large mass spectral libraries, it will still often be necessary to isolate sufficient quantities of the pure active components in order to perform structure analysis with spectrometric techniques such as HRMS, PMR, CMR, FTIR, and UV-V. Once qualitative analysis is complete, the now identified allelochemicals can be quantified if a sample of the pure reference compound is available.

As mentioned earlier, hyphenation between chromatographic and mass spectrometric components is not the only type available. Such systems as GC-FTIR-MS (Auger and Ferary, 1994; Ferary et al., 1996), and LC-NMR also offer high analytic power, but like the magnetic sector, high mass-resolution spectrometer systems, such instruments are costly and, therefore, are not likely to be in widespread use. Indeed, the high analyte selectivity afforded by the magnetic sector HRMS (and its various hybrid configurations) brought about by its capacity to separate original ions on the basis of their slight differences in precise mass, is nowadays being replaced by the inexpensive tabletop MS-MS system that uses an ion-trap detector. The prior MS-MS systems (in space) that use a series of beam-quadrupole mass filters (QqQ, or triple quads) are again much more expensive and are losing ground to the simpler and more economical ion-trap spectrometers that conduct time-based tandem MS analyses. The latter do not exhibit the spectral skewing caused by variable analyte concentration across the duration of a chromatographic peak, which often affects the output of a transmission quadrupole. The more expensive triple quad instrument retains a superior (approx. 10-fold) sensitivity to the ion-trap detector in comparable product ion monitoring modes and a superiority in the ability to perform precursor ion scans and neutral loss scans (useful in metabolite searches). However, the cheaper ion-trap excels the triple quad sensitivity (approx. 100-fold) once a full mass scan in product-ion mode (valuable for fingerprinting) is required. In addition, an ion-trap detector can deliver both EI and CI (chemical ionization) spectra in a single chromatographic run. This is achievable automatically through software switching alone, thus easily generating both molecular weight and structural information without hardware reconfiguration of the instrument. With respect to the polarity of ion analysis, however, if one desires to be able to analyze in both positive and negative ion modes like the switchable transmission quadrupole, then the instrument design must include external source ionization, as the simpler internal ion source delivers only positive ions.

The popular tandem MS mode for chromatographic detection has been especially advantageous to LC-MS studies. This is not just because the additional capability of MS-MS can often eliminate the need for extra sample clean-up steps, and provide for more rapid analytical method development and limits of detection, but also because it brings to bear more structural analysis power supplementing the usual molecular weight data on unknown compounds. The ion-trap's ability to perform multistage (in time) MS-MS (MS^2), $MS^3, \ldots,$ MS^n spectra, has opened up a wide range of structure determining experiments upon the initial ions formed by electrospray ionization (ESI), APCI, or EI in today's LC-MS systems, which significantly outstrip the capacity of the earlier, bench-top, single transmission quadrupole. There is a whole new range of opportunities for the use of these powerful techniques in application to plant allelopathy studies where molecular information is required. Apart from the rarer particle beam EI systems, LC-MS is now mostly run by using APCI or ESI methods to cover most compound masses and polarities. Such instruments may possess quaternary solvent gradient delivery, HPLC columns from <1 mm ID up to 4.6 mm ID, with mobile phase flow rates from 50 μl/min to 2 ml/min, and run in either positive or negative ion mode, or even, for some instruments, in both polarities during the same run time. Both LC-MS and GC-MS instruments frequently come with dual detectors built in. LC systems often possess a PDA that can operate simultaneously with MS and that is still useful for determining chromatographic peak homogeneity, generating UV-V chromatograms, and comparing results against the earlier literature. For the GC-MS types, simultaneous detection may also take place using FID or NPD. For bench-top LC- and GC-MS systems, depending upon the type of MS, the mass scan range can presently cover up to 3000 m/z, with scan rates around 6000 Da/sec, and with sensitivities down to the femtogram range. Within GC-MS instruments, electronic pneumatic control (EPC) is now standard and provides constant carrier gas flow rates, automatically compensating for the vacuum environment of the MS detector. This maximizes retention time and spectrum reproducibilities between chromatographic runs. Under EPC, the MS sensitivity and column resolution are nearly unaffected by oven temperature programing. At least one manufacturer offers a special retention time locking capability that helps to ensure reproducibility of retention times for the same compounds under the same instrument conditions, between different laboratories.

In conclusion, the use of the modern, economical, bench-top, chromatography–mass spectrometry system is commended to those researchers interested in the chemical basis for plant allelopathy. The use of these systems is expected to increase rapidly in the near future, especially among the developing countries. Such relatively cheap instruments offer considerable analytic power and are ideally suited to investigate the lighter mass range of secondary plant metabolites typically responsible for plant allelopathy.

(Received March 10, 2001; accepted August 6, 2001)

Abstract—It was previously reported that males of the crucifer flea beetle, *Phyllotreta cruciferae*, feeding on host foliage are attractive to both males and females in the field. Based on this evidence for an aggregation pheromone, volatiles were collected from male and female *P. cruciferae* feeding on cabbage (*Brassica oleracea*) and analyzed. For comparison, volatiles were also collected from males and females of three other flea beetle species, *Aphthona flava, A. czwalinae*, and *A. cyparissiae*, all feeding on their host, leafy spurge foliage (*Euphorbia esula*). Six male-specific compounds were isolated from *P. cruciferae*, and the same compounds plus two additional ones were isolated from males of *Aphthona flava, A. czwalinae*, and *A. cyparissiae*. The blends of compounds were relatively consistent within species, but there were characteristic differences between species. Compound structures were studied by mass spectrometry, NMR spectroscopy, UV spectroscopy, polarimetry, chiral and achiral gas chromatography, molecular modeling, and microchemical tests. Three of the compounds were identified as (+)-*ar*-himachalene; (+)-*trans*-α-himachalene; (+)-γ-cadinene. Two others were new enantiomers of himachalene hydrocarbons that were previously identified from the fir trees, *Abies alba* and *Abies nordmanniana*. Finally, there were two himachalene alcohols and one norsesquiterpene ketone that is a himachalene analog. Only (+)-*ar*-himachalene and (+)-γ-cadinene are previously known natural products. Electrophysiological activity was demonstrated for five of the compounds. The chemical and electrophysiological patterns are consistent with, but do not prove, a pheromonal function.

Key Words—Sesquiterpene, himachalene, cadinene, flea beetle, *Aphthona*, *Phyllotreta*, Chrysomelidae, Alticinae.

INTRODUCTION

Flea beetles constitute the largest subfamily (Alticinae) of the leaf beetle family, Chrysomelidae (Arnett, 1993). The beetles are known for their jumping ability and have greatly enlarged hind femora. Adults feed on host plant foliage, and the larvae typically feed on the roots of the same plant (Borror and DeLong, 1964). The group includes both agricultural pests and beneficial species. One of the four species used in this study, the crucifer flea beetle, *Phyllotreta cruciferae* Goeze, is a significant pest of canola and rapeseed in the northern prairie areas of the United States and Canada, and it also attacks cabbage, horseradish, and other crucifers in many regions (Lamb, 1989). The other three species, *Aphthona flava* Guillebeau, *A. czwalinae* (Weise), and *A. cyparissiae* (Koch), are effective biocontrol agents of the introduced rangeland weed, leafy spurge (*Euphorbia esula* L.) (Gassmann et al., 1996). These *Aphthona* species are native to Europe but have been established in the United States and Canada.

Little is known about pheromones and mating systems of flea beetles. The results of Zhang and McEvoy (1994) suggested that a female-produced sex pheromone exists in the ragwort flea beetle, *Longitarsus jacobaeae* (Waterhouse), and that only males respond to it. The chemical cue persists for hours in areas formerly occupied by females, but its chemical nature is not known. It was not clear from the report whether the pheromone is volatile enough to be attractive at a distance. Conclusions for *P. cruciferae* were quite different. Peng and Weiss (1992) demonstrated that unsexed *P. cruciferae* feeding on canola plants were clearly more attractive to both males and females than were damaged plants, beetles alone, or other controls, both in the field and in the laboratory. Then, Peng et al. (1999) compared male *P. cruciferae* to females in the field bioassay and concluded that only the males are demonstrably attractive, again to both sexes. Thus, in this species there was evidence for a male-produced aggregation pheromone.

The first objective of the present study was to discover possible pheromone component(s) in *P. cruciferae* by chemically comparing males and females. These comparisons employed collections of volatiles from beetles feeding on host plant material, to reflect the conditions of the previous, successful bioassays as closely as possible. Male-specific compounds were revealed, but they were clearly complicated in structure and the amounts collected were small. Chemical identification required key spectral techniques such as NMR, but a modest-scale program to collect volatiles from *P. cruciferae* could not provide enough material for this. During a preliminary examination of other flea beetle species, male-specific compounds were also found from *A. flava*, and coincidentally, by GC retention

times and mass spectra, these included all of the male-specific compounds from *P. cruciferae*. Although the *A. flava* compound ratios were different from *P. cruciferae*, the total amounts were considerably larger. Thus, by concentrating efforts on *A. flava*, identifying the male-specific chemicals of both species became feasible. *A. czwalinae* and *A. cyparissiae* were included in the study to further explore differences in chemical patterns among species, and these also shared the same chemical structures.

Eight male-specific compounds were chromatographically isolated, spectroscopically analyzed, and identified. Microchemical conversions among the compounds were vital to identification. Chemical standards derived from selected botanical sources aided in the characterization of the ring systems and stereochemistry. Preliminary analysis by GC-EAD indicated that identified compounds could be sensed well by beetle antennae, which would be expected for pheromone components. However, final conclusions about function must await field testing with synthetic compounds.

METHODS AND MATERIALS

Source and Care of Beetles. *P. cruciferae* for this work were field collected at various locations: canola fields in North Dakota, USA (from C. Peng), canola fields in Saskatchewan, Canada (from J. Soroka), and cabbage plots in Peoria, Illinois, USA. In the laboratory, the beetles were kept in cages and fed on seedlings of canola or cabbage, or later, on the core tissue of mature heads of cabbage. *Aphthona* species were field collected in eastern Montana and western North Dakota (from A. Caesar) or from western Montana (from R. Nowierski) from spurge-infested rangeland where *Aphthona* introductions were established. Beetles were kept in cages containing shoots of leafy spurge with cut ends in bottles of water. Spurge cuttings were from plants maintained in our greenhouse. *Aphthona* species identifications were based on LeSage and Paquin (1996) and McDaniel et al. (1992). *A. cyparissiae* is difficult to separate from another species in the United States, *A. nigriscutis* (Foidras), by external morphology. Males of *A. cyparissiae* were explicitly linked to one of the species-specific GC profiles of volatiles (presented below in the Results section) by genitalic dissection (McDaniel et al., 1992) of all individuals of a group that had produced the typical pattern.

Collection of Volatiles. Beetles were sexed by inspection of the ventral side of the abdominal tip under the microscope (LeSage and Paquin, 1996); insects were immobilized by gently guiding each one into the tapered end of a small glass tube and keeping it there with a narrow wooden rod. Beetles (usually 10–12 males or females) were introduced into volatiles collectors, which consisted of vertical glass tubes (5 cm diam. $\times$ 20 cm long) containing host plant material (chunks of mature cabbage head for *P. cruciferae* or spurge shoots with ends in water vials

for *Aphthona* species). The tube ends were closed with corks, each of which held a volatiles trap. Traps were made from 5-mm-diam. glass tubing and contained a 5 to 8-mm plug of Super-Q porous polymer (Allech Associates, Deerfield, Illinois). The Super-Q was held in place by fine stainless steel screen (which was fused into the trap wall) and glass wool. A gentle vacuum was drawn on the upper trap so that air flowed through the tubes at about 100 ml/min. The lower trap served to clean the incoming air, and the upper trap collected the emitted volatiles. The volatiles collectors were kept in an incubator at 27°C with a relative humidity of about 50%. Light was provided by three 40-W fluorescent tubes set about 0.5 m above the apparatus. The daily light cycle was 14L:10D.

The usual procedure was to service the collectors every two or three days. This included rinsing of volatiles from the filters into vials using 300 μl hexane, replacement of host plant material as needed, and analysis of each collection by GC (1 μl of the undiluted collection). There were some modifications of the above scheme: Initially, collections were processed daily, but longer periods did not lead to noticeable changes or degradation of collected chemicals, and the longer periods were adopted for convenience. Late in the study, 8–10 collections from *A. flava* were routinely combined for GC monitoring, after the consistency of GC patterns for this species had been established. Finally, occasional collections were made from host material without beetles, for comparison, but the major need was to use the equipment to accumulate the male-specific compounds.

For *P. cruciferae*, about 350 beetle-days of volatiles were accumulated for males, and about 120 for females. (One beetle-day is the amount of volatiles emitted by one feeding beetle in one day.) For the *Aphthona* species, totals for male *A. cyparissiae, A. flava*, and *A. czwalinae* were about 300, 7200, and 750 beetle-days, respectively. Totals for females were 35, 44, and 70 beetle-days, respectively. The total numbers of GC analyses made to monitor the collections were 38 for *P. cruciferae*, 15 for *A. cyparissiae*, 74 for *A. flava*, and 32 for *A. czwallinae*. Eleven GC analyses were made for uninfested cabbage, and seven were made for uninfested spurge. Samples from all groups were scrutinized by GC-MS, especially those for which GC comparisons indicated the presence of sex-specific peaks. Quantitation of GC peaks was by the external standard method, relative to heptadecane.

Instrumentation. Gas chromatography (GC) was conducted on a Hewlett Packard 5890 Series II instrument equipped with a split/splitless inlet, flame ionization detector, and autosampler and interfaced to an HP ChemStation data system. Columns were DB-5MS (30 m $\times$ 0.25 mm ID with 0.25 μm film, J&W Scientific, Folsom, California) or DB-1 (15 m $\times$ 0.25 mm ID with 0.10 μm film, J&W Scientific). A typical oven program began at 50°C for 1 min, increased at 10°C/min to 250°C, and remained at 250°C for 5 min. Inlet temperature was usually 200°C, and the detector temperature was 250°C. The carrier gas was helium, with a column head pressure of 140 kPa. The GC inlet temperature was normally cooler

than the maximum oven temperature because two of the analyzed compounds were somewhat heat-labile (see Results section below). The 200°C temperature provided acceptable compound stability while retaining injection efficiency.

High-performance liquid chromatography (HPLC) was done using a Waters 6000A pump and Waters R401 differential refractometer detector. Columns included a 25-cm × 4.6-mm-ID silica column (Adsorbosphere Silica 5μ, Alltech), treated with silver nitrate (Heath and Sonnet, 1980) for separation of unsaturated hydrocarbons, and a 25-cm × 4.6-mm-ID silica column (Econosphere Silica 5μ, Alltech) for separations by polarity. Elution solvents are given with the results for specific compounds. The flow rate was 1 ml/min.

Coupled GC–mass spectrometry (GC-MS) was conducted on a Hewlett Packard 5973 instrument, interfaced to an HP 6890 GC and HP ChemStation data system. The spectra were acquired in EI mode, with an ionization energy of 70 eV. The Wiley MS library with 275,821 spectra (Wiley, 1995) was installed on the data system. For achiral analyses, an EC-1 capillary column (30 m × 0.25 mm ID with 0.25 μm film, Alltech) or the columns described above were used, and the oven program was as for GC. The carrier gas was helium, with an inlet head pressure of 41 kPa. The temperatures for the inlet and transfer line were usually 200°C.

For chiral analysis, a Cyclodex-B column (J&W Scientific, 30 m × 0.25 mm ID × 0.25 μm film) was installed in the GC-MS system. To separate the enantiomers of compound **C**, the oven temperature was initially 50°C for 1 min, increased at 30°C/min to 140°C, and held at 140°C for 20 min; the oven was heated to 230°C between samples. Other programs were tried for other compounds. (All of the lettered compounds mentioned in the methods section are defined in the Results section.)

Nuclear magnetic resonance (NMR) spectra were obtained on a Bruker Avance 400 instrument. Proton spectra were acquired at 400 MHz and carbon spectra, at 100 MHz. Many samples were small (e.g., less than 100 μg) and were run in a Bruker Microprobe Tube (product 520-1A, Wilmad, Buena, New Jersey). The solvent was either benzene-d_6 or $CDCl_3$. Some samples were stable only in benzene, but comparing to literature spectra required acquisition in chloroform. Reported shifts are relative to TMS. Proton spectra were acquired for all samples. Carbon, DEPT, proton COSY, proton decoupling, HMQC, and nuclear Overhauser difference experiments were also run for some samples, depending on amount of available material and specific research needs. To prepare samples for NMR (always after purification by HPLC), the solvent was carefully removed by evaporation under a stream of nitrogen, followed by introduction of the NMR solvent and transfer to the NMR tube using a micropipette. If the NMR spectrum revealed the presence of nondeuterated solvent, the evaporation process was repeated.

Ultraviolet (UV) spectra were acquired on a Perkin Elmer Lambda 4B UV/Vis spectrophotometer relative to solvent blank; cuvettes had a 1-cm light path. Optical rotations were measured with a Perkin Elmer 341 Polarimeter, using a microcell

1-dm long and of 1 ml volume. Analyses of both types were run in hexane. Sample concentrations were measured by GC. An uncertainty of 15% in optical rotations and UV extinction coefficients was not unlikely.

Column Chromatography. Open columns of silica in Pasteur pipets (about 6 cm $\times$ 0.5 cm ID) were used to fractionate volatile collections and other samples by polarity. The series of elution solvents included hexane, increasing percentages of ethyl ether in hexane (5, 10, 25), and pure ether (about 5 ml, or three column volumes per solvent). Larger columns were used for some samples, depending on the amount of material to be separated.

Botanical Sources of Chemicals for Comparative Analysis. Anise seed (*Pimpinella anisum* L.) was used as a source of the sesquiterpene, α-himachalene (Burkhardt et al., 1986). Seed was purchased from a local grocery store, crushed, and extracted with hexane. The hexane extract was applied to an open column of silica and eluted with hexane to separate the sesquiterpenes from anisaldehyde and other polar constituents. α-Himachalene was purified from the other hydrocarbons by HPLC on the silver nitrate column (elution solvent 1% 1-hexene in hexane, retention volume 4.4–4.8 ml). It was recognized by mass spectral comparison to the Wiley library.

Fir tree foliage was used as the source of two rare himachalene sesquiterpenes (Khan et al., 1989), which a literature search suggested were identical to two of the beetle-derived compounds (see Results). Four small living specimens of European silver fir (*Abies alba* Miller) and one of Nordmann fir [*Abies nordmanniana* (Steven) Spach] were obtained from a nursery company (Forest Farm, Williams, Oregon). Subsequently, about 10 kg of freshly cut foliage of *A. nordmanniana* was obtained from a Christmas tree plantation (Harold Miller Landscapes, Jefferson, Oregon). The fir needles were finely chopped and extracted with hexane in small vials for initial samples and in percolators for larger batches. Purification of sesquiterpenes generally followed the scheme for *Aphthona* compounds.

"Citronella oil" from *Cymbopogon* spp., obtained from (Nucara, Coralville, Iowa) was used as the source of natural (+)-γ-cadinene (Vig et al., 1970). The oil was diluted with hexane and applied to an open column of silica. The fraction eluted with hexane was then handled further as described for the *Aphthona* hydrocarbon compounds.

Microchemical Reactions. Catalytic hydrogenation followed by GC-MS was used to determine the numbers of double bonds in the male-specific hydrocarbons and also in the comparison of ring systems between three insect-derived compounds (**A**, **B**, and **C**) and a selected plant-derived standard (α-himachalene). Hydrogen was gently bubbled from a fine needle for about 5 min at room temperature into 100 μl of methylene chloride in a conical vial, which contained 10–100 ng of sample and a trace ($<$1 mg) of platinum oxide (Adam's catalyst). Samples were analyzed by GC-MS. Hydrogenation has often been applied in sesquiterpene analysis (e.g., Andersen et al., 1977).

A microscale Wittig reaction was used to prove the structure of the beetle-derived ketone (compound **H**) by converting it into a hydrocarbon that had been previously characterized. A 0.4 M solution of methylenetriphenylphosphorane in tetrahydrofuran was prepared (Sonnet, 1974), and 20 μl of this reagent was transferred by syringe to a solution of compound **H** in a conical vial (about 1 μg in 10 μl hexane). The sample was mixed by vortexing, then allowed to stand at room temperature for 15 min. The solution was diluted with about 50 μl hexane and 20 μl water, and the layers were separated. The organic layer was passed through a small silica column with hexane, concentrated under a stream of N_2, and then analyzed by GC-MS.

Determination of the absolute configuration of compound **A** involved converting it to a product (*ar*-himachalene) for which the stereochemistry had been established. Aromatization of compound **A** (5 mg) from Nordmann fir was conducted with chloranil (2,3,5,6-tetrachlorohydroquinone) as described by Mehta and Singh (1977). After purification on silica, the product in hexane solution was concentrated to 1.1 ml under nitrogen, quantitated by GC, and submitted to polarimetry.

Partial isomerization of **A** to **C** by double-bond migration in acid solution was a step in one method for the chiral analysis of **A**. The isomerization was done by placing about 10 mg of Dowex 50W-X4 (strong cation exchange resin, acid form) into 0.5 ml of hexane solution of **A** and heating to 50°C for 16 hr. Analysis was by GC-MS on the chiral column. Isomerization also occurred when **A** was stored in $CDCl_3$.

Molecular Modeling. Assignment of the relative stereochemistry for the two asymmetric centers in compound **A** was aided by molecular modeling. The energy-minimized, three-dimensional structures for the two possible diastereomers of compound **A** were calculated using the semiempirical AM1 method available in the MOPAC computational package distributed by QCPE (Program Number 506) (Dewar et al., 1985).

Electrophysiology. Coupled GC electroantennographic detection (GC-EAD) was conducted on a Hewlett Packard 6890 GC, interfaced to antennal preparations with equipment and methods generally described by Cossé and Bartelt (2000). Volatiles collections from *A. flava* were analyzed by GC-EAD. Any compounds with actual pheromonal activity would be expected to be readily sensed by the beetle antennae (although GC-EAD activity would not necessarily imply behavioral activity).

RESULTS AND DISCUSSION

Male-Specific Compounds, Polarity, and Mass Spectra. By GC comparison of volatiles collections, males of *P. cruciferae* emitted six compounds, **A–E** and **H**, that were never detected from females (example chromatograms in Figure 1).

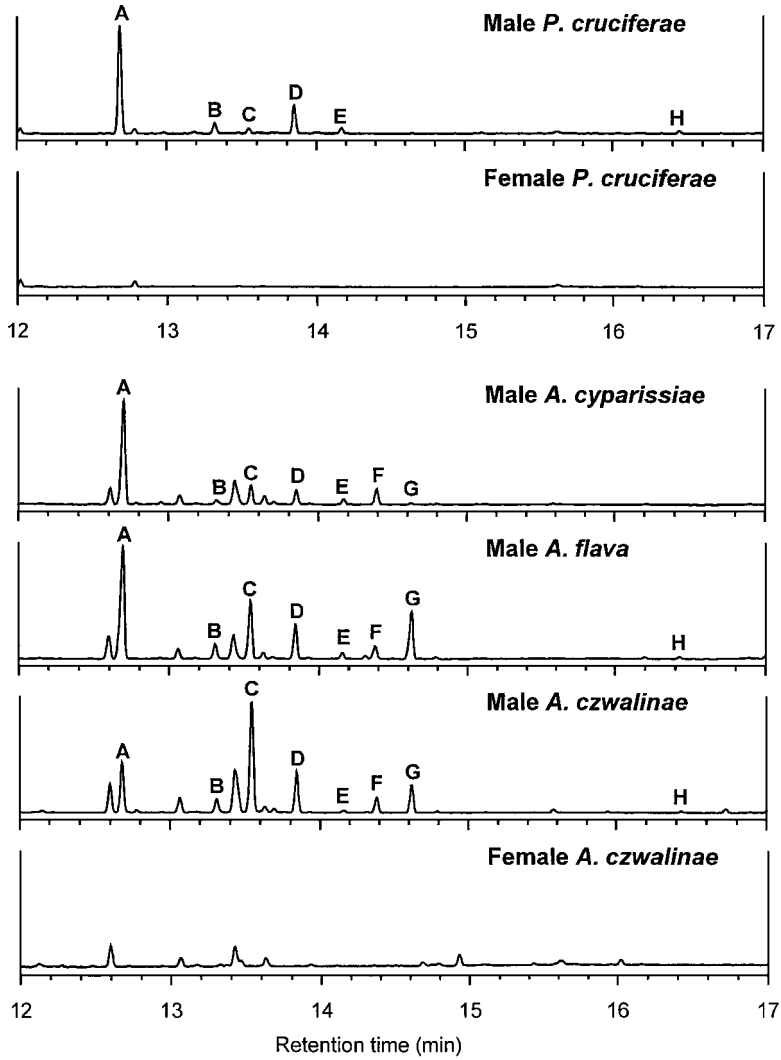

FIG. 1. Typical gas chromatograms of volatiles collected from flea beetles feeding on host material (cabbage chunks for *P. cruciferae* and spurge foliage for *Aphthona* species). Chromatograms for males consistently contained peaks (labeled **A–H**) that females lacked. They were similarly lacking from female *A. cyparissiae* and *A. flava* (chromatograms not shown). Compounds **F** and **G** were never detected from *P. cruciferae*. Compound **H** was detectable in many of the collections from *A. cyparissiae* males but not in the example shown here. In the chromatograms for males, the largest peak in the 12- to 17-min retention time window was scaled to 100%; chromatograms for females were scaled the same as for the corresponding males. Peak **A** in the chromatogram for male *P. cruciferae* represented 6 ng; peak **A** for male *A. cyparissiae*, 65 ng; peak **A** for male *A. flava*, 200 ng; and peak **C** for male *A. czwalinae*, 27 ng.

Similarly, volatiles collections from *A. flava*, *A. czwalinae*, and *A. cyparissiae* revealed eight male-specific compounds (**A–H**, Figure 1). (Only one example chromatogram for *Aphthona* females, for *A. czwalinae*, is shown in Figure 1, but those for *A. cyparissiae* and *A. flava* were similar.) Samples from females of all species were scrutinized by GC-MS for possible trace amounts of compounds **A–H**, but none were revealed. (Amounts from females as small as 1% of the major sex-specific peak from males would have been easily detectable.) The unlabeled peaks in Figure 1 were primarily host volatiles, based on GC-MS comparisons to uninfested plant material.

For all species, the usual pattern was for the male-specific compounds to appear within days of placing new beetles into the collection apparatus, but emission then continued as long as the beetles lived. All groups of male beetles eventually produced male-specific compounds. There were several consistent trends in the compound ratios (Table 1) by which the species could be recognized: *P. cruciferae* differed from the *Aphthona* species by lacking **F** and **G**. Among the *Aphthona* species, *A. cyparissiae* consistently had more **F** than **G**, but the opposite was true for *A. flava* and *A. czwalinae*. In *A. flava*, **A** was far more abundant than **C**, but the pattern in *A. czwalinae* was the reverse.

The total amount of compound emitted per male per day was greatest for *A. flava* (Table 1). *A. flava* was also long-lived, easily handled, and relatively available; therefore, *A. flava* became the major source of the material to be used for structural analysis. Most field-collected *A. flava* males emitted volatiles as long as they survived in the laboratory (usually about two months); volatiles were collected from one individual male for six months.

TABLE 1. MALE-SPECIFIC COMPOUNDS IN FOUR FLEA BEETLE SPECIES[a]

	Production of male-specific compounds			
Compound	*P. cruciferae*	*A. cyparissiae*	*A. flava*	*A. czwalinae*
Relative abundance (% of the total for **A–H** ± SD)				
A	66.3 ± 6.1	68.2 ± 2.9	50.4 ± 5.4	20.1 ± 1.9
B	6.6 ± 0.5	2.8 ± 0.1	4.5 ± 0.4	5.0 ± 0.6
C	2.9 ± 0.3	10.9 ± 2.3	16.9 ± 2.3	38.7 ± 4.3
D	17.6 ± 1.6	7.8 ± 0.1	10.9 ± 0.6	14.7 ± 1.9
E	4.0 ± 1.9	2.4 ± 0.3	1.9 ± 0.5	0.8 ± 0.4
F	0.0	6.7 ± 1.3	3.3 ± 0.9	7.8 ± 2.3
G	0.0	1.0 ± 0.3	11.6 ± 3.9	12.3 ± 5.2
H	2.6 ± 3.7	0.2 ± 0.1	0.4 ± 0.3	0.5 ± 0.3
Rate of production (total μg of **A–H** per male per day ± SD)				
A–H	0.19 ± 0.11	0.50 ± 0.12	2.9 ± 0.90	0.67 ± 0.31

[a] For each species, the data were compiled from ten chromatograms representing 10 different volatiles collections. The collections were randomly selected from among those for which emission of male-specific volatiles had commenced.

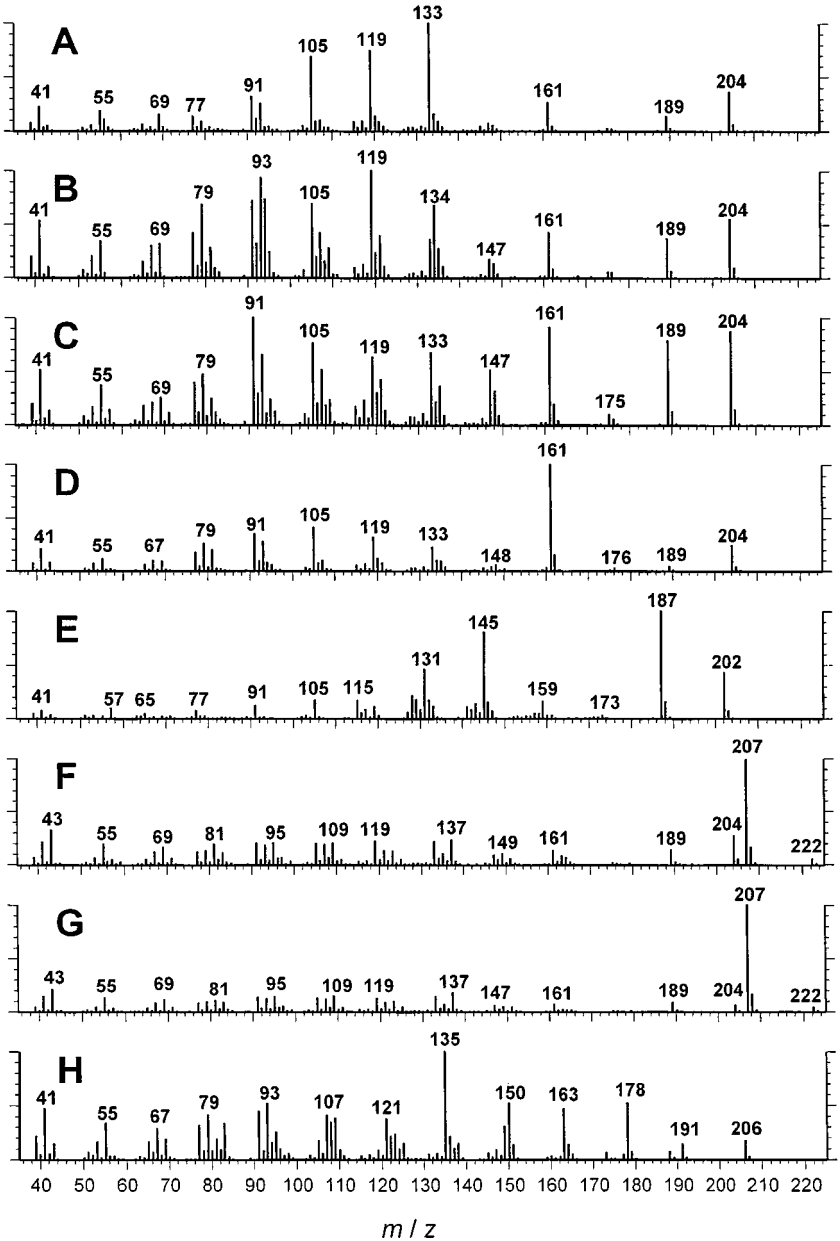

FIG. 2. EI mass spectra of the male-specific flea beetle compounds.

Compounds **A–E** from *P. cruciferae* eluted from the open column of silica with hexane, suggesting they were hydrocarbons. Mass spectra (Figure 2) indicated molecular weights of 204 for **A–D** (probably $C_{15}H_{24}$, with four double-bond equivalents) and 202 for E ($C_{15}H_{22}$, with five double-bond equivalents). Compound **H** eluted from the silica column with 25% ether in hexane. Its polarity indicated that at least one oxygen was present; thus, a molecular ion of m/z 206 could represent a molecular formula of $C_{14}H_{22}O$, with four double-bond equivalents. A fragment ion at m/z 188 ($M - H_2O$) supported the presence of oxygen.

By GC, MS, and column chromatography, six of the compounds from all three *Aphthona* species were identical to **A–E** and **H** from *P. cruciferae*. The two additional compounds (**F** and **G**) were relatively polar and eluted from silica with 25% ether in hexane. Mass spectra of these are shown in Figure 2. Molecular ions were observed at m/z 222 for both **F** and **G**, which suggested a molecular formula of $C_{15}H_{26}O$, with three double-bond equivalents. The base peak was m/z 207 (M-methyl) for both compounds, but a peak was also present at m/z 204 (M – H_2O). Credible matches to the mass spectral library were not found for any of the compounds except **D**, as discussed below.

HPLC Purification. It was clear that NMR spectroscopy and other methods requiring pure compounds would be needed for identification. Hydrocarbons **A–E** could be purified on the silver nitrate HPLC column with 0.5% 1-hexene in hexane as solvent. The retention volumes (ml after injection) were: **A**, 3.7–4.0; **E**, 4.7–4.9; **B**, 11.4–13.0; **C**,14.8–16.4; and **D**, 33.0–35.0; (hold-up volume of the column was 3.0 ml). The silica HPLC column was used for the polar compounds. With 15% ether in hexane as solvent, baseline separation of **F** and **G** was achieved (retention volumes were 15–17 and 17–22 ml, respectively); however, **H** eluted in the tail of the **G** peak (20–22 ml after injection). A second run using 3% acetone in hexane separated **H** from **G** (retention volumes were 11–12 and 17–18 ml after injection, respectively).

*Carbon Skeleton and Double-Bond Positions in Compound **A** from A. flava.* The molecular formula of **A** suggested a sesquiterpene hydrocarbon. Hydrogenation of **A** increased the molecular weight from 204 to 208, indicating that A had two double-bonds and, therefore, two rings. The UV spectrum of **A** had a maximum at 265 nm (hexane, ϵ = 7700), which was consistent with a homoannular conjugated diene system. The observed specific rotation was $[\alpha]_D = +82^\circ$ (c = 0.09%, hexane).

The proton NMR spectrum of **A** ($CDCl_3$) is shown in Figure 3. Key resonances were: δ 0.85 (3 H, d, J = 6.5 Hz), 1.06 (3H, s), 1.11 (3H, s), 1.72 (3H, br s), 5.24 (1H, m), and 5.57 (1H, s), which corresponded to four methyl groups (three aliphatic and one olefinic) and two olefinic protons. (The corresponding shifts in deuterobenzene were: δ 0.91, 1.11, 1.17, 1.80, 5.35, and 5.74, respectively). The aliphatic protons were better separated when deuterochloroform was the solvent, and subsequent analysis and comparisons to the literature

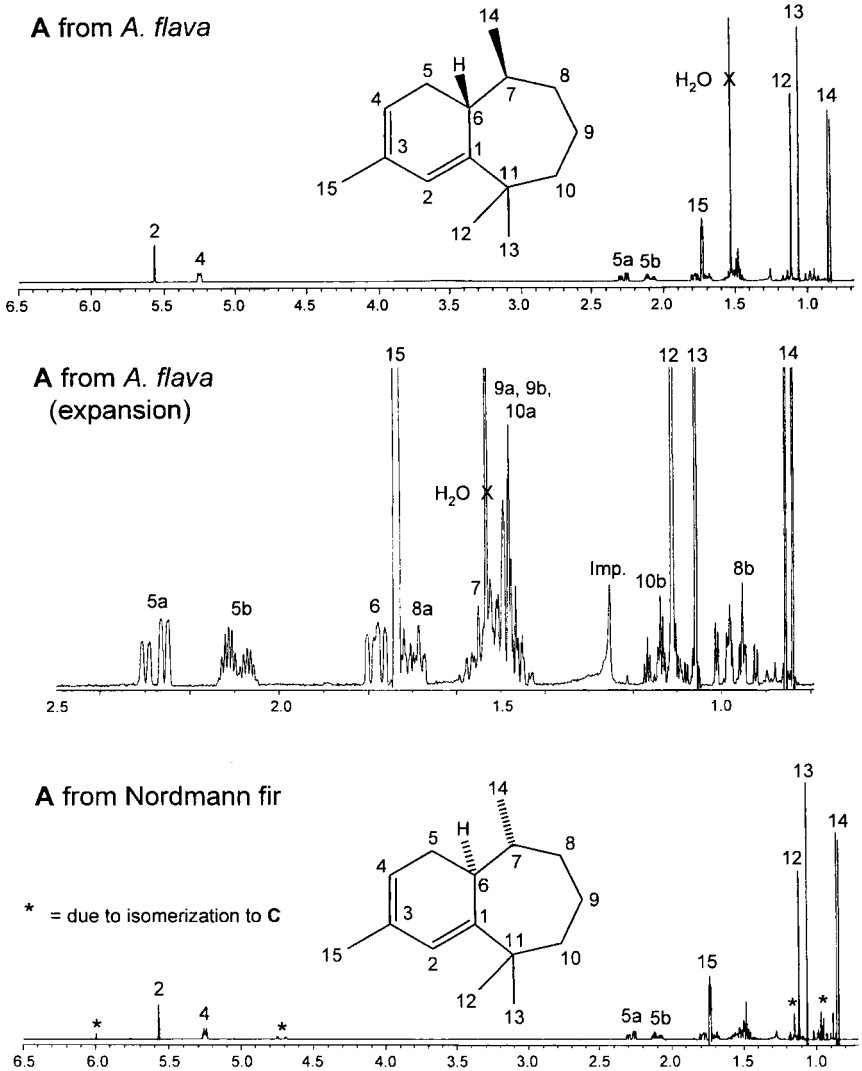

FIG. 3. Proton NMR spectra of compound **A** obtained from *Aphthona flava* and from Nordmann fir in $CDCl_3$. Stereochemistry of structures was determined by additional information (see text). Peaks due to water, an unidentified impurity, or isomerization are indicated on spectra.

TABLE 2. OBSERVED CARBON AND PROTON NMR RESONANCES COUPLING DATA FOR **A** FROM *A. flava*, AND COMPARISONS TO LITERATURE

Carbon resonances			Proton resonances				Proton–proton coupling constants (Hz)
					Literature		
Pos.	Assigned shift[a]	Literature[b]	Pos.	Assigned shift[a]	1[b]	2[c]	
1	153.57	153.45 (0)					$J_{2,4} < 1$

[a] Assignments based on COSY, decoupling, DEPT, and HMQC experiments.
[b] The numbers of attached protons reported by Khan et al. (1989) are shown in parentheses; the authors did not assign the shifts to specific structure carbons, but they are listed here matched up with the *A. flava* **A** data.
[c] Mehta and Singh (1977).

were for samples in $CDCl_3$. The observed proton and ^{13}C shifts are summarized in Table 2.

The NMR proton and COSY data led to tentative assignment of the himachalene structure shown in Figure 3 (ignoring stereochemistry, for now), and this allowed a specific search of the literature. Two instances of the proposed gross structure were found. In one (Mehta and Singh, 1977), the structure resulted from acid-induced double-bond migration in a known sesquiterpene, α-himachalene. Their proton NMR data were similar to ours in general features but not in shifts (Table 2). In the other instance, Khan and Pentegova (1988) and Khan et al. (1989) described the structure as a new natural product from European silver fir and Nordmann fir. Their NMR, UV, and mass spectral data matched the beetle-derived compound very closely, and the reported specific rotation ($[\alpha]_D = +42.5^\circ$) had the same sign as that observed for *A. flava* **A**. Khan et al. (1989) attributed the NMR

differences between the tree-derived compound and that of Mehta and Singh (1977) to different relative stereochemistry at the two asymmetric centers, and our results supported this conclusion.

Repeating the conversion of α-himachalene (Mehta and Singh, 1977) yielded a compound with a mass spectrum similar to that of **A** (Figure 2), but the GC retention time was slightly later (by 0.2 min). However, repeating the extractions of both European silver fir and Nordmann fir foliage (Khan and Pentegova, 1988; Khan et al., 1989) afforded a compound that was identical to *A. flava* **A** by proton NMR (Figure 3), carbon NMR, GC retention time, and mass spectrum. Curiously, the observed optical rotation for both tree species was negative ($[\alpha]_D = -106^\circ$, $c = 0.016\%$, hexane, for European silver fir and $[\alpha]_D = -107^\circ$, $c = 0.014\%$, hexane, for Nordmann fir), in contrast to the literature report. Thus, the isolates of **A** from *A. flava* and fir foliage in this study had an enantiomeric relationship to each other. Neither the absolute nor relative stereochemistry could be unambiguously assigned from the literature, as discussed below. Nevertheless, the fact that **A** from *A. flava* and **A** from fir were enantiomers (and must, therefore, share the same relative stereochemistry and NMR properties) was used to advantage: The abundance of **A** from fir allowed the heteronuclear correlation (HMQC) and other key NMR experiments to be run and all proton and carbon assignments to be made (summarized in Table 2). Accurate assignment of shifts was a prerequisite for further investigation of relative stereochemistry and three-dimensional structure.

Independent evidence for the himachalane carbon skeleton of *A. flava* **A** was obtained by comparing its hydrogenation products with those from α-himachalene, a natural product in which the himachalane carbon skeleton had been securely established (Joseph and Dev, 1968a,b) (Figure 4). With four asymmetric centers, saturated "himachalane" has 16 possible stereoisomers (eight pairs of enantiomers), which can be represented by up to eight discrete peaks on an achiral GC column. Hydrogenation of α-himachalene gave four GC peaks (Figure 4) because two new asymmetric centers, denoted by*, were created nonselectively, but the other two centers remained unchanged. Two of the products (at 8.24 and 8.44 min) exactly matched two products from the hydrogenation of *A. flava* **A** by GC retention times and mass spectra, which established that α-himachalene and *A. flava* **A** have the same carbon skeleton. (In fact, exactly two matching peaks were expected because only two products from **A** can have the *cis* ring junction that is present in all the products from α-himachalene). Just three hydrogenation products were observed from **A**, instead of the possible four. Either two of these have the same retention time, or one of the possible products does not form because of steric hindrance. All hydrogenation products of these compounds had nearly identical mass spectra, and only one example is shown in Figure 4. Additional minor GC peaks were seen among the hydrogenation products and were probably due to double-bond migration during the reaction.

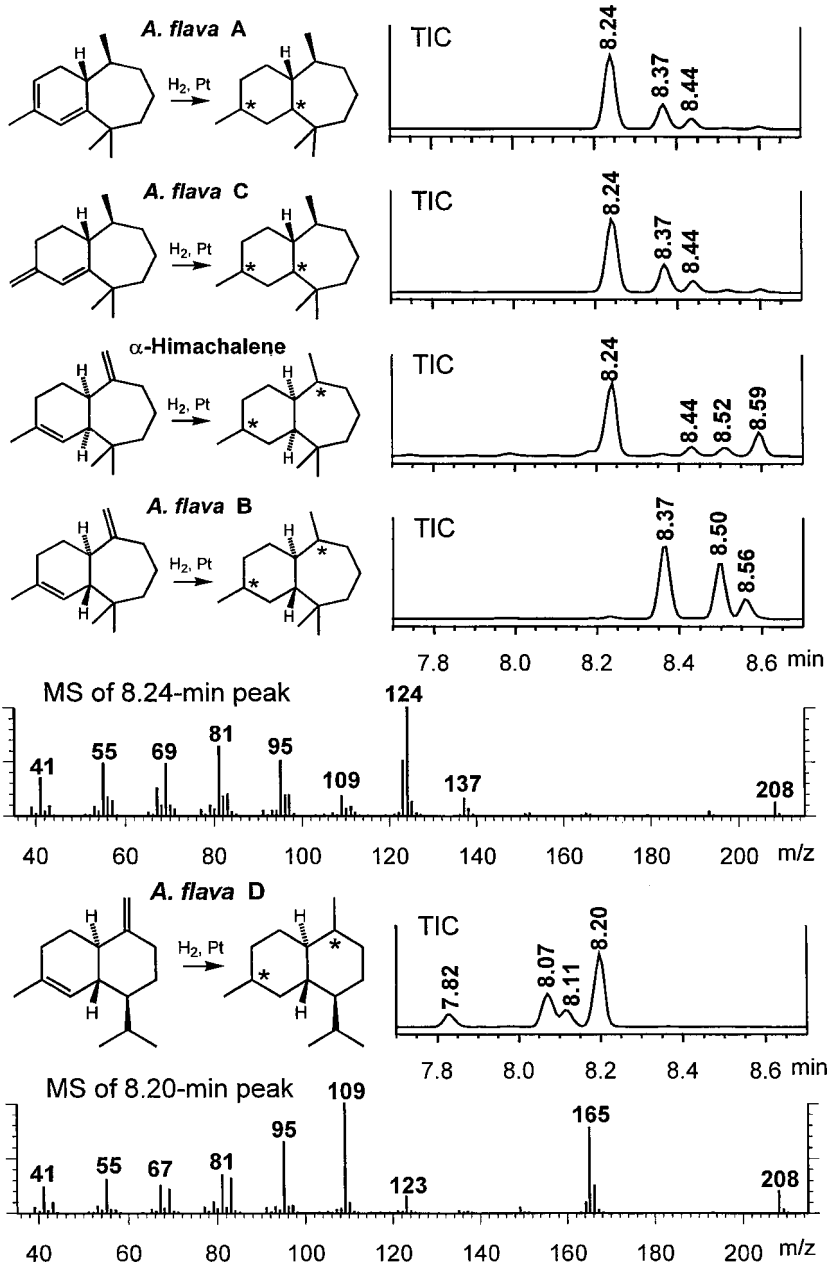

FIG. 4. Hydrogenation products from *A. flava* compounds and standard α-himachalene. Total ion chromatograms (TIC) are shown at right, and an example mass spectrum of the saturated products is shown for each carbon skeleton. Asymmetric centers created nonselectively by hydrogenation are indicated by asterisks.

Relative stereochemistry of **A** by molecular modeling and NMR:

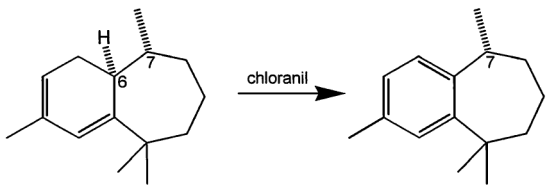
	H6 & H7 *cis*	H6 & H7 *trans*
Calculated dihedral angle H6-C6-C7-H7:	78.9 °	-162.0 °
Expected $J_{6,7}$:	~0 Hz	~9 Hz

Observed $J_{6,7}$ in **A** of 9.9 Hz supports *trans* configuration.

Correspondence between NOE data and calculated distances for *trans* isomer:

Signals	NOE	Distance (A)
Methyl 14 to H6	5%	2.72 (minimum)
Methyl 14 to H5a	8%	2.12 (minimum)
Methyl 13 to H6	7%	2.37 (minimum)
Methyl 12 to H2	17%	2.10 (minimum)
H6 to H7	2% (maximum)	3.08

Absolute configuration at C7 by conversion to known compound:



(-)-**A** from Nordmann fir (-)-7*R-ar*-himachalene

FIG. 5. Relative and absolute stereochemistry of compound **A**. Top: calculated energy-minimized structures for the possible diastereomers of **A**, along with observed NMR data and corresponding dihedral angles and distances (see text). For NOE experiments, the signal listed first was irradiated; calculated distances to methyl protons represent the minimum for the three possibilities. Bottom: Chemical conversion of **A** from Nordmann fir to compound with known absolute configuration.

*Stereochemistry of Compound **A** from A. flava.* The relative stereochemistry of **A** (whether the hydrogens at positions 6 and 7 were *cis* or *trans* to each other) was ambiguous from the literature. Mehta and Singh (1977) tentatively assigned the *cis*-H configuration to the isomer that does not match **A** from *A. flava*, based on "mechanistic considerations." Khan et al. (1989) argued that their fir compound must have the opposite relative configuration because of NMR differences, but for unknown reasons their final structure was again presented as the *cis*-H configuration (according to both their nomenclature and drawn structure). Ambiguity about the sign of rotation for the fir compound made the absolute stereochemistry uncertain also, and the entire stereochemical issue was revisited.

The three-dimensional structures for the *cis*-H and *trans*-H isomers of **A** calculated by molecular modeling are shown in Figure 5. These conformations represent the global energy minima found by the AM1 method (Dewar et al., 1985). The ring structures have remarkably similar shapes; the essential difference is that methyl group 14 is in an axial orientation in the *cis*-H isomer but in an equatorial orientation in the *trans*-H isomer. The *trans*-H structure was energetically favored by about 1 kcal/mol. The calculated dihedral angle involving H-6 and H-7 was 78.9° for the *cis*-H isomer and 162.0° for the *trans*-H isomer. From the Karplus rule (Williams and Fleming, 1980), these values would correspond to NMR coupling constants of about $J_{6,7} = 0$ Hz for the *cis*-H isomer and $J_{6,7} = 9$ Hz for the *trans*-H isomer. The observed $J_{6,7}$ for **A** from *A. flava* was 9.9 Hz, from which we conclude that **A** from *A. flava* and Nordmann fir has the *trans*-H configuration. (With the *cis*-H configuration, the large observed $J_{6,7}$ would have implied a dihedral angle close to 0°; while this conformation might occur within some seven-membered rings, the modeling calculations showed it to be energetically unfavorable in **A**.)

To further test whether the modeled *trans*-H conformation was realistic, certain calculated interatomic distances (especially those that would be strongly affected by conformation of the rings) were considered relative to the nuclear Overhauser enhancements (NOEs) observed for **A**. The NMR data supported the computed three-dimensional structure well; NOEs were detected as expected when the calculated interatomic distances were small (e.g., 2–3 Å) (Figure 5). A small NOE (<2%) was observed for H-7 when H-6 was irradiated; if these hydrogens had been *cis* to each other with a dihedral angle of ~0°, a much larger NOE would have been expected, and this further supports the assigned *trans*-H relative configuration.

The absolute stereochemistry of **A** was determined by aromatizing it to *ar*-himachalene with chloranil (Mehta and Singh, 1977) (Figure 5). The procedure preserved the configuration at carbon 7 but eliminated the asymmetric center at carbon 6; the absolute configuration of *ar*-himachalene was determined previously (Pandy and Dev, 1968), with the (+) optical rotation corresponding to the *S* configuration. Compound **A** from Nordmann fir (which was more abundantly available than that from *A. flava*) gave *ar*-himachalene (by MS, MW = 202; by GC, >99% pure) with a specific rotation of $[\alpha]_D = -2.2°$ ($c = 0.4\%$, hexane).

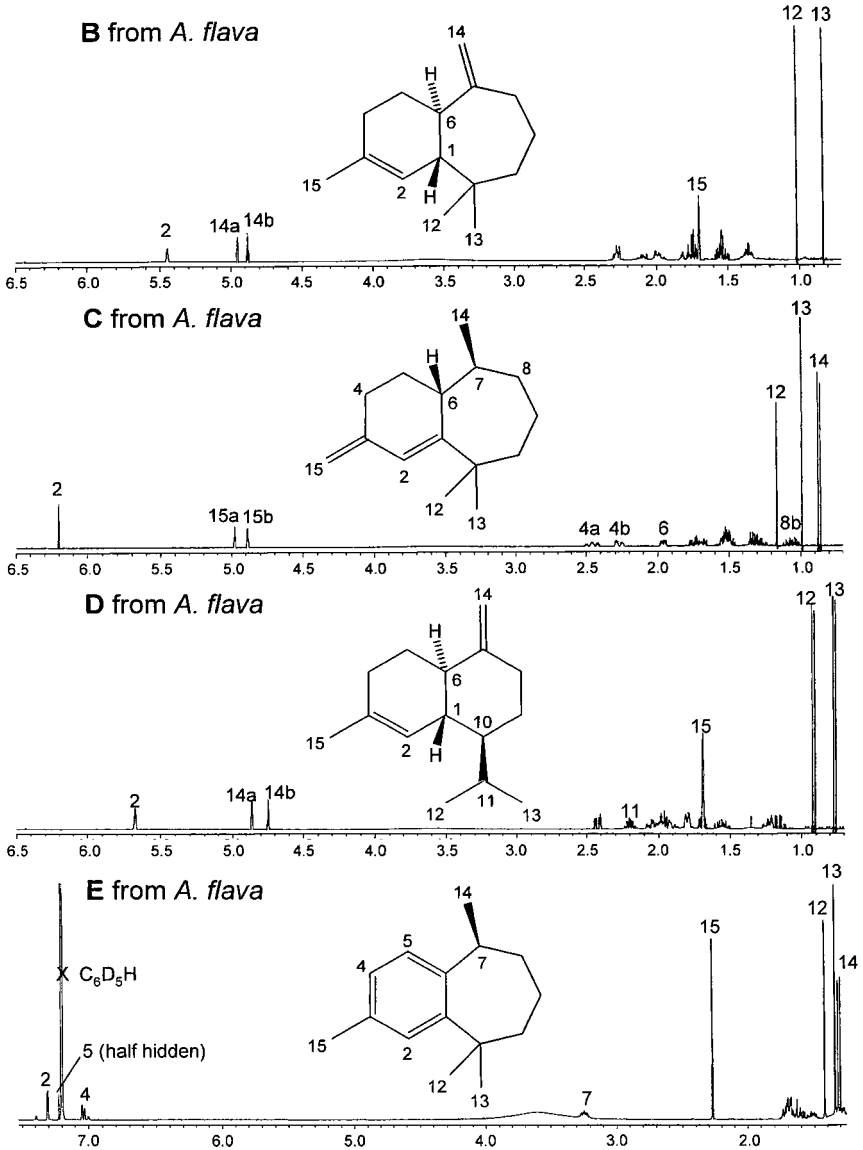


FIG. 6. Proton NMR spectra in benzene-d_6 for hydrocarbons **B–E** and final structures (stereochemistry determined by other considerations; see text).

Thus **A** from the fir samples had the 7*R* configuration, and that from *A. flava* must be 7*S*. Combining this result with the conclusion for relative stereochemistry, (+)-A from *A. flava* must have the 6*R*,7*S* configuration, and (−)-**A** from both fir species, 6*S*,7*R*. An attempt was made to check enantiomeric purity by chiral GC (Cyclodex-B column), but no separation of enantiomers was achieved. It is unknown whether other fir cultivars have different enantiomeric compositions for **A** or whether the sign of rotation reported by Khan et al. (1989) was in error.

*Compound **C** from A. flava.* As shown in Figure 4, hydrogenation of **C** gave the same products as **A**, by both GC and MS; thus, compound **C** also had the himachalane carbon skeleton. The specific rotation of **C** was $[\alpha]_D = +1.6^\circ$ ($c = 0.023\%$, hexane). The UV spectrum indicated an exocyclic conjugated diene system (maximum at 242 nm, hexane, $\epsilon = 15{,}600$). The NMR spectrum (Figure 6) had these key resonances (benzene-d_6): δ 0.87 (3H, d, $J = 6.5$), 0.99 (3H, s), 1.16 (3H, s), 4.89 (1H, br s), 4.98 (1H, br s), 6.20 (1H, s). The NMR data were consistent with a secondary methyl group, two geminal methyl groups, an exocyclic methylene, and one trisubstituted olefin in the ring system. (In $CDCl_3$, the corresponding shifts were: δ 0.95, 0.96, 1.14, 4.69, 4.74, and 5.99, respectively). These data suggested the gross structure shown in Figure 6, and Khan et al. (1989) again reported a compound from the fir species with remarkably similar NMR, UV, and mass spectra. As with **A**, analysis of Nordmann fir foliage confirmed the results of Khan et al. (1989), except with respect to enantiomeric composition.

The enantiomers of **C** were separable by GC on the chiral column. Compound **C** from *A. flava* eluted at 16.49 min and that from Nordmann fir and European silver fir eluted at 16.62 min (with nearly baseline separation). Thus, the isolates of **C** from the two sources were enantiomers, and each source appeared to be enantiomerically pure. (As little as 10% of the opposite enantiomer would have been detectable). This result was inconsistent with the optical rotation reported by Khan et al. (1989), $[\alpha]_D = +2.7^\circ$, which had the same sign as we observed for *A. flava*. Thus, for both **A** and **C**, the polarimetry data of Khan et al. (1989) are incompatible with the fir samples analyzed in this study, and their sign of rotation for **C** is discounted.

Two lines of evidence indicated that **C** and **A** had the same relative stereochemistry at the asymmetric centers. First, their hydrogenation products were exactly the same (Figure 4); *none* of the GC peaks could coincide if **C** and **A** had a diastereomeric relationship at these carbons. Second, **C** slowly isomerized into **A** in $CDCl_3$ (about 85% complete after several days at room temperature, by NMR and GC analysis); this probably was catalyzed by a trace of acid in the NMR solvent and proceeded through a cation intermediate (with the charge at C-3). This conversion would not affect asymmetric centers C-6 and C-7. The conversion did not occur in benzene. The reverse isomerization, of **A** into **C**, also occurred to a minor extent in $CDCl_3$, as shown in the Nordmann fir sample in Figure 3; by GC, the percentage of **C** in the sample before NMR was 0.3%, but this increased to

9.5% in $CDCl_3$. Khan et al. (1989) also noted the isomerization and gave a procedure for converting **C** into **A**, by heating in formic acid solution; the acid-catalyzed equilibration strongly favors **A**.

Compound **C** from Nordmann fir was shown to have the same absolute configuration at carbons 6 and 7 as **A** from Nordmann fir. The partially isomerized NMR sample of **A** from Nordmann fir (Figure 3) was analyzed on the chiral column, and the **C** derived from **A** had the same GC retention as the **C** isolated directly from the foliage (16.62 min). Both (−)-**A** and (−)-**C** from Nordmann fir have the 6*S*,7*R* configuration, and therefore, (+)-**C** from *A. flava* must be 6*R*,7*S*.

*Compound **E** from A. flava.* By GC retention time and MS, *A. flava* **E** was identical to *ar*-himachalene, the aromatization product of **A**. *ar*-Himachalene was first described from Himalayan cedar (Joseph and Dev, 1968a). The proton NMR spectrum (Figure 6) had the following shifts in benzene-d_6: δ 1.31 (3H, d, $J = 6.5$), 1.33 (3H, s), 1.42 (3H, s), 2.27 (3H, s), 3.24 (1H, m), 7.04 (1H, dd, $J = 7.9, 1.6$), 7.21 (1H, d, $J = 7.9$), and 7.31 (1H, d, $J = 1.6$). Two geminal methyls, a secondary methyl adjacent to a benzene ring, an aromatic methyl, and three aromatic protons were indicated, supporting the *ar*-himachalene structure. The corresponding shifts in $CDCl_3$ were 1.33, 1.33, 1.42, 2.31, 3.26, 6.98, 7.11, and 7.18, which were very similar to those reported by Pandy and Dev (1968) in CCl_4. The specific rotation was positive in sign but small in magnitude; thus it could not be measured accurately due to the small amount of isolated material ($[\alpha]_D < +10^\circ$, $c = 0.001\%$, hexane). As noted above, the (+) rotation corresponds to the 7*S* configuration, and **E** from *A. flava* is identical to **E** isolated from Himalayan cedar. **E** was also found in the Nordmann fir extract, but its configuration there was not established. The optical rotation was not measured, and separation of the enantiomers of **E** was not achieved on the chiral GC column.

*Compound **B** from A. flava.* Hydrogenation of **B** afforded a product that was identical in GC retention time (8.37 min) and mass spectrum to one of those from **A** (Figure 4), establishing that **B** also has the himachalane carbon skeleton. The proton NMR spectrum (Figure 6) had key resonances in benzene-d_6 at: δ 0.84 (3H, s), 1.02 (3H, s), 1.70 (3H, br s), 4.88 (1H, br s), 4.95 (1H, br s), and 5.45 (1H, br s). Like **C**, compound **B** had three methyl groups and an exocyclic methylene, but unlike **C**, one of the methyls (1.70 ppm) was olefinic. From the COSY experiment, the single olefinic ring proton (5.45 ppm) was coupled to the olefinic methyl group but not to any ring protons. An olefinic proton adjacent in the ring to a methylene group would be coupled to at least one of the methylene protons, but it would not necessarily be coupled to an adjacent methine proton. Therefore, only the double-bond locations shown for **B** in Figure 6 can be consistent with the NMR data. The corresponding proton shifts in $CDCl_3$ were 0.71, 0.96, 1.68, 4.72, 4.79, and 5.31, and there was no evidence of degradation. The specific rotation was $[\alpha]_D = +50^\circ$ ($c = 0.008\%$, hexane).

Like α-himachalene (Figure 4), the asymmetric centers of **B** are at carbons 1 and 6; however, none of the products of hydrogenation of **B** matched those from α-himachalene (the slightly different GC retention times in the last two products from each source were real and were corroborated by subtly different mass spectra). Thus, all of the hydrogenation products from **B**, and **B** itself, must have the *trans* ring junction. The NMR spectrum of **B** does not match that reported for α-himachalene, but it agrees well with that for *trans*-α-himachalene (Joseph and Dev, 1968c). These authors established that the 1*S*,6*S* configuration has a specific rotation of $[\alpha]_D = -39.5^\circ$. Because of the opposite optical rotation, **B** from *A. flava* must have the 1*R*,6*R* configuration.

*Compound **D** from A. flava.* As with **A**, **C**, and **B**, hydrogenation indicated the presence of two rings, but GC retention times and mass spectra of the products established that the ring system of **D** was very different (Figure 4). The mass spectrum of **D** (Figure 2) was much like the library spectra for γ-cadinene and α-amorphene, both of which have the cadinane carbon skeleton. The specific rotation was $[\alpha]_D = +110^\circ$ ($c = 0.016\%$, hexane). In benzene-d_6, the proton spectrum (Figure 6) had these resonances: δ 0.76 (3H, d, $J = 6.5$), 0.91 (3H, d, $J = 6.5$), 1.68 (3H, br s), 4.74 (1H, br s), 4.86 (1H, br s), and 5.68 (1H, br s). The spectrum was consistent with three methyl groups and one exocyclic methylene, and the COSY experiment confirmed that the aliphatic methyls were part of an isopropyl group. α-Amorphene was eliminated as a possibility because it has four methyl groups. The corresponding proton shifts in $CDCl_3$ were 0.74, 0.93, 1.69, 4.55, 4.66, and 5.56, and the compound was stable in this solvent.

The NMR data in $CDCl_3$ were consistent with literature data for γ-cadinene (Andersen et al., 1977; Cane et al., 1987). Citronella oil is a good source of this compound, and the compound isolated from the commercial oil matched that from *A. flava* **D** exactly by NMR, GC, and MS and agreed fairly well in optical rotation ($[\alpha]_D = +136^\circ$, $c = 0.011\%$, hexane). Carbon and DEPT data were obtained for the more abundant, botanical sample ($CDCl_3$): δ 134.76, 153.39 (0 attached hydrogens); 26.20, 44.18, 45.11, 46.89, 122.42 (1 H); 25.71, 26.52, 30.48, 36.30, 103.15 (2 H); 15.10, 21.55, 23.89 (3 H). The carbon data closely matched those of Cane et al. (1987). Cane et al. (1987) assigned the 1*S*,6*S*,10*R* configuration to the (−) form they encountered; therefore, the (+)-**D** from *A. flava* has the 1*R*,6*R*,10*S* configuration.

*Compounds **F** and **G** from A. flava.* The key to identification of polar compounds **F** and **G** was that both decomposed significantly (up to 50%) when the GC inlet was set to 250°C. HPLC-purified **F** and **G** both produced **A** and **C** (in similar amounts, recognized by mass spectrum and GC retention time). Dehydration of an alcohol was the likely mechanism of decomposition, which would not affect the ring system. Thus **F** and **G** must also have the himachalane carbon skeleton. The specific rotation of **F** was $[\alpha]_D = +72^\circ$ ($c = 0.028\%$, hexane), and that for **G** was $[\alpha]_D = +83^\circ$ ($c = 0.030\%$, hexane). The proton

NMR spectrum of **F** (in benzene-d_6) had these features: δ 0.89 (3H, *d*, $J = 6.7$), 0.96 (3H, s), 1.12 (3H, s), 1.34 (3H, s), and 5.45 (1H, s) (Figure 7). The corresponding NMR data for **G** were: δ 0.91 (3H, d, $J = 6.7$), 0.94 (3H, s), 1.15 (3H, s), 1.26 (3H, s), and 5.41 (1H, s). The data for both compounds support the presence of a hydroxyl group on carbon 3, both with respect to the shift for methyl group 15 (1.34 or 1.26 for **F** and **G**, respectively) and the appearance of this signal (a singlet). An epimeric relationship between **F** and **G** could account for their slightly different spectral and chromatographic properties. **F** and **G** decomposed within hours to **A** and **C** when placed in $CDCl_3$, but there was enough time to obtain the proton shifts (signals in the same order as for

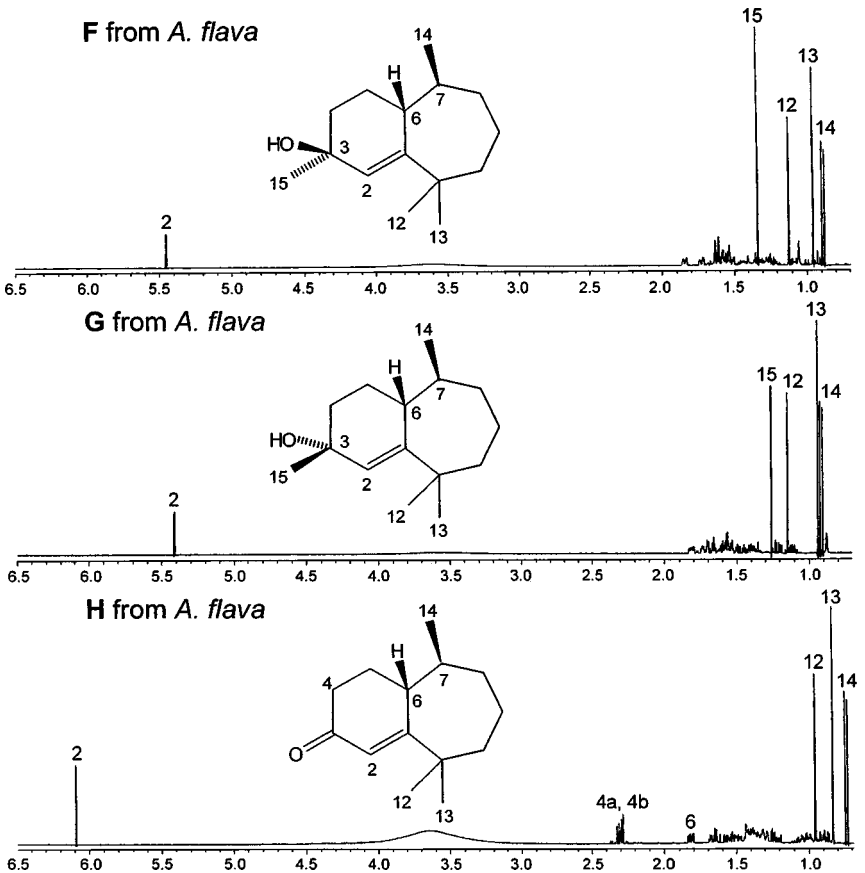

FIG. 7. Proton NMR spectra in benzene-d_6 for polar compounds **F–H** and final structures (stereochemistry determined by other considerations; see text).

benzene-d_6): 0.95, 0.93, 1.10, 1.27, and 5.41 for **F** and 0.97, 0.91, 1.10, 1.23, and 5.33 for **G**.

As tertiary allylic alcohols, **F** and **G** are especially prone to dehydration, but this reaction would not affect the stereochemistry at carbons 6 and 7. When pure **F** or pure **G** was injected onto the chiral GC column, the resulting **C** was only the earlier eluting enantiomer. Thus, (+)-**F** and (+)-**G** both have the same absolute configuration at these two centers as (+)-**A** and (+)-**C** from *A. flava* (6*R*,7*S*). Tentative assignment of configuration at carbon 3 was based on molecular modeling and the NMR shift of methyl group 15. By molecular modeling, methyl group 15 has an axial orientation in one of the epimers and equatorial in the other, and in the axial epimer, methyl group 15 and hydrogen 6 are on the same side of the six-membered ring (i.e., configuration at carbon 3 is *R*). In **G**, the relatively upfield methyl shift (1.26 ppm) would correspond to the axial orientation (3*R*,6*R*,7*S*), while the shift of 1.34 ppm observed for **F** would correspond to the equatorial orientation (3*S*,6*R*,7*S*). The consequent, relatively equatorial orientation of the hydroxyl group in **G** would make it more accessible to adsorbants during liquid chromatography and could explain its longer retention than **F** on the silica HPLC column.

*Compound **H** from A. flava.* Enough **H** was isolated (17 μg) so that a proton NMR spectrum could be acquired (Figure 7). The key resonances (in benzene-d_6) were: δ 0.71 (3H, d, $J = 6.6$), 0.81 (3H, s), 0.93 (3H, s), 6.06 (1H, s), suggesting two geminal methyl groups, a secondary methyl group, and a single olefinic proton. The spectrum of **H** looked much like those of **C**, **F**, and **G**, except that carbon 15 was lacking. A keto group on carbon 3 could account for the number of observed signals, their splittings, and the relatively downfield shifts in the six-membered ring. The UV spectrum had a maximum at 233 nm, which was consistent with a conjugated enone ($\epsilon = 27{,}500$). The micro-Wittig methylenation converted **H** into **C**, by GC retention time and mass spectrum, which established the overall ring structure and the relative stereochemistry at carbons 6 and 7. Injection of this sample onto the chiral GC column gave just one peak for **C**, at the earlier of the possible retention times (16.49 min). Therefore, **H** has the same 6*R*,7*S* configuration as **A**, **C**, **F**, and **G** from *A. flava*. Optical rotation was not measured.

Compound Configurations in Other Beetle Species. By GC on the chiral column, compound **C** from *P. cruciferae, A. cyparissiae, A. czwalinae,* and *A. flava* all have the same absolute configuration. The same is true for **F** and **G** from all *Aphthona* species, by chiral GC analysis of the **C** produced in the hot inlet. Furthermore, **A** from these species has the same configuration as **A** from *A. flava* because purification ($AgNO_3$ HPLC), partial isomerization to **C**, then chiral GC analysis gave only the earlier GC peak for **C**. Compounds **B** and **D** from these species have the same chiral GC retention times as **B** and **D** from *A. flava* (15.50 and 17.92 min, respectively). However, authentic (−) enantiomers of

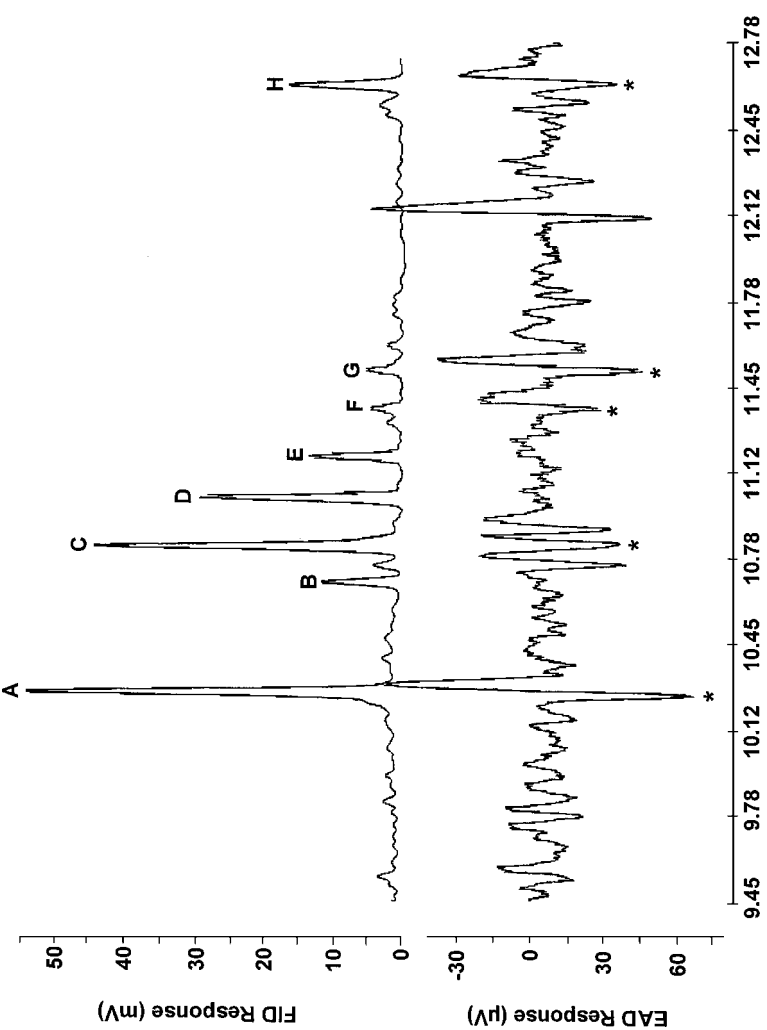

FIG. 8. Simultaneously recorded gas chromatogram (top) and electroantennogram responses (bottom) of typical female *A. flava* antenna to volatiles collection on Super Q from male *A. flava* feeding on leafy spurge. Responses to male-specific compounds are denoted by asterisks.

these compounds were not available for comparison; thus it is unknown whether the enantiomers of **B** and **D** are separable on this column. Differences among the species were not demonstrated with respect to absolute configuration of **B** and **D**, but they cannot be ruled out; there was insufficient material for optical rotation measurements. Configurations of **E** and **H** in the other species remain unstudied.

Electrophysiological Activity. In GC-EAD analyses of volatiles from male *A. flava*, both male and female *A. flava* antennae were stimulated by five of the male-specific compounds (Figure 8). Compounds **A**, **C**, **F**, **G**, and **H** consistently showed EAD activity, whereas compounds **B**, **D**, and **E** showed no EAD activity on at least 10 antennal preparations. Responses did not occur at any of these retention times to volatiles collected from females. In addition to male-specific material, several spurge-specific compounds activated male and female antennae. Initial GC-EAD analyses of compound **A** from *A. flava* with antennae of *A. czwalinae*, *A. cyparissiae*, and *P. cruciferae* indicated that the biological activity of compound **A** is a common feature among the tested flea beetle species. A comprehensive comparative electrophysiological study on male-specific flea beetle compounds is anticipated in the future.

Conclusions and Further Research. Peng et al. (1999) concluded that males of *P. cruciferae* emit an aggregation pheromone that attracts both sexes when the males are feeding on host material, based on behavioral data. The present study demonstrated chemical and electrophysiological patterns that are consistent with this model. First, blends of relatively abundant, male-specific compounds were detected and identified in *P. cruciferae* and also in three other flea beetle species. (Curiously, *P. cruciferae* and the three *Aphthona* species shared many of the same compounds, and ultimately, it was the abundance of the compounds in *A. flava* that made identification of the fairly complicated structures feasible.) Second, the blends had species-specific proportions, which could serve to allow individuals to locate others of their own species even in mixed populations. Third, male-specific compounds were readily sensed by the antennae of both sexes, as would be expected for a pheromone. Clearly, these patterns do not prove a pheromonal function, but the present identification and the anticipated synthesis of these male-specific compounds will allow definitive biological experiments to be run. The function of these compounds in nature may or may not involve attraction, but the existence of such blends is intriguing in any case and invites explanation.

The compounds themselves include several new himachalene sesquiterpenes and new enantiomers of previously identified ones. Only one of the compounds, (+)-γ-cadinene, is known to occur rather widely in nature (in plants). One would not expect compounds used as pheromone components to be abundant in the environment, and those from the flea beetles are generally not. The use of compounds such as himachalenes as pheromone components would not be unprecedented; a homosequiterpene with the himachalene ring system has been previously identified as a pheromone in the sandfly *Lutzomyia longipalpis* (Hamilton et al., 1996).

Acknowledgments—We are grateful to the following individuals for supplying beetles: Dr. Julie Soroka and Dr. Margie Gruber of Agriculture Canada, Saskatoon, Saskatchewan, Canada (*P. cruciferae*); Dr. C. Peng, North Dakota State University, Fargo, North Dakota, USA (*P. cruciferae*); Dr. Anthony Caesar, USDA-ARS-NPARL, Sidney, Montana, USA (*Aphthona* species and leafy spurge plants); and Dr. Robert Nowierski, Montana State University, Bozeman, Montana, USA (*Aphthona* species). Mr. Harold Miller of Harold Miller Landscapes, Jefferson, Oreon, USA, kindly sent us 10 kg of Nordmann fir foliage. Ms. Michele Giovannini grew the leafy spurge plants in the NCAUR greenhouse.

(Received March 1, 2001; accepted August 10, 2001)

Abstract—Responses of the European spruce bark beetle, *I. typographus* (Coleoptera: Scolytidae), to low release-rate pheromones were investigated in two experiments in a spruce forest at Wellin, southern Belgium. Dose–response of the beetle was first examined in a trapping experiment in August 1999. The major pheromone components of *I. typographus*, *(S)-cis*-verbenol (cV) and 2-methyl-3-buten-2-ol (MB) were released from window traps. Five treatments were replicated five times: (1) blank trap, (2) 0.03 and 1.2, (3) 0.11 and 4.5, (4) 0.34 and 15.2 mg/day of cV and MB, respectively, and (5) Pheroprax. Trap catches increased linearly as a function of increasing release rates of cV and MB. A second study aimed at making preliminary observations on the attraction range of the pheromones as compared to Pheroprax. A release–recapture experiment was carried out in May 2000: four trap-trees located 50 m away from a central release platform were equipped with window traps baited with increasing release rates, tested in separate releases: 0.03 and 1.2; 0.11 and 4.5; 0.34 and 15.2 mg/day of cV and MB, respectively, and Pheroprax. Recaptures increased with the release rate. Trap catches were different at lower release rates, but not between the release rate of 15.2 mg/day of MB and Pheroprax. Variations in captures in relation to wind parameters showed persistently random flight at the lower release rates. Significant upwind flight was observed for Pheroprax only. These results imply that trap interference existed for Pheroprax and suggest that its attraction range may be greater than 50 m.

Key Words—*Ips typographus*, Scolytidae, Coleoptera, release rates, dose-response, flight dispersal, Pheroprax®.

INTRODUCTION

Since the development of commercial attractants, pheromone trapping is regularly used to monitor populations of *Ips typographus*, one of the most aggressive and damaging pests of Norway spruce in Europe (Bakke, 1985; Weslien, 1992). This technique is also frequently used in mark–recapture experiments to assess the beetle's dispersal capacities (e.g., Botterweg, 1982; Weslien and Lindelöw, 1990; Zumr, 1992; Duelli et al., 1997; Byers, 1999).

Most dispersal studies have relied on commercial pheromones originally developed for mass trapping, such as Pheroprax, that have high release rates to ensure an efficient attraction of the beetles. However, one of the primary goals of recapturing marked animals is to obtain a good estimate of their flight ability. If traps close to the release point exhibit a strong attraction, most beetles primed to respond to pheromones will end up in these traps and it will not be possible to conclude much about dispersal (Turchin, 1998). Even for species requiring flight exercise, as might be the case for *I. typographus* (Duelli et al., 1997), some individuals might respond to the attractive source when they would have flown further under different conditions.

Our approach to study *I. typographus* dispersal was to recreate a flight environment as natural as possible, using live, standing trap-trees in place of traps, and low release-rate pheromones lures instead of commercial attractants (Franklin et al., 2000). In this paper, we present the design of the lures and an evaluation of their effectiveness in the field.

We first investigated the response of *I. typographus* to several release rates and compared it to Pheroprax. We then studied trap interference for these release rates, in order to make a preliminary evaluation of their attraction range as compared to that of Pheroprax. The range of attraction of pheromone lures is the maximum distance over which insects can be shown to direct their movement to the source (Wall and Perry, 1987). Most studies have been done on Lepidoptera (Wall and Perry, 1987; Elkinton and Cardé, 1988) and some on bark beetles (Schlyter, 1992) or diprionids (Wedding et al., 1995). Probably the most elaborate study on bark beetles was carried out by Turchin and Odendaal (1996), who investigated the effective sampling area of traps capturing newly emerged southern pine beetles (*Dendroctonus frontalis*).

This knowledge is crucial for the development of reliable mark–recapture experiments, but existing information for *I. typographus* is scarce and estimates vary greatly due to the few data available.

METHODS AND MATERIALS

Dispensers and Release Rates. Releases of methyl-3-buten-2-ol (MB) and *(S)-cis*-verbenol (cV) were obtained with semipermeable polyethylene (PE) bags containing the semiochemicals. Each dispenser consisted of two bags, one for MB and one for cV. Ipsdienol was not used, as it did not prove essential for *I. typographus* capture (Schlyter et al., 1987 a,b). The dispensers were built using PE sheets of different thickness sealed into 4×4 cm^2 bags, containing either 200 μl of MB impregnated on 1×1-cm^2 absorbent tissue paper protected from direct sun light by aluminum foil, or 5 mg of cV crystals. Chemicals, sources, PE thickness, and release rates are listed in Table 1. Release rates were determined from weight loss in a wind tunnel, at 0.05 m/sec and $20 \pm 2^\circ$C and calculated as the slope ($\pm$ its 95% confidence limits) of the regression of weight loss versus time for the time period when this relation was linear (i.e., when the release rates were constant) (Table 1).

Dose-Dependent Responses. Experiments with varying release rates were carried out in spruce and beech stands at Wellin, southern Belgium, in August 1999. No trees attacked by *I. typographus* were detected before, during, or after the experiments. There were five treatments, each replicated five times: (1) blank trap, (2) 0.03 and 1.2, (3) 0.11 and 4.5, (4) 0.34 and 15.2 mg/day of cV and MB, respectively, (5) Pheroprax dispenser (35.8 mg/day of the blend). The 15.2 mg/day release

rate for MB was obtained by using two dispensers each releasing 7.6 mg/day. Ratios of about 40:1 in the release rates of MB and cV were used in order to approach the ideal ratio of 50:1 mentioned by Schlyter et al. (1987c).

Each replication consisted of a line of five live, standing trap-trees spaced 75 m apart, equipped with small transparent PVC barrier traps (13 cm wide × 24 cm high, ending in a funnel connected to a collecting jar) attached to the tree trunks at breast height. MB and cV dispensers were fixed on the traps 10 cm above the collecting funnel. The trees had previously been sprayed with a pyrethroid insecticide (Ripcord 40: 400 g cypermethrin/liter, S.A. Belgian Shell, 25 ml/10 liters water) up to a height of 6 m (Franklin et al., 2000). Each replication was at least 100 m from all others. Traps were emptied, and treatments were rerandomized within each replication on seven occasions between July 24, and September 10, 1999.

Attraction Range. A simple way to establish the attraction range is to study trap interference, i.e., a lowering of catch per trap when traps baited with synthetic pheromones are placed close to each other compared to widely spaced traps (Schlyter, 1992). Another method is to compare catches with high and low release rates in a given trapping grid. We chose this latter approach for a preliminary trial, which could give insight on the range of distances to be tested subsequently in an experimental design involving several trap spacings. A release–recapture experiment was performed at Wellin in May 2000. The setup consisted of four trap-trees located in the four cardinal directions, 50 m away from a central release platform. The distance between two adjacent trap-trees was 71 m. The trapping method was identical to the one described for the dose–response experiment.

Four release rates were tested, each replicated five times, except for the lower release rate, which was replicated four times only due to adverse weather conditions (0.03 and 1.2; 0.11 and 4.5; 0.34 and 15.2 mg/day of cV and MB, respectively, and Pheroprax). Each replicate was carried out as follows: freshly emerging beetles were collected from emergence tents (Lindelöw and Weslien, 1986), counted, marked with fluorescent powder, and allowed to fly off from the release platform. After 45 min, releases were stopped and nonflyers were counted. Fifteen minutes later, traps were emptied and the number of beetles caught was recorded. Short release–recapture periods were chosen in order to maximize the number of beetles caught on their outward dispersing flight and to minimize captures of beetles returning after a long flight as can be expected from simulation models (Byers, 2000). Such release–recapture experiments, in which insects are recovered quickly, were found to provide better attraction range estimates (Wall and Perry, 1987). Short periods were also used in order to have weather conditions as constant as possible during a given replicate.

Several releases were performed during one afternoon (12:00–17:30 PM). A period of 30 min was allowed to elapse between each replicate, and the barrier traps were changed for each treatment in order to prevent the accumulation

of pheromones on the traps and in the vicinity of the trap-trees. Different colors of fluorescent powder were used to differentiate between release rates. Release rates were randomized during the afternoon so as to test the different rates at different times of the day.

Wind direction was assessed with a compass and a thread allowed to flutter freely in the wind. Wind speed was measured with a hand-held anemometer (Testovent 4200, Testoterm S.A.). Both parameters were measured at the start and end of the 60-min flight period; we took five recordings during an interval of 5 min, and an average was then calculated.

Statistical analysis of circular data was carried out with Oriana v. 1.06 software (Kovach Computing Services, Pentraeth, UK). The Rayleigh test (Zar, 1996) was used to determine whether wind direction and catches of marked beetles in the four traps were random or directed. Watson's *F*-test (Zar, 1996) was then used to compare the beetle's flight direction to the wind direction, to determine if their mean angles differed significantly.

RESULTS

Dispensers and Release Rates. Within the range studied, release rates of our PE bag dispensers decreased exponentially as a function of PE thickness (Table 1): for MB, $y = 12.9\mathrm{e}^{-0.07x}$ ($R^2 = 0.97$, $P < 0.001$) and for cV, $y = 0.54e^{-0.10x}$ ($R^2 = 0.97$, $P < 0.001$) with y corresponding to the release rate in milligrams per day and x to the PE thickness in grams per square centimeter. This decrease differed for the two components, as shown by the comparison of the slopes of the regressions on log transformed data ($t\ \mathrm{obs}_{8df} = 2.86$; $P = 0.02$).

During our tests, the release rate of Pheroprax averaged 35.8 mg/day for the blend after the 18-day test period (Table 1). This is comparable to results of Jakus and Simko (2000), who estimated the release rate of the same Pheroprax dispenser at about 27 mg/day after leaving dispensers in the field for seven weeks.

Dose-Dependent Responses. A total of 582 *I. typographus* were caught throughout the season—about 64% with Pheroprax. Trap catches increased with increasing release rates (Figure 1) from an average of 0.2 captures for blank traps to an average of 93 captures for traps baited with Pheroprax.

Analysis of variance on log-transformed counts showed differences between catches at different release rates ($F_{4,16df} = 63.6$, $P < 0.001$); post hoc analyses indicated that Pheroprax caught more beetle's than the other release rates ($P < 0.01$, Figure 1). When regression analysis was used to compare *I. typographus* catches for our PE bag dispensers, excluding Pheroprax as it had different formulation and conditioning, it showed a linear response with increasing release rates (beetle catches as a function of MB release, slope = 1.69, $R^2 = 0.39$, $P = 0.003$).

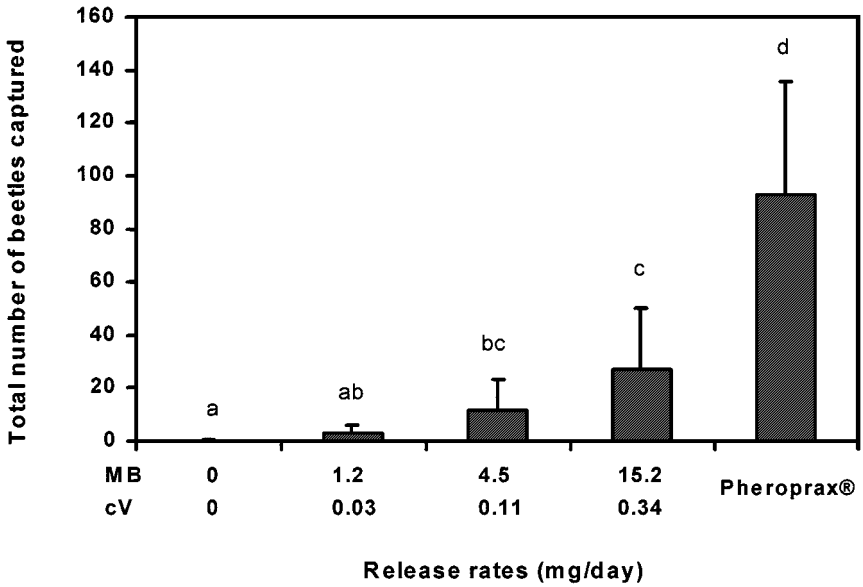

FIG. 1. Mean number of *Ips typographus* caught at different release rates of MB and cV, expressed as MB release rates (±SE). $N = 35$ replications. Pheroprax has a release rate of 35.8 mg/day. Means followed by the same letter are not significantly different, Student Newman-Keuls multiple-range test, $P = 0.01$.

Attraction Range. Results of the release–recapture experiment are shown in Table 2. Recapture of marked beetles increased with the release rate, from an average of 0.2% with the lowest release rate to 4.4% with Pheroprax. Increases in catches tended to stabilize at the two higher release rates. An analysis of variance on arcsine square-root-transformed data ($F_{3,15df} = 24.4$, $P < 0.001$) followed by post hoc tests indicated differences between the release rates, except between 15.2 mg/day of MB and Pheroprax (Student-Neuman-Keuls multiple range test, $P = 0.01$).

Capture patterns of unmarked beetles increased in a similar fashion (Table 2). Differences among average captures rates were significant ($F_{3,15df} = 11.6$, $P < 0.001$) and post hoc tests showed that captures at the two lower release rates differed, while differences were not significant between release rates of 4.5 mg/day and 15.2 mg/day of MB, and between 15.2 mg/day of MB and Pheroprax (Student-Neuman-Keuls test, $P = 0.01$).

Variations in captures in relation to wind parameters are shown in Table 3. Wind speeds and directions were averaged from measures at the start and end of the 60-min flight period. There was no correlation between wind speeds and the occurrence of wind directions ($r = 0.4$, $P = 0.07$). The beetles showed undirected

flight during most replicates, whereas the wind direction was significant on 15 of 19 occasions. At the lower pheromone release rates, *I. typographus* flights were always random, even when the wind direction was significant. Upwind flights were observed for Pheroprax replicates only (Table 3), but significant downwind flights were not observed.

DISCUSSION

The making of our own pheromone dispensers provided us with low-release-rate lures, for which we could control the release rates of each component individually. However, there were two shortcomings. First, release rates over several orders of magnitude proved impractical due to the limitation of the dispenser size and to the available PE thickness. Second, for higher release rates, the release of

the semiochemicals was constant over short time periods only five and seven days for cV and MB, respectively). This might not prove too restrictive for release–recapture studies for which daily trap collections are made, as dispensers can then be renewed regularly.

Results of our dose–response experiment follow those of Schlyter (1987c), who observed a linear increase in catches as a function of increasing release rates of cV and MB. If we consider *I. typographus* catches for the PE bag dispensers, we also obtain such a linear response with increasing release rates. This linear increase in beetle response—as opposed to the logarithmic relationship commonly found in pheromone studies—appears to be due to MB, which has an unusually steep dose–response curve in EAGs and field tests and which is the most critical pheromone component in determining the total number of beetles caught (Dickens, 1981; Schlyter, 1987b,c).

Experiments and observations providing reasonable evidence of the range of attraction of insect species to pheromones are not common. The best and most accurate estimates of the attraction range are found to require either direct observation of insects in flight or carefully timed release–recapture experiments in which insects are recovered very quickly (Wall and Perry, 1987). Such experiments for *I. typographus* were performed by Helland et al. (1984). Data were analyzed in terms of attraction radius by Schlyter (1992). In two separate trials, Helland et al. (1984) released *I. typographus* 12 and 20 m away from a central pheromone trap equipped with Ipslure, a commercial attractant similar to Pheroprax (50 mg/day of MB and 1 mg/day of cV) (Schlyter, 1987a,c). They recaptured 60.1% of the beetles within the first 10 min for the 12-m release distance but only 19.1% of those released 20 m away. From these results, Schlyter (1992) estimated the attraction range of the pheromone trap to be between 12 and 20 m, probably closer to 12 m, because the majority of the responding population was caught from this distance.

Our preliminary observations suggest that this attraction range might have been underestimated. In our second experiment, trap catches were not significantly different between the release rate of 15.2 mg/day and Pheroprax (35.8 mg/day of the blend), a fact that was observed both for marked and unmarked beetles. Moreover, if traps are interacting and result in overlapping pheromone plumes, it would be expected that most beetles would be caught in the upwind traps as a consequence of "overshooting" (Wedding et al., 1995). This was indeed observed for Pheroprax, as three of the five replicates showed significant captures upwind. At lower release rates, flight was mostly random (11 of 13 replicates), with no upwind flight for the two significant flight directions.

These results imply that traps interfered for Pheroprax at the distance studied, i.e., 50 m between the trap-trees and the release point. They also suggest that the attraction range of Pheroprax probably extended to 50 m, at least in direction of the wind. Further experiments are needed to confirm our results, but these are in line with data from Schlyter (1992). Estimations of the attraction range of *I. typographus* from regression analyses of trap interactions showed ranges of 17–67 m for lures releasing 0.24–240 mg/day of MB. Variability was extremely high, however, and confidence intervals overlapped for all estimates due to the few data points available.

This variation in experimental results shows that, in order to achieve even a crude estimate of the range of attraction of pheromones, it will be necessary to carry out many observations or experiments. Even so, our preliminary data suggest that the attraction range of commercial pheromones might be higher than is generally thought. If proved correct, this challenges the validity of earlier release–recapture studies in terms of their interpretation of *I. typographus* dispersal capacities. In most experiments, the first trap ring was close to the release platform: traps equipped either with Pheroprax or Ipslure were placed as close as 5 m

(Duelli et al., 1997), 30 m (Zolubas and Byers, 1995) and 50 m (Botterweg, 1982; Zumr 1992). Under these conditions, migrating beetles necessarily had to cross pheromone plumes and might have been primed to respond to the pheromones, while they would have dispersed further in the absence of such pheromones. Absolute dispersal distances might, therefore, need to be reinterpreted, as well as dispersal models, which assumed an exponential or power decrease in recaptures as a function of distance (e.g., Weslien and Lindelöw, 1990; Zolubas and Byers, 1995; Duelli et al., 1997). Ideally, a compromise should be found between the need to recapture enough marked beetles for statistical analysis and the study of the beetles' flight ability and variability in response to pheromones.

Acknowledgments—The authors thank MM. J. Gillissen and M. Wuidar for allowing them to carry out the experiments in the Wellin forest district. Funding for this work was provided by a F.R.I.A. PhD research grant to Anne Franklin and by the F.N.R.S. to J.-C. Grégoire. A. Franklin also thanks Dr. J. Byers and Dr. F. Schlyter for their technical advice on making pheromone dispensers.

(Received May 26, 2000; accepted August 10, 2001)

Abstract—Bioassays in a Y-tube olfactometer showed that workers of *Solenopsis geminata* (Hymenoptera: Formicidae) were attracted to venom gland extracts of queens. Gas chromatography coupled mass spectrometry analysis of individual glands of queens of *S. geminata* showed that the secretion is composed mainly of a large amount of 2-alkyl-6-methylpiperidine alkaloids and a tiny amount of a δ-lactone and a α-pyrone, which have been earlier identified as components of the queen attractant pheromone of *Solenopsis invicta* Buren. However, additional small amounts of a mixture of sesquiterpenes and pentadecene were found. The possible function of the sesquiterpenoid compounds is discussed.

Key Words—*Solenopsis geminata*, fire ants, venom secretion, sesquiterpenes, queen pheromone recognition.

INTRODUCTION

Solenopsis geminata (F.) (Hymenoptera: Formicidae) is a species that was originally distributed from the southern United States to northern South America, but due to commerce has been introduced into both Asia and Africa (Trager, 1991). In Central America, *S. geminata* is considered a sorghum and maize seed pest (Bhatkap, 1983; del Rio and Casares, 1990). On the other hand, Mackay et al.

*To whom correspondence should be addressed. E-mail: lcruz@tap-ecosur.edu.mx

0098-0331/01/1200-2437/0 © 2001 Plenum Publishing Corporation

(1990) suggested that this ant species could act as an important agent of biological control of pests. For example *S. geminata* is able to decrease the population of *Spodoptera frugiperda* (Smith) larvae, *Agrotis* sp., and *Listronotus* sp. (Lastres, 1990) in corn plantations. Workers of this myrmicine also feed on eggs, nymphs, and adults of the blood sucking bug, *Triatoma gerstaeckeri* (Stål) (Camacho and Garcia, 1981). In spite of its apparent importance, relatively few studies have been carried out on the biology and ecology of these ants. In this contribution we consider one aspect of their biology: the chemical communication between the queen and workers.

Chemical communication between ant queens and their workers has been recognized in several species of ants including *Formica consocians* (Wheeler, 1910), *Lasius alienus* (Foerster), *Pheidole pallidula* (Nylander) (Stumper, 1956), *Neivamyrmex* spp., *Labidus* spp. (Watkins and Cole, 1966), and *Myrmica rubra* Latreille (Brian, 1973), but the most studied species has been *Solenopsis invicta* Buren. Jouvenaz et al. (1974) observed that workers of *S. invicta* and *S. geminata* were attracted to areas of blotting paper to which queens of their species had been confined. Further, Glancey (1980) showed that volatiles released by the queens and extracts of queens were highly attractive to workers. Vander Meer et al. (1980) reported the venom gland of *S. invicta* was the storage site for the attractive pheromone. Later, Rocca et al. (1983a,b) identified the chemical structures of the compounds responsible for activity in *S. invicta* as (*E*)-6-(1-pentenyl)-2*H*-pyran- 2-one and tetrahydro-3,5-dimethyl-6-(1-methylbutyl)-2*H*-pyran-2-one (invictolide). Dihydroactinidiolide was also identified, but no biological activity has been yet described for this compound.

It was previously demonstrated that queens of *S. geminata* behave like those of *S. invicta* in strongly attracting their workers (Jouvenaz et al., 1974; Fierro-Santos, 1995). However, the chemical composition of the pheromone in *S. geminata* remains unknown. This work was undertaken to evaluate the response of *S. geminata* workers to venom gland extract of queens, dealated virgin queens, alate queens captured in nuptial flights, alate virgin queens, and workers and to identify the compounds present in the venom gland secretion of *S. geminata* queens. Additionally, the essential oil of *Melaleuca cajuputi*, which contains two related compounds identified in the venom gland secretions of the queen of *S. geminata*, was tested for attraction to workers.

METHODS AND MATERIALS

Insects. Colonies of *S. geminata* were excavated around Tapachula, Chiapas, Mexico, and transported to El Colegio de la Frontera Sur. The queens, dealated virgin queens, alate virgin queens, and alate queens captured in nuptial flight were placed individually in small plastic bottles (10×6 cm); the

rest of the colony was maintained in plastic bowls (30 × 50 cm), and which were used as nests. The colonies were maintained in the laboratory at 25 ± 3°C and 70 ± 5% reletive humidity, under 8–10 hr of light/day, and fed on dead insects and honey-water.

Gland Dissection. Individual queens, dealated virgin queens, alate virgin queens, alate queens captured in nuptial flights, and workers were cooled in a refrigerator, following which the venom gland together with the sting was dissected under distilled water. The Dufour's gland and sting were removed. Individual venom glands were either solvent extracted in a small tissue grinder with hexane (100 μl) or carefully dropped into thin-walled soda-glass tubes (1.8 mm ID, 20 mm long), previously sealed at one end, and the open end was then sealed in a micro flame (Morgan, 1990).

Chemical Analysis. Gas chromatography–mass spectrometry was performed with a Varian Star 3400 CX gas chromatograph linked to a Varian Saturn 4D mass spectrometer. The samples were analyzed by using a fused silica column (30 m × 0.25 mm ID) coated with poly (5% diphenyl–95% dimethylsiloxane). The over temperature was programmed from 50°C to 250°C at 15°C/min. Helium was used as carrier gas. The injector port temperature was held at 200°C, and the sample was heated in the injector for 4 min before crushing the capillary, as described by Morgan and Wadhams (1972).

Olfactometer Bioassay. Venom gland extracts of queens, dealate virgin queen, alate virgins, alate queens captured in nuptial flight, and workers were tested for worker attraction in a Y-tube olfactometer as described by Vander Meer et al. (1988). The olfactometer consisted of two 24/40 ground glass joints sealed to one of the arms of a 5-cm Y tube so that 1 cm of each Y tube arm extended through half the ground joints. Extracts were placed in one of the choice chambers. All extracts were applied to filter paper strips (3 cm × 1 cm) and evaluated at a concentration of one gland equivalent. The other choice chamber was left blank. Pure hexane was used as blank. Compressed air was split into two streams, each stream being independently controlled by flowmeters. Airflow was regulated at 0.2 liters/min into each choice chamber. Approximately 50–70 ants from laboratory colonies were confined in a 2.5-cm piece of 0.9-cm-ID Tygon tubing sealed at one end with wire gauze. The open end of the tubing was attached to the entrance stem. The initial choice of the first 20 ants that walked down the entrance tube and into one of the arms of the Y tube was recorded. Ants that were not trapped in a choice chamber and came back to the entrance stem were not counted if they made another choice. Test samples were retested with worker ants from the same colony, but the choice chamber in which the sample control were placed was reversed. This procedure eliminated any bias that was inherent in the individual choice chambers. A complete replicate was the sum of the results from the two tests. The worker response to the extract and control was compared by using a *t* test. The level of probability considered significant was $P < 0.05$. The response of

28 individual workers to the queen gland secretion extracts was bioassayed as described above.

RESULTS

Results of the Y-tube olfactometer bioassays are shown in Table 1. Venom gland extract of queens, dealated virgin queens, alate queens captured in nuptial flights, and alate virgin queens elicited a signficant response for *S. geminata* workers. The response of workers to extract of worker gland secretion was not different from the response to control. When the response of individual workers to the queen venom extract was tested, a significant response was observed. Of the 28 workers tested, only four did not respond.

Analysis by GC-MS of individual samples of excised venom glands of *S. geminata* queens revealed that the secretion is composed mainly of 2-methyl-6-alkylpiperidines. The secretion is largely dominated by *cis*-2-methyl-6-undecylpiperidine, which comprises 55% of the secretion (Figure 1). The alkaloid components were identified from the mass spectra provided by Brand et al. (1972). The secretion of the queens also contained a small amount of 11 terpenoid compounds with apparent molecular ions at m/z 204 and m/z 218, suggesting molecular formulas of $C_{15}H_{24}$ and $C_{15}H_{22}O$. Pentadecene was also found in small amounts (Figure 1). The first terpenoid eluting, present in the smallest quantity, had a mass spectrum close to that of elemene (Adams, 1989). The other two, more abundant and in a concentration ratio of 1:2, had mass spectra close to β-selinene and α-selinene, respectively, as given in Adams (1989). We compared the spectra and

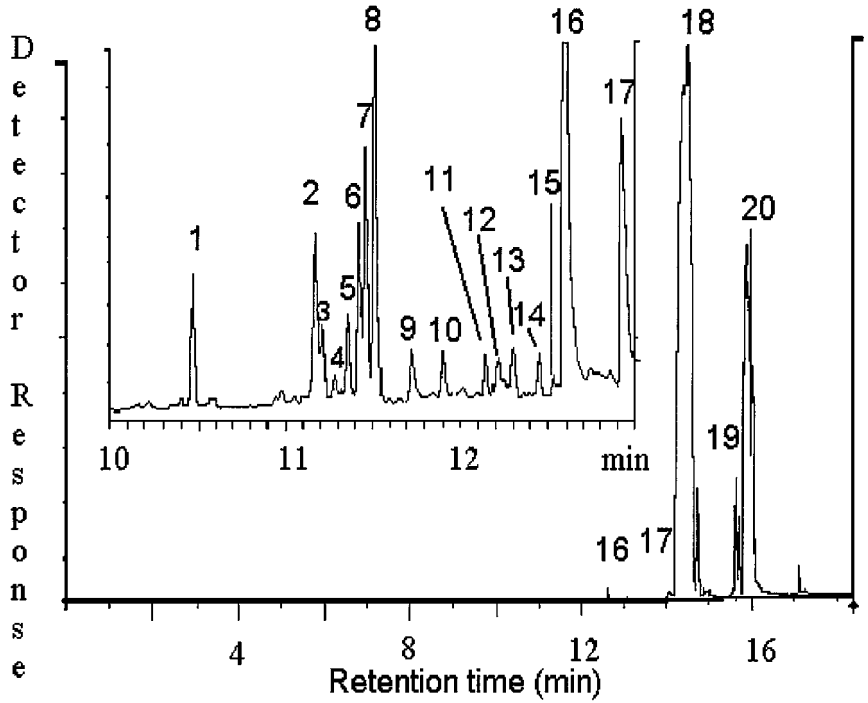

FIG. 1. Gas chromatogram of the venom gland secretion of *Solenopsis geminata* queen. The inset is an expansion for the region of 10–13 minutes. Numbers above the peaks correspond to the following substances: 1, elemene; 2, pentadecene; 3 and 4, unidentified sesquiterpenes; 5, tetrahydro-3,5-dimethyl-6-(1-methylbutyl)-2*H*-pyran-2-one (isomer); 6, tetrahydro-3,5-dimethyl-6-(1-methylbutyl)-2*H*-pyran-2-one (isomer); 7, β-selinene (isomer); 8, α-selinene (isomer); 9, (*E*)-6-(1-pentenyl)-2*H*-pyran-2-one; 10–15, unidentified sesquiterpenes; 16 and 17, 2-methyl-6-alkylpiperidines; 18, *cis*-2-methyl-6-undecylpiperidine; 19 and 20, 2-methyl-6-alkylpiperidines.

retention times of these with authentic α- and β-selinene contained in the essential oil of *M. cajuputi* (provided by J. Brophy). There were small differences in the intensities of some ions between the spectra of the *M. cajupiti* essential oil and the venom compounds, and we concluded there must be small differences in their structures. In testing the workers responses, the essential oil showed no activity (Table 1).

The two remaining compounds (peaks 6 and 9 in Figure 1) had mass spectra identical to two of the three components of the queen recognition pheromone of *S. invicta* (Rocca et al., 1983a,b): (*E*)-6-(1-pentenyl)-2*H*-pyran-2-one and tetrahydro-3,5-dimethyl-6-(1-methylbutyl)-2*H*-pyran-2-one (invictolide). One queen's venom gland contained approximately 1–5 ng of both of these compounds, but the

proportions varied considerably from one individual to another. The identifications were confirmed by injecting pure samples of the two compounds (supplied by R. K. Vander Meer). Dihydroactinidiolide, the inactive compound of *S. invicta*, was not detected in *S. geminata*. The same compounds were found in the venom gland contents of dealated virgin queens, alated queens captured in nuptial flights, and alated virgin queens, but not in workers.

DISCUSSION

Fierro-Santos (1995) demonstrated that workers of *S. geminata* were attracted to venom glands extracts of their queens. By using an Y-tube olfactometer, we confirmed those results. We also found that the venom gland extract of virgin alate queens was attractive to the workers. The suspected effect of trail laying by the first exploring ant was eliminated in assays considering the first ants, since individual workers showed a positive response to the queen venom gland extract.

In *S. invicta*, it was found previously that virgin alate queens did not attract workers (Glancey et al., 1981). The difference between species may be due to the fact that the process of production of the pheromone is faster in *S. geminata* than in *S. invicta*. However, other factors may be involved. For example, the degree of maturity of queens before leaving the nests may vary during the year and so may the onset of pheromone production. In *S. invicta*, it has been found that if queens are reared in the spring or summer, there seems to be a high probability that they will leave the nest for a mating flight before fully mature oocytes are present in their ovarioles, but if they overwinter in the parental nest, their ovaries continue to develop slowly and they begin to oviposit before they leave in early spring (Fletcher and Blum, 1983). The fundamental processes of dealation and oogenesis are usually prevented from occurring while virgin queens are still in the parental nest by the presence of one or more primer pheromones secreted by the mother queen (Willer and Fletcher, 1986). In *S. invicta*, it has been shown that immediately after the nuptial flight, queens are weakly attractive (Glancey et al., 1981).

We found that the venom gland extract of virgin delated queens of *S. geminata* was attractive to the workers. A similar phenomenon had been reported in *S. invicta* (Glancey et al., 1981). These authors found that alate queens of *S. invicta* begin to produce pheromone between six and nine days after removal of the wings, reaching their maximum activity 12 days later. A correlation between attractiveness and histolysis of wing muscles, and the presence of large number of eggs was found in this species (Glancey et al., 1981). The production of pheromone may, therefore, be linked to the biochemical, physiological, or hormonal changes associated with histolysis of wing muscles and production of eggs (Glancey et al., 1981). In other

ant species, it has been shown that virgin queens are not attractive to the workers, independent of the presence or absence of wings. For example, Carr (1962) found that virgin queens of the genus *Myrmica* were unattractive to workers whether they were alates or dealates.

By analyzing individual venom gland of *S. geminata* with the solid sampling technique (Morgan, 1990), we were able to identify (*E*)-6-(1-pentenyl)-2*H*-pyran-2-one and tetrahydro-3,5-dimethyl-6-(1-methylbutyl)-2*H*-pyran-2-one (invictolide), which have been identified as components of the queen recognition pheromone of *S. invicta*. However, we did not find dihydroactinidiolide, which is the third component of the *S. invicta* queen pheromone. Additionally, we report here for first time a mixture of 11 sesquiterpene compounds as components of the venom secretion of the queen *S. geminata*. The two more abundant sesquiterpene components had similar mass spectra of α- and β-selinene, respectively, but when they were compared with the mass spectra of the authentic selinenes from the oil of *M. cajuputi*, they showed small differences in the intensities some ions. Thus, we considered them as isomers of α- and β-selinene. In order to know whether these tentatively identified selinene isomers had any biological activity, the essential oil was tested with workers in the same way the extracts of venom glands were tested, but the ants did not exhibit any behavioral response. Sesquiterpenes have been identified from other *Solenopsis* species and their pheromonal activities documented (Vander Meer et al., 1988). The same mixture of compounds was found in the venom gland contents of dealated virgin queen and alated queen captured in nuptial flight and alated virgin queens. These results might explain why workers were attracted to the venom gland extract of virgin alated queens.

On the other hand, Jouvenaz et al. (1974) reported that *S. invicta* and *S. geminata* workers aggregated within squares on absorbent paper on which their queens had been confined. Bioassays showed that *S. invicta* workers were more attracted to squares that had held conspecific queens, but species specificity was also noted as *S. invicta* workers were attracted to areas previously occupied either by their own or *S. geminata* queens, but *S. geminata* workers were attracted only to areas occupied by queens of their own species. In field tests, Glancey et al. (1984) observed that *S. geminata*, *S. xyloni*, and *S. richteri* did not respond either to live queen extracts or synthetic compounds of *S. invicta*. Our results, and the observations obtained by Jouvenaz et al. (1974) and Glancey et al. (1984), suggest several possible explanations. The compounds responsible for attraction of *S. geminata* worker ants to their queens may be the same as those of *S. invicta*, but they are present in different proportions. The venom of *S. invicta* may contain a repellent compound (e.g., dihydroactinidiolide) for *S. geminata* workers and *S. invicta* may not detect the absence of that compound in *S. geminata*.

We know now the reason that workers of *S. invicta* are attracted to the queens of *S. geminata* is because the queen of *S. geminata* contains two components

of their queen pheromone. We suggest that a mixture of the two components of the queen pheromone of *S. invicta* plus a mixture of sesquiterpenes may act as queen pheromone of *S. geminata*. We also conclude that this mixture of volatiles is produced exclusively in the queen's venom gland, since no evidence was found of these compounds in the venom gland of workers. Further experiments are needed to explain to function of the sesquiterpene compounds.

Acknowledgments—We thank J. J. Brophy of the University of New South Wales for the gift of *M. cajuputi* oil; R. K. Vander Meer of U.S. Department of Agriculture, Gainesville, Florida, for the gift of (*E*)-6-(1-pentenyl)-2*H*-pyran-2-one, tetrahydro-3,5-dimethyl-6-(1-methyl)-2*H*-pyran-2-one, and dihydroactinidiolide; and Armando Virgen, Antonio Santiesteban, and Alvaro García Ballinas for technical assistance. L.C.L. thanks CONACYT for the award of a research studentship during which this work was begun.

(Received August 3, 1999; accepted August 6, 2001)

Abstract—The female sex pheromone of the rice leaf bug, *Trigonotylus caelestialium*, was analyzed by GC-EAD and GC-MS. Ten EAD active compounds—*n*-hexyl *n*-hexanoate, (*E*)-2-hexenyl *n*-hexanoate, *n*-hexyl (*E*)-2-hexenoate, *n*-octyl *n*-butyrate, *n*-octyl *n*-hexanoate, (*E*)-2-octenyl *n*-hexanoate, *n*-pentyl *n*-hexanoate, *n*-hexyl *n*-butyrate, (*E*)-2-hexenyl *n*-butyrate, and *n*-hexyl (*E*)-2-butenoate—were detected in the ratio of 1000:414–491:trace–5:5–11:55–71:50–63:trace–3:225:90:32 from female body extracts, and in the ratio of 1000:271–342:10–43:1–3:58–78:14–19:trace:178:36:26 from male body extracts. Field trapping tests with these synthetic compounds indicated that *n*-hexyl *n*-hexanoate, (*E*)-2-hexenyl *n*-hexanoate, and *n*-octyl *n*-butyrate are pheromone components, and mixtures in ratios of 1000:400–500:10–100 were more attractive to males. Doses ranging from 4.29 μg to 14.3 μg of the three-component mixture in the ratio of 1000:400:30 loaded into glass capillary tubes were most attractive to males.

Key Words—Female sex pheromone, Miridae, rice leaf bug, *Trigonotylus caelestialium*, *n*-hexyl *n*-hexanoate, (*E*)-2-hexenyl *n*-hexanoate, *n*-octyl *n*-butyrate.

INTRODUCTION

Males of the true bug (Heteroptera) families Pentatomidae, Alydidae, Rhopalidae, Reduviidae, and Coreidae often secrete aggregation pheromones or sex pheromones (Aldrich, 1988). Some of these pheromones have been chemically identified (aggregation pheromone: Kochansky et al., 1989; Aldrich et al., 1991,

*To whom correspondence should be addressed. Present address: Hokkaido Ornamental Plants and Vegetables Research Center, Higashi-Takikawa 735, Takikawa, Hokkaido 073-0026, Japan.

0098-0331/01/1200-2447/0

1997; Leal et al., 1995, 1996, 1998; Sugie et al., 1996; sex pheromone: Brézot et al., 1994). On the other hand, in 12 species of Miridae, females attract males of the same species (Scales, 1968; Boivin and Stewart, 1982; Thistlewood et al., 1989; McBrien and Millar, 1999), and female sex attractant pheromones have been identified for *Campylomma verbasci* (Smith et al., 1991), *Phytocoris relativus* (Millar et al., 1997), and *P. californicus* (Millar and Rice, 1998).

The rice leaf bug, *Trigonotylus caelestialium* (Kirkaldy) (Miridae), is a major pest causing pecky rice, and also injuring wheat, maize, and gramineous forage grasses in the northern part of Japan. Males are attracted and sexually stimulated by virgin females, indicating that females posses a sex pheromone (Kakizaki and Sugie, 1997). Identification of the female sex pheromone of *T. caelestialium* is reported in this paper.

METHODS AND MATERIALS

Insects and Pheromone Extraction. Adult bugs of the second generation of *T. caelestialium* were collected in an insect collecting tube (3 cm diam., 8 cm long) near a light from 20:00 hr to 24:00 hr at Hokkaido Central Agricultural Experiment Station (HCAES), Naganuma, in mid-August 1992, 1993, and 1994. Females and males were placed in separate tubes. Whole bodies of about 100–200 bugs were dipped into 30 ml of hexane and extracted for one to two days at room temperature.

Column Chromatography. After evaporation of the solvent, extracts were placed on a column packed with the Florisil containing 7% H_2O (Carroll, 1961), and successively eluted with hexane, 5%, 15%, 25%, and 50% ether in hexane.

Bioassay by Coupled Gas Chromatography–Electroantennographic Detector (GC-EAD). The responses of antennae of *T. caelestialium* males to each fraction from the Florisil column chromatography were recorded with a GC-EAD system (Struble and Arn, 1984), and the compounds in the extracts were monitored by a gas chromatograph (Hewlett-Packard HP5890) equipped with an HP-INNOWAX capillary column (Hewlett-Packard: 30 m $\times$ 0.53 mm ID $\times$ 0.25-μm film thickness) and coupled to a thermal conductivity detector (TCD). The oven temperature was programmed at 5°C/min from 60°C (1.5 min) to 220°C (30 min).

Chemical Analysis. Each EAD active compound in the fraction from Florisil column chromatography of female and male body extracts was collected from a vent of the TCD by a glass capillary tube. EAD activities were confirmed by GC-EAD, and the compounds were analyzed by gas chromatography–mass spectrometry (GC-MS). GC-MS analysis (EI mode) was performed on a Hewlett-Packard HP5971A with an HP-INNOWAX capillary column (60 m $\times$ 0.33 mm ID $\times$ 0.25-μm film thickness). The oven temperature was programmed as above. The interface temperature was 250°C. Structures of ester compounds were estimated by the characteristic fragment ions, corresponding to the C_m carboxylic moiety

(e.g., $C_{m-1}H_{2m-1}COOH_2^+$ and $C_{m-1}H_{2m-1}CO^+$), and the C_n alcohol moiety (e.g., $C_nH_{2n}^+$), and the molecular ion (M^+). Double-bond positions in unsaturated compounds were determined by adduction of dimethyl disulfide (DMDS) (Buser et al., 1983). Geometric isomerism was determined by comparing GC retention times for synthetic compounds with the polar column noted above.

Chemical Synthesis. Esters were synthesized by using dicyclohexylcarbodiimide (DCC) and aminopyridine catalyst (Hassner and Alexanian, 1978) and the same equivalent of the corresponding carboxylic acids and the alcohols. The compounds were purified by silica gel (Wakogel C-200) column chromatography with a solvent system of hexane–ethyl acetate (10–20:1). Geometric isomers were separated by silica gel–silver nitrate (16.7%) column chromatography. The purity of each compound was greater than 99.8%, and the isomeric purity greater than 99.9% by GC.

Baits. Solutions containing test samples in 1 μl hexane were loaded in the center of glass capillary tubes (Duran ringcaps 5 μl, 0.021 mm ID, 125 mm long, bent into a V shape at the center by heating with a gas burner) (Kozai and Wakamura, 1982). The hexane was evaporated at room temperature overnight, and they were used as lure in all experiments. Two virgin females in a steel net cage (soup basket; 6 cm diam. $\times$ 6.5 cm high and 1.0 mm mesh) also were used in the test for comparison to the synthetic sex pheromone.

Field Experiments. Field experiments were carried out during the second (August–September) and third (October) adult generations of *T. caelestialium* in fields of Italian rye grass at HCAES (22,500 m^2, in 1995–1997), and at Hokkaido Ornamental Plants and Vegetables Research Center (6000 m^2, Takikawa, in 1998). Water-pan traps (white, 35 cm diam. $\times$ 6 cm deep) were used. The baits were hung 20 cm above the pans with wire. Blank traps without baits were used as controls. Three to six replicates were conducted for each experiment. The traps were placed in a line 20–25 m apart on the ground in fields. The number of bugs captured by each trap was counted at intervals of one to three days, and the location of traps was rotated at the same time.

In test I, attraction activity of each of the 10 EAD active compounds, a six-component mixture of *n*-hexyl *n*-hexanoate (5 μg), (*E*)-2-hexenyl *n*-hexanoate (2.5 μg), *n*-hexyl (*E*)-2-hexenoate (5 ng), *n*-octyl *n*-butyrate (150 ng), *n*-octyl *n*-hexanoate (275 ng), (*E*)-2-octenyl *n*-hexanoate (275 ng), and a 10-component mixture of *n*-pentyl *n*-hexanoate (5 ng), *n*-hexyl *n*-butyrate (1.15 μg), (*E*)-2-hexenyl *n*-butyrate (450 ng), and *n*-hexyl (*E*)-2-butenoate (150 ng) mixed with the above mentioned six-component mixture were tested. In test II, one of the compounds of the six-component mixture was deleted to evaluate the necessity of the compound. In test III, one of the compounds of a mixture of *n*-hexyl *n*-hexanoate, (*E*)-2-hexenyl *n*-hexanoate, *n*-hexyl (*E*)-2-hexenoate, *n*-octyl *n*-butyrate, and *n*-octyl *n*-hexanoate, which were selected by test II, was deleted and the necessity of the compounds was evaluated. In test IV, attraction activity

of a three-component mixture of *n*-hexyl *n*-hexanoate (3 μg), (*E*)-2-hexenyl *n*-hexanoate (1.5 μg), and *n*-octyl *n*-butyrate (90 ng), which were selected by test III, was evaluated. Effect of the addition of either *n*-pentyl *n*-hexanoate, *n*-hexyl *n*-butyrate, (*E*)-2-hexenyl *n*-butyrate, *n*-hexyl (*E*)-2-butenoate, or all of these compounds to the three-component mixture was evaluated in tests V and VI. In test VII, effect of the addition of *n*-octyl *n*-butyrate in variable doses of 0.015–1.5 μg in a mixture of *n*-hexyl *n*-hexanoate (5 μg) and (*E*)-2-hexenyl n-hexanoate (2.5 μg) was evaluated. Effect of the addition (*E*)-2-hexenyl *n*-hexanoate in variable doses of 0.5–5 μg on a mixture of *n*-hexyl *n*-hexanoate (5 μg) and *n*-octyl *n*-butyrate (0.15 μg) were evaluated in test VIII. In test IX, optimum doses of the three-component mixture in a ratio of 1000:400:30 ranging from 1.43 μg to 143 μg were evaluated with glass capillary tubes. In test X, attraction activity of the sex pheromone, *n*-hexyl n-hexanoate (5 μg), (*E*)-2-hexenyl *n*-hexanoate (2.5 μg), and *n*-octyl *n*-butyrate (150 ng) loaded into the glass capillary tube was compared with that of traps baited with two virgin females.

Trap data (X) were transformed to square root ($X + 0.5$) before analysis of variance, and were compared by Tukey's test.

RESULTS

EAD Active Peaks in Extracts. All EAD active peaks by male antennae were contained in the 5% ether in hexane fraction from the Florisil column chromatography (Table 1). In the extracts of one female equivalent (1 FE), there were two stronger EAD peaks (about 1.05–0.95 mV), three intermediate EAD peaks (about 0.3–0.15 mV), and five weaker EAD peaks (about 0.05–0.025 mV). EAD peaks with identical retention times to those of above peaks were also detected in male body extracts.

Identification of EAD Active Compounds. EAD active compounds were identified as in Table 1: Two stronger EAD active compounds are *n*-hexyl *n*-hexanoate {H:H, abbreviation in all tables; the retention time (R_t) = 30.67 min; m/z 117 [relative intensity: 100% (base peak)], 99 (52%), 84 (40%), 200 (M^+, 0.3%)}, and (*E*)-2-hexenyl *n*-hexanoate [*E*2H:H; $R_t = 32.38$ min; m/z 117 (3%), 99 (100%), 82 (20%), 198 (M^+, 2.5%); DMDS adduct: m/z 292 (M^+), 103 ($C_3H_7CH{=}S^+CH_3$), 189 ($CH_3S^+{=}CHCH_2OCOC_5H_{11}$); synthetic *E* isomer, $R_t = 32.38$ min, *Z*-isomer, $R_t = 32.17$ min]. Three intermediate EAD active compounds are *n*-hexyl (*E*)-2-hexenoate [H:*E*2H; $R_t = 34.46$ min; m/z 115 (100%), 97 (36%), 84 (5%), 198 (M^+, 0.1%); DMDS adduct: m/z 292 (M^+), 189 ($C_6H_{13}OCOCH{=}S^+CH_3$), 103 ($CH_3S^+{=}CHC_3H_7$); synthetic *E* isomer, $R_t = 34.46$ min], *n*-octyl *n*-hexanoate [O:H; $R_t = 36.45$ min; m/z 117 (100%), 99 (40%), 112 (38%), 228 (M^+, 0.2%)], and (*E*)-2-octenyl *n*-hexanoate [*E*2O:H; $R_t = 32.38$ min; m/z 117 (3%), 99 (100%), 110 (10%), 226 (M^+, 2.3%); DMDS adduct: m/z 320 (M^+), 131

[a] Abbreviations: H:H, *n*-hexyl *n*-hexanoate; *E*2H:H, (*E*)-2-hexenyl *n*-hexanoate; H:*E*2H, *n*-hexyl (*E*)-2-hexenoate; O:B, *n*-octyl *n*-butyrate; O:H, *n*-octyl *n*-hexanoate; *E*2O:H, (*E*)-2-octenyl *n*-hexanoate; P:H, *n*-pentyl *n*-hexanoate; H:B, *n*-hexyl *n*-butyrate; *E*2H:B, (*E*)-2-hexenyl *n*-butyrate; H:*E*2B, *n*-hexyl (*E*)-2-butenoate.

[b] GC: one female equivalent of 5% ether in hexane fraction from the Florisil column chromatography was injected and separated on an HP-INNOWAX column, programmed at 5°C/min from 60°C (1.5 min) to 220°C (30 min).

[c] Investigations were performed for first six compounds in 1992 and 1993, and for all ten compounds in 1994.

($C_5H_{11}CH{=}S^+CH_3$), 189 ($CH_3S^+{=}CHCH_2OCOC_5H_{11}$); synthetic *E* isomer, R_t = 38.10 min, *Z* isomer, R_t = 37.11 min]. Five weaker EAD active compounds are *n*-octyl *n*-butyrate [O:B; R_t = 30.82 min; *m*/*z* 89 (100%), 71 (98%), 112 (24%), 201 (M+1, 0.5%)], *n*-pentyl: *n*-hexanoate [P:H; R_t = 27.65 min; *m*/*z* 117 (100%), 99 (62%), 70 (59%), 186 (M^+, 0.3%)], *n*-hexyl *n*-butyrate [H:B; R_t = 24.91 min; *m*/*z* 89 (100%), 71 (85%), 84 (45%), 172 (M^+, 0.1%)], (*E*)-2-hexenyl *n*-butyrate [*E*2H:B; R_t = 26.70 min; *m*/*z* 89 (4%), 71 (100%), 82 (15%), 170 (M^+, 1.0%); DMDS adduct: *m*/*z* 264 (M^+), 103 ($C_3H_7CH{=}S^+CH_3$), 161 ($CH_3S^+{=}CHCH_2OCOC_3H_7$); synthetic *E* isomer, R_t = 26.70 min, *Z* isomer, R_t = 26.50 min], and *n*-hexyl (*E*)-2-butenoate [H:*E*2B; R_t = 28.98 min; *m*/*z* 87 (83%), 69 (100%), 84 (4%), 171 (M+1, 1.0%); DMDS adduct: *m*/*z* 264 (M^+), 189 ($C_6H_{13}OCOCH{=}S^+CH_3$), 75 ($CH_3S^+{=}CHCH_3$); synthetic *E* isomer, R_t = 28.98 min].

These EAD active compounds were identified from whole body extracts of both sexes, and female-specific compounds showing EAD activity could not be detected.

Ratio of Compounds in Extracts. The ratios of the 10 compounds in female and male body extracts were quantified as Table 1. The relative ratios of

(*E*)-2-hexenyl *n*-hexanoate, (*E*)-2-octenyl *n*-hexanoate, and *n*-octyl *n*-butyrate to *n*-hexyl *n*-hexanoate tended to be high in female extracts, and that of *n*-hexyl (*E*)-2-hexenoate to *n*-hexyl *n*-hexanoate in male extracts.

Mean amounts of *n*-hexyl *n*-hexanoate in whole-body extracts were 127 ng per female ($N = 10$) and 27 ng per male ($N = 10$) at seven days after emergence.

Attraction Activity of EAD Active Compounds in the Field. None of the ten EAD active compounds alone attracted males, but the six- and 10-component mixtures were both equally attractive to males (test I in Table 2). When *n*-hexyl *n*-hexanoate or (*E*)-2-hexenyl *n*-hexanoate were deleted from the six- or five-component mixture (tests II and III in Table 3), the numbers of males captured were as low as those in blank traps. By adding *n*-octyl *n*-butyrate to the mixture of *n*-hexyl *n*-hexanoate and (*E*)-2-hexenyl *n*-hexanoate (test IV), the number of captured males increased. However, the deletion of (*E*)-2-octenyl *n*-hexanoate, *n*-octyl *n*-hexanoate, or *n*-hexyl (*E*)-2-hexenoate from the six- and five-component

mixtures (tests II and III), and the addition of each compound of *n*-pentyl *n*-hexanoate, *n*-hexyl *n*-butyrate, (*E*)-2-hexenyl *n*-butyrate, and *n*-hexyl (*E*)-2-butenoate (test V in Table 4), and of a mixture of these four compounds (test VI) to the three-component mixture, did not affect male attraction. No females or nymphs of *T. caelestialium* were attracted to these mixtures in any of the experiments.

Optimum Ratio and Doses of the Three Compounds for Male Attraction. The addition of 0.05–0.5 μg *n*-octyl *n*-butyrate in a two-component mixture of 5 μg *n*-hexyl *n*-hexanoate and 2.5 μg (*E*)-2-hexenyl *n*-hexanoate (in ratios of 10–100:1000:500) (test VII in Table 5), and the addition of 2–2.5 μg (*E*)-2-hexenyl *n*-hexanoate in a two-component mixture of 5 μg *n*-hexyl *n*-hexanoate and 0.15 μg *n*-octyl *n*-butyrate (in ratios of 400–500:1000:30) (test VIII), led to more males being captured than in other ratios.

[a] Mixtures were loaded in glass capillary tubes. Abbreviations are same as in Table 1.
[b] Values are means from five traps (test V) and three traps (test VI) during the period of the investigation. The means followed by the same letter in the same column in each test are not different at the 5% level by Tukey's test.

Doses greater than 42.9 μg of the three-component mixture captured smaller numbers of males than doses within the range 1.43–14.3 μg (test IX in Table 6), indicating that attraction was inhibited by excessive amounts. At all doses used, glass capillary tubes containing doses of 4.29 μg and 14.3 μg caught the largest numbers of males.

Comparison of Numbers of Bugs Captured by Synthetic Sex Pheromone and Two Virgin Females. The numbers of male bugs captured by traps baited with 7.65 μg of the three-component mixture were greater than those by traps baited with two virgin females (test X in Table 7).

DISCUSSION

The 10 compounds identified stimulated a response from male antennae. However, *n*-hexyl (*E*)-2-hexenoate, *n*-octyl *n*-hexanoate, (*E*)-2-octenyl *n*-hexanoate, *n*-pentyl *n*-hexanoate, *n*-hexyl *n*-butyrate, (*E*)-2-hexenyl *n*-butyrate, and *n*-hexyl (*E*)-2-butenoate did not affect the attraction activity, and these compounds were shown not to be necessary for attraction. In conclusion, only three compounds are responsible for male attraction: *n*-hexyl *n*-hexanoate and (*E*)-2-hexenyl *n*-hexanoate were the essential components, and *n*-octyl *n*-butyrate enhanced the male attraction in combination with the two essential components. Neither females

nor nymphs were attracted to the three-component mixture. Therefore, the three-component mixture appears to be the sex pheromone of female *T. caelestialium*. Although a clear optimum ratio of *n*-hexyl *n*-hexanoate and (*E*)-2-hexenyl *n*-hexanoate was not shown, the mixtures of *n*-hexyl *n*-hexanoate (*E*)-2-hexenyl *n*-hexanoate, *n*-octyl *n*-butyrate in ratios of 1000:400–500:10–100 were attractive to males.

In Miridae, the mixture of *n*-butyl *n*-butyrate and (*E*)-2-butenyl *n*-butyrate in *Campylomma verbasci* (Smith et al., 1991), the mixture of *n*-hexyl acetate and (*E*)-2-octenyl *n*-butyrate in *Phytocoris relativus* (Millar et al., 1997), and the mixture of *n*-hexyl acetate and (*E*)-2-octenyl acetate in *P. californicus* (Millar and Rice, 1998) were reported as attractant pheromones. The pheromones in these species

contain at least one female-specific compound. On the other hand, in the case of *T. caelestialium*, the components of the attractant pheromone were common in body extracts of both sexes. However, traps baited with *T. caelestialium* males do not attract conspecific males (Kakizaki and Sugie, 1997), and there may be other factors disturbing the attraction by the males.

In a number of true bugs, many esters have been detected from extracts or secretions (Aldrich, 1988). *n*-Hexyl *n*-hexanoate and/or (*E*)-2-hexenyl *n*-hexanoate

[c] Two virgin females were kept in a steel net cage with the germinal forage grasses.

were reported in secretions of *Blepharidopterus angulatus* (Miridae) (Knight et al., 1984) and *Homoeocerus unipunctatus* (Coreidae) (Kitamura et al., 1984), and (*E*)-2-hexenyl *n*-hexanoate was reported to be an alarm pheromone in *Riptortus clavatus* (Alydidae) (Leal and Kadosawa, 1992). However, *n*-octyl *n*-butyrate has not been reported from other true bugs. The existence of *n*-hexyl *n*-butyrate or (*E*)-2-hexenyl *n*-butyrate was reported in other mirids (Gueldner and Parrott, 1978; Knight et al., 1984; Smith et al., 1991; Millar et al., 1997).

This pheromone would be useful for monitoring *T. caelestialium* adult populations. The attraction period of the lures with the glass capillary tubes was less than two weeks, and a more long-lived pheromone dispenser should be developed for monitoring.

Acknowledgments—We thank Dr. Yukihiro Fukushi of Laboratory of Ecological Chemistry, Faculty of Agriculture, Hokkaido University, for instruction in the syntheses of the chemicals, and Dr. Kenjiro Kawasaki of the National Institute of Sericultural and Entomological Sciences for advice on GC-EAD. Dr. Tetsuo Gotoh of Laboratory of Applied Entomology and Zoology, Faculty of Agriculture, Ibaraki University, Dr. Hiroshi Noguchi of National Institute of Agro-Environmental Sciences; and Dr. Yoichi Kajino of Hokkaido Central Agricultural Experiment Station are thanked for their comments and advice. The manuscript was critically read by Dr. Sadahiro Tatsuki, Laboratory of Applied Entomology, Graduate School of Agricultural and Life Sciences, the University of Tokyo.

(Received January 1, 2001; accepted July 15, 2001)

Abstract—Secretions from the dorsal gland of male and female free-ranging adult white-lipped peccaries (*Tayassu pecari*) from Bolivia were analyzed by gas chromatography–mass spectrometry. Fifty compounds were identified, some provisionally. Secretions of both sexes contain saturated and unsaturated C_5–C_{18} carboxylic acids as well as isomers of the diterpene springene. The females' secretions uniquely possess farnesyl esters of C_8 and C_{10} carboxylic acids, whereas the males' secretions uniquely showed two compounds provisionally identified as monounsaturated C_{16} lactones. Saturated high-molecular-weight esters of C_{10} carboxylic acids are more abundant in the females' secretions than in those of the males. The secretions of both sexes also contain monoalkanoate esters of methylhydroquinone as major components.

Key Words—Dorsal gland, white-lipped peccary, *Tayassu pecari*, gas chromatography, mass spectrometry, springene, farnesyl esters, phenols.

INTRODUCTION

Peccaries (Tayassuidae) are New World artiodactyl mammals represented by three extant species: the collared (*Tayassu tajacu*), the white-lipped (*T. pecari*), and the

*To whom correspondence should be addressed. E-mail: J.S.Waterhouse@apu.ac.uk

0098-0331/01/1200-2459/0

Chacoan peccary (*Catagonus wagneri*) (Sowls, 1984). All three species possess a prominent skin gland, known as the dorsal gland, located in the middle of the rump. This organ produces strongly odorous secretions that are thought to repel predators (Epling, 1956) or to have pheromonal activity (e.g., Sowls, 1984). An analysis of the dorsal gland secretions of free-ranging *T. tajacu* from Texas revealed squalene, geranylgeraniol, and several isomers of springene—a diterpene homolog of farnesene (Waterhouse et al., 1996). High-molecular-weight, straight- and branched-chain aliphatic esters were prominent in females but were not observed in males.

We report here the results of an analysis of the volatile components of dorsal gland secretions of free-ranging *T. pecari* from Bolivia. This species, which normally travels in herds of from 50 to hundreds of individuals (Kiltie and Terborgh, 1983, and references therein), inhabits rain forests from southern Mexico to northeastern Argentina. *T. pecari* rubs its dorsal gland primarily against conspecifics during alloanointing. In this situation, peccaries stand side-by-side, facing in opposite directions, and rub their glands against each other (Sowls, 1984) (Figure 1). In the field, alloanointing has been observed among as many as four individuals simultaneously (Hernandez et al., 1995). Sowls (1984) asserts that *T. pecari* emits the strongest scented dorsal gland secretions of the three peccary species, a feature that may render it less preferred for human consumption.

METHODS AND MATERIALS

Sample Collection

Dorsal gland secretions were collected during February 1997 from adult *T. pecari* in free-ranging herds in the Noel Kempff Mercado National Park, Santa Cruz, Bolivia, at the base of the northern tip of the Huanchaca escarpment. Peccary herds were captured in a large pen constructed around a frequently used salt lick in the forest. Once in the pen, animals received 120–150 mg of equal parts of tiletamine hydrochloride and zolazepam (Telazol) in plastic darts delivered by a CO_2-powered pistol. Individuals not sufficiently immobilized for safe handling received 100 mg doses of ketamine hydrochloride injected intramuscularly. Secretions from eight males and 12 females were collected by placing the mouth of a glass vial over the duct opening of the gland and then manually applying pressure to the body of the gland. Secretions were pooled according to sex and several milliliters of hexane were added to each vial before it was sealed with a polyethylene-lined cap. Vials were shipped on solid CO_2 and stored at -70°C.

FIG. 1. A pair of *Tayassu pecari* alloanointing (photograph by O. Amaral Ferraz).

Analytical Methods

Secretion samples were diluted with further volumes of hexane. Samples (1 μl) of the resulting solutions were analyzed by gas chromatography–mass spectrometry (GC–MS) as described previously (Waterhouse et al., 1996). Identities of compounds were indicated by their mass spectra. For most compounds, identities were confirmed by comparisons of retention times with those of authentic compounds, which were obtained commercially (Sigma-Aldrich, Gillingham, UK) or synthesized. Synthesized farnesyl esters were analyzed using a second set of conditions: a Hewlett-Packard 5890 gas chromatograph fitted with a HP 1 column (50 m $\times$ 0.32 mm ID, 0.25-μm film thickness) coupled to a VG Autospec mass spectrometric detector using the following temperature program: 30–250°C, beginning at 30°C for 5 min, raised at 5°C/min, and finally held at 240°C.

Synthetic Methods

Farnesyl Esters. A mixture of (*Z*,*Z*)-, (*E*,*Z*)-, (*Z*,*E*)-, and (*E*,*E*)-farnesyl decanoates was prepared by standard methods (Khorana, 1953; Brown, 1963) using molecular equivalent amounts of farnesol and decanoic acid with a threefold molecular equivalent of dicyclohexylcarbodiimide and a catalytic amount of dimethylaminopyridine in dichloromethane at room temperature.

Methylhydroquinone Esters. Reaction in tetrahydrofuran of a 1:1 molar ratio of methylhydroquinone (Sigma-Aldrich) and either 2-methylpropanoyl chloride or 2-methylbutanoyl chloride (Sigma-Aldrich) in the presence of a molar excess of the strongly basic ion exchange resin SRA 65 (Sigma-Aldrich) in its OH form yielded products containing mono esters of methylhydroquinone. The esters were not isolated, but their identities were confirmed by their mass spectra, which display the following m/z (%) values: 2-methyl-4-hydroxyphenyl 2-methylbutanoate: 208(M^+, 4), 125(10), 124(100), 95(3), 85(3), 77(5), 57(18), 55(4), 41(13), 39(8); 3-methyl-4-hydroxyphenyl 2-methylbutanoate: 208(M^+, 5), 125(7), 124(100), 94(5), 85(3), 77(6), 67(6), 57(27), 55(5), 41(15), 39(7); 2-methyl-4-hydroxyphenyl 2-methylpropanoate and 3-methyl-4-hydroxyphenyl 2-methylpropanoate (indistinguishable mass spectra): 194(M^+, 5), 125(8), 124(100), 123(19), 95(8), 77(6), 67(6), 55(7), 43(39), 41(15), 39(14).

RESULTS AND DISCUSSION

Chromatograms obtained from male and female pooled samples are shown in Figure 2, in which peak numbers correspond to compound numbers identified in Table 1. Our analysis of *T. pecari* reveals some components in common with *T. tajacu*, its sole extant congener. We identified the following three isomers of springene in male *T. pecari*: (3*Z*,6*E*,10*E*)-α-springene, (3*E*,6*E*,10*E*)-α-springene,

and (6*E*,10*E*)-β-springene. The identities of these compounds were confirmed by comparison of their mass spectra and retention times with those of synthesized compounds (Waterhouse et al., 1996). Unlike *T. tajacu*, however, where both sexes contain all three springenes, we observe only (3*E*,6*E*,10*E*)-α-springene in female *T. pecari*. These isomers of springene were first reported from the dorsal gland of another artiodactyl, the springbok (*Antidorcas marsupialis*)

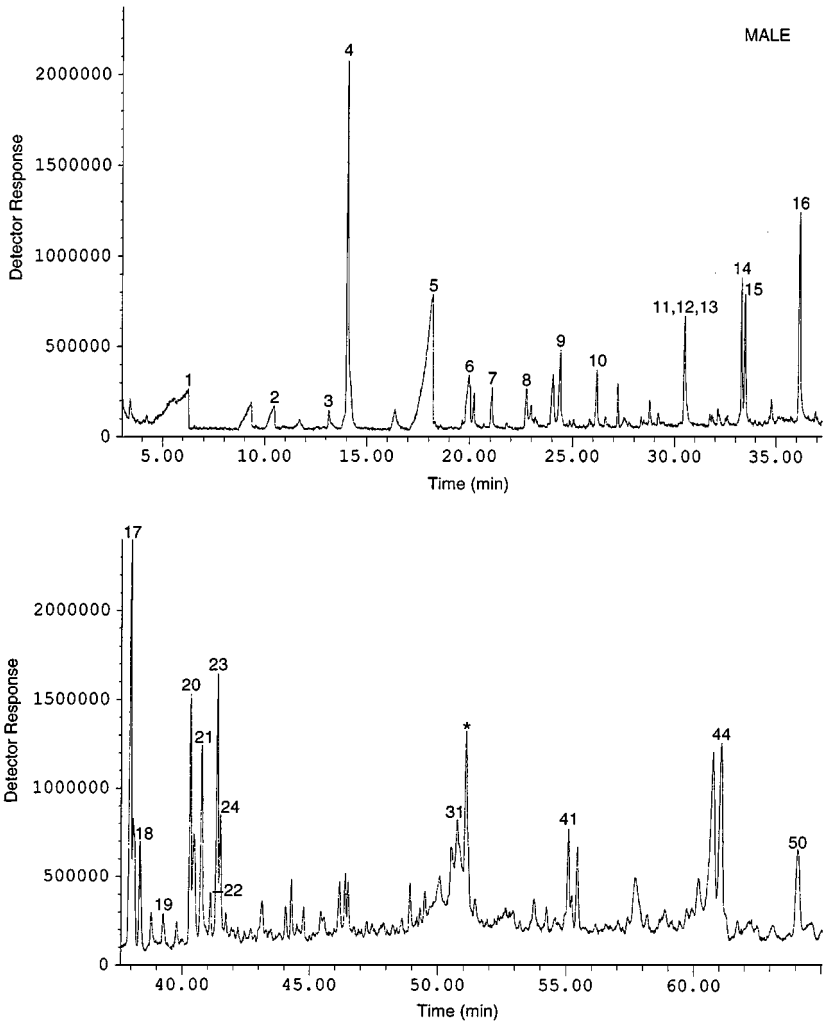

FIG. 2. Gas chromatograms of hexane extracts of dorsal gland secretions of eight male and 12 female *Tayassu pecari*.

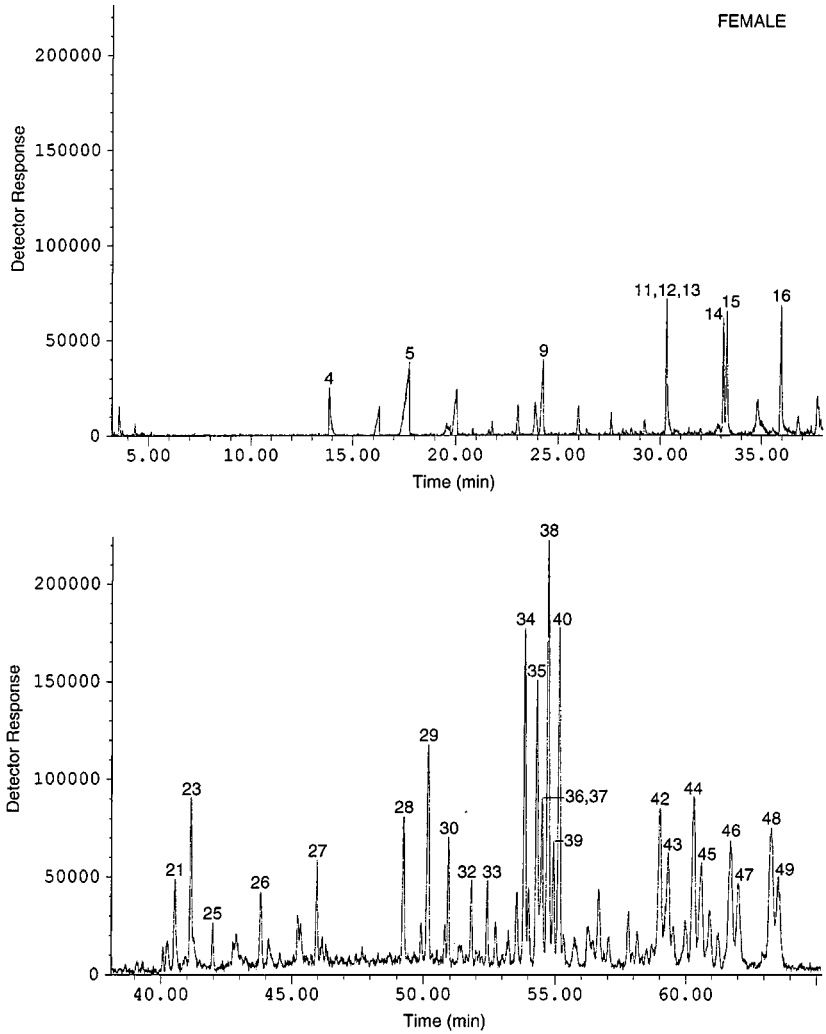

FIG. 2. Continued.

(Burger et al., 1978, 1981). Squalene (all *E* isomer) was detected in male *T. pecari*; this and another unidentified isomer of squalene were reported in both sexes of *T. tajacu* (Waterhouse et al., 1996).

We observed a variety of esters in *T. pecari*, which were largely confined to females. A total of 13 farnesyl esters were indicated in the females' secretions. The (*Z*,*Z*)-, (*E*,*Z*)-, (*Z*,*E*)-, and (*E*,*E*)-farnesyl decanoates in the secretions (**34**, **36**, **37**, and **40**, respectively) were resolved and identified by comparison of retention times

and mass spectra with those of the synthesized materials using CG-MS (second conditions). However, in both the synthesized mixture and in the secretion, the (*E*,*Z*)- and (*Z*,*E*)- isomers coeluted on GC analysis (Figure 2). Their mass spectra all show an acyl fragment at m/z 155 ($C_9H_{19}CO^+$). Compounds **35**, **38**, and **39** are also provisionally identified as farnesyl esters of C_{10} carboxylic acids, as there are very close similarities between their mass spectra and those of the synthetic farnesyl decanoates and they each show an acyl fragment at m/z 155 ($C_9H_{19}CO^+$). Full identification was not possible, but it is likely that these compounds have branching in the acid residues. Likewise, **28–31** are provisionally identified as farnesyl esters of C_8 carboxylic acids. They have similar mass spectra to those of the synthesized farnesyl esters and they show an acyl fragment at m/z 127 ($C_7H_{15}CO^+$). There is no acyl fragment observable in the mass spectra of **34** and **35**, but the similarities of their mass spectra to those of the other farnesyl esters suggests that they are also farnesyl alkanoates.

At least nine saturated esters (**41–49**) are indicated in *T. pecari.* Only two of them, hexyl 8-methylnonanoate and hexadecyl decanoate, were reported in *T. tajacu*; they were positively identified by comparison of retention times with those of the synthesized compounds (Waterhouse et al., 1996). The others were tentatively identified from their mass spectra alone, which indicate them to be alkyl C_{10}-alkanoates. Evidence for this is provided by an acyl $C_9H_{19}CO^+$ fragment at m/z 155 and a peak at m/z 173, which is in many cases the base peak and represents $C_9H_{19}CO_2H_2^+$ resulting from a double hydrogen transfer. The lack of identifiable molecular ions in the mass spectra of **41** and **46–49** does not allow the

identification of the alkyl group. Compound **42**, with a molecular ion at m/z 396 and a $C_9H_{19}CO^+$ fragment at m/z 155, is provisionally identified as a C_{16}-alkyl C_{10}-alkanoate. Similar high-molecular-weight saturated esters have been previously identified in the dorsal gland secretion of *T. tajacu* (Waterhouse et al., 1996), and esters **43** and **45** are common to both species. In *T. tajacu*, the esters are exclusive to females. Although saturated esters are not exclusive to females in *T. pecari*, they are more prominent in this sex.

We were unable to identify positively compounds **17** and **18** in the male secretions. The mass spectra of both compounds exhibit molecular ions at m/z 252 and are indicative of monounsaturated C_{16} lactones. The mass spectrum of **17** exhibits the following m/z (%) values: 252(4, M^+), 196(15), 111(11), 110(11), 109(15), 97(21), 96(24), 95(30), 83(25), 82(27), 81(36), 79(14), 69(40), 68(35), 67(46), 55(87), 54(27), 43(45), 42(25), 41(100). The mass spectrum of **18** exhibits the following m/z (%) values: 252(8, M^+), 196(6), 110(11), 109(17), 96(36), 95(37), 82(67), 81(63), 80(19), 79(24), 69(25), 68(45), 67(82), 55(68), 54(36), 43(31), 42(18), 41(100). This mass spectrum is nearly identical to that of isoambrettolide [(*Z*)-oxacycloheptadeca-10-en-2-one], a commercially available isomer of ambrettolide [(*Z*)-oxacycloheptadeca-8-en-2-one]; the latter naturally occurring C_{16} lactone is known from the ambrette seed (*Abelmoschus moschatus*) and is used as a fragrance in perfumery (Mookhergee et al., 1972; Sanz and Seoane, 1982). Isoambrettolide, however, had a retention time 1.5 min longer than that of **18**. Thus, while our data are consistent with the identification of 18 as an unsaturated C_{16} lactone, we suspend judgement on its detailed structure and that of the apparently related **17**.

Significant components of both the male and female secretion are four esters of methylhydroquinone: 2-methyl-4-hydroxyphenyl 2-methylpropanoate (**12**), 3-methyl-4-hydroxyphenyl 2-methylpropanoate (**13**), 3-methyl-4-hydroxyphenyl 2-methylbutanoate (**14**), and 2-methyl-4-hydroxyphenyl 2-methylbutanoate (**15**) (Figure 3). To the best of our knowledge, these acylated methylhydroquinones have not been reported previously. Although these compounds could be pheromonal, they could offer reductive protection to the readily oxidizable springenes, since they represent hydroquinones protected as the readily hydrolyzable monoesters. Other naturally occurring anti-oxidants based on the hydroquinone structure have been reported. For example, α-tocopherol hydroquinone (a metabolite of α-tocopherol containing a trimethylated hydroquinone unit) has been shown to be a more effective antioxidant scavenger than α-tocopherol itself (Shi et al., 1999). Phenolic compounds are known to occur in the skin gland secretions, urine, and other discharges of a variety of mammals (Albone, 1984). Burger et al. (1999) identified phenol, 3-methylphenol, 3-ethylphenol, and 3-propylphenol in the interdigital secretions of the bontebok (*Damaliscus dorcas dorcas*). More than 20 phenolics have been reported in castoreum, from the castor (anal) sacs of beavers (*Castor* sp., Rodentia) (Lederer, 1946; Tang et al., 1993). These compounds, which may function as pheromones (Müller-Schwarze, 1992), are thought to be derived from

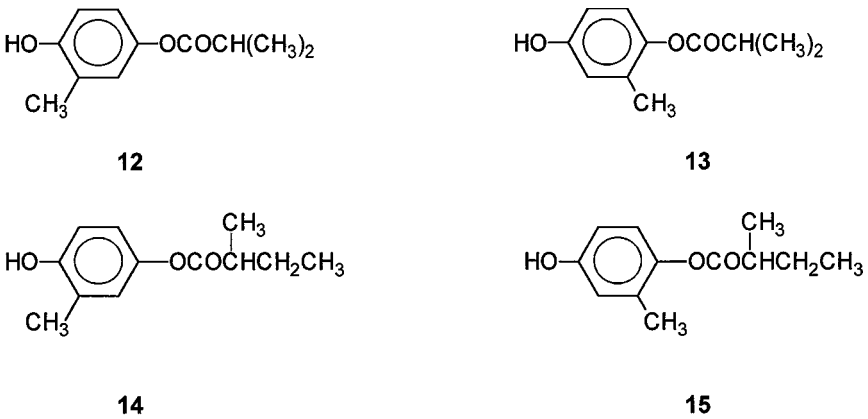

FIG. 3. Structures of monoalkanoyl esters of methylhydroquinone observed in dorsal gland secretions of *Tayassu pecari*.

woody plants, the dietary staple of beavers (Lederer, 1946; Tang et al., 1993). The phenolics that we have identified in the dorsal gland secretions of *T. pecari* may also be derived from plants. This species, like *T. tajacu*, subsists primarily on fruits and seeds (Barreto et al., 1997). *T. pecari*, however, consumes larger and harder seeds than does *T. tajacu*, a feature attributed to its greater bite force (Kiltie, 1982). The possibility that the different diets of these two peccaries underlie apparent differences in their dorsal gland chemistry needs to be examined.

Acknowledgments—We wish to thank W. B. Karesh, R. L. E. Painter, and W. B. Wallace for obtaining secretion samples; N. Tagua and J. Chuviqa for assisting in the field; D. Perrine and T. Spande for providing library searches for compounds; and Y.-Q. Li and K. Nakanishi for translations of papers. The Bolivian National Secretariat for Protected Areas granted permission to work at Noel Kempff Mercado National Park, and the National Directorate for Protection of Biodiversity issued permits. L. K. Sowls provided the photograph of alloanointing. We are grateful for gifts of isoambrettolide from J. Stephen (Cotswold Perfumery) and B. Narayanaswamy (Vinayak Impex Agencies, India). IACR receives grant-aided support from the Biotechnology and Biological Sciences Research Council of the United Kingdom.

Abstract—Mammals use urine, feces, or the secretion of specialized skin glands to mark their territories. These sources can carry different information and, thus, have different functions. Presently it is not known if beavers (*Castor* spp.) deposit castoreum (primarily a mixture of secondary metabolites from urine) from the castor sacs and secretion from the anal glands (AGS) together or alone when scent marking their territories. We hypothesized that castoreum would be the main scent signal used in the defense of beaver territories during winter and predicted that castoreum would be deposited more often than AGS. A total of 96 scent marks on snow were collected from January 1 to March 31, 1997–1999 in the Bø River, Telemark County, Norway. In order to obtain control material, we chemically analyzed AGS and castoreum from 60 dead beavers collected during January–May 1997–1999. We compared the compounds found in the dead beavers with compounds found in the scent marks on snow. Samples were analyzed by using gas chromatography–mass spectrometry (GC-MS). All 96 scent marks contained compounds from castoreum, whereas compounds from AGS were found in only four scent marks. This suggests that beavers do not specifically deposit AGS on scent mounds as they do with castoreum and that the AGS compounds we found probably were remnants of AGS from the feet or fur following pelt lubrication or coprophagy behavior. We conclude that castoreum is the main scent signal used in the defense of beaver territories during winter.

Key Words—Beaver, *Castor fiber*, anal gland secretion, castor sacs, castoreum, skin glands, snow-secretion.

INTRODUCTION

Communication and social recognition in many mammals are based on olfactory signals (Wynne-Edwards, 1962; Ralls, 1971; Schulte et al., 1994), and they use urine, feces, or the secretion of specialized skin glands to mark their territories (e.g., Müller-Schwarze, 1983; Gorman, 1984). Recent studies have demonstrated that scent types can carry different information and, thus, have different functions (Johnston et al., 1993). For instance, the study by Gorman et al. (1978) on otters (*Lutra lutra*) showed that deposits of spraints and urine may be used in the maintenance of otter territories, while the deposits of anal gland secretion (AGS) sometimes found at the latrines appear to have another function. The primary roles of skin glands of carnivores are the maintenance of the pelage and thermoregulation (Gorman and Trowbridge, 1989). The same scent may also code for different information and, thus, serve multiple functions (e.g., Quay and Müller-Schwarze, 1971; Epple et al., 1979; Johnston, 1985), while different scents may carry the same information (Baldwin and Meese, 1977; Roeder, 1980; Martin and Beauchamp, 1982).

Eurasian beaver (*Castor fiber*) and North American beaver (*C. canadensis*) possess two pairs of organs: castor sacs and anal glands (Svendsen, 1978; Walro and Svendsen, 1982). Both are suspected to be used for scent marking during territory defense (e.g., Rosell and Bergan, 1998). These are located in two cavities between the pelvis and base of the tail (Walro and Svendsen, 1982; Valeur, 1988). The anal gland is a holocrine secretory gland, but the castor sac is only a pocket lined with a layer of nonsecretory epithelium. They both open into the urogenital pouch (cloaca) (Svendsen, 1978). The castor sac is used to store what is believed to be a mixture of secondary metabolites from urine, collectively called castoreum (Walro and Svendsen, 1982). Copious amounts of castoreum deposited on scent mounds result from a process not dissimilar to urination except that the urine flushes through the contents of the castor sacs. This material can be deposited on the scent mound without the animal contacting the substrate with the cloacal region. The anal gland papillae, however, must be rubbed on the substratum in order to deposit the exudates (Wilsson, 1971; Svendsen, 1978). All age classes (except kits younger than 5 months) and both sexes defend their territories by scent marking (Wilsson, 1971; Svendsen, 1980; Welsh and Müller-Schwarze, 1989; Nolet and Rosell, 1994; Buech, 1995). Scent is usually secreted by the Eurasian beaver onto small piles of mud and debris scraped together and placed close to the water's edge and at the borders of the territory throughout the entire year (Rosell and Nolet, 1997; Rosell et al., 1998).

Both beaver species are suspected to use castoreum more frequently than AGS when scent-marking the territories (Schulte et al., 1994, 1995; Rosell and Bergan, 1998). Schulte (1993) discovered by chemical analysis that many compounds in the North American beaver scent mounds ($N = 4$) were common to castor sacs and castor fluid collected from live beavers. The presence of AGS compounds

was not examined. Field observations indicate that beavers scent mark using only castoreum, only AGS, or sometimes both (Rosell and Bergan, 1998). The odor of beaver scent marks, as detected by humans, varies greatly within site over time. Whether this is due to different beavers or different scents (castoreum and AGS smell different), or to a change in the compounds, is uncertain (Rosell and Bergan, 1998).

Castoreum consists of phenolic, neutral, basic, and acidic components (Tang et al., 1995). No clear sex difference has been detected so far (Pedersen, 1999; Sun and Müller-Schwarze, 1999). Chemical analyses of the AGS of Eurasian beavers have revealed that AGS contains free fatty acids, fatty alcohols, coprostanone, cholestenols, cyclic triterpenes, sterol esters, and wax esters. Wax esters are found only in males, whereas females possess fatty acids (Grønneberg, 1978–1979; Grønneberg and Lie, 1984). Most of the compounds in castoreum have a low molecular weight (Tang et al., 1993, 1995; Pedersen, 1999), while most of the lipids in AGS have a molecular weight above 300 (Grønneberg, 1978–1979; Grønneberg and Lie, 1984; Sun, 1996). The upper size limit for airborne pheromones is a molecular weight of about 300 (e.g., Wilson, 1963; Bradbury and Vehrencamp, 1998). Thus, AGS will normally not be volatile enough to act as an effective chemical messenger through air. One function suggested for AGS is that it serves to waterproof the fur (Walro and Svendsen, 1982). Excision of the anal glands seems to reduce the ability of the pelage to repel water (Walro and Svendsen, 1982). Prohibition of autogrooming in Eurasian beaver produces similar results (Wilsson, 1971). Both the glands that produce a secretion that waterproofs and maintains the fur and the motor patterns associated with application of the secretion would be expected to develop early in semiaquatic animals. Such is the case in beavers (Walro and Svendsen, 1982). However, several researchers have found that AGS can elicit territorial responses, similar to those shown to castoreum (Hodgdon, 1978; Müller-Schwarze et al., 1986). The secretion could be well suited to long-term signaling and may be deposited around the territory borders for the purpose of territory defense.

Castoreum may be an ideal substance for scent marking the territory because it has a minimal energetic cost to the signaler. Selection for effective signal-sending behavior harnesses odors that are already available at no extra cost (Müller-Schwarze, 1999). The large number of phenolics and terpenes in castoreum (Tang et al. 1993, 1995), undoubtedly diet-derived, may, therefore, constitute an honest signal, advertising the physical condition of the individual and, indirectly, the food supply in the territory (Müller-Schwarze, 1999). As such, beavers may have evolved a unique organ to store and excrete the secondary defense compounds produced by plants, which may in turn be used in territorial scent marking.

Presently it is not known if beavers deposit castoreum and AGS together or alone when scent marking their territories. Neither is it known how often beavers deposit castoreum compared with AGS. The aim of this study was to investigate and

to search for characteristic chemical compounds from the castor sacs and the anal glands in scent deposited on snow in an effort to resolve this issue. We hypothesized that castoreum is the main scent signal used in the defense of beaver territories during winter, and predicted that castoreum is deposited more often than AGS.

METHODS AND MATERIALS

Study Area and Animals. The study was conducted on two distinct sections of the Bø River in the municipalities of Bø and Sauherad (59°25′N, 09°03′–04′E) in Telemark County, Norway. Section 1 was 13 km long, section 2 was 11 km, and the sections were 5 km apart. The sections of the river studied averaged 35 m in width, and most of the river was ice-free during winter due to hydroelectric regulation further upstream. This provided us with the opportunity to study scent-marking behavior of beaver uninhibited by the usual constraints of winter ice (Rosell et al., 1998). Rosell et al. (1998) and Rosell and Bergan (2000) observed that scent was deposited on snow during winter in our study area. Snow, in contrast to the mud and debris normally used to build scent mounds, provides a suitable substrate for determining the deposition frequency of castoreum and AGS on scent mounds. Beavers have occupied the river since the 1920s (Olstad, 1937), and colony density was believed to be near maximum during our field studies (0.54–0.73 colonies/stream km in 1998). During October–December 1996–1998, the study area was ground-censused for active colonies by recording food caches, new mud on the lodges, and fresh feeding sites. Eight active colonies were found on section 1 in 1996 and 1997, and 7 in 1998. Eight active colonies were present on section 2 in 1998 (section 2 was not studied in 1996 and 1997). During autumn 1995, the average colony size on the Bø River (section 1) was 4.0 ± 0.6 (SD) (Rosell et al., 1998). Territorial boundaries were drawn based on the location of scent mound concentrations (Rosell and Nolet, 1997; Rosell et al., 1998) and from sight observations of animals moving up- and downstream of the lodge (Rosell et al., 1998).

Sample Collection. We collected a total of 96 scent samples on snow (hereafter called snow-scent sample, SSS) between January 1 and March 31, 1997–1999 during 14 trips in the study area. Eighteen samples were collected during 1997, 35 during 1998, and 43 during 1999. A SSS was defined as a scent mark directly on snow or in the ice (frozen), situated on a snow-covered tussock or snow mound scraped together where fluid or secretion from the castor sacs and/or anal glands had been deposited (Rosell et al., 1998). All scent marks had a detectable odorant to the human nose at 2 cm or more. Minimum distance between two different scent marks was 10 cm (Rosell and Bergan, 2000). All scent marks were collected between 08:00 and 13:00 hr and within 24 hr after the last snowfall. Beavers usually had one night without snowfall during which they scent-marked before

the marks were collected. A binocular was used to spot the scent marks from a canoe. All tracks from the water in the snow and a range of colors in the snow were investigated.

Samples from 1997 and 1998 were collected using a plastic bag as a glove to prevent contamination of the samples from skin contact. As much of the affected snow as possible was collected, judging from the light yellow to red colored stains seen at depths of 1–3 cm. Frozen samples were loosened with a clean axe. None of the samples contained debris or organic compounds (e.g., soil, mud, twigs, grass, leaves, or conifer needles) normally used to build scent mounds. The plastic bags were sealed and samples thawed at room temperature in the laboratory, emptied into sterile 100 ml plastic or glass vials with caps to minimize bacterial contamination, and then swirled thoroughly to assure a homogeneous mixture. In 1999, samples were collected directly into a plastic or glass cup with airtight caps and swirled thoroughly. The samples were then immediately frozen and stored at -20°C until analyzed. On each sampling day, we also collected control samples of scent-free snow ($N = 14$) into one vial in all territories where we found SSS with the same methods in order to check for contamination from the plastic and glass equipment used to collect the samples.

We collected castor sacs and anal glands from 60 animals shot locally during the normal hunting season from January 28 to May 6, 1997–1999 (Table 1) (Parker and Rosell, 2001), and used the castoreum and AGS from these animals as the basis for comparison with castoreum and AGS found in the SSS. We opened the castor sacs with a surgical blade and scraped the castoreum from the inside surface with a metal scapula. AGS was collected from the glands by cutting off the last 2–3 mm of the papillae and squeezing out the secretion (Rosell and Sun, 1999; Rosell et al., 2000). Sun and Müller-Schwarze (1998a) found no significant variation in the chemical compounds from the right and left gland of the North American beaver, and we, therefore, collected all secretion in the same glass vial. All samples were stored at -20°C until analyses. We sexed the animals by checking for the presence

TABLE 1. CONTROL SAMPLES OF CASTOREUM AND ANAL GLAND SECRETION (AGS) FROM DEAD MALE (M, $N = 30$) AND FEMALE (F, $N = 30$) EURASIAN BEAVERS OF DIFFERENT AGE[a]

Age[b]	Male		Female	
	Castoreum	AGS	Castoreum	AGS
<1 year (6 M, 7 F)	2	5	5	5
≥1 to 2 year (10 M, 6 F)	9	8	5	5
2.5–14 year (14 M, 17 F)	8	7	10	10
$\sum$	19	20	20	20

or absence of the os penis (Osborn, 1955). Age was determined by examining tooth root closure and annual cementum and dentine layers of the first molar (van Nostrand and Stephenson, 1964).

Control Experiment. We conducted a control experiment during April 2000 to check whether our methods could detect the compounds from the castor sacs and the anal glands in the SSS. We simulated beaver scent-marking activity by constructing artificial scent mounds of snow, on snow, and applied castoreum and AGS to them. We used scent material from the same animals (all adults 2.5–14 years old plus the number of male subadults necessary to reach a sample size of $N = 10$, see Table 1) as described above. A sample was taken from a castor sac or an anal gland, divided in two, and distributed randomly to the snow control experiment (SCE) and the lab control experiment (LCE). Ten mounds were treated with castoreum (0.5 g) from males, 10 with castoreum (0.5 g) from females, 10 with AGS (0.25 ml) from males, and 10 with AGS (0.25 g) from females. AGS from females has a high viscosity, so we used a spatula to take out the secretion from the vials and weighed it on an electronic balance. We collected the artificial scent marks 20 hr after being made using the same methods as described above for collection.

*Sample Preparation.*The SSS, including the scent-free controls, and the SCE were thawed by putting the bottles into a water bath at 35–40°C for 10 min. Afterwards, the samples were transferred to a 250-ml Erlenmeyer flask with ground joint. We added 10 ml of toluene, and the solution was swirled using a magnetic stirrer at high velocity (about 1400 rpm) for 10 min. The solution was then transferred to a separatory funnel, where it remained for 15–20 min. to allow the phases to separate. The lower water phase was tapped out and the upper organic phase filtered through a filter paper (Schleicher and Schuell no. 595, Dassel, Germany) into an evaporating flask. A PTFE sleeve for ground joints was set in the flask neck to avoid locking. The sample was evaporated in a Heidolph WB 2001 rotary evaporator to a volume of variable size (therefore, we only carried out qualitative analyses), and 1 ml of toluene was added. The solution was transferred to a vial with a snap cap that was kept in a refrigerator (<24 hr) at 4°C until the analysis was done. We also analyzed the water phase. Some of the compounds from the organic phase were found in the water phase as well, but in lower concentrations. However, we found no new compounds in the water phase.

AGS and Castoreum. From the control material (the dead animals), we transferred 0.25 ml AGS from the males and 0.25 g from the females into smaller glass vials before adding 7.5 ml of a mixture of toluene–methanol 3:1. The solutions were filtered through a filter paper (Schleicher and Schuell no. 595) and kept in a refrigerator (< 24 hr) at 4°C until analyses.

We weighed 0.5 g castoreum and added 10 ml of toluene–methanol 3:1. The sample was extracted in a Milestone MLS 1200 Mega microwave oven. The extraction program had the following cycle: 5 min at 250 W and 100°C, 5 min at

400 W and 130°C, and 5 min at 400 W and 160°C. All compounds were dissolved. The sample was then treated the same way as the AGS solution.

Chemical Analysis. We injected 1 μl of the resulting solution into a Hewlett-Packard 6890 Series II gas chromatograph equipped with a nonpolar HP-5 MS 5% phenyl-methyl-siloxane column (30.0 m long $\times$ 0.25 mm ID $\times$ 0.25-μm film thickness) connected to a Hewlett-Packard 5973 Series mass spectrometer detector with a split/splitless inlet used in the splitless mode. Helium was used as the carrier gas at a constant flow of 0.7 ml/min. The following temperature program was employed for all analyses: 130°C to 310°C at 4°C/min and kept at 310°C for 15 min. To avoid that the solvent damaged the detector, a delay of 2 min was set for every run. We used the first 60 min as the collection time because few compounds were detected after 60 min and most of these peaks stemmed from the column material. The column was regularly baked out at 315°C to remove any remaining low-boiling-point compounds. The instrument was regularly calibrated to detect possible changes in the sensitivity of the instrument. This prevented unstable conditions during the work. We characterized each compound in a sample by its GC retention time and mass spectrum, and we determined the structures of some of the compounds with a computer-aided compound search of the Wiley 275 Library, which contains about 70,000 known compounds. In addition, all mass spectra from the samples and from the library were visually compared to see if the suggestions from the computer were reasonable. We also made our own library of the compounds not found in the Wiley library, i.e., we saved 12 compounds from the castor sacs and 128 compounds from the anal glands from the dead individuals. We could, therefore, recognize many compounds from individual to individual, and also from individuals to the SSS. Since the main focus of our study was to determine if the beaver used castoreum and/or AGS in their scent-marking behavior, positive identification of these compounds was not attempted, i.e., we did not compare the compounds with a known standard. All major peaks were analyzed, but excessively small peaks were not, i.e., peaks less than twice the noise level were not analyzed. After numerous injections, we could see a small shortening in the retention times of the peaks because the column aged a little. We, therefore, presented the retention time found when the column was new. Peak retention times were rounded off to the first decimal.

Statistics. Since the data did not fit assumptions of distribution and homogeneity of variance for parametric analysis (Sokal and Rohlf, 1995), we used nonparametric statistics (Siegel and Castellan, 1988). A Mann-Whitney U test was used to compare the median number of peaks between two independent groups. We corrected for compounds in the plastic and glass equipment used to collect the samples when counting the number of castoreum and AGS compounds and omitted the smallest peaks (see above). Probability values are two-tailed and 5% was used as the level of significance. All data were treated in Minitab version 12.1 for Windows.

RESULTS

Castoreum. Chemical analysis of the 96 SSS revealed that castoreum compounds were present in all samples ($\bar{X} \pm \text{SD} = 6.75 \pm 4.18$, range = 1–17). Figure 1a is a typical example. We found 24 different compounds from castoreum in the SSS (Table 2). None of the compounds was found in all SSS, and 17 of the compounds were found in 10 or more of the SSS (Table 2). Forty-seven of the 50 (94.0%) compounds detected in the castoreum from the dead animals had a molecular weight below 300 (Table 3).

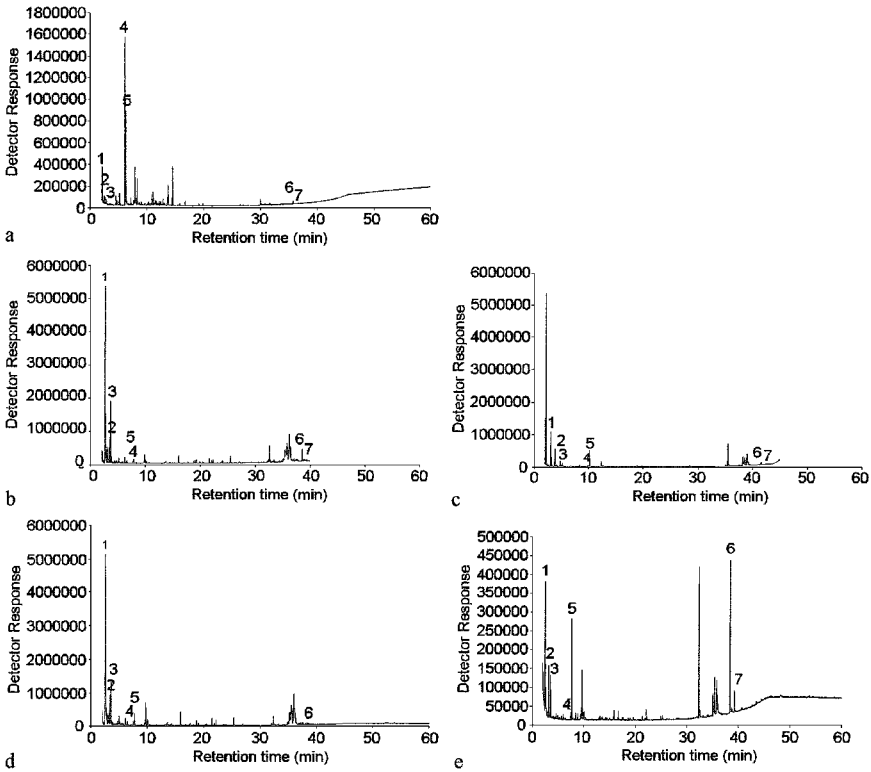

FIG. 1. Typical chromatograms of castoreum from (a) a beaver snow-scent sample, (b) a dead adult male, (c) a dead adult female, (d) from the snow control experiment with the same male as in b and (e) the same female as in c. Compound marked 1–7 in the chromatograms are tentatively identified as: 1, ethylphenol; 2, prophylphenyl; 3,4-ethyl-2-methoxyphenol; 4,4-(4-hydroxyphenyl)-2-butanone; 5, 4-(4-hydroxyphenyl)-2-butanol; 6, cholest-5-ene-3-ol; and 7 cholest-7-ene-3-ol (3β,5-α). Note that identities of the compounds have not been verified with known samples (see Methods and Materials). The *x* axis is the time in minutes, and the *y* axis is in arbitrary units.

TABLE 2. TENTATIVELY IDENTIFIED COMPOUNDS FOUND IN 96 SNOW-SCENT SAMPLES FROM EURASIAN BEAVERS

No.	Tentatively identified compound[a]	Retention time (min)	Samples (*N*)	Source[b] (Sex)[c]

[a] Numbers in parentheses match those in Figure 1.
[b] The identities have not been verified with known samples.
[c] Compounds were found both in the snow control experiment and in the dead animals used in the control experiment.

We found no difference in median number of castoreum compounds between dead males and females (males: $\bar{X} \pm \text{SD} = 22.53 \pm 2.86$, range = 18–29, $N = 19$; females: $\bar{X} \pm \text{SD} = 23.25 \pm 3.95$, range = 12–29, $N = 20$) ($W = 338.0$, $P = 0.241$). Figure 1b and 1c show typical chromatograms from a dead adult male and female. Forty-six (92%) of the detected compounds were found in both sexes. Three compounds were detected in only males and one in only females (Table 3). However, they were found in only one animal (Table 3). Forty-one (82%) compounds were found both in the SCE and in the LCE (Table 3) (compare Figure 1b and d, and 1c and e). This shows that our method could detect the compounds from the castor sacs in the SSS.

AGS. Chemical analysis of the 96 SSS revealed that AGS compounds were present in only four samples ($\bar{X} \pm \text{SD} = 7.50 \pm 4.93$, range = 2–14). Figure 2a is a typical example. These four scent marks were found on January 19, 1997; February 5 and March 13, 1998; and on March 15, 1999; they were inside four different territories. Three of the SSS were deposited directly on snow, while one was deposited on a snow-covered tussock. We found that two of the scent marks (January 19, 1997, and March 15, 1999) contained compounds from only females, and two contained compounds that were typical for both sexes. We found 20 different compounds from AGS in the SSS (Table 2).

More compounds were found in the AGS from dead males ($\bar{X} \pm \text{SD} = 55.40 \pm 10.81$, range = 29–69, $N = 20$) compared with females ($\bar{X} \pm \text{SD} = 22.70 \pm 4.93$, range = 14–30, $N = 20$) ($W = 607.5$, $P = 0.0001$). Figure 2b and c show typical chromatograms from a dead adult male and female. Overall, 56 different compounds were found in the female AGS and 126 compounds in the

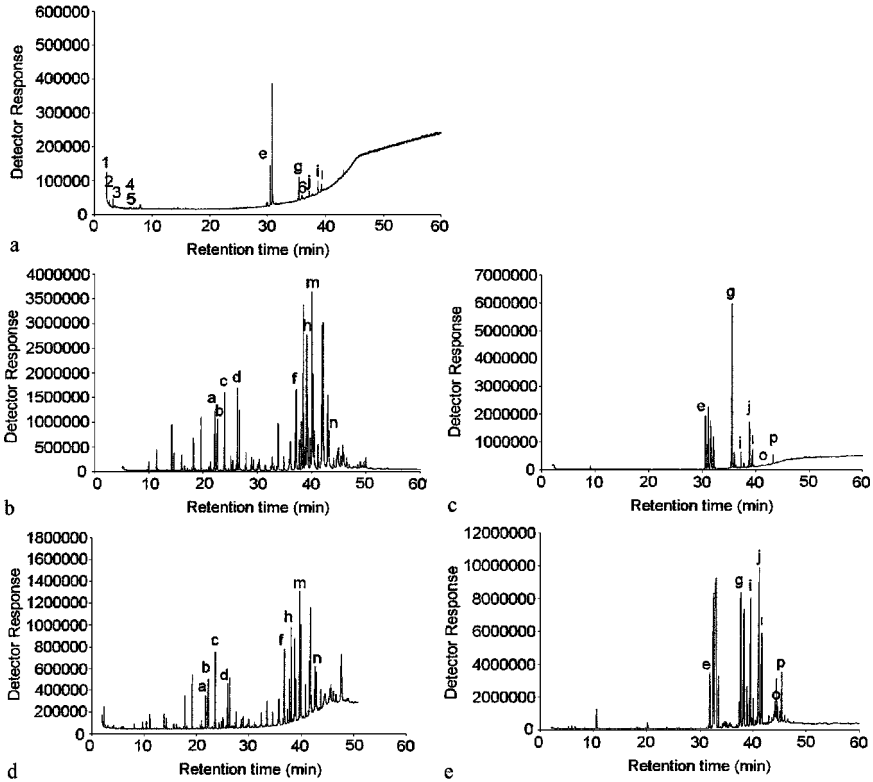

FIG. 2. Typical chromatograms of anal gland secretion from (a) a beaver snow-scent sample deposited by a female (contains both compounds form castoreum and AGS), (b) a dead adult male, (c) a dead adult female, (d) from the snow control experiment with the same male as in b and (e) the same female as in c. Compunds marked form a–p in the chromatograms are tentatively identified as: a, hexadecadiene; b, unknown; c, unknown; d, long hydrocarbon chain; e, unsaturated C_{30} hydrocarbon; f, C_{29} wax ester; g, unknown; h, usaturated wax ester; i, a steroid; j, 4-α-methylcholest-8(14)-ene-3-β; k, unknown; p, a steroid; m, unsaturated C_{32} wax ester; n, saturated C_{33} wax ester; o, a steroid; and p, a steroid. Note that the identities of the compounds have not been verified with known samples (see Methods and Materials). The *x* axis is the time in minutes, and the *y* axis is in arbitray units.

male AGS (Table 4). Nineteen compounds were found in both males and females (Table 4). Only 7 (12.5%) of the compounds detected in AGS of females and 41 (32.5%) of the compounds in the males had a molecular weight below 300 (Table 4). One-hundred thirty-three (89.3%) compounds were found both in the SCE and in the LCE (both sexes combined) (Table 4) (compare Figure 2b and d, and 2c and e). Therefore, our method detected the compounds from the anal gland in the SSS.

[b] The identities have not been verified with known samples.
[c] Compounds were found both in the snow control experiment and in the dead animals used in the control experiment.

DISCUSSION

Our results support the prediction that castoreum is most frequently deposited on scent marks (96 of 96) and appears, therefore, to be the main scent signal used in the defense of Eurasian beaver territories during January–March. AGS, however, was deposited only on 4 of 96 scent marks. This suggests that beavers do not specifically deposit AGS on scent mounds, but that the compounds we found

possibly were remnants of AGS from the feet and/or fur after pelage lubrication (Walro and Svendsen, 1982). Beavers may also get AGS on their feet and fur following coprophagy (Wilsson, 1971). AGS may, therefore, have other functions.

Beaver scent marks with castoreum might be a volatile alerting signal for attracting attention (Müller-Schwarze, 1999). Alerting signals contain no information about an individual or even a species (Müller-Schwarze, 1999). Responses to single compounds support the hypothesis that castoreum is used for signaling territorial occupancy, which requires only one bit of information in the signal for making a decision by receivers, i.e., whether the territory is occupied or not (Müller-Schwarze and Houlihan, 1991; Schulte et al., 1994; Sun and Müller-Schwarze, 1999). It may be that the lighter, volatile compounds in the castoreum direct receivers toward the less volatile but potentially more informative chemical components still present at the scent mark. This is supported by the fact that 94% of the compounds had a molecular weight below 300.

Schulte (1998) found that North American beavers discriminated among castor-fluid scents from family, neighbor, and nonneighbor adult males. The Eurasian beaver can also discriminate among scents (castoreum and AGS) from neighbor and non-neighbor individuals (Rosell and Bjørkøyli, unpublished data). However, no significant difference was found in the number of castoreum compounds between dead males and females whose castoreum chromatograms were similar (see also Pedersen, 1999). Likewise, Sun and Müller-Schwarze (1999) failed to find any consistent difference between male and female castoreum profiles in North American beaver and concluded that castoreum is unlikely to be used for sex recognition. This conclusion is in accordance with the evidence that castoreum compounds are mainly dietary derivatives, which do not differ between the two sexes (Müller-Schwarze, 1992). By contrast, the composition of AGS in both the North American and Eurasian beaver exhibits chemical sexual dimorphism (Grønneberg, 1978–1979; Grønneberg and Lie, 1984; Sun and Müller-Schwarze, 1999; this study). Whether the Eurasian beaver uses the sex difference in AGS to distinguish between individuals of different sex, needs further study.

AGS also contains information about individuality, kinship, and family membership (Sun and Müller-Schwarze, 1999). Sun and Müller-Schwarze (1997) have shown that North American beavers use AGS to discriminate between unfamiliar sibling and unfamiliar nonrelatives and that this discrimination was not shown when castoreum samples were tested. Sun and Müller-Schwarze (1998b) showed that beavers' response to AGS from unfamiliar adult males remained at about the same level, but their response to castoreum showed a descending trend. The descending trend in response to the same signal without matching the signaler demonstrates a declining importance of the signal over time, i.e., the scent-matching hypothesis (Gosling, 1982) was supported. The scent-matching hypothesis predicts, among other things, that the territory owner should make itself available for scent matching by the intruder (Gosling, 1982). Sun and Müller-Schwarze (1998a)

recently documented that related individuals shared more features in the chemical AGS profile than did unrelated individuals, and Sun and Müller-Schwarze (1998c) also demonstrated that it is possible to use some AGS compounds to classify different families.

AGS may act as a chemical messenger in the water territory (Grønneberg and Lie, 1984) sensed through close range or contact with the animal. The latter is supported by the fact that only 12.5% and 32.5% of the compounds detected in AGS of females and males, respectively, had a molecular weight below 300. It could be advantageous for a swimming mammal such as the beaver to present chemical signals in the form of lipid substances that would concentrate at the air–water interface (Albone, 1984). By lubricating the fur with AGS, which would be released into the water, beaver could also act as a "living scent mark." As AGS is insoluble in water (Svendsen, 1978), beavers downstream would receive a concentrated flow of chemical scent information in the surface film from upstream territories (Rosell et al., 1998). The recently discovered vomeronasal organ in Eurasian beavers may play a significant role here (Rosell and Pedersen, 1999). Furthermore, anal glands, which are located in the anus (Svendsen, 1978), may add AGS to the feces when beavers defecate in the water. For instance, the large complex of sebaceous and apocrine glands located in and around the anus of many species of antelope may add individual-specific secretion to feces (Barrette, 1977; Mainoya, 1980; Gosling, 1982).

However, Rosell and Bergan (1998) observed on July 21 two adult Eurasian beavers depositing AGS at the border of their territory by everting the "cloaca," protruding the anal gland openings and rubbing them against the surface as the animal walked over the scent mound. Therefore, further analyses need to clarify if beavers use the AGS on scent marks of other times of the year.

(Received March 26, 2001; accepted July 25, 2001)

Abstract—The wolf spider, *Pardosa milvina*, displays effective antipredator behavior (reduced activity) in the presence of silk and excreta cues from adults of another cooccurring wolf spider, *Hogna helluo*. However, *Pardosa* and *Hogna* engage in size-structured intraguild predation, where *Pardosa* may be either the prey or predator of *Hogna*. We tested the ability of adult female *Pardosa* to vary antipredator responses toward kairomones produced by *Hogna* that vary in size. *Hogna* were maintained on filter paper for 24 hr. We then presented the paper to adult female *Pardosa* simultaneously paired with a blank sheet of paper. One treatment had two sheets of blank paper to serve as a control. The *Hogna* stimulus treatments were as follows ($N = 15$/treatment): (1) 1 *Hogna* half the mass of *Pardosa*; (2) 1 *Hogna* of equal mass of a *Pardosa*; (3) 1 adult *Hogna*, 30 times the mass of *Pardosa*; and (4) 8 *Hogna* each 0.25 the mass of *Pardosa*. *Pardosa* decreased activity in the presence of kairomones from *Hogna* of equal or larger size, but showed no change in activity in the presence of a blank control or from a single *Hogna* smaller than itself. *Pardosa* showed a reduction in activity in the presence of cues from eight small *Hogna*. *Pardosa* avoided substrates with adult *Hogna* cues, but showed no avoidance response to any other treatment. These results suggest that *Pardosa* is showing graded antipredator behavior relative to the quantity of predator kairomones present rather than directly discriminating among the different sizes of the predator.

Key Words—*Pardosa milvina*, Lycosidae, kairomone, wolf spider, predator, size, *Hogna helluo*, antipredator, size discrimination, chemical cue.

INTRODUCTION

Many animals show defensive behavior in the presence of chemical cues produced by predators (see Kats and Dill, 1998, for a review). Antipredator responses include reduced locomotion, increased cover-seeking, or increased vigilance (reviewed in Lima and Dill, 1990; Lima, 1998). These behaviors are generally costly because they interfere with both foraging (Lima and Dill, 1990) and reproduction (Forsgren, 1992; Berglund, 1993; Hedrick and Dill, 1993; Godin, 1995). The "threat-sensitive predator avoidance" hypothesis suggests that prey should show graded responses of defensive behavior proportional to the perceived risk (Dill and Fraser, 1997; Sih, 1997; Puttlitz et al., 1999).

Prey that respond to chemical cues from predators (kairomones) rather than using other sensory cues may overestimate predation risk by exhibiting antipredator behavior even in the absence of the predator itself. This additional cost may be reduced by extracting more information about predation risk from predator cues. Variation in the composition of predator excreta may provide information about the predator's diet (Crowl and Covich, 1990; Chivers et al., 1996; Murray and Jenkins, 1999; Venzon et al., 2000; Persons et al., 2001), which, in turn, may provide information about the proclivity of a predator to feed on particular prey types (Punzo and Kukoyi, 1997; Persons and Rypstra, 2000). Other features such as age or type of chemical cue also may provide information about how recently a predator was in the area (Venzon et al., 2000) as well as the kind of predator present. In some cases, the intensity of kairomone-mediated antipredator responses may be related to the relative size of the prey compared to the predator. For example, dragonfly larvae are effective predators of small tadpoles, but are less efficient preying on tadpoles of larger sizes (Caldwell et al., 1980). Toad tadpoles show a corresponding reduction in antipredator behavior when detecting kairomones from dragonfly larvae as tadpole size increases (Laurila et al., 1997). Collectively, these sources of information may provide animals with a more accurate assessment of predation risk and allow them to modify defensive behavior, mitigating some of the costs of antipredatory behavior.

The wolf spiders *Hogna helluo* and *Pardosa milvina* are among the most abundant ground predators in agricultural fields of the midwestern United States (Marshall and Rypstra, 1999). These two species exhibit size-structured intraguild predation, whereby the role of predator and prey is determined by the relative mass of each spider during an encounter. Adult *Hogna* are typically 20–30 times the body mass of an adult *Pardosa* and are more likely to be the predator during an interspecific encounter, yet we have observed adult *Pardosa* feeding on juvenile *Hogna* as well as adult *Hogna* feeding on adult *Pardosa*. *Pardosa* may benefit from the ability to perceive relative *Hogna* size through kairomone cues since predation risk increases with increasing asymmetry in size (Samu et al., 1999). Adult female *Pardosa* exhibit reduced speed and frequency of movement in the presence of

excreta and silk from adult *Hogna* (Persons et al., 2001). Adult female *Pardosa* also will avoid substrates containing cues from adult *Hogna* when given a choice. These responses are absent when *Pardosa* are presented silk and excreta from conspecifics (Persons et al., 2001). Reduced activity results in longer periods of time in areas with predator cues; however, such behavior is adaptive since slower movement and inactivity increases survival of *Pardosa* in the presence of *Hogna* (Persons et al., 2001).

Pardosa and *Hogna* provide an opportunity to test the threat-sensitive predator avoidance hypothesis. Adults of the smaller *Pardosa* should closely match antipredator response with predation risk. *Pardosa* that interpret chemical cues from a small *Hogna* as a potential predator will incur a number of unnecessary costs. Reduced activity may impair reproductive behavior and may also impair feeding efficiency by causing the spider to avoid a potential prey item. If *Pardosa* can match defensive behavior with relative risk by assessing predator size indirectly, then the spider may minimize the associated costs of defensive behavior. It is unknown if silk and excreta change qualitatively or quantitatively with spider size or if *Pardosa* is able to detect such differences. Here, we test several predictions related to the ability of *Pardosa* to perceive *Hogna* size based on chemical information. First, adult female *Pardosa* will show decreasing activity in the presence of chemical cues from *Hogna* of increasing size, but will show no reduction in activity in the presence of chemical cues from *Hogna* smaller than *Pardosa*. Second, adult female *Pardosa* will not reduce activity in the presence of large quantities of chemical cues from many *Hogna* each smaller than itself. Third, when given a choice, *Pardosa* will avoid silk and excreta produced by *Hogna* larger than itself, but show no avoidance of cues produced by smaller *Hogna*.

METHODS AND MATERIALS

Spider Collection and Maintenance. Spider maintenance, experimental design, and testing protocols are similar to those found in Persons et al. (2001). Seventy-five adult female *Pardosa* were collected from within and along the margins of soybean fields (Oxford, Ohio, Butler County, Ecology Research Center, Miami University) in September 1998. *Pardosa* used as test spiders were fed a meal of two domestic cricket nymphs (*Acheta domesticus*) once a week followed by five additional cricket nymphs one day prior to testing to minimize possible hunger effects on activity. All spiders were maintained in 8-cm-diam. $\times$ 5-cm-high plastic translucent containers lined with moistened peat moss and kept in environmental chambers on a 13L:11D light cycle, 25°C, and 70% relative humidity. Fifty-five adult male and female *Hogna helluo* were collected from the same habitats as *Pardosa* and bred in captivity in the summer of 1998. The offspring of these

field-collected *Hogna* were used as stimuli for all trials and were maintained in a manner similar to that of *Pardosa*.

Stimulus Preparation. Silk and excreta from *Hogna* of four different sizes were collected on filter paper. One treatment consisted of chemical cues from a large *Hogna* ca. 30 times the body mass of a single *Pardosa* (mean $\pm$ SE $=$ 792.9 ± 15.9 mg). *Hogna* of this size can readily consume up to 10 adult female *Pardosa* in a single feeding bout. A second treatment consisted of silk and excreta from a medium-sized *Hogna* that was approximately equal in size to an adult female *Pardosa* (23.3 ± 1.2 mg). Predation among wolf spiders of equal mass has been shown to be infrequent (Samu et al., 1999). A third treatment used cues from a single small *Hogna* about one half the mass of an adult female *Pardosa* (11.2 ± 1.3 mg) and that can readily be consumed by *Pardosa*. We used a fourth treatment in order to uncouple cue quantity and quality. We collected silk and excreta from eight small *Hogna*, each approximately one fourth the body mass of *Pardosa* (collective mean weight $= 54.6 \pm 1.8$ mg). Each chemical stimulus treatment was paired with a blank sheet of filter paper that had never been exposed to a spider of any size or type (same experimental setup as in Persons et al., 2001). This served as a control to monitor behavioral differences. A fifth treatment consisted of only a blank sheet of filter paper.

All *Hogna* that were used as predator cues were maintained on a diet of appropriately sized crickets (*A. domesticus*) for at least two weeks prior to placing them on filter paper substrates. All stimulus *Hogna* were watered *ad libitum* and fed as many prey as they could consume within a 24-hr period. This was done to minimize any differences in silk production or excreta due to differences in amount of food allocated among groups. *Hogna* were then placed onto sheets of filter paper for 24 hr prior to testing *Pardosa* responses. Each container was previously rinsed with 95% ethanol to remove all extraneous odor cues and allowed to dry. Stimulus spiders for each size treatment had access to a small cap of water in the center of the container. The cap was moved periodically to allow silk or excreta to be deposited beneath it. The lid was closed after *Hogna* were introduced. After the 24-hr period, the filter paper was removed from the container and introduced into a test arena immediately prior to testing. For the treatment consisting of eight *Hogna*, 16 spiders were used for each paper stimulus sheet. Eight spiders were introduced onto a single stimulus sheet of paper and maintained under individual vials to prevent cannibalism or agonistic behavior between individuals. Each set of eight spiders was replaced every 6 hr with another set of eight and allowed to receive water in a separate container. These were then reintroduced onto the substrate under vials again after 6 hr.

Pardosa milvina Testing. Seventy-five adult female *Pardosa* were randomly assigned to one of five treatment pairs ($N = 15$/treatment). As described above, these treatments were: (1) large *Hogna*/blank, (2) medium *Hogna*/blank, (3) small *Hogna*/blank, (4) eight small *Hogna*/blank, or (5) blank/blank. Test *Pardosa* for

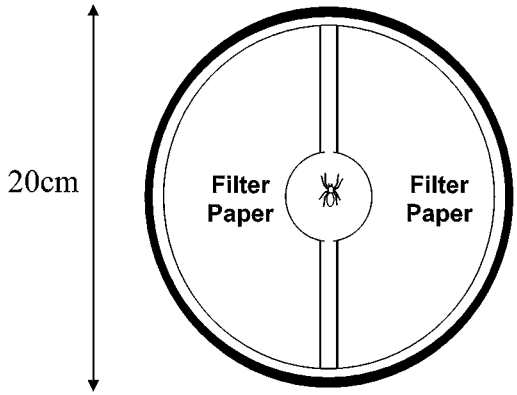

FIG. 1. Experimental apparatus used for testing chemically mediated size discrimination among *Pardosa*. Test spiders are placed in the center of the apparatus and allowed to acclimate for 1 min, after which the spider is allowed to move freely in the container for a period of 1 hr.

each treatment were fed crickets to satiation 24 hr prior to testing and weighed on an analytical balance (27.3 ± 1.0 mg).

We examined the locomotor patterns and behavior of adult female *Pardosa* exposed to each treatment pair and across pairs. Test arenas for *Pardosa* were 20-cm-diam. $\times$ 8-cm-high plastic containers consisting of two half circles of filter paper that collectively covered most of the surface area of the arena except for a 5- to 6-mm band between the two sheets (Figure 1). Additionally, a half circle was cut in the center of each sheet, and this area was used to introduce the spider.

Each spider was introduced into the center of the arena under a clear plastic vial. Each of the 15 spiders per treatment pair was presented a stimulus from a different *Hogna* of the appropriate size class, and no filter paper sheets were used more than once. After a 1-min acclimation period, spiders were allowed to move across the paired treatments for 1 hr each. Spatial positions of filter paper treatments within pairings were randomized among test subjects to eliminate any potential side bias. The test arena was swabbed with 95% ethanol between stimulus presentations to each subject and allowed to dry. Test trials were illuminated equally on all sides with four 15-W fluorescent lights installed in a square configuration above the testing arena. All spiders were tested between 07:00 and 19:00 hr.

Locomotor behavior was measured by monitoring the spiders remotely using an automated digital data collection system (Videomex-V, Columbus Instruments, Columbus, Ohio, USA) integrated into a video camera (JVC high band Saticon GXS 700). All behaviors were recorded automatically. For each test spider,

we recorded the following behaviors separately for each filter paper treatment: (1) time spent moving forward (locomotion), (2) time spent in nonforward movement (any movement of the appendages or turning of the body in place without forward locomotion), (3) time spent immobile (no visible indications of movement), (4) distance traveled (centimeters), (5) residence time (time spent on filter paper), and (6) speed (distance traveled/time spent moving forward). We also recorded the initial choice of sides for each pairing. Changes in spider movement were recorded every second and required a movement of at least one body length in that time period to be measured as forward movement. All locomotor patterns were output onto a computer printer every 5 min, and behaviors for each subject were summed over the 1-hr period.

Statistical Analyses. Because none of the behavior classes showed deviations from a normal distribution (Wilk-Shapiro normality statistic), parametric statistics were used for analyses. We used paired *t* tests to compare behavioral differences between paired filter paper treatments for each class of behavior. We used ANOVA to determine differences for each behavioral category across the three size class treatments and the blank control. A planned series of two-sample *t* tests was used to test for differences for each class of behavior between the eight *Hogna* treatment versus the medium *Hogna* treatment. This was done to determine if *Pardosa* behavior is the result of variation in the quantity or quality of *Hogna* cues.

A second set of analyses was done to compare differences in spider responses across each *Hogna* size treatment. Six one-way ANOVAs were completed with residence time, time in forward locomotion, time in nonforward locomotion, distance moved, time spent immobile, and speed as dependent variables for the blank, large *Hogna*, medium *Hogna*, and small *Hogna* size treatments. Each stimulus treatment paired with a blank was used as the independent variable. Chi-squared goodness of fit tests were used to determine differences in initial choice of sides in each treatment pairing.

RESULTS

In general, there was a decrease in *Pardosa* activity with cues from *Hogna* of increasing size. *Pardosa* showed a significant reduction in activity in the presence of all *Hogna* size treatment groups compared to blank controls except when on substrates from the small *Hogna* treatment (Figure 2). Based on paired *t* tests, mean time spent immobile and mean residence time were different when the cues were from a medium or large *Hogna* (Figure 2A, B). *Pardosa* spent more time in nonforward locomotion in the presence of cues from large *Hogna* than on a blank control sheet of paper (Figure 2A). There was no difference in any class of locomotor behavior among the double blank treatments, indicating no side bias to the testing container (Figure 2D).

TABLE 1. COMPARISON OF MEAN ACTIVITY LEVELS IN SIX CATEGORIES OF *Pardosa* BEHAVIOR FOR EACH *Hogna* SIZE TREATMENT[a]

Behavior	Control	*Hogna*			$F_{3,59}$	P
		Small	Medium	Large

Speed (cm/sec)	3.31 a	1.77 b	1.79 b	2.18 b	7.32	0.0003

[a] Different letters indicate significant differences between *Hogna* size treatment groups based on a Tukey post-hoc comparison of means test. F ratios are based on one-way ANOVAs. $N = 15$/treatment.

There was a significant difference in total time spent on each *Hogna* treatment (Table 1). Based on a Tukey *post-hoc* comparison of means, *Pardosa* spent longer periods of time on the medium and large *Hogna* treatments compared to the control. Residence time on the small *Hogna* treatment was intermediate between the control and other *Hogna* size treatments (Table 1). There was no difference in forward locomotion or nonforward locomotion across any size treatment group (Table 1). The total mean distance moved was different, with *Pardosa* traveling shorter distances on the small *Hogna* and medium *Hogna* treatments compared to the control substrate. Distance moved on the large *Hogna* substrate was intermediate between the control and other size treatments (Table 1). Time spent immobile was different on the large *Hogna* treatment compared to the control. Small and medium *Hogna* treatments were intermediate with respect to this behavior (Table 1). Speed of *Pardosa* movement was also measured and compared across treatment groups. Speed was determined by dividing distance moved by time spent in forward locomotion. *Pardosa milvina* moved slower in all *Hogna* size treatments compared to the blank control, but there were no differences in speed across size treatments (Table 1).

To determine if *Pardosa* individuals were responding to quantity of *Hogna* cues, or some qualitative difference in cues based on size, we compared the eight *Hogna* treatment to a blank control and then compared the eight *Hogna* treatment to a treatment of a single medium *Hogna*. *Pardosa milvina* showed a strong and significant reduction in activity in the presence of eight *Hogna* compared to a blank control (Figure 2E). Spiders showed more time immobile and longer residence times on the side with eight *Hogna* compared to the blank control. No other class of behavior differed between pairs. When each behavioral category (nonforward locomotion, forward locomotion, time immobile, residence time, and distance moved) was compared between substrates containing eight small *Hogna* versus a single *Hogna*, there was a significant difference in time spent in nonforward

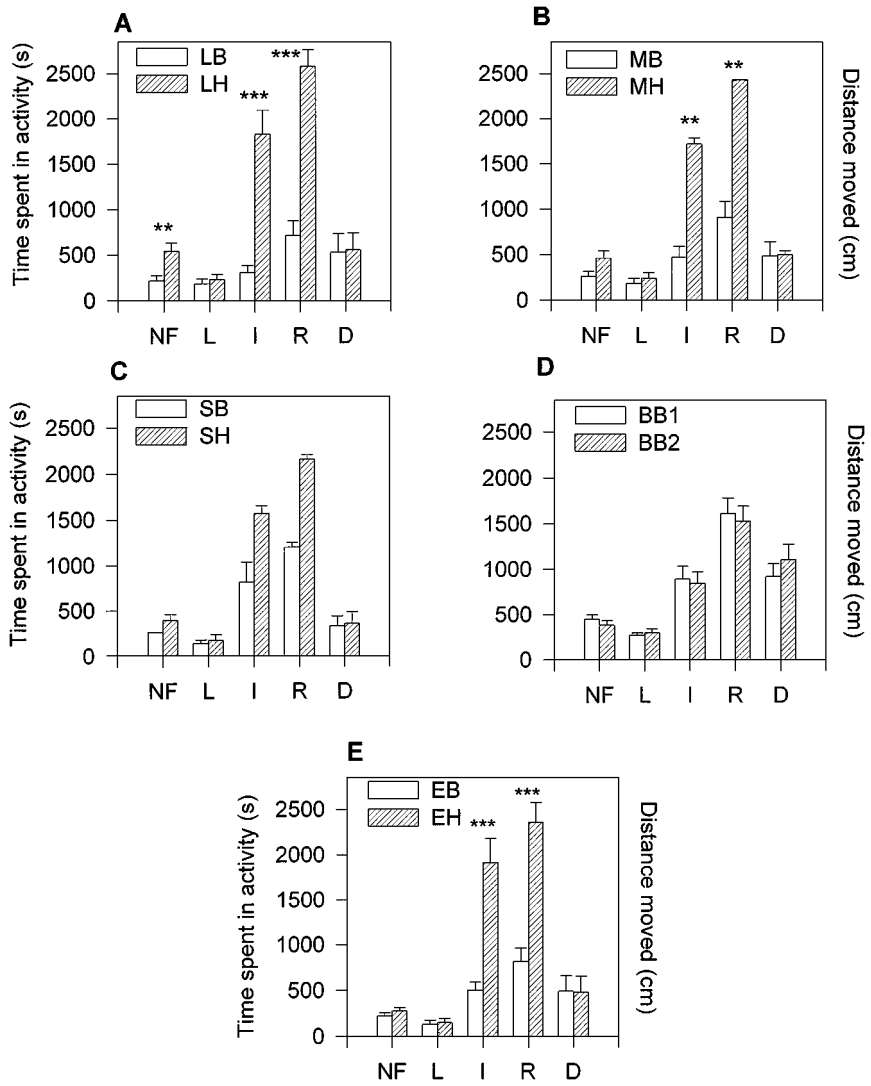

FIG. 2A–E. Comparison of activity level of adult female *Pardosa milvina* exposed to paired treatments of filter paper previously occupied by *Hogna* of different sizes or a blank sheet of paper. Behavioral categories on ordinate are as follows: NF = time spent in nonforward locomotion, L = time spent moving forward (locomote), I = time spent immobile, R = residence time on that substrate, D = distance moved. Distance moved is measured in centimeters and is represented on the same scale as time. All other behaviors are measured in seconds. Results are expressed as means ($N = 15$/treatment) ± SE. Significance levels are based on paired *t* tests for each pair of behaviors denoted as follows: $^{*}<0.05$, $^{**}<0.01$,

TABLE 2. COMPARISON OF MEAN ACTIVITY LEVELS IN SIX CATEGORIES OF *Pardosa* BEHAVIOR FOR EIGHT *Hogna* AND MEDIUM *Hogna* STIMULUS TREATMENTS[a]

Behavior	Eight *Hogna*	Medium *Hogna*	T_{28}	P
Residence time (sec)	2353.9	2431.30	0.24	0.809
Forward locomotion (sec)	151.00	242.33	1.23	0.238
Nonforward movement (sec)	275.27	460.87	2.10	0.045

Speed (cm/sec)	2.32	1.793	1.30	0.203

[a] Results are based on two-sample *t* tests. $N = 15$/treatment.

locomotion (Table 2). Spiders spent more time engaged in nonforward movement in the medium *Hogna* treatment compared to the eight *Hogna* treatment. However, there were no other behavioral differences between the two treatments (Table 2).

Avoidance behavior was found only when *Pardosa* encountered chemical cues from large *Hogna*. When given a choice between a blank sheet of paper and one with cues from an adult female *Hogna*, spiders chose the blank side more often than expected by chance (12 of 15, $\chi^2 = 5.4$, df 14, $P < 0.025$). *Pardosa milvina* showed no initial side preference when given a choice between a blank sheet and *Hogna* cues from medium *Hogna*, small *Hogna*, or eight *Hogna*.

DISCUSSION

In general, *Pardosa* spiders showed reduced activity in the presence of cues from *Hogna* of increasing size. The most commonly modified behavior was time spent immobile. This also explains the counterintuitive response of spiders spending more time on substrates with *Hogna* cues. *Pardosa* tend to become immediately quiescent upon contact with *Hogna* silk and excreta. Spiders also showed a drop in distance moved across *Hogna* size treatments, suggesting it takes much longer for *Pardosa* to leave these substrates than when encountering areas devoid of *Hogna* cues.

$^{***}<0.001$. (A) Chemical cues from large adult female *Hogna* (LH) vs. a blank (LB). (B) Chemical cues from a medium-sized *Hogna* (MH) equal in body mass to the *Pardosa* being tested vs. a blank control (MB). (C) chemical cues from a small *Hogna* (SH) half the body mass of the test spider vs. a blank (SB). (D) a double blank control, B1 and B2. (E) chemical cues from eight small *Hogna* (EH) each ca. one fourth the mass of the *Pardosa* being tested vs. a blank control (EB). Locomotor activity and initial side choice was recorded for each spider.

The overall locomotor behaviors for each *Hogna* size treatment appeared to be qualitatively the same. Although *Pardosa* responses to the small *Hogna* treatment were not significant compared to the control (Figure 2), this appears to be due to a difference in the magnitude of the response. This suggests that variation in the quantity of cue is responsible for variation in *Pardosa* reduction in movement. Moreover, compared to a control sheet, *Pardosa* had a reduction in speed as well as distance moved on the small *Hogna* treatment (Table 1). *Pardosa* exhibited a strong reduction in movement to eight *Hogna*, which appears to be a response equivalent to a medium or large *Hogna*. Since none of the eight small *Hogna* would present a predation threat, these data suggest that it is the quantity of cues that serves as the proximate source of information governing the degree of antipredatory behavior.

Other studies have shown that long periods of immobility greatly increase survival probabilities of *Pardosa* when in the presence of a large *Hogna* (Persons et al., 2001). Reduced locomotion is likely to be adaptive since wolf spider visual systems are strongly biased toward movement rather than shape cues (Rovner, 1996). Wolf spiders are much more likely to lunge at prey that move for longer periods of time (Persons and Uetz, 1997), and reduction in locomotion reduces vibrations generated through the substratum that could also be used by a predatory wolf spider to locate prey (Lizotte and Rovner, 1988).

Pardosa milvina exhibits graded antipredator responses with variation in perceived risk of predation; however, chemical cues alone provide insufficient information for an individual to discriminate between a single large *Hogna* or many smaller individuals. We cannot rule out the possibility that a high density of silk and excreta from large numbers of *Hogna* spiderlings may be an indicator of an adult female *Hogna* nearby. We have found single female *Hogna* capable of producing over 200 offspring (personal observation). The young are carried on the mother's back for a short period of time and then disperse. We believe spiderlings of the same species would rarely occur at densities high enough to produce the amount of kairomone used in this study except immediately after dispersal. It is possible that *Pardosa* could interpret such information as the presence of a large adult female *Hogna* in the area. Without visual, vibratory, or tactile cues to confirm the size of the *Hogna*, *Pardosa* appears to treat any quantity of silk and excreta equal to or greater than that which they produce as a potential predation threat. Nonetheless, *Pardosa* responses to substrates would result in a close match between appropriate antipredator response and the actual risk of predation in most cases. *Pardosa* showed an avoidance response to adult female *Hogna*, the only size class in these treatments that would pose a large potential predation risk. The fact that potential prey apparently can induce significant, albeit lower levels of antipredator behavior, suggests that *Pardosa* weighs the fitness costs of predation more heavily than the loss of a meal. Previous studies have demonstrated that *Pardosa* is unresponsive to silk and excreta from equal-sized conspecifics (Persons et al., 2001), but in this study, *Pardosa* showed

antipredator responses to *Hogna* of equal size. These results suggest that *Pardosa* is capable of discriminating between conspecific and heterospecific silk and excreta.

In general, the results show limited support for two of our three original predictions. Adult female *Pardosa* showed increasing levels of antipredator behavior in the presence of chemical cues from *Hogna* of increasing size. However, *Pardosa* showed significant levels of antipredator behavior in the presence of a *Hogna* equal in size to itself and showed some antipredator behavior, although this was not always statistically significant, in the presence of small *Hogna*. Adult female *Pardosa* appeared to increase antipredator behavior in the presence of increased quantities of chemical cues from *Hogna*, even when those cues were produced from *Hogna* that could be eaten by *Pardosa*. Finally, when given a choice, *Pardosa* tended to avoid substrates previously occupied by a *Hogna* larger than itself, but showed no substrate avoidance if the paper had supported a spider or spiders of equal or smaller size to itself. This indicates that whatever the mechanism, *Pardosa* generally demonstrates antipredator responses appropriate to the degree of predation risk.

Abstract—Interactions between insects and glucosinolate-containing plant species have been investigated for a long time. Although the glucosinolate–myrosinase system is believed to act as a defense mechanism against generalist herbivores and fungi, several specialist insects use these secondary metabolites for host plant finding and acceptance and can handle them physiologically. However, sequestration of glucosinolates in specialist herbivores has been less well studied. Larvae of the turnip sawfly *Athalia rosae* feed on several glucosinolate-containing plant species. When larvae are disturbed by antagonists, they release one or more small droplets of hemolymph from their integument. This "reflex bleeding" is used as a defense mechanism. Specific glucosinolate analysis, by conversion to desulfoglucosinolates and analysis of these by high-performance liquid chromatography coupled to diode array UV spectroscopy and mass spectrometry, revealed that larvae incorporate and concentrate the plant's characteristic glucosinolates from their hosts. Extracts of larvae that were reared on *Sinapis alba* contained sinalbin, even when the larvae were first starved for 22 hr and, thus, had empty guts. Hemolymph was analyzed from larvae that were reared on either *S. alba*, *Brassica nigra*, or *Barbarea stricta*. Leaves were analyzed from the same plants the larvae had fed on. Sinalbin (from *S. alba*), sinigrin (*B. nigra*), or glucobarbarin and glucobrassicin (*B. stricta*) were present in leaves in concentrations less than

1 μmol/g fresh weight, while the same glucosinolates could be detected in the larvae's hemolymph in concentrations between 10 and 31 μmol/g fresh weight, except that glucobrassicin was present only as a trace. In larval feces, only trace amounts of glucosinolates (sinalbin and sinigrin) could be detected. The glucosinolates were likewise found in freshly emerged adults, showing that the sequestered phytochemicals were transferred through the pupal stage.

Key Words—*Athalia rosae*, sawfly, Hymenoptera, *Sinapis alba*, *Barbarea stricta*, *Brassica nigra*, Brassicaceae, glucosinolates, hemolymph, sequestration.

INTRODUCTION

Defensive secondary metabolites of plants can be utilized by herbivorous insects when they are adapted to them. Such specialists take up certain host plant compounds and concentrate them in particular tissues or organs (Duffey, 1980). Such sequestration of toxic compounds can contribute to making the herbivores themselves unpalatable for members of the third trophic level (Duffey, 1980; Trigo, 2000). Sequestered compounds include alkaloids (Rothschild and Edgar, 1978; Dobler et al., 2000; Abe et al., 2001), cardenolides (Brower and Fink, 1985; Scudder et al., 1986; Carroll et al., 1997; Dobler et al., 1998), and flavonoids (Blum, 1981; Schittko et al., 1999). Most of the insects where sequestration has been demonstrated belong to the Lepidoptera, Coleoptera, or Heteroptera (Duffey, 1980, and references given above).

Glucosinolates are secondary metabolites with a restricted taxonomic distribution (Rodman et al., 1998; Halkier, 1999; Fahey et al., 2001) that form a binary defense system with the glucosinolate-hydrolyzing enzyme myrosinase (Rask et al., 2000). Although the glucosinolate–myrosinase system is believed to be involved in plant resistance to generalist herbivores (Louda and Mole, 1991; Li et al., 2000; Potter et al., 2000) and fungi (e.g., Manici et al., 1997), several specialist insects are not repelled by these phytochemicals (Nielsen et al., 2001, and references therein). To the contrary, glucosinolates and their hydrolysis products, such as volatile isothiocyanates (mustard oils), thiocyanates, nitriles, and others (Chew, 1988a), are involved in host plant finding and acceptance (Nielsen, 1988; Chew, 1988a,b; Louda and Mole, 1991). Even high levels of glucosinolates can apparently be physiologically handled by such specialist insects (e.g., Li et al., 2000; Agerbirk et al., 2001a).

Sequestration of glucosinolates and isothiocyanates has been investigated in two butterfly species; the glucosinolate sinigrin (allylglucosinolate) and allyl isothiocyanate could be detected in whole pupae of *Pieris brassicae* L. and *P. rapae* L. (Lepidoptera: Pieridae) (Aplin et al., 1975). Allyl isothiocyanate was detected in whole-body extracts of larvae and adults of *P. brassicae* (Aplin et al., 1975). However, the glucosinolate detection by Aplin et al. (1975) in *Pieris*

pupae may not be reproducable: none could be detected by the desulfoglucosinolate method in extracts of *P. rapae* pupae whose larvae had fed on cabbage (J. A. A. Renwick, personal communication). Furthermore, it is surprising that Aplin et al. (1975) apparently detected sinigrin as the only glucosinolate in cabbage, while a complex mixture of glucosinolates is normally found in this plant (e.g., Sang et al., 1984; Renwick et al., 1992; Mithen et al., 2000). Since the methods used by Aplin et al. (1975) are now outdated, the report of sequestration of sinigrin (and perhaps also allyl isothiocyanate) in *Pieris* sp. probably needs confirmation with modern analytical methods.

Larvae of the sawfly *Athalia rosae ruficornis* Jakovlev (Hymenoptera: Tenthredinidae, Allantinae) feed on different glucosinolate-containing plant species, such as the Brassicaceae *Armoracia rusticana*, *Barbarea* spp., *Brassica* spp., *Rorippa amphibia, Sinapis alba, Sisymbrium officinale,* and the Tropaeolaceae *Tropaeolum majus* (Liston, 1995). The integument of *A. rosae* larvae is readily disrupted when touched by predators. Droplets of hemolymph are released (Figure 1) that are unpalatable to different antagonists (Ohara et al., 1993; Schaffner et al., 1994). In this study, we investigated whether *A. rosae* takes up glucosinolates from its different host plants, whether these are sequestered in the defensive hemolymph, and whether they are transferred into the adult lifestage.

METHODS AND MATERIALS

Plants. Plants of *Sinapis alba* L. (cultivar: Salvo, seeds from Advanta Seeds B.V., Netherlands), *Brassica nigra* (L.) Koch, and *Barbarea stricta* Andrz. (seeds

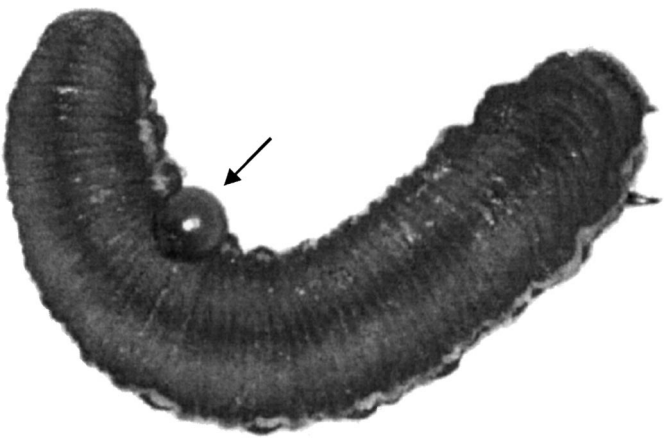

FIG. 1. Larva of *Athalia rosae*, showing a droplet of hemolymph after being touched (length of larva: 1.2 cm).

obtained as described in Agerbirk et al. 2001b) were grown in a greenhouse (20°C, 70% relative humidity, 16L:8D). Four- to 5-week-old, preflowering plants were used.

Insects. Cocoons of *Athalia rosae* were obtained from a colony descending from adults collected in the Rhine Valley, Germany, in September 2000. Insects were reared on whole plants of *S. alba* at 20°C, 70% relative humidity, and 16L:8D in the Leiden laboratory. Five fourth-instar larvae (two samples) were taken from the plants and frozen at −80°C. Five additional fourth-instar larvae (two samples) were starved for 22 hr in clean Petri dishes to empty their guts and then frozen. Hemolymph was collected from living fourth- and fifth-instar larvae by piercing the integument carefully with a needle at the middle of the abdomen without damaging the gut. Exuding hemolymph was collected with glass capillaries in 2-ml volume glass vials, weighed, and immediately frozen. Initially, hemolymph was collected from up to 20 larvae, but later samples were collected from smaller numbers. Feces (30–100 mg fresh weight) were collected by placing fourth- and fifth-instar larvae on clean filter paper in Petri dishes without plant material, and then frozen. Five female and five male adults (two samples each) were frozen directly after emergence from pupae. Pupal time lasted 13–16 days.

In addition, second-instar larvae (mean weight: 3.5 mg) that had emerged from leaves of *S. alba* were transferred to leaves of either *B. nigra* or *B. stricta*. When the larvae reached their fourth instar (mean weight: 45 mg), feces and hemolymph were collected as described above. Leaf samples (50–100 mg fresh weight) from all three species were picked from the same plants the larvae had eaten on. All samples were weighed fresh, frozen at −80°C, and freeze dried for 24 hr.

Glucosinolate Extraction and Analysis. Glucosinolates were extracted in boiling aqueous 70% methanol with benzylglucosinolate as internal standard, converted to desulfoglucosinolates, and analyzed by HPLC as described elsewhere (Agerbirk et al., 2001a), except that the detection wavelength was 226 nm (bandwidth 4 nm) because a published relative response factor for sinalbin was available at this wavelength. The relative response factors reported by McGregor (1985), as cited by Buchner (1987), were used for sinalbin (*p*-hydroxybenzylglucosinolate) (0.50), sinigrin (allylglucosinolate) (1.00), glucobrassicin (indolyl-3-methylglucosinolate) (0.26), and benzylglucosinolate (0.86). Glucobarbarin [(*S*)-2-hydroxy-2-phenylethylglucosinolate] was assumed to have the same response factor as benzylglucosinolate since the chromophores in these two analytes are identical. The internal standard and reference compounds were obtained as previously described (Agerbirk et al., 2001a,b; Nielsen et al., 2001).

The identity of the major glucosinolates sinalbin, sinigrin, glucobarbarin, and glucobrassicin was confirmed by comparison of HPLC retention time and diode array UV spectrum with authentic reference compounds and by analysis of hemolymph-derived desulfoglucosinolate samples by HPLC in conjunction with mass spectrometry (LC-MS) (Table 1). LC-MS was done on an HP1100 LC

TABLE 1. STRUCTURES AND ANALYTICAL DATA CONFIRMING IDENTITY OF GLUCOSINOLATES IN LEAVES OF *Sinapis alba*, *Brassica nigra*, AND *Barbarea stricta* AND IN HEMOLYMPH OF *Athalia rosae*[a]

		Desulfoglucosinolates		
Trivial name	Structure	HPLC R_t (min)	UV spectral data (λ_{max}, nm)	Molecular ion $[M+Na]^+$ (a.m.u.)
Sinalbin		17.6	224 276	368
Sinigrin		9.5	225	302

Glucobrassicin		28.4	219 273 (sh) 280 288 (sh)	(Not determined)

[a]HPLC retention times (R_t) and diode array UV spectral data were identical to values for authentic compounds. The molecular mass of $[M+Na]^+$ was measured by HPLC-MS and confirmed the identifications. sh – shoulder.

coupled to a Bruker Esquire-LC ion trap mass spectrometer. For reversed-phase LC, a C_{18} column (Chrompack Inertsil 3 ODS-3 S15 × 3 COL CP 29126) was used. The mobile phase was water doped with sodium acetate (50 M) (A), and methanol (B), running with a flow rate of 0.25 ml/min in the following gradient: 0–2 min isocratic 100% A; 2–40 min linear gradient 0–60% B; 40–45 min linear gradient 60–100% B, and 45–50 min isocratic 100% B. The mass spectrometer was run in positive ion mode, and $[M+Na]^+$ adduct ions were observed exclusively.

RESULTS

The dominant glucosinolate in leaves of *S. alba* was sinalbin (Table 1), which was found in a concentration of 0.1–0.3 μmol/g fresh weight. Other glucosinolates that are described for seeds and leaves of *S. alba* (Fahey et al., 2001) were not detected. Sinalbin was found in fed larvae of *A. rosae* in about eightfold higher concentration per gram fresh weight compared to leaf material. The glucosinolate was present in starved larvae at a similar concentration, confirming that the high concentration in fed larvae was not largely derived from gut contents. The glucosinolate was sequestered in the larvae's hemolymph, where high concentrations of sinalbin (about 10 μmol/g fresh weight) were found (Table 2). In larval hemolymph and adults reared on *S. alba*, varying amounts (0.1–0.4 μmol/g fresh weight, calculated as sinigrin) of an unidentified peak (possibly 1-methylpropylglucosinolate) with a retention time close to sinigrin were also observed (results not shown). In larval feces, only trace amounts of glucosinolates were detected. Sinalbin was likewise present in freshly emerged adults of *A. rosae*, in females as well as in males (Table 2).

Sinigrin (Table 1) was detected in *B. nigra* leaves, and glucobarbarin (Table 1) in *B. stricta* leaves. Larvae switched at second instar to either of these species, also sequestered sinigrin and glucobarbarin, respectively. While the concentration of glucosinolates was below 1 μmol/g fresh weight in the leaf material, they were found in concentrations between around 12 and 31 μmol/g fresh weight in the hemolymph of larvae fed *B. stricta* or *B. nigra* (Table 2). However, a further prominent glucosinolate in the leaves of *B. stricta*, glucobrassicin, was apparently not sequestered in proportion to its concentration in the leaf tissue (Table 2). Only trace amounts or no glucosinolates were detected in larval feces (Table 2).

Sinalbin could not be detected in hemolymph of larvae that were originally transferred from *S. alba* to *B. nigra* or *B. stricta*, suggesting that any sinalbin sequestered during the short time the larvae fed on *S. alba* was either metabolized or diluted below the detection level by their growth. A sequestration might also happen only in later instars. Neither sinigrin, glucobarbarin, nor glucobrassicin was detected in hemolymph of larvae that had fed exclusively on *S. alba*.

TABLE 2. CONCENTRATIONS OF GLUCOSINOLATES, SINALBIN, SINIGRIN, GLUCOBARBARIN, AND GLUCOBRASSICIN, DETECTED IN SAMPLES OF LEAVES OF *Sinapis alba*, *Brassica nigra*, AND *Barbarea stricta*, AND IN SAWFLY *Athalia rosae* REARED ON DIFFERENT HOST PLANTS[a]

Host plant	Sample	Concentration (mean ± SD, μmol/g fresh weight)				Sample no.

	larval feces	n.d.	n.d.	n.d.	n.d.	2

[a] Eggs were laid in *S. alba*, and emerging larvae partly transferred on other host plants as second instars. Starvation of larvae occurred for 22 hr. n.d.—not detected.

DISCUSSION

Larvae of the sawfly species *A. rosae* are able to take up glucosinolates from their host plants and concentrate them effectively in the hemolymph. The glucosinolates are apparently not biosynthesized *de novo* by larvae, since only those particular ones present in the hemolymph were also found in the respective host plant species the larvae had fed on.

Sequestration of plant defensive compounds in different organs has been shown previously in other sawfly species (Codella and Raffa, 1993). Species of the Diprionidae and Pergidae sequester volatile terpenoids from *Pinus* or *Eucalyptus* leaves in larval pouches of the foregut (Prop, 1960; Eisner et al., 1974; Morrow et al., 1976) and regurgitate them when disturbed. The Tenthredinidae *Tenthredo grandis* (Norton) sequesters iridoid glucosides from *Chelone glabra* L. (Bowers et al., 1993); however, the sequestering organ has not been studied. A sequestration in *Salix*-feeding species was suggested by Sevastopulo (1958). In the sawfly *Rhadinoceraea nodicornis* Konow (Blennocampinae), steroid alkaloids from the host plant *Veratrum* spp. (Melanthiaceae) are metabolized and sequestered also in the hemolymph (Schaffner et al., 1994).

Besides *R. nodicornis* and *A. rosae*, several other sawfly species of the subfamilies Blennocampinae and Selandriinae exhibit reflex bleeding when disturbed by predators. Droplets of hemolymph are readily released upon wounding (Heads and Lawton, 1985; Heads, 1986; Schaffner et al., 1994). This phenomenon is often linked to sequestration of toxic plant compounds.

The larval hemolymph of some sawfly species has a high feeding deterrent effect on ants, spiders, and birds (Ohara et al., 1993; Schaffner et al., 1994; Schaffner and Boevé, 1996). Hemolymph of *A. rosae* deterred drinking of the ant *Myrmica rubra* L. (Hymenoptera, Formicidae) even when diluted 10-fold (Schaffner et al., 1994). However, in different sawfly species, different classes of chemicals result in deterrent effects on predators. In *A. rosae*, it remains to be confirmed whether glucosinolates are responsible for the defensive activity of the hemolymph.

Sequestration of plant compounds requires several physiological adaptations (Duffey, 1980; Bowers, 1992). First, the insect must have a specific uptake mechanism. The way glucosinolates pass through the gut wall and are stored in the hemolymph is not known. However, their high concentration in the hemolymph relative to the food source suggests that an active transport mechanism exists. The hypothetical uptake mechanism seems to be nonspecific with respect to the structure of the side chain, since different structural types of glucosinolates were sequestered. Interestingly, the minor amounts of glucobrassicin in hemolymph from *B. nigra*-reared larvae (Table 2) suggests that not all glucosinolates are sequestered with the same efficiency. Second, the insects need to be protected from self-poisoning. Glucosinolates and their hydrolysis products have a deterrent, toxic, or antinutritional effect on most organisms (Louda and Moule, 1991; Potter et al., 2000; Fahey et al., 2001).

Many herbivorous insects excrete toxic plant compounds unchanged with their feces, a physiological process known as the pharmacokinetic strategy (Isman, 1992). Nicotine is, for example, for the most part excreted by the tobacco hornworm *Manduca sexta* (L.) (Lepidoptera: Noctuidae) (Murray et al., 1994). Other toxic compounds are detoxified by specific enzymes in feeding specialists (Witthohn and Naumann, 1987; Kunze et al., 1996) or by mixed function oxidases in generalists (Hodgson and Rose, 1991; Brattsten, 1992). Only trace amounts of glucosinolates were detectable in the feces of *A. rosae* larvae. Either they are almost completely absorbed by the gut wall or a certain amount is hydrolyzed or otherwise degraded while passing through the gut (e.g., Mithen et al., 2000).

With regard to different developmental stages, glucosinolates sequestered by *A. rosae* larvae were apparently passed unchanged, and in similar concentrations, into the adult life stage (Table 2). Since *A. rosae* eggs are laid in the leaf tissue, they were not studied for the presence of glucosinolates.

Female as well as male adults of *A. rosae* are also known to sequester bitter tasting clerodendrines from *Clerodendron trichotomum* (Verbenaceae) in body

tissue (Nishida and Fukami, 1990). These clerodendrines are deterrent to several predators, such as lizards and sparrows (Nishida and Fukami, 1990), and are probably deposited in the insect cuticle (Amano et al., 1999). They also play an important role in the mating behavior of this species (Amano et al., 1999).

In this study, we analyzed only the glucosinolates, but other secondary compounds of the Brassicaceae might also be sequestered, for example, proto- or pseudoalkaloids such as sinapin from *S. alba*, phenolics (e.g., quercetin, rutin), or glucosinolate hydrolysis products. Future studies will show whether the sequestration of glucosinolates is indeed effective against different predators, whether host plant chemistry is important in larval survival, and whether other bioactive compounds are present in the hemolymph.

Acknowledgments—J. K. Nielsen is acknowledged for making the HPLC equipment available for our studies. We thank H. O. Frandsen, I. Mahad, and H. de Vos for technical assistance; A. Barker (Switzerland) for providing us with the first *A. rosae* individuals to start a stock; and E. Schlatmann and coworkers for cultivating the different crucifers. This research was funded by the European Commission and is part of the Research Training Network project INCHECO (Human Potential Program, HPRN-CT-1999-00054).

(Received March 10, 2001; accepted August 1, 2001)

Abstract—An ethanolic extract of red maple (*Acer rubrum* L.) leaves (RME) applied to trembling aspen (*Populus tremuloides* Michx.) leaves reduced feeding in choice test assays with forest tent caterpillar larvae (*Malacosoma disstria* Hbn.) (FTC), whereas a trembling aspen foliage extract, similarly applied, stimulated feeding. Compounds isolated from the RME were gallic acid, methyl gallate, ethyl gallate, *m*-digallate, ethyl *m*-digallate, 1-*O*-galloyl-β-D-glucose, 1-*O*-galloyl-α-L-rhamnose, kaempferol 3-*O*-β-D-glucoside, kaempferol 3-*O*-β-D-galactoside, kaempferol 3-*O*-β-L-rhamnoside, kaempferol-3-*O*-rhamnoglucoside, quercetin 3-*O*-β-D-glucoside, quercetin 3-*O*-β-L-rhamnoside and quercetin 3-*O*-rhamnoglucoside, (−)-epicatechin, (+)-catechin and ellagic acid. All of the gallates, (−)-epicatechin, and kaempferol 3-*O*-β-L-rhamnoside deterred feeding on trembling aspen leaf disks when applied at 0.28 mg/cm^2. The two digallates deterred feeding by 90% and were the most effective. HPLC analysis indicated that ethyl *m*-digallate is present in amounts 10–100 × higher in RME (∼2.5–250 mg/g) than any other compound. Thus, ethyl *m*-digallate appears to be the major compound protecting red maple from feeding by FTC, with a minor contribution from other gallates.

INTRODUCTION

Hardwood forests are endangered by severe defoliation caused by insects. The forest tent caterpillar (FTC) (*Malacosoma disstria* Hubner) is a major pest of Canadian deciduous forests feeding mainly on poplar (*Populus* spp.), particularly trembling aspen (*P. tremuloides* Michx.). It also defoliates other species, including sugar maple (*Acer saccharum* Marsh) (Howse, 1995; Nicol et al., 1997). Red maple (*A. rubrum* L.), another prominent maple occupying a similar range (Farrar, 1995), is seldom attacked by FTC. Beavers (*Castor canadensis*) also have been reported to avoid red maple trees (Müller-Schwarze et al., 1994). Except for a 13% higher content of polyphenols in red maple (Ricklefs and Matthews, 1982), leaves do not exhibit major differences in characteristics, e.g., toughness, sugar content, water content, or nitrogen content, from those of sugar maple. Among polyphenols, tannins are considered as the major defense compounds in tree leaves, but since red and sugar maple leaves contain similar amounts of these complex molecules (Bate-Smith, 1978), some other constituent(s) must provide red maple leaves with a deterrent to feeding by FTC. In the present study, the constituents of an aqueous ethanolic extract of red maple leaves were isolated, identified, and then tested in leaf disk feeding assays in order to determine the phytochemical basis of insect resistance in red maple leaves.

METHODS AND MATERIALS

Plant Material. Red maple leaves were collected in June 1992 from 10 mature trees in Sault Ste. Marie, Ontario, Canada (lat. 46.34N, long. 84.17W). Leaves of trembling aspen were collected locally (Sault Ste. Marie) or grown in the greenhouse as needed for feeding tests. Pressed voucher specimens are deposited in the Canadian Forest Service-Sault Ste. Marie herbarium as *Acer rubrum* L. (CFS-SSM #s 1001–1010), family Aceraceae and trembling aspen (*Populus tremuloides* Michx.) (CFS-SSM #s 1255–1265), family Salicaceae.

Extraction. Fresh red maple leaves (2 kg fresh wt) were extracted at room temperature. First, leaves were steeped for 24 hr in 100% EtOH (1 g fresh wt/10 ml solvent), followed by chopping in a commercial Waring blender, and decanting the solvent. Next, the chopped residue was steeped for an additional 24 hr in 50% aqueous EtOH (10 g fresh wt/100 ml solvent). The combined ethanolic extracts (RME) were evaporated under reduced pressure until most or all of the EtOH had been removed. The residue was freeze-dried to obtain 242 g of crude extract (RME). Thus, from each gram fresh weight of leaves, 121 mg of RME was obtained. Fresh aspen leaf material (2 kg fresh wt) was similarly extracted to yield 204 g residue.

Fractionation. RME (100 g) was adsorbed onto 200 g of polyvinylpolypyrrolidone (PVPP) powder (Sigma Chem. Co., St. Louis, Missouri) preconditioned by

soaking in distilled water for 24 hr and packed in a Buchner funnel (4 liters). Elution was carried out at a slow rate using 5 liters of water followed by 5 liters aliquots of increasing concentrations (20, 50, 70, 100%) of ethanol. All five fractions were tested for antifeedant activity (data not shown) with maximum activity found in the fraction eluting with 50% ethanol, henceforth referred to as the phenolic fraction (RMP). The active fraction was concentrated under vacuum and chromatographed on Whatman No.1 chromatography paper (PC) using either BAW (*n*-butanol–acetic acid–water, 4:1:5, upper phase), water, or acetic acid–water (15:85) to isolate the pure compounds. Further fractionation was carried out on a PVPP column (7 × 120 cm ID.) using the following solvent systems: (i) CH_2Cl_2–EtOH–MeCOEt–Me_2CO (1:1:1:1), (ii) EtOH–MeCOEt–Me_2CO–H_2O (1:1:1:1), and (iii) EtOH–H_2O (1:1). Purification was achieved on a Chemco low-prep pump (model 9 1-M-8R), and fractions were tested for purity by HPLC.

HPLC. A Waters Delta Prep 4000 liquid chromatograph was used equipped with a computer and Millennium 2010 software, an autoscan photodiode array detector (Waters 996), and a Waters Nova-Pak C_{18} reverse-phase analytical column (4 μm, 60 Å, 3.9 × 150 mm ID). A modified gradient chromatographic technique (van Sumere et al., 1993) was used at room temperature: solvent A = MeOH; B = 5% aq. HCOOH; and a flow rate of 0.9 ml/min. Two fixed detection wavelengths were used, 280 nm and 350 nm, and resolved peaks were scanned from 250 to 400 nm by the photodiode array detector.

Identification of Isolated Compounds. UV spectra were recorded on a UV-Vis Beckman DU series 640 spectrophotometer. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AMX-500 spectrometer, at 500 MHz and 125 MHz, respectively; samples were dissolved in DMSO-d_6 with TMS as an internal standard. Structures of purified compounds were determined by comparison with authentic samples where available using standard methods (Harborne, 1994; Markham, 1982): acid hydrolysis in 2 M and 0.1 M HCl (mild hydrolysis) at 100°C for 60 min, enzymatic hydrolysis with β-glucosidase (Sigma) using an acetate buffer (pH 5), hydrogen peroxide oxidation, UV spectroscopy, ^{1}H NMR, ^{13}C NMR, and FAB-mass spectroscopy (positive and negative). The glycosides and aglycones obtained from hydrolysis of isolated compounds were identified by cochromatography with authentic samples (Aapin and Extrasynthese) using PC, TLC, and HPLC. Sugars released by hydrolysis were identified by PC and TLC using standards. Standard gallic acid and gallate derivatives were kindly provided by Profs. G. Gross, Universtät Ulm, Ulm, Germany, and T. Yoshida, Okayama University, Okayama, Japan.

Quantitative and Qualitative Analysis. A dilute solution (10 mg/ml) of RME or RMP was filtered and 10 μl was injected onto an HPLC column (van Sumere et al., 1993) with and without spiking with standards. Peaks were identified on the basis of retention times and UV spectra. Peak heights, measured at 280 nm, were converted to milligrams per milliliter using conversion factors obtained

for standards (Slacanin et al., 1991). Such HPLC analyses were performed in triplicate.

Insect Material. Egg bands of forest tent caterpillar, *Malacosoma disstria* Hubner, Lepidoptera, Lasiocampidae (FTC) were collected from trembling aspen trees from Cochrane and Thunder Bay, Ontario, Canada. Eggs were stored at 2°C for at least 13 weeks. Larvae were reared to the required stage on artificial diet (Addy, 1969; Singh and Moore, 1985) in environmental chambers (21°C, 80% relative humidity, and 16L:8D).

Leaf Disk Assays. Leaf disks (2-cm diam.) were cut with a #13 cork borer from freshly collected leaves and placed into a 9-cm-diam. plastic Petri plate (two disks of each species in alternating positions) to compare feeding on red maple and trembling aspen leaves. The disks were pinned in place through small holes in the bottom of the plate. Five newly molted fourth-instar larvae were placed into each of seven replicate plates. After 24 hr, the leaf disks were photocopied and the percentage of each disk remaining was determined with an Image Analyser (Artek, Image Editor and Video Memory, model 940). The antifeedant index (AI) for each plate was calculated as $\%AI = (C - T)/(C + T) \times 100$ where C is the percentage of two control disks eaten, and T is the percentage of two treated disks eaten (Blaney et al., 1994).

A second choice leaf disk assay method was used to determine the feeding deterrency of red maple and aspen leaf extracts applied to aspen leaf disks in side by side comparisons. Four, 1.5-cm-diam. disks from greenhouse-grown trembling aspen leaves were placed into a 9-cm-diam. plastic Petri plate and pinned in place. The upper surfaces of two opposite disks were each treated with four applications of 12.5 μl of 5% solutions (acetone–water, 80:20) of the extracts for a total of 2.5 mg of each crude extract. The other two disks were treated with solvent only. Five fourth-instar larvae were placed in each of 12 replicate plates for each extract. The percentage of foliage eaten was estimated visually until 35–65% of the disks in a dish were consumed. The AI was then calculated as above. The RMP extract (13 replicate plates) was also tested separately in the same fashion.

Feeding deterrency of individual compounds found in the RME extract, either available commercially or purified from the extract, was determined with the second leaf disk assay method. An equal mass (0.5 mg) of each compound was similarly applied to individual aspen leaf disks. Six to 29 replicate plates in at least duplicate tests were used for each compound. Methyl gallate was tested in 116 replicate plates as a regular standard.

Statistical analysis using appropriate parametric or nonparametric procedures was undertaken with GraphPAD InSTAT software (GraphPad, San Diego, California) or SigmaStat Statistical Software, Version 2 (SPSS Inc., Chicago, Illinois).

TABLE 1. HPLC ANALYSIS OF CRUDE RED MAPLE LEAF EXTRACT (RME) AND PHENOLIC FRACTION FROM RED MAPLE LEAF EXTRACT (RMP) ELUTED FROM PVPP WITH 50% ETHANOL–WATER

Compound	mg/g dried extract	
	RME	RMP
1-*O*-galloyl-β-D-glucose[a]	10.3	5.4

Kaempferol (galloyl?)rhamnnoside[b]	3.0	3.0

[a] Compounds isolated from red maple leaf extract and used in Table 3.
[b] The tentatively identified acylated kaempferol rutinoside and rhamnoside were most probably hydrolysed to the free glycosides during the prolonged separation and isolation steps.

RESULTS AND DISCUSSION

Identification of Isolated Compounds. Seventeen compounds were isolated and identified from *Acer rubrum* L. including the 14 listed in Table 1 and an additional three, (−)-epicatechin, (+)-catechin and ellagic acid (listed in Table 3 below). Structures (Figure 1) were established using standard procedures as described in Methods and Materials (Harborne, 1994; Markham, 1982). UV spectra, ^{1}H NMR, ^{13}C NMR, and MS were identical with standards.

Quantitative and Qualitative Analysis. The depside ethyl *m*-digallate, present at 248.5 mg/g is the predominant compound in both RME and RMP extracts (Table 1). Gallic acid is an important constituent of red maple leaf extracts (24.5 mg/g) as are 1-*O*-galloyl-β-D-glucose (10.3 mg/g), 1-*O*-galloyl-α-L-rhamnose (30.2 mg/g) and *m*-digallate (24.5 mg/g). By contrast, methyl gallate and ethyl gallate are present in RME in relatively low amounts (2.5 mg/g and 2 mg/g; respectively).

FIG. 1. Structures of some of the phenolic compounds that have been isolated from ethanolic extracts of red maple (*Acer rubrum* L.) leaves.

The presence in maple leaves of gallic acid, its esters, and glycosides was previously examined by Haslam (1965), but the identification of 1-*O*-galloyl-α-L-rhamnose is a recent discovery (Abou-Zaid and Nozzolillo, 1999). Bailey et al. (1986) isolated methyl gallate from methanolic extracts of silver maple leaves (*A. saccharinum* L.), but this constitutes the first report of its presence in red maple leaves (Table 1). Haddock et al. (1982) pointed out the significance of the depside as a hydrolyzable tannin component of red maple and related species, but this is the first report of its presence as a free compound.

Ellagic acid, (+)-catechin, and (−)-epicatechin were not detectable in the HPLC traces, but small amounts of each were present in red maple extract. Several flavonol peaks also were present, of which seven were isolated and identified. Delendick (1990) identified the three quercetin glycosides, but only one of the four kaempferol glycosides. Only quercetin 3-*O*-β-L-rhamnoside was present in excess of 10 mg/g of extract (Table 1). However, there was an estimated 28 mg/g of the putative kaempferol galloyl rhamnoglucoside in leaf extracts that was most probably hydrolyzed during the lengthy isolation procedure and purified as kaempferol 3-*O*-rhamnoglucoside.

Antifeedant Tests. Red maple leaf disks strongly deterred feeding by FTC larvae. In the choice test employed, 100% of aspen leaf disks were eaten in contrast to only 3.3 ± 6.9% of red maple leaf disks after 24 hr, giving an AI of 94.3% ($N = 7$). This result confirms the field observation by Nicol et al. (1997) that red maple is not a preferred host of FTC.

RME applied to aspen leaf disks at 1.4 mg/cm^2 deterred feeding, yielding an AI of 56.2% (Table 2). In contrast, feeding was stimulated by crude aspen leaf extract (Table 2). These findings suggest that the resistance of red maple to feeding by FTC larvae is due to specific phytochemicals present in the leaves of this species. Since the RMP fraction contains higher levels of phenolic compounds and had an

AE	1.4	12	-54.4 ± 23.5^{s}
Experiment 2			
RMP	1.4	13	$+88.1 \pm 16.3^{s}$

[a] + = antifeedant; − = phagostimulant. Wilcoxon's one-tailed test (H_1; $\mu > 0$), differences from untreated (control) aspen leaf disks indicated as s = significant ($P < 0.05$) or ns = not significant, ($P > 0.05$).

AI of 88.1% (Table 2), we suggest that these compounds might be responsible for the antifeedant activity of this fraction.

Previously reported choice tests with six commercially available phenolic compounds present in red maple also demonstrated that gallic acid and methyl gallate were feeding deterrents at 0.28 mg/cm^2 (Abou-Zaid et al., 2000b). When the full range of 14 phenolic compounds identified in red maple leaf extract was tested at 0.28 mg/cm^2 in the present study, all the gallates (gallic acid, methyl gallate, ethyl gallate, *m*-digallate, ethyl *m*-digallate, 1-*O*-galloyl-β-D-glucose, and 1-*O*-galloyl-α-L-rhamnose) showed antifeedant activity (Table 3). However, ethyl *m*-digallate and *m*-digallate were clearly the most inhibitory to feeding, with AIs of about 90% (Table 3). Only ethyl *m*-digallate was the predominant compound in both RME and RMP. Neither compound is present in sugar maple leaves (Abou-Zaid et al., 2000a). The amount of ethyl *m*-digallate in RME and RMP applied to the leaf disks in Table 2 was 0.36 and 0.42 mg/cm^2, respectively, as compared to 0.28 mg/cm^2 of the pure compound in Table 3. Only RMP inhibited feeding to the same extent as the digallate. Other compounds in RME may act as stimulants to reduce insect feeding deterrence since this extract inhibited feeding by only

[a] + = antifeedant; − = phagostimulant. Wilcoxon's one-tailed test (H_1; $\mu > 0$), differences from untreated (control) aspen leaf disks indicated as s = significant, ($P < 0.05$) or ns = not significant, ($P > 0.05$).
[b] Used as a standard for all tests.

56%. These include the flavonol glycosides that stimulated feeding in tests with the pure compounds (Table 3). A crude extract such as RME also contains free sugars, amino acids, and other soluble metabolites that are not present in RMP and may stimulate feeding. Further evidence of the potential importance of such metabolites to feeding activity is provided by the test with aspen leaf extract (Table 2), which stimulated feeding in contrast to the inhibitory effect of a similar amount of RME.

Of the two building blocks of proanthocyanidins, (+)-catechin and (−)-epicatechin, only the latter elicited inhibitory activity similar to gallic acid. Only kaempferol 3-*O*-β-L-rhamnoside showed an antifeedant effect of the six flavonols tested (Table 3).

Expression of the concentrations of the compounds in molar amounts (Table 3) makes it possible for direct comparison of biological activity. For gallic acid and its esters, biological activity would be lower than that recorded on a milligram basis. By the same token, kaempferol 3-*O*-β-L-rhamnoside is a more effective antifeedant than the AI value of 29.2 would indicate.

In conclusion, FTC are deterred by gallates. The five most active compounds in red maple all possess the galloyl moiety, suggesting that this structure may constitute the basis for the feeding deterrence of these compounds and that the functional groups attached to this basic structure may influence the level of deterrency. Of all the gallates, ethyl *m*-digallate has both the highest antifeedant activity and concentration in red maple, suggesting it is the major resistance factor.

(Received October 24, 2000; accepted August 8, 2001)

Abstract—The concentration of hydroxamic acids increased in wheat seedlings exposed to methyl jasmonate. The proteins isolated from such seedlings inhibited trypsin activity. Free-moving aphids avoided plants that had been exposed to methyl jasmonate prior to the experiment. These aphids were able to reject such plants within 15 min, and the inclination to stay on control plants lasted at least 24 hr. Electronic recording (EPG) of aphid stylet activities showed a trend towards reduction in penetration time and total time of phloem sap ingestion on jasmonate–treated plants. However, the duration of the first period of feeding was similar on treated and control plants.

Key Words—Semiochemicals, induced resistance, methyl jasmonate, hydroxamic acids, *Rhopalosiphum padi*, EPG, aphid behavior.

INTRODUCTION

Jasmonic acid (JA) and its methyl ester—methyl jasmonate (JA-ME; Figure 1)—are endogenous regulators of plant growth and development (Loake, 1996). These compounds occur in a large number of higher plant species and their synthesis is stimulated by a variety of processes, including mechanical wounding, herbivore

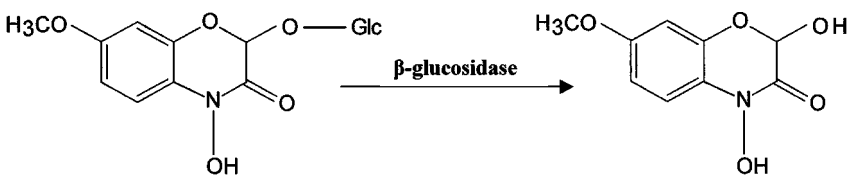
FIG. 1. Chemical structures of jasmonic acid (JA) and jasmonic acid methyl ester (=methyl jasmonate) (JA-ME).

attack, osmotic stress, and desiccation (Creelman and Mullet, 1997). JA is a key signal molecule carrying information about injury and its concentration in wounded plants increases rapidly (Reinbothe et al., 1994). JA induces expression of plant defense genes responsible for the synthesis of proteinase inhibitors, specific jasmonate-induced proteins, and metabolites directly involved in plant resistance, e.g., glucosinolates (Bennett and Wallsgrove, 1994; Bodnaryk, 1994). Similar plant responses are induced by the volatile JA-ME, which predestines it to a key role in interplant communication and induction of resistance against herbivores (Karban and Baldwin, 1997).

Cyclic hydroxamic acids (Hx) are a group of secondary metabolites characteristic of the family Poaceae (=Graminae). Hx occur in wild grasses, as well as in cultivated crops such as maize, wheat, rye, and triticale, but are absent from barley, oats, and rice (Zuniga et al., 1983; Niemeyer, 1988). In wheat, the most abundant Hx is 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) -glycoside. Upon wounding of plant tissues, this molecule is hydrolyzed to benzoxazinone (DIMBOA) (Figure 2) by endogenous β-glucosidase (Niemeyer and Perez, 1995). When consumed by herbivores, DIMBOA interferes with digestive processes within the gut by reducing digestibility and conversion of digested food, probably by inhibition of protease activity (Atkinson et al., 1992). DIMBOA inhibits the activity of many other enzymes including ATPases and enzymes of the



DIMBOA - glycoside **DIMBOA**

FIG. 2. Enzymatic hydrolysis of DIMBOA-glycoside.

oxidative chain (Bravo and Niemeyer, 1986). The level of DIMBOA in plants is associated with insect and disease resistance and allelopathic effects of cereals (Copaja et al., 1991). The highest concentration of Hx in plants is found in vascular tissues (Argandona and Corcuera, 1985; Argandona et al., 1987). Within the vascular bundle, Hx are present in phloem sap (Givovich et al., 1994), but absent from xylem (Argandona et al., 1987). Leszczynski and Dixon (1990) and Givovich et al. (1992) found Hx in the honeydew of aphids feeding on cereals, demonstrating that aphids ingest these compounds with the phloem sap. Hydroxamic acids seem to be natural defensive factors against insects, and increasing their level in plants has been suggested in breeding programs to obtain aphid-resistant cereal varieties (Escobar and Niemeyer, 1993).

The bird cherry–oat aphid, *Rhopalosiphum padi* (L.), is a worldwide pest of all major cereals and is able to transmit many persistent and nonpersistent viruses (Blackman and Eastop, 1985).

The aim of this study was to find whether the level of hydroxamic acids in plants might be affected by external factors such as JA-ME and whether this volatile chemical induces changes in the behavior of the bird cherry–oat aphid during settling, probing, and feeding on wheat. The effect of proteins from plants exposed to JA-ME on protease activity was also studied.

METHODS AND MATERIALS

Plants and Aphids. Winter wheat, *Triticum aestivum* cv. Kobra, was grown under controlled environmental conditions in hydroponic culture with keramsyte as the supporting medium [temperature 26°C (day)/21°C (night); 16L:8DL photoperiod; 65–70% relative humidity; light intensity 200 μM/m^2/sec FAR]. Hoagland's solution [$Ca(NO_3)_2$ 3.25 mmol/liter; KNO_3, 1 mmol/liter; KH_2PO_4, 1 mmol/liter; $MgSO_4$, 1 mmol/liter; Fe EDTA, 0.05 mmol/liter; H_3BO_4, 1 μmol/liter; $MnSO_4$, 0.05 μmol/liter; $CuSO_4$, 0.5 μmol/liter; $ZnSO_4$, 0.01 μmol/liter; $(NH_4)_6Mo_6O_{24}$, 0.01 μmol/liter; the acidity of the medium was set at pH 6.5 using 0.1 N H_2SO_4 or 1 N KOH] provided nutrients for the growing plants.

Aphids, *Rhopalosiphum padi*, were reared on *T. aestivum* cv. Kobra under similar controlled conditions as plants. Young apterous virginoparous females were used for experiments.

Application of JA-ME. Methyl jasmonate (JA-ME) was obtained from Serva, Germany. Six-day-old wheat seedlings were exposed to 50 μl of JA-ME that was applied to strips of filter paper attached to the top of a glass chamber (16 cm high $\times$ 9 cm diam.) for 24 or 48 hr. After exposure, seedlings were used for EPG study, direct observation of aphid behavior, and chemical analysis.

Airborne Concentration of Methyl Jasmonate. The concentration of JA-ME in the glass chamber was measured by GC-MS (GC model HP 5890II, MD model

HP 5972, column HPS) and found to be 217 nmol/liter. Only the (+)-epi form of methyl jasmonate is biologically active and rapidly isomerizes to the more stable, but biologically inactive, *trans* configured isomer. This process takes place under physiological conditions and results in a 1:9 ratio of *cis*-(3*R*,7*S*) epimer to *trans*-(3*R*,7*R*) epimer (Mueller, 1997). Therefore, we were able to determine that the concentration of total JA-ME in our glass chamber was 20 nmol/liter. According to data provided by Serva, the JA-ME preparation consists of three isomers, which means that the physiologically active concentration of JA-ME in our study was several nanomoles per liter. This fits within the range of physiological concentrations reported by other authors (Falkenstein et al., 1991; Farmer and Ryan, 1992).

Quantification of Hydroxamic Acids. Hx content was analyzed according to the procedure described by Leszczynski (1996). Plant material was homogenized in distilled water and left at room temperature for 30 min. The homogenate was adjusted to pH 3 and centrifuged at 6000 *g* for 15 min. The supernatant was extracted into ethyl ether (1:1, v/v $\times$ 3); the combined ether fractions were evaporated to dryness, dissolved in 80% methanol, and the $FeCl_3$ reagent was added. Absorbance of the complex was measured at 590 nm by using a Beckman DU 640 spectrophotometer. The concentration of Hx was determined by comparing the absorbance of the extract with a standard curve made with 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) because standards of hydroxamic acids are not commercially available. Free Hx aglucones were isolated according to the method of Woodward et al. (1978) and Leszczynski (1996). The preparation was crystallized in hexane (2$\times$) and purity determined by the method of Woodward et al. (1978). This was used as the Hx standard based on its main component—DIMBOA. Additional measurements of DIMBOA using TLC-UV (Zuniga et al., 1983) confirmed the results obtained with the ferric chloride method.

Extraction of Protease Inhibitors. Protease inhibitors were isolated by using a modification of the Jongsma et al. (1994) method. Plant tissue was immersed in liquid nitrogen and homogenized in buffer (0.1 M Tris HCl, pH 7.6) containing 5% polyvinylpolypyrrolidone (Sigma), 2 mg/ml phenylthiourea, 5 mg/ml DIECA, and 0.05 M EDTA. The homogenate was centrifuged (MPW 375) at 12,000 *g* for 20 min at 4°C. Proteins in the supernatant were precipitated with chilled $(NH_4)_2SO_4$ and centrifuged at 4°C for 10 min. The precipitate was resuspended in buffer (0.1 M Tris HCl, pH 7.6) and added to the reaction mixture for determination of enzyme activity.

Enzyme Assay. Trypsin activity was evaluated using ox trypsin type III (Sigma) and on the basis of the azocasein methods of Brock et al. (1982) and Harsulkar et al. (1999). The reaction mixture consisted of trypsin, azocasein [0.1% azocasein (Sigma) in 0.1 M glycine NaOH)], and the isolated plant protease inhibitor. Incubation was carried out at 37°C for 30 min and the reaction terminated with 5% TCA. The mixture was centrifuged at 10,000 *g* for 10 min after incubation at room temperature. An equivalent amount of 1 N NaOH was added to the

supernatant, and the absorbance at 450 nm was measured. One protease activity unit was defined as an increase in absorption of one extinction unit per minute. The unit of protease inhibition was defined as the inhibition of one protease unit under described conditions.

Olfactometry. Experiments were carried out in a Pettersson olfactometer (Pettersson, 1995). JA-ME (4 μM) was applied to one of the four arms of the olfactometer, the remaining arms served as controls (water). Five apterous, virginoparae were placed in the central arena of the olfactometer. The number of aphids in the individual arms was counted every minute for 15 min. The airflow was 4 ml/sec. Experiments were replicated eight times and the results analyzed using the *t* test.

Direct Observation of Aphid Settling: Choice Test. Two wheat leaves (one untreated control and the other from plants treated with JA-ME for 24 or 48 hr) were placed in a Petri dish containing wet filter paper. Twenty apterous, virginoparae were placed in the center of the dish, and the number on each of the leaves was counted after 15, 30, 60, and 120 min, and 24 hr. The experiment was replicated eight times and the results were analyzed by ANOVA.

EPG. The Electrical Penetration Graph technique (Tjallingii, 1995) provides information on aphid stylet activities in plant tissues and is helpful in the localization of plant resistance factors, if there are any. This technique was used to follow aphid behavior on plants exposed to JA-ME. Probing behavior of apterous, virginoparae *R. padi* was recorded continuously for 8 hr on untreated and JA-ME-treated plants prepared as described earlier. Each experiment was replicated 15 times using fresh aphids. The results were analyzed using the Kruskal-Wallis test.

RESULTS

There was an increase in Hx concentration in wheat seedlings exposed to methyl jasmonate. Hx content increased by 49% and 129% in seedlings exposed for 24 and 48 hr, respectively (Table 1). The proteins isolated from wheat seedlings exposed to JA-ME inhibited trypsin activity with the strongest inhibition found for seedlings exposed for 48 hr (Table 2).

TABLE 1. HYDROXAMIC ACID CONTENT IN WHEAT SEEDLINGS EXPOSED TO METHYL JASMONATE (JA-ME)

	Hydroxamic acid content (mmol/kg fresh wt)

JA-ME	81 ± 3	55 ± 4

[a] Activity expressed as percent of control ± SD.

In the olfactometer, fewer aphids (8.8 on average) visited the arm containing methyl jasmonate than the control arms (11.2 on average), but the difference was not significant.

Aphids did not settle on plants that had been exposed to methyl jasmonate, regardless of exposure time. Such behavior was observed during the entire 24-hr experiment (Table 3).

Electronic recording of aphid stylet activities showed a trend towards the reduction of total penetration time, and, among all penetration activities, a decrease in phloem sap ingestion from plants exposed to JA-ME (Figure 3). During the first hour of recording, probing time was 25% and 50% shorter on plants exposed to JA-ME for 24 and 48 hr, respectively, than on control plants. On the control plants, the typical aphid behavior might be observed. During the second hour after aphids had access to plants, stylet probing constituted 90% of all aphid activity (40% pathway and 50% phloem sap ingestion). Aphids showed only penetration activity from the sixth hour until the end of the recording; 90% of it was the ingestion of

phloem sap. Stylet penetration comprised 80% of aphid activity (60% pathway, and 20% phloem sap ingestion) after 2 hr spent on plants exposed to JA-ME for 24 hr. From the sixth through the eighth hours, total probing time did not change and comprised approximately 80% of all activities (pathway—20%, phloem sap ingestion—60%). Nonprobing activities took around 40% from the second hour until the end of the experiment on plants exposed for 48 hr. During that time, pathway activities decreased from 50% in the second hour to 30% in the eighth hour, and phloem sap ingestion increased from 10% to 30%, respectively. All aphids found phloem vessels and started feeding by the fourth hour of the experiment on control plants. On plants exposed to JA-ME for 24 hr, all tested aphids showed phloem sap ingestion waveforms, but much later than on control plants, i.e., after the sixth hour of the experiment. On plants exposed to JA-ME for 48 hr, 20% of tested aphids failed to locate their food source: no waveforms indicating phloem contact occurred during probing by these aphids (Figure 4).

The most important differences between aphid probing on control and JA-ME-treated plants was in total penetration time (20–30% reduction on JA-ME-treated plants), total phloem sap ingestion time (50% reduction on JA-ME-treated plants), pathway activities during the first hour (25–50% reduction on JA-ME-treated plants), and number of probes (twofold increase on JA-ME-treated plants). The duration of the first period of feeding was similar on control and treated plants (Table 4).

The time needed by *R. padi* to locate phloem sieve elements after having access to the plant was similar on control and JA-ME-treated plants. However, within a probe the duration of pathway before the beginning of sap ingestion was

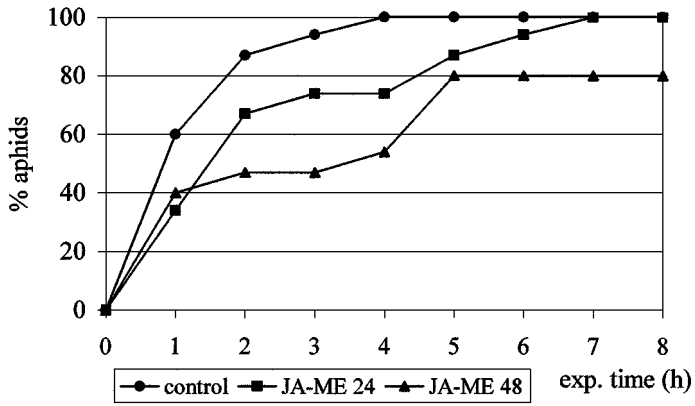

FIG. 4. Cumulative percent of *Rhopalosiphum padi* reaching phloem vessels on wheat exposed to methyl jasmonate (8-hr EPG recording).

TABLE 4. EPG PARAMETERS OF *Rhopalosiphum padi* STYLET PENETRATION ACTIVITIES ON WHEAT SEEDLINGS EXPOSED TO JA-ME

EPG Parameter	Control	JA-ME Exposure	
		24 hr	48 hr

two times shorter on plants exposed to JA-ME for 48 hr than on the control ones, and three times shorter than on plants exposed for 24 hr (Table 4).

DISCUSSION

EPG studies supported by direct observation of aphid settling showed that the behavior of *Rhopalosiphum padi* changed on plants that had been exposed to vapors of methyl jasmonate. Host-plant acceptance was delayed in the case of the tethered aphids, suggesting that these individuals might have left the plant given freedom of movement. Indeed, freely moving aphids in another experiment rejected such plants within the first 15 min of the experiment, and the inclination to stay on control plants occurred throughout 24 hr of observation. The reduction of pathway and phloem ingestion activities in aphids on JA-ME-treated plants showed that stylet penetration was deterred by factors present in the mesophyll as well as vascular tissues.

Our results correspond well with data reported by other authors. Several authors have described the negative correlation between DIMBOA content in cereals and the behavior and performance of various species of cereal aphids, including Corcuera et al. (1982), Leszczynski et al. (1989), Leszczynski and Dixon (1990),

and Thackray et al. (1990). Addition of DIMBOA to artificial diets showed its antibiotic effect on aphids (Argandona et al., 1983). DIMBOA-aglucone inhibited ATPase, trypsin, chymotrypsin, and cholinesterase activity (Atkinson et al., 1992; Cuevas and Niemeyer, 1993). According to Gonzales and Rojas (1999), the toxic effect of Hx may be related to reactive forms of oxygen that occur in the presence of Hx and may destroy cell membranes. It seems likely that the reduced ability to feed on jasmonate-treated plants may be attributed to some disorders in the aphid nervous system.

The role of JA as a stress hormone in aphid–plant interactions has not been studied. The results of the present work refer to many aspects of this relationship. The schematic drawing (Figure 5) that combines our findings with literature data shows a hypothetical model of aphid–plant interactions in light of the JA/JA-ME key role in the induction of plant resistance mechanisms against herbivores in wheat.

Exogenous methyl jasmonate (Step I) or jasmonic acid synthesized in response to the wounding of plants by aphid stylets (II) induces expression of genes (III) responsible either for the synthesis of enzymes of the shikimic acid pathway, leading to the accumulation of hydroxamic acids (IV), or the synthesis of specific proteins, the protease inhibitors (VIII).

Synthesis of Hx induced by JA-ME is followed by glycosylation (IV). This is the basic transport form of this compound (Zuniga and Massardo, 1991). In a similar way, glycosylation during synthesis of glucosinolates in Brassicaceae increases their mobility and enables their transport in the phloem (Brudenell et al., 1999). Corcuera et al. (1982) using artificial diets demonstrated that the DIMBOA-aglucone is more toxic to aphids than its glycosylated form (DIMBOA-Glc). DIMBOA-Glc may be transformed into the aglucone by endogenous plant β-glucosidase (V) (Escobar and Niemeyer, 1993) following damage to plant tissue by feeding insects. A recent report shows that wheat contains an unknown β-glucosidase (EC 3.2.1.21) characterized by a specific affinity to DIMBOA-Glc (*Sue* et al., 2000). The risk of plant damage by aphids is minimized. Their stylets penetrate plant tissues within the cell walls rather than through the inside of the cells (Tjallingii and Hogen Esch, 1993). However, sometimes plant cells may deteriorate during pathway activities of aphid stylets. In such cases, plant β-glucosidases would be activated and the concentration of DIMBOA-aglucones would increase. Niemeyer et al. (1989) and Leszczynski and Dixon (1990) showed that the content of DIMBOA-aglucones increased in plants infested by aphids. There is also evidence that salivary factors may elicit specific plant responses (Karban and Baldwin, 1997). Givovich et al. (1994) found that *Rhopalosiphum padi* was more sensitive to Hx than *R. maidis*. If stylet penetration activities of cereal aphids induce synthesis of Hx, then reduction of sampling frequency by *R. maidis* will be the strategy for reducing the possibility of intoxication, which has already been suggested by Givovich et al. (1994). It is still an open question

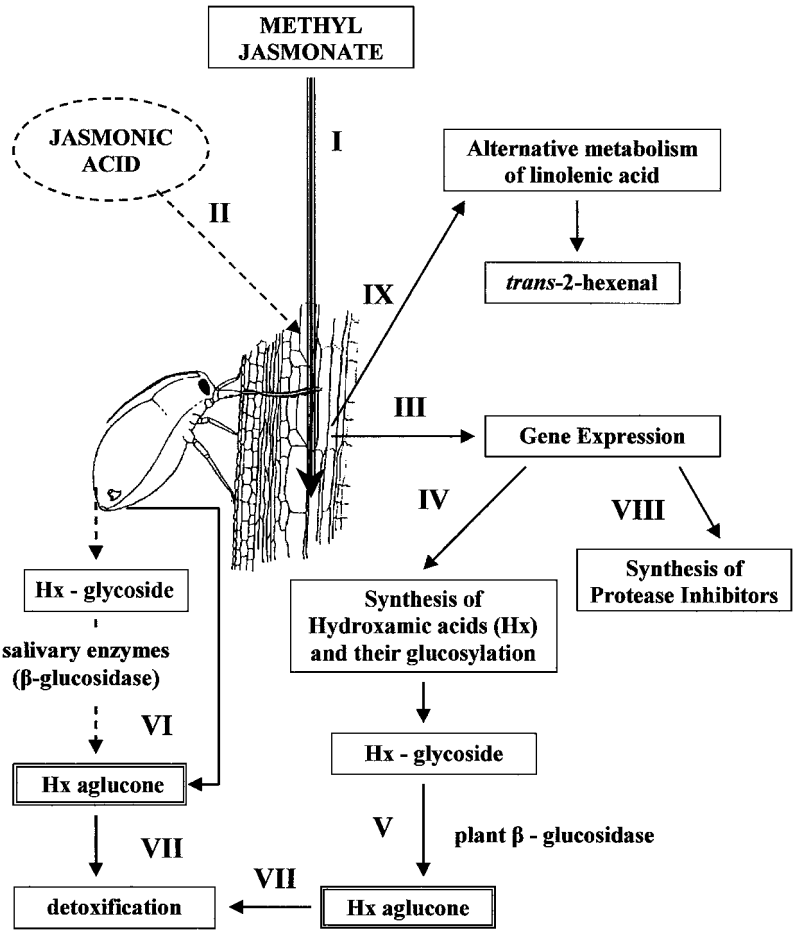

FIG. 5. Schematic representation of jasmonic acid and methyl jasmonate roles in aphid-plant relationships in cereals. **I**—exogenous methyl jasmonate; **II**—jasmonic acid synthesized in response to insect feeding; **III**—expression plant resistance genes; **IV**—synthesis, glucosylation, and accumulation of hydroxamic acids; **V**—hydrolysis of hydroxamic acid glucosides by endogenous plant β-glucosidases; **VI**—hydrolysis of hydroxamic acid glucosides by aphid salivary β-glucosidases; **VII**—detoxification of hydroxamic acids; **VIII**—synthesis of proteinase inhibitors; **IX**—synthesis of *trans*-2-hexenal.

whether β-glucosidases from aphid saliva (VI) are DIMBOA-glycoside-specific and whether they contribute to the increase in DIMBOA-aglucone concentration in aphid-infested plants (Leszczynski et al., 1993). The DIMBOA ingested by aphids with the phloem sap may be detoxified (VII) by glutathione S-transferase

(Leszczynski et al., 1993), or UDP-glucosyltransferase (Leszczynski and Dixon, 1990). UDP-glucosyltransferase may transform the toxic aglucone form of DIMBOA into the glycoside one that may be excreted in honeydew (Leszczynski and Dixon, 1990).

Aphid nutrition is based on easily available free amino acids from the phloem sap (Srivastava, 1987). However, phloem sap also contains a small amount of proteins, including chitin-binding lectins, that are considered a plant resistance factor against aphid feeding (Cole, 1994). A number of other proteins at concentrations within the range occurring in phloem sap increased mortality and inhibited growth of the pea aphid *Acyrthosiphon pisum* (Rahbe and Febvay, 1992). These ingested polypeptides are not processed by aphids (Rahbe et al., 1995), although proteases were found in the salivary glands and midgut of several aphid species including *R. padi* (Srivastava, 1987). Furthermore, aphids have nondigestive proteases sensitive to trypsin and chymotrypsin inhibitors; the oral application of these inhibitors affected the survival and development of the pea aphid (Rahbe et al., 1995). Jasmonate-induced resistance gene expression may lead to the synthesis of protease inhibitors (VIII). We found significant inhibition of trypsin by proteins from wheat exposed to the volatile methyl jasmonate and analogous results were obtained by other authors (Farmer and Ryan, 1992; Jongsma et al., 1994). Casaretto and Corcuera (1998) showed that the protease inhibitors isolated from barley leaves had no effect on the survival of *Schisaphis graminum* on artificial diets, whereas they reduced the survival of *Rhopalosiphum padi* under similar conditions. Therefore, the accumulation of protease inhibitors induced by JA-ME in wheat leaves found in the present study might be the additional factor responsible for decreased feeding activity. If the effect of PIs described for *A. pisum* by Rahbe et al. (1995) is a common phenomenon in aphids, then the jasmonate-induced plant PIs may be an important plant resistance factor applicable in aphid control on cereals. Certainly, this aspect of aphid physiology requires further study.

Pettersson et al. (1996) found that volatiles released by aphid-infected cereals could induce antixenotic effects in neighboring plants, which cause nonpreference in aphids. Hildebrand et al. (1993) observed that volatiles released by damaged potato leaves induced plant responses that reduced aphid fecundity. The volatile blend produced by plants attacked by insects may contain additional compounds than the stress-induced jasmonates that have no effect on aphid behavior (see this work). The main metabolic pathway of linolenic acid leads to jasmonates, but an alternative pathway also exists leading to the synthesis of various volatile compounds, for example *trans*-2-hexenal (IX). *trans*-2-Hexenal, one of the general green-leaf volatiles, is toxic to insects and mites (Lyr and Basamian, 1983; Pare and Tumlinson, 1999). Aphids have olfactory receptors sensitive to these compounds (Visser et al., 1996). In our experiments, free *R. padi* avoided leaves exposed to JA-ME as soon as they had contact with them. It is likely that this response was the

reaction to volatiles produced by these leaves; however, this hypothesis remains to be tested.

In this paper we report evidence for only two jasmonate-induced processes that may act as resistance mechanisms of wheat against insect herbivores. If we accept the idea that methyl jasmonate acts as an airborne signal carrying information about wounding, our results give support to the idea of a multi-way cascade response in plants, activated by stress situations.

Acknowledgments—We would like to thank M. Hojniak, MSc, Institute of Chemistry, Wroclaw University, for his help in GC-MS measurements of airborne JA-ME concentration.

ANALYZING VARIABILITY IN NECTAR AMINO ACIDS: COMPOSITION IS LESS VARIABLE THAN CONCENTRATION

MARK C. GARDENER* and MICHAEL P. GILLMAN

Ecology and Conservation Research Group

(Received May 19, 2001; accepted July 22, 2001)

Abstract—Thirty species of flowering plants were analyzed for floral nectar amino acid composition. High-performance liquid chromatography (HPLC) was used in conjunction with AccQtag derivatization to produce accurate and precise data. For any one species, the total concentration of amino acids varies greatly (average coefficient of variation 0.65), but composition is much less variable (average correlation among samples from a single species 0.85). Absolute concentration of individual amino acids is much more variable than the relative abundance (coefficients of variation 0.98 and 0.77, respectively; $N = 544$, $t = 16.98$, $P < 0.001$). When amino acids that occur in only small relative abundance (<1%) are removed from the analysis, the difference is even more marked (0.78 and 0.51, respectively; $N = 344$, $t = 15.13$, $P < 0.001$). The results highlight the need for large sample sizes when making observations concerning the absolute amounts of amino acids in nectar and for sensitive analyses of the composition, as even small changes may be biologically significant.

Key Words—Nectar, amino acid, correlation, HPLC, flowering plant, composition, variation.

INTRODUCTION

Although early studies showed that the nectar of flowering plants contained substances other than sugars (Ziegler, 1956; Luttge, 1961), it was not until Baker and Baker (1973) showed that amino acids were largely ubiquitous in nectar that studies began to examine variation in composition both between and within species. Early studies used simple ninhydrin staining techniques to quantify total amino

acid concentration (Baker and Baker, 1975). Despite limitations, the method is still used (Bernardello et al., 1991; Forcone et al., 1997). Other studies use thin-layer chromatography (TLC) to separate and identify component amino acids (Baker and Baker, 1976, 1977, 1979; Baker et al., 1978), with many studies electing to use a relative scale of concentration for the various component amino acids. More recent investigations employ high-performance liquid chromatography (Gottsberger et al., 1989; Lanza et al., 1995; Rusterholz and Erhardt, 1998), which provides a more precise and accurate determination of amino acid complement and concentration in a mixed sample (Cohen and Micheaud, 1993).

Based on TLC analysis, Baker and Baker (1977) stated that the amino acid complement of nectar was "remarkably constant" within a plant species. The relative concentrations of the amino acids present in each species were given, which, upon inspection, appeared to show impressive constancy of amino acid complement. However, the study by Lanza et al. (1995) determined that variation existed among individual plants within a single population of *Impatiens capensis* and between separate populations. Nectar from different flowers of a single individual showed no significant variability. More recently, Gardener and Gillman (2001) showed that the amino acid complement could be altered by soil fertilizer treatment, highlighting the fact that the use of HPLC allows greater sensitivity in detecting small changes that might remain undetected using previous techniques.

We present here the first quantitative assessment of the variability of nectar amino acid composition for a wide range of plant species. We also examine the variability of total amino acid concentration in those species. This is important, as previous studies have made assertions concerning the role of amino acids in nectar based upon measurements of the total concentration (e.g., Baker and Baker, 1973, 1977; Gottsberger et al., 1984). It is necessary for future studies to appreciate the variability in composition and concentration if we are to fully understand the ecological role of amino acids in nectar.

METHODS AND MATERIALS

Nectar Collection. Nectar was collected from plants growing wild in the vicinity of the Open University campus in Milton Keynes, Buckinghamshire, United Kingdom. In all cases, samples were taken from a number of individuals in the same neighborhood to minimize variability among populations or caused by soil conditions. Samples were taken at the same time of day (14:00–16:00 hr) and from flowers of approximately the same age (first day of dehiscence). This was to minimize effects of flower aging that have been shown to affect amino acid concentrations in nectar samples (Gottsberger et al., 1990; Petanidou et al., 1996). Predehiscent flowers were covered with a fine net (dress net, 1-mm mesh size) to prevent visitation by insects and so possible contamination or nectar removal. The following day the nectar of those flowers was withdrawn using 5-μl glass

graduated micropipet tubes, capillary action being enough to draw in the nectar. Precautions were taken to minimize possible contamination with pollen, which can release free amino acids in solution (Erhardt and Baker, 1990). In some species, the inflorescence was cut with sharp scissors, allowing the anthers to fall away, revealing the ovary. In other species (e.g., *Epilobium hirsutum*), this was not necessary, as the nectaries were easily accessible. In such species, care was taken to avoid touching the anthers with the pipet. The volume of each sample was determined by measuring the fluid column in the pipet. This measurement was a source of variability. Most samples were in the range of 1–2 μl. With 15 mm representing 1 μl and a measurement accuracy of 0.5 mm, this represents a random error in the range of 1–3.5%. Each sample was aspirated into a glass chromatography vial (Chromacol 02-CTVG) and frozen (at -40°C) shortly afterwards until analysis by HPLC. In total, samples from 30 plant species were collected.

Analysis of Nectar. Samples were thawed and amino acids derivatized using the AccQtag protocol (Waters Corp.) (Cohen and Micheaud, 1993) in a 0.02 M borate buffer (pH 8.6). HPLC was performed, with standards every four samples, using the following equipment: Waters 712 WISP autosampler, Waters 600 pump controller, Waters 600 HPLC pump with 510 pump-heads. Separation was achieved using a Novapak C_{18} (15 cm $\times$ 4.6 mm) cartridge with guard column. The binary solvent system was a 6:4 acetonitrile–water mix and a TEA–phosphate (pH 5.0) buffer. Detection was via a Waters 474 scanning fluorescent detector (excitation at 295 nm and detection at 350 nm). The system was monitored and data collected using the Waters Millenium^{32} software. Chromatograms were analyzed and compared to standards for identification of individual amino acids. Standard amino acids were made up to a concentration of 100 pmol/μl. In addition to all the protein-building amino acids, standards of hydroxyproline, ornithine, taurine, AABA, and GABA were used. Peak areas were compared to standards to determine the concentration of individual amino acids. From these data, the total concentration of all amino acids was determined and the proportion that each made to the total was calculated. A summary of the amino acid composition for each species is given in Appendix 1.

RESULTS

Total Concentration of Amino Acids. For each species the variability in total amino acid concentration among samples was determined by using the coefficient of variation, i.e., the standard deviation divided by the mean. Table 1 shows the coefficients for all the species analyzed. The mean coefficient was 0.67. Given this variability, the error arising from measurement of nectar in the collecting capillary is negligible.

Comparison of Composition. Each nectar sample produced a range of amino acids in varying proportions. In general, a sample contained a few, abundant amino

[a] Data columns are: number of samples analyzed (N), average intraspecific correlation (Corr), and coefficient of variation for total concentration of nectar amino acids (Vc). All correlations are statistically significant ($P < 0.001$).

acids that each contributed greater than 10% towards the total concentration, a number of smaller components with fractions in the range of 5–10%, and a larger number of amino acids each contributing <5% towards the total. These latter amino acids, many contributing <1% towards the total concentration, would undoubtedly have remained undetected if less sensitive techniques had been used.

The extent of the similarity of composition between two nectar samples can be determined by correlation of the amino acid concentrations (e.g., Figure 1). In this case, Pearson correlation coefficients were determined for all comparisons of compositions within each species. The mean correlation coefficient could be used

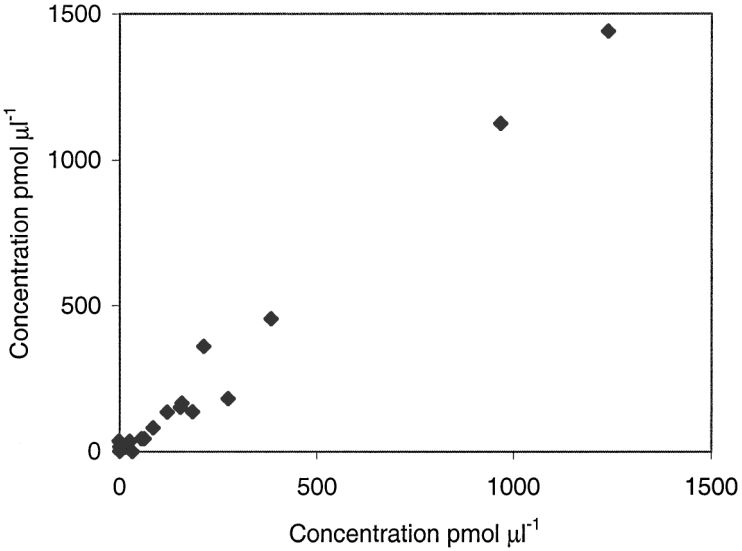

FIG. 1. Example of positive correlation of a pair of nectar samples (*Corydalis lutea*, $R = 0.993$, $N = 19$, $P < 0.001$).

to represent the variation in composition. This is a conservative (and potentially biased) measure, as one errant sample would have a greater effect upon the final mean by virtue of multiple paired comparisons. Table 1 shows the mean coefficient for each species analyzed. The mean of all the coefficients of variation was 0.88.

Correlation provides a useful tool to examine the similarity of samples. It would be expected that nectar samples from conspecifics would be more highly correlated to one another than to heterospecifics, and this could form the basis for an interesting analysis of nectar evolution, perhaps by comparing a cluster analysis of nectar samples to a molecular phylogeny.

Comparing Variability of Composition and Concentration. Although the correlation coefficient is useful as a guide to the constancy of composition, it is not directly comparable to the coefficient of variation of total concentration. In order to improve the comparison, we considered the set of samples from each plant species in turn. For each amino acid in the set of samples, a coefficient of variation for its absolute concentration was calculated. A similar coefficient was calculated for the fraction that amino acid contributed to the total (i.e., the relative abundance of the amino acid). The process was repeated for all 30 of the plant species, producing a database of 544 comparisons.

For each amino acid of each species, the coefficients of variation in absolute amount and relative amount were compared. The data were analyzed by using a

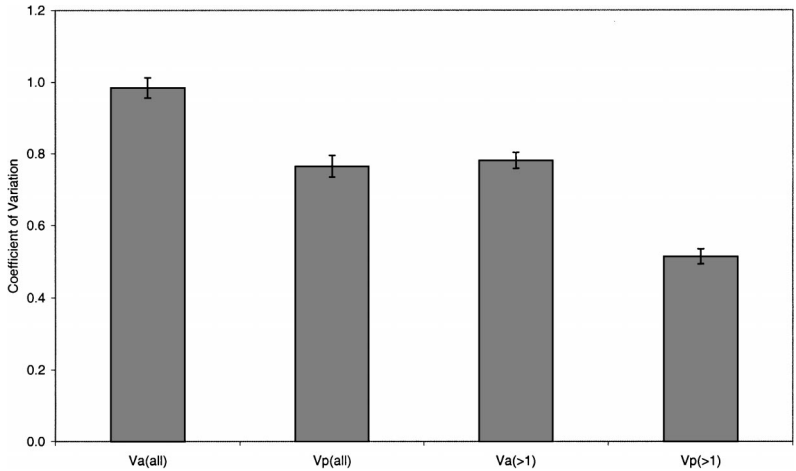

FIG. 2. Coefficients of variation for absolute concentration of amino acid and proportion (Va and Vp, respectively) for amino acids in nectar samples. First group represents all data while the second group is for amino acids contributing >1% to the sample. Error bars are standard error.

t test for paired samples, showing that the variability in absolute concentration was significantly higher than the variability in relative abundance (0.98 and 0.77, respectively, $N = 544$, $t = 16.98$, $P < 0.001$, Figure 2). It might be expected that the more abundant amino acids (>10%) would be less variable than the less abundant ones. To test this, the amino acids were categorized into abundance classes. Removing the last category (0–1%) of amino acids from the analysis, the difference in variability between absolute and relative concentration is more pronounced (0.78 and 0.51, respectively; $N = 344$, $t = 15.13$, $P < 0.001$, Figure 2). Variability of absolute concentration, in the range 0–1% was higher than all other frequency ranges (one-way ANOVA, $F_{6,537} = 18.205$, $P < 0.001$. post-hoc LSD test $P < 0.001$; Figure 3). Variability of relative abundance was also higher for this 0–1% group (one-way ANOVA, $F_{6,537} = 26.791$, $P < 0.001$, post-hoc LSD test $P < 0.001$; Figure 4).

The data in Figures 3 and 4 can be combined to produce a simple index of amino acid variability expressed as the ratio of variability in absolute concentration to variability in relative abundance (Va/V%). The ratio of variability of absolute to relative abundance changed as the component amino acids increase their share of the total (Figure 5). There appear to be three groups, the first being amino acids, contributing >20% to the total. Post-hoc LSD tests showed this group to have significantly higher Va/V% than all other groups ($P < 0.001$, one-way ANOVA, $F_{6,537} = 12.185$, $P < 0.001$). The second group was amino acids occurring in the range of 1–20%. Post-hoc tests showed no significant differences for any of

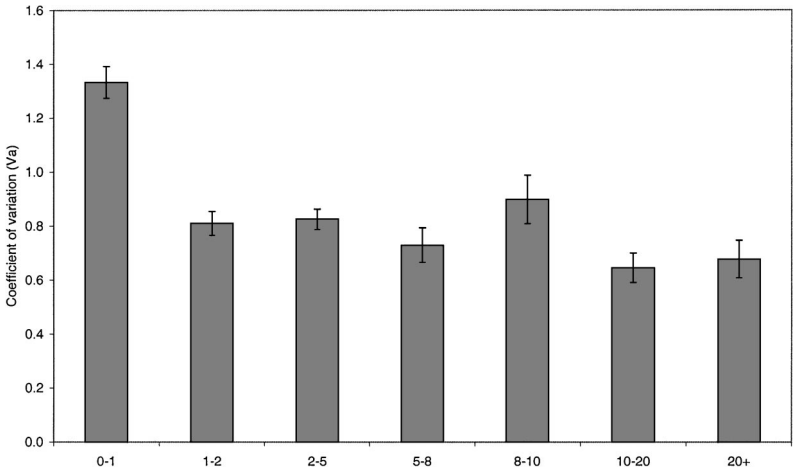

FIG. 3. Variability of absolute concentration of amino acids in nectar for various relative abundance ranges e.g., A0–1 = amino acids that contribute 0–1% to the total in the sample (one-way ANOVA, $F_{6,537} = 18.205$, $P < 0.001$).

the abundance classes within this range. A final category covers amino acids that contribute <1% to the total of the sample in which they occur. Post-hoc LSD tests show this group to have a lower Va/V% ratio than all the others ($P < 0.01$) except for the 8–10% group ($P = 0.08$) and the 10–20% group ($P = 0.13$).

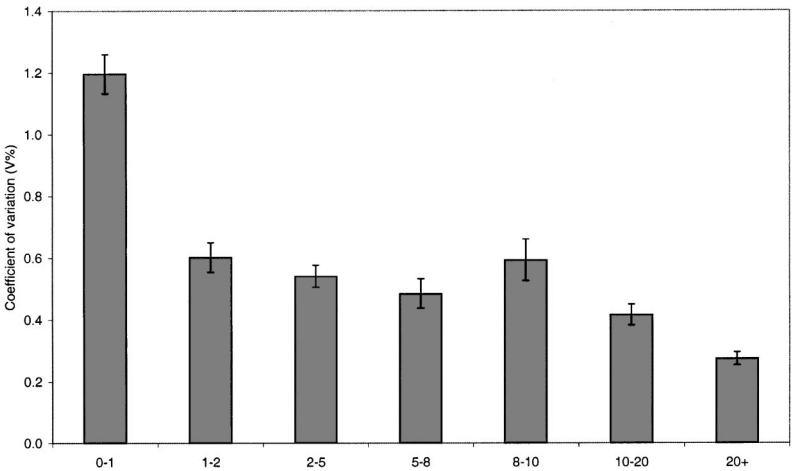

FIG. 4. Variability of relative abundance of amino acids in nectar for various relative abundance ranges (one-way ANOVA, $F_{6,537} = 26.791$, $P < 0.001$).

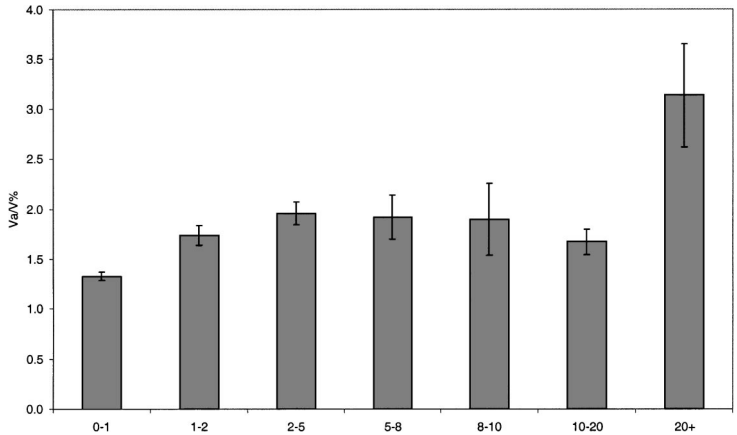

FIG. 5. The ratio of variability in absolute concentration (Va) to variability in relative abundance (V%) for amino acids occurring in nectar samples in various relative abundance ranges (one-way ANOVA, $F_{6,537} = 12.185$, $P < 0.001$).

DISCUSSION

These analyses show that the total concentration of amino acids in the nectar of any one species may vary widely. When making comparisons between species, therefore, it is important to ensure adequate replication and to use appropriately sensitive techniques. The composition, on the other hand, is much less variable. This is not entirely unexpected. The structure of the plant tissues that contribute to nectar production—the nectaries, phloem, and surrounding cells—are fixed by genetic processes and produce nectar of a certain species-specific, composition (Baker and Baker, 1977), although there can be variability among populations of a species (Lanza et al., 1995). The production of nectar is an active, energy-requiring process, which is curbed by respiratory inhibitors (Findlay and Mercer, 1971). Day-to-day environmental variations, in temperature and sunlight for example, are factors that will influence the metabolic processes of nectar production and may lead to changes in overall concentration of the nectar components. Physiological processes such as water relations may influence nectar concentration at the production stage, and evaporation may influence concentration afterwards. Longer-term environmental variables operating within a growing season, such as soil nutrients (Gardener and Gillman, 2001) and CO_2 (Rusterholz and Erhardt, 1998), are more likely to alter nectar composition by a variety of mechanisms e.g., altered metabolite availability and concentration, altered growth of plant tissues.

Acknowledgments—Thanks to Graham Jeffs from the Chemistry Department at the Open University for help and support with all aspects of chromatography. This study forms part of a PhD project funded by the Open University Department of Biological Sciences (grant SB20 5861 0).

DETOXIFICATION IN RELATION TO TOXIN TOLERANCE IN DESERT WOODRATS EATING CREOSOTE BUSH

(Received September 27, 2000; accepted August 8, 2001)

Abstract—We studied the relationship between the use of three detoxification pathways and urine pH and the tolerance of desert woodrats from two populations to a mixture of naturally occurring plant secondary metabolites (mostly phenolics) in resin from creosote bush (*Larrea tridentata*). The two populations of desert woodrats came from the Mojave desert (Mojave woodrats), where woodrats consume creosote bush, and from the Great Basin desert (Great Basin woodrats), where the plant species is absent. We fed woodrats alfalfa pellets containing increasing levels of the phenolic resin and measured three detoxification pathways and urine pH that are related to detoxification of allelochemicals. We found that the excretion rate of two phase II detoxification conjugates, glucuronides and sulfides, increased with increasing resin intake, whereas excretion of hippuric acid was independent of resin intake, although it differed between populations. Urine pH declined with increasing resin ingestion. The molar proportion of glucuronides in urine was three times that of the other conjugates combined. Based on an evaluation of variation in the three detoxification pathways and urine pH in relation to resin intake, we rejected the hypotheses that woodrats' tolerance to resin intake is related to capacity for amination, sulfation, or pH regulation. However, Mojave woodrats had higher maximum glucuronide excretion rates, and we accepted the hypothesis that within and between populations woodrats tolerate more resin because they have a greater capacity for glucuronide excretion.

INTRODUCTION

Herbivores that feed on plants containing plant secondary metabolites (PSMs) can manage owing to enzymes that metabolize the ingested toxins (Brattsten, 1992). Freeland and Jansen (1974) proposed that the amount of PSMs that an individual can ingest is related to its capacity to detoxify and eliminate PSMs. This capacity is ecologically important because it constitutes a constraint on how much of a food containing the PSM might be ingested, and so it can be used to predict diets (Belovsky and Schmitz, 1991).

The ability of herbivores to cope with PSMs can result from: (1) the capacity to habituate to aversive sensory properties of the PSM, (2) differential rates of PSM absorption, (3) variation in target site sensitivity, and (4) the capacity to detoxify PSMs, either by using different detoxification pathways or because of differences in the specific kinetics of detoxification (Lindroth, 1988). This study relates primarily to the fourth factor. Although there is a large body of literature on detoxification pathways used by mammals, and their relative affinities and capacities as enzymatic systems (Caldwell, 1986; Sipes and Gandolfi, 1991), there are three points that deserve more attention. First, almost all detoxification pathways have been studied with humans and laboratory and domestic mammals (Parke, 1968; Caldwell, 1986; Sipes and Gandolfi, 1991) and very little in wild mammal–allelochemical systems (McArthur and Sanson, 1993; Harju-Anu, 1996). Second, one of the major detoxification systems for the conjugation of phenolic compounds, glucuronidation, has been one of the more extensively studied in laboratory mammal–drug systems. A direct consequence of this is that glucuronidation usually is the only conjugation route studied in wild mammal–allelochemical systems (Lindroth and Batzli, 1983; MacCoubrey et al., 1997), although a few studies in birds measured other conjugation pathways along with glucuronidation (Jakubas et al., 1993; Guglielmo et al., 1996; Hewitt and Kirkpatrick, 1997). Third, researchers rarely determine the maximum capacities of conjugation pathways or which pathways are induced with toxin exposure and which are fixed at some constitutive level. Consequently, there are few tests of the idea that the amount of PSMs that an individual can ingest is related to its capacity to detoxify and eliminate them.

The general objective of this study was to establish the relationship between the use of three detoxification mechanisms and urine pH and the tolerance of desert woodrats (*Neotoma lepida*) from two populations to a mixture of naturally occurring PSMs (mostly phenolics) from creosote bush (*Larrea tridentata*). The detoxification mechanisms are phase II detoxification pathways that involve conjugation of endogenous substrates to toxin metabolites: glucuronidation, sulfation,

and amino acid (glycine) conjugation to form hippuric acid. These were chosen because: (1) they are the most common conjugation reactions in mammals; (2) all three can be detected in urine; and (3) their respective endogenous moieties (glucuronic acid, sulfate and glycine) can be limiting factors under nutritional stress and hence detoxification could be compromised, or, if the need for moieties exceeds their supply, the nutritional status of the animals may be compromised (Sipes and Gandolfi, 1991; Guglielmo et al., 1996).

Urine pH and the three detoxification pathways we studied relate to acid–base homoeostasis that may be affected by organic acids produced as a result of the biotransformation and metabolism of PSMs (Foley et al., 1995). These organic acids are ionized at physiological pH (Robinson et al., 1953). The resulting hydrogen ion can be excreted in the urine or buffered. However, if the animal's buffering capacity is saturated, the pH of the urine will decrease.

The two populations of desert woodrats subjected to study came from the Mojave desert (hereafter called Mojave woodrats) and from the Great Basin desert (hereafter called Great Basin woodrats). While the natural diet of Great Basin woodrats is mostly composed by Utah juniper (personal observation), the diet of Mojave woodrats is composed of at least 22% of creosote bush in some areas in the Mojave desert (Mangione et al., 2000). The leaves of creosote bush are covered with a resin (Mabry et al., 1977) that makes up 10–25% leaf dry mass. The resin is composed of 40% dry mass of nordihydroguaiaretic acid (NDGA) and the remainder of the resin is a complex mixture of partially *O*-methylated flavones and flavonols (Rhoades and Cates, 1976; Mabry et al., 1977). The resin is known to deter feeding by arthropods and to complex with protein in vitro. NDGA fed to laboratory rats at 0.5, 1, or 3% produced cysts in the kidney and vacuolation of kidney tubular epithelium (Grice et al., 1968; Goodman et al., 1970). In a previous study (Mangione et al., 2000), we found that there were differences in tolerance to creosote bush resin between these two populations; Mojave woodrats ingested more resin, and maintained body mass constant at higher concentrations of resin in the diet. Possibly, the difference in tolerance relates to differences in detoxification pathways used by woodrats from these two populations.

The specific goals of the study were: (1) to test whether desert woodrats rely more on glucuronidation compared to sulfation and glycine conjugation (hippuric acid), as occurs for other mammals; (2) to find the maximum capacities of each detoxification route and its relationship with the maximum tolerance of resin in the diet; (3) to establish whether the detoxification of the resin affects acid–base balance of woodrats; and (4) to test whether the differential use of detoxification routes explains the tolerance difference between the two populations of desert woodrats studied earlier (Mangione et al., 2000).

We investigated the overall hypothesis that the amount of resin that individuals can ingest is related to their capacity to detoxify and eliminate the PSMs by testing a number of specific predictions, which are illustrated in Figure 1

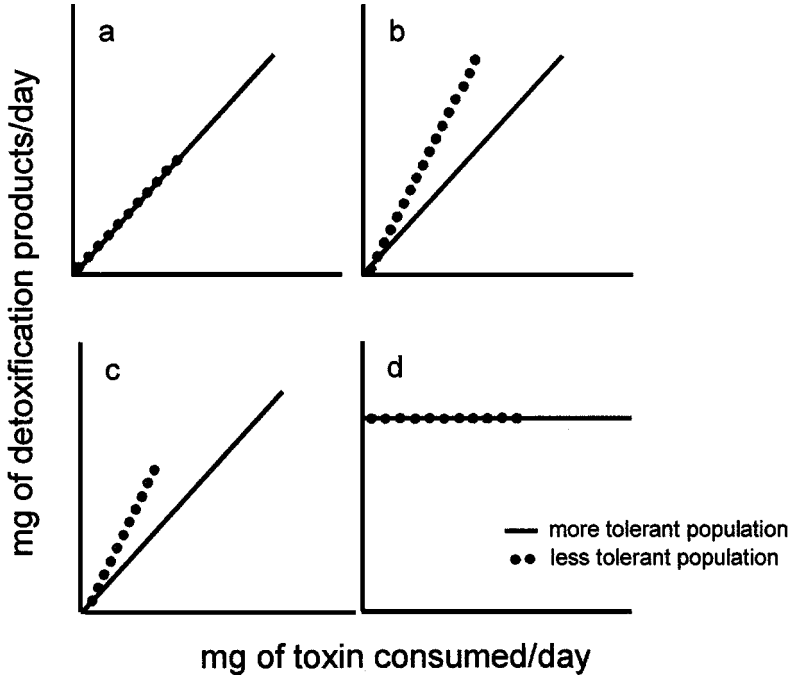

FIG. 1. Possible patterns between detoxification process(es) and toxin intake in two populations with different average maximum toxin tolerance. Plots a–c are based on the hypothesis that the amount of resin that individuals can ingest is related to their capacity to detoxify and eliminate the toxin. Plot d is based on the assumption that the detoxification process plays no limiting role in determining toxin tolerance. (a) Animals from both populations absorb the same proportion of toxin in food (same regression line), but animals from the more tolerant population can ingest more resin and exhibit higher capacity for the detoxification process. (b) Animals from the more tolerant population absorb a smaller proportion of toxin in food (lower slope), excrete less detoxification products per unit resin ingested, and, therefore, the maximum excretion rate of detoxification products may not be markedly different even though tolerance to resin is different. (c) Animals from the more tolerant population absorb less toxin per unit resin ingested, but also excrete more detoxification products. (d) Detoxification process is unrelated to toxin ingestion in animals from both more and less tolerant populations because the process plays no limiting role in the maintenance of tolerance to the toxin.

for the case of glucuronidation. First, there should be a correlation between glucuronides excreted and resin ingested per day. If animals from both populations absorb the same proportion of toxin in food, then they will fall along the same regression line, animals from the more tolerant population will tolerate more resin (higher maximum tolerable resin intake) and exhibit higher maximum glucuronide

excretion rate (Figure 1a). Alternatively, tolerance to the resin in animals from the more tolerant population occurs because they absorb a smaller proportion of toxin in food, excrete less detoxification products per unit resin ingested, and therefore maximum glucuronide excretion rate may not be markedly different even though tolerance to resin is different (Figure 1b). If differences in both absorption and detoxification are involved, then animals from the more tolerant population not only absorb fewer toxins per unit ingested resin but also excrete more glucuronides (Figure 1c). In either case (Figure 1b and c), in addition to salivary or intestinal binding, a reduction in absorption rate of a toxin could be related to the presence of an intestinal multidrug transporter system that may retard the absorption of the toxin (Epel, 1998). If there were no correlation between resin ingestion rate and reliance on a particular elimination process (Figure 1d), then we would reject the hypothesis that the amount of resin that individuals can ingest is related to their capacity to detoxify and eliminate toxin(s) by that process.

METHODS AND MATERIALS

Field Site and Sample Collection. Woodrats from the Mojave Desert were trapped at three different sites near Beaver Dam in Grand County, Utah (37°06′N, 113°58′W). Woodrats from the Great Basin were trapped in two locations 70 km apart at Jericho, Juab County, Utah (39°57′N 112°22′W) and Dugway, Tooele County, Utah (40°19′N 112°57′W) (see Mangione et al., 2000 for details on trapping methods). All woodrats were transported to the animal facility at the University of Utah and kept in quarantine for two to five months until they were tested for Sin Nombre hantavirus (Dearing et al., 1998), after which they were transported to the Department of Wildlife Ecology, University of Wisconsin, Madison, Wisconsin. Because detoxification enzymes require very short times for induction, hours to at most three to five days (Sipes and Gandolfi, 1991), and there was no induction of such enzymes, there was no concern for a reduction or alteration of the woodrats' capacity to detoxify creosote bush resin.

Animal Husbandry and Diet Preparation. Woodrats were housed in metal cages (47 × 30 × 21 cm) with screened bottoms. The animals were provided with cotton bedding and a ceramic bowl in which to nest. The room was kept at 21°C and 65% relative humidity. When not involved in experiments, woodrats were fed rabbit chow ad libitum [Harlan Teklad 8630; 17.5% crude protein, 22.0% acid detergent fiber (ADF), 2.5% fat] and 7.5% water. A slice of apple was given to the animals once a week.

Creosote bush collection and resin extraction were performed as indicated in Mangione et al. (2000) and resin was stored at 25°C for up to seven months. Resin-treated diets were prepared as follows: a known amount of resin (depending on the desired concentration of resin in the diet) was dissolved in a volume of

ethanol (95%) equal to 25% of the mass of the ground rabbit chow used in the treatment. Control diet was prepared in the same manner without addition of resin. The resin–ethanol solution and chow were thoroughly mixed, dried overnight at room temperature, and pelleted. To prevent alteration of the properties of the resin diet or palatability by the effects of heat and water (Price et al., 1980; Lindroth et al., 1984; Dietz et al., 1994), the pellet machine was refrigerated using a plastic bag filled with crushed ice and the amount of water added to make the pellets was reduced by using a 60% ethanol solution. The final pellets were dried at room temperature and stored in the freezer.

Feeding Trials. Two feeding trials were performed in this study. All experimental protocols were approved by the Research Animal Resources Center (RARC), University of Wisconsin-Madison.

Experiment 1. Nine woodrats from the Mojave Desert, six males and three females, and 8 woodrats from the Great Basin, three males and five females (five from Dugway, Tooele County, Utah and three from Jericho, Juab County, Utah), were exposed to increasing levels of resin following the procedure described by Mangione et al. (2000). At the beginning of the experiment, woodrats were offered rabbit chow with 0% resin and then switched sequentially to 1, 2, 3, 5, 7, and 9% resin. The animals were exposed to each concentration for six days. This sequence allowed the animals to habituate to the resin and permitted us to evaluate differences between populations at low and high concentrations of resin. Fresh food and water were offered daily. Body mass was measured daily, and animals were removed from the experiment if they lost 15% of their initial body mass or showed signs of sickness (e.g., swaying, not responding to sound or tactile stimuli, etc.). Water was supplied in bottles, and water intake was measured daily by weighing bottles and correcting for spillage and evaporation. Food intake was calculated daily by subtracting the dried orts (uneaten food) from the amount of food offered. Daily values of resin intake were calculated as the product of the amount of dry matter ingested per day multiplied by the proportion of resin in the diet at that particular level.

Urine was collected during days 2, 4, and six of each six-day treatment. On these days, woodrats were restricted to a portion of their cage ($16 \times 19 \times 20$ cm) with a funnel that allowed the collection of uncontaminated urine. Urine drained into an iced plastic vial to minimize bacterial growth and evaporation. The temperature of the vial remained between 0 and 5°C during a 24-hr period. Pilot experiments showed that there were no differences in food intake when woodrats were in either section of the cage (data not shown).

Experiment 2. Because some woodrats reduced their feeding rate and lost mass when fed diets with resin (Mangione et al., 2000), we performed a second, pair-fed control experiment to test whether variation in the excretion of glucuronides in urine of desert woodrats was due to variation in resin intake only and not the

reduction in food intake and mass loss. Four Mojave and six Great Basin woodrats were fed resin-free food daily (pair-fed control woodrats) at the same rate they were eating in experiment 1. Urine was collected for measurement of detoxification products.

Determination of Detoxification Products. Urine samples from the sixth day of each treatment (or from the last day a urine sample was taken if the animals had to be taken out of the experiment) were collected and used for analyses of conjugates. Urine samples were frozen at −25°C until they were used. Glucuronides were determined following the colorimetric assay described by Jakubas et al. (1993) and Blumenkrantz and Asboe-Hensen (1973). Briefly, urine samples were analyzed in duplicate. A urine sample (0.5 ml) was pipetted into a culture tube placed in an iced water bath along with 3 ml of sodium tetraborate–sulfuric acid solution (Blumenkrantz and Asboe-Hensen, 1973). The mix was shaken by Vortex and returned to the iced water bath. Tubes were then heated in a water bath at 100°C for 10 min. After cooling, 50 μl of the reagent *m*-hydroxydiphenyl (Sigma, St. Louis, Missouri) was added to one set of samples (Blumenkrantz and Asboe-Hensen, 1973). A urine sample (blank) was prepared, but the reagent was replaced by 50 μl of 0.5% NaOH. A standard curve was made with known concentrations of glucuronic acid (Sigma) between 25 and 250 μmol. The absorbance was measured at 520 nm in a Beckman DU-64 spectrophotometer. All samples were diluted between 200- and 1000-fold, depending on the treatment.

Hippuric acid concentration was determined by high-pressure liquid chromatography (HPLC) (Chen et al., 1996) on a System Gold Nouveau (Beckman), equipped with a controller (Detector Module 168) and a pump (126 Solvent Module). The analytical column used was an Ultrasphere C_{18} (5 μm) 250 × 4.6 mm ID (Beckman). Two solvents—ethanol (15%) in 20 mmol acetic acid (A) and methanol (B)—were used (see Chen et al., 1996). The total run time was 29.5 min. The gradient used was (%B): 0% at 0 min, 50% at 7 min, and 100% at 14.5 min. Between 14.5 and 19.5 min, B was maintained at 100% and then changed back to 0% at 24.5 min. A 20-μl injection loop was filled with 50 μl to ensure the delivery of a constant volume on every injection. Flow rate was 0.8 ml/min, and the separation was performed at room temperature. The HPLC settings, elution time, and solvent gradient were adapted from Chen et al. (1996) to ensure a good separation of hippuric acid in our samples. Urine samples were diluted with a 1 M sodium acetate buffer (pH 5.0 adjusted with glacial acetic acid) and filtered through 0.2-μm Acrodisc filters (HPLC certified; Fisher Scientific, Chicago, Illinois). The dilution factor varied with the level of resin in the diet. A standard curve was made with known concentrations of hippuric acid (Sigma) ranging from 25 to 250 mg/liter. Two standards were run with every batch of samples. To check for possible carryover during the runs, at least two blanks (mobile phase) were run every day, one

following three samples (six runs), and the other at the end of the day. Duplicate samples were monitored at 210 nm.

Sulfate esters were measured with a turbidimetric assay from Jakubas et al. (1993) and Lundquist et al. (1980). Briefly, 1.5 ml of diluted urine (dilution varied between 10 and 90 times the volume of urine sample available) was mixed with 300 μl of an acidic barium chloride solution to precipitate inorganic sulfate. After 5 min, the solution was centrifuged at 3000 rpm for 10 min. The supernatant was decanted and 300 μl of a 5% (mass per volume) solution of sodium carbonate was added to remove excess barium ions. The solution was centrifuged at 3000 rpm for 10 min, and 1.8 ml of the supernatant was pipetted into a culture tube with 675 μl of 10% (v/v) hydrochloric acid. The tube was topped with nitrogen gas, sealed, and heated in an oil bath at 100°C for 30 min. The hydrolysate was cooled to room temperature, and three aliquots (750 μl each) from each animal were pipetted into test tubes. Two of the aliquots were mixed with Ba-PEG-reagent (Lundquist et al., 1980), while the third was mixed with a PEG-8000 solution (150 g PEG 8000/liter of deionized water) and served as a sample blank. After mixing, samples were allowed to sit for 5 min before determining their absorbance at 600 nm. The 1%, 5%, and 7% treatments had to be discarded because of inconsistent sulfate values when different dilutions were made on the same sample. This could be an indicator that other factors may be influencing sulfate precipitation or hydrolysis. The molar proportion of total conjugates represented by glucuronides, sulfate, and hippuric acid was calculated for 0%, 2%, and 3% resin treatments, because we measured all three conjugates. Molecular weights used were 194.1 for glucuronides (glucuronic acid), 179.2 for hippuric acid, and 96 for sulfate conjugates.

An aliquot of the urine was used to measured pH (Acumet pH meter, model 15). All measurements were taken at 24°C with a pH pencil probe. Two Mojave and one Great Basin woodrat had to be excluded from pH analysis due to the low volume of urine collected.

Statistical Analysis. Relationships between detoxification product excretion rate and either resin intake rate (experiment 1, as in Figure 2) or feeding rate (experiment 2) were compared among the populations by analysis of covariance (ANCOVA, factor = population; covariate = resin or food intake). Residuals were normally distributed when values of excretion rate (milligrams per day) of glucuronides, hippuric acid and sulfates were natural log transformed; this transformation was not necessary in the case of urine pH. Interactions between covariate and factor (i.e., differences in slope) were not significant ($P > 0.05$) and are not reported.

Although regressions describe the relation between resin intake and conjugate excretion, each woodrat is considered three or more times [equal to the number of treatments (resin level)], and so the assumption of independency of data

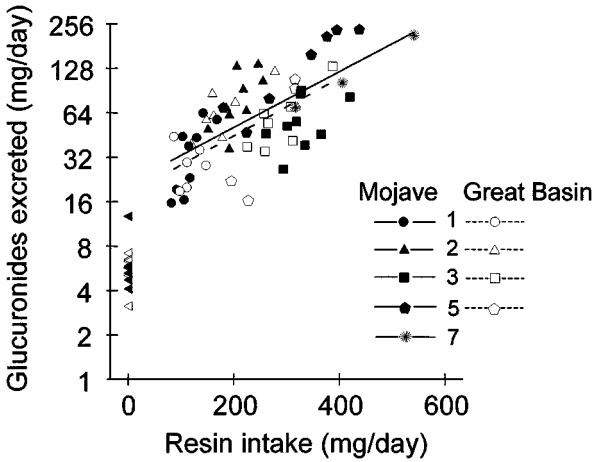

FIG. 2. Excretion of glucuronides as a function of resin intake. The solid line represents the least-squares regression for Mojave woodrats, the dashed line represents the least-squares regression for Great Basin woodrats. Each point represents one woodrat exposed to one resin treatment. The numbers between the symbols in the legend represent the treatments (i.e., percentage of resin in the diet) to which the woodrats were exposed.

points is violated. Therefore, we followed each ANCOVA with a repeated measures one-factor analysis of variance (ANOVA; factor = population, repeated measure = treatment resin level). This test was more conservative because it avoided pseudoreplication and inflation of the degrees of freedom. Treatment resin levels were compared by post-hoc contrasts (Wilkinson, 1992).

Statistical operations were performed according to Wilkinson (1992). In all cases, values are expressed as mean $\pm$ 1 standard error (SE) (N = number of woodrats). Comparisons of means between populations were made by using the t test. For all statistical comparisons, a value of $P < 0.05$ was considered significant, and $0.05 < P < 0.1$ was taken to indicate a trend.

RESULTS

Experiment 1: Effect of Resin Intake on Detoxification Pathways. Woodrats from both populations maintained a relatively constant food intake and body mass at a dietary level of 0% and 1% resin. Some Great Basin woodrats began losing body mass on 2% resin (see Mangione et al., 2000 for detailed mass records). Woodrats were removed from the experiment when eating diets with resin concentrations ranging from 3% to 9% (Table 1). Sixty percent of woodrats were removed from

TABLE 1. STATUS OF WOODRATS WHEN REMOVED FROM EXPERIMENT 1

Woodrat[a]	Treatment[b]	Body mass lost (% from initial)	Observations[c]
60 M	7	−5.1	died[d]
53 M	3	−5.5	non responsive[e]
59 M	9	−5.7	non responsive
45 M	7	−10.6	non responsive
48 M	7	−12.1	swaying[f]
61 M	7	−12.4	swaying
89 G	3	−13.7	moved slowly[g]
118 G	3	−15.0	non responsive
85 G	5	−15.0	non responsive
87 G	3	−15.6	moved slowly
34 G	5	−15.8	moved slowly
88 G	5	−16.8	moved slowly
49 M	7	−17.1	died
51 M	3	−17.4	moved slowly
33 G	5	−17.5	swaying
42 M	5	−20.1	moved slowly
94 G	5	−20.7	moved slowly

[a] M, Mojave woodrat; G, Great Basin woodrats.
[b] Diet resin level (percent) at which woodrats were removed from the experiment.
[c] Status of each woodrat was found at the time it was removed from the experiment.
[d] Woodrat found dead in the cage.
[e] Woodrat did not respond to tactile or sound stimuli and did not move.
[f] Woodrat would sway when touched or when trying to move.
[g] Woodrat moved considerably slower than when it was in treatment 0% (control).

the experiment because they lost 15% or more of body mass, whereas 40% were removed because they exhibited signs of illness before they lost 15% of their body mass (Table 1). Some woodrats that lost only 5% of body mass were removed because they became nonresponsive to tactile or sound stimuli, a sign of possible postabsorptive toxicity.

The excretion of glucuronides was positively correlated with resin intake whether controls (i.e., zero resin intake) were excluded (ANCOVA $F_{1,59} = 50.22$, $P < 0.001$) or included ($F_{1,72} = 169$, $P < 0.001$) (Figure 2). Individual woodrats from both populations exhibited similar patterns of excretion in relation to intake because there was no significant difference by population in either elevation ($F_{1,59} = 0.98$, $P = 0.32$) or slope. The influence of resin ingestion on glucuronide excretion was also apparent in the repeated-measures ANOVA

($F_{3,36} = 43.7$, $P < 0.001$) where population as a factor had no effect ($F_{1,12,} = 1.4$, $P = 0.26$).

Excretion of hippuric acid was independent of resin intake whether controls were excluded (ANCOVA, $F_{1,59} = 0.44$, $P = 0.50$) or included (ANCOVA, $F_{1,72} = 0.6$, $P = 0.44$), but was nearly three times higher in Great Basin woodrats ($F_{1,59} = 18.05$, $P < 0.001$) (Figure 3).

Sulfate excretion rate was independent of resin intake over the range measured ($F_{1,20} = 2.75$, $P = 0.11$), and there was no difference between populations ($F_{1,20} = 0.48$, $P = 0.49$) (Figure 4). However, sulfate excretion increased with resin intake when controls (zero resin intake) were included (ANCOVA $F_{1,40} = 32.6$, $P < 0.001$) (Figure 4). The repeated measure analysis on the 0%, 2%, and 3% treatments suggested that this increment reflects a resin ingestion-dependent sulfate excretion up to a plateau value. The repeated measures analysis confirmed that there was a diet-dependent increase in sulfate excretion rate ($F_{2,20} = 18.2$, $P < 0.001$) with no difference by population ($F_{1,10} = 0.016$, $P = 0.9$). The significant diet effect was between controls and the 2% resin treatment ($F_{2,10} = 7.5$, $P = 0.01$), but not between the 2% and 3% resin treatments ($F_{2,10} = 0.75$, $P = 0.5$).

Urine pH declined with resin intake rate whether controls (zero resin intake) were excluded ($F_{1,63} = 15.9$, $P < 0.001$) or included ($F_{1,78} = 14.1$, $P < 0.001$)

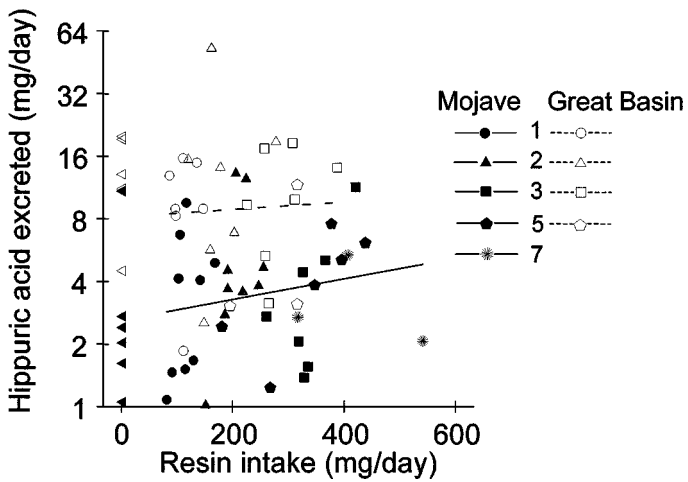

FIG. 3. Excretion of hippuric acid as a function of resin intake. The solid line represents the least-squares regression for Mojave woodrats, the dashed line represents the least-squares regression for Great Basin woodrats. Each point represents one woodrat exposed to one resin treatment. The numbers between the symbols in the legend represent the treatments (i.e., percentage of resin in the diet) to which the woodrats were exposed.

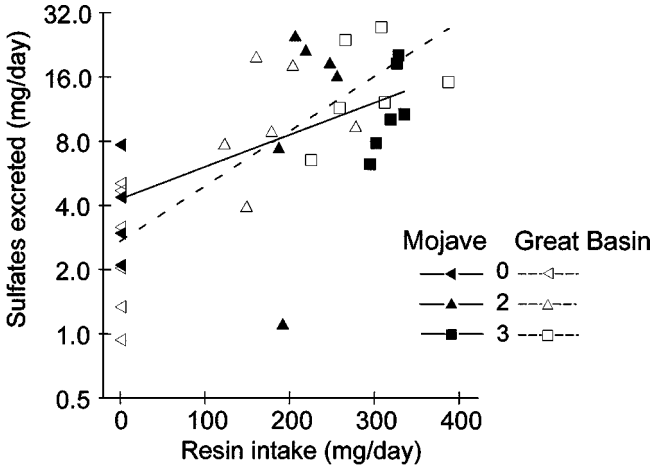

FIG. 4. Excretion of sulfates as a function of resin intake. The solid line represents the least-squares regression for Mojave woodrats, the dashed line represents the least-squares regression for Great Basin woodrats. Each point represents one woodrat exposed to one resin treatment. The numbers between the symbols in the legend represent the treatments (i.e., percentage of resin in the diet) to which the woodrats were exposed. The very lowest value at around 200 mg of resin per day (filled triangle) was identified as an outlier, but the ANCOVA is not substantially different whether it is included or excluded. The datum was included in the final ANCOVA.

(Figure 5). Individual woodrats from both populations apparently exhibited the same urine pH pattern in relation to resin intake because there was no difference by population in either elevation ($F_{1,63} = 1.8$, $P = 0.19$) or slope. The influence of resin ingestion on urine pH was also apparent in the repeated-measures ANOVA ($F_{3,36} = 13.6$, $P < 0.001$), where population was not a significant factor ($F_{1,12} = 3.53$, $P = 0.085$).

Experiment 2: Effect of Food Intake on Detoxification Pathways. Woodrats fed diets with increasing resin concentration decreased their feeding rates by as much as 50% (Mangione et al., 2000). We tested whether the variation in detoxification pathways and urine pH with resin intake (e.g., Figures 2, 4, and 5) might be explained by decreases in feeding rate. Were this the case, glucuronide excretion would increase with decreasing feeding rate on resin-free diet, whereas the opposite pattern was found in woodrats from both populations (Figure 6, top), i.e., increasing glucuronide excretion with increasing feeding rate ($F_{1,34} = 16.5$, $P < 0.001$). Analogously, were this the case for urine pH, then it would decline with decreasing feeding on resin-free diet, whereas it did not change with intake rate in either population ($F_{1,34} = 0.05$, $P = 0.83$) (Figure 6, bottom). Overall, as feeding rate changed, the extent of variation in detoxification or urine pH was nil

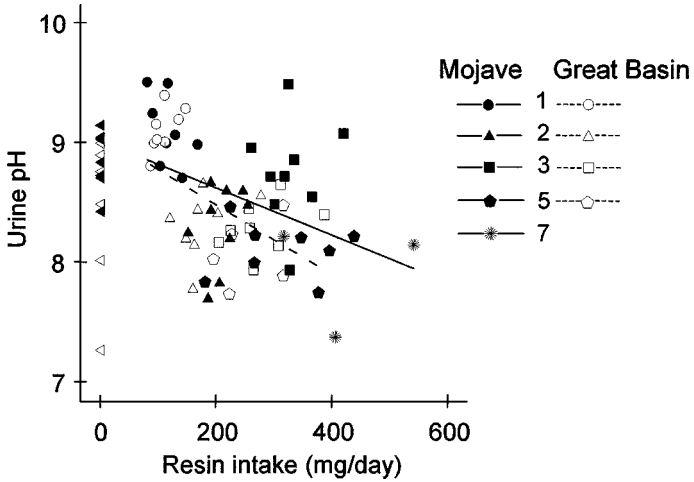

FIG. 5. Relationship between urine pH and resin intake. The solid line represents the least-squares regression for Mojave woodrats, the dashed line represents the least-squares regression for Great Basin woodrats. Each point represents one woodrat exposed to one resin treatment. The numbers between the symbols in the legend represent the treatments (i.e., percentage of resin in the diet) to which the woodrats were exposed.

or in the wrong direction and was very small compared to the much larger changes in woodrats consuming increasing amounts of resin.

DISCUSSION

Detoxification Routes Used by Woodrats. Variation in detoxification can be due to qualitative and quantitative differences (Hansen and Shane, 1994). Qualitative differences correspond to the use of different metabolic routes and the activation or deactivation of metabolic pathways. Quantitative differences are due to variations in enzyme levels. Without simultaneous study of several possible detoxification pathways and the determination of their relative capacities, little progress can be made in understanding the role of detoxification in setting the limits of toxin ingestion (MacCoubrey et al., 1997).

In this study, we considerably advanced knowledge in these regards for one natural herbivore–PSM system: desert woodrats consuming resin from creosote bush. There were no major qualitative differences in detoxification pathways among individuals or populations; all three phase II detoxification routes (glucuronidation, sulfation, and amination) were used to some degree by both woodrat populations exposed to the resin. On resin-free diet, the molar excretion

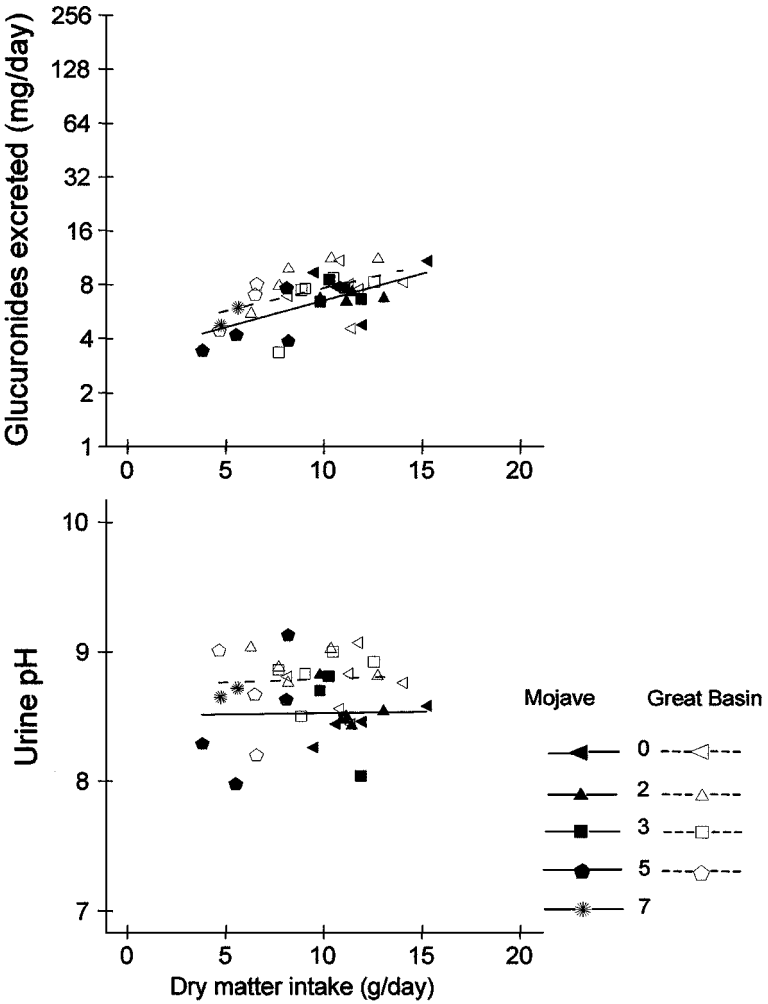

FIG. 6. Variation of glucuronides excreted (top) and urine pH (bottom) as a function of dry matter intake in pair-fed control woodrats (see Methods and Materials). The solid line represents the least-squares regression for Mojave woodrats, the dashed line is the least-squares regression for Great Basin woodrats. Each point represents one woodrat restricted to the same feeding rate it had during experiment 1 at a particular resin treatment. The numbers between the symbols in the legend represent the corresponding treatments (i.e., percentage of resin in the diet), although in this experiment there was no resin in the diets. The *y* axes of the figures match those in Figures 2 and 5 to permit comparison of these excretion rates in woodrats on resin-free diet with those of woodrats eating resin-containing diets.

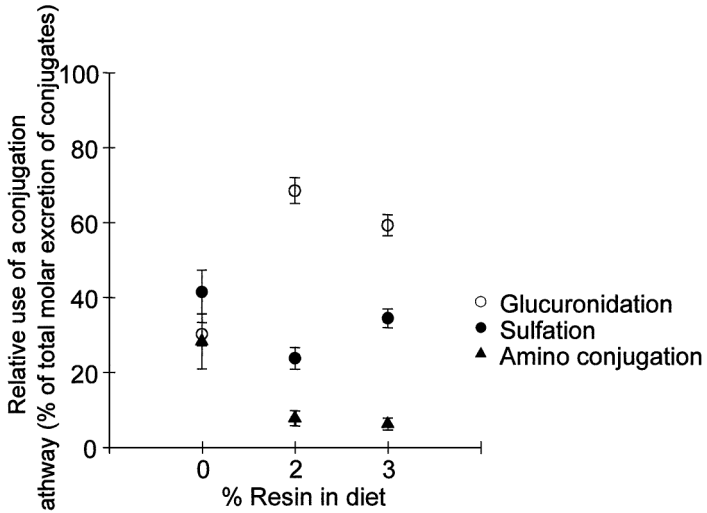

FIG. 7. Variation in the relative use of detoxification pathways versus percentage of resin in the diet. Percentages on the *y* axes were calculated as the ratio of the molar excretion rate of each conjugate to the sum of the molar excretion rates of the three conjugates times 100. Each value is the average of a pool of 12 individuals from both populations.

rates of the three conjugates (glucuronides, glycine, sulfate) were similar (Figure 7). Because glucuronides were the only conjugates that showed consistent increases in excretion with increasing resin intake (c.f. Figures 2–4), glucuronidation became proportionally more important than other conjugation pathways following resin ingestion, coming to represent about 75% of total moles of conjugates excreted (Figure 7). However, we do not know whether this is because of higher levels of specific constitutive enzymes or induction of the specific enzymes involved. Alternatively, reliance on glucuronidation may differ for woodrats reared on other diets or physiological conditions (Price and Jollow, 1988, 1989; Nanbo, 1993), or for woodrats possessing different gut microbial communities (Phipps et al., 1998).

Does Detoxification Capacity Set the Limit on Resin Intake Rate? We found no qualitative difference among woodrats to explain their differential tolerance to creosote bush resin. We also, can reject a number of hypothetical quantitative explanations.

We reject the hypothesis that the amount of resin that indiviuals can ingest is related to their capacity to detoxify and eliminate toxin(s), because hippuric acid excretion rates were independent of resin ingestion rates (Figure 3). Although the level of hippuric acid in urine of Great Basin woodrats was significantly higher than that in Mojave woodrats, this does not explain the latter's greater tolerance to resin.

Hippuric acid is a rather specific conjugate of benzoic acid. If benzoic acid is not a metabolic product of a toxic compound(s), then there would be little relationship between tolerance and hippuric acid excretion. It would be interesting to measure excretion of other benzoic acid metabolites, e.g., flavanoids with different patterns of hydroxylation such as *m*-hydroxybenzoic acid or *m*-hydroxphenyl propionic acid (Harborne, 1991). In addition, there might be other phase II conjugations that involve amino acids other than glycine, e.g., taurine (Caldwell, 1986). A good approach to test this might be to assay urine for glycine and taurine (Konishi et al., 1998; Phipps et al., 1998).

We reject the hypothesis that tolerance to resin is related to woodrat sulfation capacity because sulfate excretion increased with resin intake up to a plateau at 200 mg resin/day (Figure 4), while woodrats continued to consume resin at two to three times this level (Mangione et al., 2000) (Figure 2). The apparent saturation of sulfation in woodrats seems consistent with the observation in other mammals that conjugation with sulfate is a high affinity–medium capacity enzymatic system (Sipes and Galndolfi, 1991).

Two physiological features related to detoxification, glucuronide excretion and urine pH, were correlated with resin intake and consistent with our a priori predictions that the amount of resin that individuals can ingest is related to their capacity to detoxify and eliminate the PSMs (Figure 1). These correlations were not artifactually related to variation in feeding rate (Figure 6). While Figures 2 and 5 illustrate how individual woodrats from the two populations respond to variation in resin intake with regard to glucuronide excretion and urine pH, they are not effective for testing whether a particular detoxification mechanism or buffer capacity might be limiting, and, thereby, explain observed differences in resin tolerance among individuals or between the two woodrat populations. To test this, we regressed each individual's maximum value for glucuronide elimination or minimum value for urine pH against its maximum tolerable resin intake rate—the latter values were taken from Mangione et al. (2000), although they correspond closely to maxima from Figures 2 and 5.

The maximum excretion of glucuronides was positively correlated with maximum resin intake (ANCOVA $F_{1,13} = 8.57$, $P < 0.012$) (Figure 8, top). Individual woodrats from both populations exhibited the same pattern of maximum glucuronide excretion in relation to maximum resin intake because there was no difference by population in either elevation ($F_{1,13} = 0.63$, $P = 0.44$) or slope. This corresponds with the prediction in Figure 1a. Furthermore, the mean maximum glucuronide excretion rate of Mojave desert woodrats, 143.8 ± 23.3 mg/day ($N = 9$), exceeds that of the Great Basin desert woodrats, 67.0 ± 10.8 mg/day ($N = 8$) ($t_{15} = -2.86$, $P < 0.012$). Therefore, in accord with Figure 1a, we cannot reject the hypothesis that animals from both populations absorb the same proportion of toxin in food and that woodrats within and between populations that

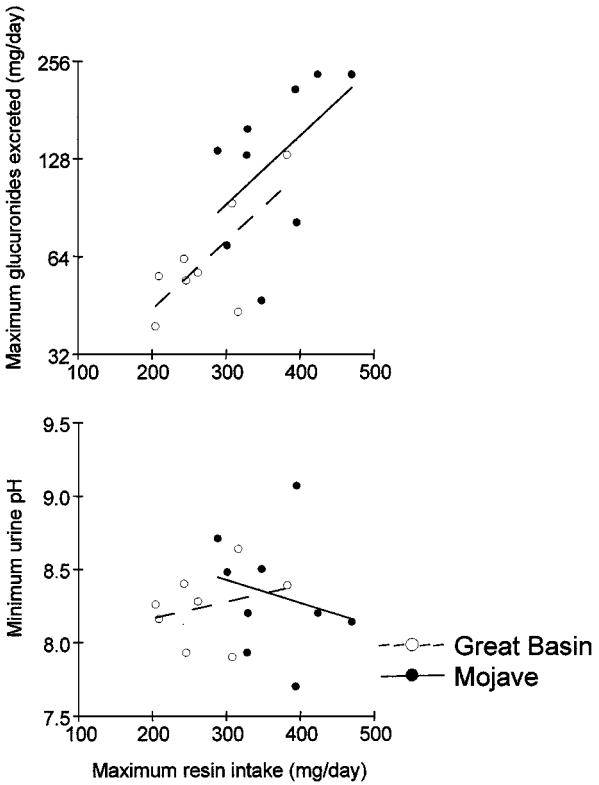

FIG. 8. Maximum glucuronides excreted (top) and minimum urine pH (bottom) as a function of resin intake. Each point represents an individual woodrat's maximum resin intake rate and corresponding maximum glucuronide excretion rate or minimum pH. The solid line represents the least-squares regression for Mojave woodrats, the dashed line represents the least-squares regression for Great Basin woodrats.

tolerate more resin do so because they have a greater capacity for glucuronide excretion.

Instead urine pH can be considered an indicator of an animal's acid–base status and its capacity to detoxify and eliminate metabolites. These metabolites are strong acids that may challenge the animal's acid–base homeostasis (McLean et al., 1993; Foley et al., 1995). However, the tolerance for resin ingestion does not relate as well to urine pH as it does to glucuronide excretion. First, the lowest urine pH of each individual was not correlated with the individual's maximum tolerable resin intake rate (ANCOVA $F_{1,14} = 0.04$, $P = 0.84$) (Figure 8, bottom). Second, the reduction in urine pH to 8 observed in desert woodrats eating creosote resin

seems modest compared to reductions to pH 7.4 that have been observed in other woodrat species exposed to other PSMs (Dearing et al., 2000). Although urine pH was decreased as woodrats ingested greater amounts of resin (Figure 5), we reject the idea that they had to cease eating resin because they reached their capacity to buffer blood from organic acids or to excrete H^+ ions. Moreover, the small R^2 (0.22, Figure 5) suggests that some other factor might be involved in reducing of uirne pH, such as diuresis (García Matilla et al., 1999).

In conclusion, we studied the relationship between three detoxification mechanisms and urine pH and the tolerance of desert woodrats from two populations to a mixture of naturally occurring PSMs (mostly phenolics) in resin from creosote bush. The excretion rate of two phase II detoxification conjugates, glucuronides and sulfides, increased with increasing resin intake, while hippuric acid excretion was independent of resin intake. The molar proportion of glucuronides in urine was three times that of the other conjugates combined. Urine pH, a possible indicator of an animal's capacity to detoxify and eliminate metabolites, declined with increasing resin ingestion. Based on an evaluation of variation in the three detoxification pathways and urine pH in relation to resin intake, we rejected the hypotheses that tolerance to resin intake is related to woodrat capacity for amination, sulfation, or pH regulation. However, we could not reject the hypothesis that woodrats within and between populations that tolerate more resin do so because they have a greater capacity for glucuronide excretion. This hypothesis might be tested by feeding woodrats other compounds detoxified by this pathway, e.g., benzoic acid, and testing their ability to further increase glucuronide excretion rate. Another way to test whether glucuronidation can set the limits for tolerance to a PSM might be by using specific inhibitors of glucuronyl transferase.

Interactions between herbivores and the PSMs they ingest are complex. There may be other explanations for some of the patterns that we have observed. For example, we did not evaluate how differences in gut microbial community structure and function might influence detoxification, or whether different woodrats eating the same amount of resin excrete similar amounts of a conjugate (e.g., sulfates) even when they might actually differ in their metabolism of specific phenols in the resin. Other possible mechanisms that might explain differences in tolerance, such as differential absorption of PSMs, differences in other phase I and II detoxification pathways, differences in target site sensitivity, and differences in the capacity to habituate to aversive sensory properties of PSMs, remain to be studied.

Acknowledgments—We would like to thank two anonymous reviewers for the useful comments on this manuscript. We are grateful to Mark Larson, University of Wisconsin, Department of Ophthalmology, for letting us use the feed pelleting facilities and to Bruce Darken for his technical assistance during this study. Thanks to Perry Chang for introducing A.M.M to the HPLC world. Anna Weber assisted with care of the woodrats and the experiments. Funding was provided by a University of Wisconsin Hatch grant (142-3779) to WHK, and the Max McGraw Wildlife Fund.

Abstract—High foliar phenolics are generally assumed to increase resistance to insect herbivores, but recent studies show that tobacco lines modified to over– and underexpress phenolics do not exhibit higher constitutive resistance to caterpillars. This is contrary to the expectation that ingestion of tobacco phenolics, particularly chlorogenic acid, should cause oxidative stress in herbivores. We investigated free radical production and antioxidant capacity of fresh crushed leaves of tobacco lines exhibiting over a sixfold difference in chlorogenic acid content to test whether high phenolic concentrations are associated with increased production of reactive oxygen species (ROS). The effects of in planta phenolic levels on feeding behavior, growth, biochemical markers of oxidative stress, and the antioxidant capacity of midgut fluid and hemolymph were assessed in tobacco budworm, *Heliothis virescens*. The experiments showed that high phenolic foliage was more prooxidant than low phenolic foliage, but the net balance in crushed tissue was antioxidant in comparison to buffer and the commercial antioxidant standard, Trolox. In *H. virescens*, the antioxidant capacity of midgut fluid was also powerful, and caterpillars fed high phenolic foliage did not exhibit the expected markers of oxidative stress in midgut tissues (altered ascorbate ratios, disulfides, or total hydroperoxides). Instead, hemolymph of larvae fed high phenolic foliage exhibited improved total Trolox equivalent antioxidant capacity (TEAC). These results suggest that the elevated foliar phenolics in some plants may have beneficial antioxidant properties for herbivorous insects, much as dietary phenolics do in mammals.

INTRODUCTION

Although plant phenolics are believed to play an important role in chemical defense against herbivores, their specific physiological effects on insects are variable and poorly understood (Harborne, 1985; Appel, 1993). They have been variously described as antifeedants (Bernays et al., 1989; Wrubel and Bernays, 1990), digestibility reducers (Feeny, 1976; but see Martin et al., 1987), and toxins (Bernays, 1981; Steinly and Berenbaum, 1985). One mechanism by which their toxicity is thought to arise is via their propensity to produce reactive by-products when oxidized (Felton et al., 1989; Ahmad, 1992; Appel and Schultz, 1992; Appel, 1993; Barbehenn and Martin, 1994). These products include semiquinone radicals and other reactive oxygen species (ROS) such as superoxide anion and hydroxyl radicals, hydrogen peroxide, and singlet oxygen (Hodnick et al., 1989; Ahmad and Pardini, 1990), that are generated during autooxidative processes and/or by the action of plant oxidases during maceration of leaf tissues.

Evidence for the prooxidant model of toxicity comes primarily from artificial diet experiments. When pure phenolics are presented in this manner, many reduce growth and survival of caterpillars (Reese and Beck, 1976; Elliger et al., 1981; Isman and Duffey, 1982a,b, 1983; Lindroth and Peterson, 1988; Felton et al., 1989, 1992; Stamp et al., 1994; Stamp and Yang, 1996; Yang et al., 1996; Ali et al., 1999). In the case of chlorogenic acid (CHA), a widespread *o*-dihydroxy phenolic, reduced insect performance is due at least in part to the antinutritive effects of oxidative by-products on dietary constituents. Aeration and addition of polyphenol oxidases to the diet enhances CHA oxidation and increases the binding of orthoquinones to nucleophilic groups of amino acids and proteins, which reduces their nutritional quality and/or bioavailability (Felton et al., 1989, 1992; Duffey and Felton, 1991; Bi et al., 1994).

It has generally been assumed that similar reactions occur in the insect digestive tract, particularly in caterpillar midguts where the alkaline pH and oxidizing redox potentials would promote the generation of harmful ROS. Such reactions would result in direct oxidative damage to midgut lipids and proteins (Appel and Martin, 1990; Summers and Felton, 1994; Appel, 1994). Summers and Felton (1994) found elevated levels of biochemical markers of oxidative stress (lipid peroxidation products, oxidized protein, and free iron) in midguts of caterpillars fed artificial diets containing chlorogenic and caffeic acid. Addition of the antioxidant ascorbic acid to the diet ameliorated some of these effects, suggesting that their toxicity was due to prooxidant behavior. Barbehenn and Martin (1994) showed that tannic acid is oxidized as it passes through the gut of *Malacosoma*

disstria, but not *Orygia leucostigma*, which is tolerant of high concentrations of this polyphenolic.

Several recent attempts to demonstrate prooxidant effects of phenolics in planta have produced results inconsistent with the prooxidant model and artificial diet experiments. In a series of experiments with transgenic tobacco (*Nicotiana tabacum*) lines modified to differentially express phenylpropanoid products, Bi et al. (1997a), Eichenseer et al. (1998), and Ali et al. (1999) found no negative effects of high foliar phenolics on growth and survival of *Manduca sexta* and *Heliothis zea*. These plants over- and underexpressed phenylalanine ammonia lyase (PAL) through sense suppression by an introduced bean PAL2 transgene (Elkind et al., 1990; Pallas et al., 1996; Howles et al., 1996) and exhibited a 6.8-fold difference in chlorogenic acid content and up to 84% difference in total flavonoid levels (Bi et al. 1997a). Since these modifications to constitutive phenolic levels have been shown to clearly influence resistance to fungal and viral pathogens (Maher et al., 1994; Pallas et al., 1996), the absence of an effect on chewing herbivores was unexpected.

The discrepancy between in planta experiments and artificial diet studies is probably due to the complex chemical interactions among phenolics, plant oxidases, and dietary nutrients and antioxidants that cooccur in fresh foliage (Bi et al., 1997b; Ali et al., 1999). High levels of phenolics in plant foliage may fail to induce prooxidant damage to herbivores if either oxidative reactions and ROS production in macerated plant tissue do not occur to the same extent as observed in artificial diets or if herbivores feeding on foliage are better able to withstand oxidative stress or damage than those on artificial diet. The purpose of the present study was to reassess the prooxidant nature of phenolics in the context of fresh foliage, rather than artificial diet. In order to appropriately interpret their effects on the herbivore, we simultaneously measured behavioral and physiological responses of *H. virescens*. We used transgenic tobacco lines modified to over- and underexpress foliar phenylpropanoids to manipulate in planta levels of phenolics. The effects of phenol content on radical production (hydroperoxides) and total antioxidant (quenching of the $ABTS^{\cdot+}$ radical) capacities of crushed foliage were measured and compared to the antioxidant capacities of *H. virescens* midgut fluid, hemolymph, and oxidative damage to the midgut. Feeding trials to measure effects of phenolics on preference, consumption, digestive efficiency and growth were conducted. Our goal was to assess the degree to which foliar phenolic levels correlate with free radical production and oxidative stress experienced by insect herbivores. A strong correlation would support the prooxidant model of phenolic toxicity and confirm the importance of herbivore traits such as gut physicochemistry and antioxidant defenses for circumventing plant chemical defenses. A weak correlation would suggest that oxidative activation of phenolics may be of less importance in antiherbivore defense.

METHODS AND MATERIALS

Insects and Plants

Heliothis virescens larvae were obtained from a colony maintained at the University of Arkansas and reared on a wheat germ-casein diet or on greenhouse grown transgenic tobacco (*Nicotiana tabacum*).

The generation of PAL modified tobacco lines and their phenotypic characteristics have been described in detail elsewhere (Elkind et al., 1990; Pallas et al., 1996; Howles et al., 1996). The 274-T4 line was developed from cv. Xanthi-nc and exhibits reduced accumulation of PAL transcripts through sense suppression (Elkind et al., 1990). The C-17 control lines have lost the bean PAL2 gene through segregation and are thus operationally wild type. In Ox lines, the gene silencing was lost following selfing, so the resulting offpring exhibit much higher PAL activity and elevated phenylpropanoid products compared to wild types (Howles et al., 1996). Two additional transgenic lines were included as part of a parallel study investigating the effects of salicylic acid (SA) on induced resistance to insects. The NahG-10 line contains the bacterial *Nah*G gene encoding salicylate hydroxylase (Gaffney et al., 1993; Delaney et al., 1994), which removes SA after it is synthesized. These plants have higher constitutive jasmonic acid levels and greater induced resistance to herbivores, apparently because the inhibitory effect of SA on JA has been removed (Felton et al., 1999). Crossing NahG-10 with Ox-434 plants produced the Ox-NahG line, which exhibits elevated phenolics and reduced SA.

Plants were propagated from stem cuttings and maintained in a greenhouse in Redi-Earth Peat-Lite soil mix (Scotts-Sierra Horticultural Products Co., Marysville, Ohio). They were watered daily and fertilized with Osmocote (N-P-K 14:14:20, Scotts-Sierra Horticultural Products Co.) each month. The greenhouse was lighted with high-pressure sodium lights (100 W) on 14 hr scotophase and a day–night temperature of $27{:}19 \pm 2^{\circ}$C. Plants were used before they reached the flowering stage.

Chemicals. Trolox (Hoffman-La Roche) (6-hydroxy-2,5,7,8-tetramethychroman-2-carboxylic acid), ABTS [2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid)], bovine methemoglobin and all other reagents were obtained from Sigma-Aldrich Chemical Co., St. Louis, Missouri.

Oxidizing Properties of Plant Foliage

Total Antioxidant Activity. The total antioxidant activity of aqueous leaf extract was measured relative to the antioxidant standard Trolox (TEAC assay) using a modified ferryl myoglobin/ABTS assay (Miller and Rice-Evans, 1994). This assay has been widely used as a general measure of antioxidant activity of food

extracts, pure compounds in solution, or body fluids, and it is appropriate for both aqueous and lipophilic systems (Rice-Evans et al., 1995, 1996). In brief, the ABTS [2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid)] radical cation is generated by the activation of metmyoglobin with hydrogen peroxide. Suppression of the ABTS·+ blue-green chromophore by the sample of interest is monitored spectrophotometrically and compared to the scavenging capacity of Trolox, a standard antioxidant, under the same conditions. We used the assay as described by Miller and Rice-Evans (1994) but used bovine methemoglobin in place of metmyoglobin.

Total antioxidant activity of foliage of the six tobacco lines was assayed using the following procedure: Two leaf discs were collected from two leaves on each of 10 individual plants of each line. Discs (9 cm) were punched from the second and third fully expanded leaves below the apical terminal using a cork borer and placed on ice. After fresh weights of the discs were recorded, each was crushed in 1 ml of PBS buffer (0.005 M phosphate, 0.145 M NaCl, pH 7.4) using four strokes of the end of a heavy steel cylinder at room temperature. Then 20 μl aliquots of this aqueous extract were assayed immediately for antioxidant activity. The total time elapsed between the harvesting of the leaf discs and the assay was less than 45 min, and spectrophotometric measures were initiated within 10 min of the time plant tissue was crushed. Preliminary experiments showed that this method produced reproducible values among discs from a single leaf. The 20 μl of leaf extract, buffer, or Trolox standard was combined in a standard 96-well microplate with 110 μl of 0.02% methemoglobin solution (in PBS buffer at room temperature) and 110 μl of ABTS solution (0.8 mg/ml) in buffer. After the initial absorbance at 590 was recorded, the reaction was initiated by the addition of 40 μl of H_2O_2 in dH_2O (0.015%) and the increase in absorbance monitored for 20 min. All reactions were performed in duplicate and a standard curve of Trolox (0.3, 0.43, 0.6, and 3.0 mM) was run with each microplate.

Hydroperoxide Production in Macerated Leaves. To estimate free radical generation in high and low phenolic tobacco foliage, total hydroperoxide (ROOH) formation in macerated foliage of unwounded plants was measured using xylenol orange, which forms a complex with the $Fe_3{}^+$ produced by the hydroperoxide-based oxidation of $Fe_2{}^+$ that can be quantified spectrophotometrically (Jiang et al., 1992). Pairs of leaf discs were punched from fully expanded leaves and immediately placed in test tubes containing either 2 ml ice cold 0.1 M KPO_4 buffer (pH 7.4) or buffer plus 900 units of catalase. Because catalase removes H_2O_2, the difference between the values from the two tubes represents the portion of total hydroperoxides specifically attributable to H_2O_2.

One leaf from the upper portion of each plant was sampled, but samples were pooled such that each test tube contained three leaf discs from three plants and was paired with a second tube (+ catalase) that contained the three corresponding discs from the same plants. The tubes were left at room temperature for 1 hr before leaf

discs were homogenized for 7 sec with an electric tissue grinder. Samples were centrifuged at 10,000*g* for 4 min to settle the cellular debris.

Leaf sample supernatant (20 μl) was combined in a microplate well with 180 μl of a reagent solution containing 100 μM xylenol orange, 250 μM $Fe_2{}^+$, 25 mM H_2SO_4, and 4 mM BHT in 90% methanol (v/v). After 30 min at room temperature, the OD_{560} was recorded and compared to a standard curve prepared with *t*-butyl hydroperoxide. Thus, the measure is a combined measure of constitutive levels of hydroperoxides in leaf tissues as well as those produced by the leaf discs during the hour after damaging.

Data Analysis. A three-way analysis of variance was used to partition variation in antioxidant activity among leaves, individual plants, and the transgenic lines. Tukey's test was used to identify treatments that differed. Variation in hydroperoxides generated in the absence of catalase across tobacco lines was analyzed by one-way ANOVA followed by Tukey's test. Levels of hydroperoxides generated in the presence of catalase did not meet the assumptions for ANOVA so were analyzed separately using a Kruskal-Wallis analysis on ranks and a Student-Neuman Keuls test to separate means.

Insect Feeding Trials

Performance. Standard gravimetric nutritional budgets were calculated for fifth-instar *H. virescens* fed over- (Ox) and underexpressing (T4) tobacco. Larvae were reared on artificial diet until they reached the premolt stage (head capsule slipping and not feeding). They were then weighed, placed individually into plastic tubs containing a preweighed tobacco leaf, and maintained at 28°C on a 16L:8D cycle. Each tub was lined with moistened paper towel, and leaves were replaced every 48 hr or as needed. Only fully expanded leaves from the upper part of the plant were used. Uneaten leaf material and frass were dried and weighed to the nearest 0.1 mg. A wet/dry conversion factor was calculated from 10 randomly selected leaves from each tobacco line from which a 9-mm disc was punched from the tip of each leaf with a cork borer.

After 72 hr, larvae were harvested and hemolymph samples collected (see below), after which the larvae were killed by freezing. It is unlikely that hemolymph removal affected dry mass. Carcasses were oven-dried at 70°C and weighed when they reached constant weight. Growth, consumption, and approximate digestibility (AD = consumption/consumption-egested) were calculated on a dry weight basis.

Feeding Preference. A 12- to 36-hr feeding preference assay with paired choices of leaf discs was performed on the following: Ox vs. C17, Ox vs. T4, and C17 vs. T4 with 16–24 replicates per test. At least 10 plants per treatment were represented in each test. A pair of leaf discs was punched from a newly expanded leaf using a 9-mm-diam. cork borer and arranged alternately with another pair from a different treatment plant in a 10- × 1-cm plastic petri dish. Dishes were lined

with moistened filter paper, and discs were held in place by impaling them on the upright points of four thumbtacks inserted through the bottom of the filter paper. An individual fourth-instar larva was placed in the center of each arena and allowed to feed for 12–36 hr until it had eaten 30–80% of the available food. Uneaten leaf disc material was digitally scanned using a Hewlett Packard flatbed scanner and the area in pixels quantified with SigmaScan Image software (Jandel Corporation, San Rafael, California). Differences in the area of leaf material consumed were assessed using a *t* test.

Oxidative Status of Herbivore Tissues. Three biochemical indicators of oxidative stress were examined in midgut tissue: total and reduced ascorbic acid, hydroperoxide formation, and total disulfides. Larvae were reared on detached leaves until they reached the fourth and fifth instars; then they were transferred to potted plants in the greenhouse for an additional four days before midgut tissues were assayed. Five to 10 larvae were placed in net bags for a total of five to seven plants per treatment. After larvae were harvested, the midguts were dissected, separated from the lumen contents, rinsed with 0.01 M KPO_4 buffer, and pooled in groups of three midguts per replicate. The number of larval replicates per plant varied from 1 to 3. After tissue samples were weighed in pretared tubes, they were homogenized (3 midguts/ml 0.01 M KPO_4 buffer) and immediately assayed as described in Summers and Felton (1994).

For total and reduced ascorbic acid, 300 μl of midgut homogenate was added to a microcentrifuge tube containing 300 μl of 10% metaphosphoric acid [to stabilize the ascorbic acid (AA)]. For total AA, 100 μl of sample was then combined with 125 μl sodium phosphate buffer (0.05 M, pH 8.4, with 3 mM EDTA, and 25 μl of 10 mM dithiothreitol (DTT) to reduce dehydroascorbic acid (DHA) to AA. After 10 min, excess DTT was removed by adding 25 μl of 5.0 mM *N*-ethyl malemide (NAM), and 100 μl of 10% trichloroacetic acid, 100 μl of 44% *o*-phosphoric acid, 100 μl of 4% 2,2′-dipyridyl in 70% ethanol, and 50 μl of 3% $FeCl_3$ were added to the incubation mix. After 40 min at 40°C, tubes were centrifuged and the OD_{520} of the supernatant was measured against a standard curve of total ascorbic acid by using a Cambridge 7520 microplate reader. To determine reduced AA, a parallel incubation was performed, except that 175 μl of sodium phosphate buffer (without EDTA) was used and no DTT or NEM was added. DHA was calculated by subtracting reduced AA from total AA.

Total hydroperoxides (ROOH) were measured using methods modified from Jiang et al. (1992): 20 μl of midgut homogenate was combined in a microplate well with 180 μl of a reagent solution containing 100 μM xylenol orange, 250 μM $Fe_2{}^+$, 25 mM H_2SO_4, and 4 mM BHT in 90% methanol (v/v). After 30 min. at room temperature, the OD_{560} was recorded and compared to a standard curve prepared with *t*-butyl hydroperoxide.

Total disulfides were measured following the method of Anderson and Wetlaufer (1975) as modified in Summers and Felton (1994). In a microplate

well, 50 μl of homogenate was combined with 50 μl 6 N NaOH and incubated for 30 min at room temperature. Then 100 μl of 6 N H_3PO_4 was added, the plate was shaken thoroughly, and 20 μl of 2.5 mM DTNB (5,5′-dithio-bis-(2-nitrobenzoic acid) in 0.05 M sodium acetate was added. After an additional 20 min, the OD_{420} was measured.

The antioxidant activity of midgut fluid was assayed using the ferryl myoglobin–ABTS assay. Intact midguts were rinsed with saline to remove any contaminating oxidases from hemolymph, then slit longitudinally and their contents (including peritrophic envelope) placed in a tared microcentrifuge tube. Preliminary experiments revealed that the midgut content preparations had very strong antioxidant activity, so after weighing to the nearest 0.1 mg, samples were diluted with 10 times their mass in volume (milliliters per milligram) with distilled water. After centrifugation for 2 min at 14,000*g*, 20 μl of the supernatant was used in the ABTS assay. Tubes were kept on ice until the time of the assay, which was performed at room temperature. The assay was replicated with nine larvae fed high phenolic (Ox) plants, nine led low phenolic (T4) plants, and six fed wild-type (C17) plants. Treatment effects on the quantity of ABTS radical formed after 10 min were tested using a one-way ANOVA.

Antioxidant activity of hemolymph from larvae fed high- (Ox) and low-phenolic (T4) plants for 72 hr (used in the nutritional performance experiment) was also measured by using the ABTS radical formation assay. Larvae were chilled and a drop of hemolymph collected from a proleg into a cold ceramic dish. Assays were initiated within 5–10 min because hemolymph tended to coagulate quickly. Undiluted hemolymph (20 μl) was used in the ABTS assay using the same methods described above for foliage and midgut fluid. Samples from nine larvae from the Ox treatment and 10 from the T4 treatment were assayed. A Mann-Whitney rank sum test was used to test for significant differences in the rate of radical formation after 20 min.

RESULTS

Antioxidant Properties of Plant Foliage. Aqueous leaf extracts from all the tobacco lines exhibited antioxidant activity that inhibited the rate of ABTS radical formation relative to the phosphate buffer control (Figure 1) over a 20-min incubation period. Three-way analysis of variance showed significant differences between tobacco lines ($P < 0.001$), individual plants ($P < 0.006$), and leaves ($P < 0.001$). An all pairwise multiple comparison (Tukey's test) showed that the low-phenolic line (T4) had the strongest antioxidant properties, particularly in comparison to the high phenolic lines (Ox and Ox-NahG) and the wild-type control (C17). Although the high phenolic line (Ox) was more proxidant than the wild-type, this difference was not statistically significant. The NahG plants exhibited an intermediate

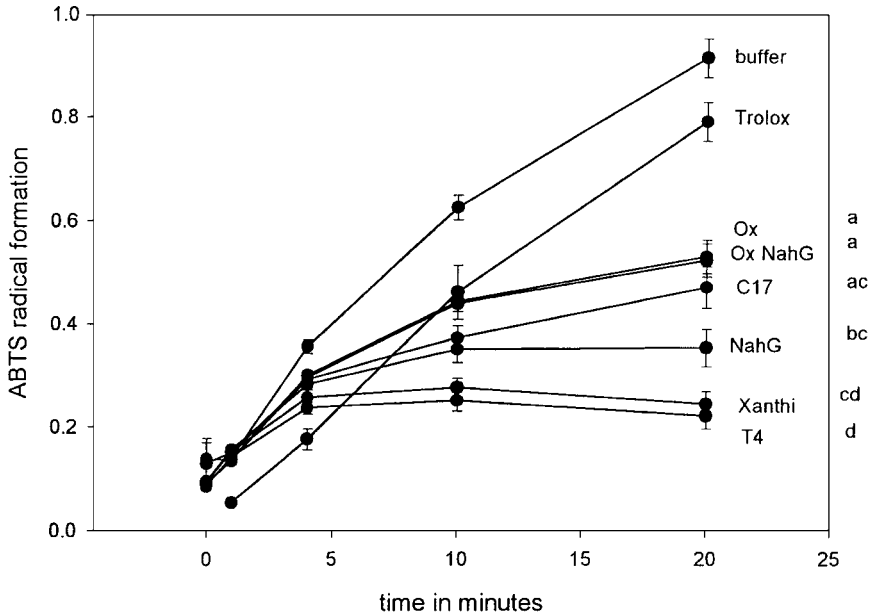

FIG. 1. Antioxidant capacity of macerated tobacco foliage as indicated by suppression of ABTS radical formation in vitro. The effects of saline buffer and 0.4 mM Trolox are included for comparison. The T4 tobacco line is lowest in phenolic content (PAL sense-suppressed), Xanthi, C17, and NahG are intermediate, and Ox and OxNahG are PAL overexpressing lines. Letters indicate significant differences at $P < 0.05$ (ANOVA followed by all pairwise multiple comparison Tukey's test).

antioxidant activity that was not significantly different from the wild-type control (Xanthi).

Total hydroperoxides were also lowest in the T4 underexpressing lines (Figure 2). The addition of catalase to the homogenization mixture did not uniformly decrease hydroperoxide levels in foliar samples, so no further attempt to estimate or analyze H_2O_2 production was made (values obtained from tubes containing catalase were analyzed separately from those without catalase and differed in significance levels, but otherwise produced comparable results). One-way analysis of variance of tubes without catalase (means separated by Tukey's test) showed the T4 underexpressing lines accumulated significantly fewer hydroperoxides than the Ox-NahG and NahG lines. Hydroperoxides appeared to be lower in the Ox and C17 lines but the differences were not significant at $P = 0.05$.

Caterpillar Feeding Trials. Larvae consumed more T4 leaf material than Ox during the trial (*t* test, $P < 0.001$), but did not differ in mass gained/day (*t* test,

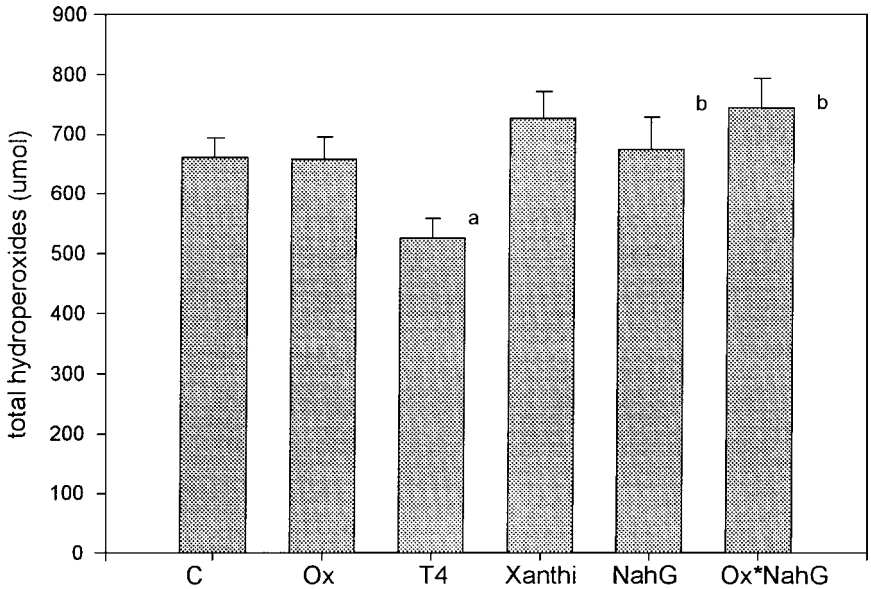

FIG. 2. Total hydroperoxides produced in macerated leaf tissues. The T4 tobacco line is lowest in phenolic content (PAL sense-suppressed), Xanthi, C17, and NahG are intermediate, and Ox and OxNahG are PAL overexpressing lines. Letters indicate significant differences at $P < 0.05$ (all pairwise multiple comparison (Tukey's test).

$P = 0.093$) and final mass of T4 larvae was only slightly higher (t test, $P = 0.064$) (Table 1). The underexpressing leaves were more digestible than overexpressing ($P = 0.003$). The dry masses of Ox and T4 leaf discs were not significantly different (3.59 ± 0.69 for Ox and 3.32 ± 0.89 for T4), suggesting that the ratio of water to lignin did not differ substantially.

In the choice trials, larvae also preferred T4 leaf discs over wild-type controls (C17) ($P < 0.001$, $N = 22$) and overexpressing (Ox) lines ($P < 0.00$, $N = 19$), indicating that the increased consumption of T4 foliage is due in part to

TABLE 1. FEEDING AND GROWTH PERFORMANCE OF FIFTH-INSTAR *H. virescens* FED PAL OVEREXPRESSING (OX) AND UNDEREXPRESSING (T4) TOBACCO FOR 72 HOURS

	Consumption (mg)	Final mass (mg)	Mass gained per day (mg)	Digestibility AD	*N*
Ox (overexpressed)	154.9 ± 20.0	47.5 ± 5.1	10.5 ± 1.7	0.49 ± 0.05	12
T4 (underexpressed	283.8 ± 22.9	58.6 ± 2.9	14.0 ± 1.0	0.68 ± 0.03	15

t test; $P < 0.001$; $P = 0.064$; $P = 0.093$; $P = 0.003$.

phagostimulatory effects. Interestingly, larvae did not discriminate between the wild-type control and overexpressed (Ox) lines ($P = 0.313$, $N = 23$).

Oxidative Status of Herbivore Tissues. Midguts of caterpillars fed different tobacco lines did not differ in total midgut ascorbic acid ($P = 0.235$), reduced ascorbic acid ($P = 0.104$), dehydroascorbic acid ($P = 0.578$), hydroperoxides ($P = 0.368$), or disulfides ($P = 0.491$) (Table 2). Undiluted midgut fluid exerted strong antioxidant properties, completely preventing formation of the ABTS radical (as strongly as Trolox) for over 40 min. There was no significant difference in antioxidant activity of diluted midgut fluid (1:10 dilution) of caterpillars fed wild-type, and over- and underexpressing tobacco (Figure 3). However, caterpillars fed high phenolic tobacco (Ox) for 72 hr had stronger hemolymph antioxidant activity than those fed the underexpressing plants (T4) ($P = 0.005$, Mann-Whitney Rank sum test, $N = 9$, Ox and $N = 10$, T4). (Figure 4).

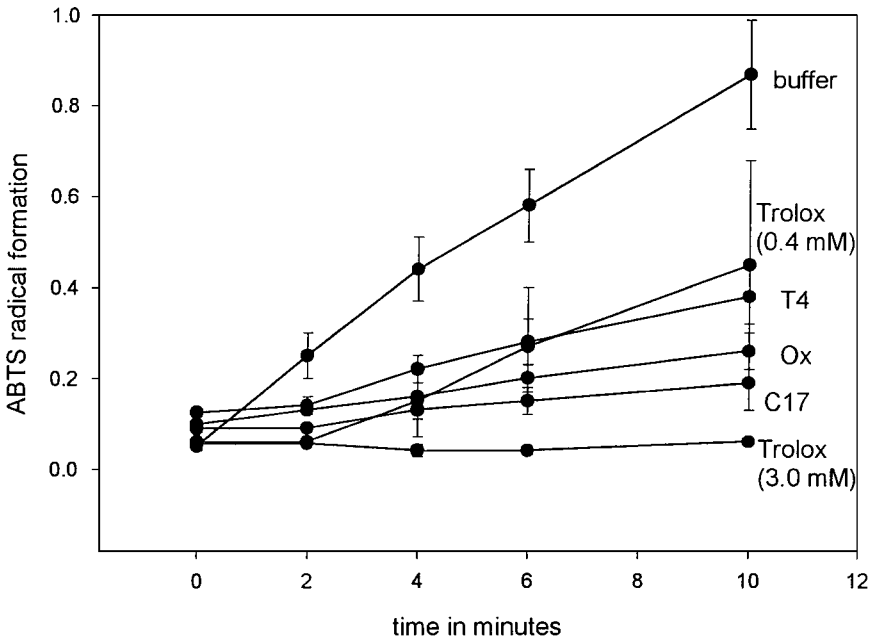

FIG. 3. Antioxidant capacity of *H. virescens* midgut fluid (diluted 1:10) as indicated by suppression of ABTS radical formation in vitro. The effects of buffer and two concentrations of Trolox (0.04 and 3.0 mM) are included for comparison. Larvae were fed detached leaves of T4 (low phenolic content, PAL sense-suppressed), C17 (intermediate), or Ox (high phenolic, PAL overexpressing) tobacco. There were no significant differences among caterpillars fed different tobacco lines.

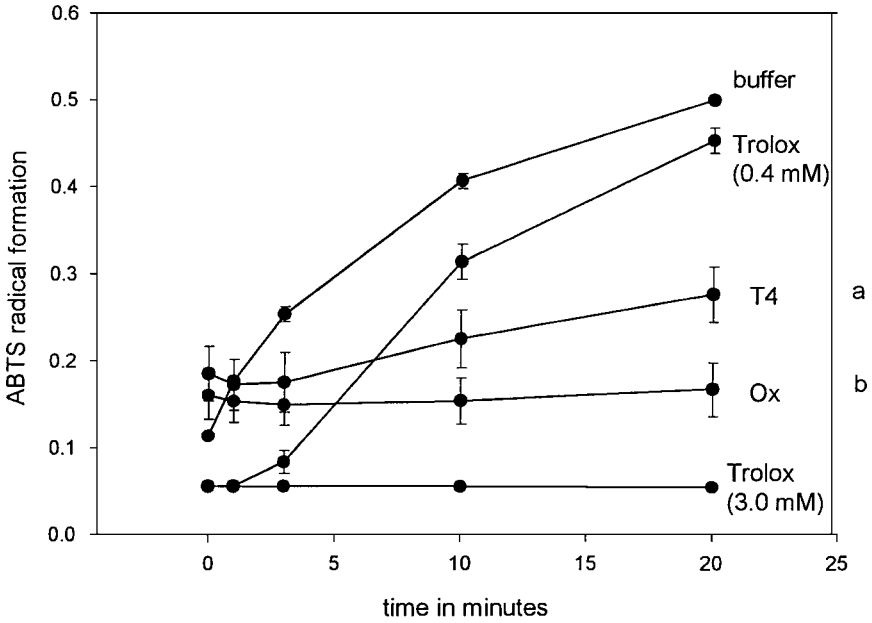

FIG. 4. Antioxidant capacity of *H. virescens* hemolymph as indicated by suppression of ABTS radical formation in vitro. The effects of buffer and two concentrations of Trolox (0.04 and 3.0 mM) are included for comparison. Larvae were fed detached leaves of T4 (low phenolic content, PAL sense-suppressed) or Ox (high phenolic, PAL overexpressing) tobacco for 72 hr prior to the assay. Letters indicate significant differences at $P < 0.05$ (*t* test).

DISCUSSION

Our experiments show that *H. virescens* larvae are relatively unaffected by the 8- to 10-fold range of variation in PAL (phenylpropanoid) expression in tobacco (Bi et al., 1997a; Ali et al., 1999). Although consumption and digestibility were lower on overexpressing plants, they resulted in very modest (not significant) reductions in growth with no indications of oxidative stress as a causal factor. These observations are in contrast to predictions from in vitro model systems and artificial diet experiments that chlorogenic acid, the predominant soluble phenolic in tobacco leaves should have strong negative, prooxidant effects on herbivores (Isman and Duffey, 1982a,b, 1983; Lindroth and Peterson, 1988; Felton et al., 1989, 1992; Stamp et al., 1994; Stamp and Yang, 1996; Yang et al., 1996). In fresh plant tissue, CHA's prooxidant effects appear to be ameliorated by the strong overall antioxidant nature of crushed foliage and the beneficial effects of dietary phenolics on antioxidant defenses of caterpillars. The demonstration that high

levels of oxidizable plant phenolics in foliage are not necessarily prooxidant when encountered by herbivores in their natural context has important implications for understanding the mode of action and biological activity of phenols that are often presumed to function in antiherbivore defense.

Our results indicate that high free radical activity in foliage does not necessarily translate into oxidative damage to herbivores. Although high phenolic lines (Ox, Ox-NahG) in our study exhibited measurably elevated hydroperoxide formation, all of the lines were strongly antioxidant compared to saline buffer, which is presumably neither pro- nor antioxidant. The overall antioxidant capacity of the chemical milieu of crushed foliage is clearly important for determining the biological impact of prooxidant phenols on herbivores. The net oxidative balance in crushed foliage depends on the predominant types of phenolics and phenolases present and can vary substantially among plant species. Hoover et al. (1998a,c) compared the effects of monophenols, catecholic phenols, tannins, peroxidase (POD), and polyphenoloxidase (PPO) activity on free radical generation in crushed cotton, tomato, and lettuce foliage. While some monophenols (ferulic and *p*-coumaric acids), the polyphenolic tannin quebracho, and mixtures of phenolics prone to redox cycling (CHA and rutin) enhanced free radical generation in the presence of POD, other combinations (e.g., monophenolics with catecholic phenolics) exhibited antioxidant properties. For example, chlorogenic acid, rutin, and catechin applied to foliage in mixtures had strong antioxidant properties and decreased free radical generation in crushed foliage by 30–60% (Hoover et al., 1998c). The tendency of this combination of phenolics to be antioxidant may explain why tomato fails to inhibit baculoviral disease, in spite of being rich in phenolics (Hoover et al., 1998b). Our results with tobacco differ somewhat in that we measured higher free radical production in high phenolic lines, but tobacco appears to be similar to tomato in that the overall nature of crushed foliage is strongly antioxidant. This may be a general pattern for solanaceous plants, which are rich in CHA and rutin, but also have smaller amounts of ferulic acid (Waiss et al., 1981; Isman and Duffey, 1982a,b; Bi et al., 1997a).

The powerful antioxidant capacity of *H. virescens* midgut fluid appears to represent an additional and significant barrier to ROS generation in the gut lumen, suppressing ABTS radical formation as strongly as the commercial antioxidant Trolox. Its antioxidant activity was much stronger than that of macerated leaf tissues, suggesting that caterpillars have biochemical mechanisms for enhancing the antioxidant properties of gut fluid. Possible mechanisms include the secretion of antioxidants such as glutathione, ascorbate, and uric acid (Summers and Felton, 1994; Mathews et al., 1997; Barbehenn et al., 2001) or enzymes such as catalase (Felton and Duffey, 1991), ascorbate peroxidase (Mathews et al., 1997) or glucose oxidase, which can deplete molecular O_2 from the gut lumen (Eichenseer et al., 1999; Johnson and Barbehenn, 2000).

One of the more surprising results was the positive effect of PAL overexpressing foliage on the total antioxidant capacity of caterpillar hemolymph. This is the first demonstration of a positive antioxidant benefit of dietary phenolics for herbivorous insects, although there is a huge body of literature demonstrating protective antioxidant effects of phenolics in green tea, red wine, and green vegetables in mammalian systems (reviewed in Kahl, 1991; Frei, 1994; Hertzog et al., 1997; Maxwell, 1997). Many phenols act as chain-breaking antioxidants (Takahama, 1985; Pincemail et al., 1986), prevent oxidation of lipids by chelating catalytic metal ions such as Fe and Cu (Afansas'e et al., 1989), and inhibit LOXs, POs, and other oxidases responsible for free radial production (Gryglewski et al., 1987; Moroney et al., 1988; Hoover et al., 1998a,b). They may also induce antioxidant defenses in caterpillars to levels that exceed the immediate need, resulting in higher overall antioxidant capacity of hemolymph and other tissues. In caterpillars, superoxide dismutase (SOD) is inducible and increases rapidly in response to dietary prooxidants, including the phenolic quercetin (Pritsos et al., 1988; Lee and Berenbaum, 1989; Ahmad and Pardini, 1990). Finally, it should be noted that the antioxidant benefit could be due to an unknown trait other than phenolic concentration that covaries with PAL expression. For example, high levels of the phenolic salicylic acid can suppress wound-induced responses by inhibiting the wound-signal cascade (Felton et al., 1999). This mechanism is not likely to have been important in our experiments because caterpillars were fed detached leaves or foliage from unwounded plants, but the possibility that PAL modification altered other biochemical pathways warrants further investigation.

Although our experiments do not support the hypothesis that high in planta concentrations of CHA have prooxidant effects on caterpillar tissues, PAL overexpression did alter feeding behavior and digestive responses of *H. virescens* in other ways. In the choice experiments, larvae showed a clear preference for low phenolic foliage. In this regard, *H. virescens* differs from *M. sexta*, which does not discriminate between PAL over- and underexpressing foliage (Eichenseer et al., 1998) and is not deterred by similar concentrations of CHA presented on artificial substrates (Boer and Hanson, 1987; Wrubel and Bernays, 1990). Early instar *H. virescens* larvae may respond differently; although late instar diet-reared larvae preferred and consumed more low phenolic foliage and grew at a slightly faster rate (this study), early instar growth and survival on underexpressing lines is poor (Ali et al., 1999). Possibly early instar larvae are more sensitive to host-specific phagostimulants than mature larvae.

Overexpression of PAL was also associated with reduced digestibility of leaves to caterpillars. Although reduced protein quality and inhibition of digestive enzymes are symptoms associated with ROS from phenolic oxidation, given our measures of the strong antioxidant capacity of crushed foliage, midgut fluid, and the positive oxidative balance of hemolymph and midgut epithelium, we believe the reduced digestibility is more likely related to changes in lignin content. Lignin

is formed by the polymerization of phenylpropanoids and is directly correlated with PAL expression (Elkind et al., 1990; Bate et al., 1994; Sewalt et al., 1997).

In summary, the results of this study show that the efficacy of prooxidant phenolics against herbivores is not easily predicted from foliar concentrations and artificial diet bioassays. Thus, from a plant's perspective, increased allocation to phenylpropanoid synthesis (through PAL) may not increase resistance to herbivores; in fact, it may have the opposite effect since some phenol mixtures can provide beneficial antioxidant properties. The demonstration of antioxidant, rather than prooxidant, effects on leaf-chewing caterpillars represents a previously unrecognized beneficial effect of phenolics on insects and emphasizes the need to examine their biological activity in the appropriate phytochemical context, rather than as single dietary additives, to fully understand their ecological role in plant herbivore interactions.

CALL FOR PAPERS

SPECIAL ISSUE ON AQUATIC CHEMICAL ECOLOGY

There will be a special issue of the *Journal of Chemical Ecology* devoted entirely to papers dealing with "Aquatic Chemical Ecology." Publication is planned for late summer/early fall 2002. The issue will consist of invited mini-reviews and contributed papers. Those wishing to submit a paper for consideration for this special issue should do so by February 1, 2001.

Please send the original and two copies of the manuscript (including illustrations) and the names and addresses of three potential reviewers to:
